When combined with surface active agents, propylene glycol was found to be a suitable sorption promotor for water-soluble drugs that are absorbed transfollicularly [30]. The absorption of fluocinolone acetonide was found to be increased by the addition of propylene glycol to the base [31]. Similar experiments with hydrocortisone as the drug gave no positive result; this could, however, be due to the different solubility properties of hydrocortisone and fluocinolone acetonide, or to other factors connected with the formulation [32]. A 1% solution of 5-fluorouracil in propylene glycol is equivalent, in its clinical effectiveness against skin cancer, to a 5% preparation in the form of an ointment [33].

For a given drug in a given form of preparation, the effectiveness of each sorption promotor varies with its concentration. The effect of the sorption promotor propylene glycol at various concentrations was studied with a 0.025% fluocinolone acetonide gel having a polyethylene glycol base. The test was carried out *in vitro* with isopropyl myristate as the receptor phase. The optimum result was obtained at an addition of about 20% [34].

In the investigation of the release of the active principle and the absorption of the antihistamine diphenhydramine hydrochloride from various plastic gel bases on histamine hives, absorption was much better from polyethylene glycol than from O/W emulsion, W/O emulsion, and hydrocarbon bases [11].

The sorption-promoting action of aqueous ethanol has been studied, *inter alia*, for theophylline. An aqueous-alcoholic solution gives the same blood level in 15 minutes as is obtained only after two hours with tablets which disintegrate immediately [35]. The peroral absorption of an aqueous-alcoholic theophylline solution is roughly equivalent to the parenteral absorption after intramuscular injection [36].

One of the most extensively studied penetrants is dimethyl sulfoxide (DMSO). Following a report from the University of Oregon [37] in December 1963 that DMSO can transport a number of well known drugs through the skin and tissues of laboratory animals, investigations were started throughout the world to examine this substance as an active principle and as an adjuvant. Its toxicity on peroral, subcutaneous, and intravenous application is extremely low. Local application leads to irritation of the skin and mucous membrane but this rapidly disappears [38].

DMSO is miscible in all proportions with water, lower alcohols, aldehydes, ketones, ethers, esters, halogenated hydrocarbons, and heterocyclic and aromatic compounds. The higher homologs are mostly readily soluble [39]. Carbohydrates also dissolve readily in DMSO [40]. DMSO is a better solvent for inorganic salts than most organic solvents. In particular, it dissolves chlorides, nitrates, and salts of organic acids. Salts dissolved in DMSO are dissociated [41,42]. In the presence of ethanol, DMSO forms complexes with many organic compounds [49].

On cutaneous application, DMSO passes rapidly through the horny layer of epidermis (stratum corneum) in man and in animals [43–45]. As has been shown by histological analyses, this process does not change the structure of the skin [46]. Further penetration through the skin layers to the vessels is so fast that only a few minutes after cutaneous application of 70 to 90% DMSO solutions, a characteristic "sulfur odor" due to the formation of dimethyl sulfide occurs in the breath. DMSO can carry many drugs with it as it passes through the skin and membrane, and can thus act as a penetration carrier. The drugs are stored in the deeper layers of the stratum corneum, in some cases as deposits that can be detected for several days. Substances having molecular weights of 3000 or more cannot, however, be transported into deeper layers by DMSO. On the other hand, increased oxygen diffusion in ischemic myocardial tissue has been observed with DMSO on application of drugs that improve the oxygen supply [47]. DMSO is thus suitable above all for

the fast transport of low molecular weight substances into deeper skin layers, and hence into surrounding structures or into the blood stream to exercise systemic effects. It is active as a sorption promotor even at low concentrations (about 10%)[48].

The reasons for the increased penetration of membranes by the dissolved drugs is not yet known[49]. It is assumed that the penetration- and permeation-promoting action is due to the fact that DMSO is a weak base and forms complexes with various substances. The affinity of DMSO for water must also be considered as a possible factor in the promotion of penetration. The ability of DMSO to form chelates, for example, could lead to the breakdown of hydration sheaths on the cell membranes, so increasing the permeability of the membrane.

The rate-determining factor for percutaneous penetration is the stratum corneum. This thick, horny, coherent, plastic-like membrane, which consists of about 15 layers of close-packed, hornified, dead cells[50], has an extremely high resistance to the penetration of most substances, including water.

Many investigations have been carried out on the promotion of sorption by DMSO. In the case of salicylic acid it was shown that pretreatment of the skin with DMSO leads to a considerable increase in skin permeability. Aqueous salicylic acid solutions containing 20% of DMSO, on the other hand, gave poorer penetration of salicylic acid than simple aqueous solutions[51] Addition of 15% of DMSO to W/O and O/W bases, however, considerably increased the percutaneous absorption of salicylic acid (cf. Fig. 4).

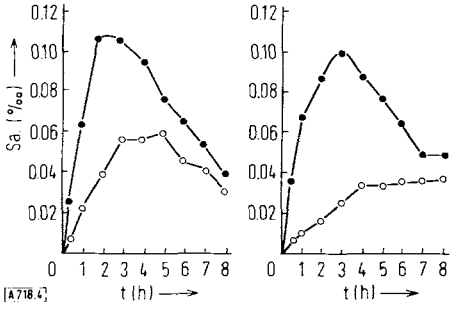

Fig. 4. Influence of DMSO on percutaneous absorption.
Left: 10% salicylic acid in an O/W cream.
Right: 10% salicylic acid in a W/O base.
• = salicylic acid (Sa) absorbed on addition of 15% of DMSO,
o = control [52].

DMSO has no effect on absorption in the application of sodium salicylate in the same bases. Practically no effect was observed on the absorption from polyethylene glycol bases[52]. The penetration of sodium salicylate, sulfadiazine sodium, Evans Blue, and heparin sodium from solutions containing 15% of DMSO, on the other hand, was considerably greater than from aqueous comparison solutions[49].

The absorption of the antiperspirant hexopyrronium bromide from 20% aqueous DMSO solution was 25 times, that of the vasoconstrictor naphazoline hydrochloride from 50% aqueous DMSO solution 50 times, and that of the corticosteroid fluocinolone acetonide from 25% aqueous DMSO solution 5 times as high as the absorption from the reference solutions[53]. These increases refer, not to the quantities per unit time, but to the total quantities that penetrated.

Whereas the penetration of the antibiotic demethylchlortetracycline hydrochloride (Declomycin) from aqueous solution takes more than three hours, penetration occurs in 20 minutes from 90%, 55 minutes from 70%, and 120 minutes from 50% DMSO solutions[54].

Figure 5 shows an interesting comparison of the effects of various solvents on the penetration of the skin by fluocinolone acetonide[25].

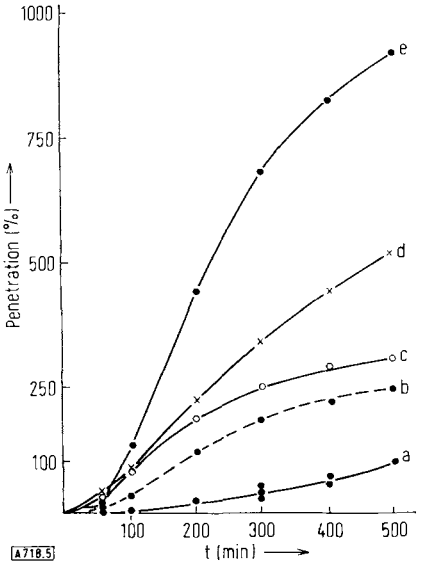

Fig. 5. Comparison of the percutaneous absorption of fluocinolone acetonide from various solvents [25]: a) Ethanol; b) tetrahydrofurfuryl alcohol; c) dimethylacetamide; d) propylene glycol; e) dimethyl sulfoxide.

Other investigations showed that DMSO has a sorption-promoting effect on the following drugs: testosterone propionate[55,61], hydrocortisone[56,57,61], triamcinolone acetonide[56], fluocinolone acetonide[57], cortisone acetate[58], 17β-estradiol[58], antitumorigenic substances such as "Cytoxan"[59] and 5-fluorouracil[60], methylene blue[41], iodine[41], iron pigments[41], hexachlorophene[62], physostigmine[63], phenylbutazone[63], local anesthetics[64], antibiotics[65], and quaternary ammonium compounds[66].

4.2. Fatty Alcohols and Esters of Fatty Acids

Many fatty alcohols and esters of fatty acids are used in dermatology as ointment bases. The most suitable base for any particular application depends on the

chemical and physical properties of the drug, the site of application, the depth to which the drug is to penetrate into the skin, and the condition of the skin.

The purpose of the ointment base is to bring the incorporated drug into the closest possible contact with the surface of the skin and to release it at the point of contact. The transfer of the drug depends on its solubility in the base and its partition coefficient between the base and the receptor phase, as well as on other factors.

As has been mentioned several times, the drug must be lipid-soluble as well as water-soluble. A drug will penetrate into the skin more readily if it is incorporated into lipids that can blend with the skin fats [67]. Attempts to produce greases having an affinity for skin have therefore been in progress for many years, but investigations on the effects of these greases on absorption have so far been relatively unsatisfactory. The improvement in the absorption of drugs with these substances involves gastrointestinal as well as percutaneous absorption. It is known, for example, that the absorption of drugs having low solubilities in water from suspensions in an aqueous vehicle is improved by the emulsification of a digestible oil in the preparation [68]. An example of this behavior is the good absorption of N^1-acetylated sulfisoxazole from an emulsion in which fatty oil acts as a sorption promotor [69]. The peroral absorption of griseofulvin can also be greatly increased by simultaneous administration of fats [70]. Some of the fatty alcohols and fatty acid esters in common use as sorption promotors are listed in Table 2.

Table 2. Fatty alcohols and esters of fatty acids used as sorption promotors.

Trade name	Composition
Cetiol®	Oleyl oleate
Cetiol V®	Decyl oleate
Cetiol A®	Hexyl laurate
Eutanol G®	2-Octyldodecanol
PCI products	Alkyl-branched fatty acid esters having low solidification point
Miglyol®	Mixture of triglycerides of saturated vegetable fatty acids of chain length C_8—C_{12}
Cremogen IP®	Mixture of esters of aliphatic dicarboxylic acids
Other liquid fatty acid esters	Isopropyl myristate
	Isopropyl palmitate
	Diisopropyl adipate

The mode of action of the fatty alcohol and fatty acid ester sorption promotors is not yet known. This action is assumed to be due to the good solvent properties of these substances for various drugs and above all to their miscibility with skin oils. Good spreading is also essential for close contact between the base and the skin [71]. Figure 6 shows the spreading capacity of several lipids and their influence on the permeability of the resulting lipid films to water vapor, *i.e.* on the loss of water through the skin. The sealing action of a lipid decreases with increasing spreadability.

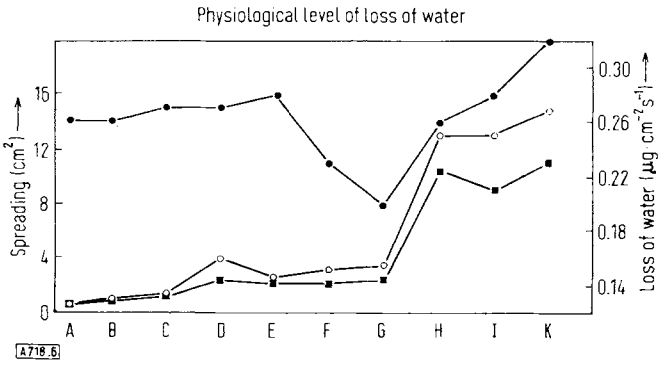

Fig. 6. Spreading capacities (■ : after 10 min, o: after 20 min, left-hand ordinate) of several lipids and their influence on the loss of water through the skin (•, right-hand ordinate). The bases plotted on the abscissa are A = partial ester, 60% C_8—C_{12}, 40% C_{18} = Witten 378 partial ester; B = castor oil, partly crosslinked, C = castor oil; D = arachis oil; E = arachis oil, partly crosslinked; F = triglyceride 60% C_{18-12}, 40% C_{18} = Softisan 378® ointment base; G = paraffin oil; H = partial ester C_8—C_{12} = Witten 812 partial ester; I = triglyceride C_8—C_{12} = Miglyol 812®; K = Pur-Cellin® oil = PCL® liquid.

Among the lipids mentioned in Figure 6, that having the greatest spreadability is Pur-Cellin® oil, which is designed to simulate the uropygial gland oil of the duck, and consists of esters of α-alkyl branched fatty acids. The branched structure of the esterified fatty acid leads to special properties, above all strong dissolving power and good wetting properties [72], as well as particularly good spreadability [73].

In investigations on the absorption of salicylic acid from various ointment bases, the best results were obtained with the triglyceride Softisan 378®, though this action is attributed to the partial fatty acid glycerides present, which act as W/O emulsifiers [74].

The fatty alcohols and fatty acids are not absorbed through the skin, since they only pass into the hornified layers but cannot pass through them. They therefore promote penetration, but not permeation.

Whereas ointment bases have different effects on the absorption of absorbable drugs, they do not in general promote sorption of non-absorbable drugs [75]. It has, however, been reported that the synthetic fats Miglyol 812® and Eitanol G® promoted the sorption of a drug that was practically non-absorbable by itself [75].

4.3. Surface Active Agents

Surface active agents (surfactants) can accelerate and increase the absorption of drugs through the skin and mucous membrane. The reason for the increase in the permeability of the tissue membrane is not yet known. It is assumed to be due to the decrease in the surface tension, the improved wetting of the skin, and the improved distribution of the drugs [76].

The surface active agents reduce the surface tension in aqueous solutions and at high concentrations also in organic solutions, until an optimum is reached at the

[76] *K. Münzel* [2], p. 324.

critical micelle concentration (CMC). Above the CMC, no further decrease in the surface tension occurs. Below the CMC the surfactant molecules are in a disordered state. At the CMC, they form spherical or laminar aggregates (micelles), which consist of about 50 to 150 molecules. On incorporation of an insoluble or sparingly soluble compound into an aqueous solution of an amphiphilic compound, the practically insoluble substance becomes colloidally dispersed ("solubilized") [77]. This process is represented schematically in Fig. 7.

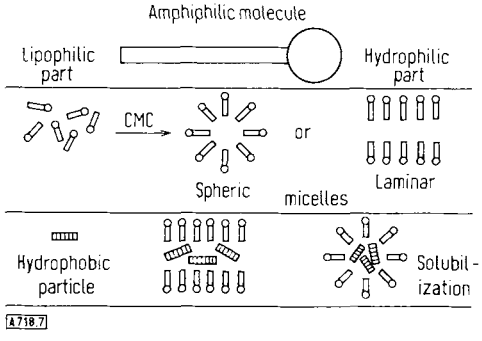

Fig. 7. Mode of action of surfactants as solubilizers [3].

An important property of surfactants is the hydrophile-lipophile balance (HLB), which is found from the saponification value (SV) and the acid value (AV) by means of eq. (3).

$$HLB = 20\ (1-SV/AV) \qquad (3)$$

The properties of the surfactants vary with their HLB values. With HLB values of 1.5–3 they are antifoam agents, 3–7 spreading agents, 3–8 W/O emulsifiers, 7–9 wetting agents, 8–18 O/W emulsifiers, 13–15 detergents, and 15–18 solubilizers.

In many cases, particularly with lipophilic drugs, the sorption-promoting action of the surfactants is undoubtedly due to the improved distribution of the drug in the micelles of the surfactant [78]. The lipid-soluble vitamins A, D, and E, for example, are absorbed much more effectively from sterile surfactant solutions than from oily solutions on parenteral application [79].

The aqueous micelle solutions may be regarded as two-phase colloidal systems, the disperse phase consisting of the colloidal micelles and the continuous phase of water. Any drug present is distributed between the two phases. The degree of partition between the disperse and the continuous phases depends on the partition coefficient K of the drug in the system in question. As free drug is eliminated from the continuous phase by absorption, part of the drug bound in the micelles is released into the continuous phase. The absorption constant in aqueous solution, k, is different from that in surfactant solution, k'. According to *Yamada et al.*, the absorption constants of drugs from surfactant solutions can be calculated as follows [80,81] [eq. (4)]:

$$k' = \frac{f_W}{f_T K + f_W} \times k \qquad (4)$$

where f_W = volume fraction of the water phase = V_W/V; V_W = volume of the water phase; V = total volume of the micelle solution; f_T = volume fraction of the micelle phase = V_T/V; V_T = volume of the surfactant; K = partition coefficient of the drug between water and micelles.

In addition to the decrease in the surface tension and the solubilization the improved wetting is also important to the sorption-promoting action of surfactants. On the one hand the contact area between the drug and the surface of the absorbing organ is increased, while on the other, surfactants improve the wettability of the surfaces of solid particles, and so accelerate dissolution in the aqueous digestive juices on peroral medication. This leads to an increased release of active principle. As an example, Figure 8 shows the influence of a solubilizer on the rate of dissolution of phenacetin [82].

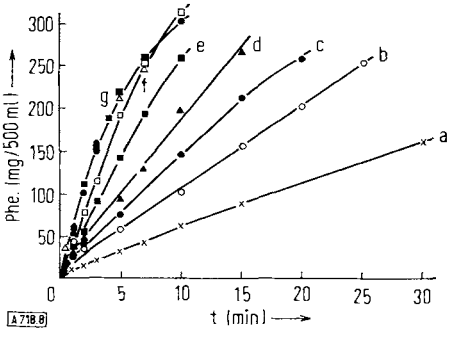

Fig. 8. Influence of the solubilizer Tween 80® on the rate of dissolution of phenacetin having a particle diameter of between 0.21 and 0.3 mm in 0.1 N HCl [82].

Ordinate: Phenacetin (Phe) dissolved. Tween 80 added: a = 0%, b = 0.001%, c = 0.002%, d = 0.005%, e = 0.01%, f = 0.02%, g = 0.05%, 0.1 and 0.2%.

Thus the addition of hydrophilizing agents to tablet preparations [83] leads indirectly to improved absorption since the surfactants used not only lead, as a result of the improved wetting, to faster dissolution and hence to faster release of the drug from the preparation, but can also give better distribution. Furthermore, anionic surfactants probably also influence the cell membranes themselves, with the result that absorption anomalies occur (cf. Section 4.3.2) [79].

It must, however, be mentioned that the three types of surfactants (nonionic, cationic, and anionic) cannot all be considered in the same way as sorption promotors for a given drug. The release of the drug and the absorption may be, not merely unaffected, but actually reduced by a surfactant if the drug reacts with the surfactant to form complexes, *e.g.* of anionic drugs with cationic surfactants or *vice versa*. Incompatibilities of this nature are extremely common [79], so that careful incompatibility studies are always necessary.

However, adverse effects due to interactions between the drug and the surfactant depend not only on the chemical constitutions of the drug and of the surfactant, but also on the concentration of the surfactant. It has been found that surface active agents in general have little or no influence on the effectiveness of drugs below a limiting association con-

centration; from this limiting association concentration up to the CMC they can have a potentiating action, while above the CMC they often reduce the effectiveness of the drug[78].

The dependence of the interaction on the CMC is illustrated in Figure 9 for the case of hexachlorophene and Tween 61® [3]. The incompatibility check in this case was carried out by a microbiological test, as is usual for drugs having an antibacterial action[84]. Addition of Tween 61® up to the CMC had no influence on the size of the inhibition zone in the agar diffusion test with *Staphylococcus aureus* SG 511. Above the CMC there is a steady decrease in activity until the drug becomes completely inactive.

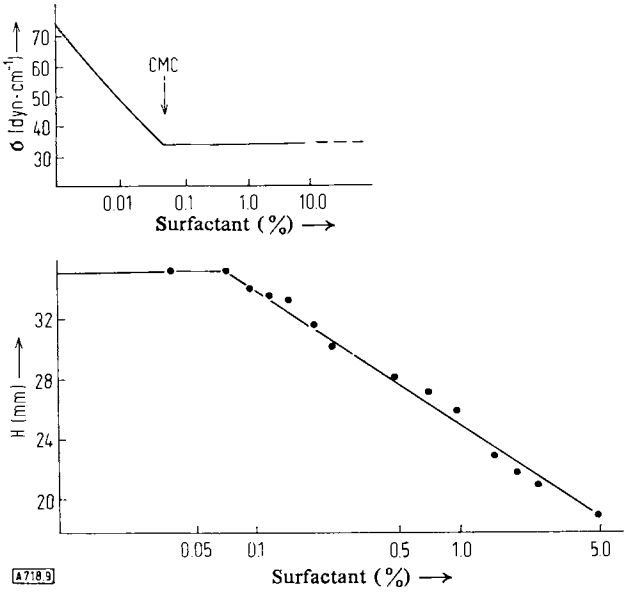

Fig. 9. Influence of Tween 61® on the size of the inhibition zone for hexachlorophene [3].

Top: The CMC of Tween 61® is determined by measurement of the surface tension, and is 0.075%.

Bottom: Addition of Tween 61® in a concentration higher than the CMC leads to a concentration-dependent decrease in activity. Ordinate: Diameter of the inhibition zone (H).

Some surfactants used as sorption promotors are listed in Table 3.

4.3.1. Nonionic Surfactants

Nonionic surfactants include derivatives of sorbitol, sucrose, and polyethylene oxide[85] (see Table 3).

Reports on the influence of nonionic surfactants on absorption are very numerous and often contradictory. The penetration-promoting action of these substances appears in general to be weaker than that of anionic surfactants. The many reported failures to observe sorption promotion and the decreases in absorption are probably mostly due to interactions between the nonionic surfactants and the drugs or to occlusion of the drug in micelles at surfactant concentrations above the CMC. The causes of the penetration-promoting action of nonionic surfactants have been studied in detail by *Levy*[86].

CTAB	Cetyltrimethylammonium bromide
	Benzalkonium chloride
	Benzethonium chloride

[a] Sorbitan is monoanhydrosorbitol ($C_6H_8O(OH)_4$).

A relatively simple method for the study of the effects of surfactants on absorption is the addition of drugs and adjuvants to aquarium water, using goldfish as subjects. This system was used to test the sorption-promoting action of Tween 80® on alcohols and pentobarbital or secobarbital sodium[87]. The quantities of the various alcohols absorbed

[87] *G. Levy, K. E. Miller*, and *R. H. Reuning*, J. pharmac. Sci. *55*, 394 (1966).

did not change appreciably. The absorption of the barbiturate was considerably faster with low concentrations of Tween 80®, but was much slower with higher concentrations. This is probably due on the one hand to a direct inhibiting action of the surfactant on the lipid membrane, and on the other to the formation of a simple but more readily absorbed non-micellar complex between the barbiturate and the Tween 80® [87].

The influence of nonionic surfactants on peroral absorption has been investigated for the case of spironolactone; much higher blood concentrations were found on addition of Tween 80® than when ordinary tablets were used [88,89].

Increased enteral absorption of vitamin B_{12} in rats was obtained with Tween 80® and Tween 85® [90].

Widely differing results have been reported for the use of nonionic surfactants in rectal absorption. Whereas *e.g.* nonionic surfactants in aqueous solution do not improve the rectal absorption of sulfonamides, since the sulfonamides are probably largely occluded in micelles [91], faster absorption was observed with Tween 61® in the investigation of the rectal absorption of salicylic acid from various suppository bases [92,93]. In the investigation of the sorption-promoting action of nonionic surfactants on the absorption of aminophylline and ephedrine from theobroma oil suppositories, it was found that the transfer of drug in the dialysis experiment can be increased by surfactants (having an HLB of 11—14 in the case of aminophylline, and having an HLB of 9 in the case of ephedrine). It is probably impossible to calculate the optimum sorption promotion in advance, and the appropriate nonionic surfactant and its optimum concentration must be determined experimentally for each drug in each base [94]. It has been shown in the case of barbiturates that the rectal absorption is also increased by the addition of nonionic surfactants as penetrant carriers [95].

Numerous reports on percutaneous absorption under the influence of nonionic substances have also been published. Tween 60® considerably improved absorption from a 6% salicylic acid/vaseline ointment on addition in concentrations of from 5 to 10%, and even a 1% addition led to a significant improvement. On the other hand, no appreciable change was observed with sodium salicylate in the same base [96].

It has been found that after treatment for four days with ointment bases consisting of vaseline containing 10% of Span 85®, Tween 85®, or Brij 96®, the phosphorus content of the epidermal phospholipids was increased by up to 90% [97], indicating that the nonionic surfactants influence the membrane structure.

4.3.2. Anionic Surfactants

The anionic surfactants (see Table 3) should be the most effective of the three types as sorption promotors. In addition to the decrease in the surface tension, the improvement of the solubilization, and the increase in wetting, these substances have the further property of being able to influence the cell membrane directly. This leads to absorption anomalies, which are due to complex formation between the sulfonates and sulfates and the calcium and magnesium ions on the intestinal wall.

The view that anionic surfactants are stronger sorption promotors than other surfactants is confirmed by the observation that nickel salts compounded with anionic substances cause eczema, whereas nickel salts combined with nonionic or cationic substances do not. This could be due to an acanthotic effect [modification of the prickle cell layer (stratum germinativum) of the skin] or to denaturation of the epidermal proteins by the anionic surfactants, allowing the nickel salt to penetrate the skin and cause sensitization [98].

Among anionic substances, the laurate ion is reported to have the greatest penetration and the strongest sorption-promoting action [99]. The most important anionic surfactants for pharmaceutical use are sodium lauryl sulfate and sodium dioctyl sulfosuccinate. In an investigation on the enteral absorption of the dye phenol red with anionic, cationic, and nonionic surfactants, only sodium lauryl sulfate and sodium dioctyl sulfosuccinate were found to have a sorption-promoting action [100].

Strophanthin-G can be absorbed both enterally [101] and rectally with sodium lauryl sulfate as a sorption promotor. Strophanthin in a dose of 1 mg/kg, which has no effect on guinea pigs when given rectally, actually exhibits a toxic action on addition of sodium lauryl sulfate [102].

Considerably higher blood concentrations of the following drugs are found on addition of sodium lauryl sulfate to preparations for rectal application: penicillin-G sodium [103,104], streptomycin [104], sodium PAS [105], and chloramphenicol [106]. On addition of sodium lauryl sulfate to Witepsol H 15® suppository base, penicillin-G blood concentrations as high as those observed after intramuscular injection are found in rabbits [107].

On local application of radioactively labeled sodium iodide in hydrophilic ointment USP, the optimum release of the active principle was obtained with the anionic surfactant Sipon ES® (ethoxylated sodium lauryl sulfate) at a concentration of 2%. The release of the drug was retarded when the surfactant concentration was increased [108].

4.3.3. Cationic Surfactants

The cationic surfactants (see Table 3) are mostly quaternary ammonium compounds, which cannot be regarded as inert adjuvants, since they have a more or less pronounced antibacterial action of their own.

The surface of the skin may be regarded as an ion-exchange membrane, which can adsorb ions on its amphoteric protein surface [109]. Under normal conditions the surface of the skin is negatively charged, so that positively charged ions can be readily adsorbed [110, 111]. This is true of quaternary ammonium compounds, which are generally readily adsorbed, but which penetrate into the skin only if it is broken [*i.e.* when the barrier layer (the stratum corneum) is damaged], or if the quaternary ammonium compounds form absorbable complexes with other substances, or if fat solvents are present [112].

Like other surfactants, quaternary ammonium compounds make wetting easier and allow more intimate contact with the surface by lowering the surface tension. Owing to their high pK values, their strong dissociation, even in alkaline media, and their low lipophilicity, they can form unabsorbable complexes with mucin, an acidic polysaccharide of the stomach and intestine [113]. Their gastrointestinal absorption is consequently often uneven and low. The absorption of quaternary ammonium compounds used for medicinal purposes can, however, be increased by the addition of a physiologically inert quaternary ammonium compound as an adjuvant, since these substances facilitate the absorption of the drug by competitive complex formation with mucin [114].

According to *Levine* [115], quaternary ammonium compounds are absorbed, not only by diffusion, but also because they are partly bonded to an endogenous anion and so transported through the intestinal wall as an adsorbable neutral complex.

Kakemi et al. [116] investigated the effect of surface active sorption promotors on the absorption of sulfisoxazole from theobroma oil suppositories in rabbits. The nonionic surfactant Tween 60®, the anionic sodium lauryl sulfate, and the cationic cetyltrimethylammonium bromide (CTAB) all gave increased release of the drug with increasing surfactant concentration *in vitro*. The highest values were obtained with CTAB. *In vivo* experiments showed that higher blood concentrations could be obtained with all three types of surfactants, but optimum values were obtained at only one particular concentration in each case, and further increases in the surfactant concentration led to a decrease in absorption.

4.3.4. Saponins

The possibility of sorption promotion was first recognized when it was observed [117] that the absorption of glucose from the digestive tract is accelerated by saponins. About 30 years ago, saponins were the only sorption promotors used in pharmacy [118]. It was found that the action of saponins (which differ considerably according to their source) improved the absorption of drugs given at the same time. Thus 0.1% of saponin was added to cod-liver oil emulsions [119].

On peroral administration of calcium, the calcium level in the blood could be increased by 41% by addition of saponin [119] Saponins have also been added to analgesic combinations. The use of saponins as sorption promotors has now almost entirely ceased because of their hemolytic action, their local irritant action, and the fact that they can lead to an accumulation of water in the lungs.

The saponins exist in aqueous solution as colloids, and this may explain their generally poor absorbability on peroral application. With the saponin aescin, for example, micelle formation occurs at a concentration of only 10^{-4} moles/l [120]. The basis of the sorption-promoting action of saponins is not yet known. The decrease in the surface tension and the improved wetting of drugs administered at the same time are undoubtedly only part of the story. Investigations on erythrocytes indicated that the membrane of the erythrocytes which is normally permeable practically only to anions, also becomes permeable to cations under the action of saponins. This leads to hemolysis. The antiedemic action of saponins is due to the fact that they mobilize the protein layer in the capillary wall, and so increase the permeability of the capillaries.

4.4. Enzymes

4.4.1. Hyaluronidase

Hyaluronidase is chemically not a uniform enzyme, but an enzyme complex [121]. It hydrolyzes hyaluronic acid, a component of the mucoprotein base substance or of the binding agents in the intercellular spaces of various tissues; this leads to a decrease in the viscosity, and the tissues consequently become more permeable to liquids.

The use of hyaluronidase as a sorption promotor is based on the observation by *Duran-Reynalds* at the Rockefeller Institute, New York, in 1928, that dye solutions injected together with hyaluronidase spread out more rapidly and over a greater distance in the tissue than in the absence of hyaluronidase. Because of this effect, the hyaluronidase is also known as a spreading factor.

Hyaluronidase is currently extracted industrially from the testes of various animals. It is used as a sorption promotor, as an additive to decrease discomfort due

[121] Medizin. Mitt. Schering *12*, 1 (1951).

to subcutaneous and intramuscular injections, for the absorption of excess fluids and blood in tissues, and to increase the effectiveness of local anesthetics [122].

Numerous articles on sorption promotion by hyaluronidase in ointment bases have been published. Increased release of the antibiotics penicillin-G, dihydrostreptomycin, tetracycline, chlortetracycline, hydroxytetracycline, and chloramphenicol was observed *in vitro* when hyaluronidase was added to the anhydrous ointment bases [123].

The investigation of the influence of hyaluronidase on rectal absorption is also interesting. The absorption of antibiotics from theobroma oil suppositories is considerably improved by the addition of hyaluronidase. For example, the absorption maximum for chloramphenicol is reached in less than an hour, and the blood concentration is doubled [124].

Some heparinoids act in the same way as hyaluronidase. The heparinoid sodium polyethylenesulfonate, for example, gives a 20—25% increase in the rate of absorption of radioiodide on percutaneous application [125]. The heparinoid Bayer 5000 HDB-E (sodium salt of a polysaccharide sulfonic acid) can increase the absorption of salicylic acid from the monosalicylate of ethylene glycol to a much greater degree than dimethyl sulfoxide.

4.4.2. Chymotrypsin

According to reports in the literature, chymotrypsin can increase the quantities of penicillin [126] and of tetracycline [127] absorbed on peroral application.

4.5. Complexing Agents

Sorption promotors from the group of complexing agents include ethylenediaminetetraacetic acid (EDTA), disodium hydrogen phosphate, sodium metaphosphate, and citric acid. It is thought that these substances form complexes with the calcium and magnesium ions that seal the pores of the mucous membrane in the intestinal wall, and that this withdrawal of the alkaline earth metal ions increases the general permeability of the epithelium of the mucous membrane. Absorption can be increased by a factor of up to 10 by the use of EDTA as a sorption promotor. The increase in absorption due to EDTA, citric acid, and sodium metaphosphate has been investigated for tetracycline [128] and heparin [129].

The increase in the antibacterial activity of benzalkonium chloride by EDTA is also due to an increase in the permeability of the cell membranes as a result of complex formation with the bivalent metals of the membrane. The positively charged benzalkonium ions can thus become attached to the free sites on the membrane [130].

4.6. Carbohydrates

Some carbohydrates and amino sugars, particularly sorbitol, and glucosamine, are reported to have sorption-promoting properties. It has been found, for example, that the absorption of vitamin B_{12} is greatly increased, both in young and in old patients, when the orally active B_{12} preparations contain sorbitol; moreover, the B_{12} concentrations reached are higher [131, 132]. Sorbitol can also increase the absorption of vitamin B_1 [133] as well as of calcium, strontium, and iron [134].

Glucosamine was initially described as a sorption promotor for tetracycline but further checks failed to confirm this report [135]. On the other hand, a sorption-promoting action due to glucosamine has been observed with sodium salicylate [136].

5. Conclusion

Many individual observations on the promotion of the penetration of various drugs have now been reported. On the bases of these results, it is already possible to deduce certain rules and to draw conclusions concerning the mode of action of sorption promotors. Owing to the great differences between various drugs and the forms in which they are applied, it is impossible to find a universal sorption promotor. It is therefore necessary in drug research to carry out biopharmaceutical studies for each drug and for each preparation form into which it is to be developed, in order to check whether a given adjuvant is suitable for use as a sorption promotor. The thoughtless use of adjuvants must be warned against, since on the one hand, uncontrolled high absorption may increase the toxicity of the drug, while on the other, interaction with the adjuvant could weaken or nullify the action of the drug. Two drug preparations from the same manufacturer, and containing the same drug in the same dose, will not necessarily have the same action, even if the chemically determined contents of the active principle are the same.

Transfer Ribonucleic Acids[1]

By H. G. Zachau[*]

Transfer ribonucleic acids (tRNAs) [2] *occur in all living organisms. In biological protein synthesis they accept activated amino acids which are then transferred to growing peptide chains. With molecular weights lying between 25000 and 30000, tRNAs are easily within the reach of today's physical, chemical, and biochemical methods. The primary structures of several tRNAs as well as some relationships between structure and function have been elucidated. Three-dimensional structure, specificity, and mechanism of action are the subjects of present research efforts.*

1. Introduction

The study of transfer ribonucleic acids began with theoretical considerations. Out of the "one-gene – one-enzyme" hypothesis was developed, in the 50's, the sequence hypothesis: the sequence of nucleotides in deoxyribonucleic acid determines the sequence of amino acids in a protein; the nucleotide sequence is translated "colinearly" into the amino acid sequence. At that time practically nothing was known about the mechanism of biological protein synthesis, but one had to assume that amino acids interact specifically with nucleotide sequences, are arranged along them, and are finally joined to form proteins.

Is the binding specificity of amino acids to the nucleic acid template determined by a specific charge pattern or through hydrophobic regions of the nucleotides? Neither suggestion is plausible when viewed from the structural and chemical properties of the molecules involved. Nucleic acids, however, do have a specific hydrogen bond pattern. Therefore *Crick*, in 1955, postulated 20 small "adaptor" nucleic acids to which the 20 amino acids are bound in covalent, high-energy bonds by 20 different enzymes. The amino-acid carrying adaptor molecules would then interact with specific nucleotide sequences of the template through H bonds [3]. In the following years RNA fractions were found [6,7], after several indications of their existence [4,5], which bound amino acids covalently and had all the other properties of *Crick*'s adaptor molecules. The fractions were originally called sRNA (soluble RNA) until the name tRNA (transfer RNA) became established. After the solution of the genetic code and the elucidation of several tRNA sequences, *Crick* refined the adaptor hypothesis (Fig.1) further. Today, as we shall see, it has been proved at least in principle.

tRNA has been isolated from animals, plants, and numerous microorganisms. In all cases the molecular

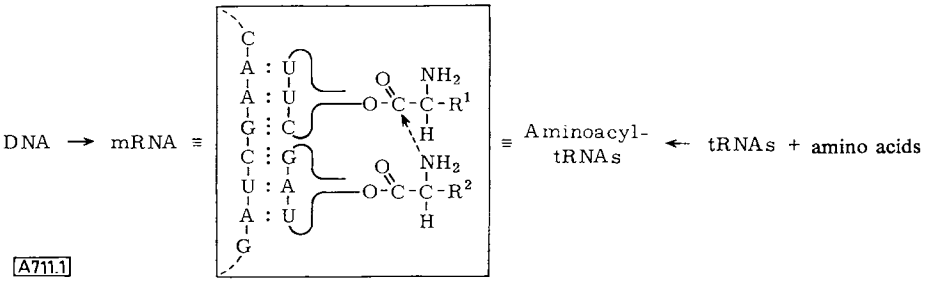

Fig. 1. Schematic representation of the adaptor hypothesis. The aminoacyl-tRNAs are arranged on the mRNA such that the amino acids are linked in the order determined by the mRNA and thus ultimately by the DNA.

weights of the nucleic acids have been between 25000 and 30000, corresponding to chain lengths of 75–85 nucleotides. Specific tRNAs, such as $tRNA^{Ala}_{yeast}$ or

[7] *K. Ogata* and *H. Nohara*, Biochim. biophysica Acta *25*, 659 (1957).

$tRNA^{Ser}_{yeast}$, were isolated from the mixture of tRNAs obtained from one organism and were found to differ structurally from one another and from the corresponding tRNAs of other organisms ($tRNA^{Ala}_{coli}$, $tRNA^{Ser}_{coli}$). The enzymes postulated by *Crick* were also found. These are the aminoacyl tRNA synthetases which catalyze the reactions

amino acid + ATP $\rightleftharpoons$ amino acyl-AMP + PP_i

and

amino acyl-AMP + tRNA $\rightleftharpoons$ amino acyl-tRNA + AMP.

Several synthetases have been purified. The tRNA-bound amino acids are transferred to the growing peptide chain on the messenger RNA/ribosome complex. (For literature on protein synthesis and genetic code see [8,9]; summary [10].)

Since only a small portion of the literature concerning structure and function of tRNAs will be cited here, the reader is referred to other sources. Isolation and fractionation of tRNAs was last reviewed 5 to 6 years ago [11,12]. More recent collections containing the most important methods are available [13–15]. Physical properties [16] and biological specificity [17,18] of tRNA have been reviewed, as have some aspects of sequence analysis and primary structure [19–23]. Mention should also be made of reviews on enzymatic methylation [24], odd nucleotides [25], and amino acid esters [26] of tRNA. Recent advances in tRNA research may be found in two Symposium volumes [9,27]. In general, if there are several publications pertaining to a specific problem, only the most recent one will be cited.

2. Isolation of Pure tRNAs

Pure compounds are needed for much of the chemical and biochemical research on tRNA. The "soluble RNA" fraction isolated from cells contains more than 20 different tRNAs as well as several other RNA species of low molecular weight. Although a few tRNAs are readily isolable from this mixture, the purification of most tRNAs is time consuming. Countercurrent distribution was the only effective method of separation [28–30] in the early days of tRNA research, and it is still the best method when larger quantities of tRNA have to be fractionated. In recent years partition, ion exchange, and adsorption chromatography, as well as combinations of these methods, have proved useful in the purification of specific tRNAs.

The principles underlying separation by any of the above methods are not fully understood; it is not known which structural characteristics of tRNAs are the basis of the separation. Chain length and nucleoside composition of $tRNA^{Ala}_{yeast}$, which travels slowly on countercurrent separation, are only slightly different from those of $tRNA^{Tyr}_{yeast}$ and $tRNA^{Ser}_{yeast}$, both of which travel with the organic phase. One could postulate that remnants of three-dimensional structure, which tRNAs perhaps still have in organic solution, are responsible for the separation. But relevant experimental data are not available. Three-dimensional structure is definitely involved in the chromatography of tRNAs on basic ion exchangers. At elevated temperatures tRNAs are eluted later, *i.e.* by higher salt concentrations than are needed at room temperature [31]. The simplest explanation for this phenomenon is that the tRNA molecules are partially unfolded at higher temperatures, exposing more phosphate groups for interaction with the ion exchanger. Since separation is particularly effective in the presence of urea or other agents that weaken internucleotide interactions [32], it is not possible that the original three-dimensional structure of tRNA is the determining factor. A more likely factor is the different amount of residual internucleotide interactions under the conditions of countercurrent distribution or chromatography; some tRNAs retain more of their three-dimensional structure than do others.

Hydrophobic side chains on one nucleotide of a tRNA, such as the isopentenyl group of $tRNA^{Ser}_{yeast}$ [33] $tRNA^{Tyr}_{yeast}$ [34], or $tRNA^{Tyr}_{coli}$ [35], are partially re-

sponsible for the molecules traveling preferentially with the upper phase. The hydrophobic base Y^+, whose structure is still unknown, has a similar effect in $tRNA^{Phe}_{yeast}$. The effect can be clearly demonstrated in this case since Y^+ can be excised from this tRNA with acid, without breaking the nucleic acid chain or drastically changing its three-dimensional structure [36]. The new product, called $tRNA^{Phe}_{HCl}$, tends to stay more in the aqueous phase during countercurrent distribution. $tRNA^{Phe}_{HCl}$ is also retained less on benzoylated DEAE cellulose [37], whose operating principle is based to a great extent on hydrophobic interactions, than is $tRNA^{Phe}$.

It is surprising that groups which are small in comparison to the whole molecule have such a profound effect on the properties of tRNAs. The findings may be explained by the fact that the hydrophobic groups are localized at an exposed part of an otherwise fairly compact molecule. Y^+ as well as the isopentenyl group are found in the anticodon regions of the tRNAs. The 3′-terminal –C–C–A sequence and tRNA-bound amino acids, which must lie on the surface of the molecule, influence the properties of tRNAs. $tRNA^{Ser}_{yeast}$ with a 3′-terminal –C–C–A migrates further in countercurrent distribution than does the same tRNA with terminal –C–C [38]. Tyr-$tRNA^{Tyr}$ can be separated from free $tRNA^{Tyr}$ by chromatography [39], and the substitution of a tRNA-bound amino acid by an aromatic group (such as phenoxyacetyl) facilitates the separation [40] of the charged tRNA from the other (uncharged) tRNAs.

3. Odd Nucleosides and Biosynthesis of tRNA

Besides the nucleosides A, G, U, and C, found in all RNAs, tRNAs contain more than thirty different odd nucleosides. A few odd nucleosides have also been found in the RNA of ribosomes. Fig. 2

A711.2

Fig. 2. Odd nucleosides found in RNA. The arrows indicate positions in which methyl group substitutions have been found. The structures of the nucleosides in the bottom row were determined within the past year [*(1)* [41], *(2)* [42], *(3)* and *(4)* [43], *(5)* [44], *(6)* [45, 46]. See ref. [25] for references regarding the other nucleosides.

shows the odd nucleosides whose structures had been elucidated up to early 1969. 10–12 other odd nucleosides have been found, the structures of which are not as yet known.

Most odd nucleosides are derived from the four main nucleosides through methylation on C, O, or N; methylation of the base and of the sugar group (2′-*O*-methylribose) has been observed and mono- and dimethyl derivatives have been found. The ability to form hydrogen bonds is decreased in some methylated nucleosides, but not in others (Fig. 2). A nucleoside, found in all tRNAs studied so far, is 5-ribosyluracil or pseudouridine (Ψ) which has a C–C bond between base and ribose instead of an *N*-glycosyl linkage. Not especially noted in Fig. 2 is ribothymidine (T) which is also very common.

Like the other RNAs of the cell, tRNAs are synthesized at particular cistrons of the DNA [47]. Since there are no nucleotides known in DNA which can determine the insertion of odd nucleotides into the tRNA chain, it is assumed that an unmodified, "virgin" tRNA is synthesized first on which the odd nucleotides are formed later through modification of the chain. It is also possible that the three 3′-terminal nucleotides C–C–A, found in all tRNAs, are missing in the newly synthesized tRNA. In animal cells and microorganisms there has been found a CCA-phosphorylase which attaches the three bases onto tRNA in a reaction independent of DNA. Attempts to isolate tRNA precursors are only starting [48].

