Mechanistic Organic Photochemistry

By H. E. Zimmerman[*]

Organic photochemical reactions can be understood as transformations of the electronically excited states of the reactant molecules. By considering Lewis structure or molecular orbital representations of these excited states it is possible to outline the several possible reactions available in the case of a given reactant. A number of different types of photochemical transformations are now reasonably well understood. In these cases one finds the same common controlling feature, namely the tendency for an excited state species to follow mechanistic pathways of minimum energy and the requirement for continuous electron redistribution in following these pathways. These preferred transformations can often be selected by inspection of relative bond orders for different types of bonding, by comparison of the potential energy surfaces available to the excited state molecules, and by use of correlation diagrams. The reactions derive from both singlet and triplet states, and one of the more reliable methods now available for identifying excited states reacting is termed the "fingerprint method". Examples of the author's mechanistic approach are given both for ketone and for hydrocarbon photochemistry.

1. Introduction

In 1961 we noted[1] that, despite the high energy employed in photochemistry, the molecular transformations encountered are generally very selective. The excited state molecule seems to transform itself in such a way that electron localization is minimized. We suggested that by use of simple Lewis structure and molecular orbital representations, one could often predict and understand the reaction route chosen by the electronically excited state of reactant. Subsequent to this we investigated the applicability of our proposal to a number of photochemical reactions. The present article summarizes some of these findings.

2. Molecular Orbital and Resonance Methods of Representing Excited States

The carbonyl group is especially useful in illustrating the two most important types of electronic excitation, n–π* and π–π*. Figure 1 shows the atomic orbitals (AO's) available at the different atoms and is really a three dimensional Lewis structure.

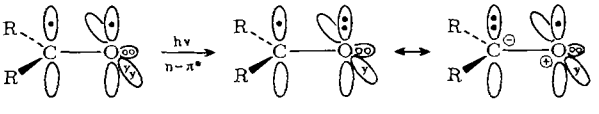

Fig. 1. Ground state *(1)* of carbonyl group. n-π* excited state resonance contributors *(2a)* and *(2b)*. ○ represents sp^n hybrid electrons; y's, p_y electrons; ●, π-system electrons. AO signifies atomic orbital representation.

In this representation there is a low energy sp^n hybrid orbital on oxygen coaxial with the sigma C–O bond and containing two electrons, a p_y non-bonding orbital containing two electrons in the ground state, and lastly a π-system deriving from interaction of two p_x orbitals.

n–π* excitation promotes a p_y electron to the π-system. In resonance terminology, two contributors result from our being able to write the promoted electrons as in the carbon or the oxygen p_x orbital. The molecular orbital equivalent picture (Fig. 2) differs only in that the two molecular orbitals (the

MO's) derived from overlap of the two p_x orbitals are depicted explicitly. In the ground state the π MO is doubly occupied but the π^* MO is vacant. In the $n-\pi^*$ excited state, a p_y electron has been promoted to the antibonding (*i.e.* π^*) MO.

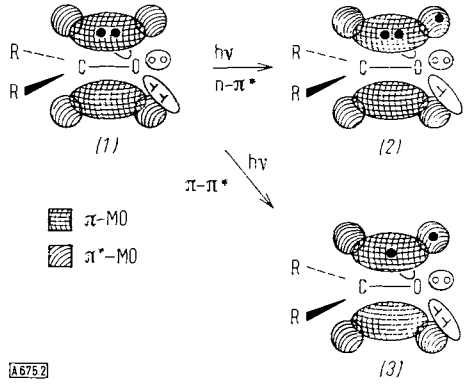

Fig. 2. Molecular orbital representation of $n-\pi^*$ and $\pi-\pi^*$ excitation of *(1)* to *(2)* and *(3)*, respectively.

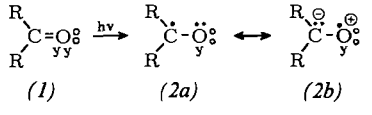
The $n-\pi^*$ excited state results on excitation by ultraviolet light of *ca.* 300 nm (depending on exact structure) where there is a weak absorption band in ketones. A second excitation process may be seen to be possible, one in which a π-MO electron is promoted to the π^* orbital. This is termed $\pi-\pi^*$ and arises usually by irradiation at shorter wavelengths where there is the intense absorption band whose position follows *Woodward*'s rules. In two dimensions $n-\pi^*$ excitation can be represented as in Fig. 3.



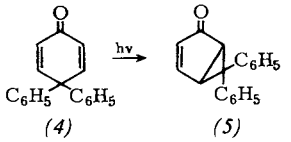


Fig. 3. Two dimensional representation of $n-\pi^*$ excitation.

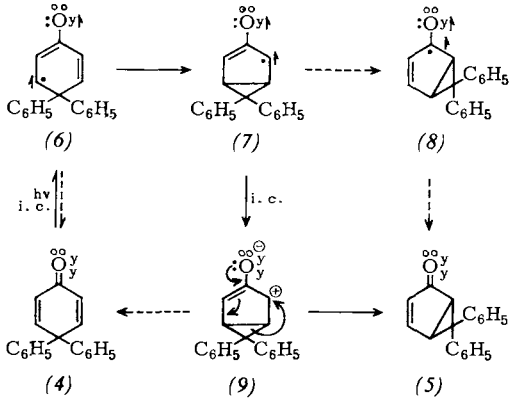
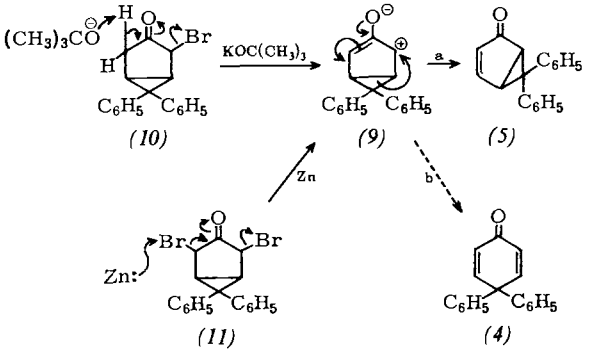


3. Cyclohexadienone Photochemistry

One of the most intriguing photochemical transformations is the "Type A"[2] rearrangement of cyclohexadienones. An example which has been of considerable interest to us is the case of 4,4-diphenylcyclohexadienone *(4)* which affords 6,6-diphenylbicyclo[3.1.0]hex-3-en-2-one *(5)*.



It was found that the reaction is unusually efficient with a quantum yield of 0.85 moles/Einstein[*]. Evidence was advanced that the reaction proceeds by way of the $n-\pi^*$ triplet excited state of the reactant, and this evidence is now summarized.

First of all, sensitization with acetophenone absorbing essentially all of the incident light gives the same quantum yield within experimental error (*i.e.* $\Phi = 0.81$). This finding can be reasonably interpreted to mean that both reactions involve the same excited state, the triplet (see Scheme 1).

Scheme 1. "Type A" rearrangement of 4,4-diphenylcyclohexadienone. The proposed mechanism of rearrangement is indicated by solid arrows. Potentially available pathways not utilized are shown by dashed arrows. The ground-state species are given in the bottom row, and above each ground-state species is drawn the corresponding $n-\pi^*$ excited state. Intersystem crossing occurs between *(4)* and *(6)*, and between *(7)* and *(9)*. The excitation energy gained on going from *(4)* → *(6)* is lost during the step *(7)* → *(9)*.

The evidence in favor of loss of electronic excitation prior to complete skeletal rearrangement is twofold. First, the triplet excited state *(8)* of 6,6-diphenylbicyclo[3.1.0]hex-3-en-2-one *(5)* exhibits behavior, when independently generated, which is not found in low conversion photolysis runs beginning with 4,4-diphenylcyclohexadienone *(4)*[3]. Secondly, the mesoionic zwitterion *(9)* has been independently generated in research by *Döpp*[4] and does indeed afford 6,6-diphenylbicyclo[3.1.0]hex-3-en-2-one *(5)* providing necessary evidence for the zwitterion being an intermediate in the photochemical rearrangements as postulated (see Scheme 2).

Scheme 2. "Photochemistry" without light (route b is not observed).

There are three interesting facets of the reaction *(4)* → *(5)*. One concerns the underlying reasons for the initial 3,5-bonding in the $n-\pi^*$ excited state of dienone. Reference to Fig. 4 shows the increased 3,5-bond

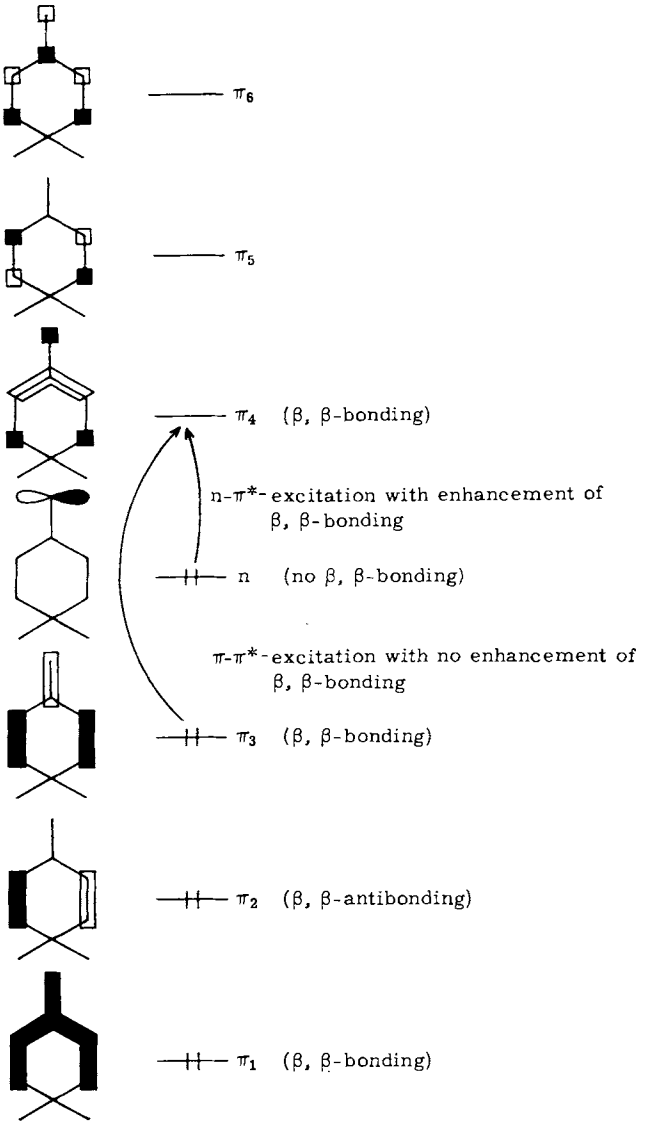

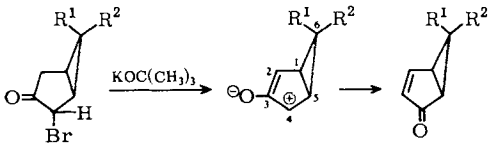

Fig. 4. Molecular orbital representation of n—π* and π—π* excitation processes for cyclohexadienones. ■, wave function positive. □, wave function negative.

order resulting on n–π* excitation [3]. The second point involves the question why the zwitterion *(9)* rearranges so efficiently to the bicyclic ketone *(5)* (process a in Scheme 2) rather than reverting to the dienone *(4)* (process b, Scheme 2). The latter process is one which an organic chemist might consider as a reasonable *a priori* possibility. The correlation diagram (Fig. 5) shows that reversion to the dienone *(4)* is forbidden by symmetry; without change in electron population an exceedingly high energy doubly excited state would result [3].

The third point of interest concerns the stereochemistry of the Type A rearrangement as observed [4a] in the non-photochemical approach to zwitterion *(9)*. When *(10a)* or *(10b)* – having two different aryl groups at C-6 – was allowed to react with potassium *tert*-butoxide, the group initially *exo* remained *exo* in the product and the *endo* group was still *endo* in the product. This finding has been confirmed indepen-

dently [4b]. Of two possible stereochemical courses for the reaction *(10)* → *(9)* → *(5)*, a pivot mechanism involving bond (C-1)–(C-6) breaking with pivoting about bond (C-5)–(C-6) and formation of bond (C-4) to (C-6) and a "slither" mechanism in which C-6 migrates from C-5 to C-4 and then from C-1 to C-5, only the latter occurs. The preferred process is equivalent to an inversion of configuration at C-6 with bond (C-1)–(C-6) breaking as (C-4)–(C-6) forms and with (C-5)–(C-6) remaining intact. This preference has been rationalized on two bases, one of which is touched upon briefly later in this article (see Section 8 and Fig. 15c).

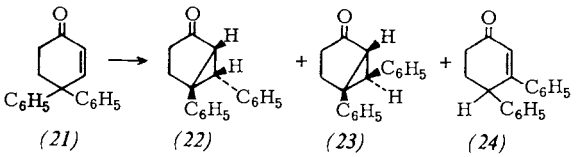
A related rearrangement is the Type B transformation of bicyclo[3.1.0]hex-3-en-2-ones to phenols. Thus the bicyclic ketone *(5)* gives 2,3-diphenylphenol and some 3,4-diphenylphenol on irradiation. The mechanism proposed is given in Scheme 3. In agreement with

Scheme 3. Type B rearrangement of 6,6-diphenylbicyclo[3.1.0]hex-3-en-2-one. Electron demotion occurs between *(12)* and *(13)*. The dashed arrows indicate processes that have not been observed. Intersystem crossing takes place on going from *(5)* to *(8)* and from *(12)* to *(13)*.

the picture of the zwitterion *(13)* rearranging and not the diradical-like excited state *(12)*, it was found by *Grunewald*[5] that 6-*p*-cyanophenyl-6-phenylbicyclo-[3.1.0]hex-3-en-2-one *(16)* gives mainly 2-phenyl-3-*p*-cyanophenylphenol *(17)* but no *p*-cyanophenyl migration product (see Scheme 4).



Scheme 4. Test for six-ring zwitterion in the reaction *(16)* → *(17)*. Whereas the cyanophenyl group would migrate in the biradical *(19)*, the phenyl group would migrate in the zwitterion *(20)*.

p-Cyanophenyl should migrate preferentially to an odd electron site while phenyl should migrate to an electron deficient center. The use of migratory aptitudes in photochemistry to determine the nature of the rearranging species is considered again later.

4. The Aryl Migration Reaction of 4,4-Diarylcyclohexenones

Irradiation of 4,4-diphenylcyclohexenone *(21)* leads to phenyl migration products (see Scheme 5). Since in the photolysis of 4,4-diphenylcyclohexadienone *(4)* (Type A transformation) such phenyl migration is an *a priori* possibility which does not occur, *Zimmerman* and *Wilson*[5a] suggested that removal of the second double bond enforces the phenyl migration and that the phenyl migration type rearrangement is less efficient than the dienone Type A process. This prediction was confirmed by quantum yield studies by *Zimmerman* and *Hancock*[6].

Quantum yields for unsensitized reaction:
Φ = 0.043 0.043 0.0003 0.0002

Quantum yields for reaction sensitized by propiophenone:
Φ = 0.040 0.039 0.0003 0.0002

Scheme 5. Examples of the fingerprint method applied to the irradiation of 4,4-diphenylcyclohexenone *(21)* to give *(22)*, *(23)*, and *(24)*.

The quantum yield measurements were obtained by inverse isotope dilution. This method has the advantage of great sensitivity so that reactions can be run to conversions as low as 1% with even relatively low quantum yields; this allows one to be certain that products are not competing for light.

Inspection of the quantum yields (see Scheme 5) with and without sensitization shows that the same distribution of efficiencies is obtained on direct irradiation as in the sensitized ones where one is dealing with preformed triplet excited state. The product and quantum yields distribution can be used as a "fingerprint", and the direct irradiations have the same fingerprint as those beginning with the triplet. This "fingerprint method" of demonstrating the intervention of triplet excited states is one of the more reliable tests available to the photochemist, and in the present case it shows that the direct irradiation of 4,4-diphenylcyclohexenone *(21)* leads to products by way of the triplet excited state.

A second aspect is of interest, namely the high stereoselectivity favoring formation of the *trans* isomer *(22)*[*] of 5,6-diphenylbicyclo[3.1.0]hexan-2-one by a factor of 140:1 over *cis (23)*. This stereochemical preference is not just a matter of mutual avoidance of two phenyl groups due to van der Waals forces, since in the *trans* isomer the *endo*-phenyl-five-ring interaction is just as severe as the phenyl-phenyl hindrance in the *cis*. This stereochemistry seems to arise from a 2,4-bonding to form the three-membered ring concerted with phenyl migration from C-4 to C-3 with inversion of configuration at C-4 (see Fig. 6).

In this process there is a disrotatory motion about bonds (C-1)–(C-2) and (C-4)–(C-5) to form the new internal three-ring bond; the net effect is one phenyl above the new three ring and one below.

It is generally insufficient merely to look at relative quantum yields in order to compare the facility with which two reactions proceed. Actually, one needs the

rate at which the excited state reacts. One can obtain the rates of triplet state rearrangements from Stern-Volmer plots (see Fig. 8) by a method discussed below. 4,4-Diphenylcyclohexenone provides an example (note Fig. 7). Here the triplet rate was found to be $k_r = 3.8 \times 10^7$ sec^{-1} [6]. Although this is a very fast reaction

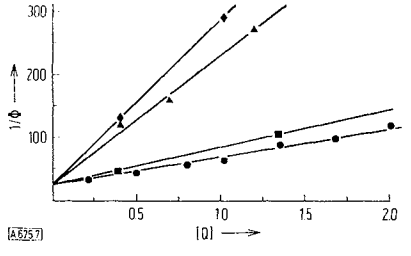

Fig. 7. Stern-Volmer plots of the reciprocal of the quantum yield $^1/_\Phi$ against the quencher concentration [Q] (mole/l). Variation of quenching rate with triplet energy of quencher for 4,4-diphenylcyclohexenone *(21)*. Quenchers: –◆– cyclohexadiene. –▲–, dimethylhexadiene. –■– 1,3-pentadiene. –●–, naphthalene.

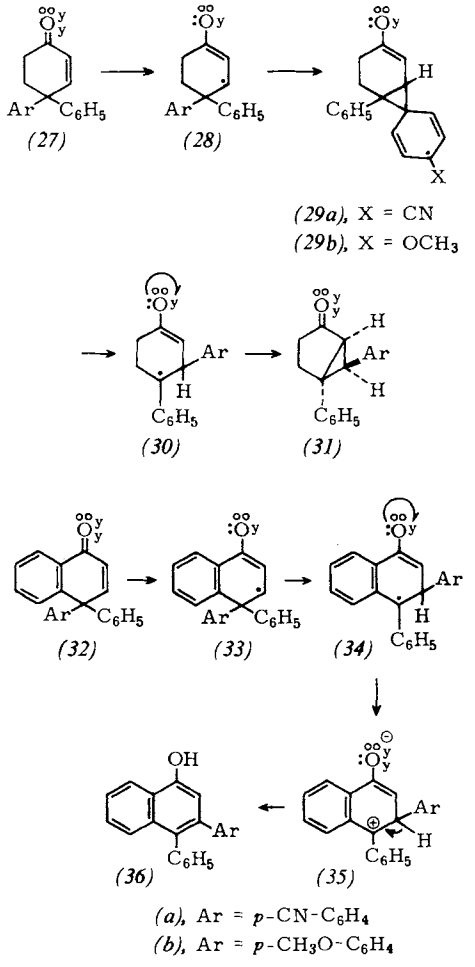
compared to the ground state rate constants, it is slow compared to the lower limit of $k_r \geq 10^{10}$ sec^{-1} found for the rearrangement of the triplet excited state of 4,4-diphenylcyclohexadienone *(6)*. Thus the phenyl migration reaction does appear to follow a higher energy pathway than the Type A rearrangement of dienones. Yet the rearrangement of the triplet of *(21)* is faster than the Type A rearrangement of 4-alkylcyclohexenones such as *(44)*; and it has been proposed that this rearrangement fortuitously effects the same skeletal change as the Type A dienone rearrangement without having a similar low energy pathway. The relative efficiencies and rates of the three types of rearrangement are summarized in Table 1.



Very recently evidence has been obtained by *Elser* [6a] that the reaction in Scheme 5 has an appreciable activation energy (*ca.* 10 kcal/mole) for excited state rearrangement and that the activation process has a "normal" frequency factor (about $10^{14.5}$). This suggests that the potential energy surfaces surrounding the excited states may be similar to ground state surfaces.

[6a] *H. E. Zimmerman* and *W. R. Elser*, J. Amer. chem. Soc., in press.

Table 1. Efficiencies and rates of triplet rearrangements of cyclohexenones and cyclohexadienones.

Reactant	Type rearrangement	Quantum yield	k_r (sec^{-1})
4,4-diphenylcyclohexadienone *(4)*	Type A	0.85	$\geq 10^{10}$ sec^{-1}
4,4-diphenylcyclohexenone *(21)*	Phenyl migration	0.043	3.8×10^7
4a-methyl-2,3,4,4a,9,10-hexahydro-2-phenanthrone	Type A	0.00084	2.9×10^5

Also of interest in connection with the photochemistry of cyclohexenones is the matter of migratory aptitudes. In both the rearrangements of 4,4-diarylcyclohexenones, such as *(27)* [7], and 4,4-diaryl-1,4-dihydronaphthalenones, *e.g.* *(32)* [8], it has been found that cyanophenyl migrates with greater efficiency than phenyl. This tells us that the β-carbon (*i.e.* C-3) of the electronically excited enone moiety is not electron deficient, since phenyl migrates preferentially to positive centers. Additionally, when the competition is between phenyl and anisyl, we find that it is anisyl whose migration is preferred [7,9]. This result tells us that the β-carbon cannot be heavily electron rich in the excited state

Scheme 6. Migratory aptitudes.

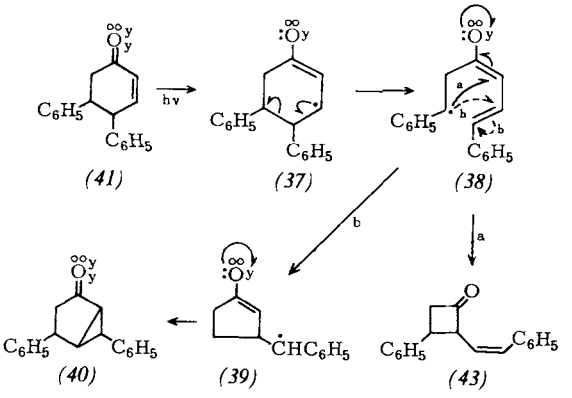
[9] *H. E. Zimmerman, R. Nasielski*, and *A. Guimanini*, unpublished.



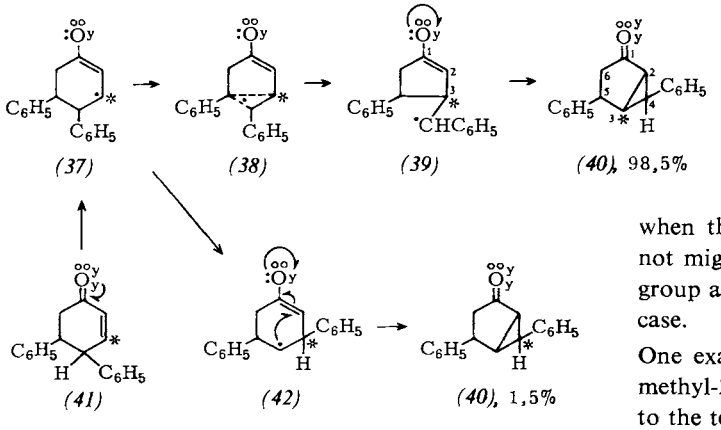
either, since anisyl would not elect to migrate to a negative center in preference to phenyl. One further point is that one might have attempted to explain the preferential migration of cyanophenyl over phenyl by the rationale that migration is to a positive center but that stabilization by the group remaining behind and not migrating is the controlling factor. However, in such a case anisyl would remain behind and this is not observed. The conclusion is that the excited state rearrangement can be pictured as a migration to an odd electron center (see Scheme 6).

Also recently evidence has been uncovered showing that not only the quantum yield for the reaction of 4,4-diarylcyclohexenones is increased by introduction of a *p*-cyano group but also the rate of triplet rearrangement is enhanced (by a factor of *ca.* 12)[9a]. The *p*-cyano group, however, does not appreciably affect the rate of excited state decay; this suggests that rearrangement and decay processes have little in common.

5. The Type A Rearrangement of Cyclohexenones

A second type of enone transformation is known. Skeletally, this is of the Type A variety; however, mechanistically it is quite different from the Type A dienone rearrangements. An example of the Type A enone rearrangement is the photochemical transformation of 4,5-diphenylcyclohexenone *(41)* to afford 4,6-diphenylbicyclo[3.1.0]hexan-2-one *(40)* along with 2-(*cis*-styryl)-3-phenylcyclobutanone *(43)*[10]. Although the same product *(40)* would arise by the phenyl migration mechanism discussed in the previous section, the mechanism of the rearrangement was established as Type A by following a C-14 label originally placed at C-3 in the 4,5-diphenylcyclohexenone *(41)*; the label was found at C-4 (cyclohexane numbering) to the extent of 98.5% showing a heavy predominance of a Type A skeletal transformation. Since 1.5% of the C-14 label originally at C-3 did remain at C-3 (cyclohexane numbering), it was concluded that a phenyl migration mechanism of the type discussed in the previous section occurred as a minor reaction (see Scheme 7).

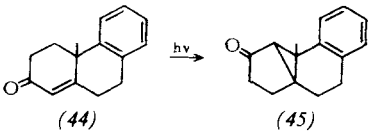
It was mentioned that 2-(*cis*-styryl)-3-phenylcyclobutanone *(43)* was a product of the reaction as well. (The intermediate *(38)* in Scheme 7 is just the bridged version of the same biradical *(38)* shown in Scheme 8



Scheme 8. Mechanism of cyclobutanone formation [10].

as open for simplicity.) The alternative mode of reaction in which the benzylic radical in *(38)* attacks C-2 rather than C-3 can be seen to afford the observed cyclobutane product *(43)*.

It may be noted in Scheme 7 that the phenyl migration route leads to intermediate species *(42)* in which there is an odd electron localized on C-4, a carbon not bearing a phenyl group. This contrasts with the situation in the rearrangement of 4,4-diphenylcyclohexenone where after phenyl migration any free valence on C-4 is stabilized by a phenyl located at this carbon and not migrating. As a consequence one can understand phenyl migration being preferred in the photolysis of 4,4-diphenylcyclohexenone *(21)* while the Type A enone rearrangement is preferred in the case of 4,5-diphenylcyclohexenone *(41)*.



It appears that the Type A rearrangement of cyclohexenones takes precedence over the phenyl migration

Scheme 7. Competitive pathways for 4,5-diphenylcyclohexenone rearrangement [10]. Upper row, Type A route. Lower row, phenyl migration. *C, ^{14}C label.

when there is insufficient stabilization by the group not migrating in the aryl migration; with one phenyl group and one alkyl group at C-4 this seems to be the case.

One example of interest is the rearrangement of 4a-methyl-2,3,4,4a,9,10-hexahydro-2-phenanthrone *(44)* to the tetracyclic product *(45)*[11]. In this case the reaction was shown to proceed by way of the triplet

(1)

[9a] *H. E. Zimmerman* and *N. Lewin*, J. Amer. chem. Soc., in press.

[10] a) *H. E. Zimmerman* and *D. J. Sam*, J. Amer. chem. Soc. *88*, 4114 (1966); b) *ibid. 88*, 4905 (1966).

excited state since the quantum yield on acetophenone sensitization ($\Phi = 0.00086$) is the same within experimental error as that on direct irradiation ($\Phi = 0.00084$) [11]. This is a case of fingerprint identification with "only one finger" employed and is not totally satisfactory since it is conceivable that the singlet and triplet might accidentally rearrange with the same efficiency. Quenching experiments proved useful in dispelling any doubt. These are represented in Fig. 8 where the reciprocal of quantum yield is plotted *versus* the concentration of naphthalene and di-*tert*-butylnitroxyl quenchers [11]. The rationale for the Stern-Volmer plot can be seen in equation (2).

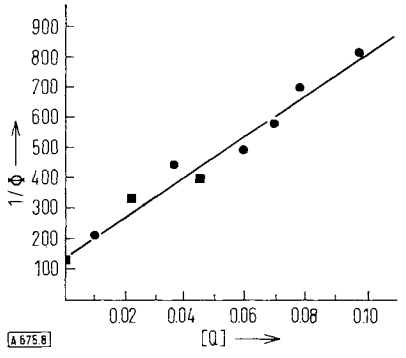


Fig. 8. Stern-Volmer plot of reciprocal of quantum yield *versus* quencher concentration. Quenchers: —■—, naphthalene. —•—, di-*tert*-butylnitroxyl.

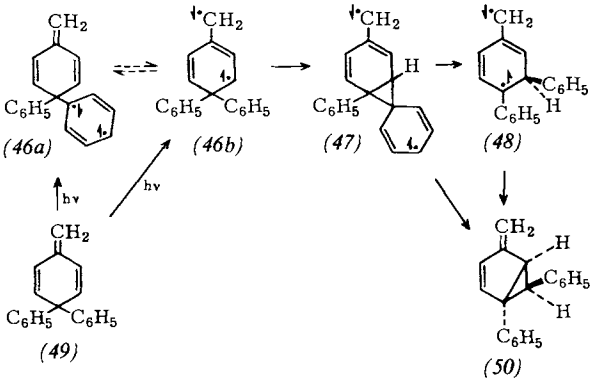


$$\frac{1}{\Phi} = \frac{\overbrace{k_r[T] + k_d[T] + k_q[Q][T]}^{\text{all triplet processes}}}{\underbrace{k_r[T]}_{\substack{\text{only triplet processes}\\ \text{leading to product}}}} = \frac{k_r + k_d}{k_r} + \frac{k_q}{k_r}[Q] \quad (2)$$

In equation (2), [T] is the concentration of triplet excited state, [Q] is the concentration of triplet quencher, and k_d is the rate constant for triplet deactivation. Equation (2) results from the definition of quantum yield, namely the ratio of the rate of product formation from an excited state to the sum of all possible rates of excited state disappearance. It can be seen that the reciprocal of quantum yield then is linear with the concentration of quencher, and that the slope of this plot is equal to the rate constant for quenching divided by the rate constant for triplet rearrangement. Where quenching is controlled by diffusion, one can substitute the known rate constants for diffusion into equation (2) for k_q and then, knowing the slope, solve for k_r.

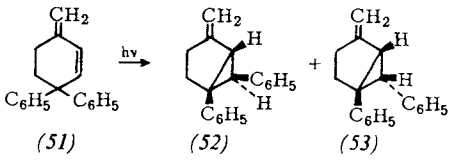
6. Methylene Analogs of Dienones and Enones

Because the photochemistry of the dienones and enones studied was postulated to be characteristic of $n-\pi^*$ excited states and to derive from a π-system having one extra electron, it seemed of interest to look at systems lacking non-bonding electrons and therefore having only $\pi-\pi^*$ excited states. One example studied was the methylene analog *(49)* of 4,4-diphenylcyclohexadienone *(4)* [12].

When 1-methylene-4,4-diphenyl-2,5-cyclohexadiene *(49)* was irradiated, the initial product was the bicyclic product *(50)*. The reaction quite clearly involves phenyl migration rather than a Type A rearrangement and hence contrasts with the behavior of 4,4-disubstituted cyclohexadienones. When a high energy photosensitizer is used, there is virtually no reaction, although the triene *(49)* quenches the benzophenone-benzhydrol reaction. The quenching of the benzophenone-benzhydrol reaction shows that triplet energy transfer from benzophenone to *(49)* is effective. The lack of product from *(49)* under these conditions shows that the triene triplet is unreactive. The rearrangement on direct irradiation then must result from the singlet excited state (see Scheme 9) [12].

Scheme 9. Rearrangement of 1-methylene-4,4-diphenyl-2,5-cyclohexadiene *(49)*.

One especially interesting aspect of the photochemistry observed is the failure of the triplet, or singlet for that matter, of *(49)* to bond between C-3 and C-5; such bonding is common and facile for the corresponding dienones. However, in the case of the dienones *(4)* such bonding is expected for the $n-\pi^*$ excited states on the basis of a high positive bond order between C-3 and C-5. In contrast, for the $\pi-\pi^*$ excited state of the triene *(49)* the bond order is zero in the Hückel approximation. Hence the lack of such bonding and of a Type A rearrangement is not unreasonable.



Another case of interest is the methylene analog *(51)* of 4,4-diphenylcyclohexenone *(21)* [13]. Here, irradiation of 1-methylene-4,4-diphenyl-2-cyclohexene *(51)* leads to phenyl migration and to formation of the two stereoisomers of 2-methylene-5,6-diphenylbicyclo-[3.1.0]hexane *(53)* (major product) and *(52)* (minor product). Again the reaction is found to be a singlet one; and the triplet, once formed, is unreactive.

The mechanism envisaged is very similar to that of triene *(49)*. We note that the stereochemistry is the

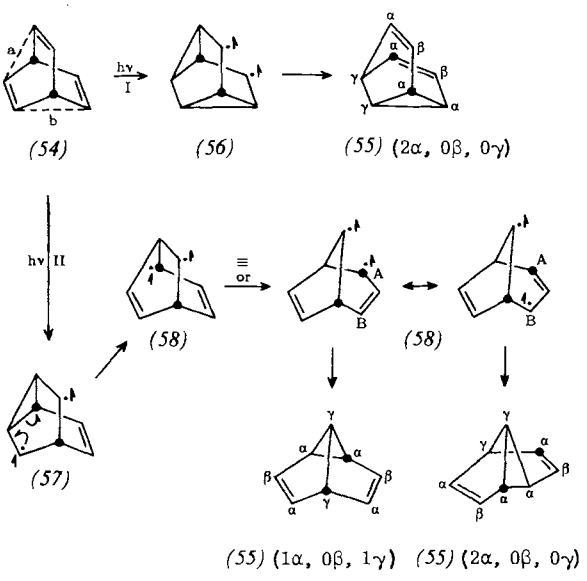
(51) (52) (53) (3)

same as that of the 4,4-diarylcyclohexenones, *e.g. (21)*, with the *trans*-product being preferred, giving weight to the view that this stereochemical course is general.

7. Further π–π^* Photochemistry

An especially intriguing photochemical reaction is the transformation of barrelene *(54)* to semibullvalene *(55)*. Since acetone sensitization is necessary for the reaction, we can conclude that a triplet excited state of barrelene is the rearranging species [14].

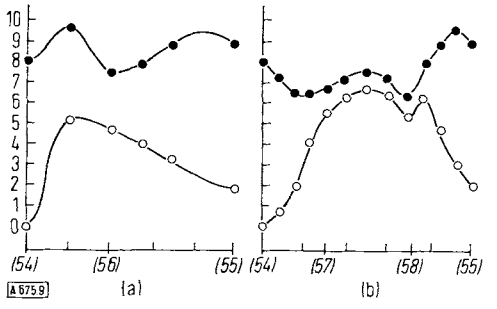


(54) (55a) (55b) (4)

Two fundamentally different mechanisms seemed possible for this transformation (see Scheme 10). A method of differentiating between these was available [15] which depended on the fact that semibullvalene undergoes exceedingly rapid valence tautomerism as shown in eq. (4) and as a consequence shows only three peaks in the NMR, those due to the *alpha*, *beta*, and *gamma* type hydrogen atoms (see eq. (4) for labeling) [14].

By photolysis of barrelene in which the vinyl hydrogen atoms were replaced by deuterium it was possible to follow the disposition of the remaining, bridgehead hydrogen atoms after irradiation. The labeling expected for the two mechanisms is seen in Scheme 10. Mechanism I predicts that the two hydrogen atoms will be located at *alpha* positions and that only this peak will be seen in the product NMR spectrum. Mechanism II predicts a distribution of 75% *alpha*, 0% *beta*, and 25% *gamma* hydrogen atoms; and it is this which is observed experimentally [15]. This prediction, however, is dependent on the triplet biradical *(58)* being a discrete intermediate with finite lifetime and thus symmetrical; the symmetrical allylic biradical *(58)* would bond at either allylic position with equal probability [*]. That the allylic biradical should have an appreciable lifetime is not surprising since it must arise from a triplet and would seem likely itself to be a triplet with intersystem crossing being necessary before collapse to product is possible.

In an attempt to understand the preference for Mechanism II, three-dimensional Hückel theory was utilized on barrelene, semibullvalene, and on each of the intermediate species utilized in the two mechanisms [15]. Thus the ground state and first excited state energies of reactant and each molecular species along the reaction coordinate of each mechanism was obtained. For geometries in between those of biradical species



(54) (56) (55) (2α, 0β, 0γ)

(57) (58) (58)

(55) (1α, 0β, 1γ) (55) (2α, 0β, 0γ)

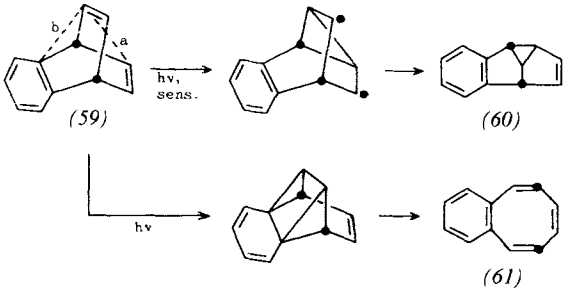
Scheme 10. Possible mechanisms for the barrelene *(54)* to semibullvalene *(55)* interconversion • signifies H label; deuterium elsewhere.

which can be written explicitly, the geometry was taken to be intermediate. From such calculations one obtains cross-sections of potential energy surfaces for the ground and excited states. These are depicted in Figs. 9a and 9b.

Figures 9a, 9b. Potential energy *vs* reaction coordinate for mechanisms I and II, respectively. –o–, ground state curve. –•–, excited state curve.

Mechanism I (Fig. 9a) leads on excitation to a species requiring quite an appreciable activation energy to bridge concertedly to give biradical *(56)*. On the other hand, the ground and excited state surfaces for mechanism II (Fig. 9b) are such that the vertically excited molecule (*i.e.* excited without change in geometry) is on a slope and has enough vibrational energy to surmount the barrier leading to the main excited-state minimum. This minimum is positioned above an electronic ground state minimum which leads preferentially to the product semibullvalene rather than back to barrelene. In agreement with this view is the failure to observe any barrelene from the irradiation of semibullvalene.

Although these three dimensional calculations are approximate and mainly of qualitative use, they present a starting point for considering the photochemical reactivity of molecules undergoing complex transformations.



[14] *H. E. Zimmerman* and *G. L. Grunewald*, J. Amer. chem. Soc. *88*, 183 (1966).

[15] *H. E. Zimmerman, R. W. Binkley, R. S. Givens*, and *M. A. Sherwin*, J. Amer. chem. Soc. *89*, 3932 (1967).

[*] This assumed negligible secondary isotope effects.

In connection with the barrelene *(54)* to semibullvalene *(55)* conversion, it is of interest that semibullvalene has very recently been shown by *Iwamura*[15a] to be formed in the photolysis of cyclooctatetraene at −50 °C. Our photochemical finding is paralleled by the elegant thermal conversion of octamethylcyclooctatetraene to octamethylsemibullvalene reported by *Criegee*[15b].

A recent development is the finding[15c] that benzobarrelene *(59)* on sensitization gives the same reaction as barrelene. However, in the present instance, the same product *(60)* can in principle arise from initial vinyl-vinyl bridging (process a) or benzo-vinyl bridging (process b). Labeling experiments[15c] show that vinyl-vinyl bonding is preferred for the triplet. However, in unsensitized runs benzocyclooctene *(61)* is formed from the singlet by a route involving initial benzo-vinyl bonding.

8. The Occurrence of Möbius Systems in Organic Chemistry and Use of this Concept in Photochemistry

One concept which has been of great utility in organic chemistry is the Hückel rule which specifies that for ground state cyclic π-electron systems, $4n+2$ electrons afford a system with appreciable delocalization stabilization and these systems are the aromatic ones; the $4n$ systems are said to be "anti-aromatic". The preceding statement is correct only when these cyclic systems are made up of a set of atomic or hybrid orbitals in such a way that there is no sign inversion (or an even number of sign inversions)[*].

However, there are systems in organic chemistry which have a single sign inversion (or an odd number of sign inversions). In an intriguing article[16], *Heilbronner* noted that it might be possible to synthesize a Möbius molecule in which twisting of the π system along the molecule would lead to eventual overlap of what was the top portion of the π system with the bottom; this is depicted schematically in Fig. 10. Additionally, *Heilbronner* gave an algebraic formula describing the molecular orbital energies of such a molecule.

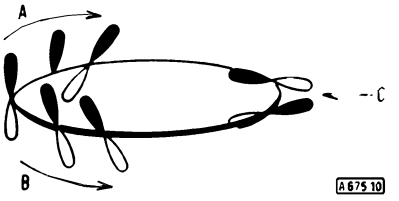


Fig. 10. *Heilbronner*'s Möbius polyene concept. A: plus lobes tilting inward. B: minus lobes tilting inward. C: sign inversion.

We suggested subsequently that it might be useful to focus attention on the presence or absence of a sign discontinuity in a molecule. In this we disregard the precise geometry and concern ourselves only with finding molecules that have such a single sign inversion in a cyclic array of orbitals which may include s orbitals as well as p.

The reason for this is that the secular determinant, the final molecular orbital energies, and also the form of molecular orbitals are not directly aware of geometry but are responsive only to the extent of overlap of such a cyclic array of orbitals in the Hückel approximation. We can term such systems "Möbius-like species", whether they are ground state or transition state molecules. Hence they are Möbius-like more in the mathematical sense than geometrically.

One point worth repeating here is that the cyclic array of orbitals one considers is the group of orbitals set up for purposes of definition and called the "basis set"; this should not be confused with groups of the same orbitals taken in combinations to form molecular orbitals.

We find that molecules composed of a single cycle of orbitals then fall into two categories: those of the Hückel variety and those of the Möbius variety. The Hückel type will always have zero or an even number of sign inversions; the Möbius type will have one or an odd number of sign inversions, depending on just how the basis set of atomic orbitals is arbitrarily chosen.

The reason for considering these two types of orbital systems is that there is a general and consistent pattern of molecular orbitals formed by each of the two. For the Hückel system this is most easily seen by using the mnemonic device of *Frost*[17] in which one draws a circle of radius $|2\beta|$ (see Fig. 11a). The polygon with the same geometry as the cyclic array of orbitals is inscribed with one vertex down. The center of the circle is taken as the energy of an electron isolated in a single orbital of the set and not allowed to distribute itself; we take this energy as our convenient but arbitrary zero. Corresponding to the vertical displacement of each intersection of the polygon with the circle there is a molecular orbital of that energy which results from quantum mechanical mixing of the individual orbitals. *Frost*'s mnemonic is a convenient way of geometrically paraphrasing *Hückel*'s original formula.

[15a] *H. E. Zimmerman* and *H. Iwamura*, J. Amer. chem. Soc. *90*, 4763 (1968).

[15b] *R. Criegee* and *R. Askani*, Angew. Chem. *80*, 531 (1968); Angew. Chem. internat. Edit. *7*, 537 (1968).

[15c] *H. E. Zimmerman, R. S. Givens*, and *R. M. Pagni*, J. Amer. chem. Soc. *90*, 6096 (1968).

[*] The set of orbitals discussed is the arbitrary, definitional set (*i.e.* the so-called "basis set") prior to mixing to give molecular orbitals. The sign refers to the wavefunction and is unrelated to formal charge.

[16] *E. Heilbronner*, Tetrahedron Letters *1964*, 1923.

[17] *A. Frost* and *B. Musulin*, J. chem. Physics *21*, 572 (1953).

If the orbitals are parallel p orbitals and at normal π bonding distances, then the value of $|2\beta|$, the radius of the circle, will be twice the normal resonance integral between two p orbitals of a π system and the MO's given by the mnemonic are those of the organic, cyclic systems. However, if the orbitals are those of a cyclic transition state or of a molecule with different overlap, the value of $|\beta|$ will vary proportionally with this overlap.

The array of molecular orbitals will be the same qualitatively but will be more compressed or expanded depending on the size of the circle. When the overlap is not equal everywhere or when some orbitals are s rather than p, then the simple picture gives only a qualitative approximation to the MO distribution.

Now, for systems with a single sign inversion (or an odd number) in a single cyclic array of orbitals the MO energies can be obtained by a mnemonic device proposed by the present author [18, 19, 19a] which gives exact solutions to the Heilbronner formula for Möbius systems. The author's device differs from the Frost-Hückel mnemonic only in inscribing the polygon with one *side* down in the circle. Also, the device is applicable to Möbius systems which are Möbius-like in the sense of merely having a single sign inversion while not geometrically resembling a Möbius system in a simple [*] manner [18, 19, 19a]. For convenience we term such systems comprised of three orbitals in a cyclic array as "Möbius cyclopropenyl", those with four orbitals as "Möbius cyclobutadiene", *etc.* These are given in Fig. 11b. Again it must be recognized that the radius of the circle is twice the resonance integral for adjacent orbitals of the species considered. As noted by *Heilbronner*, Möbius cyclic polyenes are twisted and $|\beta|$ will be a smaller quantity than the usual $|\beta_0|$. In our work we have noted that the circle radius must be adjusted for differing overlap.

Inspection of Fig. 11a shows that the bonding MO's of the Hückel systems will be filled with $4n+2$ electrons; this is no surprise. We find, on the contrary, that the bonding MO's of the Möbius systems are filled with $4n$ electrons, and this is interesting. For the first excited states in the one electron approximation, where an electron is promoted from the highest occupied to the lowest vacant MO, one finds just the reverse. Here in excited state chemistry, it is the $4n$ electron systems which have the lower electronic energy in molecules with Hückel-like orbital overlap; and the $4n+2$ electron systems which are of lower energy in molecules with Möbius-like overlap [18].

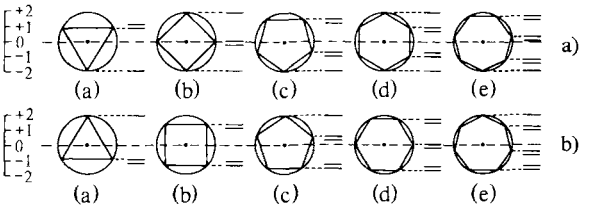

Fig. 11a. Device by *Frost* for obtaining MO energies of Hückel systems (energy units of $|\beta|$). (a): Hückel cyclopropenyl. (b): Hückel cyclobutadiene. (c): Hückel cyclopentadienyl. (d): Hückel benzene. (e): Hückel cycloheptatrienyl.

Fig. 11b. Device by *Zimmerman* for obtaining molecular orbital energies of Möbius systems (energy units of $|\beta|$) [18, 19, 19a]. (a) Möbius cyclopropenyl. (b): Möbius cyclobutadiene. (c): Möbius cyclopentadienyl. (d): Möbius benzene. (e): Möbius cycloheptatrienyl.

One application of this theory to photochemistry is in the photochemical cyclization of butadiene and hexatrienes to give cyclobutenes and cyclohexadienes, respectively. In the case of the butadiene-cyclobutadiene reaction, overlap of the top lobes at C-1 and C-4 of butadiene leads at an intermediate stage along the reaction coordinate to a species which is approximately isoelectronic with Hückel cyclobutadiene (*i.e.* no sign inversions or an even number depending on choice of the basis set of p orbitals); this closure has been termed disrotatory [20]. The intermediate species is depicted in Fig. 12a. The MO's are given by the drawing (b) in Fig. 11a.

Alternatively, different stereochemistry results by overlap of the top lobe at one end of the butadiene molecule with the bottom lobe of the other end. At some point along the reaction coordinate one has a cyclic array of orbitals with one (or an odd number) of sign inversions and with overlap between the terminal orbitals not too different in degree from that between the other adjacent orbitals. This is then a Möbius-like system; it is depicted in Fig. 12b, and the distribution of MO's is given by the drawing (b) in Fig. 11b [*].

With the MO's available for the two alternative partially closed species, we may draw a correlation diagram [21] (Fig. 13). For this one does have to know the placement of the butadiene MO's; however, additionally it is only necessary to connect molecular orbitals of reactant with those of the intermediate species with the same ordering. This mode of drawing the correlation diagram is then an alternative to the use of symmetry [20, 22].

It is seen that for the disrotatory (Hückel) closure, the highest bonding MO becomes antibonding in the reaction while this is not true in the conrotatory (Möbius) reaction. Therefore, for a ground state reaction, Hückel closure will lead to a doubly excited state of product and is said to be "forbidden" (actually in the thermal reaction one would be considering the reverse

[18] *H. E. Zimmerman*, J. Amer. chem. Soc. *88*, 1564 (1966); *88*, 1566 (1966).

[19] *H. E. Zimmerman*, Science (Washington) *153*, 837 (1966).

[19a] *H. E. Zimmerman*, Photochem. and Photobiol. *7*, 519 (1968).

[*] However, one can consider such systems to be Möbius in the geometric sense by considering the overlap of two adjacent orbitals as the attachment of two adjacent strips of surface with the plus and minus lobes of an orbital representing an upper or lower side of the strip. s-Orbitals are then considered as having only one side, plus or minus.

[20] a) *R. B. Woodward* and *R. Hoffmann*, J. Amer. chem. Soc. *87*, 395 (1965); b) *87*, 2511 (1965); c) *R. Hoffmann* and *R. B. Woodward*, *ibid.* *87*, 2046 (1965); d) *87*, 4389 (1965).

[*] A minor point is that due to the twisting and lessened overlap in these species, the radius of the circle used in Figs. 11a and 11b will be less than the usual $2|\beta_0|$. We assume as an approximation that the amount of twisting and lessened overlap is similar for the two species.

process of cyclobutenes opening to butadienes). For the photochemical process, study of the correlation diagram in Fig. 13 shows that the excited state process

which is favored is the Hückel one. These conclusions derive both from consideration of the energy of the system at the Hückel *versus* the Möbius stage as well as by consideration of the number of the antibonding electrons in the product compared to the reactant if no change in configuration (*i.e.* electron assignment) occurs in the reaction.

A few other examples of the utility of the concept are of interest. The hexatriene closure to cyclohexadiene is shown in Fig. 14. Additionally, in Fig. 15 we see

application to the two alternative 1,7-hydrogen migrations, suprafacial and antarafacial, as well as to the Type A dienone transformation.

9. Conclusion

The preceding discussion makes it clear that photochemistry is amenable to mechanistic discussion. It seems that many solution photochemical reactions follow pathways dictated by energetic considerations, tending to minimize molecular energy in the reaction process. It appears that quite often the excited state molecule rearrangement begins but that the excited state of product is not formed; rather electronic excitation is lost before this geometry is reached. The present article has summarized some of the recent results of the author's research with an attempt to focus attention on different types of findings and approaches.

Support of our research by NIH Grant GM07487 and the National Science Foundation is greatly appreciated.

Hereditary DNA Alterations[**]

By Ernst Freese[*]

Mutations and recombinations are hereditary alterations of DNA, which is found mainly in the chromosomes of cells. They can occur spontaneously and they can be induced by high energy radiation or by chemicals. This article considers the developments following the discovery of the DNA structure that have led to a molecular explanation of point mutations, of large chromosome alterations, and of recombination. In conclusion, consequences for human society are drawn from the knowledge gained.

1. Introduction

The discovery of the DNA structure by *Watson* and *Crick* in 1953, based on the experimental results of *Wilkins*, *Chargaff*, and others, has rendered feasible an investigation of mutation and recombination in molecular terms.

At that time it was known that most hereditary information is carried by chromosomes which consist of DNA, RNA, and protein. Different sites of a chromosome determine different phenotypic properties, as was revealed by *Morgan* [1] and his school by crosses of *Drosophila* mutants. These investigators found that some of the hereditary properties segregated not randomly, as expected from Mendel's laws, but more frequently remained associated. The closeness of genetic linkage between different phenotypic properties was determined by the frequency with which recombinants of the parental properties were found in the offspring. The resulting "linkage map" of many different markers turned out one-dimensional. The reciprocal recombinants between different parental markers occurred with equal frequency, which *Morgan* ascribed to reciprocal "crossing over". By a subsequent cytological examination of salivary gland chromosomes of *Drosophila*, which consist of about 2000 parallel chromosome strands, it proved possible to identify the sites determining different phenotypic properties by bands on the chromosome. In this way a one-to-one correspondence has been established between the genetic linkage map and the cytological map (see Fig. 1).

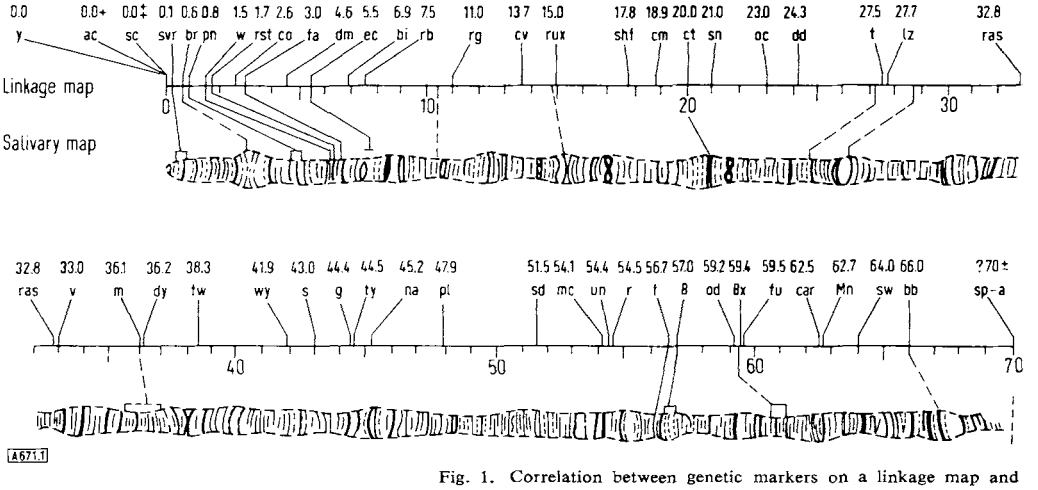

Fig. 1. Correlation between genetic markers on a linkage map and bonds on a salivary gland chromosome of *Drosophila melanogaster* [1a].

However, chromosome alterations could arise not only by the recombination of information present in two homologous chromosomes, but also by mutation, *i.e.* a hereditary alteration of information within one chromosome. Spontaneous mutations were clearly identified by *Bauer* [2] and the first X-ray induced ones by *Muller* [3].

The unit within a chromosome which determines the functional property of a particular phenotype was called a gene. Following the isolation of biochemical

mutants, *Beadle* and *Tatum*[4] postulated that one gene controls the information of one enzyme. Since genes were assumed to be complex molecules that were arranged along the chromosome strand like beads on a string, it was automatically postulated that the gene was not only the smallest functional unit but also the smallest mutational and recombinational unit.

The structure of DNA suggested that a functional unit should contain many nucleotide pairs and rendered unlikely the concept of the trinity of the gene. This concept was indeed soon disproved by *Benzer*[5] who showed that mutations could arise at many different genetic sites within a functional unit and that they could be separated by recombination (see Fig. 2). The concept gene should therefore be restricted to a functional unit.

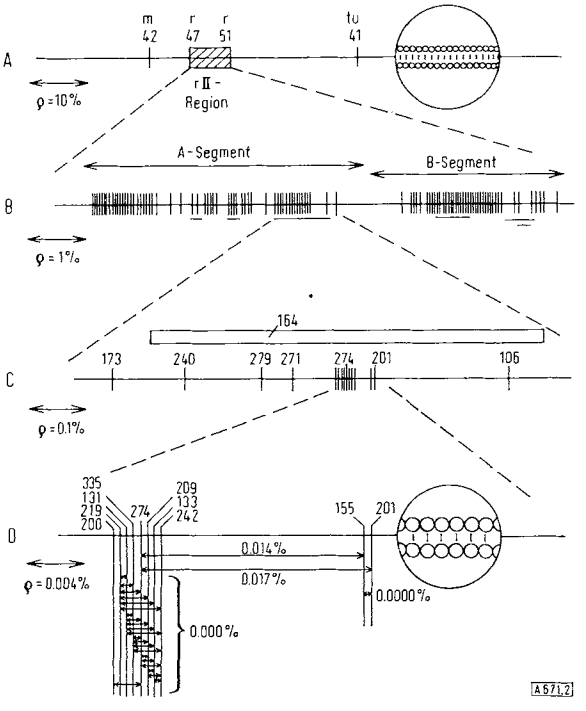

Fig. 2. Genetic fine structure determination within the genetic region determining the "r_{II}" functional property of bacteriophage T4. B, C, and D represent successive magnifications of limited areas. The circles represent nucleotides (magnification in A: × 750, in D: × 7.5). p = recombination frequency. m, tu, and r designate "minute plaque", "turbid plaque", and "rapid lysis" mutants [5a].

However, even the functional definition of a gene is ambiguous. If the final product, derived from a DNA region, is a protein, one could define a gene as exactly that base sequence that is eventually translated into a complete polypeptide. But if the final product is transfer- or ribosomal-RNA, the corresponding gene should carry that information. Finally, in the case of an operator or promoter region, which controls the transcription of adjacent DNA into messenger RNA, a gene could refer to this region which itself is not transcribed into any product. The concept gene, therefore, is imprecise but it is useful until more detailed information is available about the kind of functional unit one is concerned with.

Another loose term is used in the description of the extent of mutations. In order to distinguish small from large hereditary alterations one defines as a "point mutation" a mutation which is limited to a point by all tests that happen to have been performed: cytological, recombination, or functional tests, or the sequence analyses of mutational proteins or eventually of mutational RNA. Ideally, one would like to identify a point mutation as an alteration of a single nucleotide pair in DNA, but since a sequence analysis of DNA is at present impossible, the identification of a point mutation as the change of a single nucleotide pair can be obtained only more or less indirectly, although in some cases quite convincingly. The antipode to point mutations are large chromosomal alterations which involve simultaneously many nucleotide pairs.

2. Point Mutations

In order to understand the nature of point mutations it was necessary to find agents which induce such mutations exclusively and which react with nucleic acids in a known manner. The first promising agent was 5-bromouracil, an analog of thymine, which was known to be incorporated into DNA and which *Litman* and *Pardee*[6] had used to induce mutations in bacteriophage T4. *Benzer* and *Freese*[7] showed, by fine-structure recombination experiments, that such mutations behaved genetically as point mutations and that their distribution pattern differed from that of spontaneous mutations. Subsequently *Freese*[8] found other mutagenic base analogs, *e.g.* 2-aminopurine, and explained the mutation induction by mistakes in base pairing during or following the incorporation of the base analogs into DNA.

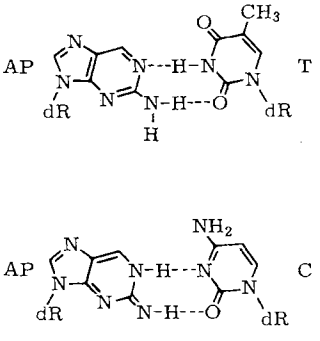

Fig. 3. Normal base pairing between 2-aminopurine (AP) and thymine (T); rare base pairing of 2-aminopurine with cytosine (C).

In Fig. 3 is illustrated the base pairing of 2-aminopurine, whose incorporation into DNA has been demonstrated. 2-Aminopurine apparently can pair normally (by two hydrogen bonds) with thymine and occasionally with cytosine; for the rare pairing it perhaps forms first one hydrogen bond to cytosine, thus inducing a tautomeric shift which permits formation of the second hydrogen bond. In the case of 5-bromouracil, again a tautomeric shift was assumed to allow the pairing of this base with guanine in place of its normal partner adenine. It has so far not been possible to measure the frequencies of the tautomeric forms.

[8] *E. Freese*, J. molecular Biol. *1*, 87 (1959).

Alternatively, *Lawley* and *Brookes*[9] have proposed that it may be the ionized form of the base analogs which undergoes the pairing mistake. The frequency of ionized bases, however, would seem to be too high to explain the mutagenic effect without any further assumptions.

Whatever the detailed reason for the pairing mistake may be, base analogs should be able to induce "base pair transitions"

Adenine ⟷ Guanine
Thymine ⟷ Cytosine

in both directions, owing to mistakes in incorporation or in replication, as illustrated in Fig. 4[8,10]. The induction of transitions in both directions has been proved by the fact that mutants induced by a base

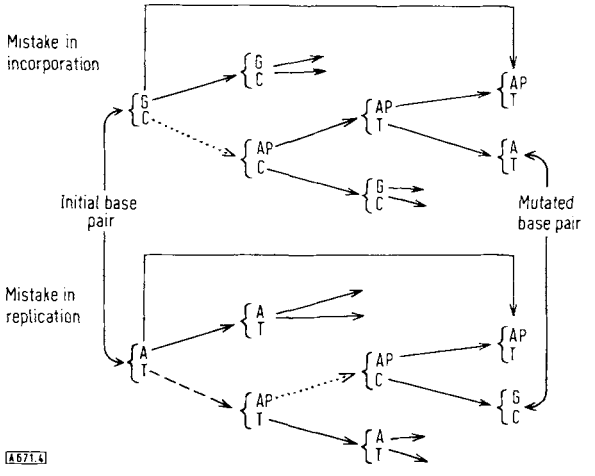

Fig. 4. Induction of base pair changes by mistakes in incorporation or replication of 2-aminopurine. The final altered base pair duplicates as such in the absence of the base analog (G = guanine, C = cytosine, AP = 2-aminopurine, A = adenine, T = thymine).

analog can also be induced to revert to the original phenotype. Nevertheless, each base analog tends to induce mutations preferentially in one direction[10]. After several DNA duplications the base pair change is established and duplicates as such indefinitely, even after the base analog has been removed.

Whereas the previous mutations were all induced *in vivo*, *Mundry* and *Gierer*[11] reported the *in vitro* induction of mutations in tobacco mosaic virus RNA by nitrous acid. Again, it was possible to explain this induction by base pairing of the deaminated cytosine and adenine with the wrong complementary base and to postulate that deaminated guanine should not be mutagenic[12], as has been verified by *Vielmetter* and *Schuster*[13] (see Fig. 5).

At about the same time, ethylating agents, which were long known to be mutagenic, were found to mutate T4 phages[14] and to react mainly with the N-7 of

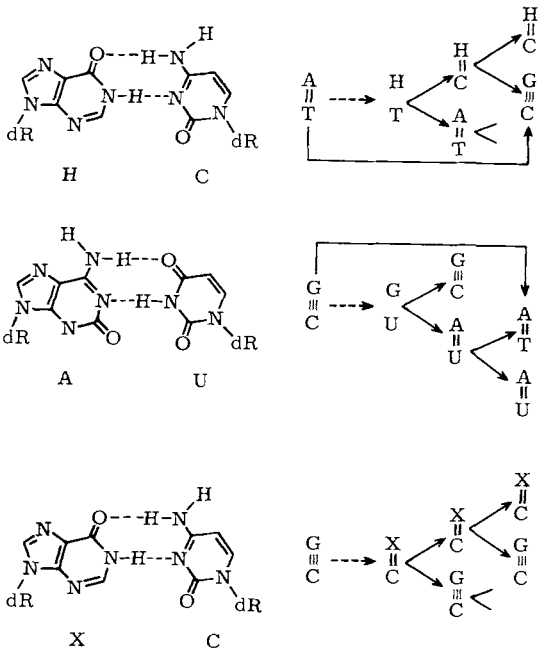

Fig. 5. Base pair changes induced by nitrous acid deamination of bases (H = hypoxanthine, X = xanthine; for other symbols see Fig. 4).

guanine, inducing base pair transitions from GC to AT[15–17] (see Fig. 6). But alkylating agents react also with cytosine and adenine and they induce inactivating DNA alterations, as will be discussed later (for reviews, see refs.[18,19]). The most specific mutagenic

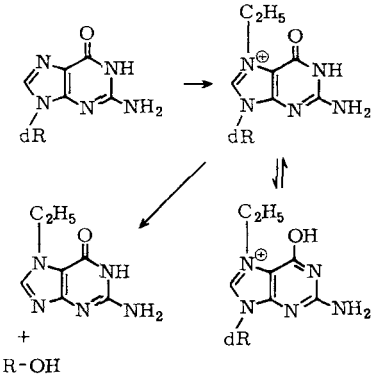

Fig. 6. Reactions of alkylated guanine leading first to "mutagenic" DNA alterations (base alterations) and later to "inactivating" DNA alterations (base removal).

agent found so far is hydroxylamine (or its *o*-methyl derivative, methoxyamine)[20,21]. It induces exclusively point mutations and reacts exclusively with cytosine, if it is used under conditions under which no radicals can be formed by reaction with oxygen.

This can best be achieved in the presence of 1 M or more hydroxylamine and 0.05 M pyrophosphate (pH = 6.5)[22]. Hydroxylamine produces 4-hydroxyaminocytosine or 6-hydroxyamino-5,6-dihydrocytosine or 4,6-bis(hydroxyamino)-5,6-dihydrocytosine, their relative frequency depending on the substitution of C-5. The substituted cytosines apparently pair mostly with adenine thus producing base pair changes from GC to AT (for a review, see ref.[23]).

The explanation of induced mutations by pairing mistakes of base analogs agreed well with the original proposal by *Watson* and *Crick*[24] that spontaneous mutations might arise by pairing mistakes of the normal bases in their tautomeric forms. If all point mutations would arise by such pairing mistakes, only base pair transitions should occur. This simple picture was clearly ruled out by *Freese*[10], who observed in phage T4 that practically all mutants induced by the above base analogs could also be induced to revert by these base analogs, whereas only 14 % of the spontaneous mutations and hardly any of the proflavin (3,6-diaminoacridine) induced mutations responded in this way. Most of the spontaneous mutations, therefore, had to be caused by some other base pair changes. *Freese* assumed as the most likely changes the replacement of a purine by a pyrimidine

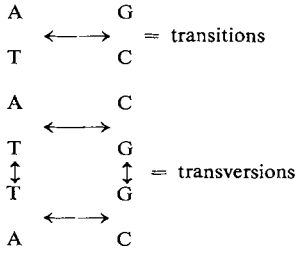

Fig. 7. The two types of base pair substitutions.

and *vice versa*, which he called "transversions" (see Fig. 7). The existence of transversions was strengthened by the fact that treatment (by low pH or ethyl ethanesulfonate), which removed a few guanine bases from DNA, induced the reversion of mutants that could not be induced to revert by any agent inducing only base transitions[25]. Figure 8 explains the induction of different base pair changes by depurination.

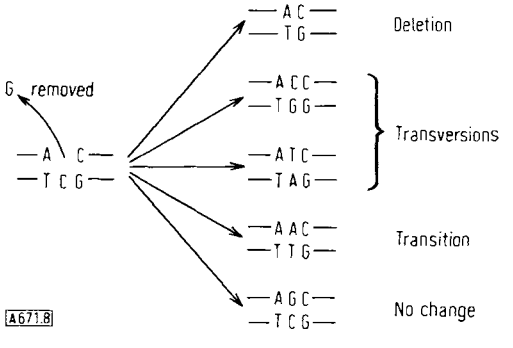

Fig. 8. Base pair changes induced by base removal from DNA.

An alternative model explaining non-transition mutants was soon proposed by *Brenner et al.*[26]. Stimulated by *Lerman*'s[27] observation of proflavine intercalation between DNA bases, they suggested that proflavine induces deletions or insertions of bases. In support of this assumption, *Crick et al.*[28] observed the division of proflavine-induced mutations into two classes (+ and −) with respect to their ability to restore the r_{II} function in double mutants. They consequently proposed the frame shift hypothesis, according to which a deletion shifts the reading frame for the translation of the nucleic acid code to the left and an insertion to the right of the original frame.

At this stage it was clear that only a correlation of amino acid changes in proteins and mutations in DNA could settle which of the above DNA alterations of the non-transition type actually occurred. On the one hand, *Yanofsky*[29] found that an amino acid at a certain position of tryptophan synthetase could be changed by single step mutations into four different amino acids. Since experiments on the cell-free synthesis of proteins had shown that each amino acid is coded by three bases, single base pair transitions altering the same amino acid could occur on three different nucleotide sites in DNA. Hence at least one of the four observed amino acid changes had to be due to a transversion. Similar data have been obtained by *Weigert* and *Garen*[30]. By the analysis of amino acid changes, *Yanofsky et al.*[31] have even shown that a particular bacterial strain spontaneously produces a very high frequency of transversions from AT → CG. On the other hand, *Terzaghi et al.*[32] have proved that proflavine-induced mutations do shift the reading frame by which the message of DNA is translated into the lysozyme protein of phage T4 (see Fig. 9). These results clearly show that proflavine induces deletions and insertions of one or a few DNA bases. All pos-

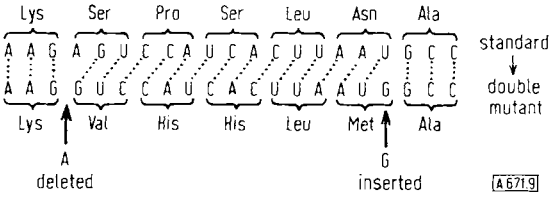

Fig. 9. Shift of reading frame resulting from deletion and insertion of one base pair in phage T4 DNA and the consequence for the amino acid sequence in the lysozyme protein.

sible types of base pair changes can therefore be produced: transitions, transversions, deletions, and insertions. Presumably, inversions and reiterations of a base sequence also exist, but they have not yet been proved experimentally.

All these base pair changes cannot only be induced, but they also arise spontaneously. Which of them occur with the highest frequency depends on the organism. In this connection, an interesting observation has been made by *Speyer* [33], who has shown that the frequency of spontaneous mutations is controlled, at least to some extent, by DNA polymerase. A temperature-sensitive phage mutant, producing an altered polymerase, showed a greatly increased frequency of spontaneous mutations.

This result raised the question of whether DNA replication actually depends on the accurate pairing, by hydrogen bonding, between the old and new DNA bases or whether the replicating enzymes might have enough specificity in themselves to mate always guanine with cytosine and adenine with thymine [33]. This problem was investigated by examining whether mutagenically altered bases would increase the frequency of mutations by the same amount in the presence of the mutant polymerase as for the normal polymerase [34]. If the polymerase would ensure the correct duplication, by actually recognizing the bases, at least some of the altered bases might be recognized differently by the mutant enzyme. No such difference was found. The authors postulated, therefore, that complementary bases pair by hydrogen bonding and that the DNA polymerase recognizes the correct structure, position, and angle of the sugar phosphate moiety of the incoming nucleotide triphosphate. The mutant polymerase presumably accepts more deviations from the correct conformation than the normal polymerase.

Drake [34a] has recently discovered another phage mutant which produces both spontaneous and 5-bromouracil induced mutations at a reduced rate. It is not known whether the more discriminating mutant polymerase can recognize bases directly or whether it recognizes the slight changes in position of the deoxyribose phosphate group that are caused in the incoming nucleotide by an alteration of the base structure.

In different organisms, spontaneous mutations arise by different molecular mechanisms and involve different base specificities. Their frequency determines the rate at which an organism can evolve by creating new base sequences. But many base pair changes in DNA do not alter the phenotypic properties of the organism, because the amino acid code is degenerate, because some amino acid changes do not alter the enzymatic properties of a protein, or because some DNA regions are not utilized. This explains why bacteria which have surprisingly similar properties and biochemical pathways have such different GC/AT base ratios [35, 36]. Their base ratio apparently has shifted slowly, the rate depending on the organism. But only those bacteria survived for which the phenotypic properties were not significantly changed or which could utilize a phenotypic change to adapt to a new ecological niche [37, 38].

3. Large Chromosomal Alterations

If we next want to understand how large chromosome alterations come about, we should know how DNA is built into the structure of a chromosome. For example, DNA molecules carrying different information conceivably could be arranged as side chains to a main chromosomal stem. But we know from genetic experiments by *Pritchard* [39] and many others that mutations within a gene are located on the same information tape as distant outside markers for other functions. Consequently, chromosome models have been proposed in which DNA molecules are one-dimensionally arranged in a long strand and covalently held together by peptide units that are connected always to one of the two strands [40,41]. Chromosomes of higher organisms could carry several identical information tapes in parallel, as suggested by the finding of chromatid and subchromatid strands in chromosomes. At the time of these proposals, DNA molecules were measured to have a molecular weight of no more than 10 million. *Davison* [42] later showed that DNA was subject to shear during its isolation and that carefully isolated DNA molecules were very much longer, with no limit being apparent. Nevertheless, measurements of the unwinding time of rotating DNA [43, 44] have shown that in larger chromosomes swivel points must exist in the information tape, at least during the duplication of DNA. It is unknown whether the interruptions in the double strand are all produced by a DNAase or whether peptide links exist. In any case, DNA itself seems to make up the major portion of the information tape. Hence, any chromosome-breaking agent that can affect DNA presumably causes the breaks owing to its alteration of DNA.

The effect of different agents on chromosomes can be cytologically detected quite early by gaps in or exchanges between the substrands of a chromosome (chromatids or subchromatids); the exchanges apparently occur because broken chromosome ends are "sticky" and tend to attach to other sticky ends [45]. These chromosome aberrations later produce chromosome breaks or other large alterations and thus mutations if the cell can still duplicate.

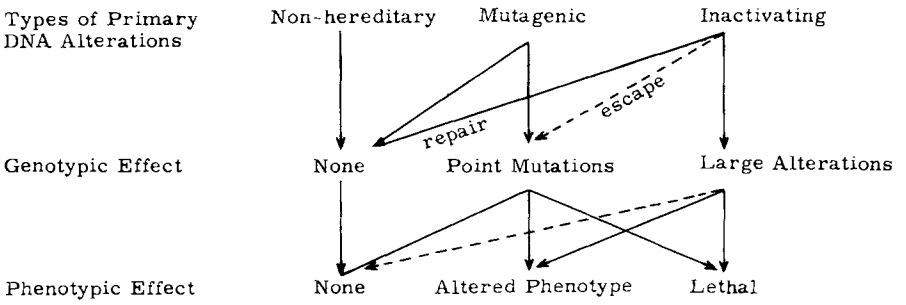

Fig. 12. Primary DNA alterations and their genotypic and phenotypic effects.

The biological effect of these agents on DNA can be measured directly by the inactivation of transforming DNA (Fig. 10a) and by the rate at which (point) mutations are induced (Fig. 10b). More specifically, one can distinguish between "mutagenic" and "inactivating" DNA alterations by measuring the frequency of linked mutations per lethal hit [19]. This is illustrated in Fig. 11: "Mutagenic DNA alterations," induced, *e.g.* by 1 M hydroxylamine, produce point mutations, as indicated by fluorescent colonies in this test; these DNA alterations do not prevent DNA duplication and therefore cannot induce chromosome breaks. In contrast, inactivating DNA alterations, induced *e.g.* by H_2O_2, inactivate transforming DNA, as measured by the number of lethal hits [equal to $-\ln$ (surviving fraction)], but they induce hardly any point mutations; these DNA alterations apparently prevent normal DNA duplication.

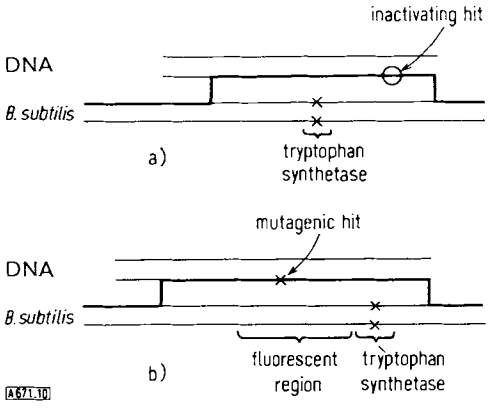

Fig. 10. Measurement of "inactivating" and "mutagenic" DNA alterations in transforming DNA of *B. subtilis*. a) Inactivation caused by an alteration of the gene for tryptophan synthetase. b) Mutation caused by a mutagenic alteration of the DNA region that is linked to the tryptophan synthetase gene and whose functional inactivity causes fluorescent colonies, if the plates contain only suboptimal (derepressing) amounts of indole.

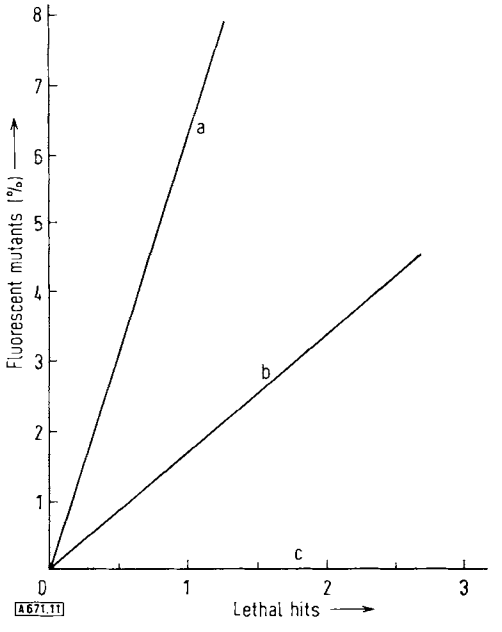

Fig. 11. Measurement of point mutagenic *versus* inactivating effect of different chemicals on transforming DNA. The mutagenic effect is determined by the frequency of fluorescent colonies, whereas lethal hits are equal to $-\ln$ survival of the tryptophan marker.

a) 1 M hydroxylamine in 0.05 M pyrophosphate, pH = 7.5, 70 °C. b) 0.1 M nitrous acid, pH = 4.2, 37 °C. c) 0.01 M hydroxylamine or 0.001 M H_2O_2 or 0.001 M disuccinyl proxide or pH = 4.2 alone or UV radiation.

Fig. 12 summarizes the possible genotypic and phenotypic effects of different primary DNA alterations. Some alterationhave no effect, either because they do not affect DNA replis cation (*e.g.* methylation) or because they are repaired. The different types (of inactivating DNA alterations are summarized in Fig. 13 for a review, see ref. [19]). The relative frequency with which the different possible genotypic or phenotypic effects are produced depends on the type of the primary DNA alteration and on the organism,

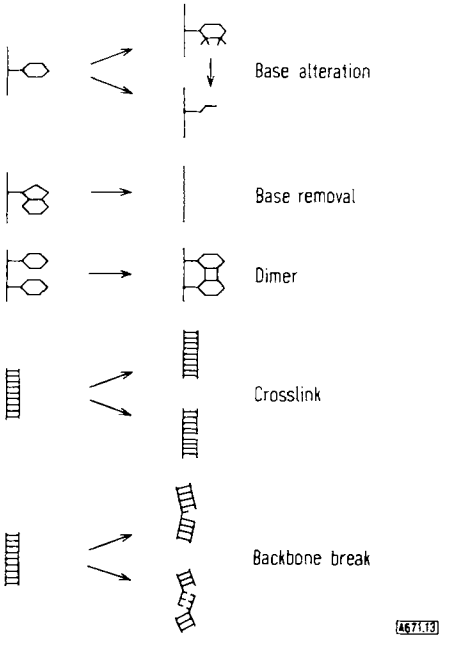

Fig. 13. Types of inactivating DNA alterations.

X-rays were the first agents for which the induction of mutations and chromosome breaks was proved by *Muller* [3]; X-rays also inactivate transforming DNA [46]. All these effects are greatly increased in the presence of oxygen [47] (for a review, see ref. [45]), hence DNA is altered not only directly by ionizing hits but also indirectly by oxidizing radicals. Many other radical-producing agents, *e.g.* peroxides and nitroso compounds and autooxidizable substances such as hydroxylamines, hydrazines, and phenols, are now known to induce chromosome breaks and to inactivate DNA (for a review, see ref. [19]).

[47] *J. M. Thoday* and *J. Read*, Nature (London) *160*, 608 (1947).

The chemical reactions of OH radicals with DNA and its components have been examined most extensively. OH radicals saturate the double bonds between C-5 and C-6 of pyrimidines [48,49] (see Fig. 14). Less frequently OH radicals remove all four bases from DNA and thus cause the back-

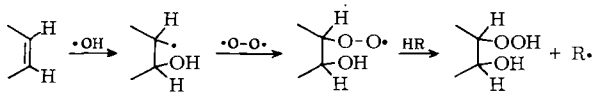

Fig. 14. Opening of 5,6 double bond of pyrimidines by OH radicals. The hydroxy-hydroperoxy-pyrimidine is relatively stable for thymine and reacts further for cytosine.

bone breakage of the sugar phosphate bonds by β-elimination, as has been analyzed by the use of oligodeoxyadenylic acid [50] (see Fig. 15). All of the above radical reactions represent inactivating DNA alterations, because the point mutagenic effect of radicals is negligible.

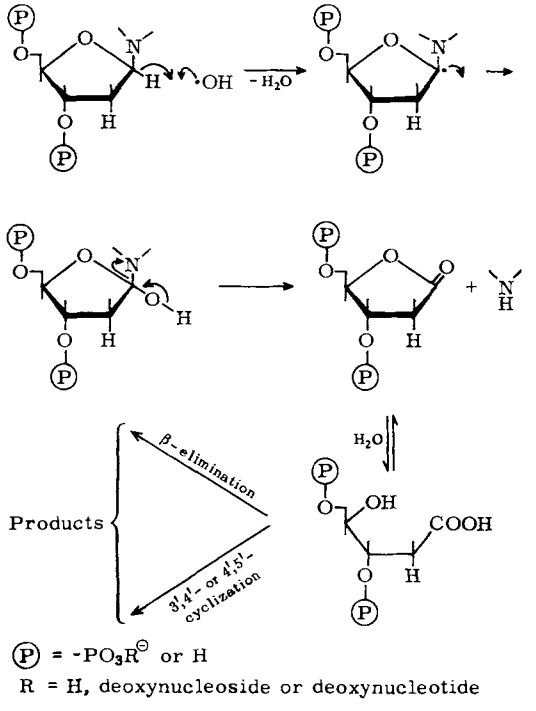

Fig. 15. Mechanisms of DNA backbone breakage by OH radicals.

Another important class of chromosome breaking agents consists of the alkylating agents of which nitrogen mustard was first discovered to induce mutations by *Auerbach* and *Robson* [52]. Other well known alkylating agents are alkylsulfates, epoxides, ethyleneimines, lactones, and diazo compounds, which are liberated at alkaline pH by *N*-alkylnitroso compounds (for review, see ref. [45]). They have in common the tendency to attack nucleophilic groups.

Brookes and *Lawley* [15] have shown, *e.g.*, that alkyl sulfates react with guanine, adenine, and cytosine, preferentially alkylating the N-7 position of guanine. When the ethylation of DNA is immediately followed by DNA duplication, many point mutations arise, apparently by base pairing mistakes of the alkylated guanine (see Fig. 6). But the alkylated guanine bases soon separate from DNA, leading to inactivating DNA alterations and backbone breaks whose number increases with the time of incubation after DNA treatment [14,16,17]. In addition to the bases, the phosphates are also alkylated with the same frequency and the intermediate triesters are occasionally hydrolyzed by the splitting of the sugar phosphate backbone [51,53].

The removal of purines, which can also be accomplished by exposure to low pH or to high temperatures, occasionally produces crosslinks in double stranded DNA (see Fig. 13). Such crosslinks within and between DNA double helices can also be produced by UV light, nitrous acid, and, in especially high frequency, by bifunctional alkylating agents (see refs. [19,45]).

Many of the above agents which induce inactivating DNA alterations cause chromosome aberrations and breakage [45]. They also induce mutations that result from large chromosome alterations, as has been shown by special genetic methods [54].

Some agents seemingly are exceptions to this correlation between chromosome breaking agents and inactivating alterations of DNA. This discrepancy results either from activating or from protective mechanisms of the cell, as will be illustrated by a few examples.

Certain carbamates produce chromosome breaks, as *Oehlkers* [55] has discovered for urethan, whereas they do not inactivate transforming DNA [56]. But they can be *N*-hydroxylated by enzymes present in many organisms [57], and the *N*-hydroxycarbamates do indeed inactivate DNA [58,59], and induce chromosome breaks [60]. Carbamates seem to undergo, therefore, a series of reactions in the cell, which eventually produce radicals which react with DNA. Aromatic amines behave similarly.

Ascorbic acid or H_2O_2 rapidly inactivate DNA [61,62], but they usually do not induce chromosome breaks [63,64]. They are, however, natural metabolites or nutrients which are utilized by enzymes inside the cell; *e.g.* H_2O_2 is rapidly broken down by catalase or peroxidase. Such compounds presumably do not often get close enough to the chromosomes, which are much of the time protected by the nuclear membrane, but they can become effective if the cellular metabolism is altered. For example, H_2O_2 induces chromosome breaks in certain tissue cultures in which the concentration of catalase is greatly reduced [63].

Other protective mechanisms are represented in Fig. 16.

Structural:	Cell membrane, only certain molecules can enter
	Nuclear membrane, protects during DNA replication
	Condensation of DNA into chromosomes, avoids tearing of DNA during segregation
	Precision of chromosomal segregation
Enzymic:	Destruction of dangerous chemicals
	Specificity of nucleotide kinases and replicases, avoids incorporation of wrong nucleotides
	Excision of wrong bases + repair
	Repair of single strand lesions by copying of complementary strand and sealing of gap
	Repair of double strand breaks by stickiness and joining of broken ends
	Maintenance of pH, ion concentration, *etc.*

Fig. 16. Cellular protection against DNA alterations.

Particularly interesting is the ability of certain enzymes to repair damaged DNA. The first molecular explanation of this phenomenon has been obtained both by *Setlov* and *Carrier* [65] and by *Boyce* and *Howard-Flanders* [66]. They discovered that thymine dimers, produced in one DNA strand by ultraviolet irradiation, can be excised and the excised region can be repaired; the repair apparently involves copying the information of the unexcised complementary strand [67]. In the meantime, it has become clear that other DNA lesions, *e.g.* a cut induced by alkylating agents, can also be repaired. Some of the repair enzymes are also used in recombination [68] and probably in normal DNA replication in which the gaps of randomly produced swivel points have to be closed.

In addition to agents which chemically alter DNA and thereby prevent its normal duplication, several nucleosides which inhibit DNA synthesis also induce large chromosomal alterations. They are, *e.g.* cytosine-arabinoside, 5-fluorodeoxyuridine, and adenosine deoxyriboside [45].

Fig. 17 finally gives a brief summary of different general causes of mutations.

Physical:	Mechanical tearing apart of DNA
	Cutting by ionizing radiation or ^{32}P decay
	Non-disjunction of chromosomes
Chemical:	Alteration or removal of DNA bases
	Incorporation of altered bases
	Intercalation of oligocyclic aromatic compounds
	Alteration of DNA backbone
Enzymic:	Production of chemicals affecting DNA
	Mistakes of the DNA replicating system
	Alteration of the DNA replicating system
	Mistakes in recombination

Fig. 17. Causes of mutations.

4. Recombination

When two genetic markers are distantly located on homologous chromosomes, recombination between them appears to involve one reciprocal exchange between the two chromosomes. However, by using closely linked genetic markers, one finds that recombination involves several nonreciprocal recombinational acts within a region of "intimate" or "effective" pairing [69, 70].

The events taking place at the molecular level remained obscure until *Meselson* [71] showed in bacteriophage λ that recombination involves the breakage and rejoining of DNA double strands. This process apparently requires several enzymes that can break, chew away, and repair single DNA strands, because *Clark* and *Margulies* [72] have found several types of mutants that are unable to undergo recombination.

The recombination process occurs usually between homologous portions of DNA, requiring the specific pairing of an extended DNA region. The nonreciprocality of recombination in small dimensions may therefore involve a cut of DNA on the left side of the pairing region for one chromosome and on the right side for the other chromosome, followed by excision of part of the DNA and repair along the pairing partner. But the details of this process are still unclear.

Recombination does not only occur spontaneously, but its frequency can be increased by several agents, all of which induce inactivating DNA alterations. It can also occur between non-homologous chromosomes, when the end of a broken chromosome pairs with that of another chromosome. Again, the molecular events accompanying this repair are unknown.

Recombination is involved even in the production of spontaneous mutations. The frequency of mutations of the deletion type greatly increases in the chromosome area in which recombination occurs [73]. The induction of deletions or insertions by proflavine also occurs especially frequently in recombining organisms such as bacteriophages. These mutations may arise by mistakes in the repair processes which accompany recombination. Consequently, a distinction between mutation and recombination is sometimes hard to make for small dimensions of DNA.

5. Applications

New mutagenic agents have been beneficial to mankind in various ways. They have been employed in the fermentation industry to isolate more efficiently fermenting strains [74]. This approach could be greatly extended by the use of multiple and regulatory mutants, to obtain strains which accumulate just about

[74] *H. J. Peppler*: Microbial Technology. Reinhold, New York 1967.

any desirable metabolite or enzyme. In agriculture, new types of wheat have been isolated, by mutagenic treatment with alkylating agents [75], but so far most new strains of plants or animals are still produced by the classical method of breeding.

Several findings have been employed in medicine. For example iododeoxyuridine is successfully employed against Herpes simplex in the eye. Neoplastic diseases are treated by cytosine arabinoside, fluorodeoxyuridine, hydroxyurea, methotrexate, or other agents which inhibit DNA synthesis; or they are exposed to agents inactivating DNA, such as alkylating agents or methylhydrazine [76].

But we have also learned to be more careful with many compounds in our environment. Certain dyes were readily discovered as carcinogens. The chromosome breaking and carcinogenic effects of X-rays, other ionizing radiations, and radioactive particles are now widely recognized and protective measures have been taken. A similar educational and legislative effort will have to be undertaken before all people will be satisfactorily protected against mutagenic chemicals.

Knowing the chemical and biological action of certain compounds, we can now predict which other chemicals, containing the same reactive groups, are potentially harmful to DNA and chromosomes. For example, all hydrazines are potentially hazardous; they are especially dangerous when they carry lipophilic groups enabling them to enter cells. Such agents are still used as antidepressants [77], all of which inactivate DNA [78], and they apparently are employed as rocket fuels [79]. Also, many carbamates are used as pharmaceutica, herbicides, insecticides, and in varnishes; some of them can probably be converted into chromosome-breaking *N*-hydroxycarbamates by the same or similar enzymes that convert urethan to *N*-hydroxyurethan. Several carbamate herbicides are known to induce chromosome breaks in plants [80]. We cannot be sure which of these compounds are activated or inactivated by enzymes in humans. It is even possible that different humans differ in this respect. However, we should not wait for decades of statistical evaluation, but start now to reduce our exposure to potential mutagens, until they have been proved harmless. If the possibility of cancer does not seem threatening enough to everyone, young people at least owe this precaution to their future children, who should not be doomed to miserable lives, caused by new hereditary defects.

New Methods of Preparative Organic Chemistry [**]

Reactions of Isocyanide Dihalides and their Derivatives

By E. Kühle
in collaboration with B. Anders, E. Klauke, H. Tarnow, and G. Zumach[*]

The readily obtainable isocyanide dichlorides can be used as starting materials for the preparation of many types of substances. Exchange reactions yield numerous derivatives of formic and carbonic acids, while heterocyclic products have been obtained by reaction with bifunctional partners. The present article deals not only with reactions that are known from the literature but also with the author's own work, some of which has not been published before.

1. Introduction

In our review of "Syntheses of Isocyanide Dihalides" [1] [***], we mentioned the relationship of these compounds to isocyanates, isothiocyanates, and carbodiimides, as well as to phosgene and thiophosgene. This relationship makes it easy to understand the reactions of the isocyanide dichlorides.

[*] Dr. E. Kühle, Dr. B. Anders, Dr. E. Klauke, Dr. H. Tarnow, and Dr. G. Zumach
Wissenschaftliches Hauptlaboratorium
der Farbenfabriken Bayer AG
509 Leverkusen (Germany)

[**] Earlier articles in this series have been published in five volumes by Verlag Chemie, Weinheim/Bergstr. An English edition has also been published.

[***] The isocyanide dichlorides should, strictly speaking, be named as imidoyl chlorides, *i.e.* as *N*-substituted chloroformimidoyl chlorides.

[1] *E. Kühle, B. Anders*, and *G. Zumach*, Angew. Chem. *79*, 663 (1967); Angew. Chem. internat. Edit. *6*, 649 (1967).

The reactivities of isocyanide dichlorides increase from the alkyl and cycloalkyl, through the aryl, to the acyl isocyanide dichlorides. Whereas many reactions of the aliphatic and aromatic members can be carried out in aqueous media, the acyl isocyanide dichlorides are readily hydrolyzed, and their reactions must therefore be carried out in non-aqueous media.

The alkyl and aryl isocyanide dichlorides react less readily than acyl chlorides, whereas acyl isocyanide dichlorides react at least as readily. α-Chlorinated aliphatic isocyanide dichlorides form a special case, since their α-chloro atom generally reacts first in nucleophilic substitutions [2].

We have studied the difference in the behavior of acyl chlorides and isocyanide dichlorides, using derivatives that also contain a chlorocarbonyl grouping. For example, 4-chlorocarbonylphenyl isocyanide dichloride (4-dichloromethyleneaminobenzoyl chloride) *(1)* reacts with aniline to form the substitution product *(2)*.

(1) *(2)*

(2) m.p. = 187 °C

In the aliphatic series, *Reusche* [3] showed that the reaction of chlorocarbonyl isocyanide dichloride *(3)* with an equimolar quantity of ethanol leads selectively to ethoxycarbonyl isocyanide dichloride *(4)*.

$$\underset{(3)}{ClCO{-}N{=}CCl_2} \xrightarrow{C_2H_5OH} \underset{(4)\ \text{b.p.} = 68\,^\circ\text{C}/20\ \text{torr}}{H_5C_2OCO{-}N{=}CCl_2}$$

According to *Oertel* [4], *(3)* reacts with epoxides in the presence of a catalytic quantity of aluminum chloride to form β-chloroethoxycarbonyl isocyanide dichlorides, *e.g. (5)* in the case of ethylene oxide.

$$\underset{(3)}{} \xrightarrow[AlCl_3]{\text{ethylene oxide}} \underset{(5)}{ClCH_2CH_2O{-}CO{-}N{=}CCl_2}$$

Cyanogen chloride can be split off from many isocyanide dichlorides; this tendency is particularly strong in chlorosulfenyl isocyanide dichloride (thiocyanogen trichloride) [5], which reacts as sulfur dichloride in many reactions.

Apart from a few reactions of isocyanide difluorides, the following discussion will be confined to reactions of isocyanide dichlorides; the isocyanide dibromides, which are more difficult to obtain, and of which only a few have been described in the literature, will be ignored.

[2] *H. Holtschmidt*, Angew. Chem. *74*, 848 (1962); Angew. Chem. internat. Edit. *1*, 633 (1962).

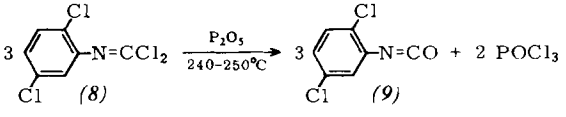
[4] *G. Oertel*, DAS 1249515 (Nov. 24, 1964), Farbenfabriken Bayer AG.

[5] *R. G. R. Beacon* and *R. S. Irwin*, J. chem. Soc. (London) *1960*, 5079.

If one of the geminal chlorine atoms in an isocyanide dichloride is replaced by another group, the reactivity of the remaining chlorine atom generally decreases. This difference in the reactivity of the two chlorine atoms can be used for selective substitutions.

2. Replacement of the Two Chlorine Atoms by Oxygen, Sulfur, or Imino Groups, and Isocyanide Formation



2.1. Isocyanates

The conversion of an isocyanide dichloride into an isocyanate has been studied by *Sell* and *Zierold* [6] with phenyl isocyanide dichloride *(6)*, which reacts exothermally with silver oxide to form phenyl isocyanate *(7)*.

$$\underset{(6)}{C_6H_5{-}N{=}CCl_2} \xrightarrow{Ag_2O} \underset{(7)}{C_6H_5{-}N{=}C{=}O}$$

In our attempts to convert isocyanide dichlorides into isocyanates, we also used the isocyanide dichloride as an acylating agent and allowed it to react with an acid anhydride. In addition to acyl chlorides, this reaction leads in principle to isocyanates; however, the yields are unsatisfactory (mostly because of secondary reactions).

After heating 2,5-dichlorophenyl isocyanide dichloride *(8)* with phosphorus pentoxide at 240–250 °C, we were able to distil off dichlorophenyl isocyanate *(9)* in a 55% yield.

(8) *(9)*

Arlt [7] recently discovered a very simple and very productive method for the preparation of isocyanates, in which isocyanide dichlorides are treated at room temperature with very strong acids, such as chlorosulfuric or dichlorophosphoric acid, and subsequently distilled. Aliphatic and aromatic isocyanates are readily obtainable by this method.

$$R{-}N{=}CCl_2 + HOSO_2Cl \xrightarrow[-HCl]{} [R{-}N{=}CCl{-}OSO_2Cl] \xrightarrow[-SO_2Cl_2]{} RN{=}C{=}O$$

Mukaiyama et al. [8] utilized the ease of dehydration of benzaldoxime *(10)* to convert phenyl isocyanide dichloride *(6)* into phenyl isocyanate *(7)*.

$$\underset{(6)}{C_6H_5{-}N{=}CCl_2} + \underset{(10)}{C_6H_5{-}CH{=}NOH} \rightarrow \underset{(7)}{C_6H_5{-}N{=}C{=}O} + C_6H_5CN + 2\,HCl$$

Kirsanov et al. [9] obtained a phosphorylated isocyanate *(12)* by reaction of a dialkyloxyphosphoryl isocyanide dichloride *(11)* with anhydrous formic acid. This method has the advantage that all by-products are gaseous.

[6] *E. Sell* and *G. Zierold*, Ber. dtsch. chem. Ges. *7*, 1228 (1874).

[7] *D. Arlt*, German Pat. Appl. F 52867 IVb/12 o (July 6, 1967), Farbenfabriken Bayer AG.

[8] *T. Mukaiyama et al.*, Bull. chem. Soc. Japan *35*, 1104 (1962).

[9] *A. V. Kirsanov*, *G. I. Derkač*, and *N. I. Liptuga*, Ž. obšč. Chim. *34*, 2812 (1964).

$$(AlkO)_2P(O)-N=CCl_2 \xrightarrow{HCOOH} (AlkO)_2P(O)-N=C=O + CO + 2\,HCl$$
(11) *(12)*

The reaction of phenyl isocyanide dichloride *(6)* with ethanol, in which hydrogen chloride and chloroethane are split off to form *N*-phenylethylurethane *(13)*, was also reported by *Sell* and *Zierold*[6].

$$C_6H_5-N=CCl_2 \xrightarrow[-HCl\ -C_2H_5Cl]{C_2H_5OH} C_6H_5-NH-COOC_2H_5$$
(6) *(13)*

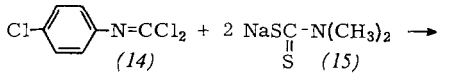
This reaction probably proceeds *via* ethyl *N*-phenylchloroformimidate, which readily loses chloroethane, the loss being catalyzed by hydrogen chloride[8,10]. The resulting isocyanate then reacts with the excess of ethanol to form the urethane.

2.2. Isothiocyanates

Whereas nearly all isocyanates can be prepared by phosgenation of primary amines, there is no general synthesis for isothiocyanates, apart from the reaction of primary amines with the expensive thiophosgene. It is therefore fortunate that isothiocyanates can be obtained in good yields from isocyanide dichlorides by two mutually complementary methods.

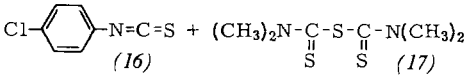
Sell and *Zierold*[6] obtained phenyl isothiocyanate in quantitative yield by treatment of phenyl isocyanide dichloride with hydrogen sulfide at room temperature. According to *Petrov et al.*[11], however, this method cannot be used with aliphatic isocyanide dichlorides. We found that even in the case of phenyl isocyanide dichloride, the isothiocyanate is formed only at about 100 °C.

The action of sulfur on 4-chlorophenyl isocyanide dichloride at 250 °C leads to the elimination of sulfur dichloride and formation of 4-chlorophenyl isothiocyanate in moderate yield[12].



2.2.1. The Sodium Sulfide Method[13,14]

Aliphatic and aromatic isocyanide dichlorides react with sodium or ammonium sulfide in aqueous acetone to give high yields (>80 %) of the corresponding isothiocyanates:



$$R-N=CCl_2 + Na_2S \rightarrow R-N=C=S + 2\,NaCl$$

This reaction can be used only for the preparation of isothiocyanates that do not react with water under the reaction conditions (20–50 °C). Thus the acylated isocyanide dichlorides derived from carboxylic acids, sulfonic acids, and phosphoric acids cannot be converted in this way into the reactive isothiocyanates. The method also fails with isocyanide dichlorides containing a functional group that reacts with water (*e.g.* COCl, NCO).

Isothiocyanates are sometimes also formed by the action of thiolates such as *(15)* on isocyanide dichlorides (cf. Section 4.3). Thus the reaction of 4-chlorophenyl isocyanide dichloride *(14)* and 2 moles of sodium dimethyldithiocarbamate *(15)* yields 4-chlorophenyl isothiocyanate *(16)* together with tetramethylthiuram monosulfide *(17)*.

(14) *(15)*

(16) *(17)*

Chloromethyl isocyanide dichloride *(18)* reacts similarly with 3 moles of *(15)* to give isothiocyanatomethyl dimethyldithiocarbamate *(19)* in a yield of more than 90% [15].

$$ClCH_2N=CCl_2 + 3\,(15) \rightarrow (CH_3)_2NCS-S-CH_2-N=C=S + (17)$$
(18) *(19)*

By the reaction of potassium *N*-*p*-toluenesulfonyldithiocarbonimidate with phenyl isocyanide dichloride, we obtained phenyl isothiocyanate and the first sulfonyl isothiocyanate. This reaction has been developed into a method for the preparation of sulfonyl isothiocyanates from *N*-sulfonyldithiocarbonimidates and phosgene[16].

2.2.2. The Phosphorus Pentasulfide Process[17]

By analogy with the reaction of isocyanide dichlorides and phosphorus pentoxide to form isocyanates (cf. Section 2.1), the isothiocyanates should be obtainable by reaction of isocyanide dichlorides with phosphorus pentasulfide. This reaction does in fact proceed in high yields when the reactants are heated in inert solvents (boiling toluene or chlorobenzene):

$$3\,R-N=CCl_2 + P_2S_5 \rightarrow 3\,R-N=C=S + 2\,PSCl_3$$

This process, which is carried out in anhydrous media, can be used even with readily hydrolyzable acyl isocyanide dichlorides (*e.g.* tetrameric cyanogen chloride) and aliphatic or aromatic isocyanide dichlorides containing a group that reacts with water (*e.g.* COCl or NCO) (yields >80 %).

Higher temperatures (*e.g.* boiling dichlorobenzene) are generally necessary for highly chlorinated groups R, and the method sometimes even fails.

1-Perchloronaphthyl isocyanide dichloride *(20)* reacts with excess phosphorus pentasulfide at 180 °C to form the isothiocyanate *(21)*. In this case the sodium sulfide method gives the naphthothiazole derivatives *(22)* and *(23)* [18].

[18] *G. Beck*, unpublished.

(20) (21) (22) (23)

(21) m.p. = 121–122 °C
(22) m.p. = 267–269 °C
(23) m.p. = 358–359 °C (decomp.)

2.3. Carbodiimides

The hydrochlorides of primary amines can be converted into carbodiimides by "iminophosgenation" The amines must be used in the form of these rather inert salts because the free bases react further with isocyanide dichlorides under these conditions, generally with direct formation of guanidines (cf. Section 4.1).

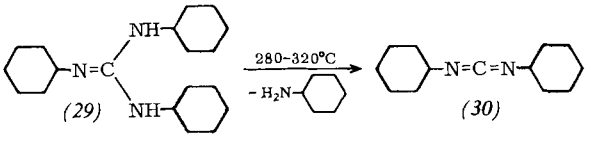
The synthesis of the carbodiimides proceeds as follows:

$$R{-}N{=}CCl_2 + H_2NR^1 \cdot HCl \xrightarrow[-3\ HCl]{} R{-}N{=}C{=}N{-}R^1$$

and is carried out between 170 and 180 °C (dichlorobenzene solution) in the case of alkyl or aryl isocyanide dichlorides[19]. Temperatures of 120–130 °C (chlorobenzene solution) are sufficient for sulfonyl isocyanide dichlorides[20].

Carbodiimides can also be obtained from isocyanide dichlorides *via* the chloroformamidines. For example, the reactions of *(6)* and *(14)* with 2 moles of *n*-propylamine at 20–30 °C lead directly to the carbodiimides *(24)* and *(25)*[20a].

$C_6H_5{-}N{=}C{=}N{-}C_3H_7$ *(24)* b.p. = 120–122 °C/11 torr
4-$ClC_6H_4{-}N{=}C{=}N{-}C_3H_7$ *(25)* b.p. = 98–102 °C/0.5 torr



This reaction can also be carried out with acyl isocyanide dichlorides; however, the isocyanide dichlorides of carboxylic acids give the desired carbodiimides only with aliphatic amines in which the amino group is attached to a tertiary carbon atom[21]. 4-Chlorobenzoyl isocyanide dichloride reacts with *tert*-butylamine at room temperature in a molar ratio of 1:1 in the presence of triethylamine to give the stable *N*-(4-chlorobenzoyl)-*N'*-*tert*-butylcarbodiimide *(26)*.

4-$ClC_6H_4{-}CO{-}N{=}C{=}N{-}C(CH_3)_2$
(26) b.p. = 135–137 °C/0.05 torr

Derkač et al.[22] have obtained phosphorylated carbodiimides such as *(27)* and *(28)* from phosphorylated isocyanide dichlorides and anilines.

$(C_3H_7O)_2P(O){-}N{=}C{=}N{-}C_6H_5$ *(27)*
$(C_6H_5O)_2P(O){-}N{=}C{=}N{-}C_6H_4{-}Br(p)$ *(28)*

Carbodiimides can also be obtained from isocyanide dichlorides *via* guanidines. N^1,N^2,N^3-Tricyclohexylguanidine *(29)*, which can be obtained from cyclohexyl isocyanide dichloride and cyclohexylamine, loses one mole of cyclohexylamine at 280–320 °C to form dicyclohexylcarbodiimide *(30)*.

(29) (30)

2.4. Isocyanides

Traces of isocyanides can often be detected by their odor in nucleophilic exchange of isocyanide dichlorides; they are undoubtedly formed in side reactions in which the isocyanide dichlorides act as oxidizing agents. The formation of methyl isocyanide *(32)* was detected by *Petrov et al.*[11] in the reaction of methyl isocyanide dichloride *(31)* with iodide, the intermediate methyl isocyanide diiodide immediately decomposing into *(32)* and iodine.

$$\underset{(31)}{CH_3{-}N{=}CCl_2} \xrightarrow{HI} [CH_3N{=}CI_2] \rightarrow \underset{(32)}{CH_3{-}N{\equiv}C} + I_2$$

By analogy with the reaction of isothiocyanates with triethylphosphine[23], we were able to convert isocyanide dichlorides into isocyanides by treatment with trialkyl- or triarylphosphines at high temperatures[24]. For example *(6)* gives phenyl isocyanide *(33)* in this reaction.

$$\underset{(6)}{C_6H_5{-}C{=}NCl_2} + P(C_6H_5)_3 \xrightarrow[-Cl_2P(C_6H_5)_3]{60-100\,^\circ C} \underset{(33)}{C_6H_5N{\equiv}C}$$

Our observations so far indicate that this method is unsuccessful in the case of acyl isocyanide dichlorides.

3. Nucleophilic Substitution of a Chlorine Atom

3.1. Chloroformamidines

Chloroformamidines are readily obtained by reaction of isocyanide dichlorides with primary or secondary amines in a molar ratio of 1:1. Twice the required

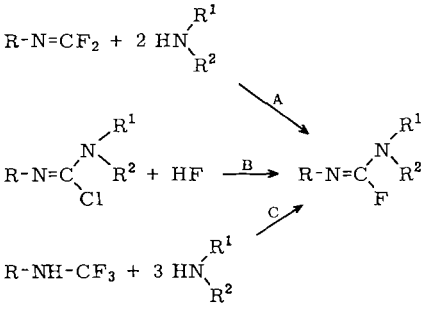
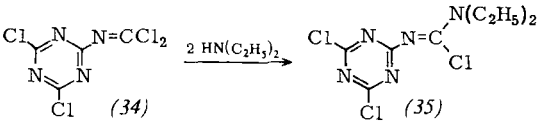
[24] *H. Malz* and *E. Kühle*, German Pat. 1158501 (May 23, 1962), Farbenfabriken Bayer AG.

quantity of amine should preferably be used, in order to bind the hydrogen chloride liberated [25].

Where the amine is expensive, a corresponding quantity of a tertiary amine may be used to bind the hydrogen chloride. The reaction, which occurs even at room temperature, proceeds only with strongly basic amines in the cases of aliphatic and aromatic isocyanide dichlorides. Higher temperatures must be used for aromatic amines; in addition to unreacted starting material, guanidines are obtained directly in this case by replacement of both chlorine atoms [6].

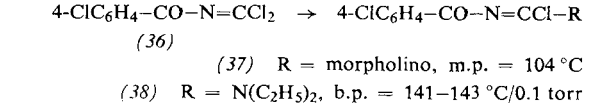


Most chloroformamidines add on hydrogen chloride in the cold to form salts, which readily lose hydrogen chloride again above their melting points.

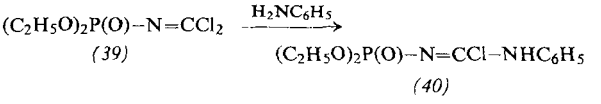


The chloroformamidinium chlorides ("urea dichlorides") are also formed in good yields on reaction of substituted ureas with phosphorus pentachloride in the cold [26], while at higher temperatures, simultaneous elimination of HCl leads directly to the free chloroformamidines [27].

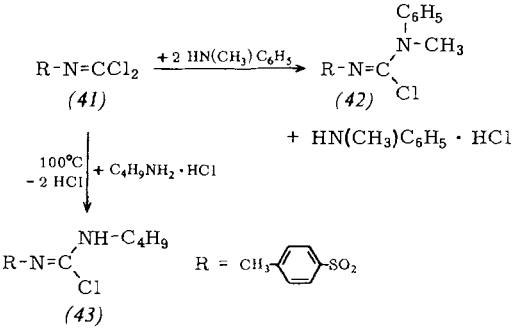
The fluoroformamidines can be obtained in three ways [28]. As in the case of the isocyanide dichlorides, a fluorine atom in the isocyanide difluoride may be replaced by an amine residue (path A). Secondly, treatment of chloroformamidines with anhydrous hydrofluoric acid leads to chlorine-fluorine exchange and formation of fluoroformamidines (path B). Finally, the *N*-trifluoromethylamines, which are described in Section 6.1, can be converted into fluoroformamidines by reaction with 3 moles of an amine (path C).



Acyl isocyanide dichlorides can also be converted selectively into acylated chloroformamidines by reaction with amines.



Thus "tetrameric cyanogen chloride" *(34)*, which may be formally regarded as an acyl isocyanide dichloride, reacts in good yields with primary and secondary amines even at −15 °C [29,30]. An example is the formation of N^1,N^1-diethyl-N^2-dichlorotriazinylchloroformamidine *(35)*.



Acyl isocyanide dichlorides derived from carboxylic acids react in a similar manner with amines to form acylated chloroformamidines. For example, we have synthesized *(37)* and *(38)* in good yields from *(36)*.

In the phosphoryl isocyanide dichloride series, *Derkač et al.* [22] described the synthesis of the phosphorylated chloroformamidine *(40)* from diethoxyphosphoryl isocyanide dichloride *(39)* and aniline.

Finally, *Neidlein et al.* [31] converted sulfonyl isocyanide dichlorides, *e.g. (41)*, into sulfonated chloroformamidines, *e.g. (42)*, by reaction with 2 moles of a secondary aromatic amine.

Sulfonylated chloroformamidines such as *(43)* can also be obtained by heating sulfonyl isocyanide dichlorides with hydrochlorides of primary amines at 100 °C.

Only 2 moles of hydrogen chloride are liberated at this temperature the third mole being lost only at 120–130 °C to form a carbodiimide (cf. Section 2.3).

3.2. Esters of Chloroformimidic Acid

Lengfeld et al. [10] obtained ethyl *N*-phenylchloroformimidate *(44)* by reaction of phenyl isocyanide dichloride *(6)* with sodium ethoxide in a molar ratio of 1:1.

[25] *E. Kühle* and *L. Eue*, German Pat. 1211163 (May 16, 1959), Farbenfabriken Bayer AG.

[26] *R. Wegler, E. Kühle*, and *L. Eue*, German Pat. 1129161 (Jan. 19, 1960), Farbenfabriken Bayer AG.

[27] *D. L. Smathers*, US-Pat. 3084192 (Apr. 14, 1959), DuPont.

[28] *E. Kühle, E. Klauke*, and *L. Eue*, German Pat. 1153743 (Aug. 12, 1961), Farbenfabriken Bayer AG.

[29] Geigy AG, Belg. Pat. 604736 (June 7, 1961).

[30] *Y. Kodama, T. Sekiba*, and *M. Kato*, J. Soc. org. synth. Chem., Japan *22*, 749 (1964).

[31] *R. Neidlein* and *W. Haussmann*, Tetrahedron Letters *1966*, 2217.

$C_6H_5-N=CCl_2 + NaOC_2H_5 \rightarrow C_6H_5-N=CCl-OC_2H_5$
(6) (44)

This reaction can also be used with aliphatic isocyanide dichlorides; the compound *(45)*, for example, is obtained in this way.

$CH_3-(CH_2)_3-CH(C_2H_5)-CH_2-N=CCl-OCH_3$

(45) b.p. = 100–101 °C/11 torr

In the case of aryl isocyanide dichlorides we use an inert, water-immiscible solvent such as chlorobenzene and an aqueous-alcoholic alkali solution[32]. This modified procedure has the advantage that owing to the presence of two phases, the excess of water-soluble alcohol can no longer react with the chloroformimidate during subsequent treatment of the reaction mixture at high temperatures, but is removed beforehand by the aqueous phase.

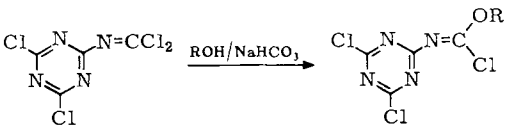
The reaction of *(6)* with ethylene oxide in the presence of triethylamine at 95–100 °C leads, not to β-chloroethyl *N*-phenylchloroformimidate *(46)*, but by a Chapman rearrangement to the isomeric carbamoyl chloride *(47)*[33].

$C_6H_5-N=CCl_2$ (6) + H_2C-CH_2 (O)

$\xrightarrow{(C_2H_5)_3N}$ $C_6H_5-N=C(Cl)-OCH_2-CH_2Cl$ *(46)*

$\xrightarrow{\rho}$ $C_6H_5-N(CH_2-CH_2Cl)-COCl$ *(47)*

Phenols, like alcohols, also react in equimolar quantities with isocyanide dichlorides to give aryl chloroformimidates, *e.g. (48)*[34]. It has been found that the best results are obtained in this case with sodium phenoxides in a polar solvent such as dioxane.



$C_6H_5-N=CCl_2$ (6) + 4-$ClC_6H_5ONa \rightarrow C_6H_5-N=CCl-OC_6H_4Cl(p)$ *(48)*

Though these compounds are sufficiently stable to be distilled, they sometimes undergo Chapman rearrangement at extreme temperatures. For example, phenyl *N*-phenylchloroformimidate *(49)* isomerizes at 330 °C to give diphenylcarbamoyl chloride *(50)*

$C_6H_5-N=CCl-OC_6H_5 \rightarrow (C_6H_5)_2N-COCl$

(49) b.p. = 170–180 °C/10 torr *(50)* m.p. = 82–84 °C

"Tetrameric cyanogen chloride" *(34)* has been converted into the *N*-(dichlorotriazinyl)chloroformimidates *(51)* and *(52)* by reaction with lower aliphatic alcohols in the presence of sodium hydrogen carbonate[35].

(34) *(51)*, R = CH_3; *(52)*, R = C_2H_5

Alimov et al.[36] obtained ethyl *N*-(diethoxyphosphoryl)-chloroformimidate *(53)* by reaction of diethoxyphosphoryl isocyanide dichloride *(39)* with ethanol in the presence of triethylamine.

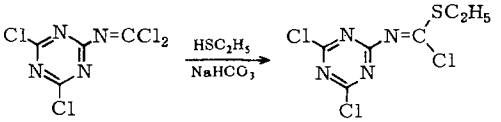
$(C_2H_5O)_2P(O)-N=CCl_2$ (39) + $HOC_2H_5 \xrightarrow{(C_2H_5)_3N} (C_2H_5O)_2P(O)-N=CCl-OC_2H_5$ *(53)*

3.3. Thioesters of Chloroformimidic Acids

A few thio analogs of the chloroformimidates, such as *(54)*, have been described, and can be prepared *e.g.* from isocyanide dichlorides and thiolates[37].

4 $ClC_6H_4-N=CCl_2$ (14) + $NaS-C_6Cl_5 \xrightarrow[\text{acetone}]{} 4\text{-}ClC_6H_4-N=CCl-SC_6Cl_5$ *(54)*

This selective chlorine exchange does not always proceed in a uniform manner with acyl thiolates such as dithiocarbamates, xanthates, and dithiophosphates.



The best methods of obtaining thioesters of chloroformimidic acids are the addition of sulfenyl chlorides to isocyanides (path A) and the reaction of sulfenyl chlorides with monosubstituted formamides in the presence of thionyl chloride (path B)[38].

$R-N\equiv C + ClSR^1 \rightarrow RN=CCl-SR^1$ path A

$R-NH-CHO \xrightarrow[SOCl_2]{R^1SCl} RN=CCl-SR^1$ path B

The acyl isocyanide dichloride "tetrameric cyanogen chloride" *(34)* has been converted into the thioester *(55)* by reaction with alkanethiols in the presence of sodium hydrogen carbonate[39].

Alimov et al.[36, 40] have also obtained a phosphorylated thiochloroformimidate *(56)* by the reaction of di-

ethoxyphosphoryl isocyanide dichloride *(39)* with propanethiol in the presence of a tertiary amine.

(39) $\xrightarrow[\text{tertiary amine}]{HSC_3H_7}$ $(C_2H_5)_2P(O)-N=CCl-SC_3H_7$ *(56)*

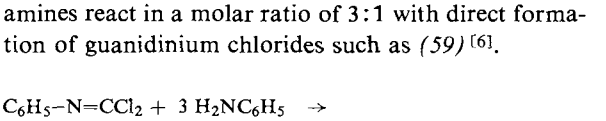
3.4. Cyanoformimidoyl Chlorides

Isocyanide dichlorides and copper(I) cyanide react when heated in equimolar quantities in a high-boiling solvent such as dichlorobenzene to give cyanoformimidoyl chlorides such as *(57)* [41]. These compounds are also obtainable by chlorination of adducts such as *(58)* [42]

$C_6H_5-N=CCl_2$ + CuCN $\xrightarrow{180\,°C}$ $C_6H_5-N=CCl-CN$ *(57)*

(6)

$\uparrow$ 2 Cl_2, $-SCl_2$



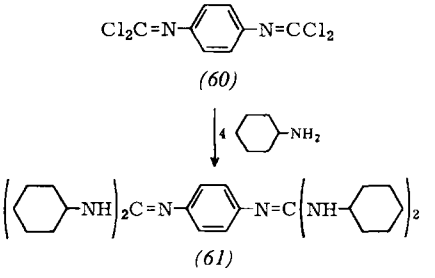
$C_6H_5-NH-CS-CN$

(57) b.p. = 124–128 °C/24 torr *(58)*

4. Nucleophilic Substitution of Both Chlorine Atoms by Similar Groups

4.1. Guanidines

Trisubstituted, tetrasubstituted, and pentasubstituted guanidines can be prepared from isocyanide dichlorides and amines. Isocyanide dichlorides and aromatic amines react in a molar ratio of 3:1 with direct formation of guanidinium chlorides such as *(59)* [6].



$C_6H_5-N=CCl_2$ + 3 $H_2NC_6H_5$ $\rightarrow$

(6) $C_6H_5-N=C(NHC_6H_5)_2 \cdot HCl$ + $C_6H_5NH_2 \cdot HCl$

(59)

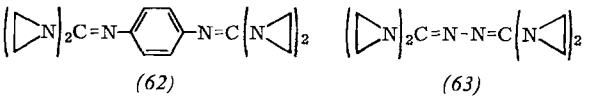
This guanidine synthesis proceeds particularly smoothly and uniformly in aqueous alkaline media at or slightly above room temperature; the guanidines are then formed directly as the free bases [43].

Tetrasubstituted guanidines are better prepared from chloroformamidines (cf. Section 3.1), which can be converted specifically into unsymmetrically substituted guanidines with primary or secondary amines.

$Cl_2C=N-C_6H_4-N=CCl_2$

(60)

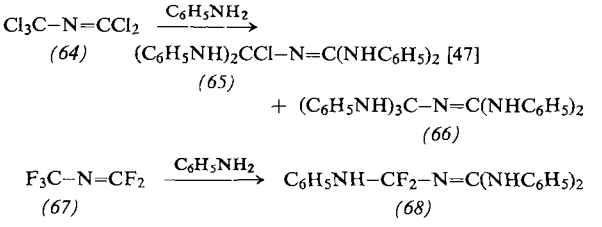
$\downarrow$ 4 $C_6H_5-NH_2$



$(C_6H_5-NH)_2C=N-C_6H_4-N=C(NH-C_6H_5)_2$

(61)

(61) m.p. = 168–171 °C



Diguanidines such as *(61)* can be obtained from bis-isocyanide dichlorides and 4 moles of an amine

Diguanidines based on ethyleneimine, *e.g. (62)* and *(63)*, have been synthesized by several research groups because of their possible action as cytostatic or chemical sterilizing agents [44, 45].

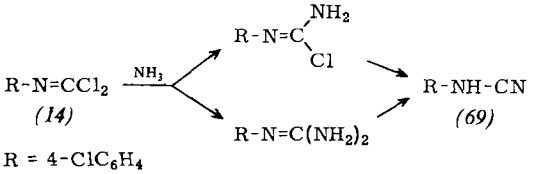
(62) *(63)*

Trichloromethyl isocyanide dichloride *(64)* and trifluoromethyl isocyanide difluoride *(67)* gave guanidine derivatives having additional amine functions in the molecule; the reactions with aniline yield the compounds *(65)* and *(66)* [11] or *(68)* respectively [46].

$Cl_3C-N=CCl_2$ $\xrightarrow{C_6H_5NH_2}$

(64) $(C_6H_5NH)_2CCl-N=C(NHC_6H_5)_2$ [47]

(65)

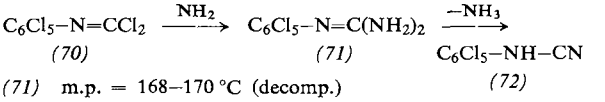


+ $(C_6H_5NH)_3C-N=C(NHC_6H_5)_2$

(66)

$F_3C-N=CF_2$ $\xrightarrow{C_6H_5NH_2}$ $C_6H_5NH-CF_2-N=C(NHC_6H_5)_2$

(67) *(68)*



With ammonia as the amine component, the reaction of isocyanide dichlorides yields cyanamides, possibly *via* chloroformamidines or even guanidines. 4-Chlorophenyl cyanamide *(69)* is obtained in this way in a yield of more than 90 % from 4-chlorophenyl isocyanide dichloride *(14)* [48].

$R-N=CCl_2$ *(14)* $\xrightarrow{NH_3}$ $R-N=C(NH_2)Cl$ / $R-N=C(NH_2)_2$ $\rightarrow$ $R-NH-CN$ *(69)*

R = 4-ClC_6H_4

On reaction of pentachlorophenyl isocyanide dichloride *(70)* with ammonia, we were able to isolate the guanidine *(71)*; this product loses ammonia above its melting point to form the cyanamide *(72)*.

$C_6Cl_5-N=CCl_2$ $\xrightarrow{NH_3}$ $C_6Cl_5-N=C(NH_2)_2$ $\xrightarrow{-NH_3}$ $C_6Cl_5-NH-CN$

(70) *(71)* *(72)*

(71) m.p. = 168–170 °C (decomp.)

(72) m.p. = 280 °C

Acyl isocyanide dichlorides give acylated guanidines or cyanamides. Similarly, diaminoguanidines such as *(73)* and *(74)* are obtained from acyl isocyanide dichlorides and substituted hydrazines.

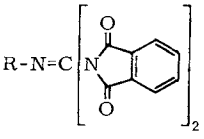
[46] *K. A. Petrov* and *A. A. Nejmysheva*, Ž. obšč. Chim. *29*, 2695 (1959).

[47] According to investigations by *H. Holtschmidt*, isomeric chloroformamidine derivatives are also formed.

[48] *E. Kühle* and *B. Anders*, DAS 1261498 (Aug. 31., 1964), Farbenfabriken Bayer AG.

(73)

(74)



(73) m.p. = 147 °C; *(74)* m.p. = 205–208 °C

Diacylated and peracylated guanidine derivatives can also be obtained from isocyanide dichlorides. The reaction of isocyanide dichlorides such as *(75)* with sulfonamides, *e.g. (76)*, in a molar ratio of 1:2 in an inert solvent at 140–150 °C leads to loss of hydrogen chloride and direct formation of 1,3-disulfonylated guanidine *(77)*.

$$\underset{(75)}{C_4H_9N{=}CCl_2} + 2\,\underset{(76)}{H_2NSO_2{-}C_6H_4{-}CH_3(p)} \xrightarrow{-2\,HCl} C_4H_9{=}C[NHSO_2{-}C_6H_4{-}CH_2(p)]_2$$

(77) m.p. = 115–117 °C

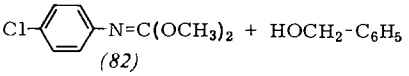
The reaction of acylated isocyanide dichlorides with 2 moles of potassium phthalimide yields peracylated guanidines, such as *(78)* and *(79)*.

(78), R = CH_3SO_2- m.p.=210–214 °C

(79), R = $(C_2H_5O)_2\overset{\overset{O}{\|}}{P}$- m.p.=145–148 °C

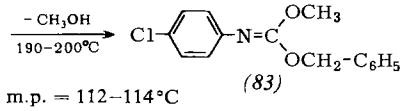
4.2. Esters of Carbonimidic Acids

The action of sodium alkoxides or alcoholic alkali solution on isocyanide dichlorides leads to esters of carbonimidic acids, such as dimethyl *N*-phenylcarbonimidate *(80)* [49].



$$\underset{(6)}{C_6H_5{-}N{=}CCl_2} + 2\,NaOCH_3 \rightarrow \underset{(80)}{C_6H_5{-}N{=}C(OCH_3)_2}$$

With chloroformimidates (cf. Section 3.2) as starting materials, it is also possible in this way to obtain carbonimidates with different alkyl groups, *e.g. (81)*.

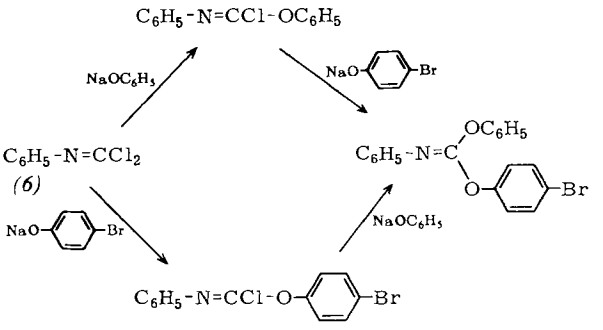


$$\underset{(44)}{C_6H_5{-}N{=}CCl{-}OC_2H_5} \xrightarrow{NaOCH_3} \underset{(81)}{C_6H_5{-}N{=}C(OCH_3){-}OC_2H_5}$$

b.p. = 120–123 °C/13 torr

Compounds of this type can sometimes also be obtained by partial transesterification of carbonimidates containing lower alkyl groups with a high-boiling alcohol at the boiling point. Thus, when heated in benzyl alcohol, the ester *(82)* loses methanol to form benzyl methyl *N*-(4-chlorophenyl)carbonimidate *(83)*.

(82)



(83)

m.p. = 112–114 °C

[49] *W. R. Smith*, Amer. chem. J. *16*, 372 (1894).

In the series of diaryl esters, *Hantzsch et al.* [34] tried in the course of stereochemical studies to prepare unsymmetrically esterified carbonimidic acids. They found, however, that the compounds synthesized by two routes are identical.

According to *Dyson et al.* [50], phenyl isocyanide dichloride *(6)* also forms diaryl carbonimidates, *e.g. (84)*, when heated at 150 °C with free phenols.

$$\underset{(6)}{C_6H_5{-}N{=}CCl_2} \xrightarrow[-HCl]{HOC_6H_5} \underset{(84)}{C_6H_5{-}N{=}C(OC_6H_5)_2}$$

From a purely formal standpoint, the reactions of isocyanide dihalides with salts of acids in which an oxygen atom carries the negative charge should also be discussed here.

(a) Reaction with salts of phosphates [51].

$$R{-}N{=}CCl_2 + 2\,NaOP(O)(O\text{-}Alkyl)_2 \rightarrow R{-}N{=}C[OP(O)(OAlkyl)_2]_2$$

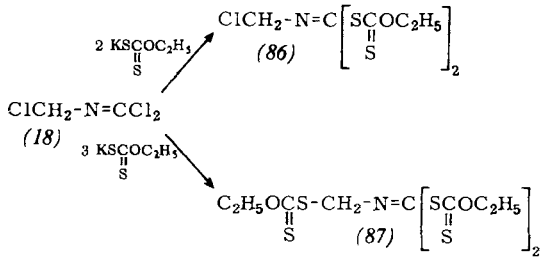
(b) Reaction with salts of sulfinic acids [52].

$$Br_2C{=}N{-}N{=}CBr_2 + 2\,C_6H_5{-}SO_2Na \xrightarrow{H_2O} (C_6H_5{-}SO_2)_2C{=}N{-}NH_2$$

4.3. Thioesters of Carbonimidic Acids

It was mentioned in Section 2.2.1 that isocyanide dichlorides react readily with thiolates to form isothiocyanates. The reaction of isocyanide dichlorides with 2 moles of a thiol or thiophenol, on the other hand, leads smoothly to thioesters of carbonimidic acids when carried out in strongly alkaline media, and particularly in aqueous alkali. The thioester *(85)*, for example, can be obtained in this way.

$$\underset{(6)}{C_6H_5{-}N{=}CCl_2} + 2\,HSC_4H_9 \xrightarrow{NaOH/H_2O} C_6H_5N{=}C(SC_4H_9)_2$$

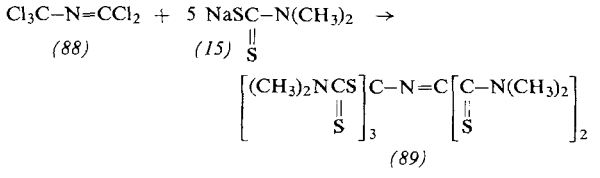


(85) b.p. = 205–210 °C/12 torr

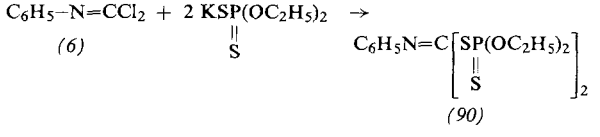
Whereas the reaction of chloromethyl isocyanide dichloride *(18)* with 3 moles of sodium dimethyldithiocarbamate leads to the formation of tetramethylthiuram monosulfide *(17)* and the isothiocyanate *(19)* (cf. Section 2.2.1), *(18)* reacts

[50] *G. M. Dyson* and *T. Harrington*, J. chem. Soc. (London) *1942*, 150.

[51] Ihara Agriculture Chem. Comp., Jap. Pat. Appl. 24399/63 (Nov. 15, 1963).

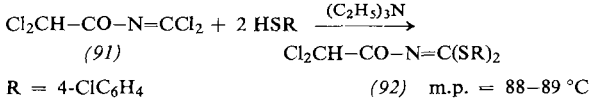


[52] *J. Diekmann*, J. org. Chemistry *28*, 2933 (1963).

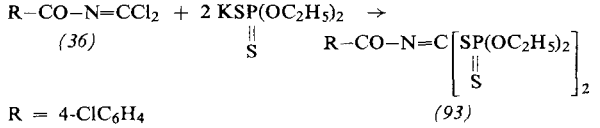


(86) b.p. = 100–103 °C (decomp.)/35 torr
(87) b.p. = 110 °C (decomp.)/10 torr

with 2 or 3 moles of potassium ethylxanthate to form the compounds *(86)* and *(87)* [53].



On reaction of trichloromethyl isocyanide dichloride *(88)* with 5 moles of sodium dimethyldithiocarbamate *(15)*, sulfur is eliminated with formation of the trisdithiocarbamate *(89)* [54].



Aliphatic and aromatic isocyanide dichlorides, such as *(6)*, react with the salts of mono- or dithioesters of phosphoric acid to give bisthiophosphoryl compounds such as *(90)* [55, 56].

Thioesters of *N*-acylcarbonimidic acids, *e.g.* *(92)* have been synthesized by several research groups from acyl isocyanide dichlorides, *e.g.* *(91)*. The reactions generally proceed smoothly with thiols in the presence of a tertiary amine or with alkali metal thiolates. The same reaction occurs with sulfonyl and phosphoryl isocyanide dichlorides.

Triacylated esters such as *(93)* are obtained by reaction of acyl isocyanide dichlorides such as *(36)* with a mono- or dithiophosphate. The reaction products are mostly very viscous oils.

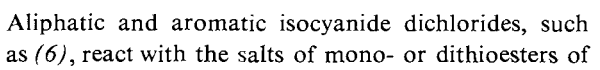
[54] *E. Kühle, H. Holtschmidt, F. Grewe,* and *H. Kaspers,* Belg. Pat. 691561 (Dec. 23, 1965), Farbenfabriken Bayer AG.

[55] *H. Malz, E. Kühle,* and *O. Bayer,* German Pat. 1138389 (Oct. 17, 1959), Farbenfabriken Bayer AG.

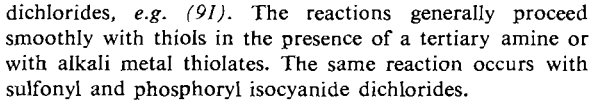
[56] *H. Malz, H. Holtschmidt, E. Kühle,* and *O. Bayer,* German Pat. 1233852 (Jan. 26, 1962), Farbenfabriken Bayer AG.



[57] *F. Sachs,* Ber. dtsch. chem. Ges. *33*, 959 (1900).

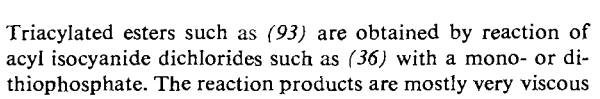
4.4. Imidomesoxalic Dinitriles

We have tried to use isocyanide dichlorides for the preparation of imidomesoxalic dinitriles, which can be obtained in special cases from aromatic nitroso compounds and malonic dinitrile [57]. Whereas the desired result could not be achieved by the action of alkali metal cyanides or hydrogen cyanide on isocyanide dichlorides, it was possible to react *e.g.* 4-chlorophenyl isocyanide dichloride *(14)* with copper(I) cyanide in a molar ratio of 1:2 at 150–180 °C. Instead of the expected 4-chloroimidomesoxalic dinitrile *(94)*, which is formed only in small quantities, the main product is a very stable, black copper complex, which we did not investigate further.



4-ClC_6H_4-N=$C(CN)_2$ *(94)* b.p. = 130–136 °C/11 torr, m.p. = 135–137 °C

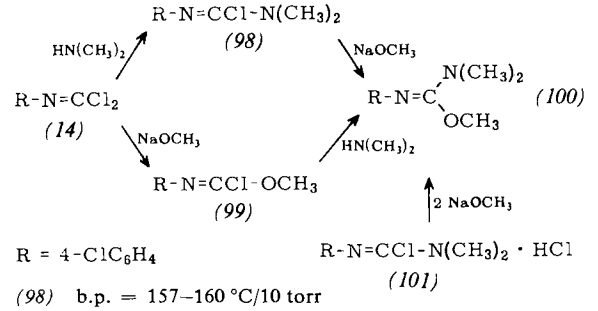
Imidomesoxalic dinitriles such as *(95)* are obtained in moderate yields (up to about 30 %) from imidocyanoformyl chlorides (cf. Section 3.4) and copper cyanide.



4.5. Carbonimidoylbisphosphonates

Isocyanide dichlorides react with trialkyl phosphites at room temperature in a sort of Arbusov reaction leading to elimination of chloroalkane and formation of carbonimidoylbisphosphonates such as *(96)* [55].

Chloromethyl isocyanide dichloride *(18)* reacts with 3 moles of triethylphosphite under the same conditions to form the triphosphonate *(97)* [56].

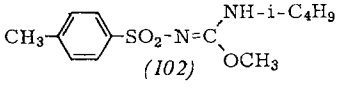


5. Replacement of the Chlorine Atoms by Two Different Nucleophilic Groups

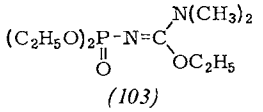
The chloroformamidines (Section 3.1), chloroformimidates (Section 3.2), and thiochloroformimidates (Section 3.3) still contain one reactive chlorine atom, which can be replaced by any nucleophilic group. This route can be used for the preparation not only of the unsymmetrically substituted guanidines discussed in Section 4 but also of isoureas, isothioureas, and unsymmetrically substituted carbonimidates and thiocarbonimidates.

5.1. Isoureas

In contrast with the mono- and disubstituted isoureas, which can be prepared by the addition of alcohols to cyanamides and carbodiimides, the *N,N,N'*-trisubstituted isoureas are practically unobtainable except from isocyanide dichlorides. The isourea *(100)* may be obtained by reaction either of a chloroformamidine *(98)* with an alcohol or phenol, or of a chloroformimidate *(99)* with an amine.



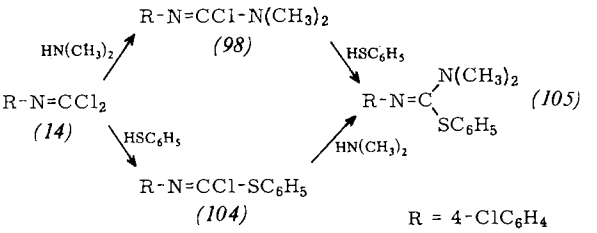
(98) b.p. = 157–160 °C/10 torr
(99) b.p. = 127–128 °C/11 torr
(100) b.p. = 147–149 °C/11 torr



Neither method presents any difficulties, but using the chloroformimide method, we have carried out the reaction as a one-reactor process with aromatic isocyanide dichlorides. The isocyanide dichloride in an inert solvent was first allowed to react with aqueous-alcoholic sodium hydroxide solution, and the isourea was then obtained in good yields by reaction with amine [58, 59].

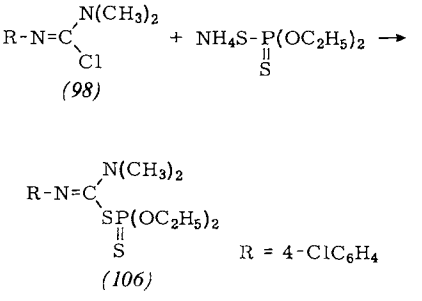
In a variant of this method, isoureas such as *(100)* are obtained by reaction of chloroformamidinium chlorides (obtainable from ureas and phosphorus pentachloride) such as *(101)* with 2 moles of sodium methoxide [60].

The *O*-arylisoureas are formed by the same principle [61]. In the case of acyl isocyanide dichlorides, the above reactions lead to *N*-acylated isoureas [examples: *(102)* and *(103)* [36]]. Both paths (*via* *N*-acylated chloroformamidines or *N*-acylchloroformimidates) are again possible.



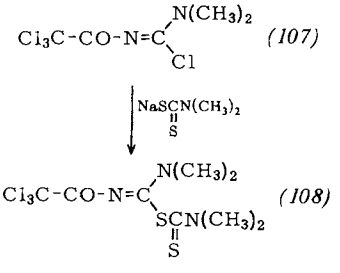
(102)

(103)



5.2. Isothioureas

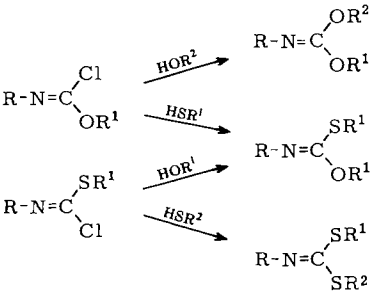
Whereas *S*-alkylisothioureas in general can be prepared by alkylation of thioureas, *S*-arylisothioureas have so far been obtained only in special cases (by addition of thiophenols to cyanamide [62]). Isothioureas such as *(105)* can be readily prepared from isocyanide dichlorides *via* chloroformamidines (Section 3.1) or thiochloroformimidates (Section 3.3) in a process similar to the above isourea synthesis.



(104) b.p. = 167 °C/0.05 torr; m.p. = 66 °C
(105) m.p. = 57–59 °C

The reaction of chloroformamidines, *e.g.* *(98)*, with dithiophosphates yields *S*-phosphorylated isothioureas, *e.g.* *(106)* [55].

(106)



N^2-Trichloroacetyl-N^1,N^1-dimethylchloroformamidine *(107)* and sodium dimethyldithiocarbamate give the isothiourea *(108)*.

(108) m.p. = 102–105 °C

5.3. Carbonimidates and Thiocarbonimidates

The reactions of chloroformimidates (Section 3.2) or thiochloroformimidates (Section 3.3) with alcohols or thiols lead to esters and monothio- or dithioesters of the carbonimidic acid (cf. Sections 4.2 and 4.3).

[58] *E. Kühle* and *L. Eue*, German Pat. 1138039 (June 4, 1959), Farbenfabriken Bayer AG.

[59] The *O*-alkylisoureas are good alkylating agents, which react with urea formation even under mild conditions in the acidic and alkaline ranges.

[60] *E. Kühle* and *R. Wegler*, German Pat. 1219020 (Oct. 10, 1959), Farbenfabriken Bayer AG.

[61] *E. Kühle*, *L. Eue*, and *O. Bayer*, German Pat. 1137000 (Feb. 10, 1961), Farbenfabriken Bayer AG.

[62] *F. Arndt*, Liebigs Ann. Chem. *384*, 322 (1911).

Whereas isocyanates or isothiocyanates readily add on amines, alcohols, or thiols, isocyanide dihalides undergo nucleophilic substitution on reaction with these compounds (cf. Sections 3 to 5). The only compounds that have been successfully added to the N=C bond of isocyanide dihalides are hydrogen fluoride, some carbonyl fluorides, hydrazoic acid, diazomethane, and epoxides.

6.1. Addition of Hydrogen Fluoride

The most extensively studied of this group of additions is the addition of hydrogen fluoride to isocyanide dichlorides or difluorides. In the case of isocyanide dichlorides this reaction proceeds as an addition-elimination, in which hydrogen chloride is split off to form *N*-trifluoromethylamines. No intermediates containing chlorine could be isolated. Even when less than the theoretical quantity of hydrofluoric acid is used, the reaction yields only the trifluoromethylamine and unreacted starting material.

According to *Barr* and *Haszeldine*[63], the addition of hydrogen fluoride to trifluoromethyl isocyanide difluoride *(67)* leads to high yields of bis(trifluoromethyl)amine *(109)*.

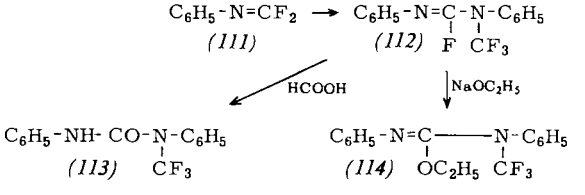
$$\underset{(67)}{CF_3{-}N{=}CF_2} \xrightarrow{HF} \underset{(109)}{CF_3{-}NH{-}CF_3}$$

The reaction of an isocyanide dichloride with hydrofluoric acid was first studied by *Petrov et al.*[64] with phenyl isocyanide dichloride *(6)*; this reaction leads to low yields of *N*-trifluoromethylaniline *(110)* together with large quantities of a "polymer".

$$\underset{(6)}{C_6H_5{-}N{=}CCl_2} \xrightarrow[-2\ HCl]{3\ HF} \underset{(110)}{C_6H_5{-}NH{-}CF_3}$$

The authors also described the perfluorination of trichloromethyl isocyanide dichloride *(64)* to form *(109)*.

We have found that aromatic isocyanide dichlorides with negative ring substituents and isocyanide dichlorides with heterocyclic substituents (*e.g.* "tetrameric cyanogen chloride") can be converted into *N*-trifluoromethylamines by hydrofluoric acid in high yields and with practically no "polymer" formation[65]. Isocyanide dichlorides containing readily exchangeable chlorine (*e.g.* acyl chlorides) are converted into their fluorine analogs by this reaction.



[63] *D. A. Barr* and *R. N. Haszeldine*, J. chem. Soc. (London) *1955*, 2532.

[64] *K. A. Petrov* and *A. A. Nejmysheva*, Ž. obšč. Chim. *29*, 2169 (1959).

[65] *E. Klauke* and *E. Kühle*, German Pat. 1170414 (May 15, 1962), Farbenfabriken Bayer AG.

The "polymer" formation reported by *Petrov*[64] for isocyanide difluorides is related to the addition of hydrofluoric acid. Our investigations indicate that this is a dimerization of the isocyanide difluoride, which proceeds rapidly under the action of heat or on catalysis by fluoro ions; an example is the formation of N^1,N^2-diphenyl-N^1-trifluoromethylfluoroformamidine *(112)*.

The structure of *(112)* has been confirmed by IR spectroscopy and by degradation reactions[66]. Thus *(112)* reacts with formic acid to give the urea *(113)*, while reaction with sodium ethoxide yields the isourea *(114)*.

(112) b.p. = 102 °C/0.1 torr
(113) m.p. = 102–103 °C
(114) b.p. = 95 °C/0.01 torr

Carbonyl difluoride also adds on to isocyanide difluorides. According to *Fawcett et al.*[67], the reaction of trifluoromethyl isocyanide difluoride *(67)* and carbonyl difluoride at 150 °C leads to bis(trifluoromethyl)carbamoyl fluoride *(115)*.

$$\underset{(67)}{CF_3{-}N{=}CF_2} \xrightarrow[150\,^\circ C]{COF_2} \underset{(115)}{(CF_3)_2N{-}COF}$$

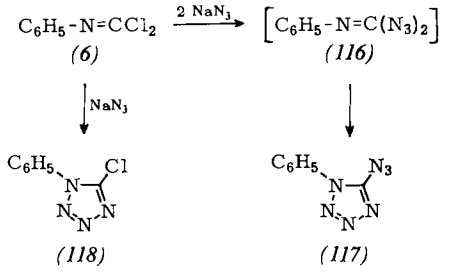
Sheppard[68] described the addition of carbonyl difluoride to aromatic isocyanide difluoride, which leads in the presence of cesium fluoride to *N*-aryl-*N*-trifluoromethylcarbamoyl fluorides in yields of more than 80 %.

6.3. Addition of Hydrazoic Acid and Diazomethane

The first reported addition to isocyanide dichlorides was the reaction of phenyl isocyanide dichloride *(6)* with 2 moles of sodium azide[69], which leads to 5-azido-1-phenyltetrazole *(117)*, probably by substitution followed by addition to the intermediate diazide *(116)*.

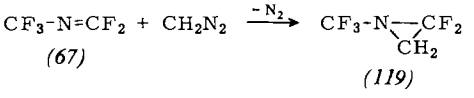
The reaction of isocyanide dichlorides, *e.g.* *(6)*, with sodium azide in a molar ratio of 1:1 gives 1-aryl-5-chlorotetrazoles, *e.g.* *(118)*[70,71].

[66] This constitution was discussed earlier by *M. Hauptschein et al.*, J. org. Chemistry *23*, 323 (1958).



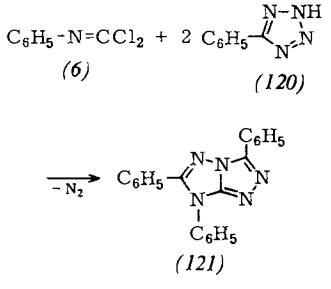
[67] *F. S. Fawcett*, *C. W. Tullock*, and *D. D. Coffman*, J. Amer. chem. Soc. *84*, 4275 (1962).

[68] *W. A. Sheppard*, J. Amer. chem. Soc. *87*, 4338 (1965).



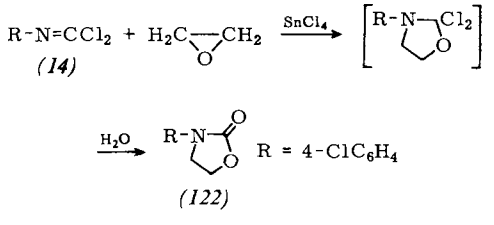
[69] *P. S. Pelkis* and *T. S. Dunajewska*, Mem. Inst. Chem., Akad. Sci. Ukr. SSR Inst. Microbiol. Epidemiol. *6*, 163 (1940); Chem. Abstr. *34*, 5829[9] (1940).

[70] *C. A. Maggiulli* and *R. E. Paine*, DAS 1251327 (Oct. 25, 1965), Eastman Kodak Comp.



[71] *J. C. Kauer* and *W. A. Sheppard*, J. org. Chemistry *32*, 3580 (1967).

Diazomethane reacts with trifluoromethyl isocyanide difluoride *(67)* with liberation of nitrogen and formation of trifluoromethylaziridine *(119)* [72].

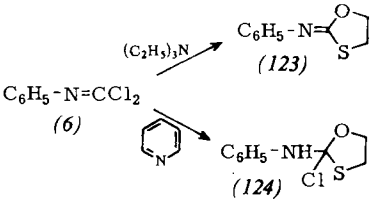


Finally, by analogy with a reaction described by *Huisgen* [73], we were able to react phenyl isocyanide dichloride *(6)* with 2 moles of 5-phenyltetrazole *(120)*. The products are nitrogen and 3,6,7-triphenyl-7*H*-*s*-triazolo-[4,3-*b*]-*s*-triazole *(121)*.

(121) m.p. = 286–288 °C

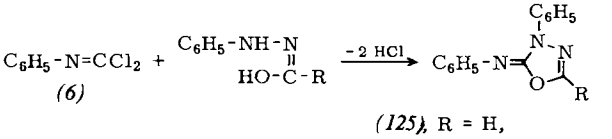
6.4. Addition of Epoxides

Oxazolidinones are obtained in moderate yields by the action of epoxides on isocyanide dichlorides in the presence of zinc chloride or tin tetrachloride followed by hydrolysis. For example, the reaction of 4-chlorophenyl isocyanide dichloride *(14)* with ethylene oxide yields oxazolidinone *(122)* [74].



7. Ring Closure Reactions

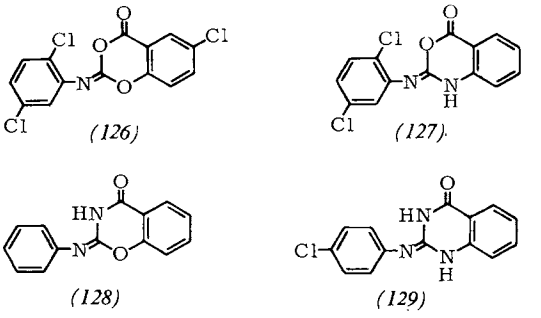
Like phosgene and thiophosgene, the isocyanide dichlorides also enter into a wide range of ring closure reactions with bifunctional nucleophilic compounds.



Some of the cyclizations can be carried out in aqueous alkaline media at room temperature, while others proceed only on heating in an inert solvent, possibly in the presence of a tertiary base.

Different reaction conditions sometimes lead to different cyclization products. Thus the reaction of phenyl isocyanide dichloride *(6)* with mercaptoethanol in the presence of triethylamine yields 2-phenylimido-1,3-oxathiolane *(123)*, while in the presence of pyridine the reaction gives 2-chloro-2-phenylamino-1,3-oxathiolane *(124)* [75].

7.1. Five-Membered Heterocycles



The five-membered heterocycles obtainable from isocyanide dichlorides have been very intensively studied. As early as 1893, *Freund et al.* [76] obtained the heterocyclic system *(125)* by reaction of phenyl isocyanide dichloride *(6)* with acylated phenylhydrazines. A selection of the heterocycles that can be obtained from isocyanide dichlorides is given in Table 1.

(125), R = H, CH_3, C_6H_5

7.2. Heterocycles with Six or More Ring Atoms

Higher membered heterocycles have so far only been prepared from isocyanide dichlorides in isolated cases. We have investigated the cyclization products formed on reaction of isocyanide dichlorides with salicylic and anthranilic acids and their amides. Each of the com-

(126) m.p. = 174–176 °C; *(127)* m.p. = 175–176 °C;

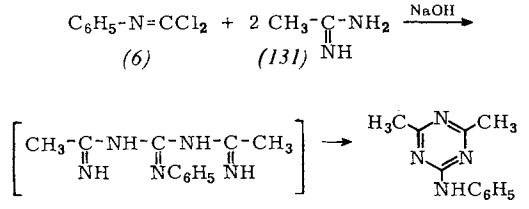
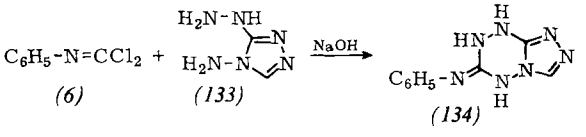
[a] In benzene with ethanediol as the sodium salt. [b] In the presence of triethylamine or pyridine. [c] In aqueous alkali.



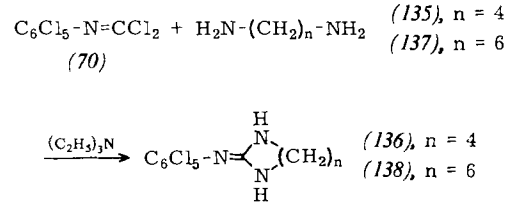
pounds *(126)–(129)* represents a member of this series [78,83].

Isocyanide dichlorides also give six-membered heterocycles, such as *(130)*, on reaction with 1,3-trimethylenediamines, 1,3-trimethylenedithiols, or 3-amino-1-propanols.



R = 4-ClC_6H_4 *(130)* m.p. = 68 °C

Symmetrical triazines are obtained, in analogy with earlier work in the triazine series [84], by cyclization of isocyanide dichlorides instead of phosgene with amidines in the presence of sodium hydroxide solution. For example, 2-anilino-4,6-dimethyl-*s*-triazine *(132)* is obtained in 87 % yield by this method.

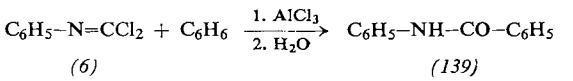


(132) m.p. = 125–126 °C *(132)*

Phenyl isocyanide dichloride reacts readily with 4-amino-3-hydrazino-1,2,4-triazole *(133)* to form the triazolotetrazine *(134)*.

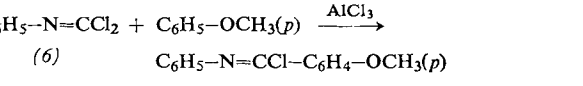
(134) m.p. = 250 °C (decomp.)

Pentachlorophenyl isocyanide dichloride *(70)* reacts with 1,4-diaminobutane *(135)* and 1,6-diaminohexane as bifunctional partners to give seven-membered *(136)* and nine-membered heterocycles *(138)* respectively.



(136) m.p. = 245–246 °C

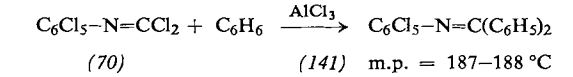
(138) m.p. = 218–220 °C (slow sintering from 160 °C)



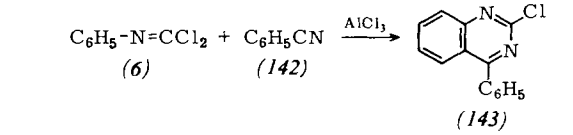
8. Other Reactions

8.1. Friedel-Crafts Reactions

The most extensively studied of the few known electrophilic substitutions of isocyanide dichlorides are the Friedel-Crafts reactions. *Dyson* and *Harrington* [50] were the first to report the reaction of phenyl isocyanide dichloride *(6)* with benzene in the presence of aluminum chloride to form benzanilide *(139)*.



We have obtained several imidoyl chlorides, such as *(140)*, by the reaction of aromatic and cycloaliphatic isocyanide dichlorides with benzene or anisole.



(140) b.p. = 159–163 °C/0.2 torr
m.p. = 70–71 °C

The second chlorine atom cannot generally be substituted even when an excess of aluminum chloride is used. The only known exception is pentachlorophenyl isocyanide dichloride *(70)*, which gives *N*-diphenylmethylenepentachlorophenylamine *(141)* in 55 % yield when heated for 30 minutes in benzene in the presence of aluminum chloride [85].

The reaction of benzonitrile *(142)* with phenyl isocyanide dichloride *(6)* in the presence of aluminum

(143) m.p. = 108–110 °C

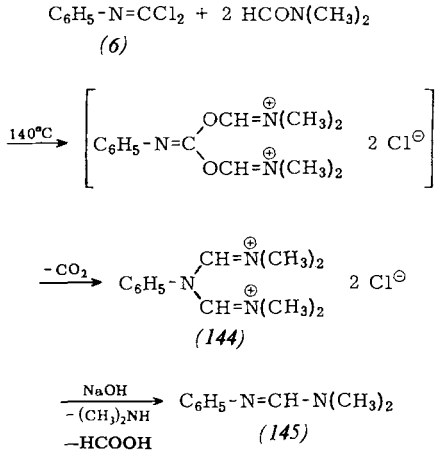
[82] *R. Neidlein* and *W. Haussmann*, Arch. Pharmaz. *300*, 180 (1967).

[83] Heterocycles in which only one Cl atom of the $NCCl_2$ group is involved in the ring closure, together with an α-Cl atom, will not be discussed here; cf. *H. G. Schmelzer, E. Degener*, and *H. Holtschmidt*, Angew. Chem. *78*, 982 (1966); Angew. Chem. internat. Edit. *5*, 960 (1966).

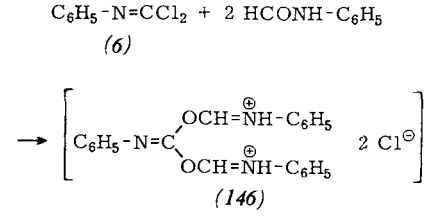
[84] *A. Pinner*, Ber. dtsch. chem. Ges. *23*, 2919 (1890).



[85] *K. Findeisen*, unpublished.

chloride is similar to the Meerwein synthesis of quinazoline [86]. Cyclization takes place with formation of 2-chloro-4-phenylquinazoline *(143)* [87].

8.2. Reactions with Formamides

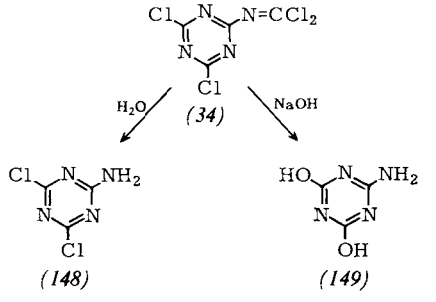


In analogy with the adducts formed from formamides and acid chlorides (*e.g.* phosgene, sulfonyl chlorides, phosphoryl chloride, thionyl chloride, cyanuryl chloride), isocyanide dichlorides react with mono- and disubstituted formamides to give adducts, which are converted into stable formamidines at high temperatures.

Thus phenyl isocyanide dichloride *(6)* and dimethylformamide (molar ratio 1:2) react exothermally at 140 °C with elimination of carbon dioxide and formation of a bisformamidinium chloride *(144)*, which loses dimethylamine on treatment with sodium hydroxide solution to form N^1,N^1-dimethyl-N^2-phenylformamidine *(145)* in 87 % yield.

(144) m.p. = 208–210 °C
(145) b.p. = 132–133 °C/13 torr

The reaction of phenyl isocyanide dichloride *(6)* with formanilide in a molar ratio of 1:2 is more complex. The first step is probably again the formation of a 1:2 adduct *(146)*, which is converted directly into N^1,N^2-diphenylformamidinium chloride *(147)* with liberation of carbon monoxide, carbon dioxide, and hydrogen chloride. Phenyl isocyanate and phenyl isocyanide have been detected as by-products, indicating a complex reaction that proceeds in several steps.



(147) m.p. = 248 °C (decomp.)

8.3. Conversion into Amines and Salts

The conversion of an isocyanide dichloride into an amine is important only if the amine is difficult to obtain by other means.

Thus pentachlorophenyl isocyanide dichloride *(70)* can be converted quantitatively into pentachloroaniline (m.p. 232–233 °C) by hydrolysis with sulfuric acid at 100 °C.

Hydrolysis of "tetrameric cyanogen chloride" *(34)* with water yields 2-amino-4,6-dichlorotriazine *(148)*, while hydrolysis in alkaline media proceeds further to 2-amino-4,6-dihydroxytriazine *(149)* [88].

The isocyanide dichlorides react with tertiary amines to form salt-like 1:1 adducts, most of which are very hygroscopic.

We thank Dr. H. Holtschmidt for stimulating suggestions and discussions regarding this work and for the isocyanide dichlorides, which are preparable by high-temperature chlorination.

Planar Complexes Containing Metal-Metal Bonds

By K. Krogmann[*]

Planar complexes, and particularly those of platinum, can form structures containing linear chains of heavy metal atoms with metal-metal distances as short as 3.1 Å. The bonding in these chains can be strengthened by partial oxidation, and the bond lengths can be reduced to 2.8 Å in this way. Model structures for the novel nonstoichiometric products, such as $K_2[Pt(CN)_4]Cl_{0.32} \cdot 2.6\ H_2O$, are considered. The bonding is also discussed on the basis of a one-dimensional band model.

1. Theoretical Introduction

Square planar complexes are formed mainly by transition metal ions having a d^8 electron configuration. The d^8 system of Pt^{II} forms planar complexes with nearly all ligands, whereas that of Ni^{II} forms such complexes only with ligands situated at the strong field end of the "spectrochemical series" [1], *e.g.* CN^-. This property of d^8 systems is due to the mutual repulsion of the d electrons and the charges, or in general the electrons, of the ligands. The d orbitals of the central atom in a planar complex are shown schematically in Figure 1.

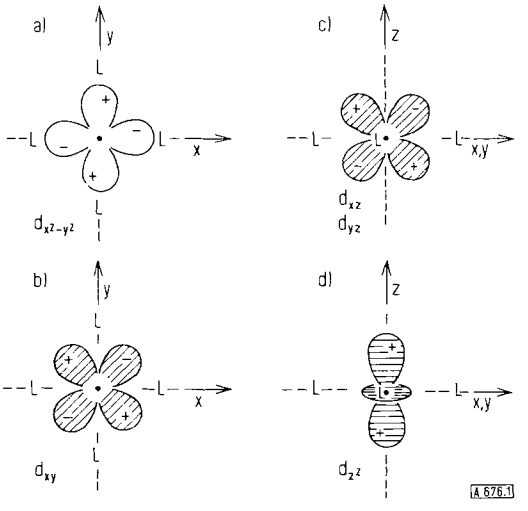

Fig. 1. d orbitals in a planar complex.

Figure 1a shows the $d_{x^2-y^2}$ orbital, which is directed toward the ligands, and Figure 1b shows the d_{xy} orbital, which lies in the plane of the ligands, but is directed between the negative charges or dipole ends. Figures 1c and 1d show "side views" of the complex and the d_{xz}, d_{yz}, and d_{z^2} orbitals, which point out of the plane of the complex. If the bonding of the ligand to the central atom is sufficiently strong and/or the mutual repulsion of the d electrons is sufficiently weak, the most favorable energy relationships are achieved by pairing of the electrons in the shaded orbitals d_{xy}, d_{xz}, d_{yz}, and d_{z^2}. The free $d_{x^2-y^2}$ orbital can then share the electrons of the ligands.

Since 3d electrons repel one another more strongly than 5d electrons, it is understandable why Pt^{II} invariably forms planar complexes whereas Ni^{II} does not always do so.

Figure 2, which shows a "side view" of the complex, is formed by combination of the parts of Figure 1. It can be seen that a considerable part of the "free" d-electron pairs lies above and below the plane of the complex. The simplest reactions that this "*z*-electron

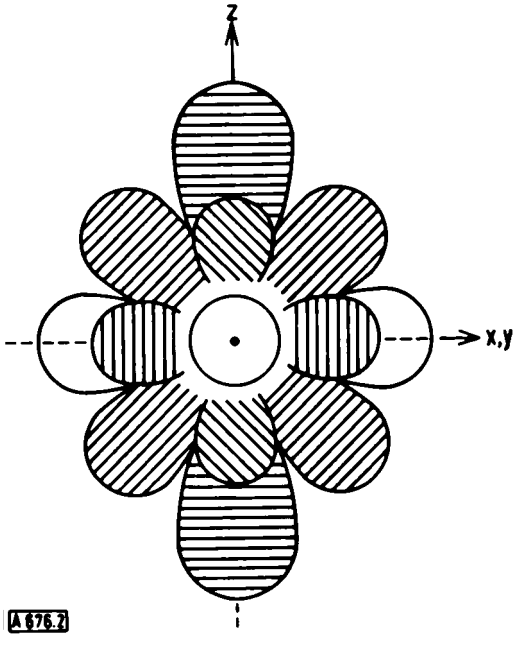

Fig. 2. d^8 system in a planar environment.

cloud" could conceivably undergo, *i.e.* oxidation and addition of Lewis acids, will only be mentioned in passing, and not considered in detail, though the picture they present is often different from that to which we are accustomed in s–p electron systems.

A general characteristic of free d electrons is their tendency to undergo $d_\pi - d'_\pi$ or $d_\pi - \pi^*_\pi$ back bonding (Fig. 3), thus forming donor-acceptor bonds of π symmetry in which the d electrons of the central atom share unoccupied ligand orbitals of suitable symmetry (*e.g.* d orbitals of Cl^- or π^* orbitals of CN^- or CO).

This often leads to considerable reinforcement of the σ bonds between the ligands and the central atom. Such intramolecular accessory reactions are particularly common in planar complexes.

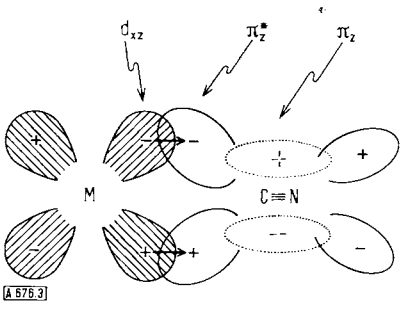

Fig. 3. π back-bonding.

Planar complexes in particular also have the ability to interact with the electron clouds of neighboring complexes; this property is not so easy to understand. Some relevant examples will be discussed below.

2. Planar Complexes in the Crystal Lattice

The $[Pt(CN)_4]^{2-}$ ion is a typical planar complex. Aqueous solutions of the alkali or alkaline earth metal salts are colorless, and absorb far beyond the visible limit in the UV [2]. In the solid state they sometimes form deeply colored crystals. Where there are several phases with different contents of water of crystallization, they can generally be recognized by their different colors. This is particularly well illustrated by the following dehydration reactions at 25 °C.

$$\underset{\text{dark red}}{Mg[Pt(CN)_4] \cdot 7\,H_2O} \xrightarrow[+\,2.5\,H_2O]{-\,2.5\,H_2O} \underset{\text{pale yellow}}{Mg[Pt(CN)_4] \cdot 4.5\,H_2O} \quad (1)$$

and

$$\underset{\text{colorless}}{Sr[Pt(CN)_4] \cdot 5\,H_2O} \xrightarrow[+\,3\,H_2O]{-\,3\,H_2O} \underset{\text{violet}}{Sr[Pt(CN)_4] \cdot 2\,H_2O} \quad (2)$$

These examples also show that the depth of color does not change in the same direction with the water content. Since neither the cations, which are hydrated to a greater or lesser extent, nor the isolated anions can absorb in the long-wave region and so cause the deep color, this property must be associated with the crystal structure.

Following the determination of the unit cell dimensions and the positions of the Pt atoms for some fully hydrated phases, *Yamada* recognized a relationship between the Pt–Pt distance and the color [3]. He showed (Table 1) the presence of an absorption band whose wave number decreases (*i.e.* its wavelength increases) with decreasing distance between the complex nuclei, and also showed that this absorption is polarized parallel to the Pt–Pt axis.

Table 1. Long-wave absorption maxima of some $M^{II}[Pt(CN)_4]$ phases, after *Yamada* [3].

Crystalline phase	Color	Pt–Pt distance (Å)	$\tilde{\nu}_{max}$ (cm^{-1})
$Ca[Pt(CN)_4] \cdot 5\,H_2O$	yellow	3.38	22800
$Ba[Pt(CN)_4] \cdot 4\,H_2O$	yellow-green	3.32	22000
$Mg[Pt(CN)_4] \cdot 7\,H_2O$	red	3.16	18000

These observations are confirmed by further investigations, which were also carried out with dehydrated alkaline earth metal tetracyanoplatinates [4,5]. The basic structure of the colored phases can be illustrated by that of the red magnesium salt, which was studied by *Bozorth* and *Pauling* [6] (Fig. 4).

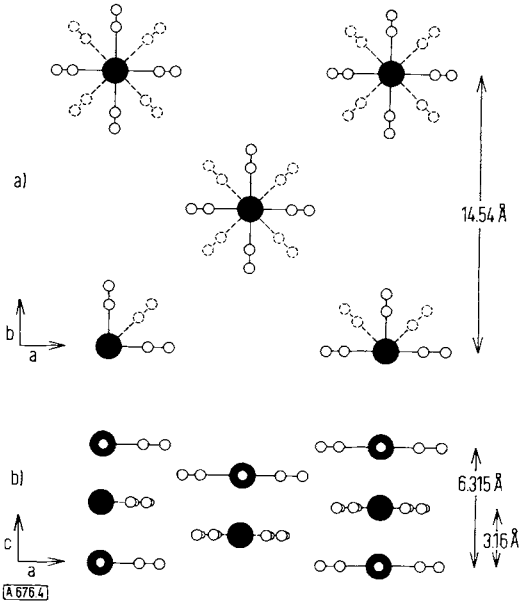

Fig. 4. Crystal structure of $Mg[Pt(CN)_4] \cdot 7\,H_2O$.
(a) Projection parallel to and (b) projection perpendicular to the tetragonal axis
● = Pt, O—O = CN. The sites of the Mg atoms are unknown.

The Pt atoms in $Mg[Pt(CN)_4] \cdot 7\,H_2O$ form a body-centered tetragonal unit cell. Thus Pt chains run through the crystal parallel to the *c* axis. The presence of weak superstructure lines for a cell having double the *c* dimension suggests that the CN groups in successive complex planes are "skew" to one another, as indicated in Figure 4. This arrangement has also been found in other $[Pt(CN)_4]$ structures [7, 8]. However, we are interested only in the chain period of 3.155 Å as given by the dimensions of the Pt cell.

These red crystals lose water even at room temperature to form a yellow phase, in which the Pt atoms form a triclinic cell whose shortest edge measures 3.36 Å. Partial dehydration probably results in a change in the coordination of the Mg^{2+} ions; in any case, the chain period is greater under the new

conditions. The bonding interaction in the chain is evidently not very strong, since it can be overcome by other lattice forces. This is also confirmed by the ready solubility of these phases in water.

Nevertheless, it can be seen from Table 2, which shows the Pt–Pt distances of many compounds of this type, that chain formation occurs in several crystal systems.

Table 2. Pt–Pt distances (chain periods) and colors of $M^{II}[Pt(CN)_4]$ phases.

Crystalline phase	Color	Pt–Pt distance (Å)	Crystal system
$Sr[Pt(CN)_4] \cdot 5\,H_2O$	colorless	3.60	monoclinic [5, 10]
$Ca[Pt(CN)_4] \cdot 5\,H_2O$	yellow	3.38	orthorhombic [7]
$Mg[Pt(CN)_4] \cdot 4.5\,H_2O$	yellow	3.36	triclinic [5]
$K_2Sr[Pt(CN)_4]_2 \cdot 6\,H_2O$	green-yellow	3.33	monoclinic [5]
$Ba[Pt(CN)_4] \cdot 4\,H_2O$	yellow-green	3.32	monoclinic [5, 11]
$K_2Sr[Pt(CN)_4]_2 \cdot 2\,H_2O$	violet-red	3.21	monoclinic [5]
$Be[Pt(CN)_4] \cdot 2\,H_2O$	dark red	3.16	orthorhombic [9]
$Mg[Pt(CN)_4] \cdot 7\,H_2O$	dark red	3.16	tetragonal [5, 6]
$Sr[Pt(CN)_4] \cdot 3\,H_2O$	violet	3.09	monoclinic [5]

Special mention should be made of the deeply colored phases formed by the Be, Mg, Sr, and K_2Sr salts, all of which have Pt–Pt distances of less than 3.25 Å. This phenomenon is not confined to tetracyano complexes, but also occurs with other ligands. Thus, in addition to the normal yellow phases containing isolated $[Pt(C_2O_4)_2]^{2-}$ ions with no Pt–Pt interaction [12], the dioxalatoplatinates(II) often form red phases, though these generally rearrange rapidly into the yellow phases.

We determined the constants of the triclinic lattice of a red modification of $Ca[Pt(C_2O_4)_2] \cdot 4\,H_2O$ by single crystal diagrams [13]; the results give a Pt–Pt distance of 3.18 Å. Structures that have been known even longer are those derived from the green Magnus salt

$$\left.\begin{matrix}[(NH_3)_2\ Pt\ (NH_3)_2]^{2+} \\ [Cl_2\ Pt\ Cl_2]^{2-}\end{matrix}\right\} 3.25\ \text{Å}$$

$[Pt(NH_3)_4][PtCl_4]$ [14, 15], containing the complex cations and anions stacked in an alternating sequence, which again gives chains of heavy metal atoms having a period of about 3.25 Å.

The chain formation in this case, unlike that in the earlier examples, is electrostatically favored, since the neighboring complexes are oppositely charged [16]. Closer approach of the metal atoms is presumably prevented by the relatively large ligands. Similar arrangements and distances have also been found for neutral complexes, *e.g.* bis(2,3-butanedionedioximato)-platinum(II) [17, 18], and for corresponding complexes with other central atoms, particularly Pd^{II} and Ni^{II} [19, 20] (Table 3). The term "columnar stacking" has been coined for structures of this type [21]. Similar compounds of Rh^{I} and Ir^{I} have recently also been found; examples of these compounds are dicarbonyl-2,4-pentanedionatorhodium(I) and dicarbonyl-2,4-pentanedionatoiridium(I) [22–25].

The units of these structures are all planar (neutral complexes or planar cations and anions). Even with no bonding metal-metal interaction, parallel stacking of such units would lead to close packing, and would thus be energetically favorable. However, if the central atoms occur as nearest neighbors outside the planes of the complex and form a linear chain, this prevents the closest conceivable packing, and so leads to a loss of van der Waals energy of attraction. On formation of a chain structure, this loss must be compensated for by a corresponding gain in bond energy in the chain.

A clear indication of the existence of a bonding interaction is undoubtedly the occurrence of the deeply colored phases in the complex salts with particularly short Pt–Pt distances (Table 2). Though the planar units in this case are similarly charged, and despite the presence of non-polar cations that are hydrated to a greater or lesser degree a chain structure is formed.

2.1. The Bonding in the Chain

In the series Ni, Pd, Pt, the bonding along the chain is weaker for the first two elements than for Pt. This is shown by the fact that, among the tetracyano complexes, only the Pt derivative forms structures having chain periods of less than 3.25 Å when the other conditions are favorable. In these cases no isomorphism is found with corresponding complexes of the lighter elements, though the distances in the complexes are probably almost the same [7], so that the pure packing effects should be similar. Isomorphism is observed only at chain periods greater than 3.25 Å, and is then the rule, as can be seen from Table 3.

$Sr[Pd(CN)_4] \cdot 5\ H_2O$	3.63	colorless [29]	
$Sr[Pt(CN)_4] \cdot 5\ H_2O$	3.58	colorless [29]	
$Mg[Pd(CN)_4] \cdot 4\ H_2O$	?	colorless	no isomorphous phases known
$Mg[Pt(CN)_4] \cdot 7\ H_2O$	3.16	red [6]	

The effect of the 5d electrons of the Pt complex is evidently stronger and extends farther outward than that of the analogous 4d and 3d systems.

To explain the formation of planar complexes, the valence bond (VB) method places eight 5d electrons of Pt^{2+} (Fig. 5a) in four d orbitals in pairs, while the fifth d function combines with a 6s and two 6p functions to form four dsp^2-hybridized functions, whose maxima are directed toward the corners of a square about the central atoms. These are used to bond the lone pairs of electrons in the four ligands, while the third p orbital remains empty (Fig. 5b). If the $5d_{z^2}$ and $6p_z$ functions are used to form two further equivalent hybrid orbitals (Fig. 5c), each of which can be occupied by one electron from the central atom, the Pt^{2+} is then able to form a linear chain with adjacent atoms having the same valence structure. Each of the neighbors contributes one electron per bond in the chain.

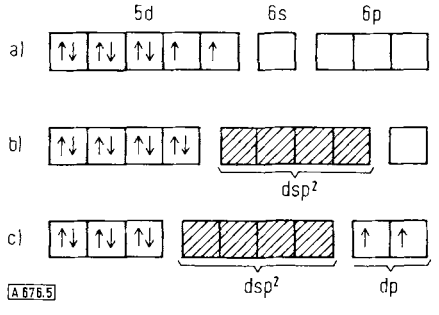

Fig. 5. Electron distribution in the Pt^{2+} ion (a) unperturbed, (b) in the dsp^2 valence state, (c) with additional dp hybridization.

This simple picture has the disadvantage that it does not show the relationship between light absorption and the Pt—Pt distance. A molecular orbital (MO) treatment as suggested first by *Rundle* and later by *Miller* [30, 31] is more suitable for this purpose. The interaction of two adjacent complex nuclei is considered first. The two $5d_{z^2}$ atomic orbitals (AO's), which have symmetry a_{1g}, split to give an antibonding and a bonding MO having symmetries a_{2u} and a_{1g} respectively. The same happens to the $6p_z$ AO's, which have symmetry a_{2u} (Fig. 6a). Since there are four electrons to be accommodated, the two lower levels (one bonding and one antibonding) are occupied. This should give no resultant bonding effect, but since non-degenerate MO's of the same symmetry "repel" each other (configuration interaction), the lower a_{1g} MO is displaced to lower energies and the upper to higher energies (Fig. 6b). The same is true of the a_{2u} MO. The total energy of the system therefore decreases and bonding occurs.

The character of the orbitals is also changed by configuration interaction. The MO's derived from $5d_{z^2}$ orbitals adopt some p character, while those formed from the $6p_z$ orbitals acquire some d character. The result therefore approaches that obtained by the valence bond method.

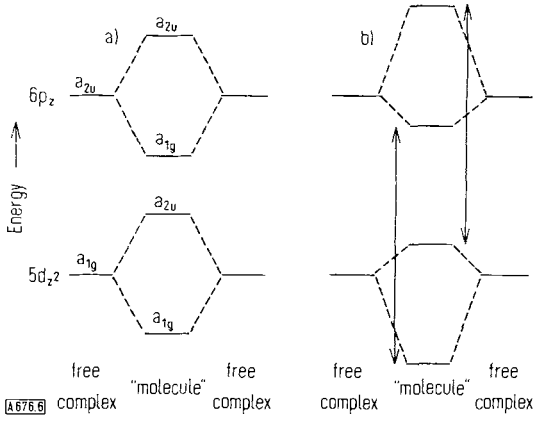

Fig. 6. MO scheme for a "molecule" consisting of two planar complexes (a) without and (b) with configuration interaction.

When this reasoning is extended to a chain of atoms (Fig. 7) the discrete levels are replaced by bands. The shorter the distance between the atoms, the broader the band becomes and the shorter is the distance between the highest occupied level in the d_{z^2} band and the lowest unoccupied level in the p_z band.

As a result of configuration interaction, the average energy of the d_{z^2} electrons decreases with decreasing chain period and so gives a bonding effect.

A clearer description can be arrived at by assuming that incomplete screening of the charge on the Pt nucleus by the 5d electron cloud along the z axis allows this charge to remain partly effective. This could provide some stabilization of the d_{z^2} electrons of the neighboring complex, were it not for the simultaneous development of forces of repulsion between the two pairs of d_{z^2} electrons, the probability densities of which are strongly concentrated around the z axis (Fig. 1d). If the $5d_{z^2}$ electrons could acquire some $6p_z$ character, they would have more lateral freedom of movement around the z axis, and the repulsion between the electrons would decrease.

[26] *H. Brasseur* and *A. De Rassenfosse*, Bull. Soc. roy. Sci. Liège *4*, 68 (1935).

[27] The lattice constant of 3.28 Å given in [26] is inaccurate. The value given here was determined by the present author.

[28] The deeper color of the Ni complexes is due to their ligand field absorption, which, unlike those of the Pd and Pt complexes, lies in the visible range, but occurs even in the absence of metal-metal interaction.

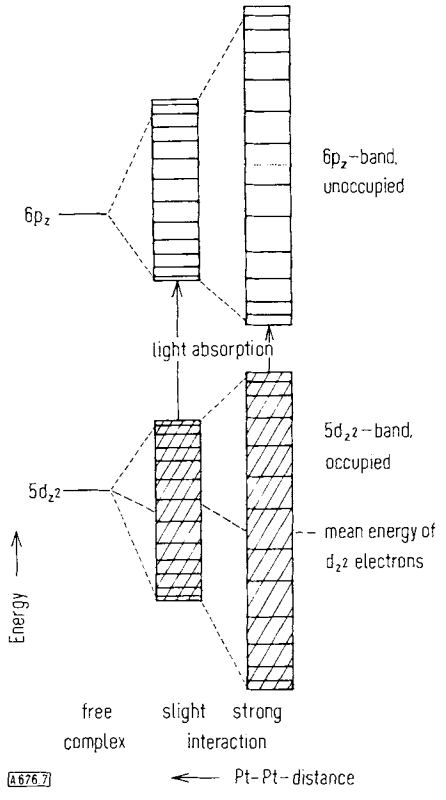

Fig. 7. Bond splitting, light absorption, and Pt—Pt distance in the chain of metal atoms.

The properties of the compounds discussed so far are easy to understand. The long-wave absorption polarized in the chain direction (z axis) corresponds to the transition from the highest occupied orbital of the d_{z^2} band to the p_z band (Fig. 7). The shorter the distance between the Pt atoms, the smaller is the energy required for this transition. When the transition is stimulated by light or heat, conductivity should be observed along the chain of metal atoms. Anisotropic semiconductor effects of this type have in fact been reported [25, 32].

2.2. Partially Oxidized Chain Compounds

The d_{z^2} band is fully occupied in Pt^{II} chains. Despite configuration interaction, the upper orbitals of this band have an antibonding effect on the chain, since they are situated above the d_{z^2} level of the free complex (Fig. 8).

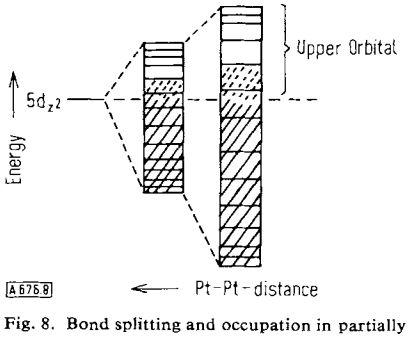

Fig. 8. Bond splitting and occupation in partially oxidized metal chains. The higher orbitals are antibonding.

[32] *H. P. Fritz* and *H. J. Keller*, Z. Naturforsch. *20b*, 1145 (1965).

The bonding in the chain should therefore be strengthened if electrons could be removed from this part of the band. The addition of a corresponding number of negatively charged particles or the removal of positively charged particles would then be necessary to preserve the electrical neutrality of the lattice. We have found examples of both types of compound.

Evaporation of an aqueous solution containing the complex salts $K_2[Pt(CN)_4]$ and $K_2[Pt(CN)_4Cl_2]$ in a molar ratio of 5:1 gives needles with a coppery sheen and having the composition $K_2[Pt(CN)_4]Cl_{0.32} \cdot 2.6\ H_2O$ [8]. On variation of the ratio of the starting compounds, the excess of Pt^{II} or Pt^{IV} complex crystallizes out together with the coppery substance. The latter is therefore a well-defined though non-stoichiometric compound having no recognizable phase range.

The crystals absorb or reflect almost all light polarized parallel to the axis of the needle and traveling perpendicular to this axis; light polarized perpendicular to this direction is absorbed only very slightly in the visible range.

The IR spectrum, unlike that of the $[Pt(CN)_4Cl_2]^{2-}$ complex, has no Pt—Cl vibration at 350 cm^{-1}; this indicates that the compound no longer contains Pt—Cl bonds. The tetragonal structure [8] contains Pt chains (Fig. 9).

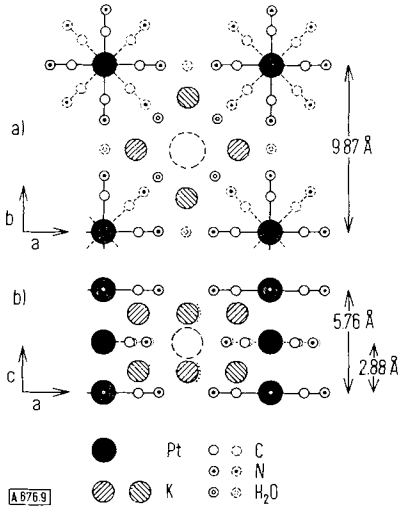

Fig. 9. Crystal structure of $K_2[Pt(CN)_4]Cl_{0.32} \cdot 2.6\ H_2O$
(a) Projection parallel to and (b) projection perpendicular to the tetragonal axis. The large circle in the center indicates the site for the chlorine atom.

In Figure 9a, looking along the c axis, one sees the superimposed planar $[Pt(CN)_4]$ complexes, the central atoms being situated at the corners of the cell and in the center of the c edge, while the CN groups lie parallel to the a and b axes and the diagonals of the faces. The second complex in each cell is thus turned through 45° in relation to the others. Figure 9b is a view perpendicular to the chain, and shows the short Pt—Pt distance of 2.88 Å. Cl^- is situated in the center of the cell, and is surrounded by eight sites for the four K^+ ions, which are arranged tetrahedrally.

The most important features of the structure are as follows: Pt^{II} and Pt^{IV} complexes cannot be distinguished, since all the Pt atoms are crystallographically identical. The period of the Pt chain is 10% shorter than in compounds of Pt^{II}. Each cell contains a site

for one Cl^-, corresponding to 0.5 Cl^- per Pt. However, this space is occupied in only 64 % of the cells, corresponding to 0.32 Cl^- per Pt. Thus the oxidation number of the Pt does not increase above +2.32.

These characteristics are understandable from the above theoretical discussion. The complexes are all of the square planar type. Owing to the partial oxidation, some of the antibonding orbitals (Fig. 8) are empty. This leads to stronger bonding in the chain and hence to a decrease in the Pt–Pt distance.

The structure may be imagined as being built up in steps from a crystallographically analogous (non-existent) phase of Pt^{II} with a Pt–Pt distance of 3.16 Å and an empty Cl^- site. Each defect electron produced in the occupied d_{z^2} band by oxidation strengthens and shortens the bond. At the same time a lattice hole is occupied by Cl^-, which has a further stabilizing effect. The gain in bond energy becomes steadily smaller with increasing oxidation, since the band orbitals being freed now are lower. The forces of repulsion between the free electron pairs and between the ligands of neighboring complexes increase rapidly with decreasing distance. The oxidation number and the distance reach final values that depend mainly on the band structure. These values do not necessarily permit the Cl^- sites to be completely occupied.

The counterpart of this structure with incorporation of extra anions is a partially oxidized chain structure with vacancies in cation sites. Examples have been found in particular among the dioxalatoplatinate complexes. These are formed on addition of a little oxidizing agent such as Cl_2 or $K_2Cr_2O_7$ to a solution of $[Pt(C_2O_4)_2]^{2-}$ salts as a violet precipitate, from which coppery needles can be isolated [33].

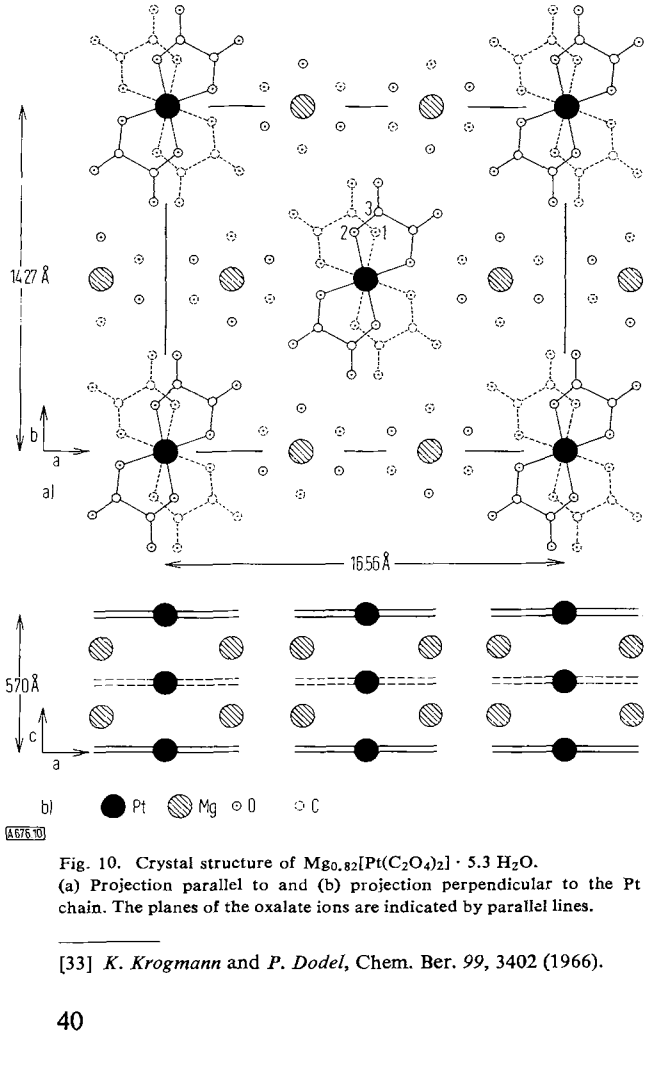

Fig. 10. Crystal structure of $Mg_{0.82}[Pt(C_2O_4)_2] \cdot 5.3\ H_2O$.
(a) Projection parallel to and (b) projection perpendicular to the Pt chain. The planes of the oxalate ions are indicated by parallel lines.

[33] *K. Krogmann* and *P. Dodel*, Chem. Ber. *99*, 3402 (1966).

Single crystals suitable for complete structure investigations were first obtained from $Mg_{0.82}[Pt(C_2O_4)_2] \cdot 5.3\ H_2O$ [34]. In this orthorhombic C-centered structure [*], the $[Pt(C_2O_4)_2]$ complexes are stacked skew one above another (Fig. 10). The Pt chains run parallel to the *c* axis with a period of 2.85 Å (= *c*/2); the Pt has an average oxidation number of +2.36. Eight sites are available for the Mg, each octahedrally surrounded by H_2O, but only 40 % of these sites are occupied. The strength of the bonding in the chains of this structure can be seen from the short distances between some atoms of adjacent complexes. For example, the O atom 1 in Figure 10a is only 2.95 Å from the C atom 3 of the complex above it, and only 2.97 Å from the O atom 2. Such short intermolecular distances are not found in other compounds. In the quinhydrone crystal, in which bonding occurs between the quinone and hydroquinone molecules, the shortest distances between unbonded atoms are greater than 3.1 Å.

Table 4 shows the partially oxidized phases and their principal data. There appears to be no strict relationship between the Pt–Pt distance and the oxidation number. It can be seen that the oxidation numbers are slightly higher and the distances slightly shorter in the dioxalato complexes than in the tetracyanoplatinates. This could mean that the tetracyanoplatinates have a different band structure, and that the orbital density at the upper limit of the band is lower or the configuration interaction fundamentally stronger. However, further examples are required to support this assumption, or measurements to confirm it.

Table 4. Partially oxidized chain compounds of platinum.

Complex	Oxidation number	Crystal system	Pt–Pt distance (Å)
$K_2[Pt(CN)_4]Cl_{0.32} \cdot 2.6\ H_2O$	+2.32	tetragonal	2.880 [8]
$K_2[Pt(CN_4]Br_{0.30} \cdot 2.3\ H_2O$	+2.30	tetragonal	2.887 [8]
$Mg[Pt(CN)_4]Cl_{0.28} \cdot 7\ H_2O$	+2.28	tetragonal	2.985 [35]
$K_{1.74}[Pt(CN)_4] \cdot 1.8\ H_2O$	+2.26	triclinic	2.960 [36]
$Li_{1.64}[Pt(C_2O_4)_2] \cdot 6\ H_2O$	+2.36	orthorhombic	2.81 [37]
$Na_{1.67}[Pt(C_2O_4)_2 \cdot 4\ H_2O$	+2.33	triclinic	2.88 [37]
$K_{1.62}[Pt(C_2O_4)_2] \cdot 2\ H_2O$	+2.38	triclinic	2.85 [37]
$K_{1.62}\ [Pt(C_2O_4)_2] \cdot x\ H_2O$	+2.38	monoclinic	2.81 [37]
$K_{1.64}[Pt(C_2O_4)_2] \cdot y\ H_2O$	+2.36	orthorhombic	2.83 [37]
$K_{1.64}[Pt(C_2O_4)_2] \cdot z\ H_2O$	+2.36	orthorhombic	2.82 [37]
$(NH_4)_{1.64}[Pt(C_2O_4)_2] \cdot 1\ H_2O$	+2.36	orthorhombic	2.82 [37]
$Mg_{0.82}[Pt(C_2O_4)_2] \cdot 5.3\ H_2O$	+2.36	orthorhombic	2.85 [37]
$Mg_{0.82}[Pt(C_2O_4)_2] \cdot x\ H_2O$	+2.36	triclinic	2.84 [37]
$Mg_{0.82}[Pt(C_2O_4)_2] \cdot y\ H_2O$	+2.36	orthorhombic	2.84 [37]
$Ca_{0.84}[Pt(C_2O_4)_2] \cdot 4\ H_2O$	+2.32	orthorhombic	2.83 [37]
$Sr_{0.84}[Pt(C_2O_4)_2] \cdot 4\ H_2O$	+2.32	orthorhombic	2.85 [37]
$Ba_{0.84}[Pt(C_2O_4)_2] \cdot 4\ H_2O$	+2.32	orthorhombic	2.85 [37]
$H_{1.60}[Pt(C_2O_4)_2] \cdot 2\ H_2O$	+2.40	orthorhombic	2.80 [37]
$H_{1.60}[Pt(C_2O_4)_2] \cdot 3\ H_2O$	+2.40	monoclinic	2.82 [37]

[37] *K. Krogmann* and *P. Dodel*, Z. anorg. allg. Chem., in press.

Mention should be made of the large Pt–Pt distance in the blue-black $Mg[Pt(CN)_4]Cl_{0.28} \cdot 7\ H_2O$ [35], which crystallizes in the same tetragonal structure as the chlorine-free (unoxidized) red salt. The *a* axis is slightly longer (14.66 instead of 14.54 Å) whereas the *c* axis, despite the addition of the chlorine, is considerably shorter (5.97 instead of 6.31 Å). The incorporation of the chlorine prevents contraction of the Pt–Pt distance to the value that would otherwise be reached. Unfortunately, no complete structure investigations have been reported for the two phases [38].

The physical properties of the partially oxidized chain compounds can be explained by the band model. The electrons of the highest occupied orbitals of the d_{z^2} band can be promoted into unoccupied levels of the d_{z^2} or p_z band by polarized absorption of light of all wavelengths. This is the reason for the deep color of the powder, while the coppery sheen of the larger crystals is due to polarized specular reflection. Because of the incompletely occupied band, conductivity and Pauli paramagnetism may be expected, and both are in fact observed [18]. The chains correspond to one-dimensional metals whose electrons exhibit a weak paramagnetism that is practically independent of the temperature. Conductivity values of up to 10^{-2} ohm^{-1} cm^{-1} in the chain direction have been observed; unlike the (appreciably lower) values for the Pt^{II} compounds, these do not increase on exposure to light. The conductivity is very difficult to measure, since lattice imperfections can hinder the one-dimensional movement of the electrons much more than in two-dimensional or three-dimensional conductors.

The phases known at present contain only oxalate and cyanide as ligands of the platinum. This limitation is probably accidental. However, since steric hindrance can be expected to be too strong in the case of larger ligands, the search for further examples should be concentrated mainly on C,N,O, and possibly F complexes. A clue may be provided by *Wöhler*'s observation that the oxidation number of the Pt in freshly precipitated Pt^{II} oxide hydrate gradually increases, but never rises above +2.5 [39]. However, an X-ray study of these phases has not yet been possible. *Waser* and *McClanahan jr.* have reported a compound $NaPt_3O_4$ having a Pt–Pt distance of 2.85 Å [40]. In a compound having this composition, the oxidation number of the Pt is +2.33.

Many of the substances discussed were described a long time ago because of their striking color [41–45]; however, their unusual stoichiometry could not be reconciled with the bonding theories held at the time.

2.3. Behavior of Partially Oxidized Chain Compounds in Solution

Do the solutions of partially oxidized chain compounds contain polymeric anions? The solubility is found to decrease noticeably. If the Pt^{II} complexes such as the alkali metal dioxalatoplatinates(II) are moderately soluble in water, the corresponding partially oxidized phases are sparingly soluble. With few exceptions, the tetracyanoplatinates(II) are very readily soluble, while their oxidized forms exhibit a diminished, though still high solubility. In the case of the tetracyano complexes, the spectra of the solutions can always be regarded as resulting from the superposition of the spectra of corresponding quantities of Pt^{II} and Pt^{IV} compounds, whereas this is true of the dioxalato complexes only at low concentrations. Thus disproportionation invariably occurs in solution. With the dioxalato complexes at sufficiently high concentrations, however, we detected pH-dependent polymerization equilibria [33,46], which undoubtedly also involve chains. Concentrated solutions are blue-black and have high extinctions ($\varepsilon > 10^4$) in contrast with the pale yellow dilute solutions.

A chain compound having an oxidation number of 2.4 contains infinite linear $[Pt(C_2O_4)_2]_n^{1.6n-}$ anions ($n = \infty$). The depolymerization, which really proceeds in many stages, may be idealized by the following equilibrium:

$$[Pt(C_2O_4)_2]_n^{1.6n-} \rightleftarrows 0.8\ n\ [Pt(C_2O_4)_2]^{2-} + 0.2\ n\ [Pt(C_2O_4)_2]^0 \quad (3)$$

The Pt^{IV} complexes complete their coordination by addition of water, from which protons can finally be removed:

$$[Pt(C_2O_4)_2]^0 + 2\ H_2O \rightleftharpoons [Pt(C_2O_4)_2(H_2O)_2]^0 \quad (4)$$

$$[Pt(C_2O_4)_2(H_2O)_2]^0 \rightleftharpoons [Pt(C_2O_4)_2(H_2O)(OH)]^- + H^+ \quad (5)$$

The removal of the proton from the Pt^{IV} complex is suppressed by the addition of acid, which thus favors the removal of H_2O and hence also polymerization. Dilute, pale yellow solutions therefore turn blue on addition of acid. Heating and dilution, on the other hand, cause depolymerization and a color change to yellow.

Corresponding polymerization phenomena in solution have not yet been measured for tetracyano complexes. On dissolution of the crystals, however, blue streaks are observed to start at the surface of the crystals and disappear into the solution.

2.4. Partially Oxidized Chain Compounds with Other Central Atoms

Planar d^8 complexes of Pd^{II}, Ni^{II}, Au^{III}, Ir^{I}, and Rh^{I} are known as well as those of Pt^{II}. It is already known that Pd^{II} and Ni^{II} have less tendency than Pt^{II} to form unoxidized chains. The same is true of Au^{III}, whose d orbitals are not so large because of the higher nuclear charge. No examples of partially oxidized chain compounds of Pd^{II}, Ni^{II}, and Au^{III} have so far been found.

On the other hand, Ir^{I} and possibly Rh^{I} could be suitable central atoms. In planar complexes their d electrons should spread farther outwards; unoxidized

[38] The structure of unoxidized $MgPt(CN)_4 \cdot 7\ H_2O$ is being studied at present in the crystallography laboratory of Liège University (private communication). No single crystals of the oxidized phase have been obtained as yet.

[46] *K. Krogmann* and *P. Dodel*, Chem. Ber. *99*, 3408 (1966).

chain compounds of both are already known [22–25]. However, the d electrons here are so reactive that *e.g.* $[Ir(CN)_4]^{3-}$ ions remove protons even from non-aqueous solvents such as alcohol and form complexes such as $K_3[IrH(CN)_5]$ [47, 48]. Thus the principal problem is still the isolation of suitable complexes.

We have nevertheless come across a known compound that may be regarded as a partially oxidized chain compound. The formula assigned to this compound is $Ir(CO)_3Cl$ [49], but it actually contains slightly more chlorine and should be formulated as $Ir(CO)_{2.9}Cl_{1.1}$. Its structure determination is not yet complete, but the Ir atoms in this compound, which has an orthorhombic crystal structure, are known to form chains having an Ir–Ir distance of 2.85 Å [50]. This is evidently another variant of the chain structures discussed earlier. In the planar complexes, the positive charge resulting from partial oxidation is compensated by statistical replacement of some of the neutral CO groups by Cl^-.

Transport Phenomena in Membranes

By P. Läuger [*]

The realization that many elementary biological processes occur at membrane-like structures has led to renewed interest in the theory of molecular transport through membranes. Coupling phenomena in membranes, some of which are very complex, can now be rationally described with the aid of the thermodynamics of irreversible processes. The investigation of theoretical membrane models has proved a valuable complement to the thermodynamic method.

1. Introduction

The systematic study of mass transport through membranes began about 1830; this early development culminated in *van't Hoff*'s classic investigations on osmotic pressure. To define osmotic pressure, *van't Hoff* used the concept of the "semipermeable membrane", an ideal partition permeable to one component of a mixture and impermeable to all other components. Following the success of *van't Hoff*'s theory, subsequent work was concentrated mainly on the preparation and investigation of semipermeable membranes. When the problems associated with this had been solved in principle, interest in membranes rapidly faded.

Nowadays semipermeable membranes appear as a limiting case of minor importance. Membranes that allow the passage of several components are much more interesting, and frequently exhibit unexpected phenomena. For example, a component may pass from the solution in which its concentration is lower into the more concentrated solution, *i.e.* against its own concentration gradient. Phenomena of this type are always due to coupled movement of molecules in the membrane. It was not until recently that the rational description of these coupling phenomena was made possible by the theory of irreversible processes.

The strongest stimuli for the present development of membrane research have undoubtedly come from biology. Living cells maintain a continuous exchange of matter with their surroundings; at the same time, however, they must also preserve concentration differences between the intracellular and extracellular spaces. The separating membrane generally exercises a complicated regulating function. It allows substances to pass through according to the metabolic requirements, and is able to distinguish sharply between structurally similar compounds such as D- and L-xylose. It is often necessary for the cell membrane to transport substances against their activity gradients by expending chemical energy. Thus according to *Schlögl* [1], biological membranes act as "barriers,

[*] Prof. Dr. P. Läuger
Fachbereich Biologie, Universität Konstanz
775 Konstanz, Postfach 733 (Germany)

[1] *R. Schlögl*, Ber. Bunsenges. physik. Chem. *71*, 755 (1967).

gates, and pumps". The elementary processes that take place at the cell membranes are so far known only incompletely.

Industrial interest in membranes has also grown considerably. Work in this field is mainly directed toward the development of selectively permeable membranes suitable for use in the petroleum industry and in metallurgy. The use of membranes for obtaining drinking water from the sea also appears promising.

2. Phenomenological Theory of the Membrane Process. Flow Coupling; Reflection Coefficient and Reverse Osmosis

There are two possibilities for the theoretical description of membrane processes. The first method attributes the macroscopically observed effects to the molecular transport processes in the membrane. This method in principle allows a very detailed description, but frequently fails because the structure of the membrane is not known with sufficient accuracy or is too complicated. The second method is given by the thermodynamics of irreversible processes[2-4]. It is not restricted by any assumptions regarding the molecular nature of the system in question; nevertheless, it leads to a number of far-reaching results.

The second method will be illustrated for the system in Figure 1, which consists of a membrane and two external phases comprising the components A, B, and C. The membrane is assumed to be permeable to A and B, but impermeable to C. We generally allow a difference Δp in the external pressure, but we shall confine ourselves first to the isobaric case ($\Delta p = 0$). If the external phases are sufficiently large and well mixed, after a certain time a stationary state is reached in which the particle flows Φ_A and Φ_B are practically independent of time.

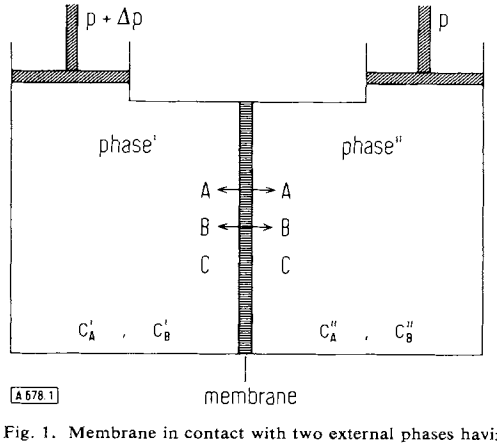

Fig. 1. Membrane in contact with two external phases having different compositions. The membrane is permeable to A and B, but impermeable to C. The volumes are so large that the concentrations c'_A, c''_A, c'_B, and c''_B are practically unchanged during the experiment.

[2] *S. R. De Groot* and *P. Mazur*: Non-Equilibrium Thermodynamics. North-Holland Publ. Comp., Amsterdam 1962.

[3] *R. Haase*: Thermodynamik der irreversiblen Prozesse. Steinkopff-Verlag, Darmstadt 1963.

[4] *D. D. Fitts*: Nonequilibrium Thermodynamics. McGraw-Hill, London 1962.

Let Φ_A and Φ_B be the number of moles of A and B that migrate from left to right through 1 cm² of membrane area per second. The thermodynamics postulates that Φ_A and Φ_B depend on the differences $\Delta\mu_A = \mu_A' - \mu_A''$ and $\Delta\mu_B = \mu_B' - \mu_B''$ of the chemical potentials of A and B[4,5].

$$\Phi_A = L_A\Delta\mu_A + L_{AB}\Delta\mu_B \quad (1a)$$

$$\Phi_B = L_{BA}\Delta\mu_A + L_B\Delta\mu_B \quad (1b)$$

However, these equations are valid only if $\Delta\mu_A$ and $\Delta\mu_B$ are sufficiently small, *i.e.* for external phases that differ only slightly in their composition[*].

The theory gives the following relationships for the coefficients L_A, L_{AB}, L_{BA}, and L_B:

$$L_A \geqslant 0, \quad L_B \geqslant 0 \quad (2)$$

$$L_{AB} = L_{BA} \quad (3)$$

$$L_{AB}^2 \leqslant L_A L_B \quad (4)$$

The modern view of the transport phenomena differs from the old view by the terms $L_{AB}\Delta\mu_B$ and $L_{BA}\Delta\mu_A$ in equations (1a) and (1b). These additional terms, which are demanded by theory as well as by experimental findings, indicate that the flow *e.g.* of component A generally depends not only on its own activity gradient, but also on the activity gradients of all the other components to which the membrane is permeable. Φ_A is therefore generally not zero if the activity (or concentration) of A is the same on both sides of the membrane. With suitable values of L_A and L_{AB}, it is even possible for Φ_A to have the direction opposite to that expected from the sign of $\Delta\mu_A$. Particle flow from low to high activity is known as incongruent transport[7,8]. It is made thermodynamically possible by the fact that a second component (B) is simultaneously migrating congruently, *i.e.* in the direction of its activity gradient.

These phenomena are combined in the concept of flow coupling. For this purpose, equations (1), (3), and (4) are written in the form

$$\Phi_A = L_A\left[(1-q^2)\Delta\mu_A + \frac{q}{\sqrt{L_A L_B}}\Phi_B\right] \quad (5a)$$

$$\Phi_B = L_B\left[(1-q^2)\Delta\mu_B + \frac{q}{\sqrt{L_A L_B}}\Phi_A\right] \quad (5b)$$

$$q \equiv L_{AB}/\sqrt{L_A L_B} \quad (-1 \leqslant q \leqslant 1)$$

[5] *A. J. Staverman*, Recueil. Trav. chim. Pays-Bas *70*, 344 (1951).