The formation of some odd nucleotides has been examined rather thoroughly. In the absence of the methyl-group donor methionine certain mutants of microorganisms produce "undermethylated" tRNA which can be transformed *in vitro* into the fully methylated form by the action of specific methylases [24]. Isopentenyl [49] and thio groups [50,51] are also added to the complete tRNA. In $tRNA^{Ala}_{yeast}$ some of the molecules contain a U in position 48, and others contain hU [52]. It seemed therefore reasonable to assume that hU is formed by hydrogenation of U in the complete tRNA chain. C may also be the parent group of hU (or of a dihydro-C which is converted into hU during the working-up procedure) since several tRNAs of *E. coli* contain A–G–C instead of the A–G–hU sequence found in yeast. Valine-specific tRNAs from two different yeast species contain hU and C in analogous positions (see Section 4). Arguing against U as parent of hU is also the finding that incorporation of the U-analog 5-fluoro-U suppresses the formation of T and Ψ but not of hU [52a]. Formation of Ψ from U is probably also accomplished in the complete tRNA but has so far not been demonstrated [53]. The fact that the triphosphate of pseudouridine can be incorporated into RNA *in vitro* does not rule out the possibility that U may be transformed in the RNA chain since RNA-polymerase accepts numerous nucleotide analogs as substrate both *in vitro* and *in vivo*.

Up to now little is known about the function of odd nucleotides. Since certain nucleases do not split next to some odd nucleotides, these nucleotides may have a protective function. Hypotheses concerning a relationship between degree of methylation of tRNA and cell differentiation or malignant growth could not be substantiated [24]. Isopentenyladenosine and other *N*(6)-substituted adenosine derivatives related to the natural cytokinin zeatin are potent plant growth factors. It is unknown, however, whether there is a relationship between their growth activity and their occurrence in tRNA. The role of odd nucleotides in codon recognition and interactions with amino acyl tRNA synthetases will be discussed in Section 6.

Odd nucleotides appear mainly in certain analogous positions of tRNAs. Up to now, however, no regularity has been found in the primary structure as would be the case, *e.g.*, if the cytidines found between several guanidines were always methylated. It should be noted that odd nucleotides are mostly found in regions that are single stranded in the clover leaf model (see Section 5). Their function in these positions could be the stabilization of a particular three-dimensional structure or a contribution to interactions of tRNA with components of the protein biosynthesis system. It is also quite probable that unmodified tRNAs already have a three-dimensional structure similar to that of modified tRNAs, and that the odd nucleotides are found predominantly in single-stranded regions because of easier access of modifying enzymes to these parts.

A surprising regularity was detected recently after purification of numerous tRNAs from *E. coli* and after a study of sA-biosynthesis [53a]: tRNAs with a 3′-terminal A in their anticodons (top line of the code table) frequently have an iA or sA next to this A, while several tRNAs with a 3′-terminal U in the anticodons (3rd line of the code table) contain tA. There is, as yet, no functional interpretation of this finding.

Animal tRNA has more odd nucleotides than yeast tRNA which is in turn more extensively modified than bacterial tRNA. However, even the tRNA of a very low order organism, T4-phage induced tRNA, contains Ψ [54]. It is difficult to believe that this refining of modification in evolution is a "freak of nature". The search for a function of the odd nucleotides remains one of the more interesting problems in nucleic acid biochemistry.

4. Primary Structures of tRNAs

The elucidation of the nucleic acid sequences of tRNAs represents a major scientific advance. *Holley* and his co-workers were the first to determine the primary structure of a $tRNA^{Ala}_{yeast}$ [52]. Structures of other tRNAs followed: from the yeast *Saccharomyces cerevisiae* ($tRNA^{Ser}_{I+II}$ [33], $tRNA^{Tyr}$ [34, 21], $tRNA^{Phe}$ [55], $tRNA^{Val}$ [56]); from the yeast *Torulopsis utilis* ($tRNA^{Val}$ [57], $tRNA^{Ileu}$ [58], $tRNA^{Tyr}$ [58a]); from *Escherichia coli* ($tRNA^{Tyr}$ [59–61]; $tRNA^{fMet}$ [62], $tRNA^{Met}$ [63], $tRNA^{Val}$ [64]); from rat liver ($tRNA^{Ser}$ [65]); and from wheat germ ($tRNA^{Phe}$ [66]). Tentative structures for $tRNA^{Phe}_{coli}$ [67,68] and partial structures for $tRNA^{Ala}_{coli}$ [69] and $tRNA^{fMet}_{yeast}$ [69a] have also been published. Elucidation of another dozen tRNA structures is under way.

The first step in a sequence analysis of a nucleic acid is its specific enzymatic cleavage into smaller parts. Two endonucleases are known which cleave specifically at certain nucleotides. Pancreas-RNase cleaves next to both pyrimidine nucleotides and most of the odd nucleotides derived from them; T1-RNase, obtained from a microorganism, hydrolyzes the RNA next to G and several G derivatives (Fig. 3). A nuclease which cleaves specifically next to A has not yet been found. The exonucleases listed in Fig. 3 are useful in the determination of nucleotide sequences of oligonucleotides, which are in turn obtained by the action of endonucleases on the nucleic acid. Chemical methods for the stepwise degradation of a chain, which are so important in protein chemistry, have not yet been developed to such a stage that they are universally applicable or usable over a large number of steps in the case of nucleic acids. First results have been reported [69b].

Once the nucleotide sequences of all oligonucleotides formed on cleavage with pancreas- and T1-RNase have been determined, it is possible to reconstruct part of the original nucleic acid chain by comparison of the cleavage products. This process is illustrated for $tRNA^{Ser}_{II}$ from yeast in Fig. 4. It was not possible, however, to reconstruct a fragment greater than about 20 nucleotides by this method. Nucleic acid research is in a more difficult position than protein chemistry as regards the puzzle of sequence analysis. Specific proteases, which cleave next to two or three of 20 possible amino acids, generally afford larger segments than do nucleases that cleave next to one or two out of four possible nucleotides. The amino acid sequence of a protein can therefore be obtained in general by comparison of several rows of peptides formed on complete cleavage with specific proteases.

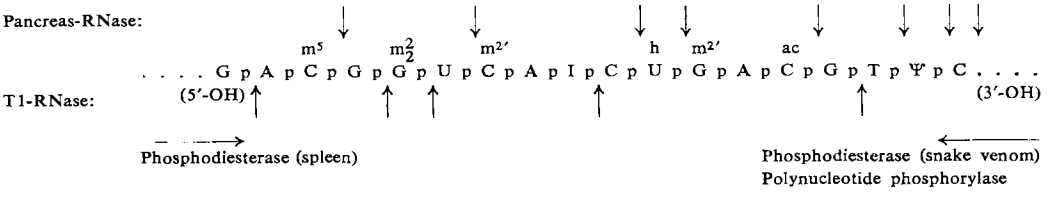

Fig. 3. A hypothetical nucleotide sequence is cleaved by an endonuclease at the positions indicated by arrows. It is degraded by exonucleases from the 5'- or 3'-hydroxyl end, respectively.

Additional methods are needed for nucleic acids. Partial digestion by endonucleases which leads to large fragments of the nucleic acid has proved useful. The method rests on the fact that in the three-dimensional structure of a tRNA certain sequences are more exposed than others and thus more susceptible to nucleolytic attack. A complex mixture of larger and smaller fragments is obtained under mild cleavage conditions. Isolation of the fragments followed by complete cleavage with a nuclease gives information on which oligonucleotides are adjacent to one another within a particular region of the tRNA. 30–40 fragments of $tRNA^{Ser}_{yeast}$ had to be analyzed [70] until the sequences of all overlapping regions were established beyond doubt. Several fragments of importance in the proof of structure are indicated in Fig. 4.

Several hundred milligrams of pure tRNA were needed for the first complete sequence analysis of tRNAs, during which methods were still being developed. Oligonucleotides were separated by column chromatography; products of the subsequent cleavages were identified by their behavior on paper chromatography, electrophoresis, and by their UV spectra. Even at the last degradation step, on the nucleoside level, enough material is left to characterize possible odd nucleosides present. In the sequence analysis of, *e.g.*, $tRNA^{Ser}_{yeast}$ the structures of the then unknown nucleosides iA and acC (Fig. 2) were elucidated by mass spectrometry and NMR [71], or by degradation and synthesis [72] respectively. iA was isolated and identified simultaneously from unfractionated tRNA [73].

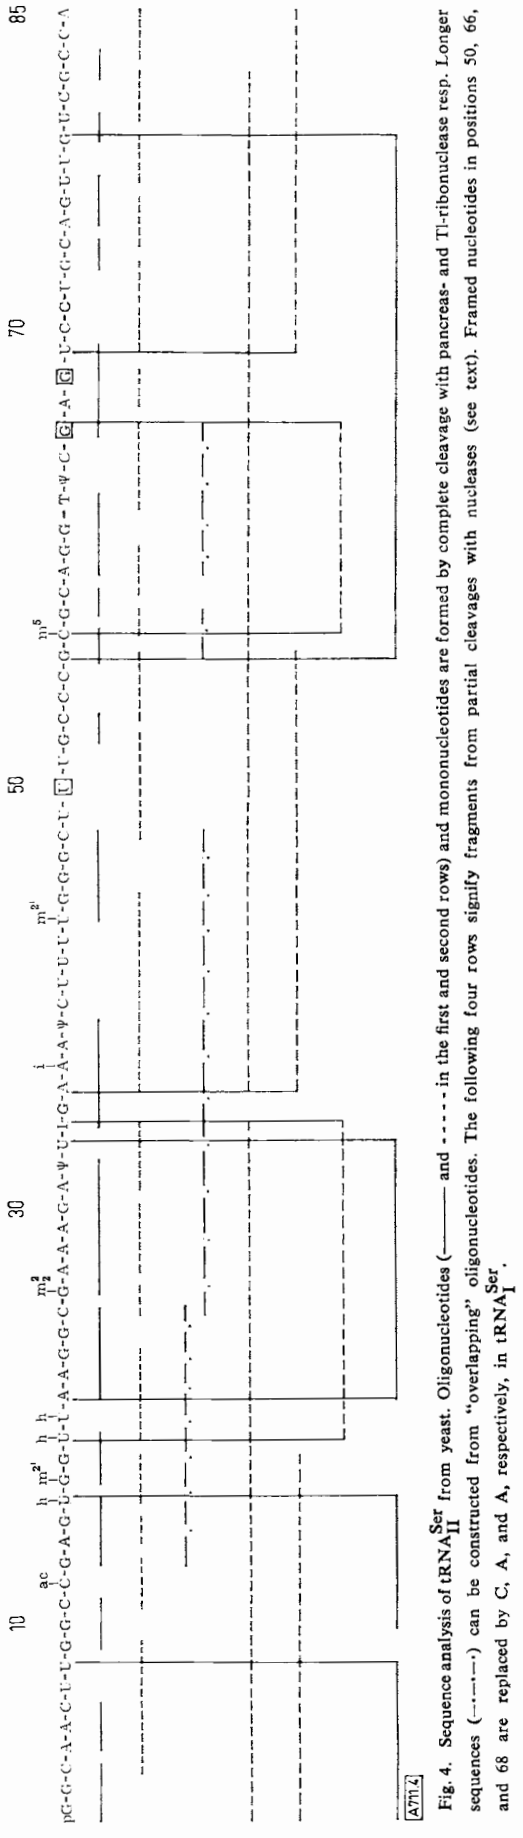

Fig. 4. Sequence analysis of $tRNA^{Ser}_{II}$ from yeast. Oligonucleotides (——— and - - - - - in the first and second rows) and mononucleotides are formed by complete cleavage with pancreas- and T1-ribonuclease resp. Longer sequences (—·—·—) can be constructed from "overlapping" oligonucleotides. The following four rows signify fragments from partial cleavages with nucleases (see text). Framed nucleotides in positions 50, 66, and 68 are replaced by C, A, and A, respectively, in $tRNA^{Ser}_{I}$.

Today it is possible to analyze a sequence using the above methods with as little as 40–60 mg of pure tRNA, provided that no extra material is needed for the elucidation of particularly complicated odd nucleosides. Even less tRNA is needed when radiochemical techniques are employed. *Sanger* and his coworkers have developed methods of sequence analysis using ^{32}P-labeled nucleic acids [74] which have been useful in the elucidation of, *inter alia*, five tRNAs from *E. coli* [59,62–64,67]. Oligo- and mononucleotides are rendered visible by autoradiography and identified by their behavior on two-dimensional electrophoresis. Such methods lead to a considerable saving not only of material but also of time. Difficulties arise only when unknown nucleotides are found since the quantities of material used do not generally suffice for a UV spectrum, to say nothing of chemical degradation reactions. In addition, it is much more difficult to obtain nucleic acids with sufficient specific radioactivity from higher organisms than from microorganisms.

A combination of conventional and radiochemical methods is possible with the help of polynucleotide kinase [75], which transfers phosphate to the 5′-hydroxyl group of oligonucleotides. If one has only small quantities of a nonradioactive nucleic acid, the cleavage products can be marked with ^{32}P [76] and characterized by *Sanger*'s methods. A method in which nonradioactive oligonucleotides are made radioactive through neutron activation [76a] is probably much more complicated.

The nucleotide sequences of the presently known tRNAs show characteristic similarities and differences. In Fig. 5 the sequences are so arranged as to emphasize the similarities. First it should be noted that certain odd nucleotides such as hU, m^2_2G, and m^5C appear predominantly in analogous regions of tRNAs. Certain characteristic distances are the same

or similar in many tRNAs, such as that from m_2^2G to the anticodon and that between the sequence G–T–Ψ'–C (found in all tRNAs) and the 3'-terminal C–C–A. Similarities and differences in the sequences will be discussed in the following Sections in relation to three-dimensional structure and the various functions of tRNAs.

The oligonucleotides of a $tRNA^{Ser}$ from American baker's yeast[77] are identical with those from $tRNA^{Ser}$ from German brewer's yeast[33] (both *Saccharomyces cerevisiae*). After a discussion about the sequence of $tRNA^{Ala}_{yeast}$ as established by *Holley et al.* this tRNA was recently isolated from the same source but by a slightly modified technique. The $tRNA^{Ala}_{yeast}$ thus obtained is longer by one nucleotide (an extra G between positions 47 and 48) and contains only U in position 48 instead of a mixture of U and hU[77a]. Sequence differences between tRNAs from various yeast strains have been found. $tRNA^{Val}$ from the yeast *Torulopsis utilis*[57] differs from that obtained from *Saccharomyces* (Fig. 5)[56]: the sequence A-G-hU-hU-G-G-hU-C-A-U was found in the hU region; moreover the tRNA is shorter by two nucleotides, *i.e.* by the hU in the S-region and G in position 12 counting from the 3'-terminal A. $tRNA^{Tyr}$ from *Torulopsis*[58a] differs from $tRNA^{Tyr}$ from *Saccharomyces*[34] in 7 positions but has the same chain length. Two groups have found sequences for $tRNA^{Tyr}_{coli}$[60] and $tRNA^{Phe}_{coli}$[68] respectively which differ slightly from those in Fig. 5 and 6. It is not yet certain whether the presence of multiple tRNAs is the cause of these discrepancies. Differences in odd nucleotides, which can be induced by various growth conditions, will be discussed in relation to multiplicity of tRNAs (Section 7).

5. Three-dimensional Structure of tRNAs

tRNAs in aqueous solution certainly do not occur as randomly coiled molecules. The best evidence for a definite three-dimensional structure is the fact the tRNAs can be (reversibly) denatured. As for proteins, there are at least one native, biologically active form and one or more inactive forms of tRNA[78,79].

Since the exact three-dimensional structure of a tRNA is not known one resorts to models. *Holley et al.* recognized after the elucidation of the primary structure of $tRNA^{Ala}_{yeast}$ that certain regions of the nucleotide sequence could form Watson-Crick base pairs (A:U; G⋮C) with other regions of the same molecule[52]. They proposed three possible models: one extended, one angled, and one clover-leaf form. No one model is preferable over the other in that it has a higher percentage of paired nucleotides giving it a more favorable energy state. Alternative models can also be constructed for most of the other tRNAs whose primary structures are known. Clover-leaf models (Fig. 6), however, have been preferred since the elucidation of the first sequences, at first primarily for aesthetic reasons. Meanwhile there are several experimental indications that at least parts of the clover-leaf model must be correct.

Support for the clover-leaf model comes, *inter alia*, from the fact that all known tRNAs can be arranged in that form although the nucleotide sequences are very different particularly in the paired regions. After the first mutation in the evolutionary process which relates $tRNA^{Ser}_{rat}$ to $tRNA^{Ser}_{yeast}$ (19 nucleotides differ) and $tRNA^{Phe}_{wheat}$ to $tRNA^{Phe}_{yeast}$ (13 nucleotides differ) there must have been a selective pressure for change of the opposite nucleotide in a paired region so that the base pairing "fits" again[66]. This train of thought can be extended from tRNAs of different organisms accepting the same amino acid to the various tRNAs of a single organism, assuming that all forms have arisen from a single "Ur"-tRNA[80,81]. The fact that the length of the paired regions remains almost constant over a range of nucleotide compositions is explicable only if these parts of the clover-leaf model play a role in the actual three-dimensional structure.

It is, however, certain that tRNAs are not planar platelets. Clover-leaf models (and other two-dimensional models) can be folded such that single-stranded loops can form further base pairs either with one another or with the 3'-terminal C–C–A sequence. This folding produces more or less compact three-dimensional structures from which the anticodon region and the amino-acid-carrying 3'-terminal A protrude. Three-dimensional models have been discussed by several authors (see below)[82–86].

It has become customary to regard paired, and therefore helical, regions as elements of secondary structure, and to consider any fixation of the paired regions in space, *e.g.*, *via* unpaired regions, as an expression of tertiary structure. Base-pairing through H bonds, however, is definitely not the only stabilizing factor of the three-dimensional structure. Coplanar stacking of bases contributes considerably to the stabilization energy. Thus *Fuller* and *Hodgson*[87] made the plausible suggestion after comparing the nucleotide sequences of several tRNAs and constructing models, that part of the anticodon region of the tRNAs is stabilized by stacking of purine bases. Such models appear closer to reality than two-dimensional clover-leaf models with 7 unpaired nucleotides in the anti-

Fig. 5. Comparison of nucleotide sequences of tRNAs. (Literature references are given in the text.) The numbers in parentheses denote chain length. The following odd nucleotides are still unknown: G+ in $tRNA^{Tyr}_{coli}$, Y in $tRNA^{Phe}_{yeast}$; Y_W in $tRNA^{Phe}_{wheat}$, X in $tRNA^{Phe}_{coli}$, X in $tRNA^{Val}_{coli}$, and C+, A+, and X in $tRNA^{Met}_{coli}$ (A+ is tA in one $tRNA^{Met}_{coli}$, *S. Nishimura, H. Ishikura,* personal communication). Sequences differing from those shown here for $tRNA^{Val}_{yeast}$ [56], $tRNA^{Tyr}_{coli}$ I su⁻ [59], and $tRNA^{Phe}_{coli}$ [67] are discussed in the text. Areas which are double stranded in the clover-leaf models (see Fig. 6) are underlined. The numbers in the bottom line designate the frequency of certain nucleotides in that position (including odd nucleotides which are derived from them).

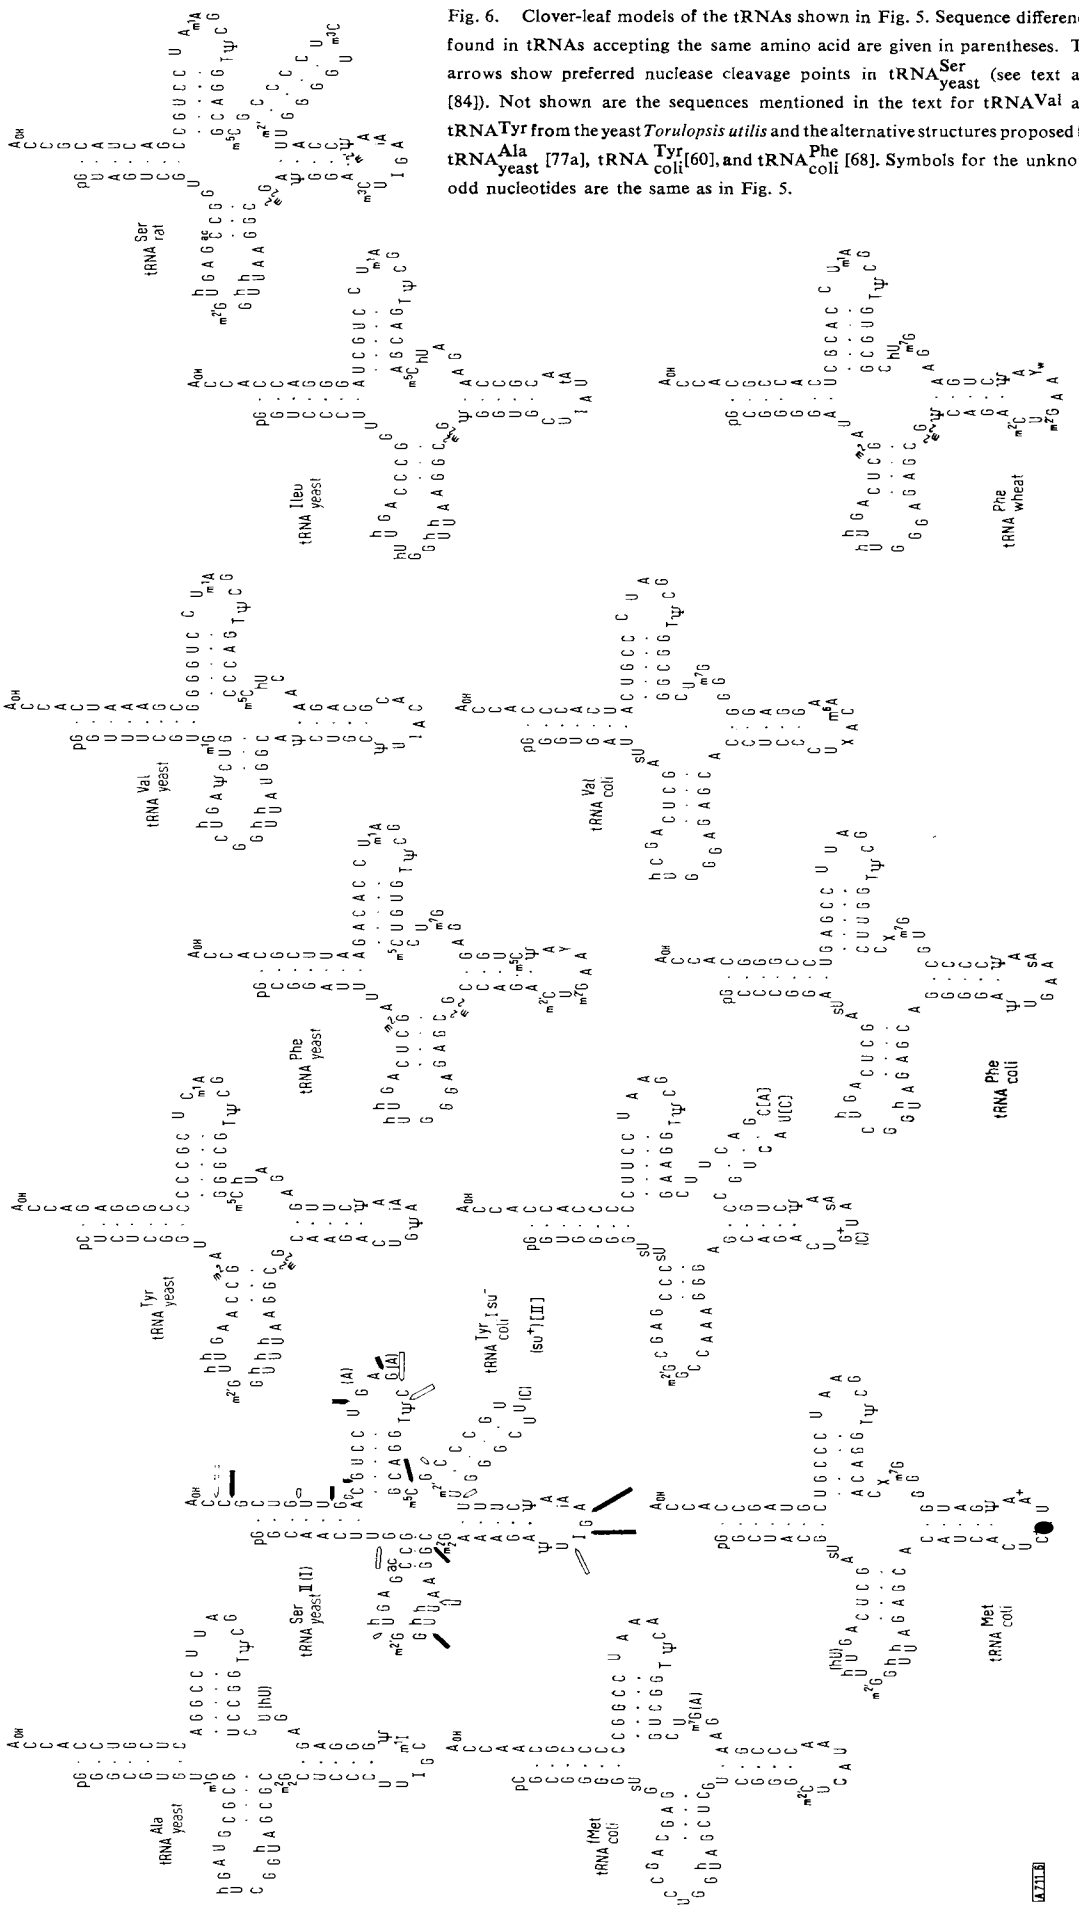

Fig. 6. Clover-leaf models of the tRNAs shown in Fig. 5. Sequence differences found in tRNAs accepting the same amino acid are given in parentheses. The arrows show preferred nuclease cleavage points in $tRNA^{Ser}_{yeast}$ (see text and [84]). Not shown are the sequences mentioned in the text for $tRNA^{Val}$ and $tRNA^{Tyr}$ from the yeast *Torulopsis utilis* and the alternative structures proposed for $tRNA^{Ala}_{yeast}$ [77a], $tRNA^{Tyr}_{coli}$ [60], and $tRNA^{Phe}_{coli}$ [68]. Symbols for the unknown odd nucleotides are the same as in Fig. 5.

codon loop (Fig. 6). If one considers only base pairing, the stem of the anti-codon loop in $tRNA^{Ser}_{yeast}$ for instance could be elongated by one such pair leaving only 5 unpaired nucleotides. Consideration of stacking allows one to construct the anticodon regions of all tRNAs, including that of $tRNA^{Ser}_{yeast}$, in the same manner. Thus the first A of the anticodon loop of $tRNA^{Ser}_{yeast}$ is included in a stacked region instead of being paired with Ψ. The rigidity of the regions stabilized by stacking is probably comparable with that of double-stranded regions of tRNAs. It is therefore not meaningful to apply very strictly the above distinction between secondary and tertiary structure.

There has been no lack of attempts to gain insight into the three-dimensional structure of tRNAs by physical methods. Only a small portion of the work can be cited here: NMR [88]; electron spin resonance [89]; melting curves (temperature-dependence of hypochromicity) [90]; temperature jump methods [90a]; IR spectroscopy [90b]; optical rotatory dispersion [83,91]; circular dichroism [92]; polarization of fluorescence [93]; phosphorescence spectra [94,95]; sedimentation characteristics in the ultracentrifuge [96,97]; flow birefringence [98]; small angle X-ray diffraction [99]; preliminary X-ray studies on tRNA-gel fibers [100]; measurement of exchange kinetics with T_2O [101]; electron microscopy [101a]; determination of chromatographic behavior [102] and kinetics of enzymatic degradation [103,104]. The methods have led to some conclusions concerning the three-dimensional structure of tRNAs. The structures change with temperature, presence of mono- or divalent cation, pH, *etc.*, and are different for uncharged tRNA, aminoacyl tRNA, and peptidyl tRNA. Statements concerning the degree of base pairing and stacking as well as those regarding the conformation of tRNA in solution are still rather tentative. Consideration of some of the more recent data would give preference to somewhat more extended models which are derived from the clover-leaf model by stacking of unpaired nucleotides rather than by formation of many additional base pairs.

It has been possible to obtain indications for elements of the three-dimensional structure and recognition sites of tRNAs (discussed below) by specific chemical [17,105] and enzymatic modification of the molecules. Alkylation and halogenation reactions probably change the three-dimensional structure of tRNAs so rapidly that little information can be gained about the original structure. The same is true of acetylation, acetacetylation with diketene [105a], and oxidation with $KMnO_4$ [106] or OsO_4 [107]. In reactions with formaldehyde [108] and other aldehydes, in the much studied reactions with hydroxylamine and its derivatives, in the deamination with HNO_2 [109], in the reaction with carbodiimides [110], and the oxidation with perphthalic acid [85] it seems that several regions, which are single stranded in the clover-leaf model, react faster than paired regions.

Reagents such as $NaBH_4$ [111] and acrylonitrile [112] are also interesting in that they react preferentially or exclusively with certain odd nucleotides. $NaBH_4$ reduces, *inter alia*, hU and acC. If these nucleotides are part of a tRNA chain, hU is reduced [111] but the acC in position 12 of $tRNA^{Ser}$ is not [113]. This can be taken as an indication that hU is unpaired and acC is protected through pairing, as is predicted from models.

Acrylonitrile, which modifies Ψ and I, does not attack the Ψ in the sequence G–T–Ψ–C found in all tRNAs under a variety of conditions [112] although, according to the clover-leaf model, this sequence is in a single-stranded region. This fact is in agreement with the finding that the G–T–Ψ–C sequence is unusually stable on partial hydrolysis with pancreas-RNase [84]. This region must therefore be protected in some way in the three-dimensional structure.

A promising method for the study of tRNA three-dimensional structure seems to be the partial cleavage

with nucleases. The preferred points of attack of pancreas- and T1-RNase in $tRNA^{Ser}_{yeast}$ [84] are indicated in Fig. 6. The length of the arrows is approximately proportional to the frequency of cleavage at the points indicated. Most cleavages occur where predicted by the clover-leaf model. This cleavage pattern can be refined by further analyses. The anticodon sequence IGA is particularly labile towards nuclease. It must therefore be in an exposed, single-stranded region; such a position is consistent with its function in the adaptor complex (Fig. 1). The anticodon sequences of most other tRNAs are also particularly labile towards nucleases. Nucleases with a preference for single stranded regions such as the sheep kidney nuclease [114] are valuable tools in the study of tRNA three-dimensional structure [115].

The above physical, chemical, and enzymatic methods are not sufficient to prove a particular three-dimensional structure. It was therefore a great step forward when six independent groups managed to produce tRNA crystals within the past year (for an account see ref. [116]). Although the crystals made so far appear not quite suitable yet for high resolution X-ray structure analysis, it will be only a matter of time until suitable samples will become available and the exact three-dimensional structure of a tRNA or several tRNAs in the crystalline state will be elucidated. tRNA models [82–86], if they are close to the true structures, may be of considerable help in X-ray analysis.

As has been mentioned, tRNAs can exist in several different conformations under physiological conditions. Therefore, in order to describe the three-dimensional structure of tRNAs in solution, it is necessary to pursue other physical methods, chemical modifications, and enzymatic cleavages which supplement X-ray data. These methods may also provide further indications as to the three-dimensional structure of tRNAs before an X-ray structure analysis has been accomplished.

6. Binding and Recognition Sites of tRNAs

6.1. Mode of Action of Binding and Recognition Sites

Each tRNA accepts only its specific amino acid in the enzymatic charging reaction. Reactions with other amino acids are below the limit of error, which is given as 1:10000 for the method used [117]. The codon-anticodon interaction and the transfer of the bound amino acid to the growing peptide chain must *in vivo* also occur with the highest precision since proteins are "molecularly uniform". The limit of error of the assay for wrong insertion is 1:3000 [118]. These data are only valid for natural amino acids. Some amino acid analogs are incorporated quite well into proteins. These analogs "fool" the aminoacyl tRNA synthetases and are not excluded in later steps of protein synthesis. In specially selected mutants of microorganisms [119,120] one has found a higher frequency of incorporation of a natural amino acid in wrong positions ("missense suppression").

A distant goal of research in this field is the explanation of the high precision of protein synthesis through an understanding of the structural elements and interactions of the enzymes, nucleic acids, and ribosomes involved. tRNAs are the most extensively studied macromolecular components of the protein synthesis system, and even for them little is known about the relationship between structure and function. In the search for nucleotide sequences or three-dimensional regions in the tRNA molecule which are responsible for interactions with a macromolecule one can differentiate between two types of structural elements: there must be specificity determining regions which are different for each tRNA, and other regions whose integrity is necessary for an interaction but which are not directly responsible for specificity. These areas, which can be alike in several or all tRNAs, may be called nonspecific binding sites. The distinction facilitates the present discussion, but it may be unnecessary one day when the recognition process is fully understood (see Sections 6.2–6.4).

6.2. Recognition of tRNAs by Various Enzymes

Let us first consider the recognition sites of tRNAs, about which little more is known than that they exist. The 3′-terminal nucleotides of tRNAs – pC, pC, and pA – are added by an enzyme already mentioned, C–C–A-pyrophosphorylase. For this reaction tRNAs must be in the native conformation; denatured $tRNA^{Leu}$ from yeast is a very poor substrate for the enzyme [121]. In the denatured tRNA either the particular recognition site is altered or the total conformation is so different from that of the native tRNA that it is difficult to form an enzyme-tRNA complex. Since there may be only one pyrophosphorylase for all tRNAs one must assume that the enzyme recognizes nucleotide sequences or elements of the three-dimensional conformation which are alike in all tRNAs of a species.

Similar considerations may hold for the structural elements that are responsible for binding of tRNAs to ribosomes and to polymerization enzymes. These interactions are not specific for individual tRNAs. It is known that ribosomes stabilize the tRNA-mRNA complex [122]. The codon-anticodon interaction takes place on the 30S subunit of ribosomes while the amino acid-charged 3′-end of the tRNAs is bound to the 50S subunit [123]. Complexes between tRNAs and polymerization enzymes have also been found [124, 125] but it is not known which regions of tRNAs are involved here.

The enzymes that modify newly formed tRNAs must orient themselves on the three-dimensional structure

of the tRNAs. As has already been mentioned, odd nucleotides, which are formed by modification, occur predominantly in regions of tRNAs that are single-stranded in clover-leaf models. ^{5}mC, iA, hU, and other odd nucleosides appear in analogous positions of the clover-leaf models; however, tRNAs containing unmodified nucleotides in these positions are also known.

It therefore follows that there must exist some recognition characteristics which are not obvious from the present models. A comparison of the nucleotide sequences in the neighborhood of the odd nucleotides in tRNAs and ribosomal tRNA [126] did not show any regularities. Similarly, it is not known which structural elements cause transformylase to formylate methionine bound to $tRNA_{coli}^{fMet}$ but not that bound to $tRNA_{coli}^{Met}$. *N*-Formyl-Met-$tRNA_{coli}^{fMet}$ is recognized by initiation factors to produce the N-terminal amino acid in many bacterial proteins. Mid-chain Met comes from Met-$tRNA_{coli}^{Met}$. The clover-leaf model of $tRNA_{coli}^{fMet}$ has five unpaired nucleotides at the 3′-terminal end whereas models of other tRNAs have only four (Fig. 6). $tRNA_{coli}^{fMet}$ and $tRNA_{yeast}^{Ser\ I}$ are the only tRNAs known which have the sequence –G–T–Ψ–C–A instead of the usual sequence –G–T–Ψ–C–G. So far no relationship has been found between these features and the particular function of $tRNA_{coli}^{fMet}$.

6.3. Binding and Recognition of Aminoacyl tRNA Synthetases

A particularly well-studied area was and still is the interaction between tRNAs and aminoacyl tRNA synthetases. One is dealing here with the most easily accessible model for the study of specific nucleic acid–protein interactions. These interactions are important at several stages of cell metabolism and particularly its regulation.

In this context the specific binding of repressors to operators may be mentioned. In the case of the lac-operon from *E. coli*, the repressor has been identified as a protein [127] and the operator as a relatively short piece of DNA. mRNA and protein synthesis begin when the repressor dissociates from the operator. It seems then that repressors can recognize nucleotide sequences (or nucleic acid three-dimensional structure).

The first specificity determining step in protein synthesis is the synthetase-tRNA interaction. There is no subsequent check on whether the tRNA is carrying the correct amino acid during the formation of peptide bonds on the ribosomes. This has been very well illustrated in the following experiment [128]. Cys-$tRNA^{Cys}$ was desulfurated with Raney nickel. In protein synthesis the resulting hybrid Ala-$tRNA^{Cys}$ inserts Ala into Cys positions of the protein chain, as expected from the adaptor hypothesis, and not into Ala positions.

The nucleotide sequence of DNA and mRNA determines only which tRNAs are adjacent on the ribosome. Which amino acids are attached to the tRNAs and subsequently built into the protein is determined by the aminoacyl tRNA synthetases which, with high precision, bind and aminoacylate only the cognate tRNA. In relation to the structural elements of tRNAs responsible for the specificity of these interactions one speaks of a "second genetic code" or a synthetase recognition code. Attempts to decipher this code will now be discussed.

The *3′-terminal sequence of tRNAs*, –C–C–A, is certainly involved in the interaction with the synthetase. The amino acid is bound by an ester linkage to the ribose of the terminal adenosine [129], predominantly to the 3′-hydroxyl group of the ribose [26]. This area of the tRNA must be in contact with the enzyme during the charging reaction. Some changes in the structure of the terminal sequence are possible without loss of charging ability, such as omission of one C in the reconstruction of a degraded tRNA with CCA-pyrophosphorylase [130], formation of I from the terminal A with a specific deaminase [131], or oxidation of the 2′- and 3′-OH groups with HIO_4 followed by reduction of the dialdehyde to the primary dialcohol [132]. Oxidation with HIO_4 without subsequent reduction or removal of terminal pA inactivates the tRNA completely. Terminally modified tRNAs are still bound to a greater or lesser extent by their synthetase [133, 134], depending on the type of tRNA and the particular modification. Different tRNAs, after the same modification, behave to a different degree as competitive inhibitors in the charging of the corresponding intact tRNAs [135]. Differences observed in these binding and inhibition studies indicate that formation and properties of synthetase-tRNA complexes differ from one tRNA to another. Attempts to detect competitive inhibition of the charging reactions with synthetic oligonucleotides or tRNA fragments have thus far brought contradictory results. The charging of $tRNA_{yeast}^{Phe}$ at least seems not to be inhibited even by large fragments of this tRNA [136].

Although the –C–C–A sequence, which is the same in all tRNAs, can only be a nonspecific binding region, the attached "*stem*" *of the clover-leaf* could be involved in specific recognition of the synthetase. It has recently been postulated [137] that the three nucleotides in positions 5, 6, and 7 from the 3′-end and the opposing

three nucleotides of the 5'-end are the main recognition site. As required by the hypothesis, this sequence is different in the various known tRNAs of a species (Fig. 6). The trinucleotide sequence is also different in $tRNA^{fMet}_{coli}$ and $tRNA^{Met}_{coli}$. In spite of this, both tRNAs are charged by the same enzyme. In addition three cases are known of heterologous charging of tRNAs with different trinucleotide sequences, *i.e.* cases in which the synthetases charge not only their cognate tRNAs from the same species but also that from another species ($tRNA^{Ser}_{yeast}$, $tRNA^{Ser}_{rat}$ [65]; $tRNA^{Phe}_{yeast}$, $tRNA^{Phe}_{coli}$ [138]; $tRNA^{Val}_{coli}$, $tRNA^{Val}_{yeast}$ [139]; sequences Fig. 5). The cross-charging experiments do not, however, refute the hypothesis, since the synthetase recognition code, just as the genetic code, could be degenerate. One result not in agreement with the hypothesis is that the charging of $tRNA^{Phe}_{yeast}$ with a synthetase from *E. coli* disappears upon formation of $tRNA^{Phe}_{HCl}$ [138] (see Section 2). This reaction involves a change in the anticodon region and is very unlikely to affect the hypothetical recognition site in the stem of the clover-leaf directly or through changes in three-dimensional structure. But there is a simple explanation: the anticodon region may be another essential binding site for the synthetase. Certain changes in this region (but not all, see below) would then lead to a loss of charging ability although the actual recognition site is intact.

The *anticodon* itself is a good candidate for a synthetase recognition site since it is different for all tRNAs of a species. Attempts to test this hypothesis by comparison of UV-inactivation curves of acceptor and transfer activity [140] have brought as few definitive results as most inactivation experiments using chemical reagents [17,105]. There are, however, three types of experiments which contradict the anticodon as synthetase recognition site. Several very specific chemical changes in or near the anticodon lead to a loss of codon recognition but no loss of synthetase recognition [36,141–143]. Several tRNAs can be cleaved in or next to the anticodon without loss of acceptor activity [144–146,146a]. In addition su^+- and su^--$tRNA^{Tyr}_{coli}$, which differ in the anticodon (Fig. 6), accept the same amino acid [59]; and it has been shown that the same synthetase charges two $tRNAs^{Ser}_{coli}$ that differ in their anticodons [147]. Although these experiments speak against the anticodon playing a role in specific synthetase recognition, they do not exclude the anticodon region as a binding site since such a function could still be performed even by a greatly modified or cleaved nucleotide sequence.

The T–Ψ–C region is the same or similar in several tRNAs and can therefore only be considered as a non-specific binding region. The *hU-containing loop* and the so-called *S-region* are sufficiently different in tRNAs to serve as recognition sites. However, cleavage of $tRNA^{fMet}_{coli}$ in the former [148] and of $tRNA^{Tyr}_{coli}$ in the latter [149] region does not destroy the acceptor activities. In addition, the dihydrouracil ring can be reductively opened without loss of any tRNA activities [111,113].

Some experiments designed to locate the synthetase recognition site were directed at the *odd nucleotides* as possibly playing a role in tRNA specificity. Numerous, partly contradictory, results with "undermethylated" tRNAs have been reported. The activities of these tRNAs seem to differ little from those of normal tRNAs under most assay conditions. The acceptor activity of $tRNA^{Ala}_{yeast}$ is the same whether U or hU is in position 48 [150]. $tRNA^{Tyr}_{coli}$ is charged with the same velocity by the synthetase from *E. coli* whether the A next to the anticodon is not, partly (with an isopentenyl group), or completely (with an additional CH_3-S-group) modified [35]. The sulfur of s^4U of $tRNA^{Met}_{coli}$ can be missing without loss of acceptor activity [150a]. Insertion of 5-fluoro-U instead of U [52a,151], or some other nucleoside analogs, influences acceptor activity as little as ethylation instead of methylation [152] (use of ethionine instead of methionine as alkyl group donor). It is certainly possible that odd nucleotides have a minor effect on the three-dimensional structure which cannot be analyzed by today's methods. A slightly improved binding to the synthetase would be in evolution already a selective advantage of the modified over the unmodified tRNA.

It is interesting to *compare the presently known nucleotide sequences* and clover-leaf models (Figs. 5 and 6; earlier comparisons see [21,27,80,84,105,152a]) with regard to synthetase recognition sites. The total number of identical or different nucleotides in various tRNAs does not seem to be important. $tRNA^{fMet}_{coli}$ and $tRNA^{Met}_{coli}$, which are charged by the same syn-

thetase, have the same or similar nucleotides in 41 positions. Almost the same number of homologies exist between $tRNA^{Tyr}_{yeast}$ and $tRNA^{Tyr}_{coli}$, for which there is no heterologous charging under most conditions [153]. $tRNA^{Met}_{coli}$ and $tRNA^{Val}_{coli}$, for which no cross-charging should be possible, have 51 homologies. It is worth mentioning that in very similar tRNAs, $tRNA^{Ser}_{yeast}$ and $tRNA^{Ser}_{rat}$ or $tRNA^{Phe}_{yeast}$ and $tRNA^{Phe}_{wheat}$ (66 and 63 homologies, respectively), which can be charged with the heterologous synthetases, the sequence differences (19 and 13 nucleotides, respectively) are found predominantly in the paired regions of the clover-leaves. In general, it seems that heterologous charging is easier and more frequent for tRNAs and synthetases from yeast and those from higher organisms than for those from bacteria. Two cases of an incorrect charging have been found: a Phe-tRNA-synthetase from the cytoplasm of *Neurospora* charges $tRNA^{Ala}_{coli}$ and $tRNA^{Val}_{coli}$ with Phe [154]; Phe-tRNA synthetase from yeast charges $tRNA^{Val}_{coli}$ I, the hU-region of which is very similar to the one of $tRNA^{Phe}_{yeast}$ [154a]. As is obvious from these results the further study of heterologous charging reactions may become quite interesting.