[*] In the isobaric case ($\Delta p = 0$), $\Delta\mu_A$ and $\Delta\mu_A$ are given by the differences $\Delta a_A \equiv a'_A - a''_A$ and $\Delta a_B \equiv a'_B - a''_B$ in the activities (R = gas constant, T = absolute temperature):

$$\Delta\mu_A = RT\,\Delta a_A/a_A; \quad \Delta\mu_B = RT\,\Delta a_B/a_B$$

where $a_A \equiv (a'_A + a''_A)/2$, $a_B \equiv (a'_B + a''_B)/2$ are the mean activities. If the external phases are ideal mixtures, the activities may be replaced by the mole fractions.

[6] *A. J. Staverman*, Trans. Faraday Soc. *48*, 176 (1952).

[7] *R. Schlögl*, Naturwissenschaften *50*, 67 (1963).

[8] *R. Schlögl*: Stofftransport durch Membranen. Steinkopff-Verlag, Darmstadt 1964.

The "coupling parameter" q, which was introduced by *Kedem* and *Caplan*[9, 10], is a measure of the extent to which the transport of A influences that of B and *vice versa*. If q is positive the flow of one substance tends to drag the flow of the second substance along in the same direction; if on the other hand q is negative, the first flow is forced back by the second (see Fig. 2).

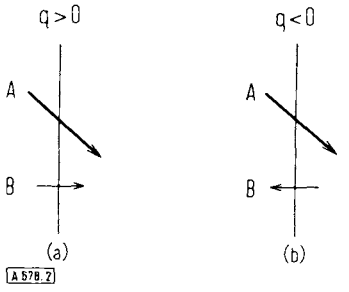

Fig. 2. Flows Φ_A and Φ_B in the special case $\Delta\mu_B = 0$ for positive (a) and negative (b) flow coupling. B migrates in the same direction as A when $q > 0$, and in the opposite direction when $q < 0$. The slope of the arrows corresponds to the gradient of the chemical potential.

When $q = 0$, the two substances migrate through the membrane independently.

A somewhat different situation arises if the pressure difference Δp in Figure 1 is no longer zero. For the sake of simplicity substance C is omitted in this case; moreover, both external phases are assumed to be dilute ideal solutions of A in B. The differences in the chemical potentials now depend not only on the concentration difference $\Delta c_A \equiv c_A' - c_A''$ but also on Δp:

$$\Delta\mu_A = v_A \Delta p + RT \Delta c_A/c_A \tag{6a}$$

$$\Delta\mu_B = v_B \Delta p - v_B RT \Delta c_A \tag{6b}$$

v_A and $v_B \approx 1/c_B$ are the mean partial molar volumes, and c_A and c_B are the mean concentrations. In experiments of this type it is usual to measure not only the flow Φ_A of the solute but also the "volume flow" $Q = v_A \Phi_A + v_B \Phi_B$. A system of equations introduced by *Staverman*[6] and obtained from equations (1), (3), and (6) has proved useful in this connection[11]:

$$Q = L_p[\Delta p - \sigma RT \Delta c_A] \tag{7}$$

$$\Phi_A = \omega_A RT \Delta c_A + c_A(1-\sigma)Q \tag{8}$$

The system is completely described by three phenomenological coefficients L_p, ω_A, and σ[*].

[9] *O. Kedem* and *S. R. Caplan*, Trans. Faraday Soc. *61*, 1897 (1965).

[10] *S. R. Caplan*, J. theoret. Biol. *10*, 209 (1966); *11*, 346 (1966).

[11] *O. Kedem* and *A. Katchalsky*, Biochim. biophysica Acta *27*, 229 (1958).

[*] The following equations are valid for dilute solutions:

$$\sigma = -L_{pD}/L_p\,, \quad \omega = c_A(L_pL_D - L_{pD}^2)/L_p \geq 0$$

$$L_p \equiv v_A^2 L_A + 2v_A v_B L_{AB} + v_B^2 L_B \geq 0$$

$$L_D \equiv \frac{L_A}{c_A^2} - 2\frac{L_{AB}}{c_A c_B} + \frac{L_B}{c_B^2} \geq 0$$

$$L_{pD} \equiv \frac{v_A}{c_A} L_A + \frac{L_{AB}}{c_A c_B} - \frac{v_B}{c_B} L_B$$

The "hydraulic permeability" L_p determines the volume flow due to a difference in external pressures at equal external concentrations ($\Delta c_A = 0$):

$$Q = L_p \Delta p \quad (\Delta c_A = 0) \tag{9}$$

If a concentration difference Δc_A is maintained between the external solutions, the particle flow Φ_A is found to be proportional to Δc_A. In the case $Q = 0$ (volumes of the external phases kept constant), Φ_A is found from equation (8) to be

$$\Phi_A = \omega_A RT \Delta c_A \quad (Q = 0) \tag{10}$$

The quantity ω_A is accordingly known as the "permeability coefficient".

The "reflection coefficient" σ was introduced by *Staverman*[5] for the interpretation of osmotic experiments. It is well known that equilibrium exists at a perfectly semipermeable membrane that is permeable to the solvent B and impermeable to the solute A when an additional pressure

$$\Delta\pi = RT\Delta c_A \tag{11}$$

is exerted on the concentrated solution. In the case of a membrane that is permeable to both components, the volume flow can also be made to disappear by the application of an external pressure Δp, but in this case Δp is no longer equal to the difference $\Delta\pi$ in the osmotic pressures of the external solutions. According to equation (7),

$$\Delta p = \sigma \Delta\pi \quad (Q = 0) \tag{12}$$

$(\Delta p)_{Q=0}$ is occasionally called the "apparent osmotic pressure".

For a semipermeable membrane, σ must have a value of 1[*]. Non-semipermeable membranes generally have σ values between 0 and 1, though σ can also be negative (cf. Section 5.2). Cases in which $\sigma > 1$ do not appear to have been observed so far, but are conceivable in principle[12].

Staverman[6] has shown that the reflection coefficient σ is also important in another experiment. In a system in which the external concentrations were initially equal ($c_A' = c_A'' = c_A$), if liquid is forced through a very wide-pored membrane, the concentration of the emerging solution will still be c_A. With small-pored membranes, in which the permeating molecules interact strongly with the membrane structure, it is generally found that one component is transported preferentially; this phenomenon is known as ultrafiltration or reverse osmosis. The concentration of the transported solution is given by Φ_A/Q; according to equation (8):

$$\Phi_A/Q = c_A(1-\sigma) \quad (\Delta c_A = 0) \tag{13}$$

[*] This condition is not sufficient for semipermeability. Equation (8) shows that since Φ_A for a semipermeable membrane must vanish for all values of Δc_A and Q, the necessary and sufficient conditions for semipermeability are: $\sigma = 1$, $\omega_A = 0$.

[12] Cf. ref. [8], p. 40.

Thus a value of $\sigma = 0$ corresponds to a completely unselective membrane ($\Phi_A/Q = c_A$). For a semipermeable membrane ($\sigma = 1$), on the other hand, $\Phi_A/Q = 0$, *i.e.* the filtrate consists of pure solvent.

3. Experimental Results for Electrically Neutral Membranes

As has already been shown in Section 2 of this article, a system consisting of a membrane and two permeable components is characterized by three mutually independent phenomenological coefficients (L_A, L_B, L_{AB}, or L_p, σ, ω). At a given temperature, these coefficients depend on the mean external concentrations. Measurements covering a wide range of concentrations are still rare. *Krämer* and *Sauer*[13] determined L_A, L_B, and L_{AB} for a cellulose membrane with several methanol/ethylene glycol mixtures (see Fig. 3)[*]. The system examined exhibits positive flow coupling; the values of the coupling parameter $q = L_{AB}/\sqrt{L_A L_B}$ are between 0.8 and 1.

Measurements of the reflection coefficient σ, which can be determined from the value of the apparent osmotic pressure (eq. (12)) and independently by ultrafiltration experiments (eq. (13)), are particularly interesting. The Onsager symmetry relation (eq. (3)) can be checked by comparison of the results obtained by the two methods. *Talen* and *Staverman*[14] obtained a value of $\sigma \simeq 0.20$, which was practically independent of the concentration, in ultrafiltration experiments with aqueous sucrose solutions at a porous quartz membrane (pore diameter about 50 Å). The apparent osmotic pressure of a sucrose solution measured at the same membrane should therefore be $^1/_5$ of the thermodynamic value, as is actually found to be the case.

This result is important for the osmometric determination of molecular weights[14, 15], since it shows that this method can be used even if the membrane is not completely impermeable to the solute. In this case the value of σ is determined by a separate ultrafiltration experiment, and the true osmotic pressure can then be calculated from the apparent value found experimentally.

In some cases the reflection coefficients σ were found to be strongly concentration-dependent, and even assumed negative values, *e.g.* at quartz membranes with solutions of polyethylene glycol in methanol or acetone[16–18]. Very small values of σ are found at quartz membranes with mixtures of low molecular weight organic substances[19].

Table 1. Experimental values of the phenomenological coefficients. The hydraulic permeability L_p and the permeability coefficient ω have been converted into the values for unit membrane thickness:

$$L_p^* = L_p \cdot d, \qquad \omega^* = \omega \cdot d$$

For comparison, the permeability coefficient for the free solution is given by $\omega_0 = D/RT$ (D = diffusion coefficient in the solution). For sucrose in water, $\omega_0 \approx 2.1 \times 10^{-16}$ moles · dyn^{-1} · s^{-1} (25 °C).

Membrane	External phase	σ	ω^* (mole · cm · dyn^{-1} · s^{-1})	L_p^* (cm^4 · dyn^{-1} · s^{-1})	Ref.
Cellulose (Sylvania "Wet Gel")	0.1 M sucrose in water	0.04	6.4×10^{-17}	8.2×10^{-13}	[21]
Cellulose (Visking dialysis tube)	0.1 M sucrose in water	0.11	1.6×10^{-17}	1.4×10^{-13}	[21]
Porous quartz membrane	0.1 M sucrose in water	0.20	—	1.2×10^{-13}	[14, 22]
Cellulose acetate	NaCl in water	≈ 1	1.2×10^{-20}	1.8×10^{-16}	[23]

It is obvious that a porous membrane that can distinguish well between solvent and solute cannot also have a high hydraulic permeability[20]. This is illustrated in Table 1: Large reflection coefficients σ and small permeability coefficients ω are associated with small values of the hydraulic permeability L_p.

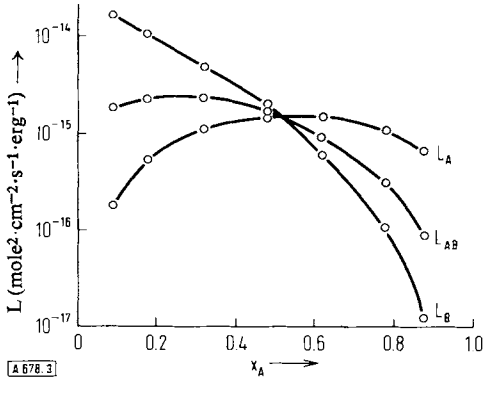

Fig. 3. Coefficients L_A, L_B, and $L_{AB} = L_{BA}$ (eq. (1)) for a cellulose membrane in contact with ethylene glycol (A)/methanol (B) mixtures x_A = mole fraction of ethylene glycol; $T = 20.0$ °C (after *Krämer* and *Sauer* [13]).

4. Transport Mechanisms

In the description of membrane structures it is possible to distinguish two limiting cases, *i.e.* pore membranes and solubility membranes. Pore membranes consist of a more or less rigid skeleton through which

run liquid-filled cavities. Examples are the above mentioned quartz membranes, which have a sponge-like structure with pore sizes of 20 to 100 Å, or highly swollen plastic films. Solubility membranes, on the other hand, are characterized by the absence of permanent pores. The membrane in this case consists of a continuous phase, which contains the permeating substance in a molecularly dissolved state. The simplest case of a solubility membrane is a thin film of a liquid that is immiscible with the external phases.

Many membranes, *e.g.* many of the interesting biological membranes, cannot be assigned to either of these classes. If the diameter of the "pores" is close to the dimensions of the permeating molecules, the distinction between a pore membrane and a solubility membrane becomes doubtful. In these cases a satisfactory description is possible only with the methods of statistical mechanics.

A number of transport mechanisms that can be described by simple membrane models will be discussed below.

4.1. Transport in Wide-Pored Membranes

Membranes are described as wide-pored if the average pore diameter is very much greater than the diameter of the permeating molecules. In this case the membrane skeleton acts merely as a geometric boundary, while the transport processes take place in the interior of the pores almost as in free solution. For simplicity we shall consider a model membrane with pores perpendicular to its surface, the length of the pores being equal to the thickness d of the membrane. If the membrane is in contact with binary ideal external phases differing in concentrations by Δc_A and Δc_B, and in pressure by Δp, the flows of components A and B for small values of Δc_A, Δc_B, and Δp are given approximately by the following expressions:

$$\Phi_A = c_A Q + w D_{AB} \Delta c_A / d \tag{14a}$$

$$\Phi_B = c_B Q + w D_{AB} \Delta c_B / d \tag{14b}$$

w is the free pore cross section per cm² of membrane surface and D_{AB} is the mutual diffusion coefficient of A and B in free solution.

The volume flow Q is determined by the hydraulic permeability L_p^* for a membrane thickness of 1 cm:

$$Q = L_p^* \Delta p / d \tag{15}$$

Thus the flow of component A consists of two parts, *i.e.* a "convective" contribution $c_A Q$ resulting from the entrainment of the molecules A in the volume flow, and a contribution $w D_{AB} \Delta c_A / d$ corresponding to Fick's first law and due to transport by diffusion. "Pressure diffusion", which makes only a vanishingly small contribution to the total transport in the case of wide-pored membranes, has not been taken into account. In the specific case of circular cylindrical pores of radius r, for which Poiseuille's law is valid, it is found for a membrane having ν pores per cm² that $w = \nu\pi r^2$, $L_p^* = \nu\pi r^4/8\eta$ (η = viscosity of the solution).

Equations (8) and (14a) show that the reflection coefficient σ disappears for a wide-pored membrane. On the other hand, the coupling parameter q (see Section 2) is generally different from zero. As an approximation, it is found [24] that

$$q \approx 1 / \sqrt{(1 + \vartheta\, c_A \nu_A / c_B \nu_B)(1 + \vartheta\, c_B \nu_B / c_A \nu_A)} \tag{16}$$
$$\vartheta \equiv \nu_A \nu_B (c_A + c_B)\, w D_{AB} / RTL_p^*$$

ϑ is of the order of magnitude of (molecular radius/pore radius)², and is therefore very small under these conditions. Thus positive flow coupling occurs in wide-pored membranes.

4.2. Transport in Solubility Membranes

Whereas the transport of the permeating substances in pore membranes is more or less strongly coupled, solubility membranes are characterized by a very low degree of coupling, since the migrating components are generally present in the membrane phase in very dilute solution, and therefore diffuse through the membrane independently of one another. If the external pressures on both sides are equal, the flow of component A is given by

$$\Phi_A = D_A \Delta c_A^m / d \tag{17}$$

D_A is the diffusion coefficient of A relative to the membrane phase and Δc_A^m is the concentration gradient in the membrane. It may be assumed that a partition equilibrium characterized by the partition coefficient $k_A \equiv c_A^m / c_A$ exists at the phase boundaries [*]. Thus

$$\Delta c_A^m = k_A \Delta c_A$$

The flows for components A and B are then given by:

$$\Phi_A = D_A k_A \Delta c_A / d \tag{18a}$$

$$\Phi_B = D_B k_B \Delta c_B / d \tag{18b}$$

The transport through a solubility membrane is thus determined by the product of the partition coefficient and the diffusion coefficient. Since the flows Φ_A and Φ_B are independent of each other, it follows directly that for an idealized solubility membrane the coeffi-

[24] *P. Läuger*, unpublished.

[*] This assumption is generally no longer permissible for very thin membranes. In this case the rate-determining step may be the passage of the particle through the phase boundary, while the diffusion within the membrane is relatively fast [25–27].

cient L_{AB} of equation (1) and hence also the coupling parameter q disappear.

Solubility membranes are particularly suitable for industrial use in separation processes. The separating efficiency of a membrane is best described by the "separation factor" γ:

$$\gamma \equiv \frac{\Phi_A/\Delta c_A}{\Phi_B/\Delta c_B} = \frac{k_A}{k_B} \cdot \frac{D_A}{D_B}$$

Since γ is independent of the thickness d of the membrane, whereas the flows are proportional to $1/d$, the membrane is made as thin as possible. With a suitable choice of the membrane phase, the partition coefficients k_A and k_B can be very different, so that the separation factor can have values greater than 10^4 [28]. It is possible in practice to use films of amorphous high polymers; useful solubility membranes can also be prepared by impregnation of a porous, inert support with a liquid that is immiscible with the external solutions.

4.3. Experimental Differentiation between Pore Membranes and Solubility Membranes

"Pore membranes" and "solubility membranes" are idealized limiting cases. The extent to which a given membrane approximates to one case or the other can be determined by comparison of the hydraulic permeability L_p with the tracer permeability coefficient ω' [23]. For the measurement of ω', the solvent is isotopically labeled (*e.g.* A = H_2O, B = HTO). A concentration difference Δc_B leads to a flow Φ_B that is proportional to the tracer permeability coefficient ω':

$$\Phi_B = \omega' RT \, \Delta c_B \tag{19}$$

Since A and B have almost identical physical properties, $k_A \approx k_B = k$, $D_A \approx D_B = D$, and $v_A \approx v_B = v$ (= molar volume). It follows from eq. (18b) that

$$\omega' = kD/RTd \tag{20}$$

The hydraulic permeability of a solubility membrane, on the other hand, is given by the equation

$$L_p = vkD/RTd \tag{21}$$

Thus for an ideal solubility membrane,

$$g \equiv L_p/v\omega' = 1 \tag{22}$$

Values of g greater than 1, on the other hand, indicate that the permeating molecules no longer pass through the membrane independently of one another. An extreme case is that of wide-pored membranes, for which $g \gg 1$. Values of g close to 1 were found by *Thau, Bloch,* and *Kedem* for several synthetic membranes [23].

[28] *R. Bloch, A. Finkelstein, O. Kedem,* and *D. Vofsi,* Ind. Engng. Chem., Process Design Development *6,* 231 (1967).

To explain the anomalous isotope flows observed in the squid axon membrane, *Hodgkin* and *Keynes* in 1955 introduced the single-file mechanism [29]. This type of transport occurs if the pores of a membrane become so narrow that adjacent particles can no longer change places (cf. Fig. 4). The movement of each permeating particle is then coupled to the movement of all the other particles in the pore.

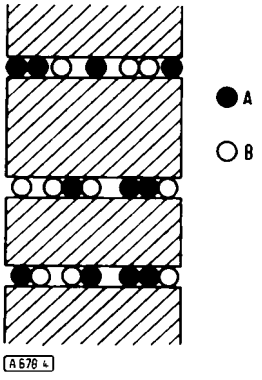

Fig. 4. Single-file transport. Adjacent particles in the pores cannot change places.

In the limiting case of very long pores, the average velocities of the particles A and B (Fig. 4) are the same. The ratio of the particle flows is then equal to the ratio of the concentrations c_A^m and c_B^m in the membrane, irrespective of the differences in the chemical potentials:

$$\Phi_A/\Phi_B = c_A^m/c_B^m \qquad \text{for all values of } \Delta\mu_A, \Delta\mu_B \tag{23}$$

This means that the coupling parameter q in equations (5a) and (5b) is equal to 1. In the limiting case of very long pores, therefore, this mechanism leads to complete positive flow coupling.

The calculation of the particle flows for finite pore lengths has been found to be very difficult. An exact treatment of a very simple model has been described by *Heckmann* [30, 31]. The pore in this case contains only two sites, each of which is either empty or occupied by a particle A or B. It is assumed that A and B can be distinguished analytically, but are physically identical in other respects. The calculations were originally carried out for gaseous external phases, but are also valid for an ideal dilute solution of A and B in a solvent C to which the membrane is impermeable. From *Heckmann*'s results, the coupling parameter is found to be given by the equation

$$q = \lambda \sqrt{\frac{c_A c_B}{(1-\lambda c_A)(1-\lambda c_B)}} \tag{24}$$

[29] *A. L. Hodgkin* and *R. D. Keynes,* J. Physiology *128,* 61 (1955).

[31] *K. Heckmann* and *H. Passow,* Ber. Bunsenges. physik. Chem. *71,* 839 (1967).

where λ is a known function of the mean total concentration $c_A + c_B$ and the jump frequencies of the two particles. The phenomenon of flow coupling is thus found even in this simple model.

Other methods have been reported for the calculation of flows in pores having more than two sites [32–36]. Time-dependent effects have also been examined [37]. Attempts to demonstrate this mechanism in synthetic membranes have not led to conclusive results [33, 38].

4.5. Carrier Transport

If the permeation of a substance is facilitated by complex formation with a molecule that is bound to the membrane, the process is referred to as carrier transport. In Fig. 5 it is assumed that the molecule A in

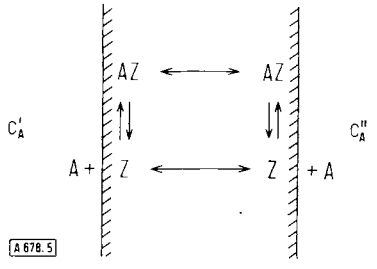

Fig. 5. Carrier transport. The molecule A combines with the carrier Z, which is bound to the membrane, to form a diffusible complex AZ. Vertical arrows: chemical equilibrium. Horizontal arrows: transport.

the free state is completely insoluble in the membrane. By reaction with the carrier molecule Z, which is present only in the membrane, a diffusible complex AZ is formed. If the rate of the reaction $A + Z \rightleftarrows AZ$ is sufficiently fast, the concentrations at the phase boundaries are given by the dissociation constant K_A

$$c'_A c'_Z / c'_{AZ} = c''_A c''_Z / c''_{AZ} = K_A \qquad (25)$$

In this equation, c_Z and c_{AZ} refer to the membrane phase, and c_A to the external phase. If $c'_A > c''_A$, a concentration gradient $(c'_{AZ} - c''_{AZ})/d > 0$ is established in the membrane, with the result that the complex is transported from left to right (see Fig. 5). At the right-hand interface the complex dissociates and A passes into the external phase, while the free carrier Z diffuses back to the left-hand interface.

Carrier transport differs from other types of transport by the phenomenon of saturation [40]. If the concentration c_A'' is kept constant, increasing c_A' brings the system ultimately to a state in which all the carrier molecules on the left-hand side of the membrane are in the form of complexes AZ. No further increase in the concentration gradient of AZ is then possible, and the flow of substance A has reached its maximum $\Phi_{A,max}$. In the special case $c_A'' = 0$:

$$\Phi_A = \Phi_{A,max} \frac{c'_A}{c'_A + 2 K_A D_Z/(D_{AZ} + D_Z)} \qquad (26)$$

$$\Phi_{A,max} = \frac{2 W D_{AZ}}{d^2 (1 + D_{AZ}/D_Z)} \qquad (27)$$

(D_Z, D_{AZ} = diffusion coefficients of the free carrier and of the complex respectively, W = total quantity of carrier in moles/cm² of membrane, d = membrane thickness).

If the external phases contain another substance B that competes with A for the common carrier, flow coupling occurs [39, 40]. Figure 6a shows the concentration profile for the case in which identical solutions of the substance A are present on both sides of the

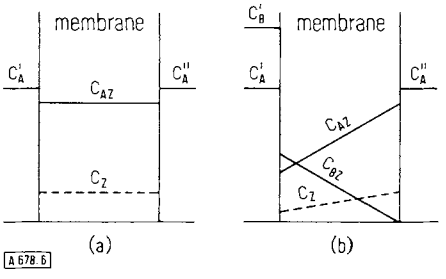

Fig. 6. Concentration profiles in a carrier transport system.
(a) System in equilibrium. The external phases consist of identical solutions of A.
(b) Addition of another substance B to the left-hand external phase. B competes with A for the common carrier Z.

membrane. On addition of the substance B to the left-hand phase (cf. Fig. 6b), the concentration of the complex AZ at the left-hand interface is decreased. A consequently migrates in the membrane from right to left, opposite to the migration of B. Thus negative flow coupling is observed in a carrier system (cf. Fig. 2). The following equation is found for the coupling parameter q:

$$q = -1 \Big/ \sqrt{\left(1 + \frac{D_Z}{D_{AZ}} \frac{K_A}{c_A}\right)\left(1 + \frac{D_Z}{D_{BZ}} \frac{K_B}{c_B}\right)} \qquad (28)$$

where c_A and c_B are the average external concentrations. In the saturation range of the carrier ($c_A \gg K_A$, $c_B \gg K_B$), q becomes equal to -1, *i.e.* complete (negative) flow coupling occurs.

Carrier transport is easily demonstrated experimentally with simple model membranes [41–44]. Carrier mecha-

nisms are very important in biology. For example, the transport of sugar through the erythrocyte membrane exhibits the characteristic phenomena of saturation and negative flow coupling [45]. However, it was necessary to extend the carrier concept considerably for biological membranes. Since the membrane thickness is only about 100 Å in this case, the existence of a freely diffusing carrier molecule is unlikely. It is therefore thought that the carrier molecule P (*e.g.* a protein) is an integral part of the membrane. The transport of a low molecular weight component A may be effected by a rotation or a change in the conformation of the complex A–P. This idea forms the basis of recent theoretical studies on the carrier mechanism [46–51].

4.6. Active Transport

Living cells are able to transport substances through the cell membrane against the activity gradients by consuming metabolic energy. Thus *E. coli* can absorb lactose even when the lactose concentration inside the cell is 2000 times that in the surrounding medium [52]. This formerly mysterious phenomenon has been circumscribed by the term "active transport" [53]. Some authors use this term to denote any particle transport against the gradient of the chemical potential (or the electrochemical potential in the case of ions) [54, 55]. According to this definition, "active transport" for uncharged particles would be identical with incongruent transport (cf. Section 2). A more common definition is as follows [56]. Active transport is a congruent or incongruent particle transport that is coupled with a chemical reaction [*].

This definition is in accordance with the fact that the free energy required for any incongruent transport must ultimately be supplied by metabolic processes. The function of the metabolic process may be simply to maintain activity differences of other substances which, by flow coupling, provoke the incongruent transport of the component in question. There is, however, evidence that a much more direct coupling exists between the chemical reaction and the transport process in biological membranes [39, 61, 62]. It is conceivable that the chemical reaction proceeds *via* an intermediate in which the carrier molecule Z is directly involved. If it is assumed that the bonding of A to the carrier is weakened by the chemical reaction, we obtain the following reaction scheme:

$$AZ + X{\sim}Y \rightarrow A + Z{\sim}X + Y' \quad \text{(a)}$$

$$Z{\sim}X \rightarrow Z + X' \quad \text{(b)}$$

(X′, Y′ = hydrolysis products of the energy-rich compound X∼Y).

If reaction (a) is catalyzed only at the right-hand interface and reaction (b) only at the left-hand interface of the unsymmetrical membrane, the substance A can be transported incongruently from left to right by consumption of the free energy made available by the hydrolysis of X ∼ Y. A reaction of this type appears to be involved in the ATP-dependent transport of Na^+ and K^+ through the cell membrane [39, 63].

5. Ion Exchange Membranes

If the membrane matrix contains electrically charged groups, additional phenomena occur. It is therefore necessary to extend the above equations before applying them to ion exchange membranes. The driving force for the transport of an ion through the membrane is now not only the activity gradient but also the electric field. Accordingly, the current and the electrical potential difference between the external phases occur as additional variables in the flow equations.

A macroscopic ion exchange membrane must satisfy the electroneutrality condition; therefore, in addition to the ions that are bound to the matrix ("fixed ions"), the membrane contains oppositely charged ions ("counter-ions"). Small quantities of "co-ions", which have the same charge as the fixed ions, are also present. In contact with aqueous external phases, ion exchange membranes absorb water; however, the quantity absorbed varies widely between membranes of different types.

Ion exchange membranes of the dissociation type (in *Eisenman*'s terminology [64]) are membranes with a high water content, in whose water-filled pores co-ions and counter-ions can move more or less freely. The ionic groups bound firmly to the matrix may therefore be regarded as completely dissociated, like a strong electrolyte in aqueous solution. This type of membrane is represented by highly swollen synthetic ion exchanger membranes based on synthetic resins.

Ion exchange resins of the association type contain only strongly bound hydration water, and in the extreme case they are practically free from water. The silicate glass membranes used to measure the activities

of hydrogen and alkali metal ions are of this type. The fixed ions are represented by the SiO^- and $AlOSi^-$ groups. The counter-ions (Na^+, K^+, *etc.*), which are situated in a medium having a low dielectric constant, are more or less associated with the fixed ions. However, they can migrate between adjacent fixed ions (*e.g.* by a defect mechanism), and they can be exchanged to a limited extent for other ions from the aqueous phase.

5.1. Ion Exchange Membranes of the Association Type

These membranes have recently been investigated in particular by *Eisenman et al.* [64–68] in an effort to obtain a better understanding of the operation of the glass electrode, the ion-specificity of which can be greatly varied by variation of the composition of the glass. The electric potential difference across a membrane of pure Na silicate glass is almost exclusively determined by the ratio of the hydrogen ion activities of the external solutions, and is practically unaffected by other cations. Introduction of Al_2O_3 or B_2O_3 into the glass matrix, on the other hand, yields membranes that are selective for alkali metal ions in neutral or alkaline media. If the external solutions contain two types of alkali metal ions i and j, the potential difference measured at vanishing current obeys the relationship:

$$\Delta\varphi = \frac{nRT}{F} \ln \frac{(a_i')^{1/n} + (K_{ij}a_j)^{1/n}}{(a_i'')^{1/n} + (K_{ij}a_j'')^{1/n}} \qquad (29)$$

a' and a'' are the alkali ion activities in the left-hand and right-hand external solutions, respectively, and n and K_{ij} are empirical constants characteristic of the composition of the glass and the ion pair (n is generally close to 1). The selectivity constant K_{ij} can assume values of between 10^5 and 0.03 for the ion pair K^+, Na^+, depending on the glass [65]; Na^+ activities can therefore be measured very accurately even in the presence of K^+. The ion selectivity is due to the following factors:

(a) Owing to the high concentration of fixed ions, co-ions are practically unable to penetrate into the membrane.

(b) The mobilities of different counter-ions differ much more in the membrane than in free solution. Moreover, tracer measurements have shown that the Na^+ and K^+ mobilities are several orders of magnitude lower than in aqueous solution [68].

(c) The exchange equilibrium of two alkali metal ions A^+ and B^+ between the membrane phase and the external solution is strongly dependent on the ionic radii and the glass structure. The equilibrium constant is determined by the free enthalpy change ΔG in the exchange reaction:

$$A^+ (aq.) + B^+ (membrane) \rightarrow A^+ (membrane) + B^+ (aq.)$$

ΔG is made up from the difference in the hydration energies and the ion-matrix interaction energies, which can be approximately calculated from the Coulomb interaction between the counter-ion and the fixed ion, using an effective ionic radius for the fixed ion. The specificity sequences of several types of glasses can be qualitatively interpreted in this way [65, 68].

In addition to their practical importance, ion exchange membranes of the association type are valuable models for biological membranes. According to *Eisenman* [65, 66], association also occurs between inorganic ions and "bonding sites" (*e.g.* $\cdots$—COO^-) in the lipoprotein matrix of biological membranes. This view can form a basis for the interpretation of ion specificities in biology.

5.2. Ion Exchange Membranes of the Dissociation Type

Most synthetic ion exchange membranes have a high water content so that their ionic groups are almost completely dissociated (see [69–77], for reviews see [8, 78–80]).

Ion exchange membranes of the dissociation type have interconnected, water-filled pores, in which co-ions and counter-ions can move rather freely. The pore liquid as a whole is electrically charged; this leads to coupling effects between mechanical and electrical processes in the membrane. For example, as a result of an externally induced volume flow, a potential difference (the streaming potential) builds up across the membrane at vanishing electric current. Conversely, an externally applied potential difference leads at vanishing volume flow to a pressure difference. These phenomena are known as electrokinetic phenomena. Moreover, the flows of all types of ions in the electric field are also coupled with one another.

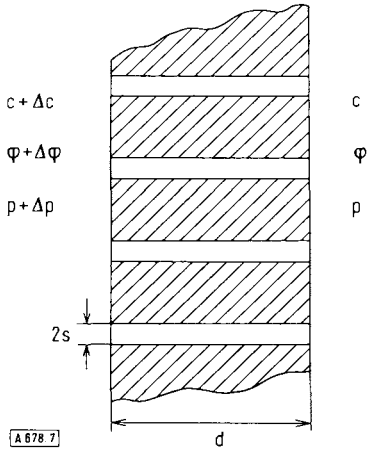

Fig. 7. Ion exchange membrane with parallel slit-shaped pores of width $2s$. The external phases differ in their electrolyte concentrations by Δc, in electric potential by $\Delta\varphi$, and in pressure by Δp.

The pore structure of true ion exchange membranes is very complicated, and is not yet known in detail. The geometrically simplest model is an arrangement of parallel, slit-shaped pores of width $2s$, which run through the membrane perpendicular to is surface (cf. Fig. 7). If ν pores are present per cm^2, the proportion of the total membrane area occupied by pores is $w = 2\nu s$. The pore walls are assumed to be covered with fixed electric charges having a surface density of γ; the concentration X of fixed ions per unit volume of pore liquid is then $\omega X = \gamma/sF$ (F = Faraday constant, $\omega = \pm 1$ = sign of the charge on the fixed ions).

The membrane is assumed to be in contact on both sides with a $z:z$ electrolyte having an equivalent conductivity $\Lambda = F(\beta_+ + \beta_-)$. Since the pore liquid may be regarded approximately as free solution, the mobilities β_+ and β_- of the cation and the anion and the viscosity η inside the pores are approximately the same as in the external media. In the general case, the external phases differ in their electrolyte concentrations by Δc, in electrical potential by $\Delta\varphi$, and in pressure by Δp. The result is the simultaneous occurrence of a cation flow Φ_+, an anion flow Φ_-, and a water flow Φ_W. It is, however, desirable on practical grounds to consider other flows, *i.e.* the "salt flow" $S \equiv {}^1/_2(\Phi_+ + \Phi_-)$, the volume flow $Q \approx v_W \Phi_W$, and the current density $J = zF(\Phi_+ - \Phi_-)$ (v_W = partial molar volume of water).

S, J, and Q vary linearly with the differences Δc, $\Delta\varphi$, and Δp if these are sufficiently small:

$$S = L_{Sc}\Delta c + L_{S\varphi}\Delta\varphi + L_{Sp}\Delta p \tag{31a}$$

$$J = L_{Jc}\Delta c + L_{J\varphi}\Delta\varphi + L_{Jp}\Delta p \tag{31b}$$

$$Q = L_{Qc}\Delta c + L_{Q\varphi}\Delta\varphi + L_{Qp}\Delta p \tag{31c}$$

The nine coefficients L_{Sc}, $L_{S\varphi}$, *etc.* can, at least in principle, be calculated from the assumptions of the model. The calculation is based on the generalized Nernst-Planck equations [75], which relate the ion flows to the concentration and potential profiles in the pore; the pressure profile in the interior of the pores must also be explicitly taken into account. The transport equations can be integrated in a closed form if the pore width s is much greater or much smaller than the Debye-Hückel distance $1/\varkappa$ [81, 82]. $1/\varkappa$ is approximately the distance over which the diffuse ion atmosphere extends in the vicinity of an electrically charged wall. Membranes for which $\varkappa s \ll 1$ are described as "fine-pored"; this condition is satisfied to a good approximation in many synthetic ion exchange membranes (pore widths between 10 and 100 Å). The calculation [83] for the limiting case $\varkappa s \ll 1$ gives [*]

$$L_{Sc} = \frac{wRT\Lambda}{2zF^2d}\,[y(a+U) + \tau a(ay-1)]$$

$$L_{S\varphi} = -\omega\frac{wX\Lambda}{4zFd}\,[1 + a(\tau+U)]$$

$$L_{Sp} = \frac{ws^2aX}{6z\eta d}$$

$$L_{Jc} = -\omega\frac{wRT\Lambda}{Fd}\,[\tau(ay-1) + y(aU+1)]$$

$$L_{J\varphi} = \frac{wX\Lambda}{2d}\,[\tau + a + U]$$

$$L_{Jp} = -\omega\frac{ws^2FX}{3\eta d} \tag{32}$$

$$L_{Qc} = \frac{2ws^2RT}{3\eta d}\,(ay-1)$$

$$L_{Q\varphi} = -\omega\frac{ws^2FX}{3\eta d}$$

$$L_{Qp} = \frac{ws^2}{3\eta d}$$

$$y \equiv \frac{X}{2zc}, \qquad a \equiv \sqrt{1 + 1/y^2}$$

$$\tau \equiv \frac{2s^2F^2X}{3\eta\Lambda}$$

$$U \equiv -\omega\frac{\beta_+ - \beta_-}{\beta_+ + \beta_-} = \frac{\beta_{\text{counter-ion}} - \beta_{\text{co-ion}}}{\beta_{\text{counter-ion}} + \beta_{\text{co-ion}}}$$

This coefficient scheme allows a rational description of the electrokinetic and osmotic effects occurring in fine-pored ion exchange membranes. For example, insertion of $\Delta c = 0$ and $J = 0$ in equations (31a)–(31c) gives the following equation for the streaming potential:

$$\Delta\varphi = -\frac{L_{Jp}}{L_{J\varphi}}\Delta p = \frac{\omega}{FX}\frac{\tau}{\tau + a + U}\Delta p \quad (\Delta c = 0,\ J = 0)$$

The other electrokinetic phenomena are obtained in a similar manner. The experimental results generally agree satisfactorily with the predicted behavior if an effective value X_{eff} is used for the concentration of fixed ions. X_{eff} can be determined from an electrokinetic experiment and is usually very much smaller than the analytical concentration X. This indicates that a large proportion of the fixed ions are trapped in "blind alleys" or weakly swollen zones of the membrane matrix, and are therefore electrokinetically inactive [84].

Ion exchange membranes also exhibit certain peculiarities in their osmotic behavior toward electrolyte solutions. How can a difference in osmotic pressure occur at a membrane whose pore diameter is much greater than the diameter of the dissolved particles? The reason for this is that the interaction between the ions of the dissolved salt and the membrane matrix is due to long-range Coulomb forces. If the concentration of fixed ions is sufficiently high, the reflection coefficient σ can assume values close to 1. On the other hand, negative σ values can also occur at ion exchange membranes. This means that if the volume transport is suppressed, an excess pressure builds up on the side of the dilute solution, in direct contrast

[81] *P. Läuger* and *W. Kuhn*, Ber. Bunsenges. physik. Chem. *68*, 4 (1964).

[82] *P. Läuger*, Ber. Bunsenges. physik. Chem. *68*, 352 (1964).

[83] *P. Läuger*, unpublished.

[*] Since "flows" and "forces" are not conjugated in equations (31a)–(31c), the Onsager symmetry relations (eq. (3)) take the form $L_{Sp}/c = L_{Qp} + L_{Qc}/2RT$, $L_{S\varphi}/c = L_{Q\varphi} + L_{Jc}/2RT$, $L_{Q\varphi} = L_{Jp}$. These relations are satisfied by equations (32).

[84] *A. Fischer*, Ber. Bunsenges. physik. Chem. *71*, 822 (1967).

with the behavior at a semipermeable membrane. The theoretical interpretation of these osmotic anomalies was provided by *Schlögl*, who was the first to calculate the potential and pressure profiles inside an ion exchange membrane. For a binary electrolyte solution:

$$\sigma = \Delta p/\Delta\pi = \Delta p/2RT\,\Delta c \quad (J = 0,\ Q = 0) \tag{33}$$

Introducing $J = Q = 0$ into equations (31a)–(31c), we obtain

$$\sigma = \frac{1}{2RT}\,\frac{L_{Q\varphi}L_{Jc} - L_{J\varphi}L_{Qc}}{L_{J\varphi}L_{Qp} - L_{Jp}L_{Q\varphi}} = 1 - \frac{2zc/X}{U + \sqrt{1 + (2zc/X)^2}} \tag{34}$$

Thus the reflection coefficient depends on the concentration ratio c/X and on the difference U in the ion mobilities [equation (32)]. For any $U < 0$ (co-ions more mobile than counter-ions), there is a range of values of c/X in which σ becomes negative. This has been repeatedly confirmed by experiment. Thus *Schönborn* and *Woermann* [85] showed that negative σ values occur at an anion exchange membrane with HCl as the electrolyte ($U < 0$), with a minimum of $\sigma \approx -0.11$ at $c/X \approx 0.16$.

Under isobaric conditions ($\Delta p = 0$), volume transport occurs from the concentrated to the dilute electrolyte solution if the reflection coefficient is negative ("negative osmosis"). Since the activity of water is higher in the dilute than in the concentrated solution, negative osmosis is practically synonymous with incongruent transport of water. The salt transport may also be congruent or incongruent [75]. Figure 8 shows the lines $Q = 0$ and $S = 0$, which separate the domains of congruent and incongruent transport in the $(U, X/zc)$ plane [81].

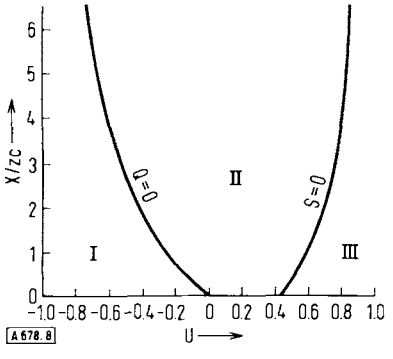

Fig. 8. Osmotic phenomena at an ion exchange membrane ($J = 0$, $\Delta p = 0$).

Region I: Volume transport Q negative, water transport Φ_W incongruent, salt transport S congruent.
Region II: Q positive, Φ_W congruent, S congruent.
Region III: Q positive, Φ_W congruent, S incongruent ($\tau = 2.0$) (see eq. (32)).

5.3. Phenomena in Composite Ion Exchange Membranes

Interesting phenomena are observed at membranes that contain both anion and cation exchange elements. The two simplest combinations are shown in Figure 9.

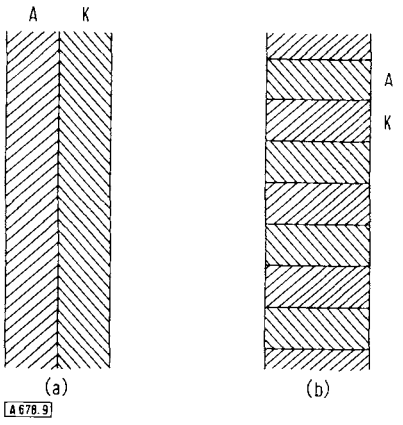

Fig. 9. Formation of composite membranes from anion (A) and cation exchange elements (K).
(a) Sandwich membrane.
(b) Mosaic membrane.

If the individual elements are arranged in series, the result is a "sandwich" membrane, while arrangement in parallel leads to a "mosaic" membrane. These basic structures are also found in biological membranes.

Experiments with synthetic anisotropic membranes were described by *Wilbrandt* [86] as early as 1935. However, a theoretical survey of the possible effects was published much later, by *Kedem* and *Katchalsky* [87]; in particular, these authors formulated the combination rules which allow calculation of the behavior of the composite membrane from the properties of the individual elements.

5.3.1. Sandwich Membranes

Membranes consisting of two parallel anion and cation exchange layers (Fig. 9a) have remarkable electrical properties; for example, they act as rectifiers. This behavior is due to the fact that the charge transport in an ion exchange membrane having a high fixed-ion concentration takes place almost exclusively by migration of counter-ions. Thus an anion-conducting phase and a cation-conducting phase come into direct contact at the interface between the A and K layers of a sandwich membrane.

If there is a potential difference $\Delta\varphi$ between the external solutions (*e.g.* 10^{-2} M NaCl on both sides), so that electric current flows in the membrane from the K layer to the A layer, Na^+ ions migrate to the interface in the K layer and Cl^- ions in the A layer. An appreciable current can be maintained in the membrane in the steady state when the current flows in this direction; NaCl is formed at the interface, and diffuses back into the external phases. If, on the other hand, $\Delta\varphi$ has the opposite sign, the ions in both layers migrate away from the interface. This leads to an increased charge unbalance in the contact zone. At high external voltages, practically the entire voltage appears as a space-charge-induced potential drop across the interface, so that only a small current can flow.

The theoretical description of this rectifier effect is relatively simple if a perfectly symmetrical system is

[85] *U. Schönborn* and *D. Woermann*, Ber. Bunsenges. physik. Chem. *71*, 843 (1967).

[86] *W. Wilbrandt*, J. gen. Physiol. *18*, 933 (1935).

[87] *O. Kedem* and *A. Katchalsky*, Trans. Faraday Soc. *59*, 1918, 1931, 1941 (1963).

considered, *i.e.* if it is assumed that the fixed-ion concentrations X in the two layers are equal and that the cation and anion have equal diffusion coefficients ($D_+ = D_- = D$). The current density J is then given approximately by

$$J = J_g \left(e^{\frac{\Delta\varphi}{RT/F}} - 1 \right) \tag{35}$$

$$J_g \equiv \frac{2c^2FD}{bX} \tag{36}$$

(c = concentration of the 1:1 electrolyte in the external phases, b = thickness of the individual layer). The current-voltage curve (eq. (35)) is shown in Figure 10.

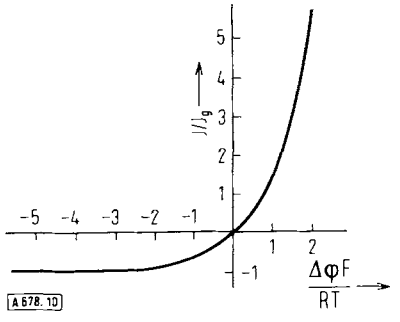

Fig. 10. Current-voltage characteristic of a sandwich membrane consisting of a cation exchange layer and an anion exchange layer (eq. (35)).

For $J > 0$ (forward direction), the current density increases exponentially with the voltage. For $J < 0$ (reverse direction), the current density can never rise above the limiting current density J_g. These predictions are confirmed by experiment [88–100].

Membranes of this type are analogous to pn-type rectifiers [90, 94].

Sandwich membranes are also useful as model systems in which the coupling between chemical reactions and transport processes can be investigated (cf. Section 4.6). *Blumenthal*, *Caplan*, and *Kedem* [101] studied the membrane system

anion exchange membrane (A)	neutral layer containing papain	cation exchange membrane (K)

An amide $R-CONH_2$ is added to the aqueous external phases as an electrically neutral "substrate", which diffuses to the intermediate layer, where it is hydrolyzed by the enzyme papain:

$$R-CONH_2 + H_2O \xrightarrow{\text{papain}} R-COO^- + NH_4^+ \tag{37}$$

Since the electrically charged hydrolysis products tend to leave the membrane by different routes ($R-COO^-$ mainly through the A layer, and NH_4^+ mainly through the K layer), a potential difference is set up between the external phases. Accordingly, an electric current can be drawn from the system, as long as the reaction (37) proceeds from left to right. These experiments show that chemical reactions and transport processes (charge transport in this case) can in fact be coupled in anisotropic membranes.

5.3.2. Mosaic Membranes

In mosaic membranes (Fig. 9b), the total flow of a given particle is made up additively from the flows through the individual elements. The phenomenological coefficients of a mosaic membrane can be obtained from the coefficients of the individual elements [87]. This gives a coefficient scheme similar to (32), which becomes particularly simple for a symmetrical mosaic membrane (A and K elements identical apart from the charge sign) [102].

According to theoretical predictions, the electrochemical properties of mosaic ion exchange membranes are quite different from those of normal ion exchange membranes. For example, the sign of the membrane potential should depend on the ratio of the areas of the A and K elements; this has recently been experimentally confirmed by *Woermann* [103]. Whereas normal ion exchange membranes are practically impermeable to electrolytes at high fixed-ion concentrations, mosaic membranes are characterized by an unusually high salt permeability [104, 105].

This is explained as follows. If all the elements were electrically insulated from one another, potential differences of opposite sign would be set up over the A and K elements when the external solutions have different concentrations. Since adjacent elements are in reality short-circuited *via* the external solutions, the potential differences cancel out and ring currents flow, transporting anions in the A elements and cations in the K elements from the concentrated into the dilute salt solution [104, 106]. In this way the salt permeability of a mosaic membrane can assume values much higher than those of the free solution [87].

The existence of ring currents in the membrane has another important consequence. Owing to the hydro-

dynamic interaction between ions and water molecules, the migrating ions in A and K elements transport water from the dilute to the concentrated salt solution. Negative osmosis is therefore to be expected in mosaic membranes. The reflection coefficient for a symmetrical mosaic membrane is theoretically given by the equation [102]

$$\sigma = 1 - \sqrt{1 - (X/2zc)^2} \qquad (38)$$

As expected, σ is always negative. The approximation $\sigma \approx -X/2zc$ can be used at high fixed-ion concentrations ($X \gg c$). Thus pressure differences many times greater than the equilibrium pressure difference $\Delta\pi$ (eqs. (11) and (12)) should occur in osmotic experiments with mosaic membranes.

According to equation (13), the reflection coefficient σ also determines the filtration behavior of the membrane; for $\sigma < 0$, the solute is enriched in the filtrate. On filtration of a dilute salt solution through a mosaic membrane having a high fixed-ion concentration, the filtrate should be a highly concentrated salt solution. This interesting effect has not yet been verified experimentally.

The Chemistry of Hypervalent Molecules[**]

By J. I. Musher[*]

Molecules formed from atoms of Groups V–VIII of the periodic table in their higher valences are studied and a general theory for their electronic and geometric structure is presented. These molecules, which we call hypervalent molecules, are unique in that a donor atom can possess two identical monovalent ligands which are bonded by different types of chemical bonds. The present study provides a simple theoretical description of such molecules using doubly-occupied lone-pair orbitals to form hypervalent bonds, and these bonds are divided into two classes as to whether they involve p electrons alone or utilize s electrons as well. While the theoretical classification is of some interest in itself, there are even more interesting problems concerning the physico-chemical properties of these molecules and the syntheses of new molecules and polymers. We thus present a brief description of the energetics, possibilities for intermolecular inversion and site-exchange, and synthetic paths for the preparation of hypervalent molecules, as well as indicate a number of new molecules which can probably be synthesized using these ideas.

1. Introduction

The Lewis-Langmuir theory of valence attributed the stability of molecules to their ability to place their valence electrons, appropriately paired off as chemical bonds, into "stable octets" [1, 2]. This theory can be said to have survived the advent of quantum mechanics with the electron-pairs being replaced by doubly-occupied molecular orbitals or approximately-localized bond orbitals, and with the "cubical atom" being replaced by the directed valences of p-bonds, so that undistorted bonds form along perpendicular axes rather than on corners of tetrahedra. Both the classical empirical theory and the modern quantum mechanical theory have been quite successful in treating molecules formed from atoms in their lowest valences such as PH_3, H_2S, and Cl_2, and the molecular orbital theory has had some success in treating coordination complexes of metal ions [3]. However, both types of theories have encountered considerable difficulties in treating the molecules formed by atoms of Groups V–VIII of the periodic table in their higher valences (*e.g.* PCl_5, $(CH_3)_2SO$, and $HClO_4$), with the classical theory referring to "expanded octets" and the quantum mechanical theory invoking d orbital participation in hybridization schemes involving large promotion energies [4]. The fact that these molecules have never received a good theoretical treatment but have some-

how always been considered as exceptions to the rule, has had the unfortunate consequence that many interesting aspects of their chemistry have been almost completely neglected by the modern chemist.

The present article is devoted to a discussion of molecules formed from higher valence atoms from a new and different point of view, in which the ground atomic configuration, as distinguished from the usual "valence state", is used as the determining factor in the molecular structure. After developing a most natural and straightforward MO theory for these molecules, we go on to discuss their unique physicochemical properties, and predict the stability of a number of new molecules and polymers, a few of which have already been synthesized [5].

We classify as "hypervalent" molecules and ions all those molecules and ions formed by elements in Groups V–VIII of the periodic table in any of their valences other than their lowest stable chemical valence of 3,2,1, and 0 respectively. We refer to these molecules as *hypervalent* (or HV) since they involve atoms, called donor atoms, which exceed the number of valences allowed them by the traditional theory, and thus utilize more electron-pairs of bonding than provide stability in the Lewis-Langmuir theory. As hypervalent molecules have chemical formulas, and often the molecular structure, of the addition product of a stable molecule with two monovalent ligands or a single divalent ligand they could also be called hypermolecules or "molecules made out of molecules" [6].

The hypervalent molecules are by no means obscure despite the fact that they have received highly inadequate consideration in the literature. They include a number of molecules first obtained in the early days of chemistry, such as PCl_5, ICl_3, and $SeCl_4$ which were prepared by *Davy, Gay-Lussac,* and *Berzelius* respectively in the years 1810, 1814, and 1818 [7]. They also include such common molecules as dimethyl sulfoxide, phosphine oxide, and iodosylbenzene, and most acids such as chloric, phosphorous, and sulfuric acids. In discussing some of these, *Moffitt* felt obliged to say "the structure of the sulphoxides and sulphones has been a point of dissension since the earliest days of valency theory [8]."

In recent years interest in some of the HV molecules has been reawakened by the spectacular discovery of the xenon fluorides in 1962. This discovery led to the publication of a number of theoretical papers on the inert gas halides with a few of these recognizing the similarity of such molecules to the classic halides PF_5, SF_4, and ClF_3 [6, 10–12]. None, however, recognized the relationship to the hypervalent oxides and sulfides, the significant difference between the p-bonded molecules SF_4, ClF_3, and XeF_2, and the molecules PF_5, SF_6, and IF_7 which also utilize the s-electrons of the donor atom. Furthermore, the application of such ideas to synthetic and physical chemistry has not previously been considered. The generality of the description of the xenon fluorides was observed by *Waters* and *Gray* who said that "the inert gas halides fit naturally into the sequence of halides of the non-metallic elements in their higher valence states" [11] and by *Rundle* in the converse sense, "From this discussion [on the polyhalide ions] it should be clear that a simple extrapolation was all that was needed to predict the rare gas fluorides" [12] although he went on to note that such an application of the theory is "not impressive after-the-fact" which was especially pertinent as he had previously gone on record against the whole idea of applying the polyiodide ion theory to molecules, as well as to other interhalogen ions [13].

On the experimental side there has been some interest shown in the properties of hypervalent molecules within the past few years particularly by *Muetterties* [14], *Cady* [15], *Holmes* [16], and their co-workers who performed NMR studies on a number of new (and old) HV compounds of sulfur and phosphorus. Other studies have used electron diffraction [17], IR [18], Raman [18], and Mössbauer spectroscopy [19] on a number of HV halides and the now classic studies of *Cornwell* and *Yamasaki* [20] examined the iodine chloride ions with EQR. The recent literature has also showed a number of differing opinions as to the interpretation of some of the experiments on hypervalent molecules [21].

In the present article a classification of the hypervalent molecules is developed by observing the several significant features which distinguish them from "octet" molecules. We first note that only in HV molecules can there exist two different types of single bonds on a given atom so that this atom is able to undergo isomerization, and that only in HV molecules can two single bonds be actually colinear. We then recognize that in a number of HV molecules, such as SF_4 and ICl_3, the pairs of colinear bonds to monovalent ligands can be described in terms of MO's – using a doubly-occupied p orbital on the donor atom in the ground atomic configuration – in the manner now accepted for the xenon fluorides follow-

ing the ideas of *Pimentel*[22] and *Rundle*[13]. This leads to the observation that when divalent ligands bond to these same donor atoms, they lie almost along the same axis as the pair of monovalent ligands, and we realize that the same type of theory can be applied to these molecules as well. The next and last step is to note that the bonds in molecules like PF_5, SF_6, IF_7, and $(CH_3)_2SO$ cannot be described in terms of doubly-occupied p orbitals since the donor atoms have reached their maximum possible valence and consequently all valence electrons including the s electrons must be used; the molecular geometry therefore takes on the highest possible symmetry, as is the case with methane.

While this classification scheme includes a large number of molecules either left out of, or inadequately represented by, the octet scheme, and variously rationalized but not in any uniform manner over the years by the quantum theory[3], it does not pretend to include all or even most molecules. The various electron-deficient molecules, and radical species, *etc.*, which are being discovered almost daily must probably remain outside any such general scheme. We have thus the benefit of considerable chemical experience, unavailable to *Lewis* and *Langmuir*, which enables us to recognize that no single empirical or theoretical picture of valence can be applied or should be distorted to fit all known molecules.

We are, however, more interested in the new aspects of physicochemical studies and the syntheses of new varieties of "non-metallo-organic" molecules that this study might encourage, than in the classification scheme itself. How deleterious an effect an oversimplified theory can have is exemplified by the fact that the chemistry of hypervalent molecules was an active area of investigation until publication of the Lewis-Langmuir theory which showed such molecules to be exceptional and ionic. From that time on their chemistry has been almost meticulously avoided by mainstream chemists until perhaps the past few years.

2. Definition and Classification

Consider the formation of chemical bonds to the representative atoms in Groups V-VIII of the periodic table, P, S, Br, and Xe. The simple quantum mechanical description of an ordinary chemical bond[3] combines one atomic orbital, singly-occupied in the ground configuration, from the donor atom with one from the ligand, to form a bond orbital or localized approximate molecular orbital,

$$\psi = \psi_d + \lambda\psi_l$$

into which the two electrons are to be placed, or the valence-bond analog thereof. Stability of molecules is inferred, for the most part, when all singly-occupied atomic orbitals are involved in chemical bonds, which, as there are 8 electrons in each atomic shell, explains why *Lewis* and *Langmuir* deduced stability empirically for electronic octets. Thus, the ground atomic configurations $P(s^2p_xp_yp_z)$, $S(s^2p_x^2p_yp_z)$, $Br(s^2p_x^2p_y^2p_z)$, and $Xe(s^2p_x^2p_y^2p_z^2)$, have, according to Hund's rule, lowest stable valences of 3, 2, 1, and 0, respectively, and form molecules such as PF_3, SCl_2, BrF, and Xe. We henceforth refer to the chemical bond so formed as covalent or CV to distinguish it from the types of bonds formed in hypervalent molecules. The simple theory argues that CV bonds should be essentially oriented along perpendicular axes, in accord with the experimental bond angles of 100° found for both PF_3 and SCl_2, and with the angles of 93.5° and 92.1° found for the corresponding hydrides PH_3 and SH_2[23].

Notice that the concept of stability we use refers to thermodynamic stability in the restricted sense in which the atoms are in local minima of potential energy even though these systems can dissociate such as by tunneling to form ion pairs; on the other hand, molecules containing an unpaired electron can be excluded – not a fully consistent procedure but relatively free of ambiguity. Thus, we are not interested in the kinetic stability which governs the lifetime of molecules in certain chemical and physical environments except insofar as to recognize that, for example, it might be their kinetic instability which makes molecules of divalent carbon atoms so rare. Also, for this argument, we explicitly refer to the ground atomic configuration since the (unobserved) diatomic molecule PF could also be considered stable when the fluorine is bonded by a CV bond to the excited atom $P(s^2p_x^2p_y)$ which now has all of its electrons paired. In this sense the octet theory was based on the fact that Hund's rule does not permit such an electron configuration as the ground state of an atom. It should be observed that the phrase "lowest stable" valence does not imply "most probable" valence, since for example, by analogy, carbon $(s^2p_xp_y)$ has the "lowest stable" valence of 2, even though the only atoms of the same configuration which have a significant number of known divalent molecules are tin and lead.

On examination of the remaining non-bonding atomic electrons ("lone pair" electrons) of the CV bonded atoms $P'(s^2)$, $S'(s^2p_z^2)$, $Br'(s^2p_x^2p_y^2)$, and $Xe(s^2p_x^2p_y^2p_z^2)$ we find that the non-bonding parts are different from those of the phosphorus (and from all elements in Groups I–V of the periodic table) in that they have respectively one, two, and three pairs of doubly-occupied p orbitals. When these atoms "expand" their valence by adding ligands, *e.g.* as in forming SCl_4, BrF_3, and XeF_2 they add them colinearly and along the axis of one of these pairs of p electrons, with little distortion to the remainder of the previously existing molecule. It thus seems reasonable to infer that these two p electrons provide the binding to the two ligands in bond wave functions of the form

[22] *G. C. Pimentel*, J. chem. Physics *19*, 446 (1951).

[23] Thoughout this paper, bond lengths and angles are taken from Tables of Interatomic Distances and Configurations in Molecules and Ions and Supplement, Special Publications 11 and 18 of The Chemical Society (London) (1958, 1965); and *A. F. Wells*, Structural Inorganic Chemistry, 3rd Edit., Oxford (1962) unless otherwise indicated.

$$\psi_1 = \psi_d + \lambda\psi_a$$
$$\psi_2 = \psi_d + \lambda\psi_b$$

where a and b refer to the singly-occupied orbitals on each of the ligands and d refers to the donor atom p orbital, the signs being appropriately chosen. We call this type of bond, and its analog for divalent ligands, *hypervalent*, or HV, and it is distinguished from covalent (CV) bonds by using only one donor orbital to form two HV bonds, as in the theory of the polyhalide ions first proposed by *Pimentel* [22], and *Hach* and *Rundle* [13]. The same argument can be seen to explain the formation of the square pyramidal BrF_5, the square planar XeF_4, and the approximately octahedral [24] XeF_6, as well as the molecules obtained by replacing each pair of monovalent ligands by a divalent ligand, such as Cl_2SO where the ClSO angle is 106°, $HOIO_2$ where all the OIO angles are 98°, and XeO_3 where the angles are ~103° [25]. Thus we can explain all molecules containing atoms of Groups VI, VII, and VIII in their valences 4, 3, and 5, and 2, 4, and 6 respectively in a unified manner in terms of hypervalent bonds, the more detailed theory of which will be discussed in Section 3. Such molecules are referred to as "hypervalent molecules of the first class" (or HV_I) since they represent most but not all of the hypervalent molecules.

It is easy to observe that atoms cannot attain their highest valences – 5, 6, 7, and 8 for atoms in Groups V–VIII – by bonding to pairs of p electrons since in the lower valence states, *i.e.* 3, 4, 5, and 6, all the p electrons are already used for either CV or HV bonding, or equivalently, there are already bonds along each of the three perpendicular axes through the donor atom. This necessitates the use of the remaining pair of non-directional, *i.e.* spherically symmetric, s electrons in forming the last pair of single bonds or the last double bond – as, for example, in PF_5, SF_6, IF_7, and XeO_4. (The donor atoms are actually of the highest possible valence for the neutral atoms in each group only because experience shows that inner shell electrons apparently do not form chemical bonds in the non-metals. Such molecules can nevertheless be considered to be particularly stable because of the inability of the donor atoms to increase their valence still further.) Based on the highly symmetrical geometry of all the molecules in this classification – which we call "hypervalent molecules of the second kind" (or HV_{II}) – it seems reasonable to suppose that the last two bonds are not formed with the two s electrons as such, but that the molecular structure of minimum energy requires complete electronic and geometric reorganization. Thus, for example, PF_5 in which the donor atom s^2p^3 electrons are used for the bonding is a trigonal bipyramid, SO_3 and SF_6 which use s^2p^4 electrons are planar and octahedral respectively, IF_7 which uses s^2p^5 electrons has the highest possible symmetry of a pentagonal bipyramid that a 7-membered system, with of necessity three-dimensional structure, can have, and XeO_4 using s^2p^6 electrons is tetrahedral (further examples are given in Section 4). Notice that in this sense methane is like an HV molecule in that it requires use of its atomic s electrons and electronic reorganization, or hybridization, it possesses a structure of the highest possible symmetry, and does not easily undergo chemical reaction [26]; furthermore it has little in common with the accepted bonding scheme for the CV molecules of atoms in Groups V–VII discussed above. In the same sense SiF_6^{2-} is an HV_{II} type ion with an electronic structure similar to that of the molecule SF_6.

Hypervalent molecules and ions are thus of two kinds and consist of the class of molecules and ions formed from elements in Groups V–VIII in valences other than their lowest stable valence.

Hypervalent molecules of the first kind can be characterized as being formed from existing molecules by the addition of two colinear monovalent ligands or a single divalent ligand such that the structure of the original molecule is essentially preserved. The hypervalent bonds utilize for the most part the doubly-occupied p orbitals on the donor atom.

Hypervalent molecules of the second kind can be characterized as being formed from existing molecules by the addition of two monovalent ligands or a single divalent ligand to bring the donor atom to its highest possible valence, such that the resultant geometry is governed principally by steric factors, the electronic structure bearing no obvious relation to that of its predecessor.

It is important to recognize the fact that in hypervalent molecules there are two different types of bonds: HV bonds using doubly-occupied p orbitals and CV bonds using singly-occupied p orbitals, and also the pseudo-HV (colinear pair) and pseudo-CV analogs in HV_{II} molecules. This occurrence of two non-equivalent ligands has no parallel in all of classical octet-theory chemistry, since the usual tri-coordinated molecules are always trigonal or pyramidal and the usual tetra-coordinated molecules are always tetrahedral (although as noted above there is a question as to these molecules possessing strictly CV bonds).

Because of the different types of bonds it is useful to have a notation which distinguishes between the possible isomers: A prime is used to signify that a monovalent (or when necessary a divalent) ligand is HV, so that, for example, the four isomers of SF_2Cl_2 would be written as SF_2Cl_2', SCl_2F_2', $SFClF'Cl'$ (d and l). The appelations "equatorial" and "axial" for CV and HV bonds respectively that have been used previously, particularly for molecules with Group V donors, have explicitly not been used for two simple reasons: First, their use is based on the idea that all of these molecules are trigonal bipyramids [27], which although true for PF_5,

[24] It does not seem productive to place great emphasis on the apparent deviation from octahedral symmetry of this molecule at the present time. The simple description presented here is intended only to provide the zeroth-order description, there surely being mixing in of other orbitals, as discussed by *Gillespie*, steric effects, and the like. Thus, we have also not been concerned with the fact that bond angles almost always deviate from the idealized 90° and 180°, ICl_4^-, XeF_2, and XeF_4 being exceptional in that they do not so deviate.

[25] *P. H. Templeton, A. Zalkin, J. D. Forrester*, and *S. M. Williamson*, J. Amer. chem. Soc. *85*, 817 (1963).

[27] *E. L. Muetterties* and *R. A. Schunn*, Quart. Rev. (chem. Soc., London) *20*, 245 (1966).

etc., is difficult to accept for the others, and as no one has as yet observed "lone pairs" experimentally it does not seem reasonable to consider them in a steric sense as ligands[28]. Second, the geometrical non-equivalence of HV and CV bonds should not be confused with that of the equatorial and axial CH bonds in cyclohexane. The latter are non-equivalent only due to the geometry of their second neighbors while the former are non-equivalent due to essentially different electronic bonding.

The fact that hypervalent molecules have two different types of chemical bonds has two most interesting and important consequences for their chemistry (in addition to the trivial observation that they possess different quantities for physico-chemical measurement such as bond lengths, bond energies, acidities, reactivities, and chemical shifts, spin-spin splittings, and quadrupole coupling constants if the nuclei are magnetic): (1) there is the unique possibility of their undergoing (unimolecular) geometrical isomerism upon a single atom, with one type of bond converting to another, either by vibrations or rotations, as well as the less unusual intermolecular processes for exchanging of sites; and (2) as distinguished from traditional chemistry in which almost any combination of monovalent ligands can form the appropriate number of CV bonds to almost any donor atom, the limited experience with HV molecules shows that not all atoms can serve as donor atoms, nor can all monovalent functional groups serve as HV ligands in each given case. This allows for a larger number of interesting physico-chemical and synthetic studies than has hitherto been recognized.

Tables 1 to 4 contain examples of the numerous types of HV_I molecules, both with monovalent and divalent ligands, and of a small number of HV_{II} molecules. From these examples, and particularly from Table 1, which leaves blanks where no appropriate molecule has yet been found, it can be seen that HV molecules are more likely to exist the larger the donor atom and the lower the group in the periodic table, and the higher the electronegativity of the ligand. This statement is, of course, an oversimplification, but as has previously been observed it does provide a relatively reliable first approximation[6,9,10].

Included among the HV molecules in the Tables are all the "onium" salts even though it is well known that the solid-state structures of some of them, particularly the ammonium salts, are strictly ionic with tetrahedral coordination about the N atom. This has been done, however, for a number of reasons: (1) X-ray studies on the highest member of the series, $C_6H_5IC_6H_5'Cl'$ have shown it to have the same dimeric T-shaped geometry as ICl_3[29]; (2) the diphenylbromonium and chloronium iodides undergo some reactions which *Nesmeyanov*[30] has been able to explain only through "covalent" structures; (3) the molecule $(C_6H_5)_3P(OH)_2$ has been described by *Sidgwick*[31a] as being wholly covalent; (4) molecules such as $C_6H_5ICl_2$ and $C_6H_5I(CH_3COO)_2$ which are also

usually described as ionic have been shown to have bonds of the HV type; and (5) the structures of many of these compounds in the gas phase, or non-aqueous solution, is unknown. The solid state structure of $NH_4^+Cl^-$ should not be generalized since crystal forces can significantly change the structure, *e.g.* PCl_5 crystallizes as $PCl_4^+PCl_6^-$; PCl_5 and $(C_6H_5)_5P$ are now accepted as being non-ionic pentacoordinated molecules, why then should $(C_6H_5)_4PCl$ be singled out as a "phosphonium salt"? In fact, most of the HV molecules have been explained theoretically since the days of *Lewis* and *Langmuir* only on the basis of their being salts and it might be in part due to the theory and the "onium" nomenclature that the covalent or hypervalent nature of these molecules has not been previously given serious consideration. Thus, it seems likely that compounds with five-coordinated nitrogen can be prepared – *e.g.* a molecule analogous to compound *(9)* (cf. Section 7 and Ref. [5a]; the I atom is replaced by an N atom whose two "free" valences are occupied by phenyl groups).

3. Theory

From the types of existing HV molecules we can deduce empirically the qualitative condition governing the formation of hypervalent bonds to be simply that: there must be a particularly strong electronic affinity between the donor atom whose valence is to be increased and the monovalent or divalent ligand to be added. An electronic affinity, of course, must exist for the formation of ordinary covalent bonds, but must be significantly greater here in order to be able to decouple and delocalize the paired electrons in the donor atom of the already stable covalent molecule. The somewhat more quantitative statement of this is that (a) the first ionization potential of the donor atom must be relatively small (which is why Sb is most likely and He least likely to serve as donor atoms); and (b) the ligand must have a relatively high electronegativity (which is why F forms HV bonds to almost all atoms and CH_3 forms them only to Sb if the "onium salts" are excluded).

It is these qualitative ideas which are included in, and serve as, the justification for the simple theory developed in this section. There will, of course, be numerous additional factors, both steric and electronic in origin, which cannot be generalized and also cannot be rationalized by even the best of the theoretical schemes presently available. It would be these factors which might exclude the existence of HV molecules such as $AsCl_5$ and CH_3ICl_2, despite their "theoretical" likelihood, if such molecules truly cannot be prepared. Furthermore, since the formation of HV_{II} molecules involves the reorganization of the pseudo-CV bonds themselves, their nature will also have a significant effect on the stability of the resultant molecules and bond energies cannot be considered as additive.

It would be highly desirable if current methods of theoretical chemistry were able to provide us with accurate wave functions for molecules as complex as even the simplest HV molecules PF_5, SF_4, and ClF_3 [31b], and if they were able to provide us with interpretations of these wave functions in terms of the limited sets of valence functions on which we "base" our "understanding" of the structure of molecules. It is doubtful that theory will ever answer the second of these wishes to the precision which the semi-empiricist expects of it. Nevertheless, it remains useful to consider, in the simplest possible way, reasonable, although crude, electronic structures for HV molecules, so that one can feel somewhat confident about their existence and their mutual relationships; furthermore, in contrast to the complicated theories invoked to explain the structures of all the new electron-deficient boron compounds and other exotic molecules of modern chemistry, the simple theory of HV-bonding is in fact simple. Many researchers have attempted to make other such simple theories quantitative in order to approximate the results that would be obtained by the exact solutions; we are rather of the opinion – on the basis of experience with small molecules, for which we have much better wave functions, but still no "understanding" of *e.g.* the dipole moment of NH_3 or the bond angle in H_2O – that such approximations can at best be deceptive.

The simple theoretical description of bonding in hypervalent molecules and ions presented here is based on the procedure used by *Pimentel* [22] and *Rundle* [13], and extended by *Havinga* and *Wiebenga* [32], for bonding in the polyhalide ions, and later applied by *Pitzer* [10], *Rundle* [12], and *Jortner et al.* [33] to the xenon fluorides. As shown in the Tables 1 to 4, there are essentially four types of hypervalent compounds, and we indicate here the theory for only one molecule of each type, taking as examples the sulfur compounds, SF_4, F_2SO, SF_6, and SO_4^{2-}, the theory for almost any other HV molecule being described in an exactly analogous manner. Only the form of the wave function is indicated in each instance, since as observed above we feel that calculations "can only lead to a symbolic and not always convenient restatement of these [physical and electronic] properties when they are already known", to quote *Moffitt*'s remarks on valence-bond theory calculations out of their original context [34].

[34] See [8], p. 410.

SF_4 is formed from the donor atom $S(s^2p_x^2p_yp_z)$ and four fluorine atoms oriented with their holes, or singly-occupied p orbitals, located two along the x-axis and one each along the y- and z-axis (Fig. 1). In the simple description of the CV molecule SF_2 the p_y and p_z orbitals, from both the fluorine atoms and the sulfur atom, are paired to form bond orbitals (or bonding "MO's"),

$$\psi_1 = \psi_{S(y)} + \mu\psi_{F^1}$$

and

$$\psi_2 = \psi_{S(z)} + \mu\psi_{F^2}$$

each of which is doubly-occupied, and where the parameter μ which determines the polarity of the bond can be obtained variationally, the functions being orthogonalized to each other and to the core orbitals if so desired. There remain in the molecule SF_2 non-bonding electrons which are essentially those electrons that were already paired off in the atomic configurations, including the core electrons. Thus the $3p_x^2$ electrons on the sulfur atom are available for HV bonding to the fluorine atoms F^3 and F^4. These bonds are formed by taking linear combinations of the single p_x sulfur orbital and each of the two p_x fluorine orbitals to form what look like ordinary polar bonds (or bonding MO's)

$$\psi_3 = \psi_{S(x)} + \lambda\psi_{F^3}$$

and

$$\psi_4 = \psi_{S(x)} + \lambda\psi_{F^4}$$

each of which is doubly occupied and where the polarity parameter λ is to be determined variationally.

The reason that stable HV bonds occur only in pairs is trivially seen to be due to the fact that both the decoupled p_x electrons from the sulfur have to be used in some form of bonding. These orbitals, so formed, differ from the usual bonding orbitals only in that the same sulfur orbital, $\psi_{S(x)}$, is used in two different bonds, and consequently the two functions, ψ_3 and ψ_4, have larger overlaps than the CV bond functions ψ_1 and ψ_2. Thus when the bond orbitals are orthogonalized, there will be more ψ_{F^4} in the orthogonalized ψ'_3 than there will be ψ_{F^2} in ψ'_1.

When the simple orbitals ψ_3 and ψ_4 are combined with the third linearly independent orbital

$$\psi_0 = \psi_{F^3} + \psi_{F^4}$$

provided by the limited basis set of $\psi_{S(x)}$, ψ_{F^3}, and ψ_{F^4}, and the matrix of coefficients diagonalized, the so-called delocalized three-center bonding orbital and non-bonding orbital, analogous to the functions given in the previously mentioned works of *Rundle* [12], *Pimentel* [22], and *Jortner et al.* [33], which are to be doubly-occupied in the MO scheme, are obtained. These can then be made again into localized or equivalent orbitals which are of the form

$$\psi'_3 = \psi_{S(x)} + \alpha\psi_{F^3} - \beta\psi_{F^4}$$
$$\psi'_4 = \psi_{S(x)} + \alpha\psi_{F^4} - \beta\psi_{F^3}$$

where α and β are constants, and these functions are the "best" functions that a minimal basis set MO calculation can provide. *Coulson* [9] has given an explicit illustration of such equivalent orbitals for the p bonding in XeF_2 as

$$\psi'_1 = \psi_{Xe} + 1.71\ \psi_{F^1} - 0.29\ \psi_{F^2}$$
$$\psi'_2 = \psi_{Xe} + 1.71\ \psi_{F^2} - 0.29\ \psi_{F^1}$$

so that the degree of "delocalization" is not very high, but the bonds are quite polar.

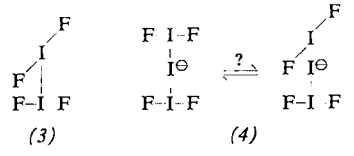
Notice the similarity of these functions to the equivalent orbitals *Coulson* obtained from an analogous calculation for methane many years ago [35], where the tetrahedral CH bond orbital was given by

$$\psi_1 = 2.56\ \psi_s + 2.94\ \psi_p + 3.31\ \psi_{H^1} - 0.69\ (\psi_{H^2} + \psi_{H^3} + \psi_{H^4})$$

in terms of 2s- and tetrahedrally directed 2p-orbitals of the carbon, the hydrogen 1s-orbital along the tetrahedral axis, and those along the three other tetrahedral axes. This illustrates the fact that just as for HV bonds, where the atomic orbitals involved in two bonds need not be orthogonal (they are one and the same) so, too, when there is any mixing of atomic orbitals or hybridization, the resultant atomic orbitals need not even be approximately orthogonal. The hybridization ratio of s to p functions in CH_4, for example, is seen to be 1:1.3 instead of 1:3 as is required by orthogonality. The same type of function will occur below when we treat HV_{II} molecules which is why we argue the similarity of CH_4 to SF_6, and have previously suggested the discarding of the accepted usage of orthogonalized hybrids as zeroth-order approximate wave functions [26].

Whether a stable SF_4 molecule can be formed according to this conception depends on the values of the parameters α and β – for example if α becomes very large ψ'_3 and ψ'_4 become essentially $2p_x$-orbitals on the fluorine atoms F^3 and F^4 – and these in turn depend on the molecular integrals. The molecular integrals themselves depend on the choice of exponents in the atomic orbitals, the estimate of the core potential, *etc.*, in the more exact method, or on the Hückel-type parameters in the SCF-Hückel procedures, all of which are related, but only qualitatively, to the electron affinity of F and the ionization potential of S. Thus the quantitative results that can be obtained by going through the calculation using different values of these parameters can give no information other than the qualitative requirements on the electron affinity and ionization potential that we had deduced empirically from the start.

There is probably very little qualitative difference between the simple bond orbital theory presented here and the Hartree-Fock theory (the "best" orbital theory) or the minimal basis set LCAO–MO theory (the most commonly used theory which includes all the electrons). These more accurate theories will differ from the simple theory as regards HV bonds mostly in that they will mix the $2p_x$ doubly-occupied orbitals of the CV bonded F atoms with the $3p_x$ doubly-occupied orbital of the S atom. There will thus be three doubly-



[35] *C. A. Coulson*, Trans. Faraday Soc. *38*, 433 (1942).

occupied x orbitals which could give HV bonding. However, these orbitals can be transformed so that they are essentially located one on each of the atoms S, F^1, and F^2, and since we know that the F atom does not have a low enough ionization potential to donate electrons to form HV bonds this clearly does not change our qualitative result at all. Had we instead started with the CV molecule SCl_2 and considered the addition of two fluorine atoms, we would have found, both by the bond orbital description and by the complete minimal basis set MO theory, that the two molecules *(1)* and *(2)* are likely to be formed, as well

(1) *(2)*

as SCl_2F_2', the analog of SF_4. It should be emphasized that on the basis of our present experience, such wild looking molecules as these, and the propellor shaped molecule *(3)* suggested previously [6] as well as its ionic analog *(4)*

(3) *(4)*

should be stable at least in the thermodynamic sense. Judging from the ease of making the usual interhalogen molecules and their kinetic stability, it should be quite possible to prepare such molecules in gas phase reactions (cf. Section 6). A particularly likely reaction to try would be

$$ICl + 2F_2 \rightarrow a\ I(F_2)Cl(F_2) + b\ I(F_4)Cl + c\ ICl(F_4).$$

The molecule F_2SO can be considered as related to SF_4 by having the two HV F atoms replaced by the single divalent oxygen atom which is bonded to the S atom using the orbitals sketched in Fig. 2. Thus, after

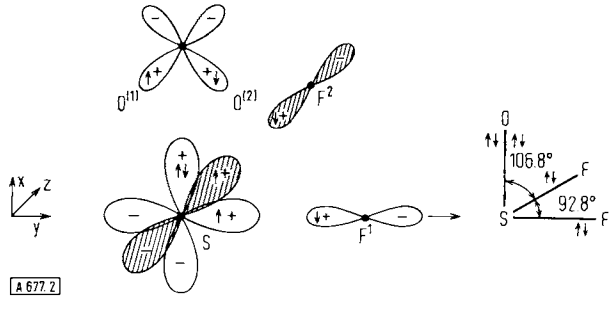


Fig. 2. The electronic and geometric structure of OSF_2.

the formation of SF_2, the two S–O bonds, *i.e.* the HV "double" bond, otherwise known as "dative", "co-ordinate-link", "dπ-dπ", *etc.*, can be described as

$$\psi'_3 = \psi_{S(x)} + \alpha\psi_O^{(1)} - \beta\psi_O^{(2)}$$
$$\psi'_4 = \psi_{S(x)} + \alpha\psi_O^{(2)} - \beta\psi_O^{(1)}$$

where

$$\psi_O^{(1)} = -2^{-1/2}(\psi_{O(x)} + \psi_{O(y)})$$
$$\psi_O^{(2)} = -2^{-1/2}(\psi_{O(x)} - \psi_{O(y)})$$

and the constants α and β as before are calculated variationally and depend on the assumptions made for the molecular integrals. The analog of "delocalized" MO theory wave functions, as in the literature for the xenon fluorides [12, 33], although not given explicitly above, has simply

$$\chi_1 = \psi_{S(x)} + \lambda\psi_{O(x)} \quad \text{(bonding, occupied)}$$
$$\chi_2 = \psi_{O(y)} \quad \text{(non-bonding, occupied)}$$
$$\chi_3 = \lambda\psi_{S(x)} - \psi_{O(x)} \quad \text{(anti-bonding, unoccupied)}$$

From this description, albeit oversimplified, the polar nature of the bond, and the necessity for the high electron affinity of the ligand are readily appreciated. In this sense, one can argue for the validity of the ionic structure $F_2S^+O^-$ which preserves the "octet" picture as emphasized by *Rundle* for the analogous case of XeF_2 [12]. We prefer not to give too much weight to this argument, since in addition to its being excessively model-dependent, it assumes arbitrarily that the bonding orbital χ_1 is non-polar, which it clearly is not.

The organic chemist may, however, continue to write the ylides as $R_2S^+C^-RR'$ with perfect equanimity. It is more cumbersome, however, to write SF_4 as $S^+F_2(F^{-1/2})_2$ and, not only more cumbersome, but more ambiguous to write SF_6 or PF_5 (or for that matter, CH_4) in the appropriate analogous manner. Incidentally, the similarity, among the various oxides of S, Se, I, *etc.*, which justifies empirically their receiving similar theoretical treatment, has been noted by a number of authors, among them *Sidgwick* [36], who has observed that "there is a marked resemblance between diphenyl selenoxide, $(C_6H_5)_2SeO$, and iodosobenzene, C_6H_5IO ... and a similar parallel may be instituted between diphenyl selenone, $(C_6H_5)_2SeO_2$, and iodoxybenzene, $C_6H_5IO_2$". Thus, it is of interest, for example, to search for ylides of I and Xe by analogy with S and Se.

While the HV_I molecules are simply described in terms of "molecules made out of molecules" without rearrangement or hybridization of electronic or geometric structure, such is clearly not the case for HV_{II} molecules. The hypervalent molecules of the second kind must involve a somewhat different description since, for example, there are not three doubly-occupied p orbitals in the ground configuration of $S(s^2p^4)$ to use in making the three pairs of colinear bonds in SF_6. Notice, however, that in the theory of HV_I molecules we dropped from the very beginning the traditional restriction that the atomic orbitals involved in bonding to different atoms be orthogonal, since actually we used a single orbital to form two bonds, and it was this restriction which had necessitated the introduction of d orbitals with their high "energy of promotion" in the traditional hybridization scheme [3]. With

[36] Cf. [31], p. 964.

the relaxation of this unnecessary and undesirable restriction, we can immediately describe the bond orbitals for SF_6. The ground hybridized "configuration", involving no energy of promotion, is $S(s^2p_x^{4/3}p_y^{4/3}p_z^{4/3})$ from which can be constructed six non-orthogonal sp^2 hybrids pointing towards the faces of an octahedron

$$\psi_{S(a)} = 3^{-1/2}(\psi_S + \sqrt{2}\,\psi_x)$$
$$\psi_{S(b)} = 3^{-1/2}(\psi_S - \sqrt{2}\,\psi_x), \textit{ etc.}$$

From these hybrid orbitals we construct the bond orbitals

$$\psi_a = \psi_{S(a)} + \lambda\psi_{F^1}$$
$$\psi_b = \psi_{S(b)} + \lambda\psi_{F^2}, \textit{ etc.}$$

where ψ_{F^1} and ψ_{F^2} are the p_x orbitals of the two fluorine atoms along the x axis. When the minimal basis-set six-electron problem is solved in the usual simple way and the solution is transformed into equivalent orbitals, the bonds will be described by wave functions of the form

$$\psi'_a = \psi_a + \alpha\psi_b + \ldots$$

or equivalently

$$\psi'_a = \psi_{S(a)} + \lambda'\psi_{F^1} + \alpha'\psi_{S(b)} + \alpha''\psi_{F^2} + \ldots$$

where the α's are relatively small. However, since there is no clear dividing line between pure CV bonds and pure HV bonds once some hybridization is introduced, we refer to these bonds in SF_6 as pseudo-HV just because they are colinear; for the same reason we refer to PF_5 as containing two pseudo-HV bonds and three pseudo-CV bonds.

There are, of course, other ways to describe the bonds in SF_6, just as there are other ways to describe the bonds in HV_I molecules, one such way being to use atomic geminals

$$\varphi_a(1,2) = 3^{-1/2}[\psi_S(1)\psi_S(2) + \sqrt{2}\,\psi_x(1)\psi_x(2)]$$

but there is no particular advantage to indicate these further at this time. It should be remembered that the exact wave function for SF_6 will be far different from any wave function we might describe here no matter how "rigorously" it has been obtained.

The HV description of a molecule such as SF_6, all of whose bonds are identical, is relatively unambiguous, whereas the HV description of, say PF_5, can utilize different amounts of s hybridization in the pseudo-CV and the pseudo-HV bonds, since these bonds can never be considered equivalent. Thus, for example, for PF_5, we can use the "configuration" $P(s^2p_x^2p_y^{1/2}p_z^{1/2})$ to form two pure HV bonds with the doubly-occupied p_x orbital, and three pseudo-CV bonds with the non-orthogonal s^2p hybrid orbitals

$$\psi_a = 3^{-1/2}(\sqrt{2}\,\psi_s + \psi_z)$$
$$\psi_{b,c} = 3^{-1/2}(\sqrt{2}\,\psi_s - \tfrac{1}{2}\psi_z \pm \frac{\sqrt{3}}{2}\psi_y)$$

or we can use the configuration $P(s^2p_xp_yp_z)$ to form pseudo-HV bonds with the usual and orthogonal sp hybrids

$$\psi_{d,e} = 2^{-1/2}(\psi_s \pm \psi_x)$$

and pseudo-CV bonds with the usual sp^2 hybrids

$$\psi'_a = 3^{-1/2}(\psi_s + \sqrt{2}\,\psi_z)$$
$$\psi'_{b,c} = 3^{-1/2}(\psi_s - \frac{\sqrt{2}}{2}\psi_z \pm \frac{\sqrt{6}}{2}\psi_y)$$

which are orthogonal among themselves but are not orthogonal to the sp hybrids, or we can use any intermediate configuration. Clearly the physical properties of molecules like PF_5 will differ from the properties of HV_I and other HV_{II} molecules as the details of the actual bonding schemes differ or are similar. The best that could be hoped for would be that the "axial" bonds of PF_5 are pure HV so that they could be compared with those of HV_I molecules, but there seems no way to evaluate the likelihood of this occurring at the present time. Incidentally, the fact that the PF bond length in PF_3 (1.53_5 Å) is exactly the same as the pseudo-CV bond length in PF_5 (1.534 Å)[17] argues for some but not too much electronic reorganization, as the CV bonds in CV and HV molecules, *e.g.* BrF(1.756 Å) and BrF_3(1.721 Å), generally differ by $\gtrsim 0.02$ Å. (In BrF_5 the CV bond length is 1.68 Å.)

The last example we describe here is the negative ion SO_4^{2-} made from the fully occupied M shell of $S^{2-}(s^2p_x^2p_y^2p_z^2)$ where the relative ionization potential which governs the formation of HV bonds is an average of the values for the electrons of S^{2-} in place of an average over the values for neutral S. The doubly-occupied orbitals can now be rewritten as orthogonal sp^3 hybrid orbitals (which we do not feel to be justifiable for the case of neutral carbon) and the simple bond orbital scheme will be exactly the same as that for F_2SO except that the orbital $\psi_{S(x)}$ will be replaced by the sp^3 hybrid orbitals, a, b, c, and d, and the $\psi_{O(x)}$ and $\psi_{O(y)}$ orbitals will be replaced by the four pairs of orbitals, $\psi_{O(a)}$, $\psi_{O(a\perp)}$, *etc.* Thus we can write, in terms of the "delocalized MO" or "ionic" description, as distinguished from the bond-orbital or equivalent orbital description,

$$\chi_1 = \psi_{S(a)} + \lambda\psi_{O(a)}$$
$$\chi_2 = \psi_{O(a\perp)}$$
$$\chi_3 = \psi_{S(b)} + \lambda\psi_{O(b)}, \textit{ etc.}$$

In this example, however, the orthogonalized equivalent orbitals will mix the "non-bonding" (χ_2, χ_4, *etc.*) into the bonding functions (χ_1, χ_3, *etc.*) so that they will not be of the simple form as for F_2SO. Furthermore, one has to choose a different axis at each oxygen atom so that the results are not affected by the arbitrary choice of the perpendicular singly-occupied orbitals. However, there is nothing new in principle and the procedure for obtaining these wave functions is straightforward.

It would be interesting to speculate as to why so many molecules and ions made from atoms in their highest valence states have such unusual kinetic stability. The present theory does not afford any significant clue as to why this should be so, other than the relatively obvious one that these molecules are unable to form even quasistable intermediates through an additive step, all the possibilities for bonding already being utilized.

4. Geometry of Some Ions

The ideas discussed in Section 3 can be applied directly to numerous specific problems in structural inorganic chemistry and we only present here the description of a few inorganic ions in order to illustrate how the theory applies in specific examples. It is assumed that these are actually ionic, being in either the solid state or in an ionizing solvent, so that they are truly represented as possessing unit quantities of electronic charge. Furthermore, the extra charge is assumed to be localized on the donor atoms for the purpose of determining the atomic configuration – an assumption which is then immediately removed by the allowance for arbitrary polarity of the bonds through the parameter λ in the bond orbitals.

Consider first the two octahedral ions PCl_6^- and $SeBr_6^{2-}$. The atomic configuration of the phosphorus atom is s^2p^4 so that all the bonding is with rearranged s-p orbitals and the ion is of the HV_{II} type, analogous to SCl_6 with which it is isoelectronic. The atomic configuration of the selenium atom is, however, s^2p^6 so that all the bonding is with p orbitals, and the ion is of the HV_I type with the s electrons inert, being isoelectronic to $KrBr_6$.

Now consider the very stable tetrahedral ions SO_4^{2-} and IO_4^- in both of which the donor atomic configurations are s^2p^6. These ions are both of HV_{II} type and possess four sp^3 HV double bonds. The donor atoms, being bound with an octet of bonds using 16 electrons, have reached the maximum valence possible under usual chemical conditions; the ions are isoelectronic respectively with ArO_4 (and ClO_4^-) and XeO_4 (and TeO_4^{2-}). The differences therefore between PCl_6^-, $SeBr_6^{2-}$ and, say IO_4^-, are that PCl_6^- and IO_4^- are both HV_{II} while $SeBr_6^{2-}$ is HV_I, but the phosphorus of PCl_6^- could in principle increase its valence to form PCl_6^{3-} as in the known PO_4^{3-}, whereas IO_4^- is of maximum possible valence. This explains in a different way from the octet theory, but in agreement with its results, why ions such as IO_5^{3-} are not formed; the atomic configuration $5s^25p^66s^2$ involves too great a difference in energies among the atomic orbitals for them to be utilized together. From the stability of these s^2p^6 ions it would seem that octacoordinated molecules with monovalent ligands are not formed more often due to the steric difficulties involved in getting eight atoms to approach sufficiently closely to provide stable bonds.

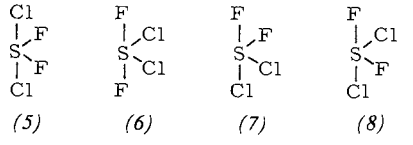
Since we have considered the tetrahedral ions SO_4^{2-}, IO_4^-, and PO_4^{3-} it is of interest to point out that the remaining oxy-ions and simple oxides also have similar geometries due to the same considerations. Thus SeO_3^{2-}, XO_3^- (with X = Cl, Br, and I), and presumably SO_3^{2-} are all distorted right pyramids, with bond angles of $\sim 100°$ since they utilize only the p electrons in s^2p^6 configurations; NO_3^- and the molecule SO_3 are both planar as they involve reorganization of the atomic configuration s^2p^4 to use all the electrons, and thus have a symmetrical structure; ClO_2^- is approximately L shaped (bond angle of 110 °), four chlorine p electrons taking part in the bonding. The less-approximately L shaped molecules SO_2 and O_3, with bond angles of 120 °, would presumably have non-equivalent oxygens if the bonding followed the typical HV pattern using the p_x and p_y electrons to form a double CV bond, and the p^2 electrons to form the HV double bond. However, as opposed to other HV molecules, the "ionic" orbital on the HV-bonded oxygen could mix with the ordinary π bond on the other two atoms, and this must lead to rearrangement of the electron configuration to agree with the symmetrical molecular structure observed experimentally. Notice, incidentally, that despite the trivial planarity of these molecules the use of the s^2 for bonding instead of the p^2 electrons is ruled out by analogy with SF_4 and F_2SO, both of which would be planar if the bonding did not use the $p_x^2p_yp_z$ electrons. This is an explicit demonstration of what has been presupposed throughout the paper: that p bonds are more easily formed than s bonds, as is expected from the relative energies of the various atomic configurations. Notice that CO_2 is linear since it involves the s electrons in s^2p^2, and so is analogous to SO_3; notice also that the geometry of the sulfuryl halides *e.g.* F_2SO_2 is such that by replacing the two halogens with an oxygen along the bisector of the XOX angle it gives exactly the planar molecule SO_3.

The "unusual" ions SbF_5^{2-} [23] and the recently discovered XeF_5^+ [37a] are isoelectronic with IF_5 and therefore it is no great surprise that they have approximately square pyramidal structures, as does IF_5; such a structure is accounted for by considering each of the species to be built from the atomic configuration s^2p^5 with the s electrons not greatly involved in the bonding. As with all HV_I molecules the ligands are somewhat bent towards each other, even in the gas phase in which there are no crystal interactions to add to the distortions. We feel that the significance attributed to these relatively small distortions and the common reference to these molecules as "distorted octahedra", with the "lone pair" electrons assigned a physical site as if they were actually observed, to be quite unwarranted. Due to the crude nature of even the best theoretical calculations presently available on these molecules no argument can be given with sufficient accuracy to show

[37] a) *N. Bartlett, F. Einstein, D. F. Stewart,* and *J. Trotter,* J. chem. Soc. (London) *A 1967,* 1190; b) *J. L. Huston,* J. physic. Chem. *71,* 3339 (1967); *H. H. Claasen, E. L. Gasner, H. Kim,* and *J. L. Huston,* J. chem. Physics *49,* 253 (1968).

that the s electrons are anything other than "essentially" inert [24,28,31b].

Let us now examine an instance of positive and negative ions of the same chemical composition, ICl_2^- and ICl_2^+. The first of these is linear, like I^-, and has the configuration s^2p^6; it is therefore an HV_I linear ion, which is most likely formed from ICl_3 by breaking the CV bound chlorine atom off as Cl^+. Notice that since this happens quite easily the HV bonds are less ionizable, *i.e.* less reactive, under certain conditions, than is the CV bond. In the cation on the other hand the iodine has the configuration s^2p^4, as in Te, so that ICl_2^+ is expected to be an L shaped CV ion – as is actually observed. For ICl_2^+ to have been linear would have required the HV bonds to exist on an atom where covalent valences were not already "saturated", which is contrary to all previous experiences. As a final example we consider $F_2IO_2^-$ which has FIF and OIO bond angles of 180° and 100° respectively just as would be expected for an HV_I ion with an atomic configuration s^2p^6, and is isoelectronic with the as yet unknown F_2XeO_2 [37b]. When the two fluorines in this ion are replaced by single divalent oxygen, the position of the latter deviates only 9° from the axis along which the two fluorines lay, with the angle between the remaining oxygens being distorted only 1° (within experimental error); the new ion IO_3^- is a symmetrical approximate right pyramid with bond angles of 99°, and of the same geometry as the molecule XeO_3 (OXeO angle of 100°) [25]. When a proton is added to make the molecule $HOIO_2$ the angles remain roughly the same and approximately equal (98 ± 3°), again as we would expect.



In concluding this section we would like to emphasize that it is not at all the iso-electronic nature of some of these ions with each other and with stable molecules that makes them take on analogous geometries and be stable. It is rather the fact that when the extra electron or hole can be considered as located on the donor atom, the addition of an electron during anion formation leads to the breaking of one CV bond (or to the formation of an HV double bond from a single CV bond) and at the same time to the stabilization of the HV bonds because the new ionization potential is lower; the removal of an electron to form the cations allows one CV bond to form where there had previously been two HV bonds, and this compensates sufficiently to let the rare example of Xe^+ in XeF_5^+ be able to donate electrons to the HV bonds. Thus, we do not subscribe to the analogy between HF_2^- and HeF_2, since the exceptionally low ionization potential of H^- (≈0.7 eV), which (crudely speaking) permits the formation of HF_2^-, becomes replaced by the drastically higher I.P. of He (24 eV). If helium could actually donate its electrons to form the proposed HeF_2 [38], which one cannot rule out despite all theoretical attempts to do so, then probably almost all combinations of atoms such as HeH_2 will also make HV molecules.

5. Geometrical Isomers

Among the most interesting consequences of the occurrence of two types of bonds in hypervalent molecules should be the existence of geometrical isomers which may possess different energies and be able to convert one to the other. However, until the present time, there has not been detected more than one isomer for any hypervalent molecule, although intramolecular inversion has been observed by NMR in the phosphorus pentahalides. The explanation for this is simple. Since the geometrical isomers involve different types of chemical bonds, as distinguished from isomers created in usual organic preparations which differ only in neighbor interactions, they will certainly differ in energy by several kcal/mole. Under equilibrium conditions only the energetically most favored isomer will be obtained.

The argument is best appreciated by considering a specific example, such as the (hypothetical) group of molecules of chemical structure SF_2Cl_2 of which there are four isomers, two of which being mirror images of each other.

(5) *(6)* *(7)* *(8)*

If we could assume that the bond energies of these molecules were additive, and if we had an estimate either from theory or experiment of these bond energies, we should be able to predict the ordering of the energy levels, and thus the most energetically favorable isomer without having to perform a complete calculation for all four. Unfortunately the crude theory described above or any tractable modification of it are not sufficiently accurate to give theoretical bond energies, and the appropriate experiments have never been performed, so that all we can do here is indicate the type of argument involved and under what conditions each of the isomers is likely to be favored.

The only information we have available is that HV bonds between two atoms are likely to be of lower energy than the corresponding CV bonds, as can be deduced either from the theory described above, or from the limited experimental data. Thus, the XeF bonds being 30 kcal/mole, have an energy less than all other halogen–F bonds, and the energy involved in bonding the two pseudo-HV chlorines in PCl_5 is ≈40 kcal/mole (if electronic rearrangements are neglected) while the CV bond energies of PCl_3 are 79 kcal/mole. However, this information alone can make no prediction as to the more energetically favorable isomer, but can only show that as long as the energies are strictly additive the d,l pairs of isomers can never be of lower energy than the two symmetrical isomers. Thus unless all the isomers have just about the same energy, isomers *(7)* and *(8)* will never be observed in equilibrium mixtures.

The energies of isomers *(5)* and *(6)* can be given in terms of the bond energies as

$$\varepsilon_{(5)} = 2\,\varepsilon_{CV}(S-F) + 2\,\varepsilon_{HV}(S-Cl)$$

and

$$\varepsilon_{(6)} = 2\,\varepsilon_{HV}(S-F) + 2\,\varepsilon_{CV}(S-Cl)$$

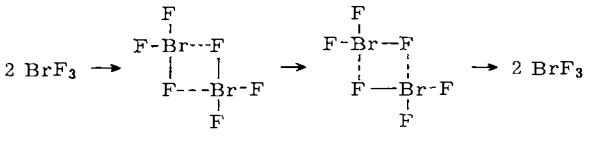
If we take $\varepsilon_{CV}(S-F)$ and $\varepsilon_{CV}(S-Cl)$ to be -110 kcal/mole and -80 kcal/mole respectively, *i.e.* close to the values determined for PF and PCl bonds in CV molecules, then the relative energies depend only on the way the ε_{HV}'s are related to the ε_{CV}'s. It is here that theory could really help if it were in the position to do so. If the values are related by a constant fraction, say $^1/_2$, then $\varepsilon_1 < \varepsilon_2$ and the $\Delta\varepsilon$ which determines the thermodynamic populations is 30 kcal/mole, *i.e.* the ratio of *(5)* to *(6)* is e^{50} at room temperature. If their difference is constant, *i.e.* if, say $\varepsilon_{CV} - \varepsilon_{HV} = 40$ kcal/mole, which is not so unreasonable as it sounds since this would exclude HV bonds between atoms whose CV bond strength is < 40 kcal/mole (*e.g.* F_2), then $\varepsilon_{(5)} = \varepsilon_{(6)}$ and the populations of the four isomers would be equal. The third possibility, of $\varepsilon_{(5)} < \varepsilon_{(6)}$, is obtained if say $\varepsilon_{HV}(S-Cl) = 0.5\ \varepsilon_{CV}(S-Cl)$ while $\varepsilon_{HV}(S-F) > 0.64\ \varepsilon_{CV}(S-F)$, and if the latter ratio is 0.77 then $\varepsilon_{HV}(S-F) = -85$ kcal/mole and the ratio of *(5)* to *(6)* at room temperature is e^{-50}. Thus, small changes in the relative energies of the different bonds cause large changes in the populations as argued above.

It is a very interesting and, for the most part, uninvestigated question, as to which of these population ratios will occur in a given case. Since in most of the HV molecules the more electronegative substituent will have a larger ε_{CV}, the question can be formulated as whether the more or the less electronegative substituent will be in an HV bond in the energetically favored isomer. The experimental observation, based on the data given in Tables 1–4, that only electronegative substituents form HV bonds is not pertinent to this question since it implies that non-electronegative substituents have positive ε_{HV}'s and consequently that no such isomer would even form.

The majority of the experimental evidence we have that does bear on this problem is from HV_{II} mixed pentavalent phosphorus molecules, which shows that an isomer with a pseudo-HV fluorine and a pseudo-CV chlorine is energetically favorable, but that an isomer with a pseudo-HV CF_3 group and a pseudo-CV fluorine is energetically favorable [14–17]. The latter is argued to be due to steric interactions since CF_3 is less electronegative than F; on the other hand the CH_3 group is not "sterically hindered" when it is pseudo-CV in CH_3PF_4 and $(CH_3)_2PF_3$. The other experimental data on molecules is from the halides $(C_6H_5)_2SeX'_2$ and $(C_6H_5)_2TeX'_2$ which are observed to have HV halogens and not be of the structure $X_2Se(C_6H_5)'_2$ [18,31]. It might, however, be possible that these molecules have not been able to equilibrate – NMR studies have not, as yet, been performed on them – and the synthetic procedure might have permitted the formation of only the observed isomers.

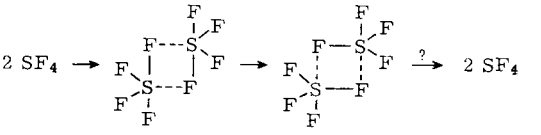
Although this discussion has not given any detailed understanding of the energetics of HV molecules – it has not even distinguished between HV_I and HV_{II} molecules – it does nevertheless show that if equilibration among isomers is permitted, information on the stability of an isomer cannot be inferred from its absence among the reaction products. The only chance for obtaining this information is to find synthetic procedures by which to prepare the energetically unfavorable isomers directly and then observe them spectroscopically or otherwise before equilibration has time to take place. We now discuss some of the possible intramolecular and intermolecular mechanisms for such equilibration and in Section 6 we consider some possible synthetic pathways that might enable the preparation of these energetically unfavorable isomers.

The possibility of conformational inversion or intramolecular isomerization such as the exchange of one CV ligand for an HV ligand, *e.g.* in the conversion of the SF_2Cl_2 molecule *(5)* into isomers *(7)* or *(8)*, is a phenomenon unique to hypervalent molecules. It is unique since it involves a considerable change in the electronic distribution of two of the ligands, electrons which were involved in an ordinary CV bond having to distort in such a way as to partially couple with the electrons in the HV bond to which it is to become colinear, and *vice versa*, not to speak of the large amounts of energy which must be involved in such a process. The conformational inversions one is accustomed to in ethane and cyclohexane derivatives, and the racemization of optically active hydrocarbons involve no such drastic changes in electron structure and the relevant energy differences and barriers are only in the vicinity of 1 kcal/mole and 3–12 kcal/mole respectively, since it is just the next neighbor interactions that are changing, the bonds themselves retaining their usual character.



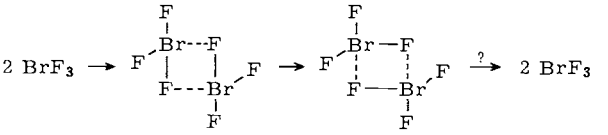
As to whether hypervalent molecules such as BrF_3, SF_4, and PF_5, can unimolecularly isomerize has not been considered theoretically outside of a classic paper by *Berry* [39], which, however, took no cognizance of the different types of bonds, so that at present we have no precise idea of what must be involved in this type of process. Our intuitive feeling is that the "barrier", if it really can be called that, would be inordinately high, so that if such molecules were infinitely dilute in inert gases at room temperature they would retain their configuration indefinitely. We should observe, however, as mentioned above, that the pseudo-CV bonds in PF_5 are quite different from the CV bonds in other molecules, and the "bond energies" might not be very different from the HV bond energies. In this case the intramolecular inversion would be less unfavorable than for other HV molecules ... to which can be added *Berry*'s arguments on the easier approach of pentavalent molecules to an inverted configuration *via* vibrations and rotations. The analysis of the

[39] *R. S. Berry*, J. chem. Physics *32*, 933 (1960).



various "mechanisms" by which pairs of HV bonds can be uncoupled electronically to become CV bonds still remains the critical problem that has yet to be investigated.

The experimental side of this problem has also not received much attention and the experiments that have been performed using NMR spectroscopy to study the lifetimes of ligands in HV and CV sites have not been designed to distinguish between unimolecular inversion and site-exchange; these experiments can certainly be extended to give more significant results. (It should be recalled that in ethane and cyclohexane derivatives the unimolecular inversion is measured NMR spectroscopically since the rate for site-exchange from carbon bonds is relatively negligible.) Measurements on PF_5 and its derivatives have shown unimolecular inversion to take place since only then is the P–F spin-spin splitting retained when the F(HV)–F(CV) splitting disappears; the occurrence of a dimeric intermediate cannot be fully ruled out [40]. Recent studies on PF_3H_2 and PF_4H [16b], however, have shown site-exchange to take place, whilst in the case of PF_5 itself "unimolecular inversion" has never been slowed sufficiently to enable the NMR observation of the different ligands. The few experiments which have been carried out on BrF_3 and SF_4 have shown a dramatic concentration dependence, which has never been extrapolated to infinite dilution, but clearly indicates the presence of a dimeric process in the inversion [14b]. Site-exchange in SF_4 has also been inferred from the absence of ^{33}S spin-spin satellites [21c]; however, only high temperature experiments on highly dilute solutes, for which site-exchange can be ruled out, will give information on the minimum energy „barrier" for unimolecular inversion. It appears that appropriate studies are currently being undertaken in the laboratories of *Muetterties* and *Holmes* and perhaps within the next few years we will have a better understanding of some of these problems.



Since we have argued that true unimolecular inversion is not likely, it must, if NMR equivalence is established experimentally, be due to a chemical reaction which alone is sufficient to change electronic structures of chemical bonds. The most probable reaction – as postulated by *Muetterties et al.* [14] for BrF_3 and SF_4 – is one which involves the formation of dimeric intermediates. This is easily envisaged for the interhalogens as

since such dimeric structures have been observed in ICl_3 and $(C_6H_5)I(C_6H_5)'Cl'$ in the solid state [29] and there is also evidence for the dimeric behavior of these compounds in non-aqueous solution [41]. A similar mechanism has been proposed for the reaction in which two iodosobenzene molecules react to give iodoxybenzene and iodobenzene [42]. The same mechanism could also provide for the exchange of sites in SF_4, but would require the readjustment of not only bond lengths from the intermediate state, but bond angles as well, *i.e.*

since the intermediate state leaves the molecules as trigonal pyramids. This mechanism is analogous to the following scheme for site exchange in BrF_3

which differs from the previously suggested scheme by a 90° rotation of the BrF_3 molecules about the axis of the HV bonds. Such mechanisms are, of course, oversimplifications, but we agree with *Muetterties* [21c] that they are more likely explanations than the others which have been proposed. As to PF_5, any dimeric postulates (on the basis of site-exchanges or of intramolecular inversion) must at present be considered mere speculation, although one can make some arguments for site-exchange in the hydrofluorophosphoranes.

One further possibility for intramolecular inversion and site-exchange is afforded by ionization – a mechanism which usually takes place mostly in aqueous solution. Thus a study of the behavior of ligands in substituted diphenyliodonium chlorides cannot be performed in aqueous solution because the carbon-iodine bonds in the $(C_6H_5)_2I^+$ ion are equivalent and have CV character (see Section 4).

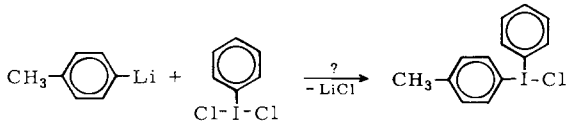
6. Synthetic Procedures

Since equilibration among the isomers of hypervalent molecules will result in only a single isomer being observable, it becomes important to look for stereospecific syntheses for each of the possible isomers so that they can at least be observed spectroscopically before they equilibrate, or even be prevented from equilibrating by freezing them onto rare gas matrices. The fact that there are two different types of bonds in an HV_I molecule only one of which occurs in the corresponding CV sub-molecule leads us to suspect the possibility that the reaction can be made to go with the retention of the original bonding structure. This

[40] A most recent and preliminary experiment reported by *S. Brownstein* [Canad. J. Chem. *45*, 1711 (1967)] argues for the likelihood of an intermolecular mechanism for the observed intramolecular site-exchange of fluorines in PF_5, and justifies this statement.

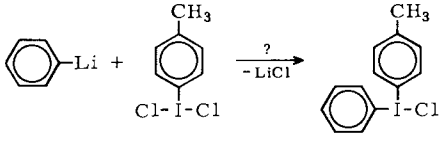
[41] *F. M. Beringer* and *M. Mausner*, J. Amer. chem. Soc. *80*, 4534, (1958).

[42] *I. Masson, E. Race*, and *F. E. Pounder*, J. chem. Soc. (London) *1935*, 1669.



would be ideal since then we could prepare, for example, the four isomers of SF_2Cl_2 by the following procedures, assuming the existence of the (hypothetical) reactants:

$SF_2 + Cl_2 \rightarrow SF_2Cl'_2$



$SCl_2 + F_2 \rightarrow SCl_2F'_2$

$SFCl + ClF \rightarrow SFClF'Cl'$ (d and l)

The idea of preservation of bond-type is perhaps difficult to accept for the experimentalist who is accustomed to the configurational inversions that ordinarily occur in organic chemistry, and in any case, it is only presented here as a working hypothesis for further study. However, the reasonableness of such a postulate can be better appreciated by considering the following possible synthesis of two isomeric iodonium salts. In the reaction of *p*-tolyllithium with iodobenzene dichloride as

and of phenyllithium with *p*-iodotoluene dichloride as

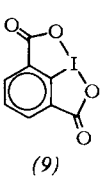
it seems most likely that under certain conditions the reaction products will be the two different isomers as shown, since the phenyl groups will attack at the site of the chlorine. This type of retention of configuration will, of course, be possible only if the reaction is weak enough so as not to cause intramolecular inversion, and if the solution is dilute enough so that intermolecular inversion *via* dimerization or other mechanisms can be excluded.

The problem of obtaining different synthetic mechanisms for the preparation of HV_{II} molecules, such as PCl_xF_{5-x} is more difficult since the obvious guess of retention of configuration here involves a CV bond being retained as a pseudo-CV bond in a flattened pyramid. Nevertheless, there should be some distribution of the initial CV bonds among the final pseudo-CV bonds, through which it should be possible to make preferentially the various products using the appropriate PCl_xF_{3-x} molecules along with ClF, F_2, or Cl_2 as starting materials.

There have been as yet few experiments which can shed light on these reactions. Among these are kinetic studies on the two gas phase reactions [15a]

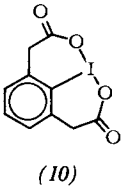
$BrF_3 + F_2 \rightarrow BrF_5$

and [43]



$IF_5 + F_2 \rightarrow IF_7$

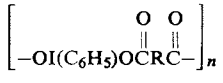
[43] *J. Fischer* and *R. K. Steunenberg*, J. Amer. chem. Soc. *79*, 1876 (1957).



which show the formation of the HV molecules BrF_5 and IF_7 to involve a single bimolecular collision which is a prerequisite for the types of syntheses suggested here. We have, however, no idea of the amount of retention of configuration, and also how general this kinetic mechanism actually is. There was also an earlier study on the addition of Cl_2 to PCl_3 as well as on the exchange of Cl_2 with PCl_5 and on the reduction of PCl_5 with Hg [44]. While the results of the experiments on the addition of Cl_2 were "not clear-cut" they definitely favored some form of addition at the pseudo-CV site. It would be interesting to perform a similar study on a molecule such as $P(CH_3)_3Cl_2$ for which intramolecular inversion could more definitely be excluded.

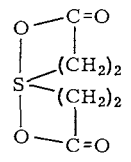
7. New Molecules

One of the interesting implications of the present study is the likely existence of large classes of HV molecules of the mixed "non-metallo-organic" kind, rarely if ever considered previously in the literature. While it is generally not considered proper to propose the existence of unusual molecules in advance of their preparation, we chose to do so here in order to illustrate the unusual possibilities for hypervalent molecules. This can be perhaps justified to a certain extent by the fact that some molecules and polymers of trivalent iodine discussed in an earlier version of the present article have since been synthesized and fully characterized [5]. We restrict our discussion to the analogs of molecules *(9)* and *(10)*

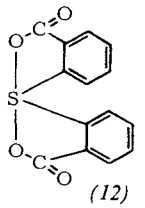


(9)

(10)

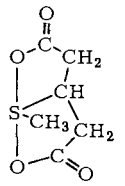


synthesized by *Agosta* [5a]; there are, however, clearly many other possible classes of HV molecules using different polyvalent HV ligands. A number of polymers analogous to the recently synthesized iodine-containing polymers of the form [5b]

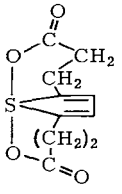


have been described elsewhere.

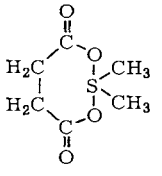
[44] *J. J. Downs* and *R. E. Johnson*, J. chem. Physics *22*, 143 (1954); J. Amer. chem. Soc. *77*, 2098 (1955). In discussing their results, these authors noted that "Consequently theoretical considerations of bond hybridization are conjectural and unsatisfactory". For other discussions on this point see pp. 1065-6 of Ref. [20a] and also *R. D. Burbank* and *F. N. Bensey*, J. chem. Physics *21*, 602 (1953), especially p. 608. Also, in view of the tendency of many workers to use NMR parameters to distinguish between "ionic" and "covalent" bonding in hypervalent molecules the author's comments on the difficulties inherent in such interpretations should be noted [*J. I. Musher*, Adv. in Magnetic Resonance *2*, 177 (1966)].



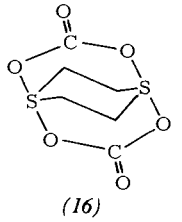
Without overqualifying our predictions, other than to observe that they are not so fanciful as they might seem, we suggest that it might be possible to synthesize molecules *(11)–(16)*.



(11)



(12)



(13)

(14)

(15)

(16)

These molecules are all related to the as yet unknown 2-thia(IV)-isopropylidene diacetate, $(CH_3)_2S(OAc)_2$, just as *(9)* and *(10)* are related to the known phenyliodonium diacetate $C_6H_5I(OAc)_2$. The fact that *(9)* and *(10)* are so unusually stable to decomposition by boiling water, as compared with the relative instability of $C_6H_5I(OAc)_2$, would argue for the likelihood of stable molecules *(11)–(16)* even though the corresponding diacetate might be sufficiently reactive as to be not isolable. From Tables 1 and 2 it seems likely that sulfur will form HV bonds to OC(O) groups, and if for some reason this does not actually occur, it will surely occur for S replaced by Se or Te. It should be noted that *(11)–(14)* will be optically active and there seems to be little likelihood of unimolecular racemization (cf. Section 5); molecule *(14)* is fixed with a bridge so as to prevent racemization[45].

[45] *K. Mislow*, private communication.

8. Conclusion

An attempt has been made to place the molecules and ions formed from atoms using their higher valences in a unified scheme through a detailed but simple theoretical description of hypervalent bonds. From the discussion it is evident that such a description is eminently reasonable and that there are numerous implications for the chemistry of these hypervalent molecules but that the experimental information necessary for a proper understanding of their physicochemical behavior is lacking. It is hoped that the present study[46], which does not intend to provide the final answers to such questions as mechanisms of inversion, synthetic paths, and the existence of unusual new molecules, will at least stimulate further consideration of this very interesting, but until now highly neglected, field of chemistry.

I am deeply indebted to numerous colleagues for their patience in discussing these ideas over the past several years. I am particularly indebted to E. J. Corey, P. Laszlo, R. Mechoulam, and my father, S. Musher, without whom these ideas might never have crystallized. I would also like to thank W. C. Agosta and H. K. Livingston who successfully synthesized the first HV molecules to be inspired by the present study in the course of their varied research programs. The manuscript was drafted while I was a guest at the Weizmann Institute of Science, Rehovot, Israel, in the summer of 1964, and the final version was completed at the same Institute this past summer. I am grateful for the kind hospitality shown me there by S. Lifson, D. Samuel, and their colleagues.

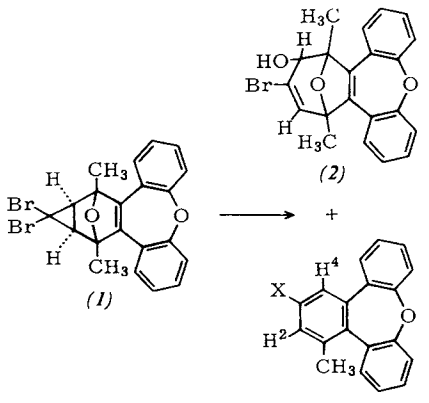
COMMUNICATIONS

An Optically Active Tribenzoxepin[**]



By *W. Tochtermann* and *C. Franke*[*]

Optically active 1-methyltribenzoxepin-3-carboxylic acid *(3b)* has been prepared as a model substance for a study of the intramolecular mobility of boat-shaped seven-membered rings[1] since the energy barriers for conformational inversion are often relatively low in oxygen heterocycles[2].

The dibromocyclopropane derivative *(1)* was obtained from 1,4-epoxy-1,4-dihydro-1,4-dimethyltribenzoxepin[3], bromoform, and potassium *tert*-butoxide in benzene at 25 °C, the yield being 31% after chromatographic separation from unchanged starting material on Al_2O_3 with CCl_4 and $CHCl_3$; it had m.p. 184–186 °C (from cyclohexane) and a ^{1}H-NMR spectrum (in $CDCl_3$)[4] τ = 2.5–2.9 (8H, M), τ = 7.53 (2H, S), τ = 8.05 (6H, S). When heated for 48 h at 100 °C with silver sulfate (molar ratio 1:1.4) in 2 N H_2SO_4/dioxane (1:2 v/v) it afforded directly[5] 3-bromo-1-methyltribenzoxepin *(3a)* [33% yield; m.p. 114–116 °C (from cyclohexane); ^{1}H-NMR spectrum (in $CDCl_3$), τ = 2.3–3.0 (10H, M), τ = 7.57 (3H, S)] as well as the cyclopropyl-allyl rearrangement product *(2)* (44% yield; m.p. 211–212 °C). The product *(2)* was isolated by recrystallization of the crude product from CCl_4; chromatography of the mother liquors therefrom on Al_2O_3 with CCl_4 gave pure *(3a)*. Polyphosphoric acid converts the alcohol *(2)* into *(3a)* in 30% yield in 2.5 h at 130 °C.

The same process can be used for preparation of 3-bromo-1-methyl-9*H*-tribenzo[*a,c,e*]cyclohepten-9-one [*(3a)*, C=O in place of O], which can be reduced to the known 1-methyl-9*H*-tribenzo[*a,c,e*]cyclohepten-9-ol by $LiAlH_4$[6].

The action of *n*-butyllithium in light petroleum on *(3a)* at −50 °C in tetrahydrofuran and subsequent carboxylation affords the carboxylic acid *(3b)* [80% yield; m.p. 220–222 °C (from benzene)], whose structure is proved by elemental analysis and IR and ^{1}H-NMR spectra [$CDCl_3$: carboxyl proton at τ = 0.2; AB system at τ = 1.80 and 1.92 with J_{AB} = 1.8 Hz (H^4, H^2), τ = 2.2–3.0 (8H, M), τ = 7.48 (3H, S)].

(1) *(2)* *(3a)*, X = Br *(3b)*, X = COOH

Keeping equimolar amounts of *(3b)* and brucine in ethanol/methanol (1 : 1–1 : 2 v/v) for some time gives a 60% yield[7] of a crystalline brucine salt that shows rapid mutarotation in acetone at 20.5 °C ($t_{1/2}$ = 200 sec; extrapolation of the specific rotation to t_0 gives $[\alpha]_{436}^{20.5} = +87°$, changing to −43 °, c = 0.013 g/ml). The dextrorotatory acid can be obtained by dissolving this salt as fast as possible in acetone at −20 °C and precipitating it rapidly with 2N HCl. Solutions of (+)–*(3b)* in acetone racemize at +20.5 °C with a half-life period of 195 sec; $[\alpha]_{436}^{20.5}$ was +135 ° after 105 sec (extrapolated to t_0: $[\alpha]_{436}^{20.5} = +190°$, c = 0.02 g/ml). Thence the free enthalpy of activation for ring inversion of *(3b)* is calculated to be $\Delta G_{20.5}^{\neq}$ = 20.8 kcal/mole, *i.e.*, *(3b)* is much more mobile than comparable systems[1].

Synthesis of *ortho*-Condensed α,γ-Diazabicyclanes Containing a Bridgehead Nitrogen Atom

By *H. Wollweber*[*]

ortho-Condensed α,γ-diazabicyclanes such as *(1)*, being formaldehyde aminals, are unstable to acids. Only introduction of at least one oxo group next to one of the nitrogen atoms is expected to stabilize derivatives to acid. The compounds *(2)*[1] and *(4)*[2] have been obtained previously. The expected stability to acids has now been observed also for compounds of type *(3)*, which moreover are now readily accessible.

Two New Valence Isomers of [12]Annulene

By *G. Schröder, W. Martin*, and *H. Röttele*[*]

We report here two new valence isomers of [12]annulene, a compound that has not yet been detected[1,2], namely, *cis, anti,cis*-tricyclo[6.4.0.$0^{2,7}$]dodeca-3,5,9,11-tetraene (dimeric benzene) *(2)* and *trans*-bicyclo[6.4.0]dodeca-2,4,6,9,11-pentaene (*trans*-4a,10a-dihydrobenzocyclooctene) *(3)*.

If the readily accessible *cis,syn,cis*-tricyclo[8.2.0.0^{2,9}]dodeca-3,5,7,11-tetraene *(1)* [3] (2.8 g) is irradiated in ether (240 ml) for 10 h at *ca.* −30 °C with a low-pressure UV lamp, a mixture containing at least four substances is obtained. Most of the unchanged *(1)* (≈ 70%) is removed therefrom as a crystalline complex by adding solid $AgBF_4$ to a tetrahydrofuran solution. Then the products *(2)* (lower retention time) and *(3)* can be obtained 90–95% pure by column chromatography, first on silica gel impregnated with 0.7% of $AgBF_4$ and then on neutral Al_2O_3, in both cases with pentane as eluant. Under the stated conditions the yields of *(2)* and *(3)* are respectively 9 and 11 %, calculated on the amount of *(1)* used [4].

The dimeric benzene *(2)* is crystalline up to *ca.* 15 °C, colorless, and thermolabile; its half-life in CCl_4 solution at 40 °C, determined by NMR spectroscopy, is 3½ h; its decomposition gives only benzene [5]. (NMR spectrum [6] of *(2)*: two singlets at τ = 4.4 (8H) and 6.78 (4H); UV spectrum [6]: λ_{max} = 266 nm, ε = 4100.) Ozonolysis in 90% acetic acid, followed by oxidation with hydrogen peroxide, leads to the known tetracarboxylic acid *(4)* [7]. With dimethyl acetylenedicarboxylate, *(2)* affords the known diadduct *(5)* [3].

The constitution of *(3)* is proved by basic isomerization (potassium *tert*-butoxide in DMSO) and subsequent hydrogenation to *(6)* [8], also by dehydrogenation by chloranil in benzene at 20 °C to *(7)* [8]. Compound *(3)* does not react with maleic anhydride at 20 °C, which clearly indicates a distorted 1,3-cyclohexadiene system that can be contained only in the *trans*-compound. (NMR spectrum [6] of *(3)*: narrow multiplet at τ = 4.28 (10H) and a pseudosinglet at τ = 6.55 (2H); UV maximum [6] at 252 nm, ε = 6000.).

Formation of *(2)* and *(3)* in a single step during photolysis of *(1)* can be excluded. These compounds are very probably the end products of a series of electrocyclic reactions that are photochemically or thermally induced, follow the Woodward-Hoffmann rule [9], and can include [12]annulene as an intermediate.

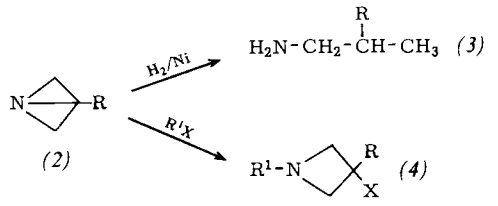
Synthesis and Properties of 1-Azabicyclo[1.1.0]butanes

By *W. Funke* [*]

3-Phenyl-1-azabicyclo[1.1.0]butane, recently described, was the first example of this highly strained bicyclic ring system [1]. We have now prepared the parent compound *(2a)* and the alkyl-substituted 1-azabicyclo[1.1.0]butanes *(2b)* and *(2c)* by a simple procedure based on the Gabriel aziridine synthesis [2].

(1) *(2)*



(a), R = H; *(b)*, R = CH_3; *(c)*, R = C_2H_5

(2)	B.p. (°C)	n_D^{20}	Yield (%)	Method	^{1}H-NMR [a]	Mol. ion (*m/e*)
(a)	51	1.4198	7	A	9.07 (2H), M; 7.87 (2H), M; 7.67 (1H), M;	55
(b)	65	1.4150	42	B	9.04 (2H), M; 8.41 (3H), S; 7.97 (2H), M;	69
(c)	87	1.4229	75	B	9.07 (2H), M; 9.03 (3H), T, J = 7 Hz; 8.08 (2H), Q, J = 7 Hz; 7.92 (2H), M	83

[a] In CCl_4 solution; τ values are given; TMS as internal standard.

The salts *(1a)–(1c)*, which are obtained from the amino diols by means of concentrated aqueous hydrogen bromide at 170 °C [3], afford the 1-azabicyclo[1.1.0]butanes *(2a)–(2c)* when heated at 70–95 °C in 17% sodium hydroxide solution (method A) or in potassium hydroxide/triethylene glycol (method B). The products *(2)* are stable in absence of air and can be distilled, but they polymerize in the presence of catalytic amounts of acid or alkylating agent.

NMR and IR spectra, elemental analysis, and molecular weights determined by mass spectroscopy confirm the structures assigned. The chemical shifts are different for the *exo*- and the *endo*-methylene protons, the multiplets at higher field being assigned to the *endo*-protons [1]. Catalytic hydrogenation

of *(2)* with Raney nickel and alcohol leads to primary amines *(3)* with absorption of 2 moles of hydrogen[4]. Acid chlorides, acid anhydrides, and thiophenol are added with formation of azetidines *(4)*.

1-Azabicyclo[1.1.0]butane (2a):

A solution of *(1a)* (40.0 g, *ca.* 0.13 mole) in water (80 ml) is added dropwise to a solution of sodium hydroxide (80.0 g, 2.0 moles) in water (400 ml) at 80 °C within 45 min. An aqueous solution of *(2a)* distils over continuously at 270 to 300 torr and is collected in a receiver cooled to −78 °C. When all the *(1a)* has been added, distillation is continued under the same conditions for a further 20 min, the distillate, which solidifies, is treated with solid potassium hydroxide, and the *(2a)* that is liberated on thawing of the mixture is evaporated at water-pump vacuum through a tube of sodium hydroxide into a cold trap. The yield is 0.5 g (7%) of gas-chromatographically pure (Apiezon) material, b.p. 51 °C.

3-Ethyl-1-azabicyclo[1.1.0]butane (2c):

(1c) (65.0 g, 0.2 mole) is added to a solution of potassium hydroxide (84.0 g, 1.5 mole) in triethylene glycol (360 ml). The mixture is warmed with stirring, at 85 °C/300 torr, and the product *(2c)* is distilled into a receiver cooled to −78 °C. After 30 min the reaction mixture is warmed rapidly to 150 °C and the distillation then interrupted. Addition of solid potassium hydroxide to the distillate led to separation of gas-chromatographically (Apiezon) pure *(2c)* (12.4 g, 75 %), b.p. 87 °C.

[4] *(2a)* polymerizes partly during the hydrogenation, so that only 1.2 moles of H_2 are taken up.

Vilsmeier Reaction of Acid Chlorides Capable of Fragmentation

By *A. Roedig* and *W. Wenzel*[*]

Perchlorobutyryl chloride *(1a)*[1] in dimethylformamide fragments even at room temperature extremely rapidly and completely to hexachloropropene *(3a)*. Since this reaction occurs in absence of a base, preliminary formation of an anion as reactive substrate does not come into consideration. Moreover, it is to be assumed that *(1a)* and DMF form a sort of Vilsmeier complex *(2a)* as intermediate.

In that case, a compound *(4)* must also be formed which is the actual active species in formation of acid chlorides from carboxylic acids and sulfonic acids by means of phosphoryl chlorides, thionyl chloride, or phosgene in DMF[2]. To find out whether fragmentation of *(1a)* is connected with formation of *(4)* we carried out the reaction in the presence of *p*-nitrobenzoic acid, which resulted in the formation of *p*-nitrobenzoyl chloride as well as *(3a)*.

(a), R = CCl_3; *(b)*, R = Cl

Since *(4)* can also be considered as a Vilsmeier reagent for aldehyde synthesis[3], fragmentation of *(1a)* in the presence of *N,N*-dimethylaniline should afford *p*-dimethylaminobenzylidene chloride, and this too we observed.

Perchloropropionyl chloride *(1b)* can be used in place of *(1a)* in the above-mentioned reactions, but less effectively, and trichloroacetyl chloride cannot used at all. The utility of *(1a)* and *(1b)* and the failure with trichloroacetyl chloride show that the organic acid chlorides and DMF must combine to a complex *(2)* capable of fragmentation and able to yield the chloride ion necessary for formation of *(4)*. The non-fragmenting DMF complex of trichloroacetyl chloride[4] is very unstable and is decomposed by water to chloral, trichloro-*N,N*-dimethylacetamide, CO_2, and CCl_4.

p-Nitrobenzoyl chloride:

p-Nitrobenzoic acid (6.4 g, 38 mmoles) is treated with *(1a)* (14 g) or *(1b)* (10.6 g) (in both cases 40 mmoles) with exclusion of moisture. Dry DMF (60 ml) is then added dropwise at room temperature and, as soon as gas evolution ceases, the mixture is heated for a further hour at 100–105 °C. The product *(3)* and DMF are distilled off at 0.01 torr, and the residual pale yellow, liquid acid chloride solidifies on cooling. M.p. and mixed m.p. 70–71 °C. Yield 7.0 g (99%) from *(1a)*, 2.3 g (32%) from *(1b)*.

p-Dimethylaminobenzylidene chloride and p-dimethylaminobenzaldehyde[5]*:*

Dimethylaniline (6.7 g, 55 mmoles) is added to *(1a)* (19.1 g, 55 mmoles) in dry DMF (40 ml) with ice cooling. When the mixture has been warmed for 2 h at 40 °C and then cooled, *p*-dimethylaminobenzylidene chloride separates as long, pale yellow needles, m.p. 64–68 °C (yield 10.0 g, 89%). [When *(1b)* is used in place of *(1a)* the yield falls to 47%.]

When this product is gently warmed with water and sufficient dilute sodium hydroxide solution is added to cause a permanent alkaline reaction, the aldehyde can be filtered off and dried; it has m.p. 73–74 °C, and the yield is 83% calculated on the benzylidene chloride used (6.0 g).

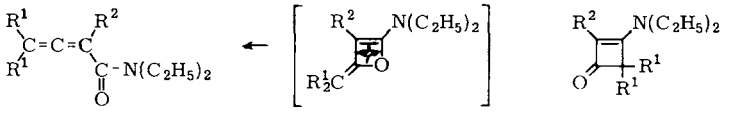
[5] According to reference [3] stoichiometric amounts of DMF are used and the aldehyde is isolated by working up with water or acid.

Cycloadditions of Ketenes to Ynamines

By *M. Delaunois* and *L. Ghosez*[*]



The *cis*-stereospecific formation of cyclobutanones[1] from ketenes and olefins, dienes, and vinyl ethers proceeds *via* a one-step multicenter cycloaddition. The reaction of ketenes with enamines, however, follows a different path involving a dipolar intermediate[2].

We have found that ketenes react readily with ynamines even at very low temperatures. Here also the cycloaddition apparently proceeds through the formation of a zwitterionic intermediate[3].

[c] Determined by gas chromatography.

The addition of diphenylketene *(1a)* to an ethereal solution of *N,N*-diethylphenylethynylamine *(2a)* or bis(*N,N*-diethylamino)acetylene *(2b)* at −50 °C leads to almost quantitative formation of cyclobutenones *(5)* and *(6)* respectively. The structure determination was based on IR and NMR findings. The reaction product from diphenylketene *(1)* and *N,N*-diethylpropynylamine *(2c)*, however, was shown to be the allenic amide *(9)* whose constitution was proved by an independent synthesis[4] from diphenylketene and the phosphonium ylid *(12)*.

(12)

When the ketene *(1b)* was treated with *(2a)* under the same experimental conditions, the crystalline cyclobutenone *(7)* was isolated in 78 % yield. Examination of the mother liquor showed a small amount of allenic amide *(11)* which was isolated by preparative gas chromatography (carbowax 20 M). With *(2c)*, however, the liquid allenic amide *(10)* was the major product. Its constitution was proved by independent synthesis from the ylid *(12)* and acetyl chloride[4]. The minor constituent was purified by gas chromatography and characterized as the cyclobutenone *(8)*.

We think these results are best explained by a multistage process involving the formation of the resonance-stabilized zwitterion *(3)* as first step. This intermediate could then cyclize in two ways leading either to a cyclobutenone *(5)* to *(8)* or to an oxete *(4)*[5] which would rapidly rearrange to the corresponding allene.

Preparation of 3-dimethylamino-2,4,4-triphenylcyclobut-2-en-1-one (5)

Diphenylketene *(1a)* (2.7 g, 0.014 mole) is added dropwise at −50 °C to a solution of *(2a)* (2.5 g, 0.014 mole) in dry ether (25 ml). After 2 h at −50 °C the reaction is slowly warmed to room temperature (1 h). The precipitate is filtered off and recrystallized from pentane. Yield 4.8 g (95 %) of *(5)*.

Preparation of N,N-diethyl-1-methyl-1-allenecarboxamide (10)

An ethereal solution of *(1b)* (0.75 g, 0.018 mole) is added dropwise at −60 °C to a solution of *(2c)* (2 g, 0.018 mole) in dry ether (25 ml). After 80 min at −60 °C, the mixture is slowly warmed to room temperature. Evaporation of the solvent and distillation gave 2.19 g (83 %) of *(10)* as a yellow liquid, b.p. 45–55 °C/0.7 torr as well as 0.19 g (7 %) of *(8)*, b.p. 132 °C/0.7 torr, purified by preparative gas chromatography (Carbowax 20 M).

Disulfene

By *G. Opitz* and *H. R. Mohl*[*]

The sulfene dimer *(1)*, which has been looked for in vain in previous formations of sulfene ($H_2C{=}SO_2$) from methanesulfonyl chloride and triethylamine and from diazomethane and SO_2, has now been obtained as follows: Methanesulfonyl chloride and an excess of trimethylamine in tetrahydrofuran at −20 °C give a powdery addition product of unknown structure[1]. When this suspension is slowly warmed to room temperature, HCl is eliminated and an ocher-brown color develops (75% of the sulfene thus formed can be detected by cycloaddition to 1-(2-methyl-1-propenyl)pyrrolidine[1]). If, after 90 h, the tetrahydrofuran is distilled off and the residue is stirred with dilute hydrochloric acid, disulfene (1,3-dithietane 1,1,3,3-tetraoxide) *(1)* remains undissolved (yield 18%).

Disulfene *(1)* is slightly soluble in most solvents but can be recrystallized from dimethylformamide (DMF) or aqueous dimethyl sulfoxide (DMSO). It decomposes with formation of a brown color above 280 °C. The calculated molecular weight is obtained by mass spectrometry and osmometry.

The NMR spectra (60 MHz) show four protons as a singlet at $\tau = 3.62$ (in DMF), 3.58 (in DMSO), 3.43 (in hexamethylphosphorotriamide), 3.13 (in pyridine)[**]. Shaking the solution with D_2O causes this signal to disappear. Addition of triethylamine to solutions of *(1)* leads to strong signal broadening, which can be reversed by an excess of trifluoroacetic acid. When triethylamine and water are both added, the H_2O and CH_2 signals of *(1)* coalesce to a common signal which is shifted to higher field on increase in the water content. Similar exchange phenomena have been observed for the somewhat less CH-acidic compound $(C_6H_5SO_2)_2CH_2$ and are ascribed to CH-acidity.

The IR spectrum of *(1)* in KBr has bands at 2830–2990 (CH), 1340 (SO_2 asym.), 1200 and 1090 (coupled vibrations), 860 (CS), and 680 cm^{-1}, indicating a symmetrical compound. The disturbance in the region of SO_2 stretching vibrations is removed on replacement of the H atoms.

The IR spectrum of the tetradeuterio derivative *(2)*, obtained by heating *(1)* with D_2O in [D_6]-DMSO, in KBr contains bands at 2150–2270 (CD), 1350 (SO_2 asym.), 1150 (SO_2 sym.), 1020, and 825 cm^{-1}. If the solution of *(1)* in DMF and a little pyridine is treated at room temperature with bromine until a permanent yellow color results, storage of the resulting mixture for 30 min and then pouring it into water affords the crystalline tetrabromo compound *(3)*, which can be recrystallized from methanol. *(3)* decomposes at 210 °C with discoloration. Its IR spectrum contains only four bands, at 1375 (SO_2 asym.), 1155 (SO_2 sym.), 825, and 695 cm^{-1}.

The most striking property of the disulfene *(1)* is its sensitivity to bases but complete stability towards acids, even towards hot concentrated sulfuric acid. Trimethylamine, triethylamine, and pyrrolidine have no effect, even when hot, if water is excluded, but ring opening occurs slowly in the presence of aqueous amines and instantaneously in the presence of dilute alkali hydroxide solutions. Reaction with potassium hydroxide solution yields potassium mesylmethanesulfonate *(4)*, identical with authentic material prepared from trimethylammonium mesylmethanesulfonate[2] and potassium hydroxide solution.

A New Synthesis of Aminoquinazolines

By *M. F. G. Stevens* and *A. Kreutzberger*[*]

The class of aminoquinazolines contains members with antimalarial[1], antiviral[2], and analgesic activity[3]. We have now prepared aminoquinazolines by a general method in which the quinazoline ring is closed before the amino group is introduced, and which proceeds by a one-stage additive cyclization.

It was known that (*o*-cyanophenyl)triazenes[4] cyclize readily and that various ring closures can be effected generally by *s*-triazines *(1)*[5]. It was thus to be expected that nitriles *(2)* of anthranilic acids would, in reaction with *(1)*, initially afford N^2-(*o*-cyanophenyl)formamidines *(3)*[6] which are the CH analogs of (*o*-cyanophenyl)triazenes. The products *(3)* are then stabilized by conversion into 4-aminoquinazolines *(4)*.

This ring closure on reaction with *(1)* is the more remarkable because *(2a)* is not cyclized by the triethyl orthoformate method (although boiling it with formic acid yields 4-hydroxyquinazoline).

	R	Yield (%)	Purification	M.p. (°C)

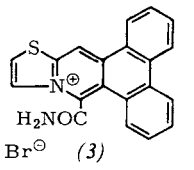
Synthesis of New Thiazolo-[3,2-*a*]pyridinium Salts[**]

By *O. Westphal* and *A. Joos*[*]

Quinolizinium salts can be synthesized by cyclocondensation of *N*-substituted 2-picolinium salts with 1,2-diketones[1]. We have similarly prepared thiazolo[3,2-*a*]pyridinium salts *(2)* from *N*-substituted 2-methylthiazolium salts *(1)* and 1,2-diketones[2] (cf. also[3]).

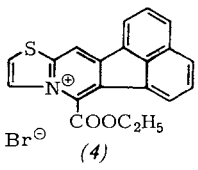
(1) *(2)*

(1a), R = COC_6H_5
(1b), R = CN
(1c), R = $COOC_2H_5$



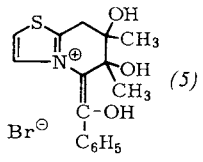
(1)	*(2)*			
	R^1	R^2	M.p. (°C)	Yield (%)
(1a)	C_6H_5	H	296	76
(1b)	2-Pyridyl	H	295 [a]	81
(1a)	2-Furyl	H	312 [a]	91
(1b)	CH_3	$CONH_2$	320	45
(1b)	C_6H_5	$CONH_2$	308–310	21
(1b)	2-Furyl	$CONH_2$	above 280 [a]	26
(1b)	2-Pyridyl	$CONH_2$	320	63

[a] With decomposition.



Condensation of *(1b)* with 9,10-phenanthraquinone leads to the pentacyclic compound *(3)*. The salt *(1c)* condenses with acenaphthaquinone to form *(4)*, whose ester group can be eliminated by heating the compound with CaO at *ca.* 220 °C.

Diacetyl and *(1a)* give the compound *(5)* which is converted into *(2)*, $R^1 = CH_3$, $R^2 = COC_6H_5$, on heating with acetic anhydride. When treated with aqueous bases, both *(5)* and *(2)*, $R^1 = CH_3$, $R^2 = COC_6H_5$, give *(2)*, $R^1 = CH_3$, $R^2 = H$.



The constitution of the salts prepared is confirmed by elemental analyses, IR and NMR measurements, and chemical degradation to 3,4-disubstituted pyridines[2,4].

(3)

(4)

(5)

6,7-Di-(2-furyl)thiazolo[3,2-a]pyridinium bromide

2-Furil (10 g) and *(1a)* (15 g) (readily accessible from phenacyl bromide and 2-methylthiazole in a little acetone at room temperature) are suspended in acetone (500 ml). A solution of di-*n*-butylamine (7 g) in acetone (50 ml) and ethanol (20 ml) is added dropwise at 0 °C with stirring over a period of 30 min. The starting material dissolves and separation of the product soon begins. Stirring is continued for a further 2 h at 0 °C, then the crystals are filtered off and washed with acetone. Ocher crystals (16 g, 91 %) are obtained which decompose above 312 °C after recrystallization from ethanol.

Aromatic and Heterocyclic 3,4-Disubstituted Pyridines[**]

By *O. Westphal, G. Feix*, and *A. Joos*[*]

Pyridine derivatives containing the same aromatic or heterocyclic substituent on C-3 and C-4 are difficultly accessible, and thus little is known about them. We have found that they can be readily prepared from 2,3-disubstituted quinolizinium salts[1] (Method 1) or from 6,7-disubstituted thiazolo[3,2-*a*]-pyridinium salts[2,2a] (Method 2). Since these salts are synthesized from 2-picoline[3] or 2-methylthiazole[2], respectively, a 2-substituted pyridine or thiazole is here formally transformed into a 3,4-disubstituted pyridine.

In method 1, the quinolinium salt *(1)* is converted by partial, catalytic hydrogenation[4] into its tetrahydro derivative, which is degraded by oxidation with, *e.g.*, potassium permanganate, to the 4,5-disubstituted 2-pyridinecarboxylic acid, and this is decarboxylated to give the 3,4-disubstituted pyridines *(2)*. Correspondingly, 2-azatriphenylene is obtained from the phenanthro[9,10-*b*]quinolizinium salt *(3)* by way of the tetrahydro derivative and carboxylic acid.

In method 2, 6,7-disubstituted thiazolo[3,2-*a*]pyridinium salts *(4)*[***] are converted into 3,4-disubstituted pyridines *(2)* by heating them with Raney nickel in 90 % ethanol.

(1) (2) (3) (4)

	R	Method	Yield (%)	M.p. (°C)	Color, shape
(2a)	C_6H_5	1	25	114	Colorless cubes
(2a)	C_6H_5	2	88	114	Colorless cubes
(2b)	2-Pyridyl	2	35–40	101	Colorless prisms
(2c)	2-Furyl	2	40–50	59–60	Pale yellow prisms
2-Azatriphenylene		1	20–30	169–171	Colorless needles

3,4-Diphenylpyridine *(2a)* is obtained directly from *(4a)* in 45 % yield; about an equal amount of 1-ethyl-3,4-diphenylpyridinium bromide is isolated, which is converted almost quantitatively into *(2a)* on heating with CaO[5]. The group R is to some extent hydrogenated during desulfurization of *(4b)* and *(4c)* by freshly prepared Raney nickel, but the crude *(2b)* thus obtained can be dehydrogenated smoothly to 3,4-di-(2-pyridyl)pyridine by hot concentrated sulfuric acid[6]. However, partially hydrogenated *(2c)* cannot be thus dehydrogenated without at least partial decomposition. In this case the undesired hydrogenation can be avoided by using aged Raney nickel (kept for four weeks under ethanol).

Except for *(2a)*[7], the pyridines prepared are new; their constitution is proved by elemental analyses and IR and NMR measurements.

3,4-Di-(2-furyl)pyridine (2c) by Method 2:

Compound *(4c)* (3.48 g) was heated under reflux with aged Raney nickel (20 g; previously kept for 4 weeks under ethanol at room temperature) in 80% ethanol (200 ml), with stirring, for 12 h. The mixture was filtered whilst hot and the filtrate was taken to dryness in a rotatory evaporator. The residue was taken up in acetone (70 ml) and filtered. The filtrate was concentrated to *ca.* 15 ml, treated with methyl iodide (5 ml), and set aside at 0 °C for 12 h. The pyridinium iodide that separated was filtered off, dried, mixed with finely powdered CaO (15 g), and sublimed at 200 °C/0.1 torr, yielding pale yellow crystals of *(2c)* (0.95 g, 45%) of m.p. 59–60 °C.

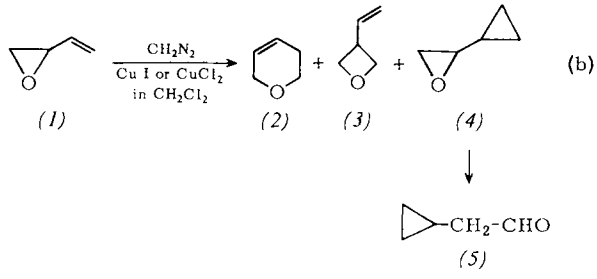
Catalyzed Reactions of Diazomethane with Vinyloxirane



By *M. Kapps* and *W. Kirmse*[*]

In the presence of a copper salt as catalyst, diazomethane and allyl halides[1], ethers, or sulfides[2] yield cyclopropane and 3-butenyl derivatives [cf. (a)].

(a)

Analogous treatment of vinyloxirane (butadiene monoxide) *(1)*[3] affords three primary products: 5,6-dihydro-2*H*-pyran *(2)* (7%), 3-vinyloxetane *(3)* (29%), and cyclopropyloxirane *(4)* (64%). The sensitive product *(4)* rearranges readily to cyclopropylacetaldehyde *(5)*.

(b)

Compounds *(2)*[4], *(4)*[5], and *(5)*[6] were identified by comparison with authentic material; the structure of *(3)* was found from its NMR spectrum (δ = 6.16, 5.16, and 4.92 ppm, each due to a vinyl-H, M; δ = 4.71, 4.43 ppm, each due to two α-H, double doublet; δ = 3.6 ppm, β-H, M) and its catalytic hydrogenation to the known 3-ethyloxetane[7].

Compounds *(2)* and *(4)* were the products to be expected from eq. (a); formation of *(3)* is the first example known to us of a carbenoid insertion of CH_2 into a C–O bond.

If reaction (b) is carried out with bis[allylpalladium(II) chloride][8] as catalyst, *(3)* is not found among the products; *(2)* (14%) and *(4)* (86%) arise in proportions similar to those given above and in addition considerable amounts of *trans*-2-butenal (crotonaldehyde) and *trans*-2-buten-1-ol (crotyl alcohol) are obtained by isomerization and reduction of *(1)*. These compounds are produced only in traces if a copper salt is used as catalyst.

Cyclopropyloxirane

By *W. Kirmse* and *Brigitte Kornrumpf*[*]

Cyclopropyloxirane *(3)*, which is produced by reaction of diazomethane with vinyloxirane in the presence of a copper salt as catalyst[1], has been prepared from vinylcyclopropane

(1) by an independent method. Suitable methods are: (a) oxidation with peracetic acid in dichloromethane in the presence of sodium carbonate[2]; (b) preparation of the bromohydrin *(2)* by *N*-bromosuccinimide in aqueous-ethereal solution[3] and removal of HBr by sodium hydroxide.

The compound *(3)* is also formed from cyclopropanecarbaldehyde and dimethylsulfonium methylide[4]. The action of diazomethane on cyclopropanecarbaldehyde affords cyclopropyl methyl ketone and *(3)* in the ratio 5:1.

The product *(3)* is rearranged by Lewis acids (BF_3, $SnCl_4$, $ZnCl_2$, CdI_2). The concentration of *(4)*, measurable by the NMR signal of the aldehydic hydrogen, soon decreases, however, owing to secondary reactions. As the initial rate shows, *(3)* reacts under catalysis by CdI_2 faster than does styrene oxide, which was the most reactive oxetane previously known[5].

Cyclopropyloxirane (3)

a) 40% Peracetic acid (5.1 g; pre-treated with anhydrous sodium acetate) is added dropwise to vinylcyclopropane *(1)*[6] (1.82 g) and anhydrous sodium carbonate (8.5 g) in dichloromethane (400 ml) at 15–20 °C. After being stirred for 4 days at room temperature the mixture is filtered, most of the solvent is distilled off through a 50-cm packed column, and the residue is fractionated through a 1-m spinning band column (Teflon band). Yield: 1.2 g (53%) of *(3)*, b.p. 39 °C/72 torr, with a trace of *(4)* as impurity (weak carbonyl bands in the IR spectrum).

b) *N*-Bromosuccinimide (13.8 g) and vinylcyclopropane (6.0 g) in ether (16 ml) are added dropwise to ether (6.5 ml) and water (9.5 ml) at 15 °C; the mixture is stirred for 1–2 days at room temperature and then extracted three times with 15-ml portions of ether. The combined ether extracts are dried over magnesium sulfate and distilled under vacuum. Yield: 6.2–6.9 g (48–53%) of *(2)*, b.p. 84–86 °C/20 torr. NMR spectrum (60 MHz, in CCl_4, chemical shifts in ppm with respect to TMS): 0.23–0.56 (4H), M, and 0.6–1.2 (1H, cyclopropane-H), 3.08–3.33 (1H, α-H), M, 2.96 (1H, –OH), S, 3.5 (2H, $-CH_2Br$), double doublet.

Compound *(2)* (6 g) is added dropwise, with stirring, to a solution of sodium hydroxide (8.8 g) in water (13 ml). After 2 h the upper phase is separated off, dried over NaOH, and distilled under vacuum. Yield: 2.4–2.6 g (80–86%) of *(3)*, (micro) b.p. 101 °C, $n_D^{24} = 1.4278$. NMR spectrum: 0.25–1.0 (5H, cyclopropane-H), M, 2.3–2.7 (3H, oxirane-H), M.

A Spiro Derivative of Norcaradiene

By *D. Schönleber*[*]

Irradiation of diazocyclopentadiene (3.0 g) *(1)*[1] in benzene (300 ml) by a Philips high-pressure lamp HPK 125 at +15 °C liberates 90% of the calculated amount of nitrogen in 3–4 h. Working up by several recrystallizations from pentane (+20 → –78 °C) gives 30–40% of a crystalline but readily polymerizable hydrocarbon, $C_{11}H_{10}$ [m.p. 25–28 °C, λ_{max} = 267 nm (log ε = 3.84)].

Surprisingly, of the pair of valence-isomeric formulas *(2)* and *(3)*, the NMR spectrum of the product unequivocally indicates formula *(2)*, that of spiro[2,4-cyclopentadiene-1,7'-norcaradiene]: apart from the signals for eight olefinic protons (τ = 3.95 m) there is a multiplet at higher field (τ = 6.40) that can only be assigned to two protons on saturated carbon atoms.

An exothermic reaction of this product *(2)* with maleic anhydride in ethyl acetate affords a 1:1 adduct of m.p. 200 to 202 °C, which according to the NMR spectrum is, however, derived, not from *(2)*, but from the tropylidene form *(3)*. The structure of *(4)* is proved by NMR spectroscopy: apart from the signals at τ = 6.75 and 6.25, whose positions correspond with those of comparable protons in the spectrum

of the cyclopentadiene-maleic anhydride adduct, there are only signals in the olefinic region (at τ = 4.54, 3.65, and 3.18 (2:2:2:4:2)[1a]).

In the above examples the position of the norcaradiene-tropylidene equilibrium[2] appears to depend on the size of the angle α: a small "counter-angle" on the spiro carbon atom favors the norcaradiene formula, and a large one favors the tropylidene formula. It is interesting that *M. Jones'* spirane[3] also has the norcaradiene structure.

An attempt to detect the equilibrium *(2)* ⇄ *(3)* at higher temperature failed because irreversible isomerizations occur at temperatures as low as 70 °C.

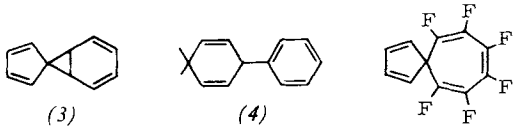
A Stable Spironorcaradiene[1]

By *M. Jones jr.*[*][2]

It has long been recognized that an entry to the elusive norcaradiene system[3] might be gained by the reaction of a carbene with benzene. This approach has met with little success since, at least in most simple systems, the cycloheptatriene form is favored at equilibrium. To date, the 7,7-dicyanonorcaradiene prepared by *Ciganek*[4,5] remains the sole example of a norcaradiene unencumbered by bridging or benzo substitution and uncomplicated by significant amounts of the cycloheptatriene form. To this we wish to add a further example, 4,4-dimethylspiro[cyclohexadiene-1,7'-norcaradiene] *(2)*.



(1) (2)

In the course of an investigation of 4,4-dimethylcyclohexadienylidene[6] it became apparent that one of the products formed on photolysis of a benzene solution of the diazo compound *(1)* was the adduct *(2)*. Thus irradiation of a solution of 200 mg of *(1)* in 1 liter of degassed benzene followed by removal of the bulk of the solvent and careful gas chromatography[7] yielded *ca.* 30 mg of a low melting solid (m.p. 40–43 °C) identified as *(2)*. High resolution mass spectroscopy[8] established the elemental composition as $C_{14}H_{16}$.

The nuclear magnetic resonance spectrum[9a] is interpretable only in terms of structure *(2)*. In the region between $\tau = 3.6$ and 4.9 there appears a quartet superimposed upon a complex multiplet. The entire group integrates for eight hydrogens and, with the exception of the quartet, resembles the downfield portion of the spectrum of 7,7-dicyanonorcaradiene[9]. A six-hydrogen singlet appears at $\tau = 8.94$ and is attributable to the equivalent methyl groups. Most important, however, is the symmetrical multiplet, integrating for two hydrogens, which is centered at $\tau = 6.47$. This is very nearly the position reported for the analogous hydrogens in the dicyano compound ($\tau = 6.53$)[4] and in spiro[2,4-cyclopentadiene-1,7′-norcaradiene] *(3)* ($\tau = 6.40$)[5]. The cycloheptatriene form is therefore eliminated.

Further structural evidence is provided by the conversion of *(2)* into *(4)* on either incautious gas chromatography or heating to 100 °C for 86 min.

(3) (4) (5)

It seems noteworthy to us that *(2)* and *(3)* are in the bicyclic form while *(5)*, synthesized by us from hexafluorobenzene[10], is a cycloheptatriene. Fluorines clearly have a determining influence and actually prefer the vinyl position to the cyclopropyl. This is in accord with the observation[11] that monofluorobullvalene prefers to keep its fluorine off the three-membered ring.

CONFERENCE REPORTS

Cytochemistry

The Gesellschaft für Biologische Chemie (Germany) held its autumn meeting on October 2 to 4, 1968, in Münster. The following report contains summaries of some of the papers.

Structural Components of the Cell Wall of *E. coli*

By *V. Braun*[*]

The cell wall of *E. coli* contains lipoprotein and lipopolysaccharide layers which, *inter alia*, carry specific receptors for attachment of bacterial viruses and for the o-antigen groups, and also has an exclusively covalently bonded macrostructure (murein, peptidoglycan) whose size is that of the bacterial surface. This macrostructure is principally responsible for the cell form. To the interior cytoplasmic membrane are assigned the important functions of respiration, oxidative phosphorylation, and active transport.

In experiments on enzymic degradation of the cell wall by hydrolases (proteinases, glycosidases, lipases) it was found that the very specific proteinase trypsin had the strongest effect. At an enzyme:cell-wall protein ratio of 1:50 the optical density of a suspension of bacterial cell walls decreases in 2 min at room temperature to 45% of the end value, which is reached after 20 min. Other proteinases react much more slowly when used in the same molar ratio and measured each at its optimum pH: pronase 0.8%, chymotrypsin 6%, and papain 24%. This specific action of trypsin indicates a particularly trypsin-sensitive peptide bond that is of importance in holding the cell wall together. If the murein layer is isolated, after incubation, by means of sodium dodecyl sulfate, it is free from covalently bound protein. Only lysine occurs as additional amino acid, in a molar ratio of 1:10 to the other components of murein.

Even after only 3 minutes' cleavage by trypsin a protein can be isolated whose lysine:arginine ratio is 4:4 and not 5:4. From quantitative amino acid analyses it is concluded that a protein of molecular weight 7000 containing about 60 amino acids is covalently bound to, on the average, every tenth murein unit (*N*-acetylmuraminyl-*N*-acetylglucosaminyl with the side chain L-Ala-D-Glu-*meso*-DAP-D-Ala)[1].

This protein is probably a lipoprotein, as shown by the following facts: if murein containing the covalently bound protein is hydrolyzed by hydrochloric acid, an insoluble component remains which is proved to be a lipid by its solubility in organic solvents, its chromatographic behavior on silica gel, and by means of staining. Trypsin or pronase can remove the lipid together with the protein of the murein layer, but only after acid hydrolysis does this lipid become soluble in chloroform and show the R_F value of the above-mentioned sample. The name murein-lipoprotein is suggested for this macromolecule.

The rapid decrease in optical density observed on cleavage of the lysine bridge between the lipoprotein and the murein layer can also be demonstrated by electron microscopy (*K. Rehn*). In ultra-thin sections the cell wall is split into two layers by treatment with trypsin for 20 min. This investigation shows for the first time a clearly homogeneous membrane lipoprotein to which an appreciable function for stabilization of the cell wall can be attributed.

Studies of the Primary Action of Phalloidin

By *M. Frimmer* (Lecturer), *H. Glossmann*, *J. Gries*, and *D. Hegner*[*]

The rapidly acting phalloidin and the more slowly acting α-amanitin play a decisive role in cases of poisoning by the bulbous leaf fungus *Amanita phalloides*. The mode of action of phalloidin can be best studied on the isolated perfused liver. The first measurable effect (noticeable after 5 min) is loss of potassium, which begins very soon, and a corresponding entry of sodium. Other metabolic changes (changes in energy relations, carbohydrate metabolism, liberation of structurally bound enzymes, *etc.*) become measurable only after some further time. The poison is taken up by the liver within a few minutes at room temperature, but extremely slowly below 10 °C. At unphysiologically low temperatures the loss of potassium and swelling of the liver do not occur or are at least much retarded.

Isolated liver-cell plasma membranes bind ^{3}H-labeled poison better than do other subcellular parts of the liver. During the first minutes of poisoning there is enrichment of the labeled phalloidin in the outer cell membrane, and it is distributed over the whole cell only later, the main portion being then bound in the inner membranes (endoplasmic reticulum).

Studies of isolated liver-cell membranes showed either a retardation or an activation of the cation-dependent ATPases, according to the experimental conditions. It is therefore unlikely that phalloidin influences active cation transport.

Electron-optical photographs of isolated liver-cell membranes show changes in the membrane structure after incubation *in vitro*; so at the beginning of poisoning the primary action is to be assumed to be on the outer protoplasmal membrane of the liver cell. With increasing enrichment of the poison in the inner cell membranes the known, morphologically visible damage to the liver cell occurs, but the change in permeability of the liver-cell plasma membrane is to be seen as the primary event of phalloidin poisoning.

Embryonic Development of the Enzyme of Fructose Metabolism

By *F. Heinz* (Lecturer) and *F. Weiner*[*]

The embryonic and postnatal development of the enzyme of fructose metabolism has been studied in the liver of rats and chickens. The activity of the following enzymes was measured: sorbitol dehydrogenase, fructokinase, aldolase with fructose 1,6-diphosphate and fructose 1-phosphate as substrate, aldehyde-dehydrogenase with D-glyceraldehyde as substrate, and triokinase. Also measured were the activities of the NAD- and NADP-specific alcohol dehydrogenases which reduce D-glyceraldehyde to glycerol and whose importance for fructose metabolism is disputed. Comparison showed that the change in enzyme activities during embryonic and postnatal development is similar for the rat and the chicken. The enzymes can be divided into three groups: 1. Enzymes that can be detected in the liver only after birth; the sole example is fructokinase. 2. Enzymes that change their isoenzyme pattern during embryonic and postnatal development, *e.g.*, aldolase; the ratio of the experimentally found rates of cleavage of fructose 1-phosphate and fructose 1,6-diphosphate under optimal conditions changes from 10:1 in the embryo to 2.6:1 in the adult rat but only from 3.8:1 to 2.3:1 in the chicken. 3. Enzymes that can be detected in the embryo and whose activities rise steadily between the embryonic and the adult state; examples are sorbitol dehydrogenases, alcohol dehydrogenases, triokinase, and also the aldehyde-dehydrogenase that is found with high activity in the liver of even embryonic rats and chickens and which changes only slightly during further development.

Our experiments show that biosynthesis of the enzyme of fructose metabolism is not determined by a single genome. Attempts to achieve faster postnatal increase in the enzyme activity by means of fructose were unsuccessful.

Evolution of Allosteric Enzymes

By *A. W. Holldorf*[*]

Allosteric control has been demonstrated for numerous enzymes during recent years. It has been analyzed mainly *in vitro*, and there have so far been few observations on the importance of allosteric effects in microorganisms *in vivo*. Metabolic changes can be demonstrated *in vivo* for mutants in which enzymes have lost their allosteric properties but retain their catalytic activity. Indirect evidence for the importance of allosteric mechanisms *in vivo* is provided by comparison of effective concentrations of allosteric effectors *in vitro* with the concentrations of these metabolites that occur *in vivo*.

We have compared three allosterically controlled enzymes: aspartate transcarbamylase with cytidine 5′-triphosphate as a negative effector; deoxycytidine 5′-monophosphate deaminase with thymidine 5′-triphosphate as a negative effector and with thymidine 5′-triphosphate as a positive effector; and thymidine kinase with thymidine 5′-triphosphate as a negative effector. The activities of these enzymes were measured under optimal conditions. The influence of effectors on these enzymes in cell-free extracts of microorganisms, lower plants, and animals, as well as in extracts of tissues of higher plants and animals was studied. Further, so far as analytically possible, the intracellular concentrations of the effectors were determined.

It was found that deoxycytidine 5′-monophosphate deaminase and thymidine kinase from all the organisms that contained them were influenced by effectors always at approximately the same concentrations, these concentrations being of the same order as the intracellular concentrations of the respective nucleotides. However, for aspartate transcarbamylase this behavior was observed only for some of the microorganisms; for all other organisms the effectors become efficient only in concentrations 10 to 1000 times as great as the intracellular concentration of cytidine 5′-triphosphate.

According to these results allosteric control of deoxycytidine 5′-monophosphate deaminase and of thymidine kinase may be of biological importance for all organisms, but that of aspartate transcarbamylase probably only for microorganisms. Allosteric control of aspartate transcarbamylase was probably

lost in the course of evolution and replaced by other controls, whereas it was retained for the other two enzymes in all organisms.

Tissue Hyaluronidase and Healing of Wounds

By *W. Heller* (Lecturer) and *F. K. Mörl*[*]

We have studied the behavior of tissue hyaluronidase and of protein-bound iodine for up to seven or nine days after a goiter operation on more than fifty men and women. The content of protein-bound iodine is a well-defined measure of the thyroxine level in the blood. There is a remarkable decrease in the tissue hyaluronidase (mean curves) on the day of the operation, although it remains in the normal region; the minimum (far below the normal value) is reached only on the third day. For an exact correlation of tissue hyaluronidase and protein-bound iodine, the curves for each patient must be studied individually. After all goiter operations the amount of protein-bound iodine increases, but that of tissue hyaluronidase decreases. In the ideal case the two curves are almost the opposite of each other. Thus in almost all the patients the corresponding maxima and minima occur at the same time. The extreme values, however, depend on the nature of the goiter. This is particularly noticeable for hyperthyrosis; nevertheless, euthyrotic patients also show the course described above for both curves, but not so strikingly.

Although there is a significant relation between tissue hyaluronidase and protein-bound iodine, it is apparent that this can be only indirect, since tissue hyaluronidase can be influenced by a proteinase inhibitor whereas protein-bound iodine is not so influenced. In this way we could obtain an increase in tissue hyaluronidase that was totally independent of the level of the protein-bound iodine in the blood.

Administration of the proteinase inhibitor thus exerts a favorable therapeutic effect, since a severe fall in tissue hyaluronidase is undesirable for wound healing. The positive influence of thyroxine in wound healing is a known fact, and was confirmed in experiments *in vitro*; it explains why wounds heal so rapidly after operations for goiter.

Allosteric Properties of Yeast Pyruvate Kinase

By *H.-J. Wieker, K.-J. Johannes* (Lecturer), and *B. Hess*[*]

In previous papers *Hess et al.*[1] demonstrated the strong cooperativity of yeast pyruvate kinase with the substrate phosphoenol pyruvate and showed that fructose 1,6-diphosphate is an allosteric activator and adenosine triphosphate (ATP) an allosteric inhibitor.

Yeast pyruvate kinase fulfils the requirements of the *Monod-Wyman-Changeux* model[1,2]. The state functions and the binding functions derived from that model, as well as the constants characterizing the enzyme, have been determined from further studies of the steady-state kinetics under the influence of fructose 1,6-diphosphate and ATP, using *Blangy, Buc*, and *Monod*'s method[3].

The number of binding sites per enzyme molecule was found to be two for the ligands phosphoenol pyruvate, fructose 1,6-diphosphate, and ATP, *i.e.*, yeast pyruvate kinase consists of two identical protomers.

An equilibrium exists between an active (R) and an inactive (T) state of the enzyme, with an equilibrium constant $[T]/[R] = L_0 = 1.5 \times 10^3$. The dissociation constants for the ligands in the R state (K_R) and in the T state (K_T) amount to $K_R = 2 \times 10^{-4}$ M, $K_T = 3.5 \times 10^{-2}$ M for phosphoenol pyruvate [non-exclusive binding coefficient $c = 6 \times 10^{-3}$], $K_R = 1 \times 10^{-4}$ M for fructose 1,6-diphosphate, and $K_T = 2 \times 10^{-3}$ M for ATP.

It can be seen from these constants that in the absence of ligands yeast pyruvate kinase is predominantly in the T state, that ATP fixes this state, and that the other two substances shift the equilibrium largely from the T to the R state.

Experiments concerning the binding of the second substrate ADP, which shows cooperativity only at phosphoenol pyruvate concentrations below 5×10^{-3} M[1], are not yet complete. Results so far indicate that binding of ADP to the enzyme-phosphoenol pyruvate complex is favored over binding to the free enzyme.

Biogenesis of Mitochondria; Pathway of the Synthesis of Mitochondrial Phospholipids

By *B. Kadenbach*[*]

Isolated mitochondria can synthesize phosphatides only in the outer membrane[1]. The origin of the phosphatides in the inner membrane, which contains about 80% of the total phosphatides, is unknown. Experiments on incorporation of $^{32}PO_4^{3-}$ into isolated rat-liver mitochondria showed highly diverging rates of incorporation (mmoles of $^{32}PO_4^{3-}$/mole of phosphatide-phosphate in 10 min) for the phosphatides studied: phosphatidylcholine 0.08; phosphatidylethanolamine 0.29; phosphatidylserine 4.9; phosphatidylinositol 0.3; lysophosphatidylcholine 2.4. Except for lysophosphatidylcholine, these rates are less than the maximal rates of incorporation after injection of $^{32}PO_4^{3-}$ *in vivo* (8, 40, 29, 20, and 2.1, respectively).

The outer membrane, the intracristale proteins, the inner membrane, and the matrix of mitochondria labeled *in vitro* were isolated by digitonin[2] and the phosphatides were separated by two-dimensional thin-layer chromatography. The soluble fractions were obtained by one hour's centrifugation at 400000 g. They contained appreciable amounts of labeled phosphatides (nmoles of phosphatide-phosphate/mg of protein): outer membrane 660, intracristale region 195, inner membrane 345, matrix 35. For phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine + phosphatidylinositol the specific radioactivity was greatest in the outer membrane. Only lysophosphatidylcholine showed the highest activity in the intracristale region. Correspondingly their content there was greatest (2.2, as compared to 0.6–0.9).

Kinetic studies of the incorporation of $^{32}PO_4^{3-}$ *in vivo* showed rapid labeling of phosphatidylethanolamine in the microsome fraction. Only after a delay of about 10 min was the mitochondrial phosphatidylethanolamine labeled. Phosphatidylcholine in both particles was labeled only after a further delay of 10 min; as in the previous case, it was labeled more rapidly in the microsomes than in the mitochondria. *In vivo* also phosphatidylethanolamine and phosphatidylserine were labeled first in the soluble and then in the insoluble mitochondria fraction. In a further experiment the transfer of labeled phosphatides from the microsomes into the mitochondria could be demonstrated directly *in vitro*. This transfer is energy- and time-dependent, as previously shown for protein transfer[3].

The results are interpreted in the sense that most of the mitochondrial phosphatides are synthesized on the endoplasmic reticulum and transported together with newly synthesized protein as a molecular complex into the mitochondria.

Physiological Role and Regulation of 10-Formyltetrahydrofolate:NADP Oxidoreductase

By *C. Kutzbach*[*]

The enzyme 10-formyltetrahydrofolate:NADP oxidoreductase[1], which was first found in pig liver, catalyzes reaction (1). Severe product inhibition by tetrahydrofolate makes quantitative tests difficult. The inhibition can be overcome by coupling with an excess of formate:tetrahydrofolate ligase (E.C.6.3.4.3) from *Clostridium cylindrosporum* [eq. (2)].

$$10\text{-CHO-H}_4\text{PteGlu} + \text{NADP}^+ + \text{H}_2\text{O} \rightarrow \text{CO}_2 + \text{H}_4\text{PteGlu} + \text{NADPH} + \text{H}^+ \quad (1)$$

$$\text{H}_4\text{PteGlu} + \text{HCOOH} + \text{ATP} \rightarrow 10\text{-CHO-H}_4\text{PteGlu} + \text{ADP} + \text{P} \quad (2)$$

$$\text{HCOOH} + \text{NADP}^+ + \text{ATP} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + \text{NADPH} + \text{ADP} + \text{P} + \text{H}^+ \quad (3)$$

PteGlu = Pteroyl-L-glutamic acid (folic acid)

On this basis a spectrophotometric (NADPH) and a radioactive (10-^{14}CHO–H_4PteGlu or ^{14}C-formate $\rightarrow$ $^{14}CO_2$) test were developed in which formate is oxidized to CO_2 by a catalytic amount of folate in accordance with eq. (3). Oxidation of formate can occur physiologically in the same way; enzyme activities of the same order (1–5 mIU/mg) as for the enzymes for eqs. (1) and (2) are found in the cytosol from the liver and kidneys of the rabbit and rat. The activity was less or not demonstrable at all in other organs or in chicken liver. In the absence of $NADP^+$ or in the presence of 0.1 M hydroxylamine the oxidoreductase catalyzes hydrolysis of 10-formyl-H_4PteGlu to H_4PteGlu and formate at, at most, 30% of the rate of the oxidation. This indicates an active formyl compound as intermediate, but no formohydroxamate could be detected.

The K_M values are 3.5 μM for NADP and 8.2 μM for (−)-10-CHO–H_4PteGlu. The same K_m and V_{max} were found with the (±)-isomeric mixture giving only 50% conversion. Thus the inactive (+)-form does not cause inhibition. However, both isomers of the product cause severe inhibition, so that the rate of reaction amounts to only *ca.* 30% of the normal value if (±)-H_4PteGlu is used in place of CHO–H_4PteGlu in a coupled test. The inhibition constants (K_i) obtained were of the order of 12 μM [(+)-isomer] and 0.5 μM [(−)-isomer]. Inhibition is approximately, but not strictly, competitive. Inhibition is specific for H_4PteGlu; 5-CHO–H_4PteGlu, 5-CH_3–H_4PteGlu, folic acid, aminopterin, and reduced aminopterin cause no inhibition up to 5×10^{-4} M. The strong specific inhibition by product indicates regulation of the tissue concentration of unsubstituted tetrahydrofolic acid by this enzyme.

The Point of Attack of Cortisol in the Cell Nucleus

By *M. Beato, J. Homoki,* and *C. E. Sekeris* (Lecturer)[*]

Parenteral administration of cortisol leads to a rapid stimulation of RNA polymerase activity of rat liver nuclei and to an increase in the template activity of chromatin for RNA synthesis. The same effects have been observed after incubation of cortisol with rat liver nuclei. We conclude therefore that the primary site of action of the hormone is to be found in the cell nucleus. To localize the point of attack more closely we have studied the processes occurring during the increase of the template activity of chromatin *in vitro*. Chromatin consists mainly of DNA, RNA, and protein. Since ^{3}H-cortisol is bound exclusively to nuclear protein, we have investigated the influence of the hormone on nuclear proteins *in vitro*.

It was previously postulated that chemical modifications of the basic nuclear proteins by acetylation or methylation are important for the regulation of RNA synthesis. Cortisol does not effect histone acetylation or methylation. We have established, however, an increase in the thiol content of nuclear proteins even after two minutes' incubation of the nuclei with cortisol. Both basic and acidic nuclear proteins show an increased content of thiol groups.

Our experiments indicate that cortisol can increase the template activity of chromatin by direct interaction with nuclear proteins.

Transport of Double- and Triple-stranded Ribopolynucleotides through Cellular Membranes

By *P. L. Schell*[*]

Uptake of homologous radioactively labeled RNA into Ehrlich Ascites tumor cells was described previously[1]. It has now been shown that ^{14}C/^{3}H double-labeled poly A · U and poly A · U_2 can enter ascites cells much faster than their constituents, poly A and poly U, or RNA mentioned initially. The cells were suspended in *Hank*'s medium which contained the polymer. After incubation, the medium was removed from the cells. Then the radioactivity could be measured either in the complete cells or from the recovered polynucleotide fractions. It is remarkable that this uptake approaches 50% of maximal loading when the system was incubated at 0 °C. Even at this temperature the initial rate of loading is very fast so that a plateau is reached after incubation times of about 30 min. During this procedure the 1:1 ratio of the partners in the case of poly A · U and the 1:2 ratio in the case of poly A · U_2 was maintained. The high molecular weight ribopolynucleotides could not have been degraded during penetration of the cell wall, since this material can be phenol-extracted from the cells and exhibits a behavior identical with that of authentic poly A · U_2 when chromatographed on a G 150 Sephadex column. Actinomycin inhibits incorporation into cellular RNA of labeled poly A- or poly U-fragments. This possibility was simulated by addition of ^{14}C-AMP to a mixture of cells and poly ^{3}H-A · U_2 in *Hank*'s medium. Hardly any ^{14}C-RNA was found alongside the standard amounts of penetrated poly ^{3}H-A · U_2 when the loaded cells where extracted by phenol. Defined double- or triple strandedness is obligatory for highly efficient entry of the polymers. The method of continuous variation was employed to offer to the cells a range of media containing different ratios of poly A to poly U. The uptake of each of the partners is maximal when the ratio A · U is 1:2. The hypochromicity, *i.e.* the base pairing by H-bridges in poly A-poly U complexes, is lost when poly A is *N*-oxidized and this loss is paralleled by a sharp decrease of cellular uptake. Separation of double or triple strands during their penetration into the cell membrane has not been observed. Any dissociation of poly

[^{14}C A] [^{3}H U_2] which would have occurred would result in isotopic dilution of the labeled helix partners in the presence of added molar excesses of either non-labeled poly A or poly U or poly A U. This effect would be noticeable in the case of irreversible or reversible helix dissociation but was not observed in either case.

Chemical and Enzymic Reactions on the Membranes of Ehrlich Ascites Tumor Cells and their Consequences for Metabolism and Permeability

By *R. Brossmer* (Lecturer), *W. Brandeis*, and *K. Kramps*[*]

In a study of the relation of chemical structure to biological function of membranes of animal cells, the cells have been modified by substances whose effect on groups in the cell surface could be defined. The effects of such modifications upon metabolism and permeability have been investigated.

Ehrlich mouse ascites tumor cells were used, but the results appear to be valid also for other types of cell.

Treating the cells with periodate (10^{-4} M to 10^{-2} M, 15 min, 37 °C) leads to changes in metabolism and permeability that vary according to the concentration employed. After treatment with 10^{-4} M periodate glycolysis is 70% of that of control cells, after 5×10^{-4} M about 50%, and after 10^{-3} M at most 5%. Similar figures are obtained for respiration.

To detect an effect on membrane function, the efflux of potassium and protein was studied in relation to periodate concentration. It was observed that the membrane became increasingly more permeable to substances of low and high molecular weight. The chemically defined action of periodate on glycoproteins and glycolipids of the cell membrane thus leads to massive changes in permeability. This is indicated also by the fact that non-permeable dyes such as Trypan Blue and Naphthalene Green V now appear within the cell. – In experiments over a long period the inhibition of metabolism caused by periodate[1] proved to be partly reversible. Thus glycolysis of the cells treated with 10^{-3} M periodate regained 45% of the control value after 5 h, and then remained constant. The diminution in metabolism thus consists of a reversible and an irreversible disturbance, in which, however, the influx of dye was the same after 5 h as at the beginning, *i.e.*, the membrane remained damaged. Transplantation of the cells became impossible only after incubation with 10^{-2} M periodate. Treatment with 0.1 M periodate (1 h, 20 °C) reduces the mobility of the cells in an electric field by 10 to 15%, and neuramidase can then cleave only little of the sialic acid (in contrast to the strong effect of the enzyme on control cells).

Whereas treating ascites cells with 0.1% of phenethyl alcohol (15 min, 37 °C) leads to only a slight diminution in metabolism, 0.5% of this alcohol reduces anaerobic glycolysis to 3% and respiration to 18% of the controls. With 0.25% of the alcohol the inhibition is wholly reversible.

A considerable disturbance of permeability is indicated by the following findings: 1. Efflux of potassium. 2. Efflux of protein. 3. Influx of dye. The cells can no longer be transplanted (0.5% of phenethyl alcohol, 15 min, 37 °C). The electrophoretic mobility is, however, unchanged.

Neither subtilisin nor lysozyme affects the metabolism or mobility; however, alkaline phosphatase reduces respiration and glycolysis by about 30%, and in this case the mobility rises by 10–15%.

The cell membrane can be modified chemically by succinylation. This not only causes positive charges to disappear but also attaches new negative charges to the cell surface. This leads experimentally to an increase of 20% in the mobility in an electric field. Cells modified in that way are morphologically intact but have special properties. Neuramidase removes about 1/3 less sialic acid than from untreated cells; metabolism is strongly inhibited.

Receptors on the Surface of Human Thrombocytes

By *R. Brossmer* (Lecturer) and *H. Patscheke*[*]

Thrombocytes that have been washed once and thus freed from their complex milieu form good experimental material since they are morphologically and functionally intact. In a search for receptors for the physiologically and pathologically important process of aggregation the following were observed.

Calcium aggregates blood platelets even without further additions, and it is immaterial whether the reaction occurs in buffer solution or in plasma (with heparin). Aggregation increases with fall in temperature, reaching a maximum at 15–20 °C. For this, 5×10^{-4} M Ca^{2+} is required, *i.e.*, 1/5 of its physiological concentration in the plasma, but even 5×10^{-5} M Ca^{2+} causes appreciable aggregation. Above 3×10^{-3} M Ca^{2+} no aggregation is caused, but rather disaggregation. Qualitatively the same results are observed with magnesium (5×10^{-4} M) but the aggregation amounts only to about 40% of that caused by calcium. The aggregations induced by calcium or magnesium are reversible at increased temperatures. The cycle can be repeated several times, merely by change of temperature. Adenosine diphosphate plays no part. Thus calcium and magnesium can be considered as the simplest aggregating materials[1]. Interaction with the cells depends on simple physicochemical phenomena.

The receptor on the thrombocyte surface can be cleaved by alkaline phosphatase; there are about 10^6–10^7 phosphate groups per thrombocyte. All other calcium-dependent aggregations, including the physiologically important one caused by adenosine diphosphate, are also blocked by this enzyme. In contrast thereto, the aggregating effect of positively charged polymers[2] is unaffected in the presence of this enzyme. In this case chemically different groups act as receptors, being partly removed by neuramidase, although the action of all the calcium-dependent substances is unaffected. Thus we have proved the existence of two types of receptor for the aggregation: 1, phosphate groups, which play a special role as metal-chelating agents; and 2. sialic acid molecules.

Studies on Adenovirus Type 12: Relations between the Virus- and Host Genomes[**] [1]

By *W. Doerfler*[*]

The objective of the experiments described was to follow the intracellular fate of the deoxyribonucleic acid (DNA) of adenovirus type 12 (Ad 12) in the early stages after infection

of hamster cells (BHK21). It can be shown that Ad 12 does not multiply in BHK21 cells. *Strohl et al.*[2] demonstrated that BHK21 cells can be transformed by Ad 12, which belongs to the group of highly oncogenic adenoviruses.

The DNA of Ad 12 can be separated from that of BHK21 cells by equilibrium centrifugation in CsCl gradients ($\Delta\rho$ = 0.006 g × ml^{-1}). This small difference in density can be increased by culturing the BHK21 cells in a medium containing 5-bromodeoxyuridine. Such cells are infected with high multiplicities of purified Ad 12, the DNA of which had been labeled with [^{3}H]thymidine. The cells are lysed at various times after infection, and the total DNA is isolated by treatment of the lysate with pronase and phenol and by equilibrium centrifugation in CsCl. The distribution of ^{3}H between the positions of cellular and viral DNA is followed in CsCl density gradients. The position of viral DNA is determined by the addition of a small amount of ^{14}C-labeled Ad 12 DNA. Cellular DNA is found at a higher density than viral DNA.

Up to about 16 h after infection the total ^{3}H activity appears at the position of viral DNA. From 20 h after infection on, an increasing proportion of the ^{3}H activity appears in the position of cellular DNA, while the ^{3}H activity at the position of viral DNA decreases. This result can be explained by any of the following assumptions:

1) Viral DNA is replicated in the presence of 5-bromodeoxyuridine and thereby becomes heavy.

2) Viral DNA is degraded to mononucleotides by nucleases, and the [^{3}H]thymidine 5′-monophosphate liberated is converted by kinases into [^{3}H]thymidine 5′-triphosphate (TTP) and reincorporated into cellular DNA. The synthesis of cellular DNA continues after infection of BHK21 cells with Ad 12.

3) The viral genome or part of it is bound to cellular DNA (integration).

Replication of the DNA of Ad 12 in BHK21 cells is not detectable[1,3]. Thus the first of the above possibilities is excluded.

One can distinguish between possibilities 2 and 3 by comparing the CsCl density gradient profiles of DNA from infected cells in the high-polymer state (180 × 10^6 Daltons) with that of DNA that has been degraded ultrasonically to fragments of 2 × 10^6 Daltons.

As shown in Figure 1, shift of the maximum of the ^{3}H activity to the position of the density hybrid would be expected after fragmentation of the cell DNA, in case viral genes had become integrated.

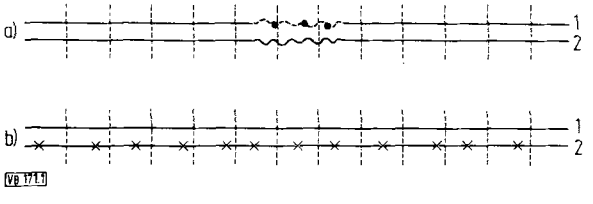

Fig. 1. a: Schematic representation of the integration of viral DNA (Ad 12) into cell DNA (BHK21). b: Uninfected control cells.

Positions at which DNA is fragmented by ultrasonication; 1, old DNA strand; 2, new DNA strand; — heavy cell DNA containing 5-bromodeoxyuridine; ~~~ heavy viral DNA containing 5-bromodeoxyuridine; .·.·.·.·. light viral DNA containing thymidine; • [^{3}H]thymidine; × [^{3}H]-5-bromodeoxyuridine.

This shift, which is due to separation of the integrated viral genes (density hybrid) from the heavy cellular DNA, would not be expected if [^{3}H]TTP had been reincorporated.

Experimentally, such a shift of the maximum of the ^{3}H activity is found after fragmentation of the DNA of 5-bromodeoxyuridine-BHK21 cells that have been infected with ^{3}H-labeled Ad 12. The shift is not observed (Figure 1b) for the DNA of uninfected control cells.

This result is consistent with the assumption that viral genes have been integrated into the DNA of BHK21 cells. The integration probably occurs by covalent linkage, since the ^{3}H activity at the position of higher density is retained also in alkaline CsCl solution (pH > 12).

Studies on the Mode of Action, Coenzyme Binding, and Structure of Yeast Pyruvate Decarboxylase

By *J. Ullrich*[*]

In enzymatic pyruvate decarboxylations with thiamine pyrophosphate [TPP] as coenzyme, (−)-2-α-hydroxyethyl-TPP [HETPP] can be trapped, accumulated, and isolated[1]. The conversion of this product by apo-enzymes is much slower than that of pyruvate by the TPP-saturated holo-enzymes[1]. Due to steric hindrance[2], HETPP recombines very poorly with apo-pyruvate decarboxylase. Furthermore, removal of the α-proton of HETPP, *i.e.* restoration of the carbanion primarily arising from the decarboxylation, is achieved only with difficulty[3]. This led to the assumption that the primary α-carbanion in the active site of pyruvate decarboxylase is further converted before protons from the medium can reach it. Prior to its release, the acetaldehyde residue is transferred to the 4′-amino group of the TPP[2] and, then, probably to an ε-amino group of the protein[2]. A 4′-amino group still occupied by the previous acetaldehyde residue gives rise to acetoin formation, a regularly observed side reaction. In D_2O, the rate of base catalysis by the ND_2 group is reduced to 50%, whereas the acetoin formation is not affected. Further evidence for a transfer of the unprotonated aldehyde residue is provided by the observation[2] that a 2-hydroxymethyl group, arising from the decarboxylation of glyoxylate, is not transferred; absence of the methyl group facilitates the access of protons from the medium and these can saturate the α-carbanion before the 4′-amino group has a chance to attack.

For further elucidation, the structure of the protein has been studied more closely. Yeast pyruvate decarboxylase has a molecular weight of *ca.* 170000[4] and four binding sites for TPP and Mg^{++}. Three of them bind strongly, one weakly[4]. In 6M guanidinium chloride two subunits are produced that are not further cleaved even in the presence of 10 mM mercaptoethanol. The protein has a high content of lipophilic and of all aromatic amino acids, and of proline, but contains only a small amount of cysteine. With TPP and Mg^{++}, it reversibly forms salts with Michaelis-Menten behavior at different and independent sites[2]. Binding of both cofactors at pH 6.8 leads to a protein rearrangement into a stable ternary complex[2], the holo-enzyme, under conformational changes. These can be measured by a small decrease in the absorbances at 190 nm and at 280 nm in the specific rotation and in the Moffitt parameter b_0, and by a corresponding change in circular dichroism. The calculated total α-helix content rises from 23–25% to about 27%. The protein fluorescence, mainly due to tryptophan, is partly quenched, probably by interaction of several of the 20 tryptophan residues in the molecule with TPP. Recombination with thiochrome pyrophosphate instead of TPP leads to a strong increase of the thiochrome fluorescence[5]. 2-*p*-Toluidinylnaphthalene-6-sulfonate, a dye that is highly fluorescent only in lipophilic environment, is attached to sufficiently large lipophilic areas of proteins[6]. Half of the dye bound to apo-

pyruvate decarboxylase is irreversibly displaced by TPP and Mg^{++}; TPP or Mg^{++} alone have no effect. The other half of the dye acts as competitive inhibitor of pyruvate decarboxylation. Thus, both types of the protein-bound dye must be located at the active site or in its close vicinity. No other large lipophilic regions seem to exist at the surface of the enzyme. TPP is apparently enclosed in a lipophilic pocket, produced by the formation of the stable ternary complex (cf.[2]). The entrance to the pocket and its immediate environment appear to be lipophilic too. Thus, an important condition is fulfilled for direct conversion of the primary α-carbanion: hindered access of protons from the medium, as long as the coenzyme is occupied by substrate.

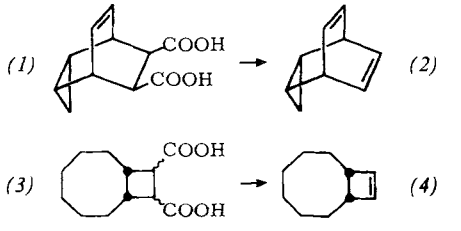
SELECTED ABSTRACTS

The microwave spectrum of methylcyclopropane was measured by *R. G. Ford* and *R. A. Beaudet* in the frequency range 8–38 GHz. From the splitting of the rotation transitions at high quantum number the potential threshold of the intermolecular rotation was determined as 2860 ± 50 cal/mole. This value is in the expected region, in contrast to the value of the torsion-potential threshold previously determined for 1,1-difluoro-2-methylcyclopropane which at 2260 cal/mole was unusally low. From these results the authors infer preponderatingly electrostatic interaction between methyl hydrogens and hydrogen or fluorine atoms attached to the ring. The dipole moment of methylcyclopropane amounts to 0.139 ± 0.004 D. / J. chem. Physics *48*, 4671 (1968) / – Hz. [Rd 932 IE]

The absorption spectra of small polar molecules in an apolar solvent (cyclohexane) were measured by *P. Datta* and *G. M. Barrow* for the far-infrared region (down to about 40 cm^{-1}). The broad absorption bands observed, whose maxima could on occasions not be determined on the apparatus used, arise from movements of the polar molecules, of rotatory type, that are disturbed by frequent collisions with solvent molecules. From the experimental values, two parameters can be determined for each solution: one gives the energy difference between two rotation states, and the other gives the mean time between two collisions with the solvent. The second parameter amounts to about 10^{-13} sec and is relatively independent of the nature of the dissolved molecule. Thence the free path of the rotating molecule in the liquid can be estimated as about 0.5 Å. Examples of the polar molecules are HCl, NH_3, CH_3I, CH_2Cl_2, CH_3CN, C_6H_5CN, $(CH_3)_3CCl$. / J. chem. Physics *48*, 4662 (1968) / –Hz. [Rd 933 IE]

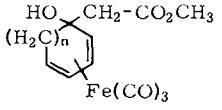
The reaction of boron monofluoride with alkynes is the subject of a report by *P. L. Timms*. BF can be obtained on a preparative scale from BF_3 and B at diminished pressure and 1800 to 2000 °C. On cocondensation (–196 °C) with acetylene it affords a yellow solid that melts and partly vaporizes when heated. The volatile fraction contains C_2H_2, BF_3, B_2F_4, and a very small amount of $C_2H_3BF_2$ [difluoro(vinyl)borane?] and $C_2H_2B_2F_4$. *(1)* and *(2)* are also isolated in a total yield of about 8%. The nuclear resonance spectra and the IR spectrum of *(1)* (m.p. –68 °C) indicate that it exists as either *(1a)* or *(1b)*. Compound *(2)*, which decomposes at 35 °C without melting and can be obtained from *(1)* by loss of BF_3, has an IR spectrum resembling that of benzoquinone. The three possible dimethyl derivatives of *(2)* are formed



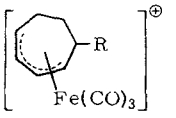
(1a) *(1b)* *(2)*

from propyne and BF, and the tetramethyl derivative is obtained from 2-butyne. / J. Amer. chem. Soc. *90*, 4585 (1968) / –Kr. [Rd 939 IE]

Conversion of liquid xenon into a metal-like state is possible by shock compression according to *M. Ross*. He reaches this conclusion because at high temperatures xenon has an abnormally large compressibility and a density that amounts to two or three times the initial value. Further, the energy difference between the valence band and the conduction band becomes rapidly smaller with increasing density. At 500 kbar and 18000 °K xenon has properties similar to those of cesium: a conduction band of 5d character is partly occupied by electrons that are supplied from the 5p valence band. / Physic. Rev. [2] *171*, 777 (1968) / –Hz. [Rd 935 IE]

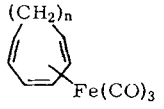


The electrolytic decarboxylation of vicinal dicarboxylic acids[1], according to *P. Radlick*, *R. Klem*, *S. Spurlock*, *J. J. Sims*, *E. E. van Tamelen*, and *T. Whitesides* as well as *H. H. Westberg* and *H. J. Dauben jr.*, is more suitable than the normal treatment with lead acetate for the introduction of a double bond, particularly into polycyclic systems. Examples: *(1)* → *(2)* (yield ≈ 35%), *(3)* → *(4)* (35%). The dicarboxylic



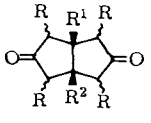
acids are readily obtainable from the anhydrides, which can be prepared by the addition of maleic anhydride to dienes. The electrolyses were carried out in aqueous pyridine in the presence of triethylamine at room temperature. / Tetrahedron Letters *1968*, 5117, 5123 / –Kr. [Rd 941 IE]

[1] *Fichter*, Helv. chim. Acta *24*, 549 (1941).

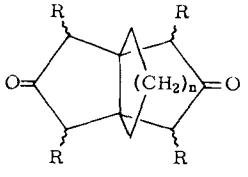


Ring expansion in organoiron compounds has been observed by *J. Lewis* and *A. W. Parkins*. The iron tricarbonyl complexes of 2,4-cyclohexadiene and 2,4-cycloheptadiene react with zinc under the conditions of the Reformatski reaction to form the hydroxy esters *(1a)* and *(1b)* respectively. These

(1a), n = 1
(1b), n = 2



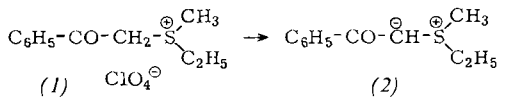
(2a), R = CO_2CH_3
(2b), R = CH_2-CO_2CH_3



(3a), n = 1
(3b), n = 2

products are converted by trityl tetrafluoroborate into *(2a)* and *(2b)*, both cations containing seven-membered rings. The action of water on *(2a)* yields the complex *(3a)* which can be converted back into *(2a)* by protonation, whereas the reaction of *(2b)* with water results in ring expansion to form *(3b)*. / Chem. Commun. *1968*, 1194 / – Kr. [Rd 942 IE]

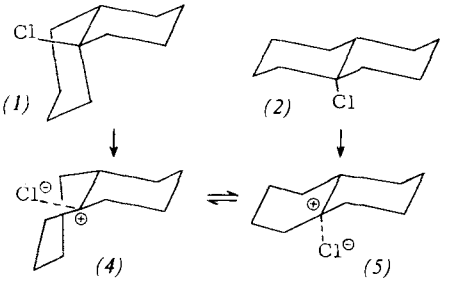
A one-step synthesis of pentalane and propellane ketones has been described by *U. Weiss* and *J. M. Edwards*. Dimethyl 3-oxoglutarate reacts with open-chain 1,2-diketones to form



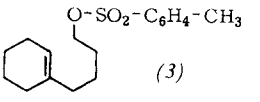
(1a), R = CO_2CH_3, R^1 = R^2 = H
(1b), R = R^1 = R^2 = H
(1c), R = CO_2CH_3, R^1 = CH_3, R^2 = H
(1d), R = R^2 = H, R^1 = CH_3

(2a), R = CO_2CH_3, n = 2
(2b), R = CO_2CH_3, n = 1
(2c), R = H, n = 2
(2d), R = H, n = 1

pentalanedione derivatives, *e.g. (1a)–(1d)*, and with cyclic 1,2-diketones to form derivatives of propellanedione *(2)*. 1,2-Cyclohexanedione and 1,2-cyclopentanedione react to form *(2a)* and *(2b)*, which can be converted into tricyclo[4.3.3.$0^{1,6}$]-dodeca-8,11-dione *(2c)*, m.p. 174 °C, yield 41%, and tricyclo[3.3.3.$0^{1,5}$]undeca-3,7-dione *(2d)*, m.p. 183 °C, yield 39%, without first being isolated. / Tetrahedron Letters *1968*, 4885 / –Kr. [Rd 943 IE]



The formation and racemization of (–)-ethylmethylsulfonium phenacylide *(2)* have been described by *D. Darwish* and *R. L. Tomilson*. The reaction of optically active ethylmethylphenacylsulfonium perchlorate *(1)* with dilute NaOH led to *(2)*, which was extracted with chloroform. *(2)*, m.p. 83–85 °C, $[\alpha]_D^{25}$ –137 ° (*c* = 0.487, benzene) racemizes with first order kinetics; the half life in CCl_4 at 50 °C is ≈ 40 min. After 160 min only 5% of *(2)* had decomposed, mainly into methyl

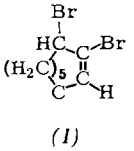


(1) $ClO_4^{\ominus}$ *(2)*

phenacyl sulfide. *(2)* racemizes about 200 times as rapidly as *(1)* in CH_3OH at 50 °C. The racemization is evidently due to inversion of the pyramidal compound. / J. Amer. chem. Soc. *90*, 5938 (1968) / –Kr. [Rd 945 IE]

Conformers of the 9-decalylium ion have been detected by *A. F. Boschung, M. Geisel*, and *C. A. Grob* during the solvolyses of *cis-(1)* and *trans*-9-chlorodecalin *(2)* and 4-(1-cyclohexenyl)-butyl *p*-toluenesulfonate *(3)*. The products obtained in

(1) *(2)* *(4)* *(5)*



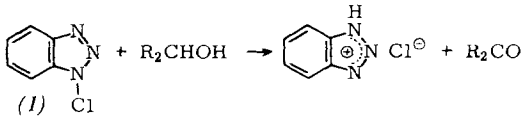
(3)

ethanol/triethylamine were as follows (in %, in the case of *(3)* based on a 55% total yield of cyclization products):

	From *(1)*	From *(2)*	From *(3)*
2,3,4,4a,5,6,7,8-Octahydronaphthalene	51	22	40.5
1,2,3,4,5,6,7,8-Octahydronaphthalene	42	78	38.5
trans-9-Decalol	5	–	6.5
cis-9-Decalol	2	–	14.5

The reaction thus does not proceed *via* a common carbonium ion. Model studies show that the replacement of the tetrahedral C-9 by a trigonal carbon would give two relatively rigid intermediates *(4)* and *(5)*, for which equilibration is slower than the formation of the products. *(3)* is thought to react *via* an intermediate similar to *(5)*. / Tetrahedron Letters *1968*, 5169 / –Kr. [Rd 944 IE]

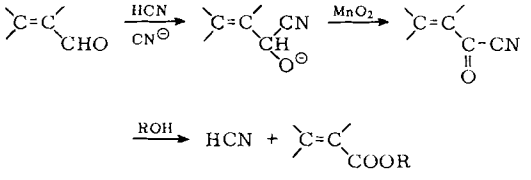
***cis-* and *trans*-2,3-Dibromocyclononene** *(1)* and *(2)* have been obtained by *D. K. Wedegaertner* and *M. J. Millam* on addition of 1 mole of bromine to 1,2-cyclononadiene in CCl_4. In the mixture of about 40% of *(1)* and about 60% of *(2)*, only the isomer *(2)* could be highly concentrated by gas chromatography. The structures were assigned on the basis of the NMR spectrum. No allyl coupling was observed; both isomers



(1)

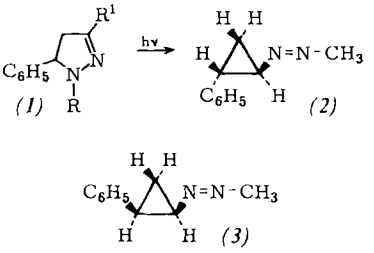
(2)

evidently prefer conformations in which the C–H bond of the methine carbon atom forms an angle close to 0 or 180 ° with the plane of the double bond. No interconversion of *(1)* and *(2)* occurs at room temperature. / J. org. Chemistry *33*, 3943 (1968) / –Kr. [Rd 946 IE]



1-Chlorobenzotriazole *(1)*, a new oxidizing agent, has been described by *C. W. Rees* and *R. C. Storr. (1)*, m.p. 105 to 106 °C, which is obtained in 90% yield by the addition of aqueous Na hypochlorite to benzotriazole in 50% acetic acid, oxidizes alcohols to aldehydes or ketones and hydrazo compounds to azo compounds. The oxidations proceed in high yields under mild conditions. The reagent is converted

(1)



into benzotriazolium chloride. *(1)* oxidizes 1-aminobenzotriazole to dehydrobenzene, while 2-aminobenzotriazole is converted into *cis, cis*-1,4-dicyano-1,3-butadiene. / Chem. Commun. *1968*, 1305 / –Ma. [Rd 948 IE]

New methods for the oxidation of aldehydes to carboxylic acids and esters have been described by *E. J. Corey, N. W. Gilman*, and *B. E. Ganem*. Active MnO_2 oxidizes conjugated unsaturated aldehydes into methyl esters of carboxylic acids in the presence of HCN, CN^-, and methanol. The reaction may be carried out *e.g.* in acetic acid at 20–25 °C in the presence of NaCN.

Examples: benzaldehyde, cinnamaldehyde, furfural, geranial, farnesal → esters > 95, > 95, > 95, 85–95, 95% yields. The reaction proceeds without *cis-trans* isomerization of the α,β double bond. Saturated aldehydes are not converted into the esters under the same conditions. AgO gives only the carboxylic acids, even from unsaturated aldehydes. / J. Amer. chem. Soc. *90*, 5616, 1968 / –Ma. [Rd 949 IE]

Photoreactions of 5-phenylpyrazolines have been studied by *H. J. Rosenkranz* and *H. Schmid*. Irradiation of *(1)*, R = CH_3, R^1 = H, in benzene with a high-pressure Hg lamp leads to the formation, *inter alia*, of *trans*- and *cis*-1-methylazo-2-phenylcyclopropane *(2)* and *(3)*, which are converted back

(1) *(2)*

(3)

into the starting compound when heated. *(1)*, R = R^1 = CH_3, similarly form *trans*- and *cis*-1-methylazo-1-methyl-2-phenylcyclopropane, while *(1)*, R = R^1 = H gives benzaldazine and cinnamaldazine, as well as the mixed aldazine. / Helv. chim. Acta *51*, 1628 (1968) / –Ma. [Rd 950 IE]

The separation of rare earths from ceramic nuclear fuels by selective iodination is proposed by *B. Amecke* and *H. L. Scherff*. The reaction of MO_2 or M_2O_3 with carbon and iodine to form tetraiodides or triiodides and carbon monoxide is thermodynamically impossible for uranium and thorium below 1500 °K, but is possible for the rare earths up to dysprosium that are formed on nuclear fission. When an intimate mixture of rare earth oxides with carbon (prepared by carbonization of a mixture of sugar and oxide) is treated with iodine transported by a current of argon, the reaction starts at 700 °C; the yield of iodide increases with rising temperature (*e.g.* to 30–45% after 14 hours at 1100 °C). Up to 77% of the rare earths could be driven off as the iodides from an oxide mixture containing 90% of UO_2 and 5% each of La_2O_3 and CeO_2, which corresponds closely to a burnt-up nuclear fuel, after a reaction time of 55 hours at 1100 °C, whereas uranium oxide does not react. The yield increases in proportion to the partial pressure of iodine between 4 and 25 torr, and more slowly at higher pressures. It may therefore be concluded that the rate-determining step is the iodide formation at low partial pressures, and the diffusion of the rare earths in the oxide mixture at higher pressures. / Radiochim. Acta *9*, 169 (1968) / –Hz. [Rd 952 IE]

BOOK REVIEWS

Advances in Free-Radical Chemistry. Volume 2. Edited by *G. H. Williams*. Academic Press-Logos Press. London-New York 1967. 1st Edit., x, 274 pp., $ 14.00.

The purpose of progress reports is to establish cross references and to provide a forum for authors engaged in various branches of a topic to expound their views. Volume 2 of "Advances in Free-Radical Chemistry" [1] meets this demand in an exemplary manner, for alonside topics of pure organic chemistry it reports comprehensively on radicals in inorganic and macromolecular chemistry.

The topic "H- and Alkyl-containing Inorganic Radicals", which was taken up in volume 1, and which is treated hardly anywhere else in the literature, is wound up by *Friswell* and *Gowenlock*. This report should stimulate a multitude of new enquiries; systematic investigation of the field is still in its infancy. An established expert in radical chemistry, *D. H. Hey*, has written a magnificant report on the well-investigated arylation of aromatic compounds. *R. A. Abramovitch* provides an excellent summary of the difficult field of intramolecular aromatic substitutions from a mechanistic viewpoint. However, important work was published after completion of the manuscript (*T. Cohen*, 1968), mechanistic conclusions are in many cases not very conclusive, and radical 1,2-aryl migrations should have been considered.

The review by *J. I. G. Cadogan* "Radical Reactions of Phosphorus Compounds" also indicates large areas of little-explored ground and permits a first systematic assessment of the topic. The article by *A. D. Jenkins*, "The Reactivity of Polymer Radicals", is of fundamental importance. The quantitative interpretaion of the reactivity of polymeric radicals complements, and is even superior to, the corresponding theories of low-molecular chemistry concerning polar effects and the significance of radical stability for reactivity.

The editor is to be congratulated on the choice of topics; the quality of presentation is in keeping with that of volume 1.