Since the synthetase recognition sites have not yet been localized in a particular region of the tRNAs, and since it is known that tRNAs with altered three-dimensional structure, *i.e.* denatured tRNAs [78, 79], do not accept amino acids, one could assume that *the three-dimensional structure as a whole* must be intact for synthetase recognition. The fact that dimers, trimers, and higher aggregates of $tRNA^{Ser}_{yeast}$ have acceptor activity [155] refutes this assumption. Such activity was confirmed for dimers of $tRNA^{Ala}_{yeast}$ [156]. The conformations of aggregates in solution are certainly different from those of monomeric tRNAs. However, certain parts of the structure may be the same in aggregates and monomers and it is these parts, not the structure as a whole, which must be recognized by the synthetase. Also experiments with tRNA fragments argue against the indispensibility of the whole tRNA for recognition: Heterologous combinations of half molecules of $tRNA^{Phe}_{yeast}$ and $tRNA^{Phe}_{wheat}$ have acceptor activity [156a], as do homologous combinations of fragments in which parts of the tRNA molecules have been omitted [156b,c].

The active sites of numerous enzymes are composed of several amino acids occurring in separated regions of the sequence but brought together through folding of the chains. Similarly, synthetase recognition sites of tRNAs could be composed of several nucleotide sequences which are not adjacent in the primary structure. The stem of the clover-leaf model, the hU- and S-regions, or sequences abundant in purines [21], have been considered as possible candidates. The sequences can be proximate in the three-dimensional structure but need not be. One would certainly assume more than one binding site. Whether one or more of these sites are responsible for the specific recognition is open to question.

The synthetase recognition sites need not lie in analogous regions of all tRNAs. It would simplify the elucidation of the recognition phenomenon if the same regions of the tRNAs were always involved. This is, however, not a necessary assumption.

Work on the synthetase recognition problem will become much easier when the three-dimensional structures of one or more tRNAs are known. It is also necessary to study the structural requirements of binding between tRNA and synthetase separately from those of the actual catalytic step (aminoacylation). Interesting beginnings in this direction are the work on synthetase-tRNA complexes [133, 134, 157, 158]. Information about the forces involved in the binding of synthetase to tRNA [159] and about the functional groups involved in the catalytic step can be obtained from exact kinetic studies of the pH, salt concentration, temperature, and organic medium dependence of the charging of native and modified tRNAs.

Implication of individual regions of tRNAs involved in synthetase recognition can be obtained with the aid of "tRNA-mutants" in which single nucleotides have been exchanged for others [159a].

6.4. The Anticodon

While the structural requirements of the nucleic acid-protein interactions are still vague, those of the nucleic acid–nucleic acid interactions in the adaptor complex (Figure 1) have largely been elucidated. Just the fact that a trinucleotide sequence has been found in all tRNAs, in analogous positions of the clover-leaf model, which is antiparallel complementary to the respective codons, practically proves the adaptor hypothesis and the localization of the anticodon. The occurrence of inosine in several of these sequences was at first surprising. However, it could be correlated satisfactorily with the behavior of those tRNAs in codon recognition by the "wobble" hypothesis [160]. *Crick* postulated that I in the first position of the anticodon could interact with three different nucleotides of the third codon position, *i.e.* with U, C, or A. In addition to A:U and G:C, G:U pairs are possible

Fig. 7. Examples of codon-anticodon pairs. The anticodons have been written in the (uncommon) 3′ ← 5′ polarity in order to show the possibility of base pairing more clearly. C^+ and G^+ in the anti-codons of $tRNA^{Tyr}_{coli}$ su^- and $tRNA^{Met}_{coli}$ are still unknown odd nucleosides with the pairing characteristics of C and G, respectively. Pairing of $tRNA^{fMet}_{coli}$ with GUG, which corresponds to a "wobble" in the first position of the codon, is a pecularity of the chain-initiating tRNA. The mutation observed in suppressor strains, which makes AUC from AUG^+ (3′ ← 5′) in the anticodon of $tRNA^{Tyr}_{coli}$, allows the su^+-tRNA to read the chain terminating codon UAG as Tyr (see text).

in this position. The necessary distance for H-bonds in "wobble" pairs is possible only when the third base of the codon (or the first base of the anticodon) "wobbles" out of the position dictated by the nucleic acid double strand.

While this hypothesis was originally proposed on the basis of only a few data, the anticodon sequences and codon binding experiments that have become known since are in complete agreement: I-containing tRNAs can serve three codons; tRNAs having U or G in the first position of the anticodon can interact with 2 codons (Figure 7). The 61 codons of the genetic code (64 in total, of which 3 are chain-terminating codons) therefore do not require 61 different tRNAs. The high degree of degeneracy of the code has not to be paralleled by a similarly high multiplicity of tRNAs (see Section 7).

Direct proof of the location of the anticodon was provided by the work on $tRNA^{Tyr}_{coli}$ [59]; $tRNAs^{Tyr}_{coli}$ su^+ and su^-, according to structure analyses, differ only in one nucleotide but behave differently in the codon binding assay (Figure 7); the differing nucleotide must therefore lie in the anticodon. Experiments with a fragment from $tRNA^{fMet}_{coli}$ [161] showed that only the anticodon loop and the paired region belonging to it, but not the rest of the tRNA molecule, are essential for codon binding; a fragment containing 19 nucleotides including the anticodon can interact with AUG and GUG on the ribosome.

Nothing is known about the functions of the other odd nucleosides which, apart from I, are found in the anticodon. It is assumed that certain odd nucleosides in the anticodons of some tRNAs are the cause of unexpected behavior in codon binding. The odd nucleotide found next to the anticodon in most tRNAs could be important for the three-dimensional structure of the anticodon loop. Modification of this nucleotide, which barely influences acceptor activity (see above), causes partial [141] or complete [36] loss of the codon-binding ability.

7. Multiplicity of tRNAs and Functions other than Amino Acid Transfer

It is unknown how many different tRNAs occur in a microorganism, a plant, or an animal. As mentioned above, there are certainly more than 20, *i.e.*, more than one tRNA per amino acid. The existence of several tRNAs for the same amino acid is called multiplicity. 40–60 major tRNA species are found in the fractionations of $tRNA_{coli}$ or $tRNA_{yeast}$. This number could be larger for higher organisms. Apart from those tRNAs known to occur in greater amounts, there are always minor peaks and "shoulders" found in chromatography or countercurrent distribution. At least some of these represent actual tRNAs. However, not every peak showing acceptor activity in a fractionation can be associated with an extra tRNA species. Aggregates, various conformations of tRNAs, heterogeneity in the 3′-terminal –CCA group *etc.*, can make the number of tRNAs appear larger than it is. A few cases are mentioned below in which several tRNAs do occur for one amino acid.

One type of multiplicity is a consequence of the degeneracy of the genetic code. Because of the possibility of a "wobble" (see Section 6.4) not 6 tRNAs are necessary for the 6 serine codons; 3 $tRNAs^{Ser}$ are however necessary. Thus one tRNA each for UCU and UCC, UCA and UCG, and AGU and AGC was found to exist in *E. coli* [147]. The I-containing $tRNA^{Ser}_{yeast}$ can serve 3 codons: UCC, UCU, and UCA. $tRNAs^{Ser}$ for UCG and AG^U_C have not yet been found in yeast. These tRNAs are present only in small amounts, if at all [162]. We arrive here at a generally important fact which is also seen for tRNAs from other organisms [163]: the genetic code is universal, *i.e.* it is valid in all organisms, but some organisms seem not to use all codons, since they do not possess the appropriate tRNAs.

A further type of multiplicity of tRNAs was first demonstrated for *Neurospora* [164] and later shown also for other organisms: mitochondria contain some tRNAs which differ from those of the cytoplasm of the cell. Thus a chain-initiating $tRNA^{fMet}$ normally found only in bacteria has also been found in mitochondria from yeast [165] and human tissue culture cells [166]. One of the $tRNA^{Ser}_{yeast}$ species

[166] *J. B. Galper* and *J. E. Darnell,* Biochem. biophysic. Res. Commun. *34,* 205 (1969).

found only in trace amounts could be of mitochondrial origin [167].

Incomplete modification is the third origin of multiple tRNA species. The coexistence of U- and hU-containing $tRNA^{Ala}_{yeast}$ [52] and of unmodified, partially, and completely modified $tRNA^{Tyr}_{coli}$ [35] has already been mentioned (see Section 3 and 6.3).

tRNAs altered in the anticodon could be included in the number of tRNAs occurring in small amounts. Their role in genetic suppression has been elucidated for $tRNA^{Tyr}_{coli}$ [59].

Up to now, such sequence differences as occur in $tRNA^{Ser}_{I}$ and $tRNA^{Ser}_{II}$ from yeast [33], which differ in three nucleotides outside of the anticodon, have no functional explanation.

Some microorganisms have tRNAs that are involved in building amino acids into the cell wall [168]. These tRNAs are probably specialized for this purpose. Also amino acid incorporation into phosphatidyl glycerol seems to work *via* aminoacyl tRNAs [168a].

Animal viruses [169] and bacteriophages [54,170] synthesize their own tRNAs which are different from those of the host cell. Also a phage induced modification of a host cell tRNA has been reported [171].

Some tRNAs from microorganisms in different growth stages [172–175] and from plant [176] or animal tissue [177–180] of different degrees of differentiation gave chromatographic elution profiles which differed from the respective standards. New acceptor activity peaks were found and the disappearance of other peaks observed. However, it has not yet been possible to show that the newly appearing or disappearing tRNAs were different in structure or function from the standard tRNAs. Aggregation or change of conformation can be excluded as origin of the multiplicity by relatively easy experiments; it is more difficult to exclude heterogeneity of the –C–C–A sequence; the primary structure has to be examined in order to distinguish whether two tRNAs differ in extent of modification or in the sequence of main nucleotides. Functional differences, such as codon binding ability, are easier to determine.

Changes in multiplicity as a function of growth stage or degree of differentiation are interesting in relation to the observation that some organisms have no tRNAs or only small amounts for certain codons. Here lies a possibility for protein synthesis regulation independent of the regulation of mRNA synthesis through repression and induction. mRNAs for certain proteins or groups of proteins could contain codons for which special "regulatory" tRNAs are necessary. These tRNAs could have to be newly synthesized or formed by modification of existing tRNAs in certain differentiation stages and degraded in later stages of development.

There is little known about the regulation of tRNA synthesis and modification. Synthesis of tRNA (and rRNA) stops in certain mutants of microorganisms if one of the 20 amino acids is missing [181]; tRNA synthesis seems to be coupled to protein synthesis in these cases. It is definitely known that amino acid activation plays a role in the regulation of amino acid biosynthesis [182,183]. The amino acid itself does not inhibit its own biosynthesis if present in high concentration in the cell. Products of the amino acid activation by aminoacyl tRNA synthetases (perhaps the aminoacyl tRNAs [184]) are involved.

8. Closing Remarks

Research into the structure and function of tRNAs is proceeding so rapidly that important new results will have been published by the time this paper appears. Methods for isolating pure tRNAs are constantly being refined. Several groups are working on the elucidation of tRNA primary structures. Synthesis of a $tRNA^{Ala}_{yeast}$ cistron, a fragment of DNA complementary to $tRNA^{Ala}_{yeast}$, is making good progress [185]. It should be possible to produce the corresponding RNA on this DNA template with the aid of RNA-polymerase. This completely unmodified tRNA is an interesting starting material for many studies, *e.g.* the elucidation of the biosynthesis and the function of odd nucleotides. The problem of tRNA three-dimensional structure should in the foreseeable future be solved with the aid of X-ray structure analysis and other methods. Knowledge of the three-dimensional struc-

ture will in turn simplify studies of the various binding and recognition sites.

tRNAs are the smallest macromolecular tools of protein biosynthesis. They differ greatly from the other nucleic acids of the cell. Through the peculiarities of their structure they are able to interact specifically not only with the synthetases, but also with ribosomes and mRNA. "It almost appears as if tRNA were Nature's attempt to make an RNA molecule play the role of a protein" [186].

Because of their relatively low molecular weight the tRNAs are still in the range accessible to exact analysis by modern physical, chemical, and biochemical methods. Therefore tRNA research may help in solving some basic questions, such as the relationship of nucleic acid structure and function, and the problem of nucleic acid-protein interactions.

The author wishes to thank his co-workers and colleagues for their cooperation in those studies mentioned in the above paper that were carried out in his laboratory. The work was generously supported by the Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie.

Cyclization of Acetylenic Compounds

By W. Reppe (deceased), N. v. Kutepow, and A. Magin[*]

Dedicated to Professor B. Timm on the occasion of his 60th birthday

Cheap acetylene produced by a new process can compete with ethylene as a starting material for the large-scale production of a number of organic products. Hydroquinone and methylated hydroquinones, which are valuable industrial starting materials or intermediates, are obtained by catalytic cyclizations.

1. Introduction

The rapid development of petrochemistry, which has been brought about by the growing demand for fuels, has led to increased production of valuable chemicals. Petrochemistry is concerned not only with the production of organic raw materials (olefins, dienes, polyolefins, acetylenes, aromatic compounds, and other products) on the industrial scale, but also with the development of new catalytic and thermal processes based on petroleum and natural gas. This led *inter alia* to the development of new acetylene processes with the object of making "acetylene chemistry" competitive with "olefin chemistry".

Some time ago acetylene was an irreplaceable starting material for the large-scale production of many organic products, such as vinyl ethers, vinyl esters, vinyl chloride, acrylic compounds, and acetaldehyde. When acetylene chemistry had reached its prime, ethylene chemistry was still in its infancy, since ethylene was more expensive than acetylene and was not available in sufficiently large quantities. The production of ethylene involved laborious processes such as the low-temperature distillation of coke-oven gas, the partial hydrogenation of acetylene, or preparation from acetylene *via* acetaldehyde and ethanol.

Cracking plants with huge capacities have now made ethylene and its homologs very cheap raw materials. Many products formerly produced from acetylene are now produced by new processes based on ethylene. Examples of such new processes are the production of acetaldehyde by *Wacker*'s process, of vinyl chloride by hydroxychlorination, of vinyl acetate from ethylene, oxygen, and acetic acid, of acrylic acid by oxidation of propene, and of acrylonitrile by *Sohio*'s process. Since there is little likelihood that the cost of ethylene will fall still further, acetylene chemistry could compete with ethylene chemistry if the cost of acetylene could be reduced to a level close to that of ethylene. One advantage of acetylene chemistry is that reactions with the extremely reactive alkyne compounds proceed more rapidly and sometimes in better yields than with olefins, which are generally less reactive.

2. Preparation of Acetylene

The processes developed at BASF for the industrial production of acetylene[1,2] by cleavage of light

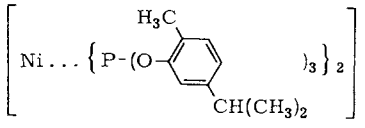
gasoline or of methane with oxygen in a burner are cheaper than the carbide process. Despite the low price of the starting materials, however, this acetylene still cannot compete in price with ethylene. Another process, the immersed flame process [1], was therefore devised at BASF. In this process, crude oil is vaporized with an oxygen-fed flame dipping into a crude oil sump, and the resulting cleavage gas containing acetylene is quenched by the surrounding oil. The immersed flame process is economical, since any crude oil may be used, and the carbon black formed as a by-product can be returned to the immersion burner as an oil-carbon black suspension for combustion. In addition to acetylene, the immersed flame process yields roughly the same amount of ethylene and synthesis gas. The trials carried out so far indicate that the immersed flame process will allow the industrial-scale production of acetylene at a price at which processes based on acetylene can compete with those based on ethylene.



3. Cyclization Reactions

Acetylene or substituted alkyne derivatives undergo a number of cyclization reactions, of which no industrial use has yet been made. Products of such cyclizations include cyclooctatetraene [3, 4], benzene [5], substituted benzenes [5] such as trishydroxymethylbenzene, and other aromatic compounds. Since benzene and its homologs are cheaply available in large quantities by catalytic dehydrogenation of linear paraffins (hydroforming process), the production of benzene by catalytic cyclization of acetylene (*Reppe* [5]) in the presence of carbonylnickel-phosphine complexes such as $Ni(CO)_2[P(C_6H_5)_3]_2$ will not come into use despite the expected lower price of acetylene. On the other hand, the Reppe cyclooctatetraene synthesis and consequently cyclooctatetraene chemistry are becoming more promising as the cost of acetylene decreases, particularly since the cyclooctatetraene synthesis gives a yield of 70 % based on acetylene, and the costs of material and of production are low.

The catalytic cyclization of alkynes discovered by *Reppe* in the 1940's, when applied to propargyl alcohol [5] in the presence of $Ni(CO)_2[P(C_6H_5)_3]_2$ as catalyst, leads in almost quantitative yield to a mixture of 1,3,5- and 1,2,4-trishydroxymethylbenzenes (in a ratio of about 1 : 1). The mixture can be readily oxidized with nitric acid to trimesic and trimellitic acids. The cyclization of propargyl alcohol is strongly exothermic, and proceeds so violently that it can be controlled only at high dilutions, *e.g.* with benzene, and by careful addition of propargyl alcohol. Recent investigations have shown [6] that it can be very readily controlled and proceeds in good yields with practically no resin formation if carbonyl-free phosphite- or thiophosphitenickel(0) complexes such as acrylonitrilebis-(tri-*o*-cresylphosphite)nickel(0) *(1)* and bis(trithymylphosphite)nickel(0) *(2)* or nickel(0) complexes with similar structures are used as the catalyst instead of carbonylnickel-phosphine complexes.

(1)

(2)

Nickel(0) complexes in which the ligands have a branched or bulky substituent (*e.g.* isopropyl, *tert*-butyl, *o*-biphenylyl) *ortho* to the hetero atom that binds the organic residue to the P atom are particularly active catalysts.

For the cyclization of alkynes with these nickel complexes, a solution of the catalyst, *e.g.* in benzene, is heated to 70 °C and the alkyne is added slowly. The reaction, which usually begins immediately, can be controlled by the further addition of the catalyst solution and the alkyne, so that the reaction temperature of 70–80 °C can be maintained without external heat-

Table 1. Cyclic trimerization products of alkynes.

Alkyne compound	Cyclization product(s)	Yield (%)
2-Methyl-1-buten-3-yne	1,3,5-Triisopropenylbenzene 1,2,4-Triisopropenylbenzene	50
Propargyl alcohol	1,3,5-Tris(hydroxymethyl)benzene 1,2,4-Tris(hydroxymethyl)benzene	95 (1:1)
3-Butyn-2-ol	1,3,5-Tris(α-hydroxyethyl)-benzene 1,2,4-Tris(α-hydroxyethyl)-benzene	89 (1:1)
2-Methyl-3-butyn-2-ol	1,3,5-Tris(α-hydroxy-α-methylethyl)-benzene	93
Methyl propiolate	Trimesic acid Trimellitic acid	85
N,*N*-Dimethyl-2-propinyl-1-amine	1,3,5-Tris(dimethylaminomethyl)-benzene	67
N,*N*-Diethyl-3-butinyl-1-amine	1,3,5-Tris(α-diethylaminoethyl)benzene	93
Propargyl ethyl ether	1,3,5-Tris(ethoxymethyl)benzene 1,2,4-Tris(ethoxymethyl)benzene	77 (1:1)

ing. This process is applicable to practically all alkynes that, apart from the CC triple bond, are saturated or unsaturated or also contain functional groups, *e.g.* alkynols, alkynyl ethers, alkynecarboxylic acids and their esters, alkynylamines, and alkynediols. Some examples of the cyclotrimerization of alkynes are listed in Table 1.

The cyclotrimerization of alkynes does not always proceed in good yields. Propargyl chloride, for example, cannot be cyclized at all, and propargyl aldehyde gives only very low yields of benzenetricarbaldehyde. The cyclotrimerization of alkynediols and their derivatives also sometimes gives unsatisfactory yields (see Table 1).

These cyclizations are gaining in importance, not only because the alkynes are becoming cheaper, but also because of the general trend toward the development of new catalytic processes for the production of aromatic compounds. The initiation of this trend was partly due to the gradual closing down of town gasworks and the consequent decrease in the supply of tar products. The syntheses of hydroquinone from acetylene, carbon monoxide, and water and of methylated hydroquinones from propyne, 2-butyne, carbon monoxide, and water, which had been partially investigated earlier, have been re-examined and developed further in the light of experience accumulated in working with acetylene at high pressures.

3.1. Hydroquinone Synthesis

In the early 1940's, *Reppe*[7] discovered that acetylene and pentacarbonyliron react in aqueous alcohol at low temperatures and pressures (50–80 °C, 20–25 atm) to give hydroquinone. This reaction course was surprising in view of *Reppe*'s alcohol synthesis[8]

$$Fe(CO)_5 + H_2O \xrightarrow{\text{Alkali}} H_2Fe(CO)_4 + CO_2 \quad \text{(base reaction)}$$

$$H_2Fe(CO)_4 + 2\,R^1CH{=}CHR^2 + 4\,H_2O \rightarrow 2\,R^1CH_2{-}\underset{\displaystyle CH_2OH}{\overset{\displaystyle |}{C}}HR^2 + FeCO_3 + CO_2 + H_2O \qquad R^1, R^2 = H, \text{alkyl}$$

by analogy with which, the reaction of acetylene, pentacarbonyliron, and water would be expected to give unsaturated alcohols.

The hydroquinone synthesis also proceeds *via* the "base reaction", and is stoichiometric with respect to pentacarbonyliron. It is therefore favored by the addition of basic substances, particularly amines. The presence of a base is not, however, absolutely necessary, since the hydroquinone is also formed in the presence of compounds containing hydroxyl groups, such as water and alcohols. The following equations illustrate the course of the stoichiometric hydroquinone synthesis[7]:

$$Fe(CO)_5 + H_2O \rightarrow H_2Fe(CO)_4 + CO_2 \quad \text{(base reaction)}$$

$$H_2Fe(CO)_4 + 4\,C_2H_2 + 2\,H_2O \rightarrow 2\,p\text{-HO-}C_6H_4\text{-OH} + Fe(OH)_2$$

$$Fe(OH)_2 + CO_2 \rightarrow FeCO_3 + H_2O$$

$$Fe(CO)_5 + 4\,C_2H_2 + 2\,H_2O \rightarrow 2\,p\text{-HO-}C_6H_4\text{-OH} + FeCO_3$$

When bases are used, the hydroquinone yields are about 30 %[9] based on acetylene or alkylated alkynes.

As in all other carbonylations, efforts were made to induce the hydroquinone synthesis to proceed catalytically, *i.e.* instead of using carbonyliron as the carbon monoxide donor, to use carbon monoxide gas under pressure with carbonyliron as a catalyst.

According to *Reppe*, the hydroquinone synthesis can proceed partly catalytically[10] in the presence of complex salts such as $[Fe(NH_3)_6][Co(CO)_4]_2$ and $[Co(NH_3)_6][Co(CO)_4]_2$.

$$2\,CH{\equiv}CH + 3\,CO + H_2O \xrightarrow[80-100\,^\circ C,\ 5-30\ atm]{\text{Catalyst}} p\text{-HO-}C_6H_4\text{-OH} + CO_2$$

Most of the carbon monoxide, as before, is supplied by the carbonylmetal. The absolute yield of hydroquinone in this process is 35–50 % based on acetylene.

By varying the reaction conditions (*e.g.* by increasing the reaction pressure to 600–700 atm, the acetylene partial pressure to about 70 atm, and the temperature to above 170 °C) and by the use of suitable solvents (*e.g.* dioxane) and introduction of the water at a measured rate corresponding to the conversion (*e.g.* by addition of salt hydrates that give off water), the hydroquinone synthesis could be substantially improved in discontinuous experiments at first[11]. Higher hydroquinone yields (up to 70 % based on acetylene) could be obtained by these measures than in the process described earlier. Moreover, a large part of the carbon monoxide required in this process is supplied by the carbon monoxide gas, and not by the pentacarbonyliron, which also acts as a catalyst. Acrylic acid, the ester of hydracrylic acid with acrylic acid, polyacrylates containing iron, and succinic and other acids are formed as by-products of the hydroquinone synthesis.

We are now applying the experience and results accumulated from the discontinuous hydroquinone experiments to a continuous process in small reaction towers. The hydroquinone can be isolated from the crude product by various methods, such as recrystallization from water after removal of the solvent by distillation. A particularly pure hydroquinone is obtained if the solvent dioxane is distilled off together with water and pentacarbonyliron, the impure hydroquinone left behind being sublimed under vacuum and the sublimate stirred with cold toluene.

One advantage of the hydroquinone synthesis with pentacarbonyliron as the catalyst is the low price of the latter as compared with those of other catalysts, such as the ruthenium and rhodium compounds.

Howk and *Sauer*[12] allowed acetylene and carbon monoxide to react in the presence of a halide, carbonyl, or chelate of ruthenium or rhodium in water or alcohol at high temperatures

[7] *W. Reppe* and *H. Vetter*, Liebigs Ann. Chem. *582*, 133 (1953).

[11] *W. Reppe* and *A. Magin*, German Pat. 1232974 (1965), BASF.

[12] *B. W. Howk* and *J. C. Sauer*, US-Pat. 3055949 (1958), Brit. Pat. 850433 (1958), German Pat. 1135486 (1959), Du Pont.

and high pressures. They used aryl derivatives of group V elements, such as triphenylphosphine and triphenylstibine, as additional activators. The hydroquinone yield in this process is 4—55 % based on the acetylenic compound. The advantage of this process is the small amount of catalyst required, while its disadvantage is the danger of decomposition of the acetylene. Thus after evacuation of the autoclave, the acetylene is dissolved in a strongly cooled solvent, and after heating to the reaction temperature, carbon monoxide is forced in under a pressure of 600–900 atm. When this procedure is used, the system sometimes lies in the acetylene decomposition range before the introduction of the carbon monoxide because of an excessively high acetylene concentration in the gas phase.

In another method, which was discovered by *Pino, Braca,* and *Sbrana*[13], hydroquinone can be prepared from acetylene, carbon monoxide, and hydrogen, *i.e.* in the absence of water or compounds containing hydroxyl groups, with a trimeric carbonylruthenium as the catalyst and in a suitable solvent at 100—300 °C and 50—350 atm, in yields of up to 33 % based on the acetylene that reacts. Small quantities of catalyst are required, and its life is long. The loss of carbon monoxide that results from the formation of carbon dioxide in the presence of compounds containing hydroxyl groups is also avoided.

The Japanese Ajinomoto Company[14] recently discovered another variant of the hydroquinone synthesis, in which acetylene dissolved in water or alcohol (0.1—2 mole/l of solvent) is allowed to react with carbon monoxide or a mixture of carbon monoxide and hydrogen at high temperatures and pressures in the presence of rhodium compounds as catalyst. The reaction is accelerated by halides. The yields based on acetylene are 60—70 %.

One disadvantage of all processes in which rhodium catalysts are used is the fact that owing to the very high price of rhodium, it is absolutely essential to recover the rhodium compounds from the reaction product, and this recovery is expensive and involves difficulties.

The hydrogen required for the formation of hydroquinone in the synthesis using pentacarbonyliron as catalyst is supplied by the tetracarbonyldihydridoiron formed in the base reaction from pentacarbonyliron and water, which reacts with fresh carbon monoxide to give hydrogen and pentacarbonyliron. The course of the reaction is practically based on the water-gas reaction, which is controlled by pentacarbonyliron as the catalyst.

$$Fe(CO)_5 + H_2O \rightarrow H_2Fe(CO)_4 + CO_2$$
$$H_2Fe(CO)_4 + CO \rightarrow Fe(CO)_5 + H_2$$
$$CO + H_2O \rightarrow CO_2 + H_2$$

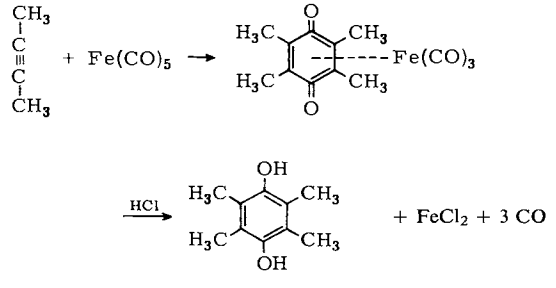
3.2. Cyclizations with Alkylated Alkynes

The hydroquinone synthesis with pentacarbonyliron as catalyst is applicable to all alkylated alkynes. Experiments have shown that methylacetylene and dimethylacetylene react more rapidly and under milder conditions than acetylene itself.



Thus a synthesis of trimethylhydroquinone from propyne, 2-butyne (1 : 1), carbon monoxide, and water with a cheap catalyst such as pentacarbonyliron has been developed on the basis of the process described for acetylene[11]. Trimethylhydroquinone is used in the synthesis of vitamin E.

Together with trimethylhydroquinone *(3)* as the principal product (≈ 55 %), however, tetramethylhydroquinone *(4)* (≈ 22 %) and 2,5- *(6)* (≈ 12 %)

and 2,6-dimethylhydroquinone *(5)* (≈ 11 %) are also formed. The yield of methylated hydroquinones, based on propyne and butyne, is up to 95 %. The formation of trimethylhydroquinone predominates even when the molar ratio of propyne to butyne is appreciably varied.

The course of the synthesis of methylated hydroquinones can be partly explained as a result of experiments by *Sternberg*[15]. This author obtained tetramethylhydroquinone by allowing two moles of dimethylacetylene to react with one mole of penta-

[15] *H. W. Sternberg,* J. Amer. chem. Soc. *80,* 1009 (1958).

carbonyliron under the action of sunlight to give a carbonyliron complex, which he then decomposed with hydrochloric acid.

It may be assumed that the synthesis of the trimethylhydroquinone from methylacetylene and dimethylacetylene proceeds *via* a carbonyliron complex having a similar structure; the complex is decomposed in this case by tetracarbonyldihydridoiron instead of by hydrochloric acid.

For the trimethylhydroquinone synthesis, it is very important to establish the reaction conditions under which it can proceed mainly catalytically.

The catalytic component of the synthesis follows from the percentage contribution of carbon monoxide gas to the total carbon monoxide consumed, the possible sources of carbon monoxide being the carbon monoxide gas and the pentacarbonyliron. Experiments in autoclaves have shown that the catalytic trimethylhydroquinone synthesis is strongly dependent on the pressure (Fig. 1). The synthesis proceeds practically stoichiometrically at 100 atm and 170 °C, but is 85–92 % catalytic at 700 atmospheres and under otherwise identical conditions.

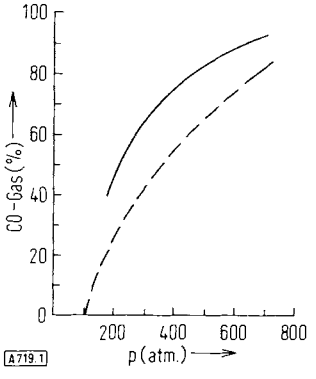


Fig. 1. Influence of the reaction pressure on the catalytic course of the trimethylhydroquinone synthesis at 160—170 °C.
Ordinate: Contribution of CO gas to the total CO consumption (from CO gas and $Fe(CO)_5$); ——: experiments in a 50 l reactor; - - - - -: experiments in a 0.8 l rolling autoclave.

The influence of the temperature on the synthesis is small over a narrow pressure range. Between 155 and 190 °C at 650 to 700 atm, the percentage contribution of carbon monoxide gas to the total carbon monoxide consumption decreases by about 10 % (autoclave experiment).

In addition to the usual advantages of catalysis, a largely catalytic course in this synthesis is even more desirable since iron ions resulting from the decomposition of pentacarbonyliron in a stoichiometric reaction form undesirable, insoluble iron compounds such as iron oxide. Moreover, iron ions react with the methacrylic and dimethacrylic acids formed as by-products to give polymeric iron acrylates containing up to 60 % of iron. All these insoluble compounds can lead to blockages in continuous-process furnaces.

On removal of the by-products and of the solvent, the mixture of methylated hydroquinones formed (referred to in future as the hydroquinone mixture) consists of about 55 % of trimethylhydroquinone and 45 % of other methylated hydroquinones. The influence of the molar ratio of propyne to 2-butyne on the composition of the hydroquinone mixture was therefore studied in autoclaves (see Fig. 2). The curves show that the percentage of trimethylhydroquinone *(3)* reaches its maximum value (55 %) at a molar ratio of propyne : 2-butyne = 50 : 50.

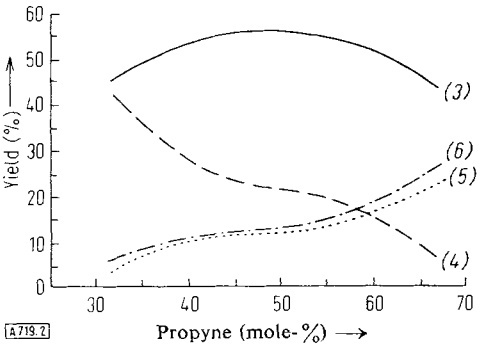

Fig. 2 Influence of the molar ratio propyne: 2-butyne on the composition of the mixture of methylated hydroquinones *(3)—(6)*.

To determine the conversion of propyne and butyne into the hydroquinone mixture as a function of the reaction conditions such as the concentrations of catalyst and of water and the contact time, we carried out experiments in 0.8 l rolling autoclaves.

The reaction mixture used generally contained about 70–80 % of dioxane, 7—9 % of propyne, and 9—10 % of butyne; the remainder consisted of pentacarbonyliron and water.

300—400 atm of carbon monoxide were forced in over the cold reaction mixture. When the reaction temperature of 170—200 °C had been reached, more carbon monoxide was pumped in to bring the pressure to the desired 600—700 atm.

Solvents such as acetone, methylpyrrolidone, and tetrahydrofuran were tried; dioxane was found to be particularly suitable.

The conversion of the alkynes into the hydroquinone mixture increases with increasing catalyst concentration. It is best to keep the pentacarbonyliron concentration below 20 % and to accept a conversion of less than 70 %. Higher carbonyliron concentrations lead to a decrease in the percentage contribution of carbon monoxide gas to the total carbon monoxide consumption, *i.e.* to a decrease in the catalytic component of the synthesis.

The influence of the water concentration in the reaction mixture on the conversion is very great at levels below 4 %. Higher water concentrations offer no advantage (see Fig. 3).

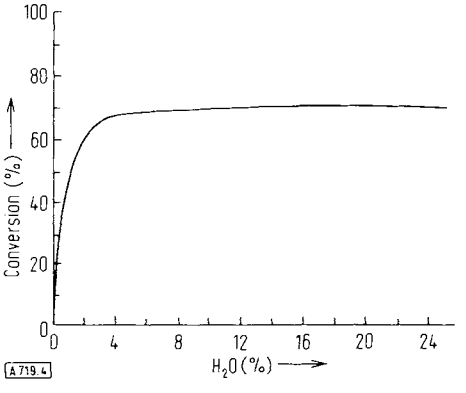

Fig. 3. Influence of the water concentration in the reaction mixture on the conversion of propyne + 2-butyne into the hydroquinone mixture.

In the hydroquinone synthesis, unlike in the trimethylhydroquinone synthesis, the yield and the conversion are reduced by higher water concentrations in the reaction medium, and the water must therefore be added at a measured rate.

While the conversion in the trimethylhydroquinone synthesis varies with the reaction conditions, the yield of hydroquinone mixture is about 95 % based on propyne + 2-butyne, with an approximately adjustable trimethylhydroquinone content of 55 %. The average space-time yield based on the mixture of methylated hydroquinones is about 1.0 in the autoclave experiments, with peak values of about 1.5 kg l^{-1} day^{-1}, corresponding to 0.55 and 0.66 kg l^{-1} day^{-1} respectively based on trimethylhydroquinone.

In the hydroquinone experiments in autoclaves under pressures of 600–700 atm, the content of alkynes in the gas phase (which consists mainly of carbon monoxide) is less than 5 %, *i.e.* well on the safe side of the explosion limit, owing to the ready solubility of alkynes in the reaction mixture. Measurements by *Zieger*[15a] have shown that the decomposition limit of pure acetylene-carbon monoxide gas mixtures at 600–700 atm is around 12 % of acetylene and 88 % of carbon monoxide, and the explosion range is reached only above this acetylene content. Since propyne and 2-butyne decompose less readily than acetylene, and the vapor pressure of the solvent has an inhibiting action on the decomposition, the discontinuous hydroquinone and trimethylhydroquinone experiments described are perfectly safe.

The trimethylhydroquinone synthesis was also carried out continuously in a small trials apparatus.

The feed (200 ml/h), which consisted of dioxane, propyne, butyne, pentacarbonyliron, and water, had approximately the same composition as the reaction mixtures in the discontinuous autoclave experiments. The continuous experiments were generally carried out at 160—200 °C and 600 to 650 atm. The feed was introduced, by means of a metering pump, into the lower part of the furnace together with the carbon monoxide, and the reaction product from the top end of the furnace was allowed to expand past a pressure inspection window into a discharge vessel.

The resulting conversions of propyne and butyne into the methylated hydroquinones were about 50–60 %, with a yield of 95 %. The conversion can be considerably increased by the use of a higher carbonyliron concentration in the reaction mixture.

By optimization of the reaction conditions, it was possible in the continuous experiments to increase the space-time yield of the methylated hydroquinones to about 1.5 kg l^{-1} day^{-1} and that of trimethylhydroquinone to about 0.7 kg l^{-1} day^{-1}.

The methylated hydroquinones *(3)—(6)* in the mixture were determined as trimethylsilyl ethers by gas chromatography and directly by NMR spectroscopy. The very small quantities of iron present in the samples for NMR spectroscopy first had to be eliminated, *e.g.* by vacuum sublimation (0.1—1 torr and up to 180 °C) of the methylated hydroquinones.

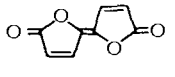
It is practically impossible to separate the trimethylhydroquinone from the other methylated hydroquinones by distillation, since all methylated hydroquinones preferentially sublime under vacuum, and must be heated so strongly for distillation that large losses occur by decomposition.

[15a] *A. Zieger* (BASF), unpublished.

Quantitative separation of trimethylhydroquinone and tetramethylhydroquinone by fractional crystallization is impossible, since the two compounds (as is shown by Debye-Scherrer photographs) are isomorphous, and so form solid solutions.

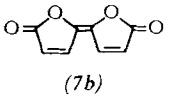
The hydroquinones could be separated in good yields by oxidation to the corresponding quinones and separation of the quinones by vacuum distillation. Hydrogenation of the pure trimethylquinone then gave trimethylhydroquinone. The separation of the methylated quinones by vacuum distillation presents no difficulties, owing to their favorable vapor pressure curves.

Methylated hydroquinones can be oxidized to quinones in various ways. In the stoichiometric method, nitric acid[16], or even iron(III) sulfate in small laboratory experiments, may be used as the oxidizing agent.



Many heavy metal salts have been examined as catalysts for catalytic air oxidation experiments. An aqueous solution of 3–5 % of $CuCl_2$ and 6 % of NH_4Cl was particularly active. The methylated quinones formed on catalytic air oxidation react with unreacted methylated hydroquinones to give quinhydrones, and they thus block the oxidation. The hydroquinones could be oxidized to the quinones in solvents such as cyclohexane, in which only the quinones dissolve, and the quinones were then separated in a simple extraction apparatus in a yield of 97 %.

To isolate the trimethylbenzoquinone, the quinones were fractionated at 10–70 torr[17]. The trimethylbenzoquinone isolated in this way was almost quantitatively hydrogenated to trimethylhydroquinone in alcohol at room temperature and at a hydrogen pressure of about 100 atm in the presence of Raney nickel.



The effective yield of 96–99 % trimethylhydroquinone is 44 % based on propyne and butyne; this value is calculated from the yield of the methylhydroquinone synthesis (95 %), the content of trimethylhydroquinone in the hydroquinone mixture (55 %), and the yields of the oxidation (97 %), the distillative separation of the quinone mixture (90 %), and the hydrogenation of trimethylquinone (98 %). The yield of the quinone distillation can be further improved.

3.3. Synthesis of Unsaturated Dilactones

According to *Reppe*, the reaction of acetylene and carbon monoxide (in a ratio of 1 : 2) in the absence of water and in the presence of complex cobalt catalysts or their components can lead under pressure to heterocyclic compounds, such as the unsaturated dilactone *(7)*, which is obtained as a *cis,trans* isomer mixture[18] [*(7a)*, m.p. 256–257 °C; *(7b)*, m.p. 234 to 235 °C].

[17] *H.-I. Joschek* (BASF), unpublished.

[18] *W. Reppe* and *A. Magin*, DAS 1071077 (1965), BASF.

The catalysts consist of octacarbonyldicobalt or cobalt salts and compounds such as ketones or nitriles, which can form complexes with $Co_2(CO)_8$, *e.g.* with the following composition [19]:

$$[Co(L)_n]^{2\oplus}[Co(CO)_4]_2^{\ominus} \quad \begin{matrix} L = \text{ketone or nitrile} \\ n = 1-6 \end{matrix}$$

The reaction proceeds at 40–100 °C with a dilactone yield of 15–40 % based on acetylene; coumarin is formed as a by-product. Substituted acetylenes give correspondingly substituted dilactones. It has also been suggested [20] that the reaction be carried out at 50–3000 atm and 60–175 °C.

4. Closing Remarks

Some of the cyclic compounds described may prove interesting as starting materials and intermediates. The condensation of trimethylhydroquinone with isophytol, for example, yields DL-α-tocopherol (vitamin E). A cheap hydroquinone can also be used for the preparation of anthraquinone by oxidation to *p*-benzoquinone, Diels-Alder reaction of the latter in a molar ratio of 1 : 2 with butadiene [21], and air oxidation of the resulting octahydroanthraquinone in ethanolic potassium hydroxide solution. The yield of anthraquinone based on benzoquinone is about 85 %. The synthesis of unsaturated dilactones may open up a new route to suberic acid if acetylene is available at a favorable price, since such dilactones can be readily hydrogenated with platinum catalysts in polar solvents to give suberic acid.

The cyclization of alkynes shows that if these compounds can be obtained at a reasonable price, they can be used for the production of cheap cyclic intermediates. The economic aspect becomes even more attractive if even cheaper materials such as carbon monoxide and water are used as well as acetylenes.

Modern Analysis[1]

By H. Kienitz[*]

Dedicated to Professor B. Timm on the occasion of his 60th birthday

The important advances being made in modern analytical methods are indicative of the fundamental changes that are occurring in the theory and practice of "analytical chemistry". "Information optimization" demands a new approach in teaching and research, and calls for the integration of chemistry with other scientific and technical disciplines.

1. Introduction

Analysis may be defined as the gaining of information about the qualitative and quantitative composition and about the steric structure of substances and chemical species. The modern paths to this type of information differ in method (chemical and physical processes), in execution (accuracy, speed, economy, and possibility of automation), and with regard to acquisition, critical examination, and representation of the results. The analyst's knowledge, discretion, and experience are applied to the task of choosing the optimum path, which best suits the manifold factors involved and the analytical problems, and provides an adequate and correct result.

A survey of the problems and sectors of analysis is given in Table 1.

Although much scientific progress and industrial development has only been made possible by the results of analytical investigations, analysis has unfortunately still not received full recognition as a subject in its own right. The manufacture of inorganic and organic products can no longer be carried out without constant analytical supervision. Trace and micro methods of analysis have found a place in every field of applied natural science, and have helped us to understand processes that were formerly beyond the reach of quantitative examination.

[1] Based on a lecture read at the General Meeting of the Gesellschaft Deutscher Chemiker at Hamburg on September 18, 1969.

Table 1.

Problems of analysis:

1. Qualitative analysis of a mixture of substances (for elements, ions, atomic groupings, functional groups, or components)
2. Quantitative analysis of parts or of the whole of a mixture of substances
3. Qualitative analysis of a chemical species (single molecule, macromolecule, unit cell)
4. Quantitative analysis of a chemical species (number and steric arrangement of the atoms and atomic groupings)

Sectors of analysis:

1. Sampling and sample preparation
2. Analytical procedure
   - A. Methods
     - a) chemical
     - b) physical, with alteration of the substance
     - c) physical, without alteration of the substance
   - B. Conditions, imposed
     - a) by the analytical problem
     - b) by the substance to be investigated (quantity, nature, and state)
   - C. Requirements
     - a) accurate, comprehensive, critical
     - b) fast
     - c) economical
     - d) automatic
3. Critical evaluation of the analytical result. Drawing of conclusions from this result

In this article we shall consider some modern developments selected from the many aspects of the analyst's work.

2. Analysis of Inorganic Solids

The sampling of inorganic solids presents interesting and often difficult problems. Sampling is the first step in the sequence sampling – sample preparation – analysis – data processing. A sample taken from a quantity of material that is often many orders of magnitude greater should be representative.

Whether or not sampling is satisfactory depends on the requirements; thus, the requirements for a preliminary analysis (accuracy ±10%) are less rigorous than those for an analysis for commercial purposes (accuracy ±1 or even 0.2%). Sampling errors are in general fully reflected in the final result. The number and size of the samples to be taken are determined statistically by the homogeneity of the material, the uniformity of its density (separation of the components), and its particle size. The probability of inclusion in the sample should be uniform for the material as a whole. This is possible, in general, only if the material is in motion. Mechanized sampling therefore always uses a moving stream of material, such as the material transported by a conveyor belt, the sample being taken on the basis of quantity or of time. This is followed by gradual mechanical reduction of the size of the sample, which is also comminuted in stages. Large-scale units capable of sampling with a reproducibility of a few tenths of one percent have been constructed in recent years for the metal and potash industries.