An Introduction to the Chemistry and Biochemistry of Fatty Acids and Their Glycerides. Edited by *F. D. Gunstone*. Chapman and Hall Ltd., London 1967. 2nd Edit., 209 pp., numerous formulas and tables, bound 63s.

The author, a student of *T. P. Hilditch*, presents the book [1] only as an introduction to the field of fatty acids. He does, however, list the representatives of this class of substances virtually completely, and discusses methods for their isolation and structure analyses with almost the same thoroughness. Long chapters are devoted to the physical and especially the chemical properties of fatty acids and their esters. The treatment is at a higher than introductory level, with many literature references to original work.

On the other hand, the chapters on the "Naturally occurring fatty acid derivatives" and on "Biosynthesis and metabolism" are presented remarkably briefly, and provide only inadequate information for the reader. Reference is made, however, to review articles, by means of which the original literature can be consulted. The literature appendix is very valuable, referring the reader both to scientific journals and to monographs. Summing up, it can be said that the book should prove very valuable to readers interested in the special problems of fatty acids. *H. Debuch* [NB 762 IE]

Dictionary of Organic Compounds, Third Supplement. By *R. Stevens*. Eyre and Spottiswoode, London, 1967, 4th Edit., 280 pp., cloth £ 10.00.

The fourth edition of the "Dictionary of Organic Compounds" was published in five volumes in 1965. To keep the work up to date, a supplement covering the recent literature and correcting errors and omissions found in earlier volumes is published every year. The entries in the third supplement, which has now appeared, refer mainly to articles published in 1966. The arrangement of the entries follows the scheme used in the main work. Additions and supplementary data relating to key words that appeared in the main work are indicated by an asterisk. A pleasing feature is the inclusion of many, carefully printed structural formulas, which always show the stereochemistry if this is known. Where practicable, the names formed according to the rules of systematic nomenclature are given for the substances listed. The entries also include the principal physicochemical properties as well as references, mainly to preparative work, but also to articles dealing with spectral data, structural investigations, isotopically labeled derivatives, *etc.* The annual supplement makes the "Dictionary of Organic Compounds" a useful addition to the organic chemist's library, and one that will always be up to date.

H. Grünewald [NB 772 IE]

The Neurosciences. A Study Program Planned and Edited by *G. C. Quarton, T. Melnechuk,* and *F. O. Schmitt*. The Rockefeller University Press, New York, 1967. 1 Edit., xx, 962 pp., numerous illustration and tables, $ 18.00.

"The human brain and the behavior correlated with its development, structure and function present a problem that is both the most complex to which man can address himself through the use of scientific methods and the most urgent from the human viewpoint". This statement taken from the foreword to the present volume, explains the foundation in 1962 of a "Neurosciences Research Program" by a group of scientists at the Massachusetts Institute of Technology. The new organization is an international and interuniversity body whose members are all indirectly or directly engaged in the study of the central nervous system and associated fields. Shortly after the foundation of the Program it was decided to hold a four-week symposium. This eventually took place at the University of Colorado in July 1966, and provided the first broad picture of contemporary knowledge of the human brain.

The 65 main papers presented at this symposium form the subject of the book under review (one paper is actually omitted, but two additional chapters are provided). This fact on its own would not justify consideration of the book in the present journal. The work is important to us because the lectures, both in their original and in their revised form, are addressed principally not to specialists, who would in any case be largely acquainted with the material, but to scientists working in neighboring disciplines.

The volume is divided into seven sections: Components of the nervous system, molecular biology (with a splendid introduction by *A. L. Lehninger*), molecular biology of brain cells, neuronal physiology, brain correlates of functional behavioral states, brain correlates of learning, interdisciplinary topics. Each section begins with an introduction which outlines the subject and places it in the context of what is already known. This is followed by the individual contributions on special problems within the subjects in question. Each paper is provided with a bibliography, thus offering an initial review of the literature. Anyone interested in the study of the central nervous system, whether he is a chemist, biologist, physicist, or psychologist, will find in this book a very useful introduction, well written and excellently edited by specialists in the field. *H. Grünewald* [NB 764 IE]

Handbook of Chemistry and Physics. By *R. C. Weast* and *S. M. Selby*. The Chemical Rubber Co., Cleveland, 1967, 48th Edit., xxvi, 1920 pp., $ 20.50.

This handbook of approximately 2000 pages has appeared annually in a new edition [1] since the end of the war (with only three exceptions), which gave it a chance of being improved and supplemented every year. It can therefore be claimed, without danger of exaggeration, that we have here the most up to date handbook of its kind. Despite its title, it offers 267 pages of mathematical tables, 1200 pages of chemical tables, 189 pages of physical tables, and 264 pages of various other tables divided more or less equally between chemistry and physics. Chemistry therefore takes up by far the greater part, if only because of the inclusion of a table of the properties of organic compounds which lists more than 13500 substances. The present, 48th edition of this work again contains several new tables among which may be mentioned a survey of the ^{1}H-NMR signals of organic structures, numerous charts of the characteristic frequencies of organic and inorganic compounds over the whole range of IR and several tables of purely chemical content. At least ten tables have been revised or supplemented.

The formulas in the large organic table are as deplorable as ever. It is really too much to except that it should be necessary to study 17 1/2 printed pages of instructions before one knows what name a particular compound may be found under in the table; fortunately, there is a formula index for the same table. The editors of this handbook should think of a solution as soon as possible which would do away with the instructions and make the contents of the table more easily accessible, perhaps by anarrangement of the formula index in such a way that the empirical formula carries not only the number of the entry but also its name, which would save a lot of unnecessary searching. As before, it is urgently desirable to carry out a thorough search through the physicochemical tables, with respect to the dimensions. It is really intolerable to find "Kg. calories", Kcal", "Kilo-cals", "Cal." and such like next to one another. It is also unnecessary that a table which contains values for ΔH_f°, ΔF_f°, $\log K_f$ and S° should have a footnote to say that "all values are expressed.

[1] Cf. Angew. Chem. *71*, 144 (1959).

[1] Cf. Angew. Chem. *78*, 912 (1966); Angew. Chem. internat. Edit. *7*, 907 (1966).

as kilo-cals per gram mole", since this footnote is simply wrong. At the same time, these objections concern superficialities, which do not detract from the reliability topicality, and breadth of the information packed in this handbook.

The Merck Index. An Encyclopedia of Chemicals and Drugs. Published by Merck & Co., Inc. Rahway, N.J./U.S.A. 8th Edit. 1968, 1728 pages, bound $ 15.00.

A new edition of the Merck Index, the eighth since it first appeared in 1889, was published a few months ago. For those who do not know this extremely useful and reliable encyclopedia, it should immediately be pointed out that it is not a list of products marketed by the American Merck Company. In addition to a 1133 page encyclopedic index of chemicals and drugs, it devotes almost 100 pages to the description of 460 name reactions, and contains a further 40 tables that are of importance to chemists in general and particularly to those employed in the drug industry.

The central part of the book is the encyclopedic section, which is, not inappropriately, headed "Monographs", and which contains entries for more than 9500 chemicals and drugs. The entries usually begin with the trivial names of the substance in question, and then list all other systematic and non-systematic names, the Chemical Abstracts nomenclature being indicated by the use of bold-face italics. The empirical formula, molecular weight, and percentage composition by elements are followed (with literature references) by data on occurrence, isolation, structural elucidation, synthesis, and the principal physical properties of the compound and of some important derivatives; information on medical use and toxicity is also given in more than 4800 cases. Structural formulas are naturally also included (almost 5000 are given altogether), and special mention should be made here of the clearly legible type.

The reviewer knows the Merck Index from years of almost daily use. A regrettable feature of earlier editions was the absence of a formula index to the encyclopedic section. This omission has now been rectified, since the eighth edition contains a formula index, as well as the comprehensive (42000 entries) cross index of names.

For those who already know the Merck Index, nothing more need be said. To those who do not yet know it, this volume must be recommended as a worthwhile addition to their library.

H. Grünewald [NB 766 IE]

Taschenbuch für Chemiker und Physiker (Handbook of Chemistry and Physics). (D'Ans/Lax), Vol. 1: Makroskopische physikalisch-chemische Eigenschaften (Macroscopic physicochemical properties). Edited by *E. Lax*, in collaboration with *C. Synowietz*. Springer-Verlag, Berlin-Heidelberg-New York, 1967. 3rd and completely revised edition, xvi, 1522 pp., bound DM 68.00 / US $ 17.00.

The familiar "D'Ans-Lax", which now appears in its third edition, is no longer in a single handbook, but is in three volumes, volume 1 of which is now ready, after the publication of volume 2 in 1964. While volume 2 contains all the data on organic compounds that are important to chemists, volume 1 is devoted to the tabulation of macroscopic physicochemical properties. (Volume 3, still in preparation, is apparently mainly for the use of physicists.)

The first volume of this work is divided into seven chapters. Chapter 1 gives a survey of systems of measurement, units and standard dimensions for macroscopic properties, and atomic quantities. Here the user will find the symbols employed further on. The second chapter contains tables in which the various macroscopic properties of the same substance are presented, the emphasis being laid on the mechanical properties. This is followed by tables of thermomechanical properties and equilibria of homogeneous (chapter 3) and heterogeneous (chapter 4) systems. Interfacial properties form the content of chapter 5, while the thermodynamic properties of elements and compounds as a function of temperature, pressure, and composition are dealt with in chapter 6. Finally, chapter 7 gives data on viscosity, diffusion, thermal conductivity, and kinetics of chemical systems.

Within a little over 1500 pages in octavo format, this volume offers all the desired information on each subject. It does so in a clearly understandable fashion that can only be called exemplary. The units are given for every measured value, and for each symbol included in tables or equations the user finds an explanation without a long search. It would be pleasant if the example set by this volume were taken as a model for tabular representations, of whatever kind and wherever printed.

Reallexikon der Medizin und ihrer Grenzgebiete. (Practical Dictionary of Medicine and Related Subjects.) Vol. 1: A-Carfimatum. Edited by *G. Thiele* and *H. Walter*. Urban & Schwarzenberg, Munich-Berlin-Vienna 1967. 1st Edit., xix + 799 pp., loose-leaf binding with plastic cover, DM 140.–.

Urban & Schwarzenberg, whom the chemist associates with "Ullmanns Enzyclopädie der Technischen Chemie", have now embarked on the publication of a practical dictionary of medicine estimated to run to about 4800 pages and more than 200000 entries. The editors in chief are *G. Thiele* and *H. Walter*, the imposing list of external collaborators numbers almost 300 names, and in view of the publisher's lexicographic tradition the work is anticipated with big expectations.

The first instalments are now available and already provide an indication of the essential features of the lexicon. Further volumes are to follow at annual intervals, and the overall work will be a six-volume loose-leaf collection in conveniently used and very robust folders. The advantage of this arrangement is that it is possible at any time to insert addenda and revisions and to keep the work up to date without having to produce a whole new edition. As regards the contents, the editors do not wish to restrict medicine to therapeutics in the strict sense, but aim at extending the framework to include all adjoining fields of importance for medical practice and teaching (an accompanying brochure names 22!). Here, the work becomes interesting to the biochemist, particularly the worker engaged in clinical or physiological chemistry. It will not serve him as an exhaustive source of information on problems within his own specialized field, but he can hope to obtain reliable information about subjects at the fringe of related fields.

To review this book as a chemist one turns perforce to those entries that concern one's own subject in the knowledge that this cannot lead to a valid view of the whole. This approach results in the pleasant feeling of finding the information reliable. Understandably, this dictionary is tailored to the needs of the medical man, *i.e.* it is less concerned with material properties of interest to the chemist than with providing data about the biological action, metabolic properties, medicinal uses, and side effects. For this reason structural formulas have generally been omitted, although some are in fact given.

By contrast, the terminology used for the chemical compounds seems unfortunate to the reviewer. The statement, in the notes on the use of the dictionary, that "Drugs and chemical substances are where possible listed under the keywords used in the official pharmacopeia" is ominous, and this forecast is indeed borne out. Under "Acetat" the reader is referred to "Azetat", acetic acid is listed under Acidum aceticum, boron trioxide under Acidum boricum anhydric-

um (!) and of course oxalic acid under Acidum oxalicum. At the same time, Acidum oxalaceticum is dealt with under oxalacetic acid and Acidium propionicum under propionic acid. Acetyl compounds receive similar treatment in that they are all to be found under "Azetyl". However, another entry is "Azetyl-Coenzym A", which more justly and "traditionally" should be "A.-Koenzym A". This procedure becomes quite incomprehensible when one arrives at "Argininosukzinat" next to "Biocytin", followed by "zytostatisch". The reviewer is baffled why confusion has been the aim in precisely the field of chemistry that is in any case a difficult one for the medical man to master, instead of an attempt to clarify this topic.

This calamity apart, the care used and effort made by the editors to collate what is most important and most worthwhile from the mass of the medical literature and to arrange it in an attractive and clear manner are quite admirable. There is no doubt that this dictionary will be numbered among the most important new publications.

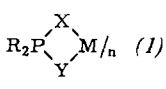
Metal Complexes of Thiophosphinic and Selenophosphinic Acids



By W. Kuchen and H. Hertel[*]

The anions of thiophosphinic and selenophosphinic acids $R_2P(X)YH$ (X = S, Se; Y = O, S, Se) can act as bidentate ligands. They combine with many metals to form complexes containing a four-membered chelate ring, or to give coordination polymers in which they form ligand bridges. The preparation, properties, and reactions of these compounds, as well as the dielectric properties and analytical use of dithiophosphinato complexes, which are also of industrial interest, are described. Some thiophosphinato and selenophosphinato complexes exhibit concentration-dependent association via ligand bridges. Evidence of the chelate nature of the ligands $R_2P(X)Y^{\ominus}$ was obtained from IR spectroscopic studies. The ligand field parameters of the anion $(C_2H_5)_2P(S)S^{\ominus}$ were deduced from the electronic spectra of octahedral diethyldithiophosphinato complexes, and the position of the ligand in the spectrochemical and nephelauxetic series were determined from these parameters.

1. Introduction

Phosphinic acids $R_2P(O)OH$ differ formally from orthophosphoric acid in that two OH groups have been replaced by alkyl or aryl groups. Partial or complete replacement of the two remaining oxygen atoms by sulfur and/or selenium yields acids having the general formula $R_2P(X)YH$ (X = S, Se; Y = O, S, Se).

The anions of these acids can act as bidentate ligands. They combine with many metals to form chelates, *e.g.* of the type *(1)*, or coordination polymers in which

(1)

they function as ligand bridges. These compounds are reviewed in the present article; the dithiophosphinato complexes are discussed first, since they have been most extensively studied.

2. Complexes of the Dithiophosphinic Acids $R_2P(S)SH$

2.1. Methods of Preparation

On reaction of Grignard reagents with P_4S_{10}, *Malatesta* and *Pizzotti*[1,2] obtained a complex reaction mixture from which they were able to separate small quantities of dithiophosphinic acids *via* their Ni^{II} and Cd^{II} salts, which dissolve very readily in organic solvents.

The best method for the preparation of dithiophosphinato complexes is from the alkali metal or ammonium salts[3], according to eq. (1)[1,2,4–13], or

$$n\,R_2P(S)S^{\ominus} + M^{n\oplus} \rightarrow [R_2P(S)S]_nM \quad (1)$$

from the free acids [3] and metal compounds, *e.g.* the oxides (or carbonates), as shown in eq. (2) [10, 25]

$$2\,R_2P(S)SH + MO \rightarrow [R_2P(S)S]_2M + H_2O \quad (2)$$

The method of eq. (2) has proved particularly useful for aromatic dithiophosphinic acids, which can be readily obtained *e.g.* by reaction of aromatic hydrocarbons with P_4S_{10} in the presence of $AlCl_3$ [3]. To prepare the complexes, the dithiophosphinic acids are then allowed to react either *in situ* [14] or after isolation in an organic solvent with the oxide or carbonate of the metal [15].

In the method of eq. (1) the dithiophosphinato complexes are precipitated by addition of the complexing agent to an aqueous solution of a salt of the metal. In some cases, however, it is preferable to reflux a suspension of the complexing agent and a metal halide in an organic solvent and to isolate the resulting complex from the solution after the sodium halide has been filtered off. This procedure is useful when the metal halide is extensively hydrolyzed in aqueous solution (*e.g.* $AsCl_3$, $SbCl_3$, R_2SnCl_2) or when the hydrated cation (*e.g.* $Cr^{III} \cdot aq$) cannot form complexes with dithiophosphinic acids [10].

Another variant of the method is the use of the thallium(I) complex of the dithiophosphinic acid instead of the alkali metal salt, this complex being allowed to react with the metal halide in organic solvents such as chloroform, dioxane, or isopropanol [16], *e.g.* according to:

$$2\,R_2P(S)STl + MX_2 \rightarrow [R_2P(S)S]_2M + 2\,TlX \quad (3)$$

The thallium(I) complexes are soluble in more organic solvents than the anhydrous sodium dithiophosphinates, which are also strongly hygroscopic. This variant is therefore preferred when it is desirable to carry out the reaction in the complete absence of water.

Dithiophosphinato complexes have also been prepared by direct reaction of tetraorganodiphosphine disulfides with metals and sulfur or with metal sulfides and sulfur.

Thus bis(dipropyldithiophosphinato)zinc(II) was obtained in a yield of about 35%, together with other products, on zinc dust distillation of tetrapropyldiphosphine disulfide. On the other hand, if the disulfides are allowed to react with metal powder and sulfur in the stoichiometric ratio in accordance with eq. (4)

$$R_2P(S)-P(S)R_2 + M + {}^2/_8\,S_8 \rightarrow [R_2P(S)S]_2M \quad (4)$$

$R = C_2H_5, C_3H_7, C_4H_9, C_5H_{11}$; M = Zn, Cd, Hg, *etc.*

the yields can be increased to 70–90%. Reaction of tetraorganodiphosphine disulfides with metal sulfides and sulfur for 3 hours at 200 °C yields bis(dialkyldithiophosphinato) complexes in yields of up to 84% [5, 10, 17] (eq. (5)).

$$R_2P(S)-P(S)R_2 + MS + {}^1/_8\,S_8 \rightarrow [R_2P(S)S]_2M \quad (5)$$

$R = C_2H_5, C_3H_7$; M = Zn, Cd

2.2. Properties and Reactions

Many complexes $[R_2P(S)S]_nM$, *e.g.* with $M = Al^{III}$, In^{III}, Tl^{I}, Pb^{II}, As^{III}, Sb^{III}, Bi^{III}, Cr^{III}, Fe^{III}, Co^{II}, Co^{III}, Ni^{II}, Zn^{II}, Cd^{II}, and Hg^{II} and $R = CH_3$, C_2H_5, C_3H_7, C_4H_9, C_5H_{11}, C_8H_{17}, $C_{12}H_{25}$, and C_6H_5, have been prepared by one or more of the above methods [1, 2, 5–17, 25]. Some other complexes are listed in Table 1.

Table 1. Complexes $[(C_2H_5)_2P(S)S]_nM$ of the platinum metals [18].

M	Color	M.p. (°C)	μ_{eff} (B.M.)
Ru^{III}	black	135–136	1.93 (294 °K)
Rh^{III}	dark brown	141–142	diamagnetic
Ir^{III}	brown	146–147	diamagnetic
Pd^{II}	dark red	137–138	diamagnetic
Pt^{II}	orange-red	144–145	diamagnetic

These complexes all crystallize well. Some of them are deeply colored, and most melt sharply without decomposing. They can often be kept for months in sealed tubes.

Bis(diethyldithiophosphinato)zinc(II) and bis(dipropyldithiophosphinato)zinc(II) are so stable thermally that they can be distilled without much decomposition even at 250–300 °C.

The complexes of dithiophosphinic acids are not wetted by water, though the Ni^{II} and Co^{II} complexes gradually dissolve. They are not affected by dilute non-oxidizing acids even when heated; on the other hand, most of them dissolve in dilute alkali when shaken vigorously. Some of the compounds, *e.g.* the zinc, cadmium, and bismuth complexes, can be reprecipitated from these solutions by acidification.

Special mention should be made of the ready solubility of dialkyldithiophosphinato complexes in organic solvents, particularly aromatic and chlorinated hydrocarbons. The complexes of aromatic dithiophosphinic acids, on the other hand, are generally less soluble.

Molecular weight determinations show that the Zn^{II} Cd^{II}, and Hg^{II} complexes of some dialkyldithiophosphinic acids exhibit concentration-dependent association in these solvents (cf. Section 4).

The nature of the Tl^{I} compounds has not yet been established. Owing to their low solubility, molecular weight determinations are possible only over a narrow concentration range, but the results obtained do show that $R_2P(S)STl$ ($R = C_2H_5$, C_6H_5) are slightly associated in benzene and chloroform [19]. It does not therefore seem justifiable to formulate these

[19] *W. Kuchen* and *H. Mayatepek*, unpublished.

compounds as salts $Tl^{\oplus}R_2P(S)S^{\ominus}$, particularly since they are non-electrolytes in dimethylformamide [16].

The strongly covalent behavior and the non-electrolyte character observed in a series of complexes $[R_2P(X)Y]_nM$ suggest that they should be formulated as chelates *(1)*. On the basis of their stoichiometry and their molecular weight, a formula in which the metal has its characteristic coordination number can be given only if the ligand is assumed to be bidentate. This characteristic coordination state can be deduced for some metal complexes from magnetic measurements and the electronic spectra [13]. The IR spectra also provide evidence that both donor atoms are involved in coordinate bonding, and hence that the complexes are chelates (cf. Section 5).

Reaction of some of these dithiophosphinato complexes with Lewis bases leads to the formation of adducts, with an increase in the coordination number of the metal. Thus the tetrahedral bis(diethyldithiophosphinato)cobalt(II) reacts with pyridine and with gaseous ammonia to give the octahedral complexes $[(C_2H_5)_2P(S)S]_2CoPy_2$ and $[Co(NH_3)_6][(C_2H_5)_2P(S)S]_2$. Similar complexes are formed by the planar bis(diethyldithiophosphinato)nickel(II) which also gives bis(diethyldithiophosphinato)dithiophenonickel(II) with thiophene. These adducts are unstable, and very readily lose the additional ligands with regeneration of the original complex [13].

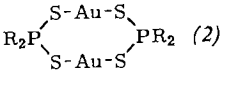
Cu^{I} and Au^{I} react with dithiophosphinate in accordance with eq. (1) to form oligomeric complexes $[R_2P(S)SM]_n$ (n = 4 or 2); such compounds are also obtained with Cu^{II} and Au^{III}. The reduction of the metal ions to the oxidation state +1 is accompanied by oxidation of the anions $R_2P(S)S^{\ominus}$ to bis(diorganothiophosphoryl)sulfanes $R_2P(S)-S_n-P(S)R_2$ (n = 1, 2, 3) [20]. Thus colorless diamagnetic tetrakis[dialkyldithiophosphinatocopper(I)] complexes, which are only sparingly soluble in organic solvents, are formed as follows

$$8\ R_2PS_2^{\ominus} + 4\ Cu^{2\oplus} \rightarrow [R_2PS_2Cu]_4 + 2\ R_2P(S)-S_2-P(S)R_2 \quad (6)$$

R = C_2H_5, decomp. *ca.* 290 °C
R = C_3H_7, decomp. *ca.* 240 °C

The degree of association was determined, within the concentration range suitable for investigation, by osmometric molecular weight determinations in benzene and chloroform. Bis(dialkyldithiophosphoryl)-disulfanes were detected as oxidation products. On the other hand, it has not yet been possible to determine the molecular weight of the corresponding phenyl compound (which decomposes at about 275 °C) because of its low solubility. It seems reasonable to assume that the tetramers have a structure similar to that of $[(C_2H_5)_3AsCuI]_4$.

In the latter compound four Cu atoms are arranged in the form of a tetrahedron, and each of these atoms is tetrahedrally surrounded by three iodine atoms and an arsine molecule. The halogen bridges connect the Cu atoms in groups of three [21]. In the present case, therefore, one of the two sulfur atoms of each chelate ligand would be coordinately bonded to three Cu atoms, taking the place of an iodine atom, while the other sulfur atom would take the place of the arsine molecule.



Attempts to achieve coordinative saturation with strong Lewis bases and hence to degrade the polymer structure have so far been successful only with triphenylphosphine, which gives the adduct bis(triphenylphosphine)diethyldithiophosphinatocopper(I), m.p. 184–186 °C (decomp.) [20] (186 °C [22]), as follows:

$$[(C_2H_5)_2P(S)SCu]_4 + 8\ P(C_6H_5)_3 \rightarrow 4\ (C_2H_5)_2P(S)SCu \cdot 2\ P(C_6H_5)_3 \quad (7)$$

Though the tetramers dissolve in pyridine or tertiary amines when heated, they crystallize unchanged from these solvents on cooling. In the course of several days, however, deep blue needles gradually separate from the colorless solutions of the tetrameric complexes in pyridine in the presence of air and moisture. These crystals are insoluble in the common organic solvents. Their composition corresponds to the formula $R_2P(S)S\cdot Cu(OH)\cdot Py_4$ (R = C_2H_5: m.p. 223–225 °C, μ_{eff} = 1.85 B.M. (296 °K); R = C_3H_7: m.p. 173–175 °C; R = C_6H_5: m.p. 220–221 °C). Their IR spectra all contain an absorption at 3000–3500 cm^{-1} such as is found for hydroxo complexes of copper [23, 24].

Reduction of $Au^{3\oplus}$ with dithiophosphinate leads, in accordance with eq. (8), to bis[diorganodithiophosphinatogold(I)], for which a cyclic structure *(2)* containing ligand bridges is proposed. (The molecular

$$6\ R_2P(S)S^{\ominus} + 2\ Au^{3\oplus} \rightarrow [R_2P(S)SAu]_2 + 2\ R_2P(S)-S-S-P(S)R_2 \quad (8)$$

(2)

R = C_2H_5: m.p. 153 °C; R = C_3H_7: m.p. 175 °C; R = C_6H_5: decomp. *ca.* 297 °C, colorless needles (from ligroin).

weight of the phenyl complex could not be determined with sufficient accuracy because of its low solubility.) The oxidation products isolated after reaction of the propyl and phenyl compounds according to eq. (8) were bis(diorganothiophosphoryl)disulfanes $R_2P(S)S_2P(S)R_2$, whereas the ethyl compound gave bis(diethylthiophosphoryl)monosulfane $(C_2H_5)_2P(S)-S-P(S)(C_2H_5)_2$ and bis(diethylthiophosphoryl)trisulfane $(C_2H_5)_2P(S)-S_3-P(S)(C_2H_5)_2$, presumably the dismutation products of initially formed disulfane [20].

The ions $R_2P(S)S^{\ominus}$ thus once again behave as strongly reducing ligands, which are evidently not very well suited for the stabilization of higher oxidation states of the metal in complexes of the type $[R_2P(S)S]_nM$, since even $[(C_2H_5)_2P(S)S]_3Co$ decomposes rapidly to give the trisulfane $(C_2H_5)_2P(S)-S_3-P(S)(C_2H_5)_2$ and the corresponding Co^{II} complex, and $[(C_2H_5)_2P(S)S]_3Fe$ is also unstable [13].

[24] *E. Uhlig*, *B. Borek*, and *H. Glänzer*, Z. anorg. allg. Chem. *348*, 189 (1966).

The dimeric gold(I) complexes behave in the same way as the tetrameric Cu^I complexes toward Lewis bases. Whereas they crystallize out unchanged from their solutions in pyridine, they react with triphenylphosphine to give *e.g.* bis(triphenylphosphine)dipropyldithiophosphinatogold(I) $(C_3H_7)_2P(S)SAu \cdot 2\,P(C_6H_5)_3$, m.p. 101 °C [20].

The reaction of Ag^I ions with dithiophosphinate yields complexes having the composition R_2PS_2Ag ($R = C_2H_5$ [4]: dec. approx. 262 °C; $R = C_3H_7$: dec. 285–287 °C; $R = C_4H_9$: dec. approx. 122 °C), which are very sparingly soluble in organic solvents, but separate out from large quantities of hot toluene or chloroform as colorless, matted needles, and darken in daylight within a few hours. Owing to the very low solubility of these compounds, molecular weight determinations have not yet been possible. However, the substances are probably again oligomers and polymers, in which the metal is coordinated either linearly or tetrahedrally by sulfur. A chain structure with ligand bridges $[\ldots Ag{-}S{-}PR_2{-}S{-}]_n$ would be expected in the first case and a structure similar to that of the compounds $[(CH_3)_3AsMI]_4$ ($M = Cu^I, Ag^I$ [21]) in the second. X-ray studies have shown that $[R_2P(S)SCu]_4$ and $[R_2P(S)SAg]_n$ are not isomorphous [20].

The reaction of dimethyldithiophosphinic acid with the trimethyl derivatives of aluminum, gallium, and indium according to eq. (9) yields organometal dithiophosphinates, which are sensitive to air and to moisture.

$$(CH_3)_2P(S)SH + (CH_3)_3M \rightarrow (CH_3)_2P(S)SM(CH_3)_2 + CH_4 \qquad (9)$$

These compounds are monomeric in benzene, and are coordinately saturated [25] since they do not react with triethylamine.

Whereas $Tl(NO_3)_3$ is reduced to thallium(I) by diethyl dithiophosphinate [20]

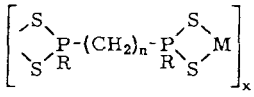
$$Tl^{3\oplus} + 3\,(C_2H_5)_2P(S)S^{\ominus} \rightarrow (C_2H_5)_2P(S)STl + (C_2H_5)_2P(S){-}S{-}S{-}P(S)(C_2H_5)_2 \qquad (10)$$

diorganothallium(III) halides R_2TlX are converted under similar conditions into the compounds $R_2P(S)STlR'_2$ ($R' = CH_3, C_6H_5$; $R = C_2H_5, C_6H_5$ [22]).

The reaction of tin(IV) halides with sodium dithiophosphinate yields dihalogenobis(dithiophosphinato)-tin(IV) [12, 22].

$$SnX_4 + 2\,R_2P(S)SNa \rightarrow [R_2P(S)S]_2SnX_2 + 2\,NaX \qquad (11)$$

$R = C_2H_5, C_6H_5$; $X = Cl, Br$



Similarly, the corresponding diorganobis(dithiophosphinato)tin(IV) complexes $[R_2P(S)S]_2SnR'_2$ are obtained from the corresponding diorganotin dihalides R'_2SnX_2 [12, 22] ($R' = CH_3, C_2H_5, C_4H_9, C_6H_5$; $R = C_2H_5, C_6H_5$) [22].

[25] *G. E. Coates* and *R. N. Mukherjee*, J. chem. Soc. (London) *1964*, 1295.

The compounds $[R_2P(S)S]_2SnR'_2$ are soluble in organic solvents, and are monomeric in benzene and in chloroform. Their stoichiometric composition suggests that the dithiophosphinato moiety again acts as a bidentate ligand, since only then does tin achieve a coordination number of six in the monomeric complexes. This is also true of the dihalogeno compounds $[R_2P(S)S]_2SnX_2$, which are non-electrolytes in dimethylformamide and nitrobenzene.

A report that bis(diethyldithiophosphinato)dichlorotin(IV) $[(C_2H_5)_2P(S)S]_2SnCl_2$ is associated [22] could not be confirmed. In agreement with earlier cryoscopic results [12], osmometric measurements in chloroform (37 °C) and in benzene (60 °C) gave molecular weight values of 504 ± 6 and 509 ± 11 respectively (averages of seven determinations each in the concentration ranges 2.858–8.446 g/l and 2.238 to 6.038 g/l), while the value calculated for the monomer is 496.1. The measurements were carried out on two samples that had been prepared exactly in accordance with the procedure given in ref. [12], and which melted at 171–172 °C (decomp.) after repeated crystallization from anhydrous toluene [19].

Finally, it should be mentioned that complexes of the type *(3)* have also been described; owing to their

(3)

M = Ni, Co; R = C_6H_5, cyclohexyl; $n = 4,5$

insolubility in organic solvents, these compounds were formulated as polymers [26, 27].

2.3. Dipole Moments

Chelates often have appreciable dipole moments, though according to the nature and steric arrangement of the ligands there should be no resultant moment.

This phenomenon, which has been studied particularly in 2,4-pentanedionatometal complexes (metal acetoacetonates), is attributed to an abnormally high atomic polarization [28, 29]. This is probably due to bending vibrations excited in the chelate rings by the alternating electric field, with deformation of molecules that are non-polar in the absence of a field [30].

It can be seen from Table 2 that dipole moments of about 1.3–2.6 D are also found for dithiophosphinato complexes [12].

This dipole moment is again probably not permanent, as is demonstrably the case in pentanedionato complexes. In the absence of an orienting polarization P_{Or}, the atomic polarization P_{At} is found from

$$P = P_{Or} + P_{At} + P_E \qquad (12)$$

[26] *K. Issleib* and *G. Döll*, Chem. Ber. *94*, 2644 (1961).

C_4H_9	3.22					

[a] 1.66 D (benzene, 20 °C) [31].

to be $P-P_E$. Table 2 shows that the atomic polarizations found from this expression for the dithiophosphinato complexes, like those in the pentanedionato compounds, correspond to 30–70% of the measured electronic polarization P_E.

The dipole moments found for the compounds $[(C_2H_5)_2P(S)S]_2SnX_2$ (X = Cl, C_6H_5, C_4H_9) (Table 2) suggest a *cis* configuration for the substituents in the octahedral complexes. Even if allowance is made for an atomic polarization of 70% of the electronic polarization for the dichloro complex:

$$P_{Or} = P-P_E-P_{At} = 1118.5\ cm^3 \qquad (13)$$

the moment is still 7.3 D, a value of an order of magnitude such as would be expected for the *cis* form. Though corresponding calculations have not been carried out for the two diorgano compounds, it seems reasonable to assume that these two complexes, in analogy with the dichloro compounds and in agreement with the appreciable dipole moments found for them, are *cis* forms [12].

2.4. Analytical Applications [32]

The suitability of the complexing agent sodium diethyldithiophosphinate for the solvent extraction and photometric determination of metals as diethyldithiophosphinato complexes has been studied for a number of examples.

For instance Cd^{II} and Hg^{II} can be quantitatively extracted as their diethyldithiophosphinato complexes from neutral or weakly acidic solutions (pH = 6–7) with carbon tetrachloride and determined photometrically, as can Pb^{II} and Bi^{III} even from very strongly acidic solutions. On the other hand, Ni^{II}, Co^{II}, Cr^{III}, Zn^{II}, Mg^{II}, and other metals can be extracted only very incompletely or not at all from the aqueous phase. This difference in behavior has been utilized for the separation and determination of the components *e.g.* of the systems Bi^{III}/Mg^{II}, Pb^{II}/Zn^{II}, Bi^{III}/Ni^{II}, and Bi^{III}/Zn^{II}. For practical analytical work, the alkali metal dithiophosphinates should have the advantage over dithiophosphates and carbamates that they are more stable in strongly acidic, non-oxidizing media. Sodium diethyldithiophosphinate remains practically unchanged for weeks even in 15 N H_2SO_4. In the presence of nitrate, however, appreciable decomposition occurs within a few hours, depending on the acidity and the nitrate content of the solution.

2.5. Industrial Use

Several patents describe suggested industrial uses of dithiophosphinato complexes, which can be used *e.g.* as vulcanization accelerators [17], as oil additives [8,9, 14,15,17,33], as stabilizers for polyolefin molding compositions [11], and, because of their outstanding color- and light-fastness, as coloring additives for plastics [34].

3. Complexes of Other Thiophosphinic and Selenophosphinic Acids

In contrast with data on the metal complexes of dithiophosphinic acids, published information on corresponding compounds of the other thiophosphinic and selenophosphinic acids is sparse, and refers mainly to the complexes of the diethyl compounds.

The complexes listed in Table 4 were prepared by methods corresponding to equation (1) and/or (2). The complexing agents used are listed in Table 3.

Table 3. Complexing agents of the type $(C_2H_5)_2P(X)YNa \cdot nH_2O$.

	M.p. (°C)	Ref.
$(C_2H_5)_2P(S)ONa \cdot 3\ H_2O$	58–59	[35a, 35b]
$(C_2H_5)_2P(Se)ONa \cdot 4\ H_2O$	50	[36]
$(C_2H_5)_2P(Se)SNa \cdot 2\ H_2O$	124–125	[37a, 37b]
$(C_2H_5)_2P(Se)SeNa \cdot 2\ H_2O$	129–130	[37b, 37c]

These sodium salts (Table 3) are obtained by neutralization of the corresponding acids or in accordance with eq. (14) in the form of readily crystallizing, color-

$$(C_2H_5)_2P(Se)Cl \xrightarrow{2\ NaSH} (C_2H_5)_2P(Se)SNa + NaCl + H_2S \qquad (14a)$$

$$(C_2H_5)_2P(Se)Cl \xrightarrow{2\ NaSeH} (C_2H_5)_2P(Se)SeNa + NaCl + H_2Se \qquad (14b)$$

less hydrates. The complexing agents containing selenium are relatively unstable, and decompose after a time with separation of elemental selenium.

	Cd^{II}	colorless	158	[37c]
	Ni^{II}	black-green	135	[38]
	Pd^{II}	dark red	196–197	[37c]
	Pb^{II}	yellow	157–158	[37c]
	Tl^{I}	pale yellow	129	[37c]
	Rh^{III}	brown-red	188–189	[39]
	In^{III}	yellow	146	[37c]
	Bi^{III}	vermilion	132	[37c]

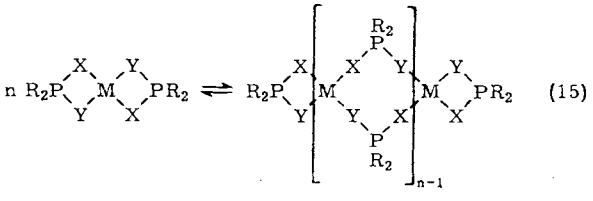
All these compounds are readily soluble in organic solvents. The diethylthiophosphinato complexes, apart from the In^{III} compound, exhibit concentration-dependent association in solution (cf. Section 4). The same is found, though to a very much smaller degree, in the Zn^{II} and Cd^{II} complexes of the acids $(C_2H_5)_2P(S)SeH$ and $(C_2H_5)_2P(Se)SeH$. The compounds containing selenium decompose, particularly in daylight, with darkening of their color within days or weeks, depending on the metal. On the whole, they are thermally less stable than the corresponding dithio complexes; their melts decompose much more rapidly and, at lower temperatures, with separation of metal sulfide and/or selenide.

The most unstable members of this series are undoubtedly the complexes of the selenophosphinic acid $(C_2H_5)_2P(Se)OH$, of which only a few have so far been obtained in a well-defined form. For example, when heated in benzene, the blue Co^{II} complex changes into a green substance that has not yet been investigated. Attempts to prepare corresponding complexes *e.g.* of Ni^{II} and Bi^{III} and of the platinum metals always led, even under very mild conditions, merely to dark inhomogeneous decomposition products [36].

The reaction of diphenylthiophosphinic acid $(C_6H_5)_2P(S)OH$ with trimethylmetal compounds in analogy with eq. (9) yields dimeric dimethylmetal-diphenylthiophosphinato complexes *(4)* [25].

Basic dialkylthiophosphinatozinc(II) complexes having the formula $Zn_4O[R_2P(S)O]_6$ (R = C_2H_5, m.p. 273 °C;

M = Al, Ga



R = C_4H_9) have also been reported [40]. They are formed by the action of the free acids on zinc carbonate, a reaction that also leads to bis(diethylthiophosphinato)-zinc(II) (m.p. 186–188 °C) [35], as was mentioned above. This difference in reaction behavior is evidently due to very slight differences in the reaction conditions.

The two substances differ in their melting points and in their analytical composition. Moreover, osmometric molecular weight determinations (benzene, 37 °C) on the basic compound in the concentration range 8–20 g/l give values that correspond to the formula $Zn_4O[(C_2H_5)_2P(S)O]_6$ (1100.4). Bis(diethylthiophosphinato)zinc(II), on the other hand, exhibits concentration-dependent association under similar conditions, with molecular weights of about 4000–6500 (cf. Section 4).

According to X-ray studies the basic compounds belong to the class of tetranuclear complexes having a 4-coordinate central oxygen atom and ligand bridges between the zinc atoms [40]. This structure has been found *e.g.* in $Be_4O(CH_3COO)_6$ [41] and $Zn_4O(CH_3COO)_6$ [42].

4. Association of Phosphinato Complexes [35a, 35b]

A number of thiophosphinic and selenophosphinic acids, and particularly their zinc(II) and cadmium(II) complexes, exhibit concentration-dependent association in benzene or chloroform. This phenomenon, which was first observed in the dithiophosphinato complexes [5, 10], and which probably involves ligand bridges as shown in eq. (15), is most pronounced in

(15)

the thiophosphinato complexes $[R_2P(S)O]_nM$. Ligand bridges of this type have now also been postulated or detected in complexes of some phosphinic acids $R_2P(O)OH$ [43].

It can be seen from Figure 1, in which a number of thiophosphinato complexes have been taken as ex-

amples, that the *octahedral* In^{III} complex is monomeric in benzene over a wide range of concentrations, whereas the *tetrahedral* complexes are associated to varying degrees.

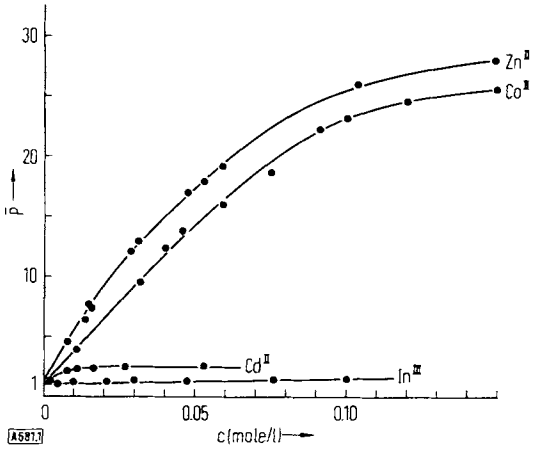

Fig. 1. Osmometrically determined average degrees of association $\bar{P}$ of complexes $[(C_2H_5)_2P(S)O]_nM$ (benzene, 37 °C).

While these compounds are evidently monomeric in very dilute solutions, their degree of association increases with concentration and tends toward a limiting value that depends on the central atom, and also on the solvent, since it decreases in the order carbon tetrachloride > benzene > chloroform [35a]. On the other hand, no temperature-dependence of the association equilibria has been detected between 37 and 60 °C.

Solutions of bis(diethylthiophosphinato)cobalt(II) and bis(diethylthiophosphinato)zinc(II) have surprisingly high viscosities, corresponding to high number average molecular weights even at low concentrations (see Fig. 1).

Viscometric measurements in benzene showed a very rapid increase in the reduced specific viscosity η_{sp}/c with increasing concentration for both complexes.

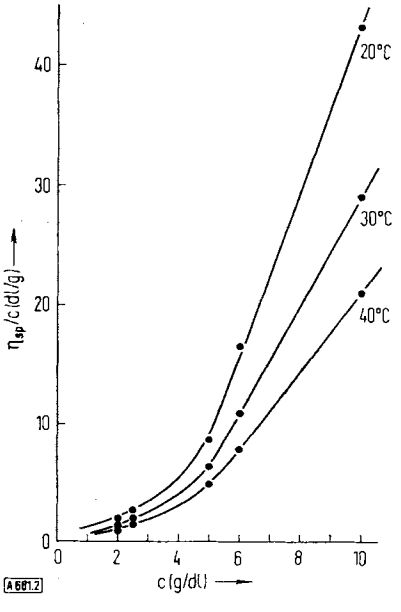

Fig. 2. Reduced specific viscosity as a function of the concentration for $[(C_2H_5)_2P(S)O]_2Co$ in benzene at various temperatures.

This observation, which is illustrated in Figure 2 for the Co^{II} compound, was also taken as evidence of an increase in association with increasing concentration [35b].

Investigations on the flow behavior of solutions of bis(diethylthiophosphinato)cobalt(II) and bis(diethylthiophosphinato)zinc(II) in benzene show no dependence of the viscosity on the shear gradient in the shear range examined (20–2500 sec^{-1}, 20 °C), and hence no structural viscosity. This behavior, like the apparently low temperature-dependence of the number average molecular weight, indicates the presence of strong bonds in the associates, such as would be expected of the postulated ligand bridges.

The nature of the donor atoms is also important to the association. Comparative measurements on Co^{II} and Cd^{II} complexes of various phosphinic acids showed that association decreases in the order

$$R_2P(O)O^{\ominus} > R_2P(S)O^{\ominus} > R_2P(S)S^{\ominus} > R_2P(Se)S^{\ominus} > R_2P(Se)Se^{\ominus}$$

The dependence of the degree of association on the size of the donor atom and on the radius and hybridization state of the metal (cf. Fig. 1) suggests that the association is mainly due to steric factors, four-membered chelate rings being replaced by less strained ligand bridges; examination of models shows that the strain in the four-membered ring  increases with decreasing radius of the central and donor atoms, whereas the formation of the four-membered ring is facilitated in the octahedral complexes by the smaller bond angle at the metal.

It can be shown *e.g.* in the case of the Co^{II} complex that the association does not tend to lead to an increase in the coordination number of the metal. Thus spectroscopic measurements show that Co^{II} is tetrahedrally coordinated in the associates, while magnetic measurements indicate that this is also the coordination state in the crystalline substance [35a, 35b].

However, factors other than steric ones must undoubtedly also be taken into account in the search for a satisfactory explanation of these association phenomena. Thus the fact that the association equilibria are at most only slightly temperature-dependent between 37 and 60 °C does not indicate that the metal-ligand bonds in the associates are energetically much more favorable. On the contrary, it suggests that entropy effects play a decisive role in the association. The importance of the part played by solvation is shown by the influence of the solvent on the degree of association.

5. IR [44] and Electronic Spectra [45]

No detailed IR spectroscopic studies, particularly normal coordinate analyses, have yet been carried out on the metal complexes of thiophosphinic and seleno-

[a] R′ = CH_3; [b] R′ = C_3H_7; [c] R′ = C_2H_5.

phosphinic acids. However, *Coates* and *Mukherjee* [25] have investigated the IR spectra of the dimeric organometal-phosphinato complexes $[R_2P(X)YM(CH_3)_2]_2$ (R = CH_3, C_6H_5; M = Al, Ga, In, Tl; X, Y = O, S), and made assignments for the P–X and P–Y stretching vibrations.

Numerous investigations [46] have shown that the P(S) and P(Se) bonds have at most only an extremely small π component. The representation of these bonds by P–S̈: and P–S̈e:, as used in the present article, thus undoubtedly corresponds more closely to the true state of affairs than a formulation involving a conventional double bond.

Irrespective of the bond order, however, complete resonance should occur in the anions $R_2P(S)S^{\ominus}$ *(5)* and $R_2P(Se)Se^{\ominus}$ *(6)*, so that only one type of phosphorus-chalcogen bond is present; X-ray studies suggest that a similar situation exists in the analogous $[(CH_3O)_2P(S)S]^{\ominus}K^{\oplus}$ [47]. This would give C_{2v} symmetry for the anions *(5)* and *(6)*. Their IR spectra

(5) *(6)* *(7)* *(8)*

should therefore contain two absorptions, which can be assigned to an asymmetric (ν_1) and a symmetric (ν_2) stretching vibration of the phosphorus-chalcogen bond. For the anions $R_2P(S)O^{\ominus}$ *(7)* and $R_2P(S)Se^{\ominus}$ *(8)*, as well as for the esters $R_2P(X)Y-R$ (C_s symmetry), ν_1 and ν_2 correspond to the different types of phosphorus-chalcogen bonds.

As can be seen from Table 5, the metal complexes also give two characteristic absorption frequencies, which are again assigned to the above-mentioned vibrations, and are denoted by ν_1 and ν_2. They are frequently split into doublets, the degree of splitting varying up to 20 cm^{-1}. This may be due to superposition of the phosphorus-chalcogen or the metal-chalcogen stretching vibration [48], to the occurrence of synchronous and asynchronous vibrations, or to rotational isomerism [49]. Furthermore, ν_{PX} is generally smaller for the complexes than for the esters, whereas ν_{PY} is generally greater; this may be regarded as evidence that X is involved in coordination, and hence of the chelate nature of the ligand.

In the case of the diethyldithiophosphinato complexes, ν_1 is found to increase in the order Co^{II}, Hg^{II}, Bi^{III}, Sb^{III}, Pd^{II}, Pt^{II}, Ir^{III}, Rh^{III}, Ni^{II}, Pb^{II}, Tl^{I}, In^{III}, Cu^{I}, Cd^{II}, Zn^{II}, Cr^{III}.

However, it is not possible to draw conclusions from this sequence alone regarding the bond order of the PS bond, and hence also of the MS bond, in these compounds since the absorption frequency of the PS bond will depend in a complex manner on the masses, force constants, bond lengths and angles, and the symmetry of the molecule as a whole, as has been suggested for the C=S absorption frequencies of metal dithiocarbamates [48]. It is interesting to note that the differences $\nu_1-\nu_2$ for the dithio complexes lie between the corresponding values for the propyl ester (in which the two PS bonds should be different) and the sodium salt (in which the two PS bonds should be equivalent). This could be explained *e.g.* by the assumption that the chelate complexes contain both non-equivalent and equivalent PS bonds, which, owing to the coordination of the donor atom, differ only in their bond orders from their analogs in the esters and in the sodium salt.

The electronic spectra of some diethyldithiophosphinato complexes $[(C_2H_5)_2P(S)S]_nM$ show substantial agreement in the positions and intensities of the bands with those of the analogous diethyl dithiophosphato compounds $[(C_2H_5O)_2P(S)S]_nM$, in which the central atoms again have a tetrahedral, planar, or octahedral environment of four or six sulfur atoms [50a].

The ligand field parameters of the ion $(C_2H_5)_2P(S)S^{\ominus}$ have been deduced from spectra of the octahedral complexes $[(C_2H_5)_2P(S)S]_nM$ [M = Cr^{III}, Rh^{III}, Ir^{III}]

The Catalytic Activity of Transition Metal Compounds in the Liquid-Phase Oxidation of Hydrocarbons

By N. M. Emanuel, Z. K. Maizus, and I. P. Skibida [*]

The way in which dissolved transition metal compounds affect the liquid-phase oxidation of hydrocarbons is demonstrated for compounds of cobalt, copper, and manganese. Kinetic investigations on model systems and comparisons with the non-catalyzed reaction show that the catalysts participate in all the oxidation steps.

1. Introduction

Non-catalyzed oxidation of hydrocarbons in the liquid phase may be considered to proceed by the following scheme [1, 2]:

$$RH \xrightarrow{O_2} R^\bullet \qquad \text{chain initiation} \quad (1)$$

$$R^\bullet + O_2 \rightarrow RO_2^\bullet \qquad \text{chain propagation} \quad (2)$$

$$RO_2^\bullet + RH \rightarrow ROOH + R^\bullet \qquad \text{chain propagation} \quad (3)$$

$$ROOH \rightarrow RO^\bullet + \dot{O}H \qquad \text{chain branching} \quad (4)$$

$$R^\bullet + R^\bullet \rightarrow R{-}R \qquad \text{chain termination} \quad (5)$$

$$RO_2^\bullet + R^\bullet \rightarrow ROOR \qquad \text{chain termination} \quad (6)$$

$$RO_2^\bullet + RO_2^\bullet \rightarrow ROH + R^1{-}CO{-}R^2 + O_2 \qquad \text{chain termination} \quad (7)$$

In the initial stage of oxidation, free radicals are formed by interaction of the hydrocarbon and the dissolved oxygen by way of a bimolecular reaction (Equation 1) or by way of a termolecular reaction:

$$2\,RH + O_2 \rightarrow R^\bullet + H_2O_2 + R^\bullet \qquad (1')$$

The radical $R^\bullet$ so formed reacts with oxygen to form a peroxy radical $RO_2^\bullet$. This reaction usually requires no activation energy and the rate constant k_2 is about 10^7–10^8 l mole^{-1} sec^{-1}. Interaction between peroxy radicals and hydrocarbons yields hydroperoxides (Equation (3)), which are subsequently converted into alcohols, ketones, and other products (Equations (4)–(7)).

Chain termination occurs mainly by recombination of peroxy radicals $RO_2^\bullet$ (Equation (7)), since at sufficiently high oxygen concentrations all radicals $R^\bullet$ succeed in reacting with oxygen. The rate constants k_7 for recombination of $RO_2^\bullet$ have been measured for a number of hydrocarbons using the intermittent light and the photochemical after-effect techniques. k_1 can also be determined from variations in chemiluminescence [3] and by means of ESR spectroscopy [2, 4].

Homogeneous catalysts induce essential changes in the mechanisms of all elementary steps of liquid-phase oxidation. Let us now consider these changes.

2. Chain Initiation by Radical Formation

2.1. Non-Catalyzed Radical Formation from Hydroperoxides

Decomposition of hydroperoxides yielding free radicals in the non-catalyzed oxidation of organic compounds is known to occur both by reaction (4)

$$ROOH \xrightarrow{k_4} RO^{\bullet} + \dot{O}H \qquad (4)$$

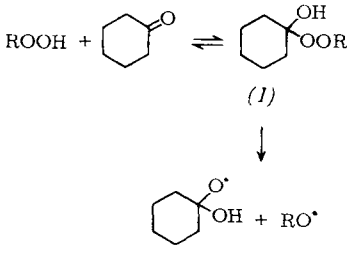
and by interaction between two saturated molecules [5, 6]. At early oxidation stages reactions (4′) and (4″) may take place.

$$ROOH + RH \xrightarrow{k_4'} RO^{\bullet} + R^{\bullet} + H_2O \qquad (4')$$

$$ROOH + ROOH \xrightarrow{k_4''} RO^{\bullet} + RO_2^{\bullet} + H_2O \qquad (4'')$$

The O–H bond in a water molecule formed by either of these reactions is very strong and has a considerably higher energy than that of the broken C–H bond in a hydrocarbon or of the O–H bond in a hydroperoxide. Consequently these reactions seem to be more advantageous from the standpoint of energetics than simple unimolecular decomposition of a hydroperoxide to free radicals according to Equation (4).

The linear dependence of the rate of radical formation on the concentration of a hydrocarbon (in an inert solvent) is evidence for reaction (4′). Measurements were made by means of the inhibitor technique. Such a mechanism of radical formation has been established, for example, for *n*-decyl-, cumyl-, and cyclododecylhydroperoxides [5–7].



Reaction (4″) was first discovered for the oxidation of olefins [8]. Later on this reaction was studied in detail for the inhibited decomposition of hydrogen peroxide and *tert*-butyl hydroperoxide and it was found to occur through an intermediate complex involving ROOH molecules bound by hydrogen bonds [9].

Decomposition of a hydroperoxide in an olefin can lead to the formation of radicals by the following reaction [10]:

$$ROOH + \rangle C{=}C\langle \longrightarrow RO^{\bullet} + \rangle \dot{C}{-}C\langle{-}OH$$

Radicals may be formed in high yields by reaction of hydroperoxides with oxidation products, such as are obtained on oxidation of hydrocarbons. Compounds such as organic acids and alcohols form hydrogen-bonded intermediates with hydroperoxides and the rate of decomposition of such complexes to radicals appears to be higher than that of the decomposition of free hydroperoxide [11, 12]. The higher rate of radical formation accounted for by hydrogen bonds between hydroperoxides and the solvent was observed also for decomposition of methyl ethyl ketone hydroperoxide in aqueous and alcoholic solutions. Complexes of ketone hydroperoxides and these solvents decompose to radicals at a rate 10 to 20 times higher than that for a free ketone hydroperoxide.

Decomposition of a hydroperoxide in a solvent or in presence of reaction products may be accelerated not only as a result of formation of hydrogen-bonded complexes, but also because of a chemical reaction with the solvent yielding more labile hydroperoxides [2]. For instance, the higher rate of decomposition of *tert*-butyl hydroperoxide in the presence of cyclohexanone is accounted for by formation of the labile intermediate *(1)*, which readily decomposes to free radicals.

2.2. Radical Formation from Hydroperoxides in the Presence of Cobalt Catalysts

Transition metal salts accelerate the decomposition of hydroperoxides shown in equations (8) and (8′).

$$ROOH + M^{n+} \rightarrow RO^{\bullet} + OH^{-} + M^{(n+1)+} \qquad (8)$$

$$ROOH + M^{(n+1)+} \rightarrow RO_2^{\bullet} + H^{+} + M^{n+} \qquad (8')$$

This mechanism of hydroperoxide decomposition was proposed by *Haber* and *Weiss* for the decomposition of hydrogen peroxide in the presence of bivalent iron ions [13].

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^{\bullet} + OH^{-} \qquad (8'')$$

The hydroxyl radical formed initiates chain decomposition of H_2O_2. Organic hydroperoxides in aqueous solutions also decompose readily under the action of transition metals to form free alkoxy radicals [14, 15]. In a

hydrocarbon medium the rate of reaction of transition metal salts with hydroperoxides is slower than in water; nevertheless, it is still considerably faster than the rate of thermal hydroperoxide decomposition.

It may be considered as established that, in a hydrocarbon medium, hydroperoxides form intermediate complexes with the catalyst [16–18]. However, the mechanism of decomposition of these complexes is not established; nor is there any information on the structures of such complexes or on the rates of their formation and decomposition to free radicals.

The mechanism of decomposition of *n*-decyl hydroperoxide in the presence of cobalt stearate has been investigated over the temperature range 60 to 100 °C [19,20]. It was found that hydroperoxide decomposition in such a system proceeds at a rate of 1.3×10^{-2} mole/l (see Fig. 1) irrespective of whether

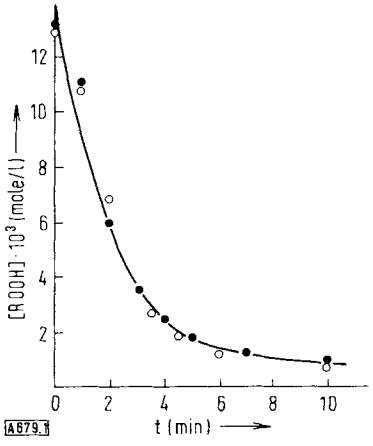

Fig. 1. Kinetics of *n*-decyl hydroperoxide (ROOH) decomposition in a flow of nitrogen at 80 °C. ○: in the presence of 1.12×10^{-3} mole/l of cobalt stearate. ●: in the presence of 1.11×10^{-3} mole/l of cobalt stearate and 8.3×10^{-2} mole/l of *N*-phenyl-β-naphthylamine. Solvent: *n*-decane.

an inhibitor (*N*-phenyl-β-naphthylamine) is present or not. Thus, it can be concluded that *n*-decyl hydroperoxide decomposes exclusively to free radicals (see Equation (4)). For this reason all further experiments on the mechanism of chain branching in *n*-decane oxidation catalyzed by cobalt stearate were conducted in the absence of an inhibitor, and the rate of formation of radicals was determined from the rate of hydroperoxide consumption. In Figure 2a the rate of free radical formation W_R in the presence of cobalt stearate is shown as a function of the initial hydroperoxide concentration $[ROOH]_0$. W_R increases linearly with hydroperoxide concentration up to the value W_{max} and then remains practically constant. This is evidence that the formation of radicals occurs *via* an intermediate hydroperoxide/cobalt stearate complex. The plot of $\log (1/W_R - 1/(2\ W_{max}))$ *versus* $\log [ROOH]_0$ is a straight line.

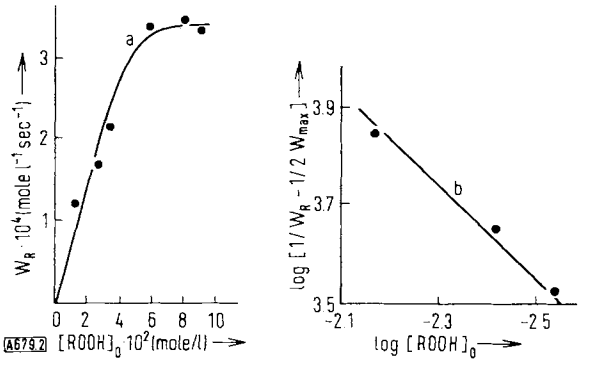

Fig. 2. a) Rate of formation W_R of radicals during the cobalt stearate catalyzed decomposition of *n*-decyl hydroperoxide (ROOH) as a function of $[ROOH]_0$. b) $\log (1/W_R - 1/(2\ W_{max}))$ as a function of $\log [ROOH]_0$. $T = 100$ °C, $[CoSt_2]_0 = 1.14 \times 10^{-3}$ mole/l. Solvent: *n*-decane.

The rate of hydroperoxide decomposition is a linear function of the square of the cobalt stearate concentration (Fig. 3). Consequently two molecules of cobalt stearate participate in the formation of radicals.

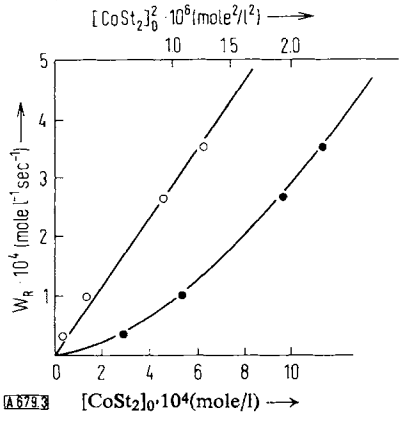

Fig. 3. Rate of decomposition of *n*-decyl hydroperoxide as a function of $[CoSt_2]_0$ (●) and $[CoSt_2]_0^2$ (○). $[ROOH]_0 = 7.5 \times 10^{-2}$ mole/l. $T = 100$ °C. Solvent: *n*-decane.

$$CoSt_2 + n\,ROOH \overset{K}{\rightleftharpoons} [CoSt_2 \cdot n\,ROOH] \quad (9)$$

$$[CoSt_2 \cdot n\,ROOH] + CoSt_2 \xrightarrow{k_4} CoSt_2(OH) + CoSt_2 + RO^{\bullet} + (n-1)\,ROOH \quad (10)$$

$$[CoSt_2 \cdot n\,ROOH] + CoSt_2(OH) \xrightarrow{k_5} 2\,CoSt_2 + H_2O + RO_2^{\bullet} + (n-1)\,ROOH \quad (11)$$

$CoSt_2$ = cobalt stearate

In this case the rate of radical formation will be

$$W_R = k_4 [CoSt_2 \cdot n\,ROOH] [CoSt_2] + k_5 [CoSt_2(OH)] [CoSt_2 \cdot n\,ROOH].$$

On substituting $[CoSt_2]$ for the $[CoSt_2(OH)]$ concentration in

$$d [CoSt_2(OH)]/dt = k_4 [CoSt_2] [CoSt_2 \cdot n\,ROOH] - k_5 [CoSt_2(OH)] [CoSt_2 \cdot n\,ROOH] = 0$$

[20] *Z. K. Maizus, I. P. Skibida*, and *N. M. Emanuel*, Ž. fiz. Chim. *40*, 322 (1966).

we obtain

$$W_R = 2 k_4 [CoSt_2] [X] \quad (12)$$

where

$$[X] = [CoSt_2 \quad n\,ROOH]$$

Assuming that equilibrium is attained rapidly enough and is not disturbed by consumption of the complex we obtain

$$[X] = K [ROOH]^n [CoSt_2] \quad (13)$$

Since in the given case the concentration of $CoSt_2$ is always considerably lower than that of hydroperoxide, the formation of a complex reduces the hydroperoxide concentration only slightly but, at the same time, considerably reduces the concentration of cobalt stearate. From equations (12) and (13), and taking into account the conditions $[CoSt_2] = [CoSt_2]_0 - [X]$ and $[ROOH] = [ROOH]_0$, we obtain for the overall rate of hydroperoxide decomposition [*]:

$$W_R = 2 k_4 K [CoSt_2]_0^2 [ROOH]_0^n / (1 + K [ROOH]_0^n)^2 \quad (14)$$

The reaction order n based on hydroperoxide, the equilibrium constant K for complex formation, and the rate constant k_4 for the decomposition of the complex to radicals can be obtained from Equation 14 using the values given in Fig. 2.

k_4 is determined from the maximum rate of hydroperoxide decomposition. Differentiating (14), we obtain

$$[ROOH]^n = 1/K \quad (15)$$

Then the maximum decomposition rate is

$$W_{max} = k_4 [CoSt_2]_0^2 / 4 \quad (16)$$

Hence k_4 can be calculated from the known cobalt stearate concentration. It may be found also from the slope of the curve for W_R *versus* $[CoSt_2]^2$, when the rate of hydroperoxide decomposition is independent of the hydroperoxide concentration (Fig. 3). In order to determine the reaction order n and the equilibrium constant K, Equation (14) is rearranged as follows:

$$1/W_R - 1/(2 W_{max}) = 1/(k_4 K [CoSt_2]_0^2 [ROOH]_0^n) \quad (17)$$

In logarithmic form, this equation is

$$\log [1/W_R - 1/(2 W_{max})] = \log (1/k_4 K [CoSt_2]_0^2) - n \log [ROOH]_0 \quad (18)$$

The reaction order n as calculated by the least squares method from the slope of the curve $\log [1/W_R - 1/(2 W_{max})]$ *vs.* $\log [ROOH]_0$ (Fig. 2b) has a value of 0.9. Thus, the hydroperoxide/catalyst complex appears to contain one $CoSt_2$ molecule and one hydroperoxide molecule.

The rate constant k_4 for complex decomposition to radicals at 100 °C, as found from W_{max}, has a value of 1×10^3 l mole^{-1} sec^{-1}. The equilibrium constant for complex formation is $K = 10$ l/mole (at 100 °C). The temperature dependence of the constants k_4 and K between 60 and 100 °C permits an estimation of the activation energy for radical formation by interaction between the $ROOH \cdot CoSt_2$ complex and cobalt stearate ($E_4 = 24.5 \pm 0.8$ kcal/mole) and the heat of the complex formation ($\Delta H = 10 \pm 0.6$ kcal/mole). The general expression for k_1 may therefore be written as

$$k_4 = 2 \times 10^{17} \exp ((-24500 \pm 800)/RT) \text{ l mole}^{-1}$$

and that for K as

$$K = 6 \times 10^{-5} \exp ((10000 \pm 600)/RT) \text{ l/mole}^{-1}$$

The results obtained are evidence that the high catalytic efficiency of cobalt salts in the decomposition of *n*-decyl hydroperoxide to radicals is accounted for by the higher rate constant k_4. It is almost a thousand times higher than that for radical decomposition of the hydroperoxide in the absence of a catalyst.

A similar mechanism is postulated for the decomposition of ethylphenyl hydroperoxide in the presence of cobalt acetate [18], as studied by the chemiluminescence technique.

2.3. Radical Formation from Hydroperoxides in the Presence of Copper Catalysts

When *n*-decyl hydroperoxide decomposes in the presence of copper stearate the part played by the catalyst is not restricted to its participation in radical formation. If an inhibitor is introduced into such a system the rate of consumption of the inhibitor is considerably lower than that of hydroperoxide decomposition. For instance at an initial concentration of $[ROOH]_0 = 0.047$ mole/l and $[InH]_0 = 2.2 \times 10^{-4}$ mole/l the rate of ROOH decomposition is 1.2×10^{-3} mole l^{-1} min^{-1},

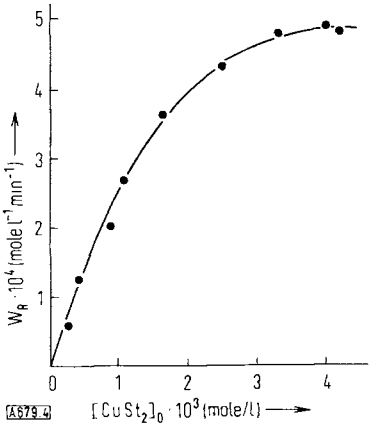

Fig. 4. Rate of formation W_R of radicals on decomposition of *n*-decyl hydroperoxide as a function of $[CuSt_2]_0$. $[ROOH]_0 = 0.047$ mole/l. $T = 80$ °C. Solvent: *n*-decane.

[*] K is the product of equilibrium constants for formation of complexes containing 1 to n hydroperoxide molecules (dimensionality l^n/mole^n).
It follows from (6) that the rate of radical formation in the presence of $CoSt_2$ will attain a certain maximum value and will then start decreasing. In the given case the region of decrease in the rate of hydroperoxide decomposition with increasing ROOH concentration was not obtained, since the hydroperoxide could not accumulate in large amounts.

and that of inhibitor consumption is 1.9×10^{-4} mole l^{-1} min^{-1}. The rate of radical formation in the presence of copper stearate was, therefore, determined from consumption of inhibitor (*N*-phenyl-β-naphthylamine). The rate of inhibitor consumption was found to be independent of concentration, *i.e.* the inhibitor reacted only with free radicals, and did not react directly either with hydroperoxides or with the other products present.

The rate of radical formation, W_R, in the presence of copper stearate, as opposed to cobalt stearate, initially increases linearly with the catalyst concentration (Fig. 4). Thus the formation of radicals is first order with respect to $CuSt_2$. Fig. 5 shows that, at low

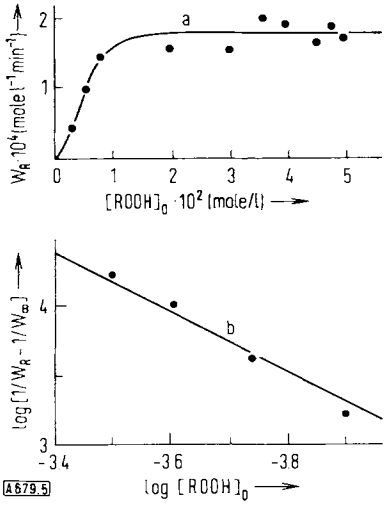

Fig. 5. a) Rate of formation W_R of the radicals on copper stearate catalyzed decomposition of *n*-decyl hydroperoxide (ROOH) as a function of [ROOH]$_0$. b) log $(1/W_R - 1/W_\infty)$ as a function of log [ROOH]$_0$. [$CuSt_2$]$_0$ = 8×10^{-4} mole/l. T = 80 °C. Solvent: *n*-decane.

hydroperoxide concentrations, W_R increases with the hydroperoxide concentration, and is independent of it at high [ROOH]$_0$ values. Thus, as in the case of decompositions catalyzed by $CoSt_2$, the formation of radicals in the presence of $CuSt_2$ occurs by decomposition of the hydroperoxide/copper stearate complex. When [$CuSt_2$] $\ll$ [ROOH] all the copper appears to be bound in a complex and any further increase in [ROOH] has no effect on the rate of radical formation.

The mechanism of *n*-decyl hydroperoxide decomposition to radicals in the presence of $CuSt_2$ may be formulated as

$$CuSt_2 + n\,ROOH \underset{2}{\overset{1}{\rightleftharpoons}} [CuSt_2 \cdot n\,ROOH] \xrightarrow{3} RO_2^{\bullet} + CuSt + HSt + (n-1)\,ROOH$$

$$CuSt + ROOH \xrightarrow{4} CuSt(OH) + RO^{\bullet}$$

Taking into account that one inhibitor molecule reacts with two free radicals and that the concentration of univalent copper remains constant we obtain

$$W_R = 2\,k_3\,[CuSt_2 \cdot n\,ROOH].$$

Assuming, as in the case of $CoSt_2$, that the equilibrium of complex formation is not disturbed by the decomposition of the complex to radicals, we find

$$W_R = k_3\,K\,[ROOH]_0^n\,[CuSt_2]_0/(1 + K\,[ROOH]_0^n) \quad (19)$$

At $1 \ll K\,[ROOH]^n$ the value W_R is independent of [ROOH]:

$$W_R = W_\infty = k_3\,[CuSt_2]_0 \quad (20)$$

It can be seen from Equation (20) that the rate constant k_3 for the decomposition of the complex to radicals may be determined from the maximum rate of the inhibitor consumption corresponding to formation of radicals (Fig. 5).

Investigation of ROOH decomposition in the presence of $CuSt_2$ over a temperature range of 60 to 100 °C yielded the following k_3 value

$$k_3 = 1.1 \times 10^7 \exp(-15500/RT)\ sec^{-1}$$

The dependence of W_R on [ROOH] in logarithmic coordinates is

$$\log(1/W_R - 1/W_\infty) = \log[1/(2\,k_3\,K\,[CuSt_2]_0)] - n \log [ROOH]_0 \quad (21)$$

From Equation (21) it is possible to determine n and K. It was found from the logarithmic anamorphose (Fig. 5a) that $n = 2$ and $K = 1.1 \times 10^9 \exp(-8000/RT)$ $l^2/mole^2$.

Investigations in the presence of copper and cobalt stearates showed that the appearance of free radicals is preceded in both cases by formation of $MSt_2 \cdot n$ ROOH complexes. Whereas the cobalt complex contains a molecule of $CoSt_2$ and one of ROOH, in the presence of copper stearate one $CuSt_2$ molecule is bound to two ROOH molecules. The mechanisms of complex decomposition are also different: the copper complex decomposes in a unimolecular manner, but the cobalt complex decomposes by a bimolecular mechanism involving a second $CoSt_2$ molecule.

Another possibility is decomposition of the peroxide in the presence of $CuSt_2$, without formation of radicals. This might be due to the cage effect, the radicals formed in the solvent cage reacting with Cu^+:

$$CuSt + R^1CH(O\dot{O})R^2 \rightarrow CuSt(OH) + R^1\text{–}C(O)\text{–}R^2$$

It has been suggested that manganese stearate acts as a catalyst in the same way [21].

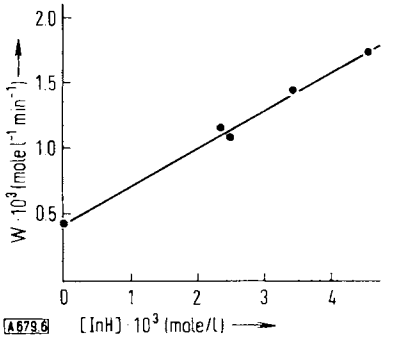

Fig. 6. Rate of decomposition W of *n*-decyl hydroperoxide as a function of the inhibitor concentration. [ROOH]$_0$ = 0.047 mole/l. T = 80 °C. Copper stearate as catalyst. Inhibitor: *N*-phenyl-β-naphthylamine. Solvent: *n*-decane.

[21] *V. M. Goldberg* and *L. K. Obukhova*, Izvest Akad. Nauk SSSR, Ser. chim. *1966*, 2217.

Introduction of an inhibitor into the *n*-decyl hydroperoxide/$CuSt_2$ system increases the rate of non-radical hydroperoxide decomposition. Fig. 6 shows that the initial rate of hydroperoxide decomposition increases linearly with the inhibitor concentration.

2.4. Radical Formation in Peroxide-Free Systems

Of great interest is the possibility of chain initiation in a system containing a hydrocarbon, dissolved oxygen, and a catalyst but no peroxides. If the metal of the catalyst is in its highest valence state, it may form free radicals by reaction with the hydrocarbon. Initiation by Co^{3+} ions in aqueous media seems to occur at high rates, as was demonstrated recently for oxidation of toluene, alcohols, and ethers by cobalt(III) perchlorate [22,23]. In a hydrocarbon medium and with cobalt(III) stearate as catalyst radical formation may occur by reaction (22).

$$CoSt_3 + RH \rightarrow CoSt_2 + HSt + R^{\bullet} \qquad (22)$$

The rate of chain initiation was found to be a linear function of tervalent cobalt concentration in the oxidation of linoleic acid in benzene [24], and of 2-methyl-2-butene in acetic acid [25] in presence of Co^{3+}.

Investigation of reactions of tervalent cobalt with olefins has shown that in acid solutions and at room temperature reaction (22) is sufficiently fast and its activation energy is 27 to 29 kcal/mole; the pre-exponential factor is 10^{20} l mole^{-1} sec^{-1} [26].

In many oxidations, reactions of type (22) seem to be of no importance since radical formation by reaction between the catalyst and the hydroperoxide occurs at a considerably higher rate. Catalysts such as cobalt or manganese salts are usually added to the hydrocarbon in a bivalent state.

Information concerning whether bivalent metal ions take part in chain initiation at the start of the reaction, or whether their initiating effect becomes possible only after appearance of peroxides is very scarce. In the absence of the hydroperoxide, the radicals may be formed by the following reactions [27,28]:

$$CoSt_2 + O_2 \rightleftharpoons CoSt_2 \cdots O_2$$
$$CoSt_2 \cdots O_2 + RH \rightarrow CoSt_2(OOH) + R^{\bullet}$$

or

$$CoSt_2 \cdots O_2 + RH \rightarrow CoSt_2(OH) + RO^{\bullet}$$

Evidence in favor of this mechanism was obtained on oxidation of methyl linoleate (RH) in benzene in the presence of cobalt stearate [28]. The rate of this reaction is independent of the hydroperoxide concentration and is found to be:

$$W = k\,[RH]\,[St_2Co].$$

A change in the polarity of the medium by addition of nitrobenzene results in a lower rate of oxidation. It may be that nitrobenzene solvates the molecules of bivalent cobalt stearate, thus preventing the formation of a complex with oxygen and, consequently, the appearance of free radicals.

The formation of radicals in the $RH/O_2/M^{2+}$ system not easy to follow since the rapid reaction of the hydroperoxide formed with M^{2+} to yield free radicals makes the study of the slower reaction involving oxygen difficult. Of great interest in this connection is the mechanism of chain initiation on oxidation of styrene in the presence of cobalt stearate [29]. The polymer peroxide formed in the oxidation of styrene is rather passive towards the catalyst. The formation of radicals was studied for the systems styrene/O_2/cobalt stearate and styrene/O_2/cobalt acetylacetonate, and in both cases the reaction rate was shown to be proportional to the styrene, oxygen, and cobalt concentrations

$$W = k\,[\text{styrene}]\,[O_2]\,[Co^{2+}] \qquad (23)$$

Equation (23) is consistent with radical formation by the termolecular reaction and by the reaction sequence (24).

$$Co^{2+} + O_2 \overset{K}{\rightleftharpoons} Co^{2+} \cdots O_2$$
$$Co^{2+} \cdots O_2 + CH_2{=}CHR \xrightarrow{k'} Co{-}O{-}O{-}CH_2{-}\dot{C}HR \qquad (24)$$

The second mechanism seems more probable. In this case the experimental constant is $k = k'K$.

The mechanism of radical formation catalyzed by pyridine-copper complexes ($Cu^{2+}(Py)_m$, $m = 1{-}4$) [30] is considerably more complicated. It was found in the oxidation of methyl ethyl ketone that the copper-pyridine complexes are very efficient enolization catalysts. This accounts for the fact that under the conditions of this reaction ketones undergo oxidation in the form of enols or enolate ions.

$$CH_3{-}CH{=}\overset{O^{\ominus}}{\overset{|}{C}}{-}CH_3 \xrightarrow{Cu^{2+}(Py)_m} CH_3{-}\overset{O^{\bullet}}{\overset{|}{C}}{=}CH{-}CH_3 \rightleftharpoons CH_3{-}\dot{C}H{-}\overset{O}{\overset{\|}{C}}{-}CH_3$$

Heterogeneous catalysts also contribute to formation of radicals in the liquid-phase oxidation of organic compounds. Thus it was found that the liquid-phase oxidation of cyclohexene and 2-methyl-2-butene in the absence of a catalyst does not start until after a rather long induction period, whereas in the presence of manganese dioxide the reaction starts immediately [31]. Similar results were obtained for liquid-phase oxidation of isobutene in the presence of MnO_2

and Cr_2O_3[32]. The composition of isobutene oxidation products in the presence of a heterogeneous catalyst is practically the same as that in the presence of azodiisobutyronitrile as initiator, suggesting that the heterogeneous catalysts studied take part in the formation of free radicals only.

3. Chain Propagation

3.1. Chain Propagation in Non-Catalyzed Reactions

The propagation of chains in a non-catalyzed reaction proceeds *via* two alternating consecutive elementary steps:

$$R^\bullet + O_2 \rightarrow RO_2^\bullet$$
$$RO_2^\bullet + RH \rightarrow ROOH + R^\bullet$$

All other oxidation products, such as alcohols, ketones, and acids, are formed from the hydroperoxide[33]. At higher conversions the peroxy radicals $RO_2^\bullet$ may react both with the initial hydrocarbon and with the oxidation products[34].

The ratio of the rate constants for the chain reaction of $RO_2^\bullet$ with hydrocarbon, hydroperoxide, and alcohol[35] are 1:9:12 for ethylbenzene oxidation, and 1:13:6.3 for *n*-decane oxidation. Thus alcohols and peroxides react with free radicals almost ten times as fast as do hydrocarbons.

Oxidation of *n*-decane affords a mixture of isomeric oxygen-containing compounds, as there is an equal probability of oxidation for each equivalent CH_2 group. It was found[36] that all isomeric decanols show practically the same reactivity in reactions with $RO_2^\bullet$.

$$RO_2^\bullet + R^1CH{=}CHR^2 \rightarrow RO^\bullet + R^1HC\!-\!\underset{\diagdown\,\diagup}{O}\!-\!CHR^2 \quad (25)$$

Alkenes can react with $RO_2^\bullet$ to form a hydroperoxide or an epoxide (oxirane) according to Eq. (25). The latter mechanism was postulated, for instance, for styrene oxidation[37]. The formation of epoxides on reaction of $RO_2^\bullet$ with olefins was recently confirmed in studies on the mechanism of conjugated oxidation (see Table 1)[39] of propene and acetaldehyde[38]. It was found that addition of an inhibitor (2,6-di-*tert*-butyl-4-methylphenol) completely stops the consumption of acetaldehyde. Some propene oxide is still formed, however, owing to occurrence of a Prilezhaev reaction (see Eq. (26) and Fig. 7).

$$ROOH + CH_2{=}CH{-}CH_3 \rightarrow ROH + H_2C\!-\!\underset{\diagdown\,\diagup}{O}\!-\!CH{-}CH_3 \quad (26)$$

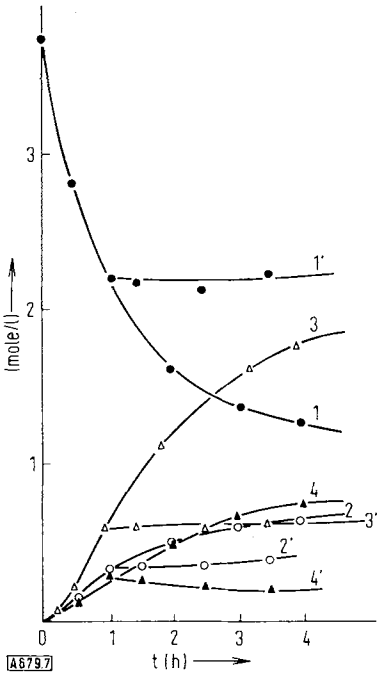

Fig. 7. Effect of the inhibitor 2,6-di-*tert*-butyl-4-methylphenol on the kinetics of acetaldehyde consumption and the accumulation of products in conjugated oxidation of propene and acetaldehyde (molar ratio 1:1) in a benzene solution at $T = 75\,^\circ C$ and p (air) = 50 atm. Figures without primes refer to experiments with no inhibitor; those with primes are for experiments with 0.02 mole/l of 2,6-di-*tert*-butyl-4-methylphenol, which was admitted 1 h after the start of the experiment. Acetaldehyde consumption (1,1'). Propene oxide (2,2'). Acetic acid (3,3'). Peroxide (4,4').

It may be seen from Table 1 that the maximum yields of propene oxide are obtained by oxidation of mixtures of propene with aldehydes and with ethyl methyl ketone involving formation of acetaldehyde as intermediate[40]. Correlating these facts with the low propene oxide yield in the absence of aldehydes, for instance in a mixture of propene and alkylaromatic

$$CH_3{-}C(=O)(-O{-}O^\bullet) + CH_2{=}CH{-}CH_3$$
$$\rightarrow CH_3{-}C(=O)(-O^\bullet) + H_2C\!-\!\underset{\diagdown\,\diagup}{O}\!-\!CH{-}CH_3$$
$$CH_3{-}C(=O)(-O^\bullet) + RH \rightarrow CH_3{-}C(=O)(-OH) + R^\bullet$$

Table 1. Examples of conjugated oxidation of propene with various other oxidizable compounds (molar ratio 2:1 for aldehydes, 1:3 for other components); yields calculated with respect to the additional components.

Additional component	Air pressure (atm)	T (°C)	Time (h)	Propene oxide in product (wt.-%)	Yield (%)
Acetaldehyde	50	60–80	1	34	70

hydrocarbons, the authors concluded that the structure of $RO_2^{\cdot}$ plays an important part in epoxidation and that acylperoxy radicals are particularly effective.

3.2. Chain Propagation in Catalyzed Reactions

Transition metal salts affect not only the reaction rate but also the ratio of reaction products, thus demonstrating participation of the catalysts in chain propagation. Our research on *n*-decane oxidation has indeed shown that the sequence of product formation and the mechanism of chain propagation in the presence of cobalt stearate are essentially different from those for non-catalyzed oxidation.

The sequence of oxidation product formation in the presence of homogeneous catalysts was established using the "open system" technique, *i.e.* with ideal intermixing reactors. When the reaction is conducted in an open system, the reagents are continuously introduced into the reactor and the partially reacted mixture is continuously withdrawn from it. The composition of the reacting mixture remains uniform all over the reactor due to intensive intermixing. Attainment of stationary concentrations of initial, intermediate, and end compounds is characteristic of such a system.

In a simple consecutive reaction

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C$$

stationary concentrations of the initial $[\overline{A}]_i$ and intermediate compound $[\overline{B}]_i$ appear to be related by Eq. (27)

$$k_1 [\overline{A}]_i^n - k_2 [\overline{B}]_i^{n_1} - v_i [\overline{B}]_i / V = 0 \qquad (27)$$

where v_i is the volumetric velocity of the flow, V is the reactor volume. On conducting the reaction at different flows we obtain a set of equations of type (27) making possible the determination both of k_1 and k_2, and of n and n_1 [41]. For complex chain reactions involving free radicals, Eq. (27) can be written as

$$k_1 [R]_i [\overline{A}]_i - k_2 [R]_i [\overline{B}]_i - v_i [\overline{B}]_i / V = 0 \qquad (27')$$

Since a change in v_i results in a different concentration of R, determination of k_1 and k_2 using this technique appears to be impossible.

In order to measure the rates of formation and consumption of a compound in such systems it is necessary to maintain a constant radical concentration, *i.e.* a constant concentration of the initiating compound, while at the same time changing the steady-state concentration of the intermediate B [42]. This can be accomplished by feeding not only A but also B into the vessel. If v_i remains constant, the steady-state concentrations of A and R will also be constant, and the steady-state concentrations of B in experiments with and without admission of B follow Equations (28) and (29), respectively.

$$k_1 [R] [\overline{A}] - k_2 [R] [\overline{B}] - v [\overline{B}] / V = 0 \qquad (28)$$

$$k_1 [R] [\overline{A}] - k_2 [R] [\overline{B}]_1 - v [\overline{B}]_1 / V + v [B]_0 / V = 0 \qquad (29)$$

For k_2 these equations give

$$1 + V k_2 [R] / v = [B]_0 / ([\overline{B}]_1 - [\overline{B}]) \qquad (30)$$

Thus, for reactions of first order with respect to B, the k_2 [R] value and, consequently, the rate of intermediate consumption may be calculated from the slope of the curve of $([B]_1 - [B])$ *vs.* $[B]_0$. When B is consumed in a reaction of *n*-th order, Eq. (30) becomes:

$$k_2 [R] V / v = ([B]_0 + [\overline{B}]^n - [\overline{B}]_1^n) / ([\overline{B}]_1 - [\overline{B}]) \qquad (31)$$

When several isomers of B are formed, the technique permits separate determination of the rate of consumption of each isomer by analyzing only the sum of isomers formed [36].

The consumption of 2-decanol during oxidation of *n*-decane in the presence of cobalt stearate was determined by the technique described above [43]. The

[42] *I. P. Skibida, Z. K. Maizus*, and *N. M. Emanuel*, Doklady Akad. Nauk SSSR *144*, 170 (1962).

[43] *I. P. Skibida, Z. K. Maizus, S. K. Ivanov*, and *N. M. Emanuel*, Doklady Akad. Nauk SSSR *167*, 1105 (1966).

steady-state concentration of the hydroperoxide, and thus of $RO_2^{\cdot}$ radicals, remained the same in all experiments (Fig. 8a). The rate and the effective rate constant for alcohol consumption were determined from the difference in steady-state concentrations of alcohol attained for different initial alcohol concentrations (Fig. 8b). The rate of alcohol formation was found from its rates of accumulation and consumption to be $W_f^{ROH} = 0.14$ mole l^{-1} h^{-1}.

In order to establish the routes of alcohol formation, the rate of alcohol formation was compared with that of hydroperoxide consumption. The latter was calculated by means of Equation (32) from the known values of k_4 and K.

$$W_d^{ROOH} = k_4 K \overline{[CoSt_2]}^2 \overline{[ROOH]}/(1 + K \overline{[ROOH]})^2 \qquad (32)$$

The rate of hydroperoxide decomposition was found to be $W_d^{ROOH} \leqslant 0.03$ mole l^{-1} h^{-1}, which is about 25 % of the rate of alcohol formation. This seemed to be evidence that the main part of the alcohol is formed directly from $RO_2^{\cdot}$. In order to obtain further confirmation the rate of hydrocarbon consumption W_c^{RH} was measured and compared with that of ROOH formation (W_f^{ROOH}):

$$W_f^{ROOH} = W_{accum.}^{ROOH} - W_d^{ROOH} \qquad (33)$$

It appeared that when $W_c^{RH} = 0.27$ mole l^{-1} h^{-1}, the value of W_f^{ROOH} is 0.044 mole l^{-1} h^{-1}, *i.e.* the rate of hydrocarbon consumption is much higher than that of hydroperoxide formation.

Moreover, $W_f^{ROOH} + W_f^{ROH} < W_c^{RH}$, thus showing that not only alcohol but also other products are formed directly from $RO_2^{\cdot}$.

The rates of formation of ketones and acids could be calculated from the steady-state concentrations of these products in experiments with and without addition of various amounts of 2-decanol (Fig. 9).

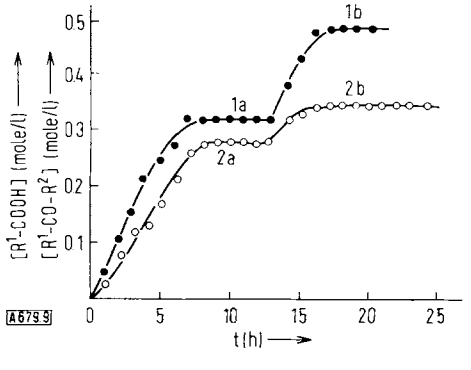

Fig. 9. Kinetic curves for accumulation of ketones (1) and acids (2) in the catalyzed oxidation of *n*-decane in an open system on successive admission of: (a) pure *n*-decane; (b) 0.51 mole/l of 2-decanol in *n*-decane. $[CoSt_2]_0 = 6 \times 10^{-3}$ mole/l in the solution admitted into the reactor. $T = 130$ °C.

Since in this case acids are the only end products of the reaction, the overall rate of their formation may be calculated from the steady-state concentration on admission of pure *n*-decane, and was found to be $W_f^{acid} = 0.095$ mole l^{-1} h^{-1}. The rate of acid formation from ketone may be established from the difference in the steady-state acid concentrations on admission of pure decane and of decane containing alcohol.

$$(W_f^{acid})_1 = K_{acid} [RO_2^{\cdot}] \overline{[B]} = \frac{(v/V)\,([\overline{A}]_1 - \overline{[A]})}{\overline{[B]}_1 - \overline{[B]}} = 0.026 \text{ mole } l^{-1} h^{-1}$$

Here $[\overline{A}]_1$ and $\overline{[B]}_1$ are steady-state concentrations of acids and ketones in experiments with admission of alcohol solutions and $[\overline{A}]$ and $\overline{[B]}$ are those for admission of pure *n*-decane. It is seen that $(W_f^{acid})_1 < W_f^{acid}$

The rates of formation of ketone from alcohol and from $RO_2^{\cdot}$ were calculated in a similar way, assuming that oxidation of ketone to acid is the only route for its consumption.

Table 2. Rates of formation and of consumption of products in the oxidation of *n*-decane catalyzed by cobalt stearate (all rates are given in mole l^{-1} h^{-1}; reaction conditions as given in Fig. 9).

	Acids	Ketones	Alcohols	Peroxides	Hydrocarbons
Overall rate of formation	0.095	0.12	0.12	0.044	—
Rate of formation from $RO_2^{\cdot}$	0.07	0.03	0.10	0.044	—
Rate of consumption	—	0.026	0.07	0.03	0.27

As shown in Table 2, the acids, alcohols, and peroxides are formed mostly from $RO_2^{\cdot}$. Formation of the main part of alcohols, ketones, and other oxidation products directly from $RO_2^{\cdot}$ in the presence of transition metal salts had previously been postulated [44–46].

Heterogeneous catalysts also contribute to chain propagation in liquid-phase oxidation [47]. Isomerization with subsequent decomposition of $RO_2^{\cdot}$, involving cleavage of the C–C or C–H bond, may occur on a solid surface, as was found earlier for gas-phase oxidation [1, 48].

Decomposition of peroxy radicals in liquid-phase oxidation was observed for *n*-butane oxidation in a metal reactor at a pressure of 50 atm over a temperature range of 100 to 200 °C; low-molecular compounds containing less than four carbon atoms were found in the oxidation products. Since 2-butyl hydroperoxide does not decompose to products containing less than four carbon atoms, it was concluded that low-molecular oxidation products, such as methanol, ethanol, formaldehyde, acetone, and CO_2, are formed directly from the 2-butyl hydroperoxy radical *(2)*, the radical

undergoing isomerization prior to decomposing. The $CH_3O^{\bullet}$ and $C_2H_5O^{\bullet}$ radicals carry on the chain by reacting with the initial butane to form alcohols and $\dot{C}_4H_9$ radicals. Under these conditions decomposition of $RO_2^{\bullet}$ occurs only by action of the metal surface (in this case stainless steel).

Concentrations of 2-butyl hydroperoxide 10 to 15 times higher than those obtained in metallic reactors accumulate when the reaction is conducted in a glass reactor. Methyl ethyl ketone and *sec*-butanol are formed along with the peroxide.

In glass vessels, the decomposition products of the butyl peroxy radical are formed in yields no higher than 1 % (with respect to the reacted butane). Increased yields are obtained in steel reactors. An increase in the surface of the metal reactor by packing it with stainless steel also results in a higher yield of decomposition products.

Homogeneous and heterogeneous catalysts also seem to play an important part in olefin epoxidation [49]. For instance, faster formation of propene oxide in the presence of cobalt stearate was observed for conjugated oxidation of propene and acetaldehyde. Great attention has recently been paid to a promising process for production of propene oxide, which is based on the reaction between ethylphenyl hydroperoxide and propene [50]. Addition of salts of molybdenum and other metals increases the yields considerably.

4. Chain Termination

Chain termination in liquid-phase autoxidation occurs by recombination of free radicals:

$$RO_2^{\bullet} + RO_2^{\bullet} \rightarrow \text{products}$$

This reaction may yield either a peroxide (ROOR) and oxygen, or three species: alcohol, ketone, and O_2. Similar mechanisms have also been proposed for catalyzed oxidation. However, when transition metal salts are present in the system, stable products could also be formed by interaction between free radicals and metals in a low oxidation state; this would seem to account for the inhibiting effect of transition metal salts. Thus a transition metal salt may both initiate chains by reaction with hydroperoxides and terminate them by reaction with peroxy radicals.

The inhibiting effect of cobalt, copper, and manganese salts, has been observed in some cases [2, 51–54]. The dual catalytic and inhibiting function of transition metal salts can lead to a very peculiar effect, that of abrupt transition from autoacceleration to a stationary regime on a very small change in the metal ion concentration. For instance, when *n*-decane is oxidized in the presence of increasing amount of copper stearate, the induction period first decreases and then gradually increases with the $CuSt_2$ concentration up to $[CuSt_2] = 0.06$ mole-%. When the concentration attains 0.065 mole-% the induction period abruptly increases from 30–40 min to 15 h [55]. Similar critical phenomena are observed for oxidation of *n*-decane in the presence of manganese stearate [56].

The phenomena observed were ascribed to participation of metal salts both in initiation and in termination of chains. The inhibiting effect of transition metal compounds seems to depend not only on the nature of the metal as such, but also on the structures and properties of the anion or the ligand bonded to the metal ion. Contribution by the anion to the effect of copper in the oxidation of *n*-decane was established for several copper compounds, such as copper stearate, copper acetylacetonate, and bis(trioctylamine)copper(II) at 140 °C in the presence of 20 % of chlorobenzene (used to increase the solubility of the metal compounds). It may be seen from Fig. 10 that in the case of acetylacetonate the critical transition is not so abrupt and the critical copper concentration is somewhat lower than with copper stearate.

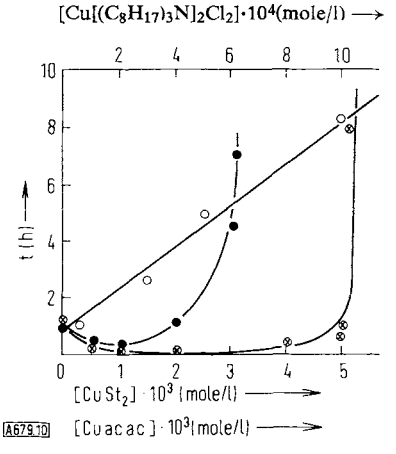

Fig. 10. The induction period for oxidation of *n*-decane/chlorobenzene (4:1) as a function of catalyst concentration. Catalysts: (⊗) copper stearate; (●) copper acetylacetonate; (○) bis(trioctylamine)copper(II)chloride. $T = 140$ °C.

The complex compound $Cu[(C_8H_{17})_3N]_2Cl_2$ showed no catalytic activity under the experimental conditions: the induction period increases linearly with the complex concentration, *i.e.* this compound inhibits oxidation.

The rate constant k in the reaction

$$RO_2^{\cdot} + Mn^{2+} \xrightarrow{k} Mn^{3+}(OH) + \text{ketone } (R = (CH_3)_2C(CN))$$

was determined by the chemiluminescence technique [57, 58]. Azodiisobutyronitrile in an inert solvent (chlorobenzene) between 60 and 80 °C was permitted to react with a stream of O_2. After attainment of a stationary radical concentration recorded by the chemiluminescence intensity, a manganese stearate solution of fixed concentration was introduced into the reactor. The luminescence intensity first dropped abruptly, and then increased again with consumption of manganese. The ratio of constants $k/\sqrt{k_7}$ was estimated from the increase in luminescence intensity, and k was determined from the known value of k_7. For manganese stearate this value appeared to be

$$k = 2.8 \times 10^8 \exp [-(4800 \pm 600)/RT] \text{ l mole}^{-1} \text{ sec}^{-1}.$$

This value is close to those for peroxy radical recombination. The reaction seems to occur *via* intermediate formation of a $St_2MnOOCHR^1R^2$ species, which subsequently decomposes to $St_2Mn(OH)$ and R_1-CO-R_2. The tervalent manganese actually appears in the reaction products as a basic salt, ketones and Mn^{3+} accumulating in equimolecular amounts.

[58] *K. C. Kooyman*, J. Catalysis *4*, 626 (1965).

The corresponding rate constant for cobalt acetylacetonate was determined from the rate of Co^{2+} consumption and appeared to be 2.0×10^4 l mole^{-1} sec^{-1} [59]. The rate constant for reaction of acetylacetonate with a styrene peroxy radical, as measured in styrene, was found to be

$$k = 2.9 \times 10^9 \exp [(-7800 \pm 1500)/RT] \text{ l mole}^{-1} \text{ sec}^{-1}.$$

Ferrocene in concentrations of less than 6.7×10^{-6} mole/l was found to be an efficient inhibitor of oxidation [60]. Copper complexes containing amines also show a strong inhibiting effect on oxidation. When *n*-decane was oxidized in the presence of a mixture of copper stearate with *N*-phenyl-β-naphthylamine, it was found that after complete disappearance of the inhibitor the reaction does not go beyond the induction period for a very long time [61]. At initial concentrations $[CuSt_2]_0 = 7 \times 10^{-4}$ mole/l and $[C_{10}H_7NHC_6H_5]_0 = 0.95 \times 10^{-3}$ mole/l the inhibitor is completely consumed within two hours, whereas the induction period of oxidation lasts for ~16 hours. A similar effect is observed for mixtures of copper acetylacetonate and bis(trioctylamine)copper(II) chloride with *N*-phenyl-β-naphthylamine.

It appears from the findings described in this paper that the salts and complex compounds of transition metals play a role in all steps of oxidation.

Electrocrystallization of Metals under Ideal and Real Conditions

By Hellmuth Fischer[*]

Ideal conditions during electrocrystallization, which are only approximately attainable, would lead to a perfect single crystal, whereas real conditions yield a monocrystalline or polycrystalline product containing many structural defects. The electrolytic production of quasi-ideal single crystals requires an overpotential that supplies at least the activation energy necessary for the formation of two-dimensional nuclei, since growth otherwise proceeds via screw dislocations with formation of a "real" crystal. The potential deviation in electrocrystallization under real conditions is due to electrochemical and/or crystallization overpotential, which can be determined separately. The investigation of electrocrystallization also offers possibilities for a systematic study of the formation of imperfections in real crystals.

1. Real and Ideal Crystals

The formation of solid crystalline matter is a very old and fundamental problem. In the early 1920's it was still thought (cf. [1–3]) that crystals grew only by continuously repeated formation of two-dimensional nuclei. The formation of two-dimensional nuclei, however, requires a relatively high activation energy. If this energy is not supplied, crystal growth should stop after the growth of the first lattice plane is complete. On the other hand, crystals frequently manage to grow in nature without the need for this work of nucleation. It was only in 1949 that a plausible explanation was provided in the form of the dislocation theory proposed by *Burton, Frank*, and *Cabrera* [4]. The basis of this theory is the presence of screw dislocations, which allow continuous growth of the crystal at extremely low degrees of supersaturation.

A 680.1

Fig. 1. Diagram of a screw dislocation (after *Frank et al.* [4]).

This growth principle is illustrated in Figure 1.

With progressive deposition of lattice particles, the dislocation spirals out of the lattice plane with a pitch equal to the interatomic distance. This can lead to the formation *e.g.* of pyramids. The growth of such a screw dislocation proceeds as follows [5]. Starting at the emergent site D of the dislocation (Fig. 2a), the

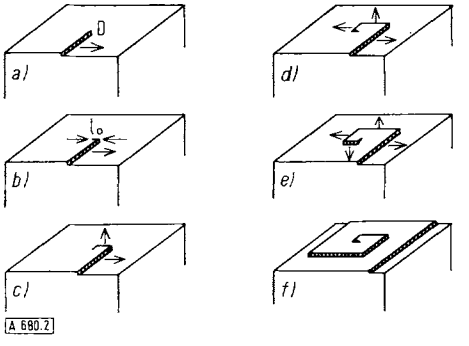

Fig. 2. Growth of a screw dislocation (after *Kaischew et al.* [5]).

edge of part of the dislocated lattice plane projects from the surface. Metal atoms are deposited on this edge in a row running parallel to it. The lattice plane step is consequently displaced perpendicular to the edge. When the side edge of the step, which simultaneously becomes longer, reaches a critical length l_0, *i.e.* the "edge length" of the two-dimensional nucleus (Fig. 2b), atoms begin to be deposited on this edge and parallel to it. This lateral step thus also moves outward perpendicular to the edge at an angle of 90° to the first step (Fig. 2c). Two further repetitions of this process complete the first turn of the screw. While all these steps continue to grow in their four directions, the second, third, fourth, *etc.* turns of the screw are formed. This leads to a very flat pyramid, the edges of which may be rounded to varying extents to reduce the edge energy.

Screw dislocations cannot be clearly recognized even under the electron microscope. They can, however, be made visible in electro-crystallization by conversion into "growth spirals". The only difference between these and the screw dislocations is the pitch, which is no longer one interatomic distance, but several hundred to one thousand interatomic distances. Spirals, of macro-steps, which are recognizable under the optical microscope, and which were obtained *e.g.* on cathodic deposition of copper with a pulsing direct current, are shown in Figure 3 [6]. The pulses lead to the continuous formation of new dislocations at the position of the screw dislocation, which build up to form the growth spiral. The formation of growth spirals has not yet been fully explained, but appears to resemble the formation of "growth layers", which also consist of macro-steps of comparable height (see Section 4.4).

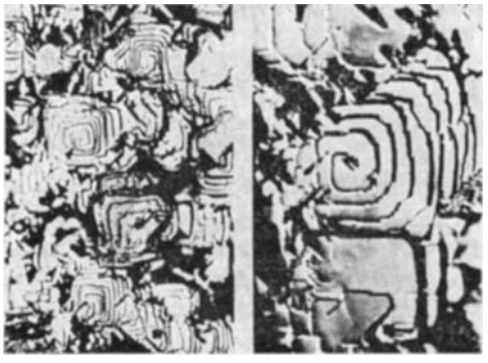

Fig. 3. Spiral growth during the electrocrystallization of copper (after *Seiter* and *Fischer* [6]).

The dislocation theory has proved extremely valuable. The more or less imperfect real crystal will therefore be compared here with the completely defect-free ideal crystal. The imperfections in a real crystal influence not only the nature of its further growth or its breakdown but also many of its physical and chemical properties. Other types of imperfections besides screw dislocations can also occur in the crystal lattice. Dimensionless imperfections, *i.e.* point defects, are where single particles have been removed from the positions that they would occupy in the ideal crystal. These defects occur either on the surface or in interstitial positions, and leave behind corresponding vacancies. Point defects, either alone or lined up to form steps, are involved in "thermal roughening" [7].

Multidimensional disorder includes edge dislocations and screw dislocations. Figure 4 shows a model of a real crystal [8] containing several types of imperfections. The point defects also include adsorbed or incorporated foreign atoms, ions, or molecules. An edge dislocation consists of a lattice plane that has been inserted between two other lattice planes, deviating from the building program of the ideal crystal. It appears on the surface of the crystal as a dislocation line. The initial stage of a screw dislocation is also shown (emergent site in the center of the left-hand side face). The atomic step of an incomplete lattice plane on the top occurs both in real and in ideal crystals.

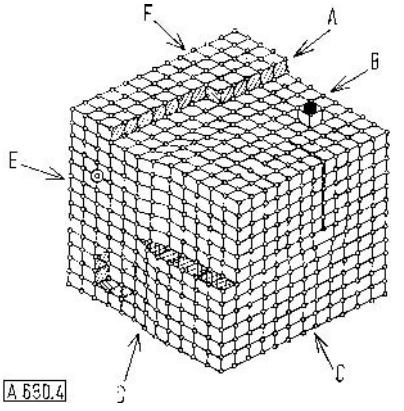

Fig. 4. Diagram of the surface of a real crystal.
A: Step; B: adsorbed ion; C: edge dislocation; D: screw dislocation; E: impurity in surface; F: kinked step (after *Gilman* in [8]).

Here we also find the kink position as "half-crystal-position". The deposition of a lattice particle here releases a particularly high deposition energy. If the row of atoms in the step is not yet complete, the incorporation of the atom leads immediately to a new kink ("repeatable step" [9]).

"Ideal" crystal growth conditions lead to a perfect structure formed in accordance with the theoretical structural plan, whereas real conditions give a structure containing many imperfections. On the basis of the habit of crystals, it is also possible to distinguish between conditions that lead to the equilibrium form of the crystal extending to infinity or to boundaries of any size even in polycrystalline aggregates that differ in their habit from the equilibrium form. Ideal conditions mean monocrystalline growth close to thermodynamic equilibrium, while real conditions lead to monocrystalline or polycrystalline growth remote from equilibrium.

It is well known that under conditions of condensation from the gas phase, the equilibrium form *e.g.* of metals having a face-centered cubic lattice, such as silver, copper, and lead, is a cube whose corners are replaced by octahedral faces and its edges by rhombododecahedral faces.

2. Electrocrystallization Compared with Condensation from the Vapor Phase

Everything that has been said so far refers to any kind of crystallization. If we now turn to the special case of the electrocrystallization of metals, phenomenological differences are clearly recognizable on comparison of its ideal course with that of a non-electric type of crystallization, *e.g.* from the vapor phase.

Figure 5 illustrates in simplified form the crystallization of a metal vapor on a solid surface of the same metal. Suppose that the surface of the substrate crystal is an equilibrium face (*e.g.* {100}) on which there is an atomic step, such as may often occur as a result of thermal roughening. A new, as yet incomplete row of atoms has been deposited on this step, with a kink

[9] See ref. [3a].

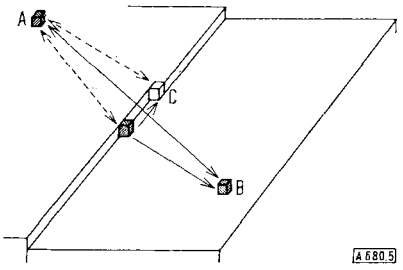

Fig. 5. Diagram of crystallization from the gas phase.
A: Metal atom in the vapor; B: adatom; C: lattice atom in the kink position.

at its end. The metal atom being transferred from the vapor phase to the solid substrate has three possibilities of reaching the energetically favorable kink position in near-equilibrium conditions: (i) it may be deposited directly in this position, (ii) it may be deposited on the step and diffuse along the edge of the step to the kink, or (iii) it may meet the surface at any point and diffuse from this point to the step and thence again to the kink.

If the position on the surface is favorable, the atom can reach the kink without first migrating to the step. In all three positions shown, the metal atom is bound less firmly to the substrate than a metal atom in the interior of the lattice. The atom situated on the surface is termed an adatom, *i.e.* it is regarded as an adsorbed metal atom. The adatom in the kink position has three nearest neighbors, and is most strongly bound in this position. The adatom on the step has two nearest neighbors, while that on the surface has only one [*].

The same simple scheme is often also used for the electrocrystallization of metals. Though the paths by which the adatom can reach the kink may be fundamentally the same [10], such a simplification can mislead one into ignoring certain differences between the two types of crystallization that are really very important.

The principal difference is undoubtedly the fact that whereas neutral metal atoms cross the metal/vapor interface in both directions during crystallization from the vapor phase, solvated or complexed metal ions (or even electrons in the other direction if *e.g.* complex anions or neutral molecules having a metal as the central atom reach the phase boundary) cross the metal/electrolyte interface in electrocrystallization. In any case the particles required for crystallization are formed at the kink or on steps or faces only after electrochemical neutralization by charge transfer.

Another important difference is that the metal surface is generally electrically charged at the metal/electrolyte interface. A condenser-like electric double layer consisting of a rigid component and a diffuse component (as in an ion cloud) is formed at this interface [11].

Thus the electrically charged metal/electrolyte interface, unlike the solid metal/metal vapor interface, is covered with oppositely charged foreign particles. Furthermore, surface-active components of the electrolyte are chemisorbed on it [12]. These foreign substances belong to the electric double layer.

Let us now follow the path taken by an initially dissolved, *e.g.* hydrated, metal ion in the greatly simplified Figure 6. The substrate is again a section of the surface

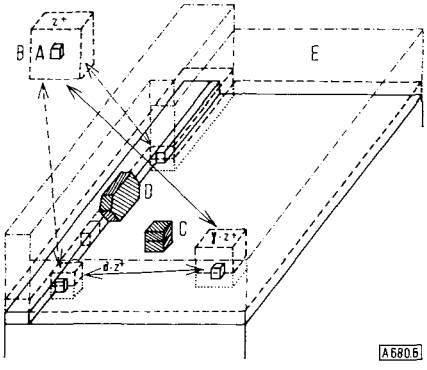

Fig. 6. Diagram of electrocrystallization.
A: Metal, B: water; C: anion; D: adsorbed organic material; E: boundary of the compact double layer.

of the crystal (same metal), *e.g.* a {100} face, with an atomic step (incomplete row of atoms) and a kink.

The hydrated metal ion follows the attraction of a strong electric field due to an externally applied DC voltage between the metal/electrolyte interface and a counter-electrode. The metal ion therefore migrates out of the electrolyte phase onto the metal phase. To reach the surface of the substrate crystal, the metal ion must pass through the electric double layer. The compact double layer (Helmholtz layer) also includes the adsorption film on the metal surface. The adsorption film will be assumed to consist mainly of water molecules, which form a largely continuous coating (only partly shown) on the metal surface. In contrast to the unhindered deposition of the metal atom from the gas phase, therefore, the metal atom must now displace one or more adsorbed water molecules from the metal surface [*] before it can enter into direct interaction with surface atoms of the metal phase.

The water film can also be partly or wholly displaced by more surface-active electrolyte components. If *e.g.* a more strongly bound organic molecule or an organic cation is adsorbed instead of a water molecule, the activation barrier for the transfer of the metal

[*] Thus we already have three energetically different states of adatoms. Their number can be greatly increased, even for the ideal crystal, if we consider the difference in their interactions with differently indexed faces, steps, and kinks. Finally the number of types of adatoms is further increased in real crystals (*e.g.* adatoms in deformed lattice regions).

ion may be too high, so that the metal ion must go around this obstacle.

If the metal ion comes into contact with the metal phase on displacement of the solvation film, charge transfer occurs, and the hydration sheath of the ion is simultaneously split. As in crystallization from the vapor phase, the positions at which these processes can take place are fundamentally the adatom position on the crystal surface, the step position, or the kink position. In all three positions the metal ion should be more or less neutralized and dehydrated on transfer.

However, the resulting adatoms, step atoms, and kink atoms are very different from the corresponding species formed by condensation from the vapor phase. An adatom in electrocrystallization is neither completely desolvated nor completely discharged. Despite the neutralization, part of the solvation or ligand sheath remains bound to the metal atom on the electrolyte side [14, 15]. Since the remaining ligand residue of charge carriers or dipoles favors polar bonding on the (charged) metal surface, the adatoms remain partly charged. As a result of ligand coupling they are naturally more bulky than the "bare" adatoms deposited from the vapor phase, and project into the double layer. To distinguish them from the neutral adatoms formed by condensation, these partly charged types formed in electrocrystallization will be called adions.

Thus in changing into adions, the metal ions do not pass through the full possible potential difference at the interface. The adion behaves on the metal side as a metal atom and can share the electron gas of the metal substrate, while on the electrolyte side it still behaves as a solvated or complexed ion.

The step atom also possesses the characteristics of the adion, but since it is more stably bound to the substrate metal, it is probably less hydrated and carries less charge than the adion. The bonding to the substrate, the hydration, and the partial charge will vary in both cases according to the crystallographic orientation of the substrate and its surface charge. The number of types of adions and step ions will thus be significantly greater than the number of types of adatoms and step atoms in condensation.

The kink atom is the closest to the firmly incorporated lattice atom of the metal surface. It is probably almost completely neutralized and less hydrated than adions or step atoms. According to calculations by *Bockris* and *Conway* [16], the activation energy for the transfer of a completely hydrated silver ion from the electrolyte to the kink position (35 kcal) is practically the same as that for a corresponding transfer into a vacancy in the surface. The activation energy for the direct transfer of a silver ion to a step is thus about 14 kcal less, while the activation energy decreases by about 25 kcal for the transfer to the adion position.

The differences in the activation energies should be very much greater for the transfer of metal ions having significantly stronger solvation bonds, *e.g.* nickel or copper ions, to the various positions on the surface. In this case there should even be an appreciable difference between the values for transfers to kink positions and to vacancies.

The target of the metal ion in its transfer to the substrate metal is, with one exception, always the kink position. It is only by incorporation in the kink position that the growth of a screw dislocation or of a step is maintained. The exception is the filling of a vacancy in the surface, which is not associated with a "repeatable step".

Incorporation into the lattice takes longer in electrocrystallization than in crystallization from the vapor phase. Even when it is deposited directly in the kink position, the metal ion, which is losing its solvation sheath, must first displace an adsorbed water molecule or other adsorbed species. In the case of more strongly surface active adsorbed species, this is often impossible, and the kink position is then blocked.

An adion diffusing on the surface or a step atom diffusing along a step has to push the adsorbed film aside. This is not possible in the case of much more strongly surface active adsorbed species, and the path to the kink position is again blocked.

The question of whether the metal ion is incorporated directly into the kink position or has to reach this position indirectly *via* the adion position and the step position has been the subject of many discussions [17, 19]. According to recent rough calculations by *Gerischer* [18] for two models (an isolated kink position in the form of a point and a line step with kink positions lined up close together), deposition of the metal ion from sufficiently concentrated solutions close to equilibrium occurs preferentially in the kink position (*e.g.* deposition of silver from $AgNO_3$ solution).

Conversely, on deposition from very dilute solution and/or farther from equilibrium, surface diffusion from the adion or step position to the kink position seems more probable (*e.g.* deposition of nickel from $NiSO_4$ solution, deposition of metal in the presence of strongly surface active inhibiting adsorbed species).

This picture is in agreement with the views of other authors [19].

3. Electrocrystallization under Ideal and Quasi-Ideal Conditions

How can we provide ideal electrocrystallization conditions for the deposition of a perfect single crystal in the equilibrium form:

In general, an ideal metal crystal will be in equilibrium with its electrolyte if the chemical potential of the metal phase over its entire surface is equal to the chemical potential of the electrolyte. We also stipulate that the ideal crystal be in its equilibrium form and extend to infinity. Furthermore, all the steps in the conversion of the metal ion into the adion, step atom, or kink atom and all the steps in the crystallization should proceed without any hindrance.

[14] *H. Gerischer* and *R. P. Tischer*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *58*, 819 (1954); *H. Gerischer*, *ibid. 62*, 256 (1958); Analyt. Chem. *31*, 33 (1959).

[15] *B. E. Conway* and *J. O'M. Bockris*, Proc. Roy. Soc. (London) *248*, 394 (1958); Electrochim. Acta (London) *3*, 340 (1961).

[16] See ref. [13], p. 232.

[17] See ref. [12], p. 118ff., 127, 156; ref. [13], p. 224ff.

[18] *H. Gerischer*: Proc. int. Conf. Protection against Corrosion by Metal Finishing, Basel 1966. Forster-Verlag, Zürich 1967, pp. 11, 15ff.

[19] *M. Fleischmann* and *J. A. Harrison*, Electrochim. Acta (London) *11*, 749 (1966).

All these conditions should be satisfied if the equilibrium Galvani potential ε_0 prevails on all the boundary faces of the crystal. *Vetter* and *Bachmann*[20] describe this by the simple Nernst equation in the form:

$$\varepsilon_0 = E_0 + \frac{RT}{zF} \cdot \ln \frac{{}_0a_{M^{z+}}}{a_0^*} \tag{1}$$

In this equation E_0 is the standard Galvani potential, R is the gas constant, T is the absolute temperature, and z is the valency of the metal ions, ${}_0a_{M^{z+}}$ is the activity of the metal ions in the electrolyte, and a_0^* is the "surface activity" of the metal phase. a_0^*, which is the most important quantity for our purposes, has a value of 1 in the equilibrium state. In general:

$$a^* = \sum_{j=1}^{j=n} K_{j+} \cdot n_{j+} \Big/ \sum_{j=1}^{j=n} K_{j-} \cdot n_{j-} \tag{2}$$

The numerator and the denominator are summed over all the energetically distinguishable surface positions of the crystal $j = 1$ to $j = n$) for the number n_{j+} of surface states of the adions, step atoms, kink atoms, and lattice atoms and the number n_{j-} of unoccupied atomic positions (*e.g.* unoccupied kink positions, surface vacancies, *etc.*) and for the rate constants $K_{j+} > K_{j-}$ of each type of position. The positive sign denotes anodic quantities and the negative sign cathodic quantities. At equilibrium the numerator and the denominator are equal, and a^* is equal to a_0^*.

The occurrence of the predicted equilibrium form has been confirmed experimentally for crystallization from the vapor phase; however, it has not yet been possible to check whether the equilibrium form corresponding to the experimental conditions, and particularly to the electrolyte concentration, has been established in the solid metal/electrolyte system, since the theoretically possible equilibrium forms in these cases are not yet known.

In any case, the habit of these forms probably differs appreciably from that of the equilibrium form (produced from the vapor phase), since the surface states occurring at the metal/electrolyte interface are different from and much more highly differentiated than those at the metal/vapor interface.

Like any crystallization, the electrocrystallization of a metal will proceed only as long as a more or less large degree of supersaturation, *i.e.* deviation from the equilibrium state, exists. A single crystal deposited electrolytically should therefore initially differ to a greater or lesser extent in its form from the equilibrium form. The (still empirical) equilibrium form should be approximately reached only when this single crystal has been left in contact with the electrolyte for a sufficiently long time with no current passing, probably by separation and rearrangement of the external boundaries with the aid of local currents[20]. The electrode potential ε prevailing at several surfaces of the single crystal that differ in their habit or relative size from the equilibrium form will deviate from the equilibrium potential ε_0. breakdown and rearrangement proceed, ε approximates more and more closely to ε_0.

Results *e.g.* of measurements on *hkl* surfaces of copper single crystals are interesting in this connection. In a hydrogen atmosphere with complete freedom from oxygen, *Jenkins* and *Bertocci*[21] initially found potential differences not exceeding about 1.5 mV between the (110) and (100) and between the (100) and (111) faces; the value decreased within 1 hour to about 0.2 mV. The habit of the faces does not undergo any visible change. It appears that only the submicroscopic defects are in fact changed.

The difference between the Galvani potential and the equilibrium Galvani potential is known in electrochemistry as overpotential $\eta = \varepsilon - \varepsilon_0$. In electrocrystallization this overpotential can arise from two principal causes: (i) hindrance during the preceding electrochemical process of conversion of a metal ion from the electrolyte into a kink atom, a step atom, or an adion on the metal surface; the hindrance may give rise to an "electrochemical" overpotential η_e[*]; (ii) hindrance during crystallization, which leads to a crystallization overpotential η_k. This latter overpotential may be due to hindrance of incorporation in the lattice (*e.g.* as a result of surface diffusion and/or displacement of adsorbed species), formation of two-dimensional lattice-plane nuclei, or formation of three-dimensional nuclei. Direct transfer into the kink position requires practically no crystallization overpotential if only a weakly bound water molecule has to be displaced. It may, however, be hindered electrochemically.

The total overpotential of electrocrystallization can thus be written

$$\eta = \eta_e + \eta_k \tag{3}$$

In the equilibrium state there should be no inhibition of any kind, and both overpotentials should therefore be equal to zero.

As was mentioned earlier, however, the electrolytic preparation of single crystals requires a certain supersaturation, which may have a corresponding overpotential $\eta = \varepsilon - \varepsilon_0$. If the crystal is not to grow *via* screw dislocations, *i.e.* is not to become a real crystal from the outset, the overpotential must supply at least the activation energy for the formation of two-dimensional nuclei.

The electrolytic growth of a substantially perfect single crystal cannot therefore occur under strictly ideal conditions. The experiment must be carried out under electrochemical conditions which, though the system may be regarded as being close to equilibrium, are really only "quasi-ideal". Thus whereas we can still take $\eta_e = 0$, an appreciable crystallization overpotential η_k must be accepted. *Vetter* and *Bachmann*[20] define this crystallization overpotential under quasi-ideal conditions as follows:

$$\eta_k = \varepsilon - \varepsilon_0 = -(RT/zF) \ln (a^*/a_0^*) \tag{4}$$

where a^* is the surface activity, *e.g.* in the electrolytic preparation of the single crystal and a_0^* is the surface activity in the equilibrium state. This equation enables us to formulate the crystallization overpotential for all cases that can arise under quasi-ideal conditions, *e.g.* the development of non-equilibrium surfaces, the formation of a small crystal instead of one of infinite size, macroscopically rough surfaces, lattice imperfections, and two-dimensional nuclei.

[20] *K. J. Vetter* and *J. Bachmann*, Z. physik. Chem. N.F. *53*, 9 (1967).

[21] *L. H. Jenkins* and *N. Bertocci*, J. electrochem. Soc. *112*, 517 (1965).

[*] This can be further subdivided into other overpotentials (charge transfer, diffusion, and reaction overpotentials).

$\varepsilon - \varepsilon_0$ is measured in the rest state, *i.e.* with no external current flowing, so that ε should slowly change into ε_0. The η_k values that occur under these quasi-ideal conditions should be of the order of 10^{-3} to 10^{-4} V.

Over the past four decades there has been no lack of successful attempts to prepare single crystals electrolytically, though these crystals were always obtained by further electrolytic growth of a "seed crystal" that had not been prepared electrochemically.

However, the experimental conditions rarely correspond to our quasi-ideal conditions. Perhaps a known case is the deposition of silver crystals from concentrated solutions of silver salts with an anion having a relatively low surface activity, such as the nitrate ion. The electrochemical processes that precede crystallization suffer practically no inhibition in this case, and η_e is consequently negligible. Since the equilibrium current density, *i.e.* the "exchange current density" i_0 for the cathodic deposition of silver, is relatively high [*] the deviation from equilibrium is not too great if the crystal is allowed to grow at current densities $> 10^{-1}$ A/cm^2. Two-dimensional nuclei can form readily under these conditions. Finally, the silver ion is only weakly hydrated. The adion of the electrolytically deposited silver should therefore be fairly similar to the adatom of silver deposited from the vapor phase.

These quasi-ideal preparation conditions approximately prevailed in an investigation by *Kaischew, Budewski,* and *Malinowski* [22], who deposited silver from solutions of silver nitrate (3–6 N) in nitric acid at 30 °C on cathodes consisting of spherical single crystals of silver (diameter 5 to 6 mm) at current densities between 5×10^{-3} and 7.5×10^{-1} A/cm^2.

The "near-equilibrium" form deposited under these conditions does not differ much in its habit from the theoretical equilibrium form of silver deposited from the vapor phase. As in the latter case, the product is a cube whose corners have been replaced by octahedral faces, but the edges are not replaced in this case by rhombododecahedral faces. The cubic and octahedral faces are known to develop under the influence of the particularly strong interaction of nearest neighbors. The rhombododecahedral faces, on the other hand, depend on the much weaker effect of next-nearest neighbors. With decreasing supersaturation, *i.e.* with increasing proximity to equilibrium, faces that are not present in the equilibrium form appear to a small extent. These deviations could be due to the differences in the surface state of the single crystal faces prepared by the two crystallization processes. Adsorption of nitrate ions may also be important in the case of electrolytically deposited silver.

However, the crystals prepared by the above authors were undoubtedly not free from dislocations. Moreover, electrolytic deposition on spherical single crystals is open to the objection that the habit found could be influenced by a non-uniform current distribution.

This problem has very recently led to work in which the entire single crystal was no longer allowed to grow electrolytically, a special apparatus being used instead to allow the growth of only one face. It is then possible to obtain a uniform current distribution. Thus the substrate used by *Budewski, Kaischew, et al.* [23] was electrolytically deposited cubic faces of single-crystal silver that filled the cross section of a glass tube.

Initially, this single crystal face also has a relatively high dislocation density; however, the screw dislocations are eliminated in this case by pre-electrolysis with deposition of silver from an $AgNO_3$ solution. The pre-electrolysis is carried out at a voltage below the crystallization overpotential η_{k_2} (about 10 mV) required for the formation of two-dimensional nuclei. In the course of this pre-electrolysis, in which the dislocations migrate out of the surface, the current density falls to zero. The surface is then practically free from dislocations.

No current flows through a perfect single-crystal face until the nucleation overpotential (about 10 mV) is reached. Beyond this overpotential, *e.g.* with a constant direct current (galvanostatic conditions), the overpotential begins to fluctuate periodically (see Fig. 7). Each period corresponds to the nucleation of a monoatomic layer (lattice plane). The period is inversely proportional to the current density.

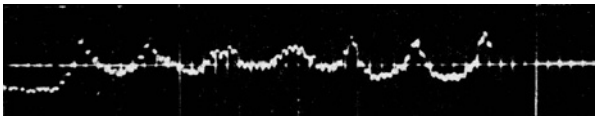

Fig. 7. Overpotential fluctuations during the growth of a dislocation-free single-crystal face ($i = 5.8 \times 10^4$ A/cm^2; abscissa: 0.2 sec/cm, ordinate: 5.2 mV/cm) (after *Budewski et al.* [23])

When the current is switched on, the corresponding adions cannot yet be incorporated. The overpotential therefore rises to a critical maximum value. It is only when this value has been reached that a nucleus of the new lattice plane can be formed from the accumulation of adions on the surface. This plane now grows by continuous addition of adions. As this lattice plane spreads out over the surface, the overpotential decreases, and reaches its lowest value when the lattice plane reaches the edges of the surface. The overpotential must rise to the critical value again before the next plane nucleus can be formed, and the process is then repeated. Thus the next nucleus is formed only when the growth of the preceding lattice plane is complete.

According to a relation found by *Volmer*, the nucleation rate, *i.e.* the number of plane nuclei formed per unit time [*], is

$$J_2 = c \exp\left(-K_{hkl}/\eta_{k_2} RT\right), \quad J_2 = 1/\tau \qquad (5)$$

where c and K_{hkl} are constants and τ is the time required for the formation of a nucleus. This relation shows that $\ln \tau$ is inversely proportional to the nucleation overpotential η_{k_2}.

[*] *Gerischer* and *Tischer* [14] found an exchange current density i_0 of 4.5 ± 0.5 A/cm^2 by the double pulse method in a 0.1 mole/l solution of $AgClO_4$.

[22] *R. Kaischew, E. Budewski,* and *S. Malinowski*, Doklady bolgarskoj Akad. Nauk *2*, 29 (1949).

[23] *E. Budewski, W. Bostanoff, T. Witanoff, Z. Stoinoff, A. Kotzewa,* and *R. Kaischew*, Electrochim. Acta (London) *11*, 1697 (1966).

[*] A different and more accurate formulation is

$J_2 = c \cdot \exp(-\pi f \varepsilon^2_{(hkl)}/ze_0 kT\eta_{k_2})$,

where f is the area occupied by an atom, $\varepsilon_{(hkl)}$ is the specific free edge energy, z is the valency, and e_0 is the unit charge.

According to *Budewski et al.*[123], one lattice plane after another can be formed as often as is desired by a continuous succession of voltage pulses (potentiostatic conditions), these pulses always exceeding the nucleation overpotential and being just sufficient for the formation of a nucleus. The measured duration of the pulses must be proportional to the nucleation time τ and inversely proportional to the nucleation rate J.

The proportionality of $\log \tau$ and $1/\eta_{1k_2}$ confirms that two-dimensional nuclei are in fact formed under these conditions.

Fig. 8 illustrates the linear relationship between the overpotential required for the formation of two-dimensional nuclei and the logarithm of the nucleation time τ.

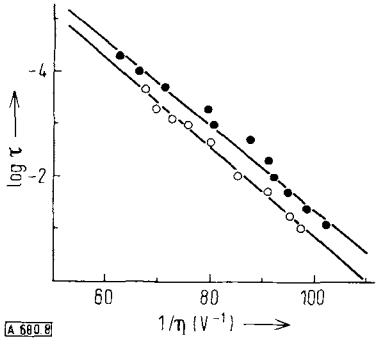

Fig. 8. Logarithm of the nucleation time τ as a function of the reciprocal of the overpotential in two-dimensional nucleation on a dislocation-free single-crystal face (after *Budewski et al.* [23]).

It was thus demonstrated for the first time that two-dimensional nuclei are in fact formed during electrocrystallization under these conditions (which are, however, special). It was thought for a long time that no such nuclei occurred in this type of crystallization. According to the data available, the work required for the formation of a two-dimensional nucleus at an overpotential of 10 mV is 8.6×10^{-13} erg.

4. Electrocrystallization under Real Conditions

4.1. Causes of Potential Deviations

As was shown earlier, it is possible, by electrolysis close to equilibrium, either to deposit single crystals having a habit that is similar to the equilibrium form, but which is by no means free from dislocations, or to form at least one equilibrium face with practically no deformations, though the latter is achieved at the cost of a nucleation overpotential.

Real conditions are characterized by a relatively large deviation from equilibrium, *i.e.* the potential ε is either very much greater or very much smaller than ε_0. Concerning the nature of the potential deviation $\varepsilon - \varepsilon_0$, which determines the nature and concentration of the adatoms, and hence also the course of the crystallization process, three cases can theoretically be distinguished. In the first case the potential deviation is due only to the crystallization, which is hindered or accelerated. This deviation will be denoted by $\varepsilon_k - \varepsilon_0$, where ε_k is the Galvani potential corresponding to the modified crystallization. This state of affairs can be achieved experimentally, though only rarely. In the second case the potential deviation is determined only by the preceding electrochemical process. The deviation from the equilibrium potential in this case is denoted by $\varepsilon_e - \varepsilon_0$, where ε_e is the Galvani potential of the modified electrochemical process.

Hindrance or acceleration of the electrochemical process nearly always leads to a change in the adion concentration on the surface of the metal, *i.e.* according to eq. (4) to a deviation of the surface activity a^* from the equilibrium activity a_0^*. This would itself lead to a crystallographic change.

With a greater deviation from equilibrium, the appreciable overpotential η_e rises above the limit below which the crystals still grow exclusively *via* dislocations. Beyond this limit, therefore, one should expect the formation of two-dimensional nuclei. This is so *e.g.* in nickel deposits formed with strong hindrance of the passage of metal ions through the electric double layer (high charge-transfer overpotential) or in very finely divided metal powders formed on strong inhibition of the transport of the metal ions to the phase boundary close to the limiting current density (high diffusion overpotential).

Inhibition of the electrochemical process without affecting the crystallization is possible only if the supply of kink positions in the crystal is so large that the transition of the metal ion still takes place only by direct incorporation into these positions from the electrolyte, *i.e.* without the formation of adions. This case is generally confined to proximity to equilibrium and special cases (see Section 4.2).

Apart from these exceptions, this second case is usually replaced by a third, the commonest case under real conditions, in which the potential deviation is determined by the electrochemical process and the crystallization. The deviation in this case is $\varepsilon_e + \varepsilon_k - \varepsilon_0$. The separation of the two effects, *i.e.* the determination of the crystallization overpotential η_k in the presence of the electrochemical overpotentials has so far proved very difficult (see Section 4.3).

4.2. Examples of Electrocrystallization

Let us consider two examples of the effect of the metal on crystallization. Whereas the conditions of the formation of two-dimensional nuclei *e.g.* during the deposition of silver on a dislocation-free substrate could be regarded as quasi-ideal so long as the preceding electrochemical process remained practically in equilibrium, this no longer seems admissible for the formation of three-dimensional nuclei, *i.e.* in the case of polycrystalline deposits. Since the formation of three-dimensional nuclei requires a much higher activation energy and overpotential, the conditions here are indisputably real.

According to *Volmer* the rate of formation of three-dimensional nuclei J_3 is given by a relation similar to

that for the rate of formation of two-dimensional nuclei [cf. eq. (5)] [*]:

$$J_3 = c' \exp(-K'/\eta_{k_3}^2 RT) \quad (6)$$

where c' and K' are constants and η_{k_3} is the overpotential required for the formation of three-dimensional nuclei.

η_{k_3} can be found experimentally with another metal as the substrate. A substrate such as platinum, tantalum, or stainless steel, generally covered with an inhibiting oxygen or oxide film, cannot simply be continued by the electrolytically deposited metal. The formation of three-dimensional nuclei from the metal deposited is therefore essential to growth.

Once formed, the nuclei grow by continuous addition of adions. The formation of three-dimensional nuclei is therefore basically only a (non-repetitive) initial process here. Quasi-ideal further growth of the polycrystalline metal deposit on a substrate of a different metal is made possible only by the intermediate layer of seed crystals adhering to the substrate.

Under deposition conditions such that no appreciable other polarizations or overpotentials can occur, an almost pure nucleation overpotential can be obtained in the initial process. In comparison with this overpotential, the overpotential that then arises during the further growth of the nuclei is relatively low. *Kaischew et al.* [24] have confirmed the validity of the Volmer relation for the initial formation of three-dimensional silver and lead nuclei on platinum single-crystal faces (which were not free from oxide). Three-dimensional nuclei of the metal were formed on another metal during a short cathodic voltage pulse with polarization. During this pulse, the nuclei formed grew into crystals that could be observed under the microscope.

The logarithm of the nucleation rate J_3 found by counting the microcrystals under an electron microscope was inversely proportional to the square of the overpotential, in agreement with the Volmer equation (6) [**].

In the quasi-ideal further growth of the nuclei there again arises the question of whether the metal ions are transferred directly from the electrolyte to the nuclei or seed crystals, or form adions only outside the nuclei. In the latter case the adions would have to make their way to the nuclei by surface diffusion.

As was shown by *Mierke* and *Schottky* [25], silver ions (from $AgNO_3$ or Ag_2SO_4 solutions of various concentrations) show a distinct preference for the first route. This was demonstrated in the example of the electrolytic formation of three-dimensional silver nuclei on platinum. According to the theory of the number of nuclei [26], the number of nuclei should show a definite dependence on the electrolyte concentration if the silver ions were deposited directly on the nuclei. If surface diffusion of the adions occurred, on the other hand, the number of nuclei should be practically independent of the electrolyte concentration. The experimental curve of the number of nuclei against the concentration agreed well with the theoretical curve.

The second example of a purely crystallization-controlled potential difference [27] is connected with changes in the corrosion potential of electrolytically deposited copper as a function of lattice imperfections. The rest Galvani potential at the metal/electrolyte interface may be regarded as a measure of corrosion resistance. As will be shown in Table 1, the rest Galvani potential changes significantly with the structure of the copper surface. Owing to the absence of external current in the rest state, the electrochemical process should be approximately in equilibrium.

Owing to their differences in structure, electrolytically deposited metals of the known structural types [27], which may be deposited *e.g.* in the presence of inhibitors with various activities, are suitable subjects for investigation. With increasing inhibition, the following structural types are obtained: the "basis-oriented reproduction type" (BR type) with its coarse crystal structure, the "field-oriented texture type" (FT type) with its fibrous structure exhibiting preferential orientation, and the "unoriented dispersion type" (UD type) with its extremely finely crystalline, randomly oriented structure.

As is shown by X-ray studies on deposits of these types [28], the sizes of coherent lattice regions decrease in the order BR, FT, UD. The densities of the subgrain boundaries, and hence the dislocation densities, increase by several orders of magnitude from the BR type to the UD type. Thus the lattice imperfections also increase in number as a result of these grain boundary effects.

If the Galvani potentials of copper of the structural types mentioned are measured in acidic $CuSO_4$ solution (in the absence of air) against the Galvani potential ε_r of a coarsely crystalline standard copper specimen whose structure has been largely re-established by annealing in a high vacuum, different reference voltages are found. The Galvani potentials measured against the same metal become increasingly negative,

[*] A different and more accurate formulation is

$J_3 = \exp -(16\pi\sigma^3 \cdot v^2 \cdot \Phi(\beta))/(3\,KT \cdot z^2 \cdot F^2 \eta_{k_3})$

where σ is the specific free surface energy, v is the molar volume, $\Phi(\beta)$ is the wetting angle of the nuclei with the substrate, z is the valency, and F is Faraday's constant.

[24] *R. Kaischew, A. Scheludko,* and *G. Bliznakow,* Ber. bulg. Akad. Wiss. physik. Ser. *1,* 137 (1950); *A. Scheludko* and *G. Bliznakow, ibid. 2,* 227 (1951); *A. Scheludko* and *M. Todorowa, ibid. 3,* 61 (1952); *B. Mutaftschiew* and *R. Kaischew, ibid. 5,* 77 (1955); Z. physik. Chem. *204,* 334 (1955).

[**] If, contrary to expectation, an appreciable electrochemical overpotential η_e had occurred (as a charge-transfer overpotential) as well as the nucleation overpotential η_{k_3}, the Volmer equation (6) could not have been confirmed so well, since instead of the observed proportionality of $\ln J_3$ to $1/\eta^2$, the hindrance of charge-transfer would have required that $\ln J_3$ be proportional to η (J_3 being proportional to the current density).

[28] See ref. [12], p. 422ff.

i.e. decreasingly noble, with increasing imperfection density *i.e.* from the BR *via* the FT to the UD structural type.

This potential difference $\varepsilon_k - \varepsilon_r = \Delta\varepsilon_g$ may be regarded as the crystallization polarization of the electrode in the (currentless) rest state. With strong lattice imperfections in the metal (and hence also on the surface of the electrode), the imperfection-induced "activity" of the metal phase increases as a function of the density of lattice deformations.

Lattice deformations of multidimensional imperfection were examined by X-ray methods in specimens of the above type. The differences in the rest Galvani potentials $\Delta\varepsilon_g$ of various structural types can be calculated from the measured density of the lattice deformations, since it is possible, with the aid of the Nernst equation [cf. eq. (4)], to write:

$$\Delta\varepsilon_g = -(RT/zF) \ln (a_{1M}/a_{2M}) \quad (7)$$

If the imperfection-induced "activities" a_1 and a_2 of two samples of the same metal having different structures are assumed to be proportional to the relative distortions (lattice deformations) C_1 and C_2 [*], we obtain

$$\Delta\varepsilon_g = -(RT/zF) \ln (C_1/C_2) \quad (8)$$

Thus the potential difference $\Delta\varepsilon_g$ is found from the lattice deformation values C_1 and C_2 obtained by X-ray measurements. The $\Delta\varepsilon_g$ values calculated in this way for deposits M_1 and M_2 agree well with the $\Delta\varepsilon_e$ values obtained by electrochemical measurement between M_1 and M_2 (see Table 1).

Table 1. Potential differences $\Delta\varepsilon_g$ (from lattice deformations) and $\Delta\varepsilon_e$ (from electrochemical measurements) between electrolytic copper samples having different structures [29].

Structural type	C_1/C_2	$\Delta\varepsilon_g$ (mV)	$\Delta\varepsilon_e$ (mV)
M_1 UD M_2 BR	2.0	8.9	8.95
M_1 UD M_2 FT	1.68	6.6	6.6
M_1 FT M_2 BR	1.19	2.1	2.2

4.3. Determination of the Crystallization Overpotential

As was mentioned earlier, the crystallization and the preceding electrochemical process will generally both be hindered or accelerated during electrolysis. We shall now try to distinguish the characteristic results of these inhibition or acceleration phenomena, and hence the potential changes due to them. Until recently the crystallization overpotential η_k could be determined only as the difference between the total overpotential η_{tot} and all the other overpotentials, which could be determined individually (and which are referred to collectively as the electrochemical overpotential η_e in this article) plus the ohmic potential drop at the phase boundary [28]. The crystallization overpotential is thus given by

$$\eta_k = \eta_{tot} - (\eta_e + \eta_\Omega) = \eta_{tot} - (\eta_D + \eta_d + \eta_r + \eta_\Omega) \quad (9)$$

This process is relatively inaccurate and is not used much owing to its laboriousness.

Electrochemical overpotentials can be eliminated under certain conditions, if the changes in potential with time are measured in the rest state (*i.e.* with no externally applied voltage). The crystallization overpotential can be found in this way, as was shown by *Vetter* and *Bachmann* [20]. The example described by *Eichkorn* and *Fischer* [29] (see Table 1) is also based on this method. Unfortunately, however, this method cannot be used for the electrolysis.

It would be possible to solve this problem for electrolysis if one could find conditions under which the electrochemical overpotentials and the desired crystallization overpotential occurred in succession. This is so if the metal is deposited on a reproducible substrate of the same metal that has an extremely high kink concentration [29]. The deposition conditions used are such that a crystallization overpotential could be confidently expected on a substrate of the same metal with a normal (*i.e.* much lower) kink density.

On deposition of metal on the highly active substrate with a high kink concentration under the conditions mentioned, the situation should initially correspond to case 2 of Section 4.1. Thus the metal is at first mainly deposited directly in the kink positions, so that there is no crystallization overpotential. This leaves only the overpotentials of the electrochemical process and the ohmic potential drop. The substrate-dependent growth form takes several seconds or even minutes to change into an individual form, depending on the deposition conditions. The electrochemical overpotentials and the ohmic potential drop remain practically unchanged, while a crystallization overpotential also appears.

The success of this procedure must have been largely due to the choice of a suitable substrate that can be regarded as definite even in the polycrystalline state. Whereas a single-crystal surface that was practically free from dislocations was used for the further growth of a single crystal under quasi-ideal conditions, the other extreme, *i.e.* a polycrystalline substrate having a particularly high surface activity (*i.e.* dislocation density) with random crystal orientation and an extremely fine grain size, was used for the "real" conditions for the determination of the crystallization overpotential η_k in the presence of the electrochemical overpotential η_e. The substrate used in our experiments was a cathodic copper deposit of the unoriented dispersion type (UD type, see Section 4.1). A deposit of this type that has been purified in a high vacuum at 250 °C has the structure mentioned. Copper was de-

[*] Obtained by Fourier analysis of X-ray line profile measurements. This gives the mean relative lattice plane displacements, from which the relative deformations of multidimensional imperfection are obtained. They are constant over the greater part of the lattice region.

[29] *G. Eichkorn* and *H. Fischer*, Z. physik. Chem. N.F. *53*, 29 (1967).

posited on this substrate in the presence of a cathode-active foreign adsorbed substance, β-naphthoquinoline (1-azaphenanthrene). On a normal copper surface, which has a relatively low kink concentration, the copper would immediately be deposited in the "field-oriented texture type" [*] under the action of the foreign substance (concentration between 10^{-7} and 5×10^{-4} mole/l). With the highly active substrate, on the other hand, the deposit at first adapts itself to the structure of the substrate, and this structure changes into the finely fibrous FT type only on further electrolysis.

During the period in which the deposit follows the structure of the substrate, the crystallization overpotential should still be negligible. The quantity measured in this period consists only of components of the electrochemical overpotential η_e. Figure 9 shows how the overpotential changes when the current density is kept constant. The following overpotential components occur: (i) $\eta_D + \eta_\Omega$ the sum of the charge-transfer overpotential η_D and the ohmic potential drop, and (ii) η_d the diffusion overpotential reached with time.

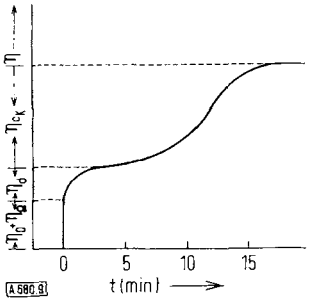

Fig. 9. Variation of the overpotential η on transition from reproduction to the individual growth form (after *Eichkorn* and *Fischer* [29]).

During a sort of incubation period, the crystal structure of the substrate is still continued in the deposit. The total polarization increases with time until a steady polarization plateau that is independent of time is reached. At this stage the deposit stops following the structure of the substrate, as can be seen under the microscope.

The preferentially oriented FT type that now occurs has a fibrous texture. It is built up uniformly from many crystal fibers, all oriented parallel to the field lines, *e.g.* perpendicular to the substrate. Each individual crystal fiber consists of numerous successive "growth layers" and each growth layer consists of a very large number of lattice planes (in the order of 1000).

4.4. Formation of the FT Structure Type

There was until now no sufficiently well founded theory of the formation of the very uniform "field-oriented texture type". The basic unit of this structure is evidently the growth layer. It was not certain whether the growth layer, and hence also the FT type, was formed *via* two-dimensional [30] or three-dimensional [31] nuclei.

As can be seen from Figure 9, the crystallization overpotential η_k corresponding to the formation of the individual layered and preferentially oriented growth form, which can be observed under the microscope, occurs above the plateau. No appreciable changes in the other types of overpotential are to be expected. The crystallization overpotential rises in an S curve with time until it reaches a steady value, which corresponds to the steady state of the substrate-independent crystallization under the deposition conditions in question. The crystallization overpotential η_{k} is thus given by the difference between the steady final overpotential and the "plateau" overpotential. The experimental S curve agrees with a calculated curve obtained by assuming that the layers are formed *via* two-dimensional nuclei [29].

On the basis of this assumption, we let the layer formation rate X, *i.e.* the number of growth layers formed per cm² per sec, be proportional to the average rate J_2 of formation of two-dimensional nuclei. On replacement of J_2 by X in the Volmer equation (5), a linear relationship between $\ln X$ and $1/\eta_{k_2}$ should be further evidence of the formation of two-dimensional nuclei.

The quantity X can be determined from the mean dimensions of the coherent lattice regions as found by X-ray analysis; these dimensions correspond to the mean dimensions of the growth layers. The average thickness of the growth layers, and hence the rate of layer formation, can be found experimentally by variation of the inhibitor concentration. This is accompanied by a change in the crystallization overpotential.

As expected, the crystallization overpotential increases with the inhibitor concentration, and reaches a value (average about 100 mV) comparable to the average electrochemical overpotential η_e. The average linear dimension of the coherent lattice regions is between 3270 and 1750 Å, depending on the inhibitor concentration. It decreases with increasing inhibitor concentration. The rate of layer formation X on the other hand, increases with increasing inhibitor concentration.

Figure 10 shows a plot of the rate of layer formation X, which is proportional to the nucleation rate, against $1/\eta_{k_2}$. It can be seen that, as expected if the

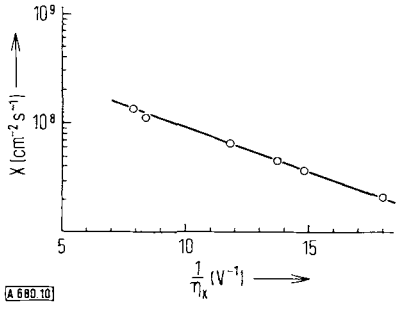

Fig. 10. Detection of the formation of two-dimensional nuclei (X = number of growth layers, η_k = nucleation overpotential) (after *Eichkorn* and *Fischer* [29]).

[*] From 1N $CuSO_4$ + 1N H_2SO_4 at 25 °C and a current density of 2×10^{-2} A/cm².

[30] See ref. [12], p. 393ff.

[31] *L. Graf*, Z. Metallkunde *42*, 336 (1951).

formation of two-dimensional nuclei is rate-determining, the relationship is linear. The activation energy found from the slope of the line is about 8×10^{-13} erg for a nucleation overpotential of 10 mV. This value agrees well with that found by *Budewski* (8.6×10^{-13} erg) for the formation of two-dimensional nuclei on silver (cf. Section 3). The two metals have the same unit cell, and dimensions are not very different.

We have thus found three pieces of evidence in favor of the formation of two-dimensional nuclei. These are the agreement of the calculated S curve with that found experimentally, the validity of the Volmer equation (5), and the agreement of the activation energies found for the formation of two-dimensional nuclei in the cases of copper and silver. It therefore seems justifiable to assume that the lattice planes in the growth layers are formed *via* two-dimensional nuclei.

The growth layer is a characteristic crystal lattice imperfection, which frequently occurs in electrocrystallization (as well as in other types of crystallization). Growth layers do not occur in the ideal crystal. In quasi-ideal growth, the formation of a new lattice plane can begin only when that of the previous plane is complete. This is confirmed by the results reported by *Budewski et al.* [23]. On the other hand, lattice plane nuclei can be formed much more frequently under real (distinctly non-equilibrium) conditions, *i.e.* they no longer have to await the completion of the previous lattice plane.

In our example the much higher nucleation frequency is partly due to the relatively high overpotential η_{le}. The activation energy for nucleation can also be further reduced by foreign adsorbed materials. In the real case, therefore, many new lattice planes will spread at short intervals over the first, as yet incomplete lattice plane (see Fig. 11, left, stage 1).

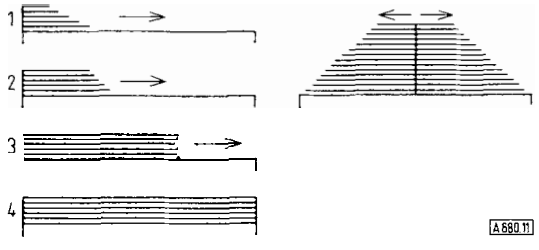

Fig. 11. Formation of growth layers and of pyramids.

The "bunching" of the individual atomic steps into a high macrostep (about 1000 atomic steps on average) (Fig. 11, left, stage 3) can be explained as follows [32]. Each of the successive lattice plane nuclei grows by deposition of metal into an atomic step extending over the substrate perpendicular to the lateral face. Metal is deposited only on the step edge with its many kinks, but not on the smooth step face parallel to the substrate, which is an equilibrium face and is therefore practically passive. There is therefore a temporarily very high local current density on the lateral face, but this must decrease very rapidly. This is ensured by the rapid increase in step edges.

[32] See ref. [12], p. 394.

The decreasing supply of metal ions and the increasing inhibition by adsorption of foreign materials slow down the growth of a given plane slightly earlier and to a greater degree than that of the next plane, so that the second plane can overtake the first. The planes then combine to form a macrostep, the growth layer. The thickness and width of the growth layer are limited by decreasing local current density (with increasing addition of atomic steps) and increasing inhibition. The decrease in the mean linear dimension of the layer due to inhibition has been confirmed experimentally (see Section 4.3).

The formation of new macrosteps is continuously repeated. This is probably how the crystal fibers of the FT type (and probably also isolated whiskers) are formed. Owing to the high nucleation frequency, very large numbers of crystal fibers are arranged in quick succession in the compact FT type, and grow parallel to one another. The number of fibers per unit area increases with the applied voltage and with inhibition.

With a combination of an adequate metal ion concentration, weak or absent inhibition, and a low current density, a given atomic step can no longer overtake those that preceded it, and macrosteps cannot be formed. The result in this case is the formation of pyramids (see Fig. 11, right).

It is in fact found that the deposition of copper from N $CuSO_4$ + N H_2SO_4 solution at 22 °C on copper having a (100) texture gives pyramids below 4×10^{-3} A/cm², whereas cubic platelets built up from growth layers are obtained at higher current densities [33]. The macrosteps of the growth spirals (see Section 1), the average height of which is comparable to that of the growth layers, are formed by a similar bunching principle. Local changes in current density on the edges of the atomic steps and different consumption rates could again enable later steps to overtake those started earlier. However, inhibition will only be slightly involved in this case, since growth spirals are readily blocked by very small quantities of inhibitors.

The fact that during growth, none of the faces on screw dislocations or spirals is exactly an equilibrium face should allow the deposition of inhibitors as well as metal ions on the faces that are not lateral faces of the steps. This may be why growth spirals do not stop growing in thickness and why they can spread out much farther than growth layers.

4.5. Formation of the UD Structural Type

The "unoriented dispersion type" (UD type), which consists of very fine, randomly oriented particles [*], is obtained when inhibition is particularly strong. Whereas the FT type is still obtained on addition of 5×10^{-4} mole/l of β-naphthoquinoline to the electrolyte, the UD type is obtained with 5×10^{-3} mole/l [34]. Preliminary experiments showed that at the higher inhibitor concentration, the overpotential no longer satisfies the Volmer equation (5), and the curve of X against $1/\eta_k$ (Fig. 10) shows a distinct deviation from linearity. This suggests that the formation of the UD type may involve three-dimensional nuclei.

[33] *H. Seiter*, *H. Fischer*, and *L. Albert*, Electrochim. Acta (London) *2*, 97 (1960), Figures 1 and 2.

[*] Average diameter about 600 Å.

[34] See ref. [12], p. 485ff.

The formation of three-dimensional nuclei has so far been detected only during the cathodic deposition of one metal on another that is covered with oxygen [24]. In the present situation, however, as in the case of the formation of two-dimensional nuclei, we are again faced with the problem of establishing the nature of the nucleus formation in the metal deposit on a substrate of the same metal in the presence of a strongly surface active inhibitor. Another difference concerns the continuity of nucleation. Whereas the formation of three-dimensional silver nuclei on platinum is only an initial process, which is stopped by the continuous growth of these first nuclei, we must expect uniform continuous nucleation, accompanied by slight growth of the nuclei, during deposition in the presence of strong inhibitors.

When copper is deposited on electrolytic copper of the BR type in the presence of a suitable quantity of inhibitor (2.5×10^{-3} to 8×10^{-3} mole/l of *o*-phenanthroline [*]), the overpotential follows the course shown in Figure 12 [35]. This curve is characteristic of deposition

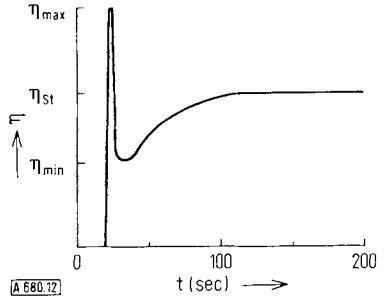

Fig. 12. Variation of the overpotential during the formation of three-dimensional nuclei (after *Eichkorn* and *Fischer* [35]).

under the conditions of formation of the fine-grain UD type on a substrate having a much coarser structure. The electrolyte was again a solution of N $CuSO_4$ + N H_2SO_4 (with added inhibitor). The adsorption of the inhibitor on the copper was allowed to reach equilibrium before deposition (25 °C, 3×10^{-2} A/cm²) was started.

At sorption equilibrium in the currentless sate, the foreign substance occupies nearly all the active sites and a large part of the inactive surface. This initial surface state leads to a high adion concentration coupled with a very rapid increase in the overpotential to the value η_{max} as soon as the current is switched on. Consequently, three-dimensional nuclei are formed everywhere almost simultaneously.

The resulting primary nucleus front, which is still controlled by the initial state, then grows out; this development is associated with a marked disturbance of the initial inhibitor adsorption equilibrium (as a result of displacement or incorporation of the inhibitor molecules in the deposit). This is accompanied by a rapid decrease in overpotential, probably because of the disappearance of the primary nucleation overpotential and part of the charge-transfer overpotential. The remaining overpotential $\eta_{i\,min}$ is the component of the charge-transfer overpotential corresponding to a steady state of inhibitor adsorption that has now been reached. This is followed at corresponding intervals by further nucleus formation and development of the nuclei. Both again reach a steady state and then proceed in a continuous manner. This corresponds to the steady overpotential $\eta_{i\,st}$.

Since the growth of the nuclei requires no appreciable overpotential, the difference $\eta_{i\,st} - \eta_{i\,min}$ must be associated with the steady nucleus formation. It increases with increasing inhibitor concentration. It is now necessary to check whether this is an overpotential η_{ik_2} or η_{ik_3}, *i.e.* whether it obeys the Volmer equation (5) or (6).

As in the detection of two-dimensional nuclei in inhibited electrocrystallization, the nucleation rate J again cannot be obtained by direct experiment. However, J can again be replaced by a quantity X, the number of particles formed per sec and per cm² (the UD type in this case). These particles correspond in size to the coherently scattering lattice regions that can be detected by X-ray measurements. It is assumed that any region of this type having an average diameter of 600 Å is derived from a single nucleation process. This is a plausible assumption.

Under the conditions of the experiment, X is given by

$$X = 1.08 \times 10^{18}/\bar{G}^3 = J \qquad (10)$$

The numerator of the fraction is the volume of copper in Å³ deposited per second and per cm² at a current density of 3×10^{-2} A/cm², and $\bar{G}^3$ is the mean volume of a coherent lattice region, $\bar{G}$ being the mean linear dimension of the region; $\bar{G}$ can be determined by X-ray measurements.

Figure 13 shows a plot of the nucleation rates J found with the aid of eq. (10) from X-ray data against the reciprocal of the square of the nucleation overpotential $1/\eta_{ik_3}^2$ for a number of inhibitor concentrations. A semilogarithmic plot gives a reproducible straight line.

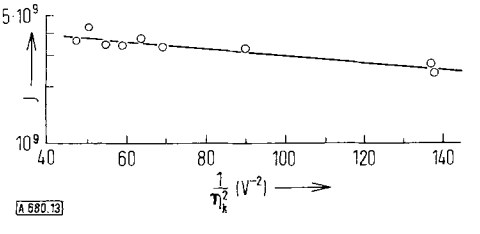

Fig. 13. Detection of the formation of three-dimensional nuclei (J = nucleation rate, η_{ik} = nucleation overpotential) (after *Eichkorn* and *Fischer* [35]).

This shows that, as was assumed, the UD type is formed *via* three-dimensional nuclei. From the data available, the work of nucleation at a nucleation overpotential $\eta_{ik_3} = 100$ mV is calculated to be 2×10^{-14} erg, while the value found for $\eta_{ik_3} = 10$ mV is 2×10^{-12} erg. These values are of the same order of magnitude as those found by other methods for the formation of three-dimensional nuclei of Ag, Pb, and Hg on platinum single crystals [24].

Reactions of Aromatic Nitro Compounds with Bases

By P. Buck[*]

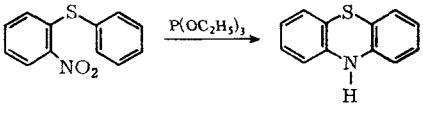
Aromatic nitro compounds can react in many ways with bases. The reaction path followed depends mainly on the degree of nitration (with a sharp jump from mononitro to di- and trinitro compounds) and the base used. Redox reactions or nucleophilic aromatic substitutions predominate with mononitro compounds, whereas Meisenheimer additions together with nucleophilic aromatic substitutions are preferred by dinitro and trinitro compounds; deprotonations are less common. The bromine in nitrobromobenzenes can be replaced by metal at low temperatures. Very weak bases generally give electron donor-acceptor complexes.

1. Introduction

Nitro compounds, and particularly aromatic nitro compounds, are readily available starting materials, and are used in many syntheses involving the introduction of nitrogen atoms or in situations where it is desired to take advantage of the versatility of the amines obtained from aromatic nitro compounds. Nitrated compounds are also frequently used for investigations on reaction mechanisms. They also play a valuable role in analytical chemistry because of their great ease of crystallization and the high extinction coefficients of nitrophenyl derivatives.

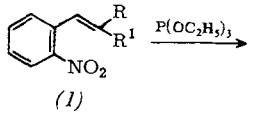
Nitro compounds are generally stable in acidic media unless they also contain groups that react with acids. Reduction in acidic solution generally leads to amines. On the other hand, most aromatic nitro compounds are very sensitive to bases, with which they can react in a variety of ways. The possibilities are outlined in Table 1.

2. Reactions of the Nitro Group and Free Radical Reactions



Attacks by bases on the nitro group are relatively rare, and are almost entirely confined to mononitro aromatic compounds, apart from partial reductions of the nitro group[1] in dinitro and trinitro compounds by $(NH_4)_2S$, NaHS, H_2S, and polysulfides, which are frequently also carried out in slightly basic solution.

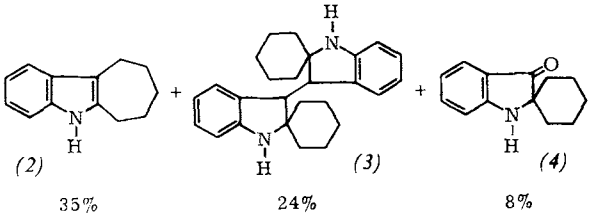
2.1. Alkaline Reducing Agents



The attack of the base on the nitro group is generally associated with reduction of the nitrogen (and simultaneous oxidation of the base). Where the base is also a reducing agent (*e.g.* $Na_4[Sn(OH)_6]$[2] or $Na[BH_4]$), the reduction of the nitro group is not surprising. Thus mononitro compounds (but not dinitro or trinitro compounds, see Sections 2.2 and 2.3) whose substituents have positive Hammett σ values are reduced to azoxy compounds in very good yields by $Na[BH_4]$ in ethanol[3]. An exception is found in the case of *p*-nitrofluorobenzene, in which nucleophilic aromatic substitution by the solvent takes precedence over reduction[3].

2.2. Bases Containing Trivalent Phosphorus

Reactions with phosphorus bases such as phosphine and triethyl phosphite have recently attracted growing interest. A particularly important use of these bases is in cyclizations *e.g.* in accordance with eq. (1)[4] and eq. (2).



(54%) (1)

(1)

$-R-R^1- = -(CH_2)_5-$ (2)

(2) 35% *(3)* 24% *(4)* 8%

The yields of the indoles corresponding to *(2)*, which are formed by rearrangement, are generally higher if R in *(1)* is a phenyl group[5,6]. (The example of eq.

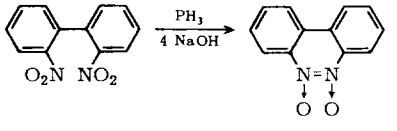
Table 1. Survey of the reactions of aromatic nitro compounds with bases.

Base \ further subst.	Mononitrobenzene			1,3-Dinitrobenzene				1,3,5-Trinitrobenzene		
	—	CH_3	*o*- or *p*-Hal	—	CH_3	4-Hal	4-OR	—	2-Hal or -OR	2,4,6-trisubst.
Alkoxides	Redox [8–11, 31]	Redox [9]	Subst [48, 49]	Add [50] Deprot [116]	CH_3-Deprot [116] Add [50]	Subst [48, 49]	Add [50] Subst [87] Deprot [116]	Add [50] Deprot [113]	Add [50, 87]	Subst [89]
Aliphatic amines			Subst [49, 92]		CH_3-Deprot [133]	Subst [48, 49]		Add [50] Deprot [114] EDA [132]	Subst [49] Add [50]	
Aromatic amines				EDA [126]		Subst [48, 49]		EDA [126]	Subst [49] EDA [126]	
Phosphites	Redox [4–6, 32, 34]	Redox [36]	(Subst) [134]							
$Na[BH_4]$	Redox [3]		Redox [3]	Add [76]	Add [76]	Add [76]		Add [75]	Add [88]	Subst NO_2^- [88]
Enolate or malonate			Subst [110]	Add [50, 63, 65, 69]	Add [50]	Add [50] Subst [49]	Add [50, 135]	Add [50, 62, 64]		
RMgX	Redox [12, 14, 42]	Redox [12]		Add [105]		Add [105]		Add [105]		
RLi	Redox [16, 17, 40]	Redox [16]	Redox and Hal-Met [18, 123]		Hal-Met [18]	Add and Hal-Met [18]			Add [18]	Hal-Met [18]



Redox = redox reaction (cf. Section 2); Add = addition to the aromatic ring; Subst = nucleophilic aromatic substitution (cf. Section 3); Deprot = deprotonation (cf. Section 4); deprotonation of the methyl group is marked. Hal-Met = halogen-metal exchange in bromine derivatives (cf. Section 5); EDA = electron donor-acceptor complex formation (cf. Section 6).

(2)[6] was chosen to show some characteristic by-products.)

The reaction with phosphine in alkaline aqueous ethanol proceeds differently[7]; the products in this case being azoxy compounds [eq. (3)]. 2,2′-Dinitrobiphenyl is only reduced to the nitroso stage [eq. (4)].

(3)

(4)

2.3. Alkoxides

Nitro groups can also be reduced by sodium ethoxide. This reaction has been known for some time[8] and has proved very useful in preparative work. In the presence of catalytic quantities (3–5%) of fluorenone or fluorenol, the reaction can also be carried out with NaOH in methanol[9]. However, the azoxy compounds formed in both cases are further reduced to hydrazo compounds by an excess of NaOH. Other alkoxides such as sodium methoxide[10] or sodium glycolate ($NaOCH_2CH_2OH$)[11] can also be used.

2.4. Organometallic Compounds

Grignard compounds and organolithium compounds also have a reducing action on mononitrobenzenes. *Gilman* and *McCracken*[12] and later *Kursanov* and *Solodkov*[13] proposed the stoichiometric equation (5) for the reaction of nitrobenzene with aryl Grignard compounds;

$$C_6H_5NO_2 + 4\,ArMgBr \rightarrow C_6H_5NH{-}Ar{-}MgBr + ArOMgBr + Ar{-}Ar + (BrMg)_2O \quad (5)$$

however, this equation can at best refer only to the principal reaction, since it gives only a very unsatisfactory description of the composition of the reaction products. The nitro group of methyl *p*-nitrobenzoate is reduced to the amino group (45% yield)[14], whereas

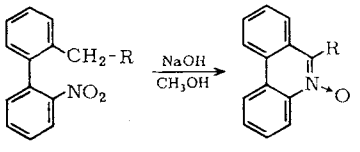
C_6H_5MgBr can add to the carbonyl group of *m*-nitrobenzaldehyde at −70 °C (77% yield) [15]. Under otherwise identical conditions, reaction at room temperature or with n-C_4H_9MgBr yields only tars [15].

Definite products such as azobenzenes and diarylamines retaining the nitrogen of the nitro compound used are generally even more difficult to obtain on reaction with organolithium bases. On the other hand, both oxygen atoms of mononitro compounds are often found quantitatively in phenols formed from the aryllithium compound [16, 17].

$$ArNO_2 \xrightarrow[2)\ H_2O]{1)\ Ar^1Li} Ar{-}N{=}N{-}Ar + Ar{-}NH{-}Ar^1 + Ar^1OH \text{ etc.} \quad (6)$$

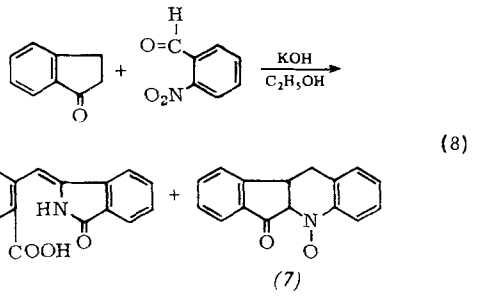
This phenol formation is also observed in the reaction of some dinitro-bromo aromatic compounds with phenyllithium [18].



2.5. Reaction Mechanisms

How should we picture the attack of the base on the nitro group? The nitro group *(5)* formally resembles the carboxylate ion *(6)*. However, *(5)* differs from *(6)*

(5) *(6)*

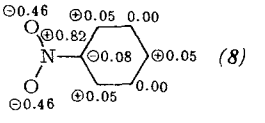


in the positive charge on the nitrogen. Because of this charge, the nitro nitrogen atom should be particularly reactive toward bases, *i.e.* it should enter into condensations similar to the Claisen ester condensation. Exactly the opposite is however found; condensations of this type are observed only in the case of biphenyl derivatives, where intramolecular condensation to form a six-membered ring is sterically favored, eq. (7) [19].

(7)

R = electron-attracting group

It is uncertain whether this is a true analog of the ester condensation, since the formation of the C–N bond need not take place with the nitro compound in its initial oxidation state. – The product *(7)* of the condensation of *o*-nitrobenzaldehyde with indanone is the only evidence of an intermolecular attack on the nitrogen of the nitro group by a carbanion [20], unless a primary condensation is assumed to occur between C-3 of the indanone and the aldehyde function.



(8)

(7)

The fundamental difference between nitro compounds and carboxylic acids (or their anions) becomes clearest in $^{16}O/^{18}O$ exchange experiments: whereas carboxylic acids in $H_2{}^{18}O$ exchange ^{16}O for ^{18}O both in acidic [21] and in basic [22] solutions, no incorporation of ^{18}O into nitro compounds has so far been detected in any case [23].

This remarkable situation is probably due to the fact that the environment of the nitrogen is completely saturated with electrons, whereas the oxygen atoms suffer from an electron deficiency. Moreover, the nitrogen cannot accept further electrons from the base. Nucleophilic attack is consequently no longer possible on the nitrogen, and should occur, if at all, on the oxygen. In agreement with this view, the oxygen of the nitro group is protonated only under drastic conditions. The pK_a value of nitrobenzene [24] is −11.38, and those of dinitro and trinitro aromatic compounds are even lower [25], whereas the value for benzoic acid [26] is +4.20.

The charge distribution found by HMO calculations [27] for nitrobenzene is shown in *(8)*. The electron density evidently has more influence than the Coulomb charge

(8)

distribution [28]: It can be shown chemically that organolithium compounds attack the oxygen and not the nitrogen (see Scheme 1).

If the lithium compound attacked the nitrogen atom of the nitro group and if the resulting phenols and (hypothetical) aromatic nitroso compounds were formed from *(9)* by a sort of Meisenheimer rearrangement,

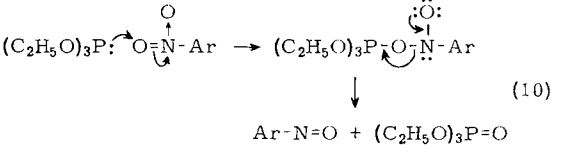
[28] This phenomenon is also found in the carbenoids [29] and the nucleophilic carbenes [30].

Scheme 1. C_7H_7 = *p*-tolyl.

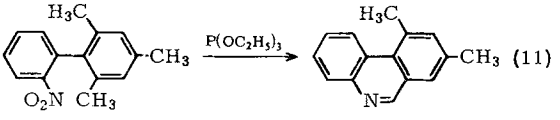
the product mixture obtained would be the same whether the starting materials were nitrobenzene and *p*-tolyllithium or *p*-nitrotoluene and phenyllithium (a). If on the other hand the oxygen of the nitro group is transferred directly to the base, phenol should be formed in one case and *p*-cresol in the other (b). It is in fact found that in agreement with case (b), the only phenol formed is that corresponding to the lithium compound used [16, 17].



The oxygen is also found in the base in all other cases, the base being oxidized. An example is the azoxybenzene synthesis mentioned in Sections 2.2 and 2.3, in which nitrobenzene is reduced in good yields by sodium methoxide in methanol [10]; if the reaction is carried out in the absence of water, azoxybenzene and sodium formate can be isolated, each in 87% yield [calculated by the stoichiometry of eq. (9)] [31].

$$4\ C_6H_5NO_2 + 3\ CH_3ONa \rightarrow 2\ C_6H_5{-}\overset{\overset{O}{\uparrow}}{N}{=}N{-}C_6H_5 + 3\ HCOONa + 3\ H_2O \qquad (9)$$

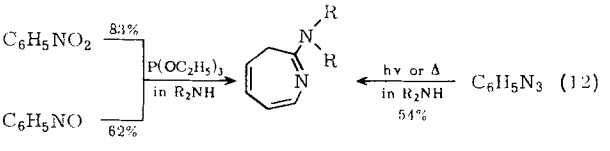
Little is known about the course of the reaction, except that the oxygen of the nitro group is (partly) transferred to the base. It may be assumed that various reactions are involved, depending on the base.



An attack on the oxygen of the nitro group by the lone electron pair of the phosphorus, eq. (10) [32], was formulated for the first time in deoxygenations by phosphorus bases.

The frequently expressed suspicion [33] that nitrene intermediates occur in reductions with phosphites has

(10)



recently been confirmed. On the one hand, the distribution of products from the deoxygenation of *o*-nitrobutylbenzene [34] with triethyl phosphite is remarkably similar to that obtained on pyrolysis of *o*-azidobutylbenzene [35], and on the other, C–H insertions *e.g.* eq. (11), are occasionally also observed in cyclizations [36].

(11)

Further evidence is provided by the formation of phosphorimidates $R{-}N = P(OC_2H_5)_3$ [34, 36].

Finally, the reaction (12), which is characteristic of phenylnitrene, has recently been detected in phosphite reductions.

(12)

Reductions of both nitrobenzene [36] and nitrosobenzene [37] in a secondary aliphatic amine lead in good yields to 2-amino-3*H*-azepines, which are also observed on thermolysis [38] or photolysis [39] of phenyl azide. On the other hand, nitrosobenzene is probably not an intermediate in the reduction of nitrobenzene with phenyllithium [16].

2.6. Free Radical Reactions

Free radical reactions must also be considered in the reactions of nitrobenzene with the organometallic compounds mentioned above, particularly since an ESR signal has been observed in the reaction of nitrobenzene with *n*-butyllithium in THF/hexane (3:1) [40].

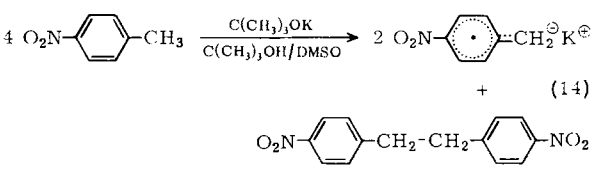
[40] *G. A. Russell, E. G. Janzen*, and *E. T. Strom*, J. Amer. chem. Soc. *86*, 1807 (1964).

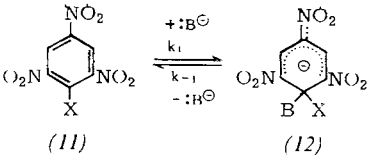


The estimated free radical concentration in this case was about 6%. Higher concentrations are obtained with tertiary aliphatic nitro compounds and organometallic compounds of alkali metals. The free radicals were identified in these cases as aminyl oxides, *e.g.* *(10)* [41].

(10)

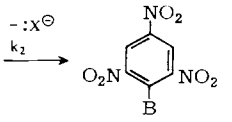
The aminyl oxide *(10)* also occurs (together with nitrobenzene radicalanions) in the reaction of *tert*-butylmagnesium chloride with nitrobenzene [42]. It is not yet possible to establish whether these radicals are formed by direct reaction or *via* a nitroso intermediate, since nitrosobenzene also gives aminyl oxides with Grignard compounds [43], with strong bases [44], and even with olefins [45].

Free radicals have frequently also been observed in reactions with alkoxides. Thus *o*- and *p*-nitrotoluene disproportionate spontaneously in the presence of potassium *tert*-butoxide in *tert*-butanol/dimethyl sulfoxide to give *o*- and *p*-nitrotoluene radical-anions and nitrobibenzyls, eq. (14) [44].



Aromatic nitro compounds without alkyl substituents do not undergo reactions of this type [46]. However, free radicals are also observed in these cases on irradiation in alcoholic methoxide solution [47].

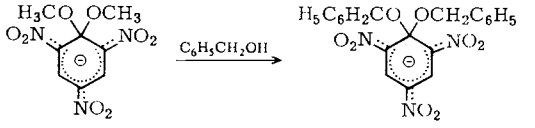
3. Meisenheimer Compounds and Nucleophilic Aromatic Substitution



The bases that reduce the nitro group according to the last section attack only the aromatic ring if there are two or three nitro groups situated *meta* to one another. The reaction can either stop at *(12)* (Meisenheimer addition) or lead to substitution if C-4 or C-2 carries a group X that can act as a nucleofugal leaving group.

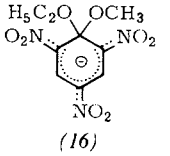
The addition and nucleophilic aromatic substitution have been fairly extensively studied and described in several reviews [48–50]. Only the fundamentals and the more recent results are discussed here.

(11) *(12)*



(15)

(13)



3.1. Structure of Meisenheimer Compounds

It was shown as early as the turn of the century that the addition products that can be isolated in many cases have the constitution *(12)*, *i.e.* they no longer contain an aromatic structure. Thus in 1900, *Jackson* isolated the dimethoxy compound *(14)*, which changes into the dibenzyloxy compound *(15)* on standing in benzyl alcohol [51].

(14) *(15)*

(16)

(16)

The equivalence of the two methoxy groups led *Jackson* to propose the structures *(14)* and (implicitly) *(15)*, while *Meisenheimer* found in 1902 that the adduct *(16)* is obtained both from 2,4,6-trinitroanisole and sodium ethoxide and from 2,4,6-trinitrophenetole and sodium methoxide [52]. Compounds of this type are known as Meisenheimer compounds.

According to HMO calculations, the accepted representations *(12)* and *(14)* to *(16)* are misleading. Despite the additional negative charge, the interruption of the cyclic conjugation leads to increased withdrawal of π electrons to the nitro groups [53].

NMR spectroscopy has proved a useful aid to the confirmation of the structure of many Meisenheimer

(17)

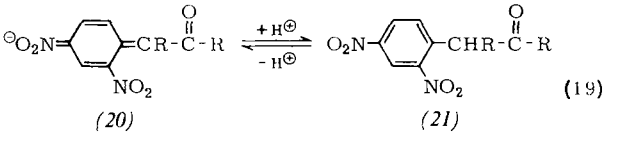
compounds [50,54]. It is not difficult to prepare these compounds as such from trinitrobenzene derivatives [55] or to record their NMR spectra in solution [54]. The same is true of corresponding compounds derived from aromatic dinitro or mononitro compounds such as *(17)* and *(18)* [56]. A compound of the type *(18)* was obtained by *Meisenheimer* [52].

(17) *(18)*

Meisenheimer compounds of dinitrobenzenes, however, are difficult to isolate, though a few have been obtained in a more or less pure state [57,58] and NMR studies have also been carried out recently [58].

3.2. Color Reactions

Dinitroaromatic compounds are used analytically in the Janovski and the Zimmermann color reactions.



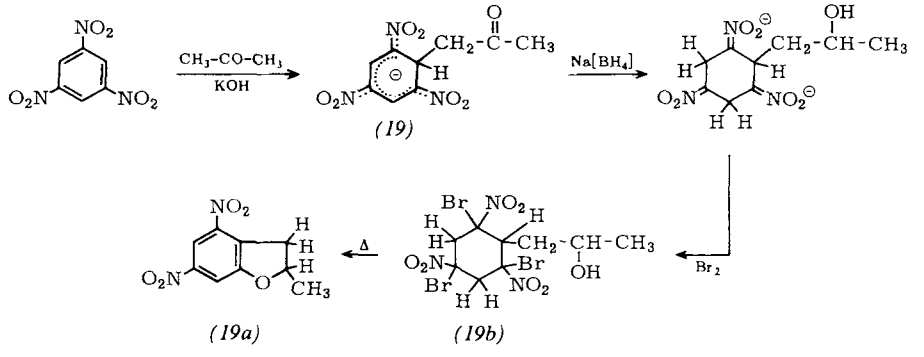
Many aromatic dinitro and trinitro compounds give a very intense blue to violet color with concentrated sodium hydroxide or sodium methoxide solution in the presence of acetone (Janovski reaction [59]). An intense violet color is also frequently obtained if the ketone is varied instead of the nitro compound. The variant with *m*-dinitrobenzene, which is known as the Zimmermann reaction [60], is particularly important in steroid chemistry, since it is a reliable test for 17-keto steroids [61].

It may be taken as certain in both reactions that a bond is formed between a carbon atom of the ketone and a carbon atom of the aromatic ring. After the reaction of 1,3,5-trinitrobenzene with acetone/KOH – the Janovski reaction is reversible – *Severin* [62] prevented the removal of the acetonyl group by reduction of the carbonyl group with $Na[BH_4]$. The compounds *(19a)* and *(19b)* were isolated.

This reaction also shows that there must be a high stationary concentration of colored Janovski complex, since 1,3,5-trinitrobenzene reacts differently with $Na[BH_4]$ [eq. (22)].

An NMR study of the Janovski reaction of *m*-dinitrobenzene indicates the structure corresponding to the formula *(19)* [63]. Janovski-Meisenheimer complexes of this type are obtained in acetone simply on addition of tertiary aliphatic amines [64].

The Zimmermann reaction, on the other hand, involves an oxidized complex *(20)*, in whose formation the nitro group itself acts as the oxidizing agent [65].



(20) *(21)*

This is also shown by spectroscopic studies, since the addition of bases to 2,4-dinitrobenzyl ketones *(21)* leads to UV absorptions that agree with those observed in correponding Zimmermann reactions [66,67].

Compounds of the types *(20)* [65,68] and *(21)* [69] have also been isolated and identified by elemental analysis [65,68] or NMR spectroscopy [69].

3.3. Site of Attack and Multiple Additions

The addition can take place on a carbon atom other than that carrying the group X (X = OCH_3, NR_2, halogen, *etc.*). Moreover, further base molecules may add to the Meisenheimer compound. Both of these possibilities are realized *e.g.* in reaction (20) [70].

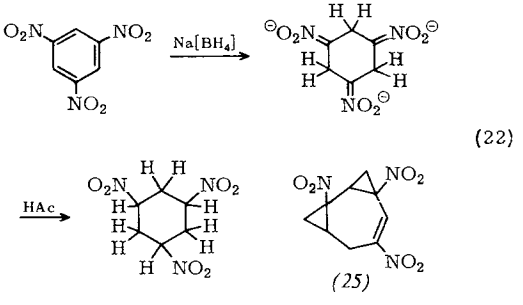
(20)

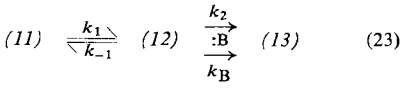


According to NMR studies, the formation of the Meisenheimer compound *(23)* in dimethyl sulfoxide also appears to be preceded by addition to C-3 to give *(22)*, which then changes rapidly into *(23)* [71].

(22) *(23)* *(24)* (21)

However, the participation of two molecules of base does not necessarily mean double addition. For example, two moles of secondary aliphatic amine react with one mole of trinitrobenzene in dimethyl sulfoxide. One amine molecule adds to give the Meisenheimer compound, which is deprotonated by the other to form *(24)*, as has been shown by NMR spectroscopy and by conductivity measurements [72, 73].

Triple additions to trinitrobenzene and picric acid are observed with diazomethane; these reactions lead to seven-membered rings such as *(25)* [74]. Trinitrobenzene is reduced to 1,3,5-trinitrocyclohexane by $Na[BH_4]$, eq. (22) [75], whereas dinitro compounds give only cyclohexene derivatives [76].



(22)

(25)

3.4. Mechanism of the Nucleophilic Aromatic Substitution

The idea that addition to the aromatic ring and nucleophilic aromatic substitution as in eq. (15) are related to each other [48] has proved extremely valuable in studies on substitution reactions of aromatic nitro compounds.

As in all two-step reactions it is necessary to distinguish two possibilities, depending on whether the ratio k_{-1}/k_2 is greater or smaller than 1. If $k_{-1} \gg k_2$ there is probably no objection to a two-step mechanism, and such a mechanism is in fact clearly indicated by kinetic studies on the base catalysis of nucleophilic aromatic substitutions on 2,4-dinitrophenyl phenyl ether [77]. The overall rate constant in this case shows a non-linear dependence on the quantity of NaOH added, as is to be expected if the decomposition of *(12)* is base catalyzed, eq. (23).

(23)

This result is confirmed by an investigation with ^{18}O-ethers [78]. On the other hand, the demonstrable existence of Meisenheimer compounds is not a conclusive argument for their occurrence as intermediates in the nucleophilic aromatic substitution; they could just as easily be products of an equilibrium side reaction [79], particularly since the addition frequently does not occur initially on the C atom to which the group X is attached, eq. (21).

Reactions in which $k_{-1} \ll k_2$ cannot yet be distinguished from those having a synchronous (*e.g.* S_N2-like) mechanism [82,83], as was shown by *Hammond* [80,81].

A third possibility, *i.e.* nucleophilic aromatic substitution by the elimination-addition (EA) mechanism, will be discussed in Section 4.2.

3.5. Electronic and Steric Effects in Addition and Substitution

The rates of nucleophilic aromatic substitution and of Meisenheimer addition increase with increasing substitution of the aromatic compound by electron-attracting groups. These may naturally be other groups than nitro groups, whose electron-attracting action is made up of two components, *i.e.* an inductive and a mesomeric component [84]. The mesomeric com-

ponent is strongly suppressed when coplanarity of the nitro group with the ring is prevented by bulky neighboring substituents. This is clear from the relative rate constants (figures under the formulas) for the substitution of chlorine in *(26)* to *(29)* by piperidine in ethanol [85].

0.001

Whether the reaction stops at the stage of the Meisenheimer compound depends mainly on how effectively the negative charge of the electron-attracting groups can be absorbed. The differences in the delocalization energies between the nitro aromatic systems and the Meisenheimer compounds (4-nitrobenzenes, −8 kcal/mole; 2,4-dinitrobenzenes, 1 kcal/mole; 2,4,6-trinitrobenzenes, 10 kcal/mole), which were successfully used by *Miller* [86] for the calculation of activation parameters of nucleophilic substitutions and additions, illustrate the enormous influence of the successive introduction of mutually *meta* nitro groups.

Consequently, no Meisenheimer compounds of mononitrobenzenes are known; those of dinitro compounds are difficult to isolate as such, whereas with trinitro compounds often no substitution [87] is observed but addition.

The effect of steric hindrance on the addition, *i.e.* the suppression of the mesomeric withdrawal of electrons by the nitro groups, is impressively demonstrated by *Kaplan*'s experiments [88]. The products of hydride additions to *(30)* and *(32)* are sufficiently long-lived to allow further additions, which lead to *(31)* (the stage at which the Cl atom is removed is unknown); *(33)*, on the other hand, exhibits only nucleophilic substitution, in which NO_2^- leaves more readily than Cl^-, as is known from other investigations [82,92]. In *sym*-trinitrotrimethoxybenzene, the methoxyl group is replaced by ethoxide [89], whereas 2,4,6-trinitroanisole gives only the Meisenheimer compound *(16)*.

Poor leaving groups X also increase the life of a Meisenheimer compound such as *(12)*. The nucleophilic

(24)

(25)

aromatic substitution is therefore catalyzed by bases in particular in nitro-fluoro compounds [90] and nitrated aryl ethers [77] (cf. Section 3.4). Experiments with 2,4-dinitrophenyl phenyl ethers having electron-attracting substituents on the electrofugal group confirm this, since they show a distinct decrease in base catalysis [91]. For the same reason, most of the Meisenheimer compounds studied have H and/or OR groups attached to the sp^3 ring carbon atom.

The rate of substitution of halogenonitrobenzenes generally decreases in the order Hal = I < Br < Cl ≪ F [48,49,92]. Thus the acceptance of a negative charge by the carbon to which the halogen is attached, which facilitates the addition of the base to the ring, has a stronger effect on the reaction rate than the leaving tendency of the halide ion. The reverse order is also found occasionally [80,93]. The relevant numerical data and the extremely high reactivity of the fluorine compounds, of which practical use can be made [94], are by no means fully understood.

In nucleophilic aromatic substitution by neutral bases, *e.g.* amines, the reaction rate exhibits a definite dependence on the dielectric constant of the solvent [95,96], except in the cases of alcohol, dimethylformamide, and dimethyl sulfoxide. The relative rate constants for different substrates can also be related to the nature of the solvent [96]. The solvent dependence has not been so systematically studied in reactions of basic ions. In this case high reaction rates are found particularly in aprotic dipolar solvents (DMF, DMSO, *etc.*) [97].

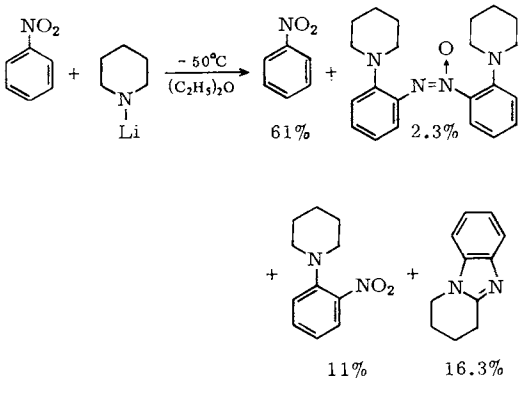
Methanol[98], dimethyl sulfoxide[99], and water[100] have a strong accelerating effect when added in small quantities to other solvents.

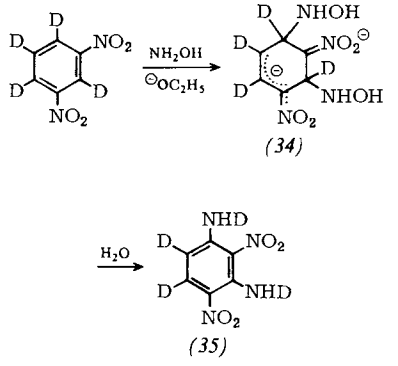
3.6. Effect of the Base on the Nucleophilic Aromatic Substitution



The nature of the base used is a factor of the utmost importance. As expected, faster substitutions are found with strongly nucleophilic bases whose electron cloud is readily deformed. *Pearson* and *Songstad* have applied the principle of "hard" and "soft" acids and bases to nucleophilic aromatic substitutions[101], but have not always succeeded in making correct predictions. In the hydrolysis of sulfonic esters, a change of base can even lead to a change in the course of the reaction. Whereas reaction (26) proceeds to the extent of 88 % by path (a) with sodium methoxide, the reaction with thiophenolate proceeds exclusively by path (b)[102].

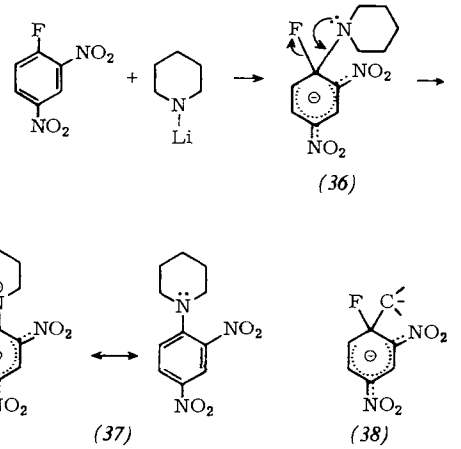
(26)

Steric hindrance of the base molecule has been studied with piperidine, 2-methylpiperidine, and 2,6-dimethylpiperidine[103,104]. The ratio of their rate constants with *p*-nitrofluorobenzene[104] is 135000:26:1.



Unlike organometallic compounds, which undergo multiple addition to the aromatic ring[105], alkali metal amides react exclusively by substitution under comparable conditions, even when only poor leaving groups such as hydride are available, eq. (27)[106].

Similar substitutions (though in the *p* position) have also been observed with piperidine and sodamide[107], as well as with sodium and potassium diphenylamides[108].



An interesting hydride substitution has been described by *Gitis et al.*[109]. [1,2,3,5-D_4]-*m*-Dinitrobenzene and hydroxylamine react in the presence of an excess of sodium ethoxide to form the intermediate *(34)*; this is decomposed by water to give *(35)*, which still contains all the deuterium originally present.

Fluorine in 2,4-dinitrofluorobenzene also undergoes more than 65 % nucleophilic substitution by lithium piperidide[16].

(28)

The striking difference between N–Li and C–Li compounds may be due to assistance of the release in the nucleofugal group by the lone pair of electrons present in all bases that

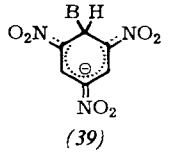
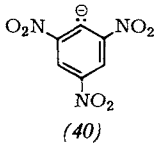
are capable of substitution. In eq. (29) the resonance stabilized 2,4-dinitrophenyl-1-piperidine *(37)* would be formed, whereas the corresponding complex *(38)* formed from a carbanion has *no* lone pair and so cannot react in the same way as *(36)*, but enters into additions instead [16].

Mononitroaromatic compounds can only rarely be nucleophilically substituted by carbanions. Substitution of *o*-nitrochlorobenzene can be achieved with potassiomalonic ester or potasioisocyanoacetic ester in *tert*-butanol, eq. (30) [110].



(30)

Pentafluoronitrobenzene is substituted in good yields in the *o* and *p* positions by pentafluoromagnesium bromide [111].

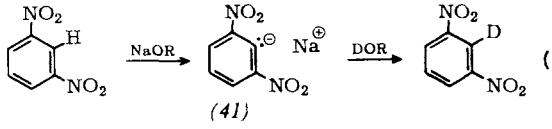


4. Deprotonation and Substitution *via* Dehydrobenzene

4.1. Deprotonation

Owing to the electron-attracting action of the nitro group, the *o*-H atoms in aromatic nitro compounds should be readily split off as protons. Few deprotonations of this type are known, however, probably because addition results in a greater energy gain. Whereas addition yields a delocalized system *(39)*, the negative charge on the carbanion *(40)* can only be stabilized inductively, and cannot be transferred to the nitro groups by resonance. The formation of Meisenheimer compounds thus occurs in preference to deprotonation, with the result that attempts to detect H/D exchange in *sym*-trinitrobenzene were for a long time unsuccessful [72, 112].

(39)



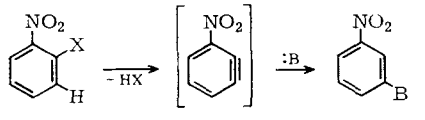
(40)

A slow H/D exchange can however be observed in a 9:1 dimethylformamide/water mixture. After 24 hours in dilute NaOD solution at room temperature, 15% of the hydrogen in *sym*-trinitrobenzene has been replaced by deuterium. At 100 °C the yield of [1,3,5-D_3]-*sym*-trinitrobenzene is 95% [113].

Other bases, both ions (*e.g.* acetate) and neutral molecules (*e.g.* 1,4-diazabicyclo[2.2.2]octane), are also effective under these conditions [114].

In *m*-dinitrobenzene, the hydrogen atom on C-2 can be exchanged under milder conditions. In addition to hydroxide [115] and methoxide [116], weaker bases are also active in this case [117], though to a smaller extent.

It has repeatedly been reported that the deep color of alkaline solutions of dinitro aromatic compounds is not due to the anion *(41)* [116]. A solution of *m*-dinitrobenzene in DMF/D_2O (0.005 M NaOD) is colorless [115]; moreover, color formation is much faster



(41)

(31)

than H/D exchange [117] at high concentrations of base, so that the concentration of *(41)* must be vanishingly small. Deep colors are therefore probably due to Meisenheimer complexes. However, nitrophenyllithiums, which can be prepared by halogen-metal exchange (cf. Section 5), also have very deep colors [118].

4.2. Substitution of Halogen by the EA Mechanism

The deprotonation of aromatic nitro compounds, though possible, is relatively unfavorable (see Section 4.1); nucleophilic aromatic substitution by an elimination-addition (EA) mechanism should therefore be unlikely. This type of reaction is generally not even considered in connection with aromatic nitro compounds, though it is very frequently observed in the nitrogen heterocycles, which are often compared with aromatic nitro compounds [118].

(32)

4.3. Substitution of NO_2^-

Since NO_2^- is a relatively good leaving group [82,95,96], a dehydrobenzene intermediate could be expected on thermolysis of *o*-nitrophenyllithium (see Section 5). However, no Diels-Alder adduct with 1,3-diphenylisobenzofuran could be detected in this case [16,17], the decomposition leaving the nitro group and its bond to the ring intact [18].

The occasionally observed substitution of a *m*-nitro group in trinitro aromatic compounds, the reason for which is not immediately obvious, is also not generally explained by dehydrobenzene intermediates. For example, when *sym*-trinitrobenzene is allowed to stand

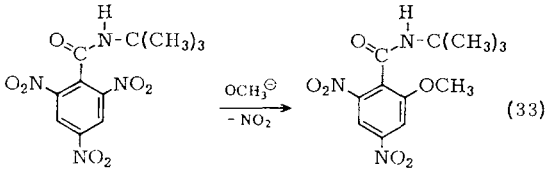
in methanolic methoxide solution, sodium nitrite and 3,5-dinitroanisole are ultimately formed [119]. According to *Foster* and *Fyfe* [50], this substitution is due to poor delocalization of the negative charge in *(42)*, so that such a species once formed decomposes rapidly, whereas the formation of the normal Meisenheimer compound *(43)* is reversible.

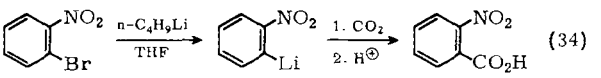


(42)

(43)

The substitution of the 2-nitro group in *(44)* by OCH_3^- or OH^- surprisingly exhibits first order kinetics (rate $=k_1$ *[(44)]*), *i.e.* it is independent of the base concentration [120].

(33)



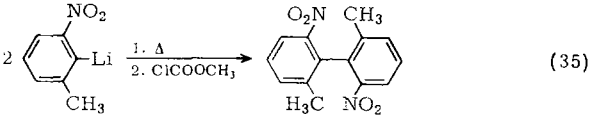
(44)

In addition to these reactions, which take place even in the dark, photochemical substitutions of the nitro group have been observed in some aromatic trinitro compounds [121], in *p*-nitrophenyl phosphate, and in *p*-nitroanisole [122].

5. Halogen-Metal Exchange in Aromatic Nitro-Bromo Compounds [123]

5.1. Mononitro Aromatic Compounds

Deprotonations are of only minor importance in nitro compounds (see Section 4.1). Halogen-metal exchange, which is made possible in the same manner by the positive nitrogen of the nitro group, and which normally proceeds very rapidly [124], is also unable to compete with other reactions at room temperature [125]. Between −100 and −110 °C, on the other hand, *o*-nitrobromobenzene is smoothly converted into *o*-nitrophenyllithium by phenyllithium or *n*-butyllithium, eq. (34).

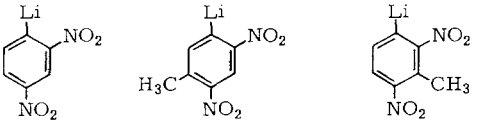


(34)

Other *o*-nitro-bromo aromatic compounds, such as 2-bromo-3-nitrotoluene, can also be converted into the lithium derivatives in this way. The yields rapidly decrease if the nitro group is *meta* or *para* to the bromine atom, since its exclusively inductive effect is then decreased (see Table 2).

Table 2. Optimum yields of carboxylic acid (from the lithium compound), bromobenzene (from halogen-metal exchange reactions), and phenol (from oxidation reactions of phenyllithium) in the reaction of nitrobromobenzenes with phenyllithium.

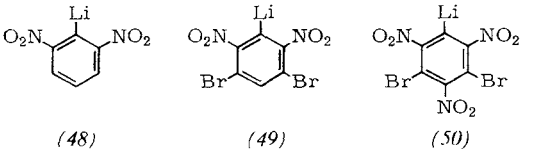
Substrate	Carboxylic acid yield (%)	Bromobenzene yield (%)	Phenol Yield (%)
o-Nitrobrombenzene	97	97	3
m-Nitrobrombenzene	16	42	70
p-Nitrobrombenzene	8	18	78



The ratio of bromine-lithium exchange to the redox reaction described in Section 2 is strongly dependent on the solvent and the reaction temperature. The redox reaction is favored by apolar solvents (ether, toluene) and high temperatures. *o*-Nitrophenyllithium decomposes exothermally at −100 °C; oxidation of the reaction products yields 2,2'dinitrobiphenyls, in which the C atoms that formerly carried the lithium atoms have become joined.

(35)

5.2. Dinitro and Trinitro Aromatic Compounds



With 2,4-dinitrobromobenzene and picryl bromide, the addition described in Section 3 predominates to such an extent that the lithium compounds formed by halogen-metal exchange are detected as at most 23% of 2,4-dinitrobenzoic acid and 13% of trinitrobenzoic acid respectively. However, by utilizing the fact that the addition is strongly inhibited if the *m*-nitro group is twisted out of the plane of the ring by bulky neigh-

boring groups, one can again obtain dinitro and trinitro aryllithiums in good yields. This steric influence can be seen from the results of the halogen-metal exchange in compounds *(45)* to *(50)*. (The yield of carboxylic acid is given under the compound.)

sym-Trilithiotrinitrobenzene *(54)* can be prepared from *(51)* with an excess of phenyllithium. *(53)* is formed at the same time by a coupling reaction.

(51) *(52)* *(53)* *(54)*

It is surprising to find that the bromine atom in *(52)* [or one of the bromine atoms in *(50)*] can be released both anionically (a) and cationically (b) under the same conditions on reaction with the same base.

6. Electron Donor-Acceptor Complexes

Aromatic nitro compounds, particularly 2,4,6-trinitro compounds, are excellent acceptor molecules for electron-acceptor complexes. Many complexes of this type are known with 1,3,5-trinitrobenzene and picric acid [126]; these include the picrates used for the identification of tertiary amines or unsaturated hydrocarbons. They have been extensively investigated by ESR [40] and NMR spectroscopy [79,127], gas chromatography [128], and other methods [126].

Owing to their low basicity aromatic amines often form only electron donor-acceptor complexes with 2,4,6-trinitro aromatic compounds, whereas aliphatic amines can give Meisenheimer compounds and possibly higher adducts. This is clear from UV spectroscopic studies. When aromatic amines [129,130] are added to solutions of aromatic trinitro compounds, a relatively uncharacteristic band immediately appears in the near UV or visible region, whereas with aliphatic amines [130,131], several bands appear in the visible region at a measurable rate.

Electron donor-acceptor complexes are preferentially formed with weak bases having suitable π bonds (aromatic amines, aromatic compounds with other electron-donating substituents, olefins, *etc.*). Hard bases (aliphatic amines OR^-, OH^-, *etc.*) generally give σ complexes, such as Meisenheimer compounds.

Electron donor-acceptor complexes can, however, also be prepared from aliphatic amines by the use of apolar solvents such as cyclohexane, though Meisenheimer compounds are also formed when the concentrations are increased [132].

I am grateful to Prof. Dr. G. Köbrich for reading the manuscript and for his interest in this work.

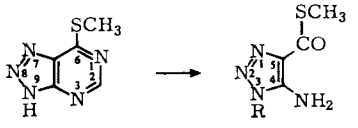
Errata

In the article "The Chemistry of Hypervalent Molecules" by *J. I. Musher*, Volume 1, January 1969, the following corrections should be made:

On page 64, left-hand column, line 5 "The first of these is linear, like I^-..." should read "The first of these is linear, like I_3^-...". On page 64, right-hand column, 12th line from bottom. "other halogen-F bonds" should read "other X-F bonds".

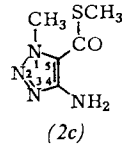
On page 65, left-hand column, line 13. "$\varepsilon_1 < \varepsilon_2$" should read "$\varepsilon_{(5)} < \varepsilon_{(6)}$".



On page 65, left-hand column, lines 21 and 22 "$\varepsilon_{(5)} < \varepsilon_{(6)}$" should read "$\varepsilon_{(6)} < \varepsilon_{(5)}$".

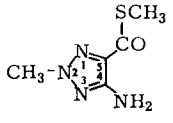
The Hydrolysis of 6-Methylthio-8-azapurines to Thiol Esters of 1,2,3-Triazolecarboxylic Acids

By *A. Albert* [*]

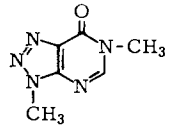


When boiled for 15 minutes with 1 M hydrochloric acid, 6-methylthio-8-azapurine *(1)* gives an almost quantitative yield of 4-amino-5-(methylthio)carbonyl-1,2,3-triazole *(2a)*, m.p. 201 °C, which could be isolated by filtration.

The 7-, 8-, and 9-methyl derivatives of *(1)* [1] gave *(2d)*, *(2c)*, and *(2b)*, melting at 132, 108, and 215 °C, respectively. They are all sparingly soluble in boiling water, but recrystallize well from a little methanol. They are stable to acid.



(1)



(2a), R = H
(2b), R = CH_3

(2c)

(2d)

(3)

A prominent peak occurs, in the ultraviolet spectrum of each compound, between 287 and 312 nm (log ε about 4.0, in methanol). The infrared spectrum (solid state) shows two very strong peaks at about 1640 (C=O stretching) and 900 cm^{-1} (=C–S stretching). The ^{1}H-NMR spectrum (in [D_6]-DMSO/D_2O) shows two peaks at τ = 6.2 (N–CH_3) and 7.7 (S–CH_3) (TMS internal standard).

Until now, thiol esters have been almost unknown in heterocyclic chemistry, but many examples are known in the benzene series with very strong infrared absorption in these two regions [2]. That the new triazoles are not the isomeric thione esters is shown by the stability of *(2a)*–*(2d)*, and by the absence of infrared absorption between 1000 and 1200 cm^{-1} [3].

With aqueous ammonia (stirred at 20 °C and then refluxed), *(2a)*–*(2d)* give almost quantitative yields of the carboxamides, identical with authentic specimens [1b–1d] (much methanethiol is liberated). Aqueous methylamine similarly gives *N*-methylamides, *e.g.* those compounds derived from *(2b)* and *(2d)* (m.p. 105 and 235 °C, respectively). Such *N*-methylamides have not previously been made. 4-Amino-3-methyl-1,2,3-triazole-5-carboxymethylamide [from *(2b)*], when heated with formamide at 225 °C, gives 1,9-dimethyl-6-oxodihydro-8-azapurine *(3)*, m.p. 207 °C, λ_{max} = 257 nm (log ε = 3.92 in H_2O [4]), quite free from 9-methyl-6-oxo-dihydro-8-azapurine, and which was isolated by filtration.

Reductive desulfurization of the thiol esters affords 4-amino-1,2,3-triazole-5-carbaldehyde and 4-amino-5-aminomethyl-1,2,3-triazole (and nuclear methylated derivatives of these) [5].

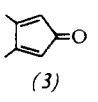
Formation of 1,2-Dimethylcyclobutadiene on Photolysis of Dimethylcyclobutenedicarboxylic Anhydride [1] [**]

By *G. Maier* and *U. Mende* [*]



Irradiation of tetramethylcyclobutenedicarboxylic anhydride leads to products [permethylated derivatives of *(6)*, *(7)*, *(15)*, and *(16)*] whose formation can be readily interpreted on the assumption of tetramethylcyclobutadiene as an intermediate stage. The products found, however, do not suffice to prove this hypothesis [1].

On irradiation of the anhydride *(1)* (Hanovia 450-W Hg high-pressure lamp; Vycor filter; ether; 18 °C; 2 h) and subsequent chromatography on silica gel we obtained a mixture of the three isomeric tetramethylcyclooctatetraenes *(7)*, *(10)*,

and *(13)*[2] (total yield 8.8%), *o*-xylene (0.6%), durene (1.0%), pseudocumene (3.0%), an inseparable mixture of ketones (11.5%), the dimer *(15)* of dimethylcyclopentadienone *(3)* (8.1%), and the cage diketone *(16)* (6.0%). The decisive intermediates seem to be the ketones, for the isolated mixed ketones gave the same hydrocarbons on renewed irradiation [though less *(10)* was formed] as did *(1)*.

The aromatic compounds were identified by gas chromatography and NMR spectroscopy. From the mixture of cyclooctatetraenes, only *(13)* could be separated cleanly; according to analysis of the NMR spectrum, the mixture contained the proportions *(7)*:*(10)*:*(13)* = about 5:2:10. In order to analyze the mixed ketones better, they were reduced by $LiAlH_4$; the alcohols formed could be separated by column chromatography; each ketone gave only one alcohol, stereospecifically. The alcohols *(5)* and *(11)*, and thus the ketones *(6)* and *(12)*, occurred in the ratio 1:2.

[a] τ values, no. of protons, type of splitting; solvent $CDCl_3$; TMS as internal standard. [b] In CCl_4. [c] IR (CCl_4): C=O bands at 1705 and 1785 cm^{-1}. [d] IR (CCl_4): band at 1755 cm^{-1}.

The alcohol *(8)* was not found, but instead a small amount of the isomeric *(14)*. [The structure was derived from the NMR spectrum.]

For the following reason, the products isolated prove that cyclobutadiene is actually formed on photolysis of anhydrides of type *(1)*: photolytic removal of CO_2 to yield *(2)*, ring opening of the latter to yield *(3)*, and addition to *(3)* of the dimethylcyclobutadiene arising from *(2)* on elimination of CO should give the ketones *(6)*, *(9)*, and *(12)*. Insofar as cyclobutadiene is a rectangular singlet molecule with localized double bonds[3] and undergoes rapid valence isomerization, the three ketones must arise in the proportion 1:1:2 – provided that steric factors do not lead to selectivity. In all the other plausible ways [dimerization of *(2)* or *(3)*, or reaction of *(2)* with *(3)* and subsequent removal of CO], only the ketones *(6)* and *(9)* or compounds of totally different structure would be formed. The relative amounts of the tetramethylcyclooctatetraenes isolated, and of the aromatic compounds and alcohols, indicate that dimethylcyclobutadiene reacts in the two forms *(4a)* and *(4b)*, the doubly methylated double bond in *(4a)* being, however, less amenable to addition than the unsubstituted double bond[***].

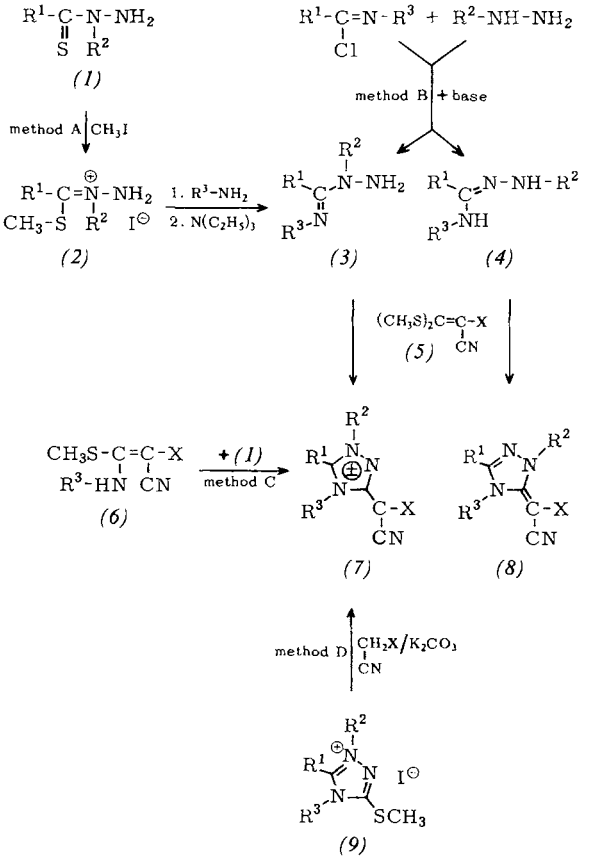
[***] *Note added in proof* (January 8, 1969): On irradiation of tetramethylcyclobutenedicarboxylic anhydride [1] in an organic glass (ethanol, isopentane, ether) at –196 °C, a deep yellow color appears which disappears immediately when the matrix melts. The adduct of tetramethylcyclobutadiene to tetramethylcyclopentadienone and the dimer of tetramethylcyclopentadienone [permethylated analogs of *(6)* and *(15)*] were isolated as the sole products. These compounds could not have been present during photolysis, since otherwise – as shown by control experiments – their photoproducts [*e.g.* octamethylcyclooctatetraene or the permethylated cage diketone *(16)*] would also have been detectable.



These results show that tetramethylcyclobutadiene and tetramethylcyclopentadienone can exist as monomers when frozen into a glass at the temperature of liquid nitrogen.

Mesoionic 3-Methylene-1,2,4-triazoles[**]

By *R. Grashey* and *Margit Baumann*[*]

Numerous mesoionic systems[1] contain heteroelements bound exocyclically. We now report mesoionic 1,2,4-triazole derivatives *(7)* with carbon as the exocyclic atom; we obtained these from N^2,N^3-disubstituted amidrazones and 3,3-bis(methylthio)acrylonitrile derivatives *(5)*[2,3].

The classical synthesis of amidrazones of type *(3)* (method **B**)[4,5] from imidoyl chlorides and monosubstituted hydrazines gives mainly N^1,N^3-disubstituted amidrazones *(4)* when arylhydrazines are used, and the products *(3)* and *(4)* must be separated before the treatment with *(5)*. However, if methylhydrazine in acetonitrile solution is used, then formation of *(3)* (R^2 = CH_3) is dominant, so that isolation of the amidrazones can be omitted and the mixture of *(7)* with a little *(8)* arising in the subsequent reaction with *(5)* can be readily separated by crystallization.

[a] Working *in situ*.

The action of primary amines on methylthiohydrazonium iodides *(2)* gives exclusively N^2,N^3-disubstituted amidrazones *(3)* (method A). In this case also the amidrazones are often prepared only *in situ*.

Lower yields are obtained on treatment of thiohydrazides *(1)* with 3-amino-3-(methylthio)acrylonitrile derivatives *(6)* [2,6] (method C), a reaction which in boiling dimethylformamide or acetonitrile containing potassium carbonate leads directly to the triazole derivatives *(7)*. A further possibility (method D) is offered by the action of malonic acid derivatives and potassium carbonate on methylthio-1,2,4-triazolium salts *(9)*, which are obtained from the mesoionic 1,2,4-triazolethiones [1,5] and methyl iodide in acetonitrile at 80 °C.

The colorless to greenish-yellow triazoles *(7)* are characterized by ease of crystallization and great stability. Analytical and spectral data (no heterocumulene band at 2000–2070 cm^{-1}), as well as molecular-weight determinations accord with the proposed structures. The nitrile or ester groups of *(7)* and *(8)* absorb between 2146 and 2193 and between 1653 and 1667 cm^{-1}, respectively, thus showing the expected bathochromic shift.

Preparation of (7e) by method (A):

Compound *(2)* [R^1 = C_6H_5, R^2 = CH_3] (1.232 g) is heated with aniline (3 ml) on a steam bath for 30 min. The crude amidrazonium salt, which crystallizes when the reaction mixture is digested with ether, is taken up in acetonitrile (10 ml) and heated with *(5)* [X = CO_2CH_3] (0.813 g) and triethylamine (1 ml) for 10 h under reflux. After concentration under vacuum, addition of methanol results in precipitation of *(7e)* (1.05 g); colorless needles having m.p. 296 to 297 °C (from acetonitrile).

A New Synthesis of Alkyl Azides [**]

By *C. H. Heathcock* [*]

Alkenes react with mercury(II) salts in aqueous solution to yield β-hydroxyalkylmercurials [1], which may be reduced *in situ* by sodium borohydride to yield alcohols [2]. We have found that an adaptation of this procedure allows the convenient synthesis of alkyl azides from certain alkenes.

General procedure:

To a solution of 0.3 moles of sodium azide and 0.1 mole of mercuric acetate in 200 ml of 50% aqueous tetrahydrofuran [3] is added 0.1 mole of alkene. After stirring at 50 to 90 °C for an appropriate period (16–70 h), the two-phase mixture is diluted with 100 ml of 15% aqueous potassium hydroxide and treated with a solution of 2 g sodium borohydride in 100 ml of 15% potassium hydroxide solution. The alkyl azide is isolated by ether extraction followed by distillation at reduced pressure.

(1)

The method works well for the synthesis of secondary or tertiary alkyl azides from terminal alkenes or strained cyclic alkenes (norbornene) but fails in the case of normal internal

Table 1. Synthesis of alkyl azides from alkenes.

Alkene	Product	Time (h)	Temp. (°C)	Yield (%)
1-heptene	2-heptyl azide	17	50	88
1-octene	2-octyl azide	24	30	55
3,3-dimethyl-1-butene	3,3-dimethyl-2-butyl azide	43	80	61
2-methyl-1-heptene	2-methyl-2-heptyl azide	40	90	50
methylenecyclohexane	1-methylcyclohexyl azide	68	90	60
norbornene	*exo*-2-norbornyl azide	16	50	75
cyclohexene	cyclohexyl azide	68	90	4
methylcyclohexene	—	40	90	< 1
styrene	—	40	90	< 1

alkenes, either disubstituted or trisubstituted. It is of interest that such unreactive alkenes do not undergo hydroxymercuration either.

The observed order of reactivity closely parallels the known order of alkene-silver(I) stability constants[4], and suggests a mechanism (eq. 1) involving a rapid prior equilibrium, giving an ion *(1)*, which reacts with azide ion in a slow step to yield *(2)*. The remarkable efficiency with which azide competes with water in the reaction argues strongly for the existence of the ionic intermediate *(1)*, since $k_{N_3^-}/k_{H_2O}$ is known to increase greatly with increasing delocalization of a cation[5].

Optically Active 2-Methylazaferrocene[**]

By *K. Bauer, H. Falk*, and *K. Schlögl*[*]

Unsymmetrically disubstituted metallocenes belong to the point group C_1; they are therefore chiral and can be obtained in optically active forms[1]. This symmetry condition is also valid for homoannularly monosubstituted azaferrocenes, which therefore should be resolvable into optical antipodes. This could now be verified for 2-methylazaferrocene *(1)*.

(−)-(2*R*)-*(1)*

Racemic *(1)* was obtained in 45% yield as an oil from the potassium salt of 2-methylpyrrole and $C_5H_5Fe(CO)_2I$ in dioxane[2]. Elemental analysis, NMR spectrum [$CDCl_3$, methyl protons at δ = 2.32, ring protons at 5.34 (1H), 4.50 (2H), and 4.22 (5H)], and mass spectrum[3] [*m/e* = 201 $(C_{10}H_{11}FeN)^+$, 186 $(M-CH_3)^+$, 135 $(C_5H_5FeN)^+$, 121 $(C_5H_5Fe)^+$, and 80 $(C_5H_6N)^+$] prove the structure *(1)*.

Reaction of *(1)* with an equimolar amount of (−)-6,6′-dinitrodiphenic acid in ethanol afforded an amorphous precipitate; addition of petroleum ether to the mother liquor yielded a crystalline, rather unstable salt, which was recrystallized twice from acetone. This salt afforded levorotatory *(1)*: $[\alpha]_D^{20}$ = −62° (*c* = 0.04, cyclohexane)[4], m.p. 42–52 °C. (+)-*(1)*, $[\alpha]_D^{20}$ = +33°, was obtained from the mother liquor of the salt crystallization.

The ORD and CD curves, and the UV spectrum of (−)-*(1)* are reproduced in Fig. 1. In 0.1 N hydrochloric acid or on addition of $BF_3{\cdot}O(C_2H_5)_2$ the $\Delta\varepsilon$-values are increased, whereas the sign of rotation remains unchanged and the Cotton effects are shifted only slightly: *(1)* in ether, −0.15 (515 nm) and +0.15 (445 nm); *(1)* in 0.1 N HCl, −0.19 (496 nm) and +0.20 (421 nm); *(1)* · BF_3 in ether, −0.31 (500 nm) and +0.32 (435 nm) (cf. Fig. 1).

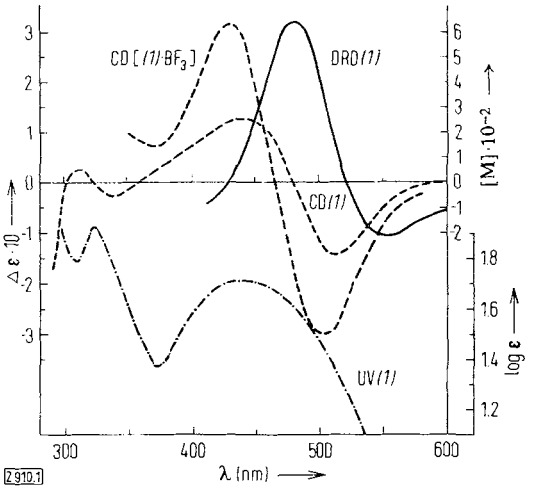

Fig. 1. ORD and CD curves and UV spectrum of *(1)* in cyclohexane, CD curve of *(1)* · BF_3 in ether.

The ORD curve of *(1)* is very similar to that of α-ethynyl- and α-cyanomethylferrocene, compounds *(2)* and *(3)*[5], respectively, in which no conformational contributions (of substituents) to the optical activity are possible either (cf.[1]).

This analogy, together with the fact that salt formation (protonation or addition of BF_3) increases the activity of the "metallocene absorption band" in the region of 430 nm, may be considered as evidence that the ring nitrogen dominates over the methyl group with regard to the perturbance of the metallocene chromophore[6], as does C≡CH or C≡N in *(2)* and *(3)*, respectively.

Therefore, the assumptions seems to be justified that (−)-*(1)*, (−)-*(2)*, and (−)-*(3)* with positive Cotton effects around 430 nm have identical chiralities, and that (−)-*(1)* consequently [by analogy with (−)-*(2)*, (−)-*(3)*, and (+)-methylferrocene-α-carboxylic acid][5] has the absolute configuration (2*R*)[1].

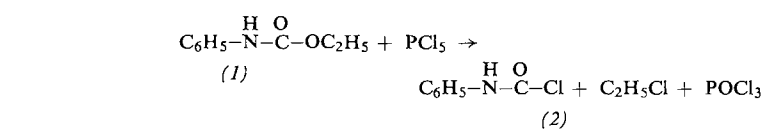
[2] For the synthesis of azaferrocene and its methyl derivatives in benzene cf.: *K. K. Joshi, P. L. Pauson, A. R. Qazi*, and *W. H. Stubbs*, J. organometallic Chem. *1*, 471 (1964). If dioxane is employed, the yield of azaferrocene can be increased from 22 to 36%.

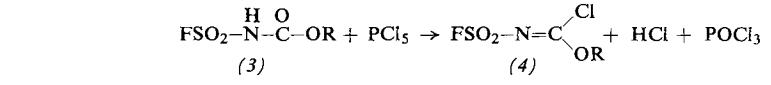
[3] We are indebted to Dr. *G. Schaden*, Darmstadt, for recording, and Dr. *H. Egger*, Wien, for the interpretation of the mass spectrum. For the mass spectrum of azaferrocene cf.: *F. Seel* and *V. Sperber*, J. organometallic Chem. *14*, 405 (1968).

[4] The optical purity of *(1)* is unknown. A tentative estimate (30–40%) seems feasible on comparing the $\Delta\varepsilon$-values (around 430 nm, "metallocene absorption band") of *(1)* with those of compounds such as *(2)*, *(3)*, or methylferrocene-α-carboxylic acid, which are similar with regard to the origin of their optical activity.



[5] *G. Haller* and *K. Schlögl*, Mh. Chem. *98*, 603 (1967).

[6] The $\Delta\varepsilon$-values of *(1)* and its salts are almost directly proportional to the molecular refractivities of $N_{arom.}$, NH^+, and N · BF_3; the dipole moment of azaferrocene in cyclohexane is 2.06 ± 0.05 D.

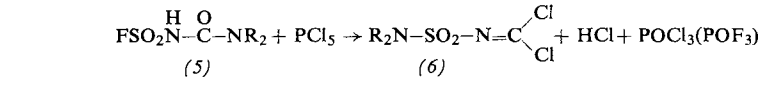


Action of Phosphorus Pentachloride on *N*-(Halogenosulfonyl)urethanes[1]

By *H. W. Roesky*[*]

Lengfeld and *Stieglitz*[2] obtained phenylcarbamoyl chloride *(2)* by the action of PCl_5 on *N*-phenylurethane *(1)*, but *Werner*[3] was able to isolate only phenyl isocyanate after this reaction. If, however, the phenyl group is replaced by a

more electronegative one, *e.g.*, fluorosulfonyl, then ester chlorides *(4)* of *N*-(fluorosulfonyl)carbonimidic acid are formed.



(4a), R = CH_3
(4b), R = C_2H_5
(4c), R = n-C_3H_7

	(4a)	*(4b)*	*(4c)*	*(4d)*
B.p. (°C/torr)	31–32/0.02	37–38/0.03	57–59/0.01	63–66/0.01
d_4^{20}	1.5829	1.4607	1.3932	1.5066
n_D^{20}	1.4349	1.4340	1.4368	1.4910
Yield (%)	57	53	59	63
Mol. wt. (cryoscop. in C_6H_6)	179.5	197	211	207
ν(C=N) (cm^{-1})	1610	1610	1610	1590
δ ^{19}F (ppm)	−51.8	−52.0	−52.3	–
δ ^1H (ppm)	−4.24	−1.52 (CH_3) −4.65 (CH_2)	−1.10 (CH_3) −1.87 (CH_2) −2.74 (CH_2O)	−1.66 (CH_3) −4.80 (CH_2) J_{H-H} = 7 Hz

At room temperature the compounds *(4)* (see Table) are colorless liquids with an aromatic odor and can be distilled at reduced pressure without decomposition.

If the alkoxy group in *(3)* is replaced by a dialkylamino group, then the analogous reactions with PCl_5 are accompanied by a rearrangement that leads to the known[4] dialkylaminosulfonyl isocyanide dichlorides *(6)*, together with POF_3.

Dimethylaminosulfonyl isocyanide dichloride: b.p. 162 to 163 °C/0.01 torr, ν(N=C) = 1600 cm^{-1}. Diethylaminosulfonyl isocyanide dichloride: m.p. 55–57 °C, ν(N=C) = 1580 cm^{-1}.

Only compound $ClSO_2-N=C(Cl)OC_2H_5$ *(4d)* could be isolated after treatment of the corresponding chlorine derivatives of *(3)* with PCl_5. The products with R = CH_3 or n-C_3H_7 cannot be distilled without decomposition at oil-pump vacuum.

Experimental:

1 mole of an alcohol is added dropwise with ice-cooling and stirring to a solution of 1 mole of fluorosulfonyl isocyanate (FSO_2NCO) in 300 ml of CCl_4[5]. 1 mole of PCl_5 is then added (or 1 mole of PCl_3 and chlorine is passed into the mixture), and the mixture is heated slowly and finally refluxed for about 6 h. CCl_4 and $POCl_3$ are then collected in a cold trap (acetone/dry ice) at water-pump vacuum, and the residue is distilled at oil-pump vacuum through a 30-cm packed column.

For *(4d)* the amount of solvent used was 200 ml and the mixture was refluxed for 3.5 h.

All the compounds were characterized by elemental analyses.

Addition Compound or Oxonium Salt? The Crystal Structures of Two Acid Hydrates

By *D. Mootz, J. Goldmann*, and *H. Wunderlich*[*]

Crystalline "hydrates" of strong acids (*e.g.* of $HClO_4$, HCl, HNO_3, *etc.*) contain H_3O ions and are therefore to be regarded as oxonium salts, $H_3O^+A^-$. In contrast, the compounds of weak acids (*e.g.* of carboxylic acids) with water are true acid hydrates, HA · H_2O. The methods available for distinguishing between these possibilities include crystal structure analysis, as well as IR and NMR spectroscopy; the first technique makes possible a simultaneous study of the stereochemistry of hydrogen bonds in such compounds, which is often of interest.

We have been able to show by crystal structure analyses of 2-phosphoric acid-1-water *(1)* and 1,2-ethanedisulfonic acid dihydrate *(2)* that *(1)* is a true acid hydrate and *(2)* is a dioxonium salt. This had already been established for the latter compound by *Blaschette* and *Bürger*[1], who used an IR spectroscopic technique.

As stated by *Smith, Brown*, and *Lehr*[2], the addition compound *(1)* crystallizes monoclinically in the space group $P2_1/c$ with four formula units in the unit cell; it is isomorphous with the corresponding arsenic compound[3]. The structure was determined from 832 independent reflections (molybdenum radiation, Weissenberg and precession photographs), and refined in the usual way (R = 0.084). The hydrogen atoms could not be located without making prior assumptions. Nevertheless, the question whether an oxonium salt or an acid hydrate is present can be answered unambiguously on the basis of the P–O bond lengths observed: In each of the two independent PO_4 tetrahedrons there are observed one particularly short bond length and three longer ones (Fig. 1[5], standard deviation 0.005 to 0.007 Å), as in the crystal structure of anhydrous phosphoric acid[4]. This finding sup-

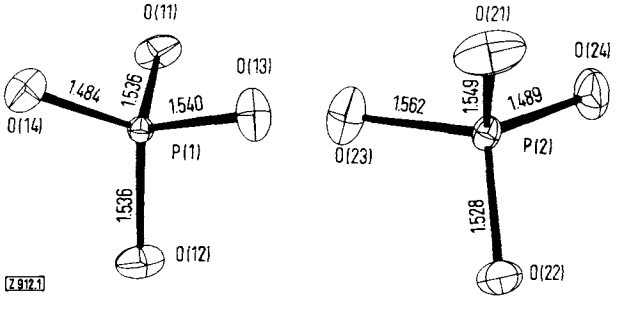

Fig. 1. The two independent PO_4 tetrahedrons in the crystal structure of 2 H_3PO_4 · H_2O *(1)*. The bond lengths are given in Å.

ports the structure $2\,H_3PO_4 \cdot H_2O$. In the case of an oxonium salt $H_3O^+H_2PO_4^- \cdot H_3PO_4$, however, two short and two long bonds should be observed in the anionic PO_4 tetrahedron.

Similar arguments applied to the structure of *(2)*, which has been determined much more accurately, indicate the presence of oxonium ions. Compound *(2)* crystallizes monoclinically in the space group $P2_1/c$ with two centrosymmetric formula units in the unit cell. With 746 independent photographic data (Cu radiation) an *R* factor of 0.059 was obtained.

The three S–O bonds are of equal length (Fig. 2, standard deviation 0.003 Å), thus clearly indicating the transfer of the acidic proton to the water molecule since the difference in length between an S–O and an S–OH bond is very large; in the case of oxonium hydrogen sulfate, $H_3O^+HSO_4$, it is 0.11 Å [6]. The difference Fourier synthesis of *(2)* was not so unambiguous regarding the hydrogen atoms of the oxonium ion.

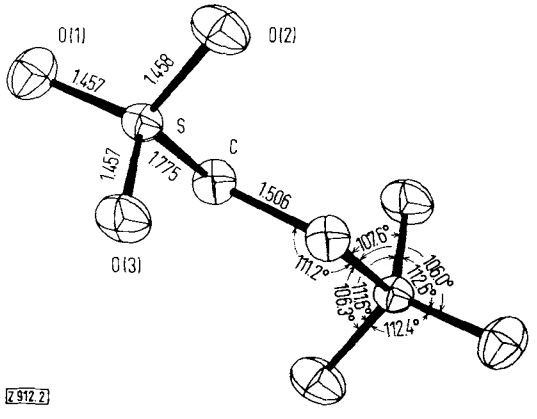

Fig. 2. The anion in the crystal structure of $2\,H_3O^+[O_3SCH_2CH_2SO_3]^{2-}$ *(2)*. The bond lengths are given in Å.

Relatively short hydrogen bonds occur in both crystal structures. Compound *(1)* shows four bridges of the type P–OH···O=P having O···O distances between 2.510 and 2.550 Å, and two of the type P–OH···OH_2 of 2.620 and 2.638 Å. Those bridges having the water molecule as proton donor are longer and cannot be assigned unequivocally without knowledge of the positions of the protons (five O···O distances between 2.897 and 3.013 Å). In *(2)* the oxonium ion is coordinated pyramidally and acts as proton donor for three short hydrogen bonds to independent oxygen atoms in different anions. The O···O distances lie between 2.549 and 2.578 Å.

Calculation of the "Optical Electronegativity" of Transition Metal Ions from NQR Coupling Constants

By *P. Machmer* [*]

The "optical electronegativity" $\chi_{opt}(M)$ of the central ions of octahedral complexes has previously been determined from the wave number *E* of the first intense charge transfer band. With the aid of equation (1) [1]

$$E = 3 \times 10^4\ cm^{-1}\ [\chi_{opt}(L) - \chi_{opt}(M)] \qquad (1)$$

the relevant UV spectroscopic data afforded the values of $\chi_{opt}(M)$ listed in Table 1. [$\chi_{opt}(L)$ denotes the "optical electronegativity" of the ligands L].

In conjunction with the examination of the nuclear quadrupole resonance (NQR) spectra [2–5] of inorganic compounds, it can be shown that characteristic electronegativity values can also be derived from the NQR coupling constants of solids. The effectiveness of this technique, which is independent of solvent effects, will now be demonstrated for octahedral chloro complexes of a number of transition metal ions. The electronegativity values $\chi(M^{n+})$ of the central ions (Table 1) were calculated according to equation (2)

$$\chi(M^{n+}) = 0.38 \times \sqrt{\left(\frac{e^2Qq_{mole}}{h}\right)_{^{35}Cl}} \qquad (2)$$

from ^{35}Cl–NQR coupling constants (values of e^2Qq_{mole}/h for the ^{35}Cl ligands were taken from the literature [6–12]; the dimensions of the proportionality factor 0.38 are $MHz^{-1/2}$.

Table 1. Electronegativities calculated from NQR coupling constants of transition metal ions in chloro complexes compared with the optical values.

M^{n+}	$\chi(M^{n+})$	$\chi_{opt}(M)$ [13–15]	Complex	e^2Qq_{mole}/h for the ^{35}Cl ligands [6–12] (MHz)
W^{4+}	1.71	1.67 [13]	K_2WCl_6	20.44
Re^{4+}	2.00	2.0	K_2ReCl_6	27.78
Os^{4+}	2.20	2.2	K_2OsCl_6	33.68
Ir^{4+}	2.44	2.4 [14]	K_2IrCl_6	41.46
Pt^{4+}	2.73	2.7	K_2PtCl_6	51.64
				51.82
				52.04
Pd^{4+}	2.76	2.7	K_2PdCl_6	53.10
Pt^{2+}	2.27	2.3	K_2PtCl_4	35.85

The relationship between the electronegativity $\chi(M^{n+})$ of the central ion and the NQR coupling constants of the ^{79}Br ligands can also be formulated quantitatively for the analogous bromo complexes (proportionality factor $0.134\ MHz^{-1/2}$).

$$\chi(M^{n+}) = 0.134 \times \sqrt{\left(\frac{e^2Qq_{mole}}{h}\right)_{^{79}Br}} \qquad (3)$$

Table 2. NQR coupling constants of the halogen ligands ^{35}Cl and ^{79}Br calculated from equations *(2)* and *(3)*.

Complex	$\chi_{opt}(M)$ [15]	$(e^2Qq_{mole}/h)^{35}Cl$ or ^{79}Br (MHz)
$KPtCl_3C_2H_4$	2.3	36.6
K_3IrCl_6	2.25	35
K_2RuCl_6	2.4	40
K_3RhCl_6	2.3	36.6
K_3MoCl_6	1.7	20
K_2WBr_6	1.71 [a]	167.6
K_2OsBr_6	2.2	268
K_2IrBr_6	2.4	319

[a] From Table 1.

If χ_{opt} (M) is known with sufficient accuracy, it is also possible to estimate the NQR coupling constants e^2Qq_{mole}/h on the basis of equations (2) and (3). Values thus obtained for the NQR coupling constants of complexes whose NQR spectra have not yet been recorded are given in Table 2 (estimated error ± 5%). The validity range of the considerations sketched out in this communication remains to be defined.

ESR Measurements under Pressure: Effect of Pressure on Chemical Equilibria involving Solvated Electrons

By *K. W. Böddeker, G. Lang,* and *U. Schindewolf*[*]

The physical properties of solvated electrons in liquid ammonia are highly pressure dependent[1]. As will be shown in this communication by considering various equilibria involving solvated electrons, the chemical properties of electrons dissolved in ammonia or in methylamine-ammonia mixtures (amine system) also are strongly affected by pressure.

The experiments were carried out ESR-spectrometrically since the solvated electrons, and in many instances the products of their reactions as well, exhibit characteristic ESR signals permitting a quantitative detection. We have investigated the reversible formation of solvated electrons by the reaction of amide ions with hydrogen[2,3]

$$e^- + NH_3 \rightleftharpoons {}^1/_2 H_2 + NH_2^- \quad (1)$$

and equilibria between solvated electrons and arene radical anions, *e.g.*

$$e^- + C_6H_6 \rightleftharpoons C_6H_6^- \quad (2)$$

The experimental arrangement is shown in Fig. 1a. The sample cell, a length of quartz capillary extending through the temperature-controlled cavity of the ESR spectrometer, is connected to the pressure generator and the storage autoclaves *via* steel capillaries by means of the pressure coupling shown in Fig. 1b[4]. The pressure generator with manometer is filled with pentane as pressure-transmitting fluid and can be closed to the remaining apparatus at valve 1. The storage autoclaves contain in glass vessels (i) the solution to be investigated (this autoclave can be cooled to −80 °C) and (ii) pure solvent used to clean the apparatus. The quartz capillaries (i. d., 1 mm; o. d., 5 mm) withstand pressures of up to 500 atm.

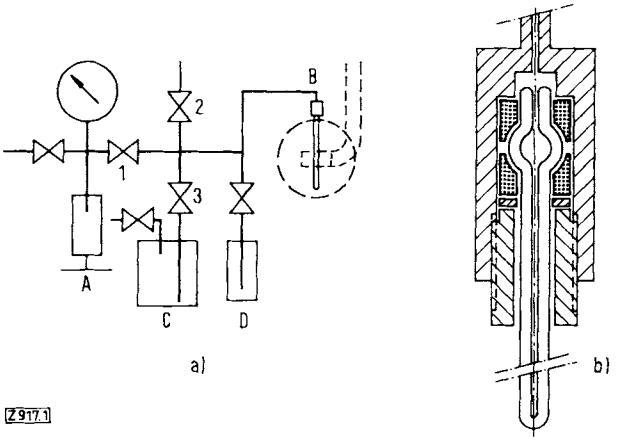

Fig. 1. a) Experimental arrangement for ESR measurements under pressure. A: pressure generator with manometer; B: sample cell with pressure coupling; C, D: storage autoclaves for solution and pure solvent; 1–3: valves; magnet and microwave guide of the ESR spectrometer are indicated by dotted lines.

b) Pressure coupling with Teflon packings connecting the quartz capillary.

To study the equilibrium (1), a 1 M solution of potassium amide in ammonia was saturated, at room temperature, with 100 atm of hydrogen in the storage autoclave and was transferred into the sample cell under this pressure. The intensity of the ESR signal of the solvated electrons, which is proportional to their equilibrium concentration ($< 10^{-4}$ M[3]), decreases by a factor of 2.3 as the pressure is raised by 300 atm (Fig. 2).

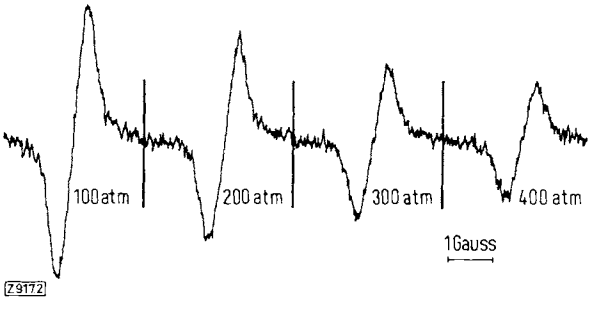

Fig. 2. ESR signal of the solvated electrons in a hydrogen-saturated (100 atm) solution of potassium amide (1 M) in ammonia at varying pressures at room temperature.

For the investigation of equilibrium (2) a solution of potassium (10^{-2} M) and benzene (10^{-1} M) in methylamine-ammonia (2:1) was prepared at −78 °C in the storage autoclave and was forced into the pre-cooled sample cell by inert gas under pressure (*e.g.*, nitrogen, 30 atm). The ESR spectrum of this system shows both the single-line signal of the solvated electrons and the spectrum of the benzene radical anions consisting of 7 lines of binomial intensity distribution (Fig. 3)[5]. On raising the pressure by 300 atm at −120 °C the concentration of solvated electrons decreases by a factor of 2.6 while that of the benzene radical anions increases by a factor of 3.2. – A corresponding pressure dependence was observed with other simple aromatic radical anions.

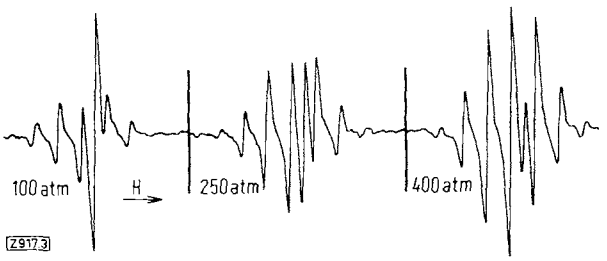

Fig. 3. Effect of pressure on the equilibrium (2) in methylamine-ammonia (2:1) at −120 °C. The electron signal appears superimposed on the ESR septet of the benzene radical anions.

According to the equation

$$d \ln K/dp = -\Delta V/RT \qquad (3)$$

the displacement of the equilibria (1) and (2), as determined from the spectra, results in a volume change associated with the reaction ΔV (= molar volume of the products minus molar volume of the reactants) of −63 and −71 ± 5 ml/mole, respectively, reflecting the large apparent volume of the electrons dissolved in the amine system.

For comparison, the equilibrium (2) was studied in tetrahydrofuran-dimethoxyethane (2:1; ether system), in which only the benzene radical anions give rise to an ESR spectrum. The intensity of the $C_6H_6^-$ spectrum, produced in the sample cell by reaction of a benzene-ether solution at the surface of a sodium wire, is independent of pressure in the region of 100 to 400 atm at −100 °C. This result indicates that the apparent volume of the diamagnetic electron species in the ether system is smaller than that of the electrons dissolved in the amine system.

Crystal Structure of 4-Thiouridine

By *W. Saenger* and *K. H. Scheit* [*]

After 4-thiouridine *(1)* had been discovered to be a constituent of tRNA of *E.coli* [1], *Lipsett* and *Doctor* [2] were able to show that tyrosine-specific tRNA from *E.coli* contains two 4-thiouridine units per molecule. Although the chemical and physical properties of *(1)* in oligo- and polynucleotides [3,4] have been investigated, the function of this nucleoside in *E.coli*-tRNA remains unclear. Since we had at our disposal analytically pure, crystalline *(1)* [5,6], we attempted to determine its structure with a view to contributing to the solution of this problem.

Compound *(1)* could be obtained in the form of yellow prismatic crystals by slow evaporation of its aqueous solution. Weissenberg photographs and diffractometer measurements showed the space group to be C2 and the dimensions of the unit cell to be a = 13.174, b = 7.492, c = 13.042 Å, β = 98.10 °. 1400 reflections were recorded with an automatic diffractometer and corrected for geometrical factors but not for absorption. The structure analysis was performed by the heavy atom technique. The usual Patterson and Fourier syntheses and five cycles of isotropic and anisotropic refinement resulted in an R factor of 0.10.

At this stage a number of structural peculiarities become clear (see Fig. 1):

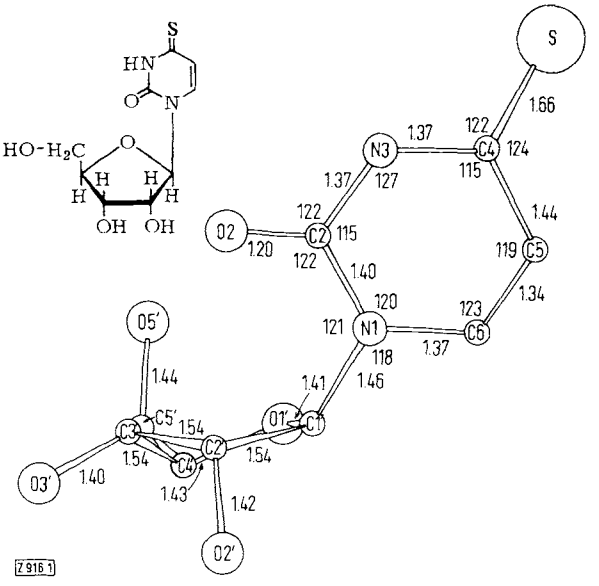

Fig. 1. Crystal structure of 4-thiouridine. Projection onto 100. Bond lengths (Å) and angles (°) not shown in the Figure are:

C4′–C5′ = 1.50	
C1′–C2′–C3′ = 103	N1–C1′–C2′ = 119
C2′–C3′–C4′ = 101	N1–C1′–O1′ = 109
C3′–C4′–O1′ = 103	C1′–C2′–O2′ = 105
C4′–O1′–C1′ = 110	O2′–C2′–C3′ = 110
O1′–C1′–C2′ = 107	C2′–C3′–O3′ = 115
C3′–C4′–C5′ = 119	O3′–C3′–C4′ = 114
C5′–C4′–O1′ = 110	C4′–C5′–O5′ = 113

a) Comparison of the nitrogen-containing rings in barium 5′-uridinephosphate [7] *(2)* and in *(1)* shows a similar arrangement of bond lengths and angles. The C-5–C-4 bond length in *(1)* is 0.03 Å greater than in *(2)*, whereas the N-3–C-4 and N-3–C-2 bond lengths are shorter by 0.025 Å, and the bond angle C-2–N-1–C-6 is reduced from 124 to 120 °.

The bond lengths C-2–O-2 and C-4–S are characteristic for keto structures [8,9]. The six-membered ring is largely planar; the ring atoms deviate from the "best" plane by no more than 0.04 Å but S and C-1 stand out from this plane by 0.48 and −0.23 Å respectively.

b) The ribose unit is puckered; the interatomic distances and bond angles agree well with those found by other authors [7,10]. C-3′ lies out of the "best" plane, which can be constructed through C-1′, C-2′, C-4′, and O-1′, by 0.59 Å, and is on the same side as C-5′; the ribose is therefore in the *endo* conformation.

c) The most surprising feature of the structure is the *syn* conformation of the nucleoside. The angle of twist about the glycosidic C-1′–N-1 bond (as defined by *Trueblood, Horn*, and *Luzzati* [10]) is +83 °. As far as we know, this conforma-

tion has not previously been observed for any pyrimidine nucleoside.

d) The molecules are arranged in the crystal such that hydrophobic and hydrophilic regions are oriented along the *a* axis. The nitrogen-containing rings are stacked parallel to one another, separated by about 3.3 Å, and form a hydrophobic channel along this axis. The ribose units occupy the interior of the unit cell and are bound to one another by water molecules (one and a half per asymmetric unit).

Further refinement of the structure is in progress.

Hydridophosphinetris(trifluorophosphine)cobalt(I)

By *J. M. Campbell* and *F. G. A. Stone* [*]

Transition metal complexes containing PH_3 as a unidentate ligand have only recently become known [1,2]. Herein we report the compound $HCo(PF_3)_3PH_3$ *(1)*, which is the first example both of a hydrido-phosphine metal complex and of a phosphine-trifluorophosphine complex.

The new compound is a pale yellow sublimable solid (m.p. $\sim 25\,^{\circ}C$) which may be prepared by irradiating mixtures of $HCo(PF_3)_4$ [3] and PH_3 (molar ratio 1:2) for periods of up to one hour by means of a mercury discharge lamp, or for longer periods by exposure to sunlight. The compound was isolated from PF_3, PH_3, and unreacted $HCo(PF_3)_4$ by fractionation in a high vacuum system (10^{-6} torr), compound *(1)* being retained at $-46\,^{\circ}C$ whereas $HCo(PF_3)_4$ is condensed at $-64\,^{\circ}C$. Final purification was accomplished using a low-temperature distillation column (yield 20%).

The complex *(1)* was characterized by its mass spectrum, and by its infrared and nuclear magnetic resonance spectra. The mass spectrum shows a parent peak at *m/e* 358 and other major peaks corresponding to the fragment ions $HCo(PF_3)_2PH_3^+$, $HCo(PF_3)_2PH_2^+$, $HCo(PF_3)_2PH^+$, $HCo(PF_3)(PF_2)PH_3^+$, $HCo(PF_3)(PF_2)PH_2^+$, *etc.*

The gas phase infrared spectrum shows ν_{max} at 2369 (νP–H), 1967 (νCo–H), 1049 (δP–H), and 925, 885, and 851 cm^{-1} (P–F vibrations).

The ^1H–NMR spectrum (pure liquid, TMS as internal reference) shows a doublet of quartets at $\tau = 6.12$, (int. 3, PH_3) with $J_{P-H} = 352$ Hz and $J_{F_3P-H} = 17.6$ Hz, and a broad absorption at $\tau = 24.4$ (int. 1, CoH). This spectrum suggests that the hydrogen atom and the phosphine group are *trans* to one another, the three trifluorophosphine groups being in the equatorial positions of the trigonal bipyramid. The ^{19}F–NMR spectrum (liquid) consisted of two multiplets (separation 1117 Hz) centered at 9.8 ppm above CCl_3F.

The complex $HCo(PF_3)_3PH_3$ was also produced by treating $HCo(PF_3)_3CO$ with phosphine, showing that CO is displaced by PH_3 in preference to PF_3.

Tris(trimethylsilyl)indium

By *H. Bürger* and *U. Goetze* [*]

In contrast to the large number of compounds in which silicon is bonded to elements of Groups IV to VII, only a few silyl derivatives of the electron-deficient elements of Groups I to III are known [1]. In most cases their formation could be deduced only from subsequent reaction products [2]. The first examples of relatively stable, fully silylated derivatives of a Group III element are the thallium compounds $(R_3Si)_3Tl$ ($R = CH_3$ [3], C_2H_5 [1]).

By means of the reaction

$$InCl_3 + 3\,(CH_3)_3SiCl + 6\,Li \xrightarrow{THF,\ -30\,^{\circ}C} [(CH_3)_3Si]_3In + 6\,LiCl$$

which is analogous to those used for the synthesis of $[(CH_3)_3Si]_4Ge$ and $[(CH_3)_3Si]_4Sn$ [4], we succeeded in preparing and isolating tris(trimethylsilyl)indium *(1)*. A yield of 40% is obtainable only by adherence to the procedure given since a higher reaction temperature and slow stirring for prolonged reaction times favor reduction of $InCl_3$ according to

$$InCl_3 + 3\,Li \rightarrow 3\,LiCl + In$$

and simultaneously inactivate the lithium metal.

On sublimation, pure *(1)* is deposited in the form of greenish-yellow crystals, which decompose under vacuum above 50 °C in the dark and above about 0 °C on exposure to daylight. The decomposition products are indium and hexamethyldisilane; the presence of CH_3In groups could not be established. In solution or in contact with its decomposition products, compound *(1)* even decomposes below room temperature.

Compound *(1)* is extremely reactive toward O_2; it is spontaneously inflammable in air and explodes at room temperature in a current of oxygen. Consequently, in order to ensure controllable combustion during CH analysis, we had to use a stream of Ar containing an increasing proportion of O_2. Owing to the sensitivity of the substance, which exceeds that of $[(CH_3)_3Si]_2Hg$, the values obtained from the C, H, and In analyses showed a scattering of up to ± 10%.

Even after extreme care had been exercised in the preparation of the sample, the IR spectrum invariably contained bands due to oxidation products (initially the strong bands due to an indium silanolate at 455 (νInO) and 895 cm^{-1} (νSiO) and subsequently those due to $[(CH_3)_3Si]_2O$ at 330 and 1060 cm^{-1}). It can be deduced from the way in which the spectra change with time that *(1)* exhibits medium absorption at 311 cm^{-1}, which can be assigned to $\nu_{as}Si_3In$, alongside those bands arising from internal $Si(CH_3)_3$ vibrations; the possibility that this band arises from decomposition products cannot be completely ruled out.

By a rapid recording technique we have, however, succeeded in obtaining an HeNe laser Raman spectrum[5], which shows no lines due to impurities and whose interpretation, together with the analytical data and the chemical properties, lends support to the structure assumed for *(1)*. The following lines were observed below 700 cm^{-1}: 111 m ($\delta_{as}Si_3In$), 157 vs (ρSiC_3), ≈ 165 sh (δ_sSiC_3), 224 w ($\delta_{as}SiC_3$), 307 s (ν_sSi_3In), 623 s (ν_sSiC_3), and 682 m ($\nu_{as}SiC_3$). Assuming a planar Si_3In system, we have carried out a normal coordinate analysis for the $(C_3Si)_3In$ unit (C_{3h} symmetry) in A′ and taken the inner potential constants of the SiC_3 group from other trimethylsilyl compounds[6].

The following set of normalized symmetry force constants simulate the Raman frequencies observed for ν_sSiC_3 (ν_1), δ_sSiC_3 (ν_2), and ν_sSi_3In (ν_3) to within ± 0.4 cm^{-1}: F_{11} 2.93, F_{22} 0.15, F_{33} 1.6, F_{12} 0.05, F_{13} 0.15, and F_{23} −0.15 mdyn/Å. If *f*(SiIn/Si′In) is limited to a value between those for $[(CH_3)_3Si]_2Hg$ (∢ Si_2Hg 180°; 0.25) and $[(CH_3)_3Si]_4Sn$ (∢ Si_2Sn 109°28′; 0.16), *i.e.* to 0.2 ± 0.05 mdyn/Å, a value of 1.2 ± 0.1 mdyn/Å is calculated for *f*(SiIn). Working on the same assumption $\nu_{as}Si_3In$ is calculated to be 305 ± 20 cm^{-1}; if the band observed at 311 cm^{-1} is real, *f*(SiIn) is 1.25 and (SiIn/Si′In) is 0.17 mdyn/Å. Therefore, *f*(SiIn) is smaller (in spite of the fact that the bonding electrons in In have the highest s character) than the SiEl stretching force constants in compounds analogous to *(1)* containing elements of the 5th period: $[(CH_3)_3Si]_4Sn$ (1.66), $[(CH_3)_3Si]_3Sb$ (1.53), $[(CH_3)_3Si]_2Te$ (1.64), and $(CH_3)_3SiI$ (1.80 mdyn/Å)[6]. This is in accord with the lability of the Si–In bond.

Procedure:

$InCl_3$ (0.05 mole), lithium turnings (0.3 g-atom), and $(CH_3)_3SiCl$ (0.3 mole) are allowed to react together in tetrahydrofuran (300 ml) at −30 °C under N_2 and with rapid stirring for 2–4 h. The solution is filtered while still cold and the tetrahydrofuran is removed under vacuum in the dark at −10–0 °C; the orange-brown residue is extracted with cold ether (100 ml) at −20 °C (under these conditions the orange-red ethereal solution can be kept for several days) and the ether is then sucked off at −30 °C in the dark. Compound *(1)* remains behind in *ca.* 40% yield as a crystalline, orange-red residue that can be sublimed portionwise at 10^{-4} torr and a bath temperature of 40 °C onto a cold-finger (+10 °C). The decomposition product $(CH_3)_3SiSi(CH_3)_3$ must be drawn off continuously.

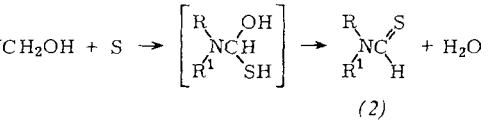
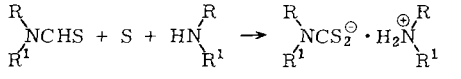
A New Preparation of Thioformamides and Dithiocarbamates



By *Ludwig Maier* [*]

Under the conditions of the Willgerodt-Kindler reaction[1,2], aromatic aldehydes react with sulfur and secondary amines to give good yields of thiocarbamides such as *(1)*. The corresponding reactions of aliphatic aldehydes appear to have been hardly investigated so far. Thus heptanal gave *n*-heptanamide in 46% yield on heating with $(NH_4)_2S_x$ and pyridine in a bomb tube[3], and morpholinium 4-morpholinedithiocarboxylate was obtained in 75% yield when morpholine was refluxed with paraformaldehyde and sulfur for 5 h[4]. Under the very mild conditions employed by *Asinger*[5], aliphatic aldehydes react reluctantly and in an unclear manner.



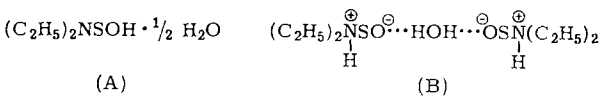
(1)

We have found that sulfur reacts readily with formaldehyde and amines, under the conditions used for the α-aminoalkylation of white phosphorus[6], to form thioformamides *(2)* and the amine salts of the corresponding dithiocarbamic acid *(3)*. If R, N, and R^1 are joined as a ring, compounds *(2)* and *(3)* can be regarded as *N*-thioformyl heterocyclic compounds or *N*-carbothialdehydes and amine salts of *N*-dithiocarboxylic acids, respectively.

(2)

(2) *(3)*

	R	R^1	*(2)* B.p. (°C/torr)	*(2)* Yield (%)	*(3)* M.p. (°C)	*(3)* Yield (%)
(a)	CH_3	CH_3	95–101/10	46	129–131	32
(b)	C_2H_5	C_2H_5	105–107/9	20	81–82	18
(c)	C_4H_9	C_4H_9	–	–	49–50	46
(d)	$-(CH_2)_4-$		100–110/1[a]	15	156–158	13
(e)	$-(CH_2)_5-$		87–89/0.07	25	168–171	18
(f)	$-CH_2CH_2OCH_2CH_2-$		[b]	59	sublimes	11
(g)	CH_3	H	125–128/12	16	–	–
(h)	C_2H_5	H	75–80/0.5	27	–	–



[a] M.p. 32–33 °C; [b] M.p. 68–70 °C.

The yields of the individual products depend on the molar ratios of the reactants and on the solvent. The highest yields of thioformamide *(2)* are obtained at a molar ratio of sulfur/dialkylaminomethanol = 3:1, and with water/alcohol (1:2 v/v) as solvent (80 °C, 4–11 h). The yield of dithiocarbamate increases steadily with increasing amounts of sulfur.

Under the above conditions morpholinomethanol does not react with sulfur; however, on addition of catalytic amounts of pyridine excellent yields of *N*-thioformylmorpholine *(2f)* are obtained.

On reaction of diethylaminomethanol with sulfur a further white crystalline product having the composition $C_4H_{12}NSO_{1.5}$ and m.p. 132–136 °C (decomp.) is formed in 6 to 9% yield along with diethylthioformamide *(2b)* and diethylammonium diethyldithiocarbamate *(3b)*. The pH of an aqueous solution (0.038 M) of this product is 6.1. On heating with hydrochloric acid SO_2 is evolved and elemental sulfur is precipitated. An aqueous solution of silver nitrate is reduced by the compound. The ^1H-NMR spectrum (in D_2O) of the compound contains signals for CH_3 at = δ 1.70 (T, J_{HH} = 7 Hz), $CH_3\underline{CH_2}$ at δ = 3.51 (Q, J_{HH} = 7 Hz), and a singlet at δ = 5.28 (1H): in $(CH_3)_2SO$ the signals for CH_3 appear at δ = 1.21, that for $CH_3\underline{CH_2}$ at δ = 2.91, and a very broad signal is observed between δ = 5.83 and 7.0 (1H). The mass spectrum contains peaks corresponding to the decomposition products

$(C_2H_5)_2NH$, sulfur (S_1 to S_8), SO_2, SO, and H_2O. These properties would be expected for a substance having structure A or B. The IR spectrum shows a sharp band at 2440

(A) (B)

cm^{-1} corresponding to $-\overset{\oplus}{N}HR_2$, thus suggesting the betaine structure B. B is therefore the first stable derivative of an *N*-sulfoxylic acid.

N-Thioformylpyrrolidine (2d) and pyrrolidinium N-pyrrolidinedithiocarboxylate (3d):

To a 37% aqueous solution of formaldehyde (15 g, 0.5 mole) are added first pyrrolidine (35.5 g, 0.5 mole), with ice cooling, and then sulfur (48 g, 1,5 mole), water (35 ml), and ethanol (100 ml); the mixture is subsequently refluxed for 4 h. The excess of sulfur is filtered off and, after removal of ethanol, the filtrate is extracted with ether. Distillation of the ether extract affords *(2d)* (9 g, 15%), b.p. 100–110 °C/1 torr, m.p. 32–33 °C (b.p. 157–160 °C/16 torr, m.p. 31.5–32.5 °C, according to ref. [7]).

Concentration of the aqueous phase yields *(3d)* (7 g, 13%), m.p. 156–158 °C, together with 20 g of a black greasy substance.

Tungsten(IV) Oxide Bromide, $WOBr_2$

By *J. Tillack* and *Renate Kaiser* [*]

In connection with investigations on the reactions occurring in halogen incandescent lamps we were able to synthesize $WOBr_3$ [1]; we have now also succeeded in preparing the hitherto unknown compound $WOBr_2$.

Tungsten, tungsten trioxide, and bromine (molar ratio 2:1:3) were transferred to an evacuated sealed tube (length 180 mm, diameter 25 mm) and placed in a temperature gradient of of 450/*ca.* 40 °C in such a way that the W/WO_3 was in the hotter half and the bromine in the cooler half of the slightly inclined tube. After about 30 min almost all of the bromine had reacted with part of the other components to give higher tungsten bromides and oxide bromides, so that further reaction could be carried out in a temperature gradient of 580/450 °C without danger of explosion.

$$2\,W + WO_3 + 3\,Br_2 \rightleftharpoons 3\,WOBr_2 \qquad (1)$$

The $WOBr_2$, which is formed in the hot zone, was deposited by a chemical transport process [2] – probably in accord with equation (2) – in the cooler half of the tube (450 °C) in the form of well-crystalline, grayish black lustrous needles.

$$WOBr_2 + WOBr_4, g \rightleftharpoons 2\,WOBr_3, g \qquad (2)$$

A slight excess of bromine (3–5 mg more bromine per ml of tube volume than required stoichiometrically) prevents dissociation of the $WOBr_2$ deposited. With a stoichiometric charge of 20 mg-atoms of tungsten, 10 mmoles of WO_3, and 30 mmoles of bromine the above procedure afforded 10.2 g of $WOBr_2$ (yield *ca.* 95%; regarding analytical procedures, see refs. [1, 3]).

Owing to the reversibility of the reaction, $WOBr_2$ may also be prepared from tungsten and oxygen or WO_2, and bromine.

In a temperature gradient of 550/470 °C the mixture described repeatedly gave large amounts of a dull, blue-black substance at 470 °C, which has the approximate composition $W_2O_3Br_3$ and which clearly differed in its chemical behavior and X-ray diffraction pattern from $WOBr_2$; this substance has not yet been investigated further.

When dry $WOBr_2$ is heated in a test tube yellowish brown fumes of WO_2Br_2 with a little bromine are evolved and WO_3 is left behind as residue. No reaction is observed between $WOBr_2$ and water or dilute acids (HCl, H_2SO_4, CH_3COOH) at room temperature; when heated to boiling with water, conc. hydrochloric acid, or dilute acetic acid nothing more than a slight blue coloration is noted, whereas conc. sulfuric acid and conc. nitric acid decompose $WOBr_2$.

The compound is attacked neither by cold nor by hot aqueous ammonia. However, treatment with 2 M NaOH yields a voluminous, blackish brown precipitate that was not examined further. In both cases, subsequent addition of approximately 3% H_2O_2 gives clear yellow solutions.

At room temperature $WOBr_2$ decolorizes a $KMnO_4$ solution that has been acidified with sulfuric acid. Organic solvents, *e.g.* ethanol, acetone, toluene, dichlorobenzene, and trichloroethylene, do not have any effect on the compound.

Regarding the X-ray characterization of $WOBr_2$, we report the following *d* values and the estimated intensities (in parentheses) of the first reflections up to $\vartheta = 38°$:

7.31 (3); 6.55 (8); 3.63 (10); 2.68 (8); 2.36 (4); 2.22 (1); 2.19 (1); 2.08 (2); 2.00 (7); 1.89 (5); 1.71 (1); 1.68 (2); 1.64 (1); 1.55 (5); 1.43 (1); 1.26 (2).

The density was determined pycnometrically in toluene at 25.0 ± 0.1 °C as 6.13 g/cm³.

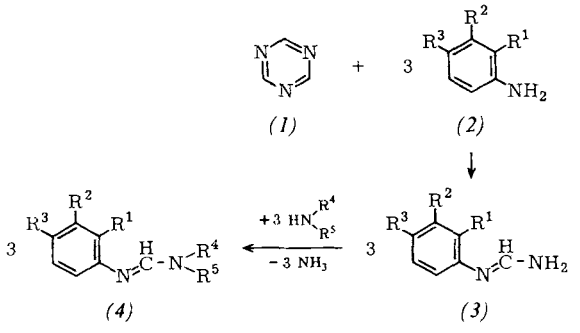
Trisubstituted Formamidines



By *M. F. G. Stevens* and *A. Kreutzberger* [*]

The aminomethinylation reaction that takes place on nucleophilic attack of *s*-triazine *(1)* on amines *(2)* [1] can be utilized in a new synthesis of aminoquinazolines [2]. The ease of this additive cyclization decreases as the basic strength of the amino group in *(2)* decreases, so that 2-amino-5-nitrobenzonitrile does not react with *(1)* under the conditions used, even in pyridine. By contrast, reaction occurs with violent evolution of ammonia when the starting materials are heated in piperidine; however, the reaction course deviates from that

of aminoquinazoline formation. The base peak at *m/e* 84 and the fragment ions observed in the mass spectrum of the end product at *m/e* 69, 56, 41, 30, and 28 are analogous to the fragments formed by formimidoylpiperidine groups[3]. On the basis of this fragmentation pattern and the molecular ion observed at *m/e* 258, and in accord with other spectroscopic and chemical data, the reaction product was identified as 1-[*N*-(2-cyano-4-nitrophenyl)formimidoyl]piperidine *(4a)*.

This reaction proves to be very amenable to variation and represents a general method for the preparation of N^2-aryl-N^1,N^1-dialkylformamidines *(4)*, in which R^4 and R^5 can also be parts of a heterocyclic ring.

Attack of *(1)* on CH-acids, such as 4-nitrophenylacetonitrile[3] and α-picoline *N*-oxide[4], in the presence of secondary amines is a reaction comparable to the formation of *(4)*. The class of trisubstituted formamidines contains representatives having ovicidal[5], herbicidal[6], antiviral, and antibacterial[7] activity.

(1) *(2)* *(3)* *(4)*

Solvolytic Ring Expansion in a Transition Metal π-Complex[1]

By *G. E. Herberich* and *J. Schwarzer*[*]

Alkyl halides and esters that carry a ferrocenyl group or a similar complex substituent in the α-position undergo solvolysis as readily as triphenylmethyl halides and esters[2,3]. The intermediate carbonium ion is stabilized by the neighboring group effect of the complex substituent, the nonbonding d electrons of the central atom or ion seemingly

(1) *(2)*

(1a): X = Br *(2a)*: X = Br
(1b): X = I *(2b)*: X = I

playing a key role in this stabilization[3]. Ligand rearrangements have not hitherto been observed during solvolyses of this kind.

We now wish to report on a novel type of an exceptionally rapid solvolysis. The 5-*exo*-halogenomethyl derivatives *(1)*[4] of cyclopentadienecyclopentadienylcobalt, which are stable in hexane solution, rearrange irreversibly in polar media to give cyclohexadienylcyclopentadienylcobalt salts *(2)*.

This is the first example of a solvolytic ring expansion in a ligand of a transition metal π-complex.

The solvolysis of *(1a)* can readily be followed by spectrophotometric techniques: the reaction is first order with respect to *(1a)*; a rate constant of $k_1 = 1.1 \times 10^{-4}$ sec^{-1} was found at 30 °C in ethanol/*n*-hexane (95:5). By contrast, compound *(1b)* rearranges in the solid state at 0 °C almost quantitatively to *(2b)* within two days.

The salts of the cyclohexadienylcyclopentadienylcobalt cation *(2)*, which has now been obtained for the first time, are red, air-stable substances that are somewhat sensitive to light; the composition of the iodide and of the hexafluorophosphate were established by elemental analysis. The constitution of the cation is evidenced by the ^{1}H-NMR (see Table 1) and by the IR spectrum. The ^{1}H-NMR spectrum

Table 1. ^{1}H-NMR spectrum *(2a)* in D_2O (60 MHz; 20 °C).

Signal	Rel. Int.	τ [a]	Multiplicity	Coupling constants (Hz)
H_a	1/4:2/4:1/4	2.83	3 [b]	J_{ab} = 5,5
H_d	5	4.53	1	
H_b, H_b'	1/2:2/2:1/2	4.69	"3" ≙ 2 × 2	$J_{ab} \approx J_{bc} \approx 6$
H_c, H_c'	1/2:2/2:1/2	6.05	"3" ≙ 2 × 2 [b]	$J_{bc} \approx J_{endo,c} \approx 7$
H_{endo}	1 [c]	7.29	2 × 3	$J_{endo,exo} = 16$; $J_{endo,c} = 7$
H_{exo}	1 [c]	8.86	2 [b]	$J_{endo,exo} = 16$

[a] Measured with respect to TMS as external reference.

[b] Further splitting of the order of 1 Hz is observed.

[c] The relative intensities of the components deviate significantly from those of a first order spectrum.

contains signals having relative intensities 1:2:5:2:1:1; the cyclohexadienyl protons show a coupling very similar to that in tricarbonylcyclohexadienyliron tetrafluoroborate[5,6]. Since the methylene group in cyclohexadienyl ligands is directed outwards (by 50 ° in the case of tricarbonyl-1,2,3,4,5,6-*endo*-hexamethylcyclohexadienylrhenium[7]), H_{exo} is more strongly shielded by the π-electrons of the cyclohexadienyl ligands, whereas the shielding of H_{endo} is reduced. At the same time, the dihedral angles $\sphericalangle H_cCCH_{endo}$ and $\sphericalangle H_cCCH_{exo}$ are changed in such a way that $J_{endo,c} > 6$ Hz and $J_{exo,c} < 2$ Hz would be expected from the Karplus equation. According to both these arguments, the doublet at τ = 8.86 must be assigned to the *exo* proton and the multiplet at τ = 7.29 to the *endo* proton. In addition to the absorption of the cyclopentadienyl ring, the IR spectrum shows various bands (in cm^{-1}: 1446 m, 1405 s, 1324 w, 1296 s, 1138 m, 1047 s, 993 s, 947 m, 901 w, 870 m, 809 m), which are all observed in other cyclohexadienyl complexes too.

In the two-phase system ether/water, compound *(2)* can be converted at 20 °C into cyclohexadienecyclopentadienylcobalt[8] (yield 90%).

$Ni_5(C_5H_5)_4S_4$, a Pentanuclear Metal Complex Containing a Square-Planar Nickel(0) Atom[**]

By *H. Vahrenkamp* and *L. F. Dahl*[*]

In continuation of our attempts to prepare $Ni_3(C_5H_5)_3S$[1], an electronic equivalent of $Co_3(CO)_9S$[2], we instead isolated $Ni_5(C_5H_5)_4S_4$ *(1)* from the decomposition of $Ni_3(C_5H_5)_3S_2$ *(2)* in ether solution. The equation

$$2\ Ni_3(C_5H_5)_3S_2 \rightarrow Ni(C_5H_5)_2 + Ni_5(C_5H_5)_4S_4$$
(2) *(1)*

indicates the probable stoichiometry of this reaction and makes it understandable why the main products from the reaction of $Ni_2(C_5H_5)_2(CO)_2$ *(3)* with elemental sulfur are nickel sulfides and $Ni(C_5H_5)_2$, since analogous formal abstraction of $Ni(C_5H_5)_2$ from *(1)* would finally lead to an $[Ni_3S_4]_x$ species. Compound *(1)* was characterized by a single-crystal X-ray study, which also further substantiated the predicted drastic influence of valence electrons on the molecular configuration of *(2)*[1] and thereby provided additional support for the bonding principles recently proposed for transition metal cluster carbonyl systems[1,3].

Crystals of *(1)* are monoclinic with two formula species in a unit cell of symmetry $P2_1/c$ and dimensions a = 7.870 ± 0.005 Å, b = 12.704 ± 0.007 Å, c = 11.661 ± 0.007 Å, β = 99 °52′ ± 1′; ρ_{calcd} = 1.97 g cm^{-3} *versus* $\rho_{obsvd.}$ = 1.96 g cm^{-3} (flotation method). Three-dimensional intensity data consisting of 838 observed independent reflections and 274 unobserved or pseudo-unobserved reflections (*i.e.*, $I < 2\sigma(I)$) were collected with Mo Kα radiation on a four-angle automated diffractometer (General Electric). The structure and composition were elucidated by application of the symbolic addition method of phase determination[4]; full-matrix least-squares refinement with anisotropic temperature factors for the nickel atoms and isotropic ones for the sulfur and carbon atoms resulted in identical unweighted R_1 and weighted R_2 discrepancy values of 6.7%.

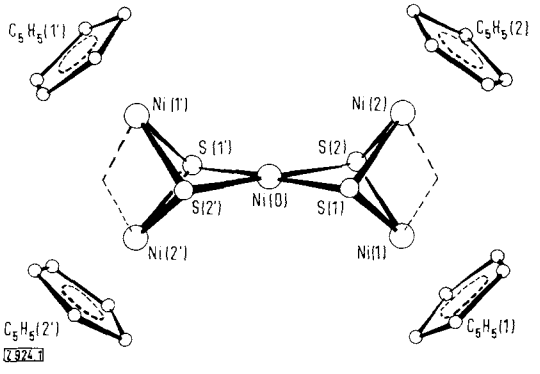

Fig. 1. Molecular configuration of $[Ni_2(C_5H_5)_2S_2]_2Ni$.

Crystalline *(1)* consists of discrete molecules (Figure 1). Each of the two molecules in the unit cell is constrained by the space group symmetry to possess crystallographic C_i-$\bar{1}$ symmetry with the central nickel atom of each molecule lying on a center of inversion. With the assumption of cylindrical symmetry for each cyclopentadienyl ligand, the entire molecule has approximately D_{2h}-2/m 2/m 2/m symmetry. The five nickel and four sulfur atoms form two distorted Ni_3S_2 trigonal bipyramids which are connected to each other by corner sharing of the one common equatorial nickel atom such as to give this unique central nickel atom a square-planar coordination with the four axially-positioned sulfur atoms. In accord with the resulting formula of $[Ni_2(C_5H_5)_2S_2]_2Ni$ and a pseudo-D_{2h} geometry, the prominent molecular dimensions are: (1) a bonding Ni(1)–Ni(2) distance of 2.495 ± 0.003 Å compared to two equivalent nonbonding Ni(0)–Ni(1) and Ni(0)–Ni(2) distances of the same value, 2.979 ± 0.002 Å; (2) six crystallographically independent Ni–S distances all equal within 0.01 Å to the average value of 2.18 Å; (3) equivalent nickel-to-(cyclopentadienyl carbon) distances of 2.14 Å (av.) and cyclopentadienyl C–C bond lengths of 1.43 Å (av.); (4) two equivalent Ni(1)-S-Ni(2) angles of 69.9 ° and 70.0 ° (indiv. esd, 0.1 °) *vs.* four equivalent Ni(1)–S–Ni(0) and Ni(2)–S–Ni(0) angles of range 86.0 to

86.3° (indiv. esd, 0.1°); (5) S(1)–Ni(0)–S(2) and S(1)–Ni(0)–S(2′) angles in the Ni(0)–S_4 plane of 82.1(1) and 97.9(1) degrees, respectively.

Considerable similarity exists between the $[Ni_2(C_5H_5)_2S_2]Ni_{1/2}$ fragment comprising one-half the molecule of *(1)* and its chemical precursor *(2)* with respect to their overall configurations and their virtually identical Ni–S and Ni–C bond lengths. The salient structural difference is that the regular trigonal bipyramidal Ni_3S_2 cluster system in *(2)* has three equivalent long Ni–Ni distances of 2.801(5) Å in contrast to the markedly distorted trigonal bipyramidal $[Ni_2S_2]Ni_{1/2}$ fragment containing one much shorter bonding and two significantly longer nonbonding Ni–Ni distances. Since the central Ni(0) atom no longer is effectively bonded directly to the other four chemically equivalent nickel atoms, the molecule *(1)* instead of being treated as an interconnected Ni_5-cluster system may simply be regarded as being composed of two $Ni_2(C_5H_5)_2S_2$ units linked together only by the Ni(0) atom. It then becomes obvious that the two identical units (in which each sulfur atom by its donation of one electron to each nickel atom has two resulting unshared electron pairs) are of the $M_2(C_5H_5)_2X_2$ type structure represented in molecular form by the electronically equivalent and structurally analogous complex *(3)* [5] and $Co_2(C_5H_5)_2\{P(C_6H_5)_2\}_2$ *(4)* [6].

The structure of the $Ni_2(C_5H_5)_2S_2$ unit with its nonplanar Ni_2S_2 bridging system closely resembles that of *(4)* [6]. The fact that a rational basis for a distinct Co–Co σ-bond of considerable bond strength was provided [6] for the phosphorus-bridged CoC_5H_5 dimer in order to account for its molecular geometry with sharply acute bridging angles and with a Co–Co bonding distance of 2.56 Å is in complete accord with the assignment of the Ni–Ni interaction in the $Ni_2(C_5H_5)_2S_2$ unit as an electron-pair bond in order for each nickel to attain a closed-shell electronic configuration. The somewhat longer Ni(1)–Ni(2) distance of 2.495(3) Å compared to the Ni–Ni σ-bonding distance of 2.36 Å observed in *(3)* [5] and of 2.33 Å found in $Ni_2(C_5H_5)_2(C_6H_5C_2C_6H_5)$ [5] is expected in that it has been shown [7] that the electron-pair metal-metal bonding distances in ligand-bridged complexes primarily depend on both the size and effective electronegativity of the bridging atoms. Through a σ-bond interaction involving the use of one of the two unshared electron pairs on each of the four sulfur atoms of the two $Ni_2(C_5H_5)_2S_2$ units, the central Ni(0) atom also attains a closed-shell electronic configuration without any direct interaction with the other four nickel atoms. To our knowledge the square-planar coordination is unprecedented for a tetracoordinated "zerovalent" nickel atom which normally forms tetrahedral-like complexes (*e.g.*, $Ni(CO)_4$ [8] and 1,5-cyclooctadieneduroquinonenickel [9]).

The changes in the Ni–Ni distances of the Ni_3S_2 system that occur on going from *(2)* to *(1)* can be nicely rationalized from the same qualitative MO considerations utilized to formulate the nickel-nickel bonding in *(2)* [1]. In this latter complex the "effective" Ni–Ni bonding among the three nickel atoms is due to only one strongly bonded electron in a nickel symmetry orbital delocalized over the entire trinickel cluster system. Experimental support of this MO formulation of weak Ni–Ni bonding in *(2)* is given by the observed long Ni–Ni distances. The formal replacement of the one cyclopentadienyl ring with two sulfur atoms not only removes the orbital degeneracy of the metal atoms in the Ni_3S_2 system but more importantly reduces the number of antibonding electrons by one. Hence, the *net* difference between the corresponding occupied bonding and antibonding levels (which are assumed to cancel one another's bonding) is *two* bonding electrons. The localization of this bonding electron pair between the two equivalent nickel atoms in each $[Ni_2S_2]Ni_{1/2}$ fragment accounts for the observed localized C_{2v} deformation from the regular trigonal bipyramidal Ni_3S_2 structure in *(2)* to give the one much shorter Ni–Ni distance of single bond value and the other two longer Ni–Ni nonbonding distances.

Procedure:

An ether solution of *(2)* [1] (prepared from 0.76 g of *(3)* and 0.10 g sulfur) was filtered and allowed to stand at room temperature under nitrogen. After one to three weeks, black crystalline *(1)* and some brown powder had precipitated on the walls of the flask. Yield 24 mg (2.7%), m.p. 135 °C (with vigorous decomposition upon rapid heating).

Preparation and Properties of $AuTe_2I$

By *A. Rabenau, H. Rau*, and *G. Rosenstein* [*]

Hydrothermal synthesis in halogen hydracids [1] is a most suitable method for the preparation of chalcogenide halides [2, 3]. Hitherto, chalcogenide halides with gold as constituent have been unknown. Reaction of gold and tellurium in hydriodic acid, however, leads to the formation of crystals of a compound, which on analysis has the composition $AuTe_2I$ *(1)*.

If an excess of gold is present in such a reaction well-developed shiny silvery single crystals of *(1)*, in the form of needles up to 1 cm and more in length, are formed: 10 g of a mixture of gold powder and tellurium (in the atomic ratio 1:1) is transferred to a quartz ampul of 10–11 ml capacity and 10 M hydriodic acid is added until the ampul is 65% full and frozen with liquid air. After sealing under vacuum, the ampul is transferred to an autoclave [4], heated to 450 °C, and then allowed to cool to 150 °C over a period of 10 days. The $AuTe_2I$ crystals which precipitate out can easily be separated from the gold crystals which are formed at the same time; only occasionally do both types of crystals associate (Fig. 1). When subjected to mechanical stress, the crystals of *(1)* easily shred longitudinally into fibers. The compound is obtained in a pure, polycrystalline form by tempering a mixture of gold powder, TeI, and tellurium (in the stoichiometric ratio 1:1:1) in a sealed ampul at 350 °C.

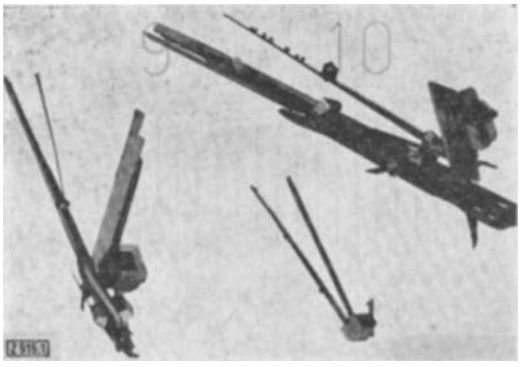

Fig. 1. Needles of $AuTe_2I$ associated with gold. (Figures in cm.)

According to DTA measurements, compound *(1)* is stable up to a temperature of 371 °C in the absence of air. The electrical resistance[5] of the crystals increases linearly with temperature – as in metallic conductors.

The compound is insoluble in dilute acids and alkalis; it decomposes in concentrated nitric and concentrated sulfuric acids.

From single-crystal photographs it can be concluded that $AuTe_2I$ crystallizes rhombically: $a = 4.735$, $b = 4.046$, $c = 12.55$ Å; $Z = 2$, $d_m = 8.00$, $d_x = 7.98$ g/cm³. Probable space groups $Pmc2_1$, Pma2, Pmma.

The indexing of a powder diagram is given in Table 1.

Table 1. Diffractogram of $AuTe_2I$.

The Crystal Structure of Zirconium(IV) Chloride: A New AB_4-type Structure

By *B. Krebs*[*]

According to *Hansen*[1], $ZrCl_4$ *(1)* ought, by analogy with $TiCl_4$, to have an SnI_4-type (molecular) structure with tetrahedral coordination of the Zr atoms. This argument, however, cannot be correct since the physical properties[2] and the vibration spectrum investigated by *Weidlein*, *Müller*, and *Dehnicke*[3] exclude a molecular structure. We have therefore carried out a complete X-ray structural analysis on single crystals of $ZrCl_4$ (flat needle-like crystals obtained by slow sublimation at about 300 °C in a closed system). *(1)* crystallizes in the monoclinic space group P2/c (C_{2h}^4) with $a = 6.361 \pm 0.004$, $b = 7.407 \pm 0.004$, $c = 6.256 \pm 0.004$ Å, $\beta = 109.30 \pm 0.04°$, $V = 278.2$ Å³. $Z = 2$; $d_{x\text{-ray}} = 2.782$ g/cm³, $d_{pyc} = 2.80$ g/cm³. A total of 614 independent reflections were measured with an automatic Hilger-Watts four angle diffractometer ($\omega/2\theta$ scan, Zr filtered Mo–K_α radiation, scintillation counter). The structure was determined by interpretation of the three-dimensional Patterson synthesis. Least squares refinement with anisotropic temperature factors afforded an R_1 factor of 4.9%. The atomic parameters are: Zr: 0; 0.1641; 0.25; Cl(1): 0.2263; 0.1076; −0.0022; Cl(2): 0.2552; 0.6371; −0.0205.

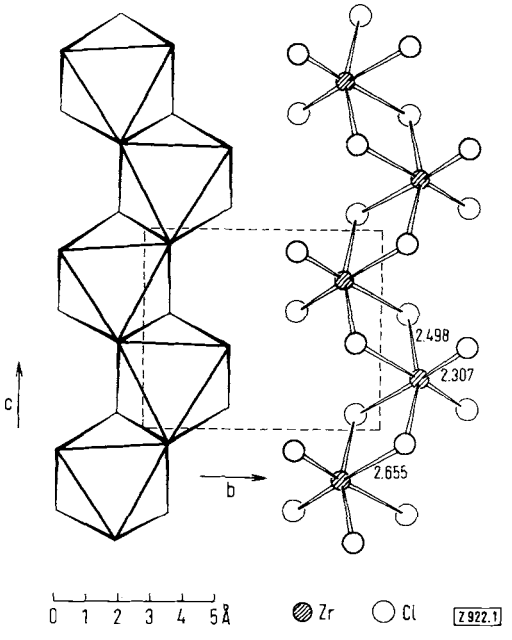

Fig. 1. Crystal structure of $ZrCl_4$. Projection of one chain on the *bc* plane.

(1) has a previously unknown AB_4-type structure (Fig. 1): $ZrCl_6$ octahedrons are coupled to each other by two edges to form a zig-zag chain; the common edges with neighboring octahedrons do not lie in a *trans*-position to one another as *e.g.* in NbI_4[4]. The chain structure gives rise to considerable macroscopic cleavability parallel to (100) and (010) of the needle shaped crystals. The $ZrCl_6$ octahedrons are very much distorted: two Zr–Cl bridge bonds having different lengths (2.498 and 2.655 Å; standard error ±0.003 Å) are present for each two terminal bond lengths (2.307 Å). The bridge bonds, which must be assumed to be 50% heteropolar in character, are significantly weaker than the terminal bonds according to their lower formal bond orders. The terminal bond lengths are comparable with those of the tetrahedral $ZrCl_4$ molecule in the gas phase (2.32 Å[5]). The shortest Zr–Zr distance of 3.962 Å between neighboring octahedrons excludes the participation of metal-metal bonding.

The atomic arrangement can be described as a relatively slightly distorted cubic close packing of Cl atoms with one quarter of the octahedral holes being occupied by Zr atoms. The twelve Cl neighbors of each Cl atom are situated at distances of 3.30 (bridge edges of octahedrons) to 3.93 Å.

The chain structure represents a transition from the more covalently bound molecular structures of $TiCl_4$ and Nb_2Cl_{10} to the corresponding more heteropolar compounds of Sc, Y, and the rare earths: The octahedron chains of *(1)* can be regarded as sections of the layers of the YCl_3 lattice ($AlCl_3$-type)[6], whilst the Nb_2Cl_{10} double octahedron[7] formally represents a section of the $ZrCl_4$ structure. Similar relationships exist between *(1)* and the BiI_3 and $CrCl_3$ layer structures. The metal-chlorine bond lengths in the series YCl_3,

$ZrCl_4$, Nb_2Cl_{10}, Mo_2Cl_{10}[8] exhibit a physically meaningful trend.

The tetrahedral form of the $ZrCl_4$ molecule in the gas phase is already latent in the distorted octahedrons of the crystal structure. Accordingly, the cleavage of the longest Zr–Cl bond with subsequent easy rehybridization at the Zr is assumed to be a plausible vaporization- and sublimation mechanism (cf.[9]). $ZrBr_4$ and $HfCl_4$, and probably $HfBr_4$, are isostructural with *(1)*.

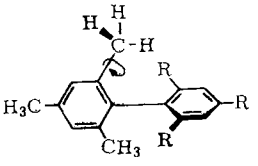
Are β-Diketone-Metal Complexes Aromatic?[1]

By *M. Kuhr* and *H. Musso*[*]

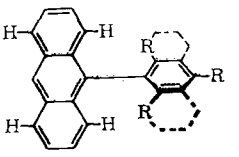
The metal chelates of β-diketones have, for a long time, been considered to exhibit a benzenoid resonance A ↔ A[1] [2] and as a consequence to possess an aromatic or quasi-aromatic character[3]. Numerous attempts to deduce such a property, as in the case of benzene, from the shift of the NMR signal for the protons bound in the plane of the chelate ring have been differently interpreted[4–6].

A A' B



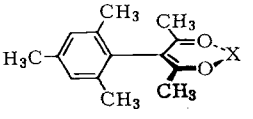
C C'

The vibration spectra of isotopically substituted 2,4-pentanedionato complexes (acetylacetonates) of various metals indicate that a complete bond delocalization is present in solution and in the crystalline state (A or B) but not in the enol form of 2,4-pentanedione (X = H), as in C ⇌ C'[1,7].



In order to determine unequivocally whether or not a cyclic conjugation of the six π electrons continues over the metal atom, we have examined derivatives of 2,4-pentanedione in which protons are situated not in the plane but over the chelate ring. A shift of the signal of such protons to higher magnetic field in the NMR spectrum is a sure indication of aromatic character[8].

From the chemical shift differences $\Delta\delta$ (cf. Table 1) of the *o*- and *p*-methyl groups in the ^{1}H-NMR spectra of phenylmesitylene *(1)* (0.30 ppm), bimesityl *(2)* (0.45 ppm), and 9-mesitylanthracene *(4)* (0.78 ppm) and of the 1,8- and 4,5-hydrogen atoms of 9-phenylanthracene *(3)* (~0.45 ppm), *(4)* (0.70 ppm), and 9,9'-bianthryl *(5)* (1.10 ppm) it can be concluded that a shift difference of *ca.* 0.5 ppm is to be expected if an aromatic ring is present beneath these protons. The observed differences in these models (0.30–1.10 ppm) depend, on the one hand, on the somewhat different average angles of twist of the two aromatic systems and, on the other, on the fact that the 1,8-anthryl protons in *(3)*, *(4)*, and *(5)* are fixed better over the other ring than are the protons of the rapidly rotating CH_3 groups in *(1)*, *(2)*, and *(4)*, in which only the mean value for the shift of favorable and unfavorable positions is indicated; finally, the electron density in the phenylmesityl- and central anthryl-ring is naturally different.



By way of comparison, the analogous shift differences in 3-mesityl- and 3-anthryl-2,4-pentanedione – *(6)*, X = H and *(7)*, X = H – are small. Since these differences in the metal complexes of *(6)* (X = K, Na, Li, Be, Al, Pd, Co) and *(7)* (X = K, Li, Be, Pd) of greatly varying stability do not increase significantly with respect to the hydrogen compounds (X = H) and the

[b] Centers of the A- and A- and D parts of the A_2B_2- and ABCD-multiplets.

free anions (X = K in DMSO), these chelate complexes do not possess magnetic anisotropy typical of aromatic compounds and consequently are not aromatic in character.

Daltrozzo came to the same conclusion *via* a different approach [9]. Use of the term "quasiaromatic" [3, 10] in connection with such systems is best avoided, since "non-aromatic" is not generally understood to be included under this heading.

It would appear attractive to study, in this way, the bonding character of further metal complexes and other five- and six-membered chelates and heterocycles (*e.g.* [11–13]), since the method used here is obviously less susceptible to polar and other effects than the position of the signals of protons in the plane of the ring [6].

According to their NMR spectra, compounds *(6)* and *(7)* (X = H) are present almost completely in the enolized form. These compounds were obtained from iodomesitylene and 9-bromoanthracene and from the chromium complex of 3-bromo-2,4-pentanedione respectively, by heating in the presence of copper powder (4 h, 240 °C) followed by acid hydrolysis: *(6)*, X = H, m.p. 83 °C, yield 40%; *(7)*, X = H, m.p. 182 °C, yield 7%. Although the Ullmann reaction is a well known classical method for the coupling of aromatic rings, it has been used here to provide evidence against the aromatic character of the metal complexes of *(6)* and *(7)*.

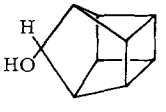
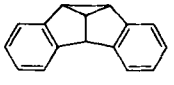
CONFERENCE REPORTS



New Olefin Reactions

A Symposium was held at the University of Manchester Institute of Science and Technology, June 25 and 26, 1968, that dealt with some of the more important recent advances and trends in olefin reactions.



G. Wilke (Mülheim, Germany) reviewed the factors which influence the reactions of olefins with transition metals. Metal-olefin complexes are in general stabilized by the presence of basic ligands in the molecule, and by partial decoupling of the olefin π-orbitals, usually achieved by ring strain in the case of cyclic olefins, or in mono-olefin complexes by rotation of the olefin so that it is at an angle to the plane of the molecule. The point was also made that complexes of chelating diolefins are more stable than the analogous mono-olefin complexes.

Several factors influence the reactivity of the complexed olefin, for example, charge transfer can occur from metal to ligand or from ligand to metal, and evidence was presented that in the compound bis(bipyridyl)cyclooctadienenickel the cyclooctadiene exists as a dianion. Hydrogen transfer reactions are also known in metal-olefin complexes, for example, the compound bis(cyclooctadiene)cobalt hydride exists as an equilibrium mixture of a σ-enyl and π-allyl structure.

R. Pettit (Austin, Texas, USA) reviewed the chemistry of cyclobutadiene complexes of transition metals and demonstrated how these complexes may be used as a convenient source of cyclobutadiene in the synthesis of organic compounds. The synthesis was reported of several *para*-bonded benzene derivatives by oxidative cleavage of $(C_4H_4)Fe(CO)_3$ in the presence of acetylenes. The preparation of pentacyclo-[4.3.0.0^{2,5}.0^{3,8}.0^{4,7}]nonan-9-ol *(1)* from 5,5-diethoxycyclopentadiene and $(C_4H_4)Fe(CO)_3$ was also described.

(1)

(2)

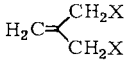
Oxidative cleavage of (benzocyclabutadiene)iron tricarbonyl in the presence of Ag^+ gives 4b,8b,8c,8e-tetrahydrodibenzo-[*b*,*e*]cyclopropa[*g*,*h*]pentalene *(2)*, by a normally forbidden (Woodward-Hoffmann rules) disrotatory ring opening of the Diels-Alder adduct, which becomes allowed when the adduct is complexed to silver.

The lecture concluded with some observations on the structure of free cyclobutadiene. A study of some Diels-Alder reactions of cyclobutadiene with dimethylmaleate and fumarate tentatively suggests that cyclobutadiene reacts in the singlet state (as a rectangular diolefin).

J. K. Hamblin (Sunbury-on-Thames, England) reported the dimerization of propene to methylpentenes (mainly 4-methyl-1-pentene) at 150 °C and about 100 atm with sodium or potassium on pure graphite or potassium carbonate. This reaction can be carried out on a pilot-plant scale and under the best conditions a yield of 92% of 4-methyl-1-pentene has been achieved.

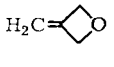
Allylic anions from propene or butenes will react with ethylene. In a typical reaction a 1:1 molar ratio of ethylene and propene gives a 92% yield of *n*-pentenes with small amounts of hexenes and heptenes. Similarly, reaction of ethylene with 1-butene gives 3-methyl-1-pentene and 2-hexene. The reactivity of the allylic anions towards ethylene decreases in the order $C_3H_5^- > n\text{-}C_4H_7^- > iso\text{-}C_4H_7^-$.

R. D. Cramer (Wilmington, Delaware, USA) dealt with olefin complexes of Rh^{I} and Rh^{III}. Ethylene can be dimerized to butenes (mainly 1-butene) in up to 95% conversion by $RhCl_3 \cdot 3\,H_2O$, $[(C_2H_4)_2RhCl]_2$, or $(acac)_2Rh(C_2H_4)_2$ in the presence of hydrogen chloride in ethanol. The mechanism of the reaction has been elucidated by a combination of kinetic and spectroscopic techniques and involves the insertion of a coordinated ethylene into the ethyl-rhodium bond in the complex $[C_2H_5Rh^{III}Cl_3(C_2H_4)S]^-$ (where S = solvent molecule) as the rate determining step. The codimerization of ethylene and butadiene to give 1,4- and 2,4-hexadiene, 3-ethyl-1,4-hexadiene, and 3-methyl-1,4-heptadiene was described. This reaction differs from the ethylene dimerization in that the reactive intermediates are π-allylrhodium complexes.



G. Wilkinson (London, England) reported that the compounds $HRh(CO)[P(C_6H_5)_3]_3$ and $HRhCl[P(C_6H_5)_3]_3$ are effective catalysts for the hydrogenation of terminal olefins at ambient temperature. The reaction with $HRh(CO)[P(C_6H_5)_3]_3$ has been shown to involve the coordinatively unsaturated Rh^{I} complex *trans*-$HRh(CO)[P(C_6H_5)_3]_2$, and the high specificity towards 1-alkenes and the lack of olefin isomerization in this reaction was explained by a combination of the influence of the phosphine ligand on the direction of addition of the metal hydride to the olefin, and the steric effect of the bulky *trans* phosphine ligands in preventing formation of the branched-chain alkyl derivative.

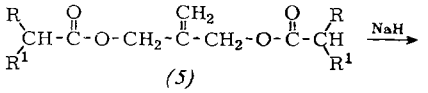
The rhodium complex $HRh(CO)[P(C_6H_5)_3]_3$ catalyzes the hydroformylation of olefins to aldehydes (normal:branched chain ratio *ca.* 20:1) in 95% yield at room temperature and 1 atm CO pressure. The efective catalyst in this reaction is thought to be $HRh(CO)_2[P(C_6H_5)_3]_2$ formed by the rapid equilibria:



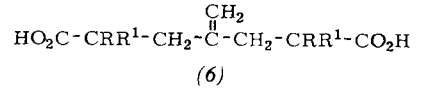
$$HRh(CO)[P(C_6H_5)_3]_3 \xrightarrow[+H_2]{\text{fast, } -CO} HRh(CO)_2[P(C_6H_5)_3]_2 \xrightarrow[+H_2]{\text{slow, } -CO} [P(C_6H_5)_3]_2CORh(CO)_2RhCO[P(C_6H_5)_3]_2$$

The iridium complex $HIr(CO)_2[P(C_6H_5)_3]_2$ has been prepared, and has been shown to exist as an equilibrium mixture of two unidentified species in solution. Neither this iridium compound nor the compound $HRhCl[P(C_6H_5)_3]_3$ are effective hydroformylation catalysts at room temperature.

F. Weiss (Lyon, France) reviewed the methods of synthesis and the chemistry of $\alpha\alpha'$-substituted isobutenes of type *(3)* (where X = halogen, OH, H, CO_2R, or CN) and the related compound 2-methyleneoxetane *(4)*.



(3)



(4)

The epoxide of compound *(3)* (X = Cl) is reported to polymerize to a high molecular weight polyether of the 'PENTON' type with triethylaluminum.

The compounds of type *(3)* (X = halogen) behave normally in substitution reactions to give, in the main, disubstituted products, although monosubstitution can be achieved under controlled conditions. Substituted isobutene derivatives undergo some interesting molecular rearrangement reactions. Thus esters such as *(5)* rearrange with sodium hydride to pimelic acids *(6)*. These pimelic acid derivatives and the diols

(5)

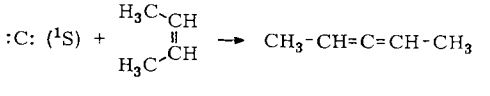
(6)

resulting from their hydrogenation are potential intermediates for high temperature lubricants. $\alpha\alpha'$-Bis(aryloxy)isobutenes readily undergo Claisen condensation to give phenols.

E. J. Corey (Cambridge, Mass., USA) reported that $Ni(CO)_4$ catalyzes allylic dimerization at 50 °C in polar solvents, this reaction having been utilized in the synthesis of C_{12}, C_{14}, and C_{18} cyclic dienes from the compounds *(7)* (where n = 6, 8, or

$$BrCH_2\text{-}CH = CH(CH_2)_nCH = CH\text{-}CH_2Br \quad (7)$$

12 respectively); only poor yields of smaller ring compounds (C_8 or C_{10}) are obtained by this method. Allyl bromide is dimerized to 1,4-hexadiene at 0 °C in ether or dimethylformamide using $(\pi\text{-}C_3H_5NiBr)_2$, but as fast ligand exchange occurs this reaction cannot be extended to prepare mixed allyl dimers. Substituted methylallyl derivatives can be obtained in 70–90% yields from $(\pi\text{-}C_3H_5NiBr)_2$ and alkyl or aryl halides in dimethylformamide, and this reaction is a particularly effective means of introducing an allyl group into an organic molecule.



Selective cross coupling of alkyl groups can be achieved using copper salts of the type $R_2Cu^-Li^+$ (R = alkyl).

$$R\text{-halogen} + R^1_2Cu^-Li^+ \rightarrow R\text{-}R^1$$

This reaction gives high yields and is of general applicability for alkyl, allyl, benzyl, aryl, and vinyl halides and geminal dihalides.

P. S. Skell (University Park, Pennsylvania, USA) described the generation of C_1, C_2, C_3, and C_4 molecules by a carbon arc at low temperatures in high vacuum. These molecules have been caused to react with a variety of substrates when condensed on to neopentane on the surface of the reaction vessel at liquid nitrogen temperature.

The C_1 molecule exists in three forms, a ^1S (singlet state; :C:), a ^1D (singlet state: :C:), and a ^3p (triplet state; :$\dot{C}$) with stabilities increasing in the order $^1S < {}^1D < {}^3p$: The ^3p and ^1D species add stereospecifically to olefins and conjugated dienes to give dicyclopropane derivatives. The high energy ^1S species gives allene derivatives with olefins by an apparent insertion into the olefinic double bond.

Evidence was presented that two forms of the C_2 molecule exist, a singlet species (:C=C:) which reacts with hydrocarbons to give ethylene, and a triplet species (·C≡C·) which gives acetylene with the same substrate. The C_3 molecule can exist in three forms: two singlet species (:C=C=C:) and a triplet species (:C=C=$\dot{C}$). The latter has been shown to add stereospecifically to olefins, whereas one of the singlet species exhibits non-stereospecific addition to olefins and gives allene and propyne with hydrocarbon substrates. The other singlet species, generated by a hot carbon filament, gives allene exclusively with hydrocarbons.

A number of short papers read at the Symposium should also be mentioned. *D. H. Johnson* (Blackley, England) reported the oxychlorination of *n*-butenes at 350 °C with γ-alumina/cupric oxide/potassium chloride catalyst to give 1,4-dichlorobutadiene isomers.

A. J. Shuttleworth (Runcorn, England) described the pyrolysis of *trans*-1,2-dichloroethylene to give mixed isomers of trichlorobenzene, small amounts of dichlorobenzenes, and four isomers of trichlorobutadiene.

R. W. Humniel (Wantage, England) reported the isomerization of *cis*-2-butene to *trans*-2-butene upon γ-irradiation in the presence of 1% sulfur hexafluoride at 30 °C in an argon atmosphere.

O. Onsager (Oslo, Norway) reported the dimerization of propene to a mixture of *cis*-2-hexene, 2,3-dimethyl-1-butene, 2-methyl-1-pentene, and 4-methyl-1-pentene with a catalyst composed of tetramethylcyclobutadienenickel dichloride, ethylaluminum dichloride, and tri-*n*-butylphosphine.

C. F. Kohll (Amsterdam, Netherlands) described the synthesis of vinyl esters by the $PdCl_2$-catalyzed reaction of ethylene and sodium acetate in glacial acetic acid.

J. M. Locke (Southampton, England) described the hydrogenation of unsaturated polymers, *n*-dodecene, styrene, or diphenylacetylene using a catalyst prepared by the addition of bis(isopropylsalicylato)nickel to *n*-butyllithium in tetrahydrofuran or diglyme.

J. D. Littlehailes (Runcorn, England) reported the hydrodimerization of acrylonitrile to give an almost quantitative yield of adiponitrile with sodium amalgam and water in the presence of quaternary ammonium salts.

D. R. Taylor (Manchester, England) described the thermal cycloaddition of allene to fluoroolefins at 130 to 160 °C to give high yields of cyclobutane derivatives. Tetramethylallene (2,4-dimethyl-2,3-pentadiene) under similar conditions gives 1:1 adducts arising by a preliminary isomerization of the allene to 2,4-dimethyl-1,3-pentadiene. [VB 177 IE]

The Specific Trypsin Inhibitor from Pig Pancreas

By *H. Tschesche*

The trypsin inhibitors of low molecular weight are plant or animal polypeptides with molecular weights of 6000–20000 (serum inhibitors: mol. wt. 75000). They may act either specifically or polyvalently and inhibit other endopeptidases as well as trypsin. The polyvalent inhibitors include, besides plant inhibitors (mol. wt. 20000), the callicrein inactivator from bovine organs which is identical with *Kunitz*'s trypsin inhibitor from bovine pancreas. Bovine pancreas contains, besides the intracellular *Kunitz* inhibitor, an inhibitor that is specific against trypsin – *Kazal*'s inhibitor – which is secreted in the fluid from the gland. Only the trypsin-specific inhibitor of the *Kazal* type is found in other species of mammals, *e.g.*, the pig [1].

The inhibitors inhibit proteases by complex formation, in that they mask the active center, usually in the ratio 1:1, as is found from the inhibition curve also for the inhibitor from pig pancreas. The reaction is competitive with this inhibitor. The dissociation constant can be estimated from the inhibition curve and is certainly less than 10^{-11} M. Whereas polyvalent inhibitors have permanent inhibition against trypsin, the specific trypsin inhibitors become inactive during the action; their inhibitory effect is only temporary [2].

This inactivation begins with selective hydrolysis of only one lysine bond in the native polypeptide chain of the inhibitor from pig pancreas (mol. wt. = 6000), which contains four lysine and two arginine units. This lysine unit lies between two disulfide bridges (loop) [3]. Its hydrolysis gives a modified inhibitor that is inactivated faster than the native molecule under physiological conditions. Its dissociation constant, which can be determined from the inhibition curve, is increased ($K_D = 10^{-9}$ M) and thus permits powerful interactions during tryptic inactivation.

The selective tryptic hydrolysis (modification) is responsible for the appearance of electrophoretically and chromatographically separable active inhibitors such as were isolated by *Kazal* and by *Fritz* and *Werle* from mammals of various kinds by way of water-insoluble trypsin resin.

The modification occurs at a lysine bond in the inhibitor from the pig and the dog, but at the arginine bond in the inhibitor from the ox. These bonds probably lie in the active center of the inhibitors [3,4]. Modification of this type is typical of all specific trypsin inhibitors of *Kazal* type; it occurs at the pH region of 2 to 10 with soluble trypsin and water-insoluble trypsin resin. The maximum of the tryptic modification occurs at pH 3.4 for the inhibitor (I) from pig pancreas. This is therefore a special substrate for trypsin (T), is bound to it as a complex owing to its high affinity for trypsin even in strongly acid solution, and, unlike other natural and synthetic substrates, is maximally hydrolyzed in this pH range because of the increasing dissociation of the complex [5]. From the selective hydrolysis, from experiments with insoluble trypsin resin, from the kinetics, and from the maximal modification at lower pH values it must be concluded that the inhibitor is being modified within the complex TI and not within a Michaelis-Menten complex TIT after further addition of excess trypsin.

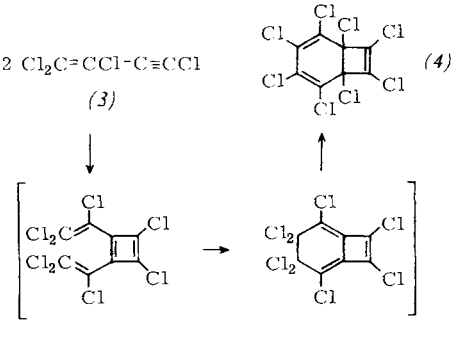
Thermally Unstable Allenes and Related Compounds



By *A. Roedig* [*]

The rate of thermal dimerization of allenes to 1,2-dimethylcyclobutane derivatives is greatly influenced by substituents. The accumulation of electron-acceptor groups destabilizes the allene system. Several dehydrohalogenations and fragmentations give rise to intermediates consisting of allenes that are thermally unstable, *i.e.*, can be preserved only below −60 °C and in some cases deflagrate in the undiluted state. They can be isolated by treating HCl-rich or HBr-rich precursors with $NaNH_2$ in liquid NH_3/propane or with a *tert*-butoxide of potassium or lithium in liquid propane or light petroleum at −75 °C.

On dimerization of trichloroallenes $Cl_2C{=}C{=}CClR$ (R = CN, $COOC_2H_5$, or C_6H_5) the electronically most active and the largest substituents appear in the exocyclic methylene groups. Kinetic measurements show that the rate of dimerization decreases in the order R = CN > $COOC_2H_5$ > Cl > C_6H_5 = Br > H. The activation entropy of dimerization of allenes is

(1) *(2)*

(3) *(4)*

strongly negative, but the activation enthalpy is relatively small (for R = Cl, $\Delta S = -45$ cal · mole^{-1} · grad^{-1}, $\Delta H = 11$ kcal mole^{-1}). A synchronous process is considered more likely than a two-stage radical mechanism.

Compared with perchloroallene, perchlorobutatriene *(1)* is remarkably stable thermally. It dimerizes only at 100 °C, giving perchloro[4]radialene *(2)*. Perchlorobutenyne *(3)*, on the other hand, dimerizes slowly even at 0 °C; the structure assigned earlier to the dimer[1] is untenable since it assumes *(1)* and *(2)* as unstable intermediates; meanwhile structure *(4)* has been proved for it by ozonolysis. The most probable course of the reaction is shown in the formula scheme.

The UV, IR, and NQR spectra, as well as the chemical behavior, indicate structure *(4)*. With nucleophilic reagents the compound gives either derivatives of perchlorobenzocyclobutene or some other aromatic compound, *e.g.*, with ammonia it gives perchlorobenzonitrile. Dechlorination gives dimers of perchlorobenzocyclobutene. Valence isomerization of *(4)* to perchlorocyclooctatetraene, whose structure is based on UV, IR, NQR, and Raman spectra, is effected by acid catalysis. Conversion into the benzocyclobutene system is more strongly favored thermally. $AlCl_3$ rearranges *(4)* and perchlorocyclooctatetraene to perchlorobenzocyclobutene. The structures of two further C_8Cl_8 isomers formed on thermal rearrangement of perchlorocyclooctatetraene are not firmly established.

Lectures at Würzburg (Germany) on December 6, 1968, and at Wayland, Mass. (USA) on May 6, 1968 [VB 182 IE]

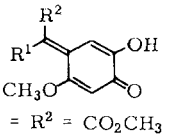
SELECTED ABSTRACTS

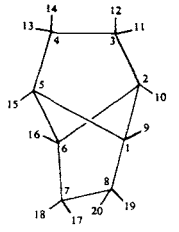


The existence of RuC, IrC, and PtB molecules has been demonstrated by *N. S. McIntyre, A. van der Auwera-Mahieu,* and *J. Drowart* using mass spectrometric methods. The metals were evaporated off graphite in Knudsen cells; boron carbide was added to the platinum. Evaluation of the intensity relationships of molecular ions and fragment ions (whose relation to one another was apparent from their identical appearance potentials) in the light of known thermochemical data afforded dissociation energies of 151.0 ± 3.0 kcal/mole for RuC, 148.4 ± 3.0 kcal/mole for IrC, and 113.3 ± 4.0 kcal/mole for PtB. / Trans. Faraday Soc. *64*, 3006 (1968) / –Hz.

[Rd 960 IE]

Alkoxy-*o*-benzoquinones, according to *H.-W. Wanzlick* and *U. Jahnke,* can be prepared by base-catalyzed addition of alcohols to *o*-quinones formed in solution. Dehydrogenation of pyrocatechol and 4-methylpyrocatechol in methanol and ethanol with PbO_2 in the presence of the alkoxide yields the alkoxy-*o*-quinones in 18 to about 60% yield. *(1)* can be

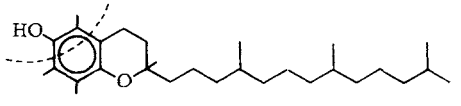
(1)



(2), $R^1 = R^2 = CO_2CH_3$
(3), $R^1 = C_6H_5$, $R^2 = CN$
(4), $R^1 = C_6H_5$, $R^2 = CO_2CH_3$

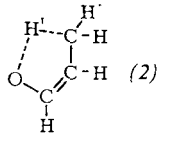
readily hydrolyzed to form 2,5-dihydroxy-*p*-quinone, which is converted into 2,5-dimethoxy-*p*-quinone by methanol and traces of mineral acid. The very reactive alkoxy-*o*-quinones form the quinonemethides *(2)*, *(3)*, and *(4)* on reaction with CH-acid compounds such as dimethyl malonate, benzyl cyanide, and methyl phenylacetate. / Chem. Ber. *101*, 3744 1968 / –Ma.

[Rd 947 IE]



The structure of tricyclo[3.3.0.0^{2,6}]octane *(1)* prepared by mercury-sensitized photoisomerization of *cis,cis*-1,5-cyclooctadiene has been determined by *J. F. Chiang* and *S. H. Bauer* by diffraction of 70 keV electrons.

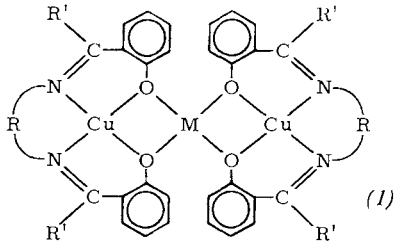
The symmetry of the molecule is D_{2d} [fourfold alternating axis (rotation + reflection) through the centers of C^3–C^4 and C^7–C^8; two twofold axes through the centers of C^1–C^2, C^5–C^6 and C^2–C^6, C^1–C^5; two planes of symmetry bisect the angles between the twofold axes]. The H^{11}–C^3–H^{12} angle is



surprisingly small (105.8 ± 1.8 °). The dihedral angle in the cyclobutane ring (126.7 ± 0.3 °) is also unusually small (145 to 147 ° in cyclobutanes). On the basis of the average vibration amplitude of the C–C bonds (0.046 Å), the rigidity of the molecular skeleton is similar to that of cyclopropane. / Trans. Faraday Soc. *64*, 2247 (1968) / –Hz. [Rd 951 IE]

The energy content of the primary oxidation products of α-tocopherol (vitamin E) *(1)* has been determined by *R. Janoschek* by a wave-mechanical calculation. The oxidation of *(1)* occurs primarily in the area indicated, with the result that a 2-methylphenoxy radical and a 2-hydroxybenzyl radical come

(1)



(2)

into consideration as tautomers of the primary product. To obtain a model for this, the energy of *(2)* was calculated as a function of the position of H′ · H′ thus moves on a potential surface having two minima, which correspond to the phenoxy and benzyl radicals. According to the calculation, the energy of the phenoxy radical lies 49.6 kcal/mole above that of the benzyl radical; the height of the potential barrier between the two forms of the radical (measured relative to the phenoxy form) is 54.6 kcal/mole. Assuming that H′ has to tunnel through the potential barrier during the transformation of the form of the radical, a mean life of 5.3 sec was calculated for the phenoxy radical. / Internat. J. Quantum Chem. *2*, 707 (1968) / –Hz.

[Rd 954 IE]

The magnetic properties of trinuclear complexes of quadridentate Schiff's bases were investigated by *S. J. Gruber, C. M. Harris,* and *E. Sinn.* The complexes *(1)* all contain the grouping CuMCu; the metal ions are linked to one another by oxygen bridges.

(1)

The observed magnetic moments are without exception smaller than expected and diminish rapidly with decreasing temperature between 400 and 80 °K. This phenomenon is interpreted as an antiferromagnetic resonance effect between M and Cu; the magnetic moments calculated on the basis of this resonance effect are in good agreement with the observed values. There is no evidence for any resonance effect between the terminal copper ions. / J. chem. Physics *49*, 2183 (1968) / –Hz.

[Rd 953 IE]

The surface species formed on adsorption of methanol and ethanol vapor on magnesium oxide have been characterized by *R. O. Kagel* and *R. G. Greenler* using IR spectroscopy. At room temperature a physically adsorbed layer is found whose structure corresponds to that of the liquid alcohols. Adsorbed alkoxide is found if this layer is desorbed by reducing the pressure and heating to about 160 °C. It can be assumed that the alcohol is dissociated by magnesium ions lying in the surface, an oxygen ion in the surface taking up the proton. If MgO is heated to 160 °C in the presence of methanol or ethanol vapor, formate and acetate are formed in the surface. On further heating, to 430 °C, alkyl carbonates are formed in the surface, which are probably produced from CO_2 (from decarboxylation of formate or acetate) and alkoxide; if there is no alkoxide in the surface, a layer of magnesium carbonate is found instead. / J. chem. Physics *49*, 1638 (1968) / –Hz.

[Rd 955 IE]

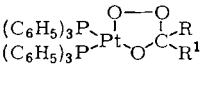
A simple method for the determination of the critical temperatures of volatile liquids has been developed by *H. W. Hoyer, A. V. Santoro,* and *E. J. Barrett.* Varying amounts of the substance to be investigated are placed in sealed ampuls and DTA cooling curves are recorded, in which separation of the sample into two phases is marked by a discontinuity. If the temperatures at which this discontinuity occurs are plotted against the overall density of the substance in the ampul, it is found that the temperature rises with increasing density to begin with and then remains constant, at the critical temperature, when the critical density has been exceeded. In this form, the method is restricted to substances whose critical pressure is not greater than about 45 atm. Comparison with values given in the literature for the critical temperatures of diethyl ether, acetone, cyclohexane, *n*-hexane, *n*-heptane, ethyl acetate, and benzene reveals deviations of up to 1.3 °C./ J. physic. Chem. *72*, 4312 (1968) / –Hz.

[Rd 956 IE]

The oxidation of hydrazine by molybdenum(VI) in the pH range of 1.2–3.2 has been investigated by *T. Huang* and *J. T. Spence* using spectrophotometric methods of analysis. During the reaction N_2 is evolved in stoichiometric quantities; no NH_3 can be detected. The reaction is of first order with respect to both reactants; the pH-dependence is complicated. Diimide has been indentified as an intermediate product both by mass spectroscopy and by interception with unsaturated organic acids. The reaction is thought to proceed as follows:

$$N_2H_5^+ + Mo^{VI} \rightarrow N_2H_2 + Mo^{IV} \quad (a)$$

$$H^+ + 2\,N_2H_2 \rightarrow N_2 + N_2H_5^+ \quad (b)$$



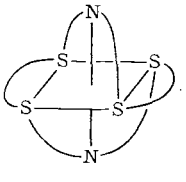
$$Mo^{IV} + Mo^{VI} \rightarrow 2\,Mo^{V} \quad (c)$$

$$2\,Mo^{V} \rightarrow Mo_2^{V} \quad (d)$$

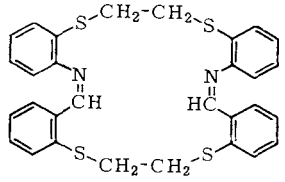
Reaction (a) is the rate-determining process, (b)–(d) are fast. The reaction system investigated has some significance as a model for the biological fixation of nitrogen by enzymes containing molybdenum. / J. physic. Chem. *72*, 4198 (1968) / –Hz.

[Rd 957 IE]

The reaction of the bis(triphenylphosphine)oxygenplatinum(0) complex with carbonyl groups has been investigated by *R. Ugo, F. Conti, S. Cenini, R. Mason,* and *G. B. Robertson.* Both the recrystallization of $[(C_6H_5)_3P]_2PtO_2$ from acetone and its reaction with methyl ethyl ketone, acetaldehyde, or benzaldehyde give the new type of ketoperoxy chelates *(1)* to *(4)*. It is assumed that the bonding of the O_2 molecule in



(1), R = R^1 = CH_3
(2), R = CH_3, R^1 = C_2H_5
(3), R = H, R^1 = CH_3
(4), R = H, R^1 = C_6H_5

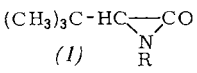


$[(C_6H_5)_3P]_2PtO_2$ resembles that of the excited $^3\Sigma_u$ state of the free O_2 molecule, *i.e.* a predominantly ionic structure $O^+–O^-$. The formation of *(1)* to *(4)* therefore has the characteristics of a conventional nucleophilic addition at the carbonyl group. The reactivity increases with increasing polarity of the carbonyl group. *(1)* is obtained as pale yellow monoclinic crystals with the lattice constants a = 9.83, b = 9.06, c = 37.90 Å, β = 95.6 °, Z = 4, belonging to the space group $P2_1/c$. The coordination of the platinum atoms is almost planar. The bond lengths have normal values; in particular, the O–O distance of 1.46 Å is characteristic of a peroxide group. / Chem. Commun. *1968*, 1498 / –Bl.

[Rd 961 IE]

A new sulfur-containing macrocyclic hexadentate ligand, 12,13,26,27-tetrahydrotetrabenzo [*e,i,o,s*]-[1,4,11,14,7,18]tetrathiadiazacycloeicosene, was synthesized by *L. F. Lindoy* and *D. H. Busch.* The complexes, which can only be octahedrally coordinated *(1)* because of the planarity of the S–N–S groups, were made by the reaction of a metal salt with 1,2-bis(2-aminophenylthio)ethane and 1,2-bis(2-formylphenylthio)-ethane, dissolved in stoichiometric quantities in the form of

(1)

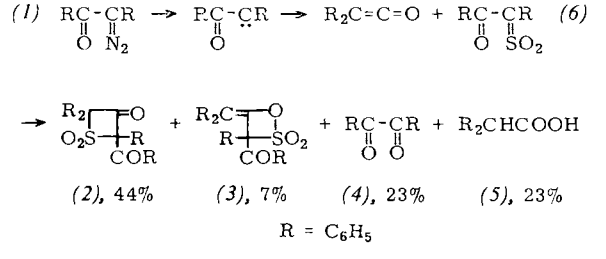


ms = *(2)*

the compounds (M ms)X_2 (M = Ni, X = ClO_4, I; M = Co, X = ClO_4). At room temperature the brown complexes (Ni ms)X_2 (X = ClO_4, I) have magnetic moments of 3.07 and 3.12 B.M., respectively. On heating (Ni ms) $(ClO_4)_2$ in DMF, the free macrocyclic compound *(2)* can be isolated in the form of yellow crystals. / Chem. Commun. *1968*, 1589 / –Ma.

[Rd 963 IE]

1-(1-Adamantyl)-3-*tert*-butylaziridinone *(1)*, a stable α-lactam, has been synthesized by *I. Lengyel* and *D. B. Uliss*; the synthesis was prompted by the fact that tertiary substituents have a pronounced stabilizing effect on α-lactams. 2-Bromo-3,3-dimethyl-*N*-adamantylbutyramide, which was obtained (m.p. 173–174 °C, 82% yield) from 2-bromo-3,3-dimethylbutyryl



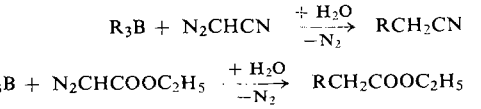
(1) R = Adamantyl

chloride and 1-adamantylamine in the presence of triethylamine in dichloromethane at 0 °C, could be cyclized with potassium *tert*-butoxide in ice-cold ethereal suspension to give *(1)*, m.p. 70 °C (λ_{max} = 254 nm [hexane], yield 65%). The compound is stable in water at room temperature; complete solvolysis is effected only after boiling for 48 hours in methanol. / Chem. Commun. *1968*, 1621 / –Ma.

[Rd 962 IE]

The formation of cycloadducts by the reaction of azibenzil *(1)* with SO_2 was observed by *T. Nagai*, *M. Tanaka*, and *N. Tokura*. The four-membered cyclic sulfones *(2)* and *(3)* were obtained, along with *(4)* and *(5)*, in boiling benzene. Diphenylketene is probably formed as an intermediate by the Wolff rearrangement, and this then undergoes cycloaddition

(1) → $R_2C{=}C{=}O$ + *(6)*



→ *(2)*, 44% + *(3)*, 7% + *(4)*, 23% + *(5)*, 23% + $R_2CHCOOH$

R = C_6H_5

with the ketosulfene *(6)*. Photochemical reaction of azibenzil with SO_2 in benzene at –5 to –20 °C (mercury high-pressure lamp) gave *(3)*, *(4)*, and *(5)* in 35, 44, and 13% yields respectively. / Tetrahedron Letters *1968*, 6293 / –Ma.

[Rd 964 IE]

Alkylation of diazoacetonitrile and ethyl diazoacetate with organoboranes, according to *J. Hooz* and *S. Linke*, is a new method of increasing the length of olefins by two carbon atoms with functional groups if organoboranes derived from olefins with terminal double bonds or cyclopentene are used:

$$R_3B + N_2CHCN \xrightarrow[-N_2]{+H_2O} RCH_2CN$$

$$R_3B + N_2CHCOOC_2H_5 \xrightarrow[-N_2]{+H_2O} RCH_2COOC_2H_5$$

The reactions with the nitrile proceed very fast even at 0 °C and give excellent yields (93–100%). The second reaction depends strongly on steric factors. For example: 1-hexene → octanenitrile, 100%; cyclopentene → cyclopentylacetonitrile, 99%; 1-octene → ethyl decanoate, 78%. / J. Amer. chem. Soc. *90*, 6891 (1968) / –Ma. [Rd 965 IE]

The dimerization products of α-methylstyrene in H_2SO_4 have been extensively investigated by *A. J. Švob* and *B. K. Černicki* by means of NMR spectrometry. Separation by gas chromatography (liquid phase SE 30) yielded six components: *cis*-2,4-diphenyl-4-methyl-2-pentene, 1,1,3-trimethyl-3-phenylindan, 2,4-diphenyl-4-methyl-1-pentene, *trans*-2,4-diphenyl-4-methyl-2-pentene, 1,3-diphenyl-3-methyl-2-butanone, and an oxidation product with $C_6H_5{-}C(CH_3)_2{-}$ and $-CH{=}C(\text{I})-CH_2-$groups. / Chimia *22*, 434 (1968) / –Ma.

[Rd 966 IE]

New catalysts for low-pressure carbonylation of methanol to give acetic acid have been developed by *F. E. Paulik* and *J. F. Roth*. A solution of an Rh compound such as $RhCl_3 \cdot 3\,H_2O$, $Rh_2O_3 \cdot 5\,H_2O$, $RhCl(CO)[P(C_6H_5)_3]_2$, $[Rh(CO)_2Cl]_2$ (5×10^{-3} M) and a halogen promoter such as hydriodic acid, CH_3I, $CaI_2 \cdot 3\,H_2O$, I_2 (0.05 M) in solvents such as benzene, water, acetic acid, methanol, and nitrobenzene catalyzes the carbonylation at 175 °C and 25 atm total pressure ($p_{CO} < 13$ atm). Appreciable carbonylation rates were observed even at CO pressures of 1 atm. There is preferential formation of acetic acid (> 99%). The active catalyst is a d^8-Rh^I complex. High rates of reaction can also be achieved at low pressure with similar homogeneous catalyst systems of Ir compounds in the presence of halogen promoters, particularly iodide. / Chem. Commun. *1968*, 1578 / –Ma. [Rd 967 IE]

BOOK REVIEWS

Handbuch der Lebensmittelchemie. (Handbook of Food Chemistry) Vol. 5, Part 2: Fruit, Vegetables, Potatoes, Mushrooms. Edited by *L. Acker*, *K.-G. Bergner*, *W. Diemair*, *W. Heimann*, *F. Kiermeier*, *J. Schormüller*, and *S. W. Souci*. Springer-Verlag, Berlin-Heidelberg-New York 1968. 1st. Edit., xxiv, 608 pp. 178 illustrations, bound. DM 174.60 / $ 43.65.

In modern food chemistry exclusive stress is no longer placed on chemical analysis; rather, the emphasis has shifted to individual factors involved in quality characteristics, to clarification of the nature and causes of changes, and to the determination of production and storage conditions influencing favorably the product quality. This theme finds its expression in the clearly arranged part of the new manual[1], both in the layout of the individual chapters, written by specialists, and in the way that newer methods of food preservation and processing (*e.g.* deep-freezing and freeze-drying) and new food sources (*e.g.* yeast and algae) are dealt with. The authors treat the subject fundamentally, without neglecting the technological aspects. Selected analytical methods are discussed in such detail that they can be applied directly. Literature references, in some cases up to 1965, are listed at the end of each contribution. 136 of the total of 178 illustrations appear in the contributions by *Czaja*. Copious numerical data are given in the tables. Printing errors are few, and the reviewer has not encountered any really serious mistakes. The very detailed subject index provides a key to the richness of the contents (an author index is dispensed with). The layout is excellent.

In the chapter "Fresh Fruit" (*H. Drews*, 75 pp.), under the "Fruit" section, there is a brief account of the fundamentals of fruit growing, the kinds of fruit, the classification of fruit into particular groups, fruit storage methods, the changes occurring during storage, and the chemical examination of fruit. There are also hints of evaluation in accordance with foodstuff legislation. The following are considered among durable fruit goods: Deep-frozen fruit (*J. Gutschmidt*, 17 pp.), canned and bottled fruit (*A. S. Kovacs*, 22 pp.), dried fruit (*K. Herrmann*, 12 pp.), and fruit in syrup (*K. Herrmann*, 4 pp.). Fruit products dealt with include preserves, jams, jellies, mousses, *etc.*, as well as semi-manufactured products (*K. Herrmann*, 45 pp.), fruit juices, unfermented wine, con-

centrates, and fruit-syrups (*K. Herrmann*, 63 pp.), fruit juice drinks, and other nonalcoholic drinks (*E. Benk*, 20 pp.). Finally there is a contribution on the microscopic examination of fruit and fruit products (*A. Th. Czanja*, 52 pp.).

The section "Vegetables" is similarly arranged. The chapter on fresh vegetables (51 pp.) is written by *P. Nehring*. Information on durable vegetable goods is given in the chapters: Deep-frozen vegetables (*J. Gutschmidt*, 33 pp.), canned and bottled vegetables (*P. Nehring*, 38 pp.), pickled vegetables (*F. Martens*, 18 pp.), and dried vegetables (*K. Herrmann*, 6 pp.), tomato juices and other tomato products, as well as other vegetable juices (*K. Herrmann*, 16 pp.). One chapter is devoted to potatoes and potato products (*H. Mohler* and *H. Sulser*, 34 pp.), and one to mushrooms and mushroom preserves (*W. Bötticher*, 31 pp.). A contribution on the microscopic examination of vegetables, salads, seasoning herbs, and edible mushrooms (*A. Th. Czaja*, 25 pp.) completes this field. The volume concludes with a chapter on the microbiological production of foodstuffs (*E. Reiff*, 14 pp.) in which yeast above all plays an important role.

The great amount of information to be found in this volume will ensure a wide readership. *J. Wolf* [NB 759 IE]

Standardmethoden der praktischen Chemie (Standard Methods of Practical Chemistry). Edited by *E. Poulsen-Nautrup*. Main group: Preparation Methods of Organic Chemistry. Friedr. Vieweg & Sohn, Braunschweig. Issue 1a: General Working Procedure. 1st Edit., 1963. viii, 54 pp., 46 illustrations, 19 tables; Issue 1b: General Working Procedure II. 1st Edit., 1966. viii, 54 pp., 49 illustrations, 18 tables; Issue 1c: General Working Procedure III, 1st Edit., 1966. viii, 50 pp., 28 illustrations, 19 tables; Issue 2: Basic Compounds I. 1st Edit., 1963. viii, 50 pp., 13 illustrations., 11 tables; Issue 3: Derivatives I, 1st Edit., 1964. viii, 50 pp.; Issue 4: Basic Compounds II. 1st Edit., 1964. viii, 60 pp., 15 illustration; Issue 11: Azo dyes. 1st Edit., 1964. viii, 44 pp., 13 illustrations 3 color tables. Each issue (in folder) DM 5.90.

"Preparative Methods", compiled by *E. Poulsen-Nautrup*, is part of "Standard Methods of Practical Chemistry". Each issue contains sets of detailed working instructions, printed on individual sheets of paper, that are suitable for use in schools. Issues 1a–1c relate to general techniques, including reaction vessels, gases, and work at elevated pressures. A thorough introduction is given to fundamental operations such as filtration, distillation, recrystallization, *etc.* Issues 2–4 each contain working instructions for ten preparations. Each sheet begins with an equation for the reaction in question, and continues with precise directions and with a discussion of the range of applications of the reaction. Hints are frequently given on testing the product purity or on preventing accidents during the preparation. Issue 3 is devoted to the preparation of derivatives, *e.g.* sodium alkoxides, and chlorides, and esters. Issue 11 covers azo dyes, describing the dyeing of wool and cotton as well as the preparation and chromatographic examination of the dyes.

The collection is highly recommended for all schools and technical colleges teaching chemistry. This series should also prove invaluable to those reading chemistry as a subsidiary subject at universities. *H. J. Bestmann* [NB 763 IE]

Dictionary of Science and Technology, English-German. By *A. F. Dorian*. Elsevier Publishing Company, Amsterdam-London-New York, 1967. 1st Edit., 1238 pp., bound, Dfl. 80.00.

Good technical dictionaries, even in such common languages as English and German, are such a rarity that it is no great exaggeration to say that they do not exist. It is thus scarely surprising that so many attempts are made to fill the void. The latest, published by Elsevier, contains more than 1200 pages, with some 50000 terms covering about 130 disciplines, predominantly in science and technology. Only two authors *A. F. Dorian* and *Liane Herzbruch*, appear to be responsible for this gigantic undertaking. The reviewer confesses that he was surprised by this, as also by the rather curious English foreward and its badly translated German counterpart.

It is of course unfair to judge such a vast work – its scope extends from Baking to Ecclesiastical History and from Biochemistry to Political Economics – on the basis of its treatment of Chemistry. At the same time it is not unreasonable to assume that the authors devoted the same degree of care to all the fields covered.

The selection of words is sensible and modern, though here and there somewhat haphazard. In many cases a brief English definition of the entry is given in addition to the translation, a very useful feature in view of the variety of subjects involved. Less pleasing is the (in the reviewer's opinion excessive) number of instances in which inaccurate or even totally incorrect renderings are given. These range from obsolete spelling (Karbonat, Oxyd) and nomenclature (Oxynaphthalin, Äthylmerkuriacetat), obvious printing errors (Magnesiumarseniat, Lutecium(!), arsine = Arsen), to downright nonsense (radius = Umkreis, ethylene = schweres Kohlenwasserstoffgas, shift = Austausch, chemical intermediate = Zwischenmittel, ethylbenzyl chloride = Benzochlorsäureäthylester !!, *etc.*).

An insert informs the user that the publishers intend to produce a German-English edition at the end of 1968, to be followed by supplementary volumes at intervals of 4 or 5 years, with an improved and revised edition of the main dictionary to appear every 8 years. The project is thus clearly an ambitious one; it seems most desirable, however, that the whole responsibility should not rest on the shoulders of just two authors, but that the help of other subject and language specialists be enlisted as a matter of urgency.

H. Grünewald [NB 769 IE]

Nobel Lectures, Physiology or Medicine 1901–1921. Sponsored by the Nobel Foundation, Elsevier Publishing Company, Amsterdam-London-New York, 1967. 1st Edit., xii, 562, bound, Dfl. 80.00.

The present volume in the "Nobel Lecture" series published by Elsevier comprises addresses given by the Medicine Prize Winners between 1901 and 1921. As usual, each lecture is preceded by the presentation speech at the prize-giving, and biographical details complete the picture.

The book is fascinating to read even if one is not a physician. Fundamental investigations are reported that belong so much to the undeniable, reliable fund of knowledge of our time that it is impossible to return to those years during which it was all discovered and formulated, often with endless toil, without inner participation. The volume begins with a lecture given by *Emil von Behring* on the serum therapy of diphtheria, which enabled this disease to be mastered. *Sir Ronald Ross* received the prize for his discovery of the etiology of malaria; this is followed by *Pavlov*'s extremely readable report about his famous experiments on the physiology of digestion. *Robert Koch*'s Nobel Lecture was entitled "The current state of the struggle against tuberculosis" and this enumeration of famous names and deeds could be continued. For the sake of topicality, special mention should be made of the lecture given by the Frenchman *Alexis Carrel*, who received his prize in 1912 for experiments on organ transplantation. The lecturer distinguishes between autoplastic transplants (within the same organism), which invariably succeed if the operation is carried out satisfactorily, and homoplastic transplants (between different living beings of the same species), which (at that time) always failed because even an organ transplanted correctly from the surgical point of view was rejected after a certain period. All this 60 years ago! It is interesting to note that in 1935 the same *Alexis Carrel* developed a machine for the sterile perfusion of isolated organs in collaboration with the famous flyer *Charles Lindbergh* who tackled the mechanical problems.

The 16 lectures forming the subject of this volume make fascinating reading which no one interested in history of modern natural science should forego.

H. Grünewald [NB 770 IE]

Carbonium Ions. An Introduction. By *D. Bethell* and *V. Gold.* Academic Press, London-New York 1967. 1st Edit., xii, 387 pp., numerous figures and tables, bound, $ 16.00 or 95 shillings.

Of the many reactive intermediates in organic chemistry, carbonium ions have attracted the closest attention during the last decade. The interest centers on the bridged carbonium ions and on stable solutions in 'superacids', in which even the methyl cation can be observed directly. Until recently there was no comprehensive treatment of the entire subject, and the present book attempts to fill this gap. Since an exhaustive treatment of the field would fill several volumes – as is evident from the 50 or so reviews and books cited – it was obviously necessary to reach some kind of a compromise. Its subtitle means that the book is addressed to students and chemical research workers active in other fields; it also means that it is a collection which can be used as a basis for introductory reading. We could thus expect at least a brief mention of all the fundamentals, while a too specialized discussion would be avoided. Finally, it should if possible offer a representative selection from the mass of available investigations. These aims have been only partially fulfilled.

After an introduction, the following subjects are considered: experimental methods in the investigation of carbonium ions (30 pp.), methods of preparation (13 pp.) and quantitative aspects of the formation of carbonium ions (51 pp.), factors which influence the stability (42 pp.), reactions of carbonium ions (60 pp.) and bridged carbonium ions (60 pp.); a few related species (acylium ions, singlet carbene, radical cations, and hetero-analogs) are mentioned briefly in the final chapter (21 pp.). The literature up to 1966 is taken into account (of the 1400 original citations, about 100 come from 1966 and 20 from 1967). The discussion is highly critical, which increases its value for the instructor or the practical chemical worker but it often appears not very didactic. An introduction should not, for example, devote nearly one quarter to 'non-classical' carbonium ions, the special position of which is debatable – the chapter is otherwise an excellent survey of all aspects of this special field – while the problem of the vinyl and aryl cations and the stereoelectronically directed course of the cyclopropyl → allyl cation rearrangement (*De Puy, Schöllkopf, Schleyer, Woodward, Hoffman*) on which intensive work has been carried out in the last few years has not even been mentioned.

The text is readable, though a little dry; the setting, printing, and production leave nothing to be desired, and only small misprints, of no significance to the understanding of the text, were found. The author index and the literature survey are excellently suited for a deeper penetration of the special subjects. The subject index is adequate. This first survey of the whole field is certain to be welcomed by many organic and physical chemists.

D. Seebach [NB 756 IE]

Organometallic Compounds. By *G. E. Coates, M. L. H. Green,* and *K. Wade.* Vol. II: The Transition Elements. By *M. L. Green.* Methuen and Co., Ltd., London 1968. 3rd. Edit., xiii, 376 pp., 86 figs., 31 tables, £ 5.0.0.

The number of publications dealing with organometallic compounds, especially those of the transition metals, has increased considerably in the last ten years. Although even in the second edition [1] the organometallic compounds of the transition elements were dealt with in about 100 pages and about 200 literature references, this work now appears as a separate volume with over 1300 references. The complex compounds are no longer arranged according to the group number of the transition element in the periodic table, but instead they are classified according to the type of the ligand. In this way, the alkyl group for example is indicated as a one-electron ligand, ethylene as a typical two-electron ligand, the π-allyl group as a three-electron ligand, and the π-cycloheptatrienyl group as a seven-electron ligand. Following this subdivision, the first seven chapters deal very clearly with a great number of characteristic complex compounds.

Another chapter is concerned with the reactions of the transition metal compounds with acetylene. A new addition is the last chapter, which deals with the catalytic reactions of transition metal compounds. In this, as the author remarks, only a few typical examples are outlined. Perhaps it is this chapter that might have been expanded, because of the increasing importance of this field in organometallic chemistry.

The book is recommended highly to advanced students of chemistry as an introduction to the organometallic chemistry of the transition metals and also to all others interested in this subject. The author is to be congratulated.

The Names and Structures of Organic Compounds. By *O. Th. Benfey.* John Wiley and Sons, Inc., New York-London-Sydney, 1966. 1st Edit. xiv, 212 pp., board 23s.

Constructing the names of organic compounds according to the rules of systematic nomenclature is not to everyone's taste, nor has everyone the patience to plough through the IUPAC rules. *O. T. Benfey* has therefore written a pocket book for his students, in which the main rules and principles of nomenclature are very skilfully introduced in question and answer form. As the text progresses, the student is increasingly obliged to think for himself in order to find the right answer (which is always given). After 100 pages, the text leaves the subject of nomenclature, and a total of 66 pages are devoted to the calculation of formal charges, the writing of electronic formulas and resonance structures, and the calculation of the number of possible isomers for monosubstituted alkanes. The remainder of the book consists of revision questions (and answers) on the various chapters and a list of names of important compounds that are not mentioned in the main part.

First or second-semester chemistry students will find that this book presents, in an easily remembered manner, information that will be of use to them at a later stage. In any case, the book will certainly provide the teacher with many suggestions for dealing with the nomenclature of organic compounds.

Plutonium Handbook – A Guide to the Technology. Edited by *O. J. Wick* with the cooperation of several associates. Preface by *G. T. Seaborg.* Gordon and Breach Science Publishers, New York-London-Paris 1967. 2 vols, x, 966 pp., numerous illustrations, diagrams, micrographs, and tables, Vol. 1. Cloth-bound. $ 26.00, Vol. 2 Cloth-bound $ 22.50. Professional Edition: Vol. 1. $ 15.50, Vol. 2 $ 13.25.

Although element 94, plutonium, has only been known for 28 years, today, along with uranium, it is the most important raw material for nuclear technology and one of the most significant primary sources of energy. Since plutonium literature has grown to an extent where it is now difficult to keep it under review, a comprehensive, critical survey has become necessary; the handbook described in this review fulfils this need very well. *O. J. Wick* has succeeded in getting some of the best-known plutonium technologists as authors of individual chapters.

The book is divided into seven sections: I. Physics, II. Metallurgy, III. Chemistry, IV. Chemical Reprocessing V. Production and Use, VI. Analysis and Inspection Procedures, and VII. Safety Precautions. It ends with a detailed author and subject index.

In section I. (*B. R. Leonhard jr.*), important nuclear data (half-lives, disintegration energies, resonance parameter,

reaction cross sections, *etc.*) are compiled into concise tables. (Unfortunately the standard work of *E. K. Hyde, G. T. Seaborg*, and *I. Perlman*: "Nuclear Properties of the Heavy Elements" has not been quoted.)

In section II, chapter 3 (*W. N. Miner* and *F. Schonfeld*) starts with a 20-page review of the physical properties of unalloyed plutonium. Regrettably, some of the results quoted are already superceded by more recent data. Chapter 4 (*H. R. Gardner*) deals with the mechanical properties of plutonium and its alloys (several tables and diagrams). The title of chapter 5: "Solid State Reactions" (*R. D. Nelson*) is somewhat misleading. It does not deal with solid state reactions in the sense of the chemist, but rather with the technologically very important single-phase changes between the allotropic modifications of plutonium. The chapter is illustrated with numerous instructive micrographs.

Chapter 6, on corrosion and oxidation (*J. T. Waber*), also provides information on corrosion protection. The references to the spontaneous ignition of unalloyed plutonium are important. Chapter 7, on the behavior of plutonium in alloys, is of interest to inorganic and physical chemists. It is divided into "Practical Aspects" (*C. C. Land*), "Phase Diagrams and Crystal Structure" (*F. H. Ellinger*), and "Alloying Theory" (*K. A. Gschneider jr.*). Sixty-five binary and ternary phases based on plutonium are described in detail; Table 7.12 contains structural data for about 80 intermetallic compounds, hydrides, chalcogenides and pnictides (binary compounds of a metal with a group V element).

Chapter 8, on refractory compounds of plutonium (*R. E. Scavdahl* and *T. D. Chikalla*), contains a wealth of information for anyone who wants to learn about, for example, reactor ceramics containing plutonium. Chapter 9, on metallography (*K. A. Johnson*), contains valuable information on the preparation of micrographs, with instructive original photographs. Chapter 10 is also important for the experimentalist ("Laboratory Techniques", *R. D. Nelson, C. C. Land*, and *F. H. Ellinger*). Unfortunately, the list of experimental techniques described is none too comprehensive. For example, references to the classical microtechniques are missing, and the number of illustrations could have been greater.

Chapter 11, ("Chemical Properties") in section III (*J. M. Cleveland*) appears superfluous, since the material could have been included in chapters 6 and 12. With its excellent survey of inorganic plutonium chemistry chapter 12 is well worth reading. Particular attention is called to the numerous clearly arranged tables containing thermodynamic and crystallographic data of individual compounds. Solutions of plutonium compounds, including those in molten salts, are described in chapter 13.

The treatment of chemical subjects is continued in volume 2, section IV (*J. M. Cleveland*). Chapter 14 ("Separation from Irradiated Uranium") does not contain detailed instructions for the separation of plutonium from irradiated uranium, but rather a comprehensive collection of separation procedures. Chapter 15 ("Plutonium Conversion Processes") is too short, with only 19 pages. For instance, no reference is given to the fully automatic plutonium reduction plant a Los Alamos (LA-1387). Chapter 16 ("Plutonium Recovery and Waste Disposal") to some extent parallels chapter 14, but is more detailed in text. Straightforward explanations of code expressions such as Redox, Purex, or Butex are lacking in chapters 14 to 16, and would have been desirable.

Fabrication and application of plutonium are treated in section V. Chapters 17 and 18 (*O. J. Wick*) describe the special metallurgical techniques developed for plutonium and its alloys; these are essentially influenced by the existence of 6 allotropic modifications of the metal, and its ready oxidation, which necessitates handling in an inert atmosphere and consequently, special furnace designs. Chapters 19 (*I. D. Thomas*) and 20 (*M. D. Freshley*) deal with the preparation and behavior of ceramic nuclear fuels based on plutonium. Attention is drawn to the many autoradiographs and micrographs.

Section VI again is of interest to the chemist. Although in chapter 21 ("Analysis", *R. J. Brouns*) a comprehensive survey of current analytical methods in plutonium technology is given, illustrations of special equipment are lacking, *e.g.* the spark chambers used for emission spectroscopy and low geometry counters for the absolute α determination. A reference in the bibliography to the compilation of Plutonium Emission Lines by *J. R. McNally* (ORNL-2154 Rev) would not have come amiss. Chapter 22 ("Inspection", *W. J. Bailey*) deals with nondestructive testing methods for fabricated pieces of plutonium or its alloys. The chapter contains numerous diagrams and photographs.

Section VII, describing safety aspects in working with the highly toxic and fissile plutonium, is considered to be of special importance, Chapters 23 (*R. C. Thompson*), 24 (*R. H. Wilson*), and 25 (*H. V. Larson*) deal with the biological effects of ingesting plutonium and with medical supervision of individuals working with plutonium. Chapter 26 (*L. G. Merker*) is devoted to the technical aspects of health protection. In spite of its very instructive illustrations, this chapter could have been more comprehensive. Although the bibliography contains a number of important reviews, reference is lacking to the numerous papers given at the Hot Laboratory Conferences.

Chapter 27 ("Nuclear Safety and Criticality", *E. D. Clayton* and *W. A. Rearden*) is of particular significance in working with larger (supercritical) masses of plutonium. There is unfortunately insufficient material on the insidiousness of the critical condition. Accounts are, however, given of critical data, and above all, practical directions are presented for protection against inadvertent critical excursions (numerous diagrams and illustrations). In chapter 28, *J. M. Nielsen* and *T. H. Beasley* describe the analytical methods used for the determination of plutonium in biological materials for the purpose of radiation survey and area monitoring.

To summarize, it may be said that the reader gets a very good general view of all parts of plutonium technology. The shortcomings mentioned are insignificant in comparison with the extent of material offered and they could easily be remedied in a second edition. The excellent presentation and the neat and clear printing make the price appear acceptable. Purchase of this book may be recommended to every chemical and metallurgical library.

The Composition and Conformation of Sugars in Solution

By S. J. Angyal[*]

The conformations of the aldoses in solution, and the compositions of the equilibrium mixtures formed from aldoses after dissolution in water, have been determined by NMR spectroscopy. Calculations based on non-bonded interactions and on the anomeric effect account for the observed conformations, and allow an approximate prediction of the α:β ratio of pyranoses in equilibrium and of the extent of anhydride formation from sugars in acid solution. In certain circumstances the furanose forms are more stable than the pyranose forms.

1. Introduction

Apart from their great biological importance, the carbohydrates are also of interest as model compounds for the study of chemical behavior and reactions, and particularly of stereochemistry. They are most suitable for this purpose because complete sets of diastereoisomers are readily available and the reactive carbonyl and hydroxyl groups allow the preparation of a great variety of derivatives. The determination by *Emil Fischer* of the configurations of all the pentoses and hexoses was a classical achievement in stereochemistry. The useful method of molecular rotation differences [1] was first established in the carbohydrate field [2]. Recognition of participation by neighboring groups, and of its steric requirements, also originated [3] in carbohydrate chemistry, as did knowledge of the steric requirements for epoxide formation by elimination [4].

Conformational analysis, in particular, is indebted to carbohydrate chemistry. The term "conformation", generally used in English, was introduced into organic chemistry by *Haworth* [5]. He considered the various possible conformations of sugar molecules and predicted "that these considerations open up a large field of inquiry into the conformation of groups as distinct from structure or configuration". The first suggestion of the importance of the conformations in the reactivity of acyclic compounds came in a paper by *Böeseken* and *Cohen* [6] on the reaction of the diastereoisomeric 2,3-butanediols with boric acid, a reagent particularly useful in carbohydrate chemistry. Studying the oxidation of aldoses by bromine, *Isbell* [7] recognized clearly, and probably for the first time, the effect of conformation on the rates of reactions; he attempted to classify sugar derivatives according to what we now call axial and equatorial substituents. The important observation that in NMR spectroscopy the coupling constants between protons on adjacent carbon atoms vary with the dihedral angle, was made on sugar acetates [8]; this observation led later to the Karplus equation [9].

On the other hand, the study of conformations is of major importance in carbohydrate chemistry. All of the monosaccharides belong to a few families of diastereomers; within these families, they differ only in their steric arrangement, and these differences can therefore be accounted for by conformational factors. If these factors could be exactly evaluated, the

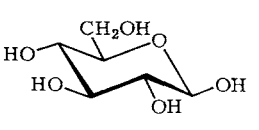
different chemical and physical properties of the various sugars could be predicted. Even without exact evaluation, semiquantitative application of conformational analysis can explain facts which, for many years, have been presented without any explanation: *e.g.*, why the equilibrium solution of lyxose [*] in water consists mostly of the α-pyranose, but that of xylose of the β-pyranose form; why the aqueous solution of altrose contains substantial proportions of furanose forms, whereas in the solution of glucose they are not detectable by our present methods; why idose is extensively converted in acid solution into an anhydride, whereas galactose is not.

It is the purpose of this paper to show how these facts are now readily explained by conformational analysis [10–13].

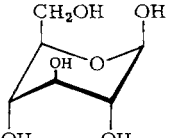
2. Conformations of Monosaccharides

2.1. Determination of Conformations



Conformational analysis of the sugars is based on the assumption that the geometry of the pyranoses is substantially the same as that of cyclohexane, and that of the furanoses the same as that of cyclopentane [10]: the substitution of two carbon-oxygen bonds for the slightly longer carbon-carbon bonds causes only a slight change in the molecular geometry. The pyranoid ring may, therefore, be in one of two chair forms or in the less stable flexible forms (skew and boat); the furanoid ring may be in one of the envelope or twist forms. In the solution of a sugar, these forms co-exist in equilibrium, but usually one conformation predominates. The physical properties, like the optical rotation, NMR spectra, *etc.*, of the sugar in solution will be determined by its predominant conformation; but chemical reactions may proceed through another conformation, though the activation energy of the reaction will then be increased by an amount equal to the difference between the free energies of the conformations.

The pyranoses will be considered first (Section 2.2) because most sugars exist and react mainly in this form, and because the conformations of the six-membered ring are clearly defined and readily recognized. The furanoses will be discussed in Section 2.5.



The conformations of pyranoses have been determined by several methods. The pioneering work of *Reeves* [14] was carried out by studying the formation of complexes from sugars in cuprammonium solution. X-ray crystallography, polarimetry, optical rotatory dispersion, and infrared spectroscopy have been used to determine the conformations of sugars, but the best source of information nowadays is NMR spectroscopy.

Reeves [14,15] determined the predominant conformations of many methyl glycosides by studying the complexes which some of them form with cuprammonium reagent. The extent of complex formation is shown by the decrease in electrical conductivity of the solution; the nature of the complex is often indicated by the change in optical rotation. By the study of suitable model compounds, *Reeves* found that complex formation requires the presence of two hydroxyl groups in close proximity: an equatorial and an axial, or two equatorial, hydroxyl groups on adjacent carbon atoms are suitable, and so are two *syn*-axial hydroxyl groups. Non-formation of a complex indicates that all hydroxyl groups are too far apart in the predominant conformation.

The method is open to the objection that a complex may be formed from a conformation other than the predominant one if the latter is incapable of reacting. Fortunately, this occurred in few of *Reeves'* examples, and most of his conformational assignments have been confirmed by later work. *Reeves* found the majority of D-sugars in what he called the C1 conformation and only methyl α- and β-D-arabinoside and methyl α-D-idoside were shown to be predominantly in the 1C conformation. [The conformations C1 and 1C are illustrated [*], for β-D-glucopyranose, by *(1)* and *(2)*.] All methyl glycosides were found to be in chair conformations, but a few (the altrosides and the lyxosides) appeared to contain substantial amounts of both chair forms in equilibrium.

(1)

(2)

The most definite and most accurate method for determining the conformations of a sugar is by complete X-ray crystal-structure analysis. It is not necessarily certain however that the conformation which occurs in the crystal is the one which predominates in solution, particularly since the conformation may vary with the solvent (Section 2.2.). X-ray crystallography yields valuable data on bond lengths, bond angles, and interatomic distances, and so far all of the pyranoid sugars which have been studied by X-ray analysis [16] have been

[*] Statements made for sugars without a D or L prefix apply equally to the D and L enantiomorphs.

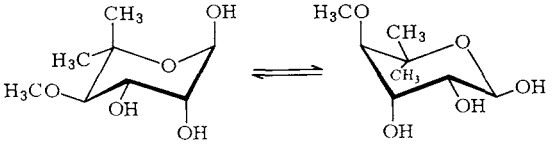
[*] In this paper, C1 and 1C always refer to D-sugars. In the L-series the assignments have to be reversed and therefore, unfortunately, the comparison of the conformations of D- and L-sugars is often somewhat confusing. As far as possible, D-sugars are used in this paper as examples; but when data are available for L-sugars only, these are given and, for clarity's sake, the conformations are designated as 1C(L) and C1(L). It must be kept in mind that the C1 form of the D-series and the 1C(L) form of the L-series are mirror images and therefore have the same (axial or equatorial) arrangement of each substituent.

[16] For a review, see *G. A. Jeffrey* and *R. D. Rosenstein*, Advances Carbohydrate Chem. *19*, 7 (1964).

found in the same chair conformations in their crystals as those which predominate in aqueous solution.

The advent of NMR spectroscopy was of utmost importance for the determination of the conformations of sugars. Although other spectroscopic methods [17], and methods based on optical rotatory power [18], have been used for this purpose, NMR is the first method which allows direct observation of conformationally significant data in aqueous solution, even when a mixture of several forms of a sugar is present. In such a case the NMR spectrum may, in favorable circumstances, be used to determine the composition of the mixture (Section 3.1) as well as the conformation of each component.

Two kinds of data provided by NMR spectra yield information on conformations: the coupling constants and the chemical shifts. The coupling constants for hydrogen atoms on adjacent carbon atoms vary with the dihedral angle according to the Karplus equation [9]:



$$J = J_0 \cos^2 \Phi + K$$

where J is the coupling constant between two hydrogen atoms attached to neighboring carbon atoms at a dihedral angle of Φ, and J_0 and K are constants. Although it is now realized that this equation gives only approximate values [19,20], and that the coupling constants also depend on the nature and on the configuration of substituents, the magnitude of the coupling constant can often clearly distinguish between two possible conformations. For example, if two adjacent hydrogen atoms in a six-membered ring are *trans*, a large value of J (7–10 Hz) indicates a diaxial, a small value (2–4 Hz) a diequatorial arrangement of the hydrogen atoms.

The anomeric [*] protons of aldoses, being on a carbon atom attached to two oxygen atoms, appear at lower field than the other ring protons and are clearly distinguishable in the NMR spectra. The coupling constant of this proton alone will distinguish between the two possible chairs of the pyranose forms of those sugars in which the protons on C-1 and C-2 are *trans* to each other; these sugars are the α-forms of altrose, idose, mannose, talose, arabinose, and lyxose, and the β-forms of allose, galactose, glucose, gulose, ribose, and xylose. A coupling constant between 4 and 6 Hz, as found in α-D-lyxopyranose, α-D-altropyranose, and α-D-idopyranose, indicates that both chair conformations are present in substantial proportions in equilibrium.

The statement that a coupling constant intermediate between those expected for the two chair conformations indicates a conformational mixture, rather than a distorted chair or a skew form, probably needs to be supported. A good example is α-noviose (6-deoxy-5-*C*-methyl-4-*O*-methyl-α-L-lyxohexose). Methyl α-novioside in pyridine solution shows $J_{1,2}$ 1.9 Hz and several of its derivatives have $J_{3,4}$ between 9.3 and 10.0 Hz, approximately the values expected for the 1C(L) form *(3)* [21]. However, in aqueous solution methyl α-novioside has $J_{1,2}$ 2.3 and $J_{3,4}$ 8.8 Hz, and α-noviose has 3.9 and 7.7 Hz, respectively [22].

As the anomeric effect becomes smaller, larger contributions (see Section 2.4.) are made by the C1(L) form *(4)* for which the expected coupling constants are $J_{1,2}$ 7.4 and $J_{3,4}$ 3.3 Hz. A distortion of the 1C(L) form to reduce the axial-axial interactions would cause a decrease, not an increase, in $J_{1,2}$; and a skew conformation cannot be found which would show the observed coupling constants. α-D-Lyxopyranose shows similar behavior [23]. *Bhacca* and *Horton* [24] have recently shown that at −84 °C the NMR spectrum of tetraacetyl-β-D-ribopyranose in [D_6]acetone displays the signals of both chair conformers in the approximate proportion of 2:1. The spectrum at room temperature, with coupling constants intermediate between those of the two chair forms, is therefore a time-averaged spectrum of the two conformers in rapid interconversion.

(3) *(4)*

If the protons on C-1 and C-2 are *cis*, the coupling constant of the anomeric proton does not distinguish clearly between the two possible chair conformations, although the value for $J1$ (eq.), 2 (ax.) is usually 2.5 to 3.5, and for $J1$ (ax.), 2 (eq.) it is 1.0–1.5 Hz [20]. Often a decision can be made by determining the coupling constants of other hydrogen atoms either by direct inspection or by analysis of the spectrum. In this way, the conformations of most of the aldohexoses and aldopentoses have been determined; they are shown in Table 1.

The chemical shift of a proton is also characteristic of its environment, and may yield information about the conformation of the molecule. The rule [25] that an equatorial proton will appear at lower field than a chemically similar but axial proton appears to be generally valid, provided that the compounds compared are epimeric and are both in the same conformation [26]. For D-pyranoses in the C1 conformation, therefore, the anomeric proton of the α-anomer appears at lower field than that of the β-form. When the opposite is true, as it is for ribose, altrose, and idose, the α-forms are, at least partially, in the 1C conformation. The chemical shifts of ring protons in

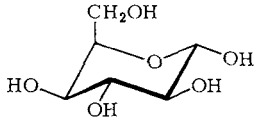
pyranoses are strongly dependent on the configurations of substituents in the ring. Axial protons, for example, are deshielded by neighboring and also by *syn*-axial hydroxyl groups. *Lemieux* and *Stevens* [20] have established simple empirical rules for predicting the chemical shifts of the ring protons in pyranoses. Comparison of the predicted values with the chemical shifts found experimentally can sometimes distinguish between two possible conformations.

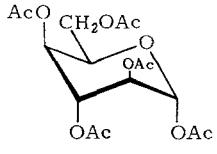
In this discussion it has been assumed that only the two chair forms need to be considered for pyranoses. In no case has a monocyclic pyranose or one of its derivatives been found in other than a chair form. The chair form is known to be energetically more favorable than the flexible form. Nevertheless, the possibility cannot be excluded that some of the pyranose sugars may exist predominantly in a skew form. The NMR spectrum provides definite proof of a pyranose being in a chair form only if the coupling constants of several ring protons can be determined; this is the case with β-D-xylose, α-D-arabinose, β-D-ribose, and α- and β-D-allose. For the other sugars, available evidence does not definitely exclude the possibility of a skew form being present.

2.2. The Conformations of Pyranoses



In aqueous solution, as the data in Table 1 show, the conformations of the aldohexopyranoses are governed mainly by the disposition of the bulkiest substituent, the hydroxymethyl group, which tends to assume an equatorial position. Hence, all of the β-anomers are predominantly in the C1 form, because the alternative 1C form involves a large interaction between the axial hydroxymethyl and the axial anomeric hydroxyl groups [see, *e.g. (2)*]. This interaction is absent from the 1C form of the α-anomers but most of these also prefer the C1 form; only α-D-idopyranose exists predominantly in the 1C form, and aqueous solutions of α-D-altropyranose and, probably, α-D-gulopyranose have substantial proportions of both chair forms in equilibrium.

In the absence of a hydroxymethyl group at C-5, the conformations of the aldopentopyranoses are governed by the dispositions of the hydroxyl groups. Thus, the D-arabinopyranoses favor the 1C form, α-D-lyxopyranose and α-D-ribopyranose are each conformational mixtures, and the other aldopentoses are predominantly in the C1 form.



Not much is known about the conformations of the ketohexopyranoses. By analogy with the aldoses, one would expect that β-D-sorbopyranose and β-D-tagatopyranose would be mixtures of the two chair forms, and the other ketohexoses would have the conformation in which the hydroxymethyl group is equatorial, that is, β-D-fructopyranose and β-D-psicopyranose would be in the 1C, and all the α-anomers in the C1 form. Quite recently, *Jochims et al.* concluded [27] from their studies of long-range couplings of hydroxyl protons that α-D-sorbopyranose and α-D-tagatopyranose are in the C1 form in methyl sulfoxide solution and β-D-tagatopyranose is in the 1C form. In the crystalline state, α-L-sorbopyranose was found by X-ray analysis to be in the 1C (L) form [28].

All the preceding discussions refer to free sugars in aqueous solution. Conversion to glycosides, introduction of substituents, and change of solvent may alter the predominant conformation because they change the anomeric effect (Section 2.4); in most cases it becomes larger and therefore the conformational equilibrium of α-forms tends to shift towards the C1, that of β-forms towards the 1C, conformation. For example, α-D-idopyranose in aqueous solution is mainly, though not wholly, in the 1C form *(5)* [29]; methyl α-D-idopyranoside in aqueous solution is a mixture of approximately equal amounts of the C1 and 1C forms [30], and the NMR spectrum of penta-*O*-acetyl-α-D-idopyranose shows it to be in the C1 conformation *(6)* [31]. On the other hand, β-D-ribopyranose in aqueous solution is mainly, though not wholly, in the C1 form [32], β-D-ribopyranose in methyl sulfoxide [23] and methyl β-D-ribopyranoside in water [33] are mixtures of nearly equal amounts of the two chair forms, but tetra-*O*-acetyl-β-D-ribopyranose in acetone solution consists predominantly (2:1) of the 1C form [24].

The extreme examples are the triacetylpentopyranosyl halides in which that conformation predominates in which the halogen atom is axial, even if all the other substituents are also axial. For a further discussion, see Section 2.4 on the anomeric effect.

Ac = CH_3CO

2.3. Calculation of the Preferred Conformations from Interaction Energies

In order to understand, and even to predict, which conformation of a particular sugar is predominant and to what extent, one would need to know the relative free energy of each conformer. Data are at present not available for the exact calculation of these free energies [34]. However, even an approximate calculation serves as a useful guide and can be readily carried out by adding the values of all the non-bonded interactions occurring in each conformer, plus the value of the anomeric effect [32]. The calculations involve two assumptions: (a) that the free energies of conformational isomers are additive functions of energy terms associated with the presence of non-bonded interactions, that is, the occurrence of one interaction in a molecule does not affect the magnitude

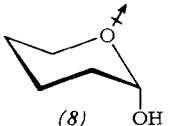
of another one; and (b) that the molecules are ideal chair forms, the shape not being affected by the interactions between substituents. Neither of these assumptions is strictly true and the results are therefore only approximate.

The interactions taken into account are not only those between axial groups but also *gauche* interactions between groups attached to contiguous carbon atoms. The values of interaction energies used in these calculations have been obtained, in aqueous solution, from the equilibria of cyclitols with their borate complexes [35] and from equilibria of sugars [22].



The following values were used in the calculations: interaction between an axial hydrogen atom and an axial oxygen atom, 0.45 kcal/mole; between an axial hydrogen atom and an axial methyl (or hydroxymethyl) group, 0.9; between two axial oxygen atoms, 1.5; between an axial oxygen atom and an axial methyl group, 2.5; between two vicinal oxygen atoms, unless they are both axial, 0.35; between a methyl (or hydroxymethyl) group and a vicinal oxygen atom, unless they are both axial, 0.45 kcal/mole. All other nonbonding interactions are believed to be negligible. These values were obtained in aqueous solutions at room temperature, and are only valid under these conditions.

2.4. The Anomeric Effect

Besides the interaction energies, another factor has to be taken into account in calculating the free energies of pyranoses. Most 1-substituted derivatives of α-D-glucopyranose (and many other sugars) are more stable than the corresponding β-D anomers, although the former have the bond to the substituent in the axial position, and the latter in the equatorial one. There appears to be an effect, first discussed by *Edward* [36] and named "anomeric effect" by *Lemieux* [11,37], which makes an equatorially attached group on the anomeric carbon atom less stable than it would be at other positions on the ring. An explanation of this effect was given [36] in terms of the repulsive interaction between the equatorial carbon-oxygen dipole and the dipole formed as the resultant of the two carbon-oxygen dipoles in the pyranose ring. These dipoles form a small angle when the substituent is equatorial, as in *(7)*, and a large one when it is axial, as in *(8)*. In accordance with this explanation, the anomeric effect varies inversely with the dielectric constant of the solvent, and is greatest when the effective charge density on the substituent atom attached directly to C-1 is high [38].

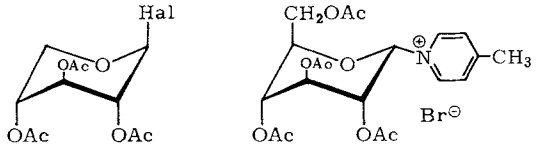
[38] *B. Coxon*, Tetrahedron *22*, 2281 (1966).

The evaluation of the anomeric effect is the least satisfactory part of the calculations of the free energies of sugars, because the anomeric effect varies considerably not only with the nature of the solvent and of the anomeric group but is affected even by the presence and the configuration of substituents in other parts of the pyranose molecule. It is difficult, therefore, to obtain reliable figures for the values of the anomeric effect under different conditions. However, the anomeric effect of a hydroxyl group in aqueous solution is comparatively small and can be readily evaluated by considering the differences between the free energies of anomers [32].

The free energy of α-D-glucopyranose should be 0.9 kcal/mole higher than that of the β-D anomer, owing to the interaction of the anomeric hydroxyl group with two axially attached hydrogen atoms in the former. In fact, the equilibrium solution contains 36 % of α- and 64 % of β-D-glucose, corresponding to a free-energy difference of only 0.35 kcal/mole. The difference between the two values, 0.55 kcal/mole, is due to the anomeric effect. A similar calculation for the D-mannopyranoses gives a difference of 1.0 kcal/mole, for the 2-deoxyarabinohexoses, 0.85 kcal/mole. The magnitude of the anomeric effect, therefore, depends on the presence and on the configuration of the hydroxyl group on C-2. The presence or absence of a hydroxyl group on C-6 (and probably in other positions) also modifies the anomeric effect [37] but, in aqueous solution, this modification is small enough to be neglected. In these calculations, the anomeric effect was taken as 0.55 kcal/mole when the oxygen atom on C-2 is equatorially attached, and as 1.0 kcal/mole when it is axially attached.



It is surprising that the anomeric effect increases with the extent of methylation of the hydroxyl groups. At equilibrium in aqueous solution D-mannose contains 67% of the α-pyranose form, 2-*O*-methyl-D-mannose 75%, 2,3-di-*O*-methyl-D-mannose 80%, and 2,3,4,6-tetra-*O*-methyl-D-mannose 86% [23]. Since the change in the non-bonding interactions of the anomeric hydroxyl group on moving it from the equatorial (β) to the axial (α) position is the same for each of these compounds, the increasing preponderance of the α-anomer must be caused by an increase in the anomeric effect. This is probably due to a decrease in the "effective dielectric constant" [39] of the molecule which, as well as the dielectric constant of the solvent, determines the magnitude of the dipole-dipole interaction. A similar increase of the α:β ratio has also been observed on methylation of other sugars [30].

The origin of the anomeric effect is not fully understood at present and its value can not yet be calculated. It is not even certain that the anomeric effect increases (by dipole repulsion) the free energy of the anomer which has an equatorial anomeric group; it is possible that it actually decreases (by dipole attraction) the free energy of the axial anomer. There are few reliable estimates of the anomeric effect; that of an amino group is less, that of an acetoxy group more, than the value for a hydroxyl group. In aqueous solution the anomeric effect of the methoxyl group is larger (by about 0.5 kcal/mole) than that of the hydroxyl group [30]. In solvents of low polarity the anomeric effect of halogen atom is so great (> 2 kcal/mole) that it often exceeds the sum of all the nonbonding steric interactions and decides the conformation of

[39] *F. H. Westheimer* and *J. G. Kirkwood*, J. chem. Physics *6*, 513 (1938).

the molecule. Thus all the triacetylpentopyranosyl halides adopt predominantly the conformation in which the halogen atom is axially oriented, even the tri-*O*-acetyl-β-D-xylopyranosyl halides *(9)* in which all the substituents are axial [40].

If a substituent is particularly bulky it will avoid the axial orientation. Thus α-D-mannopyranosyltheophylline in water, and its tetraacetate in chloroform, are in the 1C conformation, unusual for derivatives of mannose [41]. The effect of bulkiness is probably reinforced by the "reverse anomeric effect" of a positively charged substituent in *N*-(tetra-*O*-acetyl-α-D-glucopyranosyl)-4-methylpyridinium bromide which is in the 1C form *(10)* with all the other substituents axially attached [42].

(9) Ac = CH_3CO *(10)*

To calculate the free energy of a sugar in a particular chair conformation, all the interaction energies and the anomeric effect (if present) are totalled. The values listed in Table 1 for all the aldohexoses and aldopentoses were obtained in this way [32]. The conformation which has the lower free energy is, of course, the more stable one. When the free energies of the two chair forms differ by 0.6 kcal/mole or less, both conformations are listed since they would both be present in comparable amounts. It is seen that the calculations correctly predict the conformation of each aldose.

Table 1. Predominant conformations of D-aldopyranoses in aqueous solution.

Aldose	Conformation found by		Calculated interaction energies (kcal/mole)	
	NMR [20, 48, 49]	calculation [32]	C1	1C
α-D-Allose	C1	C1	3.9	5.35
β-D-Allose	C1	C1	2.95	6.05
α-D-Altrose	C1, 1C	C1, 1C	3.65	3.85
β-D-Altrose	C1	C1	3.35	5.35

2.5. The Conformation of Furanoses

The conformations of the furanoses are more difficult to establish than those of the pyranoses. In contrast to the six-membered ring which has two principal conformations, often greatly differing in stability and separated by substantial energy barriers, the five-membered ring has numerous conformations, of similar free energies, separated by low barriers.

The furanose ring is not planar. To avoid extensive eclipsing, either one atom is out of the plane formed by the other four ["envelope" form, *(11)*] or two adjacent atoms are on opposite sides of the plane formed by the other three ["twist" form, *(12)*]. A small change, mainly in the position of one atom, converts an envelope form into one of two conformationally similar twist forms. The envelope and the twist forms are the free-energy minima in the cycle of conformational interconversions of cyclopentane; for a polysubstituted cyclopentane, or furanose, a conformation intermediate between an envelope and a twist form may be the most stable one.

(11) *(12)*

The conformation of the furanose ring has been determined by X-ray crystallography in many derivatives of D-ribofuranose [43]; there is considerable variation in the shape of the furanose ring from one compound to another. NMR has also been used to determine the conformations of furanoid sugars [44–45], and the spectra have been interpreted in terms of one predominant conformation; it is possible, however, that in many cases they represent time-averaged spectra of several conformations. It is best to regard the clearly defined envelope and twist conformations of a furanose in solution as an easy way to describe what in reality is an equilibrium of rapidly interconverting forms which do not differ greatly from each other.

Because eclipsing of a carbon atom and an oxygen atom requires less energy than that of two carbon atoms, the oxygen atom in the furanoid ring tends to occupy the least puckered part of the ring; hence, usually, either C-2 or C-3, or both, will be out of the plane. In most cases, the conformation is one intermediate between the ideal envelope and twist forms, and is governed by the disposition of the substituents. The section of the ring containing C-2 and C-3 resembles the half-chair form of pyranoses, and the substituents occupy quasi-axial and quasi-equatorial positions. The predominant conformation appears to be the one in which bulky substituents are staggered as much as possible, and assume quasi-equatorial positions on the most staggered carbon atoms. The substituents therefore tend to move into the plane of the furanose ring. On the other hand, the anomeric effect is operative in the furanoses too [45], and therefore the

[45] *J. D. Stevens* and *H. G. Fletcher jr.*, J. org. Chemistry *33*, 1799 (1968).

oxygen atom on C-1 tends to take up a quasi-axial position, that is, tends to move out of the plane of the ring. Hence, *trans*-substituents at C-3 and C-4 usually form[45] a dihedral angle of less than 120°, those at C-1 and C-2, more than 120°; the constant of the coupling between *trans* hydrogen atoms on C-1 and C-2 is usually small, that between those on C-3 and C-4 usually large. On the basis of these tendencies it is often possible to predict the predominant conformation of a furanose, but a quantitative treatment, similar to that of the pyranoses, is not yet possible. The conformational behaviour of furanoses has been discussed in considerable detail by *Lemieux*[11], who made the simplifying assumption that they all have envelope conformations.

3. The Equilibrium Composition of Monosaccharides in Solution

3.1. Determination of the Composition

When a crystalline sugar – which is a single compound – is dissolved in a solvent, tautomerization occurs (of which mutarotation is the visible manifestation) and ultimately an equilibrium mixture of at least five compounds is formed: the α-pyranose, the β-pyranose, the α-furanose, the β-furanose, and the aldehydo form. Knowledge of the composition of this equilibrium mixture is the key to understanding the physical and chemical properties of sugars in solution; yet, until a few years ago, this composition had not been determined for any sugar. Only the study of the rate of the mutarotation provided some relevant information.

Mutarotation can be either "simple" or "complex"[46]. Sometimes the mutarotation may be described by the equation for a first-order reversible reaction, whether approached from the α- or from the β-pyranose ("simple" mutarotation). Then the equilibrium mixture consists predominantly of the two pyranose forms. Some sugars which show this behavior are glucose, mannose, and lyxose.

Other sugars, however, show "complex" mutarotation, consisting of an initial fast change, followed by a slow one, not necessarily in the same direction; more than two components are then involved in the equilibrium. The initial fast mutarotation is ascribed to a pyranose-furanose interconversion, and the slow one to the anomerization of pyranose forms. The occurrence of an initial fast mutarotation can be taken as an indication that substantial amounts of furanoses are present in equilibrium. Examples of such behavior are arabinose, ribose, galactose, and talose.

If the mutarotation is simple, and if both pyranose forms are available in the crystalline state and their rotations are therefore known, the proportions of the α- and β-pyranose forms can be calculated from the value of the equilibrium rotation. If the mutarotation is complex, it is still possible to calculate the contribution that the slow mutarotation (anomerization of the pyranoses) makes to the change in rotation. Provided, again, that both pyranose forms are known in the crystalline state, the extent of the slow mutarotation will give an approximate measure of the α- to β-pyranose ratio at equilibrium. The amount or proportion of the two furanose forms cannot be determined in this way, however, because the rotations of furanoses are not known.

The position of the equilibrium can also be studied by chemical reactions, of which the oxidation of aldoses by bromine has been most extensively studied[47]. The α- and β-pyranoses differ widely in their rates of reaction: the oxidation of the anomer which carries an equatorial anomeric hydroxyl group always occurs more rapidly. By studying the rate of the reaction it is possible to determine the proportion of the slowly reacting component in the equilibrium mixture; this is taken to be the pyranose with an axial anomeric hydroxyl group. The method yields useful data when only the two pyranoses are present in substantial amounts; the presence of furanoses, however, makes it unreliable since the rate of reaction of the furanoses is not known. In fact, until the advent of NMR, there was no method known capable of determining the amount of furanoses present in solution.

NMR spectroscopy has emerged as an excellent method for determining the composition of the equilibrium mixture of a sugar, particularly because it can be used in aqueous (D_2O) solution[20, 48, 49]. Whereas the signals of most of the other protons usually overlap, those of the anomeric protons of the different forms are often well separated from each other. A good example is the NMR spectrum (Fig. 1) of idose at equilibrium in aqueous solution[49]. Identification of the anomeric signals is, in most cases, easy: the pyranoses appear at higher field than the furanoses, and the β-pyranose at higher field than the α-pyranose if they both have the same conformation (Section 2.1). In the case of D-idose, the α-pyranose is predominantly in the 1C and the β-anomer in the C1 form but the signal of the α-pyranose is readily identified by its large coupling constant. Of the furanose forms, the *cis*-1,2 has a larger coupling constant than the *trans*-1,2 anomer (Section 2.5); in this particular case the signals of the furanose forms were also identified by their similarity to the signals given by the 5-*O*-methyl-D-glucofuranoses. (Gluco- and ido-furanoses have the same configuration of every carbon atom in the ring and differ only in the configuration of the extra-annular C-5 atom.) The composition of idose in aqueous solution is determined by integration of the anomeric signals. This case is a particularly interesting one because idose has never been crystallized and therefore none of the four tautomeric forms, the NMR signals of which have thus been identified, is known in the pure state.

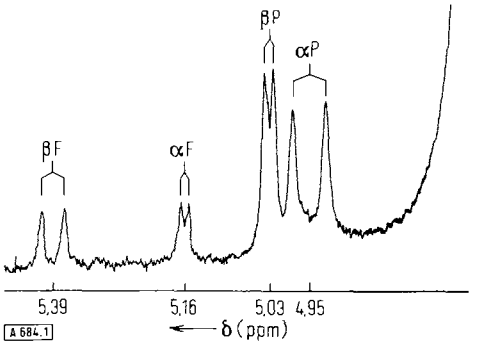

Fig. 1. The 100 MHz NMR spectrum of the anomeric protons of D-idose in D_2O solution at 60 °C. (αF, βF signify α- and β-furanose; αP, βP denote α- and β-pyranose.)

Not every aldose gives such a clear-cut spectrum as idose in aqueous solution. Nevertheless, it has been possible to determine the composition of the aqueous equilibrium solution of every aldopentose and aldohexose, except that of gulose [49]. A good spectrum was, however, obtained from D-glycero-D-guloheptose which, probably, would have a composition similar to that of gulose. The results are shown in Table 2.

Table 2. Proportions of pyranose and furanose forms of aldoses at equilibrium in aqueous solution at 40 °C [20, 49].

Aldose	Pyranose		Furanose	
	α (%)	β (%)	α (%)	β (%)
D-Allose	18	70	5	7
D-Altrose	27	40	20	13
D-Glycero-D-guloheptose	10	88	2	
D-Idose [a]	31	37	16	16
D-Talose	40	29	20	11
D-Arabinose	63	34	*ca.* 3	
D-Ribose	20	56	6	18
3-Deoxy-D-ribohexose	26	46	6	22
2-Deoxy-D-arabinohexose	47.5	52.5	0	0

[a] At 60 °C.

Only those aldoses are listed that contain detectable amounts (more than 1–2 %) of furanose at equilibrium; the compositions of the other sugars are shown in Table 3.

Consideration should also be given to the presence in the equilibrium mixture of other forms of the sugars, such as the aldehydo form, septanose, *etc.* However, the NMR spectra show no peaks additional to those of the pyranoses and the furanoses. The aldehydo forms of the sugars are extensively hydrated in aqueous solution and show only a weak signal at very low field where the aldehydic protons usually appear [50–53]. The proton of the hydrated aldehyde group resonates at $\delta \approx 5.1$, amidst the anomeric protons of the sugars but has a coupling constant (5–7 Hz) that is rare for an anomeric proton. No such signal has been detected in the spectra of any of the aldoses but it is found in the NMR spectrum of 3,6-anhydro-D-allose, a compound which for steric reasons forms neither a pyranose nor a furanose ring [52].

The equilibrium solution of D-glucose contains only 0.0026 % of the aldehydo form, as determined by polarography [54]. Glucose, of course, has the lowest free energy of all the aldohexoses; but if one assumes that aldehydo-idose has the same free energy as aldehydo-glucose, then calculation, using the free-energy values in Table 1, indicates that the aqueous equilibrium solution of idose should contain 0.04 % of the aldehydo form. This is too little to be detected by NMR.

D-Idose was reported [55] to give a positive Schiff reaction for aldehydes, unlike the other aldoses (though we were unable to confirm this report). When the pyranose form of glucose is suppressed and the sugar is forced into the less stable furanose form, as is done by blocking O-5, the amount of the aldehyde form in equilibrium should be greatly increased. Indeed, 5-*O*-methyl-D-glucose does give a positive Schiff test [56], but the NMR spectrum shows only the peaks of the two furanose forms [52]. Similarly, 3,6-anhydro-D-glucose, the pyranose forms of which are strained, shows only the furanose signals. The aldehydo form of the sugars therefore occurs in a concentration too low to be detected by NMR.

Anet [51] has recently found that 2,3,4,5-tetra-*O*-methyl-D-glucose consists in aqueous solution of about equal amounts of the aldehydo form (partially hydrated) and a septanose form. The septanoses therefore have a stability similar to that of the aldehydo form and one would not expect to be able to detect them by NMR in the equilibrium mixtures of sugars.

3.2. The α:β Ratio of Pyranoses

The α:β ratio of the pyranose forms at equilibrium varies considerably from one aldose to another but conformational analysis can explain this variation. The free-energy values given in Table 1 provide the data for calculating a "theoretical" α:β ratio [32]. Each anomer is a mixture of two chair forms, and its free energy can be calculated by taking the weighted average of the two free-energy values, corrected for the entropy change on mixing [57]. The calculated free energies of each aldose are listed in Table 3. From these values the α:β proportions in equilibrium have been calculated and they are compared in Table 3 with the ratios found by NMR. It can be seen that the agreement between the calculated and the experimentally found data is satisfactory in view of all the approximations involved in the calculations. Therefore, the α:β ratios of the pyranose forms of the aldoses are now not only known but they are also understood.

Table 3. Conformational free energies and the proportions of the α-form in aqueous equilibrium solutions of D-aldopyranoses

Aldose	Free energy (kcal/mole)		α-Pyranose (%) [a]	
	α form	β form	calc. [32]	found by NMR [20, 48, 49]
Glucose	2.4	2.05	36	36
Mannose	2.5	2.95	68	67
Galactose	2.85	2.5	36	27
Talose	3.55	4.0	68	58
Allose	3.85	2.95	18	20
Altrose	3.35	3.35	50	44
Gulose	3.85	3.05	21	<22
Idose	3.65	4.0	64	46
Xylose	1.9	1.6	37	33
Lyxose	1.85	2.4	72	71
Arabinose	1.95	2.2	60	63
Ribose	3.1	2.3	20.5	26

[a] Percentage of the two pyranose forms, *not* of all forms of the sugar.

3.3. The Furanose:Pyranose Ratio

The amount of furanoses present in equilibrium varies considerably from sugar to sugar, and in many cases it is very small. Five-membered rings are generally less stable than six-membered ones but the very considerable amount (over 30 %) of furanoses present in the equilibrium mixture of some sugars (Table 2) shows that this is not the main reason for its low proportion in the others.

The furanose:pyranose ratio in equilibrium will depend on the difference between the free energies of the

[57] Ref. [10], p. 24.

furanose and the pyranose forms. The free energies of the pyranoses have been calculated (Table 3); sugars of which the pyranose forms have low free energies, like glucose, mannose, xylose, have very little furanose in equilibrium. The relative free energies of the furanoses are not known but one can attempt to estimate them. The main interactions in five-membered rings are those between *cis* substituents on adjacent carbon atoms because these are never fully staggered. One would therefore expect furanoses with several *cis* pairs of substituents to be less stable than are those with *trans* substituents. It is particularly interesting to note that 3-deoxy-ribohexose ("3-deoxyglucose") has 28 % of furanose in equilibrium [49], whereas glucose itself has too little to be detected by NMR. It appears therefore that the interaction between O-3 and the side-chain on C-4, when these are *cis* to each other, is the most unfavorable one in the furanose ring. None of the sugars which has this interaction contains detectable amounts of furanose in its equilibrium mixture except idose, which has two rather unfavorable pyranose forms. Removal of an interaction between two *cis* oxygen atoms does not increase the stability of the furanose forms to the same extent: 2-deoxy-arabino-hexose ("2-deoxyglucose") does not show any furanose forms in its NMR spectrum.

Furanoses in which the substituents on C-2, C-3, and C-4 are all *cis* have a comparatively high free energy; accordingly, the NMR spectra of lyxose and mannose show no furanose and that of gulose shows very little. One would expect the all-*trans* furanoses of arabinose and galactose to be particularly stable, yet very little is found in the equilibrium mixtures. This may be due to *cis*-1,3 interactions, discussed in the following Section.

3.4. The α:β Ratio of Furanoses

One would expect that that anomer of the furanoses in which the hydroxyl groups on C-1 and C-2 are *trans* would always predominate at equilibrium over the *cis*-1,2 anomer. This is indeed what is found in most cases though the α:β ratio varies from sugar to sugar, indicating that other interactions also influence this ratio. However, in the equilibrium of idose and of 5-*O*-methyl-D-glucofuranose the two anomers are present in approximately equal amounts [52] at equilibrium. The comparative instability of the *trans* anomer is probably due to *cis*-1,3 interactions of the anomeric hydroxyl group with O-3 and C-5. The small coupling constant ($J_{1,2}$ = 0.7 Hz) of the *trans* anomer shows that O-1 and O-2 are both in quasi-axial orientation, and the conformation of the molecule is approximately as shown in *(13)*. Since O-3 is also quasi-axial, an interaction occurs between O-1 and O-3 which destabilizes the *trans*-1,2 anomer (β for glucofuranose, α for idofuranose). In "3-deoxy-D-glucofuranose" this interaction is not present and there is much more (3.7:1) of the β-furanose than of the α anomer.

(13)

Similar *cis*-1,3 interactions probably increase the free energy of the arabino- and galacto-furanoses. More quantitative data are required, however, for a better understanding of the non-bonding interactions in furanoses.

3.5. Equilibria in Solvents other than Water. The Effect of Substituents

The equilibrium compositions of the sugars in solution are affected by the temperature, by the nature of the solvent, and by the presence of substituents. If the solvent is less polar than water, the increased anomeric effect will, predictably, favor the α-pyranose over the β-pyranose form if the sugar is in the C1 conformation. However, other, unexpected changes in composition are also observed when the solvent or the substituents are altered.

There is now a considerable amount of information available on the composition of sugars in dimethyl sulfoxide solution, thanks to the work of *Perlin* [23, 58] who determined the compositions by comparing the NMR signals of the hydroxyl protons, rather than those of the ring protons. Aldoses with an axial hydroxyl group on C-2 (mannose, lyxose) contain a much higher proportion of the α-pyranose form in dimethyl sulfoxide than in water, whereas sugars with an equatorial hydroxyl group on C-2 (glucose, xylose) have approximately the same equilibrium composition in both solvents. An explanation of this observation is not apparent.

More striking is the increase in the proportion of the furanoses when changing from water as a solvent to pyridine [58a], dimethylformamide [58b], or dimethyl sulfoxide [23]. Arabinose, for example, contains 33 % furanose in the last named solvent, and only about 3 % in water. A great increase in the proportion of furanose also results from partial methylation; *e.g.* the equilibrium mixture of 2,3-di-*O*-methyl-D-arabinose contains 17 % furanose in aqueous solution and 65 % in dimethyl sulfoxide. As an extreme example of the effect of the solvent and methylation one can cite 2,3-di-*O*-methyl-D-altrose which changes to a considerable extent (*ca.* 80 %) into furanose forms on standing in dimethyl sulfoxide [23].

This surprising variation in the furanose:pyranose ratio is probably explained by differences in the extent of solvation. The hydroxyl group is solvated in water by forming hydrogen bonds through its oxygen and its hydrogen atom but the methoxyl group can form hydrogen bonds only through its oxygen atom. In dimethyl sulfoxide only the hydrogen atom of the

[58] *A. S. Perlin*, Canad. J. Chem. *44*, 539 (1966).

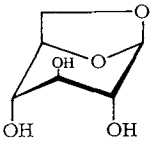
[58b] *C. C. Sweeley*, *R. Bentley*, *M. Makita*, and *W. W. Wells*, J. Amer. chem. Soc. *85*, 2497 (1963).

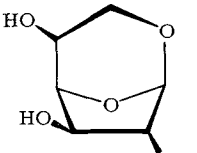
hydroxyl group will form hydrogen bonds and the methoxyl group will be weakly solvated by dipole association only [59]. The apparent bulk of the hydroxyl group in water will therefore be much larger than that of the methoxyl group in dimethyl sulfoxide. If the furanoses, with considerable eclipsing of their carbon atoms, are more destabilized by bulky substituents than are the pyranoses, the above results can be explained.

Accurate data are available for the equilibrium compositions of the methyl pentosides in methanol [60], and it is interesting to compare these with the equilibrium compositions of the corresponding sugars in water. Since the formation of glycosides and the change from water to methanol both enhance the anomeric effect, there is an increase in the proportion of the α-anomers of the pentoses (xylose, lyxose) which are in the C1 form, and of the β-anomer of arabinose which is in the 1C form. Since both anomers of ribose are conformational mixtures in aqueous solution, there is only a small change in the α:β ratio on converting them to methyl ribosides in methanol. Here, also, the 2-*O*-methyl and the 3-*O*-methyl, but particularly the 2,3-di-*O*-methyl glycosides have much more furanoside in equilibrium than have the unsubstituted glycosides. In particular, the equilibrium mixture of the methyl 2,3-di-*O*-methyl-D-arabinosides contains 75 % furanosides.

Fusion of a ring to the sugar can profoundly change the pyranose:furanose ratio by introducing strains into one or both of the forms. Thus 2,3-*O*-isopropylidene-L-rhamnose [*(14)* ⇌ *(15)*] consists in aqueous solution of about 65 % of the furanose form [61], and D-mannose 2,3-carbonate [62] and 3,6-anhydro-D-glucose [52] are completely in the furanose forms, whereas the parent sugars have no detectable amount of furanose in equilibrium. Fusion of a five- to a six-membered ring, whether 1,2 or 1,3, causes distortion of the latter, hence the pyranose forms of these sugar derivatives are strained; whereas the arrangement of two *cis*-1,2 fused five-membered rings, which occurs in the furanose forms, is free of steric strain [63] and is therefore favored.



(14) *(15)*



3.6. Equilibria in Acid Solution

When a sugar is heated in aqueous solution in the presence of a strong acid an equilibrium is set up which contains, in addition to the pyranoses and furanoses, other compounds as well. The most important amongst these are the anhydrides obtained by the formation of a glycosidic link with one of the sugar's own hydroxyl groups; these anhydrides are known as "glycosidic anhydrides" or "internal glycosides". The formation of the glycosidic anhydrides is very much slower than anomerization or pyranose-furanose interconversion. Subject to steric limitations, any of the hydroxyl groups of the sugar may take part in the formation of an anhydride; the amount of the anhydride at equilibrium will depend on the strain introduced by the formation of the anhydride ring.

The most stable internal anhydrides are the 1,6-anhydropyranoses, *e.g.*, 1,6-anhydro-β-D-glucopyranose *(16)*. The amount of this anhydride found at equilibrium varies within wide limits, from 0.2 % for glucose to 86 % for idose, according to the stability of the sugar and the steric interactions in the anhydride. In the glucose derivative *(16)*, for example, all the hydroxyl groups are axial and the interactions are severe [15]. Since the 1,6-anhydropyranoses have the conformation of the 1C form of the β-anomer, the difference between the free energy of that form and of the sugar in equilibrium provides an approximate measure of the relative stability of these anhydrides. Calculations based on the free-energy values in Table 1 provide the means for predicting approximately the proportion of the 1,6-anhydropyranoses at equilibrium [64].

(16)

(17)

Another type of glycosidic anhydride found in equilibrium are the 1,6-anhydrofuranoses, *e.g.*, 1,6-anhydro-β-D-glucofuranose *(17)*. This anhydride has the same ring system (dioxabicyclo[3.2.1]octane) as has the 1,6-anhydropyranose but there are more substituents in the five-membered (furanose) ring, and therefore more eclipsing. The proportion of these anhydrides at equilibrium is therefore much less than that of the 1,6-anhydropyranoses, and in many instances they have not yet been detected. Only in the case of D-talose are there about equal amounts (2.5 % each) of the two anhydrides in equilibrium [64].

There are indications of the presence of 1,4-anhydropyranoses (= 1,5-anhydrofuranoses) in the equilibrium mixtures of some sugars [65]. Aldoheptoses also give 1,7-anhydropyranoses and 1,7-anhydrofuranoses in addition to those already mentioned.

In acid solution of sugars there is, besides the formation of internal glycosides, also glycoside formation between sugar molecules, resulting in di- and oligo-saccharides. In dilute solution this reaction ("reversion") is negligible but in concentrated solutions of sugars it may be quite considerable. The equilibrium mixture is then extremely complex.

Catalase and Peroxidase Activity of Cu^{2+} Complexes

By H. Sigel[*]

The relation between the structure of Cu^{2+} complexes and their catalytic activity in the decomposition of H_2O_2 can be used as a "molecular probe", since it allows the deduction of the number of coordinated ligand groups in a Cu^{2+} complex from its catalytic activity. Since only coordinated ligand groups are oxidized by H_2O_2, further information about the coordination sphere of the metal ion can be obtained from the oxidation of certain parts of a ligand, which can be followed spectrophotometrically. The Cu^{2+} complexes of amides, polyamino acids, nucleotides, RNA, and native and denatured DNA have been investigated in this way. Kinetic studies provide an insight into the mechanisms of catalase and peroxidase reactions.

1. Introduction

The catalysis of the disproportionation of hydrogen peroxide by metal ions or their complexes in homogeneous systems has already been the subject of many investigations [1–3]. The best known catalyst for reaction (1) is catalase, an enzyme containing Fe^{III} porphyrin [4].

$$H_2O_2 + H_2O_2 \rightarrow O_2 + 2\,H_2O \qquad (1)$$

In the "catalase" disproportionation (1), one molecule of H_2O_2 is oxidized and another is reduced; if one of the two molecules is replaced by an H donor, *i.e.* by a substrate that can be oxidized by H_2O_2, reaction (2) occurs:

$$H_2O_2 + \text{substrate} \rightarrow \text{oxidized substrate} + H_2O \qquad (2)$$

This "peroxidase" reaction can also be catalyzed by metal ions or their complexes; the best-known catalyst for this reaction is peroxidase, another enzyme containing Fe^{III} porphyrin [4].

In view of the great biochemical importance of catalase and peroxidase, it is understandable that models (*i.e.* more or less catalytically active Fe^{III} complexes of various structures) for these two enzymes are constantly being sought – and found [5–8]; however, the activity of catalase is far superior to that of any of the known models [9].

All the existing results indicate that (*e.g.* of the elements of the first transition series) only those ions (possibly in the form of their complexes) whose 3d shells are not filled [2,9,10], *e.g.* Cr, Mn, Fe, Co, Ni, and Cu (cf. [11]), are catalytically active for reactions (1) and (2) in the homogeneous phase, whereas those with full d shells, such as Zn and Cd [10], are catalytically inactive. Among the complexes of the ions mentioned, those of Fe^{III} [5] and Cu^{II} [13] are particularly active. It is interesting to note that these ions also occur in many redox-active enzyme systems [14].

Whereas enzymes containing Fe have been extensively studied for some time [15], those containing Cu have only recently attracted much interest [12]. One of the main reasons for this is probably the fact that in many enzymes containing Fe the metal ion is bound in a porphyrin system, *i.e.* the ligand atoms are known and localized, and this facilitates the understanding of the course of catalysis. In the enzymes containing Cu (cf. *e.g.* [12]), such as tyrosinase, polyphenol oxidase, laccase, *etc.*, on the other hand, the ligand atoms are less obvious; in fact, the details of the coordination sphere of the metal ion are not known for any Cu enzyme or protein, so that one fundamental condition for the understanding of their action is lacking [16].

The principal possibilities for the coordination sites for metal ions in proteins are $-COO^-$, ArO^-, RS^-, $-NH_2$, $-CONH-$, and imidazole[17]. Consequently, Cu complexes containing at least some of these ligand groups have often been studied as models for Cu proteins or enzymes (cf. *e.g.* [17–21]).

In the present article we shall confine ourselves to a discussion of the catalase and peroxidase activity, in accordance with eq. (1) and (2), of Cu^{2+} complexes of various structures, some of which may also be regarded as models in the sense mentioned above. The attempt to characterize these catalytic processes in more detail led to a simple relation between structure and activity. This makes it possible to use the Cu^{2+} catalyzed decomposition of H_2O_2 as a "molecular probe", *i.e.* to draw conclusions regarding the structure of the Cu^{2+} complex in question from the nature and course of the catalysis.

2. Influence of the Number and Nature of the Coordinated Ligand Groups on the Catalysis

2.1. Influence of the Number of Coordinated Ligand Groups

It has repeatedly been found[22,23] that complexes of metal ions favor the decomposition of H_2O_2 only if they are not coordinately saturated, *i.e.* if they are still hydrated and so have coordination sites available for H_2O_2 or HOO^-; these sites will be described as "free". The relation between catalytic activity and free coordination sites was checked in the 1:1 complexes of the "homologous" series ethylenediamine *(1)*, bis(2-aminoethyl)amine (diethylenetriamine) *(2)*, and *N,N'*-bis(2-aminoethyl)-1,2-diaminoethane (triethylenetetramine) *(3)* with Cu^{2+}[24].

The initial rate constant k (pseudo-first order) of the decomposition of H_2O_2 was taken as a measure of the catalytic activity[23] (eq. (3)[25]):

$$k = (2.30/t) \cdot \log([H_2O_2]_0/[H_2O_2]_t)\ (\text{min}^{-1}) \qquad (3)$$

It was again found that the catalytic activity requires free coordination sites, *i.e.* it is connected with the possibility of formation of ternary Cu^{2+}-peroxo ligand complexes, which can be detected by the appearance of an absorption shoulder at about 360 nm[23,24]. As the number of free coordination sites on the Cu^{2+} decreases, k also decreases as a function of the pH value (= activity curve) (Fig. 1), *i.e.* the pH value at which the catalytic activity begins is higher; in the case of the 4-coordinate complex *(3)* it is practically zero. This relation and the occurrence of ternary Cu^{2+}-peroxo complexes indicate that the catalysis takes place within the coordination sphere.

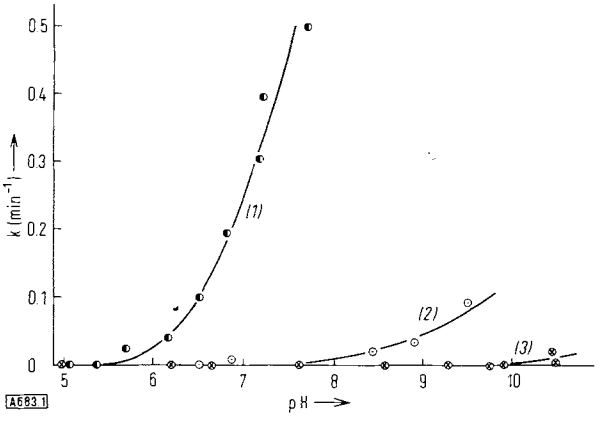

Fig. 1. Decrease in the catalytic activity of the Cu^{2+} chelates (4×10^{-4} M) with the number of free coordination sites on the metal ion, determined as the initial rate constant k (min^{-1}) of the decomposition of H_2O_2, which is pseudo-first order with respect to H_2O_2 (8×10^{-3} M), as a function of the pH value. *(1)* (◐) > *(2)* (⊙) > *(3)* (⊗).

In general, the catalysis of the decomposition of H_2O_2 begins in the neutral range with Cu^{2+} complexes having two free coordination sites, and in the weakly alkaline range with those having only one free site; Cu^{2+} complexes with no free coordination sites are catalytically

[25] Measurements [24]: Before the addition of H_2O_2, the pH was adjusted with 2 N NaOH to a slightly higher value than was desired. After the addition of H_2O_2, the pH value was measured; to determine the decrease in the H_2O_2 concentration, samples were taken at fixed intervals, titanium reagent was added, and the extinction was measured at 410 nm ($\varepsilon = 737$ l mole^{-1} cm^{-1}); cf. also *A. C. Egerton, A. J. Everett, G. J. Minkoff, S. Rudrakanchana*, and *K. C. Salvoja*, Analytica Chim. Acta (Amsterdam) *10*, 422 (1954). Unless otherwise specified, the measurements were carried out at $T = 22$ °C and natural ionic strength.

inactive, these data being based on the assumption that Cu^{2+} has a coordination number of four under the reaction conditions [26, 32].

2.2. Influence of Ligand Groups Acting as H Donors

As we have shown, Cu^{2+} complexes having free coordination sites exhibit catalase activity; on the other hand, it is known that the Cu^{2+}/H_2O_2 system oxidizes pyrocatechol [18] and *o*-phenylenediamine [31], *i.e.* it exhibits peroxidase activity. We are thus faced with the question of the relation between the catalase and peroxidase activities of Cu^{2+} complexes.

Since the measured disappearance of H_2O_2 in such a system is due to consumption of H_2O_2 by both the catalase [eq. (1)] and the peroxidase [eq. (2)] activities, the catalytic activity (measured by the H_2O_2 consumption) is defined as the sum of the catalase and peroxidase activities.

Adenosine 5′-triphosphate (ATP), adenosine 5′-monophosphate N^1-oxide (AMP N^1-oxide) (cf. [34]), and native deoxyribonucleic acid (DNA) were chosen as the ligands for these investigations [33].

All three ligands have a well pronounced UV absorption band (ATP [35] and DNA [36] at 260 nm, and AMP N^1-oxide [37] at 272 nm), so that any degradation of the nucleic bases can be followed spectrophotometrically. The pseudo-first order initial rate constant k' with respect to the degradation of the bases [eq. (4)], measured by the resulting decreases in the extinction of the system, was taken as a measure of the peroxidase activity:

$$k' = (2.30\ t) \cdot \log(E_0/E_t)\ (\text{min}^{-1}) \qquad (4)$$

The "apparent" [38] initial rate constant k' as a function of the pH value (peroxidase activity curve) is shown in Figure 2 for all three complexes.

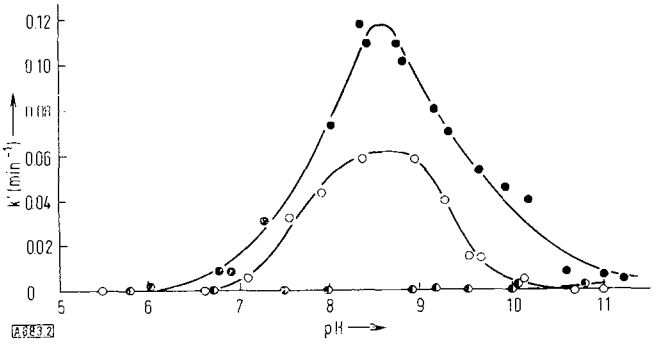

Fig. 2. Peroxidase activity ($[H_2O_2] = 8 \times 10^{-3}$ M), determined as the initial rate constant k' of the degradation of the nucleic bases, measured in 1 mm quartz cells as a pseudo-first order reaction with respect to the ligand concentration as a function of the pH value for the Cu^{2+} complexes (4×10^{-4} M) of ATP (●) and AMP N^1-oxide (○), as well as for the Cu^{2+}-DNA system (◐) ([DNA] = 0.04%; $[Cu^{2+}] = 4 \times 10^{-4}$ M, *i.e.* there are about 2.5 nucleotide units per Cu^{2+} [33]).

Comparison of the catalytic [33] activity (Fig. 1) with the peroxidase activity (Fig. 2) [39] reveals two points:

1. The peroxidase activity passes through a maximum at pH $\approx$ 8.5 (cf. [33]), whereas the catalytic activity increases "uniformly" in the pH range examined.

2. Though all three systems are catalytically active, only the bases of the two nucleotide complexes, but not those of the Cu^{2+}-DNA system, are degraded (cf. Fig. 2).

It can be concluded from these observations that:

1. The peroxidase degradation of nucleic bases is not brought about by free-radical secondary products of the catalase decomposition of H_2O_2, since the courses of the two reactions should otherwise be parallel. Moreover, free radicals, such as $HO^{\cdot}$, would probably also penetrate into the helix and reach the nucleic bases in the Cu^{2+}-DNA system (cf. Sections 4.2–4.4).

2. The degradation evidently takes place in the coordination sphere of the metal ion, and a condition for its occurrence is therefore that the nucleic bases should be complexed, as is the case in the Cu^{2+}-ATP [35] and AMP N^1-oxide [37] complexes, but not in the Cu^{2+}-DNA system.

3. Since both the catalase and the peroxidase reactions evidently proceed within the coordination sphere, it must be assumed that external factors determine the direction in which the common "intermediate" complex reacts [40] (cf. also [33]).

The above observations on the influence of the number and nature of the coordinated ligand groups on the catalytic and peroxidase behavior of Cu^{2+} complexes indicate the possibility of using this "structure-specific" behavior of Cu^{2+} complexes of unknown structure as a source of information about the coordi-

[26] Other examples of inactive tetracoordinated Cu^{2+} complexes are those with cyclam (= 1,4,8,11-tetraazacyclotetradecane) [27], hexamethylcyclam [28], and ethylenediaminetetraacetic acid [29]. Very recent studies [27] on the Cu^{2+}-phthalocyaninetetrasulfonic acid complex (a pure sample prepared in accordance with [30]) showed that this system, in contrast to earlier findings [24], is also catalytically inactive. – The assumption of the coordination number four for the Cu^{2+} in aqueous solution has also proved to be meaningful in other cases: *D. D. Perrin, I. G. Sayce*, and *V. S. Sharma*, J. chem. Soc. (London), A *1967*, 1755.

[38] "Apparent" because the unknown extinction of the degradation products of the nucleic bases should be subtracted from the measured extinction; however, the agreement of the k' values at various times was very good, indicating that the extinction coefficient of the degradation products is low.

[39] As expected, ternary Cu^{2+}-peroxo complexes are also formed in all three cases [33].

[40] A similar situation was found by *Kremer* [41] in a study on the hemin-catalyzed oxidation of ascorbic acid. Catalase also exhibits peroxidase properties if the H_2O_2 concentration in the reaction solution is relatively low, and an H donor is also present [42]. The reaction can thus again be directed in the desired direction by the choice of the reaction conditions.

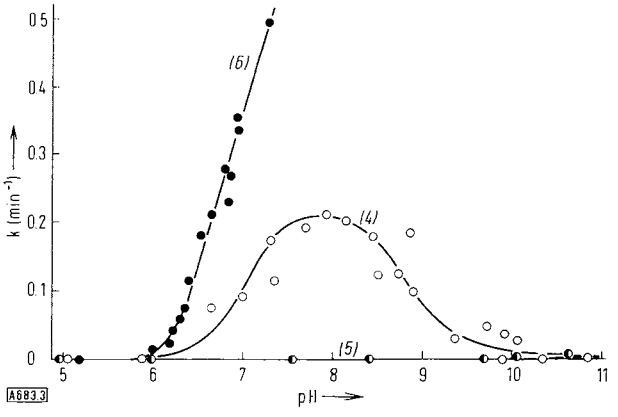
nation spheres of these complexes, *i.e.* of using the metal ion-catalyzed decomposition of H_2O_2 as a "molecular probe".

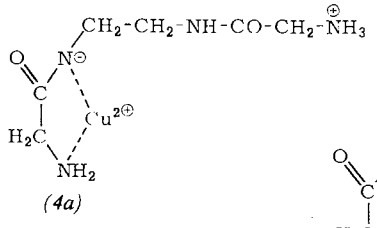
3. The Catalytic Activity as a "Probe"

3.1. *N,N'*-Diglycylethylenediamine and "Homologs"

The homologous ligands *N,N'*-diglycylethylenediamine, *N,N'*-diglycyl-1,3-diaminopropane, and *N,N'*-diglycyl-1,5-diaminopentane, the complex formation of which has been studied by *Zuberbühler* and *Fallab* [43], and in which, as in polypeptides, the coordination sites are amide and amino groups, appear to be particularly suitable for use as models for the elucidation of the relation between the catalytic activity and the number of free coordination sites in Cu^{2+} complexes [44].

The decomposition of H_2O_2 is very strongly catalyzed by the Cu^{2+} complex *(6)* (see Fig. 3). The activity curve lies in the region of Cu^{2+} complexes with two free coordination sites (cf. Fig. 1). The Cu^{2+} complex *(5)*, on the other hand, is inactive, like the Cu^{2+} complexes with no free coordination sites on the central atom.





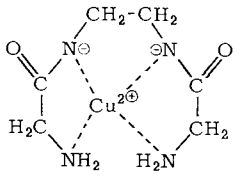


Fig. 3. Catalytic activity of the Cu^{2+} complexes (4×10^{-4} M) *(4)* (○), *(5)* (◐), and *(6)* (●), determined as the initial rate constant k (min^{-1}) of a pseudo-first order reaction with respect to H_2O_2 (8×10^{-3} M).

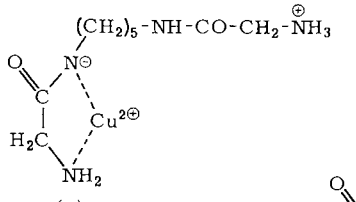
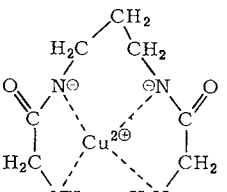
The activity of the Cu^{2+}-complex *(4)* reaches a maximum at pH $\approx$ 8 and then falls off to practically zero at pH $\approx$ 10; the Cu^{2+} complex *(4a)*, which has two free coordination sites, is evidently converted into the tetracoordinated complex *(4b)*.



These observations [44] agree with the structures deduced from potentiometric and spectrophotometric data [43], according to which *N,N'*-diglycylethylenediamine can form Cu^{2+} complexes with two free coordination sites or with no free coordination sites, depending on the pH value. The Cu^{2+} compound formed initially without deprotonation of the amide group loses an amide proton at pH = 5.49 to form the catalytically active *(4a)*; an ammonium proton is removed



(4a)

(4b)

(6)

(5)

at pK_A = 6.51, and the proton of the second amide group is lost at pK_A = 8.21 to form the inactive *(4b)*. In the case of *N,N'*-diglycyl-1,5-diaminopentane, the primary complex loses an amide proton at pH = 5.49 to form *(6)*. The ammonium group is deprotonated at pK_A = 7.47, but according to [43] it does not coordinate, so that, in agreement with the catalytic observations, a complex with two free coordination sites exists in this range. A complex analogous to *(4b)* is formed only after deprotonation of the second amide group (pK_A = 10.30) [43]. *N,N'*-Diglycyl-1,3-diaminopropane forms the catalytically inactive Cu^{2+} complex *(5)* at pH = 5.61, with occupation of all four coordination sites; the second ammonium proton and the second amide proton are lost in a single step with $pK_{A(2H)}$ = 11.33 [43].

The pH-dependent extinction at 360 nm (extinction curves, Fig. 4), which indicates the occurrence of ternary peroxo complexes, follows a course similar to the corresponding activity curves in Figure 3 for all three ligands [44].

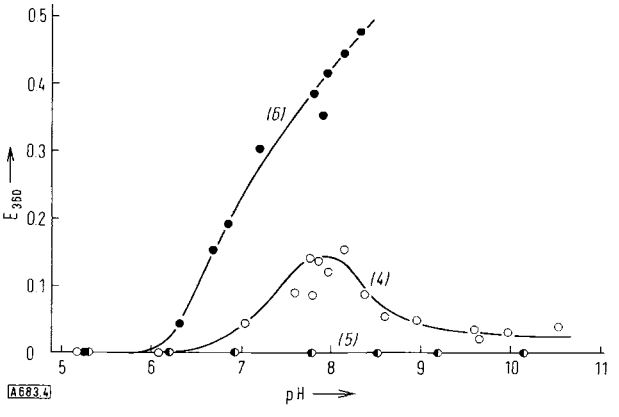


Fig. 4. Formation of ternary Cu^{2+}-peroxo complexes in media containing H_2O_2 (8×10^{-3} M), measured by the increase in extinction at 360 nm (1 cm quartz cells) as a function of the pH value for the Cu^{2+} complexes (4×10^{-4} M) *(4)* (○), *(5)* (◐), and *(6)* (●).

The results obtained with these ligands thus confirm the correlation between the catalytic activity of Cu^{2+} complexes and the number of free coordination sites.

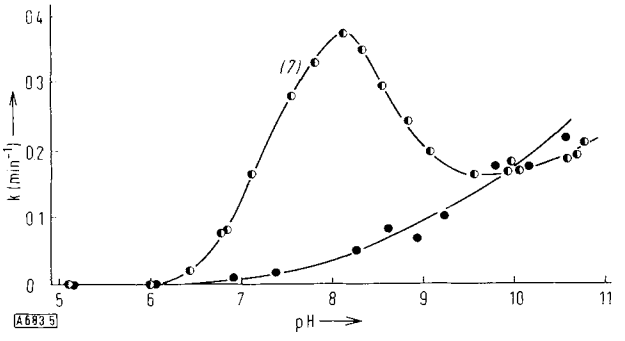
[44] *H. Erlenmeyer*, *U. Müller*, and *H. Sigel*, Helv. chim. Acta *49*, 681 (1966).

3.2. Glycine Amide

The activity curve (Fig. 5)[44] of the Cu^{2+}-glycine amide (1:1) chelate *(7a)* begins, as expected, in the region of the Cu^{2+} complexes with two free coordination sites (cf. Fig. 1), but at a somewhat higher pH value than that of the complex *(6)*, after which it initially runs parallel to the latter. The somewhat later start (cf. Fig. 3) is due to the fact that the primarily formed Cu^{2+}-glycine amide complex loses its amide proton[45] to form the more active complex *(7a)*[46] at a higher pH value than the corresponding complex of *N,N'*-diglycyl-1,5-diaminopentane. The uncoordinated "residue" in *(6)* thus does not appear to influence the catalytic activity.



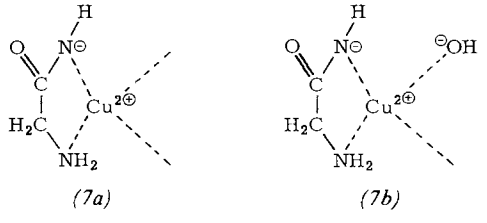


Fig. 5. Catalytic activity of Cu^{2+}-glycine amide *(7)* (◐) (4×10^{-4} M) and (for comparison) of Cu^{2+}-glycylglycine (●), determined as the initial rate constant k (min^{-1}) for the decomposition of H_2O_2, which is of pseudo-first order with respect to H_2O_2 (8×10^{-3} M).