The influence of inhomogeneities in a solid sample on the analytical result increases as the region covered by the analytical process decreases. Thus inhomogeneities are of practically no importance in neutron activation analysis, whereas they have an appreciable effect in X-ray fluorescence analysis and a strong effect in mass and emission spectrometry.

The detection limits and application ranges of some chemical and physical methods are shown in Figure 1.

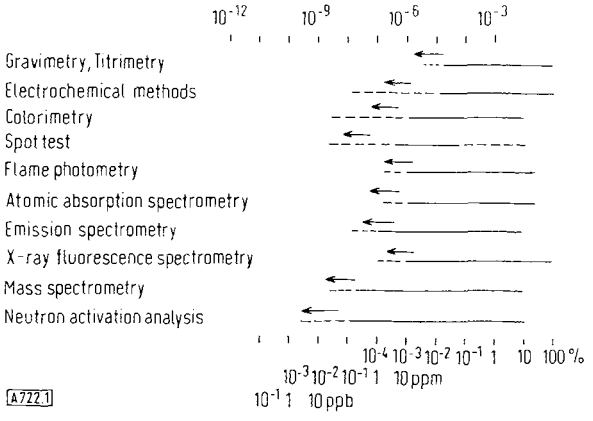

Fig. 1. Detection limits (←) and application ranges (- - - ——) of important analytical methods.

The element specificity of these methods is generally satisfactory, though masking can occur (*e.g.* in the analysis of metals) in both emission and mass spectrometry. The problem of masking can often be overcome by combination with chemical methods.

The detection limits for atomic absorption spectroscopy have recently been improved by two orders of magnitude by evaporation of the samples in graphite cells, with the result that they are now close to the limits for emission and mass spectrometry.

Wider use of neutron activation analysis has been hindered by the lack of neutron sources with adequate neutron fluxes (apart from nuclear reactors) and of detectors with narrow energy bands. The situation has been improved by neutron sources that produce neutron fluxes of up to 10^{10} n/cm² by the T(d,n)He reaction; fast neutrons are particularly desirable for the analysis of elements of the first short period, which are only weakly activated by thermal neutrons in the reactor because of their small cross section. However, activation with fast neutrons has the disadvantages that the detection limits for activation in reactors (neutron flux 10^{14} n/cm²) cannot be reached for heavier elements, and that very short-lived nuclides are formed in most cases. The detection limits for the light elements nitrogen, oxygen, fluorine, and phosphorus, on the other hand, are between 10 and 100 μg for a neutron flux of 10^9 n/cm².

The resolving power of scintillation detectors with NaI crystals and photomultipliers, such as are used for the measurement of the radiation from the activated elements, is only about one tenth of that of the semiconductor detectors that have recently come into use. Thus the relative energy half-width of the ^{60}Co γ line at 1.33 MeV is 5.9% (80 keV) when measured with an NaI(Tl) crystal, but only 0.45% (6 keV) with a Ge(Li) detector (Fig. 2).

In neutron activation analysis, in which several nuclides are activated during the irradiation, many individual nuclides can be both identified and used for very selective quantitative determinations on the basis of the typical maxima of their gamma spectra and the rate of decay of their radiation, corresponding to the half lives. Wet separations of the nuclides formed on irradiation can thus be largely avoided.

Special mention should be made of the extreme difficulty of the preparation of calibration standards for trace determinations. Conflicting results, often differing by several orders of magnitude, depending on the method (particularly in the ppm range), are not un-

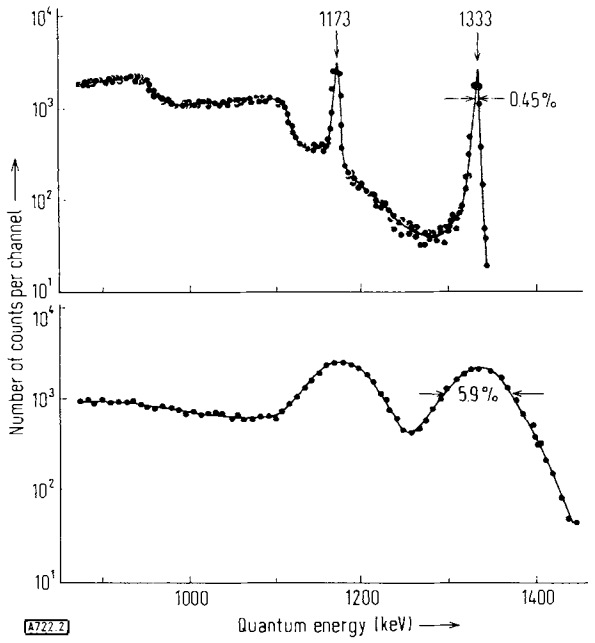

Fig. 2. Comparison of the energy spectrum of ^{60}Co recorded with a germanium detector (top) and with a scintillation detector using an NaI crystal (bottom).

common. Absolute values might be obtained by mass spectrometry if the ion sources had fixed ion yields for known ionization probabilities without interelement effects; the results are, however, at best only semiquantitative. Reliable calibration standards are therefore essential in trace analyses, whether by mass spectrometry or by any other method. Zone melting can be used for the purification and subsequent doping of samples whose melting points are not too high (≈800 to 1000 °C). Since it is very difficult to avoid inhomogeneities and contamination during the mixing, fusing, or sintering of samples, the only way of obtaining quantitative standards for trace concentrations is by chemical analysis, though some uncertainty remains even here because of possible contamination during concentration.

For compact inhomogeneous samples, where we are interested not in an average analysis but in the investigation of individual phases and their distribution in an area or volume, the examination can be carried out after mechanical or chemical separation of the phases, or otherwise by point analysis of small surface or volume elements (on ground surfaces or their sections) without phase separation.

The principal methods for the analysis of solids are surveyed in Figure 3.

Point examination of solid samples can be achieved with the aid of electron, ion, or laser beams. A region about 30 μm in diameter is evaporated from the sample *e.g.* with a laser beam to form a crater. The vapor is ionized with auxiliary electrodes and analyzed by emission or mass spectrometry. The electron beam of a "microprobe" has a diameter of ≈2 μm. It produces element-specific secondary X radiation at the surface of the sample, and the spectrum and intensity of this radiation are determined with proportional counter tubes. The scanning of the surface may also be carried

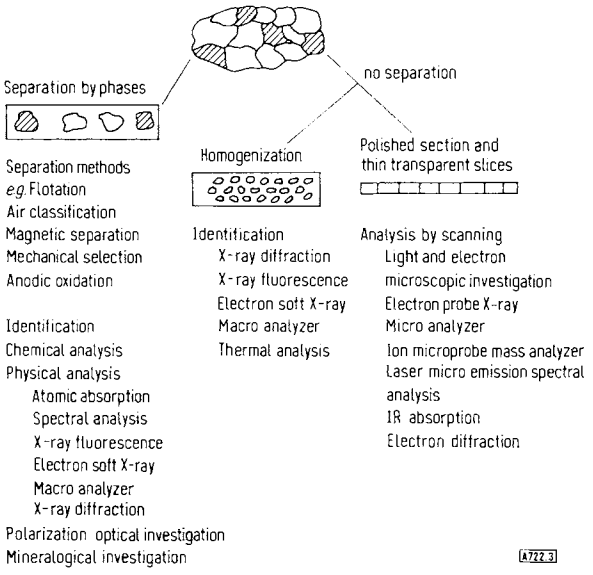

Fig. 3. Analysis of solids.

out with an ion beam, the secondary ions produced being led to a small mass spectrometer. The electron and ion microprobes give only semiquantitative analytical information for local areas; the distribution of the phases in a surface region can, however, be found very accurately by measurement of the relative areas.

With the macroprobe, the area irradiated with electrons (about 2 cm^2) is several orders of magnitude greater than with the microprobe. The X-rays produced at the surface of the sample are again used for qualitative and quantitative analysis. This is a good method for the determination of the light elements boron to sulfur. Macroprobe analysis is more sensitive to surface impurities than X-ray fluorescence analysis; moreover, its use is confined to electrically conducting samples (or samples with a conducting coating).

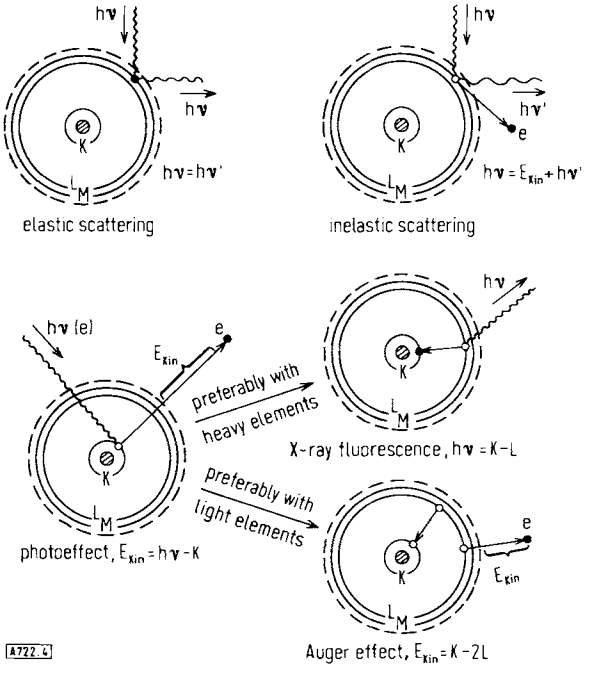

Fig. 4. Interaction of X-rays (or of electrons) with matter.

X-ray fluorescence, microprobe, and macroprobe analyses are based on atomic processes in which electrons or X-ray quanta interact with the electrons of an atom (Fig. 4).

The photoeffect involves the ejection of electrons from the inner shells by the incident X-ray quanta. The bonding state of the emitted electron can be deduced from its kinetic energy and the energy of the absorbed quantum. The vacancy left by the ejected electron is then filled by outer electrons, the energy liberated being released as an X-ray quantum (X-ray fluorescence) or in the form of a secondary emitted electron (Auger electron). For the ejection of inner electrons, the X-ray quanta may be replaced by electrons of corresponding energy.

The possibilities offered by spectroscopy based on the emission of Auger electrons will be merely mentioned here. This method can be used for the analysis of surfaces (the topmost one or two layers of atoms), and has a high detection sensitivity, particularly for light elements. It is possible in this way to detect partial coverages of 0.1 (and in special cases down to 0.01) layer of atoms. The method is therefore very promising for use in problems of catalysis, adsorption, corrosion, and surface diffusion.

The photoelectric effect, in which electrons are released from the inner (K or L) shells of an atom by X-ray quanta ($Al_{K\alpha}$ or $Mg_{K\alpha}$ radiation) has recently acquired growing analytical importance. The emitted electrons are separated in a magnetic field according to their energy distribution (ESCA, *E*lectron *S*pectroscopy for *C*hemical *A*nalysis). The element-specific energy distribution of these secondary electrons is shown in Figure 5.

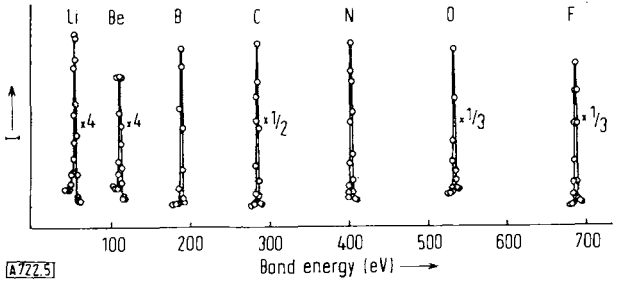

Fig. 5. Photoelectron signal of the elements of the second period (K shell).

Since the kinetic energy of the emitted electrons varies by several electron volts (1 eV $\triangleq$ 29 kcal/mole), according to the bonding state of the atoms, conclusions may be drawn, for example, regarding the bonding state of the two differently bound sulfur atoms in thiosulfate or of the differently bound iodine atoms in iodide or iodate. This method, which possesses considerable potential for the analysis of organic compounds, will be dealt with again in Section 4.

Development trends in the analysis of inorganic substances, taken as a whole, point to the need for the determination of traces, non-destructive methods of analysis, and methods that allow at least semiquantitative analysis of the smallest possible areas or volumes. There is also an increasing demand for methods that are capable of being automated.

3. Chromatography

F. F. Runge, who discovered aniline in coal tar, separated the components of dyes into brightly colored ring-shaped zones by placing a drop of a solution in the middle of a sheet of blotting paper. He mentioned this process as early as 1822, in his dissertation, and in 1850 he published a book "Zur Farbenchemie, Musterbilder für Freunde des Schönen und zum Gebrauch für Maler" (Color chemistry, patterns for lovers of beauty and for artists). Though he had discovered the basis of paper chromatography, and even introduced the "development" of colorless into colored zones, he had no thought of an analytical method. *C. F. Schönbein*, *F. Goeppelsroeder*, and *E. Fischer* also used this method during the last century for the separation of ions of inorganic salts, as well as of dyes, and it was finally introduced into analysis by *M. Tswett* as "chromatography" (derived from the Greek τὸ χρῶμα, the color). He resolved the dye leaf-green into green and yellow zones in separating columns packed with an adsorbent.

Separations of this type (on "two-dimensional" thin layers in thin layer or paper chromatography, and on "one-dimensional" columns in liquid or gas chromatography) are still referred to as "chromatography", though they are no longer used only for the separation of colored components. Chromatography has grown into an essential analytical tool, particularly gas chromatography, which can be traced back to *A. T. James* and *A. J. M. Martin*, and even to *A. Eucken* and *E. Cremer*.

Efforts are being made in all chromatographic methods to improve the separation and the detection. In the two-dimensional thin layer and paper chromatography, the separation and the specificity for certain groups of substances are improved by the successive use of diffusion effects in two directions or by the simultaneous use of different physical effects, as in electrophoresis. The detection is often based on specific color reactions. Thin layer chromatography, and to some extent also paper chromatography, have recently been developed into quantitative methods, and variances of less than 3% have been obtained for repeated determinations. Refinements are continuously being made to the technique of these methods in order to increase their basically rather limited separatory efficiency.

In the one-dimensional separation methods of column and capillary (liquid and gas) chromatography, the detection of the eluted substances is almost ideally solved for gas chromatography. The detectors are characterized by very high sensitivity over a very wide dynamic range, and combination of this with substance-specific methods (particularly with mass spectrometry, as a combination of two trace and micro methods) is particularly effective. Though liquid chromatography is also capable of giving very good separations, the problem of the detection of the eluates is still unsolved. Physical effects in the liquid phase cannot be expected to give detector signals of the same order of magnitude as those obtained in the gas phase; transfer detectors, which transfer the liquid

eluate of liquid chromatography into a flame ionization detector, side-step the problem instead of providing a true solution.

Though the substance specificity of the flame ionization detector is poor, the value of gas chromatography is that it can tell us that a substance originally thought to be pure actually contains at least as many impurities as there are additional signals in the chromatogram, apart from the principal component. It is now known that even the "purest substances" are generally accompanied by traces of numerous other substances. The uncontrolled use of analytical methods in which a substance is examined "en bloc" is thus no longer justifiable, and a chromatographic analysis should always be carried out either beforehand, simultaneously, or afterwards to enable the interpretation of the results to be completed. This is true even of the so-called highly specific methods, apart from the purely element-specific ones.

Whereas further appreciable progress in gas chromatography is to be expected only in fast and high-efficiency separations and in the ultra-trace and maximum-selectivity fields, the development of classical column chromatography into modern liquid chromatography in columns has just begun.

In gas chromatography, the techniques used in present-day practice are still lagging appreciably behind the latest developments (Fig. 6).

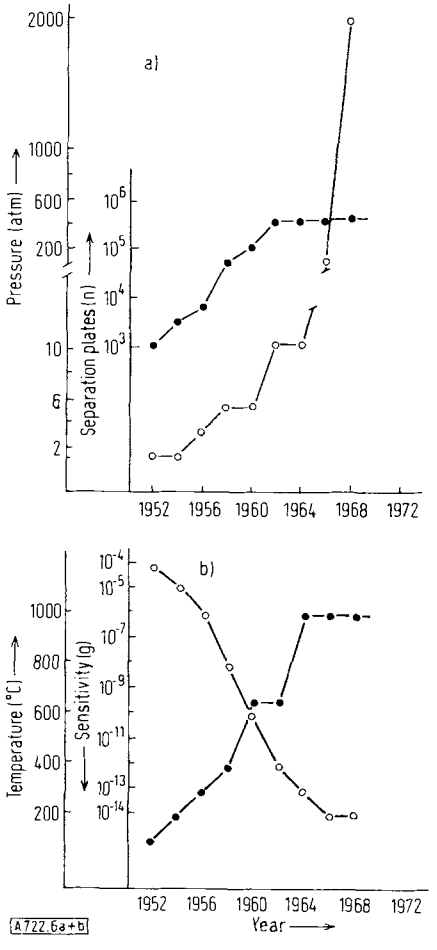

Fig. 6. Development of gas chromatography: a) Pressure (o); number of separation plates (•) — b) Sensitivity (o); temperature (•).

The present stage of development can be summed up as follows. While retaining its extremely broad scope, gas chromatography has become the most accurate quantitative method for the analysis of volatile or decomposable organic substances. The substance to be detected enters the detector at a low concentration, *i.e.* in the ideal state from the physical and measurement points of view; the matrix, *i.e.* the carrier gas, is extremely pure. Variances of down to 0.01 % are quite possible. Gas chromatography allows analyses to be carried out over the concentration range of from 10^{-5} to 100 %; in special cases, volatile stable substances in gases can be detected down to a concentration of 10^{-10} %. One sample can be resolved into as many as 400 (and in special cases up to 1000) chemical species. Quantitative determinations take about 1 to 20 min and require about 10^{-3} g of sample, though 10^{-6} to 10^{-8} g would be sufficient if it were possible to prepare and transport such small quantities of material. More than 100000 chromatographs were in use in laboratories and factories in 1968; only a few percent of these are used in process chromatography, though gas chromatography is excellently suited for automation.

The existing practical achievements are not yet enough. It is expensive to obtain information that can be evaluated directly (on-line) with a computer. Mechanization has not yet gone far enough; though semi-automatic gas chromatographs are already commercially available, their operation is unchecked and uncritical. The separating power, sensitivity, and speed in routine analyses are generally lower by more than two orders of magnitude than they need be, and in some cases than the levels required on economy grounds. For example, up to 3000 separation plates per instrument are often accepted where up to 100000 are needed to detect the components in question. The sensitivity of ordinary commercial instruments is so low that it is just possible to recognize traces at a concentration of 10^{-4} % (ppm), though traces in the 10^{-7} % (ppb) range should be detectable, and these are the very components that are often found to be of immense importance both in chemical and in biochemical processes.

Gas chromatography is today making a decisive contribution to the utilization of the capabilities of structure-specific and structure-identifying methods, and the combination of chromatographic methods is becoming increasingly important (Fig. 7).

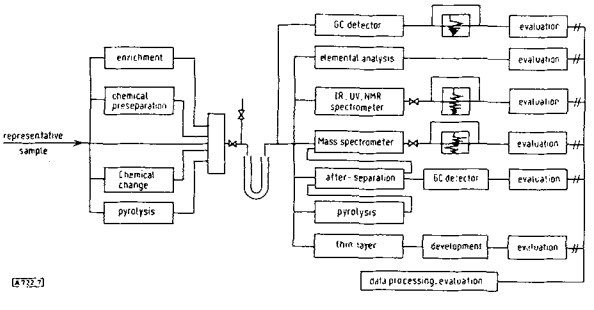

Fig. 7. Possibilities for the combination of gas chromatography with other analytical methods.

Little can be said yet about the state of modern liquid chromatography, except that the expected broad development has probably started this year. The first instruments allowing fast column chromatography with high entry pressures and high separation efficiencies with programmed gradient elution have

Table 2. Survey of chromatographic separation methods.

Mobile phase	Stationary phase	Pressure (atm)	Temperature (°C)	Geometry	Name of method	Applications and capabilities
Gas	Liquid [a]	0.1 to 10 (2000) [d]	Up to about 500 [d]	Tube dia. 0.01 to 10 mm, length a few cm to km	Gas partition chromatography	General: gas chromatography. For volatile or decomposable substances that can be converted into volatile or decomposable derivatives. Qualitative and above all quantitative analysis of all substances that are soluble in the mobile phase in seconds to minutes
Gas	Solid [b]	0.1 to 10 (2000)	−210 to 1700	Tube dia. 0.1 to 10 mm, length a few cm to 0.1 km	Gas adsorption chromatography	
Gas	Solid [c]	0.1 to 10 (2000)	−210 to 1700	As above	Gas diffusion chromatography	
Vapor (in the supercritical state)	One of the above three	[e]	[e]	As above	Dense gas chromatography	
Liquid	Liquid [a]	[d, f], depends on T	[d, f], depends on p	Tube dia. 0.1 to 10 mm, length a few cm to 0.1 km	Column chromatography with secondary names indicating the nature of the separation process, of the stationary phase, or of the material or physical programming	General: liquid chromatography. For all substances that are soluble in the mobile phase. Qualitative and quantitative analysis in seconds to hours
Liquid	Solid [b]	As above	As above	As above	As above	
Liquid	Solid [c]	As above	As above	On layers	Thin layer chromatography	
				On paper	Paper chromatography	
				In a thin film of the stationary phase on an inert rough-surfaced support	Thin film chromatography	

[a] On porous support or wall. [b] Absorbent. [c] Microporous, inert (*e.g.* glass, metal, ceramics, molecular sieve, clathrate former).
[d] Possibly programmed. [e] Depends on the supercritical data for the mobile phase. [f] Depends on the separating system.

already been constructed; however, they are still much more complicated than modern gas chromatographs. In a typical example, almost 8000 separation plates are obtained per meter of column length (diameter 2 to 3 mm) at a rate of 40 separation plates per second.

An intermediate position between gas chromatography and liquid chromatography is occupied by "dense gas chromatography", which is chromatography in the supercritical fluid state, in which elution is carried out at carrier gas pressures of up to 2000 atm. Intermolecular forces in polymers having molecular weights of up to several hundred thousand can be broken down, thus permitting separations far superior to those achievable by gel permeation chromatography. During this kind of chromatography in the supercritical region of the carrier gas, a temperature of 40 °C is sufficient to volatilize substances which would hardly have been thought to behave in such a manner, *e.g.* carbohydrates such as ribose, arabinose, xylose, and glucose at pressures of about 1400 atm in carbon dioxide.

All chromatographic methods require at least one mobile and one stationary phase.The separation of the substances in question is based on differences in the migration rate, solubility, complex formation, adsorption, and includability, and the pressure, temperature, and geometry of the system play a very important part. All possible intermediate stages and combinations are possible between "solution", "chemical bonding", "adsorption", and "sieve effect", and in general, none of these principles acts alone. It is therefore problematic to use names that involve the mechanism of action. Modern chromatographic methods are not only a decisive part of modern analysis; they also, *per se*, provide a constant feedback to the theory and practice of physicochemistry and chemistry.

4. Structural Analysis of Organic Compounds

It has been found convenient to classify organic compounds according to the manner in which the C atoms are linked. They are described according to their carbon skeleton, according to whether the C chains are linear or branched, according to whether they are single carbocyclic or heterocyclic rings or ring systems, and according to the size of the rings and the bonding of the members. Functional groups are inserted in or attached to the carbon skeleton or the heterocyclic nucleus and give rise to the great variety and complexity of organic compounds. The ordering principle of "skeleton" and "functional group" is also followed in the nomenclature. It would be particularly useful if the information and results of a structural analysis also fell into these categories.

Table 3. Comparison of some methods of structural analysis.

Method	Sample	Information
Infrared spectroscopy (microwave spectroscopy) Absorption of infrared light (or microwaves) due to excitation of vibrations and internal rotations of molecules	Solid, liquid, solution, gas or vapor 1—10 mg, in microcells from 10 μg	Structural elements and ring systems of atomic skeletons consisting of carbon and hetero atoms, functional groups, hydrogen bonds, symmetries, isomerism
Raman spectroscopy Scattered radiation whose frequency is the difference between the frequency of the incident visible light and the frequency of the excited molecular vibrations	Solid, liquid, solution 50 mg — 10 g, with laser excitation from 1 mg	As infrared spectroscopy; selection rules of the normal vibrations make the two methods complementary; valuable for symmetrical molecules
Electronic spectroscopy Absorption of ultraviolet and visible light according to the electron levels in molecules	(Solid), liquid, gas, vapor, dilute solution 0.1—10 mg	Double bonds and single electrons, particularly conjugated systems, *e.g.* aromatic compounds, heterocyclic systems with aromatic character
Nuclear magnetic resonance Absorption of radio waves due to resonance of nuclear spin moments in a magnetic field	Solution 5—100 mg	Structural elements and functional groups on the basis of the environment of protons or of nuclei that exhibit nuclear magnetic resonance (*e.g.* ^{13}C, ^{19}F, ^{29}Si, ^{31}P); determination of the hydrogen (proton) content of chemical compounds and groups
Electron spin resonance Absorption of radio waves due to resonance of electron spin moments in a magnetic field	Solid, liquid, solution 1—200 mg 5—100 mg	Detection and determination of free radicals, their structure and electron distribution
Optical rotation, circular dichroism Rotation of the plane of polarized light, difference in absorption of right-handed and left-handed polarized light as a function of wavelength	Liquid, solution 1—200 mg	Relative and absolute configuration of centers of asymmetry, conformation of asymmetric molecules
Mass spectrometry Mass and relative abundance of molecular ions and fragment ions formed on ionization of molecules usually by electron bombardment or strong electric fields	Gases, liquids, and solids that can reach a vapor pressure of 10^{-5} torr at 300 °C without decomposing $\ll$0.1 mg	Molecular weight, elemental composition, detection of hetero atoms on the basis of the natural isotope abundances, structural analysis by specific breakdown of molecules on electron bombardment
X-ray diffraction, neutron diffraction Interference of X-ray or neutron beams as a result of diffraction by the electron clouds or nuclei of the atoms of the oriented molecules in the crystal	Single crystal 1—10 mg and 0.1—1 g respectively	Determination of the complete molecular structure, steric arrangement of the atoms (distances, angles); hydrogen atoms can also be located by neutron diffraction

Some methods of structural analysis are listed in Table 3. Only those most commonly used at present will be considered in this section.

The desire to identify directly the structural units and functional groups in a molecule is satisfied to some extent by X-ray analysis (Table 4).

Table 4. Advantages and disadvantages of X-ray analysis.

Advantages	Disadvantages
Information about the entire intramolecular and intermolecular geometry	No elucidation of partial structures possible; it is always necessary to consider all the atoms in the molecule
Substance is still intact after the analysis	Substance ($\approx$0.1 mg) must exist as a single crystal ($\approx$0.1 mm^3); time required for a structural analysis 4—12 weeks

Figure 8 shows the result of an investigation by *Hoppe, Hecker, et al.*[2] on a neophorbol derivative; the perspective representation of the centers of gravity of the atoms (to the right of the electron density diagram) clearly shows a system of four rings, the two acetoxy groups, and the *p*-bromobenzoyloxy group, which, with its heavy bromine atom, was introduced to facilitate the processing of the X-ray diffraction data (fixing the phase angle).

The method can in principle be used for all compounds that exist as single crystals, whether inorganic or organic and with ionic or molecular lattices. An X-ray structure analysis always gives a picture of the complete electron density distribution in a unit cell of a crystal. It is consequently necessary to include all the atoms of the unit cell in the calculations, so that one cannot, for example, confine one's attention to a specific functional group and ignore the rest of the molecule. The method is a particularly important tool for the determination of partial conformations and absolute configurations, *e.g.* of natural products, or for the investigation of solid-state reactions of inorganic compounds for topochemical analysis by determination of intermolecular and intramolecular distances in the crystal.

Owing to the advances in automatic data acquisition and processing, it is no longer necessary to use a derivative containing a heavy atom, provided that the molecule consists of not more than 50 atoms (apart from hydrogen atoms). Measurements on many isomorph-

[2] *W. Hoppe, F. Brandl, I. Strell, M. Röhrl, J. Gassmann, E. Hecker, H. Bartsch, G. Kreibich,* and *Ch. v. Szczepanski,* Angew. Chem. *79*, 824 (1967); Angew. Chem. internat. Edit. *6*, 809 (1967).

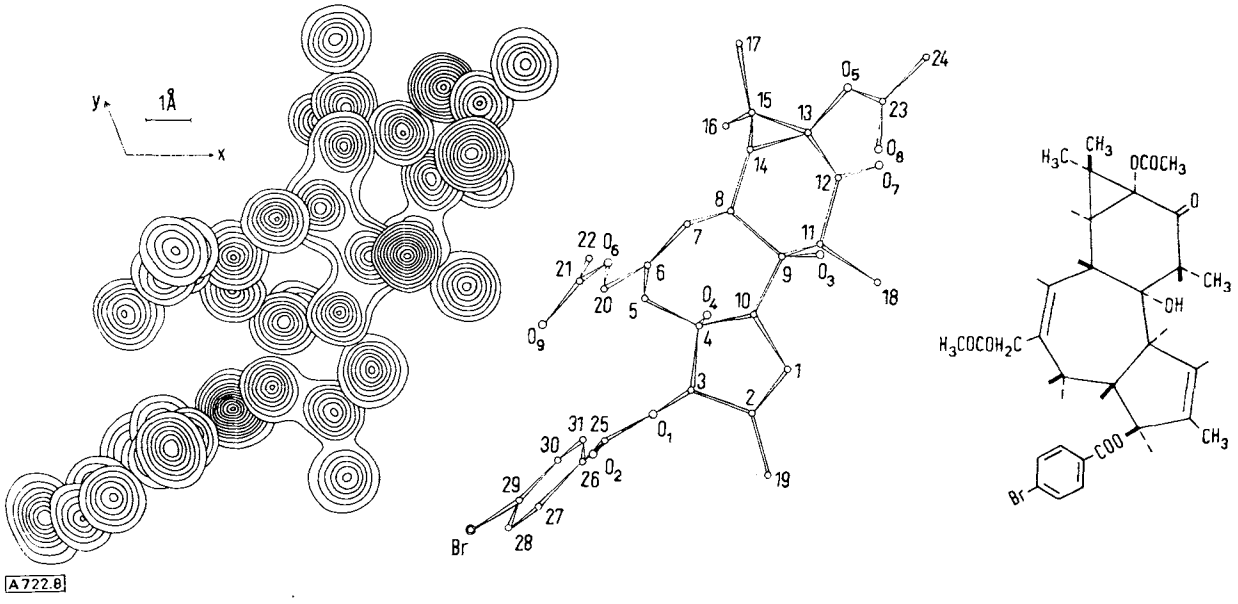

Fig. 8. Fourier analysis of neophorbol 13,20-diacetate 3-*p*-bromobenzoate.

ous derivatives are necessary in the case of large molecules; the structure of these molecules can be conclusively established if there are enough derivatives, personnel, and computer time available. The time required for a medium-large molecule containing 30 atoms apart from hydrogen is 4 to 12 weeks; the time increases roughly linearly with the number of non-hydrogen atoms up to 50 atoms, but much more rapidly beyond 50.

As can be seen from Table 3, IR, Raman, NMR, and mass spectrometry, in complete contrast with X-ray analysis, give only structural elements and environmental and symmetry relations of atomic groupings in molecules, as well as their fragmentation on electron and photon bombardment and in very strong electric fields.

The manner in which the results of the various methods can be combined to find the structure of a molecule is shown below; the information provided by the various methods is indicated, and their effectiveness is compared with that of other methods.

In connection with automatic data processing and combined interpretation, it is necessary to realize that there are basically two types of analytical information, *i.e.* information from which conclusions can be drawn directly and information from which structural elements can be recognized with the aid of empirical tables.

IR spectroscopy yields only information of the second type. The precise information obtained depends on the region of the spectrum. Very characteristic and relatively reliable information about functional groups (such as OH, NH, C≡N, C=O, C=C, C=N) is found between about 3700 and 1550 cm^{-1}, while types of substitution on aromatic rings and heavy atom substitution can be recognized from the wagging vibrations between about 900 and 400 cm^{-1}. In the region between these two, which corresponds mainly to the skeletal vibrations of the molecule, considerable frequency changes occur as a result of changes in structure, and this region cannot be used directly as a source of structural information. This region, however, is very substance-specific (fingerprint region), and is therefore particularly useful for the identification of organic compounds.

For example, the following indirect information can be obtained from the IR spectrum of ethyl *trans*-cinnamate:

Wave number (cm^{-1})	Assignment
685/715 770	C_6H_5R
1174	α,β-unsaturated ester (non-aromatic)
1271	C=C–C–O–R ‖ O
1495 1580	C_6H_6
1638	C=C (olefinic)
1712	C=O (acid or ketone or α,β-unsaturated ester)

We must now ask ourselves whether the information can be improved by the use of more sophisticated apparatus, *e.g.* by an increase in resolution. The answer is negative as far as the spectra of liquids and also of most solids are concerned, since the limit of resolution in these two cases is the natural band width. For gases, on the other hand, increased resolving power can lead to resolution of broad bands into narrower component bands (rotational structure), though this fact is not generally used in normal determinations of the structures of organic compounds. The greater accuracy of the position of the absorption bands, however, can in some cases be of additional value (groups with a C=C function between 1650 and 1800 cm^{-1}).

Raman and IR spectroscopy are based on the internal vibrations of the molecules, the so-called normal vibrations, which appear in accordance with selection rules determined by the physical principles of the

methods; thus a change in the dipole moment during vibrations leads to IR absorption bands, while a change in polarizability gives Raman lines.

Raman spectra, like IR spectra, give only empirical information. The two methods are complementary, since according to the selection rules, which are based on molecular symmetry, vibrations may be *e.g.* IR-active and forbidden in the Raman spectrum or *vice versa*, or they may be allowed or forbidden in both.

A recent important development in Raman spectroscopy is the use of lasers (He/Ne) as Raman light sources. Smaller quantities [a few μl (mm³)] can be used for measurements of this type, even when the substance is colored or slightly turbid; crystalline powders can also be used, with the result that the lattice vibrations of solids can now be readily measured. New possibilities for the determination of the crystallinity of high polymers have appeared, and it seems to be possible to determine the length of polymer chains. Finally mention should be made of the ease of measurement of the degree of polarization of Raman lines, and hence of determining the symmetry of normal vibrations, which is also of value in structural analysis, by excitation with lasers (Fig. 9).

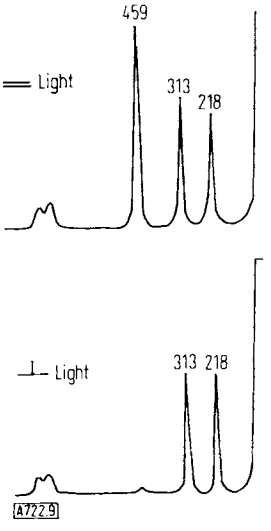

Fig. 9. Polarization measurements in the Raman spectrum of CCl_4.

Unlike infrared spectroscopy, mass spectroscopy gives information that permits direct conclusions as well as providing empirical information (cf. Fig. 10).

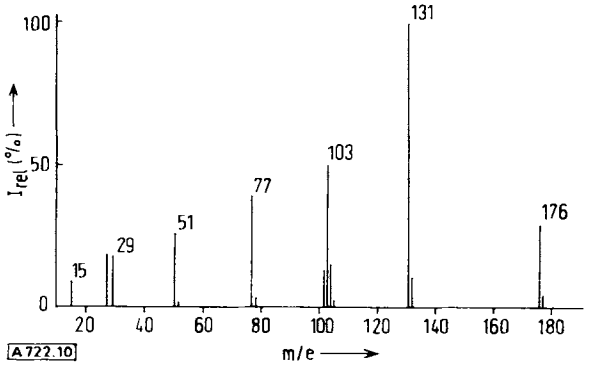

Fig. 10. Mass spectrum of ethyl cinnamate.

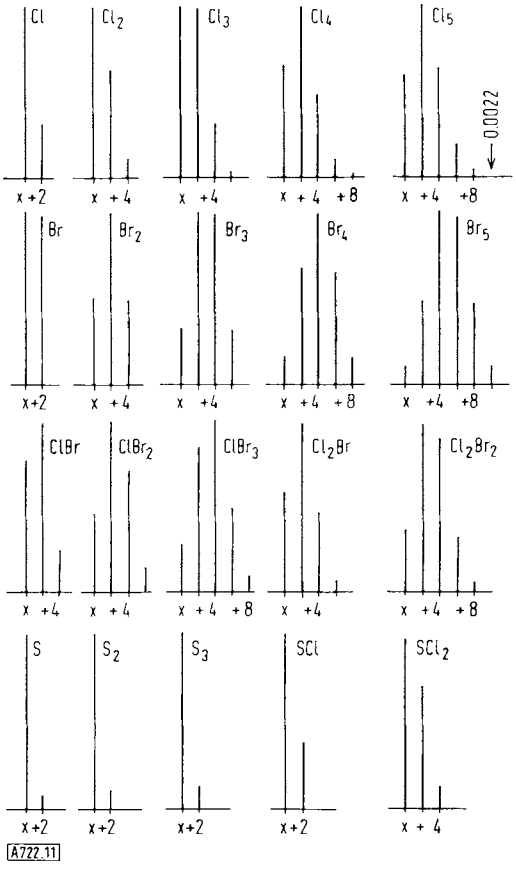
Direct statements:

Peak of highest mass number at *m/e* 176	→	Mol. wt.: 176
Even molecular mass number	→	No N atom or even number of N atoms
Absence of isotope multiplets	→	No halogen atoms
$M^+/M^+ + 1 = 100/10.5$	→	10—11 C atoms

Empirical statements:

Key fragments *m/e*	15	→	CH_3
	29	→	C_2H_5
	77	→	C_6H_5 (monosubstituted aromatic compound)
Peak differences *m/e*	176 → 131	45 →	C_2H_5O- O ‖ $-C-$
	131 → 103	28 →	$-CH=CH-$
	103 → 77	26 →	C_6H_5

The value and the direct applicability of the information obtained from isotope multiplets is demonstrated in Figure 11. Such information shows conclusively the nature and number of certain hetero atoms.



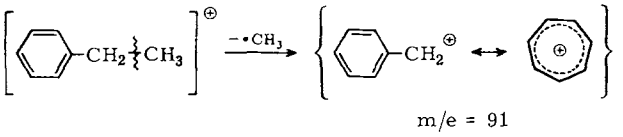


Fig. 11. Characteristic halogen and sulfur isotope multiplets.

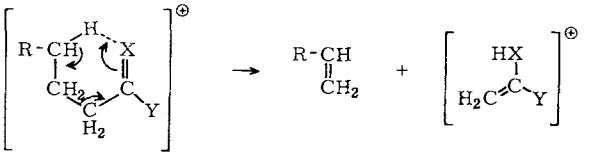

To see how the ions other than the molecular ion are interpreted in the spectrum of ethyl cinnamate (Fig.10), let us consider briefly the fragmentation processes that take place in the ion source of the mass spectrometer. These processes depend both on the energy balance of the bond cleavages involved in the fragmentation and above all on the stability of the positive and neutral particles formed. Thus the fragmentation of ethyl-

benzene, for example, is primarily controlled by the formation of the stable tropylium ion:

m/e = 91

The fragmentation paths and mechanisms are therefore molecule-specific rather than group-specific, since the formation of certain fragment ions depends energetically on the competition of different atomic groupings. In addition to the fragmentation of single bonds, rearrangements frequently also occur, subject to certain steric conditions; though these further complicate the fragmentation mechanisms, they are readily recognizable in many instances, and are then very specific. An example is the "McLafferty rearrangement":

When X = O and Y = OH, the ion of mass 60, which is characteristic of acids with more than three C atoms, is formed.

A rough interpretation of a mass spectrum can be made with the aid of empirically compiled tables of characteristic "key fragments" (*e.g.* ethyl cinnamate: mass numbers 15, 29, 77 correspond to CH_3, C_2H_5, and C_6H_5) and typical mass differences (45 $\triangleq$ C_2H_5O; characteristic of ethyl esters).

Specific syntheses of derivatives of the substance under examination and partial chemical degradation can often be of great value in structural determinations. Strongly polar substances that cannot be evaporated without decomposing are converted into derivatives that can be vaporized without decomposing (silyl ethers, trifluoroacetates, *etc.*).

It is sometimes difficult to recognize the molecular peak. For aliphatic alcohols, ethers, and carboxylic acids, as well as for branched aliphatic hydrocarbons, the intensity of this peak is usually less than 2% of the sum of the intensities of all the other signals, whereas aromatic and alicyclic compounds give very intense molecular peaks. If, however, the ionization method is changed from electron bombardment to field ionization, or if the ionization voltage in electron bombardment ionization is reduced, the peak of the molecular ion becomes quite predominant, despite the lower overall intensity of the spectrum (Figs. 12 and 13).

Wider use of field ionization mass spectrometry has been hindered in the past by the low overall intensity of the spectra. With carbon whiskers as electrodes in a field emission ion source, however, it has recently become possible to obtain sensitivities as high as those

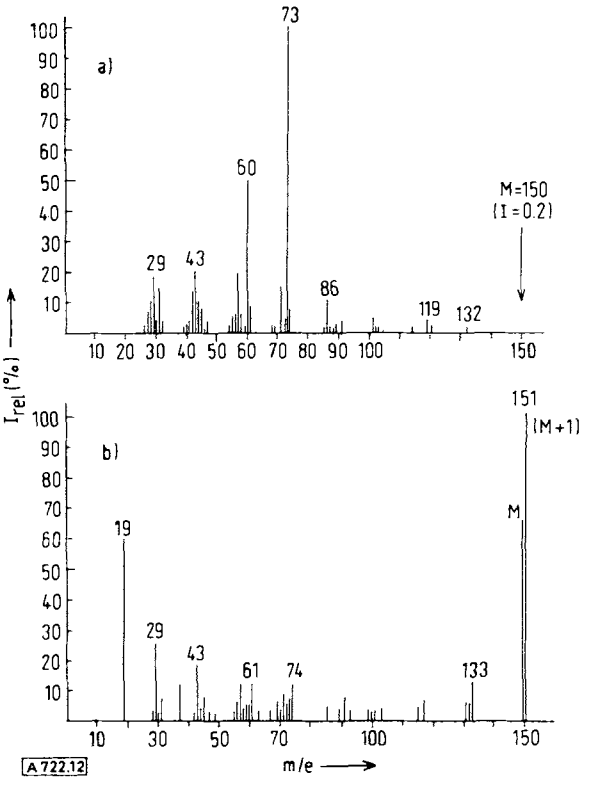

Fig. 12. Mass spectra of D-ribose a) with electron bombardment ionization [3] and b) with field ionization [4].

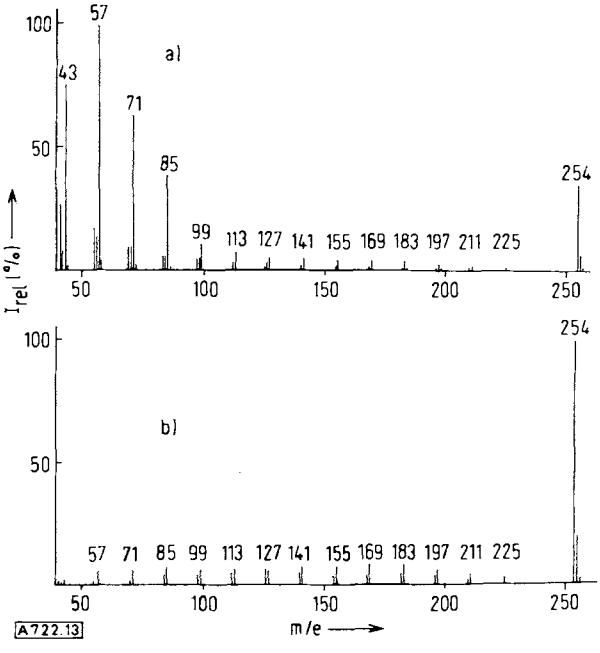

Fig. 13. Mass spectra of octadecane with ionization energies of a) 70 eV and b) 17 eV.

achieved by conventional electron bombardment ion sources [5].

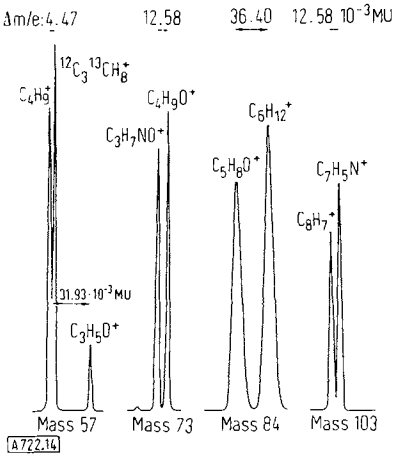
Here again we are faced with the question whether the information value of mass spectrometry could be im-

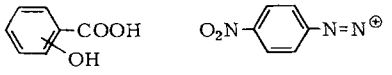
[3] *K. Biemann*: Mass Spectrometry. McGraw-Hill, London 1962, p. 350.