It is surprising that this parallelism in the activities of *(6)* and *(7a)* is confined to the low pH range. The catalytic activity of the Cu^{2+}-glycine amide complex passes through a maximum at pH $\approx$ 8, then decreases until at pH $\approx$ 9.5 its activity is roughly the same as that of Cu^{2+} complexes with only one free coordination site (Fig. 5). It is therefore assumed that at pH > 8 one of the two free coordination sites is occupied by OH^-, and a complex having the structure *(7b)* is formed.

(7a) *(7b)*

These observations were confirmed potentiometrically[47]. The primary 1:1 Cu^{2+}-glycine amide complex is deprotonated with pK^{H}_{CuHL} = 7.01 and forms the complex *(7a)* with two free coordination sites. This complex is hydrolyzed with $pK^{H}_{CuL(H_2O)x}$ = 8.07 and changes into *(7b)*, which has one free coordination site.

The extinction curve of *(7)*, unlike the activity curve, has no maximum at 360 nm[44], but exhibits saturation character beyond pH $\approx$ 7. The formation of the yellow ternary complex is thus not affected by the occupation of the third coordination site by OH^-[48], *i.e.* it requires only one free coordination site for its formation, whereas the "active" complex responsible for the catalysis evidently requires two[49] (cf. also[24,33] and Section 5).

3.3. Poly-α,L-lysine Peptide

Since polyamino acids are particularly suitable for use as enzyme models[50], the Cu^{2+} complexes of poly-α,L-lysine-670, -58, and -14[51] were compared with the Cu^{2+} complexes of L-lysine and L-lysyl-α,L-lysine with respect to the catalysis of the decomposition of H_2O_2[52]. It was surprisingly found that despite the large number of potential coordination sites in the poly-α,L-lysines, the catalytic activity of their Cu^{2+} systems (Fig. 6) lies in the range of the Cu^{2+} complexes with two free coordination sites (cf. Fig. 1)[53].

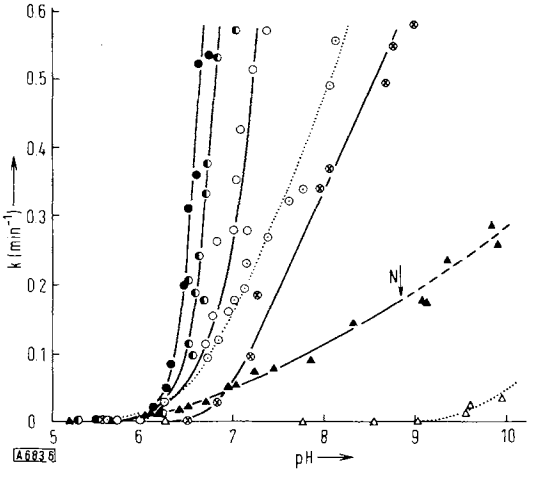

Fig. 6. Catalytic activity of Cu^{2+} systems (Cu^{2+}: lysine unit = 1:15; $[Cu^{2+}] = 4 \times 10^{-4}$ M) of poly-α,L-lysine-670 (●) and -58 (◐) and of the Cu^{2+} 1:1 systems (4×10^{-4} M) of poly-α,L-lysine-14 (○), L-lysyl-α,L-lysine (⊗), and L-lysine (▲) measured as the pseudo-first order initial rate constant k (min^{-1}) with respect to H_2O_2 (8×10^{-3} M) as a function of the pH value. The k values for the poly-α,L-lysine-14 (2:1) system (⊙) (*i.e.* 2 Cu^{2+} per ligand molecule) and the Cu^{2+}-L-lysine (1:15) system (△) are also shown (dotted curves) for comparison (see also [52]).

[45] *S. P. Datta* and *B. R. Rabin* found that the Cu^{2+} complex of glycine amide loses its amide proton; Biochim. biophysica Acta *19*, 572 (1956); cf. also *N. C. Li*, *B. E. Doody*, and *J. M. White*, J. Amer. chem. Soc. *79*, 5859 (1957).

[46] The non-deprotonated complex should have an activity similar to that of the Cu^{2+}/ glycine (1:1) system (cf. [24]).

[47] *H. Sigel*, Angew. Chem. *80*, 124 (1968); Angew. Chem. internat. Edit. *7*, 137 (1968).

[48] Up to pH $\approx$ 10.5, $[HOO^-]$ is approximately 1.2 times the corresponding $[OH^-]$ at a given pH. $pK^{H}_{H_2O_2} = 11.81$; *V. A. Kargin*, Z. anorg. allg. Chem. *183*, 77 (1929).

[49] In agreement with this the variation of the catalytic activity of tricoordinated Cu^{2+} chelates is contrary to the spectrochemical series, *i.e.* it decreases with increasing ligand field strength and complex stability, since the latter are accompanied by an increase in the difficulty of liberation of a further coordination site [24].

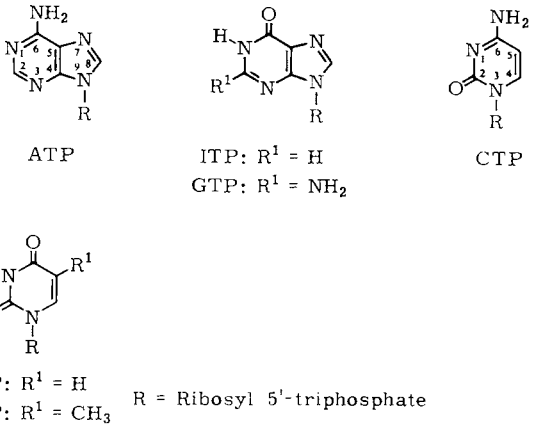
[50] *E. Katchalski*, *M. Sela*, *H. I. Silman*, and *A. Berger* in *H. Neurath*: The Proteins. Academic Press, New York 1964, 2nd Edit., Vol. 2, p. 405.

[51] The number added to the name indicates the degree of polymerization.

[52] *H. Sigel* and *G. Blauer*. Helv. chim. Acta *51*, 1246 (1968).

[53] Comparison of the activity curve of Cu^{2+}-L-lysine (Fig. 6) with that of the Cu^{2+}-glycylglycine (1:1) complex (Fig. 5) points to at least partial tricoordination of the Cu^{2+} in the lysine complex. This is conceivable (Stuart models), though such a complex is certainly not very stable. The third coordination site may also be occupied by OH^-, as in the Cu^{2+}-glycine amide complex (cf. Section 3.2). For the influence of the end groups and of the positive field of the polymer on the catalysis cf. [52].

As was shown in Section 2.2, ligand groups are oxidized by H_2O_2 only if they are situated in the coordination sphere of Cu^{2+} [33], and some Cu^{2+}-peptide complexes [54] are in fact degraded by H_2O_2. Molecular weight determinations were therefore carried out [52] in the Cu^{2+}-poly-α,L-lysine-58 system before and after the catalytic reaction [55]. The fact that the average molecular weight decreases by only 30–40% indicates only slight participation of the amide groups in complex formation in this pH range, as is to be expected purely on grounds of coordination chemistry [56]. The complex formation therefore probably occurs mainly by means of two ε-amino groups. This agrees with *Moriguchi*'s interpretation [58], according to which the complex formation between Cu^{2+} and poly-α,L-lysine involves amide groups only in the pH range around 12.



This "probe" also provides information about the complex structures of the Cu^{2+} complexes of glycylglycine amide, polymyxin B [44], and some oligomers or polymers of glycine and L-glutamic acid [52] on the basis of catalytic activity [59].

4. The Peroxidase Activity as a "Probe"

It was shown in Section 2.2 that peroxidase activity can occur only if there is an oxidizable group in the coordination sphere of the metal ion. Conversely, it will now be shown that information about the position at which a metal ion is coordinated can be obtained from the detection of peroxidase degradation of a certain group.

4.1. 5'-Triphosphates of the Ribonucleosides Adenosine, Inosine, Guanosine, Cytidine, Uridine, and Thymidine [60]

It is known (see Section 2.2) [35] that in the Cu^{2+} complex of ATP, the adenine system is coordinated to the metal ion as well as the triphosphate chain to form a macrochelate, and the adenine system is accordingly degraded by H_2O_2. *Schneider* and *Brintzinger* [61] assumed that a macrochelate of this type also occurs in the Cu^{2+}-ITP complex, and such a chelate has recently been detected in the Co^{2+}-ITP complex by *Sternlicht et al.* [62]. Information about the complex structures of the Cu^{2+}-nucleoside triphosphate complexes has now been obtained by measurement of their peroxidase activity [63,64].

The "apparent" [38] initial rate constants k' of the peroxidase degradation of the nucleic bases in the Cu^{2+} complexes of ATP (cf. Section 2.2), ITP, GTP, CTP UTP, and TTP are shown in Figure 7 as functions of the pH value. Figure 8 shows the catalytic activity; as expected, extinction curves can also be measured in every case (cf. [63]). Though the peroxidase activities (Fig. 7) of the nucleotide complexes studied differ, they indicate that the bases, as in the Cu^{2+}-ATP complex [35], take part in the complex formation to give macrochelates.

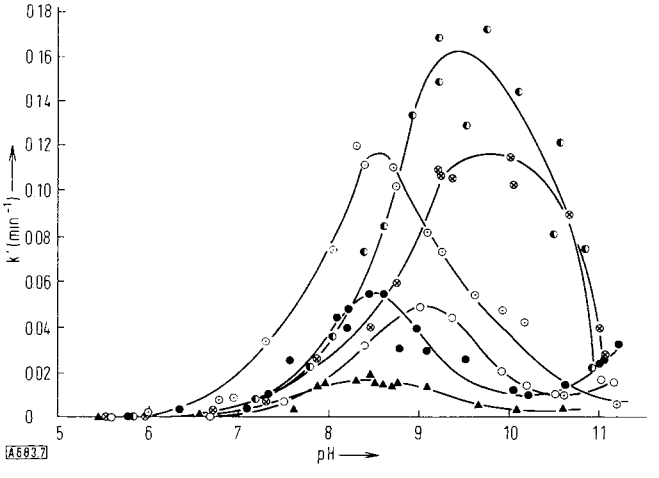


Fig. 7. Peroxidase activity ($[H_2O_2] = 8 \times 10^{-3}$ M), determined as the initial rate constant k' (min^{-1}) of the degradation of the nucleic bases, measured as a pseudo-first order reaction with respect to the ligand concentration, as a function of the pH value for the Cu^{2+} complexes (4×10^{-4} M) of ATP (○), ITP (⊗), GTP (◐), CTP (▲), UTP (●), and TTP (○). (The extinctions were measured at the maximum or in the case of pH-dependent spectra at the isosbestic point [63].)

[54] *H. Erlenmeyer, H. Sigel, H. Ch. Curtis,* and *P. Anders,* Helv. chim. Acta *49,* 19 (1966).

[55] The reaction solution stood for one day at pH = 7; other conditions as indicated in Figure 6.

[56] The participation of the amide group in the complex formation is not very probable on grounds of coordination chemistry [57]. Thus, with Cu^{2+}, glycine amide forms a complex whose amide group is deprotonated [47], whereas β-alanine amide does not [57].

[60] Abbreviations for the 5'-triphosphates: ATP, ITP, GTP, CTP, UTP, TTP.

[61] *P. W. Schneider* and *H. Brintzinger,* Helv. chim. Acta *47,* 1717 (1964).

[62] *H. Sternlicht, R. G. Shulman,* and *E. W. Anderson,* J. chem. Physics *43,* 3133 (1965).

[63] *H. Sigel,* Helv. chim. Acta *50,* 582 (1967).

[64] The Cu^{2+}-ATP complex is formed to an extent of more than 96% above pH = 7 [33], *i.e.* in the pH range in question. This is probably also true of the other Cu^{2+}-nucleotide complexes (cf. [63]).

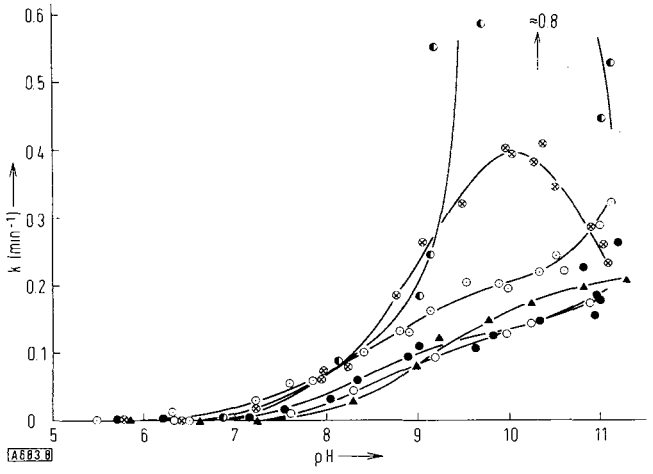

Fig. 8. Catalytic activity, determined as the initial rate constant k (min^{-1}) of the decomposition of H_2O_2, measured as a pseudo-first order reaction with respect to H_2O_2 (8×10^{-3} M), as a function of the pH value for the Cu^{2+} complexes (4×10^{-4} M) of ATP (○), ITP (⊗), GTP (◐), CTP (▲), UTP (●), and TPP (○).

The catalytic activities (Fig. 8) of the Cu^{2+} complexes of CTP, UTP, TTP, and ATP increase with rising pH over the entire range, whereas the activities of the ITP and GTP complexes pass through a maximum at pH $\approx$ 10 and then fall off again rapidly to pH $\approx$ 11. This is probably connected with the fact that the nucleic bases of ITP and GTP have two potential coordination sites, *i.e.* N-7 and the oxygen on C-6. The simultaneous coordination of Cu^{2+} to these sites and to two phosphate groups as found in the Cu^{2+}-ATP complex [35] leads to an inactive complex (cf. [63]) [66].

The fact that the base in the nucleotide complexes studied is involved in the complex formation, at equilibrium at least, should lead to a decrease in the pK_A value of the proton on N-1 in cases where this proton is present, *i.e.* in ITP, GTP, UTP, and TTP. This has in fact been conclusively demonstrated [65]. The degree of acidification [eq. (5)] [67] of the N-1 proton

$$\Delta pk_A = pK^H_{HL} - pK^H_{CuHL} \qquad (5)$$

as a result of complex formation with Cu^{2+} is approximately 2.0 pK units in all four cases; it is thus of the same order of magnitude as in the Cu^{2+} guanosine complex ($\Delta pK_A = 2.2$ [65]), in which the metal ion is coordinated only *via* the nucleic base. This confirms the participation of the nucleic bases in the complex formation in the Cu^{2+}-nucleotide complexes studied [68]. The question of the positions in the nucleic base to which the metal ion is coordinated has already been discussed [63].

[65] *H. Sigel*, European J. Biochem. *3*, 530 (1968).

[66] The fact that the peroxidase activity (Fig. 7) decreases again in every case is probably connected with the observed hydrolysis of the Cu^{2+}-nucleotide complexes [65].

[67] $K^H_{HL} = [H^+]\,[L]/[HL]$; $K^H_{CuHL} = [H^+]\,[CuL]/[CuHL]$.

[68] If the nucleic bases in the Cu^{2+}-nucleotide complexes are displaced from the coordination sphere of the Cu^{2+} by complex formation with 2,2'-bipyridyl (cf. [69]), the acidification decreases to about 0.6 pK units [65].

[70] *H. Sigel*, Chimia *21*, 489 (1967).

4.2. Native RNA, Native DNA, and DNA Denatured by Cu^{2+}

The secondary and tertiary structure of deoxyribonucleic acid (DNA) is generally accepted as being described by the helix model developed by *Watson* and *Crick* and by other authors [4]. By analogy with DNA, ribonucleic acid (RNA) is also expected to have a three-dimensionally ordered structure and definite base pairing [4]. However, the nucleic bases in this case are evidently less "protected" than in DNA. This agrees with the peroxidase activity (measured at 260 nm) [71]. The nucleic bases in the Cu^{2+}-RNA system, unlike those of the Cu^{2+}-DNA system, are degraded by H_2O_2, *i.e.* Cu^{2+} must be at least partly bonded to the nucleic bases in this case.

Degradation of the nucleic bases can however also be detected in the Cu^{2+}-DNA system if a DNA solution is allowed to stand for $1^1/_2$ days after the addition of Cu^{2+} before its peroxidase activity is measured [71]. A reference solution to which Cu^{2+} was added shortly before the measurement, on the other hand, exhibited no peroxidase activity. The Watson-Crick structure is thus destabilized by prolonged exposure to the action of Cu^{2+} (cf. also [36]), and the Cu^{2+} then penetrates into the double helix of the resulting denatured DNA. This result complements *Hiai*'s observation [72] that Cu^{2+} promotes the thermal denaturation of DNA. This type of behavior is to be expected of metal ions, since they can break H bonds by coordination.

Catalytic activity is observed in all three systems (though the magnitudes differ), as is the occurrence of ternary peroxo complexes [71].

4.3. Thermally Denatured DNA

Thermal denaturation of DNA leads to a change in its extinction at 260 nm [36, 72]. This is attributed to partial elimination of the base pairing, which should also lead to an increase in peroxidase activity. If Cu^{2+} and H_2O_2 are added to thermally denatured DNA

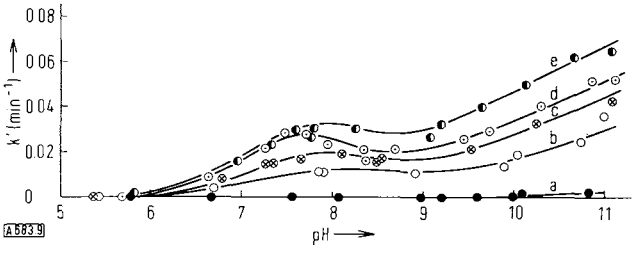

Fig. 9. Peroxidase activity of the Cu^{2+} complexes of thermally denatured DNA ([DNA] = 0.04%; $[Cu^{2+}] = 4 \times 10^{-4}$ M; $[H_2O_2] = 8 \times 10^{-3}$ M), determined as the initial rate constant k' (min^{-1}) for the degradation of the nucleic bases (pseudo-first order), measured in 1 mm quartz cells at 260 nm. DNA solutions (0.1%): (a) undenatured (●) as reference; (b) heated to 50 °C (○); (c) heated to 95 °C and kept at this temperature for 1 minute (⊗); (d) heated to 95 °C and kept at this temperature for 5 minutes (⊙); (e) heated to 95 °C and kept at this temperature for 15 minutes (◐).

[71] *H. Sigel, B. Prijs*, and *H. Erlenmeyer*, Experientia *23*, 170 (1967).

[72] *S. Hiai*, J. molecular Biol. *11*, 672 (1965).

solutions [71], it is found that the peroxidase activity increases with increasing denaturation of the DNA (Fig. 9). This confirms that the denaturation is coupled with the opening of the double helix, with the result that the bases are exposed for complex formation with Cu^{2+}. The investigation of the peroxidase activity of a Cu^{2+}-DNA system can therefore be used to distinguish between native and denatured DNA.

The catalytic activity (cf. [71]) increases to a greater degree with increasing denaturation than would be expected on the basis of consumption of H_2O_2 because of peroxidase activity. It therefore follows that the catalase activity also increases. This is probably connected with the fact that *N*-chelates are catalytically more active than *O*-chelates [23, 24]. The different charges on the complexes (*N*-chelates are generally charged positively, *O*-chelates negatively) undoubtedly affect the formation of ternary Cu^{2+}-peroxo complexes with HOO^- (cf. [70]).

4.4. Denaturation of DNA as a Function of the pH. Stabilizing Effects of LiCl, NaCl, KCl, and $MgCl_2$

0.05% aqueous DNA solutions were prepared by dissolving in each case 7.5 mg of DNA in 15 ml of H_2O at various pH values with slow stirring for 16 hours ($T = 22$ °C). After this time several samples were taken, Cu^{2+} and H_2O_2 were added, and the peroxidase activities of the samples were examined (at 260 nm) between pH 5.5 and 10.5 [73]. The resulting peroxidase activity curves (Fig. 10) clearly show the influence of the H^+ concentration on the stability of the DNA. The peroxidase activity of the samples increases with the initial H^+ concentration of the DNA solutions [74].

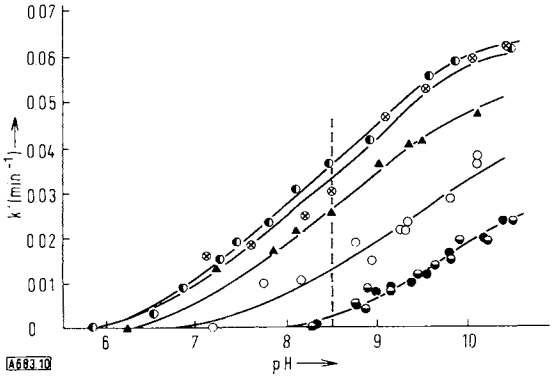

Fig. 10. Peroxidase activity of the Cu^{2+} complexes of DNA solutions (0.05%; $T = 22$ °C) aged for 16 hours at various pH values [pH = 3.0 (◐); pH = 4.0 (⊗); pH = 4.5 (▲); pH = 5.0 (○); pH = 6.0 (●), pH = 10.0 (◒)], determined as the initial rate constant (pseudo-first order) k' (min^{-1}) of the degradation of the nucleic bases. Concentration of solutions for measurement: [DNA] = 0.01%; $[Cu^{2+}] = 10^{-4}$ M; $[H_2O_2] = 8 \times 10^{-3}$ M; measured at 260 nm in 2 mm quartz cells.

If the degree of denaturation is determined at pH values between 3 and 13 by measurement of the peroxidase activity of the Cu^{2+} complexes (cf. Fig. 10) and the values k' obtained from these curves at pH = 8.5 are plotted against the pH values of the DNA solutions, one obtains a "trough-shaped" curve (Fig. 11), as was also found by *Grechko et al.* [75], who measured denaturation by the hyperchromism and the change in viscosity. It is clear from Fig. 11 that DNA suffers appreciable denaturation only in the "extreme" pH ranges. The DNA helix is very stable in solutions having pH values of 6 to 11, and the bases are thus not accessible to Cu^{2+}.

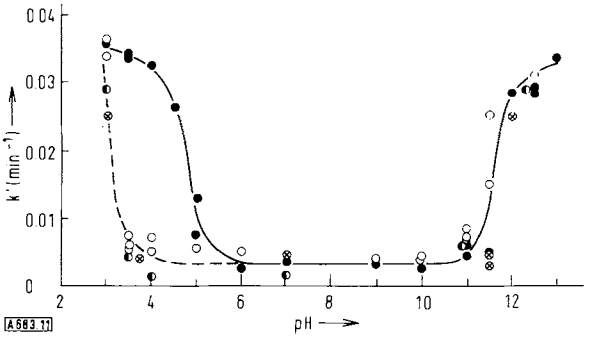

Fig. 11. Denaturation of DNA under the influence of the pH value (●) of the solution and stabilizing effect of LiCl (⊗), NaCl (○), and KCl (◐). The peroxidase activity (k') after addition of Cu^{2+} and H_2O_2 was used as a measure of denaturation, the measurements being carried out as for Figure 10. The diagram shows the k' values found from peroxidase activity curves at pH = 8.5 (cf. Fig. 10).

If the denaturation [73] is carried out in 0.05 M LiCl, NaCl, or KCl solution, the activity varies in approximately the same manner above pH $\approx$ 6. At lower pH values, however, the salts have a protective action; the increase in activity begins at a pH value about 1.5 units lower (cf. Fig. 11). The protective action of $MgCl_2$ is even more pronounced: the action of 5×10^{-4} M $MgCl_2$ is roughly equivalent to that of the monovalent salts in 0.05 M solution. This greater stabilizing action of Mg^{2+} has also been observed by *Barber* [76]. It is probably due to the greater complexing tendency of Mg^{2+} toward phosphate groups [35].

The relation between peroxidase activity and complex structure was also studied in the Cu^{2+} complex of adenosine 5′-diphosphate, in which the adenine ring is involved in the complex formation [61], and the Cu^{2+} complex of adenosine 5′-monophosphate [33], in which Cu^{2+}-adenine ring interaction (formation of a macrochelate) is also probable [33, 69, 77]. Proteins such as γ-globulin also suffer peroxidase degradation in the presence of Cu^{2+} and H_2O_2 [78]. The Cu^{2+} [54] and Ni^{2+} [79] complexes of the cyclic decapeptide polymycin B and the Ni^{2+} complexes of the linear octapeptide Val^5-angiotensin-II-Asp^1-β-amide [80] and of the tetracosapeptide β^{1-24}-corticotropin [81] are degraded similarly by H_2O_2. *Radhakrishnan* and *Meister* [82] and *Macholàn* [83] were able to show that α-amino acids in 2 *N* NaOH are primarily oxidized to keto acids by H_2O_2 in the presence of Cu^{2+}.

[73] *H. Erlenmeyer, R. Griesser, B. Prijs,* and *H. Sigel,* Biochim. biophysica Acta *157,* 637 (1968).

[74] Comparison of Figures 9 and 10 shows that more dilute DNA solutions are more susceptible to denaturation than more concentrated solutions.

5. Kinetics and Mechanism of Catalase and Peroxidase Reactions

Since the direct decomposition of H_2O_2 requires an activation energy of at least 48 kcal/mole [9], thermal decomposition under conditions such that aqueous solutions can exist proceeds only catalytically. As was mentioned earlier, in the homogeneous phase catalytically active substances are mainly ions and complexes of the transition metals [9]. The relation between structure and catalytic activity has been shown for the particular case of the Cu^{2+} complexes: it was found that the complexed Cu^{2+} must have free coordination sites available to enable it to form the ternary Cu^{2+}-peroxo ligand complexes required for the catalysis. However, this gives little information about the course of the reaction.

Glasner [84] and *Erdey* and *Inczédy* [85] studied the catalysis of the decomposition of H_2O_2 by the Cu^{2+} citrate system in the alkaline range. They found that the complex [citrate-Cu−OH]$^{3-}$ acts as the catalyst, and the decomposition rate is proportional to the photometrically measured concentration of the Cu^{2+}-peroxide complex and to $[H_2O_2]^{0.5}$ [85,86]. In the oxidation of pyrocatechol in the presence of Cu^{2+} and H_2O_2, the rate depends on the concentrations of H_2O_2, pyrocatechol, and Cu^{2+} [18]. According to the kinetic studies, the oxidizing agent in this system is probably the species $[CuOOH]^+$ (cf. also [87]).

Further information was provided by the kinetic studies described below. No buffers were added in these investigations (cf. [25]), since as weak acids or bases, these would have led to complex formation with Cu^{2+}, and would thus have complicated the system.

The decrease in the H_2O_2 concentration with time was measured [25]. The slope of the tangent to this curve for time $t = 0$ gives the initial rate $v_0 = -d[H_2O_2]/dt$ of the reaction. The logarithm of v_0 was then plotted against the logarithm of the varied concentration [X]. The points obtained in this way lay on straight lines, the slopes of which gave the relation between the rate of the catalysis and the concentration of X (cf. *e.g.* [88]).

5.1. The Cu^{2+}-Ethylenediamine-H_2O_2 System

Kinetic studies at an ionic strength of $I = 0.05$ ($NaClO_4$) and $T = 22$ °C in the pH range ≈ 6–8 showed [28] that the initial rate v_0 of disappearance of H_2O_2 is proportional to $1/[H^+]$, $[H_2O_2]$, and $[Cu^{2+}\text{-en}]^2$, the catalytic activity reaching a maximum at a ratio $[Cu^{2+}]_{total}/[en]_{total} = 1{:}1.5$ (en = ethylenediamine). These results can be summarized in eq. (6), and can be interpreted by the reactions given in equations (7a) to (7d) if it is assumed that $[Cu_2en_3]^{4+}$ and $[Cu_2en_3OOH]^{3+}$ are present only in very low concentrations [28].

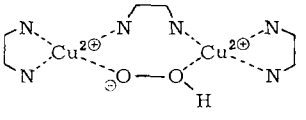
$$v_0 = -\frac{d[H_2O_2]}{dt} = k \cdot \frac{[\text{Cu-en}]^2 \cdot [H_2O_2]}{[H^+]} \cdot f([en]_{total}) \quad (6)$$

$$H_2O_2 \overset{K_1}{\rightleftharpoons} HOO^- + H^+ \quad (7a)$$

$$2\,[\text{Cu-en}]^{2+} + en \overset{K_2}{\rightleftharpoons} [Cu_2en_3]^{4+} \quad (7b)$$

$$[Cu_2en_3]^{4+} + HOO^- \overset{K_3}{\rightleftharpoons} [Cu_2en_3OOH]^{3+} \quad (7c)$$

$$[Cu_2en_3OOH]^{3+} \xrightarrow{k_1} \text{intermediate products} \xrightarrow[\text{(fast)}]{+\,H_2O_2} 2\,[\text{Cu-en}]^{2+} + en + O_2 + OH^- + H_2O \quad (7d)$$



Eq. (8) can be deduced from eq. (7) as a special case of eq. (6).

$$v_0 = -\frac{d[H_2O_2]}{dt} = k_1 \cdot [Cu_2en_3OOH] = k_1 \cdot K_1 \cdot K_2 \cdot K_3 \cdot \frac{[\text{Cu-en}]^2 \cdot [H_2O_2]}{[H^+]} \cdot [en] \quad (8)$$

The maximum catalytic activity at $[Cu^{2+}]_{total}$: $[en]_{total} = 1{:}1.5$ is reflected in eq. (7b) and (9), since

$$[Cu_2en_3]^{4+} + en \rightleftharpoons 2\,[\text{Cu-en}_2]^{2+} \quad (9)$$

the maximum formation of the postulated intermediate $[Cu_2en_3]^{4+}$ (or $[Cu_2en_3OOH]^{3+}$) is to be expected at this ratio. A binuclear structure such as *(8)* can therefore be assigned to the active complex [89]. (The

(8)

secondary reactions of the species $[Cu_2en_3OOH]^{3+}$ were discussed in [28]). Prolonged action of H_2O_2 (> 20 min) on the Cu^{2+}-en system leads to oxidation products, such as glycine, that can be detected by thin layer chromatography [28].

5.2. The Cu^{2+}-Diethylenetriamine-H_2O_2 System

Experiments [28] with the Cu^{2+} complex of the tridentate diethylenetriamine (= dien) as the catalyst (cf. Section 2.1) for the decomposition of H_2O_2 in the pH range $\approx$ 7.5 to 9.5 showed that the reaction probably proceeds differently in this case. The kinetic results are summarized in eq. (10).

$$v_0 = -d[H_2O_2]/dt = k \cdot [\text{Cu-dien}]\,[H_2O_2]/\sqrt{[H^+]} \quad (10)$$

Thin layer chromatographic investigation at pH $\approx$ 9.2 showed at least four reaction products, including iminodiacetic acid, after a reaction time of only 1 to 5 minutes. This makes the interpretation difficult.

[89] A similar structure is proposed by *M. T. Beck* for the binuclear species $[Fe_2(EDTA)O_2]$: Rec. chem. Progr. (1) *27*, 37, 53 (1966); cf. also *M. T. Beck*, *S. Görög*, and *Z. Kiss*, Acta chim. Acad. Sci. hung. *42*, 321 (1964).

5.3. The Cu^{2+}-2,2'-Bipyridyl-H_2O_2 System

Kinetic studies[90a] with the 1:1 complex of Cu^{2+} and 2,2'-bipyridyl (Bipy) showed that at pH ≈ 5.5 to 7.5 (natural ionic strength; T = 25 °C) the initial rate v_0 of decomposition of H_2O_2 is proportional to $1/[H^+]$, $[H_2O_2]^2$ (cf. Fig. 12), and $[Cu^{2+}\text{-Bipy}]$; v_0 decreases

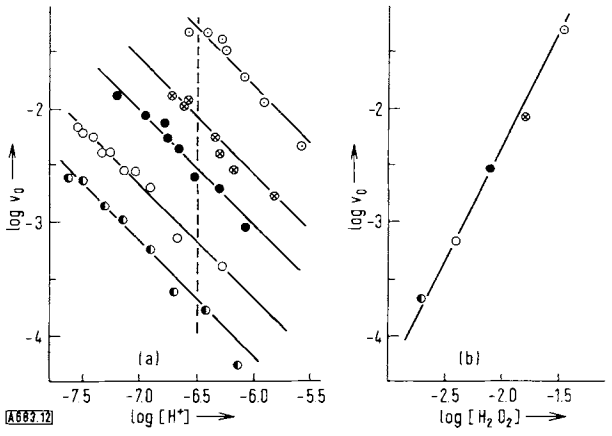

Fig. 12. (a) Catalase activity of the Cu^{2+}-2,2'-bipyridyl system ($[Cu^{2+}]$ = [Bipy] = 4 × 10^{-4} M) at various initial H_2O_2 concentrations (○ 3.2 × 10^{-2} M; ⊗ 1.6 × 10^{-2} M; ● 8 × 10^{-3} M; ○ 4 × 10^{-3} M; ◐ 2 × 10^{-3} M) as a function of the pH value, determined as the initial rate v_0 (mole l^{-1} min^{-1}) of the decomposition of H_2O_2 ($v_0 \sim [H^+]^{-1}$). (b) Evaluation of the results of (12a) at pH = 6.5 ($v_0 \sim [H_2O_2]^2$).

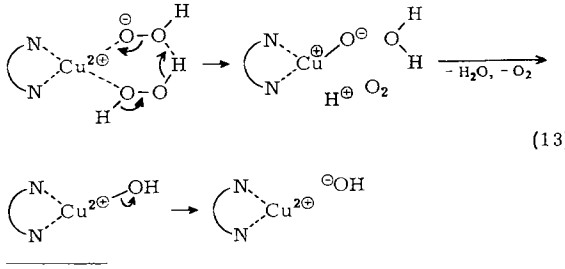
with increasing [Bipy] at constant $[Cu^{2+}]$. The investigations led to the kinetic equation (11) which can be explained by equations (12a) to (12d) if it is assumed

$$v_0 = -\frac{d[H_2O_2]}{dt} = k \cdot \frac{[\text{Cu-Bipy}]\,[H_2O_2]^2}{[H^+]} \qquad (11)$$

$$H_2O_2 \overset{K_1}{\rightleftharpoons} HOO^- + H^+ \qquad (12a)$$



$$[Cu(Bipy)]^{2+} + HOO^- \overset{K_2}{\rightleftharpoons} [Cu(Bipy)(OOH)]^+ \qquad (12b)$$

$$[Cu(Bipy)(OOH)]^+ + H_2O_2 \overset{K_3}{\rightleftharpoons} [Cu(Bipy)(OOH)(H_2O_2)]^+ \qquad (12c)$$

$$[Cu(Bipy)(OOH)(H_2O_2)]^+ \xrightarrow{k_1} [Cu(Bipy)]^{2+} + O_2 + H_2O + OH^- \qquad (12d)$$

that $[Cu(Bipy)(OOH)]^+$ and $[Cu(Bipy)(OOH)(H_2O_2)]^+$ are present only in very low concentrations. Eq. (11) can in turn be deduced from the proposed reaction course, k being replaced by $k_1 \cdot K_1 \cdot K_2 \cdot K_3$.

The active complex and its secondary reactions can be formulated *e.g.* as in eq. (13) (cf. also [91]).

[91] *L. Erdey* and *I. Inczédy*, Acta chim. Acad. Sci. hung. *7*, 93 (1955).

5.4. The Cu^{2+}-2,2'-Bipyridyl-H_2O_2-H_2N–NH_2 System

In the metal ion-catalyzed peroxidase reaction (14) of hydrazine[92] the initial rate v_0 of disappearance of

$$H_2N\text{–}NH_2 + 2\,H_2O_2 \rightarrow N_2 + 4\,H_2O \qquad (14)$$

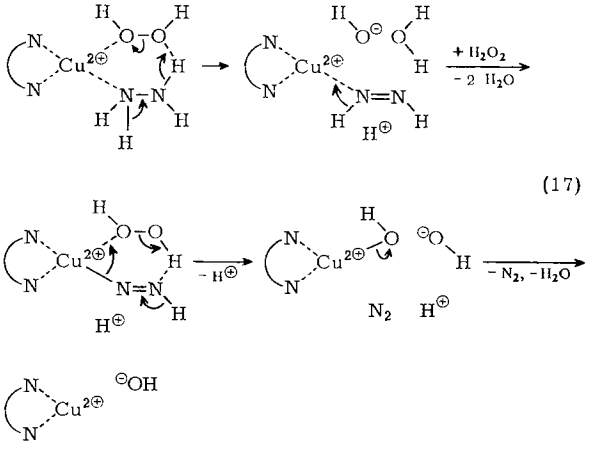
H_2O_2[90b] in the presence of Cu^{2+}-Bipy (pH range ≈ 5–6.5; natural ionic strength; T = 25 °C) is found to be given by

$$v_0 = -\frac{d[H_2O_2]}{dt} = k \cdot \frac{[\text{Cu-Bipy}]\,[H_2O_2]\,[H_2N\text{–}NH_3^+]}{[H^+]} \qquad (15)$$

Since $H_2N\text{–}NH_2$ is protonated in this range (pK_A = 8.1[90c]), the following reaction course can be formulated:

$$H_2N\text{–}NH_3^+ \overset{K_1}{\rightleftharpoons} H_2N\text{–}NH_2 + H^+ \qquad (16a)$$

$$[Cu(Bipy)]^{2+} + H_2N\text{–}NH_2 \overset{K_2}{\rightleftharpoons} [Cu(Bipy)(H_2N\text{–}NH_2)]^{2+} \qquad (16b)$$



$$[Cu(Bipy)(H_2N\text{–}NH_2)]^{2+} + H_2O_2 \overset{K_3}{\rightleftharpoons} [Cu(Bipy)(H_2N\text{–}NH_2)(H_2O_2)]^{2+} \qquad (16c)$$

$$[Cu(Bipy)(H_2N\text{–}NH_2)(H_2O_2)]^{2+} \xrightarrow{k_1} \text{intermediate products} + \text{products} \qquad (16d)$$

$$\text{intermediate products} + H_2O_2 + (\text{products}) \rightarrow [Cu(Bipy)]^{2+} + N_2 + 4\,H_2O \qquad (16e)$$

This course agrees with the kinetic findings [$k = k_1 \cdot K_1 \cdot K_2 \cdot K_3$ in (15)], provided that the equilibria (16b) and (16c) are displaced to the left.

The structure of the active complex and the subsequent reaction steps can be formulated by the scheme shown in eq. (17) [cf. also eq. (13)].

(17)

The peroxidase reaction of H_2O_2 with hydroxylamine is also catalyzed by the Cu^{2+}-Bipy (1:1) complex[90b]; the principal product is probably N_2, though N_2O, NO_2^-, and NO_3^- may also be formed[93,94]. The initial rate v_0 of disappearance of H_2O_2 at pH ≈ 4.5–6.0 (natural ionic strength; T = 25 °C) is

[92] *F. A. Cotton* and *G. Wilkinson*: Anorganische Chemie. Verlag Chemie, Weinheim/Bergstr. 1967, p. 313.

[93] Cf. [3], p. 2293; cf. also Gmelins Handbuch der Anorganischen Chemie. System-Nr. 23: "Ammonium", Verlag Chemie, Berlin 1936, p. 572.

[94] *C. P. Lloyd* and *W. F. Pickering*, J. inorg. nuclear Chem. *29*, 1907 (1967); *N. Hlasivcová, J. Novak*, and *J. Zýka*, Collect. czechoslov. chem. Commun. *32*, 4403, 4410 (1967).

proportional to $1/[H^+]$, $[H_2O_2]$, and $[Cu^{2+}\text{-Bipy}]$, but is probably independent of the concentration of NH_2OH (which is, however, consumed during the reaction). The value of v_0 decreases with increasing [Bipy]. The following expression – analogous to (11) and (15) – was found for the initial rate v_0 of disappearance of H_2O_2 in the same reaction between H_2O_2 and NH_2OH using free Cu^{2+} ion as catalyst [90b]:

$$v_0 = -\,d[H_2O_2]/dt = k[Cu^{2+}]\,[H_2O_2]\,[NH_3OH^+]/[H^+].$$

A reaction course as shown in equations (12) and (16) and an active complex as shown in equations (13) and (17) can again be formulated for this system [90a,b].

If the metal ion undergoes a valency change during the catalysis in these reactions, it must be assumed that it occurs between Cu^I and Cu^{II}, and not Cu^{III}, since on the one hand Cu^{II} is reduced to yellow copper(I) oxide by both NH_2NH_2 [95] and NH_2OH [95,96] in alkaline media, and on the other Cu^I can be reoxidized to Cu^{II} by H_2O_2 [97] (cf. also [11]).

6. Conclusion

The systems discussed here give an idea of the variety of reactions that can occur on decomposition of H_2O_2, and the examples in Section 5.3 and 5.4 also clearly show the relation between catalase and peroxidase activities. Similar active complexes, with their secondary reactions [see equations (13) and (17)], can be formulated for the systems mentioned; one of the H_2O_2 molecules can be replaced by an H donor such as H_2N-NH_2 or NH_2OH (cf. [90b]). The Cu^{2+}-2,2′-bipyridyl (1:1) complex can thus catalyze both the catalase (1) and the peroxidase (2) reactions, depending on the reaction conditions. The behavior of this catalyst is thus similar to that found with enzymes (cf. [40,42]).

A similar relation to that demonstrated in this survey between the structures of Cu^{2+} complexes and their catalytic activity is also to be expected for complexes of other metal ions.

It may be assumed that the conditions that must be satisfied by a Cu^{2+} complex if it is to be capable of catalyzing the catalase or peroxidase decomposition of H_2O_2 are also applicable to enzymes containing copper.

I am grateful to Prof. Dr. H. Erlenmeyer for his numerous suggestions. I thank Prof. Dr. S. Fallab, Dr. B. Prijs, and Dr. R. Griesser for their readiness to discuss the problems that arose. Thanks are due to the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung for support of our work.

Electrochromism and Solvatochromism

By W. Liptay[*]

The position and the intensity of electronic bands are influenced by an electric field. Pronounced changes in the position of absorption bands are mainly due to the dipole moment of the molecule in the ground state and the change in the dipole moment during the excitation process, and pronounced changes in intensity are due to the field dependence of the transition moment, which can be described by the transition polarizability. The effect of an external electric field on the optical absorption (electrochromism) of suitable molecules can be used to determine the dipole moment in the ground state, the change in dipole moment during the excitation process, the direction of the transition moment of the electronic band, and certain components of the transition polarizability tensor. These data largely determine the strong solvatochromism (solvent-dependence of the position and intensity of electronic bands), which is observed in particular with molecules having large dipole moments. Smaller contributions to solvatochromism result from dispersion interactions, which predominate in the case of nonpolar molecules. The models developed have been experimentally checked and verified by a combination of electro-optical absorption measurements (influence of an external electric field on absorption) and investigation of the solvent-dependence of the electronic bands.

1. Introduction

The absorption or emission spectrum of a substance in the vapor state can exhibit characteristic differences in the positions and intensities of the bands from the spectrum of the same substance in solution; these differences depend on the solvent [1–5]. This solvent-dependence of electronic bands is known as *solvatochromism*.

[*] Prof. Dr. W. Liptay
Institut für Physikalische Chemie der Universität
65 Mainz, Postfach 3980 (Germany)

[1] *A. Kundt*, Ann. physic. Chem. *4*, 34 (1878).

The optical properties of molecules can also be influenced by an external electric field; this phenomenon shall be called *electrochromism*. The fundamental cause of strong solvatochromism, such as is observed in polar dye molecules, is the same as that of electrochromism, *i.e.* the changes produced in the electronic bands by an electric field.

2. Electrochromism

Changes in optical absorption due to the action of an *external* electric field are basically attributable to three effects, which will be described in the following paragraphs.

2.1. Orientation Effect

As our example of a solute molecule, let us consider *p*-nitroaniline, which exhibits an intense long-wave absorption band (maximum at 28900 cm^{-1}, extinction coefficient = 13000 $lmole^{-1}\,cm^{-1}$, width at half height $\approx$ 6000 cm^{-1}) in benzene.

The absorption curve can be recorded with natural, unpolarized light or with linearly polarized light. In an ordinary solution the molecules are distributed isotropically, and both methods consequently give the same absorption curve, which can be represented as a plot of the extinction coefficient $\varepsilon^{sol}(\tilde{\nu})$ against the wave number $\tilde{\nu}$. The extinction coefficient is a measure of the intensity of the optical absorption at a given wavelength. The measure of the intensity of an absorption band is the transition moment $\boldsymbol{\mu}_{ga}^{sol}$ of the dissolved molecule, which is related to the molar decadic extinction coefficient ε^{sol} by the *integral absorption*:

$$\int_{\text{Band } (g\to a)} \frac{\varepsilon^{sol}(\tilde{\nu})}{\tilde{\nu}}\,d\tilde{\nu} = \frac{8\pi^3 N_A}{2303 \times 3hc}\left|\boldsymbol{\mu}_{ga}^{sol}\right|^2 \qquad (1)$$

The integral should be extended over the whole of the absorption band corresponding to the electronic excitation from the ground state g to a definite excited state a. N_A is Avogadro's number, h is Planck's constant, and c is the velocity of light. The transition moment $\boldsymbol{\mu}_{ga}^{sol}$ is a vector, which can also be represented by its absolute value $|\boldsymbol{\mu}_{ga}^{sol}|$ and a unit vector $\boldsymbol{m}$ in the direction of the transition moment.

$$\boldsymbol{\mu}_{ga}^{sol} = \left|\boldsymbol{\mu}_{ga}^{sol}\right| \boldsymbol{m} \qquad (2)$$

For a single molecule or for *an assembly of molecules having a definite orientation*, the extinction coefficient ε_{orient} with light polarized in the direction of the unit vector $\boldsymbol{e}$ is:

$$\varepsilon_{orient} = 3\,\varepsilon^{sol}\left|\boldsymbol{\mu}_{ga}^{sol}\right|^{-2}\left|\tilde{\boldsymbol{\mu}}_{ga}^{sol}\boldsymbol{e}\right|^2 = 3\,\varepsilon^{sol}\,(\tilde{\boldsymbol{m}}\boldsymbol{e})^2 = 3\,\varepsilon^{sol}\cos^2\gamma \qquad (3)$$

$\tilde{\boldsymbol{m}}\boldsymbol{e}$ is the scalar product of the unit vectors $\boldsymbol{m}$ and $\boldsymbol{e}$, and is therefore equal to the cosine of the angle γ between them. For an assembly of molecules having a definite orientation, the extinction coefficient depends on γ as indicated in eq. (3), *i.e.* on the polarization direction of the incident light wave. The direction $\boldsymbol{m}$ of the transition moment of molecules having a known orientation can therefore be determined from the dependence of the extinction coefficient on the polarization direction of the light. Partial orientation of molecules in solution can be achieved by means of an external electric field $\boldsymbol{F}_a$. The direction of the transition moment can be found from the change in optical absorption due to this field.

The total electric dipole moment $\boldsymbol{\mu}_g^F$ of a molecule in the electronic ground state g in the electric field is

$$\boldsymbol{\mu}_g^F = \boldsymbol{\mu}_g + \boldsymbol{\alpha}_g \boldsymbol{F}_e \qquad (4)$$

$\boldsymbol{\mu}_g$ is the permanent dipole moment, $\boldsymbol{\alpha}_g$ is the polarizability tensor, and $\boldsymbol{F}_e$ is the effective field strength at the position of the molecule. According to eq. (4), the dipole moment of a molecule is influenced by an electric field; the quantitative measure of the dependence is the polarizability $\boldsymbol{\alpha}_g$. For molecules having a sufficiently large permanent dipole moment, $|\boldsymbol{\mu}_g| \gg |\boldsymbol{\alpha}_g \boldsymbol{F}_e|$, and the polarizability term in eq. (4) may be disregarded. In this approximation the energy E_g^F of a dissolved molecule in the electronic ground state in the electric field is

$$E_g^F = E_g^{sol} - \tilde{\boldsymbol{\mu}}_g \boldsymbol{F}_e = E_g^{sol} - \mu_g F_e \cos\vartheta \qquad (5)$$

E_g^{sol} is the energy of the dissolved molecule in the ground state with no external field, and ϑ is the angle between the vectors $\boldsymbol{\mu}_g$ and $\boldsymbol{F}_e$. For molecules having a small permanent dipole moment, on the other hand, the term in eq. (4) that contains the polarizability $\boldsymbol{\alpha}_g$ is no longer negligible. Eq. (5) then also contains an additional term that depends on $\boldsymbol{\alpha}_g$. For the sake of simplicity, however, this will not be taken into account here or in the following equations.

According to eq. (5) the energy E_g^F depends on the direction of the dipole moment $\boldsymbol{\mu}_g$ in relation to the field $\boldsymbol{F}_e$. The orientation distribution of the molecules in a homogeneous field, *e.g.* between parallel electrodes, is therefore no longer isotropic. There will be more molecules with their dipole moments parallel to the field direction than with their dipole moments opposing the field direction. The distribution of the molecules over all possible orientations in the equilibrium state can be determined by means of Maxwell-Boltzmann statistics. The extinction coefficient ε_F of the dissolved molecules in the electric field is found from eq. (3) by multiplication by the Boltzmann factor $C \exp(-E_g^F/kT)$ and integration over all orientations.

[2] *S. E. Sheppard*, Rev. mod. Physics *14*, 303 (1942).

[3] *K. Dimroth*, S.-B. Ges. Beförd. ges. Naturwiss. Marburg *76*, No. 3, 3 (1953).

[4] *C. Reichardt*, Angew. Chem. *77*, 30 (1965); Angew. Chem. internat. Edit. *4*, 29 (1965).

[5] *N. Q. Chako*, J. chem. Physics *2*, 644 (1934).

The relative change in the extinction coefficient as a result of the orientation effect in an electric field is found to be

$$\left(\frac{\varepsilon_F - \varepsilon^{sol}}{\varepsilon^{sol}}\right)_{orient} = \frac{1}{30}\left(\frac{F_e}{kT}\right)^2 (3\cos^2\chi - 1)\left[3\left(\tilde{\boldsymbol{m}}\boldsymbol{\mu}_g\right)^2 - \mu_g^2\right] \quad (6)$$

χ is the angle between the direction of the external field $\boldsymbol{F}_a$ and the polarization direction $\boldsymbol{e}$ of the incident light, k is the Boltzmann constant, and T is the absolute temperature. The relative change in the extinction coefficient depends on the square of the field strength, the angle χ, and the angle γ between $\boldsymbol{\mu}_{ga}$ and $\boldsymbol{\mu}_g$, since $\tilde{\boldsymbol{m}}\boldsymbol{\mu}_g = \mu_g \cos\gamma$. For the case in which the transition moment $\boldsymbol{\mu}_{ga}$ of a band is parallel to the dipole moment $\boldsymbol{\mu}_g$ of the molecule, and the polarization direction $\boldsymbol{e}$ of the incident light is chosen parallel to the external field $\boldsymbol{F}_a$, it follows from eq. (6) that

$$\left(\frac{\varepsilon_F - \varepsilon^{sol}}{\varepsilon^{sol}}\right)_{orient} = \frac{4}{30}\left(\frac{\mu_g F_e}{kT}\right)^2 \approx 3 \times 10^{-4}$$

and for the case in which $\boldsymbol{\mu}_{ga}$ is perpendicular to $\boldsymbol{\mu}_g$ and $\boldsymbol{e}$ is again chosen parallel to $\boldsymbol{F}_a$, we obtain

$$\left(\frac{\varepsilon_F - \varepsilon^{sol}}{\varepsilon^{sol}}\right)_{orient} = -\frac{2}{30}\left(\frac{\mu_g F_e}{kT}\right)^2 \approx -1.5 \times 10^{-4}.$$

The extinction coefficient of an absorption band whose transition moment is parallel to the dipole moment increases in an electric field, while that of a band whose transition moment is perpendicular to the dipole moment decreases.

The numerical values given relate to *p*-nitroaniline (μ_g = 6.3 D); the field strength used was $F_a = 10^5$ V/cm, *i.e.* approximately the maximum external field strength that can be achieved in solution, and the temperature was T = 293 °K.

Extinction changes of the order of 10^{-4} due to the orientation effect are thus to be expected in a strong external electric field. To be able to measure the extinction changes with an error of $\approx 1\,\%$, an accuracy of about 10^{-6} is necessary; this can be achieved with a measuring set-up developed by *Labhart* [6, 7]. Measurements on the first intense band of *p*-nitroaniline showed an increase in the extinction coefficient in an electric field, *i.e.* the transition moment is parallel to the dipole moment.

The orientation effect, which leads to dichroism of the absorbing solutions in an electric field, was described by *Werner Kuhn* and his colleagues [8], and was to be used to determine the directions of the transition moments of electronic bands. However, at least two other effects are superimposed on the orientation effect. This hinders the simple determination of the directions of transition moments, but at the same time it allows the determination of additional characteristic molecular data.

2.2. Band Shift Effects

The electronic excitation of a molecule may be associated with a change in the dipole moment $\boldsymbol{\mu}_a - \boldsymbol{\mu}_g$ ($\boldsymbol{\mu}_a$ = dipole moment in the excited electronic state in question). The energy of a molecule in the ground state in an electric field is given by eq. (5). In the excited state,

$$E_a^F = E_a^{sol} - \tilde{\boldsymbol{\mu}}_a \boldsymbol{F}_e = E_a^{sol} - \mu_a F_e \cos\vartheta \quad (7)$$

E_a^{sol} is the energy of the dissolved molecule in the excited state with no external field. In the second part of eq. (7) and in the following equations, it is assumed for simplicity that the dipole moment $\boldsymbol{\mu}_a$ in the excited state is parallel to the dipole moment $\boldsymbol{\mu}_g$ in the ground state; this is in fact so in *p*-nitroaniline and, in general, in molecules having symmetry C_{2v}. For a given transition having the absorption wave number $\tilde{\nu}_a^{sol}$ in solution with no external field ($hc\tilde{\nu}_a^{sol} = E_a^{sol} - E_g^{sol}$), the absorption wave number $\tilde{\nu}_a^F$ in an electric field is given by

$$\tilde{\nu}_a^F = \frac{E_a^F - E_g^F}{hc} = \tilde{\nu}_a^{sol} - \frac{(\mu_a - \mu_g) F_e \cos\vartheta}{hc} \quad (8)$$

The change in the dipole moment ($\mu_a - \mu_g$) thus leads to a field-dependent shift of the band, which also depends on the angle ϑ between the dipole moment and the field direction, as illustrated in the term diagrams of Figure 1.

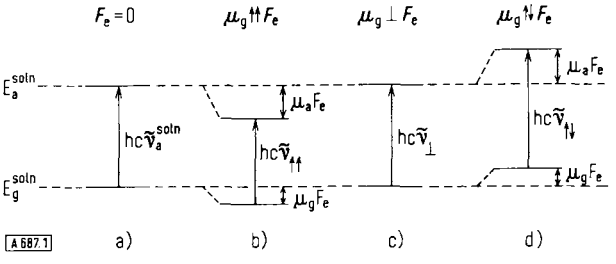

Fig. 1. Dependence of the absorption wave number on the orientation of the dipole moment with respect to the field direction ($\mu_a > \mu_g$).

Figure 1a shows the term diagram of the dissolved molecule with no external field; the difference between the two levels is proportional to $\tilde{\nu}_a^{sol}$. If the dipole moment of the dissolved molecule is oriented parallel to the field (Fig. 1b), $\cos\vartheta = 1$, so that the energy in the ground state is reduced by $\mu_g F_e$ and that in the excited state by $\mu_a F_e$. In the example considered here $\mu_a > \mu_g$; the distance between the levels E_a^F and E_g^F thus decreases, and the absorption wave number $\tilde{\nu}_{\uparrow\uparrow}$ (parallel orientation) $< \tilde{\nu}_a^{sol}$. If the dipole moment is oriented perpendicular to the field (Fig. 1c), $\cos\vartheta = 0$ and the energy levels will be the same as in the absence of an external field; thus $\tilde{\nu}_{\perp}$ (perpendicular orientation) $= \tilde{\nu}_a^{sol}$. Finally, if the dipole moment is oriented antiparallel to the field (Fig. 1d), *i.e.* $\cos\vartheta = -1$, the energy in the ground state will be increased by $\mu_g F_e$ and that in the excited state by $\mu_a F_e$; in this particular case, therefore $\tilde{\nu}_{\uparrow\downarrow}$ (antiparallel orientation) $> \tilde{\nu}_a^{sol}$.

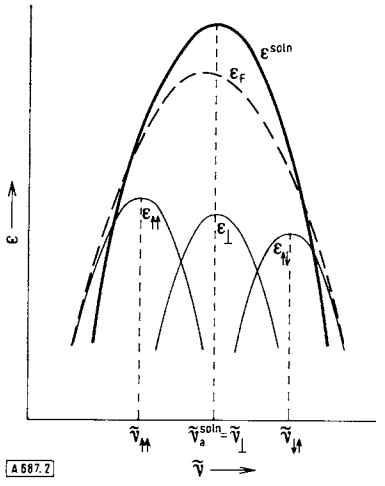

Fig. 2. Unsymmetrical broadening of an absorption band as a result of the band shift.

Figure 2 shows the absorption spectrum $\varepsilon^{sol}(\tilde{\nu})$ for the band in the absence of an external field, with a maximum at $\tilde{\nu}_a^{sol}$. For the molecules with μ_g parallel to F_e, $\tilde{\nu}_{\uparrow\uparrow} < \tilde{\nu}_a^{sol}$, *i.e.* the absorption band $\varepsilon_{\uparrow\uparrow}$ lies at lower wavenumbers. For molecules with μ_g perpendicular to F_e, the absorption band $\varepsilon_\perp$ appears at the same wavenumber as in the absence of an external field. Finally, for molecules with μ_g antiparallel to F_e, the absorption band $\varepsilon_{\uparrow\downarrow}$ is situated at higher wavenumbers than with no external field. The distribution of the molecules over the various orientations is determined by Boltzmann statistics. There are thus always more molecules with μ_g parallel to F_e than with μ_g perpendicular to F_e, and more with μ_g perpendicular to F_e than with μ_g antiparallel to F_e. The absorption component $\varepsilon_{\uparrow\uparrow}$ is therefore greater than the component $\varepsilon_\perp$, and this in turn is greater than $\varepsilon_{\uparrow\downarrow}$.

In this discussion we have picked out three possible orientations. However, the molecules are distributed monotonically over all orientations. The actual course of the absorption curve $\varepsilon_F(\tilde{\nu})$ in an external electric field is approximately as shown by the broken curve.

The band displacement effect leads to broadening of the absorption band in an external electric field. Since this broadening is unsymmetrical, the maximum of the band is also shifted. According to eq. (8) the maximum shift is $\tilde{\nu}_a^{sol} - \tilde{\nu}_{\uparrow\uparrow} = (\mu_a - \mu_g)F_e/hc$. In the example of *p*-nitroaniline $\mu_a - \mu_g \approx 8$ D, and so $\tilde{\nu}_a^{sol} - \tilde{\nu}_{\uparrow\uparrow} \approx 10$ cm^{-1}. The width of the band at half its height, on the other hand, is 6000 cm^{-1}. The shift is therefore greatly exaggerated in Figure 2, since for a 1 cm shift of the band, the width at half height should be 6 m.

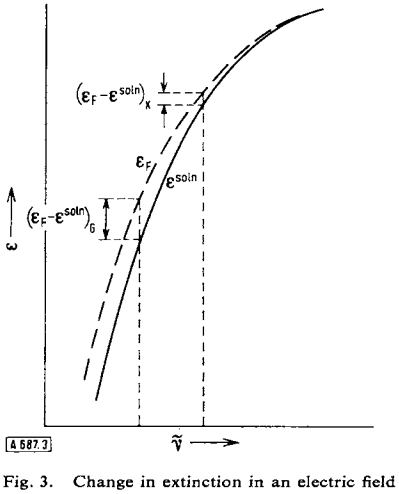

Fig. 3. Change in extinction in an electric field due to the band shift. ——: absorption curve $\varepsilon^{sol}(\tilde{\nu})$ of the dissolved molecule with no external field, - - -: $\varepsilon_F(\tilde{\nu})$ in a field.
$(\varepsilon_F - \varepsilon^{sol})_G$ represents a large change in extinction in the region of a steep rise, and $(\varepsilon_F - \varepsilon^{sol})_K$ is a small change in the region of a gradual rise.

It can be seen that the shift of the maxima of the broad absorption bands of molecules due to an external electric field, unlike the normal Stark effect in sharp spectral lines, cannot be observed directly. In the case of a constant, very small shift, the field-dependent extinction at a given wave number depends on the slope of the band, and increases with increasing steepness of the band (Fig. 3). The change in extinction due to the band shift can therefore be satisfactorily measured on steep sides of the absorption band.

To calculate the relative change in the extinction coefficient in the external electric field as a result of the band shift, it is necessary to start with equations (3) and (8), and again to average over all orientations. This gives

$$\left(\frac{\varepsilon_F - E^{sol}}{\varepsilon^{sol}}\right)_{BS} = \left(\frac{d \ln \varepsilon^{sol}/\tilde{\nu}}{d\tilde{\nu}}\right)_{\tilde{\nu}_a} \frac{F_e^2}{15\, hc\, kT} \left\{5\tilde{\mu}_g(\mu_a - \mu_g) + (3\cos^2\chi - 1)\left[3(\tilde{m}\mu_g)\tilde{m}(\mu_a - \mu_g) - \tilde{\mu}_g(\mu_a - \mu_g)\right]\right\} \quad (9)$$

The slope of the band $(d \ln(\varepsilon^{sol}/\tilde{\nu})/d\tilde{\nu})$ must be taken at the absorption wave number $\tilde{\nu}_a$ in question; since the slope is a function of $\tilde{\nu}$, the relative extinction change also depends on the wave number. The relative extinction change also varies with the square of the field strength, the angle χ, the dipole moment in the ground state, the change in the dipole moment, and the direction of the dipole moment with respect to the transition moment. In favorable cases therefore the change in the dipole moment $\mu_a - \mu_g$ and hence the dipole moment μ_a of the molecule in the excited state can be determined from the experimental quantity corresponding to the band shift. In the example of *p*-nitroaniline

$$\left(\frac{\varepsilon_F - \varepsilon^{sol}}{\varepsilon^{sol}}\right)_{BS} \approx \left(\frac{d \ln \varepsilon^{sol}/\tilde{\nu}}{d\tilde{\nu}}\right)_{\tilde{\nu}_a} \times 5$$

For a steep flank of an absorption band, the derivative of $\ln(\varepsilon^{sol}/\tilde{\nu})$ with respect to $\tilde{\nu}$ may be about 10^{-3}, so that $[(\varepsilon_F - \varepsilon^{sol})/\varepsilon^{sol}]_{BS}$ may be about 5×10^{-3}.

In the case of steep bands, the relative change in the extinction coefficient caused by the band shift may be more than ten times as great as that due to the orientation effect.

2.3. Direct Field-Dependence of the Transition Moment

If the wave function of a molecule is known, the dipole moment can be calculated by an integration process; for example the dipole moment μ_g^F of the molecule in the ground state g in an electric field is

$$\mu_g^F = \int \psi_g^{F*} \sum_i e_i r_i \psi_g^F \, d\tau \quad (10)$$

$\boldsymbol{r}_i$ are the coordinates of the positions of the nuclei and electrons of the molecule, their charges being e_i, and ψ_g^F is the wave function in the electric field. The integration must be carried out over the coordinates of all the particles over the entire space.

Similarly, the electric dipole transition moment $\boldsymbol{\mu}_{ga}^F$ for a transition between the ground state g and an excited state a in an electric field is

$$\boldsymbol{\mu}_{ga}^F = \int \psi_g^{F*} \sum_i e_i \boldsymbol{r}_i \psi_a^F \, d\tau \tag{11}$$

Thus

$$\boldsymbol{\mu}_g^F = \boldsymbol{\mu}_{gg}^F \tag{12}$$

To find $\boldsymbol{\mu}_g^F$, it is formally only necessary to replace the index a in eq. (11) by g, *i.e.* to use the wave function ψ_g^F of the ground state instead of the wave function ψ_a^F of the excited electronic state.

The dipole moment $\boldsymbol{\mu}_g^F$ in an electric field can also be expressed with the aid of the polarizability tensor $\boldsymbol{\alpha}_g$ by eq. (4). A completely analogous expression can also be given for the transition moment $\boldsymbol{\mu}_{ga}^F$ in an electric field:

$$\boldsymbol{\mu}_{ga}^F = \boldsymbol{\mu}_{ga} + \boldsymbol{\alpha}_{ga} \boldsymbol{F}_e \tag{13}$$

$\boldsymbol{\mu}_{ga}$ is the transition moment of a molecule in the absence of an external field; it corresponds to the permanent dipole moment, and will therefore be referred to as the permanent transition moment. The tensor $\boldsymbol{\alpha}_{ga}$ is a quantitative measure of the effect of an electric field on the transition moment. Owing to the analogy with polarizability, $\boldsymbol{\alpha}_{ga}$ will be referred to as the *transition polarizability* tensor. According to a quantum-mechanical perturbation calculation, its components $(\alpha_{ga})_{ij}$ are given by the following equation [9]:

$$(\alpha_{ga})_{ij} = \sum_{r \neq g} \frac{(\mu_{ra})_i (\mu_{gr})_j}{E_r - E_g} + \sum_{r \neq a} \frac{(\mu_{gr})_i (\mu_{ra})_j}{E_r - E_a} \tag{14}$$

$(\mu_{rg})_i$ and $(\mu_{ra})_i$ are the i-th components of the permanent transition moments between the states r and g and between r and a; E_g, E_a, and E_r are the energies of the states. The components of the polarizability tensor $\boldsymbol{\alpha}_g$ of a molecule can be expressed by an equation similar to eq. (14), since

$$\boldsymbol{\alpha}_g = \boldsymbol{\alpha}_{gg} \tag{15}$$

i.e. to determine the components $(\alpha_g)_{ij}$ of the polarizability, it is formally necessary only to replace the indices a by g. According to equations (14) and (15) the polarizability tensor is symmetrical: $(\alpha_g)_{ij} = (\alpha_g)_{ji}$. In general, for the transition polarizability tensor, $(\alpha_{ga})_{ij} \neq (\alpha_{ga})_{ji}$, *i.e.* the tensor is not symmetrical [9].

According to eq. (1), the intensity of an absorption band is determined by the transition moment. The transition moment can be influenced by an electric field [eq. (13)], with the result that the intensity of the band also depends on the field. For an electronic excitation with a sufficiently large permanent transition moment $\boldsymbol{\mu}_{ga}$, $|\boldsymbol{\mu}_{ga}| \gg |\boldsymbol{\alpha}_{ga}\boldsymbol{F}_e|$, and the transition polarizability tensor in eq. (13) may be neglected. In excitations of this nature, the intensity of the absorption band is practically unaffected by an electric field, as is frequently found *e.g.* in the case of *p*-nitroaniline. However, there are also electronic excitations for which the permanent transition moment is at least approximately zero, though the excitation is not forbidden by symmetry, *e.g.* in fluorenone [10]. In cases of this type the effect of an electric field on the absorption is easy to determine, even if the tensor components of $\boldsymbol{\alpha}_{ga}$ are very small. Finally, some dyes exhibit electronic excitations for which the tensor components of $\boldsymbol{\alpha}_{ga}$ are so large that the intensity is strongly dependent on the field, despite the high value of the permanent transition moment $\boldsymbol{\mu}_{ga}$ [9, 11].

To calculate the relative change in the extinction coefficient due to the direct field-dependence of the transition moment, it is necessary to start with equations (3) and (13) and average over all orientations; this gives (neglecting any change in dipole moment on excitation):

$$\left(\frac{\varepsilon_F - \varepsilon^{sol}}{\varepsilon^{sol}}\right)_{Ft} = \frac{F_e^2}{3|\mu_{ga}^{sol}|^2} \sum_{i=1}^{3} \sum_{j=1}^{3} \left\{ \left\{ \frac{2}{kT} (\alpha_{ag})_{ji} (\mu_g)_i (\mu_{ga}^{sol})_j + (\alpha_{ga})_{ij} (\alpha_{ag})_{ij} - \frac{(3\cos^2\chi - 1)}{10} \left[\frac{2}{kT} \left\{ 2 (\alpha_{ag})_{ji} (\mu_g)_i (\mu_{ga}^{sol})_j - 3 (\alpha_{ag})_{ij} (\mu_g)_i (\mu_{ga}^{sol})_j - 3 (\alpha_{ag})_{jj} (\mu_{ga}^{sol})_i (\mu_g)_i \right\} + 2 (\alpha_{ga})_{ij} (\alpha_{ag})_{ij} - 3 (\alpha_{ga})_{ii} (\alpha_{ag})_{jj} - 3 (\alpha_{ga})_{ij} (\alpha_{ag})_{ji} \right] \right\} \right\} \tag{16}$$

The relative change in the extinction thus also depends on the square of the field strength, the angle χ, the dipole moment $\boldsymbol{\mu}_g$, and the transition moment $\boldsymbol{\mu}_{ga}^{sol}$ of the dissolved molecule, as well as on the tensor $\boldsymbol{\alpha}_{ga}$ of the transition polarizability. In all the molecules studied so far, the terms of the type $(\alpha_{ga})_{ij}(\alpha_{ag})_{kl}$ are negligible in relation to the other terms.

The relative change in the extinction coefficient due to the field-dependence of the transition moment may be of the same order of magnitude as the changes due to the orientation effect and the band shift.

2.4. Electro-Optical Absorption Measurements

The measurable extinction change in the absorption spectrum of a molecule in an external electric field results from the superposition of three effects, *i.e.* the orientation effect, the band shift, and the direct effect of an electric field on the transition moment. A complete theoretical treatment leads to relations that

[9] *W. Liptay, B. Dumbacher*, and *H. Weisenberger*, Z. Naturforsch. *23a*, 1601 (1968).

[10] *W. Liptay, H. Weisenberger, F. Tiemann, W. Eberlein*, and *G. Konopka*, Z. Naturforsch. *23a*, 377 (1968).

[11] *W. Liptay, H.-J. Schlosser, B. Dumbacher*, and *S. Hünig*, Z. Naturforsch. *23a*, 1613 (1968).

permit the evaluation of experimental data [12–15]. To obtain relations of this type it is necessary to calculate the effective electric field $\boldsymbol{F}_e$ at the position of the dissolved molecule with the aid of the external electric field $\boldsymbol{F}_a$, which can be determined in the case of parallel electrodes from the applied voltage U and the distance d between the electrodes by means of the expression $F_a = U/d$. The effective field $\boldsymbol{F}_e$ in equations (5) and (6) can be expressed as the sum of a cavity field $\boldsymbol{F}_h$ and a reaction field $\boldsymbol{F}_{Rg}$ [16–17]:

$$\boldsymbol{F}_e = \boldsymbol{F}_h + \boldsymbol{F}_{Rg} \tag{17}$$

$\boldsymbol{F}_h$ and $\boldsymbol{F}_{Rg}$ can be represented as functions of $\boldsymbol{F}_a$ by means of approximations. In the approximations used, the solvent is regarded as a homogeneous dielectric continuum with the dissolved molecule situated in a cavity. In the simplest approximation the cavity is regarded as a sphere [14, 15]; however, comparison of the electro-optical absorption measurements with dielectric measurements showed that this approximation is unsatisfactory in the case of molecules whose shapes are very different from spheres, and that it is necessary to use ellipsoid-shaped cavities [9, 10]. In the calculation of the effective field $\boldsymbol{F}_e$ in eq. (7) and in the following equations, it must be borne in mind that a change in the dipole moment on excitation is associated with a change in the reaction field, *i.e.* that the reaction field of a molecule in the electronically excited state may be different from that in the ground state. According to the Franck-Condon principle, electronic excitation leads to a change only in the electronic wave function, whereas the positions of the nuclei in the Franck-Condon excited state are, to a good approximation, the same as in the ground state. To calculate the reaction field, therefore, the polarization of the solvent must be separated into electron displacement polarization and atomic and orientation polarization, only the first of these being different in the Franck-Condon excited state from that in the ground state. Finally, the anisotropic polarizability of the dissolved molecules and its change on excitation can also be taken into account. Detailed calculation shows that the change in the relative extinction coefficient in an external field for an isolated absorption band which is not superimposed by another electronic band can be represented in the following form [10, 14, 15].

$$\frac{\varepsilon_F - \varepsilon^{sol}}{\varepsilon^{sol}} = L'_\chi(\tilde{\nu}_a) F_a^2 \tag{18}$$

The quantity L'_χ, which was given explicitly in earlier publications [10, 14, 15], depends on the absorption wavenumber $\tilde{\nu}_a$, the angle χ between the polarization direction of the light and the external field direction, the dipole moment μ_g and change in dipole moment $\mu_a - \mu_g$, the transition moment μ_{ga}, and the transition polarizability tensor α_{ga}. The polarizability tensor of the dissolved molecule and its change on excitation often play a minor role. For suitable molecules, particularly molecules having (approximately) symmetry C_{2v}, the dependence of $L'\chi(\tilde{\nu}_a)$ on the wave number and on the angle χ allows the evaluation of the results of electro-optical absorption measurements and the determination of the direction of the transition moment, the dipole moments μ_g and μ_a, and certain components of the tensor α_{ga}. The dipole moment in the ground state can naturally also be obtained from dielectric measurements; comparison of the results of the two methods provides a check in particular on the electro-optical absorption measurements and the models on which they are based (cf. Table 1).

So far we have been discussing the effect of an external electric field on the optical absorption. The effect of an external electric field on emission can be treated in a similar manner [27], except that the final lifetime of a molecule in the excited state has also to be taken into account in this case, so that the excited state need not be identical with the equilibrium state.

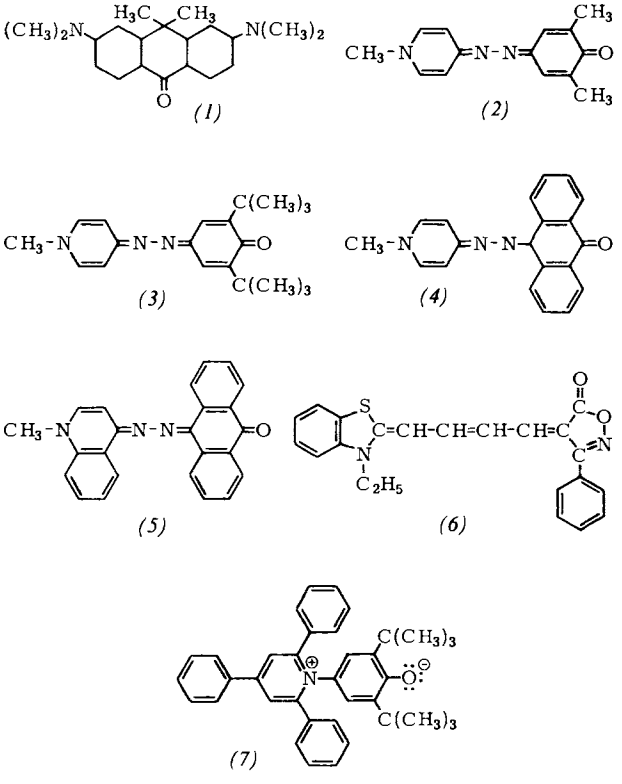

Table 1 gives the dipole moments and the directions of the transition moments that have been found so far from electro-optical absorption and emission measurements. The dipole moments μ_g, the changes in dipole moment $\mu_a - \mu_g$ on excitation, and the components $(\alpha_{ga})_{zz}$ or $(\alpha_{ga})_{yz}$ and $(\alpha_{ga})_{zy}$ of the transition polarizability are responsible for the strong solvatochromism of polar molecules (see Section 3). These quantities allow a quantitative treatment of the problem.

3. Solvatochromism

It was shown in Section 2 that the position and intensity of an electronic band can be influenced by an electric field. In any solution, molecules having a permanent dipole moment are located in an electric field, the reaction field of the dissolved molecule, as illustrated in Figure 4. The reaction field acts on the dissolved molecule in the same way as an external electric field, *i.e.* it is capable of causing a band shift and a change in the transition moment, and hence in the intensity of the band.

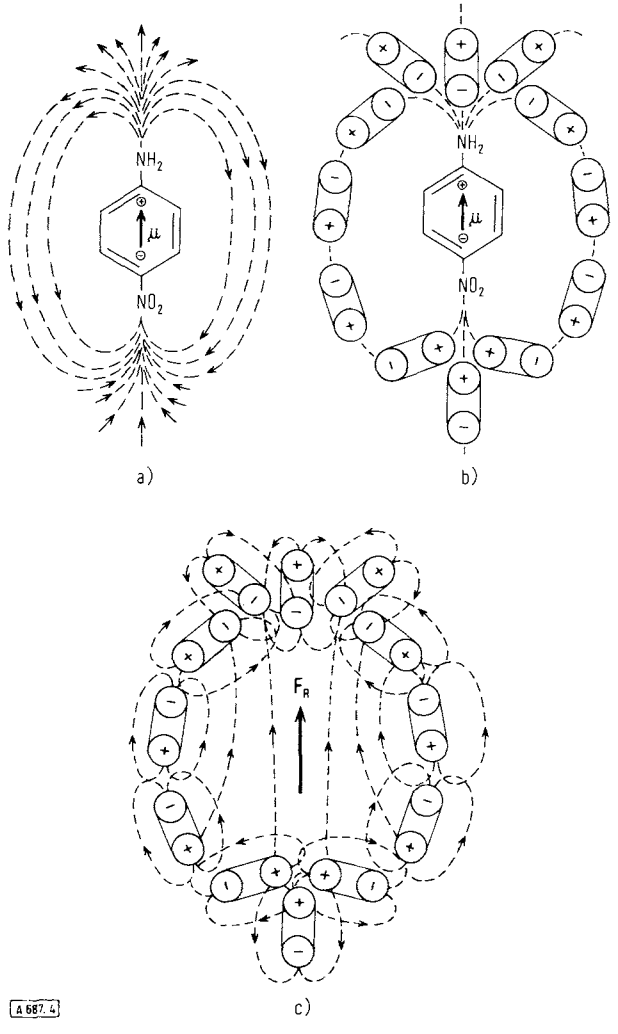

Fig. 4. Reaction field of a dissolved molecule:

(a) A molecule in the gas state with a dipole moment μ, *e.g.* *p*-nitroaniline, causes an electric dipole field in its environment, the field lines of which are shown broken.

(b) In solution, this dipole field acts on the surrounding solvent molecules. If the solvent molecules have a permanent dipole moment, they orient themselves with their dipole moment as nearly as possible parallel to the field lines. The orientation is opposed by thermal motion, so that only some of the solvent molecules are ideally oriented at any time. If the solvent molecules have no permanent dipole moment, a dipole moment is induced in the dipole field of the dissolved molecule. In the case of solvent molecules having a permanent dipole moment, the polarizability effect is superimposed on the orientation effect.

(c) If the electronic and nuclear configurations of all the solvent molecules are imagined to be frozen and the dissolved molecule then removed, a cavity surrounded by solvent molecules remains. Each of these solvent molecules has a dipole moment, which is made up from the permanent and the induced moment. Each of the dipole moments of the solvent molecules produces a dipole field in its environment, the field lines of which are shown broken. In the cavity, at the position of the dissolved molecule, the dipole fields of the solvent molecules superimpose and produce a field having the same direction as the dipole moment of the original dissolved molecule; this field is known as the reaction field $\boldsymbol{F}_R$. If the dissolved molecule is now imagined to be back in the cavity, it is clearly in an electric field.

It can be seen in Figure 4 that the reaction field depends on the nature and arrangement of the surrounding solvent molecules. The accurate determination of the (mean) reaction field, which is possible in principle by averaging methods, presents difficulties that have not yet been overcome. Useful approximations have however been developed. In the simplest approximation the solvent is regarded as a homogeneous isotropic dielectric continuum having a dielectric constant ε_{DC}. The dissolved molecules are assumed to be accommodated in this continuum in spherical cavities having a radius a, or, in a refined version, in ellipsoid-shaped cavities [9]. The dipole moment is represented by a point dipole located in the center of the spherical cavity. In this approximation, the reaction field $\boldsymbol{F}_{Rg}$ of a dissolved molecule in the electronic ground state [16,17] is given by

$$\boldsymbol{F}_{Rg} = \frac{2\,(\varepsilon_{DC}-1)}{a^3\,(2\varepsilon_{DC}+1)}\,\boldsymbol{\mu}_g' \qquad (19)$$

$\boldsymbol{\mu}_g'$ is the total dipole moment (permanent plus induced moment) of the dissolved molecule.

The changes in the position and intensity of an electronic band depend not only on the reaction field in the ground state [eq. (19)], but also on the reaction field in the excited electronic state. When the Franck-Condon principle for optical excitation processes is taken into account, the expressions for the reaction field in the excited state contain not only terms similar to that in eq. (19), but also other similar terms that depend on the refractive index n of the solution. The effect of the field on the position and intensity of electronic bands is therefore determined by the dielectric constant and the refractive index of the solution in this approximation. The effect of the reaction field is the main cause of strong solvatochromism, which is observed in particular with molecules having large dipole moments, and hence strong reaction fields. The effect of the reaction field on the electronic bands is much greater than that of an external field, for two reasons.

The first is the much greater strength of the reaction field. A molecule having an interaction radius $a = 4 \times 10^{-8}$ cm and a dipole moment of only $\mu_g' = 1$ D, in a nonpolar solvent having $\varepsilon_{DC} = 2$, has a reaction field $F_{Rg} \approx 2 \times 10^6$ V/cm; in a polar solvent with $\varepsilon_{DC} = 30$, $F_{Rg} \approx 4.5 \times 10^6$ V/cm. The maximum field strength that can be achieved with an external field, on the other hand, is not much greater than 10^5 V/cm.

Secondly, the reaction field (on average) is always parallel to the dipole moment of the dissolved molecule. In an external field on the other hand, the molecules are distributed over all possible orientations with respect to the field; at the maximum possible field strength the isotropic orientation distribution is only slightly disturbed, *i.e.* there are relatively few

more molecules with their dipole moments parallel to the field than with their dipole moments perpendicular or antiparallel to it. The contributions of the individual molecules to the change in the positions and intensities of the bands due to the external electric field thus largely cancel one another out in the average, so that the observable effects are small.

3.1. Solvent-Dependence of the Position of an Electronic Band

The solvent-dependence of the positions of electronic bands was discussed in detail in an earlier publication [28]. For a molecule having a permanent dipole moment $|\boldsymbol{\mu}_g| = \mu_{gz}$ in the electronic ground state (in the z direction) and a moment $|\boldsymbol{\mu}_a| = \mu_{az}$ parallel to it in the excited state, the solvent-dependence of the wave number $\tilde{\nu}_a^{sol}$ of the absorption maximum is given to a good approximation by the following equation

$$\tilde{\nu}_a^{sol} = \tilde{\nu}_a^{o} - \frac{(\mu_{az}-\mu_{gz})\,(F_{RM})_z}{hc} - \frac{2\,(n^2-1)}{a^3\,(2n^2+1)}\,D \qquad (20)$$

$\tilde{\nu}_a^{o}$ is the wave number of the absorption maximum in the free molecule (gas state). Eq. (20) corresponds to eq. (8), except that it also contains a term that depends on a quantity D. This term describes the solvent-dependence of the position of the absorption band due to the dispersion interactions between the dissolved molecule and the surrounding solvent molecules. For the low electronic excitations $D > 0$, so that the dispersion interactions always cause a red shift with increasing refractive index of the solution. No reliable information is available for higher excitations. The effective electric field $\boldsymbol{F}_{RM}$ in eq. (20) is the mean of the reaction fields of the dissolved molecule in the ground state and in the Franck-Condon excited state [28], *i.e.* the primary state after the excitation process. For the particular case in question the z component of $\boldsymbol{F}_{RM}$ is:

$$(F_{RM})_z = \frac{1}{a^3}\left[\frac{\varepsilon_{DC}-1}{2\,\varepsilon_{DC}+1}\left(1-\frac{2\,\alpha_{gz}(\varepsilon_{DC}-1)}{a^3\,(2\,\varepsilon_{DC}+1)}\right)^{-1} 2\mu_{gz} + \frac{n^2-1}{2\,n^2+1}\left(1-\frac{2\,\alpha_{gz}\,(n^2-1)}{a^3\,(2n^2+1)}\right)^{-1}(\mu_{az}-\mu_{gz})\right] \qquad (21)$$

ε_{DK} is the dielectric constant of the solution and n is its refractive index. α_{gz} is the z component of the polarizability tensor $\boldsymbol{\alpha}_g$ of the molecule in the ground state, transformed to principal axes. Any polarizability change on excitation is disregarded. Relations for cases in which $\boldsymbol{\mu}_g$ is not parallel to $\boldsymbol{\mu}_a$ and in which the polarizability change on excitation is taken into account are given in [28].

The solvent-dependence of the position of an electronic band can, according to eq. (20) with the aid of eq. (21), be represented by a function that depends on the properties of the dissolved molecule (μ_{gz}, μ_{az}, α_{gz}, a, D) and on the dielectric constant and the refractive index of the solvent. Since there is no correlation between the dielectric constant and the refractive index of polar solvents, at least two parameters that depend on the solvent are necessary for the general description of the solvent-dependence of electronic bands. A general description involving only one solvent-dependent parameter such as has repeatedly been sought [4], is fundamentally impossible. In the case of a dissolved nonpolar molecule, however, $\boldsymbol{F}_{RM}$ disappears, leaving only the term containing the refractive index n in eq. (20), so that the solvent-dependence of the wave number can now be described by a single parameter (*e.g.* by n). For molecules having a large dipole moment in the ground state and a large change in moment, the solvent-dependence due to the term in n is small, and the effect of the solvent on the wave number approximately depends only on ε_{DC}.

The dipole moments in the ground and excited states can be determined for suitable molecules from electro-optical absorption and dielectric measurements. The polarizability α_{gz} may be determined independently or estimated, and the quantity D may be estimated [28] or determined by matching of the experimental data. Using an estimated value a and the values ε_{DC} and n, it is then possible to calculate $[a^3(F_{RM})_z(\mu_{az}-\mu_{gz}) + 2\,hcD(n^2-1)/(2\,n^2+1)]$ *via* eq. (21) for various solvents. A plot of $\tilde{\nu}_a^{sol}$ as a function of this expression should give a straight line, from which $\tilde{\nu}_a^{o}$ and a can be obtained. This value a is then used to repeat the evaluation until a used for the calculation of the bracketed expression in eq. (21) agrees, within the limits of accuracy, with the value of a obtained as the result.

Corresponding experimental studies were carried out on *trans*-4-dimethylamino-4′-nitrostilbene [28], fluorenone [10], and some dyes [11]; the results satisfied the linear relation with reasonable accuracy, and so confirmed the above models. The solvent-dependence of the wave number of the absorption maxima of electronic bands can be described, both for an increase and for a decrease in the dipole moment on excitation, by eq. (20) with the aid of eq. (21). The solvent-dependence of the position of an absorption band is determined mainly by the dipole moment of the dissolved molecule in the ground state and the change in the dipole moment on excitation. An increase in the dipole moment on electronic excitation leads to a red shift, and a decrease in the dipole moment to a blue shift of the band with increasing dielectric constant of the solution. This change in position, which depends on the dielectric constant, is superimposed on a shift that depends on the refractive index. The latter shift is due to dispersion interactions and the change in the dipole moment on excitation, and, at least at low electronic excitations, always leads to a red shift with increasing refractive index of the solution. In the case of apolar molecules with $\mu_g = \mu_a = 0$ the reaction field $\boldsymbol{F}_{RM} = 0$ and the second term in eq. (20) disappears. The solvent-dependence is then mainly due to the dispersion interactions. These interactions can cause a strong red shift on transfer of the molecule from the

[28] *W. Liptay*, Z. Naturforsch. *20a*, 1441 (1965).

gas state into solution, but because of the smaller range of variation of the refractive index of the solvent, only a weak red shift is generally observed with increasing refractive index of the solvent, *e.g.* in the case of aromatic hydrocarbons [28]. For molecules having only a small dipole moment in the ground state and a large change in dipole moment on excitation, the reaction field $\boldsymbol{F}_{RM}$ may be largely determined by the term in eq. (21) that depends on the refractive index. This will also lead to a strong red shift of the absorption band on transfer of the molecule from the gas state into solution, and a weaker red shift with increasing refractive index of the solvent, as is found *e.g.* in the case of electron donor-acceptor complexes.

3.2. Solvent-Dependence of the Intensity of Electronic Bands

In addition to the solvent-dependence of the extinction coefficient, many molecules give a change in the width of the absorption band, with the result that the total intensity varies only slightly with the solvent [29,30]. Electro-optical absorption measurements have sometimes [9,10] shown a considerable field-dependence of the transition moment. Owing to the solvent-dependence of the reaction field, the intensities of the absorption bands were also expected to depend on the solvent in these cases, and this was in fact confirmed experimentally [10,11]. A detailed treatment of the problem [31] showed that the intensity of an optical absorption can be described with the aid of the integral absorption (see eq. (1)); the solvent dependence of the integral absorption is due to the solvent-dependence of the transition moment:

$$\overset{sol}{ga} = \boldsymbol{\mu}_{ga} + \boldsymbol{\alpha}_{ga}\,\boldsymbol{F}_{RM} + \frac{2\,(n^2-1)}{a^3\,(2\,n^2+1)}\,\boldsymbol{W}_{ga} \qquad (22)$$

$\boldsymbol{\mu}_{ga}$ and $\boldsymbol{\mu}_{ga}^{sol}$ are the transition moments in the free molecule (permanent transition moment) and in the dissolved molecule respectively; $\boldsymbol{\alpha}_{ga}$ is the transition polarizability tensor, the components of which are given by eq. (14). Eq. (22) corresponds closely to eq. (13), except that it also contains a vector $\boldsymbol{W}_{ga}$, which may be interpreted as the effect of the dispersion interaction on the transition moment. The effective electric field $\boldsymbol{F}_{RM}$ is again the mean of the reaction fields in the ground state and in the Franck-Condon excited state. For the special case of $\boldsymbol{\mu}_g$ parallel to $\boldsymbol{\mu}_a$ (in the z direction), $|\boldsymbol{F}_{RM}| = (F_{RM})_z$ is represented by eq. (21). The vector $\boldsymbol{W}_{ga}$ should generally be very small, so that for molecules having a large reaction field $\boldsymbol{F}_{RM}$, *i.e.* for molecules having a large dipole moment, the last term in eq. (22) may be ignored; for molecules having no dipole moment or having a small dipole moment, $\boldsymbol{\mu}_a^{sol}$ and hence also the integral absorption should depend only to a small extent on the solvent [29,30]. For molecules having a dipole moment, the integral absorption depends on the reaction field, which can be calculated for various solvents from the data obtained in electro-optical and dielectric measurements (cf. Section 3.1). The theoretical models have been checked and verified experimentally by means of suitable plots [10,11]. It was found that some molecules exhibited an increase and others a decrease in the integral absorption with increasing field strength, and hence with increasing reaction field [11]. The magnitude of the increase or decrease in the integral absorption is determined according to eq. (22) by the transition polarizability tensor $\boldsymbol{\alpha}_{ga}$. The behavior of a given electronic band cannot generally be predicted from other simple molecular quantities. Electronic excitations associated with a very large increase in the dipole moment may be expected to show an increase in the integral absorption, while excitations associated with a very large decrease in the dipole moment may be expected to show a decrease in the integral absorption with increasing field strength. However, this single rule is not generally valid [11].

The possibility of simple observation of the solvent-dependence of the integral absorption of an electronic band depends not only on the transition polarizability $\boldsymbol{\alpha}_{ga}$ (or more precisely the product $\boldsymbol{\alpha}_{ga}\boldsymbol{F}_{RM}$ in eq. (22)) but also on the permanent transition moment $\boldsymbol{\mu}_{ga}$. If $\boldsymbol{\mu}_{ga}$ is large, the solvent-dependence of the integral absorption can be observed only if the components of the tensor $\boldsymbol{\alpha}_{ga}$ are sufficiently large. If on the other hand $\boldsymbol{\mu}_{ga}$ is very small or zero, the solvent-dependence of the intensity of the absorption band is clear even when the components of $\boldsymbol{\alpha}_{ga}$ are small.

Particularly interesting relations are found in fluorenone [10]. The direction of the dipole moment will be referred to as the z axis. Solutions of this molecule give an absorption band at about 31000 cm^{-1} with a transition moment direction in the molecular plane parallel to the y axis. The maximum extinction coefficient ε_{max} and the integral absorption of this band are strongly solvent-dependent [dimethylformamide (ε_{DC} = 36.7): ε_{max} = 1320; ether (ε_{DC} = 4.4): ε_{max} = 685; heptane (ε_{DC} = 1.97): ε_{max} = 410]. The absorption band can no longer be observed in the gas state, and ε_{max} is certainly less than 50. Fluorenone thus has an absorption band whose intensity is almost zero in the free molecule. The intensity recorded in solution is due to the perturbation of the molecule by its reaction field. The permanent transition moment, and hence the integral absorption of the band in the free molecule, is not zero on symmetry grounds, but disappears purely by chance. The appearance of a field-induced absorption band with a transition moment in the y direction as a result of a reaction field in the z direction will be explained in more detail.

In the molecular orbital (MO) scheme the absorption band in question can be interpreted, on the basis of the experimentally observed transition moment directions and SCF–MO approximation calculations, as resulting from the excitation $\varphi_5 \rightarrow \varphi_8$ of an electron from the fifth (filled) π-MO φ_5 into the eighth (empty) π-MO φ_8. φ_5 belongs to the irreducible representation A_2 of the point group C_{2v}, and φ_8 to the representation B_1; the atomic orbital coefficients c_{5p} and c_{8p} of the MOs in the LCAO approximations are illustrated in Figures 5a and 5b. In the simple MO approximation the transition moment in question $\boldsymbol{\mu}_{ga} = e\sqrt{2}\int \varphi_5\varphi_8\,\boldsymbol{r}\,d\tau$. In the LCAO–MO approximation the equation simplifies further, the integral reducing to a sum: $\boldsymbol{\mu}_{ga} = e\sqrt{2}\sum_{p=1}^{14} c_{5p}c_{8p}\boldsymbol{r}_p$,

[29] *R. S. Mulliken* and *C. A. Rieke*, Rep. Progr. Physics *8*, 231 (1941).

[31] *W. Liptay*, Z. Naturforsch. *21a*, 1605 (1966).

where r_p are the position vectors of the atoms p. To obtain the transition moment μ_{ga}, it is necessary to form the products $c_{5p}c_{8p}r_p$ and carry out the summation over all the atoms (p = 1 to 14). Similarly the components of the transition moment $(\mu_{ga})_x$, $(\mu_{ga})_y$, and $(\mu_{ga})_z$ in the directions of the three coordinates are obtained on replacement of the position vectors r_p by their components x_p, y_p, and z_p.

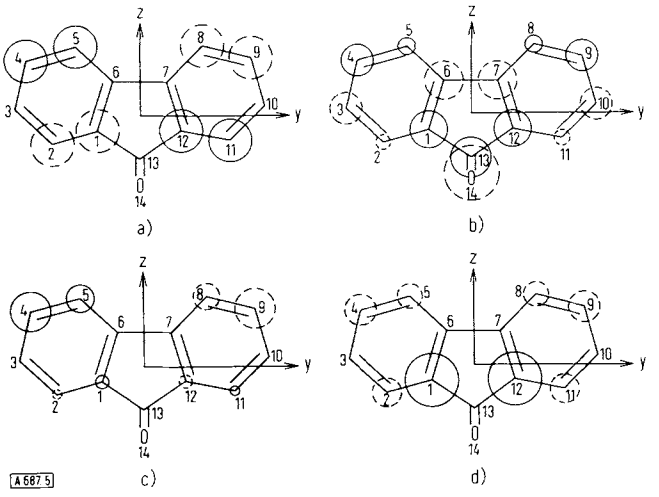

Fig. 5. Representation of the molecular orbitals φ_5 and φ_8 and of the components $(\mu_{ga})_z$ and $(\mu_{ga})_y$ of the transition moment of fluorenone (for practical reasons, the numbering of the skeletal atoms is different from that normally used):

(a) Atomic orbital coefficients c_{5p} of the fifth π-MO φ_5 (representation A_2).

(b) Atomic orbital coefficients c_{8p} of the eighth π-MO φ_8 (representation B_1).

(c) Products $c_{5p}c_{8p}z_p$ (representation B_2).

(d) Products $c_{5p}c_{8p}y_p$ (representation A_1).

The areas of the circles are proportional to the magnitude of the orbital coefficient (c_{5p}, c_{8p}) or of the product ($c_{5p}c_{8p}z_p$, $c_{5p}c_{8p}y_p$) for the atom p in question. Continuous circles denote positive signs, and broken circles negative signs.

The products $c_{5p}c_{8p}z_p$ are shown in Figure 5c. Since the xz plane of the molecule is a plane of symmetry, the magnitudes of the coefficients c_{5p} and c_{8p} on equivalent atoms, *e.g.* on atoms 1 and 12 or 4 and 9, must be the same, and so also must the magnitudes of the products $c_{5p}c_{8p}z_p$. The signs of the product $c_{5p}c_{8p}z_p$ for equivalent atoms are always dissimilar, *i.e.* $c_{54}c_{84}z_4 = -c_{59}c_{89}z_9$. The sum, and hence the z component of the transition moment, must therefore be zero. The z component of the transition $\varphi_5 \rightarrow \varphi_8$ is forbidden in the electric dipole approximation by the symmetry of the molecule and the irreducible representation of the MOs involved. It can similarly be shown that the x component of the permanent transition moment is also zero.

Figure 5d shows the products $c_{5p}c_{8p}y_p$. The y component of the transition moment is proportional to the sum of the areas, and will generally be finite. The optical electronic excitation $\varphi_5 \rightarrow \varphi_8$ is therefore generally allowed with a transition moment direction parallel to the y axis. The y component of the transition moment is zero only when the coefficients c_{5p} and c_{8p} are just such that the sum of the negative terms (sum of the negative areas in Fig. 5d; atoms 2 to 11) is equal to the sum of the positive terms (sum of the positive areas in Fig. 5d; atoms 1 and 12). The optical electronic excitation $\varphi_5 \rightarrow \varphi_8$ is then forbidden, but this is accidental, and is not due to symmetry relations. According to experimental studies, this situation occurs, at least to a good approximation, in the case of the fluorenone absorption in question in the free unperturbed molecule.

The electrons in the molecule are displaced by an external electric field or by the reaction field of the dissolved molecule. On orientation of the molecule with the dipole moment parallel to the electric field, the atomic orbital coefficients of atoms 1, 2, 11, 12, 13, and 14 will increase, while those of atoms 4, 5, 6, 7, 8, and 9 will decrease. The contributions to the integral $(\mu_{ga})_y$, *i.e.* the areas for the corresponding atoms (Fig. 5d), will thus change, the sum of the positive areas increasing and the sum of the negative areas decreasing, so that a finite transition moment in the y direction arises in an electric field in the z direction.

Similar variations of the transition moments and hence of the integral absorptions of electronic bands have also been found for some dye molecules [11].

3.3. A Relation between the Solvent-Dependence of the Position and the Solvent-Dependence of the Integral Absorption of Electronic Bands

A plot of the wave number $\tilde{\nu}_a^{sol}$ of the absorption maximum of an electronic band of a dissolved molecule as a function of $[a^3(F_{RM})_z(\mu_{az} - \mu_{gz}) + 2\,hcD\,(n^2 - 1)/(2\,n^2 + 1)]$ should, according to eq. (20) and eq. (21), be linear. It is in fact found that the experimental points for the various solvents deviate more or less strongly from linearity, and some solvents, such as dioxane and benzene, are quite irregular. The reason for the pronounced scatter is the fact that the reaction field based on the continuum model is only a rough approximation, which fails in particular in the cases of dioxane and benzene [10]. The same deviations are therefore to be expected, and are in fact found experimentally, in suitable plots of the integral absorption as a function of the field F_{RM} in accordance with equations (1), (21), and (22). The relations (20) with (21) and (1) with (21) and (22) can be checked only with the aid of a large number of solvents, so that individual deviations cancel out in the "mean".

According to eq. (20) and equations (1) and (22), both the position of the absorption band and the integral absorption depend on the average value of the reaction field F_{RM}. The reaction field can be eliminated by combination of equations (1), (22), and (20).

In a plot of $\tilde{\nu}_a^{sol}$ against a function of the integral absorption, which is possible in various cases, the deviations due to the poor approximation of the reaction field should be eliminated, as has been confirmed experimentally [10, 11].

The theory of the effect of an external field on electronic bands can be checked and confirmed by comparison of the results of electro-optical absorption measurements, electro-optical fluorescence measurements [16, 20], and dielectric measurements [9, 10]. These methods allow the measurement of the dipole moments of suitable molecules in the ground and excited states and certain components of the transition polarizability tensor. These quantities are responsible for the strong solvatochromism of polar molecules, and allow a quantitative description of the solvent-dependence of both the positions and the intensities of absorption bands. An independent check on the models was provided by various plots of the absorption wave number against functions of the integral absorption. Another possible cause of a strong dependence of the integral absorption on an external field and on the

solvent would be an equilibrium between isomers having sufficiently different dipole moments, *e.g. cis-trans* isomers. In such cases the relative quantities of the isomers could be strongly field-dependent, and hence also solvent-dependent. Since the absorption bands of isomers are usually different, the extinction of the solution would then depend on the field and on the solvent. Investigations on a number of dyes that exhibit an extremely strong solvent-dependence have indicated that this possibility is very unlikely, though it cannot be completely ruled out [11].

We are grateful to the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and the Stiftung Volkswagenwerk for their support of the experimental and theoretical studies.

Steps in Precipitation Reactions

By K. H. Lieser [*]

The combined application of various methods of investigation (e.g. nephelometry, conductivity measurements, electron microscopy, isotope exchange, BET surface area determinations, paper chromatography, coprecipitation) lead to a refined insight into the course of precipitation reactions. The formation of a new solid phase within a solution can, in the case of ionic crystals, be formally described as proceeding via a number of steps – nucleation, growth, ripening, and recrystallization (aging) – which overlap in time. The precipitation of hydroxides is a more complex process since additional chemical reactions (e.g. hydrolysis, condensation reactions) take place within the newly formed solid phase.

1. Introduction

Precipitation is a fundamental chemical operation for the separation and purification of substances. It is well known that precipitations very often give the desired result only if certain well-established procedures are rigidly adhered to, though in many cases the basis of these procedures, which have been evolved empirically, are still far from clear.

The principal process in a precipitation reaction is the formation of a new solid phase from a solution. It is convenient to distinguish the following steps: nucleation, growth, ripening, and recrystallization (aging). However, this well-established distinction is only formal, since the various steps overlap in time.

The following discussion deals mainly with the precipitation of salts (particularly sparingly soluble salts). Precipitation of hydroxides is a more complex process, since chemical reactions (*e.g.* elimination of water, conversion of basic salts into hydroxides) also occur during formation of the solid phase, depending on the pH value and time. Consequently, there are as yet hardly any theoretical schemes for the general treatment of the precipitation of hydroxides; the principal features of this process will be discussed in a separate section.

2. Steps in a Precipitation Reaction

2.1. Nucleation

The formation of submicroscopic particles (nuclei) of the new phase from a supersaturated solution is particularly interesting, but relatively difficult to observe experimentally. It generally begins only when a certain supersaturation has been reached, and proceeds very rapidly. The questions that arise in connection with the formation of a new phase have already been considered in detail by *Tammann* [1], *Ostwald* [2], and *Volmer* [3]. The kinetics of precipitation reactions have also been described by *Nielsen* [4].

Nucleation can be either homogeneous (spontaneous) or heterogeneous. Homogeneous or spontaneous nucleation occurs without the participation of other substances, by combination of the dissolved ions or molecules to form larger particles. Heterogeneous nucleation begins on small particles of foreign matter (seeds), on which ions or molecules are deposited (*e.g.* by adsorption) until a nucleus has been formed.

[1] *G. Tammann*: Kristallisieren und Schmelzen. J. A. Barth, Leipzig 1903.

[2] *W. Ostwald*: Die wissenschaftlichen Grundlagen der analytischen Chemie. W. Engelmann, Leipzig 1897.

[3] *M. Volmer*: Kinetik der Phasenbildung. Th. Steinkopff, Dresden 1939.

[4] *A. E. Nielsen*: Kinetics of Precipitation. Pergamon Press, Oxford 1964.

The seeds may be present in the solution as impurities, and can be removed by filtration. They are often more numerous in fresh than in aged solutions. Thus freshly prepared and unfiltered solutions generally contain a considerably greater number of seeds, and so give finer precipitates [5,6]. The seeds may also come from the walls of the vessel or from a glass rod [7,8]. Scratching the wall of the container with a glass rod is a well known method of initiating crystallization. Ultrasonic treatment has a similar effect [9].

In spontaneous nucleation, the number of nuclei is very strongly dependent on the concentration of the ions or molecules in the solution. Thus it is well known that finer precipitates are obtained from more concentrated than from dilute solutions.

Relatively high supersaturations are often observed in the absence of seeds. The supersaturation S is defined by

$$S = \frac{c - c_s}{c_s} \tag{1}$$

The ratio $c/c_s = S + 1 = S'$ is known as the supersaturation ratio. c is the actual concentration and c_s is the saturation concentration (solubility). The occurrence of supersaturation can be explained thermodynamically by means of the surface tension. The change in free enthalpy ΔG is given by the difference in the chemical potentials μ of the substance in question per molecule in the dissolved (μ_1) and in the solid (μ_2) state and by the surface tension σ:

$$\Delta G = -n(\mu_1 - \mu_2) + \sigma F \tag{2}$$

n is the number of molecules in a nucleus. If the nuclei are assumed to be spherical, then $F = n^{2/3} \cdot f$ [$f = (3v)^{2/3} \cdot (4\pi)^{1/3}$; v = volume of a molecule] and

$$\Delta G = -n(\mu_1 - \mu_2) + n^{2/3} f \sigma \tag{3}$$

The curve in Figure 1 shows ΔG as a function of the number of molecules in a nucleus. For small values of n, ΔG is always positive, *i.e.* very small nuclei redissolve. A metastable equilibrium exists at the maximum

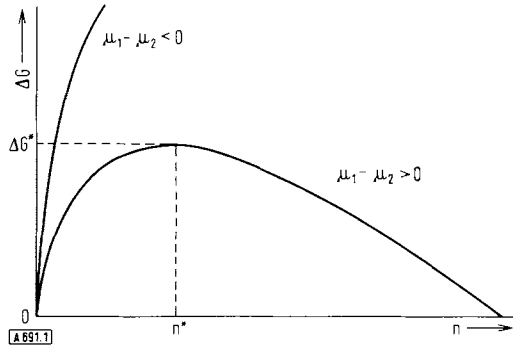

Fig. 1. Free enthalpy ΔG as a function of the number of molecules n in a nucleus (n^* = number of molecules in a critical nucleus).

of the curve (d $\Delta G/dn = 0$); this corresponds to the critical state for nucleation (denoted hereafter by an asterisk).

A nucleus in which the number of molecules $n = n^*$ is known as a critical nucleus, and particles in which the number of molecules $n < n^*$ are called subnuclei or embryos. Whereas all nuclei having $n < n^*$ redissolve, nuclei with $n > n^*$ grow into crystals. A homogeneously supersaturated solution is therefore thermodynamically in a metastable state, which can persist for a very long time. A precipitate can form only when the energy barrier ΔG^* has been overcome; in homogeneous nucleation, for example, this can occur as a result of random free enthalpy variations in small regions of the solution.

Information about the radius of a critical nucleus and the number of molecules that it contains can be obtained from the following argument. For spherical particles,

$$F = \frac{3V}{r} \tag{4}$$

Since dV/dn = v (volume of one molecule), it follows from eq. (2) that

$$\frac{d\Delta G}{dn} = -(\mu_1 - \mu_2) + \frac{2v\sigma}{r} \tag{5}$$

In the metastable equilibrium, d $\Delta G/dn = 0$, and the radius of the critical nucleus is therefore

$$r^* = \frac{2v\sigma}{\mu_1 - \mu_2} \tag{6}$$

The number of molecules in a critical nucleus is

$$n^* = \frac{V^*}{v} = \frac{2\sigma F^*}{3(\mu_1 - \mu_2)} \tag{7}$$

The free enthalpy of the critical nucleus is

$$\Delta G^* = -n^*(\mu_1 - \mu_2) + \sigma F^*$$
$$\Delta G^* = -\frac{2\sigma F^*}{3} + \sigma F^* = \frac{\sigma F^*}{3} \tag{8}$$

The surface area F^* of the critical nucleus is found with the aid of eq. (7) to be

$$F^* = 3\beta \frac{\sigma^2 v^2}{(\mu_1 - \mu_2)^2} \tag{9}$$

where β is a geometric shape factor:

$$\beta = \frac{4F^3}{27V^2} \tag{10}$$

[β = 16.76 (sphere), 20.22 (icosahedron), 22.20 (dodecahedron), 27.71 (octahedron), 32 (cube), 55.43 (tetrahedron)].

The difference in the chemical potentials is given by the ratio of the activities a in the solution (a_1) and in the solid (a_2):

$$\mu_1 - \mu_2 = kT \ln \frac{a_1}{a_2} \tag{11}$$

If the concentration and saturation concentration are used as approximations for the activities, it follows, with the aid of eq. (1), that

$$\mu_1 - \mu_2 = kT \ln (S + 1) \tag{12}$$

and from equations (7), (9), and (12):

$$n^* = 2\beta \frac{\sigma^3 v^2}{[kT \ln (S^* + 1)]^3} \tag{13}$$

S^* = critical supersaturation

Eq. (13) permits the rough calculation of the number of molecules in a critical nucleus. Measured values for the surface tension σ are available in only a few cases; it is of the order of 100 erg/cm^2. From σ and the critical supersaturation S^*, we obtain n^* values of the order of 100, *i.e.* a critical nucleus consists of about 100 molecules and has a diameter of the order of 100 Å.

The radius of a nucleus in a supersaturated solution is given by the Gibbs-Kelvin equation [10]

$$r = \frac{2v\sigma}{kT \ln (S + 1)} \tag{14}$$

which follows from equations (6) and (12). According to this equation at a certain supersaturation S, only particles of one particular size are present in the solution, this size decreasing with increasing supersaturation (Fig. 2).

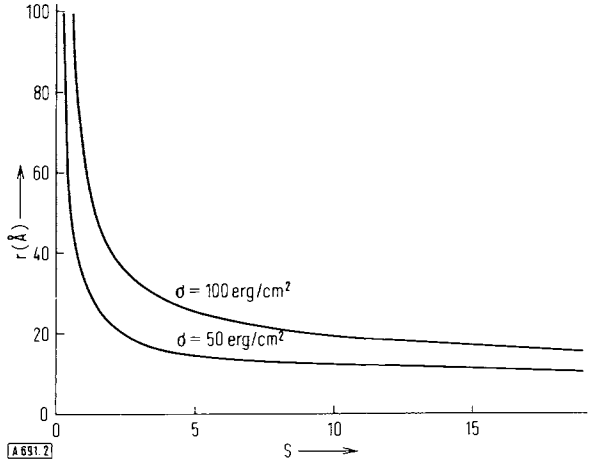

Fig. 2. Radius of the nuclei in a supersaturated solution as a function of the supersaturation S on the basis of the Gibbs-Kelvin equation for various surface tensions.

The calculation provides no details on the concentration of subnuclei in a supersaturated solution, which is very strongly dependent on the supersaturation (cf. Fig. 3). The number of critical nuclei also changes extremely rapidly with the supersaturation, so that S^* can be determined relatively accurately by experiment. Slightly below this critical supersaturation, the number of critical nuclei is still very small (*i.e.* the nucleation rate is very low), whereas only slightly above the critical supersaturation the number of critical nuclei is so large that precipitation begins almost instantaneously.

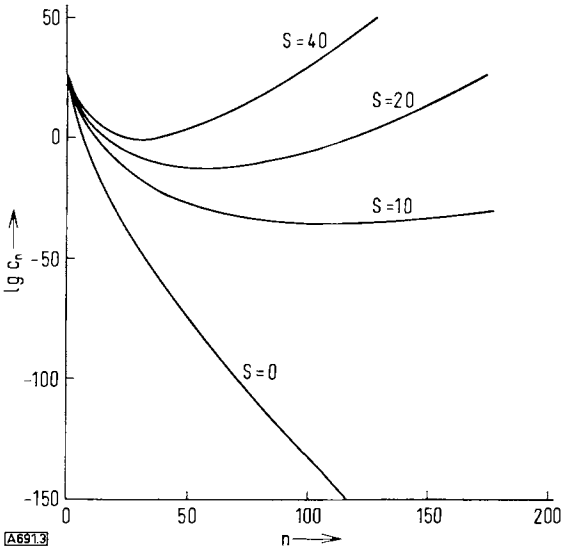

Fig. 3. Concentration of subnuclei in a supersaturated solution on the basis of theoretical considerations (n = number of molecules in a subnucleus, S = supersaturation; calculated for $\beta = 40$, $\sigma = 50$ erg/cm^2, $v = 10^{-22}$ cm^3, $c_s = 2.5 \times 10^{-6}$ mole · l^{-1}) after *Nielsen* [4].

The first equation for the nucleation rate was given by *Volmer* and *Weber* [11], and later by *Becker* and *Döring* [12]; further theoretical treatments were given by *Nielsen* [4], and *Kahlweit* [8]. The nucleation rate J (number of nuclei formed per cm^3 per sec) can be expressed by

$$J = J_0 \exp[-\Delta G^*/kT] \tag{15}$$

It follows with the aid of equations (8), (9) and (12) that

$$\log J = \log J_0 - \frac{A}{[\log (S + 1)]^2} \tag{16}$$

where

$$A = \frac{\beta \sigma^3 v^2}{(kT \ln 10)^3} \tag{17}$$

As an approximation

$$\log J \approx 30 - \frac{A}{[\log (S + 1)]^2} \tag{18}$$

The nucleation rate according to this equation can be found from a diagram (Fig. 4) [4]. For spontaneous (homogeneous) nucleation, the experimental values of J as a function of the supersaturation S lie on a curve having a constant value for A; it is therefore possible to calculate the surface tension σ with the aid of eq. (17).

Figure 4 shows that the nucleation rate for relatively wide ranges can be approximately given by a relation of the form

$$J = k_m c^m \tag{19}$$

[10] *J. W. Gibbs*: Scientific Papers. Yale University Press, New Haven 1957, p. 258; *W. Thomson*, Proc. Roy. Soc. Edinburgh 7, 63 (1870).

[11] *M. Volmer* and *A. Weber*, Z. physik. Chem., Abt. A *119*, 277 (1926).

[12] *R. Becker* and *W. Döring*, Ann. Physik *24*, 719 (1935).

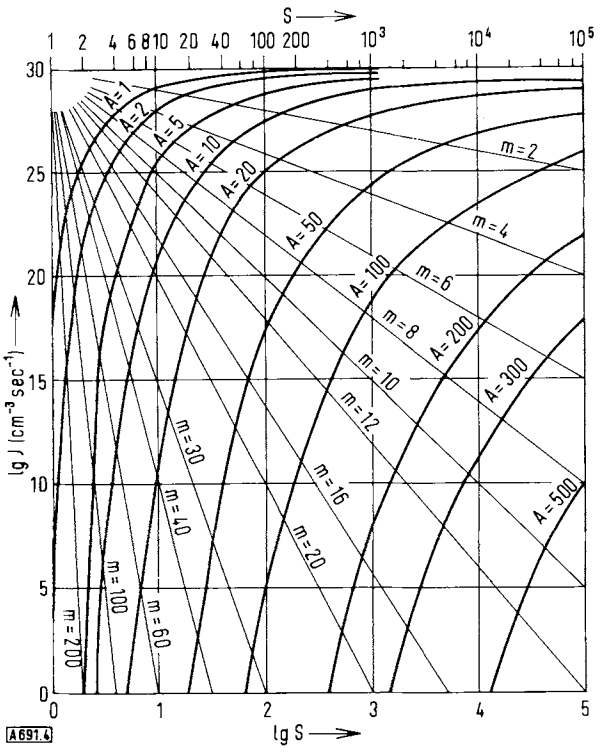

Fig. 4. Nucleation rate (number of nuclei formed per cm^3 sec^{-1}) as a function of the supersaturation for various values of A [cf. eq. (17) and (20)].

The exponent m corresponds to the slope d log J/d log c of the experimental curve, and also provides information about the size of a critical nucleus; it is found from equations (16) and (13) that

$$\frac{\mathrm{d}\log J}{\mathrm{d}\log c} = m = \frac{\mathrm{d}\ln J}{\mathrm{d}\ln (S+1)} = \frac{2\beta\sigma^3 v^2}{[kT]^3[\ln (S+1)]^3} = n^* \quad (20)$$

The surface tension can finally also be determined with the aid of this equation.

2.2. Growth

Once a critical nucleus has been formed, it can grow into a crystal in various ways. Like dissolution, this growth proceeds in small steps, *i.e.* by deposition of single ions or molecules, and not by combination of larger particles.

The first detailed theoretical treatment of crystal growth was due to *Kossel*[13] and *Stranski*[14]; the basic model is shown schematically in Figure 5.

According to this model of stepwise growth, there are non-equivalent sites on the surface of a crystal. A site marked (1) is preferred, while the edges and corners of the crystal are less favorable. The first step in the formation of a new layer has particularly unfavorable energy requirements. The particle (2), which is a surface nucleus, forms a new layer by two-dimensional growth. It is also possible that more than one surface

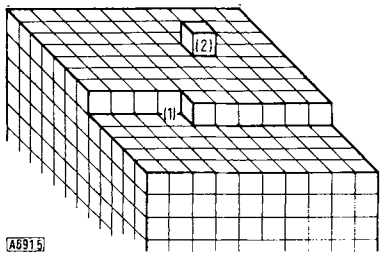

Fig. 5. Model of crystal growth according to *Kossel* [13] and *Stranski* [14].

nucleus is deposited, and in this case the zones formed by the two-dimensional growth of these nuclei overlap. If the formation of surface nuclei is very fast, a new layer is started before the growth of the last layer is complete, *i.e.* the (polynuclear) growth takes place in several layers simultaneously one upon another (cf. Fig. 6). If the formation of surface nuclei is very slow, one layer is generally formed after the last is complete (mononuclear growth); this type of growth is therefore strongly inhibited. At low supersaturations, the deposition of an ion or molecule as a surface nucleus is very unlikely, so that mononuclear growth cannot occur.

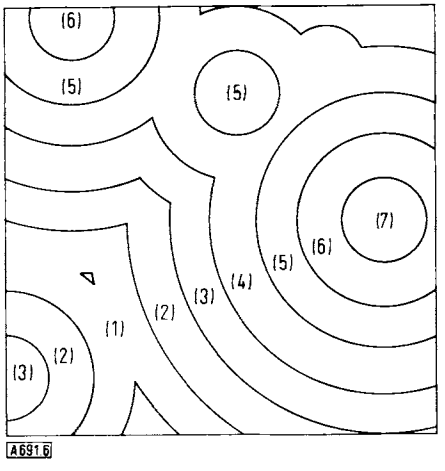

Fig. 6. Polynuclear growth (schematic; the numbers denote superimposed layers).

As an alternative to stepwise growth, *Frank*[15] proposed growth on screw dislocations (Fig. 7), where there are always energetically favorable sites for the deposition of ions or molecules. The screw dislocation is retained as a crystal imperfection, and is continuously propagated in the form of a spiral as growth proceeds.

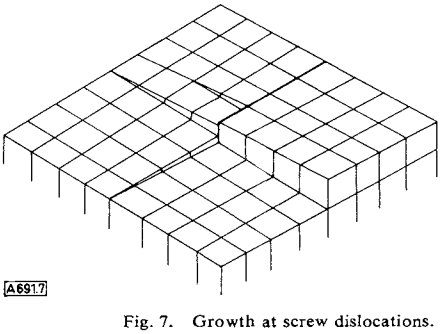

Fig. 7. Growth at screw dislocations.

[13] *W. Kossel*, Nachr. Ges. Wiss. Göttingen, math.-physik. Kl., 135 (1927); Ann. Physik *21*, 455 (1934); *33*, 651 (1938).

[14] *I. N. Stranski*, Z. physik. Chem., Abt. A *136*, 259 (1928).

[15] *F. C. Frank*, Discuss. Faraday Soc. *5*, 48 (1949).

The formation of surface nuclei is no longer necessary, and growth at screw dislocations can therefore occur even at low supersaturations. In agreement with this model, spiral growth at screw dislocations has in fact been observed in many cases.

Various consecutive processes may be important to the crystal growth:

(a) diffusion of the ions or molecules from the solution onto the surface; (b) adsorption of the ions or molecules on the surface; (c) transition on the surface; (d) transport on the surface to a suitable site.

Process (b) is very much faster than the other processes, since it is not inhibited. The processes (c) and (d) are generally indistinguishable, and are therefore known collectively as the surface reaction. The rate-determining step for the growth of the crystals may thus be the diffusion or the surface reaction.

If the diffusion is rate-determining, the growth rate of a crystal is given by

$$\frac{dn}{dt} = 4\pi D(c-c_s)r \qquad (21)$$

This yields the relation given by *Neumann* [16] for the radius of a particle as a function of time:

$$r(t) = \sqrt{2DV(c-c_s)t} \qquad (22)$$

V is the molar volume and D is the diffusion coefficient. Eq. (22) is valid only when $V(c - c_s) \ll 1$.

If on the other hand the surface reaction is rate-determining, it may be assumed that the growth rate of a crystal is proportional to the area and to the concentration difference [8], and one then obtains

$$\frac{dn}{dt} = 4\pi r^2 k(c-c_s) \qquad (23)$$

and

$$r(t) = kV(c-c_s)t \qquad (24)$$

Equations (21) to (24) are applicable provided that the linear growth of a crystal can be followed as a function of time. If growth and ripening overlap, as is usually the case in the precipitation of sparingly soluble ionic crystals, dn/dt and dr/dt may be positive or negative for a given crystal.

In many cases we are interested in the decrease in concentration in the solution as a result of crystal growth, which can be described by a kinetic equation

$$J = -\frac{dn_L}{dt} = k_m c^m \qquad (25)$$

n_L is the number of ions or molecules per cm³ of solution. However, *Marc* [17] showed that the growth rate for readily and moderately soluble substances satisfies the equation

$$J = k_m (c - c_s)^m \qquad (26)$$

[16] *K. Neumann* in [3], p. 209.

[17] *R. Marc*, Z. physik. Chem., Abt. A *61*, 385 (1908).

The exponent m is usually known as the order of the growth reaction. This is correct in the sense used in chemical kinetics for a relation of the form of eq. (25), but not for an emipirical relation of the type of eq. (26).

The progress of crystal growth can also be described by the change in the supersaturation; the characteristic quantity used [4] is

$$\alpha = 1 - \frac{S}{S_0} \qquad (27)$$

S_0 is the supersaturation at time $t = 0$. For spherical particles of (average) radius r and a constant number of particles,

$$r = r_e \alpha^{1/3} \qquad (28)$$

r_e is the (average) radius of the crystals at the end of the experiment. For the case where diffusion is rate-determining, *Nielsen* [4] derived from this relation

$$t = K_D I_D \qquad (29)$$

where

$$K_D = \frac{r_e^2}{3VD(c_0 - c_s)} \qquad (30)$$

and I_D is the "diffusion chronomal"

$$I_D = \int_0^{\alpha} \frac{dx}{x^{1/3}(1-x)} \qquad (31)$$

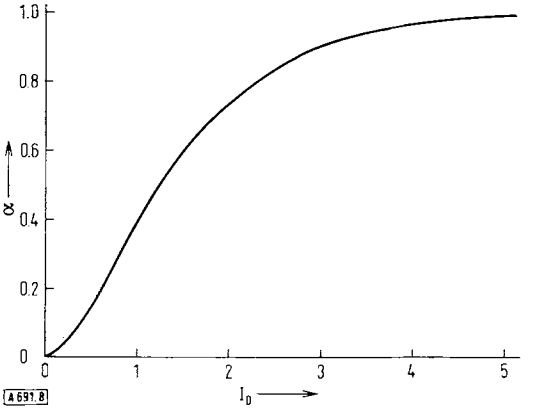

Fig. 8. Diffusion chronomal after *Nielsen* [4] [cf. eq. (27) to (31)].

Figure 8 shows α as a function of I_D. This diagram can be used for the evaluation of measurements, *e.g.* by reading off I_D for the experimental value of α and plotting it as a function of time. If the diffusion is rate-determining, as was assumed in the derivation of eq. (29), this procedure should give a straight line, the slope of which $(1/K_D)$ should according to eq. (30) give reasonable values for the diffusion coefficient D. For aqueous electrolytes, D is of the order of 10^{-5} cm² sec⁻¹ at room temperature.

For the case in which the surface reaction is rate-determining, *Nielsen* [4] uses the quantity

$$\alpha = 1 - \frac{c}{c_0} \qquad (32)$$

and with the aid of eq. (28) he obtains the following relations for mononuclear or polynuclear growth.

$$t = K_m I_m \text{ and } t = K_p I_p \qquad (33)$$

The "chronomals" I_m and I_p are shown in Figures 9 and 10 as functions of α. The indices 1, 2, 3, *etc.* indicate the order of the reaction: *e.g.* I_{p_3} is the "chronomal" for a third order polynuclear reaction. The practical application is similar to that of the "diffusion chronomal" I_D. If the graph of I_m or I_p against time gives a straight line, the "chronomal" used corresponds to the mechanism and the order of the reaction.

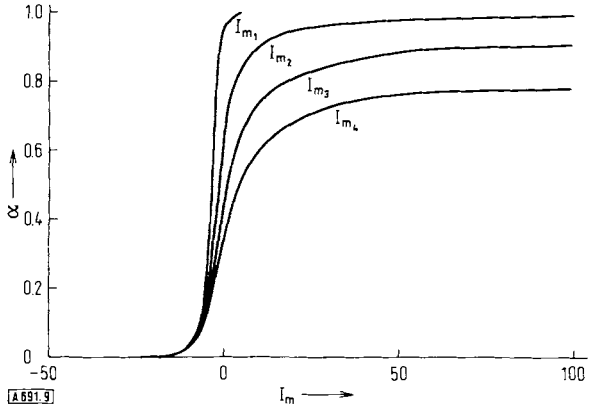

Fig. 9. Chronomals I_m for mononuclear growth after *Nielsen* [47] [cf. eq. (32) and (33)].

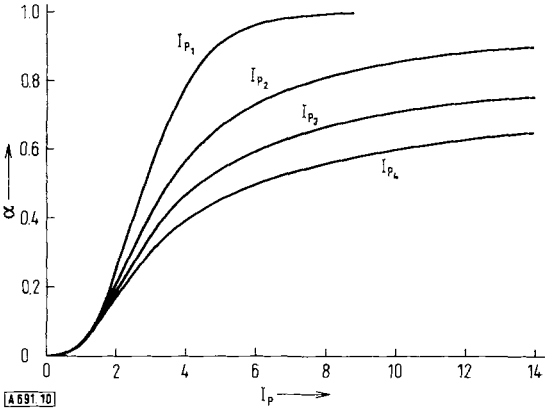

Fig. 10. Chronomals I_p for polynuclear growth after *Nielsen* [4] [cf. eq. (32) and (33)].

In this evaluation of experimental data with the aid of "chronomals", it is again assumed that the number of particles is constant and that the growth can be approximately described on the assumption of spherical particles. These two conditions are frequently not satisfied in practice. The greatest difficulty is the fact that the number of particles and the state of order are continously changing as a result of ripening processes.

2.3. Ripening

The small crystals formed by nucleation and growth in the solution are generally very imperfect; they contain many defects and crystal imperfections, and are not in thermodynamic equilibrium with the solution. The deviation from thermodynamic equilibrium increases with increasing supersaturation of the solution, *i.e.* with increasing rate of formation of the small crystals. The thermodynamically stable final state of a precipitation reaction would be a perfect single crystal, since the free enthalpy, and in particular the surface free enthalpy, is then at a minimum. It is well known that this state is never reached in a precipitation reaction, the product of which is always a large number of crystals of different sizes having greater or smaller numbers of defects and imperfections. In general, the higher the supersaturation, the smaller are the crystals and the greater is the number of imperfections. With decreasing supersaturation, the small, highly imperfect crystals show a steadily growing tendency to redissolve and to form larger, less imperfect crystals. Processes that lead to a thermodynamically more stable state, *i.e.* to larger, less imperfect crystals, are known as ripening. According to *Ostwald* [2], small crystals pass into solution during ripening, while the larger crystals continue to grow (Ostwald ripening). Another theory [18] involves the combination of small particles and growth of the resulting composite particles into larger crystals (cementation).

Information about the size of the crystals that are in equilibrium with the solution at a certain supersaturation is obtainable with the aid of the Gibbs-Kelvin equation (14) (cf. Fig. 2). However, this equation contains only the surface tension and the supersaturation as parameters, and does not include the degree of disorder of the crystal by defects and crystal imperfections. The influence of these quantities cannot be disregarded, but it cannot be accurately determined at present. The ripening leads to a change in the size disorder, and the degree of disturbance decreases, as shown qualitatively in Figures 11 and 12.

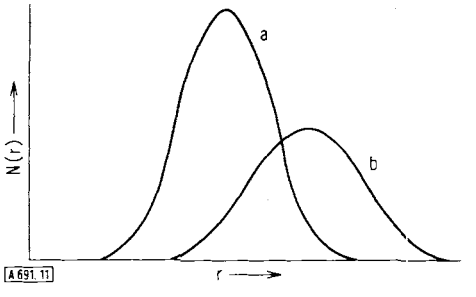

Fig. 11. Change in the crystal size distribution as a result of ripening (schematic) a: Before ripening, b: after ripening.

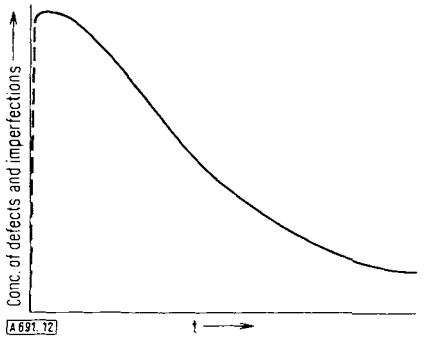

Fig. 12. Change in the concentration of defects and imperfections as a result of ripening (schematic).

[18] *J. Kolthoff*, Chem. Weekbl. *29*, 362 (1931); Proc. Kon. nederl. Akad. Wetensch. Ser. *40*, 82 (1937).

If we consider the Ostwald ripening mechanism, only some of the crystals formed in any stage of a precipitation reaction have a chance to grow further. The remaining crystals redissolve. This is true in particular during the growth stage, since the supersaturation in the solution often changes very markedly in this stage.

The rate of Ostwald ripening is subject to the same considerations as the rate of growth of the crystals. The ripening may be divided into the following processes:

(a) dissolution of ions or molecules from small crystals, (b) diffusion of the dissolved particles from the surfaces of the small crystals into the solution, (c) diffusion of the particles out of the solution onto the surfaces of larger crystals, (d) adsorption of the ions or molecules on the surfaces of the larger crystals, (e) transition to the surface, (f) transport on the surface to a suitable site.

As in the case of growth, the diffusion (b and c) or the surface reaction (a, e, and f) could be the rate-determining step.

2.4. Recrystallization

Recrystallization processes differ from ripening in that they extend over a longer period and become noticeable only after growth. The number of crystals and their size generally show little change. The supersaturation is usually zero or very small. The crystals and the solution are in a dynamic equilibrium, which leads to a continuous exchange of matter. This does not cause any externally recognizable changes, but can be followed radiochemically over a period of many months.

A crystal formed and grown at a high supersaturation usually has many internal defects and disorders. It is therefore relatively far removed from the equilibrium state, even when it is comparatively large. If it remains in contact with the solution for a long time, it has the opportunity to change into a less disturbed crystal by recrystallization. Thus it is well known that in the quantitative separation of substances by precipitation, better results are obtained by allowing the precipitate to stand for some time in contact with the mother liquor.

The experimental observation of recrystallization has not progressed very far, and no theory yielding information about the effects of various parameters (concentration of the ions of the substance itself and of foreign ions, temperature) has not yet been developed.

3. Methods of Investigation

3.1. General

Many methods are available for the investigation of precipitation reactions. In the measurement of the nucleation rate, the number of nuclei is determined as a function of time. The results are unambiguous unless the number of nuclei is simultaneously decreased by ripening. The crystal growth is usually followed by means of the change in the conductivity or concentration of the solution. It is important, for the evaluation of the results, that the number of crystals must remain constant during this process. Otherwise the growth of individual selected crystals must be followed directly, *e.g.* by observation under a microscope or by weighing.

The following methods of investigation may be considered: counting the nuclei or crystals, measurement of the linear growth of the crystals, weighing the crystals, measurement of the decrease in concentration in the solution, nephelometry, conductivity measurement, electron microscopy, isotopic exchange, determination of the surface area by the BET method, paper chromatography, and coprecipitation.

Each of these methods provides part of the picture. For a comprehensive study of a precipitation reaction it is best to use as many different methods as possible and to compare the results critically.

The first four methods listed need no explanation. The application of the others will be illustrated by examples.

3.2. Nephelometry

Figure 13 shows the results for the precipitation of barium sulfate. The nephelometric measurement gives a good picture of the course of precipitation. Nucleation becomes evident only after an induction period of about 4 minutes; the crystal growth then begins, as is shown by a steep increase in turbidity. The turbidity reaches a maximum after about 45 minutes, and then decreases slightly. This decrease is due to ripening, which is superimposed on the crystal growth.

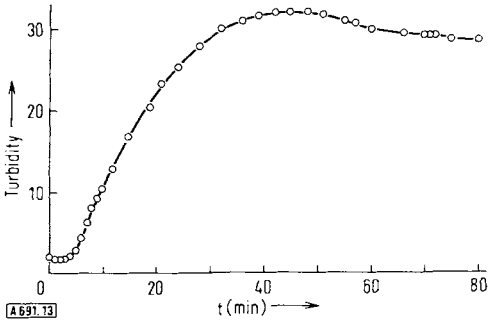

Fig. 13. Relative turbidity on mixing of equal volumes of 4×10^{-4} M solutions of $Ba(NO_3)_2$ and Na_2SO_4 as a function of time.

3.3. Conductivity Measurement

If ions in a solution form complexes or nuclei, the electrical conductivity of the solution must decrease. A pronounced decrease in conductivity is to be expected in the growth stage. The conductivity component due to the ions that are involved in a precipitation reaction is obtained by subtraction of the final conductivity after the precipitation from the value found at the time in question[19]. In the example in Figure 14 it is possible to distinguish three sections. At the beginning of the precipitation, an initial period of 0.2 to 0.5 min is recorded during which there is no change in conductivity. This initial

[19] *K. H. Lieser* and *A. Fabrikanos*, Z. physik. Chem. N.F. *22*, 406 (1959).

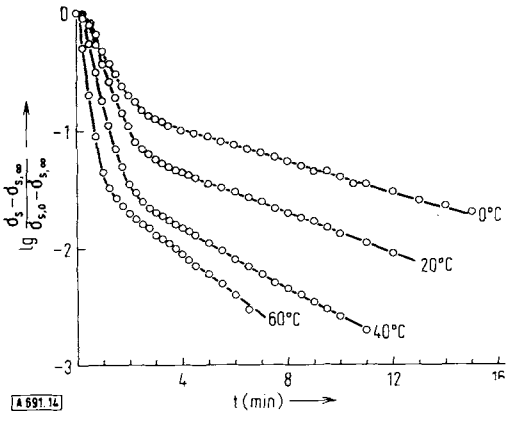

Fig. 14. Relative conductivity of the ions involved in the precipitation process on mixing of equal volumes of 2×10^{-3} M solutions of $Ba(NO_3)_2$ and Na_2SO_4 at various temperatures as a function of time.

period is not the same as the induction period found in nephelometric measurements. No new phase can be recognized optically during the induction period. During the initial period, no change is observed even in the submicroscopic range, *i.e.* no complexes or high molecular weight aggregates are formed to any appreciable extent in the solution. After the initial period the conductivity falls off rapidly with a half life of about 0.2 to 0.6 min. The decrease is exponential, and is due to the growth. The flatter part of the curve (half life about 2 to 5 min) corresponds to ripening. The assignment of the sections of the conductivity curves is in agreement with other experiments.

3.4. Electron Microscopy

The electron microscope makes it possible to observe the shape and size of the nuclei and crystals during the precipitation reaction even in the submicroscopic range.

Fixation of a given state can be achieved by the following technique[20]. The precipitation process in a sample is arrested within a few seconds by quenching on a support in an aluminum block cooled with liquid air. Ice can be removed by vacuum sublimation. Foreign substances can be completely excluded in many cases by suitable choice of the reagents used for the precipitation (so that apart from the precipitation product, only volatile substances are present).

Some examples of electron micrographs are given in Figures 15 to 17.

1 min after the start of precipitation of $BaSO_4$ by mixing 0.1 M solutions of its ions, very small particles are present and the crystals are very irregularly developed (Fig. 15a). 9 min later the content of small particles has decreased appreciably, and 3 hours after the start of precipitation (Fig. 15d) one finds crystals that, though rather more regular, are practically no larger. The investigation of the relatively dense precipitates is facilitated by ultrasonic treatment. With more dilute starting solutions ($\approx 10^{-3}$ M), the precipitation follows an entirely different course (Fig. 16). After 1 min only very small crystals are present, and these grow relatively slowly into larger crystals. After a long time the small crystals have disappeared, and all the crystals present (which are more or less well developed) are significantly larger than those obtained by precipitation from more concentrated solutions (cf. Fig. 16d and 15d). A temperature rise accelerates growth and ripening, and so leads to better-developed crystals (Fig.17). The size of the crystals is not greatly influenced by the temperature rise. The various stages of the precipitation (nucleation, growth, and ripening) are clearly recognizable in the electron micrographs in every case.

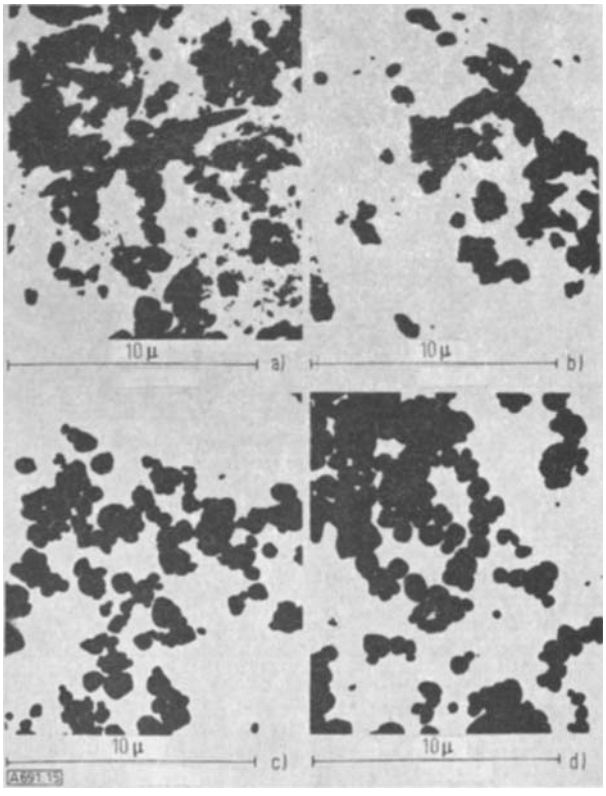

Fig. 15. Electron micrographs during the precipitation of $BaSO_4$ after mixing of equal volumes of 0.1 M solutions of $Ba(NO_3)_2$ and Na_2SO_4 at 20 °C. (a) 1 min, (b) 10 min, (c) 1 hour, (d) 3 hours after the start of precipitation.

3.5. Isotopic Exchange

Radionuclides having sufficiently high specific activities are the most suitable for the investigation of ion exchange processes.

When a solid is introduced into a solution containing exchangeable radioactively labeled ions, the activity in the solution is observed to decrease in two steps under suitable experimental conditions (Fig. 18). The fast step a, which has

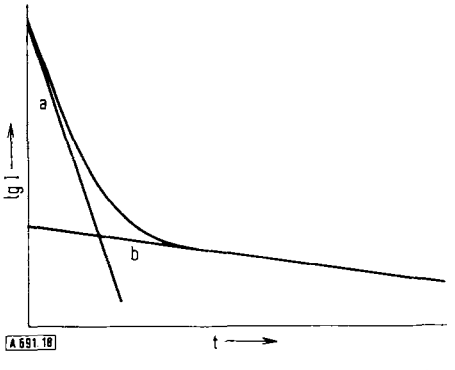

Fig. 18. Activity decrease as a function of time for isotope exchange on the surface of ionic crystals. a: Isotope exchange with the ions that were present on the surface of the solid phase at the beginning of the experiment. b: Isotope exchange with the ions that have reached the surface by recrystallization.

a half-life of the order of 1 min, is due to ion exchange of the labeled ions in the solution with the ions present on the surface of the solid at the beginning of the experiment. The surface of the solid is constantly being renewed as a result of recrystallization; labeled ions are transported into the interior of the crystal, while unlabeled ions pass to the surface. The exchange process continues until the labeled ions are uniformly distributed (apart from isotope effects) throughout the entire solid and the solution. The slow step b is caused by recrystallization. The slope of the curves in Figure 18 is a measure of the rate of the steps, and provides information about their kinetics [21]. The intercept on the ordinate is a measure of the isotopic exchange on the surface and allows the determination of the surface area of the solid. According to a relation that was first derived by *Paneth* [22, 23],

$$F = \left(\frac{I_0}{I} - 1\right) fcV\, N_L \qquad (34)$$

where I_0 and I are the number of counts per unit time in the solution before and after exchange with the surface, c is the concentration of the exchanging ions in the solution, V is the volume of the solution, N_L is the Loschmidt number, and f is the area equivalent to an exchangeable ion. The latter can be roughly calculated from the molecular weight M and the density ρ by means of the relation

$$f = \left(\frac{M}{\rho N_L}\right)^{2/3} \qquad (35)$$

or from X-ray data.

If suitable labeled ions (in the carrier-free state if possible) enter the solution during a precipitation, they take part in the precipitation reaction. The transport of matter within a short period dt is given by

$$dm = -dm_1 + dm_2 \qquad (36)$$

dm_1 is the quantity separating out from the solution, and dm_2 is the quantity passing into solution from the solid phase. Similarly, for the activity a (given by the number of labeled ions N and their decay constant λ, $a = \lambda N$) we obtain

$$da = -da_1 + da_2 \qquad (37)$$

By introduction of the specific activity in the solution $A = a/m$ we obtain at the time t_0 at which the activity is added

$$A_0 = \frac{a_0}{m_0} \qquad (38)$$

and at the time $t_0 + dt$

$$A_0 + dA = \frac{a_0}{m_0 + dm_2} \qquad (39)$$

(The specific activity in the solution is not affected by the quantity $-dm_1$ separating out from the solution.) It follows from equations (38) and (39) that

$$\frac{1}{A_0}\left(\frac{dA}{dt}\right)_{t_0} = -\frac{1}{m_0}\left(\frac{dm_2}{dt}\right)_{t_0} \qquad (40)$$

If the quantity separating out from the solution is assumed to be proportional to the surface area of the solid

$$\frac{dm_2}{dt} = \text{const} \times F \qquad (41)$$

we obtain the equation

$$-\frac{m_0}{A_0}\left(\frac{dA}{dt}\right)_{t_0} = \text{const} \times F \qquad (42)$$

[21] *K. H. Lieser, Ph. Gütlich,* and *I. Rosenbaum,* Radiochim. Acta *4*, 216 (1965).

[22] *F. Paneth* and *W. Vorwerk,* Z. physik. Chem., Abt. A *101*, 445 (1922).

[23] *K. H. Lieser* and *W. Hild,* Z. anorg. allg. Chem. *320*, 117 (1963).

The relative change in the specific activity at time $t = t_0$ is thus a measure of the surface area. If the activity is introduced at various times t_0 after the start of the precipitation, it is possible to follow the change in the relative surface area during precipitation as a function of time.

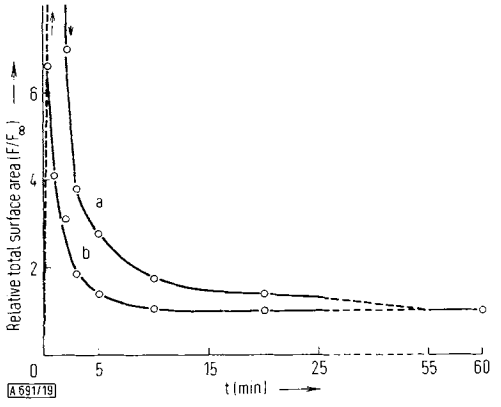

Fig. 19. Relative total surface area of the solid phase $BaSO_4$ as a function of time. (a) Precipitation by mixing of equal volumes of 10^{-3} M solutions of $Ba(NO_3)_2$ and Na_2SO_4; (b) as (a) but with 10^{-2} M solutions.

Figure 19 shows the relative total surface area of the solid phase during the precipitation of barium sulfate as found in this way. The course of the curves at the beginning of the precipitation is interesting, since the surface area of even very small particles is measured in this way. The total area of the solid phase is zero at first. Nucleation then leads to a large number of small particles having a large total area (steep ascent of the curve), from which growth and ripening yield a smaller number of crystals with a smaller total area. In the discussion of these curves we are faced with the question of when we can speak of a new phase.

The relative average crystal size $\bar{r}$ can also be calculated from the relative total area:

$$\bar{r} \sim \frac{\bar{m}}{F} \tag{43}$$

$\bar{m}$ is the quantity of solid. The average crystal size found in this way during the precipitation of barium sulfate from solutions at various concentrations is shown in Figure 20.

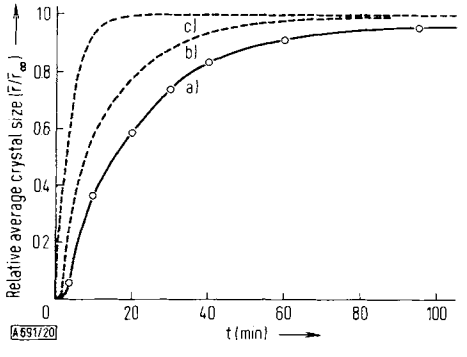

Fig. 20. Relative average crystal size on precipitation of $BaSO_4$ from solutions having various concentrations: (a) by mixing of equal volumes of 4×10^{-4} M solutions of $Ba(NO_3)_2$ and Na_2SO_4; (b) as (a), but with 10^{-3} M solutions; (c) as (a), but with 10^{-2} M solutions.

3.6. Determination of the Surface Area by the BET Method

The total surface area of a solid phase can be determined not only by isotopic exchange using equation (31) but also by the method devised by *Brunauer, Emmett,* and *Teller*[24] (BET method), which is based on the low-temperature adsorption of nitrogen. This method can be used for the study of precipitation reactions only if the processes to be studied are slow and if enough of the solid phase is available, since the BET method requires the isolation of relatively large samples (> 1 g), which must be dried under the mildest possible conditions. The BET method is therefore primarily suitable for the investigation of recrystallization.

Figure 21 shows the specific surface area of freshly precipitated barium sulfate as a function of time[25]. The precipitation from concentrated solutions shows a pronounced maximum

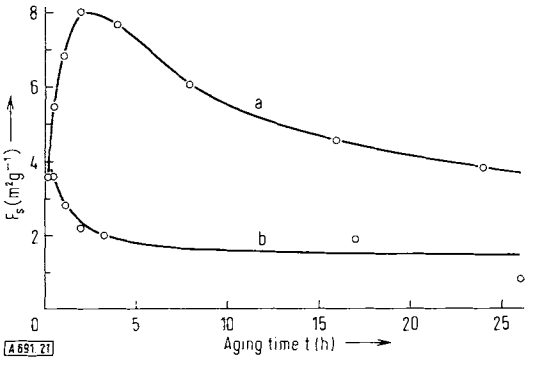

Fig. 21. Change in the specific surface area of the solid phase $BaSO_4$ as a result of recrystallization after precipitation by mixing of equal volumes of 10^{-1} M (a), and 10^{-3} M (b) solutions of $Ba(NO_3)_2$ and Na_2SO_4 at 20 °C.

that is not observed in precipitation from very dilute solutions. It can be seen from the diagram that recrystallization can cause marked changes in the solid phase, which extend over a period of about 1 day at room temperature, and take place at a correspondingly higher rate at higher temperatures (cf. Fig. 22)

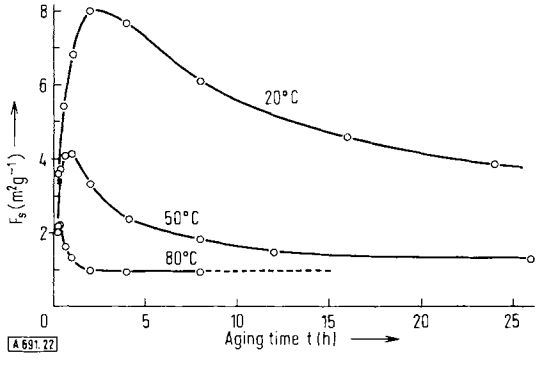

Fig. 22. Change in the specific surface area of freshly precipitated $BaSO_4$ (by mixing of equal volumes of 0.1 M solutions of $Ba(NO_3)_2$ and Na_2SO_4) as a function of temperature.

3.7. Paper Chromatography

Information about the course of a precipitation reaction can often be very easily obtained by paper chromatography. Thus the compound formed on precipitation may be radioactively labeled, samples then being taken from the suspension of solid phase in solution during the precipitation and developed on paper with an electrolyte solution having the same composition.

[24] *S. Brunauer, P. H. Emmett,* and *E. Teller*, J. Amer. chem. Soc. *60*, 309 (1938).

[25] *Ph. Gütlich* and *K. H. Lieser*, Z. physik. Chem. N.F. *46*, 257 (1965).

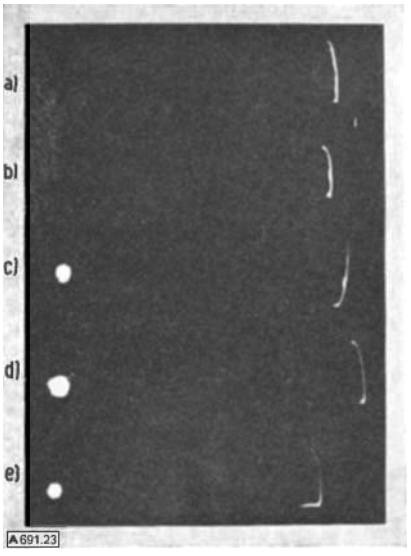

Fig. 23. Autoradiograms of paper chromatograms during the precipitation of $BaSO_4$ after mixing of 4×10^{-4} M solutions of $Ba(NO_3)_2$ and Na_2SO_4. Sample (a) 2 min, (b) 6 min, (c) 20 min, (d) 50 min, (e) 150 min after the start of precipitation.

Figure 23 shows a series of autoradiograms of paper chromatograms demonstrating the progress of precipitation of barium sulfate. No solid is present at the start, and all the barium ions migrate with the solvent front. No intermediate complexes (subnuclei) can be detected. The content of solid phase increases during the precipitation process. The chromatogram can also be evaluated quantitatively with the aid of a counter (cf. Fig. 24).

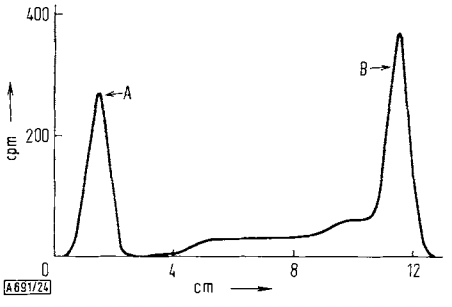

Fig. 24. Activity distribution on a paper chromatogram. A: Start, B: Solvent front.

The same principle can also be used with high-voltage electrophoresis for the investigation of precipitation reactions.

3.8. Coprecipitation

Important information can also be obtained from the behavior of foreign substances in a precipitation reaction. This is particularly true of a microcomponent, *i.e.* a foreign substance that is present in an extremely low concentration in comparison with the principal component (macrocomponent). Radiochemical methods are particularly useful for the elucidation of the behavior of microcomponents. The first detailed investigations on coprecipitation were carried out by *Hahn*[26].

Two processes may be responsible for the coprecipitation of a microcomponent, *i.e.* (1) formation of solid solution and (2) occlusion or adsorption. The tendency to form solid solutions depends on whether the macrocomponent and the microcomponent have similar ionic radii and the same charge. If these conditions are satisfied and the microcomponent is less soluble than the macrocomponent, the microcomponent is generally enriched in the solid phase. A more interesting microcomponent for the investigation of precipitation reactions is one that is occluded in or adsorbed on the solid phase. The occlusion of a microcomponent may result from chemical reactions with the macrocomponent or from adsorption during precipitation. In the latter case one should expect partial separation of the microcomponent during ripening.

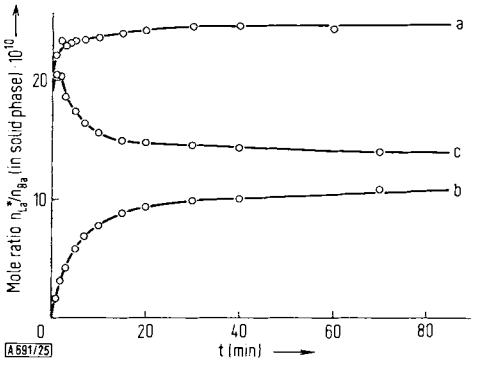

Fig. 25. Behavior of carrier-free lanthanum ions during the precipitation of barium sulfate by mixing of 10^{-3} M solutions of $Ba(NO_3)_2$ and $NaSO_4$. a: Addition of the labeled La^{3+} ions before the start of precipitation; b: addition of La^{3+} after completion of precipitation; c: occluded La^{3+} ions.

This is in fact observed. Figure 25 shows the behavior of carrier-free lanthanum ions during the precipitation of barium sulfate. The molar ratio La^{3+}/Ba^{2+} is of the order of 10^{-8} in this example. If the radioactively labeled La^{3+} ions are added before the start of precipitation, they may be occluded in or adsorbed on the surface (curve a). If on the other hand the La^{3+} ions are not introduced into the solution until the precipitation is complete, only adsorption on the surface occurs (curve b). The difference between curves a and b (curve c) shows the behavior of the occluded lanthanum ions. A proportion of these ions (about 1/3) is carried out of the solid phase again in the course of about 30 minutes. This is due to ripening, which proceeds as Ostwald ripening.

4. Experimental Results

4.1. Nucleation

A freshly supersaturated solution at first contains only ions (ion pairs) or molecules, whereas it later contains mainly nuclei or crystals. Between these there must be more or less stable intermediates known as subnuclei; these can also be described as high molecular weight complexes or aggregates of molecules. The reactions that take place during the formation of a crystal from cations A^+ and anions B^- can be summarized in the following scheme:

$$A^+ + B^- \rightleftharpoons AB \overset{A^+,\,B^-}{\rightleftharpoons} (AB)_n \overset{A^+,\,B^-}{\rightleftharpoons} (AB)_n^* \rightarrow \text{crystal} \quad (44)$$

The complexes $(AB)_n$ may contain an excess of cations or of anions (*e.g.* $[(AB)_nA_m]^{m+}$), depending on the concentrations in solution.

Radiochemical measurements show that the concentration of dissolved molecules or ion pairs AB and

[26] *O. Hahn* and *L. Imre*, Z. physik. Chem., Abt. A *144*, 161 (1929); *O. Hahn*: Applied Radiochemistry. Cornell University Press, Ithaca, N.Y., 1936.

of high molecular weight complexes $(AB)_n$ in saturated solutions is relatively small. It is about 2% of the total concentration in the saturated solution for silver halides [27], a few tenths of one percent for barium sulfate [28], and a few percent for strontium sulfate [28].

According to classical theory [3, 12] there should always be a certain amount of high molecular complexes $(AB)_n$ present in quasistationary equilibrium immediately after the saturation point has been reached; according to *Nielsen* [4] there is a certain delay before these complexes are formed.

On the basis of existing knowledge of the rates of ionic reactions [29], it must be assumed that the reversible reactions that lead to the formation of the complexes $(AB)_n$ are very fast, at least in the low molecular weight range. At higher molecular weights, inhibitions similar to those observed in crystal growth may occur.

The principal questions in the investigation of nucleation are as follows:

(a) What is the critical supersaturation or the critical supersaturation ratio?

The critical supersaturation ratio Γ is defined [30] as

$$\Gamma = \sqrt{\frac{K_{su}}{K_s}} \tag{45}$$

(K_{su} and K_s are the solubility products in the supersaturated and in the saturated states respectively); some examples of experimental values are $\Gamma = 4$ for silver chloride [8] and 7.1 for barium sulfate [31]. As is shown by the existing data, the critical supersaturation is higher for 2,2-electrolytes such as barium sulfate, strontium sulfate, and calcium oxalate than for 1,1-electrolytes such as the silver halides. The values also depend on the precipitation conditions [8, 31].

(b) How does the nucleation rate vary with the supersaturation?

The nucleation rate increases very rapidly with increasing supersaturation. This relationship, which is illustrated in Figure 4, has frequently been confirmed experimentally [4, 8] and is also clearly seen from electron micrographs (cf. Figs. 15 and 16).

(c) Can the nucleation intermediates indicated in eq. (44) be detected?

From the assumption that the solubility product is an upper ion concentration limit, and that even in the presence of a solid phase, the ion concentration cannot be increased indefinitely beyond this limit, it follows that highly supersaturated solutions must contain detectable quantities of subnuclei. Attempts to detect these subnuclei by paper chromatography or high-voltage electrophoresis have been unsuccessful. This negative result is further confirmed by conductivity measurements (Table 1).

Table 1. Conductivity before and after mixing equal volumes of $Ba(NO_3)_2$ and K_2SO_4 solutions having equal conductivities.

$c_{Ba^{2+}}$ [a] (mole · l^{-1})	σ_c [b] (Ω^{-1} cm^{-1})	$c_{Ba^{2+}}$ [c] (mol · l^{-1})	Saturation ratio (c/c_s)	σ_c [c] (Ω^{-1} cm^{-1})	Reaction time (min)
8×10^{-5}	1.09×10^{-5}	4×10^{-5}	4	2.08×10^{-5}	—
1.6×10^{-4}	4.12×10^{-5}	0.8×10^{-4}	8	4.09×10^{-5}	—
2.0×10^{-4}	5.12×10^{-5}	1.0×10^{-4}	10	5.12×10^{-5}	45
2.72×10^{-4}	7.03×10^{-5}	1.36×10^{-4}	13.6	7.03×10^{-5}	20
4.0×10^{-4}	10.15×10^{-5}	2.0×10^{-4}	20	10.1×10^{-5}	7
5.0×10^{-4}	12.7×10^{-5}	2.5×10^{-4}	25	12.6×10^{-5}	5

[a] Before mixing. [b] Specific conductivity of the starting solutions. [c] After mixing.

Barium nitrate and potassium sulfate solutions having equal conductivities were mixed and the conductivity of the mixture was then measured immediately. If no high molecular weight complexes are formed, the conductivity should not decrease (provided that the change in the activity coefficients of the ions on mixing can be neglected). It can be seen from Table 1 that there is no appreciable decrease in conductivity after mixing even at a supersaturation ratio of 25.

Contrary to the classical theory of nucleation [3, 12] which postulates that the concentration of subnuclei ought to be ≈ 2 orders of magnitude greater than that calculated from the maximum error of the conductivity measurements, the experimental results indicate that subnuclei are not present in appreciable quantities. The solution contains almost exclusively ions. The reaction in accordance with eq. (44) has not yet progressed appreciably from left to right. The concentration of the ions is higher by the factor given by the supersaturation ratio than in the saturated solution. The inhibition of the nucleation begins in the region of the higher molecular weight complexes $(AB)_n$ or in the critical nucleus $(AB)_{n^*}$. This inhibition may be due to the need for the components of the high molecular weight complexes to arrange themselves into the precursor of a crystal.

4.2. Growth

The growth of the crystals can be described by the variation of the average crystal size with time (Fig. 20).

If the crystals are to be sorted according to size, it is recommended that at least two separation methods be used and the results compared. For example, very small crystals that are retained by a membrane filter migrate with the solvent front in paper chromatography (cf. Fig 26).

It is found that for barium sulfate, strontium sulfate, and calcium oxalate, the rate of crystal growth is determined over a wide concentration range by the surface reaction, and not by diffusion in the solution [32–34]. In the case of potassium perchlorate, on the other hand, the rate-determining step is the diffusion in the

solution [35]. The inhibition of the crystal growth may be due to various factors. The following possibilities are conceivable:

(a) The ions have to overcome a potential barrier to become incorporated into the crystal lattice and to lose at least part of their solvation shell.

(b) Only a few sites on the surface are suitable for the deposition of an ion.

(c) A surface nucleus must be formed first.

Experiments in which crystals whose ripening process is complete are used and the supersaturation is such that no new nucleation is possible are particularly useful for the study of crystal growth. Experiments with calcium oxalate and strontium sulfate show clearly that even under these conditions the surface reaction is rate-determining. It is interesting to note that the growth of these crystals and the isotopic exchange on their surface have the same half life. The same processes are evidently rate-determining in both cases. This suggests, however, that the inhibition of growth is due to the factors mentioned under (a), *i.e.* to a potential barrier for the incorporation of the ions into the crystal lattice or to the removal of water of hydration.

4.3. Ripening

Ripening can be followed very easily by radiochemical methods, since in ripening by the Ostwald mechanism small crystals redissolve while larger crystals continue to grow. This is accompanied by transport of matter, which must lead to a change in the specific activity in the solution.

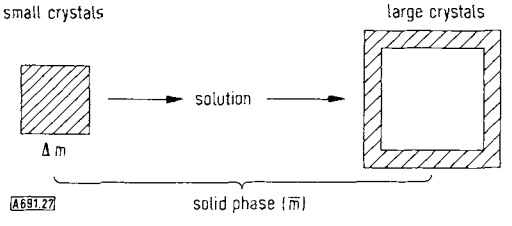

Fig. 27. Scheme of Ostwald ripening.

[35] *G. Tappe* and *M. Kahlweit*, Z. physik. Chem. N.F. *30*, 90 (1961).

Let $t = 0$ be the start of precipitation and t_0 the time at which the activity is introduced. According to eq. (38), the specific activity in the solution at time t_0 is $A_0 = a_0/m_0$. To facilitate understanding, Ostwald ripening is formally divided into two steps in Figure 27.

In the first step of ripening, a quantity Δm of small crystals is dissolved. The specific activity in the solution consequently changes to

$$A = \frac{a_0}{m_0 + \Delta_m} \tag{46}$$

In the second step the quantity Δm is deposited on larger crystals. This does not lead to a change in the specific activity in the solution. Based on the total quantity $\bar{m}$ of solid phase present at time t_0, the ratio $\Delta m/\bar{m}$ is a measure of Ostwald ripening.

$$\frac{\Delta m}{\bar{m}} = \frac{m_0}{\bar{m}} \frac{A_0 - A}{A} \tag{47}$$

$\Delta m/\bar{m}$ is the fraction of the solid phase that is dissolved and redeposited between the time t_0 of introduction of the activity and the end of the precipitation process. The ripening in fact proceeds, not in two independent steps, but continuously in very many small successive steps. However, this does not affect the validity of the treatment.

Experimental $\Delta m/\bar{m}$ values are given Table 2 for the precipitation of barium sulfate. It can be seen that *e.g.* of the solid that is present 2 minutes after the start of precipitation from 0.01 M solutions, about 37% have undergone Ostwald ripening, *i.e.* have redissolved, before the end of the precipitation. Ripening thus leads to extensive changes in the solid phase, which are associated with appreciable matter transport through the solution. The values for $\Delta m/\bar{m}$ observed at the end of the precipitation are a measure of the isotopic exchange on the surface of the solid phase.

Table 2. Fraction of the solid phase that participates in exchange of matter between the solid phase and the solution as a result of Ostwald ripening between the indicated time t_0 after the start of precipitation and the end of the precipitation of $BaSO_4$.

t_0 (min)	$\frac{\Delta m}{\bar{m}}$		t_0 (min)	$\frac{\Delta m}{\bar{m}}$	
	[a]	[b]		[a]	[b]
0.5	1.0	(0.5)	10	0.069	0.056
1	0.65	0.42	20	0.035	0.041
2	0.30	0.37	30	0.035	0.041
3	0.23	0.16	60	—	—
5	0.103	0.15	65	0.019	—

[a] Precipitation from 10^{-3} M solutions. [b] Precipitation from 10^{-2} M solutions.

The process of Ostwald ripening is thus detected and quantitatively determined in this way. No cementation takes place in the systems studied so far (alkaline earth metal sulfates, calcium oxalate).

4.4. Recrystallization

Recrystallization with the aid of the mother liquor can also be followed radiochemically. Clear differences are found in the recrystallization rates. For example, the half life of the recrystallization in the precipitation of barium sulfate is 80 min for 10^{-2} M solutions, 2000 min for 10^{-3} M solutions, and 6000 min for 4×10^{-4} M solutions.

Since precipitation from concentrated solutions yields very imperfect crystals (cf. Fig. 15), the half-life of the recrystallization is a sensitive measure of the perfection of the crystals. The lower the supersaturation at which the crystals are formed, the less imperfect they are and the smaller is their tendency to recrystallization.

Conclusions concerning recrystallization can also be drawn from the behavior of foreign ions that form solid solutions with the solid phase. The ease with which these foreign ions are incorporated into the solid phase increases as their solubility decreases and as their ionic radius approaches that of the ions of the solid phase. Thus barium ions are incorporated preferentially during the recrystallization of strontium sulfate, whereas calcium ions are not [36].

The specific surface area of the solid phase [25] passes through a maximum during recrystallization only in precipitations from relatively concentrated solutions (cf. Fig. 21). To explain this maximum, which is observed at various temperatures (cf. Fig. 22), it must be assumed that the crystals formed under these conditions are so strongly disordered that they break down during recrystallization to give smaller crystals, which then recombine and grow into larger crystals again. This process may be due to crystal imperfections that are gradually healing.

The results of these investigations explain the well known analytical practice of leaving a precipitate in contact with the mother liquor for 24 hours before filtration.

5. Some Characteristics of the Precipitation of Hydroxides

The precipitation of hydroxides differs from the precipitation of ionic crystals in the following respects:

(a) Hydroxide precipitates are generally amorphous.

(b) The treatments proposed by *Kossel* [13] and *Stranski* [14] cannot be applied to hydroxides, *i.e.* the nucleation and growth cannot be described merely by the deposition of ionic or molecular units, since chemical reactions also occur (*e.g.* reactions between OH groups with loss of water).

(c) The course of the precipitation of hydroxides depends not only on concentration, temperature, and time, but also on the pH value.

The precipitation of hydroxides is therefore a very much more complicated process than the precipitation of an ionic crystal. Though simple models exist, *e.g.* for the course of the chemical reaction and the formation of basic salts as intermediates, there are as yet no more advanced schemes for the quantitative treatment of the precipitation of hydroxides.

Information about the effects of time and pH can be obtained from radio paper chromatography [37]. Figure 28 shows the pH dependence of the quantity of high molecular weight condensation products that remains at the start of the chromatogram for the precipitation of cerium(III) hydroxide. The vertical arrows show the effect of time. The experimental values obtained immediately after the adjustment of

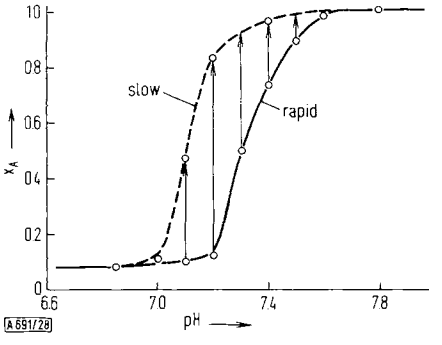

Fig. 28. Fraction of high molecular weight condensation products remaining at the start of the paper chromatogram for the precipitation of cerium(III) hydroxide as a function of the pH value and of time.

the pH (fast precipitation) are given as well as the limiting values found after several hours at a constant pH value. This diagram clearly shows the characteristic features of a hydroxide precipitation, *i.e.* the start of the precipitation of the hydroxide and the aging of the hydroxide at constant pH value.

The corresponding diagram for the precipitation of iron(III) hydroxide is shown in Figure 29.

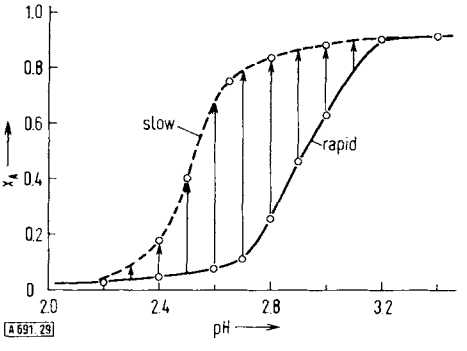

Fig. 29. Fraction of high molecular weight condensation products remaining at the start of the paper chromatogram for the precipitation of iron(III) hydroxide as a function of the pH value and of time.

Though this method does not provide new fundamental information, it does yield quantitative information on the course of the hydroxide precipitation. Intermediates can also be detected on the paper chromatograms in the region between the start and the solvent front (cf. Fig. 24); however, these intermediates cannot be identified.

[36] *W. Hild* and *K. H. Lieser*, Z. anorg. allg. Chem. *331*, 133 (1964).

[37] *A. Fabrikanos* and *K. H. Lieser*, Z. physik. Chem. N.F. *51*, 130 (1966).

The dependence of the precipitation of hydroxides on pH and time can be discussed on the basis of the scheme shown in Figure 30. Important processes involved in the precipitation are hydrolysis reactions, which lead to hydroxo complexes and hydroxides, and condensation reactions in which products having higher molecular weights are formed. The hydrolysis reactions are relatively fast, whereas the condensation reactions are slow. It is therefore not surprising that the path followed varies according to whether the pH change is fast or slow. The products may also be different. Thus the probability of occlusion of foreign substances (particularly of hydroxides being formed at higher pH values) is considerably greater when the pH change is fast. Diagrams of the types shown in Figures 29 and 30 therefore yield important information for the practical precipitation of hydroxides.

Tetrakis(cyclopentadienyl)protactinium(IV)

By *F. Baumgärtner, E. O. Fischer, B. Kanellakopulos,* and *P. Laubereau* [*]

Tetrakis(cyclopentadienyl)protactinium(IV) *(1)* is the first complex of protactinium to contain purely aromatic ligands. Surprisingly, the central atom is tetravalent in this complex. In its synthesis, Pa_2O_5 (110 mg) was first chlorinated by a $Cl_2/CCl_4/Ar$ mixture for 3 h at 600 °C. The yellowish white chlorination product that was collected as sublimate was treated immediately with $Be(C_5H_5)_2$ (2.6 g) at 65 °C. After a reaction time of 45 h, the excess of $Be(C_5H_5)_2$ was removed from the dark green reaction mixture by vacuum sublimation (80 °C/10^{-3} torr). Benzene-extraction of the residue for 110 h with exclusion of air afforded chloride-free *(1)* in the form of orange-yellow crystals (yield calculated with respect to Pa_2O_5: 54%).

The appearance of the molecular ion peak at *m/e* 491 and of a fragmentation pattern analogous to that of the corresponding compound $Th(C_5H_5)_4$ [1] in the mass spectrum (Varian MAT CH-5, electron energy 70 eV, sample temperature ~20 °C) confirm the presence of $Pa(C_5H_5)_4$.

Compound *(1)* is moderately soluble (*ca.* 1.1 mg/ml) in benzene, forming a pale yellow solution. Unlike $Th(C_5H_5)_4$ it cannot be sublimed, but decomposes above 210 to 230 °C similarly to $U(C_5H_5)_4$ [2] and $Np(C_5H_5)_4$ [3].

The IR spectrum of *(1)* (KBr disk) demonstrates the presence of exclusively symmetrical five-membered rings in that it contains characteristic bands at 784 and 811 (γ_{CH}), 1008 (δ_{CH}), 1445 (ω_{CC}), and 3078 cm^{-1} (ν_{CH}). It can also be deduced from the positions and the intensities of the bands that compound *(1)* possesses a molecular structure that is analogous to those of the other tetrakis(cyclopentadienyl) complexes of 5f elements.

Alkali-Metal (Diphenylphosphino)dithioformates and (Diphenylthiophosphinyl)dithioformates

By *R. Kramolowsky* [*]

Metal dithiocarbamates have been much investigated in the past and have been used for analytical and industrial purposes. However, of the related phosphinodithioformates only one triphenyltin [1] and one phenylzinc derivative [2] of (diphenylphosphino)dithioformic acid have so far been recorded, and only then in a brief manner [3].

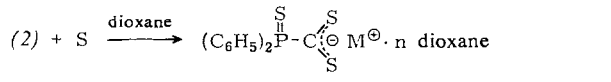
Alkali-metal (diphenylphosphino)dithioformates can be prepared by reaction of alkali-metal diphenylphosphides *(1)* with CS_2 in tetrahydrofuran (THF) at about −50 °C under nitrogen, and have been isolated as dioxane adducts *(2)* in 70–90% yield.

$$(C_6H_5)_2PM + CS_2 \xrightarrow[\text{2. ether/dioxane}]{\text{1. THF}}$$

(1)

(M = Li, Na, K)

$$(C_6H_5)_2P\text{-}C(=S)S^{\ominus}\,M^{\oplus}\cdot 1\ \text{dioxane}$$



(2)

These pale orange-yellow compounds *(2)* form pale red, stable solutions in polar solvents such as acetone, THF, and alcohol, but aqueous solutions decompose after a short time. In acetone they show their ionic character by pronounced conductivity (M = K, equivalent conductivity at 25 °C: Λ_c = 90.5 Ω^{-1} cm^2 $mole^{-1}$; v = 569.0 l·$mole^{-1}$).

Barium bis[(diphenylphosphino)dithioformate] is obtained by double decomposition of *(2)* with anhydrous $Ba(NO_3)_2$ in liquid ammonia. This salt is readily soluble in boiling NH_3

but crystallizes from this solvent at −70 °C in pale red, shiny leaflets; it resembles the alkali-metal salts *(2)* closely in its solubility properties and in being easily hydrolyzed.

In dioxane solution the alkali-metal (diphenylphosphino)dithioformates add sulfur even at room temperature, forming the hitherto unknown alkali-metal (diphenylthiophosphinyl)-dithioformates, which crystallize as dioxane adducts *(3)* in almost quantitative yield.

(2) + S $\xrightarrow{\text{dioxane}}$ $(C_6H_5)_2\overset{S}{\overset{\|}{P}}-C^{\ominus}\begin{matrix}\nearrow S\\ \searrow S\end{matrix}$ $M^{\oplus}\cdot$ n dioxane

(3)

M = Li; n = 3
M = Na; n = 1
M = K; n = 2

The ionic structure of these compounds *(3)* is shown by their solubility in polar organic solvents and by their high conductivity in acetone (M = K, equivalent conductivity at 25 °C: $\Lambda_c = 124.5\ \Omega^{-1}\ cm^2\ mole^{-1}$; $v = 551.0$ l·mole^{-1}).

In the IR spectra of *(2)* (in acetone) a broad, very intense band at 1009–1011 cm^{-1} can be assigned to the ν_{as}SCS vibration; in the case of *(3)*, ν_{as}SCS appears shifted to shorter wavelengths at 1046 (vs), the νP=S being as expected at 645 cm^{-1} (vs).

When aqueous solutions of nickel(II) salts are treated with alcoholic solutions of *(2)*, ocher-colored nickel(II) bis[(diphenylphosphino)dithioformate] *(4)* is precipitated; this dissolves to red solutions in organic solvents such as chloroform, carbon tetrachloride, acetone, and benzene; the result of cryoscopic molecular-weight determination indicates that this salt *(4)* exists as monomer in 1,2-dibromoethane and it has no electrical conductivity in acetone solution. It is diamagnetic, whence it can be assumed to be a square-planar chelate complex with low-spin configuration of the nickel(II) ion.

Experimental:

All operations are carried out under pure nitrogen. Solutions of *(1)* in THF are obtained as follows:

(a) for M = Na or K: by heating diphenylphosphine (10 ml, 10.6 g, 57 mmoles) and sodium (1.5 g) or potassium (3 g) in THF (75 ml) under reflux; or (b) for M = Li: by dissolving lithium diphenylphosphide-dioxane (16.0 g, 57 mmoles) [5] in THF (75 ml).

Either of these solutions is added dropwise, with stirring at −50 °C over 1 h, to a solution of CS_2 (3.5 ml, 4.4 g, 57 mmoles) in THF (100 ml). The THF is then mostly removed in a high vacuum, the oily residue is taken up in ether, and the ethereal solution is treated with dioxane (10 ml). The dioxane-adducts *(2)* crystallize slowly at 0 °C and are purified by dissolution in dioxane and precipitation by ether (yield 70–90%).

A Salt-Like Organic Complex Containing Molecular Nitrogen [1]

By *J. Ellermann, F. Poersch, R. Kunstmann*, and *R. Kramolowsky* [*]

Reaction of a 1:4 (molar) mixture of tetrakis[(phenylsodiophosphino)methyl]methane *(1)* [2] and CS_2 in tetrahydrofuran (THF) at 60 °C under argon gives tetrasodium neopentanetetrayltetrakis[phenyl(thiocarbonyl)phosphoranethiolate] *(2)*, which is ocher-colored and soluble in polar solvents. This product absorbs molecular nitrogen greedily and within 24 h gives a quantitative yield of the yellowish-brown complex *(3)* with the stoichiometric proportions *(2)*: $N_2 \approx 1{:}2$. The complex *(3)* is also formed directly and more rapidly by analogous reaction of *(1)* with CS_2 under nitrogen. It is remarkable that the alkali-metal (diphenylphosphino)-dithioformates *(5)* [3] that are formed from alkali-metal diphenylphosphides *(4)* and CS_2 at −50 °C do not react with N_2 [3].

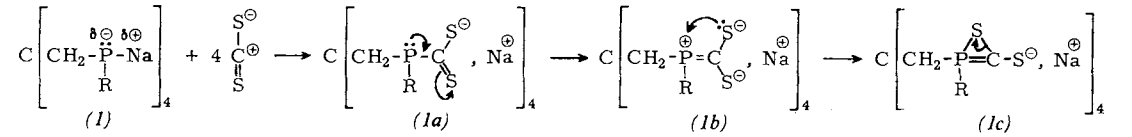
$C[CH_2P(R)Na]_4 + 4\ CS_2 \xrightarrow[60°C]{Ar} C\left[CH_2-\overset{S^{\ominus}}{\overset{|}{P}}=C=S,\ Na^{\oplus}\right]_4$

(1): R = C_6H_5 *(2)*

$\xrightarrow{N_2} C\left[CH_2-\overset{S^{\ominus}}{\overset{|}{P}}=C=S,\ Na^{\oplus}\right]_4 \cdot 2\ N_2$

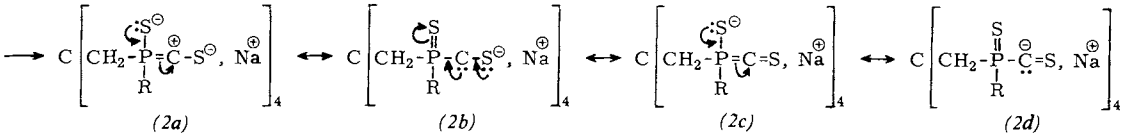
(3)

$R_2PM + CS_2 \xrightarrow[-50°C]{N_2} R_2P-C\begin{matrix}\nearrow S\\ \searrow S^{\ominus}\end{matrix},\ M^{\oplus}$



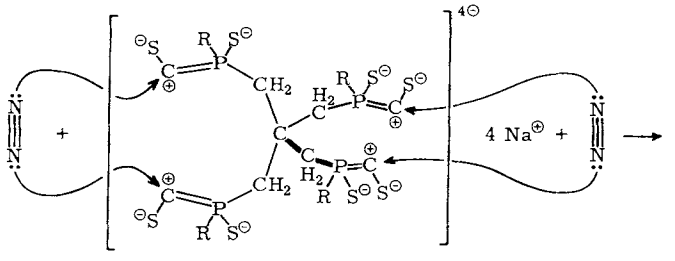
(4): R = C_6H_5 *(5)*
M = Li, Na, K

That the reactions of *(1)* and *(4)* with CS_2 lead to different types of product may be due primarily to the different reaction temperatures. Absorption of only two moles of N_2 per mole of *(2)* indicates that, like numerous other compounds containing the neopentane skeleton [4–6], the compound *(2)* functions as a twice bidentate reagent and chelating agent and that it binds N_2 in a spirocyclic 1:2 complex *(3)*.

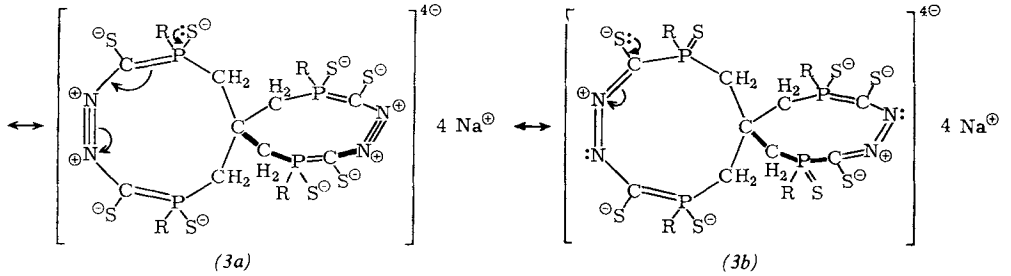


We suggest that, in the first step of the reaction, CS_2 is inserted into the polar P–Na bonds. *(1a)* can pass into *(2a)* by the regrouping *(1a)* of electrons and the rearrangement *(1b,c)*. The possibility of mesomeric stabilization between a carbonium *(2a)*, a carbene *(2b)*, a thiocarbonyl *(2c)*, and a carbanion structure *(2d)* explains both why *(2)* can be obtained as intermediate and why it is very reactive – sufficiently so to fix molecular nitrogen. As a working hypothesis we assume that *(3a)* is thus formed and stabilizes itself by mesomerism with *(3b)* and *(3c)*.

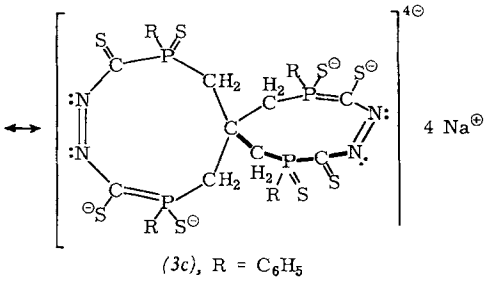
Like N_2, the isoelectronic CN^- also forms a 1:2 complex with *(2)*; from CO and *(2)* is obtained a compound that contains CO as a carbonyl group (ν>C=O: 1708 cm^{-1}). Reaction of the salt *(1)* with CO_2 gives $C[CH_2P(C_6H_5)-COONa]_4$ which is inert to N_2.



The composition and ionic character of compounds *(2)* and *(3)* are proved by elemental analyses and measurements of conductivity in dimethylformamide (DMF). The IR spectrum of *(3)* (as KBr disk) includes, besides the absorptions due to the neopentane skeleton and the phenyl groups, the following intense bands (cm^{-1}): νN=N 2090; νP–C$\begin{matrix}\nearrow S\\ \searrow N\end{matrix}$ 1166, 1050, and 902; νP=S 633. The bands at 2090 and 900 cm^{-1} are not present in the IR spectrum of *(2)*. The bond order of the N≡N bonds in *(3)* can be calculated by Siebert's method [7] from the νN≡N as being 2.6, *i.e.*, of the mesomeric

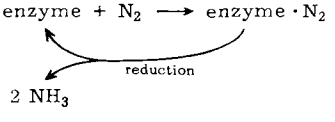


(1) (1a) (1b) (1c)



(2a) (2b) (2c) (2d)

(2a)



(3a) (3b)

(3c), R = C_6H_5

forms *(3a–c)* the greatest weight attaches to *(3a)*. Since the salt *(3)* decomposes on vaporization, no molecule ion appears in its mass spectrum; the fragment ions that occur can thus serve only as indications for the correctness of structure *(3)*. The fragment of greatest relative intensity, at m/e = 155 [CH_3–P(S)–C_6H_5], indicates the occurrence of this grouping in *(3)*; its composition is proved by the isotope peak for ^{34}S at m/e = 157. The assumption that a 1,2-shift of the phenyl group on the P–S bond occurs before further fragmentation is supported by observation of ions m/e = 109/111 (S–C_6H_5). Other fragments correspond to the tropylium cation [$C_7H_7^+$: m/e = 91; from CH_2–P(S)–C_6H_5 by elimination of PS^+ ?] and the C_6H_5 unit and their subsequent products. Similarly, expected ions from *(3)* can be seen with the composition PS (m/e = 63/65), CS (m/e = 44/46), C_4H_5 [m/e = 53; the residue of the neopentane skeleton after elimination of CH_3–P(S)–C_6H_5], N_2 (m/e = 28; second-largest relative intensity), Na (m/e = 23).

On the basis of our findings it seems possible that N_2 could be fixed also by enzymes that contain no transition-metal catalyst [8]. The extent to which compound *(3)* can be used as a model substance in this connection remains to be determined by future investigations.

Experimental:

Compound *(1)* (773 mg, 1.31 mmoles) and CS_2 (398 mg, 5.23 mmoles) in argon-saturated THF (25 ml) are warmed under argon for 4 h at 60 °C. When the solution is concentrated to *ca.* 10 ml in a high vacuum and then treated with light petroleum (40 ml), the product *(2)* is precipitated; it is washed with light petroleum (4 × 10 ml) and dried in a high vacuum (yield 85%), then having m.p. from 180 °C (dec.) and Λ (20 °C, DMF) = 182 Ω^{-1} cm^2 mole^{-1}, v = 7200 l · mole^{-1}. The product *(2)* dissolves readily in DMF, moderately in THF, ethanol, acetone, acetonitrile, dioxane, and halogenated hydrocarbons. All operations are conducted under argon; on contact with N_2 the salt *(3)* is formed. This is obtained directly by heating *(1)* (726 mg, 1.23 mmoles) with CS_2 (380 mg, 5 mmoles) in THF (20 ml) in a nitrogen atmosphere under reflux [working up as for *(2)*; yield 80–85%]; it has m.p. from 208 °C (dec.) and Λ (20 °C, DMF) = 154 Ω^{-1}cm^2 mole^{-1}, v = 7000 l · mole^{-1}. *(3)* dissolves readily in DMF,

ethanol/H_2O, and THF, and moderately to only slightly in acetone, acetonitrile, dioxane, CS_2, and halogenated hydrocarbons.

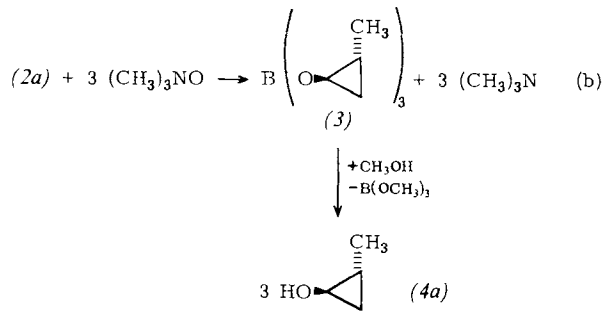
trans-2-Methylcyclopropanol from 1-Methylcyclopropene

By *R. Köster*, *S. Arora*, and *P. Binger*[*]



Reaction of 1-methylcyclopropene[1] *(1)* and diborane in pentane according to (a) proceeds *via cis* BH addition[2] to give a yield of more than 80% of tris(*trans*-2-methylcyclopropyl)borane *(2a)* [b.p. 37–40 °C/0.001 torr, molecular weight (mass spectrometric) 176 (B_1)] containing only a few (≈ 7%) 1-methylcyclopropyl groups as *(2b)* (gas chromatography). With tetraethyldiborane, compound *(1)* forms almost pure diethyl(*trans*-2-methylcyclopropyl)borane.

(a)

In diethyl ether the formation of polymeric organoboranes of unknown structure causes the yield of *(2)*[**] formed in (a) to fall to 65–70%. ^{1}H-NMR spectrum of *(2)* (undiluted): τ = 9.0 (D, $J < 2$ Hz), 9.2 (M), 9.6 (M), 10.9 ppm (M) in the intensity ratio 3:2:1:1.

Compound *(2)* reacts with trimethylamine *N*-oxide[3] in boiling toluene according to (b) giving tris(*trans*-2-methylcyclopropyloxy)borane *(3)* in 70% yield. ^{1}H-NMR spectrum

(b)

of *(3)*: τ = 6.70 (M), 9.09 (D, J = 2.5 Hz), 9.33 (M), 9.79 ppm (M) in the intensity ratio 1:3:2:1.

In a reaction analogous to (b), tricyclopropylborane[4] can also be oxidized to tricyclopropyloxyborane. Owing to the sensitivity of cyclopropanols[5], no useful results are obtained on treatment with aqueous hydrogen peroxide.

Transesterification of *(3)* with methanol leads to a 75% yield of sterically uniform *trans*-2-methylcyclopropanol *(4a)*, which contains at most *ca.* 5% of 1-methylcyclopropanol *(4b)* as a reaction product of *(2b)*. The structure of *(4a)* follows from *cis*-hydroboration[2] and from the agreement of its ^{1}H-NMR spectrum with a computer-simulated spectrum (LAOCOON I)[6]. ^{1}H-NMR spectrum of *(4a)* (undiluted): τ = 4.50 (S), 6.96 (M), 9.0 (D, J = 2.5 Hz), 9.15 (M), and 9.76 ppm (M) in the intensity ratio 1:1:3:2:1.

Tris(trans-2-methylcyclopropyloxy)borane (3)

Compound *(2)* (4.8 g, 27.2 mmole) [prepared from *(1)* and diborane in pentane] is diluted with anhydrous toluene (50 ml), and anhydrous trimethylamine *N*-oxide (6.25 g, 83.5 mmole) is added portion-wise to the solution at 80 °C. On boiling for 30 min, 4.8 g (99%) of $N(CH_3)_3$ is evolved. The excess of *N*-oxide is filtered off and the filtrate distilled under vacuum to yield compound *(3)* (4.2 g, 70%) having b.p. 74–75 °C/2 torr, n_D^{20} = 1.4288.

trans-2-Methylcyclopropanol (4a)

Removal of the azeotropic mixture $(CH_3O)_3B/HOCH_3$ (b.p. 54 °C) and of methanol from a solution of *(3)* (4.8 g, 21.4 mmole) in absolute methanol (30 ml) by distillation over a 25-cm packed column (*ca.* 3 theoretical plates) affords the compound *(4a)* [4 g, b.p. 34–36 °C/12 torr, molecular weight (mass spectrometric) 72]; gas chromatogram: 87.5% of *(4a)*, 5.7% of methylcyclopropanol *(4b)*, 1% of isobutanol, 0.1% of butyraldehyde, 4.6% of CH_3OH.

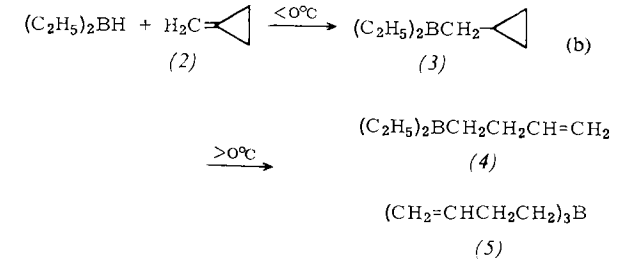
Methylenecyclopropane from Methallyl Chloride

By *R. Köster*, *S. Arora*, and *P. Binger*[*]



In continuation of previous experiments on cyclopropylborane[1] we have carried out the hydroboration[2] of 1-methylcyclopropene *(1)*. Compound *(1)* is now readily ac-

cessible by treatment of methallyl chloride with *sodium* amide in boiling tetrahydrofuran[3]. Surprisingly, however, reaction with *potassium* amide under otherwise identical conditions proceeds *via* route (a) to give a 36% yield of methylenecyclopropane *(2)*, as the only C_4H_6 hydrocarbon, instead of *(1)*.

After removal of oligomers, *e.g.* C_8H_{12} and $C_{12}H_{18}$, compound *(2)* is obtained in 97% purity (IR[4], ^{1}H-NMR[5], and mass spectra[5]). Thus the preparation of *(2)* by equation (a) is superior to all previously known methods[4–6]. Compound *(2)* is also formed quantitatively when *(1)* is passed through a suspension of KNH_2 in boiling THF, so that *(1)* cannot be ruled out as an intermediate in reaction (a).

Compound *(2)* and tetraethyldiborane react together according to equation (b) at −10 to 0 °C to give diethyl(cyclopropylmethyl)borane *(3)*, which rapidly isomerizes at room temperature to diethyl-3-butenylborane *(4)* [IR spectrum: 1637 ($\nu_{C=C}$), 990 ($\gamma_{=CH}$), 910 cm^{-1} ($\gamma_{=CH_2}$)] in a manner analogous to cyclopropylmethyllithium[7] and cyclopropylmethylmagnesium[8]. However, in the presence of pyridine the cyclopropylmethyl group of *(3)* remains intact.

Reaction of *(2)* with diborane at room temperature proceeds according to equation (b), yielding mainly tris(3-butenyl)borane *(5)*, since the cyclopropylmethyl groups of tris(cyclopropylmethyl)borane rearrange rapidly at temperatures above 0 °C. ^{1}H-NMR spectrum of *(5)* (undiluted): τ = 4.16 (M), 5.11 (M), 5.16 (M), 7.79 (M), 8.66 ppm (T, J = 8 Hz) in the intensity ratio 1:1:1:2:2.

Compound *(5)* is not completely homogeneous since hydroboration of *(2)* also gives rise to isomeric C_4H_7 groups (< 10%), presumably by inverse BH addition, which can be detected in the ^{1}H-NMR spectrum as 1-methyl-1-cyclopropyloxy groups [τ = 8.62 (S), 9.35 (M), and 9.59 ppm (M) in the intensity ratio 3:2:2] after oxidation of *(5)* by trimethylamine *N*-oxide.

Methylenecyclopropane (2)[9]

Methallyl chloride (101 g, 1.12 mole) is added dropwise over a period of 1 h to KNH_2 (64.8 g, 1.17 mole) in boiling anhydrous tetrahydrofuran (250 ml). Compound *(2)* and NH_3 are evolved and are carried by a stream of argon through 5 N H_2SO_4 (250 ml, weight increase = 14.4 g (76%) of ammonia) into a cold trap (−80 °C). A single recondensation affords 21.7 g (36%) of product; gas chromatogram: 97% of *(2)* and 3% of isobutene.

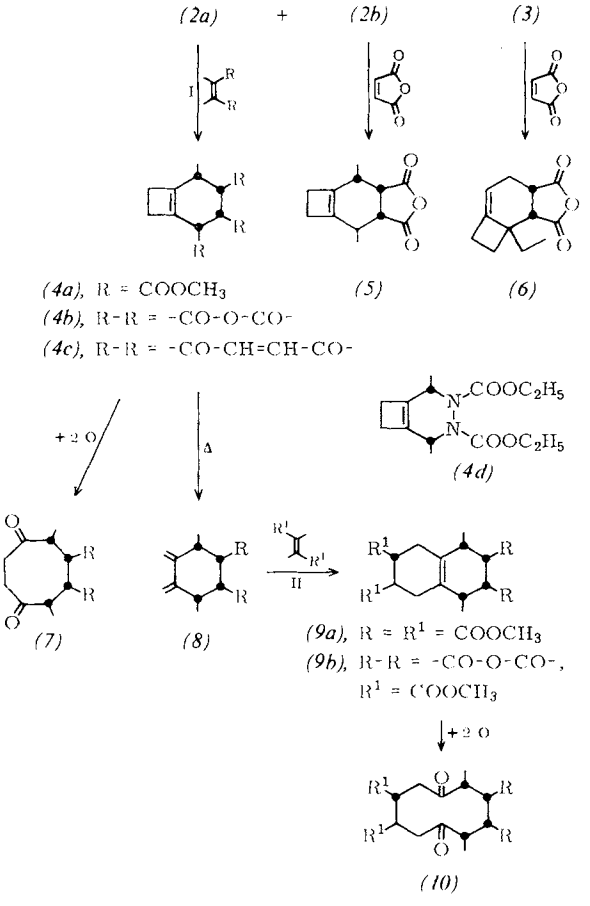
Preparation and Properties of 1,2-Diethylidenecyclobutane

By *P. Heimbach* and *R. Schimpf*[*]

The readily accessible *cis*-1,2-divinylcyclobutane *(1)*[1], which is formed catalytically in 40% yield from butadiene, undergoes ready isomerization on treatment with potassium *tert*-butoxide in dimethyl sulfoxide[2] at 40–60 °C to give *(2a)* and *(2b)* – two of the three conceivable isomers of 1,2-diethylidenecyclobutane – as well as 1-ethyl-2-vinylcyclobutene *(3)*. *trans*-1,2-Divinylcyclobutane can also be isomerized to *(2a)*, *(2b)*, and *(3)*. Compounds *(2a)* and *(2b)* were not separated by distillation.

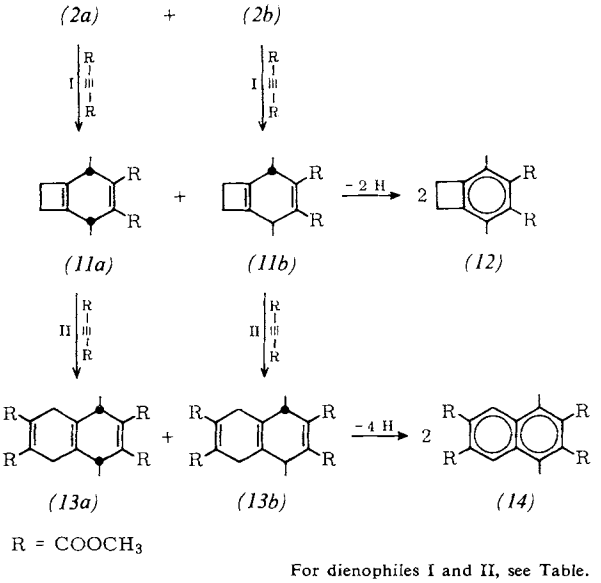


In a competing reaction, *(1)* rearranges to *cis,cis*-1,5-cyclooctadiene[3]. Since both reactions are of first order with respect to compound *(1)*, thermal rearrangement of *(1)* to *cis,cis*-1,5-cyclooctadiene can be strongly suppressed by working with high concentrations of potassium *tert*-butoxide. Moreover, *cis,cis*-1,5-cyclooctadiene undergoes partial isomerization to *cis,cis*-1,3-cyclooctadiene under the reaction conditions given above.

The equilibrium set up between *(2a)*, *(2b)*, and *(3)* in the presence of the basic catalyst can be utilized, *inter alia*, to isolate *(3)*, the isomer having the lowest boiling point, in a yield in excess of 60%, by means of a spinning-band column. Like 1,2-dimethylenecyclobutane[4–6], *(2a)* and *(2b)* can react with maleic anhydride in two steps. Compound *(3)* reacts with one mole of maleic anhydride to give *(6)*.

(2a) is considerably more reactive than *(2b)*; consequently, when a mixture of the two isomers is allowed to react under mild conditions it is only *(2a)* that actually undergoes reaction. *(2b)* can subsequently be drawn off and subjected to reaction under more drastic conditions. (Pure *(2b)* can be obtained in this way.)

The steric uniformity of the products obtained from *(2a)* or *(2b)* and the dienophile I does not depend on the reactivity of the dienophile[7].



A particular advantage lies in the fact that the four-membered ring of the primary product *(4)* opens at 140 °C to give

For dienophiles I and II, see Table.

a 1,3-diene again. The same applies to *(5)*. We were able to establish the presence of *(8)* by IR and NMR spectrometry. It can react further with the dienophile II.

Treatment of *(4)* and *(9)* with ozone and subsequent catalytic hydrogenation of the intermediate product leads to *(7)* and *(10)*, respectively, both substances being substituted in a sterically uniform manner. *(5)* reacts similarly. If, for example, dimethyl acetylenedicarboxylate is used as dienophile *(2a)* + *(2b)* afford the cyclohexadiene derivatives *(11a)* and

For dienophiles I and II, see Table.

(11b) as well as *(13a)* and *(13b)* (the formal products of the normal Birch reduction). These compounds can be oxidized to *(12)* and *(14)*, respectively, by *p*-chloranil.

A selection of the new compounds is given in Table 1.

Isomerization of (1):

Compound *(1)* (222.1 g, 2.05 mole) and DMSO (282 g) containing 47.6 g of 61.5% potassium *tert*-butoxide (remainder butanol) are stirred together vigorously for 5 h at 60 °C (± 2 °C) under a protective gas. The mixture is worked up in the following way: All volatile products are distilled off at a pressure of 10^{-4} torr, first at a bath temperature of 20 °C (F_I = 211.4 g) and then at 60 °C (F_{II} = 286.4 g). DMSO and *tert*-butanol are removed from the fractions by washing twice with water: organic phase F_I = 199.1 g; F_{II} = 16.7 g. Chromatographic analysis showed the reaction product to have the following composition: 2.7 g of *(1)* (= 98.8% conversion), 46.5 g of *(3)* = 21.2%; 75.6 g of *(2b)* = 34.4%; 68.8 g of *(2a)* = 31.4%; 4.6 g of *cis,cis*-1,3-cyclooctadiene = 2.1%; 14.0 g of *cis,cis*-1,5-cyclooctadiene = 6.4% (total rearrangement 8.5%), 3.6 g of other olefins = 1.6%; residue

Table 1. New compounds prepared from *(2a)* + *(2b)*. The IR, ^{1}H-NMR, and mass spectra are in accord with the structures given.

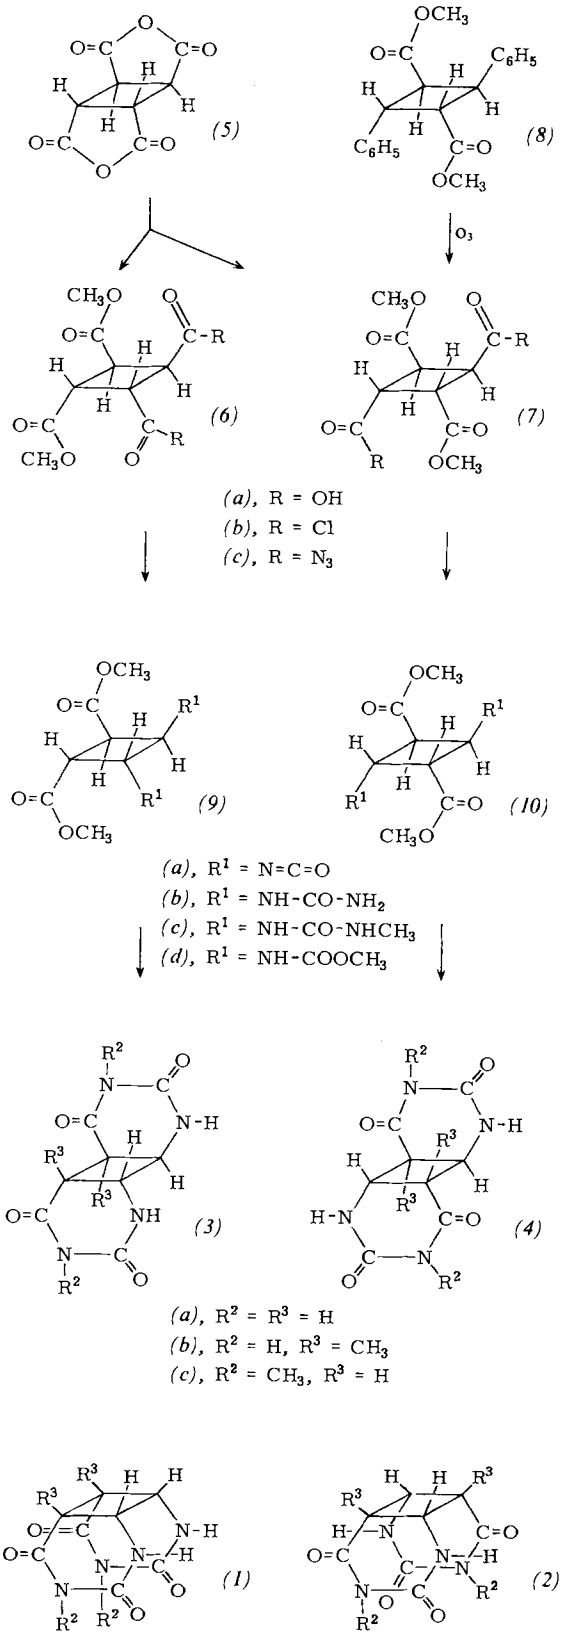
Synthesis of *trans/syn-* and *trans/anti*-Dimeric Uracil[1]



By *P. Richter* and *E. Fahr* [*]

The action of UV radiation on nucleic acids leads to, *inter alia*, dimers of thymine, cytosine, and uracil. These are considered as key compounds for biological damage by UV radiation[2]. In principle, the isomers *(1)*–*(4)* can be formed in such a dimerization. The four isomers of dimeric thymine *(1b)*–*(4b)* have been prepared by UV dimerization of thymine, thymidine, and thymidyl(3′,5′)thymidine[3]; but only the isomers *(1a)* and *(2a)* of dimeric uracil have been known to date[4]. Attempts to prepare *(3a)* and *(4a)* did not lead to products of certain structure[5]; however, these isomers have now been prepared by the following route:

When the dianhydride *(5)*, whose structure is certain[6], is boiled for 2 h with an excess of anhydrous methanol, a mixture is formed of the half-esters *(6a)* and *(7a)*, which can be separated by fractional crystallization from ethyl acetate/*n*-hexane [*(6a)*, yield 39%, m.p. 110–112 °C; *(7a)*, yield 49%, m.p. 189–190 °C]. *(7a)* is also obtained by ozonolysis of dimethyl α-truxillate *(8)*: ozone (*ca.* 17 g) is led into a solution of *(8)* (6.5 mmoles) in ethyl acetate/acetic acid (200 ml) at room temperature, 30% aqueous H_2O_2 (20 ml) is added and the mixture is left for 48 h at room temperature; the solvent is then removed in a vacuum, and the residual oil is rubbed with ethyl acetate/*n*-hexane [yield of *(7a)*, 30%].

The half-esters *(6a)* and *(7a)* are converted separately by thionyl chloride into the acid chlorides *(6b)* and *(7b)* [*(6b)*, yield 85%, m.p. 56–58 °C; *(7b)*, yield 81%, m.p. 80–82 °C], which on treatment with NaN_3 in $CHCl_3$ solution afford the unstable azides *(6c)* and *(7c)*. These azides are not isolated; when heated for an hour under nitrogen they rearrange with loss of N_2 into the isocyanates *(9a)* and *(10a)*[7], which, when gaseous NH_3 is led into their solutions in $CHCl_3$ at room temperature, give the diureido compounds *(9b)* and *(10b)* [*(9b)*, yield 76% calc. on *(6b)*, m.p. 238–239 °C; *(10b)*, yield 81% calc. on *(7b)*, m.p. 198–200 °C; isolated by filtration of the crude product that separates during the reaction and recrystallization from methanol]. When treated separately with 2 N HCl at 70 °C for 2 h, *(9b)* and *(10b)* afford the dimers *(3a)* and *(4a)* [*(3a)*, yield 90%, m.p. from 320 °C (dec.); *(4a)*, yield 75%, m.p. from 300 °C (dec.); the product that separates during the reaction is purified by washing with water]. *(4a)* is less stable thermally than *(3a)*; when boiled with 2 N HCl it is cleaved to uracil.

IR spectroscopic comparison of *(3a)* and *(4a)* with a product considered[5] to be a mixture of *(3a)* and *(4a)* showed that product was *(3a)* and not a mixture thereof with *(4a)*; a mixture is first formed, but *(4a)* decomposes under the reaction conditions.

The above method of synthesis also permits preparation of substituted dimers. For instance, *(9a)* and *(10a)* with methylamine afford, respectively, *(9c)* and *(10c)* [*(9c)*, yield 74% calc. on *(6b)*, m.p. 230–231 °C; *(10c)*, yield 79% calc. on *(7b)*, m.p. 212–214 °C], which when warmed for several hours with 2 N HCl at 70 °C pass into the dimethylated dimers *(3c)* and *(4c)* [*(3c)*, yield 54%, m.p. from 300 °C (dec.); *(4c)*, yield 32%, m.p. 226–228 °C].