[4] *H. D. Beckey* in *W. L. Mead*: Advances in Mass Spectrometry. Vol. 2. Institute of Petroleum, London 1966, p. 48.

[5] *H. D. Beckey*, Lecture read to the GDCh Section "Analytische Chemie" at Freiburg in April 1969.

proved *e.g.* by an increase in the resolving power. Even instruments having an average resolution $m/\Delta m$ of 2000–3000 resolve a signal of mass number 28 due to N_2 and CO. A tenfold increase in resolution allows the separation of lines with higher mass numbers (Fig. 14), so that the elemental compositions of fragment ions and molecular ions can now also be given. The usual accuracy of mass determinations is about





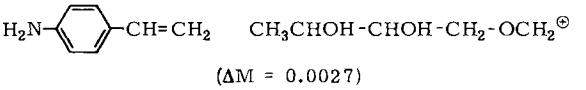


Fig. 14. Ion pairs separated by high-resolution mass spectrometry.

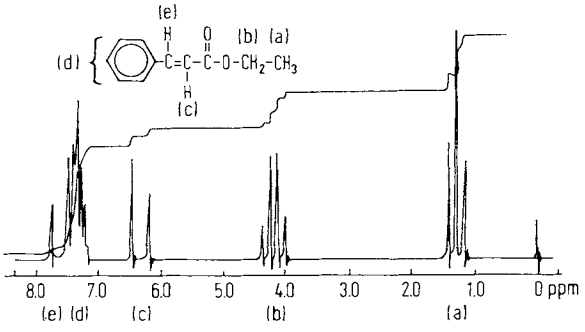
±0.0025 to ±0.003 mass units. An unknown compound *e.g.* having a molecular weight of 587.3444 ± 0.0029 could have any of the formulas $C_{28}H_{49}N_3O_{10}$, $C_{29}H_{45}N_7O_6$, $C_{33}H_{49}NO_8$, and $C_{34}H_{45}N_5O_4$. An elemental analysis giving the results C: 70.65, N: 4.90, and O: 16.65%, with a cryoscopically determined molecular weight of 290 ± 5, would give the empirical formulas $C_{17}H_{23}NO_3$, $C_{17}H_{25}NO_3$, and $C_{17}H_{21}NO$; a mass-spectrometrically determined molecular weight of 289 would rule out the second and third of these formulas.

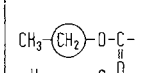
Combination with elemental analysis is particularly important if a molecule also contains other hetero atoms, such as F, S, and P, that are either isotopically pure or have no characteristic isotope ratios. Styrene, C_8H_8, is practically indistinguishable from pentanethiol, $C_5H_{11}SH$, ($\Delta M = 0.0034$), and benzene, C_6H_6, cannot be distinguished from fluoropropanol, C_3H_7OF ($\Delta M = 0.0021$). The same is true for the molecular ions and the fragments:

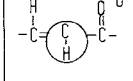
($\Delta M = 0.0013$)

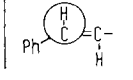
($\Delta M = 0.0027$)



The advantage of high-resolution mass spectrometry, despite certain limitations, can be seen *e.g.* in the mass spectrum of ethyl butyrate; instead of mass numbers, elemental compositions are now given for the peaks of the spectrum:







m/e			
116	$C_6H_{12}O_2$	$C_2H_8N_6$	$C_4H_{10}N_3O$
101	$C_5H_9O_2$	CH_5N_6	$C_3H_7N_3O$
89	$C_4H_9O_2$	–	$C_2H_7N_3O$
88	$C_4H_8O_2$	–	$C_2H_6N_3O$
73	C_4H_7O	–	$C_2H_5N_3$
	89 = M–C_2H_3		
	88 = M–C_2H_4		
	73 = M–C_3H_7		
	81 = M–C_2H_5O		

When arranged schematically in the form of an "element map", they can be interpreted more easily than when they are simply listed according to their mass numbers.

In principle, the elemental compositions can be calculated and an element map can be constructed with the aid of tables; since it is convenient in any case to use computers in the processing of high-resolution mass spectra, this task may also be incorporated in the program.

To illustrate the information obtainable from a nuclear magnetic resonance spectrum, let us again take the example of ethyl *trans*-cinnamate (Fig. 15).

Chemical shift (ppm)	Multiplicity	Coupling constant (Hz)	Intensity	Assignment
1.28	3 (Triplet)	7	3	
4.23	4 (Quartet)	7	2	
6.40	2 (Doublet)	16	1	
7.35	n (Multiplet)	-	5	
7.70	2 (Doublet)	16	1	

A 722.15

Fig. 15. ^{1}H-NMR spectrum of ethyl *trans*-cinnamate.

The area under the multiplet having a given shift corresponds to the number of protons, and the ratios of the areas are thus equal to the ratios of the numbers of protons in various environments. The chemical shifts and coupling constants for various atomic groupings can be found in empirical tables. The triplet a and the quartet b in the spectrum correspond to an ethyl group, and the two doublets c and e to a –CH=CH– group. The two hydrogen atoms could also be *cis*, but this would be shown by the coupling constant: *cis* ≈ 8 Hz, *trans* ≈ 16 Hz. The higher-order multiplet d, in which five non-equivalent protons couple with one another, is more complicated; it can be interpreted (cf. Fig. 16), though the interpretation is not necessary for the structural analysis, particularly in this case.

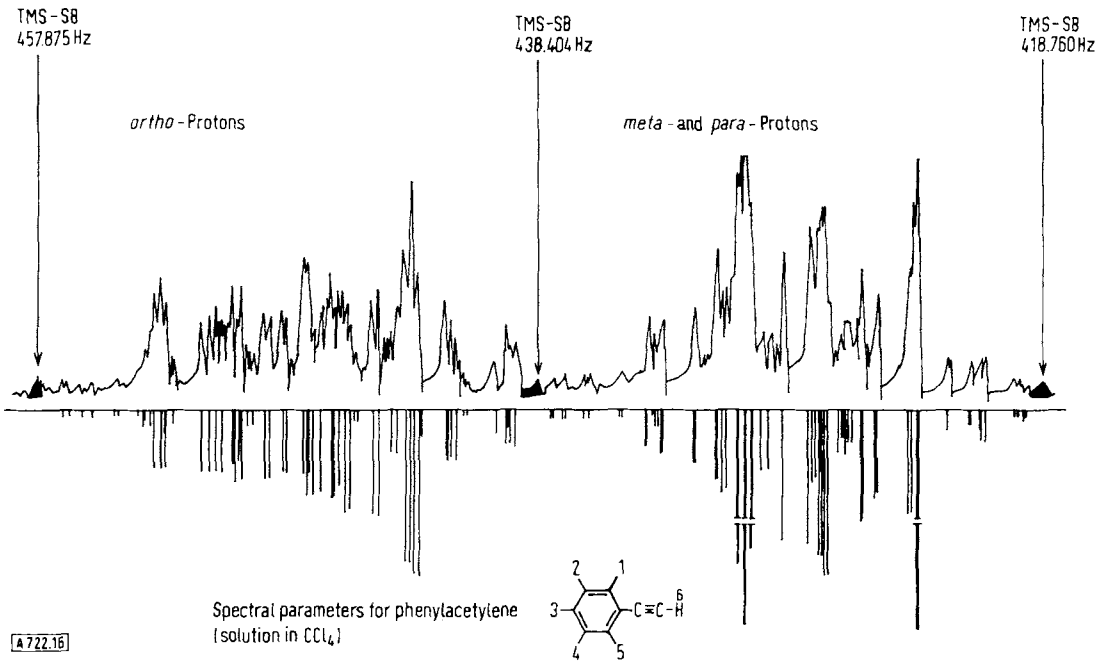


Fig. 16. Experimental and calculated NMR spectrum of the *o*, *m*, and *p* protons of phenylacetylene.

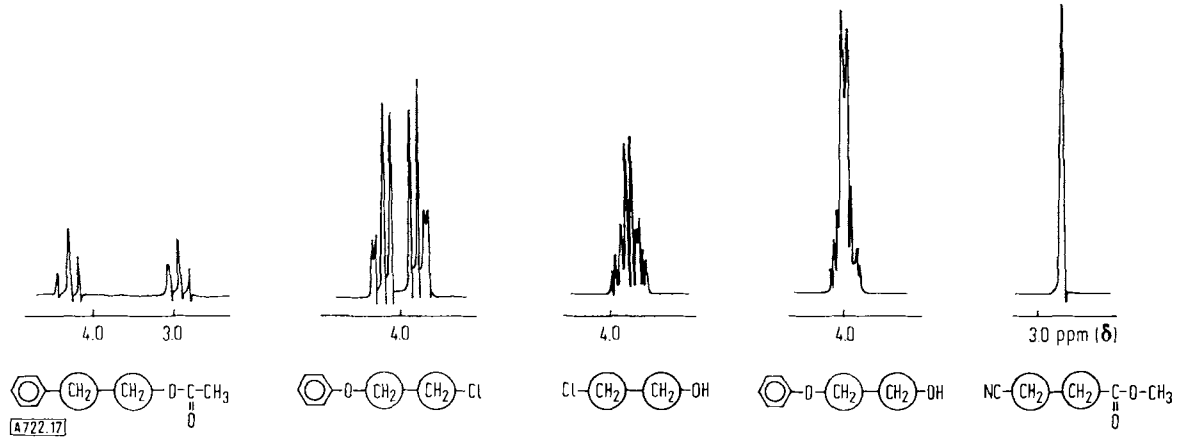

Fig. 17. Spin-spin coupling for the A_2X_2 system.

An example of the transition from lower-order to higher-order NMR multiplets is shown in Figure 17.

Neighboring CH_2 groups carry groups that can induce different intramolecular fields. The multiplet structure is characterized by the coupling constant J, the shift difference $\Delta\delta\nu$, and their ratio $J/\Delta\delta\nu$, *i.e.* the coupling factor. In the case of the A_2X_2 system, *i.e.* the two CH_2 groups, we should expect two triplets in the first order (Fig. 17, left). In the spectra from left to right, not only do the signals move closer together ($\Delta\delta\nu$ becomes smaller), but their structure also becomes more complicated, until they finally degenerate into a singlet. The structure of the multiplet is determined by the coupling factor which is <0.25 for the first order of the multiplet. If, on the other hand, it is >0.25, complicated multiplets of higher order are obtained.

As in IR and mass spectroscopy, it is reasonable to hope that the structure of the NMR multiplet might become clearer if the "resolution" were increased. This would require a decrease in the signal width, which would in turn be possible only by an increase in the constancy of the magnetic fields (fundamentally an increase in the constancy of the temperature) and of the measuring frequency. One order of magnitude (from $\nu/\Delta\nu = 2 \times 10^8$ to 2×10^9) might be gained in this way, but a natural limit is imposed by the relaxation of the internal motion of atomic groups in the molecules. It is commonly thought that the "resolution" can be improved by increasing the magnetic fields, *e.g.* from 14100 gauss and a measuring frequency of 60 MHz currently used in routine work to 23500 gauss and 100 MHz; instruments working with 51700 gauss and 220 MHz have been available for two years. A further increase in the field strength and measuring frequency still seems possible.

In connection with this development of nuclear magnetic resonance instruments, one speaks of an increase in the "resolution" of the spectra with the magnetic field strength. This is not, however, true of the resolution as usually defined in spectroscopy. On the other hand, the chemical shift increases very appreciably with increasing magnetic field strength. In the parlance of optical spectroscopy, which should be

used to describe this effect, the angular dispersion of a 220 MHz instrument is greater by a factor of 3.7 than that of a 60 MHz instrument. The multiplet groups move apart as the field strength and measuring frequency are increased, but the multiplet structure simultaneously becomes simpler. This is understandable if one considers that the coupling constants are independent of the field strength, whereas the shift difference increases with increasing field strength. The coupling factor $J/\Delta\delta\nu$, which determines the structure of the multiplicity, accordingly becomes smaller, and the multiplets become simpler.

This effect is shown in Figure 18. The same spectrum (60 MHz) of 2-chloroethanol is shown twice on the left, and the spectrum of the phenyl ether is shown (top right) for comparison. A greater difference in the shielding constants leads to a greater shift difference, and hence to a smaller coupling factor, so that the structure of the multiplet becomes simpler. In the lower right-hand diagram, which shows the 220 MHz spectrum of 2-chloroethanol, the external field is greater and the same effect is thus observed.

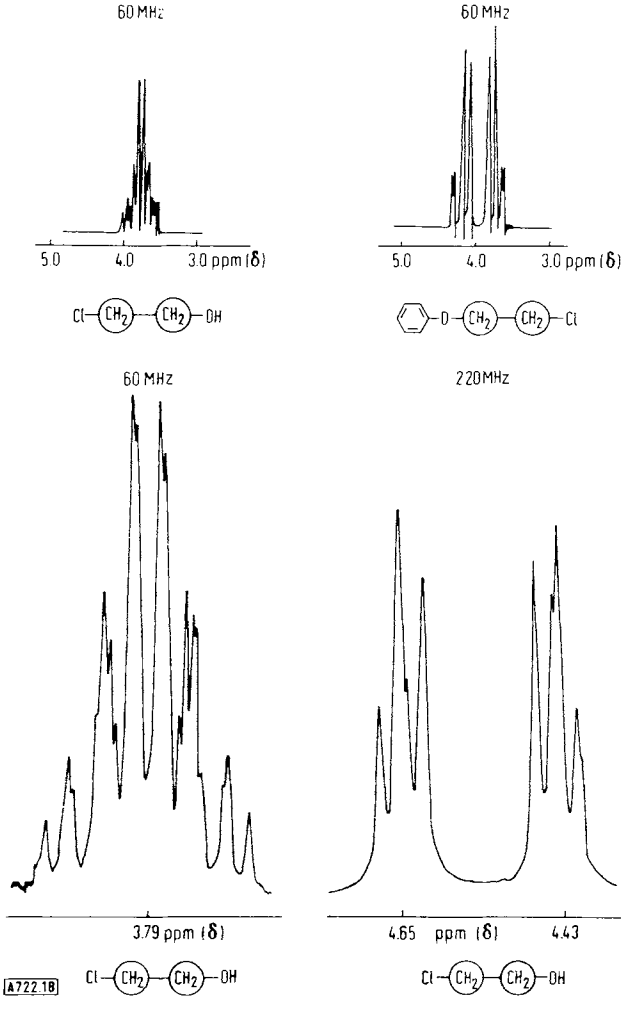

Fig. 18. ^{1}H-NMR spectra of 2-chloroethanol and its phenyl ether at various measuring frequencies.

To sum up, therefore, we can say that an increase in the field strength and measuring frequency moves the multiplets apart, and so disentangles them and makes them simpler; however, this is accompanied by a loss of information. It should also be mentioned that the signal-to-noise ratio is appreciably improved (by a factor of 3–5) by the change from 60 to 220 MHz.

It is convenient to leave the data processing and all the steps in the evaluation of information from IR, Raman, NMR, and mass spectroscopy to a computer, which can also carry out searches and comparisons in stored empirical tables of the structural elements, and can take over the functions of memory, learning, and searching:

1. Automatic data collection and conversion into a form suitable for interpretation (*e.g.* determination of mass numbers and elemental compositions in mass spectra, separation of overlapping bands);
2. Comparison with catalogs of spectra;
3. Input of reliable preliminary information;
4. Output of structural data in the form of partial structures and the arrangement of structural parts;
5. Comparison of the results obtained by different methods.

As a result of these combined integrated interpretations, the computer yields structural elements, partial structures, or complete structures, depending on the difficulty of the problem. It will provide self-consistent proposed structures as well as structures that still involve some uncertainty, and it will also list any conflicting results and negative findings. Decisions between various possibilities and the selection of the eventually proposed structure (possibly after further investigations based on intermediate results) remain the work of the chemist. The most reliable confirmation of an analysis is generally a total synthesis.

The substance whose structure is to be analyzed must be substantially pure. Separation methods, particularly chromatographic, are of great value in this connection, both preparatively and analytically as a purity check. The combination of separation and determination methods has already been described for the case of gas chromatography and mass spectrometry.

A method that should be of great importance for structural analyses in the future is one reported two years ago by *Siegbahn*[6], who named it ESCA. This method makes use of the photo-ionization of atoms by relatively soft X-ray beams (cf. Section 2). *Siegbahn* used a magnetic separation system in his electronic spectrometer. The Varian Company, which undertook the development of instrumentation for the method (also known as induced electron emission spectroscopy, IEES), introduced electrostatic separation with a multichannel store; it is possible in this way to resolve spectra with a sharpness of separation of 1 eV. Figures 19 and 20 show the corresponding spectra of acetone and ethyl trifluoroacetate, in which substitution effects on the carbon are clearly shown by a change in its bond energy (E_B) (according to *Siegbahn*). Manufacturers have recently announced the production of instruments, which no longer separate the photoelectrons in a magnetic field but by a time-of-flight principle in an electric field at a resolutions of

[6] *K. Siegbahn et al.*, Nova Acta Regiae Societatis Scientiarum Upsaliensis, Ser. IV, *20*, 1 (1967).

1 eV; these instruments will probably ensure that this new method will soon take its place alongside other methods of molecular spectroscopy. Moreover, in this case, an integrating interpretation is also possible with the aid of a computer.

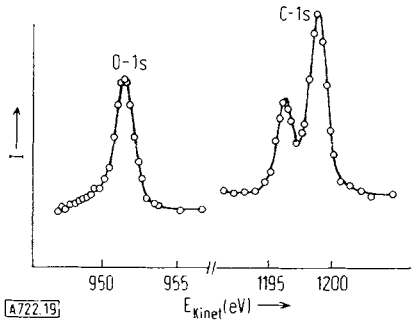

Fig. 19. ESCA spectrum of acetone.

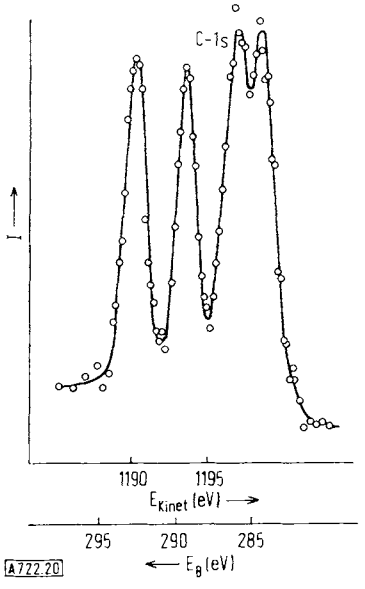

Fig. 20. ESCA spectrum of ethyl trifluoroacetate.

X-ray structure analysis provides the structure of the entire molecule, though the demands on time and work are still relatively severe. The molecular spectroscopy methods can never yield direct information about a carbon skeleton in structural analyses; they cannot show directly the presence of rings, chains, or branching. Recognition of typical ring vibrations is possible only by modern laser Raman spectroscopy employing polarization measurements, so that, with the exception of the aromatic six-membered ring, methods of molecular spectroscopy can recognize functional groups and the environments of atoms, as well as isolated steric arrangements, which can often be combined to give partial or total structures only on the basis of a well founded chemical knowledge.

5. Data Processing in Analysis

Some possibilities offered by the use of electronic data processing equipment in analysis are shown in Figure 21. Analog signals are accepted at a rate of 10000 or

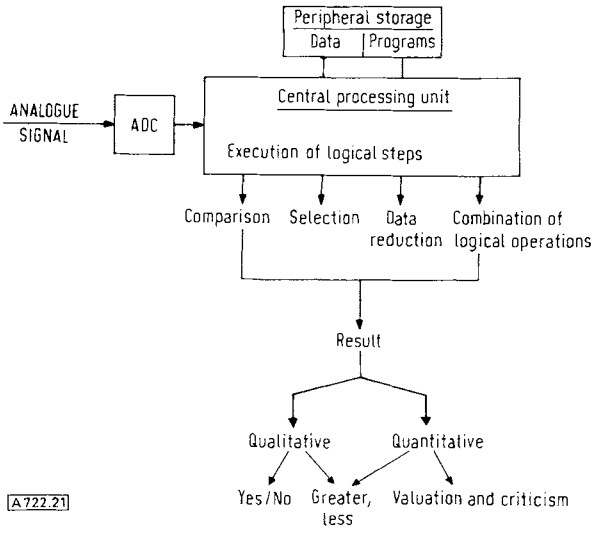

Fig. 21. Use of a computer for analytical problems.

more values per second by an analog-to-digital-converter, which passes the resulting digital values to the core memory of the computer. The data can be further processed directly in time-sharing operation during the data collection. Where the information flow is high, the incorporation of a temporary store in the peripheral equipment is often advisable in order to relieve the central unit. The information can then be recalled later, or may be passed on, after packing, to a larger processor. Using data and programs from storage units, the computer can compare, select, condense, and relate the data by logical operations, in such a way as to obtain an intermediate or final result.

An obvious step is to employ calculating machines, from small desk models to large computers, for pure calculating tasks in the processing of analytical results. With skilled programming, not only of analytical parameters, but also of standardization factors, names of substances, operating terms, *etc.*, a small computer can prepare a complete analytical account, thus easing considerably secretarial work in the laboratory and largely eliminating errors involved in calculation, transfer of data, and writing; it can, moreover, carry out comparisons with theoretical values, summation checks, calculation of standard deviations or errors in multicomponent systems. However, such a machine cannot be expected to perform special tasks corresponding to the capability of a full-scale computer.

In the examples mentioned so far, the computer is used merely as a calculating machine whose program includes a comparison with a reference value. However, it becomes much more directly involved in the analysis if it is also used for data acquisition and processing. As a calculator it simply derives an analytical result on the basis of existing experimental values, whereas in data acquisition and processing the computer itself obtains values that can be used in analysis from a large number of individual values, and manipulates these further to obtain an intermediate or final result.

This can be illustrated for the case of a titration. The end point of a titration is usually determined visually on the basis

of a color change; as soon as this color change occurs, the tap of a buret is closed and the value is read off. In electrochemical titration, the titration curve (volume of titrant used against the potential difference) can be recorded, and the end point of titration is then determined graphically as the point of inflection of the curve. It is well known that the points of inflection are indistinct, particularly when there are several potential steps, so that it is difficult to determine these points accurately. If the potential difference as a function of time is fed into the computer as a large number of individual measurements (*e.g.* every 10—15 ms), care being taken to ensure that the addition of titrant is exactly linear with time (the volume per unit time should also be accurately measurable), the computer can find the point of inflection by differentiation (formation of the first, and if necessary also the second, derivative) with much greater accuracy than is possible by hand.

The computer can also take over the data processing in the evaluation of gas chromatograms, particularly where signals overlap or where the base line is not constant. The earlier planimetric method of manual evaluation, which was subject to considerable errors (1—3%), has been steadily replaced by electric integrators, which give very good reproducibility (≈0.3%). However, these offer only an incomplete solution to the problems of base-line drift and the separation of overlapping signals. A computer, on the other hand, can fully correct for the base-line drift by constructing a tangent at the beginning and end of a signal, or of a group of overlapping signals, and determining the area above the tangent. To separate overlapping signals, an approximate gaussian curve is determined from the signals, in a chromatogram, and for the overlapping signals, the two gaussian curves are sought whose superposition best reproduces the measured signal. The simple procedure of dividing superimposed signals into area elements by vertical lines is sufficiently accurate in many cases if the assignment of the area elements is correct.

All these computer evaluations depend on the recording of the true experimental values. This is seriously affected by noise in the measurement signals and their disturbance by isolated signals due to sudden voltage or current surges, and considerable expense is involved in the elimination of these interfering factors.

As in gas chromatography, a computer can also be used in mass spectrometry for data acquisition, processing, and reduction and for obtaining analytical results.

The question of economy is also important. As is shown in Figure 22, the times taken for the various steps of the analysis differ considerably.

If the preparation of the sample and the measurement take a long time in relation to the evaluation, the use

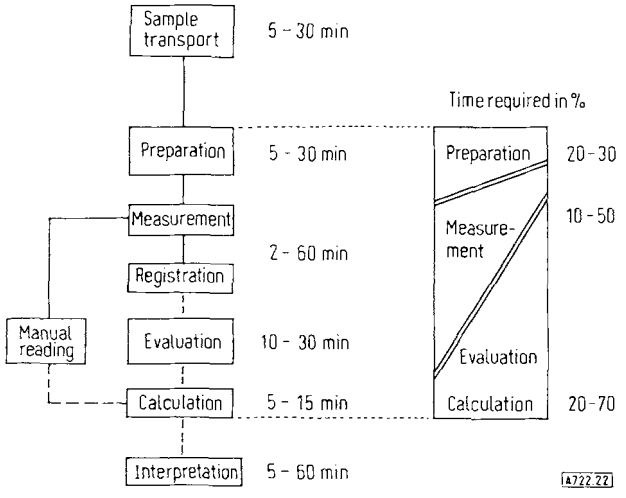

Fig. 22. Time taken for the various steps in analysis.

of a computer is not normally justified. It is advisable in such cases to modify the procedure, rationalize or mechanize individual steps, or improve the measuring method. If the number of samples for routine examination is very large while the amount of calculation is small, a programmable desk calculator or digital data collection, *e.g.* with a tape punch for off-line evaluation on a larger computer, may be advantageous.

The direct connection of smaller or larger data processing units is recommended whenever the collection and evaluation of the experimental values accounts for a medium or major part of the total work of analysis. In physical methods it is usually the collection of the experimental values that involves a great deal of manual work, which is simple, but requires care and concentration (gas chromatography, mass spectrometry); the use of medium sized computer systems is profitable in such cases.

If the times for measurement and for evaluation are roughly the same without a computer, the measuring process becomes rate-determining with automatic data processing. It is then desirable to speed up the measuring process. An example of this is gas chromatography, where the operating speed could be considerably increased, but where this has been of no interest until now because of the long times taken for the evaluation. This is a case in which the use of computers has had repercussions on the method itself.

In view of its cost, the fullest possible use should be made of a data processing system. This condition is satisfied in particular in routine operation, *e.g.* in round-the-clock industrial analyses, particularly when the data flow is matched to the capacity of the computer by connection of a large number of analytical instruments. Extremely high data flows from individual measuring instruments also justify the use of a computer for these instruments alone, provided that they are used often enough (*e.g.* in high-resolution mass spectrometry). These computers, which are intended for a single field of use, and which operate for long periods with the same program, can be profitably used with the minimum equipment for this purpose, particularly if they also take over the duties of supervision (regulation) of the measuring instrument and optimization of the measured values (improvement of the signal-to-noise ratio) (*e.g.* in nuclear magnetic resonance).

The preparation and control of the measuring processes can be carried out by a small computer. The experimental data are reduced by this computer, and may be passed to a large computer for further processing. In X-ray structure analysis, for example, the intensities of several thousand reflections from one crystal are measured with a diffractometer, which is controlled by a small computer. This computer optimizes the measuring process for each reflection, corrects the experimental values, and passes them in a reduced form to a large computer. An attempt is now made, with the aid of a suitable program, to assign phases to the measured structure amplitudes, in order to obtain a

model of the structure by a three-dimensional Fourier analysis. This model is then refined by the computer by optimum matching with the experimental data. The control of the diffractometer by the computer may be compared to automatic process control in industry, and is probably the first process to reach this level of perfection in the field of measurement.

This opens up whole new vistas for the role of computers in analytical work, though the applications at present are still rather trivial. Its role as a pure calculator is widened, and it also assumes control functions over the analytical instruments. In emission spectroscopy, for example, one measurement may be repeated several times; the mean of the individual results is used to calculate the standard deviation, which is then compared with the expected standard deviation of the analytical method. If the result is greater than the expected value, the computer decides to repeat the analytical measurement. The new result, together with the standard deviation, provides the basis of a criticism that either the sample may be inhomogeneous or the analytical method is unsatisfactory. The analyst himself must now draw his conclusions, but the basis of his decisions is provided by the computer.

Other duties of the computer are distinguishing between systematic and random errors and verifying the correctness of results. It is not difficult for the computer to store a large number of repeated measurements, find their statistical mean, and check their statistical distribution. If the distribution differs from the gaussian or other suitable distribution, the errors in the measuring process are not only purely random ones.

The error of the method is found by repeating the entire measuring process several times, and occasional measurements on calibration samples confirm or refute the correctness of the measuring process. All the intermediate calculations involved in this procedure are carried out by the computer, which provides the analyst with the quantities required as a basis for decisions, or may even itself indicate the satisfactoriness or uncertainty of analytical findings.

It is now beyond all doubt that the resulting speed of the whole measurement and evaluation operation and the increase in the accuracy and correctness of the results that is generally possible are leading to a new era in analytical work, with the scientific and economic consequences that follow from it. In recognition of the economic importance of analysis, it has become our duty to encourage and force through the decisions that are necessary to our entry into this new era.

6. Automation in and with Analytical Chemistry

The possibility of influencing an analytical process by decisions suggests a comparison with control and regulating functions in chemical processes (Fig. 23).

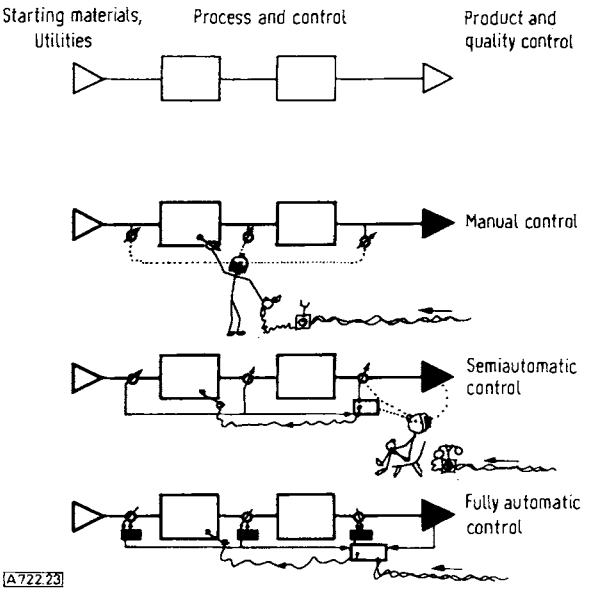

Fig. 23. Control, regulation, and automation. Stages in the unloading of the human operator in chemistry (symbolic: two-stage process).

Three stages of process control are known in industrial production, *i.e.* control (manual control), regulation (semiautomatic control), and automation (fully automatic control). In manual control, information provided by measuring instruments on the basis of the instantaneous state of the process is translated into commands by human agents. The process is thus under human supervision, and the quality of the product and the economy of production depend on the efficiency and availability of labor.

In semiautomatic process control, the same information as is used in manual control is fed into data converters. These are regulating instruments with no automatic checking or critical functions, which convert the information supplied into commands in accordance with a fixed program or simply in such a way as to maintain a predetermined state. An important characteristic of a good regulator is the ability to convert the information into commands in such a way that the desired action occurs as quickly and as accurately as possible. Data feedback allows optimum matching of the commands to the prevailing state. However, all these features cannot be compared to the specific characteristics shown by a human agent controlling a process. Though the regulator does the mechanical operations faster, better, and more continuously than a human operator, it lacks the checking and decision-making functions and the ability to adapt to different states. As the demands made by process control become more stringent, therefore, the usefulness of semiautomatic control diminishes. The stage of full automation is then necessary.

Full automation means a high degree of replacement of human activities by machines, and includes checking, decision-making, and adaptation functions. Checks can be made only by comparison of data. Decision-making and adaptation require the observation and evaluation of a change in data with time. Tasks of this nature are within the capabilities of computers. Automation in the chemical industry is thus characterized by the use of a computer, which compares data, follows their trend, and uses this as a basis for commands.

It can be seen from Figure 24 that the various steps leading from sampling, *via* the measuring process, to the analytical result can be considered in the same scheme as was used for process control (cf. Figure 23).

Manual analysis, in which a sample is subjected to transformation and measurement, has reached only the semiautomatic stage even when complex instruments are used for the production and collection of data, since the state of the sam-

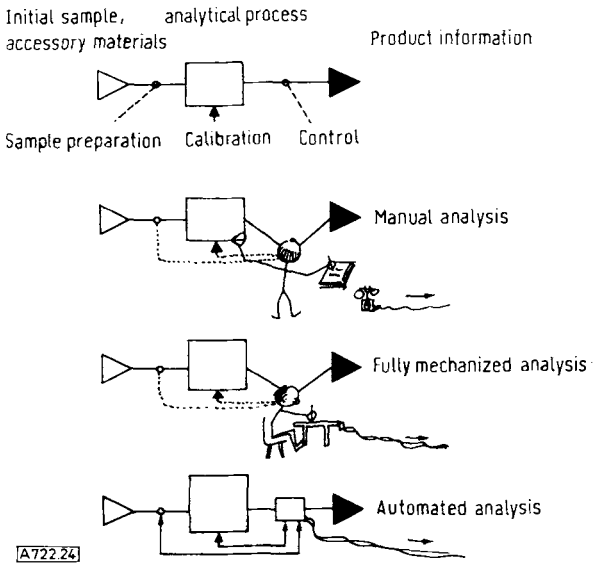

Fig. 24. Stages in automatic analysis: manual analysis, fully mechanized analysis (with checking, correction, and evaluation by human operators), and automated analysis.

ple is (unconsciously) checked by a human operator and corrected if necessary, and since the human operator must also check and correct the information produced, *e.g.* by unconscious comparison or with the aid of a calibration analysis. Transformation of the results of the measurements is sometimes necessary. It is always necessary to check in some way whether the information is "correct enough".

Analytical measurements with "automatic" instruments are comparable to semiautomatic process control. These instruments should, however, be described as automatic only if the criteria of automation (checking, correction, decision-making, and adapting) are satisfied. An automatic vending machine is much more automatic than an "automatic" titrating instrument, since it checks a coin inserted and decides whether to deliver the goods or not (*e.g.* if foreign money or a button has been used instead of the correct coin). Though an automatic vending machine can be deceived, or may refuse to deliver the goods even when a gold coin has been inserted, this error characteristic does not alter the difference between automation, as a high level of checked, corrected, and adapted mechanization, and mechanization without checking and decision-making functions.

The instruments usually referred to as automatic analysers, as well as "automatic" combustion equipment for element analyses and "automatic" titrating instruments, are instruments that function in accordance with a control program, but which contain no idea of automation. Phrases like "automatic laboratory" refer at best to the evaluation, and never to the analytical process. An automatic apparatus should be[7] an assembly of mechanism and instruments that forms an informationally closed system. The quality of being "informationally closed" is essential to the process taking place in a truly automatic apparatus. One can also say that an automatic apparatus must carry out this process in accordance with the "input/output" principle, which states that material and/or informative input quantities are processed internally with no help from external agencies, and that the results are again definite material and/or informative output quantities. The process is often specified expressly as in automatic "computer". Unlike in a machine or instrument, the individual steps in the operation of an automatic apparatus need not be predictable either in their nature or in their duration, but are varied within preset limits by internal regulating and control processes. For this purpose control signals and/or response signals are used to vary the actuating variables of the mechanisms and to match them to one another. The characteristics of the object to be acted upon must also be determined directly and introduced into the data cycle.

Where the input quantities are fixed, we speak of programmed automatic systems. Units for the elimination of variable input quantities in the form of random variables, deviations, or perturbing quantities are also known as automatic regulators or controllers. However, many units correspond to both concepts.

For true automation, the individual steps in analytical chemistry (sampling, measuring, and data processing) must be automated, *i.e.* provided with automatic checking, correction, and adaptation to changed conditions.

These requirements are already largely satisfied in data processing, and perfectly practicable proposals have been made for automatic analytical instruments. In sampling, on the other hand, the requirements can scarcely be met even in the simplest cases. Systems of two or more phases and components with different densities and volatilities raise problems that have not even been adequately thought out, far less solved.

Requirements that must be satisfied by analytical instruments for automatic process control are given below. It should be noted that an analytical method, however important it may be to the process, is incomplete unless it incorporates a checking system corresponding to the human criticism that always intervenes between sampling and evaluation of the measurements in analysis in the laboratory.

This checking system involves the storage, comparison, and checking of changes and rates of change within the analytical system. The calibration functions and the reference standards must be supervised and automatically corrected in case of deviation, as must the input of the correct measurement data.

The internal checking is a special characteristic, and one that is obviously necessary for a production process. The instrument itself decides whether the output analysis result is probably correct or whether it should be rejected. The process control learns from this decision. An automatic system must therefore constantly make yes-or-no decisions that are often difficult for a human worker.

These checking and decision-making functions are natural in automatic computers. The calculating programs always contain a loop that checks whether the calculation and logic steps carried out are correct. It is also usual with punched tapes to carry out this check by cross footing of the punched holes. Two internal checks must be distinguished for the analytical instrument:

1. the automatic checking of the function of the instrument itself and

2. the insertion of analysis of a calibration mixture at regular intervals and the detection of excessively large non-systematic errors.

The demands on the sampling system become increasingly stringent with increasing measuring sensitivity of the analytical method. The sampling reliability decides whether the (now very high) outlay on analysis and measuring equipment is justified and whether the conclusions drawn from analytical results, which are sometimes of great economic importance, are correct. It is known that the sampling, like the analysis itself, contains a systematic error that depends on the procedure and a non-systematic error that can be influenced only by the method. Whereas the magnitude (more accurately the standard deviation) of the non-systematic error can be determined by a sufficiently large number of repetitions of the measurements, the discovery and elimination of systematic

[7] Z. anal. Chem. *237*, 81 (1968).

sampling errors is sometimes very difficult. The automation of sampling is more difficult than the automation of the analytical measuring process.

The elimination of signals due to temporary strong fluctuations and to periodic fluctuations in the process is another testing problem in the automatic control of plants.

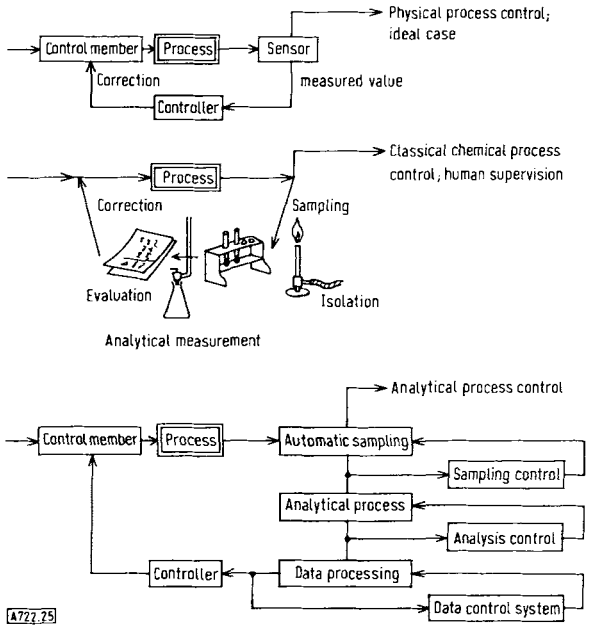

Fig. 25. Analytical data for the control or regulation of a chemical process.

Finally, Figure 25 shows the ideal combination of an automated analysis for the regulation of a chemical process.

7. Conclusion

It should be clear from the developments outlined above that modern analysis has little in common with the analytical chemistry of two or three generations ago, which is still being taught in technical colleges. The modern chemist must therefore bring himself up to date, and acquaint himself with this important branch of knowledge, which links together chemistry, physics, mathematics, biology, and medicine, as well as many branches of technology. Analysis can now claim to be an independent field of instruction and research.

Analysts with a good training in inorganic and organic chemistry, with wide knowledge and experience in analytical methods as a whole, and with a deeper knowledge of some special fields are required today in research and industry. They should be familiar with mathematics, physical measuring techniques, electronics, data processing, information theory, and logic, to enable them to take part in the development of a rapidly growing new field, *i.e.* the logical, exhaustive, and correct evaluation of analytical information from material processes, and their critical appraisal and reduction to the essential facts: the optimization of information.

The author is grateful to the staff of the Physikalisch-Analytisches Laboratorium der BASF, and particularly Dr. Günzler, Dr. Kaiser, and Dr. Seidl, as well as Dr. Brügel and Dr. Witte, for stimulating discussions.

Malonodithioamide from Dimethylaminomalonodinitrile and Hydrogen Sulfide

By *H. Eilingsfeld* and *M. Patsch* [*]

Dedicated to Professor B. Timm on the occasion of his 60th birthday

N–C bonds in quaternary ammonium salts can be cleaved reductively, *e.g.* electrolytically [1] or with sodium amalgam [2]. We have observed that even hydrogen sulfide is able to cleave an N–C bond, with reduction of the carbon released, in the case of certain ammonium salts and tertiary amines. This reaction of dimethylaminomalonodinitrile *(1)* with hydrogen sulfide leads to the formation of malonodithioamide *(4)* in very good yields.

The reaction takes place particularly readily at room temperature in pyridine and in pyridine/glacial acetic acid and ethanol/tertiary amine mixtures. Since malonodinitrile in alcohol adds one hydrogen sulfide to only one nitrile group with formation of cyanothioacetamide [3], while malonodithioamide is formed from dimethylaminomalonodinitrile under the same reaction conditions, it is assumed that the cleavage of the dimethylamino group takes place after the H_2S addition. Under certain reaction conditions (*e.g.* in benzene at 0 °C) we have been able to isolate dimethylaminomalononitrilemonothioamide *(2)* and dimethylaminomalonodithioamide *(3)*. Both products react with hydrogen sulfide in the above mentioned solvents to give the compound *(4)*.

$$(CH_3)_2N{-}CH(CN)_2 \xrightarrow{H_2S} (CH_3)_2N{-}CH\begin{matrix}CS{-}NH_2\\ CN\end{matrix}$$
(1) *(2)*

$$\xrightarrow{H_2S} (CH_3)_2N{-}CH(CS{-}NH_2)_2 \xrightarrow{H_2S} CH_2(CS{-}NH_2)_2$$
(3) *(4)*

The ammonium salt *(5)* [4], which can be prepared by *N*-alkylation of *(1)*, also reacts with hydrogen sulfide to give *(4)*.

$$[(CH_3)_3N{-}CH(CN)_2]^{\oplus}\ p\text{-}CH_3{-}C_6H_4{-}SO_3^{\ominus}$$
(5)

In order to explain the course of the reaction *(3)* → *(4)* we assume that a nucleophilic substitution by SH at the nitrogen takes place, similar to that postulated in the alkaline hydrolysis of chloroamines [5]. However, results of our previous investigations do not rule out a free radical mechanism.

The thiohydroxylamine derivative which one would expect to be formed along with malonothioamide in the cleavage of *(3)* is not stable under the reaction conditions, as the behavior of sulfenamides shows; disulfide and amine are formed.

In the case of compounds of similar structure such as aminomalonates and α-phenyl-α-dimethylaminoacetonitrile we have not been able to split off the amino group with hydrogen sulfide. Attempts have been made to cleave the N—C bond in *(3)* with thiophenols or alkylthiols; however, the reactions proved to be of a complex nature.

Preparation of malonodithioamide (4)

Hydrogen sulfide is passed into a solution of *(1)* (10.9 g) in pyridine (40 ml) and glacial acetic acid (10 ml) over a period of 10 hours at 20–25 °C. Compound *(4)* precipitates out on cooling the solution; yield 11 g (82%), m.p. 185–195 °C (decomp.) [212 °C (decomp.)[6]].

Perhydro-1,4-oxaphosphorins

By *P. Tavs*[*]

Dedicated to Professor B. Timm on the occasion of his 60th birthday

Until recently only few cyclic phosphines have become known that contain, in addition to phosphorus, another hetero atom not directly bonded to phosphorus[1–3]. This communication reports on the synthesis of perhydro-1,4-oxaphosphorins[3], the phosphorus analogs of morpholine.

UV irradiation[4] of an approximately 3% ethereal solution of an equimolar mixture of alkylphosphines RPH_2 and divinyl ether for 20–40 h leads to the heterocyclic tertiary phosphines *(1)–(4)* (work-up by distillation).

	R	B.p. (°C/torr)	Yield (%)	^{31}P chemical shift (ppm) [5]
(1)	n-C_8H_{17}	109–110/0.5	51	+52
(2)	n-$C_{12}H_{25}$	155–157/0.5	57	+52
(3)	n-$C_{14}H_{29}$	150–152/0.1	40	—
(4)	n-$C_{18}H_{37}$	211–212/0.5	42	—
(5)	H	45–48/16	7	+79 (J_{P-H} = 185 Hz)

Their structures follow from the $-CH_2-O-CH_2-$ signal in the 60-MHz NMR spectrum[6] (τ = 6.1–6.5) and the absence of a P–H absorption in the IR spectrum (2300 cm^{-1}). Compounds *(1)–(4)* react rapidly and quantitatively with methyl bromide in ether at 0 °C (quaternary salt of *(1)*, m.p. 97 to 98 °C; that of *(2)*, m.p. 139–140 °C) and with sulfur in boiling benzene (sulfide of *(1)*, m.p. 35–36 °C, recrystallized from pentane; that of *(2)*, m.p. 31–32 °C, recrystallized from methanol).