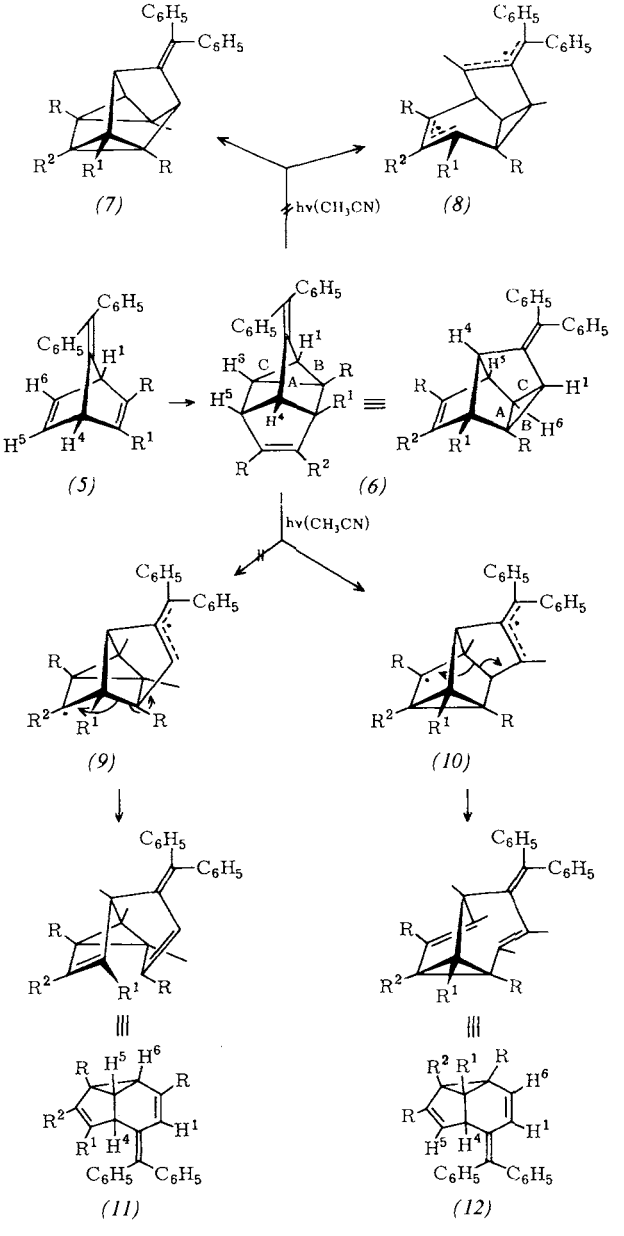
[7] When boiled for 2 h with methanol, *(9a)* and *(10a)* give, respectively *(9d)* (yield 82%, m.p. 173–174 °C) and *(10d)* (yield 70%, m.p. 164–166 °C).

Photoisomerization of Derivatives of 5-Methylenetetracyclo[4.3.0.0^{2,4}.0^{3,7}]non-8-ene[1]

By *H. Prinzbach* and *W. Auge*[*]

The rates and selectivities of photorearrangement differ for compounds of types *(1)* and *(2)*, but generally [2π + 2σ]-cycloaddition between a C=C bond and the internal cyclopropane bond A is favored, this giving compounds *(3)* and *(4)*, respectively[2,3].



The additional activation[4] of the cyclopropane bonds B and C in methylenetetracyclo[4.3.0.0^{2,4}.0^{3,7}]non-8-ene derivatives *(6a)–(6c)*[5] leaves no detectable opportunity for [2π + 2σ]-valence isomerization to afford *(7a)–(7c)*. Thus their direct activation affords the novel 5-methylenetricyclo-[4.3.0.0^{2,9}]nonadiene compounds *(12a)–(12c)* in good to very good yields[7].

In a typical experiment a degassed solution of *(6a)* (*ca.* 450 mg) in acetonitrile (250 ml) is irradiated at −20 °C for *ca.* 180 min with a Hanau Q 81 high-pressure lamp and a Vycor glass filter. The isomerization was followed by qualitative kinetic measurements (UV) which disclosed two isosbestic points, namely, at 228 and 271 nm; in spite of its high self-absorption, the product *(12a)* is largely stable under the conditions of the photolysis: brief over-irradiation decreases the yields only slightly. *(12a)* forms colorless, small crystals from methanol.

The structures of the new compounds *(6)* and *(12)*[8] are proved by their physical data (see Table)[9] and by chemical transformations[10]. As expected, the UV maxima[11] for compounds *(12a)–(12c)* are scarcely influenced by the various substitutions, and the NMR results agree well with those for model substances. The alternative structures *(11a)* to *(11c)* are excluded, as are those of products that can be derived by *a priori* very plausible isomerizations of the 1,5-diene system to bisallyl radicals such as *(8)*[14].

The excited substrates *(6a)–(6c)* become stabilized selectively by fission of the cyclopropane bond B that is activated by the ester group, which, at least for *(6b)* and *(6c)*, results in the diradicals *(10b)* and *(10c)* which are more stable than *(9b)* and *(9c)*[15]. There are previous examples[17] of a similar directing influence of methoxycarbonyl groups on the course of photochemical reactions.

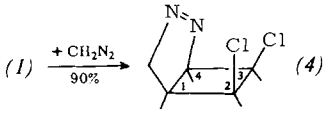
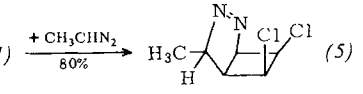
Influence of Chlorine as Substituent on the Course of 1,3-Dipolar Cycloadditions of Diazoalkanes



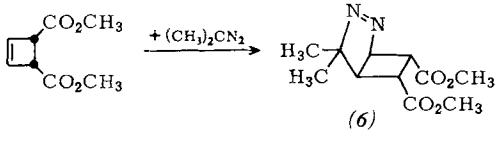
By *M. Franck-Neumann* [*]



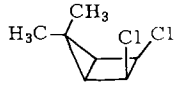
1,3-Dipolar additions of diazoalkanes represent a well known class of reactions [1] that proceed stereospecifically [2] according to a synchronous mechanism [3]. Whereas the electronic effect of substituents attached to the double or triple bond on the rate of reaction has been investigated by *Huisgen et al.* [3], little is known about the effect of substituents not attached to the double bond. As we found in earlier investigations, the highly reactive but sterically demanding compound 2-diazopropane reacts quantitatively with *cis*-3,4-dichlorocyclobutene *(1)* to form the isomeric pyrazolines *(2)* and *(3)* (ratio 1:2.5) [4].

(1) *(2)* *(3)*

If this reaction is carried out with diazomethane or diazoethane, then only one pyrazoline [*(4)* or *(5)*, respectively] is formed in each case.

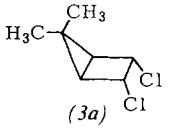


The IR and UV spectra of the adducts *(4)* and *(5)* contain the characteristic absorption bands of the azo group: $\nu(N=N)$ = 1540 cm^{-1}; λ_{max} *(4)* = 322 nm[5]; λ_{max} *(5)* = 325.5 nm; ε = 300. The NMR spectra resemble that of pyrazoline *(2)*: the situation differs from that of the pyrazoline *(3)*, the chemical shifts of the protons H-2, H-3, and H-4 in *(2)* all lying in the same region. Like *(2)*, the adducts *(4)* and *(5)* are much more strongly polar than *(3)* (behavior on thin-layer chromatography, solubility).

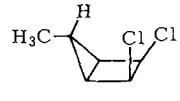


These results can only be explained if the pyrazolines *(2)*, *(4)*, and *(5)* are assumed to be in the *cisoid* form.

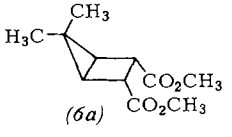
In contrast, *cis*-dimethyl 1,2-cyclobutenedicarboxylate[6] does not react with an excess of diazomethane; the sole product of its reaction with 2-diazopropane is the adduct *(6)* [$\nu(N=N)$ = 1540 cm^{-1}, λ_{max} = 328 nm (ε = 218), yield 85%], which has been shown to have a *transoid* structure by NMR spectrometry.



(6)



Confirmation of the stereochemistry of the pyrazolines *(2)*, *(3)*, *(5)*, and *(6)*[5] is also provided by their sensitized photolysis[4] to the bicyclo[2.1.0]pentane derivatives *(2a)*, *(3a)*, *(5a)*, and *(6a)* (IR spectrum shows no double bonds; only end absorption is observed in the UV spectrum).



(2a)

(3a)

(5a)

(6a)

The two methyl singlets in the spectrum of *(3a)* and of *(6a)* appear close to each other and have almost the same values of δ (0.96 and 1.27, and 0.98 and 1.21 ppm, respectively), whereas a large difference is observed in the case of *(2a)* (0.92 and 1.62 ppm). It must therefore be concluded from the observed δ value of 1.02 ppm (doublet with J = 6 Hz) that the methyl group in *(5a)* is in the *exo* position. The signal due to H-2 and H-3 also shows that *(2a)* and *(5a)*, and also *(3a)* and *(6a)*, have the same stereochemistry[7].

(2a), δ = 4.72 ppm (T), J = 2 and 2.5 Hz;

(5a), δ = 4.74 ppm (T), J = 1.8 and 2.4 Hz;

(3a), δ = 4.13 ppm (slightly split singlet), J = 0.8 and 0.8 Hz;

(6a), δ = 2.86 ppm (broad singlet), $J \leq 0.8$ Hz.

From these observations it must be assumed that in the transition state the chlorine atoms of *cis*-3,4-dichlorocyclobutene interact with the nitrogen atoms of the diazoalkanes, thereby causing orientation of the molecule and acceleration of the addition.

A New Route to Inosatriamines and Triamino Sugars

By *F. W. Lichtenthaler, P. Voss*, and *N. Majer*[*]

Numerous synthetic routes have been devised[2] to the inosamines, inosadiamines, and mono- and di-amino sugars that occur in Nature[1], yet there has so far been no systematic investigation of inositols or sugars containing three amino groups although two 1,3,5-inosatriamines[3,4] and two triamino sugars[5,6] have been prepared. Continuation of our work on the diamination of cyclic nitro diols[6,7] has now led to a new and satisfactory synthetic route to this class of compounds.

2-Nitroalkyl acetates can be converted into nitro amines in one stage by amines or ammonia[8] and this reaction can be applied to cyclic nitro di- and oligo-acetates of types *(1)*, *(2)*, *(9)*, and *(14)* which yield vicinal triamino compounds on hydrogenation of the primary products.

In this way penta-*O*-acetyl-1-deoxy-1-nitroinositol with the *scyllo*- *(1)* or *myo*-configuration *(2)*[9] gives, in both cases, di-*N*-acetyl-2-deoxy-2-nitro-*scyllo*-1,3-inosadiamine *(3)*, decomp. 296–298 °C, in 50–60% yield[10] on treatment with concentrated aqueous ammonia-dioxane (1:1) for 10 h at 25 °C and subsequent *N*-acetylation by acetic anhydride in methanol. Further acetylation by acetic anhydride converts *(3)* into the pentaacetate *(4)*, decomp. 295–298 °C, with CH_3CO resonances at τ = 8.09 (9H) and 8.26 (6H) in [D_6]-DMSO. Hydrogenation of *(3)* over 10% palladium-charcoal and subsequent acetylation affords, smoothly, hexaacetyl-*scyllo*-1,2,3-inosatriamine *(5)*, m.p. 296–298 °C (decomp.)[11] whose acetyl resonances (9H, S, at both τ = 8.09 and 8.28 in [D_6]-DMSO, τ = 7.96 and 8.07 in D_2O) unambiguously prove the presence of three acetoxy and three acetamido groups, all in the equatorial orientation[12].

(2), R^1 = OAc, R^2 = H
(3), R^1 = H
(4), R^1 = OAc
(5)
(6)
(7)
(8)
R = $C_6H_5CH_2$

The results of treating *(1)* or *(2)* (1 mole) with benzylamine (3 moles) in dioxane at 25 °C for 12 h are sterically less homogeneous, for a crystalline mixture of three nitro diamines (70% yield) results, from which the *myo*-isomer *(6)*, rhombs, m.p. 153–154 °C, can be isolated in 7% yield by fractional crystallization, whereafter thin-layer chromatography of the mother-liquor[13] affords the *scyllo*- [*(8)*, needles, m.p. 142 to 143 °C] and the *muco*-compound [*(7)*, needles, m.p. 144 to 145 °C] in 5 and 18% yield, respectively. The configurations of *(6)*–*(8)* were assigned unambiguously from the splitting patterns for the ring-protons in the 100 MHz spectra[14] and in the case of *(8)* by hydrogenation and acetylation to *(5)*.

Methyl tri-*O*-acetyl-3-deoxy-3-nitro-β-D-glucopyranoside *(9)*[15] affords analogously methyl 2,4-bis(acetylamino)-2,3,4-trideoxy-3-nitro-β-D-glucopyranoside *(10)* [(53% yield), dec. at ~ 280 °C, $[\alpha]_D^{22} = -9.3°$ (c = 0.4 in CH_3OH)] when treated with ammonia in methanol and then *N*-acetylated. Hydrogenation of *(10)* over 10% palladium-charcoal in 10:1 methanol-glacial acetic acid gives the acetate salt *(11)* [decomp. from 240 °C, $[\alpha]_D^{22} = -14.2°$ (c = 1 in H_2O), in 85% yield], and appropriate acetylation then yields the tetraacetate *(12)* [m.p. 324–326 °C (decomp.), $[\alpha]_D^{22} = -13.5°$ (c = 0.3 in H_2O)] or the tri-*N*-acetate *(13)* [decomp. 315 °C, $[\alpha]_D^{22} = -11.8°$ (c = 0.5 in CH_3OH)].

The *gluco*-configuration of these compounds follows from the NMR spectra (in [D_6]-DMSO): the proton on C-3 in *(10)* was shown at τ = 4.88 as a 10-Hz triplet, which proves the axial orientation of H-2, H-3, and H-4; and these assignments are confirmed[16] by the positions of the *N*-acetyl resonances of *(10)* (6 H, S, at τ = 8.22) and the acetyl resonances of *(12)* [8.00 (3H), 8.26 (6H), 8.28 (3H)].

(9)
(10)
(11), R = H; R^1 = H • HOAc
(12), R = R^1 = Ac
(13), R = H; R^1 = Ac
(14), R = OAc, R^2 = Ac
(15), R = NHAc, R^2 = Ac
(16), R = NHAc, R^2 = H

Under the same conditions as for *(9)*, the triacetylnitrosorboside *(14)*[17] is diaminated to yield benzyl 3,5-bis(acetylamino)-3,5,4-trideoxy-4-nitro-α-L-glucopyranoside *(16)* [m.p. 260–261 °C (decomp.), $[\alpha]_D^{23} = -97°$ (c = 0.4 in CH_3OH)] and two further, as yet unidentified products. The configuration was deduced from the NMR data for *(15)* [m.p. 224–225 °C, $[\alpha]_D^{23} = -63°$ (c = 0.5 in CH_3OH)]: after elimination of the 3,NH coupling by double resonance for H-3 and H-4, a characteristic AB system appeared for which J_{34} = 9 Hz can be calculated.

Triaminopentoses and triamino-6-deoxyhexoses may also become readily accessible by applying the reaction sequence diamination → *N*-acetylation → hydrogenation to other nitro sugar acetates[18]. Synthesis of dinitroinosatriamines[14] and triamino sugar nucleosides[19] has already been realized.

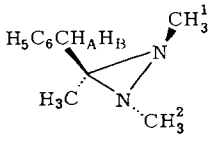
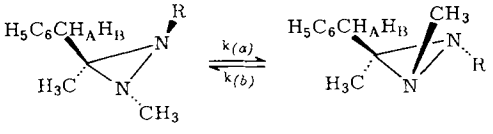
Separation of Invertomers (Diastereoisomers) of Diaziridines. Slow Inversion at Tervalent Nitrogen Atoms[1]



By *A. Mannschreck* and *W. Seitz*[*]

At temperatures up to 100 °C diaziridines *(1)* with different substituents R^1 and R^2 on the nitrogen atoms give ^{1}H–NMR spectra showing two resonances for the groups R on the ring



carbon atom[2]. It is thence concluded that inversion of at least one nitrogen atom is a relatively slow process; lower limiting values of 21 kcal/mole can be calculated for the free enthalpies of activation $\Delta G_c^{\ddagger}$. It was therefore predicted[2] that it should be possible to separate the 'invertomers' (diastereoisomers) of suitably substituted diaziridines and similarly also of oxaziridines. *Brois*[3] and *Felix* and *Eschenmoser*[4] have isolated the isomers of 1-chloroaziridines; the presence of optically active oxaziridines[5] has been recently proved[**]; but stable invertomers of diaziridines have not previously become known.

(1), R = H or CH_3

(2)

(3a), R = $CH_2C_6H_5$
(4a), R = H

(3b), R = $CH_2C_6H_5$
(4b), R = H

A limiting value for $\Delta G_c^{\ddagger}$ can also be obtained for *(2)* having equal substituents on the nitrogen atoms but different groups on the ring carbon atom. Compound *(2)* was prepared with m.p. 24–26.5 °C from benzyl methyl ketone, methylamine, and *N*-methylhydroxylamine-*O*-sulfonic acid by a procedure analogous to that described by *Schmitz*[6]. The *N*-methyl signals, of equal intensity, at τ = 7.43 and 7.59 (in diphenyl ether at 28 °C) are not broadened at 159 °C, whence a lower limit of 22 kcal/mole is obtained for $\Delta G_c^{\ddagger}$. Furthermore the spectrum contains, besides the multiplet for the phenyl protons, only the *C*-methyl singlet at τ = 8.92 and the AB absorption of the methylene group at 7.17 and 7.35 (J = 13.9 Hz). These findings can be accommodated only by the *trans*-structure *(2)*.

We have realized the predicted separation in the case of *(3a)* and *(3b)*. The mixture obtained in the synthesis from benzyl methyl ketone, benzylamine, and *N*-methylhydroxylamine-*O*-sulfonic acid gave two non-crystalline products *(3a)* and *(3b)* when twice subjected to preparative thin-layer chromatography at 20 °C on silica gel (Merck's HF_{254}) with 9:1 benzene/ethanol as eluant:

	R_F	$n_D^{19.8}$	τ (N–CH_3)	τ (N–CH_2)	τ (C–CH_3)	τ (C–CH_AH_B)
(3a)	0.6	1.5545	7.64	6.20	8.88	7.06; 7.29 (J = 13.9 Hz)
(3b)	0.5	1.5572	7.46	6.43	8.81	7.15; 7.28 (J = 13.9 Hz)

The τ values (in CCl_4 at 28 °C) agree with those of known diaziridines[2]. The *(3a)* obtained showed no signals of the other isomer, but the experimental samples of *(3b)* still contained 6% of *(3a)*. Elemental analyses and molecular weights accorded with expectation; so did the IR spectra, which differed only slightly, namely, in the region 1080 to 1130 cm^{-1}; both products exhibited the oxidizing power characteristic of diaziridines An equilibrium containing 49.8 ± 0.4% of *(3a)* was established with a half-life of 431 min in C_2Cl_4 solutions at 70.0 °C, whether *(3a)* or *(3b)* was the starting material. Thence the rate constant $k_{(3a)} = k_{(3b)} = 1.34 \times 10^{-5}$ sec^{-1} and $\Delta G^{\ddagger}_{(3a)} = \Delta G^{\ddagger}_{(3b)} = 27.3 \pm 0.2$ kcal/mole were calculated[7].

Compounds *(4a)* and *(4b)* behaved analogously: pure *(4a)*, m.p. 27–28 °C, crystallized from a solution of their mixture[8] in pentane at −10 °C. Repeated removal of *(4a)* by crystallization and thin-layer chromatography afforded 90%-pure *(4b)* with m.p. < 5 °C. Under the experimental conditions used for *(3a)* and *(3b)* the values $R_{F(4a)} = 0.4$, $R_{F(4b)} = 0.3$, $\Delta G^{\ddagger}_{(4a)} = 27.1$, and $\Delta G^{\ddagger}_{(4b)} = 26.3$ kcal/mole were obtained[9]; thus one isomer preponderates (75.3%) in the equilibrium mixture and we attribute the structure *(4a)* to it for steric reasons. The assignments of *(3a)* and *(3b)* could only be made on the basis of this finding.

Since no sign of by-products appeared during any of the equilibrations carried out, we assign a low probability to mechanisms in which the three-membered ring is opened; it is more likely that the isomers are interconverted by consecutive inversions at the nitrogen atoms[10].

Intramolecular Photocycloaddition of *N,N'*-Alkylenedimaleimides [**]

By *F. C. De Schryver, I. Bhardwaj*, and *J. Put* [*]

Maleic anhydride and maleimide derivatives can undergo photoaddition reactions with other double or triple bonds or with themselves[1,2]. A large number of intramolecular photocycloadditions of this kind are known[3] but, as stated by *Eaton*[4], "the proximity of the condensing systems in these examples might have special significance in the ease of the cycloaddition reaction".

In most hitherto known intramolecular photodimerizations, C_4 cycloaddition[2] results in formation of a five- or six-membered ring. We wish to report the photocyclomerization of dimaleimides *(1)*, in which the reacting double bonds are separated by an alkyl chain, to the tetracyclic compounds *(2)*.

The reaction is carried out in CH_3CN or CH_2Cl_2. The structure of the product is confirmed by the IR and NMR spectral data, and especially by the mass spectra (see Table). The absorption characteristics of the –CH=CH– system in *(1)* are no longer present in *(2)*, but have been replaced by bands that can be attributed to a cyclobutane ring. The ultraviolet spectra of the products *(2)* show no absorption due to a –CH=CH–CO system at about 300 nm.

f	CH_2OCH_2	129.5 [e]	3100, 698, 840	6.81	100	320 (decomp.)	3040	—	236	

[a] In KBr. [b] Resonance signals of the four cyclobutane protons, all signals are singlets. All spectra recorded in $CDCl_3$ except for *(1b)* and *(2b)* which were recorded in [D_6]-DMSO; *(2a)* and *(2f)* are not sufficiently soluble. [c] Molecular weight measured with a Mechrolab 301 A vapor pressure osmometer in $CHCl_3$. [d] 136–141 °C [5]. [e] 128–132 ° [6].

Long-range intramolecular cyclomerizations of this kind also seem to occur during UV irradiation of dinucleotides containing pyrimidine bases[7].

As expected, when the two maleimide moieties are joined by a rigid phenyl ring, as in *m*-phenylenedimaleimide, no intramolecular cyclization occurs but a polymeric material is formed.

The cyclodimerization of *N,N'*-hexamethylenedimaleimide *(1d)* to 5,12-diazatetracyclo[10.2.1.1^{2,5}.0^{3,14}]hexadecane-4, 13,15,16-tetraone *(2d)* was studied in more detail. A tenfold increase of the concentration of *(1d)* (5×10^{-3} mol l^{-1} to 5×10^{-2} mol l^{-1}) resulted in a small decrease in the yield from 95% to 85%, the remainder being polymeric material. Addition of benzophenone as photosensitizer also decreased the yield to 80%, while the presence of oxygen in no way inhibited the reaction. Most surprising is the ease and speed of the reaction. Under the same conditions and in the absence of a sensitizer, *N*-butylmaleimide yields only 15% of the expected dimer.

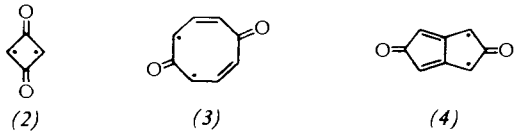
Formal Diradicals Which Should Have Singlet Ground States[1]

By *R. Gleiter* and *Roald Hoffmann*[*]

Molecules whose every classical valence structure is at best a diradical one generally emerge theoretically and experimentally as triplet ground states. We have for some time been interested in the problem of stabilizing the singlet states of such formal diradicals[2]. Two novel procedures for accomplishing this task are reported in this communication.

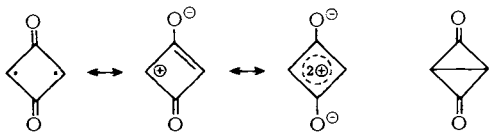


Consider trimethylenemethane, a typical carbon diradical, which in a D_{3h} geometry possesses a degenerate pair of nonbonding π orbitals. These are to be occupied by a pair of electrons, and theoretically[3] and experimentally[4] the ground state of the system appears to be a triplet. Of the two nonbonding orbitals A and B, A has density at C_1, whereas orbital B by symmetry does not[5].

A B *(1)*

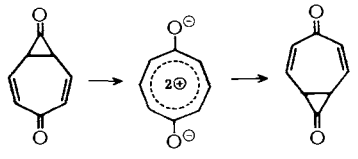
Substitution in trimethylenemethane of an oxygen atom for CH_2 at the C_1 position would be anticipated to break the degeneracy of A and B by stabilizing A and leaving B unaffected. The resulting species is oxyallyl *(1)*, the ring-opened zwitterionic form of cyclopropanone. A previous calculation which we carried out on this molecule[2b] showed that the lowest singlet was considerably stabilized, but that a triplet remained the ground state of the molecule by 0.1 eV. In order to obtain diradicals with singlet ground states we scrutinized the molecular orbitals of a large number of carbon diradicals, keeping an eye out for those molecules in which one nonbonding molecular orbital possessed electron density at one or more carbon atoms which did not appear in the other nonbonding orbital. After substituting the appropriate number of oxygens in these differentiated positions we carried out Pariser-Parr-Pople calculations with extensive configuration interaction[6].

We discovered three species, *(2)–(4)*, which were definitely singlet ground states, and a number of other borderline cases. The position relative to the ground state of the first two excited states of *(2)–(4)* is listed below the corresponding formula.



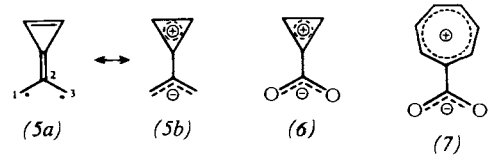
(2) *(3)* *(4)*

$^1B_{2u}$	2.03	$^1B_{2u}$	1.71	$^1B_{2u}$	2.15
$^3B_{2u}$	0.99	$^3B_{2u}$	0.34	$^3B_{2u}$	0.88
^1A_g	(0)	^1A_g	(0)	^1A_g	(0)



We have drawn diradical valence structures for *(2)–(4)*, but the calculations in each case showed final charge distributions characteristic of the expected polar resonance structures, such as *(2a)* and *(2b)*.

Each of these molecules would be expected to be highly colored. Substituted derivatives of *(2)* are known[7,8], and are strong chromophores.



(2) (2a) (2b) (2c)

A remaining unanswered question is whether these planar molecules are in fact more stable than the nonplanar bicyclic isomers [*e.g.* *(2)* → *(2c)*]. Some extended Hückel calculations indicate that *(2)* is more stable than *(2c)*, but we do not consider the result very reliable in this instance. The stabilization of *(3)* is of great interest, since it suggests the possibility of achieving a Cope rearrangement with negative activation energy.

(3a) (3b) (3c)

A related class of molecules is exemplified by *(5)*. The classical valence structure *(5a)* implies a diradical; however, the resonance structure *(5b)* clearly suggests a closed shell, and

(5a) (5b) (6) (7)

the simple Hückel calculation gives a gap of 0.704 β between occupied and unoccupied levels[9]. Nevertheless, according to our SCF calculations the ground state of *(5)* is a triplet, some 1.1 eV below the lowest singlet – the energy gap is thus not large enough for stabilization of the singlet state.

We noticed, however, that the highest occupied MO of *(5)* was an essentially localized nonbonding allyl orbital at C-1 and C-3, whereas the lowest unoccupied MO was localized in the three-membered ring. Replacement of the methylene groups at C-1 and C-3 by oxygens produced the necessary selective stabilization of the highest occupied MO.

The ground state of the cyclopropenylium carboxylate *(6)* is a singlet, with a $^3B_2$ state 0.97 eV above it. Similarly we find a singlet ground state for the cycloheptatrienylium carboxylate *(7)*, with a $^3B_2$ state 0.97 eV above it.

[5] A convenient basis, symmetry adapted for reduction of symmetry from D_{3h} to C_{2v}, is chosen for the degenerate orbital.

[6] The details of our particular variant are given in reference [2a]. We always included all singly and doubly excited configurations, and many higher excited configurations as well. The final results for the species *(3)*, for example, are for the 70 most significantly contributing configurations selected from a total of some 800 examined. Pariser-Parr-Pople calculations are normally quite reliable for π-electron spectra; however we have no calibration points for these diradicals, and we consider the results only qualitatively informative.

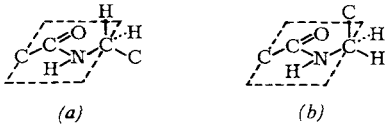
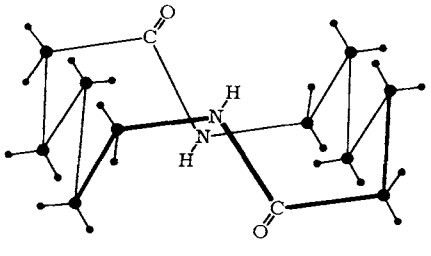
The Thermal Oxidation of *N*-Vicinal Methylene Groups in Polyamides, a Reaction Dependent on Conformation



By *H. Krüssmann*, *G. Valk*, *G. Heidemann*, and *S. Dugal*[*]

In the thermal oxidation of polycaprolactam *(1)*, as in the thermal oxidation of low-molecular weight alkyl amides, the *N*-vicinal methylene group (arrowed) is the preferred site of attack[1,2].

(1)



This group is distinguished by an interaction (hyperconjugation) which takes place between its protons and the 4π electrons of the carboxamide group[3]; an interaction which should be particularly intensive if the *N*-vicinal methylene group is in the *trans*-conformation to the amide group (Fig. 1).

(a) (b)

Fig. 1. *trans* (a) and *gauche* (b) conformations of the *N*-vicinal CH_2 group. The dotted parallelogram indicates the plane of the amide group.

Proof of this hypothesis was afforded by thermally oxidizing compounds *(1)* and 1,8-diazacyclotetradecane-2,9-dione [cyclo-bis(ε-aminocaproyl)] *(2)* at 200–220 °C. *(1)* and *(2)* consist of the same fundamental units; in contrast to *(1)*, compound *(2)* contains α-methylene groups in the *gauche* position only[4,5].

(2)

Under the reaction conditions the rotations of the α-methylene groups of *(1)* are no longer frozen in, so that a statistical distribution of *gauche*- and *trans*-conformations of the α-methylene groups occurs in the ordered as well as in the disordered region, whilst the conformation of *(2)*, which melts at 348 °C, remains stable[6]. Oxidation and subsequent hydrolysis leads to the formation, among other degradation products, of an homologous series of aliphatic mono- and dicarboxylic acids, aldehydes, amines, and ω-amino acids[1,2]. In order to eliminate the influence of possible different degrees of oxidation the ratio of adipic acid to *n*-butylamine was chosen as a measure of the reactivity of the *N*-vicinal methylene groups. *n*-Butylamine is not a secondary product of *N*-vicinal oxidation; it is bound as amide and occurs exclusively by way of chain cleavage as a result of loss of the α-carbon atom of the fundamental unit.

The adipic acid and *n*-butylamine were each determined gas chromatographically, the former as the dimethyl ester after ether extraction of the hydrolyzate and the latter as trifluoroacetamide after steam distillation of the hydrolyzate.

The ratio of adipic acid to butylamine in the hydrolyzate of thermally oxidized *(1)* is substantially greater than that in the hydrolyzate of thermally oxidized *(2)* (Table 1).

Table 1. Amounts of adipic acid and butylamine obtained as degradation products in the thermal- and photooxidation of polycaprolactam.

	Thermal oxidation		Photooxidation
	(1)	*(2)*	*(1)*
Adipic acid (c_1) (μmole/113 g)	12000	3000	5000
n-Butylamine (c_2) (μmole/113 g)	10	160	300
c_1/c_2	1200	19	17

A further indication of the dependence of the reactivity of *N*-vicinal groups on the conformation can be gained from the photooxidation of *(1)*[7]. The ratio of adipic acid to butylamine in the hydrolyzate of photooxidized *(1)* is of the same order of magnitude as that in the hydrolyzate of thermally oxidized *(2)*. In the photooxidation, in which the secondary reactions proceed *via* the same mechanism as the thermal oxidation[8], a constant ratio of *trans* and *gauche* *N*-vicinal methylene groups is obtained since under the reaction conditions the rotations of the methylene groups are frozen in. The disordered regions, in which the *N*-vicinal methylene groups are predominantly in the *gauche* conformation, are the only regions vulnerable to attack by oxygen.

The investigations show that the *N*-vicinal methylene groups in the *trans* conformation to the amide group are about 60 times more reactive than the *N*-vicinal methylene groups in the *gauche* position.

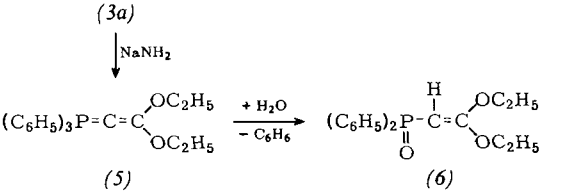
O-Alkylation of Alkoxycarbonylalkylidenetriphenylphosphoranes

By *H. J. Bestmann*, *R. Saalfrank*, and *J. P. Snyder*[*]

Alkoxycarbonylalkylidenetriphenylphosphoranes *(1)* undergo *C*-alkylation on treatment with alkyl halides[1]. We have now found that *O*-alkylation occurs when *(1)* is treated with triethyloxonium tetrafluoroborate *(2)* to give the hitherto unknown 1-substituted 2-ethoxy-2-alkoxyvinyltriphenylphosphonium tetrafluoroborates *(3)* and *(4)*.

(1) *(2)*

(3)



+

(4)

	R	R^1	*(3)* m.p. (°C)	yield (%)
(a)	H	C_2H_5	105	68
(b)	$C_6H_5-CH_2$	C_2H_5	178	97
(c)	C_6H_5	C_2H_5	182	99
(d)	$H_3CO_2C-CH_2$	C_2H_5	151	98
(e)	$H_5C_2O_2C$	C_2H_5	107	95
(f)	Br	C_2H_5	178 (decomp.)	98

If $R^1 \neq C_2H_5$ then a mixture of the geometric isomers *(3)* and *(4)* is formed, as suggested by our NMR-spectroscopic investigations[2]. Reaction of *(1)* with R = H and $R^1 = CH_3$ affords, for example, a mixture of 67% *(3)* [^{1}H–NMR: τ = 5.93 ($O-CH_3$), S] and 33% *(4)* [^{1}H–NMR: τ = 6.50 ($O-CH_3$), S]. In all the examples investigated, we found that protons of the O–R group *cis* to the triphenylphosphine group are shielded by the phenyl rings and appear at higher τ values than the corresponding protons of the *trans* O–R group.

Compound *(3a)* can be converted by sodium amide into the pale yellow crystalline ylid *(5)* [m.p. 83 °C, ^{1}H–NMR: τ = 8.95 (6 H ~ CH_3), T; 5.63 (4 H ~ CH_2), Q; 2.85, M; 2.00 (aromatic protons, total 15 H), M], which loses benzene on reaction with water to give the phosphine oxide *(6)* (m.p. 164 °C).

(3a) *(5)* *(6)*

General procedure for the preparation of (3), $R^1 = C_2H_5$

A solution of *(1)* (0.1 mole) in anhydrous dichloromethane is added to a well-cooled solution of *(2)* (0.1 mole) in the same solvent under nitrogen. After 30 min the reaction mixture is evaporated to dryness under vacuum and the residue is recrystallized from dichloromethane/ethyl acetate.

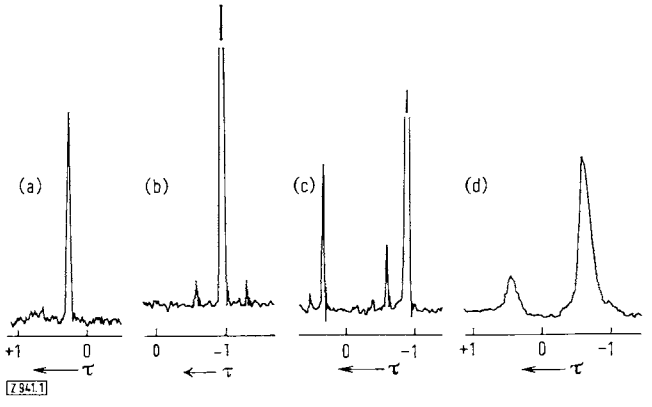
Temperature Dependence of the NMR Spectrum of a Soluble Ziegler-Natta Catalyst

By *K. H. Reichert* and *M. Mallmann*[*]

Biscyclopentadienylmethyltitanium(IV) chloride and trimethylaluminum react extremely rapidly with each other to form a titanium-aluminum complex. Formation of the complex is followed by very slow loss of methane[1]. The NMR signals of the methyl protons of $(C_5H_5)_2TiClCH_3$ (a) and of $Al(CH_3)_3$ (b) are shown in Figure 1.



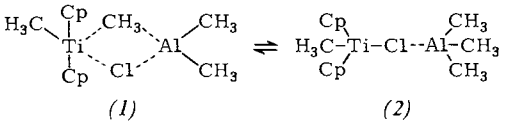


Fig. 1. ^1H—NMR spectrum a) of a 0.5 M solution of $Cp_2TiClCH_3$ in benzene at 33 °C; b) of a 0.5 M solution of $Al(CH_3)_3$ in benzene at 33 °C; c) immediately after mixing solutions of both compounds in toluene at 33 °C, $[Cp_2TiClCH_3] = 0.38$ mole/l, $[Al(CH_3)_3] = 0.5$ mole/l; d) after cooling the reaction solution to −60 °C. TMS was used as external standard.

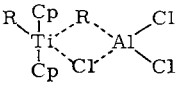
Immediately after the mixing of the above components, three resonance signals (c) appear in the ratio 1:0.47:3.8. The two outer signals appear at almost the same position as do those of the starting compounds. The intensity of the middle signal is very much dependent on temperature. It decreases when the temperature is lowered and completely disappears at −40 °C. The ratio of the intensities of the remaining signals (d) is about 1:4. On increasing the temperature the middle signal reappears. At the starting temperature the original signals are once again obtained; the ratio of the three intensities, however, changes somewhat (1:0.37:4). The process is reversible. These findings can be best explained by assuming an equilibrium to be present between the two different structures *(1)* and *(2)* of the primary titanium-aluminum complex.



(1) *(2)*

Cp = Cyclopentadienyl

At low temperatures, the titanium-aluminum complexes ought to have a tetrahedral structure *(2)* in agreement with the proton resonance signals occurring in the ratio 1:4. (excess of alkylaluminum). With increasing temperature the equilibrium is displaced in favor of the octahedral complex *(1)*; an additional signal, that of the bridge methyl group, is then to be observed. The very slow decomposition taking place after complex formation and during the time of measurement can be disregarded at the concentration ratios given. Only after several hours is a slight change of the original spectrum to be observed.

If the interpretation of this finding is valid then the respective structural parts of the complex formed are also to be considered when the question of these catalytic systems is discussed from the standpoint of polymerization active species. An octahedral structure[2] is generally assigned to the active species. Our results[3] suggest that the complex *(3)* should initiate polymerization.

CONFERENCE REPORTS

Fluorinated Inorganic Radicals

By *H. J. Emeléus*[*]

In recent years the chemistry of fluorine-containing radicals such as BF, CF_3, SiF_2, NF_2, $N(CF_3)_2$, SO_3F, and $(CF_3)_2NO$ has been widely studied and substantial advances in preparative inorganic chemistry have resulted.

The radicals BF and SiF_2 are typical of those formed in high temperature reactions at a low pressure between the element and its fluoride (BF_3 or SiF_4). Under these conditions *Margrave* and his co-workers have shown that the SiF_2 radical reacts, for example, with ethylene to form the cyclic compounds $(CH_2)_2(SiF_2)_2$ and $(CH_2)_4(SiF_2)_2$. Higher boron and silicon fluorides such as B_3F_5 and Si_4F_{10} have also been described, as well as mixed boron-silicon fluorides ($SiF_3SiF_2BF_2$ and $SiF_3(SiF_2)_2BF_2$).

The NF_2 radical, which *Colburn* showed to be formed in the reversible dissociation of N_2F_4, combines with other free radicals. With NO it forms NF_2NO and with SF_5, formed *inter alia* by the thermal dissociation of S_2F_{10}, it yields SF_5NF_2. It may also be added to olefins and will abstract

hydrogen from compounds such as thiols to give NF_2H. The bistrifluoromethylamino radical, though less reactive, has yielded many new derivatives, though not directly. These include $Hg[N(CF_3)_2]_2$, $[(CF_3)_2N]_2S$, $[(CF_3)_2N]_2S_2$, $[(CF_3)_2N]_2Se$, and $(CF_3)_2NSeCl$. Addition of $(CF_3)_2NCl$ to PF_3 or PF_2Cl gives phosphorus(v) derivatives and with $P(CF_3)_3$ and $(CF_3)_2NCl$ it is possible, by stepwise elimination of CF_3Cl, to form $P[N(CF_3)_2]_3$.

The radical FSO_2O, formed in the reversible thermal dissociation of bis(fluorosulfonyl)peroxide, FSO_2OOSO_2F, has been shown, largely by *Cady* and his co-workers, to undergo a number of typical addition reactions. Thus with C_2F_4 it forms $FSO_2O(CF_2)_2OSO_2F$ and, with SF_4, $FSO_2OSF_4OSO_2F$. It also reacts directly with halogens to give fluorosulfonates (*e.g.* $ClSO_3F$, $I(SO_3F)_3$).

The bistrifluoromethyl nitroxide radical, first isolated by *Blackley* and *Reinhard*, forms a violet gas with much the same stability as nitric oxide. It is formed by the oxidation of $(CF_3)_2NOH$ and has now been shown to react at room temperature with mercury to form crystalline $Hg[ON(CF_3)_2]_2$, from which the radical may be recovered quantitatively at 85 °C. The radical reacts with PF_3 to give $PF_3[ON(CF_3)_2]_2$. The mercurial is also a useful reagent for the transfer of the $(CF_3)_2NO$ group, $POCl_3$ and $PSCl_3$ forming $PO[ON(CF_3)_2]_3$ and $PS[ON(CF_3)_2]_3$, respectively, while BCl_3 gives $B[ON(CF_3)_2]_3$.

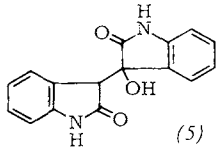
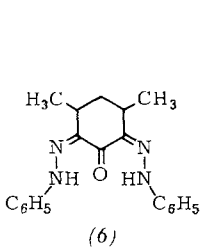
Potassium Nitrosobissulfate as Specific Oxidizing Agent in Organic Chemistry

By *H.-J. Teuber* [*]

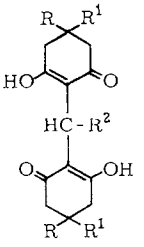


Enols, like phenols, are oxidized by potassium nitrosobissulfate (Fremy's salt), $ON(SO_3K)_2$. Dihydroresorcinol and dimedone are converted into the tertiary alcohols *(1)* and *(2)*, respectively; the former product can also be synthesized from its components, 1,2,3-cyclohexanetrione and dihydroresorcinol. *(1)* and *(2)* are cleaved by phenylhydrazine to the tris(phenylhydrazones) *(3)* and *(4)* and are

(1), R = H
(2), R = CH_3



(3), R = H
(4), R = CH_3



(5)

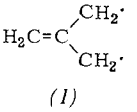
cyclized to furan derivatives by acids or by catalytically excited hydrogen. Oxindole is analogously oxidized to the compound *(5)*, which affords isoindigo by dehydration. In the case of 4,6-dimethyl-1,3-cyclohexanedione the formation of a dimer (aldol reaction) does not occur, but the oxidation product formed (as in the reaction with selenium dioxide) can be isolated as bisphenylhydrazone *(6)*.

(6)

(7a), R = R^2 = H, R^1 = C_6H_5
(7b), R = H, R^1 = C_6H_5, R^2 = CH_3
(8), -R-R^1- = -$(CH_2)_5$-, R^2 = H

A competing reaction that is also observed with *(1)* and *(2)* preponderates when 5-phenyl-1,3-cyclohexanedione and spiro[4.5]decane-7,9-dione are oxidized in aqueous-alcoholic solution: the starting ketone condenses with the aldehydes formed from the methanol (or ethanol), giving *(7a)* [or *(7b)*] or *(8)*. It is thus proved that under these conditions alcohols are dehydrogenated to aldehydes. In the case of 2-methyl-1,3-cyclohexanedione the ring is cleaved; this occurs also with 1,2-cyclohexanedione, which is converted into adipic acid (*J. Hohn*).

In acid solution benzhydrazide affords N_2 and benzoic acid, but in alkaline solution gives benzaldehyde and benzoylbenzylidenehydrazine (*G. Köhler*).



Lectures at Kiel (Germany) on November 21, 1968,
and at Stuttgart (Germany) on December 5, 1968

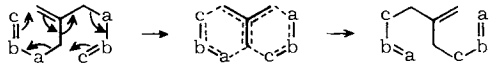
Trimethylenemethane, a Theoretically and Synthetically Valuable Allylic Structure

By *F. Weiss* [*]

Trimethylenemethane, in the form of the diradical 2-methylene-1,3-propanediyl *(1)*, is an interesting allylic species containing the skeleton of α,α'-disubstituted isobutenes *(2)*.

(1)

(2)



The theoretically predicted triplet ground state of *(1)* has recently been confirmed by EPR studies of the diradical produced by low-temperature photolysis of 4-methylene-1-1-pyrazoline and of 3-methylenecyclobutanone. This reactive 1,3-diradical can, like the cyclobutadienes, be isolated as its stable tricarbonyliron complex.

The properties of the 1,3-diradical as intermediate can be explained on the basis of its triplet structure. For instance, it affords practically no methylenecyclopropane, but instead 1,4-dimethylenecyclohexane, *i.e.*, a coupling product, when α,α'-dihaloisobutenes react with potassium vapor, when 6-methylene-1,4-dioxepane-2,3-dione is pyrolyzed, when the above-mentioned photolysis reactions are carried out, and when trimethylenemethane-tricarbonyliron is photolyzed in pentane. If other triplet radicals are also formed in the first step, then *(1)* can react partly with them, *e.g.*, with triplet methylene produced from diiodomethane. Cycloaddition of *(1)* to olefins such as butadiene, cyclopentene, and cyclopentadiene has been achieved only in the photochemical reactions mentioned above.

Trimethylenemethane intermediates produced under nonradical conditions also behave unusually. Reaction of α,α'-

dichloroisobutene with tetracarbonylnickel leads to 1,4,7-trimethylenecyclononane in good yield, and this reaction with magnesium gives a series of macrocyclic and open-chain oligomers as well as methylenecyclopropane and 1,4-dimethylenecyclohexane.

The symmetrical structure of α,α'-disubstituted isobutenes permits a double allylic rearrangement in accord with the general scheme *(3)* → *(4)* → *(5)*. These reactions have been

(3) *(4)* *(5)*

specially studied in connection with the Claisen rearrangement; examples are rearrangement of isobutenylenedicarboxylic esters by NaH to γ-methylenepimelic acids and of aryl ethers of isobutenediol at 200 °C to bisphenols. Further, interesting thermal rearrangements can be effected with cyclic ethers of isobutenediol: At 450 °C 5-methylene-1,3-dioxanes give the isomeric methylallyl ester and, if C-2 carries a vinyl group, also the isomeric glutaraldehydes. At 200 °C 3,4-dihydro-3-methylene-2*H*-[1,5]benzodioxepin gives a 2,4-cyclohexadienone by a (presumably stepwise) Claisen rearrangement, and at 450 °C this is further converted into isomeric products consisting mainly of a furylcyclopentenone.

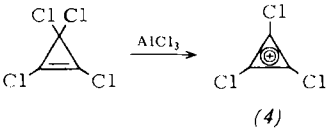
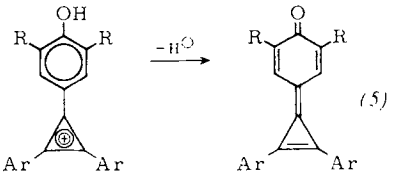
New Aromatic Systems

By *R. West* [*]



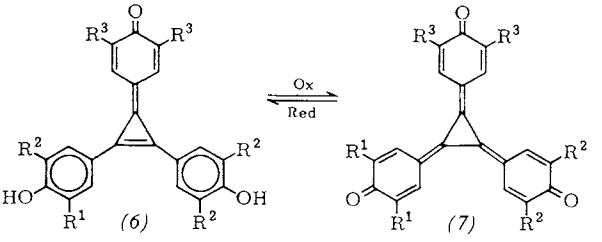
It has recently been recognized that the cyclic anions $C_nO_n^{2-}$ of squaric acid *(1)*, croconic acid *(2)*, and rhodizonic acid *(3)* form a homologous series of aromatic compounds.

(1) *(2)* *(3)*



Structural studies show that these anions have symmetric, planar structures with considerable π-bonding contributions from the C–C bonds. The properties of the substances are, in general, in good agreement with predictions of the Hückel-LCAO–MO theory.

Reaction of tetrachlorocyclopropene with $AlCl_3$ leads to the trichlorocyclopropenylium ion *(4)*, which is an aromatic system where the C–C bonds are even stronger than in benzene. One, two, or three of the chlorine atoms can be replaced by aryl groups when $C_3Cl_3^+$ is treated with aromatic hydrocarbons.



(4)

If one of the aromatic rings carries a *para*-hydroxy group, the triarylcyclopropenylium ion is readily deprotonated to a quinonoid system *(5)*.

(5)

If all three aromatic rings carry hydroxyl groups, compounds *(6)* are obtained which can be oxidized to triquinonoid cyclopropanes *(7)*. Compounds *(7)* are stable, dark purple solids with a quite new electronic structure.

(6) *(7)*

In the redox processes *(6)* ⇄ *(7)*, anion radicals and monoradicals can be shown by ESR spectroscopy to occur as intermediates and they can be characterized.

Studies on the Mechanism of Mixed Function Oxygenations

By *V. Ullrich* [*]

Mixed function oxygenations occur according to the equation:

$$RH + DH_2 + O_2 \rightarrow ROH + D + H_2O$$

where RH is an organic substrate and DH_2 is a reduced hydrogen-donor. The very complicated course of these enzymatic reactions can be considered according to three points of view:

1. How is the oxygen molecule activated? 2. How are the electrons transferred to the oxygen? 3. How is the electron transport coupled with the hydroxylation of the substrate?

To obtain an insight into the activation of the oxygen molecule the model systems described previously [1] have been developed further. Reduction of oxygen by the iron(II)-thiosalicylic acid complex leads to an electrophilic oxenoid complex [**] which hydroxylates aliphatic and aromatic compounds and compounds containing isolated double bonds in the same way as enzymically activated oxygen does. A decisive role in this system is played by sulfur as ligand, which in combination with the Fe^{2+} ion makes two-electron reduction of the oxygen molecule possible.

In many mixed-function oxygenases cytochrome P 450 participates in the activation of oxygen. A reaction velocity $t_{1/2}$ of about 300 msec and 1:1 stoichiometry have been established for its reaction with oxygen. The unusual spectral and chemical properties of cytochrome P 450 can be explained on the basis of its function as a two-electron donor.

Participation of cytochrome P 450 in activation of oxygen has been shown in the case of hydroxylation of cyclohexane by the microsomal fraction of liver by the photochemical action spectrum of the CO-complex.

As observed with other substrates of microsomal mixed function oxygenase systems[2] cyclohexane causes a change in the spectrum of oxidized cytochrome. The extent of the spectral shift is directly correlated with the enzyme activity. This confirms the assumption[2] that the change in the spectrum is caused by formation of an enzyme-substrate complex. Only about 12% of the cytochrome present in rat-liver microsomes can form this enzyme-substrate complex, although this level is increased to 32% by pretreatment of the animals with phenobarbital.

It can be deduced from studies on the rate of reduction of the cytochrome that the enzyme-substrate complex is reduced appreciably faster than substrate-free cytochrome, thus indicating a coupling of electron transport with hydroxylation.

Simultaneous Transport of Mass and Heat with Wall Reactions (Hydrogenation of Ethylene on a Platinum Catalyst in an Annulus)

By *G. Jeromin* and *F. Fetting* [*]

During heterogeneous exothermal reactions on catalytically active walls temperature gradients are set up under adiabatic conditions between the surface and the gas stream in flow reactors. If the reaction rate is so high that it is determined only by the rate of mass transport, an analogy can be assumed between the removal of heat from the hot wall and transport of mass to the catalytically active wall; in such cases it is relatively easy to calculate the wall temperatures that are achieved in the stationary state. The temperature plateau depends on the adiabatic excess temperature and thus on the reaction enthalpy as well as on the concentrations of the reacting components.

These relations have been treated theoretically for several years past, but experimental material is available only rarely and for 'local' conditions (on a thin wire). In the present work the temperatures achieved were studied in connection with their dependence on the size of the influences for integral conditions.

Hydrogenation of ethylene (reaction enthalpy $\Delta H_R = -32$ kcal/mole) was used as model reaction. The gas mixture throughout contained 5 vol-% of ethylene with various amounts of hydrogen, nitrogen, or argon. The reaction took place on a 5- or 25-cm long platinum film prepared on a longer glass tube (outer diameter 18.1 mm) which formed the inner tube of an annular-space reactor. The temperature along the catalyst wall was measured in a simple manner by means of a thermoelement that could be moved along the internal wall of the inner tube.

The measurements showed the steep rise in temperature of about 100–200 °C where the gases first reach the catalyst. Since the Lewis number was more than unity the temperature increased in all cases along the catalyst layer. The temperature finally reached depended on the conversion that had resulted and only indirectly, by way of this quantity, on the flow rate. Transition to turbulent flow increased the wall temperatures slightly in spite of the drop in conversion. Increasing the length of the reactor in front of the catalyst to permit development of the flow-rate profile did not yield any unequivocal result. Such investigations can give practical indications of the temperature distribution at different positions, *e.g.* in platinum gauze, as in combustion of ammonia to nitrous oxide and in preparation of hydrocyanic acid by *Andrussov*'s method. They provide a clear example of the application of the analogy between heat and mass transport coupled with a heterogeneous chemical reaction.

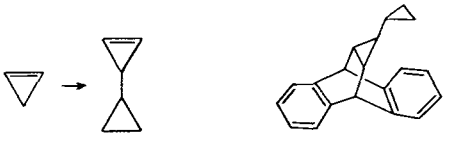
SELECTED ABSTRACTS

A new rearrangement of β-lactams has been observed by *K.-D. Kampe*. *N*-Bromo- and *N*-chloro-2-azetidinone *(1)* rearrange in the presence of C–C unsaturated compounds, *e.g.* allyl chloride, vinyl chloride, and vinyl ether, and catalytic



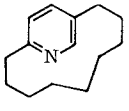
(1) *(2)*

X = Br, Cl

quantities of radical-formers to give β-bromo- and β-chloroalkyl isocyanates *(2)*. The groups R^1–R^4 are inert substituents. / Tetrahedron Letters *1969*, 117 / –Ma.

[Rd 968 IE]

The thermal dimerization of cyclopropene, one of the most reactive of the olefins, has been investigated by *P. Dowd* and *A. Gold*. Whereas extremely vigorous polymerization occurs at room temperature, the dimer *(1)* is obtained at –25 °C in CH_2Cl_2 or *n*-pentane solutions. The dimerization proceeds

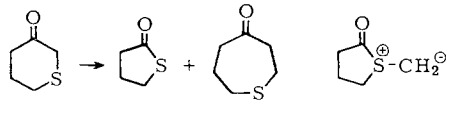


(1) *(2)*

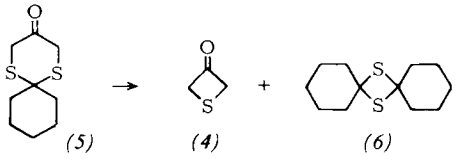
possibly by the "ene" mechanism. *(1)* can be isolated by gas chromatography at room temperature, but owing to its extreme instability it must be stored at –78 °C. At 10 °C it is converted by anthracene in $CHCl_3$ into the adduct *(2)*, m.p. 117–117.5 °C. / Tetrahedron Letters *1969*, 85 / –Ma. [Rd 969 IE]

The anodic oxidation of Ag_2O to AgO in KOH solutions was investigated by *M. Fleischmann, D. J. Lax,* and *H. R. Thirsk.* Ag/Ag_2O electrodes were oxidized at a controlled potential which was varied in 20-mV steps over a range of 300 mV and the voltage-time graphs were recorded. Ag^+ ions in the Ag_2O react with adsorbed OH radicals in the rate-determining step to give AgO and H^+. Once formed, AgO nuclei continue to grow in three dimensions at the Ag_2O/electrolyte interface. At low electrode potentials, because of the preceding OH^- discharge equilibrium, it is found that the reaction is first order with respect to OH^-; at high electrode potentials the areas on which the AgO grows are completely covered, and the reaction becomes independent of the potential and the OH^- concentration. / Trans. Faraday Soc. *64*, 3137 (1968) / –Hz. [Rd 958 IE]

The kinetics of the evaporation of sodium chloride from the (100) faces of single crystals has been investigated between 450 and 650 °C by *J. E. Lester* and *G. A. Somorjai* using a vacuum microbalance. For crystals the steady rate of evaporation depends on the dislocation density at the surface, and increases if the latter is increased by means of mechanical pressure. The relative rates of evaporation of NaCl and Na_2Cl_2 were measured by mass spectrometry; with non-stressed crystals the activation energies for the evaporation are 53 ± 1 kcal/mole for the monomer and 62 ± 1 kcal/mole for the dimer. In the temperature range investigated, between 30 and 5% of the vapor was found to be the dimer, irrespective of the surface dislocation density. Addition of Ca^{2+} greatly reduces the rate of evaporation, and Br^-, OH^-, and O_2^- have no measurable effect. / J. chem. Physics *49*, 2940 (1968) / –Hz. [Rd 959 IE]



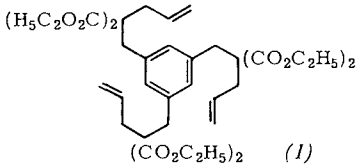
[*n*]-(2,5)-Pyridinophanes have been synthesized by *H. Gerlach* by acid-catalyzed ring closure of bis(β-aminovinyl) diketones to give [*n*]-(2,5)-pyridinophan-*n*-ones and subsequent Wolff-Kishner reduction of the latter. The NMR spectra of the new *ansa*-compounds show a strong upfield shift of the signals due to the methylene protons, which is particularly pronounced for bridges having $n < 12$, as well as restricted rotation of the pyridine nucleus; it therefore proved possible to isolate



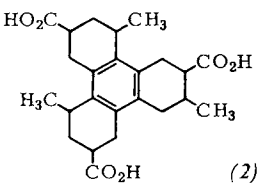
(1)

diastereoisomeric [*n*]-(2,5)-pyridinophanols. [9]-(2,5)-Pyridinophane *(1)* was resolved into the thermally highly stable enantiomers. / Chimia *22*, 493 (1968) / –Ma. [Rd 971 IE]

The photochemistry of thiacycloalkan-3-ones has been investigated by *K. K. Maheshwari* and *G. A. Berchtold.* Irradiation of thiacyclohexan-3-one with a 450-W lamp in *tert*-butanol (19 h, 78% conversion) afforded thiacyclohexan-3-ol (16%)



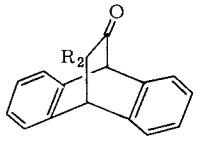
(1) *(2)* *(3)*



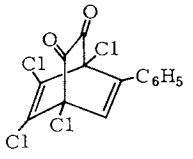
(5) *(4)* *(6)*

and *tert*-butyl 4-methylthiobutyrate (14%), whereas in 1,1,2-trichloro-1,2,2-trifluoroethane (Freon-113) (8h, 90–95% conversion) tetrahydrothiophen-2-one *(1)* and thiacycloheptan-4-one *(2)* are each formed in 6–8% yield. The ylid *(3)* may possible be responsible for insertion of the CH_2 group during the formation of *(2)*. Ring expansion and contraction in this manner has not been observed with other compounds of this kind. Irradiation of 1,3-dithiacyclohexan-5-one in acetonitrile gave thietan-3-one *(4)* (21%), and compound *(5)* in Freon-113 yielded *(4)* and *(6)*. / Chem. Commun, *1969*, 13 / –Ma. [Rd 972 IE]

A synthesis of symmetrically substituted triphenylenes by triple ring closure of tris(4-pentenyl)benzenes has been described by *P. Canonne* and *A. Regnault.* Compound *(1)*, obtained from tris(bromomethyl)benzene and an excess of sodioallylmalonic ester, is hydrolyzed, decarboxylated, and cyclized to compound *(2)* by heating for 7 hours with $AlCl_3$.



(1)



(2)

Reduction with $LiAlH_4$ and aromatization with Pd/C at 250 °C yields 1,3,5,7,9,11-hexamethyltriphenylene (m.p. 97 °C), whereas treatment with Pd/C at 320 °C affords 1,3,6,8,10-pentamethylcyclopenta[*def*]triphenylene (m.p. 192 °C). / Tetrahedron Letters *1969*, 243 / –Kr. [Rd 976 IE]

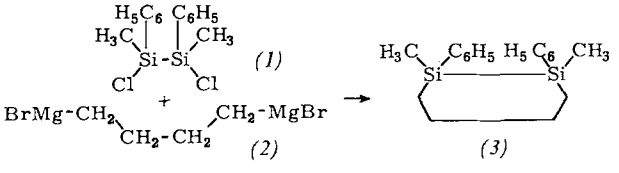
"Bis(carbon monoxide)", C_2O_2, is probably formed on photolytic decomposition of cyclic compounds such as *(1)* and *(2)* having a dioxoethylene bridge in benzene[1], according to *J. Strating, B. Zwanenburg, A. Wagenaar,* and *A. C. Udding.* Compound *(1)* affords anthracene and CO (by decomposition of C_2O_2) in 100% yield, and compound *(2)* gives tetrachlorobiphenyl (97%) and CO. The mass spectrum of *(1)* shows, *inter alia*, a strong peak at M – 2 CO, a peak at

(1), R_2 = O
(2), R_2 = 2 H

(2)

m/e 56 ($C_2O_2^+$), and a negligible peak at M – CO. The photolysis of compound *(3)* to anthracene, dianthracene, and ketene (60% yield after 1 h) lends support to the concept that the bridge is removed as a whole. Pyrolysis of compounds such as *(1)* and *(2)*, which requires high temperatures, also leads to CO. / Tetrahedron Letters *1969*, 125 / –Kr. [Rd 977 IE]

[1] Cf. *D. Bryce-Smith* and *A. Gilbert*, Chem. Commun. *1968*, 1319.



The regularity of the electronic work function for metal electrodes in electrolyte solutions on irradiation with UV light ($\lambda = 365$ nm) has been investigated by *Y. V. Pleskov* and *Z. A. Rotenberg*. In concentrated solutions of electrolyte, the photocurrent I is related to the electrode potential φ over a wide range according to the equation

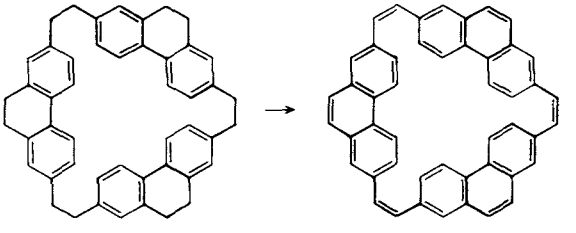
$$I = A\,(\varphi_0 - \varphi)^{5/2} \qquad (1)$$

where A is a constant. The threshold potential φ_0 amounts to -0.31 ± 0.03 V measured against the saturated calomel electrode, a value that is independent of the nature of the electrode metal (Hg, Pb, Tl/Hg, In/Hg were investigated). The electronic work function for mercury (at zero charge potential) in the electrolytes is 3.26 eV. In dilute electrolyte solutions, in which the potential drop from the electrode to the bulk of the solution extends over a fairly large distance, a current-voltage curve analogous to eq. (1) is obtained if φ is replaced by $\varphi - \psi_1$; ψ_1 denotes the potential at a distance of one ionic radius from the electrode surface, which can be determined by a model calculation. Measurement of the photocurrent and evaluation according to eq. (1) permits determination of the zero charge of metals in electrolyte solutions. / J. electroanalyt. Chem. Interfacial Electrochem. *20*, 1 (1969) / –Hz. [Rd 978 IE]

Reactions of *N,N*-bis(trifluoromethyl)hydroxylamine *(1)* with sulfur and nitrogen halides in the presence of CsF have been examined by *J. A. Lott, D. P. Babb, K. E. Pullen,* and *J. M. Shreeve*. New compounds of the type $(CF_3)_2NOX$, which are stable at 20 °C, were isolated and characterized by their IR, NMR, and mass spectra. $[(CF_3)_2NO]_2SO_2$ and $(CF_3)_2NOSO_2F$ are formed from *(1)* and SO_2F_2 in the molar ratio 2:1 and 1:1 respectively, $[(CF_3)_2NO]_2SO$ and $(CF_3)_2NOS(O)F$ from *(1)* and SOF_2 in the molar ratio 7:3 and 3:5 respectively, and $[(CF_3)_2NO]_2S$ and $[(CF_3)_2NO]_2S_2$ from *(1)* and SCl_2 and S_2Cl_2 respectively. The unstable compound $(CF_3)_2NONF_2$ is formed in the corresponding reaction of *(1)* with NF_2Cl. / Inorg. Chem. *7*, 2593 (1968) / –Bl. [Rd 979 IE]

1,2-Dimethyl-1,2-diphenyl-1,2-disilacyclohexane has been prepared by *K. Tamao, M. Ishikawa,* and *M. Kumada* from compound *(1)* and the Grignard reagent *(2)* (yield 75%); the same authors resolved the compound into its stereoisomers by fractional distillation or preparative gas chromatography. They also succeeded in synthesizing the analogous 1,2-bis-(*p*-chlorophenyl) compound, the isomer having the shorter

(1) *(2)* *(3)*



retention time and the greater dipole moment being recognized as the *cis* form. *cis-* and *trans-(3)* can be oxidized stereospecifically with perbenzoic acid to *cis-* and *trans*-2,7-dimethyl-2,7-diphenyl-1-oxa-2,7-disilacycloheptane, respectively. – 1,2-Difluoro-1,2-dimethyl-1,2-disilacyclohexane, which is formed with NH_4HF_2 from *cis,trans-(3)*, *cis-(3)*, or *trans-(3)* in concentrated sulfuric acid, is always obtained in the *cis-trans* ratio of 1: ≈ 1.9. Addition of ethanol to solutions of the fluoro compounds in hexane or benzene can also give rise to *cis-trans* isomerization, which is reported to proceed *via* a compound containing pentacoordinated silicon. / Chem. Commun. *1969*, 73 / –Kr. [Rd 981 IE]

Potassium 2-germaacetate *(1)* has been obtained by *P. M. Kuznesof* and *W. L. Jolly* on reaction of germylpotassium with carbon dioxide in melting 1,2-dimethoxyethane as a white salt-like substance that is relatively stable in aqueous solution at room temperature. The structure of its anion is deduced to be analogous to that of acetate from the IR and UV spectra of *(1)* and from the course of its hydrolysis (water, 2 days at 85 °C), according to

$$GeH_3CO_2^- + H_2O \rightarrow GeH_4 + HCO_3^-$$

Acidification of an aqueous solution of *(1)* affords a solution of 2-germaacetic acid ($pK = 3.5$), which decomposes with a half-reaction time of *ca.* 30 min at pH = 2 to CO as well as non-stoichiometric amounts of GeH_4 and an insoluble orange solid containing Ge and H. / Inorg. Chem. *7*, 2574 (1968) / –Bl. [Rd 980 IE]

[2.2.2](2,7)Phenanthrenophanetriene *(2)* has been synthesized by *W. Jenny* and *R. Paioni* from hexahydrophenanthrenophane *(1)* and *N*-bromosuccinimide; the reaction first affords a hexabromo derivative that is subsequently debrominated with zinc. The deep yellow compound *(2)*, which is very

(1) *(2)*

difficultly soluble in nearly all the common solvents, does not melt below 500 °C, and turns red above 300 °C. Its structure was proved by the mass spectrum [molecular ion at *m/e* 606 (390 °C)] and the NMR spectrum (in $AsCl_3$). On further heating a peak appears in the mass spectrum at *m/e* 600, which could indicate dehydrogenation to [12]coronaphthene. / Chimia *23*, 41 (1969) / –Kr. [Rd 982 IE]

BOOK REVIEWS

Reallexikon der Medizin und ihrer Grenzgebiete (Encyclopedia of Medicine and Related Fields) Vol. II: Cargile Membrane to E-cell. Edited by *G. Thiele* and *H. Walter*. Urban & Schwarzenberg, Munich 1968, 1st Edit., 805 pp., loose-leaf binding with plastic covers, DM 140.–.

The second volume of this encyclopedia has appeared surprisingly soon after the first[1], and it too makes an excellent impression. The most important terminology found in medical and related literature have been compiled and interpreted with great expertise and certainly with great industry. The illustrations aid in understanding the text, in particular those of the more complicated chemical structures. If one may form a conclusion about the entire work on the basis of the chemical, biochemical, and physicochemical entries,

[1] Angew. Chem. *81*, 43 (1968); Angew. Chem. internat. Edit. *8*, 87 (1969).

the verdict is very favorable. Few inaccuracies of expression are found, and the editors seem to have succeeded in avoiding obvious errors to the extent that thorough random sampling did not reveal any mistakes. It is a pity that in the case of chemical terms antiquated spelling (z and k instead of c) and nomenclature more common in pharmacy has been included, instead of adhering strictly to the style used in the standard works of the German chemical literature. However, it must be emphasized that this is an encyclopedia for students of medicine though chemists active in the areas bordering the medical sciences will find much useful information, not available elsewhere in such a precise and handy form.

H. Grünewald [NB 773 IE]

Das Fischer Lexikon Chemie (The Fischer Encyclopedia – Chemistry) A–Z. Edited by *H. Kelker, F. Klages, R. Schwarz,* and *U. Wannagat.* S. Fischer-Verlag, Frankfurt 1968. New edition, 400 pp., 46 figures, bound. DM 4.80.

The "Chemistry" volume of the Fischer Encyclopedia, which first appeared in 1961 and of which 125000 copies have since been sold, has now been published in a new edition. Many of the entries have been brought up to date, others have been revised or included for the first time, and nearly everywhere it has been necessary to include recent developments. The editors have done this thoroughly and skilfully and the new edition deserves if anything even greater success than the first.

Comparatively few key-words are given (42 altogether), but each represents an article covering several pages and imparting the relevant information in textbook-like manner. The attraction of the volume lies in the fact that the alphabetical arrangement of the entries gives rise to an unconventional structure, differing from the usual textbook; it allows related material to be kept together, and frequently leads to unfamiliar aspects.

A point worth making is that the index should also have been seen and corrected by the authors. This procedure was evidently not followed in the case of the present volume, as is shown by the numerous misprints which have no place in a book of this kind.

Anyone who likes to have his chemistry near him to read on the train, in the waiting room, or at his desk, will be delighted with this volume.

H. Grünewald [NB 774 IE]

ABC Biologie (The ABC of Biology). Edited by *G. Dietrich* and *F. W. Stöcker.* Verlag Harri Deutsch, Frankfurt-Zürich. No date given. 920 pp. 14 color plates. Plastic binding, DM 49.80.

This volume is welcome, even if one does not agree that biology is daily "penetrating deeper into social life" (foreword). It attempts to provide something like a synthesis of biology, physiology, botany, and zoology, and in this it is eminently successful. For a biochemist in particular, the concepts of biology that derive from the observation of the entire organism are not always completely clear, and accurate definitions of the terms are often needed. The encyclopedia covers about 6000 entries. The numerous illustrations in the text and longer articles containing comprehensive and comparative explanations of particularly important entries are of special value.

The information is in general reliable, but it does not always reflect the latest developments in the field (*e.g.* insulin), either in style or in content. There are occasional errors (*e.g.* $h\nu$ = Planck's constant), and the "germanized" spelling, which makes looking up references unnecessarily difficult, is regrettable. All this does not, however, detract from the value of this volume. The chemist who wants to check up on the meaning of biological concepts would be well advised to have this work in his private library.

H. Grünewald [NB 775 IE]

Appretur der Textilien. Mechanische und chemische Technologie der Ausrüstung (Textile finishing. Mechanical and chemical finishing technology) by *W. Bernard.* Springer-Verlag, Berlin-Heidelberg-New York, 1967. 2nd revised Edit., viii, 406 pp., 403 figures, DM 78.–.

In the eight years that have elapsed since the publication of the first edition, there have been many changes in textile finishing. Not only have new cotton finishing processes (particularly for high-grade finishing) been introduced, but processes have also been developed in the synthetics field, such as antistatic treatment, hydrophilic treatment, and the fixing of synthetic or mixed fibers. It was also necessary to consider technical innovations in connection with finishing aids into account.

The first chapter of the book describes mechanical finishing operations, dealing on the one hand with new methods and on the other with new machinery. The second part is concerned with chemical finishing. In addition to the usual stiffening, weighting, and filling processes, the chemicals required in their execution are also discussed. This is followed by modern finishes such as antistatic treatment, chemical finishing for wool textiles, oil-repellent and dirt-repellent finishing, and high-grade finishing. In describing the processes the author emphasizes the practical application, and spends no more time on chemical aspects than is necessary.

The book is well arranged and contains excellent illustrations, so that it is fairly easy for the reader to gain a picture of the range of finishing processes and machinery.

At the end of the book there is a very useful list of suppliers of finishing machinery and finishing agents and a comprehensive subject index. The book is a valuable aid not only for the practical textile worker but also for all those whose professional training requires a knowledge of textile finishing.

H. Rath [NB 781 IE]

Lehrbuch der Pharmakognosie. Auf phytochemischer Grundlage (Textbook of pharmacognosy. On a phytochemical basis). By *E. Steinegger* and *R. Hänsel.* Springer-Verlag, Berlin-Heidelberg-New York 1968. 2nd Edit., xii, 531 pp., numerous figures and tables, DM 78.–.

This book, which first appeared five years ago as "Lehrbuch der allgemeinen Pharmakognosie", is a "comparative, descriptive plant biochemistry" in which attention is centered on medicinal plants, their active principles, and their use. The main part of the book, which deals with the various drugs, is accordingly arranged largely on a phytochemical basis. This is particularly true of the following chapters: "Plant acids as main active principles" (5 pp.), "Carbohydrate drugs" (43 pp.), "Glycoside drugs" (104 pp.), "Tannin drugs" (10 pp.), "Proteins and enzymes" (17 pp.), and with certain limitations also "Fats, oils, and other lipids" (22 pp.). Occasionally, when it seems more appropriate to the authors for didactic reasons, an alternative classification system is used. Thus the chapter on "Alkaloid drugs" (93 pp.) is arranged more in accordance with botanical principles, while the chapters on "Ethereal oils, resins, and balsams" (79 pp.) and on drugs whose active principles are unknown (49 pp.) are arranged in accordance with therapeutic principles. A special chapter is devoted to "Drugs from microorganisms" (32 pp.). This layout is largely retained from the first edition, though the various sections have been very carefully revised and updated almost throughout.

Each chapter is preceded by a survey of the group of substances in question. The botanical origins and extraction of the various drugs, their contents, and their special properties, physiological action, and therapeutic importance are discussed in detail.

The reduction of the number of pages from 595 to 531 is mainly due to trimming in the general section, in which special chapters devoted to drug morphology and to systematic, genetic, and physiological problems of pharmacobotany in the first edition have been omitted from the

second edition. On the other hand, the chapter entitled "Introduction to the phytochemical principles of pharmacognosy", which also belongs to this section, has been expanded (55 pp.) and brought into line with current knowledge. Probably the most striking change is the complete rearrangement of the formulas, which has resulted in a considerable improvement.

This book, which is intended primarily for pharmacy students and for practising druggists, contains a wealth of information for anyone concerned with drug research and phytochemistry, and can therefore be strongly recommended.

E. Sprecher [NB 780 IE]

Einführung in die Naturphilosophie, Band I: Naturerkenntnis und Wirklichkeit. Band II: Die Erkenntnis des Lebendigen. (Introduction to Natural Philosophy. Vol. I: The understanding of nature and reality. Vol. II: The understanding of Life) by *H. Sachsse*. Verlag Friedr. Vieweg und Sohn, Braunschweig 1968. 1st Edit., Vol. I: 232 pp., 7 figures, DM 17.50; Vol. II: 289 pp., 35 figures, 23 tables, DM 22.80.

In these two works the author does not adopt the normal approach of fusing together the results of natural scientific studies and philosophical apriorisms. Instead, he reflects – starting from the basis of scientific theory – on classical and modern problems of the science of experience and philosophy (Part I includes natural law, probability, space measurement, formulation of theories, and the concept of substance; Part II embraces causality and finality, regulation and control, data processing, deliberation, and spontaneity) to come closer to an understanding of man, using human behavior as an example.

By a skilful choice of material, supported by numerous examples, diagrams, and sketches, the author succeeds in presenting a readable, interesting work. The book guides the reader rather than throwing about terms and serving up the results. The objectivity and stimulating presentation of this important contribution to the metatheory of natural science – with its aim of serving the interdisciplinary exchange of information – merits wide distribution.

A. F. Kremmeter [NB 783 IE]

Chemie in nichtwäßrigen ionisierenden Lösungsmitteln, Bd. III: Chemie in flüssigem Distickstofftetroxid und Schwefeldioxid (Chemistry in non-aqueous ionizing solvents, Vol. III: Chemistry in liquid dinitrogen tetroxide and sulfur dioxide). Edited by *C. C. Addison, W. Karcher,* and *H. Hecht*. Friedr. Vieweg und Sohn, Braunschweig 1967, Pergamon Press, Oxford. 1st Edit., xiv, 206 pp., 27 figures, 35 tables, DM 68.–.

In the first part of this book[1] *C. C. Addison,* who (as a glance at the literature list shows) has himself worked mainly in this field, discusses dinitrogen tetroxide as a solvent. The second part, dealing with chemistry in liquid sulfur dioxide, was written by *W. Karcher* and by *H. Hecht,* a co-worker for many years of *G. Jander,* who himself worked in this field. Both parts are thus written by experts who are very familiar with the subjects discussed.

The physical and chemical properties of the pure solvents are first described, and the solubilities of many substances and solvate formation are then reported, organic substances also being included in the case of dinitrogen tetroxide. Solvolysis reactions and the reverse "neutralization-like" processes are described in terms of heterolytic dissociation of the solvent

$$N_2O_4 \rightarrow NO^+ + NO_3^- \quad \text{and} \quad 2\,SO_2 \rightarrow SO^{2+} + SO_3^{2-}$$

though it should be said that this is only a working hypothesis in the case of sulfur dioxide.

[1] Cf. Angew. Chem. *79*, 731 (1967); Angew. Chem. internat. Edit. *6*, 719 (1967).

The very different character of the two solvents is made very clear: one is a substance having a predominantly fast oxidizing action, whereas oxidations and reductions are strongly inhibited in the other. (This naturally affects the ranges of application of the solvents.) Both parts of the book show very impressively the numerous preparative possibilities offered by the two solvents. The well printed book is also well worth reading by those who are interested in theoretical aspects of inorganic chemistry. *F. Seel* [NB 779 IE]

Production of the Boranes and Related Research. Chief editor: *R. T. Holzmann,* edited by *R. L. Hughes, I. C. Smith,* and *E. W. Lawless*. Academic Press, New York-London, 1967. 1st Edit., x, 533 pp., numerous figures and tables, $22.00.

Between 1950 and 1965, many new discoveries have been made by scientists working for various companies in the USA in the borane field and a number of problems have been thoroughly investigated in connection with the high-energy fuel development program. Since only provisional or partial reports on the results of "Project Hermes", "Project Zip", and "Project HEF" have been published, though the projects were suspended in 1959, this first compilation in book form is very welcome.

The book is divided into a section on starting materials for the preparation of boron hydrides and one on their preparation. Further chapters are devoted to alkylboranes and carboranes. Separation, purification, and analysis methods are described. However, a short chapter on boron-nitrogen chemistry is not properly tied in. Extensive chapters on toxicology, IR spectra, molecular structures, and physical properties of boranes and carboranes are also included. The text is supplemented by tables covering several pages.

The 1673 references, some of which (pp. 490–504) are not related to the text, include several hundred articles that are difficult to obtain. This is the particular value of the book. On the other hand, the results obtained by many other research groups are not all included.

The book should find a place in every library because of its abundant tabular material and the source data. It provides those who work in the field of boron compounds with a very good compilation of the literature on boron hydrides.

R. Köster [NB 784 IE]

The Chemistry of Boron and its Compounds. Edited by *E. L. Muetterties*. John Wiley & Sons, London-New York 1967. 1st Edit., xiv, 700 pp., 200 figures, 220 s.

Numerous monographs on boron chemistry have been published in recent years. A book is now available which, in one volume, contains a complete and up to date account of boron chemistry. The editor has engaged the services of a number of well known research workers for the treatment of the individual subgroups so that a competent review approaching the frontiers of research is ensured.

After an introduction to the properties of the element that are dependent on the structure of the boron atom (structural properties, multicenter bonds, polyhedral structures, acceptor properties, problems of multiple bonds), *J. C. Hoard* and *R. C. Hughes,* discuss the element and compounds having a high boron content (130 pp.). They give a very instructive report on the modifications of boron as well as of metal borides and the significance of the structures in the light of the multicenter bond theory. One chapter is devoted to a discussion of "The Structural Chemistry of Borates" (54 pp.) by *J. O. Edwards* and *V. I. Ross*; here the main emphasis is placed on a clear system of classification based on structural principles. In the reviewer's opinion the work of *Lehmann* has been somewhat neglected. Mechanistic aspects considerably enhance the topical character of the chapter entitled "The Structure and Acidity of Boric Acid and its Relation

to Reaction Mechanisms" (*R. P. Bell, J. O. Edwards,* and *R. B. Jones,* 14 pp.).

M. F. Hawthorne gives an exemplary discussion of the boranes (102 pp., including a wealth of experimental material). The main stress is on decaborane chemistry, polyhedral borane ions, and the carboranes; the chemistry of diborane and tetrahydridoborates are considered in an undeservedly brief manner. An excellent critical review of boron halides is given in a short space by *G. May* (52 pp.). 66 pages are devoted to the boron-nitrogen compounds. The layout of the section written by *K. Niedenzu* and *J. W. Dawson* resembles that of their book; however, more recent results are considered. *M. F. Lappert* arranges the boron-carbon compounds (174 pp.) according to their reactivity and to general considerations, which leads to a useful comparative account. The classes of compounds discussed by *G. W. Parshall* and *E. L. Muetterties* demonstrate how relatively small our knowledge is of boron-phosphorus (30 pp.), boron-sulfur, and boron-selenium compounds. Particularly in this field a certain lack of reliable information becomes apparent.

Unfortunately the index of the book is not very attractive, containing as it does too many wrong page numbers. On the other hand, the number of printing errors in the text is small. All in all, the book gives a good review of a still highly topical and ever-fascinating field of chemistry, its variety and peculiarities that stem from multicenter bonding and the related bond theory problems. The reader quickly recognizes a certain independence of this element in the periodic system, and the fact that despite the enormous developments made in the last 15 years many parts of boron chemistry still represent unknown territory and even the well explored fields still conceal problems. This book can be recommended to anyone wishing to gain an overall picture of the chemistry of boron.

Reviews in Macromolecular Chemistry. Edited by *G. B. Butler* and *K. F. O'Driscoll.* Marcel Dekker, Inc., New York 1967. 1st Edit., Vol. I, vii, 449 pp., numerous illustrations and formulas, $16.50; Vol. II, viii, 380 pp., numerous illustrations, $16.50.

The constantly increasing number of scientific publications makes it difficult or impossible for the individual to keep abreast of advances in all fields of interest; reviews are therefore becoming increasingly important for the fast and comprehensive dissemination of knowledge. The advantage of reviews over handbooks is that they are up to date and can deal with very specialized topics.

The present series of books edited by *Butler* and *O'Driscoll* provides a brief survey of current topics in macromolecular chemistry. Though there are several such series of publications in this field, this new arrival must be welcomed for its breadth of subject. However, it remains to be seen whether the coordination and arrangement of the topics is such as to avoid duplication of effort. Volume 1 of this series contains seven articles, which give some idea of the wide outlook of the book.

K. O'Driscoll and *T. Yonezawa* present a critical review of the application of molecular orbital theory to the polymerization of vinyl compounds. Though the authors distinctly state that MO theory has so far enjoyed only limited success in the calculation of polymerization processes, the review shows that considerable progress has been made in the field of free-radical polymerization.

A. Gurgiolo contributes an excellent report on developments in polyalkylene oxides in 1963 and 1964. The initiators and polymerization mechanisms are compared; in addition to a detailed description of the physical properties of the polymers, the use of crosslinked polyalkylene oxides in the elastomer field is discussed. Though this comprehensive article (150 pp., 352 references) deals with applied aspects mainly by reference to the literature it still provides a good review.

The article by *D. Lyman* on "Polyurethanes" is intended mainly for chemists working with synthetic polymers; in contrast to the book of the same title by *Vieweg/Höchtlen,* which appeared at about the same time, this author deliberately ignores the technological side of polyurethane chemistry. This is a very readable report, which provides a rapid survey of the polyurethane field. However, the fact that the discussion is mainly concerned with linear polyurethanes should be indicated in the title.

L. Reich and *S. Stirala* describe the uncatalyzed, uninhibited thermal oxidation of saturated olefins. The literature is covered up to and including 1964, and the extensive experimental data are well arranged.

Thermally stable polymers are discussed in an article by *W. de Winter.* Although the article is written very concisely, it is easily readable (24 pp., 161 references) and gives a good survey of the state of development up to 1965.

D. Lyman presents a review of biochemical polymers. The clearly written article deals mainly with the use of polymers as organ substitutes. The influence of the chemical structure, shaping, and the surface state on the tissue compatibility and the polymer-blood reaction are discussed; however, little information is given on the use of hydrophilic polymers.

Advances in gel permeation chromatography are described by *J. Johnson, R. Porter,* and *M. Cantow.* The article covers the literature up to 1966, and deals mainly with separations in organic solvents. The literature data on the influence of experimental parameters on the form of the maxima are critically compared.

Volume 2 of this series also contains seven articles. Polymers containing phosphorus in the main and side chains are discussed in two contributions by *M. Sander* and *A. Steininger.* The comprehensive article (178 pp.) presents a good survey of the rapid development that has taken place during the past ten years in the chemistry of organophosphorus polymers.

The theory of polyester formation is discussed by *D. Salomon,* with special reference to the alkyd resins. Microgel formation and its influence on the polymer structure are dealt with in particular detail.

General symmetry considerations for stereoregular polymers are discussed in a short article by *A. Liquori.*

After a general survey of polymerizability and the polymerization mechanism of cyclic compounds, *R. Patsiga* describes the few known cases of successful copolymerization of vinyl compounds with cyclic compounds.

The other contributions also deal with interesting topics in macromolecular chemistry. *K. Ramey* and *W. Brey* report on the use of high-resolution NMR spectroscopy to establish the structures of polymers; *D. Blackadder* reviews the field of polymer single crystals, and an article by *G. Cameron* and *J. MacCallum* deals with the thermal degradation of polystyrene.

These reviews, which appear as separate items in the Journal of Macromolecular Science, will be widely read; the choice of subjects guarantees an excellent survey of current topics in macromolecular chemistry.

W. Heitz [NB 782 IE]

Molecular Orbital Theories of Bonding in Organic Molecules. By *R. L. Flurry, jr.,* Marcel Dekker, Inc., New York 1968, 1st Edit., x, 334 pp., numerous figures and tables, $17.75.

As is mentioned in the Introduction of the book, the author wrote it with two objects in mind. Firstly, he wished to provide an understanding of chemical bonding on the basis of the MO theory, and secondly he wished to offer accurate procedures for those who would like to carry out semi-empirical MO calculations for themselves. The second aim has been largely achieved. The eighth chapter provides a very good summary of the formalism of the Pariser-Parr-Pople (PPP) method and its variants. The brief survey (in

Chapter 9) of the current calculation methods for σ electrons is a welcome inclusion.

In the first two thirds of the book, the author follows the principle of proceeding from formally simple to formally difficult methods (this does not mean from conceptually simple to conceptually difficult), with the result that the reader understands nothing correctly, since the basis for understanding or the definitions already used usually appear about fifty pages later. For example, the elegant Longuet-Higgins method for the determination of certain molecular orbitals is given at a point where its relation to the actual HMO theory and its importance for molecules containing heteroatoms are not yet clear. The author also fails to take the opportunity of showing the relation between this method and the qualitative resonance theory.

In the discussion of the spectra of polyenes on the basis of the electron gas model, no reference is made to the importance of bond alternation. In spite of its unfortunate arrangement and the presence of a number of chapters that appear superfluous to the reviewer (*e.g.* on calculation tricks to simplify the Hückel equations), the book is more precise and more correct in many details than other comparable discussions. Little is said on the topic mentioned in the title, *i.e.* the MO theory of chemical bonding in organic molecules. The book would be better named "Procedures for Semiempirical MO Calculations".

Lysozymes: A Chapter of Molecular Biology

By P. Jollès[*]

Hen egg-white lysozyme was the first enzyme whose tertiary structure could be elucidated. The peptide chain of this enzyme is arranged in two sections, of approximately equal size, that are separated by a deep cleft. Substrates (and inhibitors) are bound in this cleft via hydrogen bonds and are hydrolyzed under the action of Glu 35 and Asp 52, which form the active site of the enzyme. Although the lysozymes, which occur in many species of animals and plants, exhibit differences in their chemical behavior, they have the same qualitative biological activity; quantitatively important differences have been noted which also concern the specificity. Infection of E. coli with bacteriophages gives rise to a lysozyme whose formation is controlled by the phage DNA. The fact that mutated lysozymes are produced when the phages are treated with mutagens opens new fields of research in molecular biology.

1. Introduction

Hen egg-white lysozyme (EC 3.2.1.17) is one of the most extensively studied enzymes: its primary structure, the disposition of its disulfide bonds, its spatial behavior (first three-dimensional structure of an enzyme molecule), its active center, specificity, and mode of action have all been investigated in detail.

Lysozymes are not only found in hen and other bird egg-whites but are widespread enzymes, occurring in many human tissues and secretions, and in various other vertebrates and invertebrates; their presence has also been established in bacteria, phages, and plants. For these reasons, many fruitful comparative studies have been carried out, concerning mainly the relationship between their chemical structure and their biological activity. The purpose of the present review is not to summarize the research done since 1963 [1], but rather to draw the attention of the reader to some particular points and developments that are of interest for the study not only of the lysozymes but also of other enzymes.

2. Hen Egg-White Lysozyme

2.1. Primary Structure and Disulfide Bonds

The sequence of hen egg-white lysozyme was determined by *Jollès et al.* [2,3] and by *Canfield* [4]; it is a protein containing 129 amino-acid residues which

form a single polypeptide chain cross-linked at four places by disulfide (–S–S–) bonds [5–7] (Fig. 1).

2.2. Three-Dimensional Structure

The conformation of lysozyme has been determined by X-ray analysis [8]. The method depends on the preparation and study of a series of protein crystals into which additional heavy atoms, such as uranium atoms, have been introduced without otherwise affecting the crystal structure. The first successful applications of this method were in the study of sperm-whale myoglobin by *Kendrew* and of horse hemoglobin by *Perutz*. Comparison of the electron density distribution at 2 Å resolution with the primary structure revealed the spatial arrangement of each of the 129 amino acid residues of hen egg-white lysozyme and permitted the positions of some 95% of the atoms to be located to within about 0.3 Å.

The molecule may be considered in two parts. The first 40 residues form a right-hand wing in which the peptide chain is coiled twice around a core of non-polar residues in a stable-looking conformation (α-helix structure). Residues 41–95 branch out to form a left-hand wing which appears to have a less rigid conformation and contains a high proportion of polar residues. The remainder of the chain partially closes the gap between the two wings and wraps around the outside of the right-hand wing leaving a pronounced cleft between the two parts of the molecule [9].

In contrast to the myoglobin molecule, which consists of long stretches of α-helix linked by generally short non-helical corners, the α-helix content of lysozyme is only about 40%; there is evidence that nearly all of the helices are distorted to some extent from the standard structure, usually without affecting the number of residues per turn of helix [10]. There are three runs of helix, each about 10 residues long (5 to 15, 24 to 34, 88 to 96) for which the axial translation per residue and number of residues per turn fall close to the α-helix values of 1.5 Å and 3.6, respectively, given by *Pauling* and *Corey* (Table 1). There is a further shorter length of helix (80 to 85) which appears to be quite close to the 3.0_{10} type of hydrogen bond arrangement and an isolated turn (119 to 122) of 3.0_{10} helix (Figure 2).

Table 1. Parameters of helical regions of hen egg-white lysozyme [10].

Residues	Unit rise (Å)	Unit rotation (°)	Units per turn
5–15	1.51	100.2	3.59
24–34	1.48_5	98.3	3.66
80–85	1.66	106.6	3.38
88–96	1.45_5	96.7	3.72

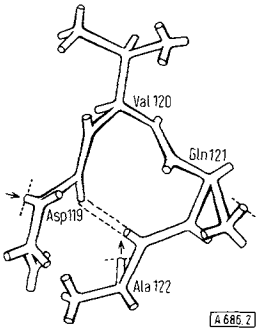

Fig. 2. A single turn of 3.0_{10} helix, showing also the conformation of Val 120 [10]. The hydrogen bonds are represented by dashed lines.

Another interesting but non-helical region [10] is formed by residues 41 to 54 where the chain doubles back on itself to form two strands arranged in the manner of an antiparallel pleated sheet (*Pauling* and *Corey* [11]) such as is thought to be the basic structure of silk fibroin [12] (Fig. 3).

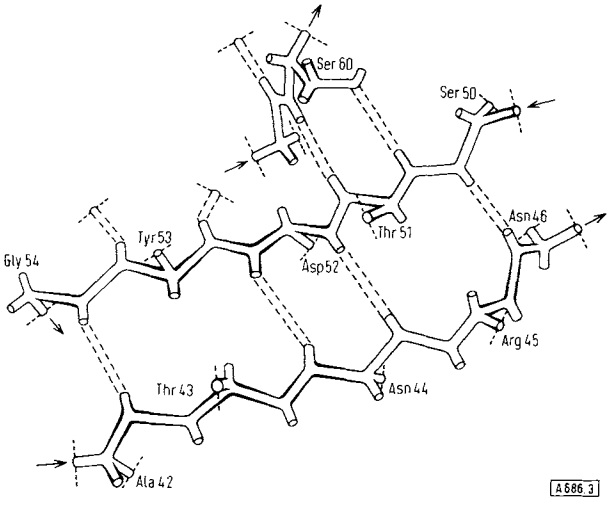

Fig. 3. Region between Ala 42 and Gly 54 where the main chain folds back on itself to form an antiparallel pleated sheet arrangement [10]. The hydrogen bonds are represented by dashed lines.

The acidic (Asp and Glu) and basic (Lys, Arg, and His) side chains and the terminal groups are all distributed over the surface of the molecule; this is also true of the remaining polar side chains, with two exceptions (Glu 57; Ser 91). In contrast, the great majority of the non-polar or hydrophobic side chains are in the interior of the molecule [10], where they are by no means distributed uniformly throughout the length of the chain. There is none between residues 38 and 55 and the deep cleft in the molecule seems to divide it into two parts of markedly different character (right-hand and left-hand wings, see above). In fact, lysozyme, like myoglobin, is quite well described as an oil drop with a polar coat [13].

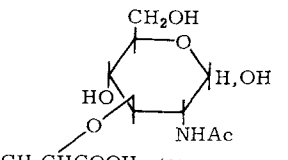
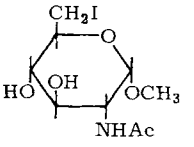
2.3. The Activity of Lysozyme

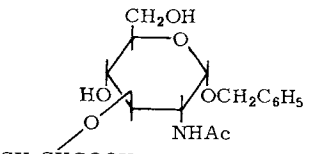
Simultaneously with his discovery of lysozyme, *Fleming*[14] discovered a gram-positive species of bacteria, *Micrococcus lysodeikticus*, which is particularly susceptible to the action of the enzyme. It was many years later when *Salton*[15] demonstrated that the substrate is located entirely within the bacterial cell wall. An indication of the type of linkage attacked by lysozyme was first established when *Berger* and *Weiser*[16] showed that lysozyme also degrades chitin, the linear polymer of *N*-acetylglucosamine (NAG). They concluded that the enzyme possesses β (1→4) glucosaminidase activity.



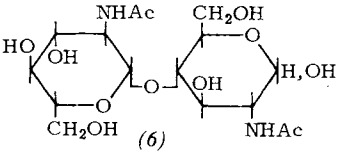
Salton and *Ghuysen*[17] subsequently isolated a tetrasaccharide containing equimolar amounts of NAG and *N*-acetylmuramic acid (NAM) from lysozyme digests of *M. lysodeikticus* cell walls. On incubation with lysozyme, this tetrasaccharide yielded a disaccharide containing NAG and NAM. It was deduced that the tetrasaccharide is a dimer of this disaccharide in which the two units are joined by the lysozyme-sensitive β (1→4) linkage. Its complete structure was established only in 1963 by *Jeanloz et al.*[18] as *N*-acetylglucosaminyl-β-(1→4)-*N*-acetylmuraminyl-β-(1→4)-*N*-acetylglucosaminyl-β-(1→4)-*N*-acetylmuramic acid *(1)*.



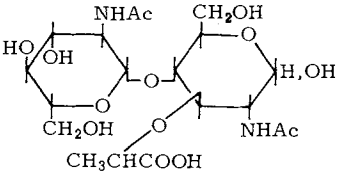
(1)



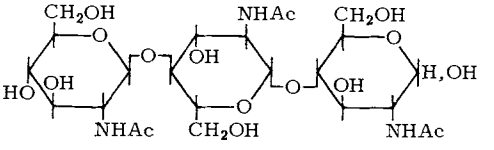
(2)



(3)



(4)



(5)

(6)

(7)

(8)

The proposed structure of the cell-wall mucopolysaccharide, containing alternate units of NAG and NAM residues joined by β (1→4) linkages, is very similar to the structure of chitin, the only difference being the inclusion of NAM residues in the former; it is therefore probable that the effects of lysozyme upon chitin and upon the bacterial cell walls are very closely related. In fact, a large proportion of the recent work on the activity of lysozyme has been concerned with its properties as a chitinase, especially during its interaction with relatively short oligomers of NAG. NAG *(2)* and other simple amino-sugar molecules *(3)–(7)*, including trimeric NAG *(8)*, act as competitive inhibitors of the activity of lysozyme by binding to the enzyme in the same way as a part of the large substrate molecule. Experiments at low resolution with low molecular weight inhibitors related either to the bacterial cell wall substrate or to the poly-NAG substrate have shown that the sugars bind the lysozyme at a number of different places in the cleft between the right-hand and left-hand wings of the lysozyme molecule[9,19,20].

Trimeric NAG *(8)* fills the top half of the cleft and is bound to the enzyme by a number of interactions; six strong hydrogen bonds have been identified, two of them connecting an NAG residue to the side chains of the tryptophan residues 62 and 63. Among the more important nonpolar interactions are those between the NAM residue and the ring system of Trp 62: these deserve special mention because they are affected by small changes in the conformation of the enzyme molecule that occur on reaction with the trisaccharide *(8)*[13].

Insofar as the complex formed by tri-NAG and the enzyme is stable, it differs from the enzyme-substrate complex involved in catalysis. Furthermore, it is known that at low concentrations, tri-NAG is rather an inhibitor than a substrate that is broken down. As tri-NAG fills only half of the cleft, the presence of more sugar residues, filling the remainder, would appear

[19] *L. N. Johnson* and *D. C. Phillips*, Nature (London) *206*, 761 (1965).

[20] *C. C. F. Blake*, *L. N. Johnson*, *G. A. Mair*, *A. C. T. North*, *D. C. Phillips*, and *V. R. Sarma*, Proc. Roy. Soc. (London), Ser. B *167*, 378 (1967).

necessary for the formation of a reactive enzyme-substrate complex. In fact, another three sugar residues can be added to the tri-NAG in such a way that satisfactory interactions can take place between the atoms of the substrate and those of the enzyme [13]. However, the forth sugar residue must be distorted a little out of its most stable "chair" conformation into a conformation in which its carbon atoms 1, 2, and 5 and the oxygen atom attached to C-5 all lie in a plane [13]. The distortion assists in breaking the substrate below the fourth sugar. This observation and many other results indicate that the linkage which is broken is the one between the fourth and the fifth sugar residue (between C-1 and the oxygen in the glycosidic linkage). The most reactive groups in the vicinity of this bond are the side chains of Asp 52 and Glu 35.

According to observations by *Phillips* [13], *Blake et al.* [20], and *Vernon* [21], the events leading to the rupture of the bacterial cell wall probably take the following course:

1) The substrate becomes attached to the enzyme and is held in position by hydrogen bonds and by other forces; in the process the ring of the fourth sugar residue becomes distorted and takes up a conformation favoring formation of a carbonium ion.

2) A proton is transferred to the glycosidic oxygen atom from the side chain of Glu 35.

3) Heterolysis of the C_1 carbon-oxygen bond gives a carbonium ion which is stabilized by interaction with the negative charge of the side chain of Asp 52.

4) The disaccharide obtained from the hexasaccharide diffuses away and a water molecule attacks the carbonium ion, thus completing hydrolysis (Fig. 4).

It is apparent that three factors are responsible for the catalytic effect: general acid-catalysis; activation of the substrate by distortion; and electrostatic interaction.

At this stage, it is fitting to quote a remark made by *Perutz* [22]: "For the first time we have been able to interpret the catalytic activity of an enzyme in stereochemical terms. It seems rash to generalize from the structure of one enzyme, but we may broaden our base by elevating myoglobin and haemoglobin to the rank of honorary enzymes, as *Monod* has suggested, and call the heme groups their active sites. What these three proteins have in common is the distribution of polar and non-polar side chains; the interior of the lysozyme as well as that of the globin chains is made up largely of hydrocarbons, providing a medium of low dielectric constant. In each case the active center lies in a pocket formed by this non-polar medium, and the pocket contains some polar residues which are essential for activity."

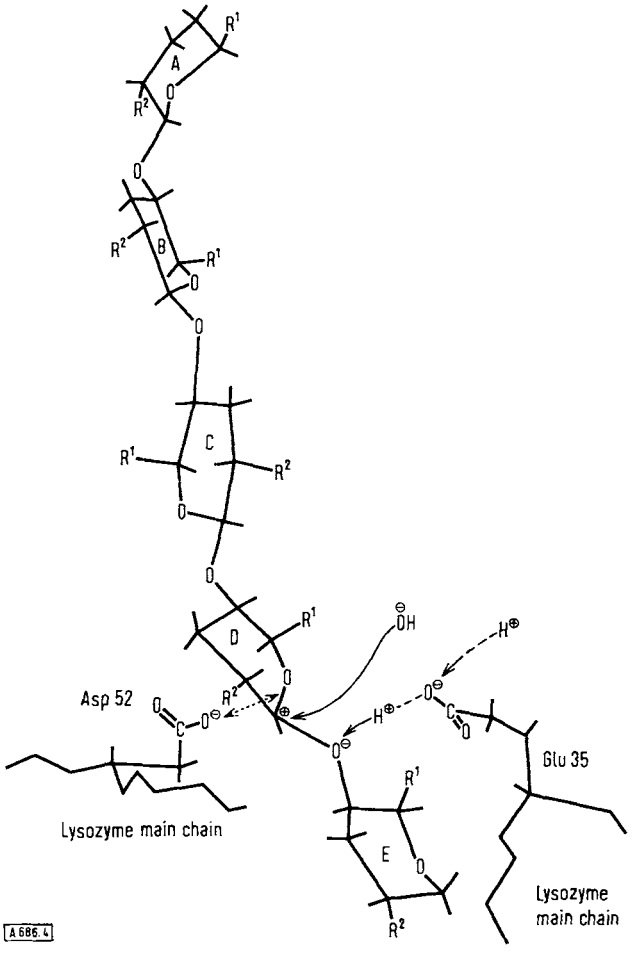

Fig. 4. Splitting of substrate by lysozyme is believed to involve the proximity and activity of two side chains, Glu 35 and Asp 52. A proton probably becomes detached from the OH group of residue 35 and attaches itself to the oxygen atom that joins rings D and E, thus breaking the bond between the two rings [13].

[21] *C. A. Vernon*, Proc. Roy. Soc. (London), Ser. B *167*, 389 (1967).

2.4. Biosynthesis of Lysozyme

The incubation of minced hen oviduct with ^{3}H-leucine was undertaken by *Canfield* and *Anfinsen* [23], and led to the formation of radioactive lysozyme. The distribution of radioactivity in the leucine residues along the polypeptide chain of the reduced, carboxymethylated protein was established by isolation of leucine-containing peptides produced by trypsin digestion. The peptides were then hydrolyzed and the specific radioactivities of the leucine residues were determined. Samples of radioactive lysozyme isolated from oviduct minces that had been incubated for 3 and 5 minutes, showed unequal labeling of leucine residues, and the relative specific radioactivities were found to increase from the NH_2-terminal to the COOH-terminal end of the chain.

These observations [23] are consistent with the model of amino acid assembly in which the polypeptide chain grows unidirectionally, initiation occurring at the NH_2-terminal end and termination at the COOH-terminal end. It seems reasonable to assume [13] that the folding of the protein chain to its native conformation begins at the amino end even before synthesis is complete. Parts of the polypeptide chain, particularly those near the terminal amino end, may fold into stable conformations that can still be recognized in the finished molecule and that act as "internal templates", or centers around which the rest of the chain is

[22] *M. F. Perutz*, Proc. Roy. Soc. (London), Ser. B *167*, 448 (1967).

[23] *R. E. Canfield* and *C. B. Anfinsen*, Biochemistry *2*, 1073 (1963).

folded [13]. The three-dimensional model provides support for these ideas, especially as the first residues at the terminal amino end form a compact structure.

2.5. Relationship between Structure and Activity

2.5.1. The NH_2- and COOH-Terminal Sequences

The NH_2- and COOH-terminal sequences are split off by aminopeptidase and carboxypeptidase respectively. The shortened enzymes, des-lysylvaline-lysozyme [24] and des-arginylleucine-lysozyme [25] are always active. At low ionic strength the des-arginylleucine-lysozyme is even slightly more active than the native molecule, whereas at high ionic strength it proves to be significantly less active.

2.5.2. Role of the Tryptophan Residues

Hen lysozyme contains six tryptophan residues per molecule. Recent X-ray studies at a 2 Å resolution demonstrated the importance of some of these residues for the biological activity [8, 19]. Other studies in this field were made by chemical and physical methods [19, 26, 27] (see Table 2).

According to recent investigations by *Kronman et al.* [37] *N*-bromosuccinimide shows no specificity in its reaction with the tryptophan groups of lysozyme. Caution must therefore be exercised in the use of this reagent for determining the extent of "exposure" of side chains of native proteins.

2.5.3. Role of the Histidine Residue

Numerous investigations on lysozymes whose molecules contain only one histidine residue have shown that this amino acid is not involved in the active site. Fully active lysozymes containing no histidine have, in fact, been isolated from duck egg-white [38].

2.5.4. Role of the Cystine Residues

Hen egg-white lysozyme contains four disulfide bridges. With the discovery of lysozymes containing three [39], two [40], or no [41] cystine bonds per molecule, it appeared that these latter are not essential for biological activity. However, *Jollès et al.* [42] showed that the presence of disulfide bridges is important for the heat stability of the enzymes. Lysozymes with four cystine bonds are relatively stable in acidic or neutral solution when heated for 0.5 or 1 min at 100 °C. Human lysozymes (three cystine residues) are a little more heat sensitive; when the cystine content drops to only two residues, as in goose lysozyme, the heat stability is almost lost.

Table 2. Relationship between the chemical modification of tryptophan residues and the biological activity of hen egg-white lysozyme.

Reagent	Number of modified tryptophan residues		Conversion product	Amino acid (no.)	Ref.

It has also been established that the lysozyme with the smallest cystine content has the highest specific activity [42]. If the specific activity of hen egg-white lysozyme is set at unity, then a value of the same order is found for the duck enzymes, and 3 ± 0.5 for the human lysozymes and 5 ± 0.5 for the goose enzyme. Interaction between the substrate and the active center of the goose enzyme probably occurs more easily because this enzyme exhibits a lower degree of folding.

2.5.5. Reactivation of Reduced Lysozyme

Lysozyme fully reduced with β-mercaptoethanol in 8 M urea can be reactivated by enzymic and non-enzymic procedures. Enzymic reactivation [43, 44] occurs, without any induction period, by disulfide interchange [45]. Non-enzymic reactivation proceeds by oxidation of the reduced protein in buffered solutions containing small amounts of β-mercaptoethanol. The reoxidized lysozyme has the same tertiary structure as the native enzyme [46, 47]. Active lysozyme can also be regenerated from the mixed disulfide of hen lysozyme and cystine [48].

2.5.6. Cross-linking of Lysozyme

The cross-linking of lysozyme has been effected by reaction with phenol-2,4-disulfonyl chloride. The cross-linked protein retains its enzymic activity, has approximately the same molecular weight as native lysozyme, and, according to optical rotatory dispersion analysis [49], has essentially the same conformation.

2.5.7. Irradiation of Lysozyme

Crystallized lysozyme has been irradiated with doses of X-rays between 1 and 100 millirads and with γ-rays from ^{60}Co [51]. Doses of a few millirads have no measurable effect on activity or on the amino acid composition of lysozyme. However, increased doses convert the original protein into a large number of modified proteins showing an increased or reduced lysozyme activity. Only X-ray doses of the order of magnitude of 100 mrads produce changes in the amino acids which can be determined with an Autoanalyzer. These changes involve mainly the sulfur-containing, the aromatic, and the long chain aliphatic amino acids [50].

2.5.8. Conclusion

The importance of residues 35 (Glu) and 52 (Asp) and of some Trp residues for the biological activity led to a number of synthetic assays. Thus the synthesis of polypeptides having carboxyl functions in hydrophobic as well as in hydrophilic regions (Phe/Glu = 1/0.3; mean molecular weight 63650) has been reported [52]; it was claimed that they are able to degrade the cell walls of *M. lysodeikticus*. The syntheses of short sequences of hen lysozyme were reported by *Morley* [53] and *Jollès* [54].

2.6. Application of Physico-Chemical Methods to the Study of Lysozyme

On interaction with either a substrate or an inhibitor lysozyme displays a red shift in its ultraviolet spectrum and it was implied from model studies that tryptophan was involved in this shift [55, 56].

In the presence of *N*-acetylglucosamine, the circular dichroism of lysozyme increases in the aromatic range, a phenomenon that is also attributed to participation of tryptophan [57].

Significant changes in the tryptophan fluorescence can occur on binding of appropriate inhibitors [58, 59]. Large changes in the tryptophan fluorescence of lysozyme and of the lysozyme-tri-*N*-acetyl-D-glucosamine complex are observed with changing pH and are associated with changes in the ionization of certain groups of the enzyme [58, 60, 61]. These fluorescence changes occur over a pH range in which the gross conformation is thought to be invariant. The selective quenching of tryptophan fluorescence in lysozyme by iodide ions is also observed [62]. Fluorescence changes in ultraviolet-irradiated lysozyme were studied by *Churchich* [63].

The optical rotatory dispersion of aqueous solutions of lysozyme has been measured over a wavelength range of 195–600 nm [64]. By this technique, questions regarding the conformation of the enzyme under different conditions have been investigated [64–67].

Recent progress in the application of NMR to problems of protein structure and function has made it possible to obtain more detailed information on the behavior of enzymes in solution [68]. Partial assignments in the low field (aromatic) region of the lysozyme spectrum, a comparison of several denatured conformations, and spectral changes resulting from inhibitor binding were reported [68].

The elucidation of the tertiary structure of lysozyme has stimulated various attempts to find stereochemical rules relating the primary to the tertiary structure [69]; this approach might be complemented by a statistical analysis of the amino acid sequences [70]. A method of recognizing α-helical segments in the polypeptide chains with known primary structure is currently being investigated [71].

Sophianopoulos [72] and *Antonini* [73] found that the enzyme polymerizes reversibly with increasing pH at 20 °C; between pH 5 and 9, the dimer predominates.

Before concluding this section, mention should be made of the studies by *Hamaguchi* [65] concerning the effect of different reagents, of pH, and of temperature on the stability and conformation of lysozyme.

2.7. Mechanism of Action of Lysozyme

Lysozyme has been used extensively in degrading bacterial walls (see Section 2.3.) [17, 18]. The influence of various chemical modifications of the walls on lysozyme sensitivity were recently studied by *Salton* [74] (Table 3) and *Hara* [75]. The isolation of a disaccharide

Table 3. The influence of chemical substitution of cell walls on lysozyme sensitivity [74].

Modification	Effect
O-Acetylation (OH)	Complete inhibition
Esterification (COOH)	Partial inhibition
Diethylammonium salt formation (COOH)	Partial inhibition
Deacetylation at nitrogen	Inhibition
N-Succinylation ($-NH_2$)	Stimulation
Reaction with 1-fluoro-2,4-dinitrobenzene ($-NH_2$)	No effect
Reaction with 5-dimethylamino-1-naphthalene-sulfonyl chloride (DANS) ($-NH_2$)	No effect

(NAG–NAM), of two disaccharide peptides, and the corresponding tetrasaccharides from lysozyme digests of *Micrococcus lysodeikticus* cell walls was described in detail by *Sharon* [76, 77]. These compounds have been used for the study of the enzymic activity of lysozyme. The synthesis of derivatives of muramic acid made possible further investigations on the specificity of the enzyme [78]. Once it had been shown that lysozyme acts on colloidal chitin [16], there followed a number of reports on the purification of soluble *N*-acetylglucosamine oligosaccharides of varying chain lengths [79, 80] and of the action of the enzyme on these compounds [81] ("chitinase activity" EC 3.2.1.14, of lysozyme).

One of the low-molecular-weight substances that have been investigated in detail as a substrate for lysozyme is the tetrasaccharide NAG–NAM–NAG–NAM. Digestion of this compound into disaccharide has been followed by *Sharon* [76] by paper chromatography, colorimetry, and polarimetry. Together with the disaccharide, numerous oligosaccharides were characterized.

In addition to hydrolysis, lysozyme also catalyzes transglycosylation [76, 82]; it is feasible that hydrolysis of the tetrasaccharide does not proceed by direct cleavage but by a transfer mechanism (Scheme 1). Transglycosylation reactions were also reported with short-chain chitin oligosaccharides [83–86].

2 tetraose (D–D) → Hexaose (D–D–D) + Disaccharide (D)
D–D–D + D–D → D–D–D–D + D
2 D–D–D → D–D–D–D–D + D
2 D–D–D → D–D–D–D + D–D

Scheme 1. Course of the transglycosylation reaction induced by lysozyme [82].

"D" stands for the cell-wall disaccharide isolated from *M. lysodeikticus* (NAG–NAM).

Lysozyme can also act as a transferase; thus *Sharon* [87] observed that the enzyme is able to transfer NAG-NAM residues to a variety of mono- and disaccharide acceptors (NAG, D-glucose, D-glucosides, *etc.*) and to form and cleave β(1→2) glycosidic bonds. *N*-acetylglucosamine, and closely related oligosaccharides strongly inhibit the enzymic activity of lysozyme [88], as also do derivatives of D-glucosamine [89]. Fluorescence studies show that these inhibitors interact with the tryptophan residues in the active site of the enzyme (Table 4).

Table 4. Changes in the position of the emission maximum (λ_{max}) and in the height of the emission maximum (Q) of lysozyme on addition of an inhibitory sugar [88].

Sugar [a]	Conc. for 50% inhibition (mM)	$\Delta\lambda_{max}$ (nm) [b]	ΔQ (%) [c]
Tetra-NAG	~1	−10	+40
Di-NAG	0.6	−10	+25
Di-NAG–NAM	3	−10	−12
NAG–NAM pentapeptide	3	−10	+ 7
Gal-NAG	7	−10	+18
NAG	7	0	− 7
NAG–NAM	12	0	−12
NAG–NAM methyl ester	25	0	−12
Cellobiose	>100	0	0

[a] The oligosaccharides are β (1→4) linked.
[b] $\Delta\lambda_{max}$ = shift in the emission maximum.
[c] ΔQ = change of the height of the emission maximum relative to that of the enzyme alone (= 100%).

Further synthetic lysozyme substrates, which can be assayed colorimetrically, have been described by *Lowe* [90] and *Osawa* [91].

2.8. Immunological Studies

Tsugita et al. succeeded in isolating four immunologically active peptides from a peptic digest of lysozyme and in elucidating their chemical structures; these peptides seemed to bear at least one antigenic determinant [92,92a]. A peptide obtained by trypsin degradation, consisting of three peptide sequences Trp 62 → Arg 68, Asn 74 → Leu 83, and Leu 84 → Lys 96 linked by two disulfide bonds Cys 64 → Cys 80 and Cys 76 → Cys 94, was also found to exhibit weak but definite immunological activity. According to *Bonavida et al.* [93], lysozyme treated with cyanogen bromide retains a large proportion of the immunological features of the native enzyme. The proximity of the enzyme active center and an antigenic determinant of lysozyme has also been suggested [94]. Univalent antibodies of low molecular weight (3.5 S) could be purified by gel-filtration and DEAE-cellulose chromatography from lysozyme antisera of rabbits [95]. A selective fractionation of anti-lysozyme antibodies of different determinant specificities and the formation of antibodies with specificity directed against a unique region in native lysozyme have recently been described [95a].

3. Lysozymes of Different Origins

Lysozymes are widely distributed enzymes; they are found in a great number of organs, tissues, and secretions (spleen, kidney, leucocytes, tears, saliva, milk, serum) of vertebrates. They also occur in invertebrates, bacteria, phages, and plants. Previous studies with hen egg-white lysozyme led us to attribute the following properties to this enzyme [1]: (a) basic protein; (b) low molecular weight (15000); (c) stability at acidic pH at higher temperatures; (d) lability at alkaline pH; (e) lysis of suspensions of *Micrococcus lysodeikticus*; (f) its action on an appropriate substrate liberates compounds that can be detected by reagents for reducing sugars and amino sugars. However, our recent research [96] in this field has shown that this definition of a lysozyme must be at least partly modified. A brief survey of the purification, analysis, structure, and properties of some lysozymes will be undertaken in the second part of this review.

3.1. Purification, Analysis, and Structure

3.1.1. Two Different Lysozymes in the Same Secretion: Duck Egg-White Lysozymes [97]

During ion-exchange chromatography of a duck-lysozyme rich material on Amberlite CG-50, two (sometimes three) enzymes were characterized [97], *i.e.* duck lysozymes I, II, and III (in the order of elution from the column). Two of them (II and III) were always found, even when the enzymes were purified from a single egg of a well defined species; they are devoid of histidine [97–100] (Fig. 5).

Duck II: H-Lys-Val-Tyr-Ser-Arg-Cys-Glu-Leu-Ala-Ala-Ala-Met-Lys-
Hen: H-Lys-Val-Phe-Gly-Arg-Cys-Glu-Leu-Ala-Ala-Ala-Met-Lys-
Duck III: H-Lys-Val-Tyr-Gln-Arg-Cys-Glu-Leu-Ala-Ala-Ala-Met-Lys-
Human milk: H-Lys-Val-Phe-Glu-Arg-Cys-Glu-Leu-Ala-Arg-

Arg-Leu-Gly-Leu-Asp-Asn-Tyr-Arg-Gly-Tyr-Ser-Leu-Gly-Asn-Trp-Val-
Arg-His-Gly-Leu-Asp-Asn-Tyr-Arg-Gly-Tyr-Ser-Leu-Gly-Asn-Trp-Val-
Arg-Leu-Gly-Leu-Asp-Asn-Tyr-Arg-Gly-Tyr-Ser-Leu-Gly-Asn-Trp-Val-

Cys-Ala-Ala-Asn-Tyr-Glu-Ser-Ser-Phe-Asn-Thr-Glu-Ala-Thr-Asn-Arg-
Cys-Ala-Ala-Lys-Phe-Glu-Ser-Asn-Phe-Asn-Thr-Gln-Ala-Thr-Asn-Arg-
Cys-Ala-Ala-Asn-Tyr-Glu-Ser-Gly-Phe-Asn-Thr-Glu-Ala-Thr-Asn-Arg-
-Trp-Glu-Ser-Gly-Tyr-Asn-Thr-Arg-

Asp-Thr-Asn-Gly-Ser-Thr-Asx-Tyr-
Asp-Thr-Asn-Gly-Ser-Thr-Asp-Tyr-
Asp-Thr-Asn-Gly-Ser-Thr-Asx-Tyr-
-Ser-Thr-Asp-Tyr-

Fig. 5. Chemical structures of the N-terminal moities (53 amino acids) of duck egg-white lysozymes II and III. Comparison with hen egg-white lysozyme [100]. N-terminal sequence and peptides in the active site (Glu 35 and Asp 52) of human milk lysozyme [107]. Asx denotes Asp or Asn.

[99] *J. Jollès, J. Hermann, B. Niemann*, and *P. Jollès*, Europ. J. Biochem. (Berlin) *1*, 344 (1967).
[100] *B. Niemann, J. Hermann*, and *J. Jollès*, Bull. Soc. Chim. biol. *50*, 923 (1968).

Thus it was possible, for the first time, to isolate from the *same* secretion *two* lysozymes which not only exhibit different chromatographic behavior but also have slight structural differences [99, 100], which cannot be deduced from a simple comparison of the amino acid compositions. However, these slight differences do give rise to differences in reaction velocities, in the behavior towards a competitive inhibitor such as NAG [101], and in the apparent affinity constants for the bacterial substrate [102] (Table 5).

3.1.2. An Unusual Bird Lysozyme: Goose Egg-White Lysozyme [40]

Only one lysozyme could be isolated from geese of different species and characterized by ion exchange chromatography. Its amino acid composition is quite different from those of other bird egg-white lysozymes [40, 103]. The low cystine (two residues/molecule) and tryptophan (three residues/molecule) contents [104] are of special importance. Goose lysozyme is very labile at higher temperatures, even at acidic pH [101]; its reaction velocity against *M. lysodeikticus* cells [102] and its specificity toward low molecular weight substrates at pH 6.2 are very different from those of other lysozymes [104, 105].

3.1.3. Lysozymes from Normal Human Tissues and Secretions

Jollès et al. [39, 96] obtained a great number of lysozymes from normal human tissues and secretions in a chromatographically pure state by ion exchange chromatography on Amberlite CG-50, *i.e.* lysozymes from milk [106, 107], tears [107], saliva [108], placenta [109], spleen, serum, and leucocytes [110]. All these human enzymes exhibit a very similar behavior on chromatography while differing considerably from bird lysozymes. In this connection it is worth mentioning that two hen lysozymes (egg-white and lung) were found to show widely diverging chromatographic behavior; the same applies to two dog lysozymes (spleen and kidney) [1].

Amino acid analyses of all the human lysozymes yielded comparable results. These data seem to indicate the probable identity of the enzyme in all human tissues and secretions. The analytical results are in agreement with recent observations of *Osserman* and *Lawlor* [111]. However, the data concerning the duck enzymes II and III, which embody structural differences despite very similar analyses, suggest that caution should be exercised in interpreting the results obtained for human lysozymes. A comparison of the tryptic peptides of the reduced carboxymethylated enzymes seems necessary. Detailed chemical structure studies concerning milk lysozyme are already in progress [107].

The peptide maps obtained by electrochromatography from milk and saliva lysozymes seem almost identical [107]. Research designed to clarify possible dissimilarities between other human lysozymes is currently in progress. The human lysozymes isolated by *Jolles et al.* have all approximately three to four times the activity of hen egg-white lysozyme (when titrated with suspensions of *M. lysodeikticus* at equivalent concentrations).

3.1.4. Lysozymes from Leukemia Patients

In the case of some leukemias, large quantities of lysozyme(s) are found in the blood [112] and/or in the urine [111]. *Jollès et al.* [112] determined the serum lysozyme concentration in a group of patients with a variety of diseases of hemopoietic tissues. A correlation was observed between the serum lysozyme level and the granulocyte count; a possible relationship with the monocyte count was also suggested. The lysozymes of serum and leucocytes from patients suffering from chronic myelogenous leukemia were purified and analyzed [110]. Their composition seemed identical with that of the enzymes from normal tissues. However, on ion-exchange chromatography on Amberlite CG-50 the main active peak was always followed by a smaller one; a comparison of the peptide maps of both enzymes will be necessary to ascertain whether they are identical or not.

Osserman and *Lawlor* [111] purified human serum and urinary lysozymes in monocytic and monomyelocytic leukemias and found a close correspondence with the values found for healthy human beings [107]. *Jollès* confirmed, by an automated method [113], that only those leukemia patients suffering from an acute myeloblastic leukemia excrete large quantities of lysozyme; during purification of the enzyme two biologically active peaks were again observed on ion-exchange chromatography [114]. Their specific activities were higher than those from normal human lysozymes.

3.1.6. Phage Lysozymes: A Contribution to the Study of the Genetic Code. First *in Vitro* Synthesis of an Enzyme

Escherichia coli cells produce a lysozyme after infection with bacteriophage [115]. Since this process is controlled by phage DNA, various mutants of lysozyme can easily be obtained by treating phage with mutagens [116]. Some important problems regarding

H-Met-Asn-Ile-Phe-Glu-Met-Leu-Arg-Ile-Asp-Glu-Gly-Leu-Arg-Leu-Lys-Ile-Tyr-Lys-Asp-Thr-Glu-Gly-Tyr-Tyr-Thr-Ile-Gly-Ile-Gly-His-Leu-Leu-Thr-Lys-Ser-Pro-Ser-Leu-Asn-Ala-Ala-Lys-Ser-Glu-Leu-Asp-Lys-Ala-Ile-Gly-Arg-Asn-Cys-Asn-Gly-Val-Ile-Thr-Lys-Asp-Glu-Ala-Glu-Lys-Leu-Phe-Asn-Gln-Asp-Val-Asp-Ala-Ala-Val-Arg-Gly-Ile-Leu-Arg-Asn-Ala-Lys-Leu-Lys-Pro-Val-Tyr-Asp-Ser-Leu-Asp-Ala-Val-Arg-Arg-Cys-Ala-Leu-Ile-Asn-Met-Val-Phe-Gln-Met-Gly-Glu-Thr-Gly-Val-Ala-Gly-Phe-Thr-Asn-Ser-Leu-Arg-Met-Leu-Gln-Gln-Lys-Arg-Trp-Asp-Glu-Ala-Ala-Val-Asn-Leu-Ala-Lys-Ser-Arg-Trp-Tyr-Asn-Gln-Thr-Pro-Asn-Arg-Ala-Lys-Arg-Val-Ile-Thr-Thr-Phe-Arg-Thr-Gly-Thr-Trp-Asp-Ala-Tyr-Lys-Asn-Leu-OH

Fig. 6. The amino acids equence of T4 phage lysozyme [41]. The sequence of T 2 phage lysozyme is the same with 3 substitutions: Asn (40) → Ser, Ala (41) → Val, Thr (151) → Ala [115a].

the genetic code may well prove solvable by comparing the chemical structure of mutated lysozymes with that of wild type lysozyme. By use of acridines such as proflavine, which is known as a frame-shift mutagen [117], one can determine not only the absolute RNA code words for amino acids *in vivo* but also the direction of reading of lysozyme messenger RNA and its nucleotide sequence. *Tsugita et al.* [118] have already determined 16 absolute code words for eleven amino acids, demonstrated the direction of messenger RNA reading, and elucidated a part of the nucleotide sequence of the messenger RNA of T4 phage lysozyme from a comparative study of the chemical structure of the proteins of wild type and double proflavine-induced mutants.

The complete amino acid sequence of T4 phage lysozyme was also elucidated [41]. The molecular weight was reported to be *ca.* 18000. No common primary structure was found between T4 phage lysozyme and egg-white lysozyme, but the distribution of basic, acidic, and hydrophobic amino acids seems to be similar. T4 phage lysozyme contains no S–S bridge and only two tryptophan residues per molecule. It is less stable than the hen enzyme [119].

Active lysozyme of bacteriophage T4 has been synthesized in a cell free system programmed by RNA from cells infected with the phage. The appearance of this lysozyme in the *in vitro* system has the characteristics of a *de novo* synthesis, which is mRNA specific and is inhibited by chloramphenicol, puromycin, and RNase. The incorporation of amino acids and the appearance of lysozyme activity have similar kinetics and a similar dependence on Mg. RNA from a T4 mutant with an amber mutation in the lysozyme structural gene is unable to stimulate the synthesis of lysozyme, thus showing that the measured activity is that of phage lysozyme [120, 121].

3.1.7. Lysozymes from Invertebrates

Jollès et al. [123, 124] have found traces of lysozyme(s) in many species of invertebrates; annelids, molluscs, and echinoderms contain larger quantities. Of special interest are the observed seasonal variations of the amount of enzyme [125], as well as the fact that these enzymes possess a high chitinase activity. The presence of lysozyme-like substances in insects has been reported by *Mohrig* [125a].

3.1.8. Lysozymes from Plants

The presence of bacteriolytic activity in plant tissues was first reported by *Fleming* [14] in 1922. Later *Meyer et al.* [126] reported lysozyme activity in crude proteolytic enzyme preparations from papaya and fig latex. In 1955, *Smith et al.* [127] prepared a crystalline lysozyme from papaya latex and quite recently *Howard* and *Glazer* [128] studied such a lysozyme in detail. It was found that papaya lysozyme has a molecular weight of about 25000, that glycine is its sole amino-terminal residue, and that the molecule consists of a single polypeptide chain. Papaya lysozyme lyses *M. lysodeikticus* cell walls at a rate one-third of that exhibited by egg-white lysozyme; however, it displays a chitinase activity toward tetra-*N*-acetyl-D-glucosamine 400 times that of hen lysozyme. No involvement of tryptophan residues in the active site of papaya lysozyme could be demonstrated. Similar observations have been made by *Jollès et al.* [122] with a turnip lysozyme.

3.2. Reaction Velocity, Specificity, and Mode of Action

Lysozymes from different animal species and sometimes also from different organs or secretions of the same animal are chemically different but have qualitatively the same biological activity, *i.e.* they promote lysis of a suspension of dead cells of *Micrococcus lysodeikticus* (basic definition of a lysozyme)[129].

Quantitatively the reaction velocity differs from one enzyme to another; differences in the specificity[96,105], behavior toward inhibitors[101,102], *etc.*, were later observed. In all these experiments, various substrates were employed, *e.g.* dead cells of *M. lysodeikticus*, cell walls from lysozyme sensitive bacteria (*B. megatherium*), cell walls from Mycobacteria[130], soluble substrates from *M. lysodeikticus*, polymers of *N*-acetylglucosamine obtained from chitin (chitotetraose, *etc.*), and cell-wall saccharides such as NAG–NAM–NAG–NAM.

3.2.1. Reaction Velocity. Apparent Affinity Constants

Under the same conditions, bird egg-white lysozymes digest many of the above mentioned substrates more rapidly than do human lysozymes[96,129]. At pH 6.2, duck lysozymes seem to have the most complete and most rapid action on chitotetraose and chitopentaose[105]. Affinity constants of seven different lysozymes for the bacterial substrate are shown in Table 5[102].

Table 5. Apparent affinity constants of lysozymes from different origins for *Micrococcus lysodeikticus* cells [102].

Lysozyme		Apparent affinity constant (mg cells/l)
Human		
	normal leucocytes	90 ± 10
	normal plasma	100 ± 5
	milk	110 ± 10
Avian		
	hen egg-white	115 ± 10
	duck egg-white II	150 ± 10
	duck egg-white III	200 ± 20
	goose egg-white	400 ± 100

3.2.2. Specificity and Mode of Action

The action of hen, duck, and human lysozymes on the substrates mentioned in Section 3.2 leads not to the formation of free sugars or amino acids but, in many cases, to the disaccharide NAG–NAM[96,129]. Like the hen enzyme, duck lysozymes and human-tear lysozyme degrade the tetrasaccharide NAG–NAM–NAG–NAM to the disaccharide NAG–NAM but not to free amino sugars. About 30% of the tetrasaccharide was not hydrolyzed. However, transglycosylation products were observed thus suggesting that the mode of action of these four lysozymes is the same[131]. The four lysozymes mentioned digest tetra-NAG and penta-NAG in a similar manner: the same digestion products are observed including free NAG and transglycosylation products. The quantity of tetra-NAG not digested varies at a given pH from one enzyme to another[105].

However, the goose lysozyme behaves differently: at pH 6.2 *M. lysodeikticus* cells are digested rapidly but the lysis soon stops. Low molecular weight substrates, such as NAG–NAM–NAG–NAM or chitotetraose are gradually attacked only at lower pH[105]. The reaction products obtained from the cells also vary with the pH[104].

3.2.3. The Behavior of Lysozymes in the Presence of an Inhibitor

It has been shown that hen egg-white lysozyme can be inhibited by NAG[19,30]. Under the same experimental conditions, this inhibitory action varies greatly from one enzyme to another[101]. The human lysozymes are more strongly inhibited by NAG than is hen lysozyme. At pH 6.2, the two duck enzymes are inhibited to less than 50% and goose lysozyme is practically uninhibited (Fig. 7). Similar results were

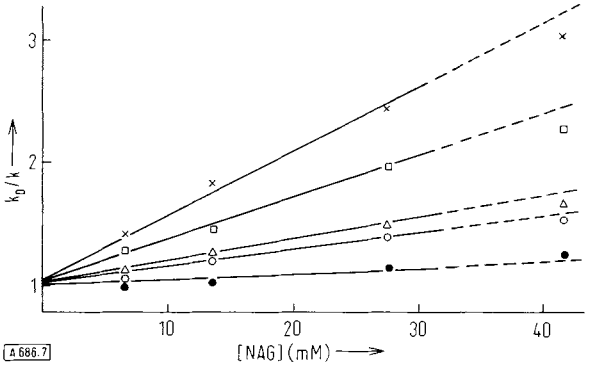

Fig. 7. Inhibition of the action of different lysozymes (0.63×10^{-6} M) on *M. lysodeikticus* cells by NAG (at pH 6.2) [101]. × = human, □ = hen, △ = duck II, ○ = duck III, ● = goose.

obtained with tetra-NAG[101]. Other inhibitors of hen lysozyme, such as histamine or L-histidine methyl ester[88], also inhibit goose lysozyme at concentrations similar to those used for the hen enzyme[101].

3.2.4. Immunological Comparison of Lysozymes

Arnheim and *Wilson*[132] purified lysozyme by Sephadex G-75 chromatography from the egg-whites of 17 species of birds in the order Galliformes and tested

for reactivity with antichicken lysozyme. The chicken and its closest relative, the jungle fowl, have lysozymes that appear to be indistinguishable from each other. The lysozymes of all the other species tested (partridges, quails, pheasants) could be distinguished from the chicken enzyme by quantitative micro-complement fixation. Immunodiffusion failed to detect most of these differences in antigenic structure. A particularly close relationship was observed between the lysozymes of the chicken, partridge, and American quails.

Ossermann and *Lawlor*[111] reported some immunochemical data which suggest the identity of the human lysozymes studied until now. Dissimilarities to bird egg-white enzymes were substantiated by the failure of the antiserum to a human lysozyme to inhibit the activity of the egg enzyme.

4. Concluding Remarks

4.1. Definition and Significance of Lysozymes

The results described in Section 3 necessitate a slight revision[96] of the definition of a lysozyme given in Sections 1 and 2. It is possible to imagine a lysozyme with an isoelectric point lower than 10.5–11 (hen enzyme); the molecular weight can be higher than 15000, as for the phage enzyme (18000)[119]; the stability at higher temperatures is lost when the cystine content of the enzyme becomes too low[42]. A property common to all the enzymes studied so far is the ability to rapidly lyse bacteria such as *M. lysodeikticus* by splitting β (1 → 4) linkages between a NAM and a NAG residue. Behavior towards low molecular weight substrates seems to depend on the pH, at least for some of the enzymes[104].

Only few details are available concerning the role of lysozymes *in vivo*[133]. Hen egg-white lysozyme is the only lysozyme yet to have been used clinically, owing to its basic character (addition to cow milk) and its antibacterial action. The latter can be explained in terms of enzymic action on substrates in the cell walls of gram-positive and gram-negative bacteria, although the substrates are not easily accessible in the gram-negative type. *In vivo* in the presence of substances such as enzymes, complement fractions, immunoglobulins [133a], or nucleic acids [133b], lysozyme seems to have some additional properties that have not yet been studied.

In vivo lysozyme can be included in an artificial structure formed by phospholipids and protein that is, by components common to many biological membranes, capable of masking its catalytic activity[134]. The demonstration of such a phenomenon may offer a new approach in the study of enzyme latency and may be of some importance in the development of a theory of membrane formation.

4.2. The Place of Lysozyme Among the Enzymes Degrading Peptidoglycans

The enzymes degrading peptidoglycans of bacterial cell walls are mainly bacteriolytic endoenzymes. They can be grouped into three classes: carbohydrases, acetylmuramyl-L-alanine amidases, and peptidases[135]. Carbohydrases include endoacetylmuramidases, endoacetylglucosaminidases, and exoacetylglucosaminidases. Lysozymes belong to the group of endoacetylmuramidases, which also include the "32 enzyme" from *Streptomyces albus* G[136], the "F_1 enzyme" from *St. albus* G[137], the "B enzyme" from *Chalaropsis*[138], and Autolysin from *Streptococcus faecalis*[139].

It is worth mentioning that lysozyme and penicillin, which were both discovered by *Fleming*, react with the same peptidoglycan from bacterial cell wall. Lysozyme splits the NAM–NAG linkage and penicillin mainly prevents biosynthesis of the peptide bridges. Furthermore, penicillin inhibits the lytic action of lysozyme, probably because it bears a structural resemblance to a portion of the bacterial cell wall, *N*-acetylmuramic acid[140] (Fig. 8).

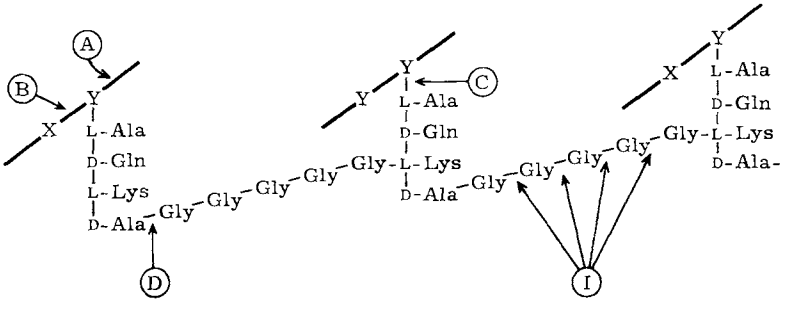

Fig. 8. A fragment of the peptidoglycan of *Staphylococcus aureus* showing point of cleavage by various enzymes [135]. X = NAG; Y = NAM; A = lysozyme; B = endoacetylglucosaminidase; C = acetylmuramyl-L-alanine amidase; D and I = endopeptidases.

4.3. Lysozyme and Evolution

Lactose synthetase (EC 2.4.1.c) catalyzes the following reaction[141]:

UDP-D-galactose + α-D-glucose → lactose + UDP

The soluble enzyme from milk requires the presence of two proteins, A and B, for activity; individually these proteins do not exhibit any catalytic activity. The present view is that A and B proteins are naturally occurring subunits and that enzymic activity is dependent upon the formation of an AB complex. The B protein was crystallized and identified as α-lactalbumin. Its structure was also established (Fig. 9). It

Fig. 9. Amino acid sequence of bovine α-lactalbumin compared with the sequence of hen egg-white lysozyme [142]. Asx stands for Asp or Asn; Glx for Glu or Gln.

shows that α-lactalbumin has a close structural similarity to hen egg-white lysozyme. According to *Brew et al.* [142], the wide distribution of lysozyme in the animal kingdom taken in conjunction with the unique occurrence of α-lactalbumin and lactose in milk suggests that the direct evolution of α-lactalbumin from a lysozyme in an ancestor of the mammals was a prime step in the evolution of lactose synthetase and of the mammary gland. α-Lactalbumin also seemed to be involved in reactions leading to the synthesis of β(1→4) linkages whereas lysozyme hydrolyzed such bonds. However, more recently the B protein appeared to act as a substrate modifier, changing the specificity of the A protein (inhibition of Gal-NAG synthesis in favor of Gal-Glc synthesis). Furthermore, a genetic relationship also exists between avidins and lysozymes [143].

Although lysozyme and α-lactalbumin have similar chemical structures [142] the latter has no lytic activity, probably because residue 35 (Glu) of hen lysozyme, which is important for the catalytic activity, is replaced by a hystidine residue.

However, despite the fact that hen egg-white-, phage-, and papaya-latex lysozymes have entirely different chemical structures, they all promote lysis of *M. lysodeikticus* cells. The main function of hen egg-white lysozyme, other bird lysozymes (even the goose enzyme with its quite different behavior), human lysozymes (mol. wt. 15000) [96, 107], *etc.*, which have similar structures and active sites (Fig. 5), seems to be digestion of bacterial cell walls, whereas phage lysozyme (mol. wt. 18000) [119] seems to exhibit a specific affinity for *E. coli* cells. On the other hand, papaya-latex lysozyme (mol. wt. 25000) [128] is much more a chitinase than a lysozyme and the tryptophan residues no longer seem to be involved in the active site. This is also true for turnip lysozyme and lysozymes from invertebrates. The question thus arises whether such enzymes can still be called lysozymes, which should primarily be muramidases (lysozyme = *N*-acetylmuramylhydrolase) with slight chitinase activity. The chitinase activity must be present, since an enzyme obtained from *Chalaropsis* which has only muramidase activity was not called lysozyme [144].

Biosynthesis of Lichen Substances, Products of a Symbiotic Association

K. Mosbach[*]

Lichens are composed of algae and fungi living together in symbiotic association and forming characteristic, often polycyclic lichen substances that are rarely encountered in other organisms. While the cultures of the unassociated individual constituents of the lichens can live for an unlimited time some doubt surrounds their viability in nature; their biosynthetic powers are not additive in the lichens. The results concerning the biosynthesis of the lichens that are discussed in the present article were obtained mainly with ^{14}C-labeled compounds.

1. The Makeup of Lichens

The lichens, about 15000 species of which are now known, are symbiotic forms of life composed of a fungal part (mycobiont) and an algal part (phycobiont). Symbiosis generally represents a close and enduring association of unlike organisms. Lichens are the most advanced form of this symbiotic process, called also mutualism, in which both organisms demonstrably gain from the association.

The properties of a lichen association differ sharply in many respects from those of the individual partners. Firstly, although the fungus and the algae require moisture (hygrophilia), they often occur in dry locations when combined as lichens (xerophilia). Algae are plants that prefer full light (photophytes), while fungi prefer shade (sciophytes); as lichens they thrive both in extremely light and in dark places. Secondly, the lichen association produces a new morphological unit, which is effected chiefly by a differentiation of the fungal component during combination with the algal component. Protective devices against evaporation are formed, as well as supporting structures and reproductive organs foreign to either partner alone. Thirdly, many "lichen substances" are formed in the associated organism, whose aromatic representatives with few exceptions occur solely in lichens.

The morphology of the lichens is characterized by great variety. Three essential forms can be distinguished: Crustose lichens are little differentiated, their thallus grows to only a few millimeters, and they grow in close contact with their substrata. Foliose lichens are more highly organized forms with a deciduous leaf-like thallus structure. Fruticose lichens display highly differentiated forms with stems, small branches, and leaves; they anticipate the differentiation of roots, buds, and leaves that occurs in flowering plants. Some beard lichens (*Usnea*) grow to a length of 5 m[1] (Fig. 1).

The fungal component determines especially the appearance of the lichen. Most lichen fungi belong to the class of sac fungi (*Ascomycetes*) but some lichens are encountered, mainly in the tropics, in which basidia fungi (*Basidomycetes*) occur as lichen formers. Finally, a few cases are known of imperfect fungi (*Deuteromycetes*) forming mycobionts. In the course of evolution the lichen fungi have become so far adapted to the association that they are unable to exist for any length of time without an algal partner. By way of contrast, lichen algae can occur as individual species. 12 genera of the blue-green algae (*Cyanophyceae*) and 21 genera of green algae (*Chlorophyceae*) are able to form lichens. Among the blue-green algae the genus *Nostoc* is the most abundant; and among green algae the single-cell *Trebouxia* predominates and, for example, forms about 80% of Scandinavian lichens[2].

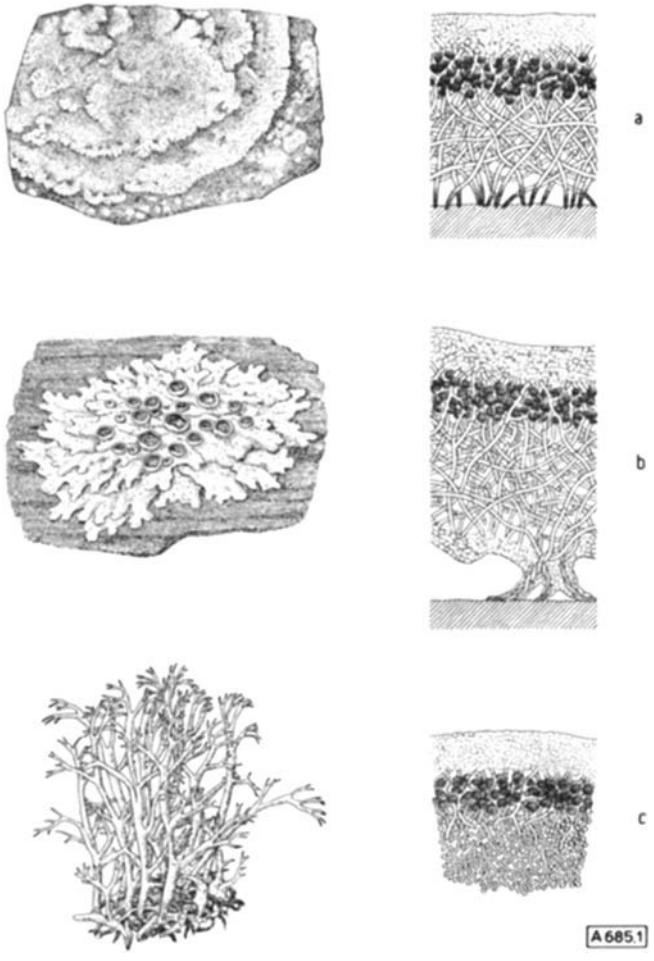

Fig. 1. Left: The three principal forms of lichens: crustose, foliose, and fruticose.

Right: (a) and (b) longitudinal sections through the lichen thallus, (c) cross-section through a stem. The lichen tissue is composed of the algal layer (dark) and the fungal hyphae (after *V. Ahmadjian* [1], reproduced by kind permission of the copyright holder).

S-22007 Lund (Sweden)

[1] *V. Ahmadjian*, Sci. American No. 2, 124 (1963).

[2] *R. Santesson*, Symbolae bot. upsal. *12*, 1 (1952).

A lichen alga can form associations with different lichen fungi to form varying types of lichens. Mostly, the lichen thalli contain only a single type of alga but in a few cases two are present; for example, in the Alpine sac lichen *Solorina crocea* a separate nitrogen-fixing blue-green algal zone is located underneath the peripheral green algal layer. Such a combination is known as trisymbiosis. On the other hand, one lichen fungus can associate with different algae [3]. For example, the morphologically indistinguishable lichen types *Lobaria pulmonaria* and *L. retigeria* represent fungus-green algae and fungus-blue-green algae associations respectively [4].

The lichen components can be separated and cultivated relatively easily. While the morphology of the isolated lichen fungus generally differs sharply from that in the natural lichen combination, the isolated lichen algae do not alter their appearance to the same extent. The aim of the lichen biologist to recombine isolated symbionts by a "lichen synthesis" has recently moved nearer to being achieved. The two symbionts have been cultivated together under special conditions, with the fungal hyphae enveloping the algae to form of a pseudo-parenchyma (Fig. 2) [5a]. *Ahmadjian* [6] has recently succeeded in obtaining differentiated lichen-like structures by this method, and these studies should provide a deeper insight into the course of "lichenization", a phenomenon difficult to observe in nature. In addition, it should be possible to create new types of artificial lichens by combining mycobionts and phycobionts.

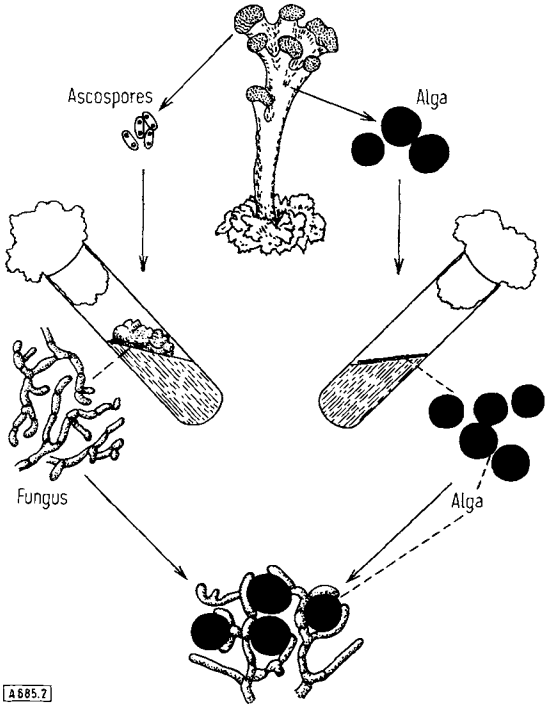

Fig. 2. Isolation of the two symbionts from a lichen and their recombination (schematic) (after *M. E. Hale* [5a], reproduced by kind permission of the copyright holder).

The two symbionts are very closely bound, with the fungal cells generally enveloping the algal cells or penetrating them with special sucking organs (haustoria) to ensure rapid exchange of metabolites (Fig. 3) [7]. (Regarding the biology of the lichens, see [5, 7–10].)

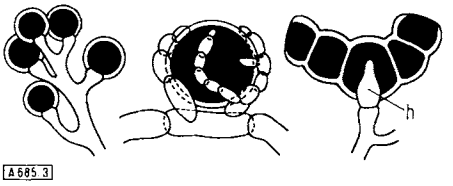

Fig. 3. Several forms of coupling between lichen algae and lichen fungi (h = haustoria) (after *G. Follmann* [7], reproduced by kind permission of the copyright holder).

The study of lichen physiology can be approached from two directions. Either the physiology of the individual symbionts or that of the intact lichen thallus is investigated. Many of the physiological studies that have been carried out on lichen components will not be discussed here, for the physiology of the lichen is not simply that of the sum of the properties of the two symbionts. The lichen organism must rather be regarded as a new functional entity.

2. The Metabolism of Lichens

Carbon for the lichen is furnished primarily by the photosynthetic activity of the algal partner. *D. C. Smith* succeeded in identifying the carbon compounds that participate in the transport of the fixed carbon from the alga to the fungus [11–13]. Pieces of identical shape were cut from the thallus of *Peltigera polydactyla*, a lichen with a blue-green *Nostoc* alga, and introduced into a medium containing $NaH^{14}CO_3$. Individual thallus pieces were collected at intervals, and the algal layer was separated from the medulla layer consisting only of fungal hyphae. As expected, the activity initially appeared in the algal layer and the [^{14}C]-glucose formed migrated from there into the fungal portion. After a 45-min incubation period in light, 60% of the fixed carbon was present in the fungal part in the form of mannitol [11, 12]. By contrast, in *Xanthoria aureola* lichen, which contains the green alga *Trebouxia* as phycobiont, the first labeled product was ribitol which was subsequently converted into mannitol and arabitol in the mycobiont [13]. A comparative study with four different *Lobaria* lichens containing *Trebouxia* and *Nostoc* algae led to the establishment of the two following principal patterns of carbohydrate movement [14].

Alga		Fungus
(*Trebouxia*) → Ribitol	→ (→Ribitol	→ Mannitol and Arabitol)
(*Nostoc*) → Glucose	→ (→Glucose	→ Mannitol)

[14] *D. H. S. Richardson*, *D. C. Smith*, and *D. H. Lewis*, Nature (London) *214*, 879 (1967).

Accordingly, the algal partner participating in the symbiosis appears to influence the type of pattern of carbohydrate movement. *Fox* and *Mosbach*[15,16] have determined the appearance of ^{14}C-activities in the tridepside gyrophoric acid [see *(15)* in Fig. 8] following incubation of the lichen *Umbilicaria papulosa* in light by a different technique. Labeling of the depside occurred within 1 min. Since at least the monocyclic units of these compounds must be synthesized in the fungal part, the entire sequence takes place during this short time, *i.e.* photosynthesis in the alga, transport of the sugar alcohols to the fungus, and biosynthesis of the depside from acetate and malonate units formed from the sugar alcohol.

Lichens from Arctic and Alpine regions display a high photosynthetic activity even at low temperatures. Thus, carbon fixation of *Letharia vulpina* at $-5\,^{\circ}C$ and ice formation in the pith layer still occur at half the rate measured under optimum conditions, and some lichens even continue photosynthesis at $-24\,^{\circ}C$[17,18]. The supply of carbon by photosynthesis is likely to be supplemented by saprophytic feeding in the natural environment of the lichens, *i.e.* by absorption of organic substances through the thallus or rhizines (adherent fibers).

Nitrogen is supplied to the organism by absorption of both organic and inorganic nitrogen compounds by the lichen thallus, *i.e.* mainly by the fungal partner. *Henriksson*[19] and *Scott*[20] were able to show with ^{15}N that lichens with blue-green algae can also fix atmospheric nitrogen. Undoubtedly, the lichens seldom contain sufficient nitrogen compounds, and for this reason the slow growth and the slow protein synthesis of the lichens can be interpreted as an adaptation to the given conditions during the course of evolution.

Little is known about the vitamin balance of intact lichens, but thiamine and biotin are known to be essential to the isolated mycobiont. Pure cultures of the phycobionts secrete large amounts of vitamins into the medium[21]. From the above data, which were obtained for individual symbionts, it may be concluded that the intact lichen is at least in part provided with vitamins by the phycobionts.

Mineral salts are supplied to the lichen by the thallus, which absorbs the salts dissolved in rain water. The mineral content in the thallus is often remarkably high; for instance, the *Diploschistes scruposus* lichen contains 10% of zinc calculated on the dry weight[22].

Radioactive fallout was also found in high concentrations in living lichens[23], which are characterized by a pronounced resistance to γ-radiation[24]. Finally, the water balance is determined by the mycobiont, which serves also to protect the algal partner against drying out and strong sunlight.

3. Biosynthesis of Lichen Substances

3.1. General

Lichen substances are generally low-molecular organic compounds. They represent secondary metabolites which, like the many corresponding fungal metabolites, have so far been ascribed a direct biological role in only few instances. The structures of about 120 lichen substances are known at the present time. *Emil Fischer*'s original synthesis of a depside represented an important contribution to this subject[25]. Work by *Robertson* and *Barton*[26,27] on the dibenzofuran derivative usnic acid [see *(20)* in Fig. 11] deserves special mention, as do also the investigations by the study groups led by *Asahina*, *Sheshadri*, and *Shibata*. Comparative mass spectrometry with positive and negative ions is a valuable tool for these studies, particularly for the elucidation of depside structures in which the acid and alcohol portions yield strong mass peaks[28]. (For a survey of lichen chemistry see[28–34], bibliography in[35].)

Is a separate treatment of the biosynthesis of lichen substances justified? The fact that particularly the important aromatic lichen substances, *i.e.* depsides, depsidones, depsones, dibenzofurans, and pulvic acid derivatives (see Figs. 6 and 15) almost all occur solely in lichens speaks in favor of this approach. Furthermore, an investigation should embrace a study of whether, and to what extent, the two symbionts participate in the biosynthesis of such structures. It is characteristic of aromatic lichen compounds that they

are all dicyclic or tricyclic, unlike the monocyclic aromatic metabolites occurring, for example, in molds. Generally, they form a high percentage of the dry weight of the lichens, *e.g.* the depside lecanoric acid forms up to 20%[36]. In molds secondary aromatic compounds are generally formed in corresponding amounts only under normal culture conditions, *i.e.* when the medium contains much glucose. Finally, any elucidation of the biosynthetic pathways leading to the lichen substance should put the chemotaxonomy of the lichens on a sounder basis.

Until recently knowledge regarding the biosynthesis of lichen substances was restricted to theoretical postulates, since it was assumed that the slow-growing organisms are unsuitable for direct experiments. However, *Mosbach* was able to show[37] that the lichen *Umbilicaria papulosa* incorporated 4% of [^{14}C]-diethyl malonate, which was added as a precursor, in the tridepside gyrophoric acid *(15)*. Such a high rate of incorporation is comparable with that found in molds. *Shibata*'s classification in somewhat modified form is a suitable basis for a detailed discussion of the biosynthesis of lichen substances[38] (Table 1).

Table 1. Classification of lichen substances with references to the Sections in which they occur.

carbohydrates (3.2.)	polyols polyglycosides polysaccharides (3.2.)

shikimic acid group (3.5.)	diketopiperazines, terphenylquinones, pulvic acid derivatives (3.5.)	
others		dimethyl sulfone, cholinesulfuric acid

3.2. Carbohydrates

Lichens are distinguished by their high polyol content. The compounds that have been found so far are *meso*-erythritol, D-arabitol, D-ribitol, D-mannitol, D-volemitol ($C_7H_{16}O_7$), and siphulitol ($C_7H_{16}O_6$), the first deoxy-sugar alcohol found in nature[39]. According to investigations by *Lindberg et al.*[40] on 60 types of lichens, the occurrence of the individual sugar alcohols appears to vary with the lichen genus. However, D-mannitol occurred in all the species investigated. Erythritol occurs in some lichens as the ester of orsellinic acid (montagnetol) and of lecanoric acid (erythrin). Polyol glycosides have only recently been found in lichens. Of the three known glycosides, umbilicin (2-*O*-β-D-galactofuranosyl-D-arabitol) may be mentioned here[41].

The cell walls of the hyphae consist mainly of lichenin or isolichenin, and more rarely of pustulan, glucan, and other, as yet unidentified, polysaccharides, some of which occur solely in lichens. Lichenin, which is found in several lichens, is a linear polymer built up from β-D-glucopyranose units; its molecular weight (20000–40000) lies between those of starch and cellulose[42]. Although investigations have not been carried out on the biosynthesis of lichen carbohydrates, it would appear that the relevant pathways probably follow other familiar patterns. The sugar alcohols which are generally present as intermediates during the carbon flow from the alga to the fungal partner seem to have a special significance.

3.3. The Acetate-Polymalonate Group

The group of compounds derived from acetate-polymalonate comprises by far the greatest number of lichen substances, their biosynthesis proceeding *via* condensation of a "starter" acetyl-SCoA[*] unit with *n* malonyl-SCoA units. Another name for compounds of this type is polyketides, a term coined by *Collie*[43], who interpreted these structures as polymeric ketenes. In the widest sense, saturated fatty acids belong to this group as reduced polyketides, but it is better for the term to be restricted to aromatic compounds.

3.3.1. Higher Fatty Acids and Lactones

The higher fatty acids occurring in lichens and their lactones can be divided into three groups: γ-lactone acid derivatives (seven members *e.g.* lichesterinic acid *(1)*), dibasic fatty acids [rocellic acid *(2)*], and tribasic fatty acids [caperatic and rangiformic acids *(4)*]. In addition, two tetrahydroxy fatty acids have been detected[44] (*e.g.*: ventosic acid $CH_3(CH_2)_8(CHOH)_2$-CH_2-$(CHOH)_2(CH_2)_7COOH$]. All aliphatic lichen acids are optically active. So far the absolute configurations of only rangiformic and rocellic acids are known[45] (rangiformic acid = methyl dihydrogen (+)-(2*S*:3*S*)-1,2,3-heptadecanetricarboxylate; rocellic acid

= (+)-(2*S*:3*R*)-2-methyl-3-dodecylsuccinic acid). No biosynthetic investigations on the lichen substances listed here are as yet available.

Gatenbeck and *Måhlén* have recently succeeded in synthesizing enzymatically the related compounds decylcitric acid *(3a)* and spiculisporic acid occurring in fungi by condensation of lauryl-SCoA with oxalacetate or α-ketoglutarate respectively [46,47]. Formation of the lichen acids is likely to proceed analogously by an aldol condensation of long-chain alkanoyl-SCoA units with keto acids, which, in turn, are formed by condensation of "starter"-acetyl-SCoA with *n* molecules of malonyl-SCoA. The lichen substances shown in Fig. 4 are therefore probably formed by condensation of myristoyl- or palmitoyl-SCoA with oxalacetic acid or pyruvic acid. In the γ-lactone acids the corresponding β-hydroxy fatty acids are possible condensation units. According to a recent publication [47a], the protolichesterinic acid occurring in lichens is formed by condensation of palmitic acid with pyruvic acid as suggested above.

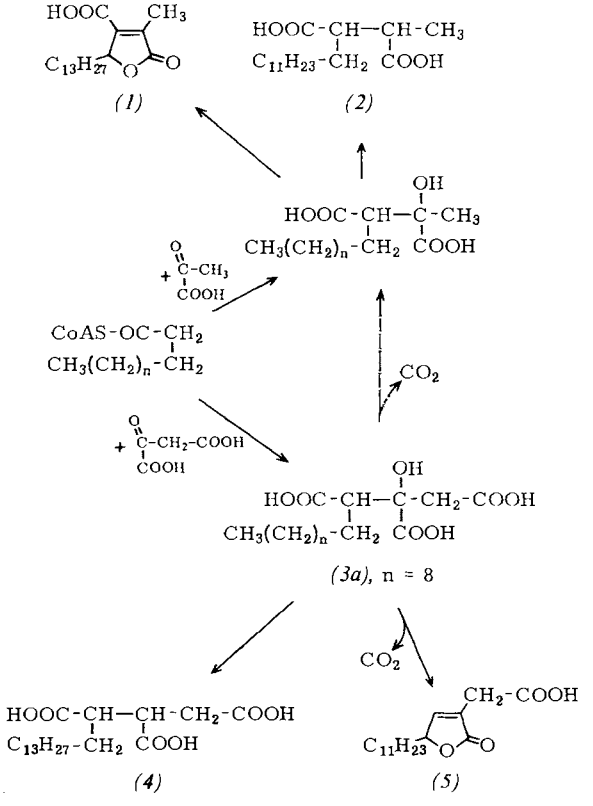

Fig. 4. Proposed biosynthesis of lichesterinic acid *(1)*, rocellic acid *(2)*, rangiformic acid *(4)*, acarenoic acid *(5)*, and decylcitric acid *(3a)*, $n = 8$, (fungus).

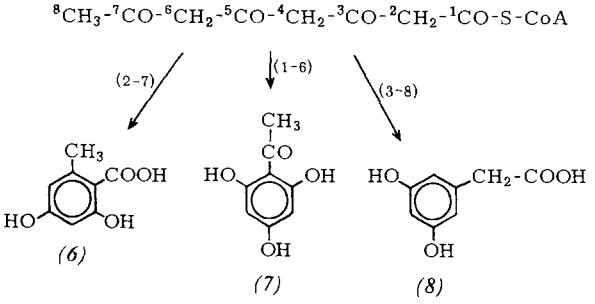
3.3.2. Aromatic Polyketides

The structures of about 100 aromatic lichen substances have so far been elucidated; a number of these compounds exhibit antibiotic properties and no less than 90 of them are aromatic polyketides. In most cases orsellinic acid and its homologs are the principal structural units. In molds, orsellinic acid *(6)* occurs in the free form [48,49]; in lichens, however, it is present almost exclusively in the form of condensed dicyclic or tricyclic compounds. According to isotopic studies with ^{14}C and ^{18}O [50–53], *(6)* is formed by the condensation of an acetyl-SCoA unit with three malonyl-SCoA units to form a (tentatively) hypothetical 3,5,7-trioxooctanoic acid, which is probably bound enzymatically as a thiol ester and cyclizes by an internal aldol condensation. Alternatively, aldol condensation can lead to 3,5-dihydroxyphenylacetic acid *(8)*, and Claisen condensation to acetylphloroglucinol *(7)* (Fig. 5).



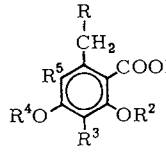


Fig. 5. Three possible alternative cyclizations of 3,5,7-trioxooctanoic acid to the aromatic compounds *(6)*–*(8)*. (The acid is bound to coenzyme A or more likely to a multienzyme).

The formation of these compounds very probably occurs on a multienzyme complex in analogy with fatty acid biosynthesis [54], as indicated by enzymatic experiments with other polyketides, *e.g.* 6-methylsalicylic acid and alternariol [54,55]. Orsellinic acid and its homologs, the principal structural units of the aromatic lichen substances, appear in many derivatives (Table 2), in which the β-orsellinic acid group (position

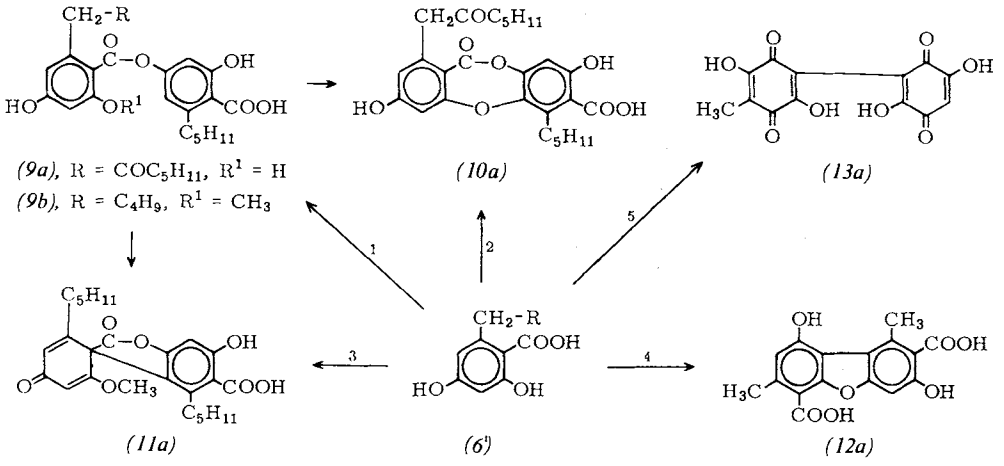

Fig. 6. Proposed biosynthesis of the five types of condensation products of orsellinic acid *(6)*, and its homologs occurring in lichens. *(9a)* = olivetoric acid, *(9b)* = dihydropicrolichenic acid, *(10a)* = physodic acid, *(11a)* = picrolichenic acid, *(12a)* = pannaric acid, *(13a)* = pyxiferin.

3 substituted with C_1 units) generally contains no aliphatic side chains (R=H). These structural units can form five types of condensation products (Fig. 6):

1. Esterification forming a depside *(9)*.
2. A cyclic depside (depsidone) *(10)*.
3. A depside with an additional C–C bond (depsone) *(11)*.
4. A cyclic ether with an additional C–C bond (dibenzofuran) *(12)*.
5. Products with a central C–C bond (bibenzoquinone) *(13)*.

Together with the pulvic acid derivatives (see Section 3.5) the first four types form the actual aromatic lichen substances. Except for the nidulins (mold depsidones) and the *m*-digallic acid occurring in tannins (depsides in algae and higher plants) they are restricted to the lichens.

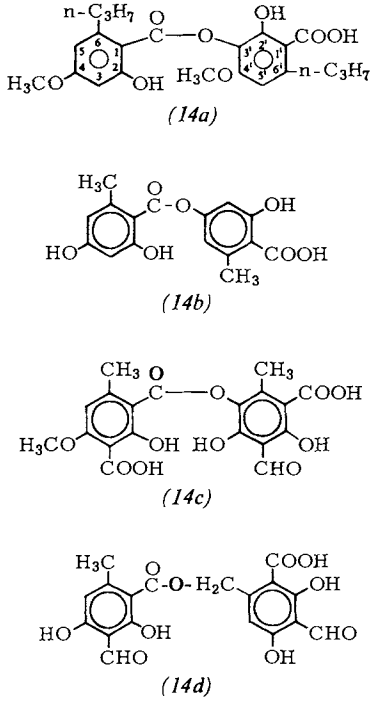

Fig. 7. Representatives of the four depside subgroups. *(14a)* = sekikaic acid, *(14b)* = lecanoric acid, *(14c)* = thamnolic acid, *(14d)* = barbatolic acid.

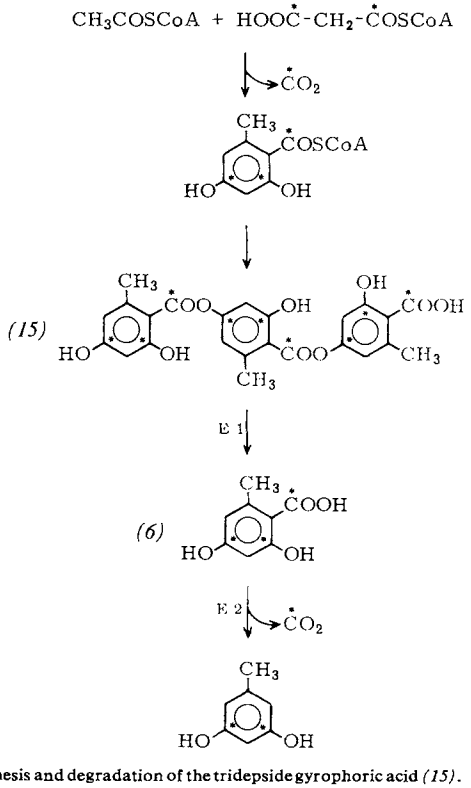
3.3.2.1. Depsides

The depsides have 40 known representatives and thus constitute the largest group of aromatic lichen substances; according to the type of linkage they can be divided into four subgroups (Fig. 7).

The first biosynthetic work on aromatic lichen substances was carried out with the gyrophoric acid-producing *Umbilicaria papulosa* [37]. $CH_2(^{14}COOC_2H_5)_2$ was added to the lichen thallus in agitated cultures; after a 3-day incubation period, 4% of the added activity was incorporated into gyrophoric acid *(15)*. As expected, subsequent degradation of labeled *(15)* gave the same specific activity for all three



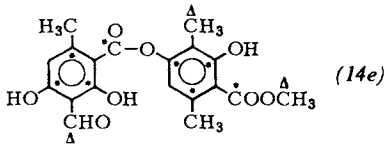


Fig. 8. Biosynthesis and degradation of the tridepside gyrophoric acid *(15)*. Labeling pattern (*) obtained after incubation with $CH_2(^{14}COOC_2H_5)_2$. Degradation is effected by means of depsidase (E1) from the alga and with orsellinic acid decarboxylase (E2) from the fungus. (The orsellinic acid is bound to coenzyme A or to an enzyme during depside formation.)

orsellinic acid molecules in the positions emanating from the malonyl-SCoA, while only a very slight activity appeared in the positions derived from the acetyl-SCoA "starters" (Fig. 8).

The subsequent experiments with the depside atranorin *(14e)*, which belongs to the β-orsellinic acid group, with ^{14}C-labeled acetic and formic acids demonstrated specific incorporation of formic acid in the CHO and CH_3 groups of the depside [56] (Fig. 9).

(14e)

Fig. 9. Labeling pattern in the depside atranorin *(14e)* after incubation with $CH_3{}^{14}COOH$ (*) and $H^{14}COOH$ (Δ).

S-Adenosylmethionine is a possible activated form of these groups derived from the C_1-fragment pool. Subsequently is was shown by using tritium-labeled compounds that the monocyclic units of atranorin can once more be reunited by the lichen to form the depside [57].

Little is known about the individual steps of this process. It may be taken as certain that the monocyclic units are formed by the fungal partner. The evidence is firstly that they occur in molds, and secondly that in lichen fungi that normally form depsides while in lichen association in pure culture, only orsellinic acid or haematommic acid (3-formylorsellinic acid) have been found [58]. It is possible that the algal partner subsequently enzymatically condenses these compounds, which are probably present as activated orsellinoyl-SCoA esters. A parallel to such work distribution between the two symbionts is found in the enzymatic degradation of lichen depsides (see Fig. 8) [59].

On the other hand, such enzymatic condensation of activated monomers can also take place in the fungal part. A third alternative is the possibility that the whole depside biosynthesis takes place on a single multienzyme complex, in which two or three orsellinic acid synthetase complexes are so closely coupled together that a direct condensation of the enzyme-bound monomers can occur. This could be one explanation why tridepsides but no didepsides occur in certain lichens.

It may be assumed that higher orsellinic acid homologs such as olivetoric acid *(9a)* are built up of one acetyl-SCoA and *n* malonyl-SCoA units in analogy with the "C_{10} acid" (6-acetonyl-2,4-dihydroxybenzoic acid) [60]. A condensation of separately formed alkanoyl-SCoA units with orsellinic acids is less likely.

3.3.2.2. Depsidones and Depsones

Approximately 20 depsidones occur among the lichen substances. It is not yet possible to distinguish between the following alternative biosynthetic pathways:

1. intramolecular oxidative phenol coupling [61,62] of the depside by a "depside dehydrogenase".

2. formation without the participation of a free intermediate depside on a separate "depsidone multienzyme complex".

The first alternative is supported by the appearance in lichens of depsidones that correspond to several of the depsides. In addition to the depside-depsidone pair olivetoric acid *(9a)* – physodic acid *(10a)* reproduced in Fig. 6, the pairs atranorin-virensic acid *(14e)*, microphyllinic acid – α-collatolic acid and sphaerophorin-grayanic acid occur. In some types of lichens olivetoric acid and physodic acid also appear together [63], and, finally, further evidence is provided by the synthesis of the depsidone diploicin by oxidation of the corresponding depside with manganese dioxide [64]. Depsidones derived from depsides such as sekikaic acid *(14a)* or thamnolic acid *(14c)* have not been found. In the first case the methoxy group prevents the otherwise biosynthetically plausible $C^{\bullet}-O^{\bullet}$ coupling. Instead, the depsides that are probably present as biradicals during phenol dehydrogenations can undergo an alternative $C^{\bullet}-C^{\bullet}$ coupling of the type that is realized in the depsones.

Only one depsone, picrolichenic acid *(11a)* has so far become known [65]. It is probably formed from the corresponding depside, dihydropicrolichenic acid *(9b)* by such an intramolecular oxidation. The recent synthesis of *(11a)* by oxidation of *(9b)* with manganese dioxide is in agreement with this postulate [66].

3.3.2.3. Bibenzoquinones

Despite the frequent occurrence of bibenzoquinones in independently living fungi, a lichen representative, pyxiferin *(13a)*, has only recently been found [67]. Fig. 10 demonstrates that pyxiferin is closely related structurally to the fungal bibenzoquinon esoosporein

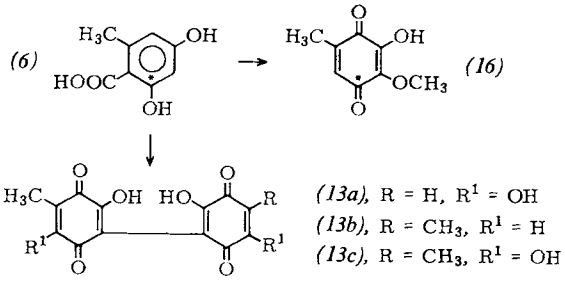

Fig. 10. Proposed biosynthesis of pyxiferin *(13a)*, R = H, R^1 = OH; structures of the fungal bibenzoquinones phoenicin *(13b)*, R = CH_3, R^1 = H, and oosporein *(13c)*, R = CH_3, R^1 = OH. Fig. 11. Proposed biosynthesis of dibenzofurans: porphyrilic acid *(17)*, strepsilin *(18)*, and usnic acid *(20)*. Labeling pattern in *(20)* after incubation with [$^{14}CH_3$—CO]-acetylmethylphloroglucinol. (The condensing units are bound to coenzyme A or to an enzyme.)

(13c) and phoenicin *(13b)*. The biosynthesis of the monocyclic quinones probably proceeds *via* orsellinic acid, as was shown for the fungal toluquinone fumigatin *(16)* [68]. The two monocyclic portions are thought to combine by oxidative phenolic coupling [69]. Furthermore, it has been shown that in the biosynthesis of phoenicin *(13b)* added orsellinic acid and also orcin are incorporated in specific manner [70].

3.3.2.4. Dibenzofurans

Dibenzofurans are essentially encountered only in lichens. Rhodomyrtoxin [71] is the only representative yet to have been found outside the lichen group. Of the seven dibenzofurans whose structures have been elucidated, five can be interpreted as condensation products of orsellinic acid and its homologs; only usnic acid *(20)* and isousnic acid [72] are composed of two acetylphloroglucinol units. The usnic acids are the sole aromatic lichen substances to contain acetylphloroglucinol in place of orsellinic acid as the skeleton unit; methylation of the nucleus, which probably occurs before aromatization, apparently determines the type of cyclization (Claisen) involved. *Barton et al.* [73] were the first to succeed in synthesizing usnic acid *(20)* in their classical work involving oxidation of acetylmethylphloroglucinol with potassium hexacyanoferrate(III). The initially formed hydroxydihydrousnic acid *(19)* was subsequently dehydrated with sulfuric acid to form *(20)*. Recently, *Pentilla* and *Fales* succeeded in effecting the same coupling enzymatically with a peroxidase system [74]. Finally, *Shibata et al.* [75] were able to demonstrate with ^3H- and ^{14}C-labeled acetylmethylphloroglucinol that usnic acid is formed from these units in the lichen thallus. By contrast, labeled acetylphloroglucinol was not incorporated in usnic acid *(20)* (Fig. 11). According to these findings, the biosynthesis of usnic acid and probably that of other dibenzofurans proceeds by oxidative phenol coupling and subsequent dehydration. The question whether separate dehydrogenases and dehydratases, or a multienzyme complex are involved had admittedly not yet been answered.

3.3.2.5. Chromones, Xanthones, Anthraquinone, and Chromanone

Chromones *(21)*, xanthones *(22)*, anthraquinones *(23)*, and chromanones *(24)* cannot be regarded as typical lichen metabolites since they also occur in other organisms. Biosynthetic investigations of such lichen compounds are not so far available; their common property is the postulate of a β-polyoxomethylene chain as a precursor, as is indicated in Fig. 12, al-

[71] *S. Trippet*, J. chem. Soc. (London) *1957*, 414.

[72] *S. Shibata* and *H. Taguchi*, Tetrahedron Letters 1967, 4867.

[73] *D. H. R. Barton, A. M. Deflorin*, and *O. E. Edwards*, J. chem. Soc. (London) *1956*, 530.

[74] *A. Pentilla* and *H. M. Fales*, Chem. Commun. *1966*, 656.

[75] *H. Taguchi, U. Sankawa*, and *S. Shibata*, Tetrahedron Letters *1966*, 5211.

though the less probable formation by condensation of two separately formed polyketide chains or their cyclized products, as was demonstrated for the biosynthesis of citromycetin [76], cannot yet be entirely ruled out.

The two known chromones, lepraric acid [77] and rupicolin *(21a)* [78], probably result from the condensation of an acetyl-SCoA unit with four malonyl-SCoA units.

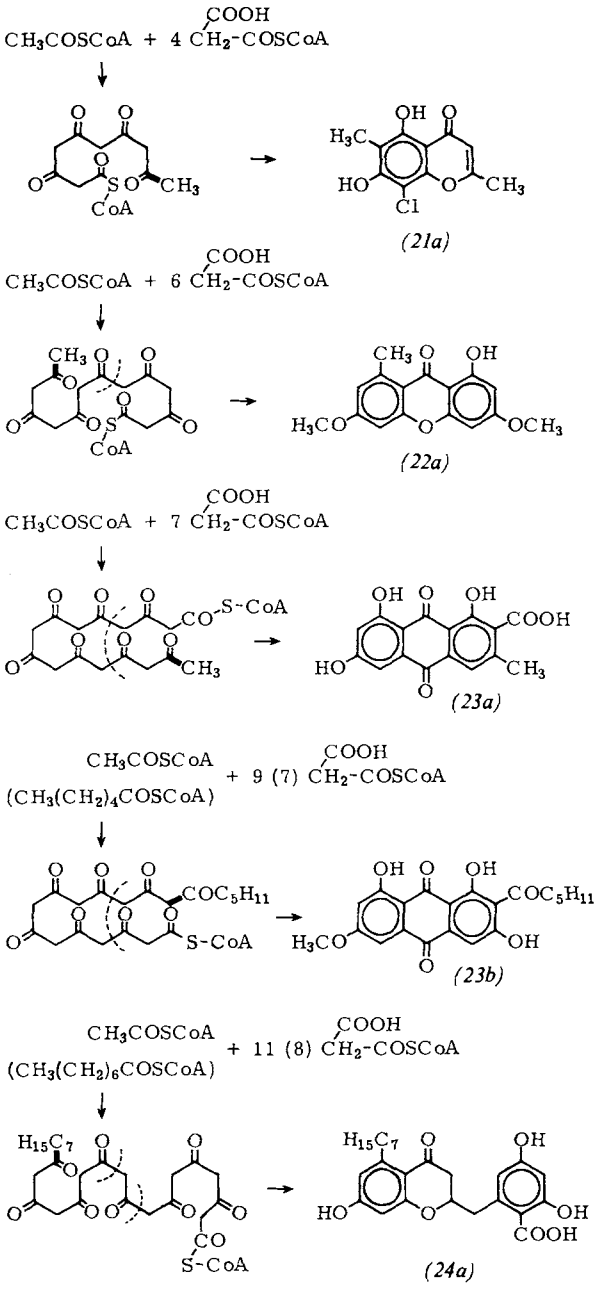

Fig. 12. Proposed biosynthetic pathways of non-condensed aromatic lichen polyketides from a β-polyoxomethylene chain. The "starting" positions are indicated by heavy lines, while the dotted lines show the theoretically possible formation of such compounds from two separate units. (The above polyoxomethylene chains are bound to coenzyme A or more likely to a multienzyme.)

The six xanthones *(22)* are probably formed analogously from one acetyl-SCoA molecule and six malonyl-SCoA molecules. The recently established structure for thiophanic acid (2,4,5,7-tetrachloro-1,3,6-trihydroxy-8-methylxanthone), a tetrachloroxanthone [79], is of interest, as is also the large number of chlorine-substituted aromatic lichen metabolites.

The structures of ten anthraquinones *(23)* from lichens have so far been elucidated. Biosynthetic investigations on fungal anthraquinones by *Gatenbeck* [80] and *Shibata* [81] point to a formation from an acetyl-SCoA molecule and *n* malonyl-SCoA units. While the cyclization step leading to endocrocin *(23a)* corresponds to the ring closure leading to orsellinic acid, solorinic acid *(23b)* exhibits a parallel to the acetylphloroglucinol cyclization (cf. Section 3.3.2.1 for the pentanoyl side-chain). Finally, siphulin *(24a)* [82] is the only chromanone *(24)* yet to have been found. Here too a formation *via* a long C_{24} β-polyoxomethylene chain is the most probable alternative.

3.4. The Mevalonic Acid Group

One diterpene, (−)-16α-hydroxykaurane [83], a series of interesting triterpenes [28], and several steroids (ergosterol, β-sitosterol, Vitamin D_2) and carotenoids (β- and γ-carotene as well as several xanthophylls) have been found among the lichen substances whose biosynthesis can be derived from mevalonic acid *(25)*. Results of biosynthetic investigations on these lichen metabolites are not available, but it may be assumed that their formation follows the familiar pattern (Fig. 13) [84].

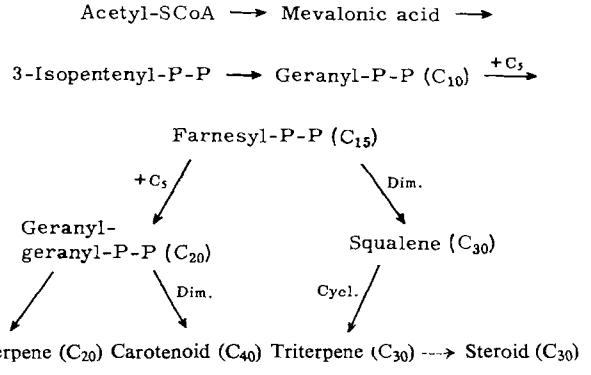

Fig. 13. Biosynthetic pathways of mevalonic acid group compounds.

The triterpenes are all pentacyclic; zeorin and leukotylin are distinguished by a rare five-membered ring E. Zeorin *(26)*, the most frequently occurring lichen

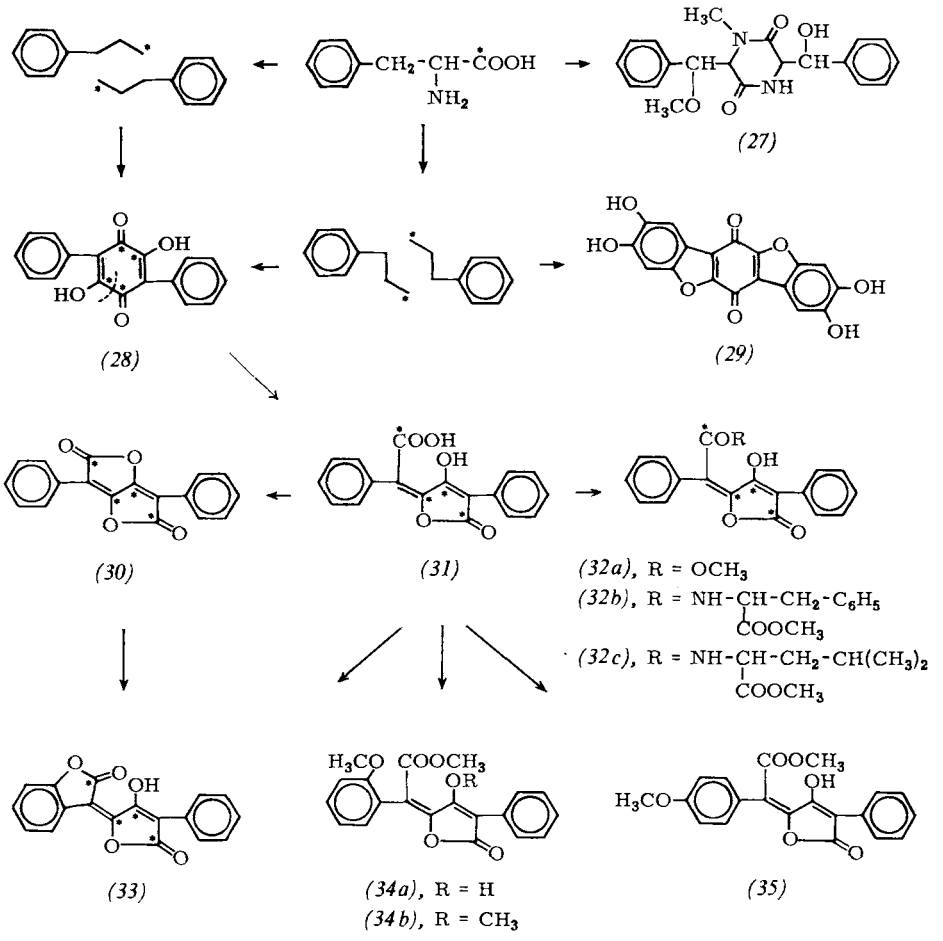

Fig. 15. Biosynthesis of aromatic lichen compounds of the shikimic acid group from C_6–C_3 fragments. In compounds whose formation was demonstrated experimentally from [1-^{14}C]-phenylalanine the ^{14}C-labeling obtained has been marked with an asterisk. *(32b)* = rhizocarpic acid, *(32c)* = epanorin, *(34a)* = leprapinic acid, *(35)* = pinastric acid.

terpene (6α,22-dihydroxyhopane)[85,86] is probably formed by the cyclization of squalene *(25)* (Fig. 14). A direct precursor of lichen triterpenes with an oxygen function in position 3 (as in friedelin) may be 2,3-epoxysqualene[87].

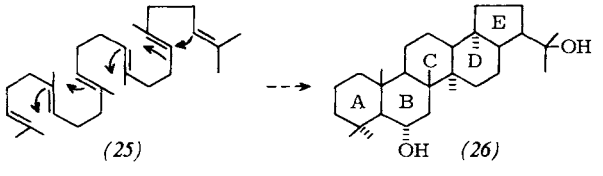

Fig. 14. Cyclization of squalene *(25)* to form zeorin *(26)*.

3.5. The Shikimic Acid Group

Only twelve aromatic lichen compounds belong to the shikimic acid group. *i.e.* their biosynthesis proceeds in the sequence: phosphoenolpyruvic acid + erithrytyl 4-phosphate → shikimic acid → chorismic acid → prephenic acid → C_6–C_3 derivatives. A diketopiperazine, picrorocellin *(27)*, two terphenylquinones, telephoric acid *(29)*, and polyporic acid *(28)*, as well as nine pulvic acid derivatives *(30)–(35)* have so far been found in lichens (Fig. 15). Phenylquinones are widespread especially among fungi; in contrast, the mainly yellow pulvic acid derivatives must be regarded as typical lichen substances. While picrorocellin *(27)* is evidently formed by direct condensation of two phenylalanine units, the terphenylquinones are formed by condensation of two (probably activated) phenylpyruvic acid derivatives, as has been shown for the fungal quinone volucrisporin, a *meta*-dihydroxyterphenylquinone[88]. The subsequent oxidative ring opening of the symmetrical terphenyls such as polyporic acid then leads to the pulvic acid derivatives with their characteristic diphenylbutadiene system, as experiments with [1-^{14}C]-DL-3-phenylalanine[89,90] and [^{14}C]-polyporic acid quinone[91] have shown.

The role played by the two symbionts in the biosynthesis of lichen substances has recently been established for the pulvic acid derivatives. *Thomas*[92] had shown that isolated lichen fungi are able to form "stictaurin", subsequently shown to be a mixture of calycin *(33)*

and pulvic acid dilactone *(30)*. Recently the four pigments pulvic acid *(31)*, pulvic dilactone *(30)*, calycin *(33)*, and vulpinic acid *(32a)* were isolated from the extract of a lichen fungus culture of *Candellariella vitellina* [93]. Here, the algal component apparently plays no direct part in the biosynthesis.

The appearance of vulpinic acid was surprising, because it is not formed in the corresponding natural lichen associations. Recently, pulvic acid derivatives have also been found in independent living lichen-like fungi [94].

4. Conclusions

As has been stated previously, the lichen symbionts can collaborate during the degradation of compounds such as depsides to phenols. The question whether such a collaboration takes place, and if so to what extent, during the biosynthesis of such compounds, has not yet been clarified. Even if the algal component contains none of the enzyme systems that participate directly in these syntheses, its metabolic activity, and particularly its photosynthesis, provides the prerequisites for collaboration.

In general, both symbionts profit from the association in the various symbiotic forms of life that occur in nature, *inter alia* through exchange of metabolites. It is known that the bacteria present in the digestive tract of mammals imbibe the foodstuffs present and in turn supply a number of vitamins to the host. During the symbiosis of the nitrogen-fixing nodular bacteria with legumes, the nitrogen fixed in the nodules is given up to the plant partner which, in turn, furnishes carbon compounds. In mycorrhiza, the symbiotic association of fungi with higher plants, the fungal partner supplies the water and mineral salts required, and abstracts assimilates from its plant partner. The high degree of integration in symbiotic associations is demonstrated particularly clearly by the appearance of substances and structures that the individual substances could not produce [95]. Examples are a special hemoglobin, leghemoglobin, that participates in the fixation of nitrogen in the nodules of legumes [96,97], the development of rhizotamines (root nodules) in actinomycetes symbioses, and the morphogenetic effect of the intestinal flora in mammals on the development of the lymphatic system. The related problems of the nature and degree of exchange of metabolic products and its regulation, and the nature of the substances that influence the morphology of the symbiotic organism, in short the "biochemistry of symbiosis", are still largely unresolved.

In conclusion a parallel is drawn, as *Dubos* [98] has already indicated, between the intact lichen thallus and an individual cell. For this purpose the cell is regarded as a small-scale symbiotic form of life made up of semiautonomic, genetically independent, closely integrated small organs. Evidence for such a view is provided by the presence of DNA in chloroplasts [99] and mitochondria [100] and by the existence of a special messenger-RNA fraction on the polysomes of plasmatic membranes [101]

Structure and Biosynthesis of the Ergot Pigments[1]

By B. Franck[*]

In addition to the well known alkaloids, ergot contains two groups of yellow to red pigments, between which there is a close and novel biogenetic relation. The pigments are anthraquinonecarboxylic acids and dimeric hydroxanthone derivatives (ergochromes), the structures of which, including the absolute configurations at 80 centers of chirality, have been completely determined. The intermediates involved in the biosynthesis have been largely established by feeding with labeled precursors, and its course by model experiments.

1. Introduction

Whereas interest in natural products chemistry was formerly centered mainly on the isolation of new physiologically active compounds, the determination of their structure, and their synthesis, attention is now also being given to their biosynthesis. Some years ago, pigments that are present in ergot drugs attracted our interest from this point of view. The properties of these pigments were indicative of unusual structures. Natural products with new structural principles frequently permit significant advances in the explanation of biogenetic relationships, and the ergot pigments did not disappoint us in this respect.

Ergot (Fig. 1) is found in nature on ears of rye. It is the permanent mycelium of the filamentous fungus *Claviceps purpurea*. The dramatic history of its investigation is divided into three phases: the discovery of its toxicity, its use as a medication, and the elucidation of the structures and biosynthesis of its ingredients[3].

From early times right up to the present century, the consumption of unpurified grain containing ergot has repeatedly led to devastating mass poisonings, which spread like an epidemic with the ergot fungus. This poisoning, which was known as ergotism, could lead to mutilation and death as a result of severe contraction of the peripheral blood vessels. It was only around 1600 that ergot was recognized as the cause of ergotism. It had previously been recorded in writing that with careful dosage, ergot is a valuable drug in midwifery[4]. The isolation and complete structural elucidation of the ergot alkaloids is mainly due to *Stoll et al.*[5].

Ergot research reached a climax in the last decade with the elucidation of the biosynthesis of these alkaloids with the aid of radioactively labeled precursors and the recently discovered methods for the cultivation of the ergot fungus on synthetic nutrient solution[6,7]. This led to the important

realization, which has since been confirmed in many other examples[8], that terpene units are involved in the biosynthesis of indole alkaloids.

As with the ergot alkaloids, the investigation of the ergot pigments has also led to a fundamental biogenetic discovery. One group of these pigments, the ergochromes, are formed from anthraquinones[9–11] by oxidative ring opening[54–56]. No such ring opening of the very stable anthraquinones had previously been known either in the extensively studied chemistry of the anthraquinones or in their metabolism. The anthraquinones, which occur widely in nature (more than 100 are known at present) were therefore mostly regarded as "metabolic end products". This unsatisfactory view has now been refuted by the ring opening of anthraquinones in the ergot fungus.

2. The Anthraquinonecarboxylic Acids Endocrocin and Clavorubin

When aqueous methanol is poured over crushed ergot or dried mycelium of liquid cultures of the ergot fungus, a cherry-red extract is formed. Separation by partition chromatography on cellulose (Fig. 2) showed that this color is due to two hydroxyanthraquinonecarboxylic acids, which were isolated in the crystalline form[9]. The orange-red anthraquinone derivative was found to be endocrocin[9] *(1)*, which had previously been isolated from the Japanese tree lichen *Nephromopsis endocrocea*[10] and from *Aspergillus amstelodami*[11], and was found shortly afterwards in *Penicillium islandicum*[12]. The red compound known as clavorubin is a very similar compound; since it dissolves much less readily in the pure state[13], it was converted into the crystalline methyl ester for structural investigation. It was found that clavorubin *(2)* has the same structure as endocrocin, with the addition of a hydroxyl group on C-5; it can accordingly be prepared by specific oxidation[14] of endocrocin with manganese dioxide in concentrated sulfuric acid[15].

(1), R = H
(2), R = OH

Endocrocin and clavorubin were the first group of intensely colored and acidic (pK_a = 4.2) ergot pigments to be characterized. The concentration of these pigments in ergot (40 mg/kg), however, is much lower than that of the ergochromes described in the next section.

3. Isolation of the Light Yellow Ergochromes

The ergochromes are a group of light yellow, weakly acidic (pK_a = 8.5–9.4) ergot pigments, which can be obtained from the chloroform extract of ergot that has been degreased and pretreated with aqueous tartaric acid. The ergochrome content of ergot is about 5 g/kg, which is much higher than that of endocrocin *(1)* and clavorubin *(2)*, and is even higher than the yield of ergot alkaloids (approx. 2 g/kg)[2].

Though the first ergochrome preparations were isolated by *Dragendorff*[16] around 1877 (Table 1), the structure of the ergochromes was unknown until recently. The difficulties in the investigation of these compounds can now be traced to their great sensitivity to hydrolysis and the extreme similarity of their properties. Since many differ only in the configura-

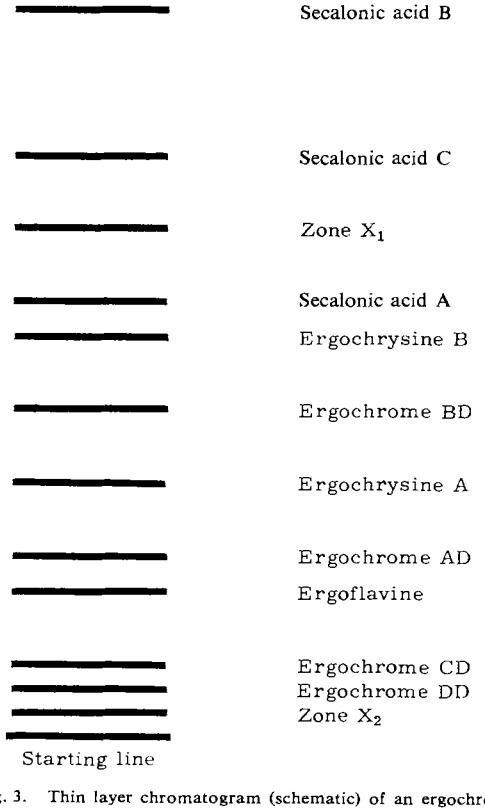
tions of a few of the many centers of chirality, it was not possible to obtain them in the pure and homogeneous state by classical separation methods.

We achieved the complete separation of the ergochromes only by chromatographic methods. The mixtures of ergochromes were first isolated from ergot from various sources [22], and all the preparation methods for the pigment samples described previously [16–21] were repeated [24]. The chromatographic separation (which is made difficult by the low solubility of the ergochromes) and characterization was first carried out with a basic solvent system on buffered paper [23]. Diastereoisomeric ergochromes, however, were separated for the first time by *Gottschalk* [24,25] with chloroform/2-pentanone (9:1) on silica gel G, which is impregnated with oxalic or tartaric acid. It was found that the preparations described earlier (Table 1) are mixtures containing up to 13 components. The only exception was ergoflavin, which is not accompanied by diastereoisomers, and which *Freeborn* [20] obtained in the pure state by crystallization. Apart from ergoflavin, a total of nine ergochromes have been isolated in the pure and sterically homogeneous state by preparative chromatography using the above-mentioned system on columns of thin layer silica gel. Figure 3 shows the zones due to these ten pigments, as well as those of two unidentified trace components X_1 and X_2, in the thin layer chromatogram of an ergochrome mixture.



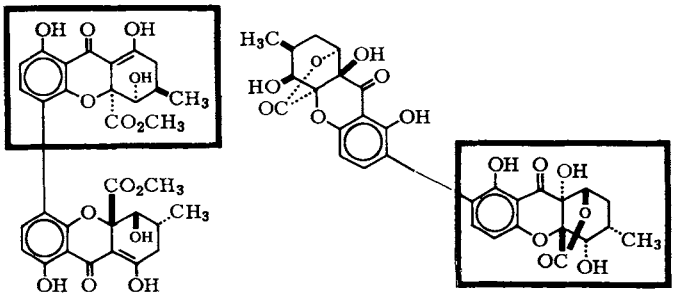


Fig. 3. Thin layer chromatogram (schematic) of an ergochrome mixture (chloroform/methanol = 100:1 on silica gel G containing tartaric acid).

4. Determination of the Constitution of Ergoflavin and of the Diastereoisomeric Secalonic Acids A and B

The principal component of the ergochromes is secalonic acid A. On the basis of degradation with alkali and ozone, partial synthesis, and NMR and mass spectra, we have obtained the structure *(3a)* for this compound [23,25,26]. The structure of ergoflavin *(4)* was established independently and almost simultaneously by *Whalley et al.* [27] and *McPhail et al.* [28] by a combination of chemical investigation with X-ray structure analysis. The pigments are symmetrical dimerization products of two xanthone derivatives, and differ in that the halves of the secalonic A molecule are linked in the *p* position with respect to the free hydroxyl group, while those of the ergoflavin molecule are linked in the *o* position.

(3a) *(4)*

Two other ergochromes, secalonic acids B and C, differ only in the configuration of some centers of chirality, and are therefore diastereoisomers [26,29].

As with other aromatic-hydroaromatic natural products, the determination of the constitution of secalonic acid A took place in two parts. The aromatic skeleton was first established by UV spectroscopy and vigorous degradation with alkali, and the saturated part of the molecule was then characterized by ozonolysis and by NMR and mass spectroscopy. The UV spectrum is very similar to that of 5-hydroxy-2-methylchromone *(8)*. As was found by *Bergmann* [30] and *Stoll* [21] for

[22] These were ergot drugs from Canada, Portugal, Spain, Germany, Austria, Hungary, Poland, Russia, and Japan, most of which had been obtained by artificial inoculation of rye plants with *Claviceps* strains.

mixtures of ergochromes, secalonic acid A gives 2,4,2′,4′-tetrahydroxybiphenyl *(5)* on alkali fusion, so that two 5-hydroxychromonyls must be joined *via* the phenyl nuclei. Possibilities for the chromophore of the pigment were therefore an 8,8′-bichromonyl *(6)* or a 6,6′-bichromonyl *(7)*. The two bichromonyls, which had not previously been described, were synthesized by the reaction sequence shown in the scheme [31]. The 5,5′-dimethoxy-2,2′-dimethyl-8,8′-bichromonyl *(9)* obtained by Ullmann condensation could be converted into *(6)* by normal dimethylation, and into *(7)* by a new variant of the Wessely-Moser rearrangement [32, 33]. Thus both bichromonyls were available in good yields by a simple reaction sequence. Comparisons using the Gibbs color reaction [34], which is specific for phenols with the *p* position unoccupied, showed that secalonic acid A is an 8,8′-bichromonyl derivative, and therefore contains a basic skeleton that had not previously been known in natural products [23, 31].

According to its mass spectrum and elemental analysis, secalonic acid A has the empirical formula $C_{32}H_{30}O_{14}$. Two C-methyl groups, two aliphatic methoxycarbonyl groups, and six acetylatable hydroxyl groups were found [23]. The attachment of the functional groups and the other parts of the molecule indicated by the empirical formula to the 8,8′-bichromonyl skeleton was determined from the NMR and mass spectra and from the ozonolysis [23, 26]. Two doublets in the aromatic region of the NMR spectrum of secalonic acid A must be attributed to two pairs of adjacent aromatic protons, on the basis of their intensity and spin coupling (J = 8.5 Hz). The positions on the aromatic nuclei of the 8,8′-bichromonyl skeleton *(6)* in secalonic acid A *(3)* are therefore unoccupied. The NMR spectrum also showed that the basic skeleton of this pigment is symmetrically substituted, since instead of two doublets one would otherwise expect four with half the intensity [23].

The mass spectrum of the secalonic acid contains an intense fragment at m/e = 166 and derived fragments at m/e = 135 and 107, showing that a molecule of methyl cresotate *(10)* is readily split off on electron bombardment. According to this observation, each half of the basic bichromonyl skeleton must carry a six-membered carbocycle on the heterocycle. This carbocycle is readily aromatized, and carries a hydroxyl group, a methoxycarbonyl group, and a methyl group.

Ozonolysis of secalonic acid at 0 °C in ethyl acetate gave methylsuccinic acid and α-hydroxy-β-methylglutaric acid *(11)*, the carbon atoms of which must have been arranged in the ergochrome as shown. This together with the NMR spectrum shows that secalonic acid A has the structure *(3)* [26], and the cresotic acid split off in the mass spectrometer is the 1,3,5-isomer [35].

The similarity of the UV spectrum of secalonic acid A to that of 5-hydroxy-2-methylchromone *(8)* and the NMR spectrum indicate that, as in decalin-1,8-dione [36], the β-dicarbonyl system must be enolized [37]. According to the UV, IR, NMR, and mass spectra and the pK_a value, secalonic acid B is practically the same as secalonic acid A, but differs in its melting point, R_f value, and molar rotation. Experiments carried out in the same way show that secalonic acid B *(3b)* is a diastereoisomer of secalonic acid A *(3a)* [26].

5. Derivatives of Secalonic Acids A and B

Derivatives were required for the investigations on the configuration of the secalonic acids and for the elucidation of their biosynthesis. The possibilities for the conversion of secalonic acids into derivatives are however limited by the sensitivity of the allyl ether grouping to hydrolysis and the tautomerism of the enol system. Methylation under mild conditions with dimethyl sulfate or diazomethane gives reaction mixtures containing many components, no hydrogen is absorbed on catalytic hydrogenation [23], and acetylation by warming with acetic anhydride/sodium acetate leads to extensive changes [21]. The secalonic acids *(3)* can however be converted into crystalline diethyl *(13)*, di-*n*-propyl *(14)*, diisopropyl *(15)*, and di-*n*-octyl derivatives by transesterification with HCl/alcohol mixtures [39], and into desmethoxysecalonic acids *(17)* by treatment with HBr/glacial acetic acid [40, 54].

A stable, well-crystallized derivative of secalonic acid A *(3a)* has been prepared by removal of the enol group as follows [41]. After blockage of the tautomerism by acetylation under particularly mild conditions to form the hexaacetate [23], the enol double bonds could be readily hydrogenated.

On subsequent removal of the acetyl groups, the resulting aldol was simultaneously dehydrated. Rehydrogenation gave *(18)*, which, unlike secalonic acid A, no longer has an acidic group, and is therefore called "secalon A" [41].

6. Relative and Absolute Configuration of Secalonic Acids A and B

The configuration of the ergochromes, and particularly of the secalonic acids, at their various centers of chirality is important to the understanding of their structural variability and their biosynthesis. The NMR spectra of secalonic acids A and B (Fig. 4) are surprisingly simple when one considers the high molecular weights and complicated structures of these compounds. When the complete constitution was known, it could be deduced from these spectra that these two ergochromes are perfectly symmetrical, *i.e.* they consist of two halves that are identical even in their stereochemistry. This greatly simplified the determination of the configuration, since each of the two secalonic acids could be treated as if it consisted of only one half of its molecule, with three centers of chirality on C-6, C-5, and C-10.

Of these, the methyl-substituted C-6 can be cut out with ozone, as described earlier. Since the dextrorotatory methylsuccinic acid formed on ozonolysis of secalonic acid A has the *R* configuration, this is also the configuration of C-6 in the secalonic acid. With this absolutely fixed center of chirality as a basis, the relative arrangement of the adjacent hydroxyl group was found from the NMR spectrum (Fig. 4) [26].

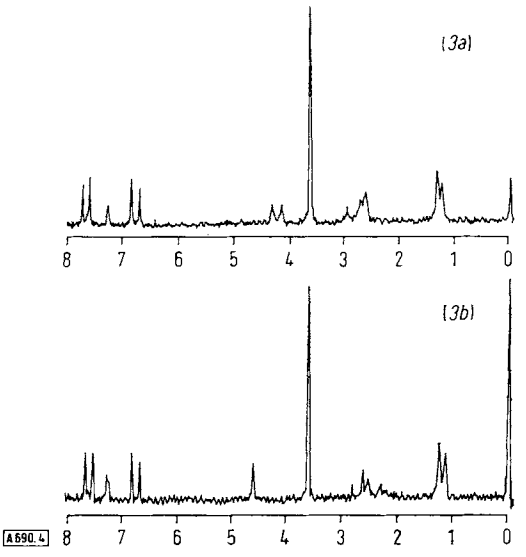

Fig. 4. NMR spectra of secalonic acids A *(3a)* and B *(3b)* in deuteriopyridine (from [26], data in δ values).

Since the spin coupling of the two protons on C-5 and C-6 showed that these are *trans*-diaxial with respect to each other, the methyl group and the hydroxyl group are also *trans* to each other *(3a)*. Similarly, the methyl center C-6 in secalonic acid B is found to have the *S* configuration, and is *cis* to the adjacent hydroxyl group *(3b)*.

To determine the configuration of the ring fusion center C-10, which carries the methoxycarbonyl group, the rotatory dispersion and mass spectra of the two diastereoisomeric secalonic acids were first compared [26]. The rotatory dispersions of secalonic acids A and B are practically mirror images, with opposite Cotton effects (Fig. 5). This indicates that the centers of chirality nearest to the chromophore, which cause the greatest chiralic disturbance, *i.e.* those at C-10, have opposite configurations (cf. [42,43]).