Reaction of 1 mole of PH_3 with 1 mole of divinyl ether in 500 ml of pentane with addition of 0.05 mole of azoisobutyronitrile[4] in an autoclave at 78–80 °C for 12 hours yields the unsubstituted heterocycle *(5)*, P–H absorption at 2250 cm^{-1}, molecular weight (determined by mass spectrometry) 104. In the 220-MHz NMR spectrum, the resonance signal of the equatorial and of the axial ring protons of *(5)* is resolved into four multiplets: τ = 6.0, 6.8 ($O-CH_2-$) and τ = 8.0, 8.5 ($P-CH_2-$)[7]. The P–H signal appears at τ = 6.85 (J_{P-H} = 185 Hz, further splitting into triplets). β,β'-Diphosphinodiethyl ether, b.p. 83–85 °C/0.5 torr, P–H absorption at 2290 cm^{-1}, is formed in 10% yield along with compound *(5)*. The fragment of highest mass in the precision mass spectrum of the former compound is $C_4H_{11}OP_2^+ = (M-H)$. Its 220-MHz NMR spectrum shows two multiplets at τ = 6.85 ($O-CH_2$) and τ = 8.5 ($P-CH_2$), as well as the P–H signal at τ = 7.5 (J_{P-H} = 193 Hz, further splitting into triplets).

UV irradiation of compound *(5)* and an excess of 1-octene in ethereal solution leads to 4-octylperhydro-1,4-oxaphosphorin *(1)* in 68% yield.

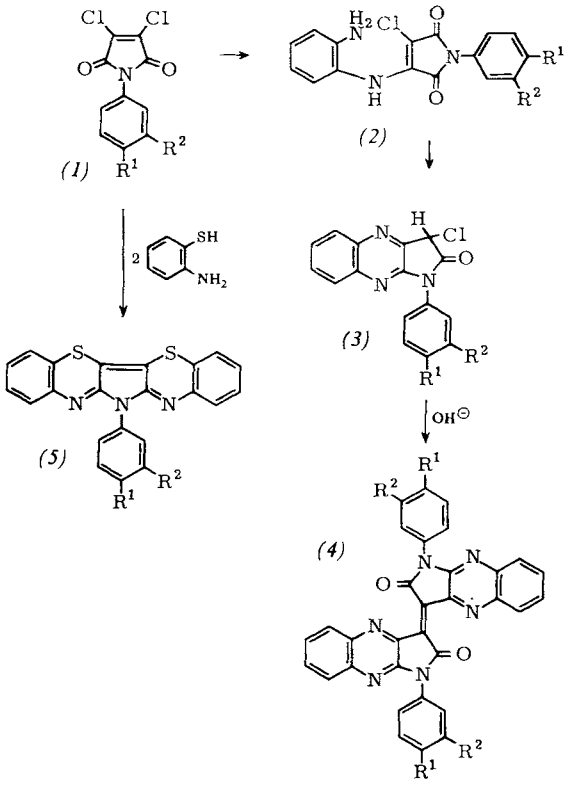
Novel Pigments from Dichloromaleimides



By *P. Dimroth* and *F. Reicheneder*[*]

Dedicated to Professor B. Timm on the occasion of his 60th birthday

We have prepared the novel pigment systems 1,1'-diphenyl-2,2',3,3'-tetrahydro(3,3'-bipyrrolo[2,3-*b*]quinoxaline)-2,2'-dione *(4)* and 7-phenylbenzothiazino[2',3' : 3,2]pyrrolo-[4,5-*b*]benzothiazine *(5)* by reaction of dichloromaleimides with *o*-phenylenediamines and *o*-aminothiols respectively. Both classes of compounds are intensely colored and exhibit pigment-like character.

The reaction product *(2)* expected[1] to be formed by reaction of *N*-phenyldichloromaleimide *(1)* with *o*-phenylenediamine, *e.g.* by heating the components in glycol monomethyl ether, cyclizes with elimination of water during recrystallization (*e.g.* from DMF) to give the quinoxaline derivative *(3)* in very good yields. When heated with bases such as alcoholic sodium- or potassium hydroxide, amines, or magnesium oxide, compound *(3)* undergoes condensation with elimination of HCl and formation of the isoindigoid dye *(4)*. The same reaction takes place when the substituted compounds

(1) and *(2)* are used as reactants. The derivatives of *(4)* (R^1 = R^2 = H, red-violet; R^1 = Cl, R^2 = H, Bordeaux; R^1 = OCH_3, R^2 = H, violet) thus obtained have a pigment-like character (insolubility, thermostability, weather resistance, coloring power); they are suitable, *e.g.* for the coloring of lacquers, PVC, polystyrene, polyamides, and polyolefins.

(5)	R^1	R^2	Color	Suitable for coloring:
(a)	H	H	orange	styrene, hard PVC, printing inks
(b)	Cl	C_6H_5—NH—CO	yellow	styrene, hard PVC, printing inks
(c)	Cl	*p*-C_6H_5—NH—CO-C_6H_4—NH—CO	yellow	lacquers, PVC, thermoplastics
(d)	*p*-C_6H_5—NH—CO-C_6H_4—NH—CO	Cl	orange	lacquers, PVC, thermoplastics

If *N*-phenyldichloromaleimide is allowed to react with *o*-mercaptoaniline instead of *o*-phenylenediamine (*e.g.* by boiling under reflux for 6 hours in glacial acetic acid — recrystallization from *N*-methylpyrrolidone) the polycyclic compound *(5a)*, a brilliant, intensely orange colored compound, is formed. The reaction can be carried out with any substituted dichloromaleimide and *o*-aminoarenethiols and thus affords a method for the preparation of a new class of yellow to red pigments. Red pigments in particular are obtained by anellation of the mercaptoaniline — sometimes by using 2-amino-1-thionaphthol — or by using derivatives of *N*-aminodichloromaleimide (*e.g.* *N*-benzoylaminodichloromaleimide). Yellow pigments are formed when imides having electron donors in the alkyl group (*e.g.* chlorine, *N*-chloroamide) are used in the reaction.

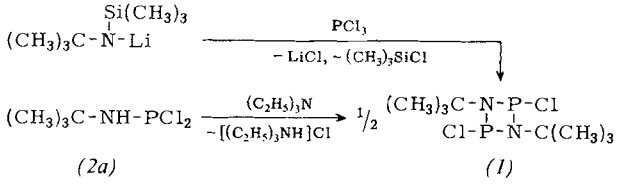
1,3-Di(*tert*-butyl)-2,4-dichlorodiazadiphosphetidine

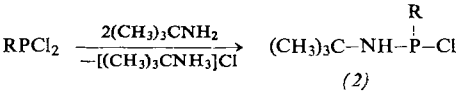


By *O. J. Scherer* and *P. Klusmann*[*]

The existence of four-membered phosphorus(III)-nitrogen ring compounds of the general composition $(RNPCl)_2$ (compounds in which R = C_6H_5 [1] and CH_3 [2] have, for example, been described) has been disputed on the basis of results of recent investigations [3,4].

We have now been able to prepare 1,3-di(*tert*-butyl)-2,4-dichlorodiazadiphosphetidine *(1)* by two different methods:

(i) by reaction of lithium *tert*-butyltrimethylsilylamide with phosphorus trichloride



(ii) from *N*-*tert*-butylaminodichlorophosphine *(2a)* by elimination of HCl (yield 60%)

Compound *(1)*, colorless crystals having m. p. 42—44 °C (b. p. 90—93 °C/0.1 torr), is readily soluble in ether, benzene, and CCl_4. A 1:2:1 triplet (J^{31}PNCCH = 1.0 Hz) ascribable to the $(CH_3)_3C$ group can be observed in the ^{1}H-NMR spectrum (60 MHz). The alternative compound, $(CH_3)_3CN(PCl_2)_2$, was excluded by elemental analysis (*e. g.* Cl calc.: 25.8%; exp.: 25.1%).

Attempts to carry out substitution reactions on *(1)* with dimethylamine or methyllithium led only to complicated mixtures of substances.

N-Alkylaminodihalogenophosphines $RNHPX_2$ [5,6] and *N*-alkylaminohalogenoalkylphosphines RNHPRX [7], compounds of type *(2)*, have been little investigated; the majority of these compounds are not particularly stable at room temperature. If *tert*-butylamine is added dropwise with cooling to PCl_3 or $RPCl_2$ (both components being diluted with ether), thermally stable *N*-*tert*-butylaminochlorophosphines *(2)* are formed in various yields; these products can be purified by distillation and are readily soluble in benzene and ether.

(2a): R = Cl; yield 30% (*ca.* 20% of *(1)* is simultaneously formed); b.p. 53—58 °C/6 torr, m.p. −40 to −38 °C; J^{31}PNCCH = 2.2 Hz.

(2b): R = CH_3; yield 40%; b.p. 48—52 °C/5 torr, J^{31}PNCCH = 1.3, J^{31}PCH = 11.0 Hz.

(2c): R = $(CH_3)_3C$; yield 80%; b.p. 35—36 °C/0.1 torr; J^{31}PNCCH = 1.0, J^{31}PCCH = 13.3 Hz.

Unlike compound *(2a)*, compounds *(2b)* and *(2c)* do not form diazadiphosphetidine derivatives on addition of bases.

Preparation of (1):

A solution of $(CH_3)_3C[(CH_3)_3Si]NLi$ (73 mmoles) [prepared from $(CH_3)_3CNHSi(CH_3)_3$ (10.6 g, 73 mmoles) and *n*-C_4H_9Li/hexane solution (33.0 ml, 73 mmoles)] in ether (50 ml) is added slowly and dropwise with stirring at room temperature to a solution of PCl_3 (10.0 g, 73 mmoles) in ether (100 ml). After the exothermic reaction the mixture is filtered through a G3 frit, the filtrate is concentrated under vacuum (water pump), and the residue is heated to 130 °C in order to complete the elimination of $(CH_3)_3SiCl$. Fractional

distillation of the filtrate at reduced pressure yields 7.5 g (75 %) of pure *(1)*.

Hexapotassium μ-Thiobis(hexacyanomolybdate(IV)), a Novel Molybdenum Complex

By *A. Müller* and *P. Christophliemk*[*]

Passage of H_2S into an alkaline molybdate solution containing a large excess of KCN affords green, crystalline hexapotassium μ-thiobis(hexacyanomolybdate(IV))-4-water $K_6[(CN)_6MoSMo(CN)_6] \cdot 4H_2O$ *(1)*. The values obtained in a series of elemental analyses correspond to the composition given for the complex. Several experiments yielded products whose analyses, IR and electronic spectra, and powder photographs were in agreement with one another.

The solid-state IR spectrum of *(1)* in nujol shows the following main absorption bands (in cm^{-1}): νOH 3490; νCN 2133, 2123, 2112 (measured at high resolution, ±1 cm^{-1}); δOH 1660; δCN(?) 630; δCN, νMoC, and ν_{as}MoSMo: 485, 443, 387, 376, 356.

Electron absorption spectrum (aqueous solution): 620 nm ($\varepsilon = 1.4 \times 10^2$ l $mole^{-1}$ cm^{-1}), 369 (10^5), 295 ($\approx 10^3$), 263 ($\approx 2 \times 10^3$), and 232 ($\approx 10^4$). Whereas the first band is to be ascribed to a d→d transition, that at 369 nm, which has an exceptionally high intensity, is due to an electron transfer π(S)→d(Mo). The shift of this band toward shorter wavelengths compared with thiomolybdates without a bridging sulfur atom[1,2] is physically meaningful; the increased intensity compared with the corresponding band of thiomolybdates appears to be characteristic of an Mo-S-Mo group. The three remaining bands lie in the region expected for d(Mo)→π*(CN) transitions[3,4,5]. The solid-state electronic spectrum of *(1)* is identical with the solution spectrum between 650 and 300 nm. Since the solid-state electronic spectra of *(1)* and of the anhydrous complex *(2)* are in agreement with each other, it appears unlikely that water is coordinated to molybdenum; such a bonding would raise the coordination number of molybdenum to 8.

The molar conductivity Λ (18 °C, H_2O; $v = 10^3$ l $mole^{-1}$) of 665 cm^2 Ω^{-1} $mole^{-1}$ was to be expected for a complex salt that dissociates into seven ions. Complex *(1)* is diamagnetic both in the solid state and in aqueous solution. The five most intense lines in the powder photograph have the *d* values (relative intensities): 8.34_6 (92), 7.62_8 (64), 7.02_5 (74), 3.77_0 (55), 3.04_8 (100) Å.

The anion $[(CN)_6MoSMo(CN)_6]^{6-}$ can be precipitated from aqueous solution as $[Cr(NH_3)_6]_2[(CN)_6MoSMo(CN)_6] \cdot 4H_2O$, whose IR spectrum is analogous to that of the potassium salt.

Procedure:

H_2S is passed into a concentrated solution of potassium molybdate containing a five-fold excess of potassium cyanide (*e.g.* 40 g of MoO_3 + 90 g of KCN in 250 ml of 25% KOH) until the solution assumes an intense green color. On addition of acetone, a dark green oil is precipitated which solidifies on repeated washing with acetone, ethanol, and methanol. The crude product, which still contains a considerable amount of potassium molybdate, is recrystallized from aqueous solution with methanol until the IR spectrum no longer contains a band between 1200 and 800 cm^{-1}. The pure salt *(1)* is pale to grass green; the yield amounts to about 20%, referred to MoO_3. The anhydrous salt *(2)* is obtained when *(1)* is dried over P_4O_{10} in vacuum at 100 °C for two days.

The Catalytic Mixed Oligomerization of Butadiene and Alkynes

By *W. Brenner, P. Heimbach, K.-J. Ploner*, and *F. Thömel*[*]

Reaction of butadiene with 2-butyne (molar ratio 10 : 1) on Ni^0-triphenylphosphine catalyst leads to the formation of 4,5-dimethyl-*cis,cis,trans*-1,4,7-cyclodecatriene[1,2] (yield based on reacted butadiene ≈85% at 25% conversion; referred to 2-butyne >90% with ≈100% conversion). Equally good yields of ten-membered ring compounds can be

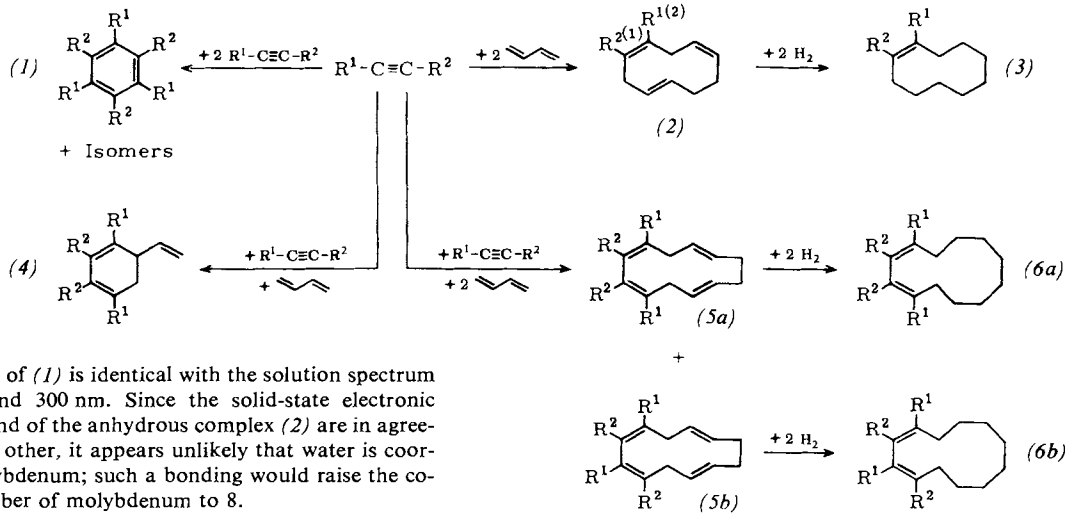

Table 3. Physical data of the previously undescribed mixed oligomers.

[a] Prepared from the sodium salt of methyl propargyl ether and ethyl bromide in liquid NH_3. B.p. 120 °C/760 torr; $n_D^{20} = 1.4235$. [b] The three compounds of type *(6)* were isolated in the pure form by preparative gas chromatography.

prepared if alkyl-substituted alkynes or alkynes in which the functional groups are separated from the triple bond by at least two methylene groups are used[3,4]. In addition, we could isolate further mixed oligomers of type *(4)* and *(5)* from butadiene and alkynes; these were identified by IR, ^{1}H-NMR, and mass spectroscopy.

Table 1. Dependence of yields of mixed oligomers on the molar ratio of butadiene : 2-butyne and on the catalyst. Reaction temperature 20 °C [3].

Catalyst	Butadiene : 2-butyne [a]	*(1)*, $R^1 = R^2 = CH_3$	Yield [b] *(2)*, $R^1 = R^2 = CH_3$	*(5)*, $R^1 = R^2 = CH_3$ [c]

Ni^0 +	1 : 1	2.3	58	19
$(C_6H_5O)_3P$	10 : 1	0.8	44	1.2

[a] Molar ratio at the beginning of the reaction.
[b] Wt.-% in reaction product.
[c] Small amounts of the *cis,cis,cis,trans* isomer is formed along with the *cis,cis,trans,trans* compound.
[d] Yield based on reacted 2-butyne ≈78%.
[e] Yield based on reacted 2-butyne >90%.

At higher alkyne concentrations, twelve-membered ring compounds *(5)* and aromatic compounds *(1)* are formed in higher yields. The twelve-membered ring compound *(5)*, $R^1 = R^2 = CH_3$, can be prepared from 2-butyne and butadiene in much better yields if triphenylphosphite-Ni^0 is used as catalyst instead of triphenylphosphine-Ni^0 (see Table 1).

The formation of the various mixed oligomers is dependent to a great extent on the nature of the substituents at the triple bond (see *e.g.* Table 2).

Two of the three isomeric twelve-membered ring compounds *(6)* are formed in the reaction of 1-methoxy-2-pentyne. So far we have been able to prepare a mixed oligomer of type *(4)* in about 20% yield from butadiene and 2-butyne (1 : 1) using Ni^0-catalysts containing no phosphorus ligands. Reaction of two molecules of phenylacetylene and one molecule of butadiene on Ni^0-triphenylphosphine catalyst at −10 °C leads to the formation of a 1,3-cyclohexadiene derivative in 25% yield[5]. That the phenyl groups are situated in the 1,4-position is confirmed, *inter alia*, by the UV-spectrum (λ_{max} = 343 nm, ε_{max} = 25770 l mole^{-1} cm^{-1} in hexane; cf.[6]). Furthermore, the compound can be isomerized quantitatively to 2′-ethyl-*p*-terphenyl (m.p. 38–39 °C, λ_{max} 264 nm, ε_{max} = 21000 l mole^{-1} cm^{-1} in hexane, cf.[7]) by potassium *tert*-butoxide in dimethyl sulfoxide.

Other catalytically formed cyclic mixed oligomers having the molar composition butadiene: alkyne = 3 : 1 and 2 : 3 have not as yet been isolable in the pure form.

Experimental

Bis(cyclooctadiene)nickel(0)[8] (8.5 mmoles) and $P(C_6H_5)_3$ (8.5 mmoles) are dissolved at −80 °C in a mixture of toluene (100 ml), alkyne (0.25 mole), and the desired amount of butadiene in a graduated pressure ampoule. The course of the reaction can be followed qualitatively by reference to the volume contraction. Methoxymethyl-, phenyl-, and carboxylate-substituted alkynes sometimes react too violently at 20 °C under these conditions; the reactions should therefore be carried out at temperatures below −10 °C.

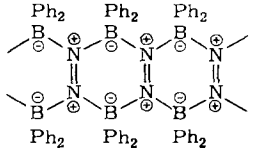
Bis(diphenylboryl)diimine [1]

By *N. Wiberg* and *G. Schwenk* [*]

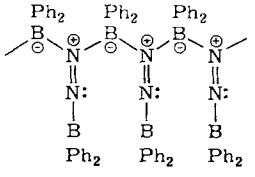
In most cases silicon-nitrogen compounds are readily cleaved by Lewis acids at the Si–N bond [2]. Treatment of bis(trimethylsilyl)diimine [3] should thus lead to a synthesis of new derivatives of diimine, R–N=N–R:

$$(CH_3)_3Si{-}N{=}N{-}Si(CH_3)_3 + 2\ R{-}X \rightarrow 2\ (CH_3)_3Si{-}X + R{-}N{=}N{-}R$$



By using chlorodiphenylborane [R–X = $(C_6H_5)_2B$–Cl] in this way we obtained the first pure "azoborane" [4], namely, the brilliant yellow bis(diphenylboryl)diimine *(1)*. This compound completes the series of diimine derivatives R_2N_2 in which the two groups R attached to the diimine residue run from the element of the third to that of the seventh Group of the first short Period:

R_2N_2; R =



>B	>C	>N	–O	F
yellow	yellow-red	colorless	colorless	colorless

Compound *(1)* is not the sole product; about 70% of the reactants undergo an obscure reaction leading to nitrogen and an oil containing boron-nitrogen compounds of unknown composition.

The diimine *(1)* is polymeric, insoluble in the usual solvents, and extremely unreactive; thermal decomposition occurs only slowly above 400 °C, with loss of all the nitrogen. The compound is stable towards acids, but decomposes in the basic pyridine, giving up half its nitrogen. Two structural formulas *(1a)* and *(1b)* (Ph = C_6H_5) require consideration:

(1a)

(1b)

In *(1a)* the valency requirements of all the nitrogen and boron atoms are fully met; in *(1b)* only half the nitrogen and boron atoms are so satisfied, the other half having a free n-electron pair or an electron deficiency. The findings that organic azo compounds can be only singly protonated and that *(1)* dissolves in pyridine with decomposition are in favor of structure *(1b)*; this formula appears the more probable also because of the color of the compound which, as for other azo compounds, may depend on an n→π* electron transition [5].

Experimental:

Solutions of bis(trimethylsilyl)diimine (15.5 mmoles) and chlorodiphenylborane (31 mmoles) each in methylene dichloride (20 ml) are mixed at −40 °C, the reaction being carried out in the absence of oxygen. The mixture becomes deep blue for a short time and evolves nitrogen. When evolution of nitrogen is complete there is a clear yellowish-orange solution, from which analytically pure *(1)* separates slowly at −25 °C as a yellow precipitate.

ESR Spectra of Radical Anions of Aliphatic Azo Compounds: *tert*-Butyl and Trimethylsilyl Derivatives of Diimine [1]

By *U. Krynitz*, *F. Gerson*, *N. Wiberg*, and *M. Veith* [*]

Successive replacement of the tertiary carbon atoms of the relatively stable, pale yellow di(*tert*-butyl)diimine (azoisobutane) *(1)* [2] by the group-homologous silicon atoms leads by way of the less stable, red *tert*-butyl(trimethylsilyl)diimine *(2)* [3] to the extremely unstable, pale blue bis(trimethylsilyl)-diimine *(3)* [4]:

$(CH_3)_3C{-}N{=}N{-}C(CH_3)_3$ *(1)*

$(CH_3)_3C{-}N{=}N{-}Si(CH_3)_3$ *(2)* (α, β)

$(CH_3)_3Si{-}N{=}N{-}Si(CH_3)_3$ *(3)*

In this paper, we report on the radical anions $(1)^{\ominus}$, $(2)^{\ominus}$, and $(3)^{\ominus}$ of these three compounds, which are of theoretical interest as simple π-electron radicals. In contrast to the situation with the known radical anions of aromatic azo compounds [5], the π-spin population in $(1)^{\ominus}$, $(2)^{\ominus}$, and $(3)^{\ominus}$ should be limited mainly to the azo group. This applies particularly to $(1)^{\ominus}$, whereas in the radical anions $(2)^{\ominus}$ and $(3)^{\ominus}$ the unpaired electron can be delocalized to some extent in unoccupied silicon orbitals of suitable symmetry [6].

The radical anions were prepared by reduction of *(1)*, *(2)*, and *(3)* with sodium or potassium in tetrahydrofuran (THF). THF was preferred to 1,2-dimethoxyethane as solvent since it was found that *(2)* and *(3)* are considerably less stable in the latter solvent. However, the radical anions $(1)^{\ominus}$ and $(2)^{\ominus}$ are remarkably stable: after standing for several hours at temperatures below 0 °C their concentration has decreased only slightly. This is only partially true for $(3)^{\ominus}$; although this radical anion is very stable when the counter ion is Na^+, it decomposes even in a few minutes above −50 °C when the counter ion is K^+. The ESR coupling constants for $(1)^{\ominus}$, $(2)^{\ominus}$, and $(3)^{\ominus}$ are listed in Table 1, where the assignments for $a_{N\alpha}$ and $a_{N\beta}$ in the case of $(2)^{\ominus}$ are based on

Table 1. Coupling constants (in gauss) of the magnetic nuclei in $(1)^{\ominus}$, $(2)^{\ominus}$, and $(3)^{\ominus}$. Solvent: THF.

comparisons with *(1)*$^{\ominus}$ and *(3)*$^{\ominus}$ and on HMO calculations. The characteristic spectra are reproduced in Figures 1a—1d.

Not enough information is presently available for a detailed discussion of the ESR results (Table 1). In the first place, it is questionable whether the parameters that have been proposed for the relations between ^{14}N coupling constants and π-spin populations in other cases [7] may be used here. Secondly, the hybridization state of trimethylsilyl-substituted nitrogen atoms in *(2)* and *(3)* has not been clarified. Even with these limitations the following relations are evident:

1. The sums of the coupling constants $a_{N\alpha} + a_{N\beta}$ decrease along the series *(1)*$^{\ominus}$, *(2)*$^{\ominus}$, and *(3)*$^{\ominus}$: 16.5; 15.2 (15.0); 13.2 (12.5). The decreases correspond to the expectation that trimethylsilyl substituents should have an appreciable share of the π-spin population [6]. It is informative to compare the ^{14}N coupling constants ($a_{N\alpha} = a_{N\beta}$) of the two symmetrical radical anions *(1)*$^{\ominus}$ and *(3)*$^{\ominus}$ with the corresponding values for the radical anion *(4)*$^{\ominus}$ of azobenzene [5]: *(1)*$^{\ominus}$ 8.25; *(3)*$^{\ominus}$ 6.25 (6.62); *(4)*$^{\ominus}$ 4.84 gauss. The capacity of trimethylsilyl substituents for sharing π-spin population is thus intermediate between the capacities of alkyl and of aryl substituents.

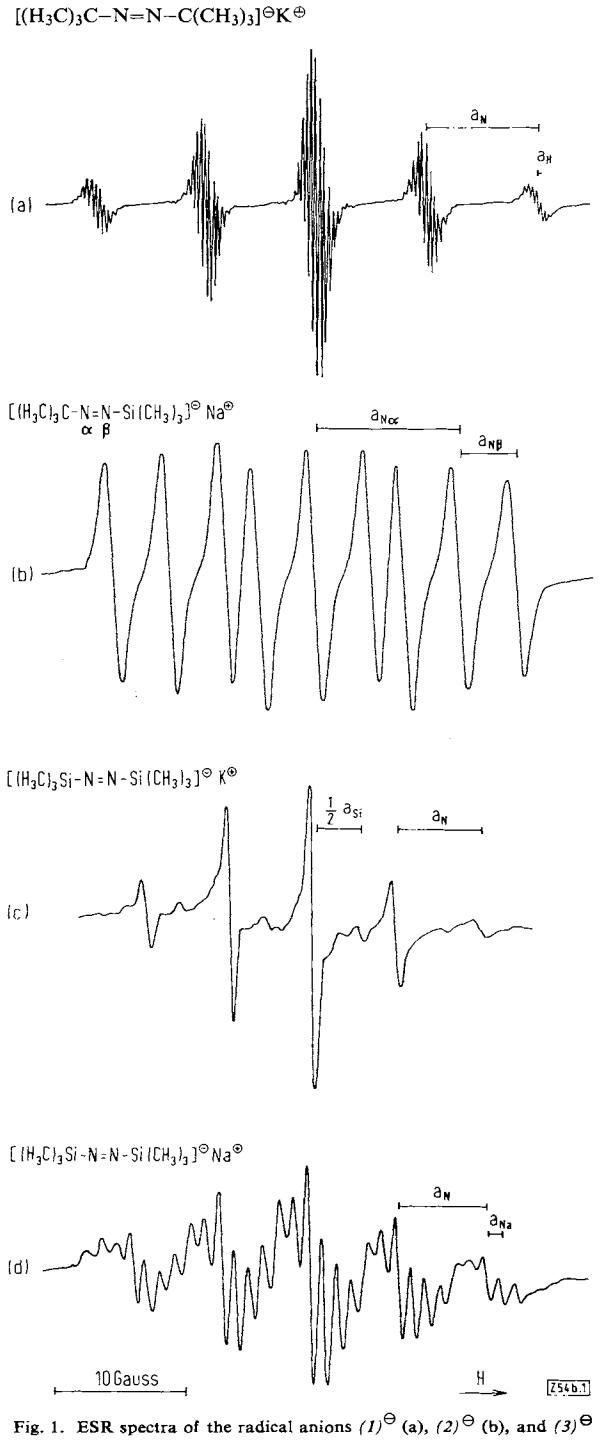

Fig. 1. ESR spectra of the radical anions *(1)*$^{\ominus}$ (a), *(2)*$^{\ominus}$ (b), and *(3)*$^{\ominus}$ (c and d).
Solvent: THF; temperature: 0 °C for a, b, and c, −80 °C for d.

2. In contrast to radical anion *(1)*$^{\ominus}$, where a coupling constant $a_H(C-CH_3) = 0.32$ gauss could be measured (cf. Fig. 1a), the corresponding splittings could not be resolved in the spectra of *(2)*$^{\ominus}$ or *(3)*$^{\ominus}$ (cf. Figs. 1b, c, d). The reason for this probably lies in the small size of $a_H(Si-CH_3)$, which for *(3)*$^{\ominus}$ is likely to be at most 0.1 gauss in view of a line width of 0.6 gauss. This finding cannot yet be interpreted.

3. An additional hyperfine splitting was observed for *(3)*$^{\ominus}$ with Na^+ as counter ion: $a_{Na} = 1.05 \pm 0.05$ gauss (Fig. 1d). The splitting pattern (seven lines of relative intensities 1:2:3:4:3:2:1) corresponds to interaction with two equivalent ^{23}Na nuclei, a phenomenon that has already been found for ketyls in THF with Na^+ or Li^+ as counter ions [8]. Since the electronic structures of the azo and the keto group are related, similar associations might be involved in the two cases. An additional splitting by ^{39}K nuclei of two equivalent K^+ counter ions was not observed either for *(3)*$^{\ominus}$ or for the ketyls mentioned above, probably because of lack of association (larger volume of the K^+ ion) and/or of non-resolution (appreciably lower magnetic moment of the ^{39}K isotope). The former explanation is favored in the case of *(3)*$^{\ominus}$ by the almost identical line widths in the spectra concerned (Figs. 1c and 1d) and also by the stabilization, already indicated, of the radical anion by Na^+ counter ions.

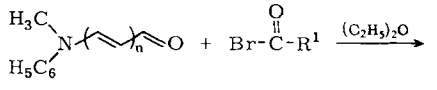
O-Acylated Vinylogous Amides [1]

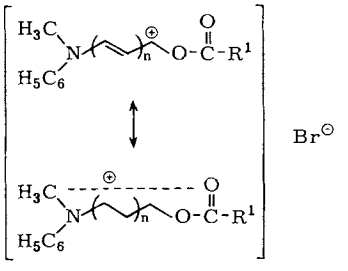
By *H. G. Nordmann* and *F. Kröhnke* [*]

Vinylogous amides (formamides) *(2)* react extremely smoothly with methylene-active compounds such as *N*-(*p*-bromophenacyl)pyridinium bromide *(1)* in acetic anhydride in a kind of vinylogous formylation to give vinylpyridinium salts of the type *(3)* [3].



O-Acylated vinylogous amides were assumed to occur as active intermediates in order to explain the unusually high reactivity of vinylogous amides in the above reaction [2, 3]. We have now succeeded in isolating these compounds for the first time [4, 5].

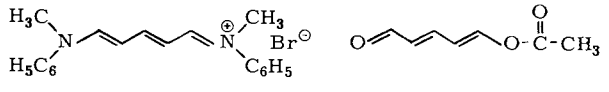
(1) (2) (3)



R =  n = 1,2

The amides *(2)* were treated with acetyl and benzoyl bromide *(4)* in anhydrous ether at 0 °C with rigorous exclusion of moisture (baked-out apparatus, argon). The *O*-acylated amides *(5)* were precipitated immediately as analytically pure, pale yellow to yellow substances in 89—98% yield.

(2) (4)

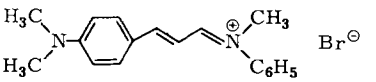


n = 1, 2
R^1 = CH_3; C_6H_5

(5)

The salts *(5)*, which are extremely sensitive to moisture, can be manipulated under argon and stored undecomposed for a considerable time in a Schlenk tube at −20 °C. The results of elemental analysis correspond to the calculated values.

The IR spectrum (nujol) of the compounds *(5)* shows intense, sharp bands in the carbonyl region. The compounds dissociate into *(2)* and acyl bromide *(4)* in inert, non-acylating solvents such as chloroform[6]; they are practically stable in acetic anhydride and acetyl chloride. *(5)*, $n = 2$, $R^1 = CH_3$, is hydrolyzed immediately to the symmetrical vinylogous amidinium salt *(6)* and to *O*-acetylglutaconaldehyde *(7)* by water.



(6) (7)

The formation of *(7)* serves as a proof of the structure of *(5)* since *(7)* can only arise from an *O*-acylated vinylogous amide but not from an *N*-acylated one[7]. The salt *(6)* is formed from the deacylated salt *(5)* and the *N*-methylanilinium bromide that is formed by C—N cleavage on hydrolysis of *(5)*[8]. The surprising formation of symmetrical vinylogous amidinium salts from vinylogous amides in the presence of acylating reagents, which has been observed by other workers[2,9], is doubtless also a "symmetry reaction" of this kind. Compounds *(5)* also react with *N*-methylaniline to give salts of type *(6)*.

We have treated *(5)*, $n = 1$, with *N,N*-dimethylaniline to give the deeply colored immonium salt *(8)*, which affords *p*-dimethylaminocinnamaldehyde on hydrolysis. Compound *(3)*, $n = 1,2$, is formed from *(5)*, $n = 1,2$, and the pyridinium salt *(1)*.

The salts *(5)* could also be identified by UV spectroscopy when moisture was rigidly excluded from the sample: the active intermediate formed from *(2)*, $n = 2$, ("Zincke aldehyde") in acetic anhydride proved identical — apart from the anion — with *(5)*, $n = 2$, $R^1 = CH_3$.

(8)

As highly reactive electrophiles, the *O*-acylated vinylogous amides show a pronounced similarity to the vinylogous "Vilsmeier reagents"[2], the vinylogous formimidyl chlorides[10], and the *O*-alkylated vinylogous amides[11].

Electrochemical Oxidation of Aldehydes, Formic Acid, and Carbon Monoxide at Tungsten Carbide Electrodes in 2 N Sulfuric Acid

By *H. Binder*, *A. Köhling*, *W. Kuhn*, and *G. Sandstede*[*]

Because of their stability towards acids the borides, carbides, nitrides, and silicides of the transition metals have been investigated regarding their suitability as electrode materials[1]. Tungsten carbide (WC) has been proved to be electrocatalytically active for the oxidation of hydrogen[2]. We have confirmed that of all the compounds of this type investigated, WC alone exhibits such an activity and, furthermore, we have found that substances other than hydrogen can be oxidized at WC anodes.

For our potentiodynamic and stationary galvanostatic measurements we used the half-cell arrangements described in reference[3].

Various carbonaceous compounds, namely aldehydes, formic acid, and carbon monoxide are converted at WC electrodes at 70 °C. The activity of freshly prepared tungsten carbide is not very high and commercial products are usually not suitable because of their small surface area. However, as for hydrogen[4], the conversion of other fuels significantly increases after anodic loading of the electrodes at 600 to 700 mV (referred to an H_2-electrode in the same electrolyte) over a period of several hours in the presence of reducing agents such as formaldehyde or hydrazine. This is the case not only for electrodes of porous sintered WC but also for plastic bonded hydrophobic electrodes containing WC as catalyst. The current-voltage curves shown in Figure 1 were obtained with formaldehyde and acetaldehyde after such an activation in the presence of hydrazine. The rate of

oxidation of formaldehyde exceeds by far that of acetaldehyde; a current density of up to 50 mA/cm² can be achieved at voltages lower than 300 mV. However, evolution of gases at the electrodes is insignificant and it can be concluded that the current-producing reaction step is the oxidation to formic acid, which can be further oxidized only slowly. The current density increases greatly with the concentration of the aldehyde in the electrolyte.

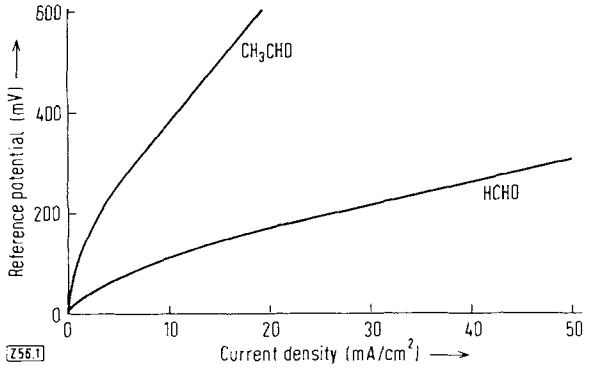

Fig. 1. Stationary galvanostatic current-voltage curves for the oxidation of formaldehyde and acetaldehyde at tungsten carbide in 2 N H_2SO_4 at 70 °C.

The oxidation of acetaldehyde proceeds without evolution of gas, *i.e.* only acetic acid is formed; carboxylic acids, however, cannot be oxidized at WC electrodes. Formic acid is an exception, as it behaves as an hydroxyaldehyde; at sufficiently high temperatures it oxidizes at voltages slightly above 0 mV with evolution of CO_2. Gas is also evolved at the electrode at 90 °C under open circuit conditions, in this case it is probably the evolution of carbon dioxide and hydrogen, which is due to the dehydrogenation of the formic acid (HCOOH → CO_2 + H_2). In the oxidation of formic acid the reaction rate decreases substantially with decreasing temperature (Fig. 2).

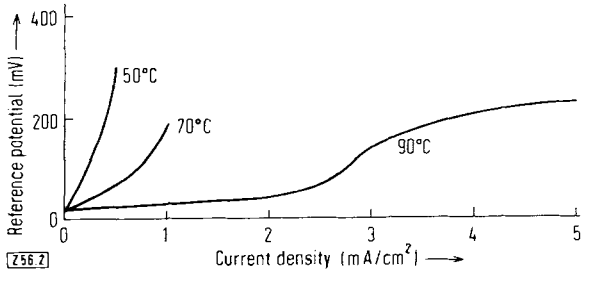

Fig. 2. Stationary galvanostatic current-voltage curves for the oxidation of formic acid at tungsten carbide in 2 N H_2SO_4 at 50, 70, and 90 °C.

At 90 °C and 300 mV the current density is 5 mA/cm² and at 50 °C it decreases to about 10 % of this value. The anomalous character of the curve at 90 °C can easily be explained as follows: At open circuit the hydrogen formed as a result of dehydrogenation of HCOOH determines the potential of the electrode; the rest potential is about 0 mV. At low galvanostatic loading the hydrogen formed by dehydrogenation is first oxidized. At higher current density the formic acid is oxidized directly; this reaction requires a larger overvoltage. Above 300 mV the oxidation reaction is inhibited (clearly recognized in periodic current-voltage curves), and the potential increases rapidly with only a slightly higher loading to about 700 mV; presumably from this point onwards the tungsten carbide itself is attacked.

Several higher aldehydes (*e.g.* propanal, glycolaldehyde, benzaldehyde) can also be oxidized, although in poor yield, to the corresponding carboxylic acids; dark colored condensation products are usually formed at the same time. Alcohols are not converted at WC electrodes under analogous experimental conditions.

At WC gas electrodes even carbon monoxide can be oxidized; however, the current density (3 mA/cm² at 500 mV) is small compared with that reached in the oxidation of hydrogen (150 mA/cm² at 300 mV).

An Optically Active Heteroocine

By *G. Ege* and *W. Planer* [*]

The ^{1}H—NMR spectrum of 7-methyl-4-phenyl-8*H*-1,3,5,6-dithiadiazocin-2-one *(5a)* shows an AB spectrum for the methylene protons; a chiral conformation was deduced on the basis of this fact [1]. Failure of the signals to coalesce when the sample is heated to 150 °C suggested that the substance can be resolved into optical antipodes.

Optical resolution has now been achieved with the carboxyl derivative *(5b)*. Reaction of dimethyl terephthalate and hydrazine hydrate (molar ratio 2:1) in boiling dioxane for eight days afforded the methyl terephthalate hydrazide *(1)* in 60 % yield [2]. In a series of reactions carried out in a single flask (1. CS_2 + KOH, 2. chloroacetone, 3. HCl), *(1)* gave the thiazolinethione *(2)* [80 %; m.p. 199—201 °C (from methanol); ^{1}H—NMR spectrum (CF_3COOH): δ = 2.44 (3H/d); δ = 4.17 (3H/s); δ = 6.82 (1H/q); δ = 8.12—8.45 (4H/m); $J_{CH_3\text{-}H_5}$ = 1.2 Hz], which is cyclized to the hydro-

gen sulfate *(3)* on treatment with concentrated sulfuric acid[1,3] [85 %; m.p. 259—260 °C (decomposition); ^{1}H-NMR spectrum (CF_3COOH): δ = 2.97 (3H/s); δ = 4.17 (3H/s); δ = 7.90 (1H/s); δ = 8.17—8.51 (4H/m)].

If a solution of *(3)* in aqueous KOH, which has been allowed to stand at room temperature for several hours, is added dropwise to boiling dilute hydrochloric acid, compound *(5b)* is obtained [80 %; m.p. 230 °C (decomposition); ^{1}H—NMR spectrum ([D$_6$]—DMSO): δ = 1.85 (3H/s); AB system: δ_A = 3.76, δ_B = 3.46, J_{AB} = 10 Hz; δ = 7.80—8.20 (4H/m)]. The yellow compound *(4)*, which is precipitated on acidification of a cooled alkaline solution of *(3)*, is formed as intermediate in the above reaction [90 %; m.p. 208—212 °C; UV spectrum (methanol): λ_{max} = 411 (ε = 330), 291 (8040), and 251 nm (18800)]. Compound *(4)* can be converted into *(5b)* both thermally and by the action of acids.

The optical resolution of *(5b)* was carried out with brucine in methanol. After repeated recrystallization from methanol the brucine salt shows a specific rotation of $[\alpha]_{436}^{20}$ = —885 ° (*c* = 0.5; chloroform). Decomposition of this salt with dilute hydrochloric acid gave levorotatory *(5b)* having a specific rotation of $[\alpha]_{436}^{20}$ = —2250 ° (*c* = 0.5; acetone). The ORD curve exhibits the expected Cotton effect. Dextrorotatory *(5b)* was obtained by working up the mother liquor of the brucine salt.

To the best of our knowledge, the heteroocine *(5b)* is the first eight-membered, monocyclic heterocycle not fused to a benzene nucleus whose chirality does not arise from an asymmetric C atom and whose optical resolution has been achieved. Moreover, the activation parameters for ring inversion are exceptionally high. We calculated the following values from the rate of racemization of *(5c)* bearing in mind that $k_{rac} = 2\,k_{inv}$: E_A = 30.6 kcal/mole, log *A* = 12.1, and at 120 °C $\Delta G^{\ddagger}$ = 32.1 kcal/mole, $\Delta H^{\ddagger}$ = 29.8 kcal/mole, and $\Delta S^{\ddagger}$ = —6 e. u.

Attempts to determine the optical purity of levorotatory *(5b)* from the NMR spectra (60 MHz) of a number of diastereomeric derivatives of *(5b)* according to the method of *Raban* and *Mislow*[4] were unsuccessful. Experiments to determine the optical purity by the method of isotopic dilution are in progress.

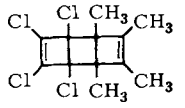
1,2,3,4-Tetrachloro-5,6-dimethyl(Dewar-benzene)

By *R. Criegee* and *R. Huber*[*]



1,2,3,4-Tetrachloro-5,6-dimethyl(Dewar-benzene) (1,2,3,4-tetrachloro-5,6-dimethylbicyclo[2.2.0]hexadiene) *(6)* has been prepared by the following novel route: Treatment of a mixture of hexachlorocyclobutene *(1)*[1] and 3,4-dichloro- and 3,4-dibromo-1,2,3,4-tetramethylcyclobutene *(2)*[2] in boiling ether with lithium amalgam afforded the mixed dimer 1,6,7,8-tetrachloro-2,3,4,5-tetramethylbicyclo[4.2.0.0^{2,5}]-octadiene *(3)* in 15—20% yield, alongside octachlorotricyclo[4.2.0.0^{2,5}]octadiene *(4)*[3]. The products were separated by preparative thin-layer chromatography.