The configuration at the ring fusion center could not be assigned on the basis of the rotatory dispersion, *i.e.* the question which secalonic acid has the methoxycarbonyl group *cis*, and which *trans*, to the adjacent hydroxyl group could not be answered directly. A

mass-spectrometric comparison of stability at C-10 was helpful in this respect. It is clear from the mass spectra of secalonic acids A and B that the ester group in secalonic acid A has the less stable *cis* configuration, and can be split off particularly readily by electron bombardment. This difference in stability became even more impressive when the energy of the electrons was decreased from 70 to 21 eV, as well as in the transesterification products of secalonic acids A and B [*(13)*, *(14)*, and *(15)*] with large alkyl residues on the ester group on C-10 [26,39,44].

(3a)

(3b)

The assignment of the configuration at C-10 in the secalonic acids in accordance with *(3a)* and *(3b)* was confirmed as follows by comparison with ergoflavin *(4)*, the configuration of which has been established by X-ray analysis [28]. Since the center of chirality at the ring fusion in the secalonic acids and similar ergochromes determines the course of the rotatory dispersion, this course should be similar for the same configuration on C-10 and the same chromophore. To allow a comparison of the C-10 configuration of a secalonic acid with that of ergoflavin, the secalonic acid must be converted into a derivative having the chromophore of ergoflavin. A suitable derivative of secalonic acid A is secalon A *(18a)* [41]. Since the course of the rotatory dispersion of secalon A is similar to, but in an almost mirror-image relation with, that of ergoflavin *(4)* (Fig. 5), these two compounds must have opposite configurations at the ring fusion center. This provides further confirmation of the absolute configuration of secalonic acid A as shown in *(3a)*, and hence also of secalonic acid B as shown in *(3b)*.

7. Structure and Absolute Configuration of the Other Seven Ergochromes

If the half molecules of the three symmetrical ergochromes described so far are denoted by A, B, and C, secalonic acids A and B and ergoflavin have the structures A–A, B–B, and C–C respectively (Table 2). Three other ergochromes, which we call secalonic acid C and ergochrysins A and B [45,46], were also obtained in the pure, sterically homogeneous state by our chromatographic separation method [24,29] for the diastereoisomeric secalonic acids. These were found to be the three *unsymmetric* dimerization products of the xanthone derivatives A, B, and C (Table 2). Their structure was found surprisingly easily from the fact that they behaved in all the investigations like a mixture of two of the symmetric pigments just discussed [45,47]. This is true of the UV, IR, NMR, and mass spectra, rotatory dispersion, circular dichroism, derivatives, and chemical degradation reactions. As an example, Figure 6 shows the UV spectra of ergochrysin A together with those of secalonic acid A and ergoflavin. Thus secalonic acid C, ergochrysin A, and ergochrysin B have the structures A–B, A–C, and B–C (Table 2).

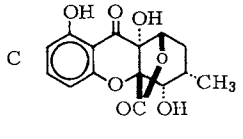
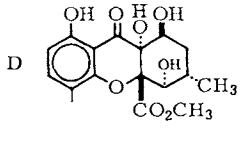
Four other ergochromes[44,46] attracted attention during their chromatographic purification by instability to solvents containing acids. They could be completely converted into one of the ergot pigments described above by heating for a short time in glacial acetic acid. The mass spectra showed that this rearrangement was accompanied by a loss of 32 mass units, corresponding to the removal of methanol. Further spectroscopic and chemical characterization of the pigments and their transformation products showed that the new ergochromes all contain a xanthone derivative of structure D, which is converted into the ergoflavin half C in hot acetic acid, with elimination of methanol and closure of the lactone ring. On the basis of the structures of the ergochrome halves in Table 2, therefore, these four ergochromes have the structures[49] A–D, B–D, C–D, and D–D. They can be readily converted into ergochrysins and ergoflavin by conversion of the ergochrome half D into the ergoflavin half C as follows:

A–D → A–C (ergochrysin A)
B–D → B–C (ergochrysin B)
C–D → C–C (ergoflavin)
D–D → C–C (ergoflavin)

Table 2. Structures of the ergochromes obtained from ergot by chromatography.



A–A = Ergochrome AA [4,4'] *(3a)* (Secalonic acid A)

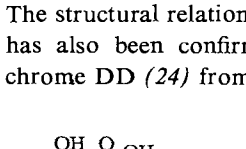


B–B = Ergochrome BB [4,4'] *(3b)* (Secalonic acid B)

C–C = Ergochrome CC [4,4'] *(4)* (Ergoflavin)

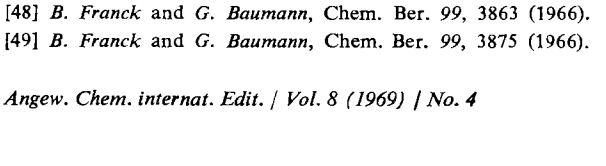
A–B = Ergochrome AB [2,2'] *(3c)* (Secalonic acid C) [26]

A–C = Ergochrome AC [2,2'] *(20a)* (Ergochrysin A) [48]



B–C = Ergochrome BC [2,2'] *(20b)* (Ergochrysin B) [48]

A–D = Ergochrome AD [2,2'] *(21)*



B–D = Ergochrome BD [2,2'] *(22)*

C–D = Ergochrome CD [2,2'] *(23)*

D–D = Ergochrome DD [2,2'] *(24)*

The structural relation between C and D ergochromes has also been confirmed by synthesis of the ergochrome DD *(24)* from ergoflavin *(4)*.

(4) *(24)*

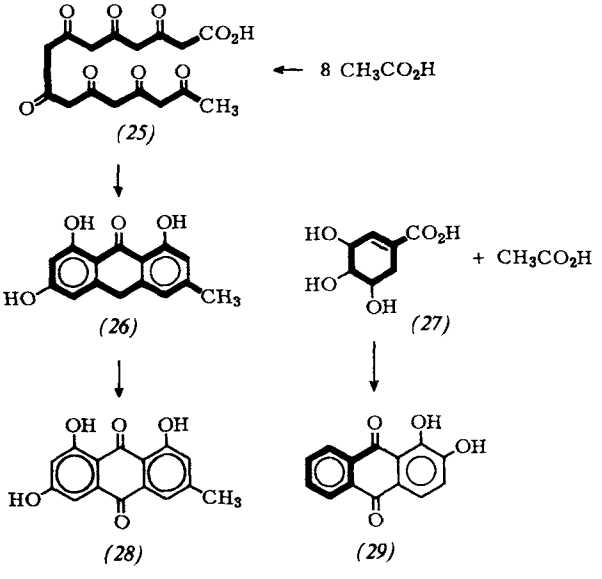
[48] *B. Franck* and *G. Baumann*, Chem. Ber. *99*, 3863 (1966).
[49] *B. Franck* and *G. Baumann*, Chem. Ber. *99*, 3875 (1966).

For the determination of the complete structure of the new ergochromes, it was still necessary to establish the positions in which the halves of their molecules are linked. According to the NMR spectra, only linkage to the phenyl nucleus in the *o* or *p* position with respect to the phenolic hydroxyl group could be considered. Comparison with the synthetic bichromonyls *(6)* and *(7)* showed that the secalonic acids *(3a)* and *(3b)* have *p,p'* linkage[23,31], whereas *o,o'* linkage is found in ergoflavin *(4)*[27]. The *o,o'* linkage in ergoflavin is also shown[48] by its positive Gibbs reaction[34] and the detection of a weakly acidic grouping (pK_{DMF} = 9.4[50]), which can be attributed to the *o,o'*-dihydroxybiphenyl structure[51].

Since the ergochrysins behave in the same way as ergoflavin *(4)* in this respect[48], these must also have *o,o'* linkage of the molecule halves. This simultaneously establishes the type of linkage for the last four ergochromes AD, BD, CD, and DD, since these are converted into *o,o'*-linked ergochrysins or ergoflavin under conditions so mild that a change in the basic skeleton is inconceivable. Thus all ergochromes containing a C or D half exhibit *o,o'* (=2,2') linkage, while the others, *i.e.* the three secalonic acids, have *p,p'* (=4,4') linkage.

Including ergoflavin (the structure of which was established by *Whalley*[27] and *McPhail*[28]), the structures and absolute configurations are completely known for a total of ten ergochromes from ergot. The configurations were determined for not less than 80 centers of asymmetry. The result is remarkable, since the ergochromes form an unusually complete group of natural products, which contains all ten possible combinations of two of the four xanthone derivatives A, B, C, and D (Table 2). This allows the simple nomenclature given in Table 2, which avoids the need for separate names for the ergochromes.

8. Biosynthesis of the Ergochromes from Acetate and Emodin



The structures of the ten ergochromes and the two anthraquinone-carboxylic acids from ergot pointed to a biogenetic relationship, since they all contain tricyclic C_{15} systems with similar arrangement of the substituents. There can now be practically no doubt about the biosynthesis of endocrocin *(1)*, since *Gatenbeck*[52] has shown that its decarboxylation product emodin *(28)* is formed by condensation of eight molecules of acetic acid *via* acetyl and malonyl coenzyme A. A heptaoxopalmitic acid *(25)* and emodinanthrone *(26)* may occur as intermediates[52]. Endocrocin may in turn be regarded as a precursor of many natural anthraquinone pigments, and un-

[50] Apparent p*K* value from titration with 0.1 N NaOH in 80% aqueous dimethylformamide at 20 °C.

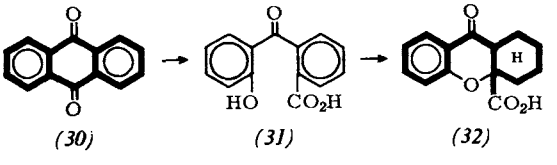
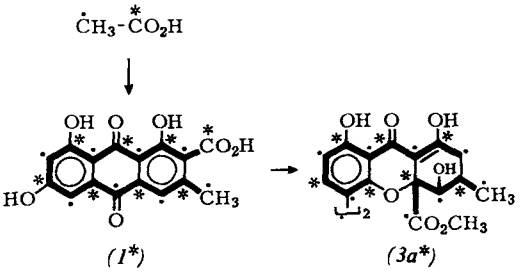
[52] *S. Gatenbeck*, Acta chem. scand. *12*, 1211 (1958).



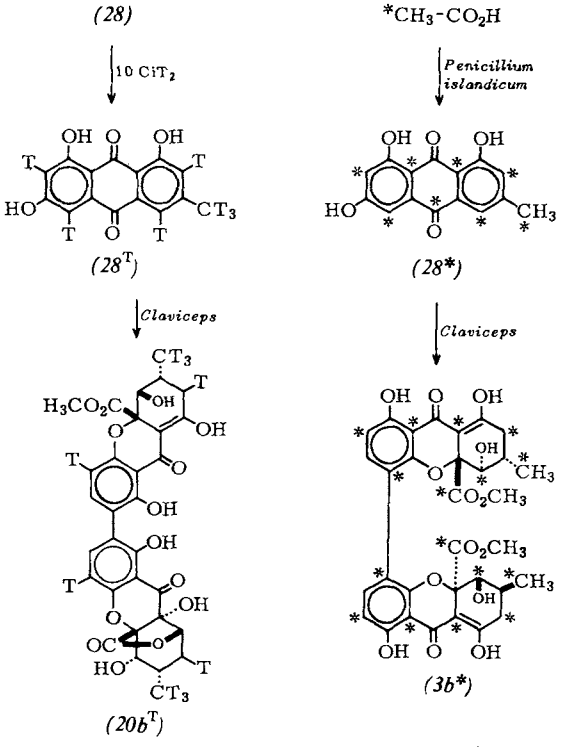
doubtedly also of clavorubin. According to recent results obtained by *Leistner* and *Zenk* [53] a somewhat different biosynthetic route involving shikimic acid *(27)* must be assumed for the formation of alizarin *(29)* in *Rubia tinctorum*. However, alizarin comes from a plant, and not from lower fungi, as do endocrocin and related anthraquinones.

The ten ergochromes can also be derived from endocrocin by a simple, biogenetically possible reaction sequence. They all contain the basic skeleton *(32)* in each half of the molecule. This skeleton could be formed from an anthraquinone *(30)* in two steps: (1) oxidative cleavage of the anthraquinone to form the benzophenone-carboxylic acid *(31)*; (2) ring closure to form the xanthone derivative *(32)* by phenol oxidation.

The ergochrome ring system is thus formally and (as was to be concluded) biogenetically a "*seco*-anthraquinone". Dimerization of the "*seco*-anthraquinone" halves to form the ergochrome should be possible by phenol oxidation in the *p* or *o* position with respect to



the phenolic hydroxyl group. It has been shown by feeding with radioactively labeled acetate [54] and emodin *(28)* [55] that this biogenetic hypothesis is correct.



In order to carry out the isotope experiment, it was first necessary to know whether the ergot fungus forms all the ergochromes even when it does not parasitize rye plants, *i.e.* when it is grown on a synthetic nutrient solution. This would prove that the ergot pigments are true metabolic products of the fungus, the biosynthesis of which does not require the cooperation of the rye plant. Furthermore, feeding experiments with labeled precursors are much easier to carry out on liquid cultures. There were fortunately strains of ergot fungus that formed a deep red mycelium containing all the ergochromes as well as endocrocin and clavorubin after cultivation on mannitol/cane sugar solution [56]. Thus the ergot fungus synthesizes the same pigments in liquid cultures as on the rye plant. This is remarkable, and is by no means always the case with the ergot alkaloids [57].

In three experiments, sodium acetates labeled in the carboxyl group with ^{14}C and in the methyl group with ^{14}C or ^{3}H were fed to well established liquid cultures. Degradation of the ergochromes [*e.g. (3a*)*] collected after further growth showed the radioactivity distribution that is to be expected if the pigments are formed from acetic acid *via* endocrocin *(1*)* or emodin and their oxidative ring cleavage.

Direct proof of the biosynthesis of ergochromes from anthraquinones was provided by feeding with emodin which was labeled with ^{14}C in one experiment and with tritium in another. The tritium-labeled emodin was

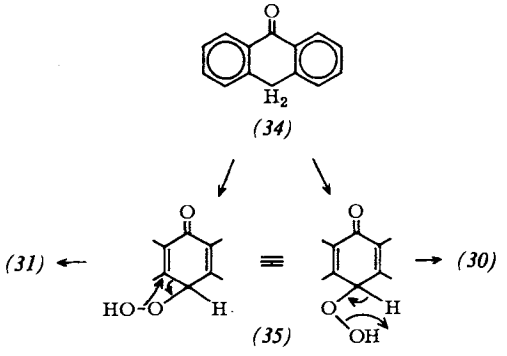
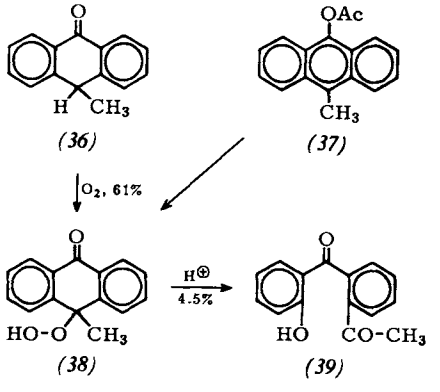
obtained by Wilzbach tritiation with 10 Ci of tritium gas, and the ^{14}C-labeled emodin by feeding sodium [2-^{14}C]-acetate to the fungus *Penicillium islandicum* followed by isolation of the biosynthetically formed radioactive emodin. In agreement with the biosynthesis of emodin as elucidated by *Gatenbeck* [52], the radioactive carbon atoms of the emodin *(28*)* formed from sodium [2-^{14}C]-acetate alternate with unlabeled atoms. After the labeled emodins *(28^T)* and *(28*)* had been fed to *Claviceps*, the radioactive ergochromes BC *($20b^T$)* and BB *(3b*)* (incorporation rates 1.2 and 0.5%) and other ergochromes are isolated. Their radioactivity distribution as found by chemical degradation clearly shows that the labeled emodin is completely converted into the ergochromes, with ring opening.

9. Model Experiments on the Biosynthesis of Ergochromes



The oxidative ring opening of an anthraquinone during the biosynthesis of ergochromes was puzzling. Though the quinoid ring can be opened by vigorous reagents such as chromic acid or strong bases, the molecule is always halved at the same time [58,59]. It is also surprising that the course of the biological degradation of the natural anthraquinones was still unknown, whereas their biosynthesis had been largely elucidated [52,53]. Since anthraquinones occur in large quantities in nature (the dry matter of many common microorganisms contains 20–30 wt.-% of anthraquinones [60]), whereas accumulation has been observed in only a few places [61], intensive biological degradation must occur. This is also of pharmacological interest, since several anthraquinones are used as drugs.



(28) *(33)*

On the basis of these considerations, the behavior of 20 hydroxyanthraquinones, including emodin *(28)* and endocrocin *(1)*, toward peracids under the conditions of the Baeyer-Villiger oxidation was systematically studied [62]. Though benzophenone is readily cleaved all the anthraquinones studied were found to be inert. A reaction of this type is therefore unlikely for metabolism.

Oxidative ring cleavage of an *anthrone (34)*, on the other hand, would be conceivable. Anthrones are precursors of the anthraquinones in their biosynthesis from acetate units, and could also be readily formed by reduction of anthraquinones. According to a hypothesis proposed by *Money* [63] in connection with the biosynthesis of other natural products, autoxidation of an anthrone *(34)* should lead to a hydroperoxide *(35)*, which then rearranges to form the benzophenone derivative *(31)*.

Attempts to verify this hypothesis experimentally with the unsubstituted anthrone *(34)* did not at first have the desired result [62,63], since the very unstable anthrone hydroperoxide *(35)* is dehydrated during its preparation, and yields the anthraquinone *(30)*. On the other hand, 10-methylanthrone hydroperoxide *(38)*, which had not previously been described, and which was obtained in good yields and in the crystalline state by autoxidation of 10-methylanthrone *(36)* in the presence of azodiisobutyronitrile, was found to be stable [62]. *(38)* was also formed by the action of methylmagnesium iodide on 10-methylanthranyl acetate *(37)*, followed by autoxidation [62,64]. The 10-methylanthrone hydroperoxide could be rearranged, with ring opening, into 2-hydroxy-2'-acetylbenzophenone in glacial acetic acid/dilute sulfuric acid. This

proton-catalyzed reaction probably proceeds in the same way as the analogous rearrangement of cumene hydroperoxide. This was the first successful oxidative

[63] *T. Money*, Nature (London) *199*, 592 (1963).

[64] This reaction does not lead to the transannular peroxide, as was assumed by *Julian*, *Cole*, and *Diemer* [65].

[65] *P. L. Julian*, *W. Cole*, and *G. Diemer*, J. Amer. chem. Soc. *67*, 1721 (1945).

ring opening of an anthrone, which is a conceivable model reaction for biogenetic changes.

The second step in the biosynthesis of ergochromes from anthraquinones consists in the ring closure of a hydroxybenzophenone to form the xanthone derivative. This could proceed as a phenol oxidation. Thus *Lewis* and *Warrington*[66] obtained 2,6-dihydroxyxanthone *(41)* in high yield by oxidation of trihydroxybenzophenone *(40)* with potassium hexacyanoferrate(III). The condensation product *(44)* which

contains the complete basic skeleton of a half molecule of the secalonic acids (bold type) *(3)*, was obtained in a similar manner from 2,5,2′,4′-tetrahydroxy-4,6-dimethylbenzophenone *(42)*[67]. In this case the oxidation with iron(III) chloride leads first to the crystalline *p*-quinone *(43)*, which undergoes alkali-catalyzed condensation to form the dienone *(45)*. Subsequent reduction and catalytic hydrogenation yields *(44)*.

10. Closing Remarks

As a result of the investigations of recent years, twelve ergot pigments have now taken their place beside the ergot alkaloids. Ten of these pigments, the ergochromes, owe their biosynthesis to a hitherto chemically and metabolically unknown oxidative ring cleavage of anthraquinones, which are formed in nature from acetate units. The ergot fungus thus again proves to be an organism that is characterized by the great versatility of the products and reactions of its metabolism. Since results obtained for this fungus are probably also valid for other organisms[68], the ergot fungus may be regarded as a particularly worthwhile object of study for biogenetic relations.

Several research teams and colleagues have played an important part in obtaining the results described here. The nutrition experiments were carried out with the cooperation of Doz. Dr. Gröger and Dr. Erge from the Institut für Biochemie der Pflanzen der Deutschen Akademie der Wissenschaften at Halle/Saale[54, 55]; *thanks are due to Prof. Dr. S. Shibata (University of Tokyo), Doz. Dr. G. Snatzke (Bonn University), and Messrs. Carl Zeiss, Oberkochen, for rotatory dispersion and circular dichroism measurements. I am particularly grateful to my colleagues mentioned in the references, who participated in the investigation of the ergot pigments at the Universities of Göttingen and of Kiel. The investigations were generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Farbenfabriken Bayer, Werk Elberfeld. I am also grateful to the Stiftung Volkswagenwerk for the use of a mass spectrometer. Valuable drugs were supplied by the Dr. Schwarz Arzneimittelfabrik, Monheim.*

Deactivation of Excited States[**]

By L. M. Stephenson and G. S. Hammond[*]

Nature abhors an electronically excited state and strives to convert this energy to other forms. This article is concerned with the various pathways involved in the degradation of electronic excitation to ordinary "thermal" forms, but will primarily discuss the quenching of excited states by other molecules. The authors include as examples only those photo-transformations and interactions encountered in solution.

1. Introduction

During phototransformations and interactions occurring in solution, the high frequency of collision with solvent in general establishes a Boltzmann distribution among vibrational and rotational levels in the *lowest* lying, electronically excited states within a very short time span ($< 10^{-11}$ sec) following excitation. Reference to a Jablonski energy diagram (Figure 1)

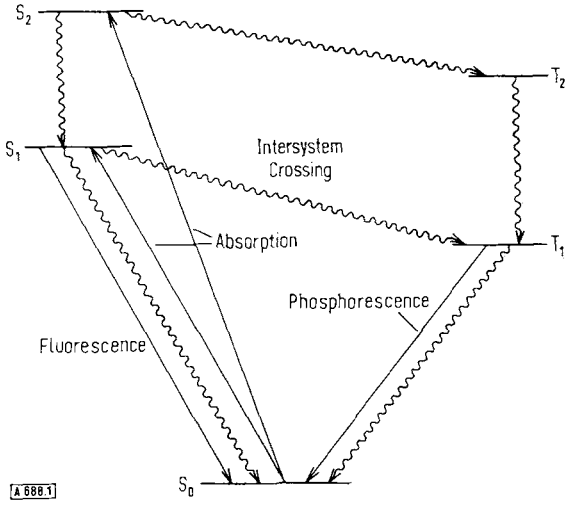

Fig. 1. Jablonski diagram. Solid arrows show absorption and emission of light, wavy arrows indicate radiationless processes.

will serve to clarify this point. The energy gap between the ground state and the lowest lying excited states is generally sufficiently large so that the vibrational overlap [1] between these states is slight. As a consequence, modes of deactivation other than nonradiative decay are frequently sought from lowest excited singlet and triplet states. Vibrational overlap between higher excited states, which are often separated by only small energy gaps, is much larger and leads to extremely rapid rates of nonradiative decay to the lowest excited states in any multiplicity manifold.

[**] Contribution No. 3625 from the Gates and Crellin Laboratories of Chemistry.

[1] The importance of vibrational overlap in determining rates of nonradiative decay has been delineated by *G. W. Robinson* and *R. P. Frosch*, J. chem. Physics *37*, 1962; *38*, 1187 (1963).

Most organic molecules contain even numbers of electrons which are spin paired and occupy orbitals that may be classified as localized, delocalized (as in conjugated unsaturated systems), or nonbonding (such as the pairs on oxygen and nitrogen). In addition, organic molecules, which are composed primarily of light atoms, have rigidly defined spin selection rules for electronic transitions. These molecules usually have ground singlet configuration, and display only spin allowed, singlet-singlet transitions in absorption spectra in the absence of strong external perturbation.

Following the rapid deactivation of the initially produced excited-singlet state to the lowest excited-singlet state, what pathways of deactivation do exist for this momentarily "trapped" molecule? Physical processes which degrade singlet states are familiar; fluorescence and nonradiative decay, both to the ground state and crossing to the excited triplet manifold. This latter process, known as intersystem crossing has proved to be of immense importance to photochemistry. The triplet state populated by the intersystem crossing process may also emit light (phosphorescence) or may return to the ground state by nonradiative paths. Events of more interest to photochemists include bond formation or fragmentation in the excited state (chemical quenching), energy transfer to suitable substrates, and formation of excited complexes (exiplexes) having decay characteristics different from those of the excited monomers.

2. The Chemical Quenching of Excited States

Because of the considerable energy possessed by electronically excited states, activation barriers for chemical reactions are frequently easily overcome. Conceptually, the quenching of excited states by bond formation or fragmentation is very simple; in practice the details are often difficult to explore. Two quenching mechanisms of this type have received considerable attention in our laboratories, *i.e.* the photoreduction and photoreactions of ketones and the photodimerization of conjugated dienes.

The photochemical reaction of ketones with alcohols is a familiar method for the production of pinacols [2].

[2] *A. Schönberg* and *A. Mustafa*, Chem. Reviews *40*, 181 (1947).

Until the late 1950's, however, little effort had been directed toward elucidation of the reaction mechanism, although the involvement of free radicals was generally accepted. In 1960, *Bäckstrom* and *Sandros* [3] were able to show compelling evidence for the identification of the reactive species as the triplet state of the ketone. Their results were focused on a study of the energy transfer from benzophenone *(1)* to biacetyl, monitored by the observation of induced phosphorescence from the latter. *Hammond, Moore,* and *Foss* [4] were able to obtain results in substantial agreement with those of *Bäckstrom* and *Sandros*. By using benzhydrol *(2)* as the hydrogen donor the reaction was simplified by virtue of the fact that only a single kind of free radical was produced.

$$\underset{(1)^*}{(C_6H_5)_2CO^*} + \underset{(2)}{(C_6H_5)_2CHOH} \xrightarrow{k_r}$$

$$2\,(C_6H_5)_2\dot{C}OH \rightarrow (C_6H_5)_2COH{-}COH(C_6H_5)_2 \qquad (1)$$

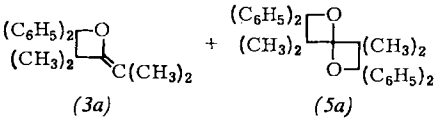
The dependence of the quantum yield of benzophenone disappearance ($\Phi_{-(1)}$) on benzhydrol concentration was explained in terms of the competition of unimolecular decay [reaction (2)] with pinacol formation [reaction (1)]

$$\underset{(1)^*}{(C_6H_5)_2CO^*} \xrightarrow{k_d} \underset{(1)}{(C_6H_5)_2CO} \qquad (2)$$

Treatment of $(C_6H_5)_2CO^*$ as an unstable intermediate led to eq. (3).

$$1/\Phi_{-(1)} = 1/a + k_d/ak_r\,[(2)] \qquad (3)$$

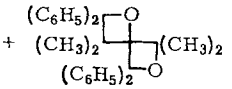
The constant a is the yield of benzophenone *(1)*. Experimental results showed that $a = 1.0$ and that $k_d/k_r = 0.05$ moles/liter. Since k_r cannot be larger than the diffusion-controlled limit, the data demanded the conclusion that the excited state $(C_6H_5)_2CO^*$ be longer lived than the excited singlet state. The hypothesis that the excited state produced by absorption of light by benzophenone undergoes quantitative intersystem crossing to yield a long lived triplet excited state, which is the chemically reactive species, has thus proved durable.



In a subsequent study, *Hammond* and *Leermakers* [5] showed that carbonyl compounds such as naphthaldehyde and acetonaphthone, which possess lowest triplet states of $\pi \rightarrow \pi^*$ rather than $n \rightarrow \pi^*$ configuration, are relatively unreactive in photoreduction. The effect is striking because the lifetimes of $\pi \rightarrow \pi^*$ triplets are longer than those of $n \rightarrow \pi^*$ triplets. The strong dependence of chemical reactivity on electronic configuration of the excited states dispels the vague notion that energy rich, excited molecules are nondiscriminating in their chemical reactivity.

$$R_2CO^* + \gtrless C{=}C \lessgtr \longrightarrow \begin{matrix} R_2C{-}O \\ | \\ \gtrless C{-}C \lessgtr \end{matrix} \quad (3)$$

Other typical photoreactions have also been shown to occur from $n \rightarrow \pi^*$ lowest excited triplet states, including the widely studied oxetane-forming reaction [6, 7].



Arnold and *Glick* [8], and *Hammond et al.* [9] have obtained, for example, the oxetane *(3a)* and the two dioxaspiroheptanes *(5a)* and *(5b)* from the allene *(4)* and benzophenone.

$$\underset{(1)}{(C_6H_5)_2CO} + \underset{(4)}{(CH_3)_2C{=}C{=}C(CH_3)_2} \xrightarrow{h\nu}$$

(3a)

(5a)

(5b)

Further data obtained by *Leermakers* and *Hammond* [10] confirmed the supposition that triplet states are involved in the photoreductions and photoreactions of ketones. A number of compounds were found to quench the photoreduction of benzophenone by benzhydrol. Interestingly, many quenchers, such as 2-acetonaphthone, naphthalene, *cis-* and *trans*-1,3-pentadiene, azulene, 1-naphthaldehyde, display remarkably similar quenching efficiencies. Since the compounds above all possess triplet energies lower than that of benzophenone it was inferred that the quenching mechanism must involve energy transfer from benzophenone at close to the same rate for all quenchers, presumably at or near that of a diffusion controlled process. Other quenchers, with triplet energies higher than that of benzophenone, such as cyclohexene, are considerably less efficient.

The use of specific quenchers for triplet states is now a commonplace technique for determining the spin multiplicity of a photoreactive state. An often overlooked criterion for energy transfer, however, is the production of an excited state of the quencher. This is perhaps most easily demonstrated when employing the conjugated dienes as quenchers [10–12].

Irradiation of solutions of conjugated diene and benzophenone (at wavelengths only absorbed by benzophenone) leads to *cis-trans* isomerization in the case of 1,3-pentadiene, and dimerization occurs with many

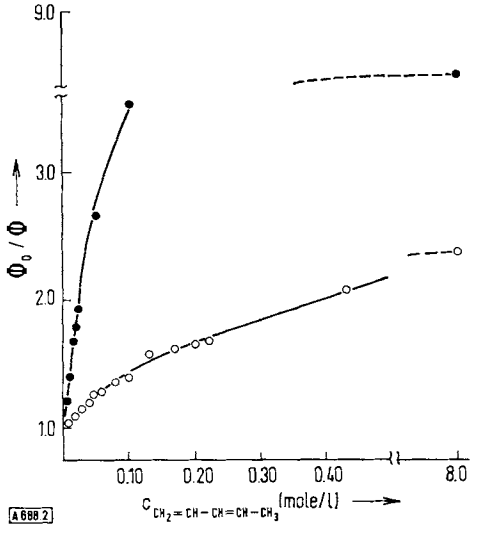
[12] This fact coupled with the existence of an unusually large singlet-triplet splitting has made 1,3-pentadiene the "quencher of choice" in many recent photochemical studies.

dienes at high concentrations. Neither reaction proceeds with high efficiency from the excited singlet states of the diene, and the product distribution for dimers in no way resembles that formed from ground state molecules in thermal reactions. The triplet state was thus specifically implicated in the photoreactions of the ketones quenched by the dienes.

Triplet quenchers, such as 1,3-pentadiene, were employed more recently by *Hammond* and *Wagner* [13,14] to prove the reactive character of both singlet and triplet states in Norrish Type II photoelimination. The cyclobutane derivative is usually only a minor product.



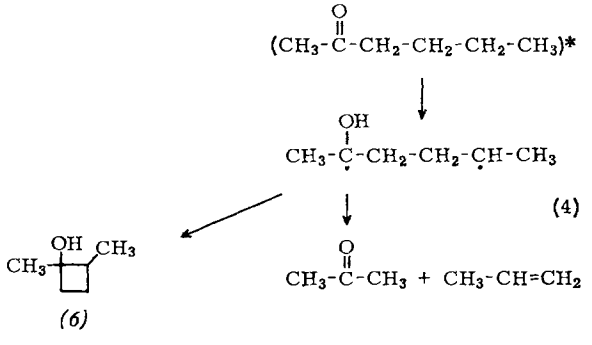


Fig. 2. Ratio (Φ_0/Φ) of quantum yield for disappearance of ketone with no quencher to quantum yield at given quencher concentrations *vs* concentration of quencher (1,3-pentadiene). Φ_0 = quantum yield for disappearance of 2-pentanone (●) and 2-hexanone (○) without quencher; Φ = quantum yield with 1,3-pentadiene as quencher.

Quenching data in Figure 2 show that, even at high pentadiene concentration (8 M), 2-hexanone still gives a significant amount of cleavage [see reaction (4)], and

that a lesser, but still significant portion of the 2-pentanone reaction is unquenched. The most obvious interpretation is that the phototransformations have sizable singlet-state contribution (see Table 1). These results underline the fact that singlet and triplet states

of physical deactivation, whereas corresponding excited singlets decay much more rapidly.

The reaction of conjugated dienes in their ground states with excited triplet states of dienes to produce dimers furnishes our second example of chemical quenching. Dimers are produced smoothly when the excited triplet states are produced *via* energy transfer from benzophenone or other appropriate triplet energy donors.

The dimerization of 1,3-butadiene [15], 1,3-pentadiene and isoprene [16], 1,3-cyclopentadiene [17], and 1,3-cyclohexadiene [18] has been studied in detail. Product mixtures, although complex, could be accounted for by assuming that the addition reaction occurs in two discrete steps, first formation of an intermediate biradical, and then cyclization of the biradical to form the final products. The process is illustrated below for the dimerization of 1,3-cyclohexadiene *(7)* (Table 2) [19] and isoprene *(8)*.

A plot of 1/(yield of dimer) *vs* 1/(diene concentration) in a set of matched samples subjected to equivalent irradiation is linear. Information concerning the lifetime of the diene triplet was obtained by use of azulene quenching. In the presence of a high concentration of diene, small amounts of azulene are not expected to influence the transfer of energy from sensitizer to diene. However, addition of slightly more than 10^{-2} M azulene is capable of quenching the dimerization by more than a factor of 1/2 (see Figure 3). Clearly the

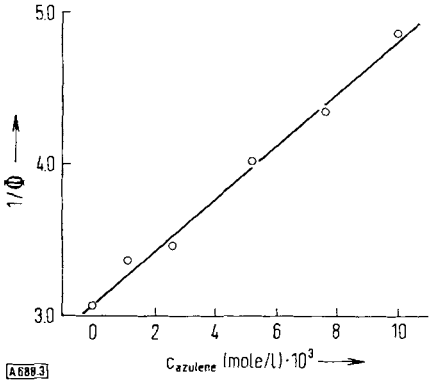

Fig. 3. Quantum yield for dimerization of isoprene in the presence of varying concentrations of azulene.

azulene is capable of quenching the diene triplet state. From the slope of the plot the ratio of the quenching constant to the rate constant for the attack of diene triplet on ground state molecules is found to be 1.2×10^3. This indicates that the rate constant for reaction must be about 2×10^6 liter mole^{-1} sec^{-1} or less; analysis of the dependence of quantum yield on diene concentration gives the ratio of the rate constant for the dimerization reaction to that for radiationless decay of triplets and places a lower limit of 2×10^{-8} sec on the triplet lifetime [20].

Attempts to extend these methods to cross additions of dienes have led, not unexpectedly, to complex mixtures of products. In addition, attempts to add dienes to olefins photochemically have met with little success [21]. It is important to note, however, that bond formation between the excited state and other molecules is an important quenching pathway, even for rather short-lived states, and that high yields of products are obtained from such interactions. This fact will be of importance later in discussions of other quenching phenomena [22] (see Section 4.1).

3. Triplet Energy Transfer in Solution

The transfer of triplet excitation energy from donors to acceptors is an efficient pathway for the quenching of excited states. The photochemical significance of the production of chemically reactive states of the acceptor was illustrated in the previous section. The energy transfer process will now be outlined for the photochemical *cis-trans* isomerization of the stilbenes [24–26].

The following generalized mechanism will prove adequate for discussion. Here S is sensitizer in a singlet, $S^{*(1)}$, or triplet, $S^{*(3)}$, excited state, with c = *cis* olefin, t = *trans* olefin, and T = olefin triplet states [27].

Three types of measurements have been made: quantum yields of sensitized *cis* → *trans* isomerization, measurements of the stationary state composition of the system following prolonged irradiation, and flash spectrophotometric measurement of the rates of decay of sensitizer triplets in the presence of the isomerizable olefins.

[15] *G. S. Hammond, N. J. Turro,* and *A. Fischer,* J. Amer. chem. Soc. *83,* 4674 (1961).

[16] *G. S. Hammond* and *R. S. H. Liu,* J. Amer. chem. Soc. *85,* 477 (1963).

[17] *J. Turro* and *G. S. Hammond,* J. Amer. chem. Soc. *84,* 2841 (1962).

[18] *D. Valentine, N. J. Turro,* and *G. S. Hammond,* J. Amer. chem. Soc. *86,* 5202 (1964).

[19] *R. S. H. Liu, N. J. Turro,* and *G. S. Hammond,* J. Amer. chem. Soc. *87,* 3406 (1965).

[20] This derives from the hypothesis that azulene will quench at (or probably less than) a diffusion controlled rate, estimated at 6×10^9 liters mole^{-1} sec^{-1}. The deactivation of a diene triplet state probably involves a process in which a twisted triplet reverts to a planar ground-state form. Energy transfer requiring a change in geometry of one of the reactions will, in all probability, be slower than the diffusion controlled rate (see Section 3). 1,3-Cyclohexadiene, which has recently been studied by *G. F. Vesley* in these laboratories, appears to be incapable of undergoing very extensive distortion in excited states. Consequently, the high susceptibility of cyclohexadiene to quenching by azulene confirms this viewpoint.

[21] *R. S. H. Liu* and *G. S. Hammond,* J. Amer. chem. Soc. *86,* 1892 (1964).

[22] This also seems to be at the heart of the most satisfying argument against a mechanism for energy transfer involving bonding of the sensitizer and substrate, rather than physical excitation transfer. See references [19] and [23].

[27] The mechanism implies that *cisoid, transoid,* and *nonplanar* triplet states of the olefin are indistinguishable or are rapidly interconverting species. Although data indicate that decay to *trans* stilbene becomes slightly more favorable at higher temperature, thus indicating a small barrier to interconversion between *transoid* and *nonplanar* (or *cisoid*) triplet states, no evidence forcing the abandonment of the common triplet hypothesis has been found with α-methyl- or α,α'-dimethyl-stilbenes.

energy transfer to *cis* or *trans* olefin

$$T \xrightarrow{k_c} c \quad (10)$$

$$T \xrightarrow{k_t} t \quad (11)$$

decay of substrate triplet states to *cis* or *trans* ground states

Applying reactions (5)–(11) the stationary state measurements are expected to be determined by the product of two functions, an excitation ratio and a decay ratio [eq. (12)]. From this several predictions can be made regarding the behavior of the photo-

$$[cis]/[trans] = \underbrace{(k_2/k_1)}_{\text{excitation ratio}} \times \underbrace{(k_c/k_t)}_{\text{decay ratio}} \quad (12)$$

stationary state with respect to the sensitizer triplet energy. Barring steric effects, or other unanticipated difficulties, sensitizers with triplet energies greatly in excess of both *cis*- (57 kcal/mole) and *trans*-stilbene (50 kcal/mole)[28] should transfer energy at equal rates to both isomers, and, if the decay ratio is independent of sensitizer, as the mechanism implies, a high energy region of similar photostationary states would be obtained. As the sensitizer energy is varied between $\sim$ 57 and $\sim$ 50 kcal/mole a falloff in transfer rates to *cis* stilbene is expected, thus pumping the system to *cis* rich mixtures. As the sensitizer energy drops below 50 kcal/mole, it is expected that the stationary state will again level off, and with the deficiency made up as activation energy the excitation ratio would assume the value

$$k_2/k_1 = e^{-(57\,000-50\,000)/RT}$$

and lead to an extremely *cis* rich mixture.

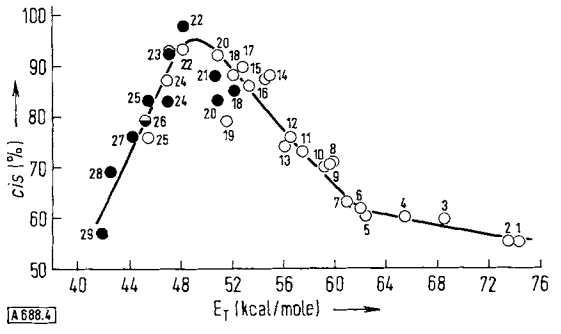
Values obtained for the *cis*/*trans* photostationary state ratios of stilbene with varying sensitizer triplet energies agree with these predictions to only a limited extent (Fig. 4). In the high energy region a near "ideal" behavior is noted, but, although rate constants near that of a diffusion controlled reaction are noted, a slightly sloping line cannot be ignored.

Valentine has considered various factors as sources of possible inefficiency in exothermic energy transfer[29]. He concludes that energy transfer to the *cis* isomer is not diffusion controlled and becomes more rapid as the sensitizer energy increases. Steric factors may well be important and it should be noted that the structure of the sensitizer becomes less complex with higher energy.

[28] *D. F. Evans*, J. chem. Soc. (London) *1957*, 1351; from oxygen perturbed singlet-triplet spectrum

[29] *D. Valentine*, Ph.D. Thesis, California Institute of Technology, Pasadena, California, 1966.

In a closely related study, *Herkstroeter, Jones*, and *Hammond*[30] have shown evidence for considerable steric interference in energy transfer from benzophenone derivatives with bulky *ortho* substituents, with transfer rates to *cis*-stilbene being more strongly affected than those to *trans*-stilbene. Figure 4 shows



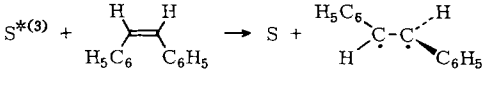


Fig. 4. Photostationary states for the stilbenes, measured (○) and predicted from k_q measurements (●). E_T = triplet energy of sensitizer. that as the sensitizer triplet energy drops from $\sim$ 60 kcal/mole to $\sim$ 50 kcal/mole[31] the photostationary states indeed move to *cis*-rich mixtures. At low triplet energies, however, instead of leveling off, the curve again returns to *trans*-rich mixtures, clearly unexpected behavior. This result may be rationalized in two ways; either transfer of energy to *cis*-stilbene is decreasing less rapidly than predicted, or rates of transfer to *trans*-stilbene decrease more rapidly than predicted (or both).

In preliminary communications, *Hammond* and *Saltiel*[32] adopted the former approach. In particular, they suggested that *cis*-stilbene is converted directly to a *transoid* or nonplanar (shown above) excited triplet during energy transfer. The planar *trans* triplet is known to possess a lower energy than the planar *cis*

form and nonplanar triplets are predicted, on the basis of calculations[33,34], to have lower energy. Consequently, transitions from *cis*-stilbene to either the

[30] *W. G. Herkstroeter, L. B. Jones*, and *G. S. Hammond*, J. Amer. chem. Soc. *88*, 4777 (1966).

[31] The 3–5 kcal/mole excess energy needed to obtain efficient transfer is not well understood but is found in many systems, including ones more rapid than stilbene.

[32] *G. S. Hammond* and *J. Saltiel*, J. Amer. chem. Soc. *85*, 2516 (1963).

[33] *D. S. McClure*, Symposium on Photochemistry, California Institute of Technology, Pasadena (1966).

[34] *P. Borrell* and *H. H. Greenwood*, Proc. Roy. Soc. (London) *1967*, 453.

trans, planar, or twisted triplet states should require less energy than excitation to the planar *cis* triplet. This process is not observed spectroscopically (it would violate the Franck-Condon principle) and hence is termed a non-vertical transition or a non-vertical energy transfer. The key postulate is that energy transfer with non-vertical excitation of the acceptor may occur when vertical transitions are forbidden for energetic reasons. The phenomenon is expected to be an important factor only if one or both of the partners is a flexible molecule, *i.e.*, a molecule having significantly different equilibrium geometry in ground and excited states.

Confirmation of this point of view was later obtained by *Hammond* and *Herkstroeter*[35] in a study of these energy transfer rates by kinetic flash spectrophotometry[36]. A solution containing a sensitizer and one of the isomerizable substrates is flashed with a high-intensity light pulse. A significant fraction of the sensitizer molecules are promoted to excited triplet states by light absorption followed by intersystem crossing. Decay of sensitizer triplets is then monitored by absorption spectroscopy. Decay is accelerated in the presence of substances to which the sensitizers can transfer their excitation.

Measurement of the dependence of decay rates on the concentration of the quencher allows evaluation of bimolecular rate constants for the quenching reaction. A number of sensitizers were studied using the isomeric stilbenes and 1,2-diphenylpropenes (α-methyl-

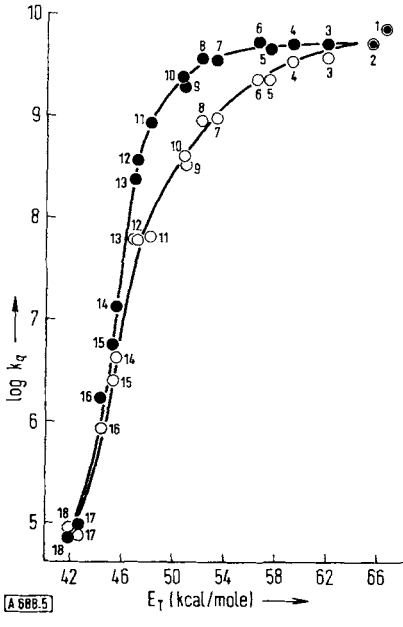

Fig. 5. Rate constants for quenching of sensitizers by *cis*- (○) and *trans*-stilbene (●). k_q = quenching constant. E_T = triplet energy of sensitizer. Fig. 6. Rate constants for quenching of sensitizers by *cis*- (○) and *trans*-1,2-diphenylpropene (●). k_q = quenching constant. E_T = triplet energy of sensitizers. Sensitizers: 1, triphenylene. 2, thioxanthone. 3, 2-acetonaphthone. 4, 1-naphthyl phenyl ketone. 5, fluorenone. 6, dibenz[*a,h*]anthracene. 7, duroquinone. 8, benzil. 9, dibenz[*a,c*]anthracene. 10, pyrene. 11, benz[*a*]anthracene. 12, benzanthrone. 13, 3-acetylpyrene. 14, acridine. 15, 9,10-dimethylbenz[*a*]anthracene. 16, anthracene.

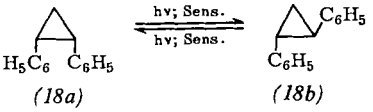
stilbenes) as quenchers. Plots of the logarithms of the quenching constants (log k_q) against the triplet energies of the sensitizers (E_T) are shown in Figures 5 and 6. If the energy deficiency for the low energy sensitizers were made up as activation energy, the straight line portion of these figures should follow equation (13).



$$\Delta \log k_q/\Delta E_T = -1/(2.303\ RT) \qquad (13)$$

The slope predicted by this equation is observed for *trans*-stilbene. For *cis*-stilbene the rates of energy transfer fall off much more slowly than a classical mechanism would imply. The postulate of nonvertical energy transfer is fully consistent with these results. Nonvertical energy transfer is inferred to be operative with both isomers of α-methylstilbene, since slopes smaller than the classical value are observed with both isomers.

Several other systems have also been discussed in terms of nonvertical energy transfer, among these the photosensitized interconversion of norbornadiene *(16)* and quadricyclene *(17)*[37] and the *cis* → *trans* isomerization of 1,2-diphenylcyclopropane *(18)*[38].

The triplet excitation energy of quadricyclene has been measured as 92 kcal mole^{-1} [39] and the vertical excitation energy of diphenylcyclopropane is probably nearly as high as that of benzene. Consequently, it was felt that energy transfer, coupled with bond breakage, could be involved – another example of nonvertical energy transfer. However, recent investigations [40] have shown that the quadricyclene – norbornadiene interconversion involves strong interaction with excited singlet states of the sensitizers in many cases and that triplet energy transfer may not be involved at all.

In similar findings, *Cole* and *Hammond* [41] were able to induce asymmetry into *trans*-diphenylcyclopropane using optically active naphthalene derivatives as sensitizers; once again, singlet state interactions are responsible for the sensitized reaction [40]. Application of the concept of the nonvertical mechanism for triplet energy transfer of these systems was obviously an overenthusiastic application of the theory. However, re-examination of the original cases confirms the utility of the hypothesis in those examples. The scope of the phenomenon is essentially undefined at this time.

An examination of the revised Saltiel plot (Figure 4) shows several interesting features [42].

The chemical response of the system (*e.g.*, the [*cis*]/[*trans*] ratio) changes abruptly as the triplet energy of the donor passes through a point of the energy scale 2–3 kcal/mole higher than that of the acceptor. Note that with the stilbenes the curve begins a steep rise in the region of 60 kcal/mole and a descent in the region of 50 kcal/mole. If the notions of the previous sections concerning energy transfer rates are correct these points should be near the spectroscopic excitation energies of the triplet states of the stilbenes.

The photochemical dimerization of isoprene leads to the compounds *(9)–(15)*, which may be classed as cyclobutanes, cyclohexenes, and cyclooctadienes. Table 3 gives the product distribution with various sensitizers. Five of the compounds, *(9)*, *(10)*, *(11)*, *(14)*, and *(15)*, behave as a unit and their formation is competitive with the production of the two cyclohexenes *(12)* and *(13)*. These trends are shown in

Table 3. Composition of products from photosensitized dimerization of isoprene *(8)*.

4. Applications of Quenching Studies

Apart from yielding some understanding of triplet energy transfer and the behavior of excited states of various substrates, the studies of *cis-trans* isomerization and other modes of chemical deactivation of excited states have pointed to several useful applications.

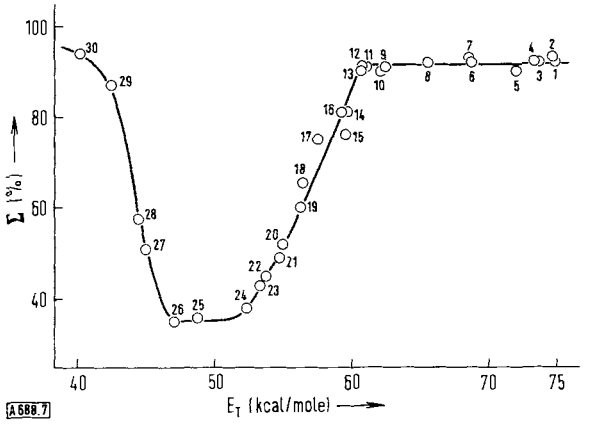
[39] *P. S. Wei*, Ph.D. Dissertation, California Institute of Technology, Pasadena, California, 1968.

[40] *S. Murov*, *R. S. Cole*, and *G. S. Hammond*, J. Amer. chem. Soc. *90*, 2959 (1968); *S. Murov* and *G. S. Hammond*, J. physic. Chem. *72*, 3797 (1968).

[41] *G. S. Hammond* and *R. S. Cole*, J. Amer. chem. Soc. *87*, 3256 (1965).

[42] Reference [25] gives a Saltiel plot displaying much more fine structure than can be found in Figure 4. Many of the minima responsible for this structure have now been removed. It is found that the isomerization induced by several sensitizers, namely the quinones and the brominated sensitizers such as eosin, proceeds by mechanisms other than energy transfer. It is significant that many of these stationary states are closer to the composition at thermal equilibrium than that mixture induced by normal sensitization. A thorough analysis of this problem is incomplete.

Figure 7 where the sum of the yields of the cyclobutanes *(9)–(11)* and cyclooctadienes *(14)* and *(15)* is plotted against the triplet excitation energies of the sensitizers. The reasonable postulate is made that the



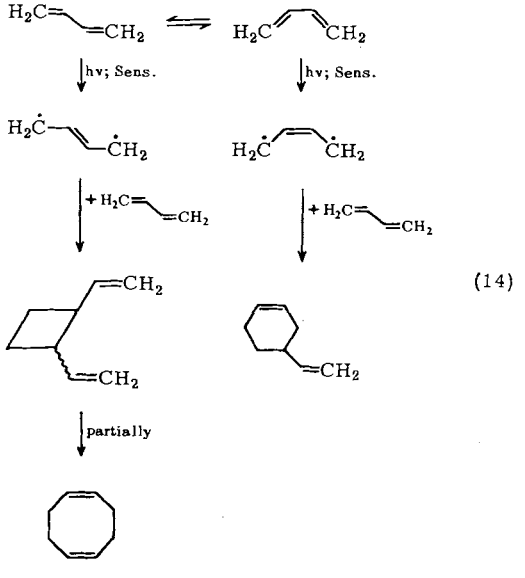


Fig. 7. Dependence of isoprene dimer composition on triplet energy of sensitizer. Σ = sum of *(9)*, *(10)*, *(11)*, *(14)*, and *(15)*. E_T = triplet energy of sensitizer. For sensitizers 1—30, see Table 3.

cyclohexenes are derived from interaction between *transoid* ground states and *cisoid* excited triplet states and that the cyclobutanes are derivable from *transoid* ground and excited states. The cyclooctadienes, while in principle derivable from an interaction between *cisoid* ground- and *cisoid* excited-states, may actually be formed by thermal rearrangement of the *cis*-dimethylcyclobutanes [see reaction (14)].

(14)

If the interpretation of the origin of the products is correct, the first break in the curve should correspond to a decrease in the rate of energy transfer to the *transoid* diene, predominantly present in solution (~ 95% in isoprene at room temperature). Thus the lowest triplet state of the *transoid* olefin was assigned an energy of approximately 60 kcal/mole. The next break in chemical response occurs at ~ 50 kcal/mole and represents a decrease in the rate of energy transfer to the *cisoid* form, whose triplet energy was assigned a value of 50 kcal/mole [43]. Using high pressures of O_2, *Evans* [44] has observed these highly forbidden $S_0 \rightarrow T$ absorptions and places the energy for isoprene triplet (a model *transoid* diene) at 60 kcal/mole and for cyclohexadiene (a model *cisoid* diene) an energy of 53 kcal/mole. Obviously, the method of chemical spectroscopy provides a useful adjunct to optical spectroscopy in this case.

4.2. Quantum Yields of Isomerization. A Method of Triplet Counting

In addition to placing nonvertical energy transfer on a firm experimental basis, the flash spectroscopic results of *Herkstroeter* also demonstrated the insensitivity of the olefin triplet decay ratio to the structure of the sensitizer. Using the triplet decay ratio and the ratio of rate constants for quenching by *cis* and *trans* species, values of expected photostationary state compositions were calculated and found to be in good agreement with experimental values.

Recognizing this fact, *Lamola* and *Hammond* [46] were able to show that the quantum yield for *cis* → *trans* isomerization of an olefin is a function of only three variables; the yield of sensitizer triplets produced by intersystem crossing, the efficiency of energy transfer to the olefin, and the triplet decay ratio of the olefin triplet. In addition, the work of *Herkstroeter* had made it clear that energy transfer rates could compete very favorably with triplet decay rates with all but the very lowest energy sensitizers. Thus, nearly 100% efficiency in triplet energy transfer could be effected in most cases even at relatively low acceptor concentrations.

Preliminary studies with benzophenone confirmed these ideas, since this sensitizer was already known to intersystem cross with unit efficiency (see Table 4).

Table 4. Quantum yields for *cis-trans* olefin isomerization by benzophenone (*c* = *cis*, *t* = *trans*).

Olefin	$\Phi_{c\rightarrow t}$	$\Phi_{t\rightarrow c}$	$\Phi_{c\rightarrow t} + \Phi_{t\rightarrow c}$
α-methylstilbene	0.55 ± 0.01	0.44 ± 0.01	0.99 ± 0.02
1,3-pentadiene	0.44 ± 0.01	0.55 ± 0.01	0.99 ± 0.02
1-phenylpropene	0.51	0.51	1.02

The quantum yield for sensitized, *cis* → *trans* isomerization in the absence of the *trans* isomer is given by Equation (15).

[43] Figure 7 is reminiscent of the Saltiel stilbene curve (Figure 4), and again would seem to demand the postulation of a nonvertical energy transfer. Flash kinetic studies which confirm this feeling even for the relatively rigid 1,3-cyclohexadiene, have been performed by *G. F. Vesley*. However, recent work by *Liu* and *Edman* [45] shows that sensitization with low-energy sensitizers sometimes involves energy transfer from more highly excited triplet states. This phenomenon may have made some contribution to data shown in Figure 7.

[44] *D. F. Evans*, J. chem. Soc. (London), *1960*, 1735.

[45] *R. S. H. Liu* and *J. R. Edman*, J. Amer. chem. Soc. *90*, 213 (1968).

[46] *A. A. Lamola* and *G. S. Hammond*, J. chem. Physics *43*, 2129 (1965).

$$\Phi_{c\to t} = \left(\frac{k_{ic}}{k_f + k_{ic}}\right)\left(\frac{k_1[c]}{k_1[c] + k_d}\right)\left(\frac{k_t}{k_t + k_c}\right) \quad (15)$$

k_{ic} = rate constant for intersystem crossing by the sensitizer.

k_f = rate constant for fluorescence by the sensitizer.

k_1 = rate constant for triplet energy transfer to the *cis* substrate.

k_t, k_c = rate constants for decay of substrate triplets to *trans* and *cis* ground states.

k_d = rate constant for unimolecular decay of sensitizer triplets to the ground state.

If, as with benzophenone, energy transfer is 100% efficient [47], the intersystem crossing yield (Φ_{ic}) of the sensitizer is obtained by merely summing the quantum yields of isomerization.

$$\Phi_{c\to t} = \Phi_{ic}\, k_t/(k_t + k_c) \quad (16)$$

$$\Phi_{t\to c} = \Phi_{ic}\, k_c/(k_t + k_c) \quad (17)$$

$$\Phi_{c\to t} + \Phi_{t\to c} = \Phi_{i.c.} \quad (18)$$

The intersystem crossing yield of a sensitizer is a matter of some practical interest to a photochemist. This measurement, coupled with measurements of fluorescence and phosphorescence yields, allows a complete detailing of the extent of nonradiative decay [1,48,49] from both the singlet and triplet manifolds.

Hammond and *Lamola*, exploiting the method outlined above, were able to develop a simple and accurate method for the measurement of intersystem crossing efficiencies in solution at room temperature. Unfortunately, the highly variable rates of this reaction could not be rationalized in terms of molecular structure, or other obvious parameters. The data seemed to demonstrate the occurrence of some nonradiative decay from the excited singlet state in several systems (notably naphthalene and derivatives, see Section 4.3), in contradiction to the implication of theory [48].

4.3. Complications in the Triplet Counting Scheme; Complex Formation in the Excited State

The necessity for the postulation of nonradiative decay from the first excited-singlet state of aromatic hydrocarbons, as suggested by the data obtained by *Lamola*, has found strong disagreement in the literature. Deuteration has no effect on singlet lifetimes, indicating a lack of nonradiative decay from that state [47]. Furthermore, *Lamola*'s unpublished value for benzene intersystem crossing, 0.24, disagreed sharply with values estimated by *Lim* (0.80 [50]) and *Noyes* and *Ishikawa* (0.78 [51])

The inherent simplicity and usefulness of the method made an investigation of these anomalies desirable. 1,3-Pentadiene, the most widely employed triplet counter because of its high singlet energy and low triplet energy (> 100 and < 60 kcal/mole, respectively), formed the focus of this study. The finding that conjugated dienes are capable of quenching the fluorescence of aromatic hydrocarbons revealed one important source of error in triplet counting experiments [52]. It is further observed that products characteristic of the diene triplet photoreactions do not arise from the singlet quenching.

Figures 8, 9, and 10 show the quenching of naphthalene fluorescence by *cis*-1,3-pentadiene, a Stern-Volmer treatment of the quenching data, and the decreasing *cis* → *trans* quantum yield as the concentration of *cis*-1,3-pentadiene is increased. Data of this type have allowed corrections to be applied to the earlier results obtained by *Lamola* for several aromatic hydrocarbons, in particular naphthalene and derivatives. These data agree closely with those obtained by *Wilkinson* and co-workers [53, 54] who employed a different

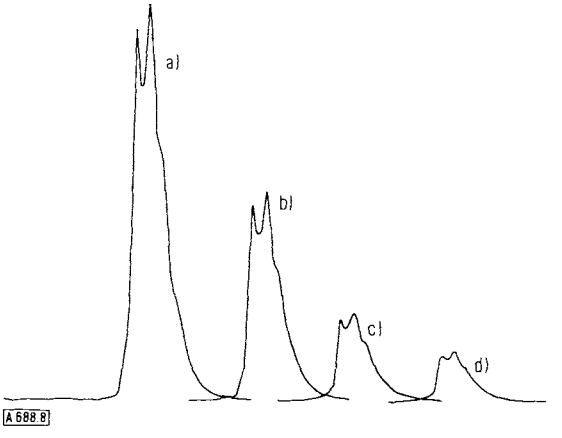

Fig. 8. Naphthalene fluorescence in the presence of a) 0.0, b) 0.1, c) 0.4, d) 0.8 mole/l of *cis*-1,3-pentadiene (relative).

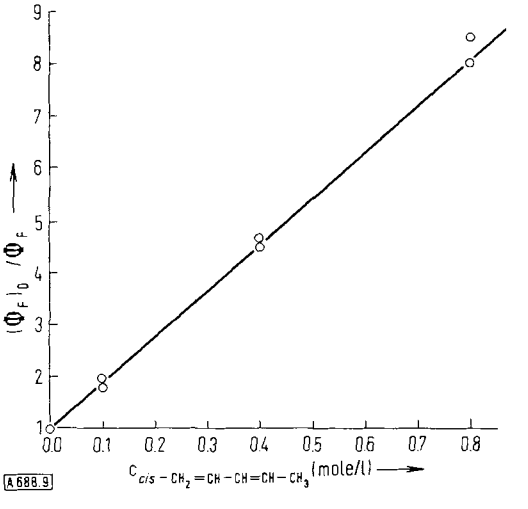

Fig. 9. Stern-Volmer treatment of naphthalene quenching by *cis*-1,3-pentadiene.

[47] This is most easily demonstrated by showing that $\Phi_{c\to t}$ is invariant with increasing olefin concentration.

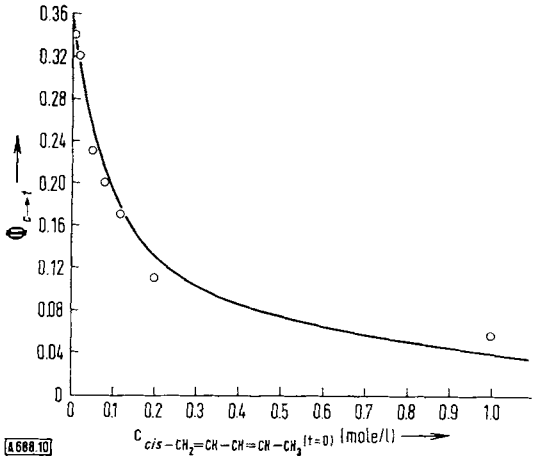

Fig. 10. The *cis-trans* isomerization quantum yield for 1,3-pentadiene sensitized by naphthalene as a function of initial *cis*-1,3-pentadiene concentration.

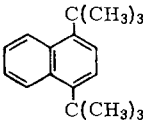
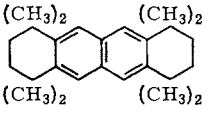
method of triplet counting. Substantial support is found for the conclusion that, in the absence of specific quenchers, nonradiative decay from the first excited-singlet state of aromatic hydrocarbons is unimportant.



The mechanism of this singlet quenching process is a subject of continuing study. Quenching by conjugated dienes is ineffective in inducing photochemical transformations typical of the diene triplet state. In addition, careful searches have revealed no evidence for products which characteristically arise from excited singlet states of the dienes. In particular, no trace of cyclobutene is produced from 1,3-pentadiene, hexatriene is not formed from cyclohexadiene, nor are any of the several rearrangement products of myrcene found. All processes are known to proceed from the excited singlet following direct irradiation. Adducts are sometimes formed from the aromatic compound and the diene but the quantum yields of such products are far too small to account for more than a small part of the quenching. "Chemical quenching" and transfer of singlet energy are thus eliminated as mechanistic possibilities.

Table 5. Quenching of fluorescence of aromatic hydrocarbons by dienes.



Aromatic	Diene	$c^1/_2$ [a] (mmole/l)	$k_q \times 10^{-9}$ [b] ($l mole^{-1} sec^{-1}$)
Naphthalene	2,5-Dimethyl-2,4-hexadiene	2.63	3.96
Naphthalene	1,3-Cyclohexadiene	3.95	2.50

Naphthalene	*trans*-2-*trans*-4-Hexadiene	16.8	0.62
Naphthalene	*trans*-2-*cis*-4-Hexadiene	20.5	0.51
Naphthalene	*cis*-2-*cis*-4-Hexadiene	45.3	0.23
Naphthalene	3-Methylenecyclohexene	61.2	0.17
Naphthalene	*trans*-2-Methyl-1,3-pentadiene	94.2	0.11
Naphthalene	*trans*-1,3-Pentadiene	95.0	0.11
Naphthalene	*cis*-1,3-Pentadiene	113	0.092
Naphthalene	2,3-Dimethyl-1,3-butadiene	680	0.015
1-Methyl-naphthalene	1,3-Cyclohexadiene	12	1.1
Anthracene	1,3-Cyclohexadiene	67	2.96

[a] $c^1/_2$ is the concentration required to quench half the fluorescence.
[b] Calculated assuming τ_S for naphthalene = 77 nanoseconds, as estimated by oxygen quenching.

For the most part, this quenching must be described as a catalysis of the nonradiative decay of the quenchers. The rates observed for naphthalene quenching are shown in Table 5 and do not exceed those expected in diffusion controlled reactions. Results also show [55] that addition of alkyl substituents to naphthalene, as in *(19)* and *(20)*, reduces sensitivity to quenching by 1,3-pentadiene [*(19)*, $k_q = 13 \times 10^6$ l mole^{-1} sec^{-1}; *(20)*, $k_q = 8.7 \times 10^6$ l mole^{-1} sec^{-1}; naphthalene, 140×10^6 l mole^{-1} sec^{-1}].

(19)

(20)

We tentatively conclude that quenching not only requires that the two molecules be in contact but that the contact be sufficiently intimate to be subject to steric hindrance.

A model designed to account for the reactivity relationships has been formulated and assumes that, within a complex formed between excited singlet state quenchee (A) and ground state quencher diene (Q), a small amount of the electronic excitation is delocalized to the quencher.

$$A^*Q \leftrightarrow A \cdot Q^*$$

Since the singlet excitation energies of the dienes are considerably greater than those of the quenchers, the contribution from the second configuration is expected to be small. However, the importance of the A · · Q* structure arises primarily from its effect on the rate of internal conversion, not from its contribution to the binding energy of the complex. This suggests that the weak coupling may allow the excited complex to borrow some of the very rapid, nonradiative decay characteristics of the diene.

Organometal Sulfides as Ligands in Pentacarbonylchromium(0) Complexes[**]

By *H. Schumann, O. Stelzer,* and *W. Gick*[*]

Organo-germanium, -tin, and -lead sulfides are astonishingly stable compounds, a fact which is explained in many cases as a result of the participation of the sulfur's lone pair electrons in the metal-sulfur bond in terms of (p → d) π-type multiple bonding[1]. Accordingly, trimethylgermyl- and trimethylstannyl-sulfides ought to exhibit a different complex chemical behavior from dialkyl- or diaryl-sulfides, which occur in a number of complexes as σ-donors[2]. Results of previous investigations[3] showed that in the reactions of transition metal carbonyls and organotin sulfides the tin-sulfur bonds are cleaved; stable complexes with organotin sulfides as ligands could not be prepared.

We have now been able to synthesize for the first time stable carbonylchromium(0) complexes with organometal sulfides as ligands by means of the reaction of bis(trimethyl-germyl)-, bis(trimethylstannyl)-, phenyltrimethylgermyl-, or phenyltrimethylstannyl sulfide with hexacarbonylchromium under UV irradiation in tetrahydrofuran (THF) at room temperature[4].

$$(CH_3)_3M\text{-}S\text{-}M(CH_3)_3 + Cr(CO)_6 \xrightarrow{h\nu} \begin{matrix}(CH_3)_3M\\ \diagdown\\ \quad S\text{-}Cr(CO)_5\\ \diagup\\ (CH_3)_3M\end{matrix}\ \textit{(1)} + CO$$

$$(CH_3)_3M\text{-}SC_6H_5 + Cr(CO)_6 \xrightarrow{h\nu} \begin{matrix}(CH_3)_3M\\ \diagdown\\ \quad S\text{-}Cr(CO)_5\\ \diagup\\ C_6H_5\end{matrix}\ \textit{(2)} + CO$$

(M = Ge, Sn)

The choice of solvent in this reaction is particularly important. If pentane is used as solvent instead of THF then the rate of reaction is slowed down considerably; this may be due, on the one hand, to the difference in solubility of the hexacarbonylchromium in these solvents and on the other to the part played by THF in the course of the reaction[5]. Compounds *(1)* and *(2)* are sensitive to atmospheric oxygen and to water; they are essentially less stable thermally than are the corresponding organometal-phosphine complexes[6].

As a result of removal of the degeneracy of the E_1 vibration under the influence of the asymmetrical ligands[7], the IR spectra show four CO-stretching vibrations for the $Cr(CO)_5$ skeleton whose positions are only slightly dependent on the complex partner. Further, there is only a trivial change in the frequencies of the CrS- and MS-stretching vibrations within the series. In the case of all four compounds an absorption band, corresponding to their yellow color, is to be observed in the region of 250–800 nm which is shifted into the long-wave region on going from M = Ge to M = Sn.

Cpd. M =	Decomp. pt. (°C)	νCO (cm^{-1})	δCH₃ [a] (Hz)	νCrS (cm^{-1})	νMS (cm^{-1})	νMS [b] (cm^{-1})	λ (nm)
(1a), Ge	70	2066 1984 1930 1912	−49	449	383 360	414 366	420 ε = 895
(1b), Sn	95	2087 2004 1956 1937	−45	447	325 348	366 321	435 ε = 816
(2a), Ge	45	2079 1996 1949 1930	−46	446	367	374	413 ε = 774
(2b), Sn	45	2074 1996 1949 1926	−44	451	342	342	417 ε = 1200

[a] 5% solution in $CDCl_3$, TMS as external standard.
[b] In the free organometal sulfide.

From the remarkable stability of *(1)* and *(2)* it follows that the blocking of a lone electron pair of the sulfur in organometal sulfides by complex formation does not necessarily lead to the cleavage of the metal-sulfur bond and that consequently organogermanium- and organotin-sulfides can occur as σ-donors in transition metal complexes in the same way as do dialkyl- or diaryl sulfides.

Experimental:

12 mmoles of organometal sulfide and 12 mmoles (2.6 g) of hexacarbonylchromium are dissolved in 50 ml of THF (previously dried over CaH_2) in an irradiation apparatus. The solution is stirred with a magnetic stirrer and irradiated with a high pressure mercury vapor lamp[4]. A slightly reduced pressure in the gasometer that is used for the measurement of the CO evolved favors the reaction, which is complete after a period of 2 h irradiation; the solution turns orange yellow in color. The solvent is removed under vacuum and the reaction products (in all cases a pale yellow powder; yields quantitative) can be recrystallized from pentane at −40 °C. The products can be further purified by sublimation at 30–75 °C/10^{-5} torr.

Synthesis of the (±)-Juvenile Hormone of the Giant Silkworm Moth *Hyalophora cecropia* L.

By *H. Schulz* and *I. Sprung*[*]

The *H. cecropia* juvenile hormone was identified by *Röller et al.*[1,2] as methyl *cis*-10,11-epoxy-7-ethyl-3,11-dimethyl-*trans*-2,*trans*-6-tridecadienoate *(7)*. Since then several syntheses of this insect hormone have been published[3–6]. *Corey*[4], *Johnson*[6], and *Zurflüh*[8] report highly stereospecific reactions, of which the synthesis by *Zurflüh et al.* leads only to 6-ethyl-10-methyl-*trans*-5,*cis*-9-dien-2-one *(4)*. These very elegant procedures, however, require a very considerable number of steps.

We now describe a new synthesis based on the construction scheme $C_4 + C_6 + C_5 + C_2$.

Our synthesis involves three steps for building the C_{17} skeleton, permits the preparation of all eight possible pairs of isomers, and allows variations to be introduced at C-3, C-7, and C-11 of the juvenile hormone. Stereospecific syntheses, on the other hand, do not, of course, allow preparation of the other isomer pairs, nor can other substituents be introduced at all the positions named above.

Our synthesis starts from simple materials. From γ-butyrolactone and ethyl acetate or propionate are prepared two α-acyl-γ-butyrolactones which give the ω-bromo ketones on ketone fission in the presence of hydrogen bromide. The carbonyl group is then protected as ethylene ketal, and the bromo ketals are treated with triphenylphosphine, which gives the triphenylphosphonium salts needed for the first two carbonyl-olefinations.

The phosphorane *(1)* is obtained from the phosphonium bromide and sodamide in liquid ammonia and gives a 69% yield in the Wittig reaction with 2-butanone. According to gas-chromatographic analysis the resulting mixture of *cis-trans*-isomers of the ethylene ketal contains 63% of the *cis*- and 37% of the *trans*-compound; 42% of the *cis*-C_{10} ketal was obtained by distillation through a 100-cm Teflon spinning band column and on hydrolysis with 3 N perchloric acid in tetrahydrofuran and subsequent column chromatography on silica afforded the unsaturated ketone *(2)* in 96% yield.

Treating this ketone with the phosphorane *(3)* [7] in a second Wittig reaction led to a 74% yield of the mixture of C_{15} ethylene ketal isomers, containing equal parts of the *cis-cis*- and the *trans-cis*-compound. Distillation separated 29% of the *trans-cis*-isomer and this was hydrolyzed by perchloric acid in water-tetrahydrofuran to the ketone [8], which was isolated in 92% yield on column chromatography on silica.

On treating the phosphorane *(5)* with the ketone *(4)* in a bomb tube at 175 °C for 17 h [9] under nitrogen we obtained a 76% yield of the C_{17} methyl ester which contained 54% of the desired *trans-trans-cis*-compound *(6)*; 52% [calculated on the isomer mixture *(6)*] of this isomer was isolated on distillation through a spinning band column. Finally the C_{17} ester *(6)* was epoxidized by *m*-chloroperbenzoic acid in ethylene dichloride at 0 °C, whereafter chromatography afforded the juvenile hormone in 43% yield.

The intermediates *(2)*, *(4)*, and *(6)*, and the compound *(7)*, gave correct elemental analyses; their structures were confirmed by IR and NMR spectra and their purity was ascertained by gas chromatography. The structure of *(7)* was also confirmed by its mass spectrum.

In a biological test on *Tenebrio molitor* [10] our material showed activity comparable with that of a sample obtained from *Röller et al.* [11].

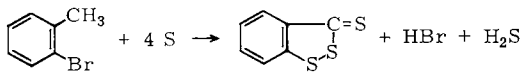
A New Mode of Formation of Sulfur-Containing Heterocycles

By *M. G. Voronkov* and *A. N. Pereferkovich* [*]

Aryl halogenoalkanes can react with sulfur at 200–250 °C to give various types of sulfur-containing heterocycles [1]. We have now found that bromo and iodo derivatives of aromatic hydrocarbons also react with sulfur at temperatures above 180 °C to form primarily diaryl polysulfides:

$$2\,ArX + n\,S \xrightarrow[-X_2]{} Ar\,S_n\,Ar \quad (X = Br, I;\ n \geqslant 2)$$

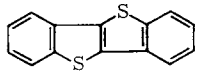


The di- and trisulfides isolated by vacuum distillation are probably partially formed by decomposition of the higher polysulfides.

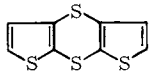
In a few cases copper(II) sulfide, which does not react with aryl halides under the reaction conditions, was used for fixation of the liberated halogen. The presence of free halogen or SBr_2 lowers the yield of diaryl polysulfides.

A mixture of 20.4 g (0.1 mole) of iodobenzene, 1.6 g (0.05 g-atom) of sulfur, and 4.8 g (≈ 0.05 mole) of CuS is boiled (190–200 °C) and stirred for 25 h. The reaction mixture is then diluted with benzene, filtered, and the residue left after removal of the solvent is distilled under vacuum. In addition to 7.5 g of unchanged iodobenzene, 5.0 g of an oily product is obtained which crystallizes out on standing and has a thiophenol-like smell. After recrystallization from *n*-hexane the yield of diphenyl disulfide (m.p. 60–61 °C) is 3.0 g (44% yield referred to reacted iodobenzene).

When a mixture of *p*-bromotoluene (17.1 g, 0.1 mole), sulfur (1.6 g, 0.05 g-atom), and CuS (4.8 g, ≈ 0.05 mole) is boiled for 25 h, di-*p*-tolyl disulfide (m.p. 44–45 °C; lit. [2] m.p. 45 to 48 °C) is obtained. If double the amount of sulfur is added, di-*p*-tolyl trisulfide (m.p. 80–81 °C; lit. [2] m.p. 82 °C) can be isolated from the reaction product.



Sulfuration of *o*-bromotoluene (without CuS) leads to the formation of 3*H*-benzo[*c*]-[1,2]-dithiole-3-thione *(1)*. The



(1)

latter is prepared by boiling a solution of *o*-bromotoluene (17.1 g, 0.1 mole) in *o*-dichlorobenzene (30 ml) with sulfur (32.0 g, 1 g-atom) in the presence of dimorpholine disulfide (0.01 g) for 30 hours. The sulfur that precipitates out when the reaction mixture is cooled is filtered off and the residue left after removal of solvent from the filtrate is distilled under vacuum. An oil, which crystallizes out on standing and has a boiling range 170–210 °C/2 torr, distills over. This is mixed with dimethylformamide and then filtered; the red crystals [2.7 g (15%) of crude substance, m.p. 88–89 °C] obtained after removal of dimethylformamide from the filtrate are then washed with ether. After purification, the crystals melt at 95–96 °C (lit.[2] m.p. 95–98 °C). The intermediate formation of di-*o*-tolyl polysulfides was verified by thin layer chromatography and confirmed by sulfuration of di-*o*-tolyl disulfide, which afforded *(1)* in 7% yield.

Dropwise addition of *o*-bromotoluene to a boiling (230 °C) mixture of sulfur and *o*-chlorobenzene leads to the formation of *(1)* (1%) and of dibenzothieno[3,2-*b*]thiophene *(2)*, which occurs on pyrolysis of *(1)*[3]. After heating compound *(1)* for 5 hours at 260–280 °C, the presence of *(2)* and sulfur could be detected by thin layer chromatography.

(2)

(3)

2-Iodothiophene also reacts with sulfur; however, in this case di-2-thienyl sulfide is apparently formed as primary product alongside the hitherto unknown dithieno[2,3-*b*,3′,2′-*e*]-[1,4]-dithiine *(3)* (m.p. 88–89 °C, *m/e* 228).

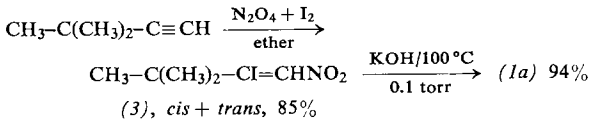
Nitroacetylenes[1]

By *V. Jäger* and *H. G. Viehe*[*]

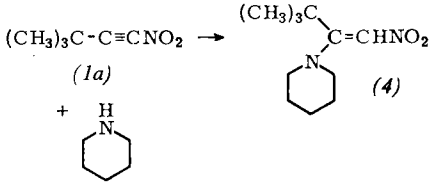


The synthesis of *tert*-butylnitroacetylene [3,3-dimethyl-1-nitro-1-butyne] *(1a)* described in this communication affords, to the best of our knowledge, and contrary to earlier claims[2], the first representative of this class of compounds. In nitroacetylenes, the triple bond is polarized in the opposite sense to that in the reactive ynamines *(2)*[3]. Compound *(1a)* is a greenish-yellow, volatile, lachrimatory liquid having m.p. ~ −3 °C and b.p. ~ 55 °C/15 torr.

(1) *(2)*

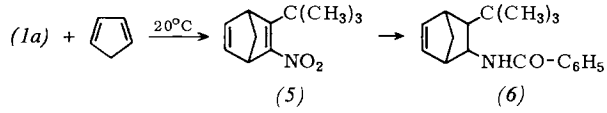
(1a), R = $C(CH_3)_3$

The nitroacetylenes *(1)* promise to be highly reactive as electrophiles, and also as dienophiles and dipolarophiles. Moreover, the combination of an electronegative sp-hybridized carbon with a nitro group suggests such high ground state energy[3] that the thermal stability of these compounds should be limited. Nevertheless, *(1a)* is readily isolable, and can be detonated neither by shock, nor by heating, nor by a glowing wire. Pure *(1a)*, which has a half-life of 2–3 days at room temperature, was synthesized in the gas phase by elimination of hydrogen iodide from 2-iodo-3,3-dimethyl-1-nitro-1-butene *(3)* over solid KOH.



(3), *cis* + *trans*, 85% *(1a)* 94%

Like the main isomer *(3a)*, the mixture of isomers of *(3)* (15:85) obtained in the above reaction (analogous to the case in ref.[4]) gives analytically pure *tert*-butylnitroacetylene *(1a)*[5]. Its IR spectrum is highly characteristic: The strongest bands correspond to the nitro group (ν_{as} = 1512 cm^{-1}, ν_{sym} = 1350 cm^{-1}) and the CC triple bond (ν = 2231 cm^{-1} with a shoulder at 2270 cm^{-1}). NMR signals appear at δ = 1.34 and 0.75 ppm in CCl_4 and in C_6D_6, respectively (TMS as internal reference).



Chemical evidence for the structure *(1a)* comes from the smooth reduction by $LiAlH_4$ in ether to the known compound 3,3-dimethylbutylamine[6].

In spite of its relatively high stability in the pure state, *(1a)* reacts readily with bases; primary and secondary amines add rapidly in dilute solution to give nitro-enamines, and triethylamine forms products of higher molecular weight. In the absence of a solvent this reaction proceeds explosively, the mixture bursting into flames. Piperidine in ether converts *(1a)* into a single isomer of the monoadduct *(4)* [orange-yellow crystals having m.p. 59.5–60 °C] in an exothermic reaction. The latter compound can be reduced by $LiAlH_4$ in ether to the amine, which was isolated as benzamide.

(1a) *(4)*

The exceptional reactivity of *(1a)* as a dienophile – compared to ethyl *tert*-butylacetylenecarboxylate and the corresponding nitrile – is apparent in its reaction with cyclopentadiene. Whereas the other two *tert*-butylacetylene derivatives do not react even over a period of several days, according to gas-chromatographic analysis, *(1a)* yields the norbornadiene derivative *(5)* (yellow liquid, b.p. ~ 50 °C/0.1 torr) quantitatively within two hours. Reduction with $LiAlH_4$ and benzoylation gives the benzamide derivative *(6)*.

(5) *(6)*

On repetition of earlier attempts to synthesize nitroacetylenes[2] bearing ethyl, propyl, and phenyl substituents by removal of HBr from α-bromonitroolefins with primary and secondary amines, we obtained dark, decomposable oils in agreement with the literature. Unlike *(1a)*, however, these products showed no C≡C absorption in their IR spectra and at least four components were detected by thin-layer chromatography. Although elemental analysis gave approxi-

mately fitting results for nitrogen, those found for the other elements deviated strongly from the correct values. Further, our experience with *(1a)* shows that primary or secondary amines cannot be used for the preparation of nitroacetylenes, since they add immediately to the triple bond.

Spectroscopic evidence for the existence of nitroacetylenes having R = C_6H_5 and *n*-C_4H_9 was obtained from attempts at their synthesis.

3,3-Dimethyl-1-nitro-1-butyne (1a)

Compound *(3)* (5.0 g) is distilled slowly (*ca.* 1 g/h), in a manner similar to that employed in a bulb-tube distillation, under a pressure of 0.1 torr through a glass tube (length 30 cm, i.d. 1.5 cm) containing KOH and heated to 100 °C. The contents of the receiver, which is cooled with acetone/Dry Ice, are dissolved in *n*-pentane. The solution is dried over Na_2SO_4 and the solvent is drawn off, leaving 2.35 g (94%) of a pale yellowish green, volatile, strongly lachrimatory liquid having m.p. ~ −3 °C and b.p. ~ 55 °C/15 torr. The NMR spectrum shows a signal at 1.34 (CCl_4) and 0.75 ppm (C_6D_6), and the IR spectrum contains bands at 2967, 2874, 2270, 2231, 1512, 1368, 1350 cm^{-1}. UV spectrum: $\lambda_{max}^{n\text{-hexane}}$ = 238 nm (log ε = 3.9).

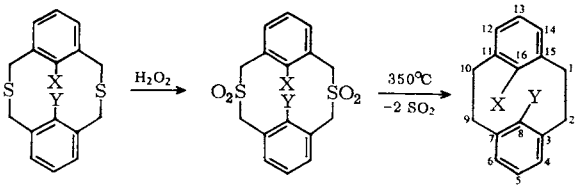
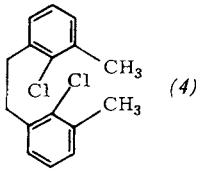
A New Cyclophane Synthesis[1, 2]



By *F. Vögtle*[*]

During ^{1}H–NMR investigations of 1,10-dithia[2.2]metacyclophanes[3] and 1,10-dithia-16-aza[2.2]metacyclophanes[4] carrying substituents in the interior of the ten-membered ring it appeared desirable to compare these compounds with the hitherto unknown [2.2]metacyclophanes of type *(3)*[5], X ≠ Y, that are substituted in an analogous fashion and contain no sulfur. The usual Wurtz synthesis[6] is not suitable for their preparation, since it inevitably affords mixtures of products in the case of unsymmetrical cyclophanes.



We obtained compounds *(3a)–(3d)* as almost colorless distillates that crystallize on solidification by pyrolysis (1–5 h, 350 °C[7]; yield 15–20%[8]) of the disulfones *(2)* prepared from the 2,11-dithia[3.3]metacyclophanes *(1)* and H_2O_2.

It was not possible to detect a monosulfone in which the C–C linkage had already been formed on one side. It is remarkable that only the unsymmetrical [2.2]metacyclophanes *(3b)* and *(3d)* are formed from the unsymmetrical sulfones *(2b)* and *(2d)*; in both cases symmetrical products could not be detected, even in traces (mass spectrometry). Linkage of the fragments therefore occurs exclusively by an intramolecular process.

The [2.2]metacyclophane structure was established for compounds *(3b)–(3d)* by mass spectrometry and proton magnetic resonance. In the ^{1}H–NMR spectrum, both the methylene

(1) *(2)* *(3)*

(4)

	X	Y	*(3)*, M. p. (°C)
(a)	H	H	132–133
(b)	H	F	108–109
(c)	F	F	158–159
(d)	H	Cl	126–127
(e)	Cl	Cl	see text

groups [AA'BB' system for *(3c)*, ABCD system for *(3b)* and *(3d)*] and the internal aromatic protons of *(3b)* and *(3d)* [τ = 5.63 and 6.06, respectively; *(3a)*: $\tau_{H(8)}$ = 5.71; in $CDCl_3$] absorb at characteristically high field strengths.

Under similar conditions, pyrolysis of *(2e)* does not afford 8,16-dichloro[2.2]metacyclophane but leads to a mixture of crystalline products – apparently owing to the mutual steric hindrance of the two "internal" chlorine atoms. The main component of the mixture was shown by mass spectrometry to be compound *(4)*, in which linkage has occurred only on one side; some pyrene was also detected by UV spectroscopy.

The symmetrical starting compounds *(1a)*[9], *(1c)*, and *(1e)* were prepared by reaction of the ω,ω'-dibromo-*m*-xylenes with sodium sulfide in accordance with the dilution principle; the unsymmetrical representatives *(1b)* and *(1d)* are obtained from the disodium salt of ω,ω'-dimercapto-*m*-xylene and ω,ω'-dibromo-2-fluoro- or -chloro-*m*-xylene, respectively, also at high dilution[10].

By means of this ring-contraction method we were able to prepare a number of other sterically hindered or strained ring systems, *e.g.* 2,2''-ethano-*m*-terphenyl[11], [2.2]metaparacyclophane[12], [2.2]paracyclophane, and [2.2.0]metacyclophane.

[11] *F. Vögtle*, Chem. Ber., in press. The compound is formed in quantitative yield.

[12] Pyrolysis of the sulfone is probably the most convenient method of preparation for [2.2]metaparacyclophane at least.

Synthesis of Substituted Cyclopentadienones by Ring Contraction

By *W. Ried, W. Kunkel,* and *P. B. Olschewski*[*]

In attempts to convert 5-alkoxy-3-benzyl-5-hydroxy-2,6-diphenyl-2-cyclohexene-1,4-diones *(3a)* and *(3b)* by an excess of acetic anhydride into the acetyl compounds *(4a)* and *(4b)* and thence by loss of acetic acid into the alkoxy quinones *(6a)* and *(6b)*[1], respectively, gave, not only the expected compound *(4a)* or *(4b)*, but also surprisingly the new, deep red 5-benzyl-3-oxo-2,4-diphenyl-1,4-cyclopentadiene-1-carboxylates *(5a)* [m.p. 158 °C (from methanol); IR spectrum, ν_{CO} = 1720 cm^{-1}; ^1H–NMR spectrum (in $CDCl_3$)[2], τ = 2.5–3.0 (15 H), D; τ = 5.9 (2 H), S; τ = 6.65 (3 H), S] and *(5b)* [m.p. 105 °C (from methanol or ethanol); IR spectrum, ν_{CO} = 1720 cm^{-1}]. Compound *(3a)* or *(3b)* (2.5 mmoles) was heated with acetic anhydride (60 ml), the initial colorless solution becoming deep red; the hot mixture was poured into water.

The mixed products were separated by chromatography on silica gel with benzene as eluant. The yields of *(5a)* and *(5b)* increased monotonically with increasing reaction time. After 6-hours' heating of *(3a)* or *(3b)* in acetic anhydride the yields obtained were 10% of *(5a)* with 64% of *(4a)* [m.p. 168 °C (from light petroleum); ν_{CO} = 1710, 1740 cm^{-1}] or 16.5% of *(5b)* with 61% of *(4b)* [m.p. 127 °C (from light petroleum); ν_{CO} = 1710, 1730 cm^{-1}].

The acetyl compounds *(4a)* and *(4b)* can also be converted into the esters *(5a)* and *(5b)*, respectively, and are thus apparently intermediates. However, it is unlikely that the alkoxy quinones *(6)* are intermediates in production of the five-membered ring compounds as the known compound *(6a)*[1] is not converted into *(5a)* under the above reaction conditions.

For synthesis of the starting materials *(3a)* [m.p. 136 °C (from methanol or light petroleum; ν_{CO} = 1730 cm^{-1}] and *(3b)* [m.p. 150 °C (from ethanol or light petroleum); ν_{CO} = 1720, 1740 cm^{-1}], 3-benzyl-5-hydroxy-2,6-diphenyl-1,4-benzoquinone *(1a)*[1] was converted into *(2a)* [m.p. 149 °C (from methanol); ν_{CO} = 1740, 1750 cm^{-1}] and *(2b)* [m.p. 127 °C (from ethanol); ν_{CO} = 1740, 1750 cm^{-1}], respectively, by bromine or *N*-bromosuccinimide in the presence of methanol or ethanol, respectively, and then debrominated catalytically by hydrogen or by treatment with zinc in glacial acetic acid.

The structures of the esters *(5a)* and *(5b)* were proved by elemental analyses, by IR, ^1H–NMR, and mass spectra, and also chemically, by decarbonylation of the dimethyl acetylenedicarboxylate Diels-Alder adduct[3] of *(5a)* to give trimethyl 6'-benzyl-*p*-terphenyl-2',3',5'-tricarboxylate and by reduction[4] of *(5a)* with zinc and glacial acetic acid to methyl 5-benzyl-3-oxo-2,4-diphenyl-2-cyclopentenecarboxylate.

Alkali-Metal Tetraorganylborates from Triorganylboranes

By *M. A. Grassberger* and *R. Köster*[*]

Tetraorganylborates are of importance for the preparation of organic and organometallic compounds and as analytical reagents[1]. We have found that the alkali-metal tetraorganylborates *(2)–(9)* can be prepared from alkali-metal tetraethylborates *(1)* and triorganylboranes at 130–180 °C in accordance with reaction (a) (cf. Table 1). Presence of solvent is not usually necessary.

$$3\ MB(C_2H_5)_4 + 4\ BR_3 \rightleftharpoons 3\ MBR_4 + 4\ B(C_2H_5)_3 \qquad (a)$$

(1a), M = Li — *(2)–(9)*

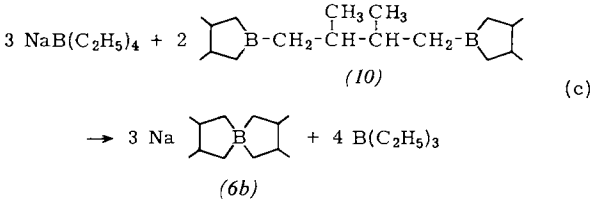
(1b), M = Na

Table 1. Alkali-metal tetraorganylborates MBR_4.

	M	R	Temp. (°C)	Yield (%)	M.p. (°C) [c]
(2b)	Na	Butyloxy	140	100	>350
(3b)	Na	Allyloxy	130	77	>350
(4b)	Na	Crotyl	140	86	130
(5b)	Na	Methallyl	135	85	166
(6b)	Na	[a]	140	91	30
(7a)	Li	Phenyl	180	92 [b]	>350
(8a)	Li	Benzyl	160	70	198
(8b)	Na	Benzyl	140	95	200
(9b)	Na	Pyrrolyl	145	81	>350

[a] *cis-trans* mixture of isomers. See eq. (c) for formula.
[b] Obtained with a 50% excess of BR_3.
[c] All compounds except *(6b)* decompose on melting.

In solution, an equilibrium always sets in. For example, compound *(5b)* reacts with an equimolar amount of triethylborane in dimethyl sulfoxide at room temperature to give trimethallylborane and sodium triethylmethallylborate.



The hitherto unreported sodium tetraallylborates *(4b)* and *(5b)*, as well as sodium tetrabenzylborate *(8b)*, can, in particular, be obtained in good yields from the easily accessible[2] sodium tetraethylborate *(1b)* (m.p. 144 °C). The alkali-metal tetraethylborate can be recovered by reaction of alkali-metal hydride and ethylene with the triethylborane formed at the same time in reaction (a)[2].

Lithium tetraethylborate *(1a)* reacts much more rapidly than does the sodium salt *(1b)*. Whilst, for example, lithium tetraphenylborate *(7a)* can be obtained in good yields by reaction of *(1a)* with excess triphenylborane at 180 °C, reaction with *(1a)* under similar conditions yields practically pure sodium ethyltriphenylborate. In boiling xylene, however, exchange of the last ethyl group for the phenyl residue takes place when the sodium salt is used in the reaction.

With trialkylboranes BR_3 (where $R > C_2H_5$) dehydroboration cannot always be avoided. For example, in the preparation of sodium tetrabutylborate in boiling toluene, compounds with B–H bonds are formed.

$$3\ NaB(C_2H_5)_4 + 4\ B(n\text{-}C_4H_9)_3 \xrightarrow{110\,^\circ C}$$
$$3\ NaB(n\text{-}C_4H_9)_{4-x}H_x + 4\ B(C_2H_5)_3 + 3\ x\ C_4H_8 \qquad (b)$$

With tricyclohexylborane, dehydroboration is the main reaction. In contrast, the borolanyl derivative *(10)* reacts smoothly with *(1b)* to form 2,3,7,8-tetramethyl-5-boraspiro-[4.4]nonane *(6b)* [3].

(5b) is hydrolyzed quantitatively by water. Sodium tetrabenzylborate is stable towards air and water; the slightly soluble potassium tetrabenzylborate precipitates out when $K^{\oplus}$ ions are added in aqueous solution.

Sodium tetrabenzylborate (8b)

On heating 14.2 g (50 mmole) of tribenzylborane and 5.68 g (37.8 mmole) of compound *(1b)* to 140 °C triethylborane (3.6 g) distills off. The residue is boiled in 30 ml of anhydrous benzene and then filtered. 13.65 g of *(8b)* is recovered as residue; the filtrate is then concentrated to *ca.* 5 ml whereupon a further 0.6 g of *(8b)* is precipitated. 14.25 g (95%) of pure *(8b)* is obtained. ^1H–NMR spectrum (dimethyl sulfoxide, *ca.* 30%): τ = 2.95 ppm (S), 8.49 ppm (Q, $J_{11_{B,H}}$ = 5.5 Hz), in the intensity ratio 5:2.

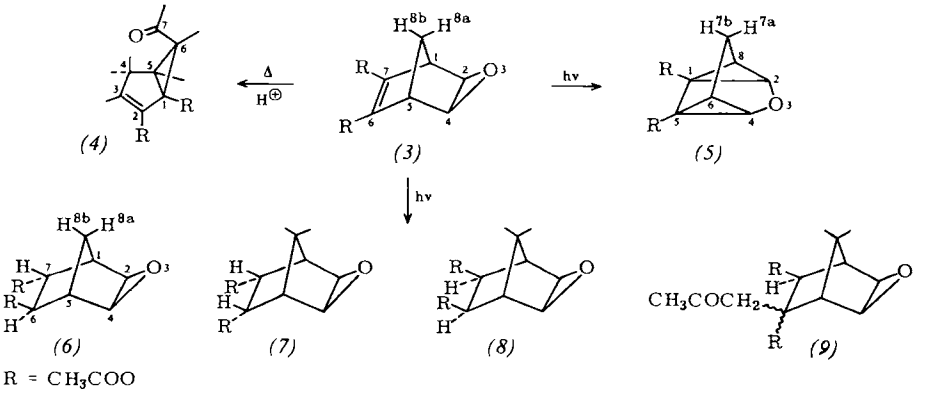
Photochemical Olefin-Oxirane Cyclodimerization[1]

By *H. Prinzbach* and *M. Klaus* [*]



Intramolecular ($2\pi + 2\sigma$) cycloadditions between ethylene and cyclopropane units to give cyclopentane derivatives [*(1a)* → *(2a)*] have been accomplished both photochemically [2] and thermally [3]. Taking compound *(3)* as an example, we shall now show that a corresponding valence isomerization between a CC double bond and an oxirane ring [*(1b)* → *(2b)*] can also be achieved photochemically [4].

(a), X = CH_2, CR_2
(b), X = O

The double bond and the three-membered ring in the *exo*-epoxynorbornene system *(3)*, which is stabilized by the ester groups R [5] and which preferentially undergoes thermal or proton-catalyzed isomerization upon C–O scission to bicyclo[3.1.0]hexenecarbaldehyde *(4)*, are arranged favorably for the valence isomerization *(1b)* → *(2b)* [2b]. On UV irradiation (Hanovia 450 W high pressure mercury lamp, Vycor filter) of an oxygen-free solution of *(3)* in CH_3CN (5.0 g of *(3)* that has been purified by crystallization [6] / 500 ml CH_3CN, −20 °C), the intensity of the absorption maximum at 254 nm decreases only very slowly; after removal of the solvent from the reaction solution obtained on irradiation for about 14 h, 1.4–1.5 g (28–30%) of a mixture of *(5)*, *(6)*, and *(8)* could be isolated by distillation (10^{-3} torr, *ca.* 120 °C). Colorless crystals of *(5)* are obtained when the mixture is seeded with a sample that has been purified by gas chromatography (0.8–1.0 g; 16–20%).

No *(5)* is formed in ether or cyclohexane; a very rapid reaction takes place (5 g/2 h) yielding a mixture (48–52%) of the dihydro compounds *(6)*, *(7)*, and *(8)*, in addition to polymeric material. Nor can *(5)* be detected after irradiation in acetone (Pyrex filter). *(6)* and *(8)* as well as the addition compound *(9)* can be distilled off from the polymeric residue in a total yield of 55%.

[a] Satisfactory elemental analyses were obtained. [b] In ethanol. [c] In CCl_4. [d] NMR spectrum in $CDCl_3$, acetonyl group: τ = 8.0 (S) (3 H), τ = 6.6, 6.9 (AB, J = 18 Hz) (2 H). [e] Partly masked by ester signals; when recorded in $CDCl_3/C_6D_6$, H^7 clearly lies at τ = 6.3 (D) ($J^{7,8a}$ = 1.5 Hz). [f] Partly masked by CH_3O signal (τ = 6.7); when recorded in C_6D_6/CCl_4, H^6 clearly lies at τ = 6.7 (D) ($J^{5,6}$ = 5.8 Hz).

Like the isocyclic system[2b], the tetracyclic ether *(5)* is thermally very stable and does not react with dimethyl acetylenedicarboxylate below 200 °C. When HCl gas is passed into a solution of *(5)* in CCl_4 (0 °C) stereospecific addition of HCl occurs to give *(10)*.

The highly water-sensitive α-halogeno ether *(10)* is converted into the stable acetal *(11)* on treatment with methanol; with water *(10)* immediately forms the lactone *(12)*.

The *exo* position of the epoxide ring in *(3)* is evidenced by $J^{1,2}=J^{4,5}\sim0$ Hz and by the difference in δH^{8a} and δH^{8b} [7]. The photoisomer is shown to have the structure *(5)* by spectroscopic data and by its reaction to form *(10)*, *(11)*, and *(12)*: end absorption in the electronic spectrum; disappearance of the C=C– band (1610 cm^{-1}) and the epoxide band (855 cm^{-1})[8] in the IR spectrum; NMR signals in the intensity ratio 2:2:1:1 (retention of the plane of symmetry) having chemical shifts and coupling constants that agree well with those measured for model compounds[2b,9].

The stereochemistry of the addition of HCl is apparent from $J^{5,6}$ [10], $J^{4,5}$, and from the M-coupling $J^{4,8b}$ in the spectrum of *(10)*. The absence of this M-coupling in the spectrum of *(11)* and the formation of the lactone *(12)* confirm that inversion occurs during substitution to form *(11)*. The structures of the co-products *(6)*, *(7)*, *(8)*, and *(9)* were determined mainly from NMR data; in the case of compound *(9)* the stereochemistry at C-6 is not clear.

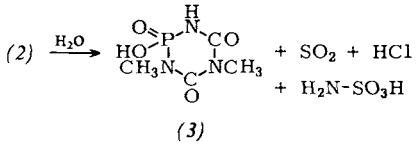
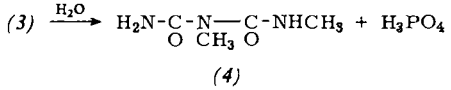
Synthesis of a Derivative of 6-Thia-2-phosphonia-1,3,5,8-tetraazabicyclo[2.2.2]oct-4(5)-ene Chloride[1]



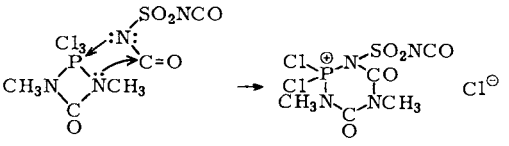
By *H. P. Latscha* and *W. Klein*[*]

During our investigations of the reactions of phosphorus compounds with isocyanates, we have synthesized the compound 2,2-dichloro-3,8-dimethyl-6,6,7-trioxo-6-thia-2-phosphonia-1,3,5,8-tetraazabicyclo[2.2.2]oct-4(5)-ene chloride *(2)* from 1,1,1-trichloro-2,4-dimethyl-1,2,4-phospha(v)-diazetidin-3-one *(1)* and sulfuryl diisocyanate.



(1) *(2)*

Compound *(2)* is colorless, extremely sensitive to water, and decomposes above 132 °C with evolution of gas. It is soluble in cold nitromethane, from which it may be precipitated in well formed crystals by addition of anhydrous benzene. The ^{31}P–NMR spectrum of a nitromethane solution of *(2)* contains a signal at −44.5 ppm (85% aqueous H_3PO_4 as external reference). The ^1H–NMR spectrum consists of a singlet (δ = 3.81 ppm) and a doublet (δ = 3.56 ppm), in the intensity ratio 1:1, that can be assigned to two nonequivalent methyl groups. The splitting of the doublet is caused by the coupling of the protons of a methyl group with the phosphorus nucleus (J_{PH} = 11.1 ± 0.2 Hz).



(3)

(4)

Compound *(2)* reacts with water to give 1-hydroxy-2,4-dimethylperhydro-1,2,4,6-phospha(v)-triazine-1,3,5-trione *(3)* and 1,3-dimethylbiuret *(4)*, which were both characterized by their mass numbers.

During the formation of *(2)*, the isocyanate molecule is observed to react in two different ways: one isocyanate group of the sulfuryl diisocyanate reacts with *(1)* to give the non-isolable species *(2a)*. Previous experiments have shown that the isocyanate group is inserted between the phosphorus atom and the nitrogen atom[3,4].

(1) *(2a)*

The formation of a phosphonium salt is indicated by the negative value of the chemical shift of the phosphorus nucleus[3,5].

The second isocyanate group of the sulfuryl diisocyanate reacts with the carbonyl group of *(1)* with elimination of CO_2.

Preparation of compound (2)

A solution of sulfuryl diisocyanate[7] (15 g, 0.1 mole) in benzene is added dropwise, with stirring, to an ice-cooled solution of *(1)*[6] (22.5 g, 0.1 mole) in anhydrous benzene; an exothermic reaction soon sets in with vigorous evolution of gas. After about 2 hours' stirring at room temperature, a white crystalline precipitate of *(2)* is formed in almost quantitative yield. The product can be purified by recrystallization from nitromethane/benzene.

A New Synthesis of Thioformamide

By *R. Tull* and *L. M. Weinstock*[*]

We wish to report the synthesis of thioformamide *(1)* from hydrogen cyanide and hydrogen sulfide. This versatile intermediate for the synthesis of thiazoles has been prepared heretofore by the reaction of formamide with phosphorous pentasulfide[1,2] and by treatment of dithioformic acid with ammonia[3], methods which have not achieved economic significance. Many higher homologs of thioformamide have been prepared from the corresponding nitriles and hydrogen sulfide[2,4], but there is no record of the application of this reaction to hydrogen cyanide, the simplest member of the series. Indeed, previous attempts to effect this reaction in the gas phase or in aqueous solution were unsuccessful[5,6].

(1)

The use of ammonia and tertiary amines has provided yields of thioformamide in the range of 50–70%. No thioformamide was detectable when strong base catalysts such as sodium methoxide were employed, presumably because of the more rapid polymerization of hydrogen cyanide under these conditions. The reaction of hydrogen cyanide and hydrogen sulfide can be conducted in either nonaqueous protic or aprotic solvents under 13–17 atm hydrogen sulfide pressure at room temperature or at 50 °C. The simplicity of the reaction allows the synthesis of thiazoles without isolation of thioformamide.

For example, hydrogen cyanide (4.0 ml, 0.1 mole) and then triethylamine (0.7 ml, 0.005 mole) are added to 30 ml of benzene at 5–10 °C. The mixture is saturated with hydrogen sulfide at 13–17 atm in a bomb and shaken for 16 h at 20 °C. The mixture can be assayed by removal of the benzene and measurement of the thioformamide content by UV spectroscopy [λ_{max} (CH_3OH) = 263 nm (ε = 12500)]. In the above example the yield by assay is 50%. When 0.1 mole of triethylamine is used the yield by assay is 70%.

Treatment of the benzene solution with 10 ml (0.12 mole) of chloroacetone (after removal of the hydrogen sulfide by partial evaporation) under reflux for one hour provided 4-methylthiazole in 53% yield.

Thioformamide could be isolated in 40% yield from a reaction of hydrogen cyanide (0.1 mole) and an excess of hydrogen sulfide in presence of 0.1 mole of ammonia in methanol solution. The isolated thioamide was converted into 4-methylthiazole in 85% yield.

[6] The reaction of potassium cyanide with hydrogen sulfide in aqueous solution forms 5-aminothiazole-2-thiocarboxamide [5] (chrysean). We have repeated this reaction and have confirmed the proposed structure of chrysean.

A New Method for the Preparation of Organomagnesium Compounds of Pyridine[1]

By *H. H. Paradies* and *M. Görbing* [*]

Pyridylmagnesium compounds may be prepared by simultaneous addition of ethyl bromide and halogenopyridine to magnesium[2]; they react analogously to Grignard compounds[3,4].

In order to elucidate the reaction mechanism and the structure[5] of this class of compounds we treated halogen derivatives of pyridine with phenylmagnesium bromide or iodide in anhydrous polar solvents.

The reaction that occurs proceeds neither by a normal addition-elimination mechanism[6,7] in the case of 2-bromopyridine, nor by an elimination-addition mechanism[7,8] in the case of 3-halogenopyridine. Gas chromatography of the hydrolysis products of the pyridylmagnesium bromide or iodide, which is formed in high yield during the reaction, failed to establish the presence of 2-phenylpyridine or 3- or 4-phenylpyridine. It is essential for the success of the new preparation that the products be insoluble in the organic solvents.

Typical procedure for the preparation of 2-pyridylmagnesium bromide:

3-Chloropyridine (2 mmole) is dissolved in anhydrous ether (THF) (30 ml) under purified nitrogen. An ethereal (or THF) solution of phenylmagnesium bromide (10 ml, 40%) is then added over a period of 10 min. Reaction starts immediately and is complete within 15 min. The finely crystalline product is collected on a glass filter (1 G 2), dried over $CaCl_2$ in a stream of N_2, and stored under N_2. The corresponding reactions with phenylmagnesium iodide do not give such good yields:

Hal-C_5H_4N	Yield (%) [9] X = Br	I	Solvent X = Br	I
2-Cl-	85	60	ether	
3-Cl-	80	60	ether	
4-Cl-	63	40	THF	
2-Br-	90	60	THF	THF, ether
3-Br-	95	60	THF	THF, ether
4-Br-	70	31	THF	

In contrast to the products obtained according to ref.[3], the white crystalline pyridylmagnesium bromides and iodides prepared by the above procedure are odorless. They do not melt below 350 °C and are insoluble in anhydrous solvents. The substances react with benzaldehyde to give the corresponding secondary alcohols which were characterized by their melting points.

The *d* values calculated from Guinier photographs and results of analysis clearly show that the compounds prepared in the above manner are identical with those synthesized by the method of *Proost* and *Wibaut*[4].

Heptavalent Plutonium

By *C. Keller* and *H. Seiffert* [*]

Krot and *Gel'man*[1] recently obtained evidence for the existence of heptavalent neptunium by oxidation of Np^{VI} with ozone in alkaline solution and were later able to confirm this finding by use of other oxidizing agents[2]; we then succeeded in preparing Li_5NpO_6, the first crystalline compound containing Np^{VII}[3]. Similar investigations also pro-

vided indication of the existence of plutonium having oxidation numbers in excess of +6[3]. We have now been able to obtain pure pentalithiumplutonium(VII) hexoxide, Li_5PuO_6.

Preparation of Li_5PuO_6:

A finely powdered mixture of Li_2O and PuO_2 (*ca.* 3:1; an excess of Li_2O has been found necessary) is heated slowly ($\approx$ 6 °C/min) in a stream of pure oxygen to 430 ± 10 °C and kept at this temperature until no further increase in weight can be detected (*ca.* 2 h); regarding the weighing procedure see reference[4]. Typical quantities: 83.51 mg Li_2O + 252.46 mg PuO_2 (Li:Pu = 5.95:1) ——Δm at 430 °C (*ca.* 2 h, $p(O_2)$ = 1 atm): 22.40 ± 0.1 mg; these data afford a valency of 6.98 ± 0.02 for the plutonium.

The X-ray diffraction pattern of the greenish-black Li_5PuO_6 shows the lattice to be hexagonal with $a = 5.19 \pm 0.02$ Å and $c = 14.48 \pm 0.02$ Å [space group $R\bar{3}$ (?), $d_{X\text{-ray}}$ for $Li_5{}^{239}PuO_6$ = 3.53 g/cm³]. Li_5PuO_6 is isotypic with the analogous compounds of Np^{VII}[3], Tc^{VII}[5], and Re^{VII}[6]. The ternary oxides $Li_6M^{VI}O_6$, $Li_7M^{V}O_6$, $Li_8M^{IV}O_6$ probably also have the same crystal structure, as was first established by *Scholder*[7]. However, plutonium is the first element to occur in all four types of compounds[8–10]. It is therefore not surprising that only one phase, *i.e.* a solid solution of Li_6PuO_6 and Li_5PuO_6, is observed with partially oxidized samples in which the plutonium has a mean oxidation number between +6 and +7 (cf. ref.[8,9]). An accurate crystal-structure determination of compounds of the type Li_xMO_6 has been carried out by *Trömel* and *Hauck* with Li_8SnO_6[11].

Since both Re^{VII} and Tc^{VII} form ternary oxides with alkali and alkaline-earth metals, corresponding compounds of heptavalent plutonium should also be preparable. This is indicated qualitatively, *e.g.*, by the fact that the products of the reaction $Na_2O_2 + PuO_2 + O_2$ (400 °C) show the typical absorption spectrum of Pu^{VII} on dissolution in water.

Li_5PuO_6 dissolves in water and in LiOH solutions to give a green coloration. Such solutions are not stable and are quantitatively converted into yellow solutions of Pu^{VI} within 2–3 min, the rate of reaction being inversely proportional to the concentration of LiOH. It may be concluded from qualitative observations on plutonium in dilute LiOH solution[8] that two absorption bands at 400–410 nm and 620–630 nm, respectively, are to be assigned to Pu^{VII}. Oxidation of Pu^{VI} to Pu^{VII} in LiOH solution can be performed by addition of $K_2S_2O_8$ to the hot solution. Like Np^{VII}, Pu^{VII} is stable only in alkaline solution; reduction to Pu^{VI} occurs immediately on acidification.

Mechanism of Oxidative Dimerization of Aminobenzenes[1]

By *F. Effenberger, W. D. Stohrer*, and *A. Steinbach*[*]

Compounds of type *(3)*, which hitherto have not been isolated[2], are postulated as intermediates in the oxidative dimerization of *N,N*-disubstituted anilines.

We have been able to prepare the red σ-complexes *(3)* in the crystalline state [UV absorption of *(3a)* in C_2H_5OH: λ_{max} = 431 nm, ε = 12800; λ_{max} = 346 nm, ε = 41000] by oxidation of symmetrical triaminobenzenes *(1)*[3]; on reaction with bases, these complexes afford the hexaaminobiphenyls *(4)*.

	—R—R—	R^1	X	(3) M.p. (°C)	(3) Yield (%)	(5) M.p. (°C)	(5) Yield (%)
(a)	$-(CH_2)_4-$	H	CBr_5	177–178	33	—	—
(b)	$-(CH_2)_4-$	H	ClO_4	254–256	91	200 to 201	93
(c)	$-(CH_2)_4-$	CH_3	ClO_4	158–159	82	—	—
(d)	$-(CH_2)_4-$	C_2H_5	ClO_4	123–127	96	—	—
(e)	$-(CH_2)_5-$	H	ClO_4	215–216	56	—	—
(f)	$-(CH_2)_2-O-(CH_2)_2-$	H	I_3	140–145	2.5	—	—

The oxidation was carried out at room temperature with silver salts in dimethylformamide and with tetrahalogenomethanes, cyanogen halides, or halogens in dichloromethane. The salts *(3)*, whose structure has been established by elemental analysis, molecular-weight determinations and ^{1}H-NMR spectra [*(3b)* in liquid SO_2: H_α = singlet at τ = 5.03, H_β = singlet at τ = 5.67] are obtained in good yields.

Noteworthy is the occurrence of a stable $CBr_5^\ominus$ anion in the reaction of 1,3,5-tripyrrolidinobenzene with CBr_4 in dichloromethane. No CBr_4 is liberated from *(3a)* by extraction with ether for several days. Compound *(3a)* is formed smoothly from *(3b)* by treatment with alcoholic sodium perchlorate solution. The structure of $CBR_5^\ominus$ is at present being investigated.

On warming or on being allowed to stand in polar solvents the dimers *(3)* dissociate into the radical cations *(2)*, which abstract H from the solvent to form compounds *(6)*[4,5]. The tendency to dissociate is far greater in the case of the alkyl-substituted derivatives *(3c)* and *(3d)* than in the case of *(3b)*.

The radical cations *(2)*, which are obviously not very stable, cannot be detected by ESR spectroscopy[6]. Evidence of their intermediate formation is, for example, formation of a green salt in the oxidation of *(1)*, R–R = $(CH_2)_4$, R^1 = H, in the presence of atmospheric oxygen to which we ascribe the structure *(5)* on the basis of elemental analysis, molecular-weight determination, and spectroscopic data [UV absorption in CH_3OH: λ_{max} = 627 nm, ε = 3300, λ_{max} = 431 nm, ε = 10680; ^{1}H-NMR spectrum in $CDCl_3$: H_α = singlet at τ = 4.69; IR absorption: ν(C=O) = 1700 cm^{-1}. Chemical proof of the structure of *(5)* has yet to be carried out.

Experimental:

a) *1,1'-Bi(2,4,6-tripyrrolidinocyclohexadienylium) pentabromocarbonate (3a)*

CBr_4 (19.9 g) is added to a solution of 1,3,5-tripyrrolidinobenzene (8.56 g) in dichloromethane (50 ml) cooled to −5 °C. The reaction mixture immediately turns deep red. The solvent is subsequently distilled off under vacuum, and the oily residue is dissolved in 30 ml of hot chloroform and filtered. After a short time 6.8 g (33%) of brick-red crystals, m.p. 176–177 °C, precipitate, which can be recrystallized (m.p. 177–178 °C) from chloroform.

b) *1,1'-Bi(2,4,6-tripyrrolidinocyclohexadienylium) perchlorate (3b)*

Pulverized $AgNO_3$ (1.7 g) is added with stirring to a suspension of 1,3,5-tripyrrolidinobenzene (2.85 g) in dimethylformamide (15 ml) under pure nitrogen at −5 °C. The deep-red reaction mixture is stirred for 10 min, filtered, and the filtrate added dropwise to 100 ml of ether. An oil separates which crystallizes on rubbing. The crystalline paste is filtered by suction, and the recovered solids are dissolved in 100 ml methanol and treated with 20 ml of a saturated aqueous $NaClO_4$ solution. Compound *(3b)* precipitates as brick-red crystals (yield 3.5 g (91%); m.p. 254–256 °C).

Investigation of Superadditivity in Photographic Development by Current-Voltage Curves at a Silver Electrode

By *M. Brezina, W. Jaenicke*, and *H. Raithel*[*]

Mixtures of certain developers give rise to higher rates of development than the pure components (referred to the same overall molar concentration). This phenomenon, which is called superadditivity, has hitherto been investigated on the basis of measurements of the increase in density with time during the development; a complete elucidation has not yet been presented.

Since the effect also occurs on physical development of silver grains[1,2], to which the electrode theory of photographic development applies, an investigation by electrochemical methods should be possible[2]. We have studied the systems hydroquinone/1-phenyl-3-pyrazolidone (Phenidone®) and hydroquinone/*p*-methylaminophenol (metol)[3] at a stationary silver disk electrode in phosphate-, borate-, or carbonate-buffered solution in the pH range between 8 and 11.3 with and without the addition of sulfite. The current-voltage curves were recorded with a Radiometer PO4 polarograph at 400 mV/min from negative to positive potential and also in the reverse direction.

Phenidone is found to be an almost reversible redox system with a transfer of one electron per molecule, also in the presence of SO_3^{2-}. Hydroquinone is oxidized irreversibly, its overvoltage being dependent on electrode pretreatment; it decreases with the pH and increases considerably in the presence of sulfite and/or gelatine (up to 200 mV). Even the addition of very small amounts (1%) of phenidone to hydroquinone reduces the overvoltage. The height of the wave is therefore increased until hydroquinone behaves almost reversibly as the amount of phenidone increases. Even with very small concentrations of phenidone no kinetic wave of phenidone occurs. Regeneration of phenidone by hydroquinone in homogeneous phase can therefore be excluded as a cause of superadditivity. The catalytic activity of the additive must therefore be due to a heterogeneous process. Perhaps specifically adsorbed phenidone is acting as electron-transferring agent.

Metol behaves similarly to phenidone.

Acceleration of development by phenidone by addition of hydroquinone cannot be interpreted in terms of such a process. In this case it should be borne in mind that whereas phenidone is oxidized in a one-electron step, hydroquinone in the presence of sulfite can contribute four electrons per molecule; consequently, acceleration can also be observed here when phenidone is partially replaced by equimolar quantities of hydroquinone.

1,1,3-Trimethylisopropylindenium Tetrachloroaluminate

By *M. Strohmeyer, K. H. Hiller*, and *K. Witte*[*]

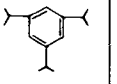
In the propylation of a technical aromatic mixture in the presence of $AlCl_3$/HCl we have obtained 1,1,3-trimethylisopropylindene *(1)*[1] which forms 1,1,3-trimethylisopropylindenium tetrachloroaluminate *(2)* on reaction with $AlCl_3$ and HCl.

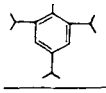
The structural determination of *(1)* and *(2)* has been largely confirmed by the NMR spectrum, from which, however, the

position of the isopropyl groups cannot be established [*(1)*: δ = 1.60 (H_a), S; 1.60 (H_b), D (J_{bd} = 7 Hz); 2.35 (H_c), D (J_{ce} = 1.4 Hz); 3.25 (H_d), sept.; 6.22 (H_e), Q; 7.42 ppm (H_f), S; *(2)*: δ = 2.10 (H_a), S; 1.97 (H_b), D; 3.96 (H_c), S; $\approx$3.8 (H_d), M; 4.42 (H_e), S; 8.42 (H_f), M; 9.13 ppm (H_f), D (J_{vic} = 9 Hz), (TMS external standard)]. Oxidation of *(1)* with chromic acid, however, leads to the formation, among other things, of terephthalic acid[2] provided that *(1)* is substituted in the *p*-position (*i.e.* on C-5 or C-6).

Reaction of indene with $AlCl_3$ and HCl does not lead to a definite complex but to polymers only. Assuming that the isopropyl group occupies position 6 in *(2)*, the formation of polymers is ascribed to the positive charge in both important boundary forms being localized on the tertiary C-atom, whilst an indenium ion shows secondary C-atoms in the corresponding positions. Moreover, the substituents can take on partial charges.

The complex *(2)* is extraordinarily stable and exhibits interesting properties as a Friedel-Crafts catalyst. We have investigated the transalkylation and the isopropylation in the presence of $AlCl_3$/HCl as well as of *(2)* at 25 °C. 99% 1,2,4-triisopropylbenzene was used for the transalkylation which, with benzene (molar ratio 1:2) mainly disproportionates to cumene, *m*- and *p*-diisopropylbenzene, as well as to 1,3,5-triisopropylbenzene. The concentration of free $AlCl_3$ and of that present in *(2)* is 0.75%.





In contrast to $AlCl_3$/HCl, which consumes 1,2,4-triisopropylbenzene within an hour, the complex *(2)* shows practically no transalkylation properties. In the isopropylation of toluene and cumene under normal conditions (Table 1) the isomeric distribution of the main product is very much different in the presence of each of the two catalysts.

In experiments 1 and 3, as well as in 2 and 4, however, the *para- : meta-* ratio agrees very well. Further, it is worthy of note that we could not obtain essentially higher *p*-diisopropylbenzene and *o*-cymene values in other catalyst systems with degrees of propylation of 0.27 or 1.26. The results show that *(2)* is a much weaker isomerization catalyst than $AlCl_3$/HCl on account of its lower acidity.

1,1,3-Trimethylisopropylindenium tetrachloroaluminate (2)

8 parts by weight of propene and 30 parts by volume of HCl are added to 215 parts by weight of a technical aromatic mixture (benzene 8 parts, cumene 78 parts, *m*-diisopropylbenzene 8 parts, *p*-diisopropylbenzene 4 parts, triisopropylbenzene 2 parts) at 50–70 °C in presence of 0.5 parts by weight of $AlCl_3$. 200 g of the lower phase of the reaction mixture is treated with water; the fraction boiling below 240 °C is distilled from the organic phase. The residue is cooled to 0 °C and the crystals which separate out are filtered off and dissolved in 120 g of methanol with warming. On cooling 52 g of *(1)* (m.p. 50–51 °C) separates out. – 60 g (0.3 mole) of *(1)* is dissolved in 250 g of hexane. About 15 l of HCl is introduced per hour and 40 g (0.3 mole) of sublimed $AlCl_3$ is added slowly with vigorous stirring within 75 min at a temperature of 35–40 °C. On completion of reaction, 109 g (88%) of compound *(2)* (m.p. 78–80 °C) crystallizes out.

Coordination Chemistry

The first part of the Eleventh International Conference on Coordination Chemistry, which was sponsored by IUPAC, took place at Haifa (Israel) on September 8–12, 1968. For the first time, various selected topics were treated in plenary symposia. In this way specialized branches of research were introduced to a relatively large number of participants. An introductory lecture was followed by four papers concerned with characteristic facets of the subject, thus providing a basis for a general discussion amongst the 450 scientists (representing 30 countries) who were present.

1. Coordination Compounds in Homogeneous Catalysis

Complex compounds of transition metals occur as catalytically active intermediates in numerous processes, including some of considerable technical importance (*e.g.* hydrogenation, oxidation, polymerization, carbonylation). A number of factors responsible for the versatility of such catalyst systems were indicated in an introductory lecture by *J. Halpern* (Chicago, USA). Thus, the central metal atom may be capable of stabilizing reactive intermediates inside the coordination sphere. By way of contrast, stable molecules can be "promoted to an excited state" by coordinative bonding to the metal: an activation of this kind is assumed to occur, for example, with σ-bonded hydride or alkyl ligands, as well as with π-bonded olefins, allyl systems, or aromatic compounds. Pre-orientation of ligands in a manner specific for a particular reaction or rearrangement can occur within the coordination shell of the metal. Moreover, the metals of Group VIII are also capable of alternately adopting different oxidation numbers and of varying their number of coordinatively bound ligands.

L. Vaska (Potsdam, N.Y., USA) reported on the reversible activation of covalent molecules (H_2, O_2, SO_2, CO, C_2H_4) by addition to *trans*-$[P(C_6H_5)_3]_2Ir(CO)Cl$. The kinetic and thermodynamic data for this reversible addition in a homogeneous phase differ characteristically from those for the adsorption of a gas onto solid metal surfaces. – According to *P. Heimbach* (Mülheim/Ruhr, Germany), the central metal atom can also serve as a "template" in organic synthesis. Coupling of two butadiene molecules within the coordination sphere of nickel(0) leads to a C_8 chain, bound to nickel, which can be converted into *cis,cis*-1,5-cyclooctadiene or 1,3,7-octatriene, depending on the reaction conditions and on the concentration of additional donor ligands (amines, tertiary phosphines, or phosphites), or into 10- or 12-membered ring systems by addition of further unsaturated hydrocarbons.

The significance of homogeneous catalysis in biochemical systems was referred to by *G. L. Eichhorn* (Baltimore, USA). Biological macromolecules (proteins, porphyrin systems, nucleic acids) surround the metal ion, functioning as multidentate ligands, and often induce a high and specific reactivity at a particular coordination position of the complex.

The investigation of homogeneous hydrogenation continues to occupy a focal point of catalyst research, and a number of new catalyst systems for this reaction were presented at Haifa. Decarbonylation of organic carbonyl compounds (aldehydes, acid chlorides, acid anhydrides) by means of rhodium(I) compounds of the kind $[P(C_6H_5)_3]_3RhCl$ is becoming more and more important. Papers dealing with molecular nitrogen as a ligand in transition metal complexes were received with particular interest. *A. D. Allen* (Toronto, Canada) gave a review of metal compounds containing the grouping M–N≡N. It appears that the ruthenium(II)-pentammine system is particularly able to take up molecular nitrogen; however, N_2 complexes of Fe, Co, Ni, Os, and Ir have also been prepared. Since the coordinatively bound nitrogen cannot simply be reduced to NH_3, the technically interesting conversion of atmospheric nitrogen into ammonia remains distant music in spite of the biological example of nitrogen-reducing enzymes. According to *J. Chatt* (Brighton, England), experiments with isotope-enriched nitrogen show that even in the case of the "classical" example $[Ru(NH_3)_5N_2]^{2+}$ the hitherto assumed partial hydrogenation of the N_2 ligands by tetrahydridoborates cannot be reproduced.

2. Photochemistry in Coordination Compounds

A. W. Adamson (Los Angeles, USA) listed the possible reactions of photochemically excited complex molecules. Irradiation in the frequency range of ligand-field transitions (d→d) generally leads to substitution processes within the coordination shell, without any change in the type of complex or in the oxidation number of the central metal atom. On the other hand, excitation of the intense charge-transfer transitions in the near ultraviolet often promotes a redox process between the metal and ligand system, as for example with Co^{III} or Cr^{III}. In addition, spin-forbidden transitions can also play a role; it often appears that one and the same reaction can start from more than one excited state.

A. D. Kirk (Victoria, Canada) reported the influence of Cr^{III} complexes on the formation of I_3^- during photolysis of iodide solutions. In the reaction, the coordination compound undergoes intermediate reduction to Cr^{II} by acceptance of a hydrated electron; the actual oxidizing agent for the iodide ion is dissolved oxygen, which acts *via* secondary formation of chromium peroxide compounds or H_2O_2. *L. E. Orgel* (San Diego, USA) presented a model system in which $[Fe(CN)_6]^{4-}$ first oxidizes to $[Fe(CN)_6]^{3-}$ on ultraviolet irradiation and then is cleaved to 1/2 $(CN)_2$ and $[Fe(CN)_5(H_2O)]^{3-}$ in the presence of visible light; the resulting cyanogen may play a role in the phosphorylation of nucleosides. – Finally, *D. Valentine jr.* (Princeton, USA) described the photolytic cleavage of paramagnetic μ-peroxodicobalt(III) compounds of the type $[(NH_3)_5Co{-}O_2{-}Co(NH_3)_5]^{5+}$ and $[(NH_3)_4Co{-}(O_2, NH_2){-}Co(NH_3)_4]^{4+}$. These dinuclear complexes disproportionate in ultraviolet light to give O_2 and an equimolar mixture of octahedral Co(II) and Co(III), coordinatively unsaturated fragments such as $[Co(NH_3)_5]^{3+}$ being formulated as intermediates.

3. Kinetics and Mechanism of Reactions of Coordination Compounds

The last of the "Plenary Symposia" was opened by *M. Eigen* (Göttingen, Germany) with a lecture on the stability and dynamics of many complexes involving ions of the main groups in inert-gas configurations, which play a part in biological mechanisms of transport and activation. The competing complex formation of these ions often shows specific differences in formation- and rate constants, which are exploited in Nature, as, for example, with the pairs Mg^{2+}/Ca^{2+} and Na^+/K^+. *G. Schwarzenbach* (Zürich, Switzerland) went into investigations on the deprotonation of hydrated metal cations and subsequent condensation to multinuclear complexes which characterize the first steps of a neutralization reaction (with NaOH). It proved possible to obtain excellent pK_1 values in a number of cases (Be^{2+}, Cr^{3+}) by means of rapid pH measurements. – The rate of chelate formation

with diamine ligands, the subject of the paper presented by *J. Bjerrum* (Copenhagen, Denmark), was also determined with the aid of pH measurements. In the *trans*-$[(NH_3)-PtCl_2-NH_2(CH_2)_nNH_2]$ system, the stable five-membered ring incorporating ethylenediamine ($n = 2$) is formed about 100 times as fast as the corresponding six-membered ring with trimethylenediamine ($n = 3$).

M. Anbar (Rehovot, Israel) reported on the reaction of a large number of transition metal complexes with hydrated electrons. The rate of this process depends on the nature and on the oxidation number of the central metal atom, as well as on the ligands; in many cases the process is diffusion controlled. Since the activation energy invariably lies below 4 kcal/mole, a tunnel mechanism was suggested for the transfer of the electron to the central metal atom.

The second part of the Eleventh ICCC took place on September 16–18, 1968, at Jerusalem. The subjects dealt with were: Coordination compounds in solvent extraction (in conjunction with the 5th International Conference on Solvent Extraction Chemistry), and coordination compounds in non-aqueous solvents.

4. Coordination Compounds in Non-aqueous Solvents

A. I. Popov (East Lansing, Mich., USA) reported on IR-spectroscopic investigations of alkali metal and ammonium salts in various solvents (dialkyl sulfoxides, 2-pyrrolidone derivatives, tributyl phosphate, pyridine). In all cases a band was observed between 450 and 200 cm^{-1} whose frequency is characteristic of the cation and of the solvent but not of the anion. The extinction of this band is proportional to the concentration of the cation and independent of the concentration of anions. Solid solvates of alkali metal salts with dimethyl sulfoxide (DMSO) of various stoichiometric ratios (1–4 moles of DMSO per metal ion) exhibit spectra similar to those of the corresponding solutions. It is concluded that the observed band is due to the vibration of the solvated cation in the solvent cage. NMR investigations on lithium salt solutions in DMSO indicate the existence of a definite solvate $Li(DMSO)_2^+$ whilst in the case of sodium and ammonium salts, although there is considerable interaction with the solvent, no definite stoichiometry is indicated.

The donor number (DN) introduced by *V. Gutmann* (Wien, Austria) affords a measure of the solvent properties of a donor solvent. It is defined as the negative reaction enthalpy for the reaction between a donor solvent and antimony pentachloride in the gas phase. The ability of the solvent to ionize dissolved salts increases with increasing donor number, while the formation of complex compounds with competing ligands becomes more difficult. This relationship has been studied by means of the formation of halogeno- and pseudohalogeno complexes of divalent cobalt of the type $[CoX_4]^{2-}$ ($X^- = Cl^-$, Br^-, I^-, NCS^-, N_3^-) in various solvents.

The formation of mixed cadmium-nitrate-halide complexes by addition of a cadmium halide to a eutectic lithium nitrate/potassium nitrate melt was discussed by *M. Zangen* (Yavne, Israel) who studied the distribution of cadmium between the salt melt and a eutectic polyphenyl mixture at 150 to 200 °C. From the measurements it was concluded that the melt contained all the species of the type $[CdX_n(NO_3)_{4-n}]^{2-}$ (X = Cl, Br, I; $n = 0,1,..,4$), of which only the dihalide ($n = 2$) – after loss of the two nitrate ions – can distribute between the two phases. Further, it was shown that the complex $[CdXX'(NO_3)_2]^{2-}$ which forms on addition of two halide ions is considerably more stable than the corresponding zinc or mercury complex.

5. Solvent Extraction: Fundamental Studies

Extraction of metals by organic compounds has frequently been used to gain information concerning the complexes present in the aqueous or in the organic phase. In such investigations the dependence of the distribution coefficient on the concentration of the extractant and of the anions in the aqueous phase is followed. However, a lecture by *Y. Marcus* (Jerusalem, Israel) on "mass action law and non-ideality in solvent extraction systems" pointed out that much care is needed in the interpretation of such data. For example cryoscopic and osmometric studies show that dialkyl hydrogen phosphates, $(RO)_2P(O)OH$, dimerize in organic solvents *via* hydrogen bonding. In the case of sulfonic acids, such as dinonylnaphthalenesulfonic acid, association to even higher aggregates is observed. Long chain alkylammonium salts are likewise associated in nonpolar organic solvents, and to some extent dimerization is even observed with neutral phosphoric acid esters such as tributyl phosphate. An increase in the concentration of the extractant often leads to a change in the polarity of the organic phase. Variation of the composition of the aqueous phase can lead to a change in the water activity and as a consequence to a change in the concentration of the water extracted into the organic phase. The same is true for the extraction of acids by the extractant. In view of these many deviations from ideal behavior the question which now in fact remains open is: why does the partition coefficient so frequently vary with an integral power of the concentration?

A number of communications were concerned with studies on the association of long chain alkylammonium salts in nonpolar solvents. *E. Högfeldt* has employed the two-phase EMF titration for the computer calculation of association constants. *O. Levy* (Jerusalem, Israel) reported on measurements of the dielectric constants of tertiary and quaternary ammonium salts in benzene. The dipole moments of the monomeric salts and the dimerization constants were calculated using the equations by *Fuoss et al.* and by *Bange et al.* The association constants obtained by these two methods were in good agreement but were lower than those calculated from vapor-pressure measurements. *G. Scibona* (Rome, Italy) has investigated the extraction of zinc chloride with trilaurylammonium chloride/benzene solutions. The association constants of the species occurring in the organic phase can be calculated from partition data and from parallel measurements of the vapor pressure lowering. *D. Gourisse* (Fontenay-aux-Roses, France) has studied third phase formation in the extraction of nitric acid and of thorium nitrate with trilaurylamine. Light scattering measurements showed that in both cases the particle size greatly increases shortly before third phase formation starts. In many systems a splitting into two phases was observed after 5 hours' ultracentrifugation at an average gravitational field of 10^5 g, whereas no third phase appeared under normal gravitation. It is assumed that the formation of the second organic phase is due to the coalescence of amine salt micelles.

A comprehensive report on the coordination compounds which are responsible for synergistic effects was given by *T. V. Healy* (Harwell, England). The word "synergism" denotes the enhancement of metal extraction by a mixture of two extractants compared with extraction by each of the extractants alone. The effect was first observed in the extraction of uranium by mixtures of dialkyl hydrogen phosphates and trialkyl phosphates and was later confirmed with numerous other tetra- and trivalent metals with such extraction systems. Here the synergism is due to the formation of an adduct of the neutral donor molecule with the metal dialkyl phosphate complex in the organic phase. Another mechanism was observed in the extraction of alkali metals by bis(2-ethylhexyl) hydrogen phosphate (HDEHP) in the presence of substituted phenols (S). In the synergistic complex $MS_4(DEHP)$ the phenol molecule occupies the first coordination sphere; the $DEHP^-$ anion is presumably bound to a phenol. In the extraction of numerous metals with β-diketones, such as thenoyltrifluoroacetone (TTA), synergistic effects were observed with donor molecules such as trialkylphosphates, ketones, amides, and alcohols. In many cases the donor molecule is bound directly to the metal, often with substitution of water molecules. In the case of alcohols, however, there is indication of bonding to the β-diketone.

F. Baumgärtner (Karlsruhe, Germany) reported on the kinetics of extraction and back-extraction of uranium(VI) and plutonium(IV) by tributyl phosphate (TBP). Contrary to the older view that the kinetics of extraction is controlled by diffusion, measurements on drops showed the participation of one or more "interfacial complexes" in the rate-determining step. The formation of such a complex at the interface between the two liquid phases can be described by the Langmuir adsorption-desorption theory if one considers that adsorption and desorption may take place from both sides of the interface. From the kinetic data the following picture of the extraction mechanism may be drawn: As soon as the metal enters the interface in ionic or neutral form it belongs to the interfacial complex; the latter successively adds TBP molecules from the organic phase and NO_3^- ions from the aqueous phase, there being no indication of the sequence of this addition. When the coordination shell of the complex is complete, the complex can be desorbed into the organic phase. However, since all the steps taking place at the interface are reversible, it is also possible that the interfacial complex is re-desorbed into the aqueous phase. Furthermore, exchange reactions can take place between the interfacial complexes. Back-extraction from the organic into the aqueous phase can be described in an analogous fashion.

6. Solvent Extraction: Technical Applications

The most important application of liquid-liquid extraction in recent years has been the processing of spent nuclear fuels in which uranium and plutonium are separated from fission products by extraction with tributyl phosphate (TBP) from nitric acid solution (Purex process). In the processing of fuels with high plutonium concentrations (in particular those from fast breeder reactors), the concentrations of uranium and plutonium change in each stage of the multi-stage Purex process, and since each of the two metals influences the extraction of other, the distribution coefficients are also altered in each stage. Consequently, optimization of the process by calculation is difficult. *W. Ochsenfeld* (Karlsruhe, Germany) now reported on the development of empirical functions for the calculation of the distribution coefficients in the system $Pu(NO_3)_4$–$UO_2(NO_3)_2$–HNO_3–TBP–*n*-dodecane. The equilibrium "constants" for the extraction equilibrium

$$M^{n+} + n\,NO_3^- + a\,TBP \rightleftharpoons M(NO_3)_n\,(TBP)_a$$

$$\tilde{K}_M = \frac{[M(NO_3)_n\,(TBP)_a]}{[M^{n+}]\,[NO_3^-]^n\,[TBP]^a}$$

was expressed as a function of the total ionic strength μ:

$$\tilde{K}_{Pu} = 12.163 - 9.033\,\mu + 2.230\,\mu^2 - 0.163\,\mu^3$$

$$\tilde{K}_U = 8.791 + 6.071\,\mu - 6.176\,\mu^2 + 1.579\,\mu^3$$

These functions describe the extraction in the concentration range 20–30 vol-% TBP, 0.1–0.6 mole/l U^{VI}, 0.01–0.2 mole/l Pu^{IV}, 0.6–3.0 mole/l HNO_3 with good accuracy.

The extractant TBP suffers considerable radiation damage, particularly in the processing of highly burnt fuels. Zirconium is particularly well extracted by the degradation products of the TBP, so that the decontamination factors for this fission product are strongly reduced. As *P. Faugeras* (Fontenay-aux-Roses, France) pointed out, the coextraction of zirconium can be suppressed by addition of small amounts (10^{-3} to 10^{-2} mole/l) of fluoride ions. The separation of the fission product ruthenium was also improved at the same time. In this way, decontamination factors of $> 10^5$ for Zr and $> 10^4$ for Ru could be demonstrated with solutions containing up to 10^3 Ci/l fission product activity.

In the extraction of the lanthanides by TBP, the distribution coefficient is not a monotonic function of the atomic number, but deviations occur in the Gd-Dy region. *D. G. Karracker* (Aiken, S.C., USA) showed, by spectroscopic investigations, that this is due to a change in the coordination number of the extracted complexes $Ln(NO_3)_3(TBP)_3$ (Ln = lanthanide). The band shape of the hypersensitive transitions in these $Ln(NO_3)_3(TBP)_3$ complexes suggests a coordination number of 8 for Nd^{3+}, 6 for Er^{3+}, and 6 or 7 for Ho^{3+}. Corresponding results were obtained with different trialkyl phosphates and with tri-*n*-amylphosphine oxide as ligands. ^{31}P- and ^1H-NMR spectra strongly confirm these conclusions, while the Raman spectra seem to indicate bidentate bonding of the nitrate ions, also in the case of the heavy lanthanides.

Ce^{III}, like all trivalent lanthanides, is extracted by bis(2-ethylhexyl) hydrogen phosphate (HDEHP). As *L. A. Bray* (Richmond, Wash., USA) has observed, Ce^{III} is oxidized to Ce^{IV} during washing of the organic phase with a concentrated (6 to 7 M) nitrate solution. Likewise, Ce^{III} is oxidized to Ce^{IV} when it is extracted from concentrated nitrate solutions. Oxidation is complete within 30 sec and proceeds equally fast both in air and in an argon atmosphere. However, if a nitrite "scavenger" such as sulfamic acid is added, the rate of oxidation is considerably reduced. Evidently the nitrous acid (or one of its reaction products) acts as a catalyst in the oxidation. The above effect is significant in the separation of cerium from the other lanthanides.

A flow scheme for the isolation of the transplutonium elements americium and curium from highly radioactive Purex waste solutions was developed by *G. Koch* (Karlsruhe, Germany). Americium, curium, and the lanthanides are extracted by HDEHP from the citrate-complexed aqueous phase. Americium and curium are partitioned away from the rare earths by selective back-extraction of the actinides by an aqueous solution, which is 1 M in lactic acid and 0.05 M in sodium diethylenetriaminepentaacetate and is adjusted to a pH of *ca.* 3. The flow sheet was tested with weakly active synthetic solutions and gave good decontamination factors for lanthanides, zirconium, niobium, ruthenium, and iron. Kinetic experiments showed that in the case of several elements, the extraction kinetics plays a dominant role in the purification effect. For example, on the basis of equilibrium distribution coefficients iron(III) would be expected to accompany the actinides, but since the extraction as well as the back-extraction are slow, a good separation from iron is accomplished in the countercurrent process.

The extraction of lanthanides as tartrate or malonate complexes by long chain primary amines has been studied by *D. Kuiper* (Delft, Netherlands). Tartaric and malonic acid (H_2L) are extracted by the amine (A) as $(AH)_2L$ at lower acid concentrations and as (AH)HL at higher acid concentrations. The distribution coefficients of the lanthanides increase with increasing $(AH)_2L$ concentration and decrease in the presence of (AH)HL. By a series of different experiments the composition of the extracted complexes was found to be $(AH)_5LnL_4$.

Metabolic Transformation of Antimalarial Drugs as a Basis for the Development of New Active Substances

By *P. Nickel* [*]

The last 20 years have seen considerable progress in malaria therapy; nevertheless, the disease still presents a very serious problem in many tropical countries. The increasing occurrence of cases of therapy-resistant malaria in South America, and above all in Southeast Asia, in recent years has provided new impetus to the search for effective antimalarials.

During metabolism, the chinchona alkaloids are hydroxylated at C-2 of the quinoline ring, thereby losing their antimalarial

activity. This hydroxylation is hindered and the activity of the alkaloids increased by the presence of substituents, especially phenyl. Owing to toxic side-effects, however, no representative of this much-investigated class of compounds has yet found application in therapy.

The activity of Plasmochin® [8-(4-diethylamino-1-methylbutylamino)-6-methoxyquinoline] must be due to a metabolite since the substance itself is inactive *in vitro*. As long ago as 1942, *Schönhöfer* suspected that quinoid forms were responsible for the activity, which was later confirmed by the discovery of the highly effective metabolite 8-(4-diethylamino-1-methylbutylamino)-5,6-dihydroquinoline-5,6-dione.

The assumption that a similar mode of action could apply to the 6-aminoquinolines led to the discovery of the extremely effective, yet highly toxic, 6-(4-diethylamino-1-methylbutylamino)-5,8-dimethoxyquinoline (*Schönhöfer* and *Schulemann*, 1961). Our investigations of the effects of substituents on the antimalarial activity of this compound indicate a certain similarity to the state of affairs with 8-aminoquinolines.

Proguanil [N^1-(*p*-chlorophenyl)-N^5-isopropylbiguanide] is also inactive *in vitro*; 2,4-diamino-5-(*p*-chlorophenyl)-6,6-dimethyl-5,6-dihydro-1,3,5-triazine (known as cycloguanil) was isolated as active metabolite in this case. Since this compound is rapidly excreted, it is not very effective in humans. However, an intramuscular injection of a difficultly soluble salt of the metabolite does provide protection against infection for a period of several months. Its activity is attributed to inhibition of dihydrofolic acid reductase.

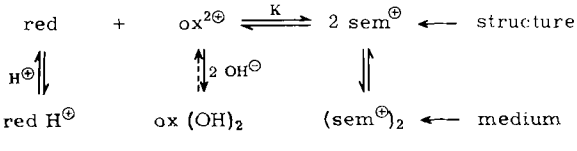
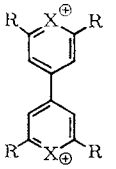
Reversible Redox Systems with Stable Radical Cations



By *S. Hünig* [*]

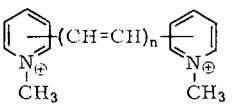
In principle, compounds of the general formula *(1)* can exist in three oxidation states that are related by two one-electron transfers [1]. Whether the radical ion $(1)_{sem}$ can be detected



$(1)_{red}$ $(1)_{sem}$ $(1)_{ox}$

or isolated depends both on its thermodynamic stability, which can be expressed as $K = [sem^{\oplus}]^2/[red]\,[ox^{2\oplus}]$, and on the reactivity of each of the three components towards the medium.

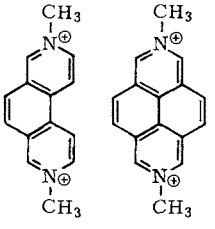
K is determined polarographically from the redox potentials and in the cases studied amounts to $\sim 10^3$–10^9, depending on the structure of the compound *(1)*. This lecture was confined to compounds of the Weitz type *(2)* (X = N–CH_3) [2] and variations thereof. For example, introduction of *O (3)* or *S (4)* both lead to stable radical ions which have fully resolved EPR spectra and dimerize reversibly at higher concentrations in CH_2Cl_2. Nucleophiles remove $ox^{2\oplus}$ irreversibly, so that complete disproportionation occurs. The systems *(5)* to *(7)* show the same value $\sim 10^3$ for *K*. However, with the



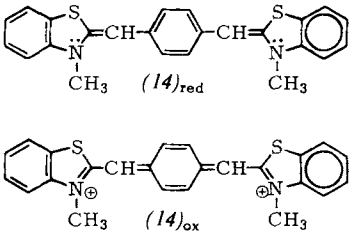
R = H, CH_3, C_6H_5

(2)$_{ox}$, X = N–CH_3

(3)$_{ox}$, X = O



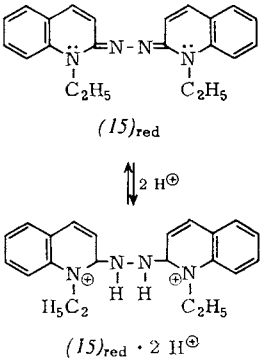
(4)$_{ox}$, X = S



n = 1: *(5)*, 2,2'; *(6)*, 2,4'; *(7)*, 4,4'; *(8)*, 2,3'; *(9)*, 4,3'; *(10)*, 3,3'

n = 3: *(11)*, 4,4'

'*meta*'-derivatives *(8)*–*(10)* the second reduction step is irreversible. Prolongation of the vinylene chain as in *(11)* rapidly reduces *K*, but the vinylene bridges in *(12)* and *(13)* have hardly any influence. The methine groups in *(1)* can be partly or wholly replaced by phenylene groups or N atoms;



(12)$_{ox}$ *(13)*$_{ox}$

(14)$_{red}$ *(14)*$_{ox}$

for example, the species *(14)* that is known [3] in the reduced and the oxidized form, comproportionates to the stable green radical ion $(14)_{sem}$. The system *(15)*, which can also be isolated in all three oxidation states, forms a very stable radical ion, which disappears reversibly on addition of acid owing to disproportionation to $(15)_{ox}$ and $(15)_{red} \cdot 2\,H^{\oplus}$.

(15)$_{red}$

(15)$_{red} \cdot 2\,H^{\oplus}$

Physical and Chemical Probes for Enzyme Conformation

By *G. K. Radda*

The response of bovine liver glutamate dehydrogenase (GDH) to allosteric inhibitors has been examined by a variety of methods.

8-Anilino-1-naphthalenesulfonate is a convenient probe for the conformational equilibria in the enzyme, which depend on the allosteric ligand GTP and coenzyme NADH, since the fluorescence of the bound dye is sensitive to the physical state of the protein[1]. The same system has been used to measure the rates of allosteric transitions. By fast reaction techniques these were shown to be biphasic, each phase representing some structural transitions in the enzyme with half-lives of 20 and 200 msec[3].

GDH can be desensitized by the modification of one tyrosine residue per subunit (M.W. 52000) without any effect on its activity. The same results are obtained when modification involves nitration by tetranitromethane or *O*-acetylation by *N*-acetyl imidazole.

The reaction of GDH with 2,4,6-trinitrobenzenesulfonate has been analyzed in terms of reaction rates of amino groups of different reactivities[3] of which one group per subunit reacts particularly fast and is involved both in the catalytic and allosteric properties of the enzyme. When this group reacts the allosteric response is lost considerably faster than is the catalytic activity[4]. This phenomenon is more clearly demonstrated when the enzyme is inactivated by an active site directed irreversible inhibitor [4-(iodoacetamido)salicylic acid]. Amino acid analysis and spectral and fluorescence data show that this inhibitor reacts with up to 5.4 SH groups per oligomer (M.W. 310000).

A mathematical theory (based on the binomial theorem) is proposed which accounts for the observations[5] in terms of the response of individual subunits to GTP by the sequential model of *Koshland et al.*[6]. All these observations were incorporated into a physical model for the regulatory properties of GDH which required conformational changes in the subunits followed by a rearrangement of the subunits into a different geometry. Further support for this model was obtained from electron microscopic studies of the two forms of GDH.

Transmitter Mechanisms in Isolated Neurons

By *E. Giacobini*[*]

New quantitative microchemical techniques for the measurement of enzyme activity, metabolites, and transmitters in single nerve cells have become available recently. Several enzymes related to the metabolism of transmitters can now be studied with high precision and accuracy in individual neurons.

The cell population in the L7 ganglion of the cat has been used as a model to study the correlation between chemistry and pharmacology of autonomic neurons. Both cholinergic fibers (sweat secretor and vasodilator) and adrenergic fibers (vasoconstrictor) originate from this ganglion. The activity of several enzymes [acetylcholinesterase (AChE), cholineacetylase (ChAc), and monoamine oxidase (MAO)] as well as monoamines have been studied in the total ganglion, in single cells, and in subcellular fractions.

The results obtained by these analyses show that the sympathetic ganglia of the cat contain two distinct cell populations; firstly, a "cholinergic" population, representing in L7 about 10–15% of the ganglion cells. This population is characterized by the presence of ChAc, high concentrations of AChE, and the absence of monoamine fluorescence and MAO activity. The second is an "adrenergic" population, about 72–88% of the ganglion cells. It exhibits fluorescence for noradrenaline and MAO activity and contains low or moderate AChE activity and no measurable ChAc activity.

In the sympathetic ganglia of the cat the level of AChE and ChAc is well correlated when the ganglion is regarded as a whole; however, the AChE-containing neurons are much more numerous than the ChAc-containing neurons. ChAc is localized mostly preganglionically in the nerve terminals whereas AChE is localized both pre- and postganglionically. The postganglionically localized AChE is present not only in the postsynaptic membrane but in the cell body and in the postganglionic fibers as well. These enzymes are also highly concentrated in the postsynaptic terminals. AChE therefore has a more "diffuse" distribution than ChAc. Actually AChE is present also in "adrenergic" neurons while ChAc is probably restricted to "cholinergic" neurons. The presence of AChE in the neuron does therefore not represent an indication that the neuron is "cholinergic".

Reactions of Organotin Radicals

By *W. P. Neumann*[*]

The first synthesis of an organotin compound, which was carried out as long ago as 1849 by *E. Frankland*, who prepared $(C_2H_5)_2SnI_2$ from C_2H_5I and elemental zinc, obviously involved a free-radical reaction. 100 years were to pass, however, before renewed interest was directed toward organotin radicals[1]. Much more accurate information about such radical reactions was afforded by investigations on the course of the free-radical hydrostannation of olefins. Depending on the type of olefin, the first step can be reversible as *e.g.* is shown in the case of pure *cis*-piperylene (1,3-pentadiene) *(1)*.

(1)

From experiments, three generally valid conclusions can be drawn:

1. Organotin radicals are formed easily by abstraction of hydrogen from organotin hydrides. The Sn–H group is an unusually strong radical scavenger and in all cases investigated (C-, alkoxy-, acyloxy-radicals) is superior to radical scavengers such as thiols and far superior to hydroquinone.

2. Organotin radicals are very useful and very mild reagents. They add selectively to unsaturated systems such as C=C-, C≡C-, or N=N groups, enter into numerous free-radical reactions, and are of great use in the elucidation of free-

radical reaction mechanisms *e.g.* in peroxides and azo compounds[2]. They are strongly nucleophilic.

3. In the absence of other reaction partners at temperatures below 150 °C, the organotin radicals $R_3Sn^{\bullet}$ (R = CH_3, C_2H_5) do not usually decompose but rather dimerize irreversibly to hexaalkyl distannane.

Discussion of further possibilities of occurrence and reaction of organotin radicals requires a knowledge of the dissociation energies of covalent bonds to the tetrahedral tin atoms; only few such values are as yet known (Ref.[1,3] and recent results obtained in our laboratory by partial calculation from known mass spectrometric appearance potentials of $R_3Sn^{\oplus}$) and are given in Table 1.

Table 1. Dissociation energies, *D*, of $(CH_3)_3Sn-X$

X	*D* (kcal/mole)
CH_3	55
C_2H_5	50
$CH=CH_2$	60
$CH_2-CH=CH_2$	≈37
$CH_2=C_6H_5$	39
C_6H_5	63
$Sn(CH_3)_3$	57
H	≈35
NR_2	(≈65 to 70)
O–COR′	≈95
Cl	≈85
Br	76
I	62

Not only Sn–H but also Sn–C bonds are cleaved under the influence of light of $\lambda \leqq 400$ nm ($\geqq 70$ kcal) and can thereby initiate such reactions. Sensitizers are, of course, necessary since most organotin compounds only absorb measurably below 250 nm. These values are of significance in the photochemistry of organotin compounds, a topic that is still in its infancy.

X-Ray Structural Analysis of Alkylthiostannic Acids (Monoalkyl Sesquisulfides)

By *C. Dörfelt, E. F. Paulus*, and *H. Scherer*

Alkylthiostannic acids are obtained by the reaction

$$n\ RSnCl_3 + 1.5\ n\ Na_2S \rightarrow (RSnS_{1.5})_n + 3n\ NaCl.$$

The empirical formula $(RSn)_2S_3$[1] and the structural formula R–Sn(S)–S–Sn(S)–R[2] are given in the literature. We, and other research workers[3], have suggested double the molecular weight.

In order to clarify the problem we have carried out a three-dimensional X-ray structural analysis[4] on the methyl compound.

The methyl compound crystallizes monoclinically with $a = 9.768$ Å; $b = 17.39$ Å; $c = 10.96$ Å; $\beta = 109°$. Systematic extinctions yield the space group C2/c or Cc. Four units having the empirical formula $(CH_3Sn)_4S_6$ are present in the unit cell (1767 Å^3). Symmetry properties of the Patterson synthesis calculated on the basis of 1424 reflections permit only the space group C2/c: The molecule has a two-fold symmetry axis; the tin atoms, whose coordination was obtained from the Patterson synthesis, occupy a normal position; the empirical formula $(CH_3Sn)_4S_6$ is confirmed.

Successive Fourier syntheses furnished also the positions of the sulfur and the carbon atoms. Further refinement of the results by the least squares method has not yet been carried out. Methylthiostannic acid has an adamantane-like structure, in which the adamantane skeleton is made up of tin and sulfur atoms. The tin atoms occupy the corners of the tetrahedron, the sulfur atoms the corner of an octahedron including the tin tetrahedrons, and the carbon atoms of the methyl group are situated on the corners of a tetrahedron that surrounds the sulfur octahedrons. The tin-tin bond length is 3.8 Å, the tin-sulfur bond length 2.35 Å, and the tin-carbon bond length 2.1 Å.

Contrary to former representations of the structure we suggest a single bond rather than a double bond to be present between the tin and sulfur

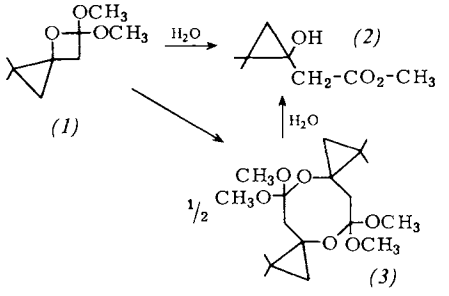
SELECTED ABSTRACTS

6,7,8,9-Tetrahydro-5*H*-benzo[*d*]silepins *(1)*, a new class of compounds, have been synthesized by *L. Birkofer* and *E. Krämer*. 7,7-Disubstituted members of this series were obtained by reaction of the Grignard compound derived from

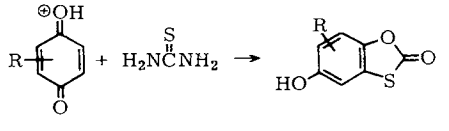


(1)

1,2-bis(β-bromoethyl)benzene with disubstituted dichlorosilanes. Bromination of the 7,7-dimethyl derivative with *N*-bromosuccinimide led by way of hetero-ring opening to 1,2-divinylbenzene, whereas reduction of the 7,7-dichloro derivative by $LiAlH_4$ afforded the parent compound *(1)*, R = H (b.p. 104 °C/12 torr, m.p. 9–10 °C). / Chem. Ber. *102*, 427 (1969) / –Ma. [Rd 970 IE]

The reaction of acetylenes with difluoroamine has been studied by *K. Baum*. 3-Hexyne was found to give 3-hexanone, 3,3-bis-(difluoroamino)hexane, 3-difluoroamino-3-fluorohexane, and *N*-(α-difluoroaminopropyl)propionamide when the reaction was catalyzed by the BF_3 complex of phosphoric acid. Similarly, 1-hexyne afforded 2-hexanone, 2,2-bis(difluoroamino)-hexane, 2-difluoroamino-2-fluorohexane, and *N*-(difluoroaminomethyl)valeramide. When H_2SO_4 was used as catalyst, 3-hexyne, 1-hexyne, and propargyl chloride yielded 3,3-, 2,2-

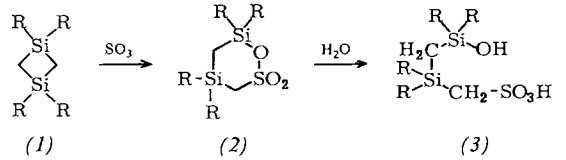
bis(difluoroamino)hexane, and 1-chloro-2,2-bis(difluoroamino)propane, respectively. The reactions were carried out at the boiling temperature of difluoroamine, *i.e.* −23 °C; they probably proceed *via* vinyldifluoroamine compounds. / J. Amer. chem. Soc. *90*, 7089 (1968) / −Ma. [Rd 973 IE]



Reaction of 2,2-dimethylcyclopropanone and 1,1-dimethoxyethylene leads, according to *N. J. Turro* and *J. R. Williams*, to the formation of a novel ortho ester *(1)*, the first of its kind containing a four-membered ring (yield 90%). Treatment of *(1)* with water gives *(2)*. Both compounds decompose on

(1) *(2)* *(3)*

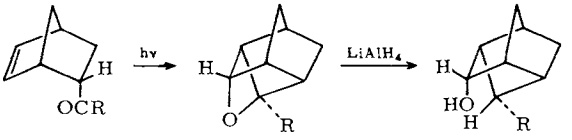
standing for several hours. If compound *(1)* is kept in hexane for two weeks, an unusual dimerization occurs to yield compound *(3)* (yield 39%). Compound *(3)* also affords *(2)* on treatment with water. / Tetrahedron Letters *1969*, 321 / −Ma. [Rd 974 IE]



A single-step synthesis of 5-hydroxybenz[*d*]—[1,3]oxathiol-2-ones *(2)* is reported by *P. T. S. Lau* and *M. Kestner*. A large variety of derivatives of *(2)* can be prepared in excellent yields from quinones and an excess of thiourea on heating in aqueous HCl and acetic acid. Good results are also obtained with H_2SO_4 or trifluoroacetic acid. The reaction probably proceeds *via* addition of thiourea to the protonated quinone *(1)*,

(1) *(2)*

thus forming an *S*-(2,5-dihydroxyaryl)thiuronium salt, which cyclizes to 5-hydroxybenz[*d*]-[1,3]oxathiol-2-imine; hydrolysis of this compound affords compounds *(2)*. / J. org. Chemistry *33*, 4426 (1968) / −Ma. [Rd 975 IE]

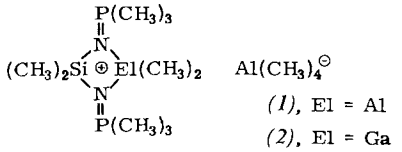


Ring expansion by insertion of SO_3 has been observed by H. *Schmidbauer*, *L. Sechser*, and *M. Schmidt* for 1,1,3,3-tetramethyl-1,3-disilacyclobutane *(1)*, which is converted into 2,2,4,4-tetramethyl-1-oxa-2,4-disila-6-thiacyclohexane 6,6-dioxide *(2)*, m.p. 35–37 °C, yield 96%, in the process. Insertion

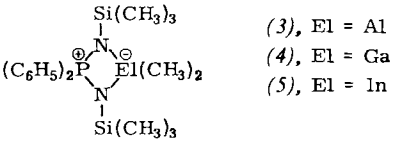
(1) *(2)* *(3)*

of SO_3 into metal-carbon bonds is already known. Compound *(2)* is decomposed to a hydroxysilylsulfonic acid *(3)* on treatment with water. / Chem. Ber. *102*, 376 (1969) / −Kr. [Rd 983 IE]

The photocyclization of 5-acylnorbornenes is the subject of a report by *R. R. Sauers*, *W. Schinski*, and *M. M. Mason*. On irradiation in oxygen-free benzene, the *endo*-isomer *(1)*, like other γ,δ-unsaturated ketones, is converted into the tricyclic "oxetane" *(2)*, whereas the *exo*-isomer resinifies instead of undergoing the expected sigmatropic rearrangement. Reductive cleavage of *(2)* yields the secondary alcohol tricyclo-



(1) *(2)* *(3)*

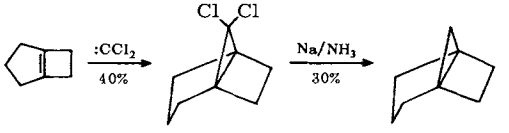


[3.3.0.0^{3,7}]octan-2-ol *(3)* which is readily converted into the ketone and other derivatives. Examples: *(2)*, R = CH_3, b.p. 60 °C/10 torr; *(2)*, R = $C_6H_5CH_2$, b.p. 89–91 °C/0.75 torr; *(3)*, R = H, m.p. 134–135 °C; *(3)*, R = α-naphthol, m.p. 174–175 °C./Tetrahedron Letters *1969*, 79 / −Kr. [Rd 984 IE]

Esters of fluorosulfinic acid with lower alcohols (alkyl fluorosulfites) FS(O)OR have been prepared by *F. Seel*, *J. Boudier*, and *W. Gombler* by distillation of the corresponding ester of chlorosulfinic acid with potassium fluorosulfite in an apparatus made of materials resistant to fluorosulfinic esters (*e.g.* polytetrafluoroethylene). *Zappel*[1] had already used this method (using glass apparatus) to prepare the 1-ethoxycarbonylethyl ester of fluorosulfinic acid. The esters have an unpleasant odor, are thermally highly stable, and react with water to give HF, SO_2, and ROH. Methyl fluorosulfite reacts with trimethylamine to give $[N(CH_3)_4]SO_2F$ and with Lewis acids such as BF_3 to give $[OSOCH_3]^{\oplus}[BF_4]^{\ominus}$, which decomposes to SO_2, CH_3F, and BF_3. Methyl fluorosulfite decomposes powdered glass to give, *inter alia*, SiF_4, $SO(OCH_3)_2$, SO_2, CH_3F. Examples: FSO_2CH_3, b.p. 46.5 °C, yield 75%; $FSO_2-CH_2-CH(CH_3)_2$, b.p. 99 °C, yield 40%. / Chem. Ber. *102*, 443 (1969) / −Kr. [Rd 985 IE]

New four-membered inorganic ring systems have been described by *H. Schmidbaur*, *W. Wolfsberger*, *K. Schwirten*, and *H.-H. Pickel*. Salts such as *(1)* or *(2)* were obtained from bis(trialkylphosphoranylideneamino)dialkylsilanes and trialkylaluminum or trialkylgallium. In contrast, trimethylindium gave only an open chain product. In competition experiments – reaction of the silicon compound with the aluminum and the gallium compound – only compound *(1)* is

(1), El = Al
(2), El = Ga

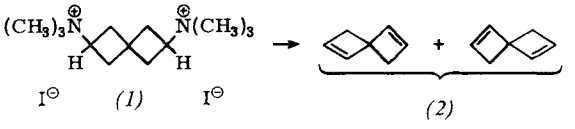


(3), El = Al
(4), El = Ga
(5), El = In

formed. The zwitterions *(3)–(5)* could be prepared from trimethylsilylaminotrimethylsilyliminodiphenylphosphorane and the trimethyl compounds of Al, Ga, and In. *(1)–(5)* are colorless compounds that are extremely sensitive to water and

[1] *A. Zappel*, Chem. Ber. *94*, 873 (1961).

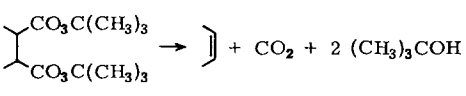
to oxygen. *(1)* and *(2)* decompose without melting, and *(3)–(5)* melt at 114–116 °C, 78–80 °C, and 62–65 °C, respectively. / Chem. Ber. *102*, 556, 564 (1969) / –Kr.
[Rd 986 IE]



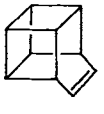
Tricyclo[3.2.1.$0^{1,5}$]octane *(3)* has been prepared by *K. B. Wiberg* and *G. J. Burgmaier* by addition of dichlorocarbene to *(1)* and removal of the chlorine. The structure of *(3)* was

(1) *(2)* *(3)*

proved by NMR spectroscopy and by reaction with acetic acid – a reaction in which *(3)* is converted exclusively into bicyclo[3.2.1]oct-1-yl acetate. *(3)* is remarkably thermally stable; its half-life at 195 °C is more than 20 h. / Tetrahedron Letters 1969, 317 / –Kr.
[Rd 987 IE]

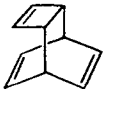


The synthesis of spiro[3.3]hepta-1,5-diene *(2)* has been described by *J. P. H. Houbiers, L. A. Hulshof*, and *H. Wynberg*. Reaction of an aqueous suspension of Ag_2O on the spiran derivative *(1)* and pyrolysis at 150–160 °C/50 torr leads to the formation of *(2)* in *ca.* 27% yield. The compound can be purified by gas chromatography; b.p. 71.6 °C/762 torr. *(2)* has a rigid unsymmetrical 1,4-diene system similar



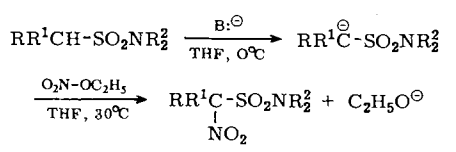
(1) *(2)*

to 5-methylenebicyclo[2.2.1]hept-2-ene and must exist in two optically active forms which have not, as yet, been isolated. / Chem. Commun. *1969*, 91 / –Ma.
[Rd 988 IE]



A new synthesis of alkenes from *vic*-dicarboxylic acids by decomposition of peresters of the latter has been reported by *E. N. Cain, R. Vukov*, and *S. Masamune*. Reaction of *tert*-butyl peroxide on dicarboxylic acid dichlorides in neutral non-aqueous solution leads to the formation of the di-*tert*-butyl peresters *(1)*, which decompose to the alkenes either thermally, *e.g.* in *tert*-butyl benzene on heating to 110 to 135 °C in a stream of N_2, or photolytically at room temperature in O_2-free benzene on irradiation with a medium-pressure mercury vapor lamp. Cyclohexene was obtained thermally in 38% yield, norbornene thermally in 34% and photolytically in 30% yield. The hydrocarbon *(2)* occurred

(1)



(2)

(3)

photolytically in 40% yield, whilst in the thermolysis of the corresponding perester it isomerized to *(3)*. / Chem. Commun. *1969*, 98 / –Ma.
[Rd 989 IE]

The base-induced α-nitration of sulfonamides has been described by *W. E. Truce* and *L. W. Christensen*. Benzylsulfonamides and many *N,N*-dialkylalkanesulfonamides can be converted, with bases, into a stabilized sulfonamide carbanion, which reacts with alkyl nitrate to form α-nitrosulfonamide. In the case of benzyl derivatives, potassium *tert*-butoxide is suitable as base for the formation of the anion

while *n*-butyllithium is required in the case of aliphatic sulfonamides. The yields are between 21 and 66%. α-Nitrosulfonamides with free α-hydrogen can be easily brominated./ Tetrahedron *25*, 181 (1969) / –Ma.
[Rd 990 IE]

The crystal structure and atomic radius of metallic radium have been determined by *F. Weigel* and *A. Trinkl* on samples of metallic radium obtained in the following manner: A mixture of RaO and aluminum was heated inductively to 1100 to 1200 °C at $< 10^{-6}$ torr in micro crucibles placed in the lower ends of quartz X-ray capillaries; the micro crucibles were manufactured from iron having a low carbon content. The radium metal formed in accordance with the reaction

$$3\ RaO + 2\ Al \rightarrow 3\ Ra + Al_2O_3$$

sublimes directly onto the air-cooled walls of the capillaries above the crucibles as a dull gray metallic mirror. When reaction is complete the capillaries are sealed by a microburner and the reaction product is recrystallized by repeated heating under an IR lamp and cooling with liquid nitrogen. After such recrystallization the radium metal mirror becomes bright and silvery and gives an easily interpretable X-ray diagram. Evaluation of the latter gives a cubic space-centered lattice with $a_0 = 5.148 \pm 0.015$ Å and with two atoms in each unit cell, isotypic with barium metal. From the lattice constant it can be calculated that with two atoms in the unit cell, the density is 5.50 g cm^{-3} and the atomic radius is 2.32 ± 0.02 Å. / Radiochim. Acta *10*, 78 (1968) / –FW. [Rd 991 IE]

Californium(III) oxide fluoride, CfOF, in the form of a bright green single crystal has been obtained by *J. R. Peterson* and *J. M. Burns* during attempts to prepare californium(III) fluoride; its parameters could be measured on a computerized X-ray diffractometer. CfOF crystallizes with the fluorite type structure, space group Fm3m, with statistical distribution of the O and F atoms. The lattice constant has the value $a_0 = 5.561 \pm 0.004$ Å; the Cf–(O,F) distance is 2.408 Å. / J. inorg. nuclear Chem. *30*, 2955 (1968) / –FW.
[Rd 992 IE]

The solid-state reaction of zinc oxide with iron(III) oxide has been investigated by *R. Parker, C. J. Rigden*, and *C. J. Tinsley* by means of thermogravimetric and magnetic measurements. Owing to the diamagnetic character of the Zn^{2+} ion the results of such measurements permit conclusions to be drawn regarding the nature of the intermediates. If a mixture of ZnO and Fe_2O_3 powder is heated to 400 °C and over, the Fe_2O_3 releases oxygen and a spinel lattice is established at a grain boundary. Zinc ions can diffuse through this lattice

with relative ease; if reoxidation is hindered, diffusion of zinc continues until a homogeneous spinel phase is established in which the zinc/iron ratio is determined only by the oxygen deficiency. Subsequent oxidation affords zinc ferrite and γ-iron(III) oxide containing 21% of zinc in solid solution. The last named phase decomposes above 515 °C into zinc ferrite and α-iron(III) oxide. / Trans. Faraday Soc. *65*, 219 (1969) / –Hz. [Rd 993 IE]

Space-charge layers in surface-proximate regions of single crystals of zinc oxide have been investigated by *B. Hoffmann* using electroreflection. The technique is based on the periodic changes in the reflecting power of the surface of the crystal for light in the region of the ground state lattice absorption (near ultraviolet) on application of an alternating electric field oriented perpendicular to the surface of the crystal. Comparison of the phase of the external field and the alternating component of the reflecting power affords the sign of the space charge in the proximity of the surface. By raising the partial pressure of oxygen in the environment of the crystal it proved possible to observe the change from an excess layer (electronic transition gas-crystal) to a depletion layer (electronic transition crystal-gas). The partial pressure of oxygen at which this change takes place depends on the intensity of irradiation and on the concentration of mobile charge carriers in the crystal. / Z. Physik. *219*, 354 (1969) / –Hz. [Rd 994 IE]

The molecular geometry of thiirane *S*-oxide was determined by *W. F. White* and *J. E. Wollrab* from the rotation spectrum, paying particular attention to the orientation of the SO bond relative to the C_2S ring. As is also evident from NMR and Raman data, the molecule belongs to the symmetry group C_s (only one plane of symmetry). Values for the CS bond length (1.821 Å) and the angles CSC (48.47°) and CCS (65.76°) were taken from thiirane, the CH bond length was set at 1.09 Å and the angle HCH at 110.0°; it was further assumed that the HCH plane bisects the CCS angle. The bond lengths CC and SO were thus calculated as 1.494 ± 0.003 Å and 1.473 ± 0.005 Å, respectively. The angle α between the SO bond and the plane of the ring (or the bisector of the CSC angle) is 67.3 ± 0.4°. The bond lengths CC and SO correspond within the limits of accuracy to those in thiirane and dimethyl sulfoxide respectively; the considerable widening of the angle α compared with dimethyl sulfoxide ($\alpha \approx 45°$) is attributed to the decrease of the CSC angle owing to ring formation. The dipole moment of thiirane *S*-oxide is 3.66 D. / Chem. Physics. Letters *3*, 25 (1969) / –Hz. [Rd 995 IE]

Isolation of protease inhibitors with water-insoluble enzyme resins has been described by *H. Fritz et al.* A technique was used in which enzymes (trypsin and plasmin) are bound to copolymers of maleic anhydride. The resulting polyanionic enzyme resins are suitable for isolation of inhibitors having isoelectric points above 4–5. Polyamphoteric resins, which are formed when bis(methylamino)ethane is bonded to the intact anhydride groups of the enzyme resin, exhibit a considerably higher specific binding capacity towards inhibitors and are also suitable for isolation of inhibitors having low isoelectric points. Moreover, such inhibitors are released at considerably higher pH values from polyamphoteric resins than from the corresponding polyanionic resins. The binding capacity of the resins remains constant over several months of storage between 0 and 4 °C in the presence of chloroform or phenol. The following inhibitors were isolated: trypsin inhibitors from pig pancreas, sheep pancreas, guinea-pig seminal vesicles, soya beans; trypsin-kallikrein inhibitor from bovine lung. / Hoppe-Seylers Z. physiol. Chem. *350*, 129 (1969) / –He. [Rd 996 IE]

Various molds produce Aflatoxin B on foodstuffs, as has been shown by *E. Hanssen*. Since Aflatoxin B shows hepatotoxic and lethal effects in human beings and other animals, and also has a carcinogenic action on human liver cells, consumption of foodstuffs affected by mold should be avoided. Even after excision of the mycelium such foodstuffs cannot be consumed without risk since the poisons are capable of migration. They could be detected at a considerable distance from the mycelium. / Naturwissenschaften *56*, 90 (1969) / –He. [Rd 997 IE]

The characterization of t-RNA and of aminoacyl-t-RNA synthetase has been achieved by *V. Neuhoff et al.* by analysis of picomolar quantities of dansyl amino acids using two dimensional chromatography. By means of this method it is possible to determine 10^{-12} to 10^{-13} mole of dansylated amino acid (radioactively labeled) both quantitatively and qualitatively. Of the many applications of this method may be mentioned: The characterization of t-RNA and aminoacyl t-RNA synthetase; the testing of purity of specific t-RNA (a minimum of 5% of each of the desired t-RNA's can be obtained from a specific t-RNA preparation) and of commercial radioactively labeled amino acid preparations. / Hoppe-Seylers Z. physiol. Chem. *350*, 121 (1969) / –He. [Rd 998 IE]

BOOK REVIEWS

Arzneimittel. Entwicklung, Wirkung, Darstellung (Drugs. Their Development, Action, Preparation). By *G. Ehrhart* and *H. Ruschig*. Verlag Chemie GmbH, Weinheim/Bergstrasse 1968. 1st Edit., 2 vols. totalling xii, 1921 pp., 90 illustrations, 277 tables. Linen DM 248.–.

It is no longer possible to treat problems of drug chemistry without comprehensive information from the literature. Thus it is as essential nowadays for the chemist to know the principles and methods of pharmacology and medicine as it is for the physician and the pharmacologist to know those of chemistry and biochemistry. So it is a difficult task to conceive and to bring about a review of the comprehensive information about drugs. That may be why there has hitherto been no such a work in modern German literature; to undertake this task it was first necessary to find a team of experienced industrial scientists who had all the necessary tools of industrial and information science. *G. Ehrhart* and *H. Ruschig*, both of them schooled for ten years in leading positions in a large research team, set themselves this task, and it may be stated at once that they have met it with great success. Their reference work is in two volumes, the first devoted to pharmacodynamics and the second to chemotherapy.

The subject matter is divided uniformly in the two volumes, into 29 chapters each with four sections, according to scientific and medical interests.

An *introduction* describes the historical development of the various groups of drugs, together with the general practical and theoretical principles; it contributes considerably to an understanding of the detail that follows, and awakens the

interest and curiosity of the layman. In parts this introduction is very detailed and informative; for instance, chapter 10, on psychopharmacy, is divided into the following subsections: 10.11 Types of psychopathological condition; 10.12 Historical background of psychiatric therapy; 10.13 Clinical types of psychopharmacy; 10.14 Applications of psychopharmacy; and 10.15 Clinical pharmacodynamic aspects. The material is well chosen; its arrangement is didactically apt and clarified by representative tables and illustrations.

The next section, on *pharmacological and chemotherapeutic tests*, is particularly valuable for the chemist and biochemist. That it includes recent developments is illustrated, for example, by chapter 13 on coronary vasodilators where attempts to measure sympathoinhibitory action are described as well as the current methods of determining coronary circulation. Further, the division of sympatholytics into α- and β-groups and their pharmacological recognition are treated in detail in chapter 3. It must, however, be clearly recognized that it can be no object of the present treatise to describe pharmacological methods in detail; the pharmacological section serves rather to give the reader a rapid survey whilst inducing him to study the specialist literature.

The *development* of groups of medicaments is described in the third section. This section begins, in general, with the history of drugs and their constituents, leading on to synthetic compounds in chronological series. In this way the evolution of relationships is described, and all who are interested in relations between structure and activity will find much of interest therein. Here also are recorded the metabolism and toxicity of many of the compounds.

The last section is devoted to the *preparation of drugs*. The authors seem to have been remarkably successful in choosing the most important of the usually numerous alternative synthetic methods, and they have documented them mainly by reference to patents. Confusion by an excess of material has been happily avoided. Those concerned with drug synthesis are sufficiently served by wide-ranging references to the literature.

A chapter on "The structure and mode of function of the nervous system" and an appendix on "The route and behavior of drugs in the organism" contribute considerably to an understanding of the division into 29 chapters.

The impressive success of this book was confirmed for the reviewer soon after its appearance: in his Institute, where research on drugs is carried out, it is already one of the sources of information that is in greatest use and most frequent demand. The picture that it gives of the relations between experiment and medical and scientific theories gives it an appeal to all, whether it be to chemists, biochemists, pharmacologists, bacteriologists, biologists, or physicians. It can also be recommended to students who are interested in drug research and wish to choose this field for their life's work.

Inevitably there are some mistakes, but they are of such minor importance in relation to the range and achievement of this book that they will not be detailed here; they have been notified to the authors so that they may correct the next edition.

The authors, their co-workers, and the publishers deserve thanks and recognition for this clearly arranged, well illustrated, and carefully selected review, which will become a standard work for all who are interested in research on drugs.

E. Biekert [NB 807 IE]

Molecularbiologie. Bausteine des Lebendigen (Molecular Biology: Units of Life). Edited by *Th. Wieland* and *G. Pfleiderer*. Umschau-Verlag, Frankfurt 1967. 2nd Edit., 296 pp., numerous illustrations, bound DM 19.80.

In this volume 20 scientists report in 17 articles "in clear style on the most important discoveries" that form the essence of modern molecular biology. An introduction by *M. F. Perutz* gives an exemplary brief and penetrating review of the decisive stages in the historical development and the "dogmas" of molecular biology, after which the reader is introduced to the world of subcellular particles. There follow accounts of the "classical" subsections of molecular biology: DNS, the genetic code, the structure and synthesis of proteins, the mode of action of enzymes, molecular evolution, and then finally discussions of photosynthesis, contractile structures, biological membranes, immunochemistry, the biochemistry of viruses, and neurobiology.

The value of the contributions lies in the fact that they are not written for the expert. All the authors have taken the greatest trouble that their material, which is in part far from simple, shall be as clear as possible, often using colored illustrations. Nevertheless this is no book for the layman, in spite of what the publisher says. The text will be intelligible only to those who already know something about the relation between chemistry and biology and, in particular, to those who are familiar with scientific vocabulary. Such readers can be advised without reservation to obtain the book for a first and reliable introduction into the principles of molecular biology. The success of this volume can best be judged by the fact that a second edition has become necessary only six months after appearance of the first; in several respects the second edition gives a more complete and rounded picture of the field.

H. Grünewald [NB 808 IE]

Synthetic Methods of Organic Chemistry, Vol. 22, Yearbook 1968. By *W. Theilheimer*. From the series: Synthetische Methoden der Organischen Chemie, Jahrbuch mit deutschem Registerschlüssel. S. Karger, Basel-New York 1968. 1st Edit., xxiv, 558 pp., DM 227.–.

The annual "Theilheimer"[1] has become such a standard work for preparative chemists that it is almost unnecessary to mention a new volume. The present volume contains a selection of 996 syntheses from 1966/1967; the well established though somewhat complicated classification system is retained. All fields of investigation are represented, and a surprisingly large number of heterocyclic and alicyclic ring syntheses are included. As before, the concise procedures given often provide an adequate working basis with no need to refer to the literature. The text is supplemented with clear formulas. A detailed keyword index (87 pp.), which also covers the two previous volumes, greatly increases the value of the book. The six pages on "Trends" are a goldmine of the latest original methods. The presentation and print are again excellent.

S. Hünig [NB 778 IE]

The Organic Compounds of Zinc and Cadmium. By *N. I. Sheverdina* and *K. A. Kocheshkov*. From the series: Methods of Elemento-Organic Chemistry. Edited by *A. N. Nesmeyanov* and *K. A. Kocheshkov*. Volume 3. North-Holland Publishing Company, Amsterdam 1967. 1st Edit., x, 252 pp., many figures, Dfl. 36.–.

In the present book 120 pages are devoted to the classical preparative chemistry of organozinc compounds and 77 to that of organocadmium compounds, both topics enjoying the same comprehensive treatment. A complete chapter is devoted to the Reformatzky reaction (*K. A. Kocheshkov* and *L. V. Abramova*, 43 pages). The task that the authors have set themselves can be summarized in the terms "Preparation of ....." and "Reactions with .....", and they have accordingly set out the voluminous subject matter in a clear manner. Each chapter has its own bibliography. The chemistry of the alkylzincs was last published as a monograph some 30 years ago, whereas that of the alkylcadmiums

[1] Cf. Angew. Chem. *79*, 283 (1967); Angew. Chem. internat. Edit. *6*, 277 (1967).

has never appeared in monograph form. A welcome fact is that experienced authors, known and valued for many years in the field of organometallic chemistry, have taken this task upon themselves.

The literature is covered as far as it has been considered in the Russian abstracts publication (Ref. Ž. Chim) up to July 1, 1963. A series of randomly chosen examples showed that publications up to the middle of 1961 have been considered; references from 1962 or 1963 are seldom encountered and concern primarily Russian papers. For instance, of the 176 references on pages 233–239, 22 are from 1959, 13 from 1960, and there are not any from 1962 or 1963. Understandably, the achievements of Russian chemists receive a broader treatment.

The analysis of the compounds covered is dealt with in short sections and considers only elemental analyses and short tables of melting points and boiling points. Analytical techniques such as spectroscopy are not included.

As a result of the preparative tone of the work, modern structural chemistry and reaction mechanisms, which have of late attracted greatly increased interest in organometallic chemistry, are not done full justice. Just an occasional reference is made to dissociation energies.

As is the case with the other volumes of this series[1], the considerable value of the present book could have been increased by inclusion of a detailed subject index. It appears to the reviewer that additional keywords would have been desirable, *e.g.* bond energies, bond lengths, dipole moments, dissociation, infrared, mechanism, NMR, Raman, reaction-spectroscopy, stereochemistry. In the case of Japanese literature and patents, translations from the Russian abstracts publication (Ref. Ž. Chim.) would have been better replaced by references from Chemisches Zentralblatt or Chemical Abstracts.

Not least because of the chapter on the Reformatzky reaction, the book is not only useful for the organometallic chemist, but represents a valuable reference work for all chemists engaged in preparative work, and certainly fills a gap in the existing literature. *W. P. Neumann* [NB 789 IE]

Atlas of Electron Microscopy. Biological Applications. Edited by *F. Scanga*. Elsevier Publishing Company, Amsterdam 1964. 1st Edit., xxvi, 331 pp. 496 illustrations, bound, *ca.* DM 118.–

Sight is man's most important sense. Experimental work indicates that the contours of an object which the eye sees distorted appear similarly distorted to the touch. It is interesting to observe the efforts made by chemists to render the objects of their research visible, in order to be able to exercize a measure of visual control over the results of the experiment. It is therefore not surprising that the development of electron microscopy has led to spectacular advances in science generally, and specially in biology, by permitting us to see a previously invisible realm of nature.

F. Scanga, of the Istituto Superiore di Sanità, in Rome, has gathered together the most interesting photographs so far taken with the electron microscope into an atlas which is, in its way, unique. The work begins with a fifteen-page summary of the technique and the possibilities of application of electron microscopy. This is followed by 482 photographs of viruses, bacteria, cell constituents, animal and plant cells, and finally of shells.

Anyone who finds the observation of nature pleasing will welcome this book, revealing as it does the forms and structures governing the elementary processes of life.

Framework Molecular Models. Construction set with 24-page instruction leaflet. Prentice-Hall, Englewood Cliffs, N.J./USA, DM 32.80.

The need for comprehensibility has repeatedly led chemists to attempt to represent their molecules in the form of large, but correctly scaled models. The best known are the Stuart models and the stereomodels of Dreiding. Recently, in the USA, *Fieser* has developed a cheaper plastic version of the Dreiding models.

Stereomodels can also be constructed with the "Framework Molecular Models" set. This set differs from the Dreiding models, in that it provides no prefabricated "atoms," but small, rigid tetrahedra, trigonal bipyramids, and octahedra, all made of wire rods, as well as a large number of differently colored plastic tubes, which fit closely over the metal rods, and which can be cut by the user to a scale of 1 Å = 1 inch, so that they represent covalent bonds or the van der Waals radii of individual atoms. The kit also contains linear and curved connecting rods, the latter serving for the construction of π-bonds. Twelve chemical elements may be represented by the twelve colors of the plastic tubes. Plastic tubes marked with two colors are provided for a number of frequently occurring combinations of elements (O–H, N–H, C–H. C–N, and C–O). The coloring of the models permits the observer, as in the case of the Stuart models, to recognize rapidly the molecular structure.

With this set it is possible to construct atomic models of the hybridized states sp^3, sp^2, dsp^3, sp, and d^2sp^3. It would be desirable to enlarge the kit with parts that would allow representation of hepta- and octacoordinated complexes. For this it would only be necessary to produce appropriate metal frameworks onto which the plastic tubes could be fixed.

The kit has other advantages: it is easy to handle, and the corresponding models are to scale and very clear, as they also show the positions of free electron pairs. What is more, it is available at a reasonable price. One would like to see this useful set in the hands of every student of chemistry, and would recommend it especially to everyone who has to teach the subject, since in chemistry there is nothing to beat a good model. *H. Grünewald* [NB 777 IE]

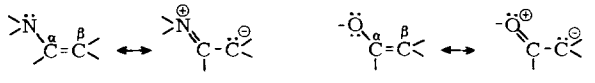
The Chemistry of Enol Ethers



By F. Effenberger [*]

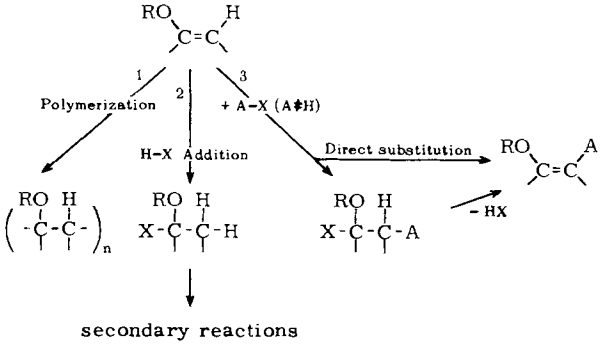
Dedicated to Professor H. Bredereck on the occasion of his 65th birthday

Enol ethers (vinyl ethers) are intermediate in their reaction behavior between olefins and enamines. This article presents a survey of reactions leading to bond formation at the β–C atom of enol ethers; polymerizations and additions of acidic H–X compounds are not reviewed.

1. Introduction

Enamines *(1)* have acquired great importance in preparative organic chemistry in the course of the past 15 years [1]. Their reactivity toward electrophiles is due to the high electron density on the β-C atom.

(1) *(1a)* *(2)* *(2a)*



In the enol ethers *(2)* [2], which are also reactive derivatives of ketones and aldehydes, the electron density on the β-C atom is also increased, though to a smaller extent than in the enamines. Since the ammonium structure *(1a)* is energetically more favorable than the oxonium structure *(2a)*, *(1a)* makes a greater contribution to the resonance equilibrium *(1)* ↔ *(1a)* than does *(2a)* in *(2)* ↔ *(2a)*.

Thus, enol ethers are intermediate in their chemical properties between olefins and enamines. *Wislicenus*, who was the first to prepare ethyl vinyl ether, also reported on the halogenation, hydrolysis, and polymerization of this simple enol ether [3]; however, systematic study of the chemistry of enol ethers started only with the development of productive syntheses [4]. Enol ethers exhibit three fundamental types of reactions:

1) Cationic polymerization in the presence of Lewis acids.

2) Reactions with H–X compounds to form either the carbonyl compound from which the enol ether is derived or its derivatives. Examples are the hydrolysis of enol ethers to form carbonyl compounds and the addition of alcohols to enol ethers to form acetals.

3) Reactions with compounds A–X resulting in bond formation between A and the β-C atom of the enol ether; these reactions afford both addition and substitution products. The present article mainly covers reactions of this type.

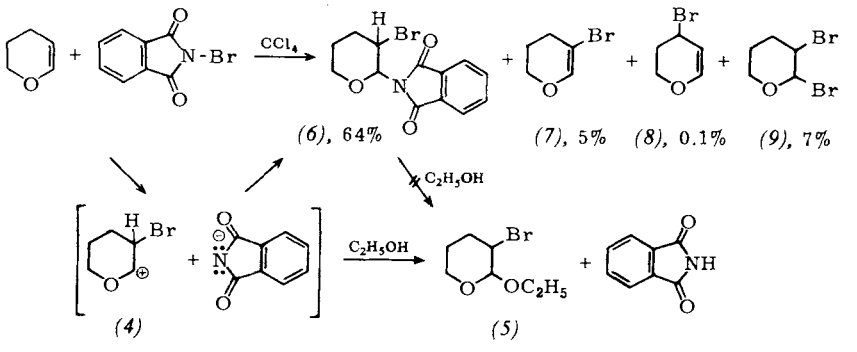
Different groups of workers have calculated the resonance interaction of a free pair of p electrons on the oxygen with the CC double bond, which largely determines the reaction behavior of the enol ethers[5]. An experimental measure of the resonance interaction is provided by the ^1H–NMR spectrum; thus, important conclusions regarding the steric configuration and possible resonance structures can be drawn from the chemical shift of the β–H atoms and the respective coupling constants[6].

2. Reactions of the β-C Atom of Enol Ethers with Hetero Atoms

2.1. Halogenation[7]

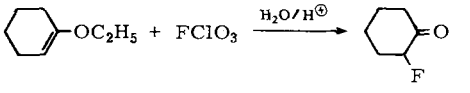


The addition of chlorine and bromine to vinyl ethers has been studied mainly by *Shostakovskii et al.*[8–10]. In the case of low molecular weight alkyl vinyl ethers the reaction is so vigorous that cooling is necessary. The reaction is generally carried out at about 0 °C in CCl_4 or $CHCl_3$. Bromination occurs without a catalyst[10], whereas peroxides are added in chlorinations to prevent polymerization[11].

1,2,2-Trihalogeno ethers are often formed as by-products together with the 1,2-dihalogeno ethers *(3)*[7,12]. E1 elimination, which is the initial step in by-product formation, is favored to such an extent by the resonance-stabilized ionic intermediate *(3a)*[9,12,13] that it proceeds even under very mild conditions.

Attempts to iodinate enol ethers with elemental iodine are unsuccessful and yield polymers[3,14]. Under the conditions of the iodoform reaction, alkyl vinyl ethers are converted into iodoform and potassium formate; 1,2-diiodo ethers and iodoacetaldehyde are assumed to occur as intermediates[15].

Enol ethers have also been treated with *N*-bromoamides instead of bromine[16,17]. For example, 2,3-dihydropyran reacts with *N*-bromophthalimide predominantly by a polar mechanism[18]. The ionic intermediate *(4)* can be intercepted by addition of alcohol to form *(5)* and phthalimide. Under these conditions, *(6)* does not react with alcohol to form *(5)*. Compound *(7)* arises from either *(4)* or *(9)*,



(6), 64% *(7)*, 5% *(8)*, 0.1% *(9)*, 7%

(4) *(5)*

whereas *(8)* and *(9)* are thought to be formed *via* free radicals. A polar intermediate corresponding to *(4)* is also assumed to occur in the chlorination of vinyl ethers with chlorine in alcohol[19].

The fluorination of enol ethers, which is particularly important for the introduction of fluorine into steroids, can be achieved in very good yields under mild conditions (in pyridine at 0 °C) with perchloryl fluoride[20].

Cyanogen chloride adds to ethyl vinyl ether in the presence of radical generators to give 2-ethoxy-3-

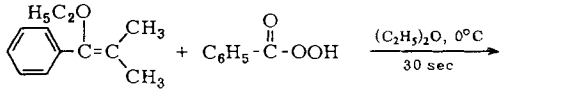
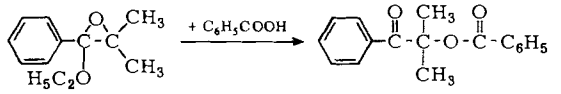
chloropropionitrile in 9 % yield; the reaction is assumed to proceed by a short-chain free-radical mechanism [21].

2.2. Oxidation

Enol ethers are relatively stable to atmospheric oxygen [22]; they are attacked only by stronger oxidizing agents such as ozone, perbenzoic acid, or salts of heavy metals in higher valency states.



The ozonization of enol ethers, like the ozonization of olefins, leads to cleavage of the double bond and therefore is of analytical interest [23,24]. It is, however,

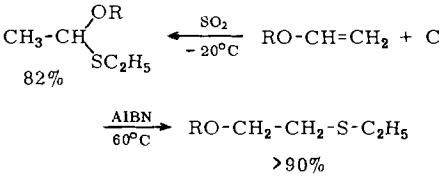


(10)

important for the preparation of the otherwise difficultly accessible ω-formyl carboxylic acids *(10)* from cyclic enol ethers [25]. In competitive ozonization of enol ethers and olefins, the polarized double bond of the enol ethers is broken more rapidly [24].

Epoxy ethers were originally formulated as stable reaction products in the reaction of enol ethers with perbenzoic acid [26,27]. This was later found to be incorrect [28,29]. Epoxy ethers *(11)* can be isolated only when structural factors are favorable and by rapid operation at low temperatures, since the benzoic acid formed otherwise reacts

(11) 90% *(12)*



further with *(11)* to give *(12)* [28]. Thus, the epoxy ether derived from 1-ethoxy-1-cyclohexene cannot be isolated, whereas the epoxide of the corresponding acetoxy compound can be obtained in moderate yields [30].

Oxidation of enol ethers with lead tetraacetate, other lead(IV) carboxylates [35], thallium(III) acetate, or benzoyl peroxide results in addition of two acetoxy groups to the CC double bond [31–34].

The addition of benzoyl peroxide probably proceeds by a free-radical mechanism [33]; in the reaction with lead(IV) acetate, however, polar addition of $Pb(OAc)_3^{\oplus}$ + $AcO^{\ominus}$ is more likely [36] than the free-radical pathway [37].

2.3. Reactions with Sulfur Compounds

Whereas water and alcohols add to enol ethers in accordance with the Markownikoff rule to yield aldehyde derivatives, S–H compounds also give the anti-Markownikoff addition products [38–43]. The direction of addition depends entirely upon the reaction conditions [40,42]. At low temperatures and with catalytic quantities of SO_2, a polar addition mechanism leads to aldehyde derivatives. At higher

(SO$_2$) R = C_2H_5, C_4H_9

(AIBN) R = C_6H_5, p-CH_3–C_6H_7, C_4H_9, C_6H_{11}

temperatures, in the presence of radical generators such as azoisobutyronitrile (AIBN), or on UV radiation [44], anti-Markownikoff addition products are formed.

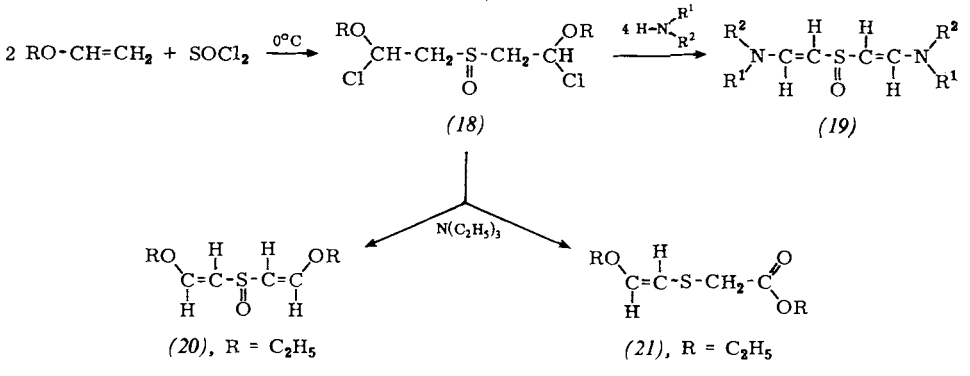
Since the reactivity of vinyl ethers in this reaction is higher than that of olefins it was concluded that the thiyl radical initially formed acts as electron acceptor [45].

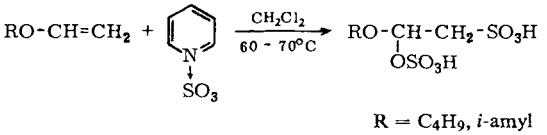
Investigations on reactions of derivatives of positive bivalent sulfur with enol ethers have been mainly confined to sulfenyl chlorides, which give addition



products *(13)* or substitution products *(14)*, depending on the reaction conditions and on the nature of the substituents [46–49].

isolated, but can be converted into the more stable alkoxy compounds *(17)*.

The only tetravalent sulfur compound whose reactions with enol ethers have been extensively studied is thionyl chloride [53–55], though the reaction of SF_4 with methyl trifluorovinyl ether has been mentioned [56].



$SOCl_2$ reacts with an excess of vinyl ether under mild conditions to form bis-β-alkoxy-β-chloroethyl sulfoxides *(18)* as colorless crystalline compounds, which yield the sulfoxides *(19)* on treatment with primary and secondary amines, and the elimination product *(20)* as well as the rearrangement product *(21)* on reaction with tertiary amines [55]. Because of steric and electronic factors, the reaction proceeds more slowly with substituted vinyl ethers, leading only to 1:1-addition compounds [55].

The sulfur is always bonded to the β-C atom of the enol ether, in agreement with the reaction type proposed by *Kharasch et al.* for sulfenyl chlorides, the sulfur carrying a partial positive charge [50]. Exclusive *trans* addition [49] indicates a sulfenium ion *(15)* as intermediate [49,50].

The analogous addition compounds *(16)* of vinyl ethers with dialkoxyoxophosphoranylsulfenyl chloride [51] and with disulfur dichloride [52] cannot be

Electrophilic addition can be accomplished with the pyridine-SO_3 adduct as a sulfonating agent [57], whereas SO_2Cl_2 gives only polymers [58].

Enol ethers can be converted into thioamides by reaction with elemental sulfur in the presence of secondary amines [59].

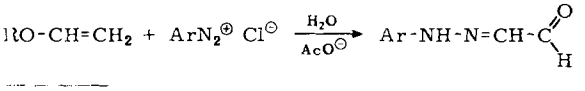
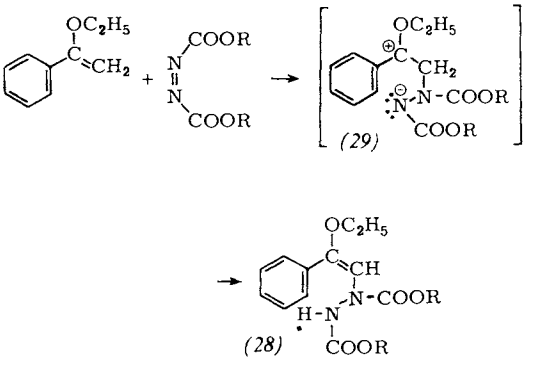
2.4. Reactions with Nitrogen Compounds

Nitrosyl halides add smoothly to enol ethers below −20 °C [60–62]. The resulting β-nitroso α-halogeno ethers *(22)* are generally dimeric [61], and, with the exception of the perfluorinated derivatives [63], they are not very stable. They react with alcohols and bases to form the stable acetals *(23)*, which can also be obtained directly from enol ethers and alkyl nitrites [63].



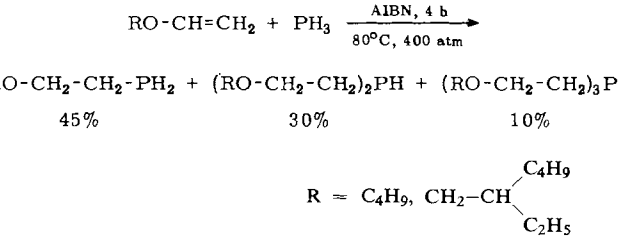
The reaction of nitryl halides and dinitrogen tetroxide with enol ethers is much less satisfactory. For example, the reaction of butyl vinyl ether with nitryl chloride at −20 °C in chloroform yields 20 % of 1,2-dichloroethyl butyl ether and only traces of 1-chloro-2-nitroethyl butyl ether [64]. Reaction with N_2O_4 leads only to decomposition and polymerization of the vinyl ethers [65].



Only alkyl perhalogenovinyl ethers react with nitryl halides or N_2O_4 to give definite addition compounds *(24)* and *(25)* respectively, which can be converted into the esters *(26)* and *(27)* by hydrolysis [66,67].

Diazonium salts undergo an electrophilic reaction with enol ethers to form glyoxal phenylhydrazones at 0 °C in sodium acetate buffer solution [68]. Attempts to isolate the unhydrolyzed substitution products in non-aqueous media were unsuccessful [69].

The nitrogen in azodicarboxylic esters is also electrophilic, and can react with enol ethers; reaction with α-ethoxystyrene, for example, yields the Diels-Alder cycloadduct together with a comparable amount of the substitution product *(28)* [70], which *Huisgen* assumes to be formed *via* a dipolar intermediate *(29)* [71].



2.5. Phosphorylation

The enol ethers can react with P–H compounds or with phosphorus halides to form compounds containing C–P bonds. Dialkyl phosphites add smoothly to vinyl ethers in the presence of free radical generators to give exclusively anti-Markownikoff products

(30)

(30) [72,73]. Reaction with phosphine under similar conditions leads *via* a free-radical chain mechanism to a mixture of mono-, di-, and trialkylphosphines [74].

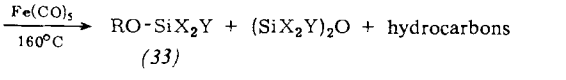
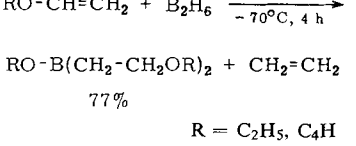
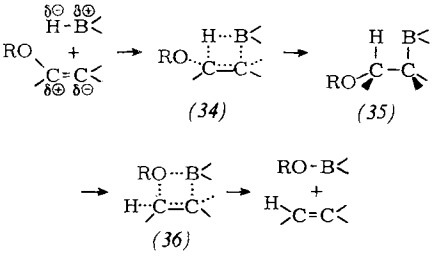
Halides used include phosphorus pentachloride [75,76] and ethyl- and phenyltetrachlorophosphoranes [77-79], all of which give β-substitution products of the vinyl ethers. Acceleration of the reaction on addition of $FeCl_3$ supports the assumption of an ionic mechanism [77].



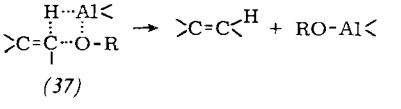


2.6. Reactions with Hydrides of Silicon, Boron, and Aluminum

The reaction of silanes *(31)* with vinyl ethers results either in addition to form *(32)* or in cleavage of the ether linkage to yield *(33)*, depending on the catalyst and the reaction conditions [80-83].

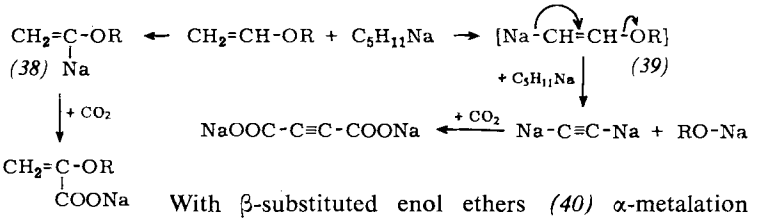


Addition and cleavage occur concurrently in the reaction of diborane with alkyl vinyl ethers [84].