(5)

(6)

(7)

Only the electron-rich double bond of *(3)* reacts with ozone in pentane at room temperature[4]. On degradation according to the method given by *Story*[5] the ozonide *(5)* loses acetic anhydride, the thermal reaction leading to tetrachloro-*o*-xylene *(7)* whereas the photochemical process (CCl_4, —25 °C, laboratory immersion lamp S-81, 1.4 amp, 15—20 h) gives tetrachloro-*o*-(Dewar-xylene) *(6)* in 82% yield. *(6)* was freed from accompanying *(7)* by vacuum sublimation.

Compound *(6)* undergoes thermal isomerization to *(7)* and has a half-life of 20 min at 120 °C and 9 h at 90 °C.

[d] 1,2-Dichlorocyclobutene stretching vibration.

1,2,3,4-Tetrachloro-5,6-dimethyl(Dewar-benzene) (6)

To a vigorously stirred, refluxing solution of *(2a)* (9.6 g) and *(2b)* (21.2 g) in anhydrous ether (50 ml) are added (i) 0.67% lithium amalgam (528 g) and (ii), dropwise over a period of 3 h, a solution of *(1)* (33.4 g) in anhydrous ether (200 ml). After two further hours the reaction mixture is filtered and the mercury residue washed four times with 100 ml portions of hot chloroform. The solvents are removed from the filtrate and extracts, and the residue obtained is dissolved in cyclohexane (200 ml) and filtered through aluminum oxide (400 g). Washing of the adsorbent with pentane (1.5 l), removal of the solvents, and washing with cold methanol yields a colorless crystalline mixture of *(3)* (8—9 g) and *(4)* (2—3 g). The products can be separated by preparative thin-layer chromatography on silica gel.

A 10-g portion of the mixture of *(3)* and *(4)* in pentane (200 ml) is treated with an excess of ozone at room temperature, whereupon a colorless crystalline precipitate is formed. The precipitate and mother liquor are transferred to a column packed with silica gel (400 g) and eluted with pentane (1 l); 2—3 g of *(4)* can be isolated from the pentane eluate. The ozonide *(5)* is eluted from the column with an ether/

pentane mixture (1:5) and is obtained in the form of leaflets on removal of the solvent (yield 8–9 g).

A solution of *(5)* (917 g) in CCl_4 (7 ml) is irradiated under nitrogen in a glass ampoule at −20 °C for 15–20 h. The contents of the ampoule are chromatographed on silica gel (30 g) and eluted with pentane (500 ml). Evaporation to dryness leaves 578 mg of crystals from which compound *(6)* (534 mg, 82%) is obtained by sublimation at 30 torr (bath temperature 75 °C); compound *(7)* (44 mg, 7%) remains behind as residue.

Direct Conversion of Aromatic Nitro Compounds into Isothiocyanates

By *G. Ottmann* and *E. Kober* [*]

Isothiocyanates *(2)* could previously be synthesized from nitro compounds *(1)* only by reduction to the amines and reaction of the latter with, *e.g.*, carbon disulfide and a heavy metal salt or with thiophosgene [1].

We have now been able to accomplish the direct conversion of aromatic nitro compounds (nitrobenzene, dinitrobenzene, and their derivatives) into isothiocyanates by reaction with carbon disulfide or carbonyl sulfide in presence of selected bases.

The reaction is best performed by heating the nitro compound in an autoclave with a) carbon disulfide and alkali metal alkoxide or phenoxide, b) carbon disulfide and an alkyl or aryl sulfide, or c) carbonyl sulfide and an aryl sulfide. Optimum results are obtained at a reaction temperature of between 150 and 170 °C, and by employing carbon disulfide (methods a and b) or carbonyl sulfide (method c) as both reactant *and* solvent. In other solvents, such as benzene, toluene, benzonitrile, *o*-dichlorobenzene, carbon tetrachloride, or 1,1,2-trichloro-1,2,2-trifluoroethane, the reactions result in conversions and yields lower than those reported in the Table.

$RNO_2 \rightarrow RNCS$
(1) *(2)*

R	Base	Meth.	Conversion of *(1)* (%)	Yield of *(2)* (%)
C_6H_5	CH_3ONa	a	66	50
C_6H_5	CH_3SNa	b	34	58
C_6H_5	$S(CH_2CH_2SNa)_2$	b	50	51
C_6H_5	C_6H_5SNa	b	73	61
C_6H_5	*m*-CH_3–C_6H_4SNa	b	93	73
C_6H_5	*m*-CH_3–$C_6H_4SC(S)SNa$	b	53	77
m-CH_3–C_6H_4	CH_3ONa	a	50	66
m-CH_3–C_6H_4	*m*-CH_3–C_6H_4SNa	b	71	87
p-CH_3–C_6H_4	*m*-CH_3–C_6H_4SNa	b	59	75
m-CH_3–C_6H_4	C_6H_5SNa	c	99	55
m-CH_3O–C_6H_4	CH_3ONa	a	41	81
o-CH_3O–C_6H_4	*m*-CH_3–C_6H_4SNa	b	50	88
p-CH_3O–C_6H_4	C_6H_5SNa	c	96	53
m-Br–C_6H_4	CH_3ONa	a	80	58
m-Cl–C_6H_4	*m*-$CH_3C_6H_4SNa$	b	74	84

The conversion of aromatic nitro compounds into isothiocyanates by method a) is accompanied by concomitant formation of anilines in varying amounts. This undesired side reaction is more favored by phenoxides than it is by alkoxides. The formation of anilines is arrested or at least reduced to insignificant levels, and both conversions and yields are increased, when aryl sulfides are employed as base (method b). The aryl sulfides are oxidized predominantly to disulfides, which were isolated. Similar but slightly reduced conversions and yields are achieved when the nitro compounds are treated in CS_2 with a sodium aryl trithiocarbonate, *e.g.* *m*-CH_3–$C_6H_4SC(S)SNa$, formed from sodium *m*-tolyl sulfide and carbon disulfide. Nearly complete conversion of the nitro compounds takes place under the conditions of method c); however, the formation of anilines is not controlled so effectively as in method b).

Extension of the reaction (method b) to aromatic dinitro compounds, *e.g.* *m*-dinitrobenzene, gave 3-nitrophenyl isothiocyanate and small amounts of *m*-phenylene diisothiocyanate. Aliphatic nitro compounds do not react satisfactorily under the above conditions.

m-Tolyl isothiocyanate (method b)

A 300-ml stirring autoclave was charged with 13.7 g of *m*-nitrotoluene, 7.3 g of sodium *m*-tolyl sulfide, and 50 ml of carbon disulfide. The mixture was heated at 160 °C for 3 hours. The crude reaction product was distributed between 100 ml of ether and 75 ml of cold water. The organic layer was dried with $CaCl_2$ and distilled over a spinning band column. Yield 9 g of *m*-tolyl isothiocyanate (87% based on 71% conversion of *m*-nitrotoluene).

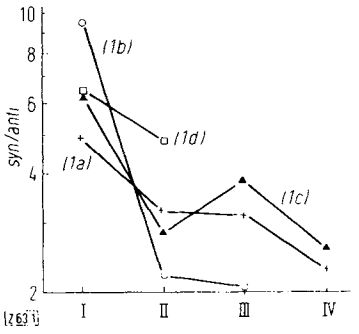
The Carbene/Carbenoid Problem [**]

By *M. Schlosser* and *G. Heinz* [*]

Competitive experiments may afford definitive information about unisolable intermediates in reaction sequences [1]. If a short-lived species S is really the product-forming agent and can be formed from two different starting materials A and B, any reaction products C + D are formed in the same proportions independently of whether the postulated intermediate is derived from A or from B:

In connection with the problem whether "free" carbenes (here C_6H_5–$\ddot{C}H$) or "carbenoids" (carbene-metal salt adducts, here C_6H_5–CHLiX) add to olefins, giving cyclopropane derivatives [2], we have treated the benzyl halides *(1a)*–*(1d)* with butyllithium in the presence of cyclohexene *(2)*, then measuring the proportions in which the products *syn*- and *anti*-7-phenylnorcarane are formed in four solvents (Fig. 1).



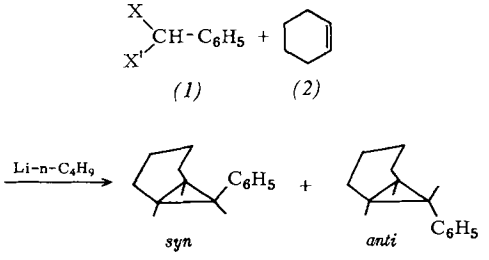


Fig. 1. Proportions of *syn-* and *anti*-7-phenylnorcarane obtained from cyclohexene, butyllithium, and the benzyl halides *(1a)*—*(1d)*.

Conditions: Butyllithium (20 mmoles) in hexane (12.5 ml) was dropped during 1 h into a solution of the halides (40 mmoles) in cyclohexene (6 ml) and a solvent (6 ml) (I = light petroleum, II = diethyl ether; III = tetrahydrofuran, IV = 1,2-dimethoxyethane) at 0 °C. The products were identified by gas chromatography, comparison being with authentic reference samples.

(a), X = H, X′ = F
(b), X = H, X′ = Cl
(c), X = X′ = Br
(d), X = Br, X′ = F

The observed dependence of the *syn/anti* ratios on the preceding step provides only *apparent* confirmation of the carbenoid hypothesis, since the starting materials benzyl fluoride *(1a)* and benzylidene bromide fluoride *(1d)* lead to different proportions of diastereomers, although these must in both cases proceed through the same "carbenoid" C_6H_5—CHLiF. This discrepancy leads to the idea that the product-forming agent — whether it be "free" carbene or a "carbenoid" — may be liberated in differently reactive states according to the mode of its formation.

If the differences in reactivity of these intermediates of differing origins can be ascribed to differing conditions of excitation even in solution[3], then the *syn/anti* ratio should change if the concentration of substrate (here the olefin) and thus the number of collisions before reaction are changed.

We found that under the influence of butyllithium the benzylidene dibromide *(1c)* and cyclohexene give *syn-* and *anti*-7-phenylnorcarane in the ratio 5.7:1. The *syn/anti* ratio increases monotonically to more than 30:1 if the cyclohexene *(2)* is mixed with increasing amounts of light petroleum (I) (to a volume ratio of 1:12). Benzyl chloride *(1b)* behaves similarly (Fig. 2).

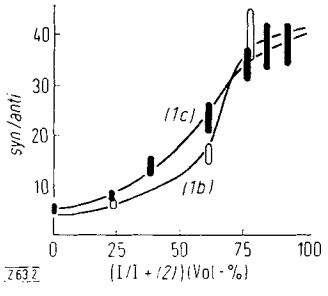

Fig. 2. Dependence of the proportion of *syn-* and *anti*-7-phenylnorcarane on the olefin concentration in reaction of butyllithium on cyclohexene and *(1c)* or *(1b)*.

Conditions: To a solution of the halide (20 mmoles) in a mixture (6 ml) of light petroleum (I) and cyclohexene *(2)* at 0 °C, is added butyllithium (10 mmoles) in the same cyclohexene-light petroleum mixture, dropwise at 0 °C. The products were identified by gas chromatography, comparison being with authentic reference samples.

The increase in stereoselectivity cannot be ascribed to a specific solvation effect: 1-phenyl-2-propylcyclopropane and 7-phenylnorcarane are formed with a *syn/anti* ratio of 3.2:1 and 4.6:1, respectively, in a mixture of pentene, cyclohexene, and light petroleum of composition 20:77:3; if the proportions in the mixture are 20:23:57 the *syn/anti* ratio is 2.9:1 or 26:1 respectively! Further, the *syn/anti* ratio also increases with increasing dilution of the substrate if toluene is used as solvent in place of light petroleum.

The results can be — but need not necessarily be — interpreted as indicating that phenylcarbene C_6H_5-$\ddot{C}$H is the true cyclopropane-forming agent in both cases.

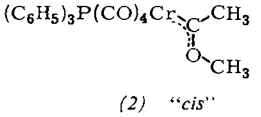
Hindered Rotation about the C—O Bond in Methoxy(methyl)carbene Ligands[1]

By *C. G. Kreiter* and *E. O. Fischer*[*]

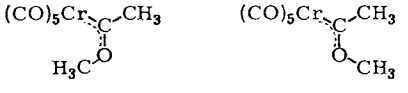


X-Ray structure analyses of pentacarbonyl[methoxy(phenyl)-carbene]chromium(0)[2] *(1)* and *cis*-tetracarbonyl[methoxy-(methyl)carbene]triphenylphosphinechromium(0)[3] *(2)* have shown that the carbene-carbon atom and its three bonds, as well as the carbon atom of the methoxyl group, lie almost in one plane; the carbene-carbon atom is thus sp^2 hybridized and has a "free" p-orbital perpendicular to the bonding plane. The Cr—C distance for the carbene ligands (2.05 and 2.04 Å, respectively) correspond to a bond order[4] of *ca.* 1.2. The electron deficiency on the sp^2 carbon atom is not relieved by the weak metal-carbon back-donation but rather by π-interaction with one of the free electron pairs of the oxygen. Thus the bond lengths between the carbene-carbon and the oxygen atom (1.31 and 1.33 Å, respectively) are much shorter than for C—O single bonds; their partial double-bond character is thus in agreement with the position of the methoxyl group in the sp^2 plane.

The orientation of the methoxyl group is not the same in *(1)* and in *(2)*. If the carbene-carbon/oxygen bond is taken as a "double bond", then the *O*-methyl group is in the *trans-* and *cis*-position to the *C*-phenyl and *C*-methyl group, respectively.

cis-trans Conversions by rotation about a C—O bond should be readily demonstrable by NMR spectroscopy provided

(1) "*trans*"



(2) "*cis*"

that the double-bond contribution is not too great[5]. Previous ^{1}H-NMR measurements with methoxy(methyl)carbene complexes were explained on the assumption that one isomer only exists preferentially between −50 and +120 °C[6].

In a more recent study, however, we have found additional information: pentacarbonyl[methoxy(methyl)carbene]chromium(0)[7] *(3)* in [D_6]-acetone at +40 °C shows two sharp signals of equal intensity at τ = 5.32 and 6.97 severally, which can be assigned unambiguously to the *O*-methyl and the *C*-methyl group. When the solution is cooled, these signals first become broader and then each splits into two broad signals of approximately equal intensity, that finally become completely sharp at −40 °C; the phenomenon is reversible.

The spectrum at −40 °C can only be interpreted as being due to a mixture of *cis-trans*-isomers of *(3)*. These isomers differ only in their orientation of the *O*-methyl group towards the *C*-methyl group. It is striking that the signals at τ = 5.11 and 7.00 have the same half-width as have those at τ = 5.61 and 6.83. The half-widths of the first pair are slightly the greater; this is presumably caused by the differing HCOCCH coupling constants of the protons of the two methyl groups in the isomers.

We assigned the signals analogously to those of pentacarbonyl[(methylamino)(methyl)carbene]chromium(0)[8]. An X-ray analysis showed that this complex is formed in the *cis*-form[9]; it is not converted thermally into the *trans*-isomer, but only by base catalysis. Shielding of the *N*-methyl group is greater for the *cis*- than for the *trans*-isomer; the HCNCCH coupling is much greater in the *trans*- than in the *cis*-complex[8]. We assume that in *(3)* also the *O*-methyl group of the *cis*-isomer is more strongly shielded than that in the *trans*-isomer, as is also indicated by the HCOCCH coupling which can be estimated from the line widths.

"*trans*" *(3)* "*cis*"

When the mixture of isomers is warmed the lifetime of both isomers decreases, as shown in broadening, coalescence, and sharpening of the signals. The shapes of the signals permit the lifetimes of the isomers to be calculated[10] at various temperatures; and an activation energy of 12.4 ± 1.0 kcal per mole was determined for conversion of one isomer of *(3)* into the other. The steric findings do not allow any energy difference to be recognized between the *cis*- and the *trans*-form, yet different solvents appear to stabilize the isomers differently. In [D_6]-acetone and [D_4]-methanol the two isomers are present in about equal concentrations, but in [D]-chloroform, chlorobenzene, and fluorobenzene the *trans*-isomer clearly predominates.

Table: Chemical shifts and relative quantities of the *cis-trans*-isomers of pentacarbonyl[methoxy(methyl)carbene]chromium(0) *(3)* at −40 °C in various solvents.

Solvent	τ (OCH_3) *trans*	*cis*	τ (CCH_3) *trans*	*cis*	Relative amounts (%) *trans*	*cis*
[D_6]-Acetone	5.11	5.61	7.00	6.83	50	50
[D]-Chloroform	5.19	5.69	7.03	6.99	90	10
[D_4]-Methanol	5.17	5.66	7.03	6.95	61	39
Chlorobenzene	5.83	6.78	7.49	7.76	84	16
Fluorobenzene	5.77	6.70	7.44	7.69	83	17

Alteration of any of the three substituents on the carbene-carbon atom has a characteristic influence on the rotation around the C—O bond, so that ^{1}H-NMR spectroscopy becomes an important tool for clarification of bonding problems in carbene complexes.

The Main and Secondary Reactions between Alkylidenetriphenylphosphoranes and Isothiocyanates

By *H. J. Bestmann* and *S. Pfohl*[*]

Reaction of alkylidenetriphenylphosphoranes *(1)* with isothiocyanates *(2)* leads either to betaines *(3)* (when R exerts a +I effect) or to ylides *(4)* (with groups R exhibiting a −I effect and R = H), whose subsequent reactions offer new preparative possibilities.

(1) *(2)* *(3)* *(4)* *(7)* *(5)* *(8)* *(6)* *(9)* *(10)*

R	R^1	*(3)* or *(4)*, m.p. in °C (yield in %)	R^2	*(5)*, m.p. in °C (yield in %)	*(6)*, m.p. in °C (yield in %)	*(7)*, m.p. in °C (yield in %)	*(8)*, b.p. in °C/torr (yield in %)	R^3	*(9)*, b.p. in °C/torr (yield in %)	*(10)*, m.p. in °C (yield in %)

The Wittig reaction of *(4)* with aldehydes affords *N*-substituted thiocarboxamides *(7)* of α,β-unsaturated acids. Both *(3)* and *(4)* undergo *S*-methylation on treatment with methyl iodide; the phosphonium salts *(5)* isolated after this reaction can be converted into the ylides *(6)* by treatment with sodium methoxide. Starting from *(6)*, hydrolysis gives thioimidic acid derivatives *(8)*, Wittig reaction affords the corresponding derivatives of α,β-unsaturated acids *(9)*, and reaction with methyl iodide leads to the substituted vinylphosphonium salts *(10)*.

Thiocinnamanilide

A solution of phenyl isothiocyanate *(2)*, $R^1 = C_6H_5$, (6.75 g, 50 mmoles) in anhydrous benzene (50 ml) is added dropwise and slowly to a salt-free benzene solution of methylenetriphenylphosphorane *(1)*, R = H[1], (50 mmoles). After 12 hours' stirring the initially oily precipitate becomes crystalline. The precipitate is filtered off under vacuum and recrystallized from chloroform/ethyl acetate. M.p. 203 °C, yield 17.0 g (85%) of *(4)*, R = H, $R^1 = C_6H_5$. — To a suspension of this ylide (8.2 g, 20 mmoles) in benzene (150 ml) is added benzaldehyde (2.1 g, 20 mmoles) and the reaction mixture is stirred at room temperature for 48 h, whereupon dissolution occurs. The benzene is subsequently distilled off and the residue recrystallized from isopropanol. M.p. of the thiocinnamanilide *(7)*, R = H, $R^1 = R^2 = C_6H_5$, is 136 °C (value given in literature 128—129 °C[2]), yield 3.5 g (73%).

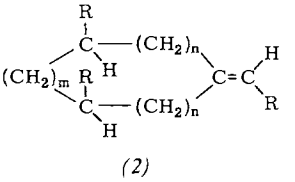
Partial Asymmetric Synthesis of Substituted Benzylidenecycloalkanes[1]

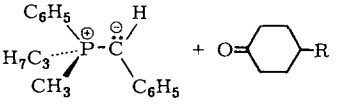
By *H. J. Bestmann* and *J. Lienert*[*]



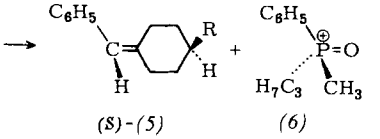
Cycloalkanes having an exocyclic double bond and an even number of C atoms in the ring, which bears a substituent at the greatest possible distance from the double bond, are chiral molecules [type *(1)*]. The same applies to all *cis*-disubstituted cycloalkanes with a exocyclic double bond having two identical substituents at equal distances from the double bond [type *(2)*]. In both cases it is essential that R and $R^1 \neq H$, although $R = R^1$ is possible.

We have found that optically active molecules of types *(1)* and *(2)* can be obtained by partial asymmetric synthesis, the route selected being a Wittig reaction of the corresponding ketones with optically active alkylidenephosphoranes. We chose benzylidenemethylphenyl-*n*-propylphosphorane *(3)* as the optically active ylide since the absolute configuration of the phosphonium bromide obtained from *(2)* on liberation of HBr by sodamide is known[2].

(1)



$n = 0, 1, 2, 3 \ldots .$
$n = 0$ = allene



(2)

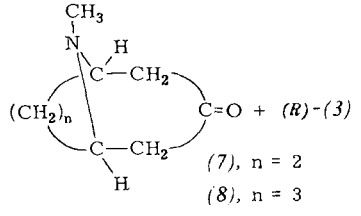
$n = 0, 1, 2, 3 \ldots .$
$m = 0, 1, 2, 3 \ldots .$

The reaction of *(3)* with 4-substituted cyclohexanones *(4)* leads to optically active 4-substituted benzylidenecyclohexanes *(5)*, belonging to type *(1)*. The absolute configuration of *(5a)* has already been determined[3]. It was found that reaction of the (*R*)-ylide *(3)* [configuration as shown in *(3)*], which is obtained from (*S*)-(+)-benzylmethylphenylpropylphosphonium bromide[4], with 4-methylcyclohexanone *(4a)* affords (*S*)-(+)-benzylidene-4-methylcyclohexane *(5a)* in an optical yield of 43%.

(R)-(3) *(4)*

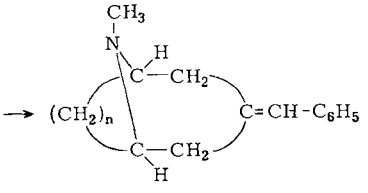
(S)-(5) *(6)*

(a), R = CH_3 *(c)*, R = $C(CH_3)_3$ *(e)*, R = OC_2H_5
(b), R = C_2H_5 *(d)*, R = OCH_3



Ylide	Product	$[\alpha]_D$ of *(5)* (°)
(*R*)-*(3)*	(*S*)-*(5a)*	+25.8
(*S*)-*(3)*	(*R*)-*(5a)*	−25.4
(*R*)-*(3)*	(*S*)-*(5b)*	+20.1
(*S*)-*(3)*	(*R*)-*(5b)*	−19.9
(*R*)-*(3)*	(*S*)-*(5c)*	+21.8
(*S*)-*(3)*	(*R*)-*(5c)*	−21.1
(*R*)-*(3)*	(*S*)-*(5d)*	+ 4.5
(*R*)-*(3)*	(*S*)-*(5e)*	+ 5.9

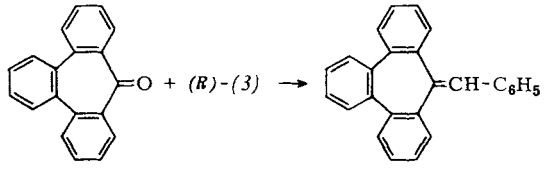
All compounds *(5)* obtained from (*R*)-*(3)* show a negative Cotton effect in the ORD curves. The form of the CD curves is also similar. We therefore conclude that all these compounds possess the (*S*) configuration, whereas the (*R*) enantiomers of *(5)* are formed preferentially on reaction of (*S*)-*(3)* with the cyclohexanones *(4)*.



In all the reactions the ylides *(3)* were obtained from the optically pure phosphonium salts. Since the compounds *(5b)*—*(5e)* have not yet been obtained in optically pure form, and since attempts to resolve them into the pure enantiomers have so far been unsuccessful, no optical yield can be given for their preparation.

The (*R*)-(+)-methylphenylpropylphosphine oxide *(6)*, whose absolute configuration is known[5,6], is formed alongside *(5)* in all reactions in which the (*S*)-(+)-phosphonium salt is used as starting material. The specific rotation $[\alpha]_D = 18.4°$ to 18.8° found for *(6)* indicates that the Wittig reaction proceeds in the usual way, *i.e.* with complete retention of configuration at the phosphorus atom[6,7].

Reaction of tropinone *(7)* and pseudopelletierine *(8)* with (*R*)-*(3)* affords the optically active compounds *(9)* and *(10)*, respectively, which belong to type *(2)*.



(7), n = 2
(8), n = 3

(9), n = 2 $[\alpha]_D = -89.5°$
(10), n = 3 $[\alpha]_D = -51.40°$

Nothing can be said about the optical yield of *(9)* and *(10)*, or about their absolute configurations. Mention should be made of the fact that these molecules cannot be described by the Cahn-Ingold-Prelog rules[8].

Tribenzocycloheptene derivatives having an exocyclic double bond are chiral[9]. We obtained the optically active compound *(12)* from the ketone *(11)*[10] and (*R*)-*(3)*. As for compounds *(9)* and *(10)*, no statement can be made regarding the optical yield, absolute configuration, and assignment of compound *(12)* to the (*R*) or the (*S*) series.

(11) *(12)* $[\alpha]_D = -8.6°$

3-Nitrophthalic Anhydride as Blocking Agent in Merrifield Polypeptide Syntheses[1]

By *Th. Wieland, Chr. Birr*, and *H. Wissenbach*[*]

In stepwise synthesis of peptides by the Merrifield method[2] each incomplete reaction step decreases the homogeneity of the final product. The greatest effect is seen in the coupling steps in which a small part of the free amino ends of the peptide chain may escape reaction with the attaching *tert*-butoxycarbonyl (BOC) amino acid and can thus lead at the following step to formation of a false sequence. Our object was to block the undesired faulty peptide at its free amino end after each coupling step, and to do this in such a way that after removal of the finished peptide from the resin all the compounds formed from the false peptides could be separated easily and simply from the desired polypeptide.

We found 3-nitrophthalic anhydride to be a suitable blocking agent for this purpose. It is an energetic acylating agent, attacking even relatively unreactive amino groups; the resulting 2-carboxy-3-nitrobenzoyl derivatives are such strong acids owing to the "*ortho*-effect" of the nitro group (*o*-nitrobenzoic acid has $pK \approx 2.3$) that they can be readily separated even from acid peptides by chromatography on an anion exchanger.

To demonstrate the utility of this blocking agent we have built up the plastein-active[3] pentapeptide L-tyrosyl-L-leucylglycyl-L-glutamyl-L-phenylalanine on a polystyrene carrier. 5 g of polystyrene was chloromethylated and then esterified with BOC-phenylalanine (4 mmoles); after removal of the BOC group[2], the next BOC-amino acid was condensed on by dicyclohexylcarbodiimide in methylene dichloride, but the latter acid was used, not in three-fold molar excess, but only in equimolar amount so as to simulate unsuitable conditions. Glutamic acid was used as its BOC-γ-benzyl ester. Contrary to previous procedures, after each condensation the resin was washed three times with 35 ml each of methylene dichloride, ethanol, and dimethylformamide (DMF), then reacted with a solution of 3-nitrophthalic anhydride (870 mg, 4.5 mmoles) in DMF (20 ml) for 3 min, and shaken with a solution of triethylamine (1 ml) in DMF (5 ml) for 30 min. It was then washed with 35 ml of DMF, dioxane, ethanol, and glacial acetic acid three times each, and the BOC group of the last BOC-amino acid added was removed[2].

Subsequent debenzylation and removal of the products from the resin by HBr in trifluoroacetic acid gave a mixture (*ca.* 2 g) which was digested with ether and then separated by chromatography on Dowex 1 × 2 in an acetic acid gradient (water → 50% acetic acid). This eluted first unknown by-products (*ca.* 200 mg) then the desired pentapeptide (980 mg) after a small, easily separable fore-fraction, and much later the mixture of blocked acidic intermediate peptides (100 mg).

The pentapeptide was electrophoretically and chromatographically homogeneous and on total hydrolysis gave the amino acids Phe, Glu, Gly, Leu, and Tyr in the proportions 0.98 : 1.13 : 1.00 : 1.07 : 0.89 (*D. Georgopoulos*). In the plastein reaction[3] with pepsin, a 25-mg sample gave 14 mg (60%) of water-insoluble polypeptide mixture.

Paper electrophoresis at pH 6.5 separated the blocked intermediate peptides into the four expected constituents (2-carboxy-3-nitrobenzoyl derivatives of Phe, Glu-Phe, Gly-Glu-Phe, and Leu-Gly-Glu-Phe), which appeared with approximately equal intensity on development with the *tert*-butyl hypochlorite-tolidine reagent[4].

Single-step Synthesis of Pyridines from 3-Aminoacrolein and Carbonyl Compounds

By *E. Breitmaier* and *E. Bayer*[*]

3-Aminoacrolein *(1)*[1,2] cyclocondenses with carbonyl compounds of type *(2)* to give pyridine derivatives of type *(3)*; R^1 and R^2 may also be part of the ring.

(1) *(2)* *(3)*

	R^1	R^2	Pyridine derivative	B.p. (°C/ 12 Torr)	Yield (%)	Ref.
(a)	$COOC_2H_5$	CH_3	Ethyl 2-methyl-3-pyridine-carboxylate	107–108	50	[3]
(b)	$COCH_3$	CH_3	3-Acetyl-2-methylpyridine	104–105	55	[4]
(c)	$-(CH_2)_4-$		5,6,7,8-Tetra-hydroquinoline	98– 99	20	[5]

The cyclocondensation proceeds *via* a Schiff base – formed between the amino group of *(1)* and the carbonyl group of *(2)* – combined with a Knoevenagel reaction between the formyl group of *(1)* and the methyl group of *(2)*.

General procedure:

Ammonium acetate (50 mg) is added to a mixture of 3-aminoacrolein *(1)*[1,2] (0.05 mole) and a carbonyl compound *(2)* (0.06 mole) and the mixture is stirred under reflux for 12 hours at an oil-bath temperature of 110 °C. The oily reaction mixture is then poured into ether (100 ml) and the resulting ether solution is dried with magnesium sulfate and filtered under vacuum. The ether is evaporated off and the residue is fractionated at 12 torr.

The structure of the pyridines *(3a)*–*(3c)* can be established on the basis of their ^{1}H-NMR spectra.

Crystal Structure of Bis(cyclooctatetraene)titanium

By *H. Dietrich* and *M. Soltwisch*[*]

The violet π complex bis(cyclooctatetraene)titanium synthesized by *Breil* and *Wilke*[1] crystallizes monoclinically in the space group $Pb(C_s^2)$ with $a = 7.00$, $b = 12.26$, $c = 7.92$ Å, $\gamma = -114.85°$, $V = 617$ Å^3; $Z = 2$, $d_{x\text{-ray}} = 1.378$ gm/cm^3. The crystal structure was determined from X-ray diffraction data recorded on a counting-tube diffractometer using filtered $Cu_{K\alpha}$ radiation.

The molecule contains one planar and one boat shaped cyclooctatetraene ring. The planar one (C–C bond length 1.41 ± 0.02 Å[2]) is symmetrically attached to the titanium atom (all Ti–C bond lengths 2.32 ± 0.02 Å[2]), while the nonplanar ring is bonded to the titanium atom *via* four carbon atoms only. In the Figure the two shorter Ti–C bond lengths (2.2 Å each) are marked by full lines, the two longer ones (2.5 Å each) by broken lines. The coordination of the titanium is thus very similar to that in tris(cyclooctatetraene)-dititanium[1,3], in which, however, the two shortest Ti–C bonds to the non planar ring are about 0.1 Å longer.

The crystal is partially disordered. Apparently another molecular form exists in which the nonplanar ring interacts with the titanium atom *via* three carbon atoms only (shortest Ti–C bond length 2.2 Å). At present the discrepancy factor is $R = 10\%$.

Proton Magnetic Resonance Studies on Polysaccharide Derivatives

By *H. Friebolin, G. Keilich,* and *E. Siefert*[*]

Proton magnetic resonance studies on synthetic polymers such as polystyrene, PVC, poly-α-methylstyrene are generally complicated by the broad signals of the individual protons. The line broadening arises mainly from conformative and configurative factors, and in the case of copolymers from composition factors. Once a degree of polymerization of 20 has been exceeded, the ^{1}H-NMR spectra of these polymers remain almost unchanged and differ considerably from the spectra of the monomers.

The acetyl and benzoyl derivatives of polysaccharides exhibit a quite different behavior. We have conducted measurements on a large number of different tri-*O*-acetyl- and tri-*O*-benzoyl-polysaccharides having degrees of polymerization from about 30 to 3000 (molecular weights ranging from 9000 to 900000) in $CDCl_3$ with the aid of a 220 MHz spectrometer. Figure 1

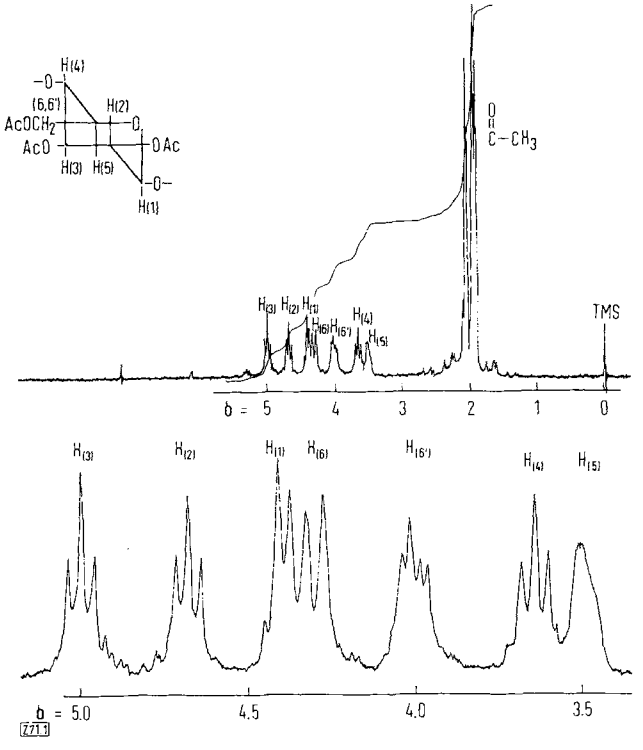

Fig. 1. ^{1}H-NMR spectra of 2,3,6-tri-*O*-acetylcellulose having a degree of polymerization of ≈200 (mol. wt. *ca.* 60000). Measuring frequency: 220 MHz; solvent: $CDCl_3$ (TMS); T = +60 °C.

shows the ^{1}H-NMR spectrum of a 2,3,6-tri-*O*-acetylcellulose having a degree of polymerization of *ca.* 200 (mol. wt. *ca.* 60000). The signals of all seven ring protons are seen individually between δ = 3.5 and 5 ppm alongside the separate signals belonging to the three methyl groups of the acyl substituents in positions 2, 3, and 6. The width of the lines is only about double that occurring in the monosubstituted monosaccharide. The signals can therefore be assigned to the various ring protons by means of the spin-spin coupling constants, and the configuration of the substituents and the nature of the glycosidic bond between the monomers can be determined unequivocally. The coupling constant J_{12} = 8 Hz corresponds to an axial-axial coupling between H(1) and H(2), *i.e.* H(1) is in an axial position; it therefore follows that the monomer units are joined by β-glycosidic linkages. The configuration of the monomer units corresponds to that of glucose since, according to the magnitude of the coupling constants, the protons on C-2, C-3, and C-4 are axial. The spectrum is thus in accord with the generally recognized structure of cellulose.

We also hope to be able to assign the signals of the acetyl-substituents in order that we may use this method, *e.g.*, to elucidate the structure of partially acetylated celluloses possessing industrial interest.

As a second example we shall give the 220-MHz spectrum of 2,3,6-tri-*O*-acetylamylose having a degree of polymerization of *ca.* 100 (mol. wt. *ca.* 30000) together with assignments (see Figure 2). The coupling constant for this compound J_{12}

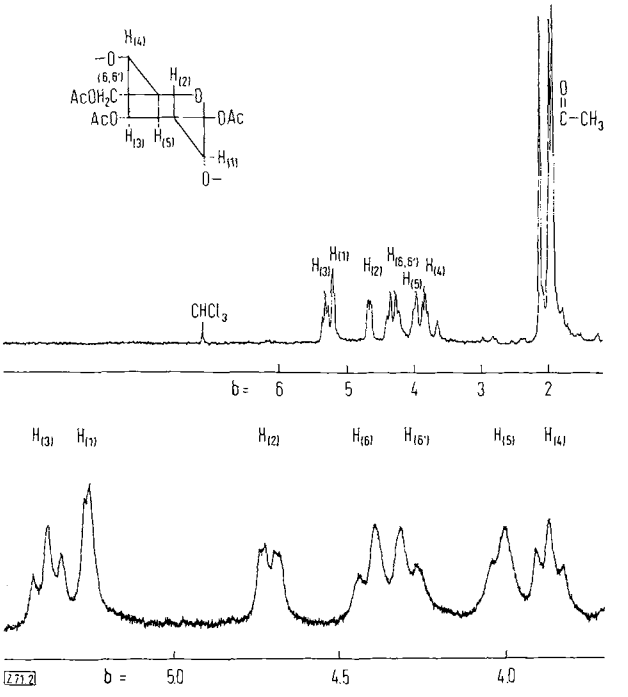

Fig. 2. ^{1}H-NMR spectra of 2,3,6-tri-*O*-acetylamylose having a degree of polymerization of ≈100 (mol. wt. *ca.* 30000). Measuring frequency 220 MHz; solvent: $CDCl_3$ (TMS); T = +20 °C.

is only about 3 Hz. This value, which was deduced from the splitting of the H(1) signal, corresponds to a coupling between axial and equatorial protons. Since the magnitude of the coupling constant J_{23} reveals that the proton on C-2 is in the axial position, H(1) must be equatorial. The magnitudes of the other coupling constants indicate that the protons on C-3 and C-4 are axial. The methyl signals of the three *O*-acetyl groups occur separately as in tri-*O*-acetylcellulose; the signals have not yet been assigned. Thus the structure hitherto assumed for amylose – α-glycosidically linked glucose units – is confirmed by the ^{1}H-NMR spectrum.

We obtained ^{1}H-NMR spectra showing the same excellent resolution and proving similarly amenable to analysis with 2,3,6-tri-*O*-benzoylcellulose and -amylose having degrees of polymerization from 100 to 200.

For all such polysaccharide derivatives the signals of all the ring protons are still separate at degrees of polymerization in excess of 1000 (mol. wt. > 500000); they are, however, broadened to such an extent that the individual coupling constants can no longer be determined.

The ^{1}H-NMR spectra of other polysaccharide derivatives — such as those of dextran, mannan, and pullulan — can be analyzed in a similar fashion. The spectrum of tri-*O*-benzoyl-pullulan (α-1,4 : α-1,6 linkages in the ratio 2 : 1) can be interpreted, *e.g.*, directly as a superposition of the spectra of the corresponding amylose(α-1,4) and dextran(α-1,6) derivatives.

Since the development of this method of spectral analysis we have been able to identify an unknown polysaccharide (*ca.* 2—3 mg), isolated from biological material, as cellulose by comparison of the spectrum of the tri-*O*-benzoyl derivative with that of an authentic sample. ^{1}H-NMR studies have thus

proved to be a useful tool for the structural elucidation of polysaccharides.

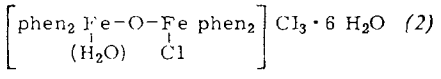
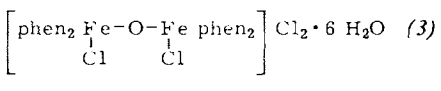
Radiochemical Investigation of the Coordination State of Iron in the Dinuclear Iron(III)-1,10-Phenanthroline Complex Ion



By *P. Gütlich*[*] and *B. W. Fitzsimmons*[**]

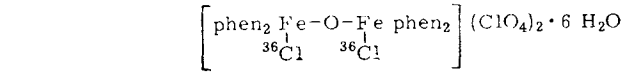
In aqueous solution iron(III) chloride and 1,10-phenanthroline (phen) form a dinuclear complex which, on the basis of chemical analyses and its behavior in solution, was originally formulated as



(1)

with a double OH bridge[1]. Results of magnetic[2–7] and potentiometric measurements[1,6] are in accord with a dinuclear structure for the complex compound, in which iron has the oxidation number +3. Recent studies on magnetic behavior[8] lend support to a high-spin iron(III) model with $S = 5/2$ and $g = 2.00$ and without any contribution by temperature-independent paramagnetism (TIP). Moreover, these results, together with IR spectroscopic findings[9], strongly suggest a single oxo bridge between the two iron atoms (formula *(2)* or *(3)*).

(2)



(3)

The number of chlorine atoms directly coordinated to iron was hitherto uncertain.

We have now been able to confirm unequivocally the proposed structure *(3)* by radiochemical methods.

The iron(III)-1,10-phenanthroline complex was prepared, in the presence of $^{36}Cl^-$ ions (Cl-36: $t_{1/2} = 3.1 \times 10^5$ a; 0.7 MeV β^-), according to the method given by *Gaines et al.*[1]. The results of elemental analysis were in good agreement with the values calculated for the empirical formula $Fe_2O(phen)_4Cl_4 \cdot 6H_2O$. The IR spectrum (700—900 cm^{-1}) corresponded with previously recorded data[8]. The count rate i_1 of an aliquot of the solution of the ^{36}Cl-labeled compound in methanol was measured with a scintillation counter. Another aliquot was cooled in a Dry Ice/acetone bath and treated with a methanolic solution of $LiClO_4$; the resulting precipitate, the sparingly soluble perchlorate of the iron(III)-1,10-phenanthroline complex ion, was centrifuged off and its count rate i_2 determined. The ratio $i_2 : i_1$ obtained from five experiments conducted under identical conditions was found to be 0.497 ± 0.005. This means that 49.7% of the total ^{36}Cl activity of the starting compound $Fe_2O(phen)_4Cl_4 \cdot 6H_2O$ was present in the cationic complex of the sparingly soluble perchlorate after precipitation. This finding is explicable only if the perchlorate has the structure:

and the labeled starting material the structure *(3)*.

ESR Spectra of the Radical Anions of *N*-Trimethylsilyl Derivatives of Aniline and *p*-Phenylenediamine[11]

By *F. Gerson, U. Krynitz*, and *H. Bock*[*]

Amino substituents, as electron donors, lower the electron affinity of aromatic compounds. For this reason radical anions can be prepared neither from aniline and *p*-phenylenediamine nor from their *N*-alkyl derivatives. If the *N*-hydrogen atoms or *N*-alkyl groups are replaced by trimethylsilyl groups two effects are to be expected: A) interaction between the lone electron pair of the nitrogen and unoccupied silicon orbitals of suitable symmetry; B) twisting of the bis(trimethylsilyl)amino substituent out of the benzene π-plane due to the large spatial demands of the bulky trimethylsilyl residues[2]. As shown for example by the ionization energies[3], both effects impair the conjugation of the nitrogen lone pair with the aromatic π-electron system and consequently lower the donor character of the amine substituents.

(1)

(2)

N,N-Bis(trimethylsilyl)aniline *(1)* and *N,N,N',N'*-tetrakis(trimethylsilyl)-*p*-phenylenediamine *(2)*[3] ought, therefore, to exhibit a stronger tendency to accept an additional π-electron than the corresponding *N*—H- and *N*-alkyl compounds. In fact, both corresponding radical anions $(1)^{\ominus}$ and $(2)^{\ominus}$ are accessible from *(1)* and *(2)* respectively by reduction with potassium in 1,2-dimethoxyethane (DME) at low temperatures.