Dialkylboranes and dialkylaluminum hydrides lead only to cleavage of the ether linkage, with formation of the expected olefins [85,86].

The uncatalyzed reactions of these hydrides with enol ethers proceed by like mechanisms. The polarized metal-H bond adds across the polarized CC double bond, the reaction proceeding *via* the transition state *(34)* [87]. The addition compound *(35)* can then undergo ether cleavage *via (36)* [88]. Addition and elimination proceed stereospecifically as *cis*



reactions [87,88]. In the reaction with dialkylaluminum hydrides direct cleavage *via* the transition state *(37)* is less likely [86].

2.7. Reactions with Organometallic Compounds

This section will deal only with reactions whose course is influenced by the CC double bond. Pure ether reactions are not discussed.

Paul and *Tchelitcheff* found that pentylsodium metalates enol ethers in the α- or β-position of the double bond [89]. Whereas the α-metalated compound *(38)* is stable under the reaction conditions, the β-metalated enol ether *(39)* immediately rearranges into an alkyne and an alcohol.

With β-substituted enol ethers *(40)* α-metalation predominates, while α-substituted compounds are metalated only in the β position [89].

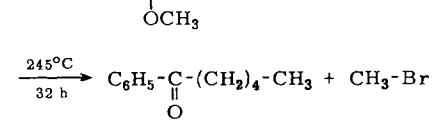
Acetylene was also obtained in the reaction of phenyl vinyl ether with triphenylmethylsodium [90], indicating β-metalation in this case.

Organolithium compounds, which are less reactive than the sodium derivatives, do not react with enol ethers below −30 °C [91]. At higher temperatures, no definite reaction products are obtained apart from a little acetylene [92].

Grignard compounds, in which the polarity of the C-metal bond is even lower than that of the Li–C bond, evidently do not metalate enol ethers, but form normal adducts *(42)*. The negative alkyl residue of the Grignard compound can then react with the α-C atom of the vinyl group to form an olefin *(43)*, or a ketone *(44)* may be formed by cleavage of the ether linkage [93–95]. The reaction course depends on the nature of R^1.

Organomercury compounds often exhibit different behavior, owing to substantially homopolar character of the C-metal bond [96]. Mercury salts add to enol ethers smoothly and in excellent yields [97–100]. The acylals *(45)* formed with mercury(II) acetate can be

easily converted into *(46)* by treatment with other Hg salts and water [98]. With yellow mercuric oxide and catalytic quantities of mercury(II) acetate, *(47)* is formed [99]. Reaction in the presence of alcohol leads directly to the acetals *(48)* [100]. Since the addition takes place exclusively in one direction, electrophilic addition of the mercury salt to the enol ether must be assumed.



3. Reactions of Enol Ethers leading to the Formation of C–C Bonds

The nucleophilic enol ethers should undergo polar C–C linkage with electrophilic carbon compounds. The difficulty with this reaction arises from the fact that few reactants are sufficiently electrophilic to react with enol ethers in the absence of Friedel-Crafts catalysts, which, however, usually cause polymerization of the enol ether.

3.1. Alkylation of Enol Ethers

Whereas enamines are sufficiently nucleophilic to undergo *C*-alkylation without the need for catalysts [101], this reaction is generally not feasible with enol ethers.

The only data available regarding alkylation with alkyl halides refer to the reactions of α-methoxystyrene with benzyl bromide, *n*-butyl bromide, and chloroacetic ester [102]. It is, however, by no means certain that enol ether is stable at the high temperatures used.

Solvolysis of 1,4-dihydro-3,5-dimethoxybenzyl *p*-toluenesulfonate *(49)*, which leads *via (50)* to 1,6-dimethoxycycloheptatriene *(51)* [103], may be regarded as an intramolecular alkylation of an enol ether. The S_N2 alkylation of the enol ether is made possible by the favorable steric conditions.

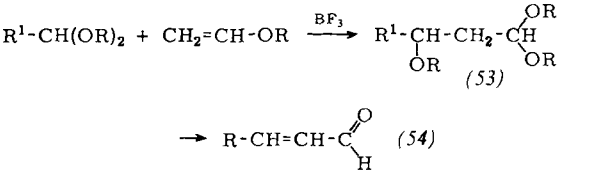
(49) (50) (51)

The reaction with tropylium salts, which yields cycloheptatrienylacetaldehydes *(52)* [104], may also be regarded as an alkylation of an enol ether.

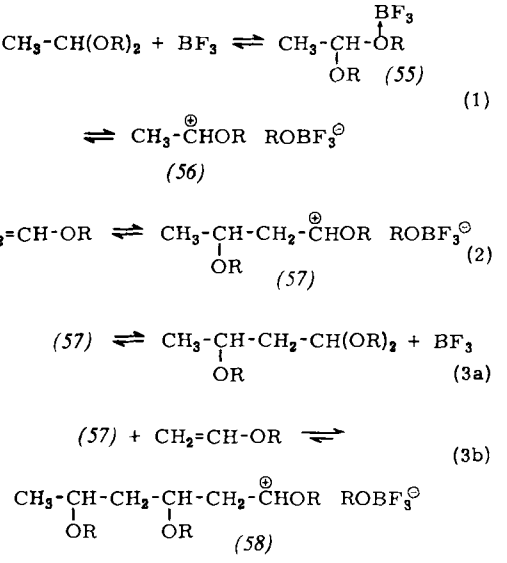
(52), 60%



$R^1 = R^2 = CH_3$, H; R = C_2H_5, $CH(CH_3)_2$, C_4H_9

The importance of correct choice of reaction conditions is emphasized by the ease of polymerization of vinyl ethers under the action of tropylium salts [105].

3.2. Reaction of Acetals with Enol Ethers



In contrast with alkylation, the polar C–C linkage of enol ethers with aldehydes and ketones or their derivatives is of considerable importance [106]. The reaction of acetals with enol ethers is particularly important, providing a valuable supplement to the aldol condensation, to which it is greatly superior in many cases by virtue of the specificity of the reaction.

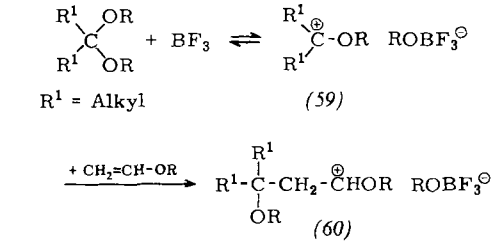
It was first observed in 1939 that acetals add to enol ethers in the presence of BF_3 [107]. The addition compounds *(53)* can lose alcohol to yield α,β-unsaturated aldehydes *(54)* [108]. Since the new acetal *(53)* can again add to the enol ether, a definite chain lengthening by two C atoms per step is possible.

(53) *(54)*

Hoaglin and *Hirsh* have proposed a carbonium ion mechanism [108] comparable to the mechanism of the acidic aldol condensation, with R in place of H.

(1)

(2)



(3a)

(3b)

(56) *(57)* *(58)*

The acetal reacts with the catalyst to form an adduct *(55)*, which ionizes because of the stabilization of both cation and anion; whether dissociation is complete or proceeds only as far as the formation of ion pairs will not be discussed. Nucleophilic reaction of the vinyl ether with the carbonium fluoroborate *(56)* yields *(57)*, which adds either the anion in accordance with eq. (3a) or a further mol. equiv. of vinyl ether to give *(58)* as in eq. (3b). *(58)* can then again react with the anion or with another mol. equiv. of vinyl ether. Reaction (3a) is favored by a high acetal/vinyl ether ratio [108] and by higher reactivity of *(56)* as compared with *(57)*.

Comparison of the reactions of ketals with those of aromatic aldehyde acetals demonstrates the influence of the reactivity of the carbonium ion. Ketals give practically no 1:1 addition product, even when less than 1 mol. equiv. of the vinyl ether is present, since *(60)*, being more reactive than *(59)*, immediately

R^1 = Alkyl *(59)* *(60)*

reacts further with the vinyl ether. The acetals of aromatic aldehydes, on the other hand, give mainly the 1:1 adduct even at an acetal/vinyl ether ratio of only 1:1, since *(61)* is much more reactive than *(62)*, and so reacts preferentially with the vinyl ether [109].

The reactivity of acetals toward vinyl ethers increases in the order: saturated acetals < aromatic acetals <

[104] *M. E. Vol'pin, I. S. Akhrem,* and *D. N. Kursanov,* Ž. obšč. Chim. *30*, 159 (1960); Chem. Abstr. *54*, 22535h (1960); Chem. Abstr. *60*, 13180g (1964).

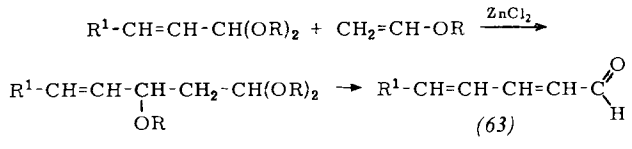
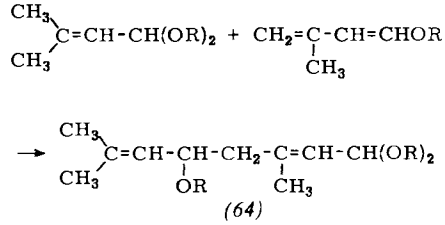
(61)



(62)

α,β-unsaturated acetals. Even the inert saturated acetals react with normal vinyl ethers to give the 1:1 compound in 60 to 70 % yield if the acetal is present in excess [108].

Since the catalysts used can also cause polymerization of vinyl ethers, the addition of acetals is also influenced by the tendency of the enol ether toward polymerization, which increases in the order 1-unsubstituted enol ethers < 1-substituted enol ethers < 1-alkoxydienes [110, 111]. Thus saturated acetals add to 1-unsubstituted enol ethers; with 1-substituted enol ethers and 1-alkoxydienes, on the other hand, polymerization predominates. The more reactive aromatic acetals undergo addition even with readily polymerizable enol ethers.



The advantage of this reaction over the aldol condensation is that the enol ether, as a potential carbonyl compound, acts only as a nucleophile, and the acetal only as an electrophile [112, 113]. For example, four products are to be expected, and are in fact found, in the alkaline aldol reaction of propionaldehyde with acetaldehyde, whereas the reactions of propionaldehyde acetal with ethyl vinyl ether and of acetaldehyde acetal with ethyl propenyl ether each give only one product.

The reaction of α,β-unsaturated aldehyde acetals with vinyl ethers is often used for the synthesis of polyenes *(63)* [114]. Alkoxydienes have also been used as the

(63)

enol ether component, *e.g.* for the synthesis of ethoxycitral acetal *(64)* [112, 115].

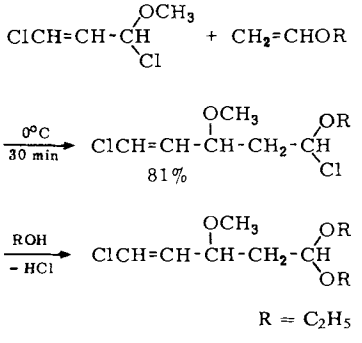
The reaction of enol ethers with acetals is also important in carotenoid syntheses. Thus, one industrial synthesis of β-carotene involves condensation of a vinyl ether and a propenyl ether with acetals [116]. Another process for the synthesis of symmetrical carotenoids (C_{40}) starts with C_{14} acetals and a symmetrical C_{12} dienol ether [117].

Cyclic acetals also add to vinyl ethers, an additional possibility in this case being transacetalization if this yields more stable products [118, 119].



In the case of the thioacetals, only the most reactive members add to enol ethers [120], since the alkylthio group does not stabilize the carbonium ion so well as an alkoxy group.

R^1 = C_6H_5, C_6H_5-CH=CH, R^2-CH=CH

On the other hand, ionization should be facilitated in α-halogeno ethers, and these compounds do, in fact, react particularly readily with vinyl ethers [121].

R = C_2H_5

A reaction comparable with that of enol ethers with acetals is the dimerization of vinyl ethers with BF_3 in the presence of mercury salts, which proceeds *via* an Hg-addition compound [122, 123].

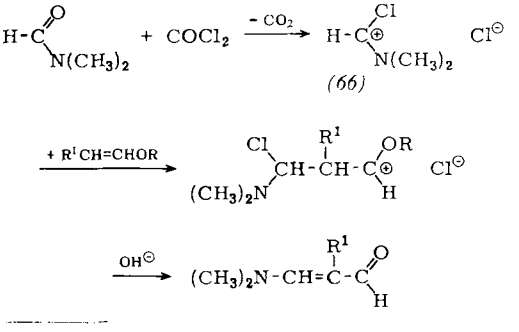
Polymerization of the enol ether is prevented by addition of Hg salts. The resulting acetal can react further with an excess of vinyl ether in the presence of BF_3, but this occurs only to a small extent [122].

The reaction of Schiff bases with enol ethers in acetic acid may be included in the same group as the acetal reaction [124].



3.3. Formylation and Acylation of Enol Ethers

An important variant of the acetal reaction is the reaction of enol ethers with ortho esters [106].

The most extensively studied reaction in this group is the formylation of enol ethers with orthoformates [106, 125, 126] to give derivatives of malonic dialdehyde *(65)*, which are valuable starting materials for the synthesis of heterocycles [127]. The higher ortho esters ($R^1 \neq H$) are much less reactive, and apart from formylation, the only other acylations of enol ethers so far have been with orthoacetates, with limited success [128].

[124] *L. S. Povarov* and *B. M. Mikhailov*, Izvest. Akad. Nauk SSSR, Ser. chim. *1964*, 1910; Chem. Abstr. *62*, 2730g (1965).

Enol ethers can also be formylated by reaction with Vilsmeier-Haack agents [129]. The formylating agent *(66)* formed from dimethylformamide and phosgene is the most suitable for reaction with enol ethers [130,131], since it shows little tendency to initiate polymerization.

Acylation of enol ethers in the presence of Friedel-Crafts catalysts is possible only if the enol ether has little tendency to polymerize. This condition is met *e.g.* by enol ethers of the steroids, which can therefore be acylated in the presence of BF_3 [132].

The electrophilic potential of acylating agents can also be increased by substituents. While acetyl chloride itself does not react with vinyl ethers, monochloroacetyl chloride causes polymerization, dichloroacetyl chloride yields the addition compound *(67)*, and trichloroacetyl chloride gives the substitution product *(68)*. *(67)* and *(68)* are formed in very good yields [133].

Oxalyl chloride also has a high electrophilic potential. It adds to enol ethers at room temperature, with primary formation of the α-halogeno ether *(69)* which reacts readily with nucleophiles, such as triethylamine, to give *(70)* [134].

Exclusive *cis*-addition of oxalyl chloride has been found for dihydropyran [135].

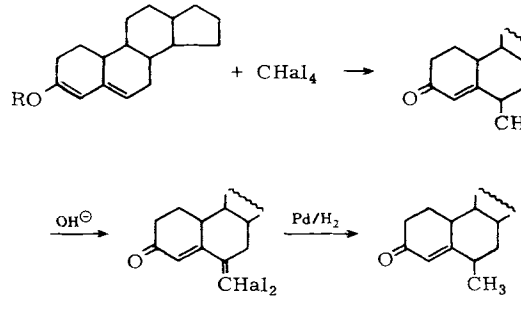
(69)

(70)

Phosgene, which is also a strongly electrophilic acid chloride, reacts with enol ethers at about 0 °C to form acyl chlorides of α,β-unsaturated carboxylic acids [136, 137], while at about 50 °C polymerization occurs [138]. The β-alkoxyacryloyl chlorides readily obtainable by this reaction are useful starting compounds for the synthesis of heterocycles [139].



3.4. Reaction of Tetrahalogenomethanes with Enol Ethers

A new C–C bond is also formed in the addition reactions of enol ethers with tetrahalogenomethanes, which proceed by a radical mechanism (in the presence of benzoyl peroxide or on irradiation) [140–143].

Hal = F, Cl, Br

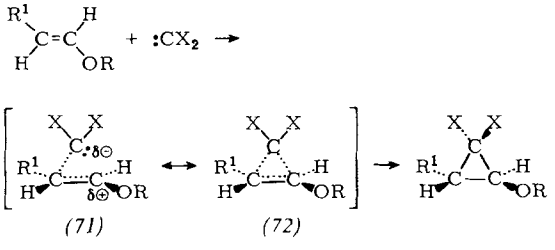
Fluorine, chlorine, and bromine compounds are used. When mixed tetrahalogenomethanes are employed, bromine, which is most readily removed as a free radical, becomes attached

to the α-carbon atom of the enol ether [144]. The reaction with tetrahalogenomethanes can also be applied to steroids, and permits *e.g.* the introduction of a methyl group [145].

4. Cycloadditions

Enol ethers are particularly suitable for use in the study of cycloadditions for the following reasons:

1) They are electron-rich olefins, intermediate between olefins and enamines in their polarization, and can therefore react both by a concerted mechanism and *via* dipolar intermediates. A polar reaction is favored in the case of enamines [146] and a synchronous reaction in the case of olefins.



2) The ratio of addition to substitution with enol ethers is also intermediate between that with enamines, which tend to undergo substitution, and that with olefins, most of which undergo addition. The reactions with enol ethers often lead to primary addition products, whose conversion into the substitution products is amenable to study [147].

3) Stereoisomeric enol ethers are easy to prepare, and generally do not isomerize during the reaction, so that the steric course of the cycloadditions can be readily observed.

Most of the cycloadditions with enol ethers described so far result in the formation of two new σ bonds, leading to three-, four-, five-, or six-membered rings. Following a suggestion by *Huisgen*, these are known as 2+1, 2+2, 2+3, and 2+4 cycloadditions [148], the enol ether being the 2-component, though it may also be the 4-component in the 2+4 combination.

4.1. 2+1 Cycloadditions

This type of cycloaddition is represented by the reaction of carbenes or nitrenes with enol ethers.

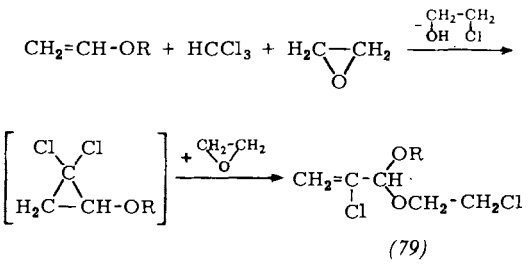
Dihalogenocarbenes react more readily as electrophiles with enol ethers than with olefins [149, 150]. The reactions lead almost exclusively to cycloaddition, insertion occurring only in isolated cases.

The stereospecific *cis*-addition observed with olefins [151] was confirmed also for the addition of halogenocarbenes to enol ethers [152]. The reaction may therefore be concluded to be an essentially synchronous cycloaddition of the singlet carbene to the double bond [149].

The stability of the resulting cyclopropane derivatives depends on the enol ether used, and in the case of cyclic ethers it increases with increasing ring size [153, 154]. Thus *(73)* can be distilled under greatly reduced pressure, but rearranges quantitatively into *(74)* above 60 °C [153]. The ring expansion in *(75)* occurs only at 140 °C, and, on heating in quinoline, one mol. equiv.

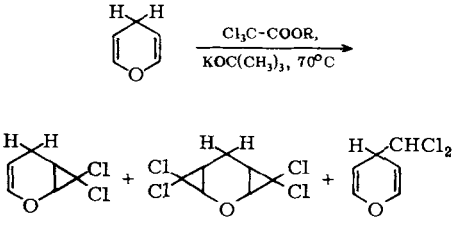


(73) *(74)* *(75)* *(76)* *(77)* *(78)*

of HCl is simultaneously eliminated with formation of *(76)*. *(77)* and *(78)* do not give isolable quantities of ring expansion products when heated [155].

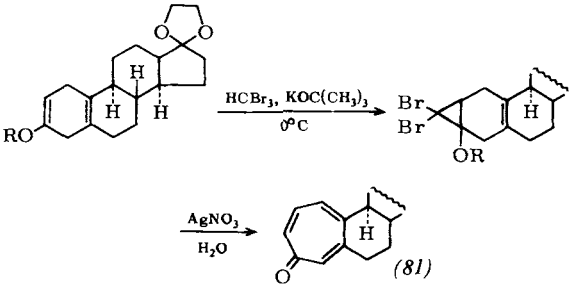
The difference in the tendency toward rearrangement is due not only to ring strain, but also to the ionization of the C-halogen bond, which is distinctly influenced by the neighboring group participation of the ether oxygen [154].

Entropy measurements [156] show, in agreement with the Woodward-Hoffmann rules for a thermal reaction [157], synchronous opening of the three-membered ring.



When enol ethers are allowed to react with haloforms and two mol. equiv. of ethylene oxide, the intermediate

(79)



cyclopropane derivative in most cases immediately undergoes secondary reaction to form *(79)* [158].

Carbenes also add to divinyl ethers [159] and to the moderately stable 4*H*-pyrans [160]; in the latter case, mono- and dicycloaddition are accompanied to a small extent by insertion to form *(80)* [160].

(80)

The addition of carbenes to enol ethers followed by ring expansion is frequently used in syntheses [158, 161, 162]. Tropolone-analogous steroids *(81)* can be prepared particularly easily in this way [163, 164].

(81)

4.2. 2+2 Cycloadditions

As electron-rich alkenes, enol ethers very readily enter into 2+2 cycloadditions with electrophilic π systems. *Staudinger* and *Suter* reported on the addition of diphenylketene to ethyl vinyl ether as early as 1920 [165].

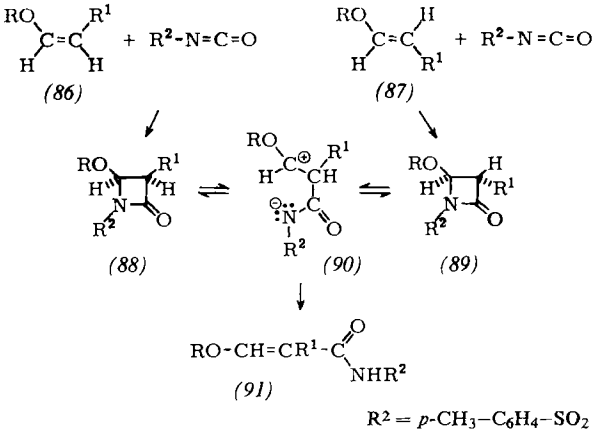
The orientation in these cycloadditions is unequivocally fixed by the polarization of the starting compounds in the ground state[166].

(82) (83)

Apart from ketenes[167,168], halogeno and cyano olefins[169–171] have also been treated with enol ethers. Cyclobutane derivatives, which are stable under the reaction conditions, are formed in each case.

Heterocumulenes, *e.g.* isocyanates, react with enol ethers to yield four-membered heterocycles *(84)*, which are less stable than cyclobutanes, and therefore enter into secondary reactions such as the formation of substitution compounds *(85)*[172,173].



(84)

(85)

N-Sulfinylsulfonamides and sulfenes react in a like manner[174–176].

These 2+2 cycloadditions are of interest not only for synthetic purposes, but more so from the point of view of their mechanism, and particularly in connection with the question whether the process is a two-step reaction *via* a polar intermediate or a one-step multicenter addition. Both the stereospecific and the non-stereospecific cyclobutane ring closures of *cis*- and *trans*-1,2-dicyano-1,2-bis(trifluoromethyl)ethylene with *cis* and *trans* enol ethers are interpreted as proceeding *via* a polar intermediate[171]. The experimental data on the addition of ketenes to enol ethers, however, can be better interpreted by a one-step multicenter process[167].

cis and *trans* Enol ethers *(86)* and *(87)* react stereospecifically with sulfonyl isocyanates to give the β-lactams *(88)* and *(89)*, respectively, which isomerize *via* ring cleavage into an equilibrium mixture, or are converted irreversibly into the substitution product *(91)*[177,178].

(86) (87) (88) (90) (89) (91)

$R^2 = p\text{-}CH_3\text{–}C_6H_4\text{–}SO_2$

For $R = R^1 = CH_3$, the kinetics of hydrolysis reactions prove *(86)* to be more stable by 0.53 kcal/mole than *(87)*[179]. The position of the equilibrium *(88)*/*(89)*, on the other hand, indicates that *(89)* is 0.27 kcal/mole more stable than *(88)*[178].

According to the correlation proposed by *Hammond* between reactivity and the transition state[180], therefore, the relative stabilities of the starting compounds and end products in the above cycloadditions show that the transition state for the addition of the *cis* enol ether is closer to the four-membered ring than the transition state for the addition of the *trans* ether (see Fig. 1).

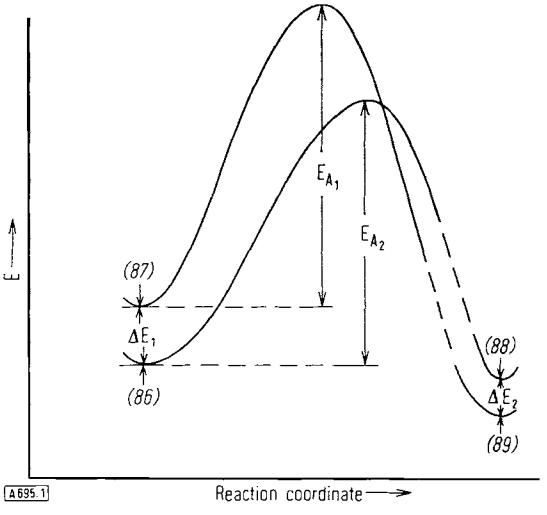


Fig. 1. Energy profiles for the cycloaddition of *cis*-*(86)* and *trans*-1-methoxy-1-propene *(87)* to tosyl isocyanate to give the azetidinones *(88)* and *(89)*, respectively.
$E_{A_1} = 10.2$ kcal/mole, $E_{A_2} = 9.4$ kcal/mole.

The reaction rate of *cis* enol ethers increases more rapidly than that of *trans* ethers with increasing dielectric constant of the solvent[178]. If the bonds in the transition state are assumed to differ in length[181], the observed solvent dependency of the reaction rate does not allow greater charge separation in the transition state for the addition of the *trans* ether than for the addition of the *cis* ether. We therefore conclude that the

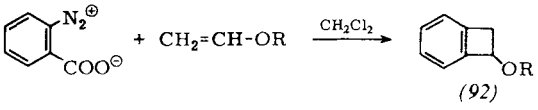
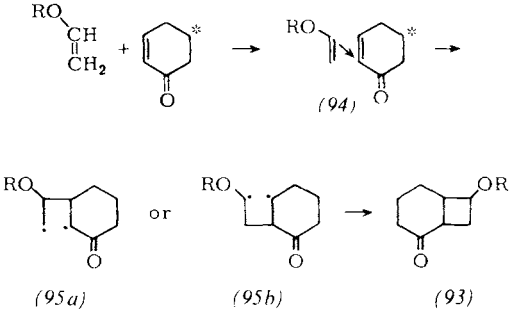
intermediate *(90)* does not occur in the cycloaddition itself. *(90)* must be postulated, however, for the isomerization *(88)* → *(89)* as well as for formation of *(91)*.



The Woodward-Hoffmann rules in their original form forbid thermal 2+2 multicenter cycloadditions[182], but in their further developed form they allow synchronous mechanisms for the cycloadditions mentioned. One possibility would be the assumption of a crossed arrangement of the double bonds, for which a synchronous $\pi_s^2 + \pi_a^2$ cycloaddition is thermally allowed[157].

$\pi_s^2 + \pi_a^2$ $\quad$ $\pi_s^2 + \pi_s^2 + \pi_s^2$ $\quad$ $\pi_s^2 + \pi_a^2 + \pi_a^2$

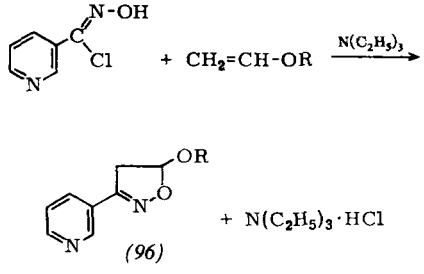


If the C=O double bond is taken into consideration, the reactions of ketenes and isocyanates with enol ethers may also be regarded as 2+2+2 cycloadditions. As $\pi_s^2 + \pi_a^2 + \pi_a^2$ and $\pi_s^2 + \pi_s^2 + \pi_s^2$ processes, respectively, these reactions are thermally allowed[183].

Dehydrobenzene also undergoes a 2+2 cycloaddition with enol ethers to give *(92)*[184]. There is no evidence for a polar intermediate.

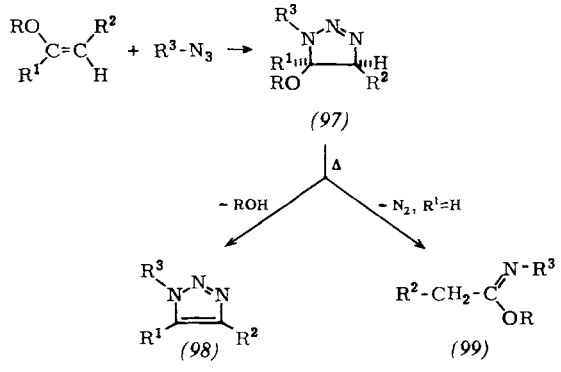
(92)

Photochemical 2+2 cycloadditions have also been investigated. The formation of bicyclo[4.2.0]octanones *(93)* in good yields from enol ethers and 2-cyclohexen-1-ones is formulated as a reaction of the enol ether in the ground state with the excited ketone *via* an oriented π complex *(94)* and a diradical intermediate *(95)*[185].



(94) $\quad$ *(95a)* $\quad$ *(95b)* $\quad$ *(93)*

In the photo-cycloaddition of diphenylacetylene to 2,3-dihydropyran, the first excited triplet state of the acetylene is assumed to react with the enol ether in the ground state[186].



It should be generally possible to employ enol ethers as dipolarophiles in 1,3-dipolar cycloadditions, which were developed by *Huisgen* and his school[187]. Enol ethers do indeed react smoothly with nitrile oxides produced *in situ* to form substituted isoxazolines *(96)*[188]. Diazomethane forms 3-alkoxypyrazolines[189], and phenylsydnone gives alkoxypyrazoles[190].

The reactions with organic azides are particularly illuminating as regards the reaction mechanism[191–193].

(96)

These compounds combine with open-chain and cyclic enol ethers in a stereoselective *cis* addition to form 1,2,3-triazol-1-ines *(97)*. Depending on the structure of the enol ether, either alcohol is eliminated with

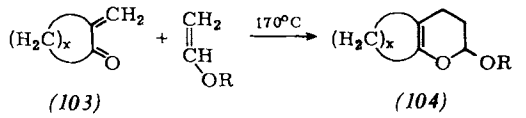
formation of triazoles *(98)* or N_2 is given off to yield esters of imidic acids *(99)* [191]. The mechanism proposed is a one-step multicenter reaction with bonds of different lengths in the transition state [187, 191, 193].

The formulation of partial charges in the transition state is substantiated by the fact that the direction of addition is determined purely electronically [191], in contrast with the steric control otherwise found in 1,3-dipolar cycloadditions. Further evidence of a polarized transition state is provided by comparison of the rates of reaction with picryl azide and phenyl azide; whereas the ratio of the reaction rates with olefins is 590–1434:1, that with enol ethers is 46000:1 [193]. Despite this evidence of polar structures, a true σ complex can be ruled out.

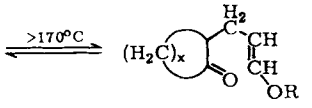
4.4. 2 + 4 Cycloadditions

Recent reviews have dealt in detail with the influence of substituents, including alkoxy groups, on the course of Diels-Alder reactions [194, 195]. Consequently, this influence need not be discussed in detail here. Alkoxy groups in the diene favor the addition with normal electronic requirements [195, 196], even though steric effects often play a more important part than electronic effects [196].

The increased reactivity of alkoxydienes is exemplified by the fact that paraformaldehyde reacts with 1-alkoxybutadienes, but not with butadiene [197]. If the electronic influence is reinforced by favorable steric effects, as in *(100)*, the reaction proceeds particularly readily with formation of *(101)* or possibly *(102)* [198].



(102)

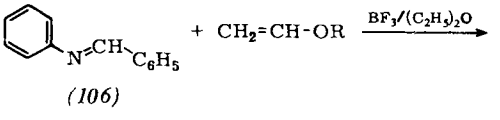


Less clear than the influence of alkoxy groups in the diene is the reaction of enol ethers as dienophiles in Diels-Alder additions with "inverse" electronic requirements [194, 199]. Cyclones, hexachlorocyclopentadiene, and 1,2,4,5-tetrazines have mainly been employed as electron-deficient dienes, all of which react smoothly with enol ethers [200–203].

Little sensitivity of the rates of reaction toward substituent effects, as in other diene additions, comparable energy and entropy of activation, as well as large steric influence all make a multicenter mechanism a rather probable one for diene addition with "inverse" electronic requirements.

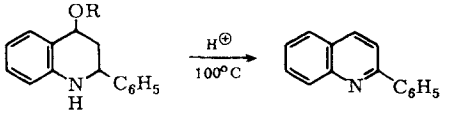
The cycloadditions of α,β-unsaturated carbonyl compounds *(103)* with electron-rich olefins to form dihydropyrans *(104)* [204] may also be regarded as Diels-Alder additions with "inverse" electronic requirements, though there are

(103) *(104)*



(105)

some mechanistic differences. On addition of acid, for example, the reaction rate is increased if the diene component is protonated but decreased if the olefin is protonated; the reaction is therefore assumed to involve an electrophilic attack on the olefin with a polar intermediate [205].



Moreover, the conversion of *(104)*, $x = 3$, $R = C_2H_5$, into *(105)* above 170 °C [206] does not correspond to the behavior of Diels-Alder adducts but suggests ring opening with a possibly polar intermediate, which is transformed into the substitution product *(105)* by tautomerism.

The cycloaddition of α,β-unsaturated carbonyl compounds with enol ethers is used, *inter alia*, in steroid chemistry [207].

Schiff bases *(106)* also act as "diene components" in cycloadditions with enol ethers [208]. Since the reactions

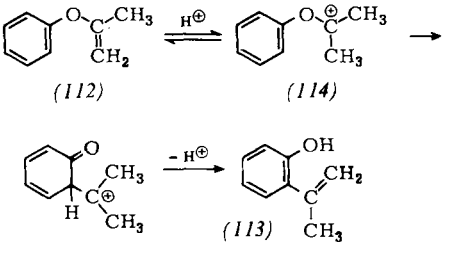
are stereospecific, a cyclic six-center mechanism is postulated [208]. However, the catalyst used indicates at least partial charge separation.

A two-step or multi-step mechanism is assumed for the 2+4 cycloaddition of thioaroyl isocyanates to enol ethers and enamines [209].

The reaction of aldehydes with enol ethers, in which 1,3-dioxanes *(110)* are formed as isolable intermediates [210,211], offers a possible synthetic route to α,β-unsaturated carbonyl compounds (cf. Section 3.2).

(109) *(111)*



(110)

If the (hypothetical) intermediate *(111)* [210,211] is assumed to occur, the enol ether is no longer a true cycloaddition partner in this case.

5. Rearrangements of Enol Ethers [212]

5.1. Acid-Catalyzed Rearrangement

When *(112)* is heated for 5 hours with 10 % glacial acetic acid/sulfuric acid, the principal product is 2-isopropenylphenol *(113)* [213]. The mechanism is unknown [212]. Since *(112)* is converted almost entirely

(112) *(114)*

(113)

into *(113)*, and not into the *p* derivative, an intramolecular mechanism involving electrophilic substitution of the protonated compound *(114)* is probable. An approximately synchronous course with a four-membered transition state for the *o* rearrangement and a six-membered transition state for the *p* rearrangement is more likely than complete cleavage, in view of the instability of the cleavage products resulting from heterolysis.

[213] *J. B. Niederl* and *E. A. Storch*, J. Amer. chem. Soc. *55*, 284 (1933).

5.2. Thermal Rearrangement of Alkyl Vinyl Ethers

Normal alkyl vinyl ethers rearrange into aldehydes or ketones in the presence of dehydration catalysts such as aluminum oxide, zirconium oxide, and B-phosphate at 200–300 °C [214–216].

The α-alkoxystyrenes *(115)* isomerize more readily into alkyl phenyl ketones *(116)* [217–219]. On the strength of stereochemical observations in the rearrangement of ethers with optically active alkyl residues, the use of labeled compounds, and the study of the influence of free-radical generators (X–X), *Wiberg et al.* have shown this rearrangement to involve an intermolecular free-radical chain reaction [219].

(115) *(116)*

Chain termination reactions

$$2\ X\cdot \rightarrow X\text{-}X;\quad X\cdot + R\cdot \rightarrow X\text{-}R;\quad 2\ R\cdot \rightarrow R\text{-}R$$

The rearrangement of α-benzyloxystyrene *(115)*, R = CH_2–C_6H_5, proceeds *e.g.* in 88 % yield at only 70 °C in the presence of azoisobutyronitrile, whereas, in the absence of free radical generators, a comparable yield is obtained only on heating to 207 °C [219].

5.3. Thermal Rearrangement of Allyl Vinyl Ethers

The synthesis of allyl vinyl ethers and their tendency to rearrange were first described in 1938 [220]. The rearrangement proceeds much more readily than in the case of normal alkyl vinyl ethers, and is further favored by α-substituents on the vinyl group [220]. The rearrangement temperatures of the allyl vinyl ethers

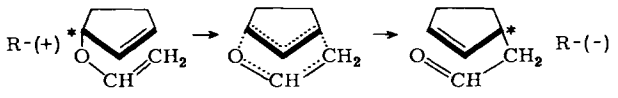
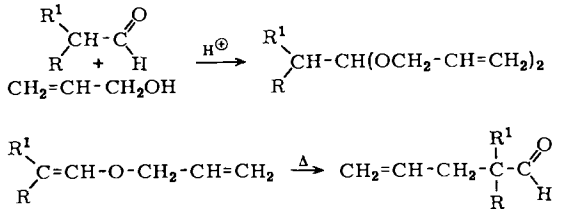
[219] *K. B. Wiberg* and *B. I. Rowland*, J. Amer. chem. Soc. *77*, 1159 (1955); *K. B. Wiberg, T. M. Shryne*, and *R. R. Kintner*, *ibid.* *79*, 3160 (1957); *K. B. Wiberg, R. R. Kintner*, and *E. L. Motell*, *ibid.* *85*, 450 (1963).



[220] *C. D. Hurd* and *M. A. Pollack*, J. Amer. chem. Soc. *60*, 1905 (1938); J. org. Chemistry *3*, 550 (1939).

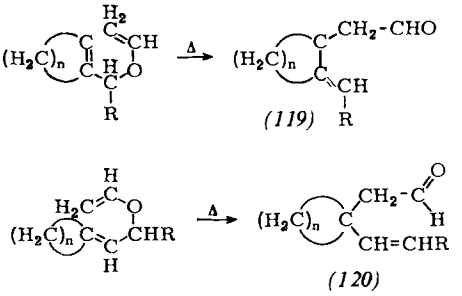
with R = H, CH_3, and C_6H_5 are 255, 210, and 175 °C respectively.

The activation parameters of the strictly monomolecular rearrangement point to a cyclic transition state [221,222]. The assumption of a cyclic electron shift is further supported by experiments with compounds labeled with ^{14}C [223] and by the possibility of stereospecific angular alkylation [224].



A particularly elegant proof of the cyclic transition state is the rearrangement of the optically active vinyl ether *(117)* into the optically active aldehyde *(118)* at 180 °C, which shows conclusively that the new C–C bond is *cis* to the broken C–O bond [225]. The rearrangement mechanism of allyl vinyl ethers is therefore

(117) *(118)*

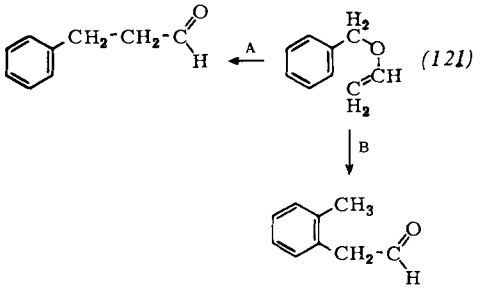


similar to that of allyl phenyl ethers, though the tautomerization leading to the more stable phenol in the Claisen rearrangement does not occur in this case.

The rearrangement of allyl vinyl ethers is also of preparative value. In addition to the angular alkylation [224], it provides an easy route to substituted 4-pentenals; the allyl vinyl ethers formed by elimination of alcohol from the diallyl acetal cannot as a rule be isolated, but immediately react further [226].

4,7,10-Undecatrienal (triallylacetaldehyde) can be synthesized by repetition of this reaction step, R = R^1 = H [227].

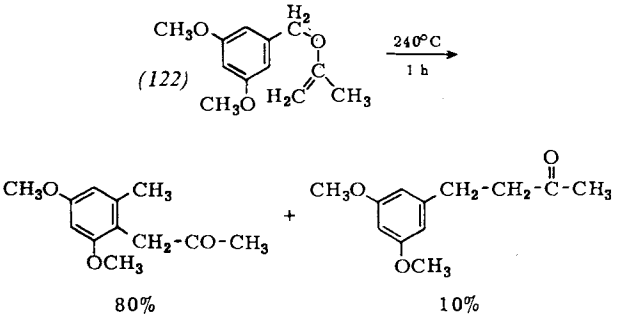
If H atoms in the allyl group are substituted, it is possible [228] to synthesize compounds such as *(119)* and *(120)*.



(119)

(120)

Propargyl vinyl ethers can be rearranged in the same way as allyl vinyl ethers [229,230]. However, one-electron shifts and combination of radical fragments are assumed to be involved in this case [229].



For benzyl vinyl ethers such as *(121)*, thermal rearrangement can be formulated in two ways, *i.e.* by a free-radical mechanism for an alkyl vinyl ether (pathA) or synchronously for an allyl vinyl ether (path B).

(121)

Benzyl vinyl ether itself does not rearrange below 300 °C; with di-*tert*-butyl peroxide, free-radical reaction by path A occurs at 170 °C [231].

3,5-Dimethoxybenzyl isopropenyl ether *(122)*, on the other hand, reacts mainly by path B, emphasizing the favorable effect of electron-donating groups on the rearrangement of allyl vinyl ethers [232].

80% 10%

The 3-methoxybenzyl compound gives both rearrangement products in comparable yields [232].

6. Closing Remarks

The chemistry of enol ethers is characterized by its similarity to the chemistry of enamines. The advantage of the enhanced nucleophilic character of the enamines

is frequently offset by the disadvantage that they form stable nitrogen addition products, thus forestalling a *C* reaction. It is often difficult, on the other hand, to find agents of sufficiently high electrophilic potential to react with enol ethers without initiating polymerization. Thus, the two classes of compounds complement each other well in their reactions as derivatives of ketones and aldehydes. *C*-Substitution reactions with phosgene, oxalyl chloride, and sulfonyl isocyanates, for example, which proceed very smoothly with enol ethers, are impracticable with enamines because of the formation of comparatively stable *N*-reaction products. Halogenation, and, in general, reactions tending to proceed *via* free-radical rather than polar mechanisms are also easier to carry out with enol ethers than with enamines. Since, in addition to the electrophilic and free-radical reactions discussed here, enol ethers may also react with nucleophiles, there is a wide field for their preparative use.

We are grateful to the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for the support of our work on enol ethers.

Cycloadditions with Polar Intermediates

By R. Gompper[*]

Dedicated to Professor H. Bredereck on the occasion of his 65th birthday

A discussion of the criteria that have been used to distinguish experimentally between one-step and two-step cycloadditions shows that in most cases useful information can be obtained only by isolation or interception of intermediates; the isolation of intermediates is also of preparative importance.

1. Introduction: Mechanistic Criteria

The preparative and theoretical importance of cycloadditions as a reaction principle is obvious from the many original papers and reviews on the subject [1]. Cycloadditions can proceed in one step or in two (even more than two are possible when more than two components are involved). The one-step reaction (cf. Fig. 1) has only a single transition state; in the two-step reaction, a dipolar intermediate is formed first (free-radical processes will not be considered here), and this is then cyclized or, if prototropy is possible, it reacts further to form a substitution product. Other possibilities are the conversion of "synchronously" formed cycloadducts into dipoles and the simultaneous occurrence of one-step and two-step cycloadditions.

When is a two-step cycloaddition to be expected?

1. Two-step cycloadditions are to be expected when concerted processes are forbidden according to the Woodward-Hoffmann rules [2–4].

2. Polar two-step cycloadditions may be possible if the charges occurring in dipolar intermediates can be adequately stabilized by substituents.

Under these conditions it is necessary to check experimentally whether a cycloaddition proceeds in one step or in two. The following criteria have been used:

1. Isolation or detection (spectroscopic, kinetic, by interception reactions) of intermediates.

2. Stereochemistry. Stereospecificity is the logical result of a synchronous cycloaddition. In two-step cycloadditions, the stereochemical course depends on the relative rates of the ring closure and of the internal rotation in the dipole. Several examples (*tert*-butyl vinyl sulfide or ethyl vinyl ether + 1,2-dicyano-1,2-bis(trifluoromethyl)ethylene [5], tetramethoxyethylene + 1,2-dicyanoethylenes [6], 4-methyl-1,2-butadiene + dimethyl maleate or fumarate [7,8], dehydrobenzene +

ethyl propenyl ether[9] or 1,2-dichloroethylene[10]; decomposition of episulfones[11,12], and decarboxylation of β-lactones[13]) show that two-step cycloadditions or the two-step decomposition of cycloadducts can be stereospecific or strongly stereoselective. This stereospecificity is possible only if the intermediate dipole has the structure *(2)*, which is "fixed" mainly by charge transfer, rather than the structure *(1)*, which is favored only by electrostatic attraction of the charge centers (illustrated for 1,4-dipoles). The fact that some stable 1,4-dipoles are colored suggests that they have

(1) *(2)*

D = electron donor, A = electron acceptor

the structure *(2)*. Another argument in favor of *(2)* is the fact that the reaction of *trans*-1,2-dicyano-1,2-bis-(trifluoromethyl)ethylene with *cis-n*-propyl propenyl ether (and also the *cis-cis* combination) gives less rearranged cycloadduct in polar than in apolar solvents[5].

3. Substituent effects and orientation phenomena. Substituents that help to stabilize the charges in polar or dipolar intermediates should also do so in the transition state, and should thus either make two-step cycloadditions possible or increase their rate in relation to systems with "neutral" substituents. It should therefore be possible to recognize two-step cycloadditions in this way. On the other hand, one-step cycloadditions have polar transition states (cf. Fig. 1), and may therefore also be influenced by variation of substituents.

Cycloadditions in which the orientation of the partners in the adduct is contrary to the polarity of the substituents are certainly not two-step polar reactions.

4. Effect of the solvent on the reaction rate. It is often argued that polar two-step cycloadditions should be strongly accelerated by polar solvents, and that a reaction rate that is influenced only slightly or not at all by the solvent is evidence of a concerted cycloaddition. This view is based on the solvent theory developed by *Hughes* and *Ingold*[14] for S_N reactions (because of the many specific interactions between the solvent and the substrate, however, it deals with only one aspect of the solvent problem[15,16]); the deciding factor in cycloadditions should thus be the difference in the dipole moments of the starting materials and of the transition state (for the theoretical treatment of the reaction of dipole molecules with dipole molecules, cf. [17,18]).

In connection with the above-mentioned specific interactions between the solvent and the reactants or the transition state, the following factors must also be considered in the discussion of the effect of the solvent on cycloadditions: rearrangement of the solvent structure (cf.[19]); "built-in solvation"[20,21] corresponding to *(1)* and *(2)*; different "hardness"[22,23] of the charge centers in the species that occur along the reaction coordinate, and hence different interactions with the chosen solvents.

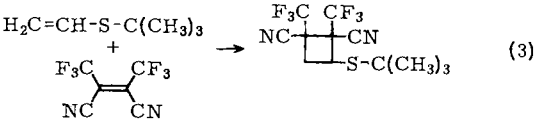
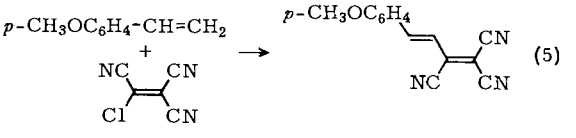
[23] *G. Klopman,* J. Amer. chem. Soc. *90*, 223 (1968).



Even when only the Hughes-Ingold theory is used, however, it is necessary to start with the idea that two-step cycloadditions are consecutive reactions, so that the solvent effect depends on the relation of the activation energies E_a^1 and E_a^2 of the two steps (cf. Fig. 1; for sake of simplicity, the solvation of starting materials and products is not considered). If the dipole formation is irreversible and $E_a^1 \gg E_a^2$, the first step is rate-determining in all solvents, and a change from polar to apolar solvents should be associated with an increase in the reaction rate. If $E_a^1 \ll E_a^2$, on the other hand, the reaction rate must be expected to decrease. Finally, if $E_a^1 \approx E_a^2$, the case illustrated in Figure 1b is also possible, *i.e.* $E_a^1 > E_a^2$ in nonpolar solvents while $E_a^{1'} < E_a^{2'}$ in polar solvents. Since $E_a^1 < E_a^{2'}$, a change from an apolar to a polar solvent should, as a simplification, lead to a (small) decrease in the reaction rate. Relatively small positive or negative solvent effects should generally result in this case. The reaction rate is also expected to increase in polar solvents when the dipole formation is reversible. A one-step and a two-step cycloaddition can therefore be distinguished only if the solvent effect is very large.

Moreover, the transition state of the first step of a two-step cycloaddition and that of a one-step cycloaddition (Fig. 1a) in which the formation of the two new bonds is not quite synchronous should have similar structures and polarities. Thus if the first step of a two-step cycloaddition is rate-determining, the solvent must have a similar effect on the reaction rate in these two types of cycloadditions.



The validity of these remarks is borne out by Table 1. It can be seen that while reactions (1) to (3) exhibit relatively large solvent effects, (5), though mechanistically closely related to (1), shows a marked decrease in the solvent effect, which is not much higher than for the ketene-enol ether reaction (7). The addition (6), which proceeds *via* a dipole intermediate, the S_N2 reaction (4), and the two-step Diels-Alder reaction (8) also belong to this group. The cycloadditions (10) and (14) of a ketene to vinyl ketones, which tend to be regarded as two-step reactions (ketenes normally give four-membered rings on reaction with 1,3-dienes; see Section 2.2.1), exhibit practically the same solvent effect as the synchronous cycloadditions (12) and (13). The effect of the solvent on the rate of the S_N2 reaction (11), the transition state of which should lie close to the

product[41], is also very small. As expected, the solvent is of no importance in the free-radical cycloaddition (16). On the other hand, the cycloadditions (9) and (15), which undoubtedly proceed *via* dipolar intermediates, show remarkably little effect.

The solvent can influence not only the rates of cycloadditions but also the composition of the products. The solvation of the dipoles changes their reactivity; ring closure to form the cycloadduct may be accompanied in certain circumstances by prototropy (formation of substitution products) and/or addition of dipolarophiles. There are probably different types of solvated dipoles in cycloadditions, corresponding to ion pairs in S_N reactions. In nonpolar solvents, dipoles corresponding to intimate ion pairs could make it difficult to distinguish between a two-step cycloaddition and a one-step cycloaddition with a polar transition state.

5. Kinetic isotope effects (cf. [8,40]).

6. Activation parameters. On the basis of experimental values for the Diels-Alder reaction[39,40] (as a model concerted cycloaddition), relatively low activation enthalpies and strongly negative activation entropies must generally be expected for one-step cycloadditions, in agreement with theoretical considerations. It can be seen from Table 1 that these are in fact necessary conditions for one-step cycloadditions, but not sufficient, since the values for two-step cycloadditions lie in the same range.

In conclusion, therefore, the criteria 2–6 can be used only in special cases. This basically leaves criterion 1. The most important examples of two-step cycloadditions will be presented below from this point of view (a different interpretation from that given may also be possible for some reactions). It must be emphasized that one-step and two-step cycloadditions, like S_N1 and S_N2 reactions, should be regarded as limiting cases.

2. Preparative Examples

2.1. Cycloadditions a=b + c=d

According to the Woodward-Hoffmann rules[2–4], the "synchronous" formation of cyclobutanes from olefins is thermally forbidden. Thus such reactions are mainly free-radical processes[39,42,43] (even here there is evidence of polar effects[44]). Exceptions are the reactions of electron-rich olefins (*e.g.* enol ethers, enamines) with electron-deficient olefins (tetracyanoethylene[45], tetracyanovinyl chloride[45], 1,1-dicyano-1,1-bis(trifluoromethyl)ethylene[46], 1,2-dicyano-1,2-bis(trifluoromethyl)ethylene[5], acrylic acid derivatives, methyl vinyl sulfone, and nitroolefins[47,48]). Existing evidence of the occurrence of dipolar intermediates in these reactions includes: the absence of stereospecificity[5]; the anomalous course of the reaction of tetracyanoethylene with 2-ethoxy-3,4-dihydro-2*H*-pyran[24]; the fact that cyclobutanones are formed from enamines and nitroolefins in nonpolar solvents, whereas β-nitroethyl enamines are formed in polar solvents and even 1:2 cycloadducts can be detected[48];

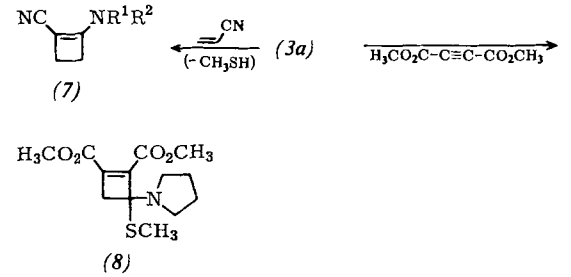
the formation of 2:1 cycloadducts from styrene and tetracyanoethylene (on heating in xylene)[24] and from enamines and methylenemalonic ester[47]; the synthesis of benzofurans[49–51] and of a tetrahydrocarbazole[52] from enamines and *p*-benzoquinone or 1,4-cyclohexadienediylidenebis-(benzenesulfonylamine); the formation of *o*-acetylphenyl acetate from dehydrobenzene and α-ethoxyvinyl acetate[53].

The isolation, and hence the direct detection, of 1,4-dipoles *(5)* was achieved for the first time in the reaction of compounds of the ketene acetal series *(3)*, in particular ketene *S,N*-acetals *(3a)*[54], with methylenemalononitriles *(4)* in acetonitrile at −40 °C[55].

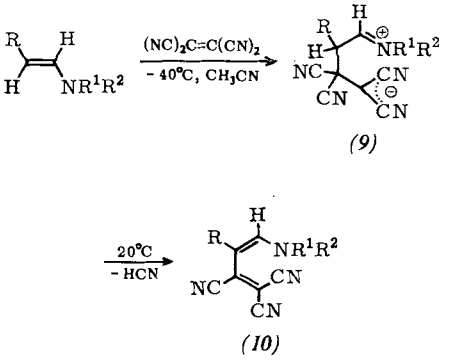


(3) *(4)* *(5)* *(6)*

(a), X = SCH_3; *(b)*, X = $N(CH_3)_2$
R = H, CH_3, C_2H_5, *n*-C_3H_7, C_6H_5; $R^1 + R^2 = (CH_2)_{2-4}$
R^3 = C_6H_5, $C_6H_4NO_2$-*p*, CF_3, CN; R^4 = H, CF_3, CN

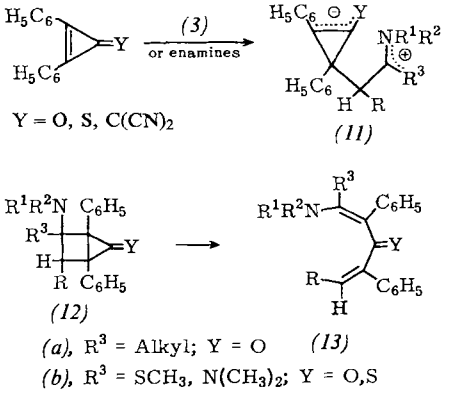
Red to blue π complexes are formed first. The yellow to orange-red color of the crystalline 1,4-dipoles *(5)* is probably due to intramolecular charge transfer. The butadienes *(6)* are formed from *(5)* as the final products.

Reaction of *(3a)*, R = H, with acrylonitrile yields the cyclobutenes *(7)*[55,56] (cf. the reactions of other ketene acetal derivatives with esters of acrylic acid[57]), and reaction of *(3a)*, R = H, $R^1 + R^2 = (CH_2)_4$, with acetylenedicarboxylic ester leads to cyclobutene *(8)*[54]



(7)

(8)



(cf. also[58]; other ketene acetals give only butadienes[59]). No 1,4-dipoles have yet been detected here. On the other hand, it has been verified experimentally that the formation of benzocyclobutenes from dehydrobenzene and enamines[52] or enol ethers[9] proceeds in two steps.

Except in the case of *N*-acyl-enamines[24], no definite products had formerly been obtained by the reaction of enamines with tetracyanoethylene. The 1,4-dipoles *(9)* have now also been obtained in the same manner as *(5)*[60]. When the temperature is raised they are converted into the butadienes *(10)*.

(9) *(10)*

The interesting reaction of enamines with diphenylcyclopropenone to give *(13)*[61] is thought to proceed *via* a primary (one- or two-step) cycloaddition to give *(12a)*. Since the dipoles *(11b)* were obtained in the reaction of ketene *S,N*-acetals with diphenylcyclopropenone and diphenylcyclopropenethione[62], the

Y = O, S, $C(CN)_2$ *(11)*

(12)

(a), R^3 = Alkyl; Y = O *(13)*
(b), R^3 = SCH_3, $N(CH_3)_2$; Y = O,S

dipoles *(11)* are probably generally intermediates in the (intermediate) formation of *(12)*. An important point for the discussion of the solvent effect is the fact that the formation and further reaction of *(11b)* are only slightly (factor <10) accelerated or retarded by a change from nonpolar to polar solvents[62]. The reaction

of ynamines with diphenylcyclopropenone [63] probably proceeds similarly.

Ynamines [64,65] and ynediamines [66,67] react with acetylenedicarboxylic ester to give benzene derivatives. It is not yet known whether only 1,4-dipoles or also cyclobutadienes occur as intermediates. A two-step reaction is also conceivable for the formation of cyclobutanes from 9-*tert*-butoxybicyclo[6.2.0]decapentaenes [68] and tetracyanoethylene (cf. related reactions with dimethylenecyclobutenes [69] and 1,2-dibenzylidene-3,4-phenylcyclobutane [70]).

It should also be mentioned that 7,7,8,8-tetracyano-*p*-benzoquinodimethane adds ketene *S,N*-acetals at C-7 (unlike other *p*-benzoquinones [49–52], which take up enamines at C-2) and gives the dipole *(14)* [60].

(14)

Acetonitrile surprisingly favors the formation of the green π-complex, and tetrahydrofuran that of the yellow dipole *(14)*.

There are many examples of cycloadditions in which hetero-1,4-dipoles occur as intermediates, and which give either four-membered heterocycles in accordance with the scheme 2 + 2 → 4 or six-membered heterocycles by 2 + 2 + 2 → 6 in the course of a 1,4-dipolar cycloaddition [71]. In addition to the examples presented in reviews [58,71–73], mention should also be made of the following. The cycloaddition of chloral to morpholinoisobutene to form a 1,3-dioxane [49] may be regarded as a model for the Prins reaction (for the mechanism, see [74]); ynamines react with carbonyl compounds and imines [75]; diazanorcaradienes undergo cycloaddition with two molecules of acetylenedicarboxylic ester, and probably form 1,4-dipoles with tetracyanoethylene [76]; iminoborons react with phenylacetylene to give benzo-1,2-azaborines *via* a 1,4-dipole [77]; cyclic enamines react with cyanoallene to form methylenecyclobutanes and cyclopentenes [78]; ketene acetal and benzenediazonium chloride give a pyridazine [79]; 1:2 and 2:1 cycloadducts are obtained from dimethylcyanamide and hexafluoroacetone [80]; two 2:1 cycloadducts formed *via* 1,4-dipoles can be isolated by the action of acetylenedicarboxylic ester on tetramethylthiourea [81]; hexafluoroacetone and hexaphenylcarbodiphosphorane combine to form a 1,2-oxaphosphetane [82].

2.2. Cycloadditions a=b + d=e=f

A large volume of data exists on cycloadditions of heterocumulenes d=e=f (*e.g.* ketenes, isocyanates, isothiocyanates, carbodiimides, carbon disulfide [73,83,84], carbon dioxide, sulfur dioxide, sulfenes [83,85], sulfinylamines [82,86]) to double and triple bonds. A selection of such reactions will be discussed below.

2.2.1. Reactions with Ketenes

Are the 2 + 2 cycloadditions of ketenes to C=C bonds one- or two-step reactions? It is significant for the answer to this question that "apolar" 1,3-dienes do not react by the Diels-Alder scheme, but always give almost exclusively cyclobutanones [87–89]. Retro-Diels-Alder reactions in which ketenes are split off are thermally possible only under extreme conditions [90]. This indicates a multi-center process for the ketene-olefin reaction, which is also thermally allowed according to the Woodward-Hoffmann theory in its new form [91,92].

It is concluded from the stereospecificity of the cycloaddition of ketenes to enol ethers [89,93–95] and from

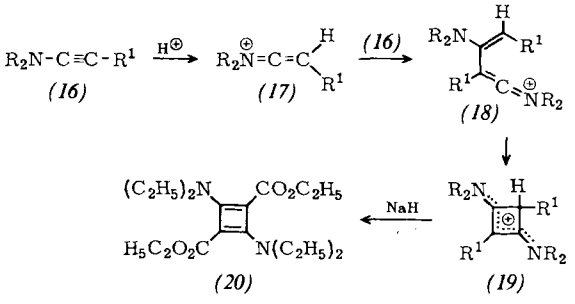
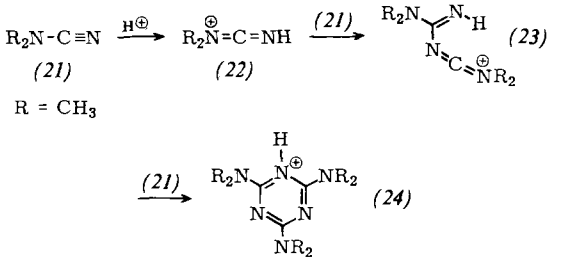
the relatively small solvent effect [29] (see Table 1) that this is a multi-center process with a polar transition state. In the reactions of enamines [73,83,96–98] and ketene acetals [73,83], on the other hand, there is considerable evidence of a two-step reaction. Ynamines evidently also undergo two-step cycloaddition with ketenes [99–101]; the same is true of ethoxyacetylene [102,103]. If ynamines and alkoxyacetylenes exhibit similar mechanistic behavior here, the same could also be expected of the enamines and enol ethers, in which the reactivity varies in the same manner as in the acetylene derivatives. Thus a two-step mechanism should not be rejected *a priori* for the cycloadditions of ketenes and enol ethers. One might even ask whether cycloadditions of ketenes to olefins could also be two-step processes. Still, bis(trifluoromethyl)ketene takes up vinyl benzoate [104] and olefins [105] on the C=C and C=O bonds, and 1,1-diphenylethylene reacts with diphenylketene to give a 1:2 cycloadduct [106].



A similar picture is found for the course of the cycloaddition of ketenes to C=C bonds when the problem is approached with the aid of a simple HMO model [107]. According to this treatment, the transition state of the two-step process has a lower energy, at least in the case of the electron-rich olefins, than that of the synchronous process; there appears to be no great difference between the two transition states in the case of "normal" olefins. However, there still remains the question how a two-step mechanism can be reconciled with stereospecificity. The model *(2)* for dipoles cannot be used because of the special bonding in the ketene or in a dipole derived from ketene and olefin. It must be replaced by the dipole *(15)*, a dipolar homoallyl system with hindered rotation about $C_\alpha - C_\beta$ (the formation of cyclobutanones from ketenes and 1,3-dienes can also be explained on the basis of *(15)* by



(15)

orbital symmetry considerations [107]). It will be shown in the following sections that electron-rich olefins often react with heterocumulenes to give 1,4-dipoles.

A particularly interesting reaction is the "dimerization" of ynamines *(16)* to form cyclobutenecyanines *(19)* [75,108,109]. This may be formulated as an attack of the ketene iminium ion *(17)* on *(16)*. The intermediate *(18)* then cyclizes to give *(19)*, from which the crystalline cyclobutadiene *(20)* can be prepared if

suitable substituents are present [108]. Dimethylcyanamide *(21)*, the aza analog of *(16)*, reacts similarly to form the protonated hexamethylmelamine *(24)* [110] (for the trimerization of nitriles cf. [111]). However, the cation *(23)* formed from *(22)* and *(21)* does not

give a four-membered ring, but undergoes cycloaddition with *(21)* in accordance with the scheme for polar 1,4-cycloadditions [112].

The two-step course of the formation of β-lactams from azomethines or amidines and ketene [73,83,84,113–116] is indicated by the fact that 1:2 adducts are often obtained. It has been shown [117] that the lactam and the 1:2 cycloadduct are formed from a common dipolar intermediate. In liquid SO_2, the solvent can add to the 1,4-dipole [118]. It is possible that the reaction of diphenylketene with 4-phenylimino-2-cyclo-

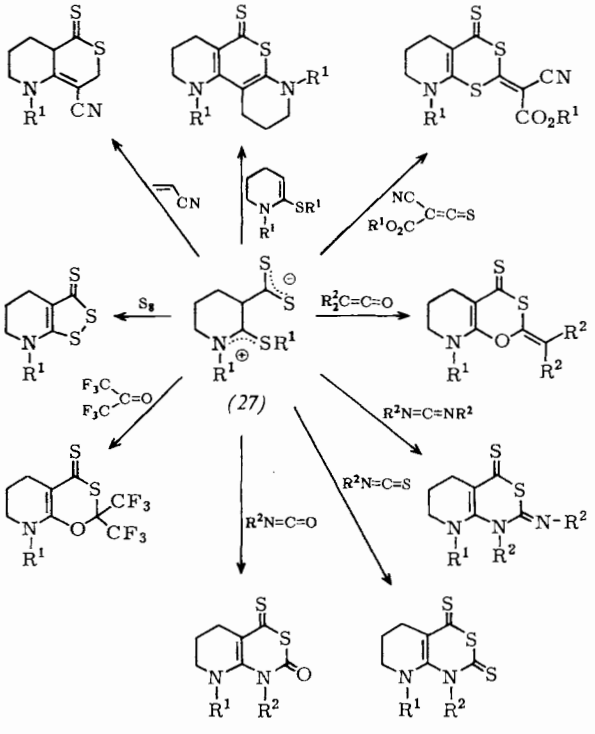
hexadien-1-one[119] proceeds *via* two dipolar intermediates, *i.e.* one in the formation of a β-lactam and the other in the rearrangement of the latter into 5-hydroxy-1,3,3-triphenyloxindole.

The combination of carbodiimides with ketenes to form azetinones[120,121] also involves 1,4-dipole intermediates. Hydrolysis experiments show[121] that these dipoles are relatively long-lived.

Little is known about the mechanism of the cycloaddition of ketenes to C=O bonds[73,122]. The detection of 1:2 and 2:1 cycloadducts[122] and the fact that liberation of CO_2 occurs even at 0 °C in the system dichloroketene/isatin or 2,3-coumarandione[122] are indications of the occurrence of dipolar intermediates.

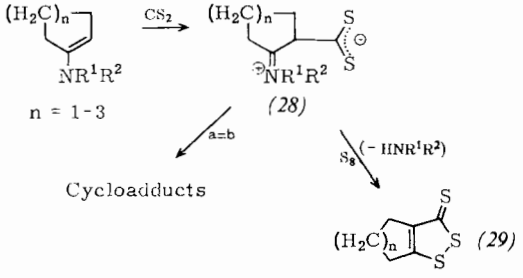


2.2.2. Reactions with Carbon Disulfide, Carbon Oxide Sulfide, and Carbon Dioxide

Introduction of carbon disulfide into solutions of ketene acetals *(3)* in acetonitrile at −40 °C leads to the crystalline red 1,4-dipoles *(25)*[123]. The structure of

(25) *(26)*

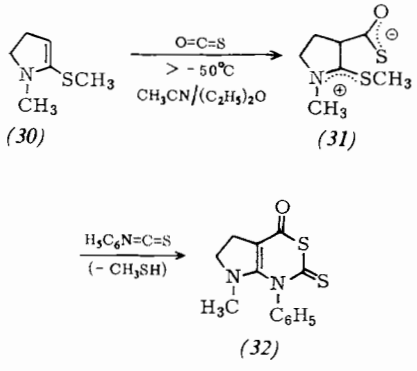
the latter has been confirmed by IR and NMR spectra and by their reactions. When heated, they decompose partly into the starting materials and partly with



Scheme 1. $R^1 = CH_3$, $R^2 = C_6H_5$.

formation of "dimers", which probably have the structure *(26)*[124].

The compounds *(25)* are the first 1,4-dipoles that can be used to examine the scope of a 1,4-dipolar cycloaddition. Scheme 1 shows the variety of possible reactions for *(27)* (the cycloaddition is always followed by loss of CH_3SH from the primary adduct), which is practically as wide as that of other types of cycloaddition. Heterocumulenes are particularly suitable for use as 1,4-dipolarophiles.



Instead of *(3)*, enamines can also react with carbon disulfide to form 1,4-dipoles *(28)*[25] (for solvent effect and activation parameters, see Table 1).

(28) *(29)*

The cycloadditions of *(28)* correspond to those of *(25)* and *(27)*; the formation of *(29)* proves the course of the synthesis of trithiones from enamines, carbon disulfide, and sulfur.

Reaction of the ketene *S,N*-acetal *(30)* with carbon oxide sulfide yields the 1,4-dipole *(31)*, which is stable up to about −35 °C[125], and which can react with phenyl isothiocyanate to give *(32)*.

(30) *(31)* *(32)*

Passage of carbon dioxide into solutions of *(3a)* in acetonitrile/ether at −70 °C leads to the 1,4-dipoles *(33)* (sometimes crystalline and sometimes only in solution)[125]. These dipoles are extremely sensitive to heat, and vigorous evolution of CO_2 begins at −60 °C. Addition of acetylenedicarboxylic ester to solutions of *(33)* leads to the α-pyrones *(34)*. Diphenylketene and phenyl isocyanate on the other hand react, not with *(33)*, but with the *(3a)* that is present in equilibrium to form *(35)* and *(36)*. Different products are obtained at higher temperatures (and in other solvents).

The 1,4-dipoles *(33)* are model substances for the "intimate ion pairs"[126] that occur on decarboxylation of β-lactones,

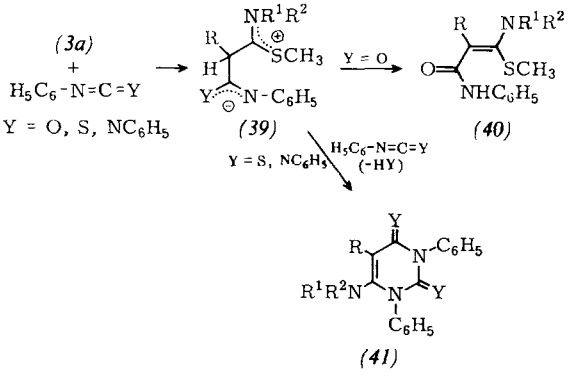
and possibly also in their formation from β-hydroxy and β-halogeno carboxylic acids[13]. The (presumably) dipolar intermediate in the rearrangement of 2-oxabicyclo[2.2.0]-hex-5-en-3-one to 2-oxatricyclo[2.1.1.$0^{5,6}$]hexan-3-one[127] should also be mentioned here.

2.3.3. Reactions with Isocyanates, Isothiocyanates, and Carbodiimides

The mechanisms of the cycloadditions of chlorosulfonyl isocyanate[128–130] and of arylsulfonyl isocyanates[131] have been particularly extensively studied. If the addition of chlorosulfonyl isocyanate to allenes is a polar two-step process, it must be concluded that the cycloaddition to olefins proceeds in a similar manner, though it is stereospecific[129]. This is impressively supported by the formation of the lactam *(38)* from hexamethyl(Dewar benzene) and chlorosulfonyl isocyanate with *(37)* as a dipolar intermediate[132].



p-Toluenesulfonyl isocyanate undergoes stereospecific cycloaddition to ethyl 1-butenyl ether[131,131a]. These kinetic data are consistent both with a concerted and with a two-step process[131a]. The concept of a dipolar intermediate, which could be formulated similarly to *(2)* or analogously to *(15)* is supported by the observation that ethyl isobutenyl ether gives a 1:2 cycloadduct with chlorosulfonyl isocyanate[133].

The formation of mixtures of 4-amino-2-quinolones and 2-amino-4-quinolones[99] on reaction of aryl isocyanates with ynamines[99,134] can be explained on the basis of a dipolar primary adduct that reacts further in two directions.

The reaction of azines and azomethines with sulfonyl isocyanates unquestionably proceeds *via* 1,4-dipolar intermediates[135]; not only do azines give triazolotriazoles and azomethines give 1:2 and 2:1 cycloadducts (perhydro-*s*-triazines), but caprolactim methyl ether actually gives a stable zwitterion. The same picture is found in the cycloadditions of isocyanates and isothiocyanates to amidines and guanidines (2:1 cycloadducts)[136,137] and to carbodiimides[138]. In the absence of catalysts, fluoro ketones and alkyl isocyanates give mainly 1,3-oxazetidinones[139].

Dimethylamino isocyanate surprisingly dimerizes *via* an ylid intermediate to give a triazole derivative[140].

The reactions of *(3a)* with phenyl isocyanate, phenyl isothiocyanate, and diphenylcarbodiimide[124] at room temperature are summarized in Scheme 2. Whereas the isocyanate gives the substitution product *(40)* [compare, however, the formation of the pyrimidine

Scheme 2.

(36) under different conditions], the reactions with the isothiocyanate and the carbodiimide lead *via* the 1,4-dipoles *(39)* to the pyrimidines *(41)*. Reactions with benzenesulfonyl isocyanate and isothiocyanate lead to the stable 1,4-dipoles *(42)*[125], which undergo cycloaddition with *(3a)* or diphenylketene.

2.2.4. Reactions with Sulfur Dioxide, Sulfenes, Sulfines, and Sulfinylamines

Ketene *S(O),N*-acetals, ketene aminals, and enamines combine with liquid sulfur dioxide at −60 °C to give the dipoles *(43)*, which are stable in solution up to about −40 °C [125]. Their reaction with acetylenedicarboxylic ester leads in the case of the "enamine

dipole" to dihydrothiophene *S,S*-dioxides *(44)*. In the case of the "*(3a)* dipoles", only the *(3a)* present in equilibrium reacts, and *(45)* is formed *via* a new 1,4-dipole [compare the formation of the cyclobutene *(8)* under different conditions]; a similar situation is found for the reaction of tetracyanoethylene with *(43)*. Zwitterions of the type *(43)* have been suggested as intermediates in the conversion of episulfones into olefins [11,12].

Sulfenes attack only electron-rich olefins [85]; the resulting mixture of four-membered ring sulfones and vinyl sulfones can be explained on the basis of dipolar intermediates. Polar solvents favor the formation of the open-chain products [141,142]. Sulfene does not undergo stereoselective cycloaddition with *cis*-propen-

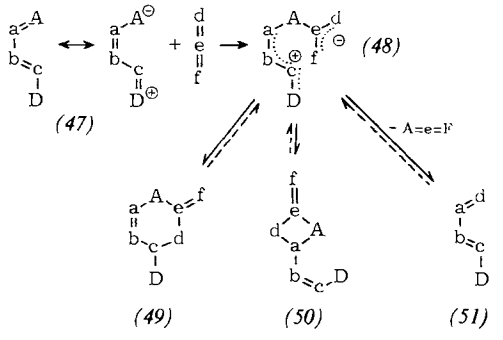
ylmorpholine; stereospecificity is, however, found in the cycloaddition of mesylsulfene to *cis*- and *trans*-butenyl butyl ethers [143].



An interesting zwitterionic 1:1 adduct *(46)* is formed from 9-sulfinylfluorene and morpholinocyclohexene [144].

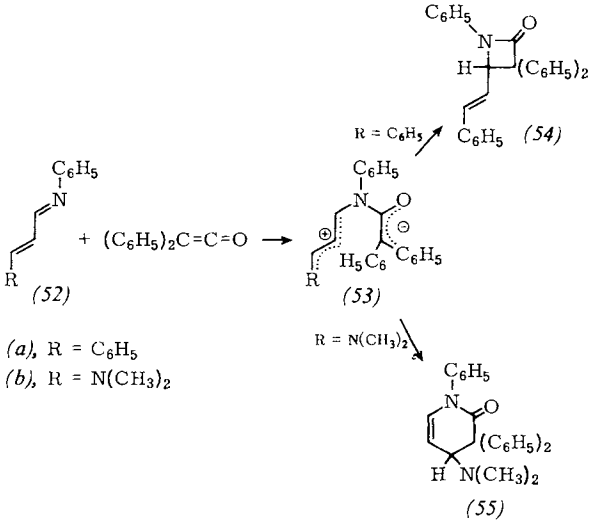
Enol ethers combine stereospecifically with *N*-sulfinylsulfonamides to form thiazetidine 1-oxides [131]; pyridine 1-oxide gives a 1,5-dipole [145].

2.3. Cycloadditions of Heterocumulenes to Polar 1,3-Dienes and Hetero-1,3-dienes

In the discussion of the cycloadditions of ketenes to olefins, it was mentioned that 1,3-dienes give only cyclobutanones [146] (even methyl 1-buten-3-yn-1-yl ether adds diphenylketene only at the triple bond [97]). The isolation or detection of 1,4-dipoles in reactions of electron-rich ("polar") olefins with heterocumulenes suggests that reactions of "polar" 1,3-dienes or hetero-

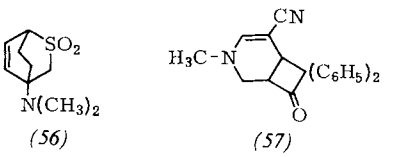
1,3-dienes *(47)* with heterocumulenes d=e=f might also lead to the formation of dipolar intermediates *(48)*, which then change into either four-membered rings *(50)* or six-membered rings *(49)*. The elimination of a different heterocumulene from *(48)* to give new

A = electron acceptor; D = electron donor



[143] *G. Opitz,* Angew. Chem. *80,* 633 (1968); Angew. Chem. internat. Edit. *7,* 646 (1968).

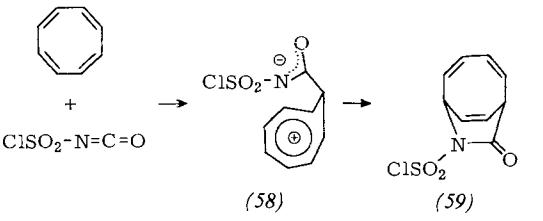
[144] *W. A. Sheppard* and *J. Diekmann,* J. Amer. chem. Soc. *86,* 1891 (1964).



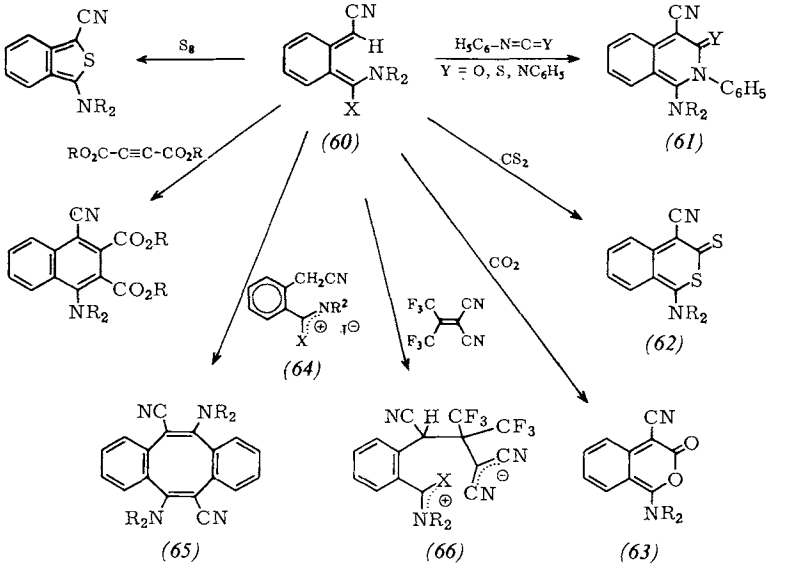
[145] *R. Albrecht* and *G. Kresze,* Chem. Ber. *98,* 1205 (1965).

[146] 2-Methoxy-1,3-butadiene appears to be an exception: *J. C. Martin, P. G. Gott, V. W. Goodlett,* and *R. H. Hasek,* J. org. Chemistry *30,* 4175 (1965).

hetero-1,3-dienes *(51)* would also be conceivable. The relative importance of the ring closure of *(48)* to form *(49)* should increase with increasing stability of *(48)*, since the most favorable conformation for the formation of *(49)* can then be reached by internal rotation [*(47)* will often be transoid]. This view is strongly supported by the reactions of the azomethines *(52a)* and *(52b)* with diphenylketene[33]: *(52a)* gives the azetidinone *(54)*, and *(52b)* gives the dihydropyridone *(55)*, since the positive charge of the dipole *(53)* is much more strongly delocalized in the case of *(52b)* than in that of *(52a)*.



(a), R = C_6H_5
(b), R = $N(CH_3)_2$



(56) *(57)*

sulfide has also been reported[149]. Whereas ketene undergoes 1,4-cycloaddition with 1-piperidinobutadiene[150], the reaction of 2,3-dihydrodimethylaniline with diphenylketene yields only acylation products[33]. 5-Cyano-1-methyl-1,2-dihydropyridine again undergoes cycloaddition with diphenylketene to give *(57)*[33]. An important 1,4-cycloaddition is the addition of chlorosulfonyl isocyanate to cyclooctatetraene[151,152]. The dipolar intermediate *(58)*, in which

(58) *(59)*

the positive charge in the homotropylium system is delocalized, achieves stability by formation of *(59)*. (It is not certain whether the 1,4-cycloadditions of dehydrobenzene[153] and 4-phenyl-1,2,4-triazoline-3,5-dione[154] to cyclooctatetraene proceed *via* dipolar intermediates.) The reaction of simple 1,3-dienes with chlorosulfonyl isocyanate leads first to β-lactams,

X = SCH_3, NR_2^1; R = CH_3

2.3.1. Reactions of Polar 1,3-Dienes

As the simplest butadiene derivatives of the type *(47)*, 1-dialkylaminobutadienes undergo 4 + 2 cycloaddition as a minor reaction, together with a double 2 + 2 cycloaddition, on reaction with sulfene[147,148]. 2,3-Dihydrodimethylaniline, on the other hand, gives only the adduct *(56)* on reaction with sulfene[85]. The synthesis of α-pyrones from dienamines and carbon di-

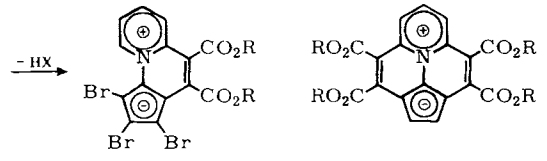
which change into dihydropyridones when heated to 40 °C [130].



The deep blue *o*-quinodimethanes *(60)* form a class of very strongly polar or polarizable 1,3-dienes [155]. Unlike "normal" *o*-quinodimethanes, they do not undergo valence isomerization to form benzocyclobutenes. They readily enter into cycloadditions with heterocumulenes (as well as with sulfur and acetylenedicarboxylic ester); after elimination of HX from the primary adducts (which cannot be isolated), it is possible to isolate the heterocyclic "*o*-quinodimethanes" *(61)–(63)*. The dibenzocyclooctene *(65)* is probably formed, not by direct dimerization of *(60)*, but by the action of *(64)* on *(60)*. The assumption that 1,6-dipoles occur as intermediates in all these reactions is supported by the isolation of *(66)* [156].

The pyridinocyclopentadienylides *(67)* are both 1,*x*-dipoles and 1,3-dienes. The reaction with acetylenedicarboxylic ester (which is related to the ketenes) to give *(68)* and *(69)*, as well as other products [157]. Though the mechanism of these reactions is not yet known (the formation of substitution products points to dipolar intermediates), there is little doubt that two steps are involved in the conversion [157] of the pyridinobenzimidazolylides *(70)* [157,158] into the adducts *(71)*.

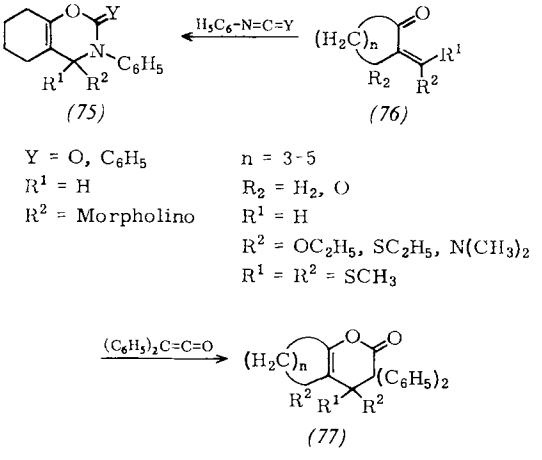
(68) *(69)*

R = H, CH_3 *(70)* *(71)*

2.3.2. Reactions of Vinyl Ketones and Related Compounds



In reactions of α-β-unsaturated ketones with ketenes, δ-lactones have mostly been obtained only as by-products [159–163] (for the reaction in the presence of Lewis acids, see [164]). Good yields of 1,4-cycloadducts *(73)* are, however, obtained when *(72)* or *(74)* is heated with diphenylketene [33]. The stabilization of the positive charge in the intermediate corresponding to *(48)* by the electron-donating substituents present in *(72)* and *(74)* evidently favors the formation of the six-membered ring.

(72) *(73)* *(74)*

(a), Ar = *p*-$C_6H_4N(CH_3)_2$, $R_2 = H_2$
(b), Ar = C_6H_5, $R_2 = C_6H_5CH$

Better examples of *(47)* than the simple vinyl ketones are β-acyl enol ethers, thioenol ethers, enamines, ketene acetals, ketene *O,N*-acetals, ketene aminals, and ketene mercaptals. Some of their reactions [83] with ketenes [165–169] (cyclobutanones are assumed to occur as intermediates in some cases [167,168]) and sulfenes [142,170] to give α-pyrones and δ-sultones, respectively, and the cycloadditions of diphenylketene, phenyl isocyanate, and diphenylcarbodiimide

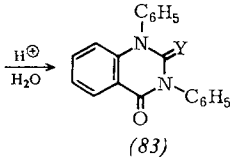
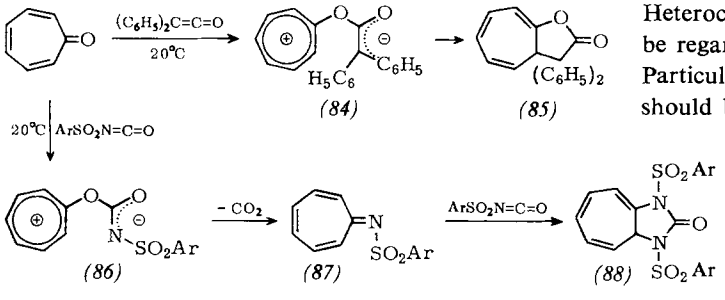
(78) (79)

Another example is the synthesis of *(79)* from the benzil hydrazone *(78)* and diphenylketene [33].



The reactions of the *o*-quinodimethanes *(60)* are related to the cycloadditions of diphenylketene to the *o*-quinonemethide *(80)* to form *(81)* [171] and of phenyl isocyanate and phenyl isothiocyanate to the *o*-quinonemethidimine *(82)* to form the quinazoline *(83)* [173].

(80) (81)



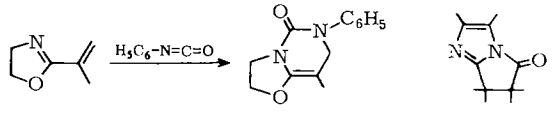
(82)

(83)

Special mention should be made of the synthesis of 1,3-oxazines from fluorinated *N*-acetylimines and ketenes [174].

Compounds of the type *(47)*, for which the positive charge in dipolar intermediates *(48)* is distributed only

(84) (85) (86) (87) (88)



over C atoms (partly in aromatic ring systems), include tropone, cyclopropenone, and phenalenone [172]; these compounds should be predisposed to two-step cycloadditions with heterocumulenes. Tropone actually undergoes cycloaddition with diphenylketene even at room temperature [172, 175], and the product *(85)* can be isolated in practically quantitative yield (for proof of structure, see [172]). Evidence in favor of the intermediate occurrence of *(84)* includes the fact that the imidazole derivative *(88)* is formed as well as the tropone imine *(87)* in the corresponding reaction with *p*-toluenesulfonyl isocyanate [172, 176], indicating the formation of *(86)* as an intermediate.

(89) (90)

Tropone gives *(89)* on reaction with dichloroketene [177], and *(90)* on reaction with mesylsulfene [178]. In the reactions of diphenylcyclopropenone [172, 179] and phenalenone [172] with ketenes and sulfonyl isocyanates, the cyclopropenone imines, methylphenalenes, and phenalenone imines remaining on elimination of CO_2 from the zwitterionic primary adducts can no longer undergo cycloaddition with heterocumulenes.

Further examples of reactions of vinyl ketone imines [cf. *(52)* and *(87)*] are the additions of phenyl isocyanate to *(91)* to form *(92)* [180] (a two-step course is

(91) (92) (93)

indicated by the fact that no reactions occur with dienophiles) and those of ketenes, phenyl isocyanate, benzylideneaniline, and *anti*-benzaldoxime to 1,4-diazafulvenes [181] *e.g.* to form *(93)*.

2.3.3. Reactions of "*o*-Quinoid" Ketenes and Acylheterocumulenes

Heterocumulenes having the general formula *(94)* may be regarded as polar diene systems of the type *(47)*. Particularly strong polarization or polarizability should be found in the "*o*-quinoid" derivatives *(95)*.

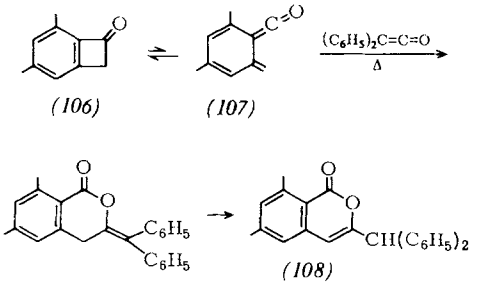
(94) (95)

Cycloadditions of ketenes, isocyanates, carbodiimides, ketones, azomethines, isonitriles, and electron-rich olefins to acylketenes, acyl and thioacyl isocyanates, acyl and imidoyl isothiocyanates [182], and acylsulfinylamines [183] to form six-membered rings (see [83]), some of which can be formulated as Diels-Alder reactions, nevertheless fit readily into the scheme *(47)* → *(48)* → *(49)* (important evidence is provided *e.g.* by the observation that thioacyl isocyanates, unlike other dienes, undergo cycloaddition to the C=N bond of imidazoline-4,5-diones [184]).

(100) is characterized by a tendency to dimerize [corresponding to the cycloaddition *(47)* + heterocumulene] and to undergo cycloadditions with heterocumulenes and with polar systems containing multiple bonds [83,173,185,186]. Examples are dimerizations to form *(102)* [188] and *(105)* [187]. Cycloaddition of pyridine yields *(103)* [188] (this compound, prepared from *N*-phenylanthraniloyl chloride and pyridine [190], was assigned a betaine structure) and *(104)* [187] (the primary adduct is dehydrogenated; the pyridine may be replaced *e.g.* by quinoline, isoquinoline, and 1-methylimidazole).



The slowness of the valence isomerization *(100)* ⇌ *(101)* is also shown by the failure of previous attempts to use benzocyclobutenones in the same way as benzocyclobutenes for cycloadditions [191]. The successful

Scheme 3.

Systems *(100)* of the quinoid type *(95)* can be obtained by elimination of CO_2, HCl, or N_2 from *(96)* to *(98)* [83,173,185–188]. Scheme 3 is an attempt to treat all the reactions from the same point of view. With *(96)* and *(97)* as starting materials, it was possible to detect *(100)*, but not *(101)* [*i.e.* the situation is similar to that found for *(60)*]. This indicates that the valence isomerization *(100)* ⇌ *(101)* is slower than the other secondary reactions of *(100)* [compare the isolation of a naphthazetinone having the constitution *(101)* [189]].

conversion [156] of dimethylbenzocyclobutenone *(106)* *via (107)* into the isocoumarin *(108)* confirms the view presented here for the behavior of polar diene systems toward heterocumulenes.

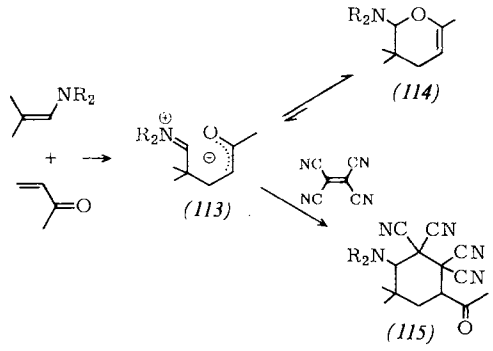
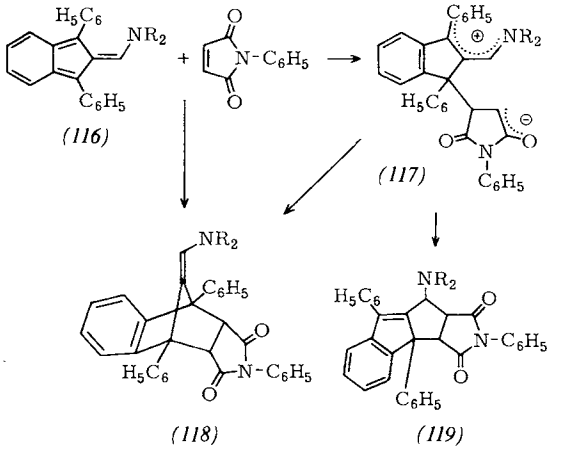
Compounds of the type *(100)* may be expected, not only to isomerize into *(101)*, but also to undergo fragmentation into dehydrobenzene and a heterocumulene. Only one example of this is known at present, *i.e.* the decomposition of *o*-benzenediazoniumcarboxylate *via* a β-lactone to form dehydrobenzene[192] [similar to *(99)* → *(101)*]. Mention should also be made of the 1,6-dipolar cycloaddition of *o*-benzenediazoniumcarboxylate to dehydrobenzene[193].

The 2-diazoniumphenoxides ("*o*-quinone diazides") and α-diazoketones, which react with ketene imines and ketenes to give 1,4,5-oxadiazepines and γ-lactones respectively (cf.[194,195]), are formally also systems of the type *(47)*.



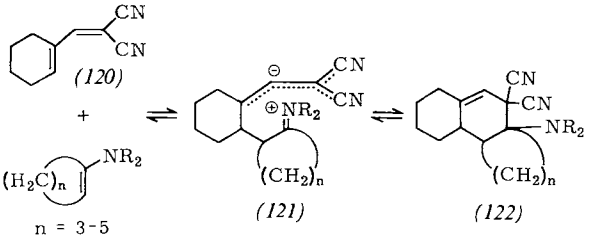
2.4. Diels-Alder Reactions

The question whether Diels-Alder reactions[40] and the decomposition of Diels-Alder adducts[196] are one-step or two-step reactions has been extensively discussed, particularly in connection with diradical intermediates. In addition to the vast majority of synchronous processes, however, there are also several examples (*e.g.* 5-cyano-1-methyl-1,2-dihydropyridine + acrylonitrile[197]; esters of phosphonous and phosphinous acids + 3-benzylidene-2,4-pentanedione[198]; 4-methyl-1,3-pentadiene + tetracyanoethylene[199]) in which dipolar intermediates must be considered. For example, the electronically closely related compounds *(110)* and *(111)* react with ketene *S,N*-acetals[55,57] to give *(109)* and *(112)* respectively. This means that either the activation energies of the 2 + 2 and 2 + 4 cycloadditions are very close to each other



(109) *(110)* *(111)* *(112)*

or both reactions have a dipolar intermediate. The latter possibility is supported by the two-step cycloaddition of 3,4-dihydroisoquinolines to α,β-unsaturated ketones[200], and particularly by the reaction of dimethylaminoisobutene with vinyl methyl ketone[201], which leads *via (113)* to the six-membered ring adduct *(114)*. On reaction of *(114)* with tetracyanoethylene, the dipole *(113)* that is present in equilibrium is intercepted as *(115)*.



(113) *(114)* *(115)*

The isobenzofulvene *(116)* reacts with *N*-phenylmaleimide to give a mixture of *(118)* and *(119)*[202]. Whereas *(119)* can only be formed *via (117)*, the formation of *(118)* can be explained both as a "synchronous" Diels-Alder reaction and as a two-step cycloaddition *via (117)*. It is interesting to note that the 1,3-unsubstituted isobenzofulvene gives only an adduct corresponding to *(119)*. As a (10π + 2π) cycloaddition, the sequence *(116)* → *(117)* → *(119)* is reminiscent of the reaction of pyrrocoline with acetylenedicarboxylic ester[203].

(116) *(117)* *(118)* *(119)*

1,6-Dipolar intermediates *(121)* can be detected directly in the reaction of *(120)* with enamines[30,204]. The colorless Diels-Alder adducts *(122)* are formed at room temperature in apolar solvents and at about

(120) *(121)* *(122)*

−20 °C in polar solvents. At −40 °C, on the other hand, the reaction yields the yellow crystalline dipoles *(121)*, which give *(122)* when warmed [*(122)* reopens

Spectroscopic Investigation of Various Phosphorus-Sulfur Bonds

By J. Goubeau [*]

Dedicated to Professor H. Bredereck on the occasion of his 65th birthday

The results of spectroscopic investigations on phosphorus-sulfur compounds, and particularly the force constants, reveal several factors that decisively influence the bonding. The effects of hybridization, the other bonding partners and their electronegativities, the π-bonding components, and the ionic charge are discussed. It is shown that the P–S bond, unlike the P–O bond, never attains full double bond character, despite its great variability.

1. Introduction

It was shown in two earlier articles [1] that the force constants calculated from the vibration spectra provide more than qualitative information about the various bonds in a molecule. It has been deduced from a large volume of data, mainly on nitrogen compounds, that bond orders of 2 (double bonds) or more are to be expected if the sum of the Pauling electronegativities of two bonding partners is 5 or more and if their difference is not greater than 1.5.

To clarify the situation further, it was necessary to investigate the bonding of pairs of elements for which the sum of the electronegativities (Σx) is smaller than the limiting value of 5. An investigation of this nature was carried out on a broad basis by *Bürger* [2] on silicon-nitrogen compounds. This pair of elements has an electronegativity sum just below the limiting value ($\Sigma x = 4.8$), together with a relatively high electronegativity difference ($\Delta x = 1.2$). The highest bond order observed, 1.3, is in agreement with the rules proposed.

We have studied the pair of elements phosphorus and sulfur, for which the electronegativity sum (4.6) is again only slightly smaller than the limiting value indicated, but whose electronegativity difference $\Delta x = 0.4$ should be more favorable toward the formation of multiple bonds. Both elements belong to the second short period, so that d electrons must also be taken into account. This combination is particularly interesting because of the different oxidation states of phosphorus, the effects of which have also been studied. Since seriously weakened multiple bonds were to be expected for this pair of elements, all the factors that could influence the force constants had to be checked. The changes in P–S force constants due to:

1) hybridization,

2) inductive effects,

3) ionic charges, and

4) π bonds

are therefore reported in this article.

Nearly all the force constants given (k values in mdyne/Å) were calculated by the method described earlier [1]. Where bond orders are given, they correspond to the Siebert rule [3].

2. Effect of Hybridization

This effect was first observed for C–H bonds, whose force constants increase rapidly with increasing s component [4, 5]. A similar effect has also been found for various phosphorus compounds, if one assumes mainly p bonding in compounds of trivalent phosphorus, sp^3 hybridization in compounds containing tetracoordinate phosphorus, and sp^2 and pd hybridization in the equatorial plane and along the longitudinal axis, respectively, of the trigonal bipyramid in compounds of pentacoordinate phosphorus.

The force constants of several phosphorus compounds are compared from this point of view in Table 1. Examples have been chosen in which the part played by other effects is as small as possible. To facilitate comparison, the various force constants are given in the right-hand half of the table on the basis of a value of 100 for the force constant of the sp^3 hybrid. The values agree well among themselves, and also agree in their order of magnitude with the corresponding values for C–H bonds [5], particularly when one considers that the bonds of trivalent phosphorus are certainly not pure p bonds, since the bond angles at the phosphorus atom vary between 95 and 105 °C, indicating an appreciable and varying s component. A change from sp^3 to p is accompanied by a 6–21% decrease in the force constant, while a change from sp^3 to sp^2 results in a 5% increase. As expected, the greatest decrease (about 35%) in relation to sp^3 is found for the axial bond of the trigonal bipyramid (pd).

Table 1. Dependence of the force constants of various phosphorus compounds on the hybridization of the phosphorus atom.

Hybridization	 pd	 p	 sp^3	 sp^2	pd	p	sp^3	sp^2
k(P–H)		3.10 [a]	3.30 [b]	3.59 [c]		94	100	109
k(P–CH_3)		2.77 [d]	3.05 [e]			91	100	
k(P–F)	4.52 [f]	5.19 [g]	6.34 [h]	6.38 [f]	71	82	100	101
k(P–Cl)	1.63 [i]	2.36 [j]	2.66 [k]	2.78 [i]	61	89	100	104
k(P–Br)		1.84 [l]	2.66 [m]			79	100	
k(P–OCH_3)		3.72 [o]	4.87 [p]			76	100	
Mean					66	85	100	105
Values for C–H bonds						75	100	105

The force constants were calculated from the spectra of the following compounds:
[a] PH_3; [b] $BH_3 \cdot PH_3$; [c] H_2PF_3; [d] $P(CH_3)_3$; [e] $SP(CH_3)_3$, $OP(CH_3)_3$; [f] PF_5; [g] PF_3; [h] OPF_3; [i] PCl_5; [j] PCl_3; [k] $SPCl_3$; [l] PBr_3; [m] $SPBr_3$; [o] $P(OCH_3)_3$; [p] $OP(OCH_3)_3$.

The only force constants available for the discussion of the effect of hybridization in phosphorus-sulfur compounds are those of the fully sulfur-substituted compounds $P(SCH_3)_3$, $SP(SCH_3)_3$, and PS_4^{3-} (see Table 2).

Table 2. Force constants of various phosphorus-sulfur compounds.

	p $P(SCH_3)_3$	sp^3 $SP(SCH_3)_3$	sp^3 PS_4^{3-}	p	sp^3
k(P–SCH_3)	2.06 2.22	2.56		81 78	100
k(S–P)		4.16	2.51		

Two values are given for $P(SCH_3)_3$, since rotational isomerism gives rise to two pairs of PS_3 stretching vibrations; both values were calculated for an all-*cis* model. The values of k(P–SCH_3) are themselves sufficient to demonstrate the effect of hybridization, since here again the change from sp^3 to p leads to a decrease of about 20%. The differences in the k(S–P) values are due to the effects of ionic charge and of π bonds (see Sections 4 and 5).

The experimental results available at present show that the force constant increases with increasing s component for all phosphorus compounds. The maximum changes are around 40%, and 20% in the case of phosphorus-sulfur bonds.

3. Effect of the Other Ligands

This effect is most easily demonstrated for series of compounds in which the sulfur, *e.g.* in $SP(SCH_3)_3$, is systematically replaced by other atoms. The simplest case is probably the replacement of the sulfur by oxygen, since the model is retained in full as regards its structure, so that satisfactory comparability of the values is to be expected. Two series of compounds are obtained, depending on whether just the three SR groups are replaced or these three groups and the sulfur atom substituted. The results of our calculations are shown in Table 3. Table 4 gives the same P–S and P–O force constants based on the values in $SP(SCH_3)_3$ and $OP(OCH_3)_3$ as standards (= 1.00).

Table 3. Force constants of the transition series $SP(SR)_3$ – $OP(OR)_3$.

	SPS_3	$SPOS_2$	SPO_2S	SPO_3
k(P–SCH_3)	2.56	2.76	3.23	
k(P–OCH_3)		3.90	4.17	4.59
k(S–P)	4.16	4.39	4.53	4.52
	OPS_3	$OPOS_2$	OPO_2S	OPO_3
k(P–SCH_3)	2.71	3.18	3.27	
k(P–OCH_3)		3.91	4.34	4.87
k(O–P)	8.71	9.05	9.38	9.83

Table 4. Force constants of the transition series $SP(SR)_3$ – $OP(OR)_3$ based on k(PS) in $SP(SCH_3)_3 = 1$ and k(PO) in $OP(OCH_3)_3 = 1$.

	SPS_3	$SPOS_2$	SPO_2S	SPO_3
k(P–SCH_3)	1.00	1.08	1.26	
k(P–OCH_3)		0.80	0.86	0.94
k(S–P)	1.00	1.05	1.09	1.08
	OPS_3	$OPOS_2$	OPO_2S	OPO_3
k(P–SCH_3)	1.06	1.24	1.28	
k(P–OCH_3)		0.80	0.89	1.00
k(O–P)	0.89	0.92	0.95	1.00

Each substitution of a sulfur atom by a more electronegative oxygen atom leads to an increase in all the force constants. This is true of the replacement both of the sulfur in the S–CH_3 groups and of the lone sulfur atom. The greatest changes (20–30%) occur for k(P–SCH_3) and k(P–OCH_3), whereas the S–P and O–P force constants change by only up to 10%.

If the SCH_3 groups in the two compounds $SP(SCH_3)_3$ and $OP(SCH_3)_3$ are replaced by the more electronegative chlorine atom (Table 5), it is again found that replacement of sulfur by oxygen leads to an increase of between 6 and 38% in all the force constants. The substitution of the SCH_3 groups by chlorine also leads in five out of six cases to a 13 to 21% increase in the force constant. However, k(P–SCH_3) decreases in the series $SP(SCH_3)_3$–$SPCl_3$, the major part of the decrease occurring with the introduction of the first chlorine atom. It is not yet certain whether this is due to failure of the calculation procedure as a result of strong coupling of νPCl with $\nu_s PS_2$ or to a real effect. The values of the P–Cl force constants are surpris-

Table 5. Force constants of the transition series $SP(SCH_3)_3$ – $SPCl_3$ and $OP(SCH_3)_3$ – $OPCl_3$.

	SPS_3	$SPClS_2$	$SPCl_2S$	$SPCl_3$	Δk (%)
k(P–SCH_3)	2.56	2.40	2.38		– 7
k(P–Cl)		2.36	2.45	2.66	+17
k(S–P)	4.16	4.40	4.60	4.89	+13
	OPS_3	$OPClS_2$	$OPCl_2S$	$OPCl_3$	
k(P–SCH_3)	2.71	2.93	3.28		+21
k(P–Cl)		2.66	2.75	3.00	+14
k(O–P)	8.71	9.23	9.68	10.24	+17
Δk(P–SCH_3) (%)	+6	+22	+38		
Δk(P–Cl) (%)		+13	+12	+12	

ingly low, and point to a distinct polar bonding component.

The only available example of tricoordinate phosphorus is the series $P(SCH_3)_3$ – PCl_3. As can be seen from Table 6, both force constants remain absolutely constant in this series. The same is found in the series PCl_3 – $P(OCH_3)_3$. The changes in both cases lie within the limits of error. Definite inductive effects are observed only in the series PCl_3 – PF_3, but they are generally smaller than for sp^3-hybridized phosphorus; p orbitals probably influence one another less than sp^3 orbitals. Other effects are probably also involved, since the P–SCH_3 force constants also exhibit anomalous behavior in the series $SP(SCH_3)_3$ – $SPCl_3$, if any importance is to be attached to variations of a few per cent.

Table 6. Force constants of the transition series $P(SCH_3)_3$ – PCl_3, PCl_3 – $P(OCH_3)_3$, and PCl_3 – PF_3.

	$P(SCH_3)_3$	$P(SCH_3)_2Cl$	$P(SCH_3)Cl_2$	PCl_3	Δk (%)
k(P–SCH_3)	2.06	2.03	2.04		–1
k(P–Cl)		2.36	2.32	2.36	±0
	PCl_3	$PCl_2(OCH_3)$	$PCl(OCH_3)_2$	$P(OCH_3)_3$	
k(P–Cl)	2.36	2.30	2.26		–4
k(P–OCH_3)		3.64	3.72	3.72	+2
	PCl_3	PCl_2F	$PClF_2$	PF_3	
k(P–Cl)	2.36	2.46	2.79		+19
k(P–F)		4.64	5.01	5.19	+12

Thus P–S force constants also depend on the electronegativity of the other bonding partners. Increasing electronegativity leads to increases of between 0 and 30% in the k values.

4. Effect of Ionic Charge

The force constants in $SP(SCH_3)_3$ and PS_4^{3-} are given in Table 2. Both species contain an sp^3-hybridized phosphorus atom, to which four sulfur atoms are attached; the main difference between them is the triple negative charge on the ion. k(S–P) in the anion is 2% lower even than k(P–SCH_3) in $SP(SCH_3)_3$, which has a value of 2.56. It would, however, be premature to conclude that the force constants are lowered by negative charge. Thus the change from $OP(OCH_3)_3$ to PO_4^{3-} is accompanied by a 10% increase in the force constant. The difference is probably due to very marked differences in the π-bonding components, as indicated by the bond orders (PS_4^{3-} 1.06, PO_4^{3-} 1.42).

We were again interested here by the changes resulting from the replacement of sulfur by the more electronegative oxygen. The force constants of the series PS_4^{3-} – PO_4^{3-} are given in Table 7. Comparison of these values with those in Table 3, which also refer to replacement of sulfur by oxygen, shows that while the directions of the changes are the same, they are smaller (14% as compared with 28%).

Table 7. Force constants of the transition series PS_4^{3-} – PO_4^{3-}.

	PS_4^{3-}	PS_3O^{3-}	$PS_2O_2^{3-}$	PSO_3^{3-}	PO_4^{3-}	Δk(%)
k(P–S)	2.51	2.60	2.60	2.86		+14
k(P–O)		6.03	6.11	5.84	6.20	+ 3

A question that arises in connection with these ions is whether the negative charges are located preferentially on the oxygen or (less likely) on the sulfur, or are uniformly distributed over the two types of atoms. In the first case the P–S bond in PSO_3^{3-} would be expected to exhibit a strong double-bond effect, *i.e.* to show a considerable increase in the S–P force constant (the same applying to the P–O constant in PS_3O^{3-} in the second case). These changes should be distinct even in $PS_2O_2^{3-}$. Since the force constants remain practically unchanged over the entire series, it can be concluded that the charges are fairly uniformly distributed over all four atoms.

The maximum effect of the ionic charge on the P–S force constant is probably of the order of 12%. Because of the small number of examples available, no general statement can be made about this effect, since it is probably also combined with π-bonding effects.

5. Effect of π Bonding

Compounds of the type $S-PX_3$ are particularly suitable for the investigation of this problem. In $S-P-(SCH_3)_3$, k(S–P) is greater than k(P–SCH_3) by 63% (Table 2). This difference is greater than any of the other force-constant differences discussed so far. Like the O–P bond in $O-PX_3$, the S–P bond must be assumed to have an appreciable π component. This conclusion was reached some time ago on the basis of the vibration spectra [6] and the interatomic distances [7]

$OP(SCH_3)_3$	1202	8.71	73	$SP(SCH_3)_3$	700	4.16	80

in phosphorus-sulfur compounds. Calculation of the bond orders for the two force constants in $S-P-(SCH_3)$ by *Siebert*'s method[4] gives 1.16 (close to a single bond) for $P-SCH_3$ and 1.57, which is considerably higher than the value for a single bond, for S–P. The compound is in a state that lies between the two canonical structures:

Numerous investigations on the analogous oxygen compounds had shown that the frequency of the $O=P<$ vibration and the corresponding force constant decrease with decreasing electronegativity x of the other bonding partners[8]. Since a similar effect was also to be expected for the SP bond, a large number of compounds of this type were synthesized and examined spectroscopically, so that many SP force constants are available for discussion.

The stretching frequencies and force constants of some OPX_3 and SPX_3 molecules are compared in Table 8. The order found from the OP frequencies and force constants is retained in this table for the corresponding sulfur compounds. It must first be pointed out that the frequencies and force constants for the oxygen compounds show parallel variations; the above-mentioned dependence on electronegativity is found only to a rough approximation. The sulfur compounds, on the other hand, exhibit rather confusing behavior. Whereas the SP force constants again follow roughly the same order as for the oxygen compounds, the SP stretching frequencies follow no recognizable pattern. The low values of the frequency and force constant for $SP[N(CH_3)_2]_3$ and $SP(CH_3)_3$ are particularly interesting. Thus there is no simple dependence of the force constant on the electronegativity of the other bonding partners; the present general investigation gives a maximum change in the SP force constants of about 35%. The variations are similar in magnitude to those attributed to inductive effects (Section 3), and are also comparable with those of the OP force constants.

The unexpected behavior of the SP stretching vibrations is due to strong coupling with the other stretching vibrations of the molecule. In contrast to the OP vibration, which is situated well outside the range of the other stretching vibrations, and which may therefore be regarded as characteristic, the SP vibration lies in the middle of this range. In the case of the light bonding partners (F, OCH_3, $N(CH_3)_2$, CH_3) the $\nu_s PX_3$ vibrations which couple strongly with the νSP, are situated at higher frequencies and so displace νSP to lower frequencies (563–695 cm^{-1}). For the heavier partners Cl, SCH_3, and Br, the $\nu_s PX_3$ lie below νSP and displace νSP to higher frequencies (700–752 cm^{-1}). This coupling can, however, be largely compensated in the force constant calculation, as is shown by the results in Table 8, and the further discussion.

Figure 1 shows a plot of all the calculated SP force constants against the sum of the electronegativities of all three partners, the Pauling values being used for the atoms bonded directly to the phosphorus. Examination of the values for all the compounds SPX_3 now

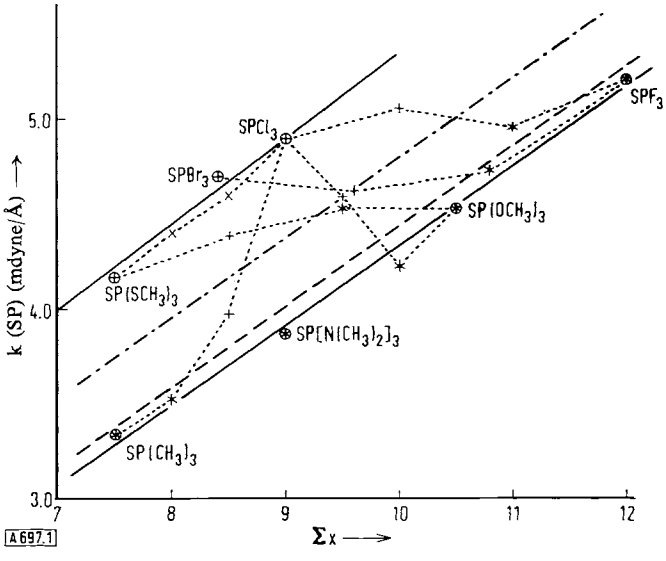

Fig. 1. SP force constants of compounds of the type $SP(X, Y)_3$ plotted against the sum of the Pauling electronegativities of the three other bonding partners.

⊛ : Three bonding partners from the first short period.

✳ : Two bonding partners from the first short period, and one from higher periods.

\+ : One bonding partner from the first short period, and two from higher periods.

⊕, × : Three bonding partners from higher periods.

reveals a remarkable effect: All the SP force constants for the compounds with the light atoms of the first short period lie on one straight line, and the values for compounds with the heavier atoms, including bromine, lie on another. The slopes of the two lines are roughly equal, indicating that the dependences of the S–P force constants on the electronegativity are the same. This result suggests that the procedure used to calculate the force constants cannot cope with the strong coupling

[8] *J. V. Bell, J. Heisler, H. Tannenbaum,* and *J. Goldenson,* J. Amer. chem. Soc. *76* 5185 (1954); *L. W. Daasch* Spectrochim. Acta *13,* 257 (1958); *L. C. Thomas* and *R. A. Chittenden* Spectrochim. Acta *20* 467 489 (1964).

of the SP vibration with the PX_3 vibrations, so that the observed discrepancy is due to the method of calculation. It must, however, be mentioned that the distance between the two straight lines is almost 1 mdyne/Å, corresponding to deviations that normally lie well outside the limit of error of the calculation process. Another possibility is that elements of the higher periods have a special effect on the SP force constant.

Further information is provided by compounds with mixed substituents of the type SPX_2Y or $SPXY_2$. A total of six series of this nature have so far been examined spectroscopically. One of these series, $SPCl_3$ – $SP(SCH_3)_3$, leads from heavy to heavy partner atoms. The k(SP) values for this series lie surprisingly close to the straight line for compounds with heavy atoms (cf. Table 5 and Fig. 1). The five other transitions lead from light to heavy partner atoms. If the dependence on electronegativity is assumed to be the same for the compounds with mixed substituents as for compounds containing only light or only heavy partner atoms, we obtain the average lines (---) for SP force constants with two light atoms and one heavy one and (–·–·) with two heavy atoms and one light one. The mean deviation from these average lines is ±0.15 mdyne/Å (≈4%), and so lies within the limit of error of the method. If these deviations were due to the calculation method, both types of compounds with mixed substituents should give approximately equal deviations midway between the two limiting lines. However, the nature of the deviations shows a pronounced dependence on the number of heavy atoms. The first heavy atom introduced leads to an average increase of 0.10 mdyne/Å, the next 0.37, and the third 0.50, giving a total increase of almost 1.0 mdyne/Å (20%). Thus elements from higher periods, which possess d electrons, more strongly favor the double bond form with $d\pi-p\pi$ interaction. It should be mentioned that the same effect is observed in the OP compounds. This indicates that there has been no failure of the calculation method.

Our examination shows a very strong dependence of the SP force constant on the electronegativity of the neighboring atoms. The values found lie between 5.21 (SPF_3) and 3.33 mdyne/Å ($SP(CH_3)_3$). The bond orders as found from these values by *Siebert*'s method lie between 1.89 and 1.33, while values between 2.44 and 1.88 are obtained for the OP bond orders. This comparison alone shows the very much smaller tendency toward double bond formation with the pair of elements phosphorus and sulfur. If the results are considered in conjunction with the rules given earlier (cf. Section 1), the limit given for the electronegativity sum is confirmed, since even in the most favorable case, a bond order of only 1.89 is obtained for S–P. This still corresponds to a very much higher double bond component than that found for the grouping Si–N. This is an excellent illustration of the strong influence of the electronegativity difference: ΔxSP = 0.4, ΔxSiN = 1.2. Thus SiN is well outside the limiting range for double bonds with respect to the sum and difference of the electronegativities, whereas SP is very close to this range.

6. Summary

P–S force constants of between 2.06 and 5.21 mdyne/Å are found for many phosphorus-sulfur compounds. The differences can be traced to four factors, which have been demonstrated separately in examples. The changes (maximum 40%) that accompany changes in hybridization are due to differences in the s components of the bonds, the force constant decreasing with decreasing s component. The other bonding partners also have a distinct influence on the force constant. In the case of tetracoordinate phosphorus, an increase in the electronegativity of the partners leads to a distinct increase (up to 30%) in the k(P–S) values. Practically no effect is observed with tricoordinate phosphorus. The force constant of the phosphorus-sulfur bond is decreased by transition from neutral molecules to negatively charged ions. Finally, it was found for many compounds of the type $S-PX_3$ that this bond exhibits partial double-bond character, which depends on the electronegativity of the other bonding partners. Thus the bond order in SPF_3 is 1.9, while that in $SP(CH_3)_3$ is 1.3. Bonding partners with d electrons also have an appreciable strengthening effect, as has also been found for the O=P bond.

I am grateful to the Deutsche Forschungsgemeinschaft and the Bundesministerium für wissenschaftliche Forschung for provision of the spectrographs, and to the Fonds der Chemischen Industrie for financial support of the work. Thanks are also due to Dr. Fritzowsky, Dr. Köttgen, Dr. Ombarek, Dr. Pohl, and Dipl.-Chem. Pulay for the preparation and spectroscopic examination of the compounds discussed and to Dr. Blaich, Dipl.-Chem. Lentz, Dipl.-Chem. Pulay, Dr. Sawodny, and Dr. Sirag Eldin for the calculation of the force constants.

Excimers

By Th. Förster [*]

Dedicated to Professor H. Bredereck on the occasion of his 65th birthday

Excimers are molecular associates that exist only in excited electronic states. They are therefore detectable only in emission spectra, and particularly in fluorescence spectra. Despite their short lifetimes, they are responsible for many photophysical and photochemical effects.

1. Introduction

The concentration quenching of fluorescence is a phenomenon that has been known for a long time. It was discovered only recently, on the other hand, that instead of quenching, many fluorescent organic compounds exhibit a change in the fluorescence spectrum, *i.e.* a new component becomes evident in such a spectrum with increasing concentration. Since no corresponding change is observed in the absorption spectrum, the new fluorescence component must be ascribed to an associate formed only *after* absorption of light in the electronically excited state [1]. The term "excimers" has become widely accepted for associates of this type [2].

The fluorescent properties of crystals of many organic compounds and of macromolecular substances are due to excimers, as are the properties of some liquid scintillator systems. Excimers have also been detected as intermediates in many photochemical reactions, and it may be assumed that they are also involved in analogous radiochemical processes. An attempt will be made in this article to present a brief survey of existing knowledge in this field [3].

2. Excimer Formation of Pyrene in Solution

The role of the association of excited molecules as the cause of a change in the fluorescence spectrum with concentration was first recognized by us in the case of pyrene and some of its derivatives [4]; and the formation of excimers is still most easily demonstrated for pyrene.

Spectra of (oxygen-free) solutions of this compound at various concentrations in *n*-heptane at room temperature are shown in Figure 1. The structured spectrum observed at concentrations of 5×10^{-5} M and less is the fluorescence spectrum

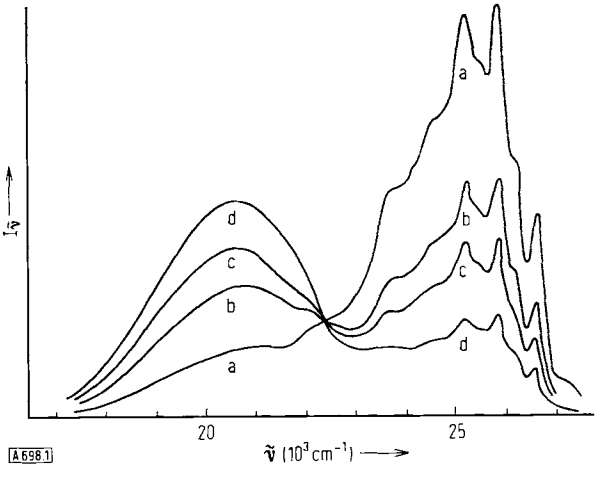

Fig. 1. Fluorescence spectra of pyrene in *n*-heptane. $t = 20$ °C, c (mole/l): 5×10^{-5} (a), 1.8×10^{-4} (b), 3.1×10^{-4} (c), 7.0×10^{-4} (d).

of monomeric pyrene, which extends from the UV to the violet region of the visible spectrum. An additional unstructured component appears at higher concentrations in the blue region, *i.e.* at longer wavelengths, and this component ultimately becomes the only one present. If, as in this example, the spectra are recorded for the same absorption of the exciting light, all the curves intersect at a single point. Such an "isoemissive" or "isostilbic" point [5] of an emission spectrum occurs if the spectrum consists of contributions due to only two components. It corresponds to the isosbestic point of an absorption spectrum, though the latter remains unchanged in the present case over the entire concentration range in which the fluorescence change occurs. Because of this validity of the Beer-Lambert law, as well as other observations, the blue fluorescence component is attributed to an associate that exists only in the excited electronic state, *i.e.* to an excimer. The absorption and fluorescence spectra of oxygen-free pyrene solutions remain unchanged on prolonged irradiation, and no stable photoproduct can be detected.

The mechanism of excimer formation can be deduced from the quantitative course of the fluorescence

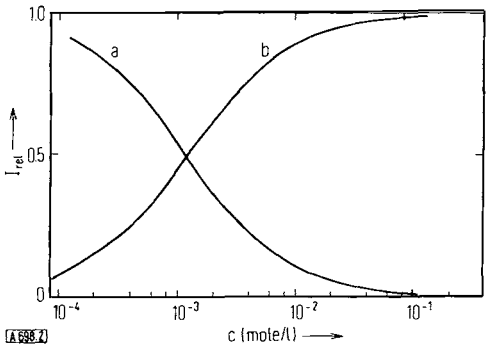
[5] From στίλβειν: shine. I am grateful to Dr. *H. E. A. Kramer*, Stuttgart, for this suggestion.



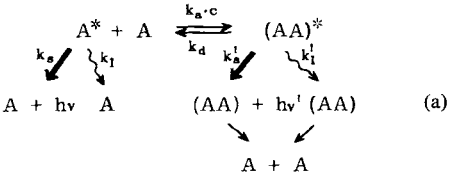


Fig. 2. Relative intensities of monomer component (a) and excimer component (b) of the fluorescence of pyrene in benzene. t = 20 °C. Half-value concentration $c_h = 1.2 \times 10^{-3}$ mole/l.

change. The concentration dependence of the intensities of the two fluorescence components for equal absorption is shown in Figure 2 for pyrene in benzene. The slopes of the curves correspond to a bimolecular mechanism for the formation of the excimer by combination of an electronically excited molecule A* (in the lowest excited singlet state) with an unexcited molecule A (in the singlet ground state). Together with the processes of fluorescence emission, the radiationless deactivation of the excited monomer and of the excimer, and the dissociation of the excimer to be discussed later, this leads to the following reaction scheme [4,6]:

⟶ : Normal ("adiabatic") reaction processes without alteration of existing excitation.
▬▶ : Radiation processes.
〰▶ : Radiationless ("diabatic") deactivation processes.

According to reaction scheme (a), the concentration dependences of the fluorescence quantum yields η and η' of the monomeric and excimeric components are

$$\eta = \eta_{max} / \left(1 + \frac{c}{c_h}\right) \quad (1) \qquad \eta' = \eta'_{max} / \left(1 + \frac{c}{c_h}\right) \quad (1')$$

i.e. a Stern-Volmer equation (1) for the monomer component and a corresponding inverse relation (1') for the excimer component. η_{max} and η'_{max} are the maximum quantum yields of the two components for very low and very high concentrations, respectively, and c_h is the half-value concentration which is common to both relations.

The relative quantum yields are identical with the relative intensities in Fig. 2. Their concentration dependences agree with equations (1) and (1'), the half-value concentration being $c_h = 1.2 \times 10^{-3}$ mole/l. The ratio of the quantum yields becomes

$$\frac{\eta'}{\eta} = \frac{\eta'_{max}}{\eta_{max} c_h} c \quad (2)$$

[6] *E. Döller* and *Th. Förster*, Z. physik. Chem. N.F. *34*, 132 (1962).

and thus increases in proportion to the concentration. Provided that the dissociation of the excimers can be ignored ($k_d = 0$), the quantities occurring in equations (1) to (2) are

$$\eta_{max} = \frac{k_s}{k_s + k_1} \quad (3) \qquad \eta'_{max} = \frac{k'_s}{k'_s + k'} \quad (3')$$

$$c_h = \frac{k_s + k_1}{k_a} \quad (4)$$

For $k_d = 0$, the decay of the monomer emission is purely exponential, with an average decay time $\tau = 1/(k_s + k_1 + k_a c)$. The excimer emission, on the other hand, follows a complicated bi-exponential course passing through a maximum, such as is also found in the formally analogous case of secondary products of a radioactive decay series.

The first confirmation of a time dependence of this type was provided by the different and concentration-dependent quenching of the two fluorescence components by oxygen [4,7]. *Birks, Dyson,* and *Munro* later managed to follow the emission from both components directly on flash-excitation [8]. The curves given in Figure 3 for pyrene in cyclohexane at a concentration slightly above the half-value concentration confirm the expected time characteristics.

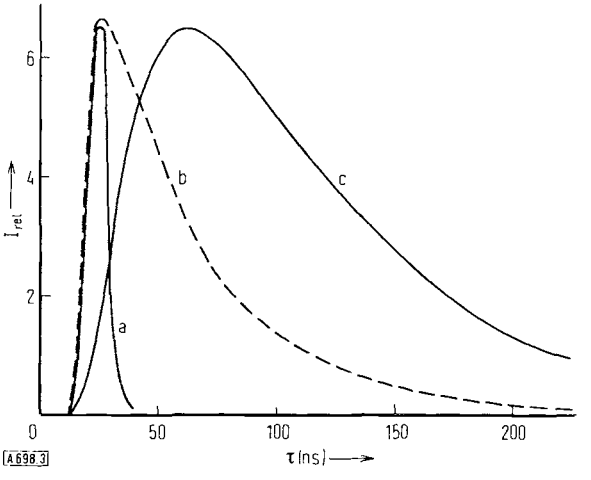

Fig. 3. Time dependence of excitation (a), monomer component (b), and excimer component (c) of pyrene in cyclohexane. $c = 5 \times 10^{-3}$ mole/l [8].

The association reaction that takes place during the brief excitation of the monomer has to be very fast, and hence diffusion-controlled. Both k_a and c_h should therefore depend on the viscosity of the solvent. The half-value concentrations measured in various inert solvents (aliphatic and aromatic hydrocarbons, alcohols) do in fact increase with increasing viscosity, though the strict proportionality expected from eq. (4) is not observed. This is due to the thermal dissociation of the excimers, which has not yet been taken into account.

This is obvious from the temperature dependences of the two fluorescence components, which are shown in Figure 4 for pyrene in liquid paraffin at a medium

[7] *K. Kasper*, Z. physik. Chem. N.F. *12*, 52 (1957).

[8] *J. B. Birks, D. J. Dyson,* and *I. H. Munro*, Proc. Roy. Soc. (London) *A 275*, 575 (1963).

concentration [6]. The opposing intensity variations of the two components above and below 80 °C are due to the fact that the formation of the excimer predominates at low temperatures, while its dissociation with reformation of the excited monomer predominates at high temperatures. This process is indicated in scheme (a), where it has been assigned the rate constant k_d. When it is taken into account, equations (1) to (3′) remain unchanged, but eq. (4) is replaced by the more general expression for the half-value concentration:

$$c_h = \frac{k_s + k_1}{k_a}\left(1 + \frac{k_d}{k_s' + k_1'}\right) \qquad (4')$$

If dissociation predominates ($k_d \gg k_s' + k_1'$), the half-value concentration no longer depends on k_a, alone, but on the ratio k_d/k_a; it is then determined by the excimer dissociation *equilibrium*, and is independent of the viscosity of the solvent.

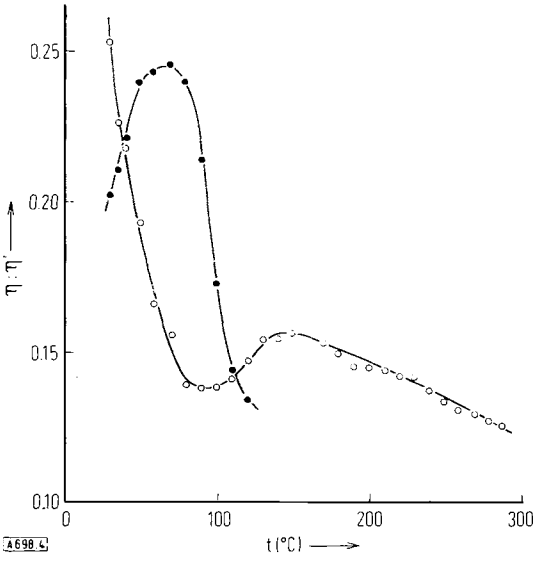

Fig. 4. Temperature dependence of the fluorescence of pyrene in liquid paraffin. $c = 5 \times 10^{-3}$ mole/l [6].
○: quantum yield of the monomer component, ●: of the excimer component.

If dissociation is appreciable, some of the excited monomers pass through the excimer stage, so that the decay of the monomeric component is no longer exponential. As dissociation equilibrium is approached the difference in the time dependences of the two components disappears [8a].

Figure 5 shows the temperature dependence of the half-value concentrations of pyrene in various inert solvents [9]. In the high temperature range (left), c_h increases with rising temperature and is practically independent of the nature of the solvent; in this range the excimer dissociation equilibrium is established. At lower temperatures c_h becomes diffusion-controlled, and increases with solvent viscosity.

These temperature functions can be used to find the kinetic and thermodynamic parameters of excimer formation. The most interesting quantity is the *enthalpy* of dissociation of the excimer, for which

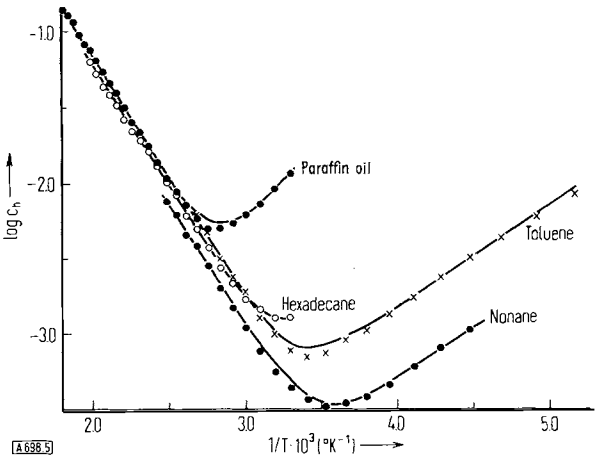

Fig. 5. Temperature dependence of the half-value concentration for the change in the fluorescence spectrum of pyrene with concentration [9].

values between 10 and 11 kcal/mole have been found in various solvents [6, 10]. With the aid of the fluorescence decay time, the *entropy* of dissociation of the excimer (based on unit concentrations) is found to be about 20 cal/deg·mole. These values indicate strong bonding and a rigid configuration for the excimer of pyrene.

3. Excimer Formation of other Aromatic Compounds

Following the discovery of excimer formation for pyrene (1954), it seemed that the ability to form excimers was confined to this hydrocarbon and a few of its derivatives such as 3-chloropyrene and the related benzo[*b*]pyrene, whose fluorescence change had already been observed by *Bandow* [11], but (as later by other authors [12]) had been attributed to ground state association. A weak excimer component was also found for some 9-alkylanthracenes [13], though not for anthracene itself. Another one was detected by *Berlman* for 2,5-diphenyloxazole and attributed to excimers [14].

Since 1962, changes in fluorescence spectra with concentration have also been observed (though only at lower temperatures or considerably higher concentrations than in the case of pyrene) for many aromatic compounds, *e.g.* benzene [15], naphthalene [16, 17], benz[*a*]anthracene [18, 19], perylene [19], anthanthrene [19],

and a large number of derivatives [20–26], including substituted anthracenes [26a,b]. Anthracene itself does not give a fluorescence change, but exhibits concentration quenching; this is also due to the formation of an excimer, which does not however emit, but undergoes transformation into the stable dianthracene (cf. Section 11). *Birks* and *Christophorou* [22] have collected data on excimer formation of many aromatic compounds.

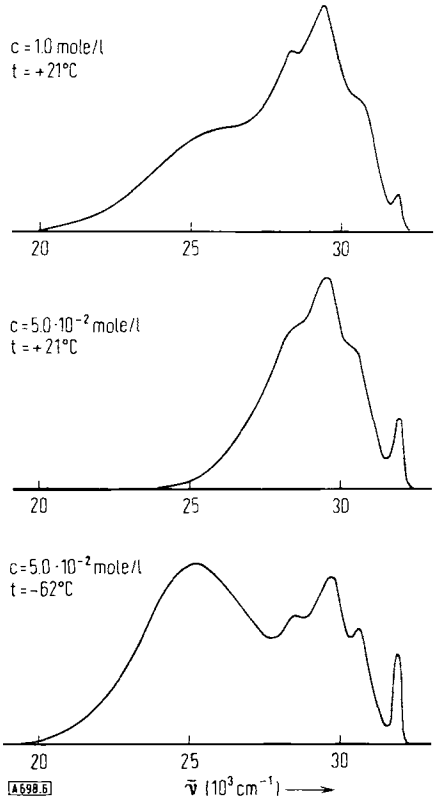

Fig. 6. Fluorescence spectra of naphthalene in toluene at various temperatures and concentrations [16].

As an example, Figure 6 shows the fluorescence spectra of naphthalene in toluene [16]. The excimer component is barely visible at room temperature even at very high concentrations, and emerges only at low temperatures. Domination of excimer fluorescence similar to that found in moderately concentrated pyrene solutions is observed only for a few liquid methylnaphthalenes [27–29].

The conditions for the occurrence of excimer fluorescence in the cases discovered later show that such excimers are less tightly bound, and that excimer dissociation occurs even below room temperature. Accordingly, the dissociation enthalpies are low, *e.g.* 5–6 kcal/mole for benzene [23] and for naphthalene [24,30,31]; alkyl substituents, which should sterically hinder excimer formation, reduce these values further. The dissociation entropies, on the other hand, are similar in magnitude to that of the pyrene excimer ($\approx$ 20 cal/deg·mole).

Despite the difference in the dissociation energies, the differences between the fluorescence maxima of the monomer and the excimer are almost as large in these cases as for pyrene, *i.e.* about 6000 cm^{-1}, which corresponds to an energy difference of 17 kcal/mole, and thus exceeds the dissociation energy of the pyrene excimer, and even more so than those of other aromatic excimers.

Figure 7 shows the potential-energy diagram, after *Stevens* and *Ban* [30], for a sandwich configuration of the excimer resulting from the mutual approach of the two components with their molecular planes parallel. According to this diagram the ground state of the excimer is *unstable*. This explains not only the diffuse character of excimer fluorescence, but also the failure of all attempts to find a corresponding component in the absorption spectrum without additional fixation of the excimer components.

The time characteristics of fluorescence have been studied for naphthalene [32], benz[*a*]anthracene [21],

and derivatives of these compounds [33]. In the case of naphthalene, excimer dissociation attains complete equilibrium, and the same purely exponential decay is observed for both components.

4. Further Investigations on Excimers in Solution

In the equilibrium case, the change in the fluorescence spectra with concentration is controlled by the equilibrium of excimer formation; the dissociation enthalpy of the excimer can be found from the temperature dependence of this equilibrium. Similarly, the volume expansion connected with dissociation, or its negative, the volume contraction, occurring on formation of the excimer from the monomers, should be obtainable from the pressure dependence of the effect.

The fluorescence properties of aromatic compounds in solution depend on pressure even in the absence of any molecular association, but appreciable variations occur only at pressures above 10 kbar. The intensity ratios of the monomer and excimer components, on the other hand, vary at much lower pressures. The direction of this variation depends on whether excimer formation is diffusion- or equilibrium-controlled [34,35]. In the former case, *e.g.* for pyrene below room temperature, the excimer component is found to decrease, but this is merely due to the pressure-induced increase in solvent viscosity. On the other hand, for naphthalene and other compounds where the dissociation equilibrium is established, the excimer component increases with pressure [36] (cf. Fig. 8).

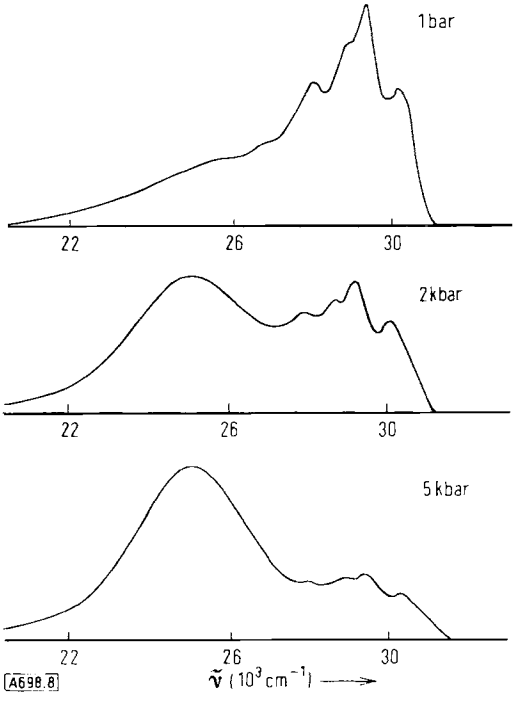

Fig. 8. Fluorescence spectrum of 1,6-dimethylnaphthalene in *n*-heptane at various pressures. t = 20 °C; c = 0.32 mole/l [30].

The pressure dependences of naphthalene-excimer formation in a series of different solvents gave almost identical values of 16 cm³/mole for the volume contraction. This contraction is considerable if compared to twice the molar volume of naphthalene in the crystalline state (224 cm³/mole). If a sandwich structure is assumed, the distance between the two molecular planes in the excimer can be estimated from the volume contraction to be about 3.0 Å [36].

Aromatic hydrocarbons can be solubilized in water by suitable detergents; they solve in the lipid phase, which has a well defined micelle structure under suitable conditions. In such solutions of aromatic hydrocarbons, the extent of excimer formation should be governed, not by the overall concentration of the aromatic compound in the solution, but by its local concentration in the lipid phase. It is in fact found that 2-methylnaphthalene, whose fluorescence change in homogeneous solutions corresponds to a half-value concentration of about 1 mole/l, has a similar value with cetyldimethylbenzylammonium chloride as the detergent [37]; on the other hand, pyrene in the same system has a half-value concentration of 2.6×10^{-2} mole/l, which is greater by a factor of 20 than that in a comparable homogeneous solution. This deviation is due to the size of the micelles, which must contain at least two molecules of the aromatic compound if the excimer is to be formed. Estimation of the micelle size on this basis leads to values similar to those found by the usual methods.

5. Intramolecular Excimers

Larger molecules in which two or more aromatic residues are flexibly linked to each other by aliphatic carbon atoms should be capable of forming intramolecular excimers, and their fluorescence spectra should contain an excimer component that is independent of concentration. According to *Hirayama* [38], this is the case with di- and triphenylalkanes whose phenyl groups are joined by aliphatic chains containing exactly *three* carbon atoms. The fluorescence spectra of two such compounds are shown in Figure 9; the intensity ratios of the two components in these cases depend on the solvent, but not on the concentration. Their absorption spectra are normal and resemble those of ethylbenzene or of diphenylalkanes with shorter or longer connecting methylene chains that are incapable of excimer formation because of steric or statistical factors. Solutions of polystyrene and of polyvinylnaphthalene, in which the aryl groups are again linked by aliphatic chains of three carbon atoms, give fluorescence spectra containing both monomer and excimer components at room temperature [39]. At 77 °K, polystyrene shows only the monomer component, probably owing to an activation barrier to the formation of the excimer.

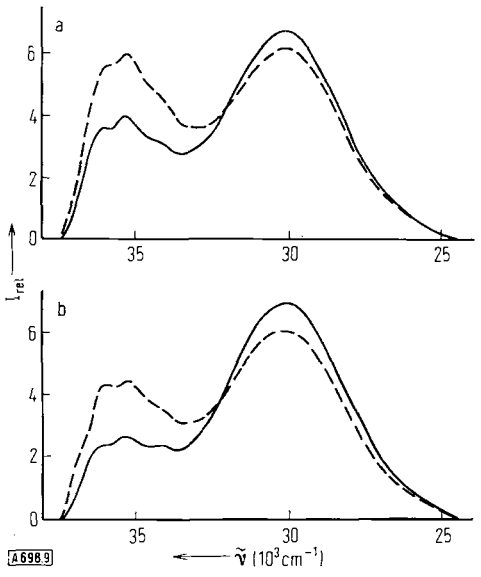

Fig. 9. Fluorescence spectra of 1,3-diphenylpropane (a) and 1,3,3-triphenylpentane (b) in cyclohexane (——) and 1,4-dioxane (---) [38].

Nucleic acids and synthetic di- and polynucleotides also exhibit excimer fluorescence, though their absorption spectra are monomolecular [40].

In paracyclophanes, two phenyl groups are linked by methylene chains in the *p,p'* position [39,41,42]. The fluorescence spectrum of [4,4]-paracyclophane (in solution at room temperature) shows only the excimer component, while those of [4,5]- and [6,6]-paracyclophanes contain practically no excimer component; all these compounds have normal absorption spectra. [2,2]-Paracyclophane exhibits pure excimer fluorescence, but its absorption spectrum is also different from those of its homologs. In this case it appears that even in the unexcited state, the distance between the two phenyl groups is appreciably shorter than that of closest approach between freely mobile groups.

6. Excimer Fluorescence in Crystals and Stable Aggregates

The fluorescence of crystalline pyrene is blue and structureless, and its maximum (4600 Å) hardly differs from that of the long-wave component in solution (4760–4780 Å). This fluorescence is also due to excimers. In this connection, *Ferguson* [43] recalled attention to the fact that in the crystal lattice of pyrene, the molecules are arranged in parallel pairs with an interplanar distance of 3.53 Å [44]. According to *Stevens* [45] a general relationship exists between fluorescence and the crystal structure of aromatic compounds. Naphthalene, anthracene, phenanthrene, and other "elongated" molecules favor structures of an A type, in which adjacent molecules are oriented almost perpendicular to one another. The fluorescence spectra of such crystals are not very different from those of dilute solutions, and may be regarded as monomer spectra. "Disk-shaped molecules", on the other hand, favor structures of a B type, in which the molecules are either arranged in *pairs*, as in pyrene, benzo[*g,h,i*]perylene, and perylene (α-form), or *stacked* in columns in the crystal lattice, as in perylene (β-form), coronene, ovalene, and benzo[*b*]pyrene (monoclinic form). Excimer fluorescence occurs only in crystals of the B type, in whose lattices adjacent molecules have an arrangement similar to that in the excimer. Nevertheless, this arrangement is by no means the same, as is shown by the absorption spectra of type B crystals, which (apart from a slight Davydov splitting) are very similar to the solution spectra. Thus here too the excimer configuration is achieved only after light absorption, with further approach of two molecules that were already adjacent. The observation that α-perylene no longer exhibits excimer fluorescence at very low temperatures [46] could be explained by a freezing of this configuration change.

The monomer fluorescence exhibited by many crystalline aromatic compounds in agreement with their lattice type changes at high pressures (10 to 50 kbar) into a structureless band at a longer wavelength. This has been observed for crystals of naphthalene [47–49], anthracene [48–50], phenanthrene [49], benz[*a*]anthracene [50], chrysene [50], and naphthacene [51]. The structureless band is generally interpreted as excimer fluorescence, though the red shift in relation to the monomer emission is not always as large as in solution. In the case of pyrene [52] and α-perylene crystals [53], which exhibit excimer fluorescence even at normal pressure, this fluorescence shifts to still longer wavelengths as the pressure is increased.

Many observations suggest that the excimer fluorescence is emitted preferentially by lattice defects, which act as traps and capture the initially delocalized excitation energy. In addition to their excimer fluorescence, microcrystals of pyrene exhibit a weak monomer component, which is attributed to surface defects [54]. For crystals that give excimer emission only at high pressures, the fluorescence change is frequently irreversible, so that after return to normal pressure the spectrum still has an excimer component, which disappears only after a relatively long time or on annealing. The degree of reversibility seems to depend both on the size of the crystal and on the irradiation at

high pressure [49]. An extreme case of a disordered lattice exists in solids having amorphous structures, which are obtained in the case of organic substances by condensation from the vapor at low temperatures. Films of anthracene prepared in this way at −70 °C exhibit excimer fluorescence, which changes into monomer fluorescence on crystallization [55, 56].

Excimer formation appears from these observations to concern parallel pairs of adjacent molecules within the crystal rather than the crystal as such. One should therefore also expect excimer fluorescence from *isolated* pairs of molecules having a similar configuration. According to *Ferguson*, such "sandwich dimers" can be produced from supercooled solutions of the aromatic compounds in vitreously solidifying solvents by controlled heating and recooling [57], and, in the case of anthracene and some of its derivatives, also by photolytic decomposition of the stable photodimers [58]. The controlled heating method yields sandwich dimers of pyrene [57] and perylene [59], whose absorption and fluorescence spectra differ considerably from those of the monomeric compounds, but are similar to those of the crystals. Obviously, these sandwich dimers too emit only after further approach of their components.

Sandwich dimers of 9- and 9,10-disubstituted anthracenes, which also give excimer fluorescence, have also been obtained by one or other of these methods [60,61]. The dimers of anthracene itself are particularly interesting. In agreement with its crystal type (A), anthracene gives only monomer fluorescence both in solution and in the crystalline state. Different dimers are obtained by controlled heating and by photolysis of dianthracene, the first resulting in monomer fluorescence and the second in excimer fluorescence [62]. It can be concluded from the absorption spectra that only the latter has a sandwich configuration, whereas the molecular planes in the other dimer are inclined at about 55° to each other. The sandwich dimer and the 55°-dimer also differ very markedly in their fluorescence decay times at 77 °K (≈ 200 and ≈ 10 ns respectively) [63]. It has been deduced from fluorescence decay times that deformed anthracene crystals contain lattice defects corresponding to the 55°-dimer [64].

7. Excimers from Triplet States or Free Radicals

The formation of excimers is not restricted to the combination of a singlet excited monomer with an unexcited monomer (Scheme (a)). They can also be formed *via* two monomers in metastable triplet states (denoted by (†) to distinguish them from singlet excited states (*)):

$$A^{\dagger} + A^{\dagger} \rightarrow (AA)^{*} \; [\rightleftarrows A^{*} + A] \qquad (b)$$

To produce a singlet excimer, the excitation energies of the two triplet molecules, which would not be sufficient alone, are added together.

An excimer formed in accordance with Scheme (b) should be evident in the spectrum of "delayed fluorescence", *i.e.* an emission that has the same spectrum as fluorescence, but a longer decay time because of the time spent in the triplet state.

The first indication of process (b) came from the observation by *Stevens* and *Hutton* that on flash excitation, the excimer component of pyrene in solution persists over several milliseconds [2]. *Parker* and *Hatchard* [65] later found that this is due to a separate, slowly decaying, low-intensity component, which is superimposed on the normal fluorescence, and is proportional to the square of the excitation intensity. This *biphotonic* nature of the process led to its interpretation by the reaction scheme (b).

The monomer component also appears with that of the excimer in delayed fluorescence. The ratio of the two components varies with temperature and concentration in a manner similar to, but not exactly the same as, that in prompt fluorescence. [66–68]. At higher temperatures, the excited monomer (as indicated in (b)) is regenerated by dissociation of the excimer, but with the excimer component predominant because of incomplete equilibration. The singlet excited monomer may also be formed directly by an energy transfer process between the two separate triplet molecules [69]:

$$A^{\dagger} + A^{\dagger} \rightarrow A^{*} + A \qquad (b')$$

At low temperatures and correspondingly high solvent viscosities, process (b′) and the monomer component predominate in delayed fluorescence. This process involves electron *exchange* between the two molecules, and so takes place only over short distances, though not necessarily so short as the distance for excimer formation by process (b).

The concurrent processes (b) and (b′) are considered together in the Parker-Stevens mechanism of delayed fluorescence. A different mechanism, according to which excimer and singlet excited monomer are formed *via* an intermediate higher excited excimer state, has been proposed by *Birks* [70–72] and further discussed by other authors [73–75].

Excimer components have also been found in the delayed fluorescence of solutions of naphthalene [76], benzo[*b*]pyrene [66], benz[*a*]anthracene [71], and phenanthrene [77]. In delayed as well as in prompt fluorescence, the emission of less strongly bound excimers is confined to a narrow temperature range, in which the approach of the triplet molecule is sufficiently fast, but the dissociation of the excimer is not yet too pronounced.

Excimers should be formed not only by electron exchange between two molecules in triplet states but also by electron *transfer* between a radical-anion and a radical-cation (both in their unexcited states):

$$A^- + A^+ \rightarrow (AA)^* \qquad (c)$$

The excimer emission then appears as *chemiluminescence*. With radical-anions and radical-cations produced by alternating current electrolysis under potentiostatic conditions, *Chandross*, *Longworth*, and *Visco* [78] obtained chemiluminescence spectra with monomer and excimer components as well from several aromatic hydrocarbons. A subsequent quantitative investigation of the concentration dependence of the two components for 9,10-dimethylanthracene in dimethylformamide confirmed reaction scheme (a), though participation of other processes cannot be ruled out [79].

8. Unsymmetrical Excimers

Just as dissimilar molecules can form stable associates and complexes, they should also be capable of forming excimers. The existence and stability of unsymmetrical excimers whose components differ in their excitation energies, ionization potentials, or electron affinities is important to the problem of the bonding mechanism in excimers.

Aromatic compounds having very similar constitutions, and differing *e.g.* only in the position of the alkyl substituents, should produce unsymmetrical as well as symmetrical excimers in mixed solutions, though their structureless fluorescence spectra would be difficult to identify. Mixed excimers of this type *e.g.* between anthracene and 9-alkyl- or 9,10-dialkylanthracenes [80,81], between pyrene and 1-methylpyrene [82,83], and in other systems of the same kind have been detected by specific excitation of one component or by measurement of the total excimer fluorescence as a function of composition. The formation enthalpies of mixed excimers have also been determined [84]. The combination of formation and rapid dissociation of mixed excimers represents a mechanism for the transfer of excitation energy from one component to the other. A non-fluorescent or weakly fluorescent component can thus quench the fluorescence of the other, as has been observed *e.g.* in the case of 9,10-dialkylanthracenes by 9-bromo- or 9-acetylanthracenes [85–87]. The mixed excimer of anthracene and 9,10-diphenylanthracene can also be detected in delayed fluorescence; obviously, it is formed from the triplet states of the two partners in accordance with (b) [88].

The formation of unsymmetrical excimers between molecules of aromatic compounds having essentially different excitation energies is less obvious. Investigations on solid solutions of perylene in pyrene [89] and on mixed solutions of both compounds in a liquid solvent [90] have revealed changes in the fluorescence spectra, but no typical excimer bands have been found.

More favorable conditions for the formation of unsymmetrical excimers are provided by molecules having very different ionization potentials and electron affinities. Pairs of this type tend to form *electron donor-acceptor complexes* [91] (EDA or charge-transfer complexes) in the solid state or even in solution, where they give rise to broad structureless absorption bands in addition to those of the components. Besides these stable complexes, others have been discovered that exist only in the fluorescing excited state. For example, the fluorescence of pyrene (acceptor) in dilute benzene solution is replaced by a structureless component at a longer wavelength on addition of dimethylaniline (donor) [92,93]. Since this phenomenon is analogous to excimer formation [94–96], the terms *heteropolar* exci-

mers or *hetero*-excimers are used [97]. The fluorescence effect in this case and the well-known quenching of fluorescence by non-absorbing impurities are related in the same manner as the concentration-induced fluorescence change and concentration quenching.

Hetero-excimers have been found with numerous aromatic hydrocarbons as acceptors and several aromatic amines as donors in nonpolar solvents [95,96]. The excimer band shows a red shift with increasing electron affinity of the acceptor and with decreasing ionization potential of the donor. For the same donor, a linear relation is found between the wave number of the band maximum and the electron affinity or the reduction potential of the acceptor [98]. In most of the cases studied the acceptor was the lower excitation energy so that it becomes primarily excited under usual conditions. Nevertheless, there are also examples for the opposite case [99]. The fluorescence of a heterotriple complex has also been reported [100]. Nonspecific solvent effects may lead to spectral effects similar to those of the formation of hetero-excimers but should be interpreted differently [101].

Unlike the fluorescence of symmetrical excimers, that of hetero-excimers exhibits an appreciable solvent dependence. The spectrum shifts toward the red with increasing dielectric constant of the solvent, as is to be expected in view of the polar nature of hetero-excimers [94,102,103]. The fluorescence yield and the decay time decrease simultaneously, which has to be interpeted by a solvent dependence either of the electronic structure of the excimer [104] or of its formation and decomposition kinetics [105].

9. Triplet Excimers

A question of considerable theoretical interest is whether molecules in metastable triplet states form triplet excimers with molecules in singlet ground states:

$$A^{\dagger} + A \rightarrow (AA)^{\dagger} \qquad (d)$$

These should appear as an additional component in the phosphorescence spectrum, the properties of which are similar to those of the excimer component in the fluorescence spectrum. Diffuse regions in the low-temperature phosphorescence spectra of some halogenobenzenes in the crystalline state [106] and in solution in organic glasses [107] have been interpreted in this way. The hitherto clearest evidence of the existence of triplet excimers has been found in alcoholic solutions of naphthalene, for which an excimer-like component is superimposed on the monomer phosphorescence over a narrow temperature range around 180 °K [108].

10. Origin of the Excimer Binding Energy

The electronic state of a symmetrical singlet excimer could obviously be described by a resonance hybrid with uniform distribution of the excitation energy over both components:

$$A^*A \leftrightarrow AA^* \qquad (e)$$

We therefore assumed at first that the stability of the pyrene excimer was due to excitation (or exciton) resonance between the two configurations in formula (e) [1]. Greater stability is then to be expected if the state of the excimer is derived, not from the lowest-energy state ^1L_b (77 kcal/mole) of the monomer, but from the state ^1L_a, which is only slightly higher (86 kcal/mole) and also has a very high oscillator strength ($f = 0.35$) [109,110]. States with even higher energies have also been considered [110a].

A second hypothesis for the state of the excimer was proposed by *Ferguson* [43], who interpreted it as a charge-transfer state. A resonance hybrid can again be formulated for a symmetrical excimer:

$$A^+A^- \leftrightarrow A^-A^+ \qquad (f)$$

According to this hypothesis, the energy of the excimer should depend on the difference between the ionization potential and the electron affinity of the monomer. A good correlation exists between this difference and the position of the excimer emission [77,111]; however, since the correlation with the position of the ^1L_a state is equally good [112], it is impossible to decide in favor of one of the two hypotheses.

The first quantum chemical calculations on excimers from parallel molecules of naphthalene, pyrene, *etc.* were performed by *Konijnenberg* [113] and by *Murrell* and *Tanaka* [114] by the semi-empirical PPP method. These calculations showed that with acceptable values of the parameters involved, and particularly of the distance between the two molecules within the excimer, the position of the excimer band can be reproduced only if both excitation- and charge resonance are taken into account.

This corresponds to a combination of (e) and (f) and to a more general formulation of the excimer state as a resonance hybrid:

$$A^*A \leftrightarrow AA^* \leftrightarrow A^+A^- \leftrightarrow A^-A^+ \qquad (g)$$

Depending on the particular case, either the neutral or the ionic configurations may predominate. The formulation (g) can likewise be applied to unsymmetrical and hetero-excimers.

Quantum chemical calculations have been carried out for the excimers of anthracene and perylene as well as for those of naphthalene and pyrene [114, 115]. In addition to highly symmetrical sandwich configurations (D_{2h}), less symmetrical ones have also been discussed [116, 117]. Similar calculations for the benzene excimer, the treatment of which includes the paracyclophanes, have also been carried out for configurations of lower symmetry [118–120].

Besides the PPP method, simpler and less conventional semi-empirical methods have also been used, several of them based on orbitals extending over both components of the excimer [112, 121].

Most of these calculations give only the excitation energy of the excimer as a function of its geometrical configuration. The latter itself, and particularly the equilibrium distance between the planes of the two excimer compounds, can only be deduced from the agreement of calculated and experimental values for the position of the excimer band. Values between 3.0 and 3.6 Å were obtained in every case.

Quantum chemical calculations of the actual energy states, *i.e.* the potential surfaces of the excimer and its unstable ground state, have been carried out only for a few examples, *e.g.* benzene [122] and naphthalene [123], by simplified semi-empirical methods. The potential surface of the ground state of the benzene excimer has also been used for the calculation of the spectral distribution of its emission [124].

11. Excimers as Intermediates in Photochemical Reactions and Photophysical Processes

Photochemical reactions, apart from trivial exceptions, are chemical reactions proceeding from excited electronic states. Excimers occur as intermediates in photochemical dimerizations in which an excited and an unexcited molecule form a stable dimer whose components are linked by principal valences. The best-known example is the photodimerization of anthracene with formation of dianthracene. This reaction, which proceeds from the excited singlet state state [125, 126], was assumed to occur *via* an electronically excited associate [127, 128], later to be identified as the excimer [126, 129]. Very probably, the photochemical reaction is the reason for the concentration *quenching* of fluorescence at room temperature; instead of emitting, the excimer undergoes transformation to the stable photodimer. At lower temperatures [55, 56] or in the presence of bulky substituents [62, 129] in position 9 or 10, this transformation is suppressed, so that excimer fluorescence occurs.

It is also very probable that the photodimerizations of naphthacene, pentacene [130], and 2-alkoxynaphthalenes [131, 132] occur *via* excimers. The (unsensitized) photodimerization of acenaphthylene [133] is known to involve two different mechanisms, one of which leads to the *syn* dimer and the other to the *anti*. A mechanism proposed for the formation of the *syn* dimer proceeds *via* the excimer [134].

The photodimerization of thymine is of interest in biology, and particularly in genetics, since it is involved in the inactivation of deoxyribonucleic acid by UV irradiation. Excimers are also assumed to participate in this process [135, 136].

An important photophysical process is the intermolecular transfer of electronic excitation energy, which plays an important part in the function of the widely used liquid scintillators. These consist of an aromatic solvent, generally toluene, with a dissolved substance that fluoresces at longer wavelengths, *e.g.* 2,5-diphenyloxazole (PPO). Their function depends on the transfer of excitation energy initially produced in the solvent to the solute. This could occur as a radiationless process between separated molecules [137]. However, since excimers are rapidly and reversibly formed in toluene and other common solvents [138, 139], processes such as

$$A^* + A \rightleftarrows (AA)^* \rightleftarrows A + A^* \qquad (h)$$

which are evidently analogous to the Grotthus proton transfer process, must also be considered [140, 141]. This may be a useful principle in the search for new scintillator systems [142]. Excimers also appear to be involved in the transfer of electronic excitation from host to guest molecules in crystals under high pressure [143].

A New Type of Corrin Synthesis

By Yasuji Yamada, D. Miljkovic, P. Wehrli, B. Golding, P. Löliger, R. Keese, K. Müller, and A. Eschenmoser [*]

Work towards a synthesis of vitamin B_{12} has inspired a new type of corrin synthesis. The key step is a light-induced 1,16-hydrogen transfer leading to an antarafacial ($\pi \rightarrow \sigma$)-cycloisomerization of a seco-corrinoid metal complex. The construction of the seco-corrinoid ligand system is achieved by coupling monocyclic ring precursors in their enamide or enamine form through the methods of sulfide-contraction via oxidative coupling and of iminoester-enamine condensation.

The structural and functional uniqueness of vitamin B_{12} and B_{12}-coenzymes continues to stimulate chemical research on corrins in a number of laboratories [1]. One of the important contributions to the synthetic aspects of the field has recently come from *A. W. Johnson* and his collaborators [1c] through their synthesis of corrinoid complexes from tetrapyrrolic precursors. In addition, the continuing investigations in the Harvard and ETH (Zürich) laboratories towards a synthesis of vitamin B_{12} have produced results of a methodological [2] and theoretical [3] nature which, among other things, have induced the development of a new type of corrin synthesis. This is exemplified by the synthesis of (±)-palladium(II)-15-cyano-1,2,2,7,7,12,12-heptamethyl-*trans*-corrin perchlorate *(20)*.

The concept of corrin synthesis used in our previous work [4] requires the construction of two bicyclic intermediates *(1)* and *(2)* containing the A/D- and B/C-moieties respectively, followed by coupling of the C

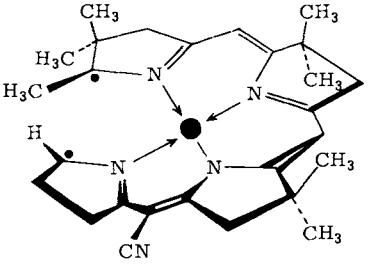

Scheme 1.

and D rings in an iminoester-enamine condensation, and finally by an A/B-cyclization of type *(3)*→*(7)* within a robust [5] transition-metal complex. Inherent in this concept is the configurational problem which arises in the preparation of the A/D-component. In contrast, a cyclization between the rings A and D to the macrocyclic ligand is a characteristic of the conversion of tetrapyrrolic precursors to tetradehydro-corrins [1c,6]. An A/D-cyclization, though mechanistically completely different, is likewise the key step in the new corrin synthesis; namely, a light-induced 1,16-hydrogen transfer leading to a constitutionally and configurationally specific cycloisomerization of a seco-corrionid metal complex *(6)* to the corresponding trans-corrin complex *(7)*. The possibility of incorporating such an "all-or-nothing" process into the planning of a multistep project illustrates once again the new dimension bestowed on organic synthesis by the heuristic concept of sigmatropic rearrangements propounded by *R. B. Woodward* and *R. Hoffmann* [7].

Models of metal complexes *(6)* display the ligand system coiling around the metal ion and one of the ring D methylene hydrogens in position 19 lying directly underneath (or above) the exocyclic methylidene group of ring A; this is the case the more one tries to hold all four ligand nitrogen atoms in a common plane with the coordination center [cf. *(6a)*]. The models also suggest that such planoid complexes optimally fulfill the geometrical prerequisites for an antarafacial sigmatropic 1,16-hydrogen transfer from carbon 19 of ring D to the methylene carbon at ring A. The formal primary product of such a presumably

(6a)

(6b)

endothermic [8] process would be a 15-center 16-electron-π-system *(6b)*, which is separated from the *trans*-corrin complex *(7)* by a correspondingly exothermic, antarafacial electrocyclic 1,15-(π→σ)-isomerization.

Fig. 1 shows the symmetry of the two HMO's π_8 and π_9 [9] which, in the sense of a Woodward-Hoffmann frontier orbital analysis [7], are relevant to both antarafacial processes, namely the 1,16-hydrogen transfer and the 1,15-(π→σ)-isomerization. The prognosis is: whereas the latter process is symmetry allowed in the ground state, the hydrogen transfer would have to be induced photochemically (if it could be induced at all). So far, the experimental findings are in accord with this prognosis.

A second feature of the new type of corrin-synthesis is the construction of vinylogous amidine systems from thiolactams and enamides by oxidative coupling followed by sulfide-contraction. The method has developed from the problem of preparing a B/C-component for a synthesis of vitamin B_{12} [10,11,2b] and represents

[5] With the exception of the method for the synthesis of metal-free corrins (see *A. Fischli* and *A. Eschenmoser*, Angew. Chem. *79*, 865 (1967); Angew. Chem. internat. Edit. *6*, 866 (1967).

[8] No classical Kekulé structure can be formulated for the π-system of *(6b)* if one neglects 1,3-σ bonds. The HMO-model of the *(6b)*-chromophore puts two π-electrons in a non-bonding orbital (see [9]).

[9] The data of Fig. 1 result from a simple HMO-treatment of the corresponding 16- and 15-center π-systems neglecting metal ions. The following set of parameters has been used: $\beta_{CN} = 0.8\ \beta_{CC}$, $\alpha_N = \alpha_C + 1.5\ \beta_{CC}$ (symmetry invariant in the range $\alpha_C \leqslant \alpha_N \leqslant \alpha_C + 2\ \beta_{CC}$); *A. formally an intramolecular version of the iminoester-enamine condensation method.

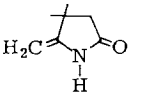
The condensation centers of both the lactam thiocarbonyl carbon and the enamide methylidene carbon are first oxidatively linked by a sulfide-bridge [cf. *(8)*]. An intramolecular thioiminoester condensation in the presence of a phosphorus thiophile leads then to the vinylogous amidine system. The simplest mechanistic pathway includes an intermediate formation of the corresponding episulfide derivative *(9)*; the transfer of sulfur to thiophiles with concomitant carbon-carbon double bond formation is a well-known property of episulfides [12].



(8) *(9)*

[12] A possibility which cannot be ruled out consists of the formation of both the π-, as well as the σ-(C,C)-bond within a (>S=P<) complex. The sulfide-contraction method formally belongs to a group of reactions loosely defined in the literature as "Sulfur Extrusion Reactions"; see *J. D. Loudon* in *N. Kharash*: The Chemistry of Organic Sulfur Compounds, Pergamon Press, London 1961, Vol. *I*, 299. On the desulfurization of episulfides with thiophilic phosphorus compounds, see *N. P. Neureiter* and *F. G. Bordwell*, J. Amer. chem. Soc. *81*, 578 (1959); *D. D. Denney* and *M. J. Boskin*, *ibid. 82*, 4736 (1960); *M. Sander*, Chem. Reviews *66*, 326 (1966). On the application of the sulfide-contraction method to the preparation of metal-free corrins see [5].

Reaction with benzoyl peroxide has proved to be the simplest method for oxidative coupling of thiolactams and enamides. The identified intermediate in the coupling reaction is the readily formed bis-imidoyl-disulfide [13] which undergoes an acid-catalyzed electrophilic substitution at the methylidene carbon of the enamide; thereby the liberated equivalent of thiolactam is reconsumed by further oxidation. In a variation of this procedure, the isolated disulfide can be coupled with the potassium salt of the enamide [14].

The sulfide-contraction procedure and the iminoester-enamine condensation are preparatively complementary methods which allow the construction of the corrin chromophore from cyclic precursors in either their enamide or enamine form. The experimental realization of this concept is exemplified by the synthesis of seco-corrinoid complexes *(6)* starting from the simple monocyclic precursors *(4)* and *(5)*; The following Scheme [16] surveys the results of this synthesis together with those so far obtained on the cycloisomerization problem (*i.e. (6)→(7)*).

[14] A modification of the sulfide-contraction method, which can be applied to the preparation of vinylogous amides (and vinylogous amidines) has been developed independently at Harvard University [2a] and the ETH Zürich [1e, 2b, 15]. Thus, secondary thiolactams can quite generally be alkylated on sulfur by α-bromoketones or α-bromocarboxylic esters; the alkylation products undergo a base-induced desulfurization in the presence of a thiophilic phosphorus compound with concomitant contraction to a C-acyl-enamine. (Sulfide-contraction method *via* alkylative coupling.) An analogous observation had previously been made by *E. Knott*, (J. chem. Soc. (London) *1955*, 916).

[15] *P. Dubs*, Dissertation, ETH Zürich, 1969.

[16] The Scheme lists the spectral data of the compounds in the following order: λ_{max} values of the UV.-spectrum (log ε – values in brackets; sh = shoulder), selected bands from the IR.-spectrum (s = strong, m = medium, w = weak intensity), the signals of the proton resonance spectrum in δ-values referred to δ (tetramethylsilane) = 0 ppm, and finally, selected peaks of the mass spectrum (% intensity in brackets). The yields apply to crystalline, spectroscopically pure material. Correct analytical data have been obtained for all compounds formulated in the scheme. RT = Room temperature.

Coupling of two molecules of the monocyclic enamide *(4)* by the sulfide-contraction process requires protection of the highly nucleophilic carbon-carbon double bond of the potential thioamide partner. This protection is best provided by the cyanide group which can easily be introduced in alkaline medium [22] and which survives the conditions of the subsequent reactions; eventually it can be cleanly expelled from vinylogous imidines by strong base. In contrast to the enamide *(4)* itself, the cyanolactam *(10)* can be converted without difficulty to the corresponding thiolactam *(11)* by the classical P_2S_5 method [23].

Under the conditions of the oxidative coupling, the enamide *(4)* is practically inert towards benzoyl peroxide; thus the oxidative dimerization of the thiolactam *(11)* to the disulfide *(11a)* and its coupling with the enamide *(4)* to form the mixed sulfide *(12)* can be combined in a single procedure. However, the disulfide *(11a)* can also be isolated in high yield as a labile, yet crystalline compound from reaction of the thiolactam *(11)* with half a mole of benzoylperoxide in the absence of the enamide *(4)* (see appendix to Scheme 2) [24].

The constitutional type *(12)* [25] of the coupling products obtained in this way has been verified by analytical and spectroscopic data on crystalline samples in a number of cases including the present one. Although it is usually possible to isolate these sensitive compounds, it is preparatively preferable to desulfurize the crude coupling products directly after removal of benzoic acid by means of an organic polymer base or solid potassium carbonate. Simple heating of compound *(12)* with triphenylphosphine produces the

[22] This enamide-protection method was first used in another connection by *R. B. Woodward* and *A. Wick* (unpublished). The addition of CN^- in alkaline medium doubtless occurs not to the enamide (4) directly, but rather to the N-acyl-ketimine isomer; see the addition of nitromethane to (4) in basic medium [4d].

[23] *W. Walter* and *K. D. Bode*, Angew. Chem. *78*, 517 (1966); Angew. Chem. internat. Edit. *5*, 447 (1966).

[24] A detailed description of reaction sequences of type *(11)*→*(12)*→*(13)* can be found in *P. Löliger*, Dissertation, ETH Zürich, 1968, p. 76–104.

[25] The configuration at the (–S–C=C) double bond is arbitrarily formulated.

vinylogous amidine *(13)* in high yield, together with triphenylphosphinesulfide. Treatment of the amidine *(13)* with potassium *tert*-butoxide (CN^--elimination from the presumably doubly deprotonated derivative) leads to the familiar bicyclic lactam *(14)*, previously prepared in other ways [4, 5, 26]. This lactam is the product of a formal carbonyl-methylidene self-condensation of the monocyclic enamide *(4)*, a process which points in a most direct way towards the structure of the corrin chromophore. The sulfide-contraction method is one which experimentally simulates such a transformation.

The repetition of this process adds another vinylogous amidine unit to the bicyclic lactam *(14)* to form the tricyclic analog *(16)*. In this more complicated case, the base-induced version of the oxidative coupling had to be used [NH-deprotonation of the lactam *(14)* and reaction with the isolated disulfide *(11a)*]. The crystalline tricyclic sulfide *(15)* [25] can be desulfurized in the desired way by heating with triphenylphosphine alone; however, the preparatively important observation has been made that boron trifluoride drastically catalyzes the sulfide-contraction in this case. This catalytic effect is mechanistically ambiguous; the working hypothesis was that coordinative bridging of the flanking nitrogen atoms would result in a steric acceleration of contraction.

Experiments towards the addition of the fourth ring *via* an enamine-iminoester condensation led to an instructive experience. In contrast to the bicyclic analog [4], the direct *O*-alkylation of the tricyclic lactam *(16)* with triethyloxonium tetrafluoroborate proved to be preparatively useless, because presumably indiscriminate *O*- and *N*-alkylation occurred. This difficulty is overcome in the corresponding silver complex *(17)*, in which the sp^2-electron pairs of at least two of the three nitrogen atoms are blocked towards alkylation by digonal coordination with the silver ion. Alkylation of the silver complex and subsequent reaction with the ring component *(5)* [27] in its free enamine form produce the tetracyclic condensation product which is conveniently isolated from the reaction mixture in the form of its magnificently crystalline diamagnetic nickel(II) complex *(18a)*. Cyanide ions remove the nickel(II) with great ease, thus allowing the preparation of complexes of other metal ions, *e.g.* of the crystalline palladium(II) complex *(18b)*. The cyanide protecting-group is removed by deprotonation with potassium *tert.*-butoxide to yield the seco-corrinoid palladium(II) complex *(19)*. The constitution of this diamagnetic complex is convincingly verified by analytical and spectroscopic data, particularly by its transparently interpretable proton resonance spectrum. The same is true for the spectroscopically similar and again diamagnetic nickel(II) complex which can be prepared analogously from *(18a)*.

Ultraviolet light from a mercury high pressure lamp, or simply sunlight, transform oxygen-free solutions of the palladium(II) complex *(19)* in pyrex vessels at room temperature into the (±)-palladium(II)-15-cyano-1,2,2,7,7,12,12-heptamethyl-*trans*-corrin complex *(20)* without detectable by-products. The constitution and configuration of the crystalline cyclization product are beyond doubt: the UV-, IR-, NMR- and mass-spectra are identical with those of a complex which was prepared for the purpose of comparison by the classical synthetic route *(3a)*→*(3b)*→*(20)*. The trans-configuration of the A/D ring junction is likewise beyond doubt, since (±)-dicyano-cobalt(III)-15-cyano-1,2,2,7,7,12,12-heptamethyl-*trans*-corrin, synthesized previously from the same intermediate *(3a)* [4d], has recently been characterized by an X-ray structure determination carried out by *P. Galen-Lenhert* [28].

Under reaction conditions which almost quantitatively convert the palladium(II) complex *(19)* into the *trans*-corrin complex *(20)*, no reaction of the corresponding nickel(II) complex could be detected spectroscopically. The same holds for the irradiation of the nickel complex at higher temperature (*e.g.* in triglyme at 150 °C). In the first instance, X-ray structural analysis will have to provide information as to whether or not it is justified to correlate this drastic reactivity difference with a corresponding difference in the geometry of the two seco-corrinoid complexes. It is well known that the palladium(II) ion has a stronger tendency towards a planar coordination than the nickel(II) ion [29]. Finally, no UV-spectroscopic indication for the occurence of a thermally-induced cycloisomerization *(6)*→*(7)*, of either the palladium complex *(19)* or the related nickel complex, has been obtained so far.

The fact of the cycloisomerization *(19)*→*(20)* (surprising as it is, after all) does lend substance to the reaction mechanism *(6a)*→*(6b)*→*(7)* envisaged in the planning stage of the work, but, of course, it does not confirm it. In particular, the light-induction and the observed nickel-palladium reactivity difference pose a series of questions which are not answered yet. The experimental study of these and other questions is proceeding.

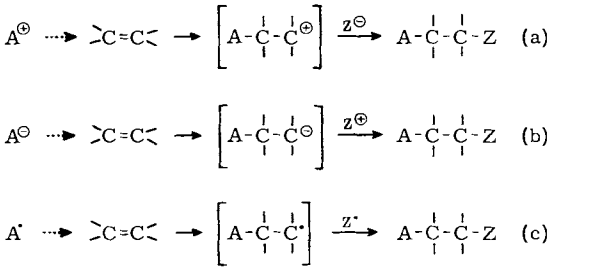
Conjugated Additions in Hydrogen Fluoride

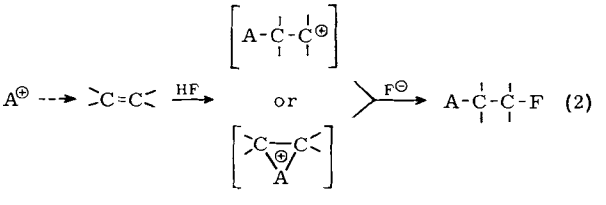
By L. S. German and I. L. Knunyantz [*]



Fluorine and another substituent can be added in a single step to compounds having CC double bonds in anhydrous hydrogen fluoride. It is possible in this way to obtain e.g. α-fluorinated β-halogeno, β-alkyl, β-nitro, and β-amino compounds, and also (in some cases by secondary reactions) fluorinated ethers, alcohols, esters, and carboxylic acids, β-fluoro alcohols can be obtained by conjugated "hypofluorination" in the presence of oxenium ions.

1. Introduction

Fluorinated organic compounds containing functional groups can be obtained by several methods. For example, the desired number of fluorine atoms may be introduced into a (simple) organic molecule, followed by a functional group, or a compound that already contains a functional group may be fluorinated. Among the methods for the simultaneous introduction of fluorine and a functional group, conjugated addition to olefins with the aid of fluoride ions occupies a special place. "Conjugated" additions are additions in which two substituents that were not connected to each other in the starting compounds are added to the double bond [eq. (1)].



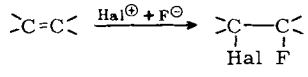
(1)

(a) (b) (c)

These reactions may proceed by (a) electrophilic, (b) nucleophilic, or (c) free radical mechanisms. In reactions of the ionic type, the attacking species A need not carry a full charge; AB could be a polar molecule containing sufficiently electrophilic [case (a)] or nucleophilic centers [case (b)].

(2)

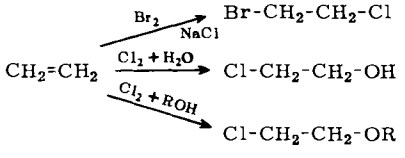
[*] Dr. L. S. German and I. L. Knunyantz
Institute of Elementoorganic Compounds of the Academy of Sciences of the USSR, Moscow (USSR), Vavilof Street 28



The present article will deal with electrophilic conjugated additions in which the intermediate cation is stabilized by fluoride ions from hydrogen fluoride [case (a) with MZ = HF, eq. (2)].

In this process the hydrogen fluoride also acts as an electrophilic catalyst. The acidity of the medium can, if desired, be increased by addition of SbF_5 or BF_3, or decreased by addition of metal fluorides, ethers, *etc.*

The ease with which the acidity of the solvent (and hence the electrophilicity of the process) can be altered, the high concentration of fluoride ions per unit volume, and the ready availability of hydrogen fluoride permit the use of the latter as a specific bifunctional medium (catalyst-reagent) in conjugated additions.



2. Synthesis of Organofluorine Compounds

2.1. Halogenation

(3)

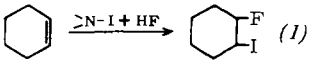
Conjugated halogenation is a classic example of a conjugated addition [1]. The method has been used for the preparation of halogeno ethers, vicinal dihalogenoalkanes with different halogen atoms, *etc.*

(4)

The first attempts to use fluoride ions in conjugated halogenations were unsuccessful. Thus the reaction of elementary bromine with ethylene in hydrofluoric acid led only to 1,2-dibromoethane [2]. The reaction of chlorine with ethylene in saturated $NaHF_2$ solution, which leads to 1-chloro-2-fluoroethane, was described

[1] *E. Biilmann*, Recueil Trav. chim. Pays-Bas *36*, 313 (1916); *J. Conant* and *E. Jackson*, J. Amer. chem. Soc. *46*, 1727 (1924); *A. Francis*, *ibid.* *47*, 2340 (1925); *P. Bartlett* and *D. Tarbell*, *ibid.* *58*, 466 (1936).

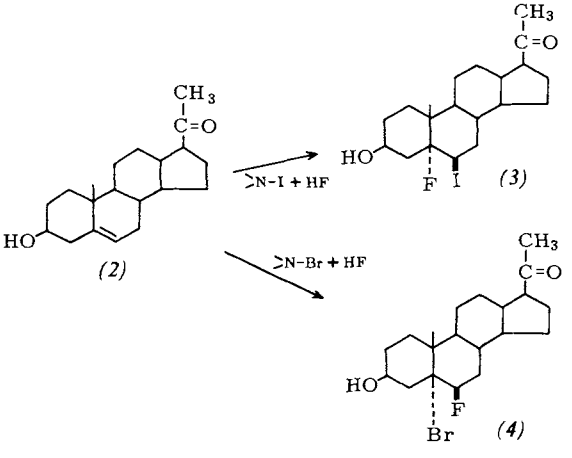
[2] *A. I. Titov* and *F. L. Maklyaev*, Ž. obšč. Chim. *24*, 1631 (1954).



in 1954[3]. Other applications of the method and its reproducibility were not, however, reported.

The conjugated addition of bromine and fluorine to double bonds of steroids was achieved independently by two groups of investigators in 1959, by reaction of the steroid with *N*-bromosuccinimide and HF in CH_2Cl_2/tetrahydrofuran[4,5].

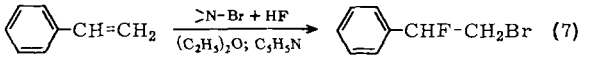
$$\geq C{=}C\leq \xrightarrow{\geq N\text{-}Br + HF} \underset{Br\ F}{\geq C{-}C\leq} \text{ - trans} \qquad (5)$$



This method has become very widely used for the synthesis of steroids containing fluorine, particularly 6-fluoro steroids having a hormone action. The favor in which this reaction is held is due to its high selectivity and its stereospecificity, giving only *trans* addition products (for further examples see[6–10]).

The addition of chlorine and fluorine to double bonds of steroids has been effected in a number of solvents with *N*-chlorosuccinimide/HF[8,9,11]. Vicinal fluoroiodohydrocarbons can be readily obtained by treatment of olefins with *N*-iodosuccinimide/HF in tetrahydrofuran; for example, *(1)* is obtained in 73% yield[11].

(1)



A number of anomalies have been observed in the conjugated iodination of steroids containing double bonds. Thus the reaction of *N*-iodosuccinimide and HF with Δ^5-steroids such as *(2)* yields 5α-fluoro-6β-iodo compounds such as *(3)*, whereas bromine and fluorine add to *(4)* in the reverse sense[12].

The conjugated addition of bromine and fluorine to 1-alkenes (molar quantities of *N*-bromosuccinimide, excess of HF, diethyl ether as the solvent) gives 1-bromo-2-fluoroalkanes in 70–80% yield, together with insignificant amounts of 2-bromo-1-fluoroalkanes[13]. Reaction with the solvent yields brominated ethers $RCH(OC_2H_5)CH_2Br$ as by-products. Branched olefins, such as 2-ethyl-2-butene, do not react so readily.

$$R\text{-}CH{=}CH_2 \xrightarrow[(C_2H_5)_2O]{\geq N\text{-}Br + HF} \begin{matrix} R\text{-}CHF\text{-}CH_2Br \\ + \ R\text{-}CHBr\text{-}CH_2F \end{matrix} \qquad (6)$$

The conjugated halogenation of styrene under the usual conditions yields an appreciable quantity of tarry products, but this quantity can be greatly reduced by addition of pyridine.

(7)

As is usual in electrophilic additions to allyl halides, both possible orientations are found in the conjugated bromination of allyl bromide.

$$CH_2{=}CH\text{-}CH_2Br \xrightarrow{\geq NBr + HF} \begin{matrix} CH_2Br\text{-}CHF\text{-}CH_2Br & 22\% \\ CH_2Br\text{-}CHBr\text{-}CH_2F & 32\% \end{matrix} \qquad (8)$$

The esters of some α,β-unsaturated acids[14,15], as expected, give exclusively the esters of the α-bromo-β-fluoro carboxylic acids on bromination.

$$\begin{matrix} R\text{-}CH{=}CH\text{-}COOCH_3 \\ \downarrow \geq N\text{-}Br + HF \\ R\text{-}CHF\text{-}CHBr\text{-}COOCH_3 \\ R = H,\ C_6H_5 \end{matrix} \qquad (9)$$

Diethyl maleate and diethyl fumarate react similarly[14]. A new synthesis of methyl α-fluoroacrylate *(5)*[14,15] was achieved by conjugated addition of "BrF" to the CC double bonds of allyl trichloroacetate.

Apart from *N*-bromosuccinimide and *N*-bromoacetamide, 1,3-dibromo-5,5-dimethylhydantoin and 1-bromo-3,5,5-trimethylhydantoin[15] have also been successfully used as brominating agents in conjugated additions. 1,3-Dibromo-5,5-dimethylhydantoin has the advantage that it is readily soluble in ether/HF.

The conjugated chlorination of some olefins and halogenoolefins in anhydrous HF with chlorine or

(5)

hexachloromelamine was investigated in 1966 [16]. Thus when chlorine and ethylene are passed simultaneously into an excess of anhydrous hydrogen fluoride at −20 to −30 °C, some 1-chloro-2-fluoroethane is obtained by conjugated "chlorofluorination", together with 1,2-dichloroethane formed by addition of chlorine. 1,1-Dichloroethylene reacts similarly.

$$\begin{aligned} CH_2{=}CH_2 &\xrightarrow{Cl_2 + HF} CH_2Cl{-}CH_2F \quad 17\% \\ &\quad + \\ &\quad CH_2Cl{-}CH_2Cl \quad 75\% \\ CH_2{=}CCl_2 &\xrightarrow{Cl_2 + HF} CH_2Cl{-}CCl_2F \quad 21\% \\ &\quad + \\ &\quad CH_2Cl{-}CCl_3 \end{aligned} \qquad (10)$$

The formation of two chlorination products can probably be explained by the fact that ionization of the chlorine molecule ($Cl_2 \rightarrow Cl^+ + Cl^-$) is negligible in anhydrous HF, and the unionized chlorine molecule adds as a whole to the double bond. The yield of chlorofluoroalkane should therefore be increased by an increase in the Cl^+ concentration; it did in fact increase slightly when HF containing urea was used. The intermediate *N*-chlorination products of urea might transfer chlorine in this case.

Chlorofluoroalkanes can be obtained in 60–65% yield by the addition of an olefin to a mixture of hexachloromelamine and HF at or slightly above atmospheric pressure [16]. Examples of suitable olefins are ethylene, propene, 1,1-dichloroethylene, and 1,1-difluoroethylene, as well as methyl acrylate. The chlorofluorination of cyclohexene proceeds readily in HF/hexachloromelamine/diethyl ether.

The addition to unsymmetric olefins is oriented strictly in accordance with the polarity of the double bond, as is to be expected of an ionic process.

$$\begin{aligned} CH_3{-}CH{=}CH_2 \\ CF_2{=}CH_2 \\ CH_2{=}CH{-}COOCH_3 \end{aligned} \xrightarrow{>NCl + HF} \begin{aligned} CH_3{-}CHF{-}CH_2Cl \\ CF_3{-}CH_2Cl \\ CH_2F{-}CHCl{-}COOCH_3 \end{aligned} \qquad (11)$$

The conjugated halogenation of olefins in the presence of HF probably proceeds in the same way as other conjugated additions. The first step is the attack of the Cl^+, Br^+, or I^+ ion on the π bond of the olefin to form a three-membered 'onium complex with the halogen. The second step is the nucleophilic attack of the fluoride ion on this complex, with formation of the *trans* adduct as usual.

$$>C{=}C< \xrightarrow{Hal^\oplus} >C(\overset{\oplus}{Hal})-C< \xrightarrow{F^\ominus} >C(Hal)-C(F)< \qquad (12)$$

Hal = Cl, Br, I

The positive ion formed from the olefin and the halogen cation is capable of an electrophilic attack on the aromatic nucleus [16]. Thus the reaction of hexachloromelamine with a mixture of ethylene and benzene in the presence of HF yields 8% of β-chloroethylbenzene, together with 1-chloro-2-fluoroethane and mono- and dichlorobenzenes. The possibility that β-chloroethylbenzene is formed in a secondary reaction, such as the alkylation of benzene by initially formed 1-chloro-2-fluoroethane, has been ruled out by special experiments, which showed that benzene is not alkylated by either 1-chloro-2-fluoroethane or 1,2-dichloroethane under the conditions of the reaction.

The competing electrophilic attack of Cl^+ on the aromatic nucleus could be responsible for the low yield of β-chloroethylbenzene. At lower olefin concentrations and with higher π-electron densities on the aromatic molecule than on the olefin, the reaction generally yields halogenobenzenes.

2.2. Nitration

$$>C{=}C< \xrightarrow{NO_2^\oplus + F^\ominus} >C(NO_2)-C(F)<$$

The first example of a conjugated nitration of olefins was the reaction of a 10% solution of HNO_3 in HF with 1,1-dichloroethylene at −10 °C. Other olefins also react under these conditions [17].

$$\begin{aligned} CH_2{=}CCl_2 \\ CHCl{=}CCl_2 \\ CH_2{=}CHCl \\ CF_2{=}CF_2 \\ CH_3{-}CH{=}CH_2 \end{aligned} \xrightarrow{HNO_3 + HF} \begin{aligned} NO_2{-}CH_2{-}CCl_2F \\ NO_2{-}CHCl{-}CCl_2F \\ NO_2{-}CH_2{-}CHClF \\ NO_2{-}CF_2{-}CF_3 \\ NO_2CH_2{-}CHF{-}CH_3 \end{aligned} \qquad (13)$$

It was later found that the reaction rate depends only slightly on the excess of HF, but is strongly dependent on the nature of the double bond in the olefins [18–21]. Thus the nitrofluorination of 1,1-dichloroethylene and of 1,1-difluoroethylene is sufficiently fast even at −60 °C, whereas the reaction of trifluoroethylene under these conditions is slower by a factor of six. Fluoronitroalkanes are formed only slowly from tetrafluoroethylene and from chlorotrifluoroethylene at 10–20 °C, and increased pressures and temperatures are necessary for the successful nitrofluorination of hexafluoropropene. The relative rates and the reaction order confirm the ionic and electrophilic nature of the process.

If the double bond in the olefin is not sufficiently polar, nitrofluorination yields two isomeric fluoronitro-

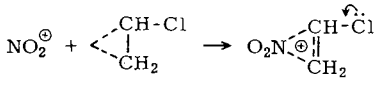
alkanes. Examples are the reactions of allyl chloride and chlorotrifluoroethylene [18].

$$CH_2{=}CH{-}CH_2Cl \xrightarrow{HNO_3+HF} \begin{matrix} NO_2{-}CH_2{-}CHF{-}CH_2Cl \\ + \\ CH_2F{-}CH(NO_2){-}CH_2Cl \end{matrix} \quad (14)$$

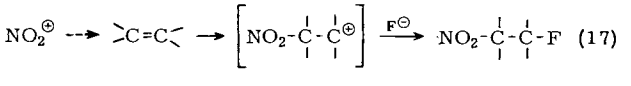
$$CF_2{=}CFCl \xrightarrow{HNO_3+HF} \begin{matrix} CF_2Cl{-}CF_2NO_2 \\ + \\ CF_3{-}CFCl{-}NO_2 \end{matrix}$$

Many organofluorine compounds can be prepared from the resulting fluoronitroalkanes [21–26] [for examples see eq. (15)].



(15)

The nitrofluorination of ethylene followed by acid hydrolysis of the resulting β-fluoronitroethane to form monofluoroacetic acid could be of industrial interest [20, 21].



Nitrofluorination of methyl acrylate gives methyl 3-fluoro-2-nitropropionate, which can be converted into methyl 3-hydroxy-2-nitropropionate. Reduction of this last compound followed by hydrolysis yields DL-serine [26].

The nitrofluorination, as illustrated here for the case of chloroethylene, probably proceeds by formation of a three-membered transition complex and subsequent ring opening by fluoride ions [17]. An alternative is suggested in eq. (17).

(16)

$$\xrightarrow{F^{\ominus}} O_2N{-}CH_2{-}CHClF$$

(17)

It would probably be possible to decide between these two possibilities by nitrofluorination of *cis-trans* isomeric olefins. If the reaction proceeds *via* a transition complex in accordance with eq. (16), it should lead only to *trans* addition, whereas eq. (17) does not permit stereospecific addition.

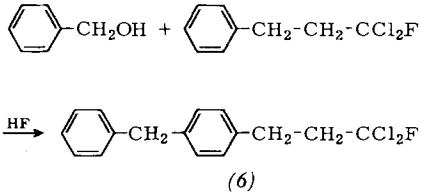
2.3. Alkylation

The HF-catalyzed alkylation of olefins has been extensively studied in connection with the industrial production of paraffins from higher olefins. Higher alkyl fluorides were formed as undesirable by-products. Some of the reactions described could be interpreted as typical conjugated "fluoroalkylations".

Thus 1-fluoro-3,3-dimethylbutane was obtained in 26% yield, together with a large quantity of polymeric products, from isobutylene and ethylene in HF [27]. 2-Methyl-1-butene similarly gives 1-fluoro-3,3-dimethylpentane.

tert-Butyl and *tert*-amyl alcohols have also been successfully used in the conjugated fluoroalkylation of ethylene [28].

$$CH_3{-}\underset{\underset{R}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}OH + CH_2{=}CH_2 \xrightarrow{HF} CH_3{-}\underset{\underset{R}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}CH_2{-}CH_2F \quad (18)$$



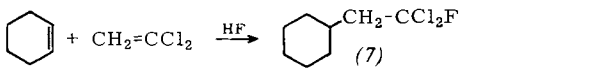
$$R = CH_3,\ C_2H_5$$

Alcohols having labile hydroxyl groups react under mild conditions with 1,1-dichloroethylene in HF to form halogeno hydrocarbons containing CCl_2F groups [29].

$$ROH + CH_2{=}CCl_2 \xrightarrow{HF} R{-}CH_2{-}CCl_2F \quad (19)$$

R = *tert*-butyl, *tert*-amyl, benzyl, α-phenethyl

Benzyl alcohol gives *p*-(3,3-dichloro-3-fluoropropyl)-diphenylmethane *(6)* as a by-product, formed by electrophilic benzylation of the initially formed dichlorofluoropropylbenzene.



(6)

Cyclohexene reacts with 1,1-dichloroethylene to form (2,2-dichloro-2-fluoroethyl)cyclohexane *(7)*.

[29] *L. S. German* and *I. L. Knunyantz,* Izvest. Akad. Nauk SSSR, Ser. chim. *1967*, 675.

(7)

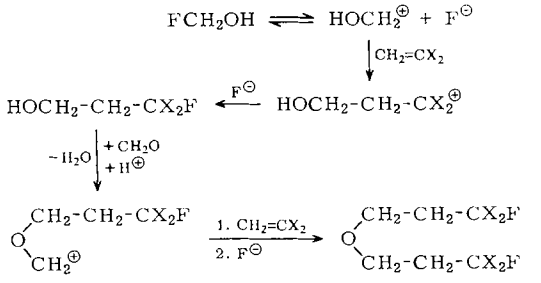
The conjugated fluoroalkylation of olefins in the presence of anhydrous HF can generally be described by a carbonium ion mechanism. However, the course of the reaction is influenced by complex formation and solvation, which are characteristic of hydrogen fluoride solutions; in the alkylation of some aromatic compounds in the presence of HF, no free carbonium ions could be detected. Thus the reaction of benzene with optically active *sec*-butanol in HF yields *sec*-butylbenzene, which is also active[30]. Kinetic studies on the alkylation of toluene with *tert*-butyl chloride in HF were also incompatible with the intermediate formation of *tert*-butyl cations[31]. The carbonium ion concept can, however, be successfully applied in most cases, with the reservation that the carbonium ion need not exist as a kinetically independent species.

2.4. Hydroxymethylation and Related Processes

The electrophilic α-hydroxyalkylation of olefins (Prins reaction) is often used for the synthesis of compounds such as 1,3-glycols, 1,3-dioxolanes, and halogeno carboxylic acids[32]. The Prins reaction in HF offers a convenient route to organofluorine compounds containing oxygen. The reaction of tetrafluoroethylene with formaldehyde in anhydrous hydrogen fluoride[33]

$$CF_2=CF_2 \xrightarrow[50\,^\circ C]{(CH_2O)_x + HF} CF_3-CF_2-CH_2OH + CF_3-CF_2-CH_2-O-CH_2F \qquad (19a)$$

yields pentafluoropropanol and the corresponding fluoromethyl ether, as well as a number of by-products[34]. When 80% hydrofluoric acid or a mixture of HF with H_2SO_4 is used, only pentafluoropropanol is obtained. Hexafluoropropene reacts similarly[35].



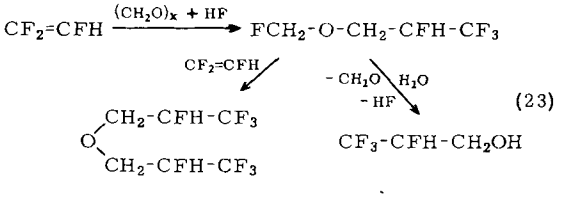
$$CF_3-CF=CF_2 \xrightarrow{(CH_2O)_x + HF} (CF_3)_2CF-CH_2OH \qquad (20)$$

1,1-Difluoroethylene, 1,1-dichloroethylene, and 1-chloroethylene react readily with a 15% solution of paraformaldehyde in HF to give symmetrical fluoro ethers[36,37] (a similar process was described in[34]).

$$2\,CH_2=CXX^1 \xrightarrow{(CH_2O)_x + HF} (CFXX^1-CH_2-CH_2)_2O \qquad (21)$$

(a), X=X¹=Cl; *(b)*, X=X¹=F; *(c)*, X=H, X¹=Cl

According to[34], the reaction of HF with paraformaldehyde yields fluoromethanol and symmetrical difluorodimethyl ether. Hydrogen fluoride, as a strong acid, facilitates dissociation of the fluoromethanol into a hydroxymethyl cation, which carries out an electrophilic attack on the double bond of the olefin[*], and a fluoride ion.



Whereas fluoromethyl pentafluoropropyl ether is formed as the principal product according to eq. (19), a second olefin molecule is inserted into the C–F bond of the fluoromethyl group in the case of halogeno olefins containing hydrogen.

This abnormal behavior can probably be explained by the difference in the ease of dissociation of the C–F bond in fluoromethyl ethers of the type $CX_3-CH_2-CH_2-O-CH_2F$ (X = halogen) and in perfluoro alcohols with unfluorinated CH_2OH groups. For example the pentafluoroethyl group in $C_2F_5-CH_2-O-CH_2F$ reduces the basicity of the ether oxygen, so that the dissociation at the C–F bond is also reduced[**]. If the polyhalogenoalkyl group is situated farther away from the oxygen atom, its inductive effect is much weaker and the fluoromethyl group can readily dissociate at the C–F bond.

$$CF_3-CF_2-CH_2-O-CH_2F \not\longrightarrow CF_3-CF_2-CH_2-O-CH_2^+ + F^- \qquad (22)$$

$$CF_3-CH_2-CH_2-O-CH_2F \longrightarrow CH_3-CH_2-CH_2-O-CH_2^+ + F^-$$

It should be mentioned that the reaction with trifluoroethylene yields 2,3,3,3-tetrafluoropropanol as well as the symmetrical ether[37]. The alcohol is probably formed by hydrolysis of the intermediate fuoromethyl ether.

After condensation of 1,1-dichloroethylene with CH_2O in HF, the ester *(8)* and the ether *(9)* were isolated. The formation of these compounds can be described by eq. (24).

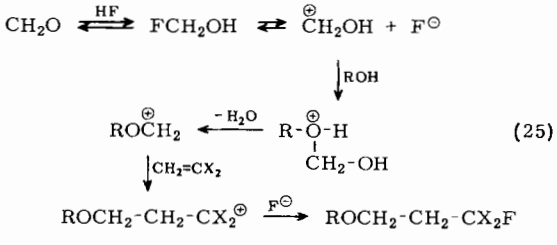
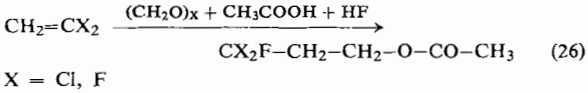
[*] Bis(fluoromethyl) ether can also dissociate at the C–F bond, but this does not appreciably influence the condensation scheme.

[**] The condensation of $C_2F_5-CH_2-O-CH_2F$ with $CF_2=CF_2$ is possible only at high temperatures and under pressure.



The cation with the charge on the dichloromethyl group can thus not only be stabilized by fluoride ions but can also carry out an electrophilic attack on the carbonyl oxygen in formaldehyde.

A hypothesis on the intermediate formation of fluoro alcohols in the condensation of formaldehyde with halogenoolefins containing hydrogen in HF was later verified [38, 39]. According to this hypothesis this reaction in the presence of aliphatic alcohols yields only unsymmetrical ethers.

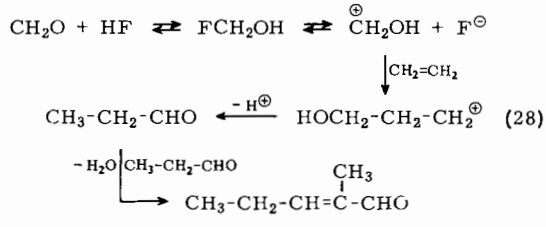


R = CH_3, C_2H_5, C_4H_9, $ClCH_2$–CH_2
X=X¹=F; X=X¹=Cl; X=Cl, X¹=H

We proposed the scheme shown in eq. (25) for this reaction.

Many alcohols (excluding benzyl and allyl alcohols, which readily dissociate in HF) can take part in condensations of olefins with formaldehyde.

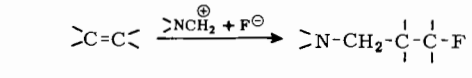
1,1-Dichloroethylene and 1,1-difluorethylene can be acetoxymethylated [38].



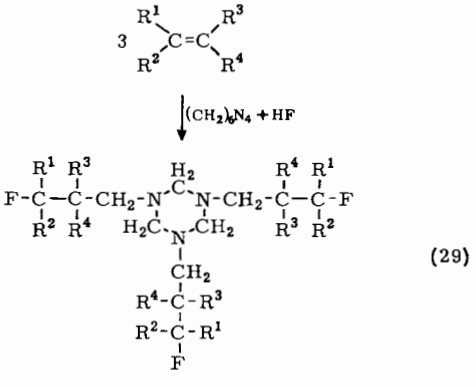
X = Cl, F

These esters are formed in the same manner as the unsymmetrical ethers [see eq. (25)]. Direct reaction of the halogeno olefins with formaldehyde to form a symmetrical ether containing fluorine competes effectively with ester-formation.

The action of propene on paraformaldehyde and HF leads to bis(3-fluorobutyl) ether, together with appreciable quantities of polymeric products [40].



The reaction of ethylene with paraformaldehyde and HF in solution yields about 43% of 2-methyl-2-pentenal [40]. We believe that the reaction proceeds in accordance with eq. (28).



How does the β-hydroxypropyl cation change into (protonated) propionaldehyde? In our opinion a hydride ion migrates from the α to the γ position of the cation. The driving force for the isomerization is the tendency of the system to form a stable oxonium ion.

2.5. Aminomethylation

In conjugated aminomethylation in anhydrous HF with hexamethylenetetramine, chloroolefins and fluoroolefins react under mild conditions to give *sym-*

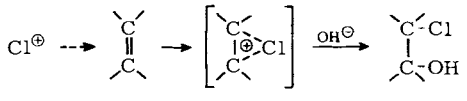
(30)

hexahydrotriazines containing *N*-polyhalogenoalkyl groups [41,42].

The hydrolysis of the *sym*-hexahydrotriazines readily yields the amines; moreover, this reaction also proceeds during the conjugated aminomethylation. We propose the course shown in eq. (30). The indicated cleavage of hexamethylenetetramine in anhydrous HF has actually been established [43].

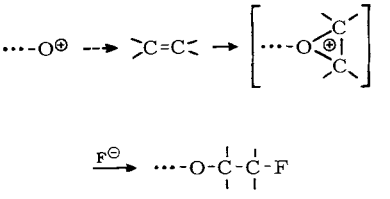
Acetamidomethylation of halogenoolefins in HF solution yields *N*-(polyhalogenopropyl)acetamides [42]. The reaction proceeds *via* protonation at the nitrogen, elimination of water, and addition of the halogenoolefin and the fluoride ion.



(31)

(a), $R^1 = R^2 = Cl$, $R^3 = R^4 = H$
(b), $R^1 = R^2 = F$, $R^3 = R^4 = H$
(c), $R^1 = R^2 = R^3 = F$; $R^4 = H$
(d), $R^1 = R^2 = R^3 = R^4 = F$

2.6. Conjugated Hypofluorination

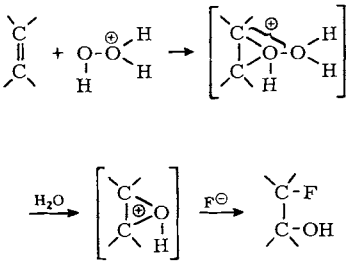


The chlorination and bromination of olefins in alkaline media are widely used methods for the preparation of β-halogeno alcohols. The conjugated hypohalogenation is generally assumed to follow eq. (32).

(32)

Hypofluorination by this scheme is impossible, since the fluorine molecule does not dissociate into the ions ($F_2 \rightarrow F^+ + F^-$) under the usual conditions.

One possibility for ionic hypofluorination could be the reaction of an olefin with an oxenium ion in the presence of a fluoride-ion generator. This reaction was carried out in 1966 with 1,1-dichloroethylene and 1,1-difluoroethylene, which were treated with a solution of CrO_3 in anhydrous HF [44].



(33)

We believe that the initially formed chromyl difluoride carries out an electrophilic attack on the double bond of the olefin.

$$CX_2{=}CH_2 \xrightarrow{1.\ CrO_3 + HF,\ 2.\ H_2O} CX_2F{-}CH_2OH \qquad (34)$$

X = F or Cl

Hydrogen peroxide reacts in the same way as chromyl fluoride with halogenoolefins in HF. It is known that in strongly acidic media, H_2O_2 forms the conjugate acid $H_3O_2^+$, which is an OH^+ donor. The reaction of H_2O_2 and olefins in HF solution can thus be formulated in accordance with eq. (35).

(35)

The reaction of 1,1-dichloroethylene with 85 to 90% H_2O_2 in anhydrous HF gives 2,2-dichloro-2-fluoroethanol in 7% yield [45].

$$CCl_2{=}CH_2 \xrightarrow{H_2O_2 + HF} CCl_2F{-}CH_2OH \qquad (36)$$

The yield can be improved to 25–30% by addition of acetic anhydride. Dichlorofluoroethyl acetate is formed as a by-product.

The reaction should proceed more readily in more strongly acidic solution. The overall yield of dichlorofluoroethanol and its acetate is in fact increased to 42% in the presence of catalysts for electrophilic reactions (*e.g.* BF_3 or SbF_5). Similarly, 2-chloro-2-fluoroethanol