The ESR spectra (Fig. 1a and 1b) are very similar to each other; they exhibit five main components, which correspond

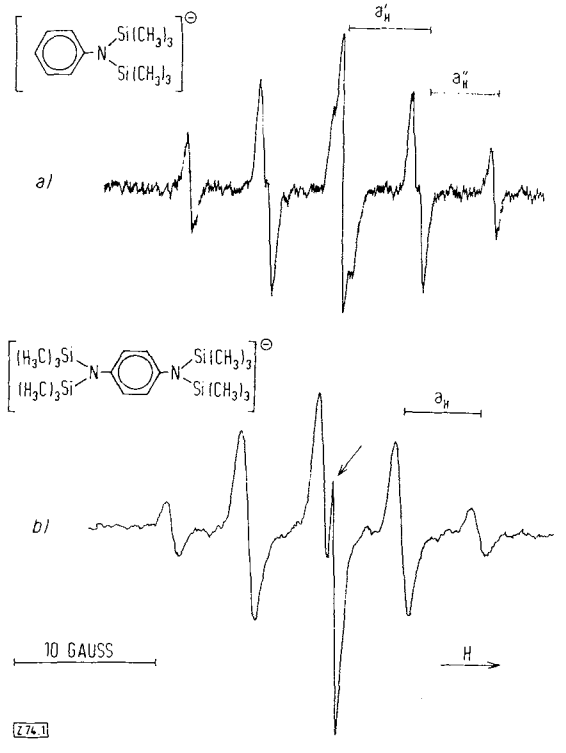

Fig. 1. ESR spectra of the radical anions *(1)*$^{\ominus}$(a) and *(2)*$^{\ominus}$(b). Solvent: DME; counterions: K^+; T: −90 °C. The upper arrow in b) shows the signal of the solvated electron.

to the splitting patterns of the radical anions of mono- and *para*-disubstituted alkylbenzenes[4]. This proves that despite the above mentioned effects A and B, the bis(trimethylsilyl)-amino substituent still clearly functions as an electron donor. Consequently, in *(1)*$^{\ominus}$ and *(2)*$^{\ominus}$ — as in the radical anions of mono- and *para*-disubstituted alkyl derivatives — the symmetrical orbital of benzene

$$\Psi_{a^+} = 0.577\,(\Phi_1 + \Phi_4) - 0.289\,(\Phi_2 + \Phi_3 + \Phi_5 + \Phi_6)$$

is more strongly destabilized than its antisymmetrical counterpart

$$\Psi_{a^-} = 0.500\,(\Phi_2 - \Phi_3 + \Phi_5 - \Phi_6)$$

(The two lowest antibonding orbitals Ψ_{a^+} and Ψ_{a^-} are degenerate in unsubstituted benzene.)

In *(1)*$^{\ominus}$ and *(2)*$^{\ominus}$ the unpaired electron thus occupies the orbital Ψ_{a^-}, which leads to the π spin population being distributed almost exclusively among the four centers 2, 3, 5, and 6.

The coupling constants for both pairs of equivalent ring protons in *(1)*$^{\ominus}$ are $a_{H'} = 5.7 \pm 0.1$ and $a_{H''} = 5.1 \pm 0.1$ gauss. For the four equivalent ring protons in *(2)*$^{\ominus}$ a coupling constant of $a_H = 5.43 \pm 0.05$ gauss has been recorded. These values are comparable with the corresponding data for the radical anions of toluene ($a_{H'} = 5.45$ and $a_{H''} = 5.12$ gauss) and *p*-xylene ($a_H = 5.34$ gauss) respectively[4]. If an HMO model similar to that for the toluene radical anion is used for the interpretation of the coupling constants of the ring protons in *(1)*$^{\ominus}$ then $a_{H'}$ can be assigned to the ring protons on the centers 3 and 5, and $a_{H''}$ to those on centers 2 and 6. The coupling constants of the ^{14}N nuclei in *(1)*$^{\ominus}$ and *(2)*$^{\ominus}$ and of the *p*-proton in *(1)*$^{\ominus}$ could not be measured directly since the unresolved small splitting due to the large sets of equivalent trimethylsilyl protons results in additional line broadening. From the observed widths of the hyperfine components (0.6 gauss for *(1)*$^{\ominus}$ and 0.8 gauss for *(2)*$^{\ominus}$), these coupling constants can be approximately derived: a_H (4) and $a_N \leqslant 0.5$; $a_H(Si{-}CH_3) \leqslant 0.1$ gauss.

The electron donor effect of bis(trimethylsilyl)amino substituents is also confirmed by the observation that under the same conditions the signal of the solvated electrons occurs in the spectrum of *(2)*$^{\ominus}$ (Fig. 1b) but not in that of *(1)*$^{\ominus}$ (Fig. 1a). The equilibrium[5]

$$\text{Amine} + e^{\ominus}_{solv} \qquad \text{Amine}^{\ominus} + \text{DME}$$

must accordingly be shifted less strongly to the right in the case of the disubstituted compound *(2)* than in the case of the monosubstituted *(1)*.

Tetrafluoroorthoperiodic Acid and Iodine Dioxide Trifluoride

By *A. Engelbrecht* and *P. Peterfy*[*]

If, as in the preparation of pentafluoroorthotelluric acid from an orthotellurate and fluorosulfonic acid[1,2], $Ba_3H_4(IO_6)_2$[3] is allowed to react with a 20-fold excess of HSO_3F and the reaction mixture then distilled under reduced pressure a fraction is obtained which contains tetrafluoroorthoperiodic acid, $HOIOF_4$, and HSO_3F in the ratio 2 : 1.

$$Ba_3H_4(IO_6)_2 + 14\,HSO_3F \rightarrow 2\,HOIOF_4 + 8\,H_2SO_4 + 3\,Ba(SO_3F)_2$$

The ^{19}F-NMR spectrum shows that both the *cis* (C_{2v}) and the *trans* form (D_{4h}) of the pseudooctahedral ion $[OIOF_4]^-$ are present in a ratio of about 3 : 1 in the mixture at 20 °C. The spectrum contains two triplets (with slight intensity perturbations of the second order) due to the ion with C_{2v} symmetry, and, superimposed on the triplet at higher field strength, a singlet which we assign to the isomer having D_{4h} symmetry. We have not, as yet, been able to separate the isomers from the excess of fluorosulfonic acid or the isomers from each other.

On addition of SO_3 (60% oleum) the mixture turns yellow; yellow needle-like crystals having the composition IO_2F_3 (mol. wt., mass spectrometrically, 216), m.p. 41 ± 0.5 °C, sublime *in vacuo* from the resulting mixture.

$$HOIOF_4 + SO_3 \rightarrow IO_2F_3 + HSO_3F$$

The ^{19}F-NMR spectrum of molten IO_2F_3 contains two doublet-triplet systems (AB_2 spin systems) in the ratio ≈ 3 : 1. This indicates also (assuming the fundamental structure of IO_2F_3 to be trigonal bipyramidal) the presence of two isomers (C_{2v} and C_s). Assignment of the different doublet-triplet combinations to the two isomers is possible from the results of investigations on alkyl- and arylfluorophospho-

ranes[4]; the signals of the axial F atoms always appear at lower field strengths than those of the equatorial atoms. The same reasoning is used in the case of isomers of SF_4 derivatives[5]. The relative positions of the multiplets are also in accord with the rule that the axial positions are occupied by the most electronegative ligands. As shown in Table 1, the chemical shifts of each of the axial and equatorial fluorine atoms agree very well even in the case of the two isomers of $HOIOF_4$; all these resonance lines lie between those of IFI[6] and IF_5[7] and very close to the resonance lines of OIF_5[6].

Chemical shifts and coupling constants (56.4 MHz).

		Sym.	Type	$\delta^{19}F$ (ppm) [a] axial	equatorial	J_{FF} (Hz)

$HOIOF_4$	3:2 in HSO_3F	C_{2v}	A_2B_2	−167	−145	221

[a] External standard CF_3COOH.
[b] Measured against SiF_4 as internal standard (SiF_4: 83.8 ppm against CF_3COOH) [6].

Procedure

$Ba_3H_4(IO_6)_2$ (86 g) is added slowly with ice-cooling to HSO_3F (200 g), and $HOIOF_4$ (30 g) in admixture with HSO_3F is distilled from the reaction mixture (b.p. 46 °C/≈1 torr; yield 64%). For conversion into IO_2F_3, 60% oleum is added in small portions and the IO_2F_3 thus formed is immediately sublimed off at 30 °C/≈1 torr. Yield of IO_2F_3 about 24 g (80%).

IO_2F_3 ignites on contact with inflammable organic substances, is wetted only slowly by water, and hydrolyzed to HF and H_5IO_6. On exposure to direct sunlight, it decomposes with liberation of oxygen.

$$IO_2F_3 \xrightarrow{h\nu} IOF_3 + {}^1/_2O_2$$

partly in the form of ozone.

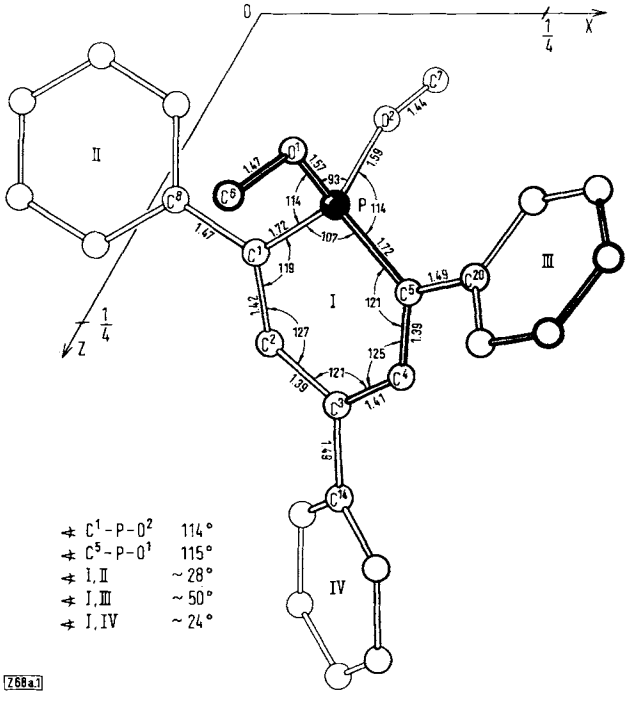
Crystal and Molecular Structure of 1,1-Dimethoxy-2,4,6-triphenylphosphorin

By *U. Thewalt*[*]

Dimroth and *Städe*[1] have been able to obtain 1,1-dialkoxy- and 1,1-diaryloxyphosphorins *(2)* by oxidation of 2,4,6-trisubstituted phosphorins *(1)* with mercury(II) acetate in the presence of alcohols or phenols.

(1)



(2)

The compounds *(2)*, like phosphorins themselves, are characterized by their unusual stability. Since X-ray structure analyses[2,3] on two compounds of type *(1)* show that the six π electrons in the C_5P rings are delocalized (planar form of the ring, equal C—P bond distances of about 1.74 Å, aromatic C—C bond lengths), the molecular geometry of a compound of type *(2)* having tetracoordinate phosphorus seems of interest.

Monoclinic prismatic crystals of 1,1-dimethoxy-2,4,6-triphenylphosphorin *[(2)*: $R^1 = R^2 = C_6H_5$; $R^3 = CH_3$], which fluoresce yellow-green, were obtained by cooling a benzene/ethanol solution[4].

Crystal data: space group $P2_1/c$; $Z = 4$; $a = 16.53$, $b = 7.01$, $c = 20.98$ Å, $\beta = 119.8°$; $d_{X\text{-ray}} = 1.22$, $d_{exp} = 1.22$ g/cm³. The intensities of the strong X-ray reflections were measured with an automatic two-circle diffractometer; those of the weaker ones were estimated visually from Weissenberg photographs (all with $Cu_{K\alpha}$ radiation). From a total of 4161 independent reflections, 953 were unobserved.

The structure determination was carried out by means of the symbolic addition method[5] using 333 reflections with $E \geqslant 1.7$. The positional and isotropic temperature parameters of the atoms other than hydrogen were refined by the least squares method. The conventional R value for the 3208 observed reflections is 15.5%. Localization of the hydrogen atoms was not performed. The molecular structure and main bond lengths and angles are given in the figure.

Z68a.1

Projection along the *b* axis of a 1,1-dimethoxy-2,4,6-triphenylphosphorin molecule. The estimated standard deviations of the bond lengths (Å) and angles (°) are 0.01—0.02 Å and 1—2° resp.

The C—P bond lengths (1.72 and 1.72 Å) lie between the value for the C—P single bond and that for the C=P double bond of tetracoordinate phosphorus (*e.g.* in $(C_6H_5)_3P{=}CH_2$[6], C—P distance = 1.82 Å; C=P distance = 1.66 Å); similar distances (1.73—1.75 Å) were also observed in com-

pounds *(1)* [2,3]. The C—C bond lengths in the phosphorin ring (I) agree, within experimental error, both mutually and with the C—C bond lengths in benzene. The C_5P ring deviates slightly but significantly from planarity (deviations from the C^2PC^4 plane: C^1, −0.11; C^3, 0.07; C^5, −0.02 Å).

The three bonds to the phenyl rings project out a little from the C^2PC^4 plane (C^8, −0.33; C^{14}, 0.17; C^{20}, −0.20 Å). The C—P—C bond angle, like that in the phosphorins *(1)* [2,3], is relatively small, having a value of 107°; the symmetrical variation of the remaining inner angles of the central ring is worthy of note.

The O^1PO^2 plane is perpendicular to the C^1PC^5 plane; the O^1PO^2 angle of 93° is surprisingly small. The P—OCH_3 bond lengths (1.57 and 1.59 Å) are comparable with the P—OR distances found in phosphoric esters.

The observed P—C bond distances suggest participation of the d orbitals of phosphorus in these bonds. The aromaticity of the central ring I can be deduced from its near planarity and from the bond lengths. The three bonds between the rings have a length corresponding to that of a $C(sp^2)$—$C(sp^2)$ single bond. The phenyl rings are twisted with respect to the plane of the central ring; the configuration is not propeller-like. The C—C distances in rings II and III are, within the limits of error, the same as those of normal aromatic bond lengths. In ring IV, on the other hand, unrealistic distances (1.28 to 1.45 Å) — due to extensive thermal motion of this ring — are observed.

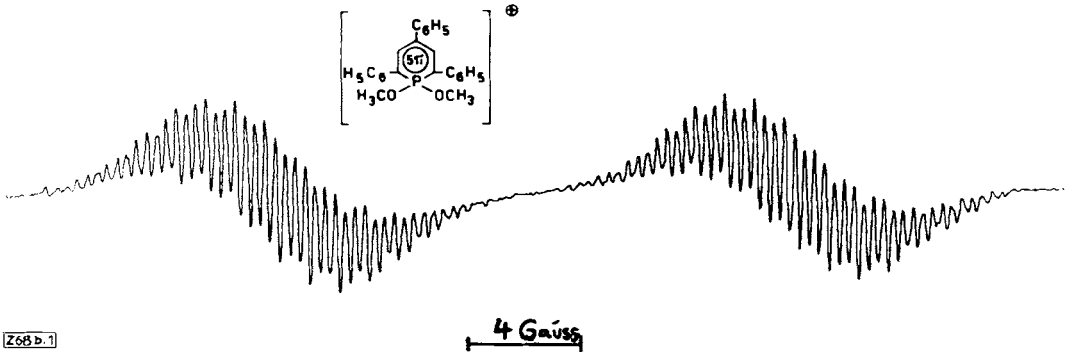
New Free-Radical Reactions with Phosphorins

By *K. Dimroth, A. Hettche, W. Städe*, and *F. W. Steuber* [*]



Oxidation of 2,4,6-trisubstituted phosphorins *(1)* with mercury(II) acetate in the presence of alcohols or phenols leads to the formation of compounds containing tetravalent phosphorus, *i.e.* to 1,1-dialkoxy- or 1,1-diaryloxyphosphorins *(2)* respectively [1]. In our opinion, this reaction proceeds in the first step *via* the phosphorin radical cation [2,3].

We have now been able to prepare 1,1-diaryloxyphosphorins using 2,4,6-triphenylphenoxyl as oxidizing agent and the phenoxide from this reaction as reaction partner; thus, reaction of 2,4,6-triphenylphosphorin with 2,4,6-triphenylphenoxyl in the molar ratio 1 : 2 leads to formation of 1,1-bis-(2,4,6-triphenylphenoxy)-2,4,6-triphenylphosphorin.

(2) *(1)* *(3)*

A further reaction of this type is that of phosphorins with tetraphenylhydrazine. When 2,4,6-triphenylphosphorin was allowed to react with the diphenylaminyl radical formed on heating the hydrazine the first representative of a new class of compounds *(3)* was formed, namely 1,1-bis(diphenylamino)-2,4,6-triphenylphosphorin (yellow fluorescing crystals, m.p. 179 °C; ^{31}P-NMR: δ −29.5 ppm (δH_3PO_4 = 0), $J_{PH^3,5}$ = 36 Hz in pyridine as solvent; UV: λ_{max} (ε): 439 (8.45×10^3) 330 nm (1.9×10^4) in cyclohexane as solvent). The phosphorin radical cation can be detected by ESR spectroscopy in this reaction too.

The compounds of type *(2)* and *(3)* must — as crystal structure analysis shows [4] — contain an aromatic system with spd hybridization at the tetravalent phosphorus.

Also in agreement with this assumption is the fact that compounds *(2)* and *(3)* can be readily oxidized both electrolytically and by lead(IV) benzoate to give a new class of stable radical cations. The ESR spectrum of the 1,1-dimethoxy-2,4,6-triphenylphosphorin radical cation ($|a_P|$ = 18.4 gauss) is shown in Figure 1. The radical cation of 1,1-bis(trideuteriomethoxy)-2,4,6-triphenylphosphorin gives exactly the same spectrum.

This indicates that the delocalization of the unpaired electrons is mainly limited to the aromatic system.

1,1-Bis(2,4,6-triphenylphenoxy)-2,4,6-triphenylphosphorin

A solution of 2,4,6-triphenylphenoxyl (2.2 g, 6.8 mmoles) in benzene (20 ml) is added dropwise at room temperature to a solution of 2,4,6-triphenylphosphorin (1.1 g, 3.4 mmoles) in benzene (20 ml). The mixture is stirred for 2 hours. Yield 1.6 g (48 %) of yellow crystals having m.p. 249–251 °C; UV: λ_{max}(ε): 425 (1.32×10^4), 323 (1.70×10^4), 251 nm (9.20×10^4) in cyclohexane.

1,1-Bis(diphenylamino)-2,4,6-triphenylphosphorin

A mixture of 2,4,6-triphenylphosphorin (324 mg, 1 mmole) and tetraphenylhydrazine (390 mg, 1.16 mmole) in 30 ml dry benzene is heated for 2 hours. The benzene is then evaporated and the dark green fluorescing, viscous residue is taken up in a little benzene/*n*-hexane and chromatographed on an SiO_2 column. The product thus obtained can be recrystallized from ethanol/acetone; m.p. 179 °C (decomp); yield: 340 mg (52 %).

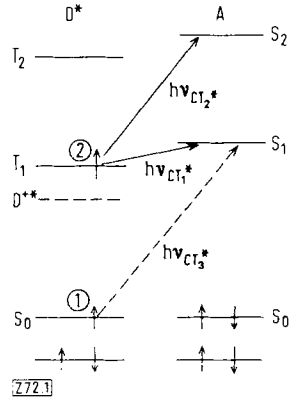
Electron Transfer from an Excited Electron Donor in the Triplet State to an Acceptor Molecule



By *G. Briegleb* and *H. Schuster*[*]

We have investigated the influence of electron donor-acceptor (EDA) complex formation on the triplet-triplet (TT) absorption spectrum of the electron donors (D) naphthalene *(1)* and phenanthrene *(2)* in complexes with the electron acceptors (A) tetrachlorophthalic anhydride *(3)* and pyromellitic dianhydride *(4)*. The TT absorption spectra were recorded in *n*-propyl ether glass at $T = 96$ to 118 °K by flash spectrophotometry[1]. The triplet state of *(1)* and *(2)* in the complex $|DA|$ with *(3)* or *(4)* was excited by irradiation within the frequency of the charge transfer (CT) absorption bands *via* the singlet excited state $|\dot{D}^+\dot{A}^-|_S^*$ of the complex with subsequent "intersystem crossing" energy transfer $|\dot{D}^+\dot{A}^-|_S^* \rightarrow |D_T^*A|$. This excitation mechanism was possible since the condition $E_{|\dot{D}^+\dot{A}^-|_S^*} > E_{|D_T^*A|}$, or in the case of complexes with donor-triplet excimers $E_{D\cdot\cdot|\dot{D}^+\dot{A}^-|_S^*} > E_{|DD_T^*A|}$, was fulfilled. The triplet state had to be excited *via* the CT singlet state in order to prevent a triplet excitation of the free donor molecules not bonded in the complex.

The TT absorption spectra of complexed *(1)* and *(2)* in the frequency range 20 to 25 × 10^3 cm^{-1} exhibit characteristic changes compared to the TT absorption spectra of the free donors *(1)* and *(2)*[2]. The triplet lifetime is also reduced by complex formation, *i.e.* the probability of the $T \rightarrow S_0$ transition is increased. The TT spectrum of complexed triplet excimers of *(1)* and *(2)* was measured at slightly higher temperatures (106—113 °K) and/or in the presence of an excess of donor. It was also possible to detect the excimers in the phosphorescence spectrum by irradiation within the frequency of the CT band at $T = 100$ to 120 °K and in the presence of an excess of the donor[2].

The ionization energy of the triplet excited donor bonded in the complex $|D_T^*A|$ is reduced by the energy required for $T_1 \leftarrow S_0$ excitation. Hence CT* absorption bands corresponding to *transition of an electron from the triplet excited donor to an unoccupied energy level of the acceptor* in frequency ranges of relatively long wavelength could be expected. We first found CT* bands of this kind in complexes $|D_T^*A|$ of triplet excited *(1)* and *(2)* with *(3)* and *(4)* after the population of $|D_T^*A|$ had been increased by flash excitation in the frequency range of the CT bands of the complexes $|DA|$ in the *ground state* in solutions in *n*-propyl ether glass at 96 to 118 °K.

The experimentally determined CT* frequencies of the CT* band maxima are given in the Table, as are the CT* frequencies $\tilde{\nu}_{CT_1^*}$, $\tilde{\nu}_{CT_2^*}$, and $\tilde{\nu}_{CT_3^*}$ for a transition of the D_T^* electron 1 or 2 of the T_1-excited donor to various energy levels of the acceptor calculated[3] assuming the various

possibilities of electron transition (energy level scheme, see Figure). Comparison of the observed and estimated $\tilde{\nu}_{CT^*}$ values shows that $\tilde{\nu}_{CT_1^*}$ does not correspond to the measured CT*-absorption bands. No distinction can be made between $\tilde{\nu}_{CT_2^*}$ and $\tilde{\nu}_{CT_3^*}$ within the limits of accuracy of estimation. A superposition of both transitions is conceivable, thus providing a possible explanation *inter alia* for a diffuse broadening of the CT* band in the case of the phenanthrene complex *(2)—(3)*.

N-Halogenoimidosulfur Difluorides and *N,N'*-Dihalogenosulfur Diimides

By *K. Seppelt* and *W. Sundermeyer*[*]

N-Halogenoimidosulfur difluorides *(2)* have previously been prepared by reaction of halogens with *N*-fluoroformylimidosulfur difluoride[1], $FC(O)NSF_2$, in the presence of cesium fluoride or by reaction of halogens with bis(difluorosulfur(IV)imido)mercury[2], $Hg(NSF_2)_2$.

We have recently investigated the cleavage of *N*-halogenobis(trimethylsilyl)amines *(1)* with non-metallic halides[3] and have found a further route to compounds *(2)* by reaction of *(1)* (X = Cl, Br) with sulfur tetrafluoride.

$$\underset{(1a),\ X = Cl}{X{-}N[Si(CH_3)_3]_2} + SF_4 \rightarrow \underset{(2)}{X{-}N{=}SF_2} + 2\,(CH_3)_3SiF$$
$$(1b),\ X = Br$$

	Tetrachlorophthalic anhydride *(3)*				Pyromellitic dianhydride *(4)*			
	$\tilde{\nu}_{CT^*_{exp}}$	$\tilde{\nu}_{CT_1^*}$ [a]	$\tilde{\nu}_{CT_2^*}$ [a]	$\tilde{\nu}_{CT_3^*}$ [a]	$\tilde{\nu}_{CT^*_{exp}}$	$\tilde{\nu}_{CT_1^*}$ [a]	$\tilde{\nu}_{CT_2^*}$ [a]	$\tilde{\nu}_{CT_3^*}$ [a]
$[Naphthalene]_T^*$	19—20	6.5	18.4	18.5	16.5	3.7	15.7	15.7
$[Phenanthrene]_T^*$	[b]	6.4	18.4	15.4	16.0	3.4	15.4	12.4

$\tilde{\nu}$ in 10^3 cm^{-1}.

[a] Calculated [3] (cf. energy-level diagram).
[b] The position of $\tilde{\nu}_{CT^*}$ could not be determined accurately (no clear maximum).

The physical and spectroscopic data found for the products *(2)* are identical with those found by earlier workers[1,2]. This new method of preparation of *(2)* confirms the assumption that these compounds are *N*-halogenoimidosulfur difluorides and not the isomeric difluoronitridosulfur halides, $N \equiv SF_2X$. Previous evidence for the structure *(2)* was based mainly on the occurrence of nitrogen-halogen fragments in the mass spectrum; however, the possibility of these fragments arising from recombination could not be ruled out.

The analogous reaction of *N*-iodobis(trimethylsilyl)amine *(1c)* with sulfur tetrafluoride does not lead to the still unknown *N*-iodoimidosulfur difluoride (cf.[2]) but (presumably *via* this compound as unstable intermediate) to *N,N'*-diiodosulfur diimide *(3)*.

$$\underset{(1c)}{2\,I{-}N[Si(CH_3)_3]_2} + SF_4 \rightarrow \underset{(3)}{I{-}N{=}S{=}N{-}I} + 4\,(CH_3)_3SiF$$

A solution of SF_4 in 1,2-dichloroperfluoroethane is added dropwise at about 0 °C to a solution of *(1c)* in the same solvent. An orange-red crystalline precipitate forms that can be recrystallized from methylene chloride. Compound *(3)* melts and simultaneously explodes at 106 °C. Similarly to S_4N_4, it explodes on impact and a distinct smell of SO_2 is noticeable; on ignition it deflagrates with simultaneous emission of violet iodine vapor. The crystals are almost insensitive to hydrolysis and are only slightly soluble in organic solvents such as methylene chloride, carbon tetrachloride, and benzene. Compound *(3)* was identified by elemental analysis and by mass spectrometry[4] [*m/e* = 314 (INSNI 100%), 187 (INSN 6%), 173 (INS 4%), 141 (IN 2.5%), 127 (I 11%), 60 (NSN 3.5%), 46 (SN 7.5%), and 32 (S 2%) together with a few recombination fragments such as I_2 and IS; 13 eV]. The IR spectrum (KBr) contains bands at 1094 (s), 1047 (vs), 950 (s), 631 (s), 465 (m), 327 (m), and 297 cm^{-1} (m).

N,N'-Dibromosulfur diimide Br—N=S=N—Br *(4)* can be prepared under the same experimental conditions. Compound *(4)* is much more soluble in the above mentioned solvents than is *(3)*. The pale yellow crystals of *(4)* melt at +0.5 °C with partial decomposition; they are more sensitive to impact than the crystals of *(3)*.

The mass spectrum [*m/e* = 218, 220, 222 (BrNSNBr 33%), 139, 141 (BrNSN 3%), 125, 127 (BrNS 12%), 93, 95 (BrN 14%), 79, 81 (Br 38%), 60 (NSN 2%), 46 (SN 100%), and 32 (S 39%); 70 eV], the IR spectrum (nujol) [1127 (s), 1035 (vs), 921 (s), 657 (s), 603 (m), 519 (m), 417 (m), and 370 (w)], and the Raman spectrum[5] [1133 (w), 926 (vs), 662 (m), 608 (m), 533 (s), 426 (w), 379 (m), 198 (m), and 88 (w)] are in agreement with the assumed structure *(4)*. Attempts to prepare the homologous chlorine derivative of *(3)* and *(4)* have so far failed.

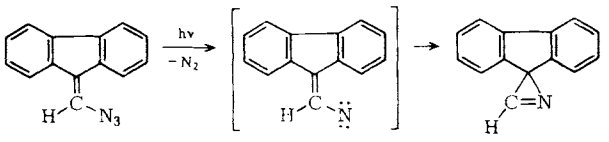
Synthesis and Reactions of a 2*H*-Azirine Unsubstituted on C—3

By *W. Bauer* and *K. Hafner*[*]

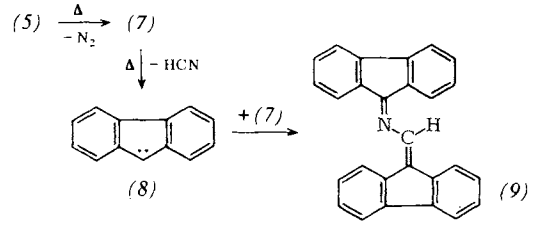
Thermolysis[1] or photolysis[2] of 1-alkyl or 1-aryl-vinyl azides *(1)* (R^1 = R^2 = H, aryl, alkyl; R^3 = aryl, alkyl)[3] leads to the formation of 2*H*-azirines with a substituent at C-3 *(2)* and to ketenimines *(3)*. However, the decomposition of "terminal" vinyl azides *(1)* (R^1 = R^2 = H, aryl, alkyl; R^3 = H) gives only the nitriles *(4)*[4] and none of the expected, and formerly unknown, 2*H*-azirines which lack a substituent at the 3-position.



(1) *(2)* *(3)* *(4)*

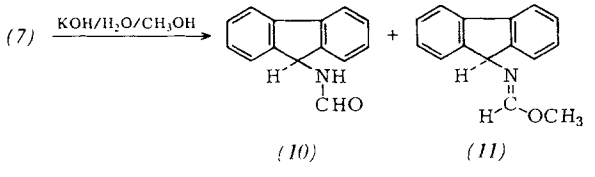
Using the reaction scheme which is generally used for the synthesis of substituted fulvenes from 6-fulvenyl tosylates we have been able to prepare the "terminal" vinyl azide 9-(azidomethylene)fluorene *(5)*[5] from 9-fluorenylidenemethyl tosylate and sodium azide[6] and to study its reactions. Whilst *(5)* reacts with triphenylphosphine to give the corresponding iminophosphorane[7] (yield 77%, yellow prisms, m.p. 206—207 °C), the thermally rather unstable spiro[2*H*-azirine-2,9'-fluorene] *(7)* could be prepared as the first C-3 unsubstituted 2*H*-azirine by photochemical decomposition of *(5)* in anhydrous diethyl ether at −15 ° (UV lamp Type Q 81, Original Hanau, Duran glass, irradiation time 1 h) and careful work-up (isolation at −70 °C, recrystallization at −50 °C). Presumably the initial formation of the nitrene *(6)*

Comp.	Yield (%)	M.p. (°C)	UV λ_{max} (nm) (log ε)	NMR (τ) [a]	IR (cm^{-1})
(7)	74	83—85 (decomp.) yellowish needles (*n*-hexane)	234 (4.31), 260 (4.19), 270 (4.43), 284 (4.10) (dioxane)	−0.35 (1 H/s), 2.11—3.17 (8 H/m) ($CDCl_3$)	1665 [13] (C=N) (CCl_4)
9-Isocyano-fluorene	10	113—115 (subl.) colorless needles (petroleum ether)	224 (4.34), 231 (4.18), 267 (4.28), 279 (4.15), 292 (3.44), 302 (3.16) (dioxane)	2.17—2.9 (8 H/m), 4.47 (1 H/s) ($CDCl_3$)	2140 (−N≡C) (KBr)
(9)	21	325—327 red needles (ethyl acetate)	237 (4.72), 263 (4.71), 304 (4.06), 332 (4.18), 439 (4.27), 453 (4.28) (dioxane)		1600 (C=N) (KBr)
(10)	36	215—217 colorless needles (ethyl acetate)	227 (4.28), 236 (4.12), 270 (4.21), 293 (3.66), 305 (3.67) (dioxane)	1.3 (1 H/broad), 1.61 (1H/m), 2.31—2.83 (8 H/m), 3.91 (1 H/d) ([D_6]-DMSO)	3280 (N—H), 1665 (C=O), (KBr)
(11)	21	139—141 yellow platelets (methanol)	225 (4.35), 233 (4.16), 270 (4.24), 293 (3.72), 305 (3.74) (dioxane)	1.99 (1 H/s), 2.18—2.9 (8 H/m), 4.82 (1 H/s), 6.28 (3 H/s) ($CDCl_3$)	1650 (C=N), (KBr)



[a] TMS as internal standard.

(5) (6) (7)



is followed by intramolecular cyclization to give *(7)*. Irradiation of *(7)* in anhydrous diethyl ether at −15 °C (UV lamp Type Q 81, Original Hanau, quartz glass, irradiation time 6 h) leads to the formation of a mixture of 9-cyano-[8] and 9-isocyanofluorene[9], which can be separated by layer chromatography (Silica gel PF_{254}, petroleum ether/ether 4 : 1). Under the same conditions compound *(5)*, like *(7)*, can also be converted into these two compounds (yields 38% and 8% resp.) — presumably *via* intermediate formation of *(7)*.

Thermolysis of *(5)* and of *(7)* in anhydrous petroleum ether in the presence of atmospheric oxygen and absence of moisture yields *N*-(9-fluorenylidene)-9-fluorenylidenemethylamine *(9)*[6] in addition to 9-fluorenone (24%).

(8) (9)

That fluorenone and *(9)* are formed both from the azide *(5)* and from the azirine *(7)* suggests that thermal decomposition of *(5)* also involves the formation of *(7)* as an intermediate. The products are presumably formed by reaction of 9-fluorenylidene *(8)*, produced by elimination of HCN from *(7)*, either with oxygen[10] or with *(7)*. It is perhaps surprising that neither alkaline nor acidic hydrolysis of *(7)* gives a dihydropyrazine derivative[11]. On the other hand, *(7)* reacts with KOH in methanol-water to yield a mixture of *N*-(9-fluorenyl)formamide *(10)*[11] and methyl *N*-(9-fluorenyl)-imidoformate *(11)*[12].

[7] *W. Bauer*, Dissertation, Technische Hochschule Darmstadt, 1968.

[8] The compound is identical with the 9-cyanofluorene synthesized from 9-fluorenylaldoxime and thionyl chloride; *W. Wislicenus* and *K. Russ*, Ber. dtsch. chem. Ges. *43*, 2719 (1910).

[9] 9-Isocyanofluorene was synthesized independently by reaction of *(10)* (obtained from 9-fluorenylamine and ethyl formate in 92% yield) with tosyl chloride/pyridine.

[10] *W. Kirmse*, *L. Horner*, and *H. Hoffmann*, Liebigs Ann. Chem. *614*, 19 (1958).

[11] *(10)* is identical with a sample synthesized from 9-fluorenylamine and ethyl formate.

[12] Reaction of *(7)* with methanolic-aqueous HCl also affords *(10)* (12%) along with 9-fluorenone (15%) and 9-fluorenol (8%).

[13] The discrepancy between the C=N absorption in the IR spectrum of *(7)* and the C=N absorption of 2*H*-azirines substituted on C-3 (1740–1780 cm^{-1}) [2] cannot, as yet, be explained.

Trifluoromethylfluorosulfane and 1,2-Bis(trifluoromethyl)disulfane 1,1′-Difluoride

By *F. Seel* and *W. Gombler*[*]

The existence of sulfenyl fluorides RS—F has hitherto been established only in a limited number of cases by NMR spectroscopy: R = $(CF_3)_2CF$[1] and CF_nCl_{3-n} (n = 0 to 3)[2]. We have now been able to convert trifluoromethylchlorosulfane *(1)* quantitatively into trifluoromethylfluorosulfane (trifluoromethanesulfenyl fluoride, "perfluoromethyl mercaptan") *(2)* by reaction with mercury(II) fluoride and to study the physical and chemical properties of the sulfenyl fluoride.

The gaseous compound CF_3SF is characterized unequivocally by its mass spectrum (CF_3^+ 100, CF_3SF^+ 90.5, CF_2S^+ 29.2, CF_3S^+ 23.8, SF^+ 17.2) and by its extremely simple IR spectrum which demonstrates the extensive independence of the CF stretching vibrations (1190 and 1152 cm^{-1}) and the SF stretching vibration (808 cm^{-1}). Surprisingly, the NMR spectrum of the liquid compound was much more complicated than expected (cf. Figure and Table). It contains not only a signal characteristic of sulfenyl fluorides at extremely high δ values, with a 1,3,3,1 quadruplet splitting owing to spin coupling with the CF_3 group and an associated doublet that is to be assigned to the CF_3 group, but also the very intense signals (two triplets having a quartet fine structure, four superposed quadruplets) due to a more complicated compound. The positions of the signals and their fine structure show the compound to be a dimer of *(2)*, 1,2-bis(trifluoromethyl)disulfane 1,1′-difluoride *(3)*. The fact that addition of potassium fluoride increases the sharpness of the signals suggests that exchange processes are occurring *via* hydrogen fluoride which is inevitably formed in small amounts during the preparation of *(2)* and *(3)*. NMR studies also showed that the equilibrium between *(2)* and *(3)* is established only slowly below 0 °C. In the liquid phase it lies mainly on the side of *(3)*. Whereas the sulfenyl chloride *(1)* boils at −1 °C[3], the vapor pressure above the dimer of *(2)* amounts to only 300 torr at 0 °C. (Exact vapor pressure measurements are difficult owing to the slow equilibration and readiness with which the substance decomposes.)

Compounds *(2)* and *(3)* are converted quantitatively into hexafluorodimethyldisulfane *(4)* and trifluoromethylsulfur trifluoride *(5)* within the course of several hours at room temperature, particularly in the presence of potassium fluoride; the stoichiometry of the disproportionation

$$3\,CF_3SF \rightarrow \underset{(2)}{CF_3SF_2SCF_3} + \underset{(3)}{CF_3SF} \rightarrow \underset{(4)}{CF_3SSCF_3} + \underset{(5)}{CF_3SF_3}$$

could be established by integration of the areas under the NMR signals.

(2) and *(3)* react rapidly with base metals (*e.g.* Mg) and relatively noble metals (such as Cu and Hg) to give the metal fluoride and *(4)*. The walls of pure nickel vessels that have been rendered passive with SF_4 are comparatively resistant

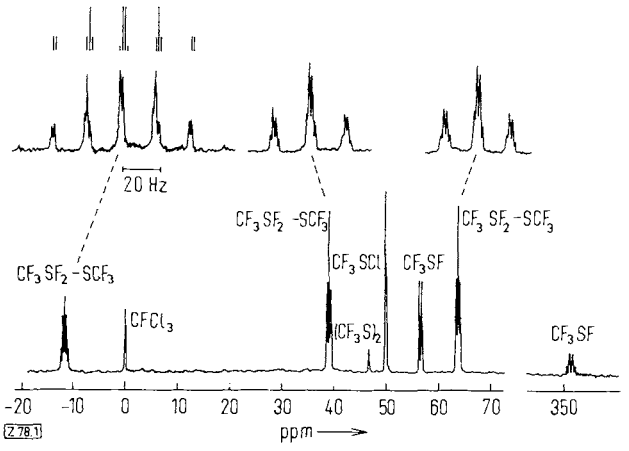

Figure: ^{19}F-NMR spectrum of a mixture of the compounds *(1)*, *(2)*, *(3)*, and *(4)*.

(The decomposition products *(4)* to *(7)* were identified by NMR and mass spectrometry. No indication was found for a hydrolysis product $CF_3S(O)SCF_3$ corresponding to *(3)*.)

Procedure:

The preparation of *(2)* and *(3)* was carried out in a vacuum apparatus consisting of a glass U-tube and two pure-nickel or platinum U-tubes that are separated from one another by nickel or stainless-steel valves and can be closed to the atmosphere by means of taps made of the corresponding material (glass or metal). HgF_2 (an approximately five-fold excess is used) must form a 5-cm layer in the central U-tube. Prior to reaction the sulfenyl chloride is condensed into the glass U-tube and frozen with liquid nitrogen. Transport of the diluted gas through the HgF_2 layer, which is heated externally to 130 °C, is effected by heating the first U-tube to −80 °C and cooling the third one with liquid nitrogen. Compound *(1)* should not contain any HCl, and the HgF_2 should be completely free from oxide; the apparatus must also be previously purged with SF_4 to remove layers of water and oxide.

Table: ^{19}F-NMR data ($CFCl_3$ as internal standard) for trifluoromethylsulfur compounds at −50 °C. F_a = equatorial, F_b = axial fluorine atom bonded to sulfur; F_c = fluorine atoms of the trifluoromethylthio group, F_d = fluorine atoms of the other CF_3 group.

	CF_3SCl *(1)*	CF_3SF *(2)*	$CF_3SF_2SCF_3$ *(3)*	CF_3SSCF_3 *(4)*	CF_3SF_3 *(5)*	CF_3SFO *(6)*	$CF_3SO_2SCF_3$ *(7)*
δF_a (ppm)		+351.5			+48.8	+22.1

CONFERENCE REPORTS

Rare Earth Organometallic Sandwich Complexes

By *A. Streitwieser jr.* [*]

It is convenient to consider the important bonding in ferrocene $(\pi\text{-}C_5H_5)_2Fe$ as derived from the overlap of the highest occupied molecular orbital of two parallel cyclopentadienyl rings with a vacant atomic orbital at the central metal. There are two such degenerate orbitals in each of which a vertical nodal plane divides the wave function into four parts whose symmetry permit overlap with the corresponding d_{xz} and d_{yz} atomic orbitals of iron.

If this approach is applied to the next higher homolog, the cyclic 10-electron π-rings, the highest occupied molecular orbitals now have two orthogonal vertical nodal planes that require an eight-lobed f_{xyz} or $f_{z(x^2-y^2)}$ atomic orbital of a central metal for appropriate symmetry-permitted overlap. Such accessible f-atomic orbitals are to be found in the rare-earth elements and particularly in the actinide rare-earths; for example, uranium. A suitable cyclic 10-π electron system to test this concept is cyclooctatetraene dianion. *R. D. Fischer* [1] has previously discussed the possibility that the sandwich complex $U(C_8H_8)_2$ may derive stability from the involvement of f-orbitals.

The reaction of cyclooctatetraene dianion with uranium tetrachloride in THF produces blue-green crystals that are stable to water and to aqueous acid or alkali. The compound can be sublimed or recrystallized from benzene or toluene. The compound is pyrophoric but controlled air oxidation yields uranium oxides and cyclooctatetraene. Mass spectral analysis gives a parent peak for $U(C_8H_8)_2$ and the fragmentation pattern indicates a ferrocene-like sandwich structure. X-ray analysis [2] confirms the sandwich structure with planar 8-membered rings in a D_{8h}-configuration. An inspection of the possible electronic structures shows that all of the appropriate molecular orbitals of the two π-rings have symmetry that permits overlap with suitable atomic orbitals of the uranium. The relative stability of the complex to hydrolysis compared with similar sandwich complexes of cyclooctatetraene dianion with several transition elements prepared by *Breil* and *Wilke* [3] suggests that additional bonding is involved in the uranium compound such as that involving the f-orbitals.

Internal Oxidation and Related Phenomena in Alloys

By *J. L. Meijering* [*]

Oxygen is soluble to some extent in certain metals such as Ag, Cu, Ni, and Fe. If such a metal A contains in solid solution a small amount of an element B with a stronger oxygen affinity, then oxygen often diffuses inward more rapidly than element B diffuses outward, and the oxide of B is then formed not on the surface, but in the interior of the sample. There is generally a fairly sharp boundary between the zone of internal oxidation (A—BO) and the zone without it (A—B). The depth of this boundary increases with the square root of time.

Both external and internal oxidations occur when *e.g.* nickel containing 1 % of Al is heated. The internally oxidized zone is under a surface layer, which consists mostly of NiO. In some alloys, *e.g.* Pd with 70 atom-% of Cu, the same oxide (here Cu_2O) may form both in this surface layer and in the interior of the sample [1]. This is partly because the solubility product of Cu_2O in Pd is relatively high, so that the boundary becomes very blurred.

The solubility product of the oxide is very important for the degree of dispersion. The smaller the difference between A and B in affinity for oxygen, the higher the solubility of the oxide, and the more it can agglomerate. In silver, the stable oxides MgO, BeO, and Al_2O_3 are almost molecular dispersions, as indicated by the lattice parameters, the electrical resistance [2], and electron microscopy [3].

In the internal oxidation of *e.g.* Ag—Mg and Cu—Be alloys, the finely dispersed oxide causes considerable hardening. The precipitation hardening or the cold rolling of silver alloys and copper alloys bring about a comparable hardening, but this is destroyed by subsequent heating to 400 °C, while oxidation hardening is performed even at 800—950 °C. Practical applications lie in the field of electrical contacts [4].

When element B is present in a fairly high concentration, internal oxide films are often formed between the oxide particles. Regular variations in the oxide concentration can come about by disturbances in the reaction balance at the oxidation boundary. These disturbances may be caused by changes in the oxygen pressure or the temperature, or also by a special geometry of the sample [5].

Phenomena analogous to internal oxidation occur *e.g.* with nitrogen, carbon, and hydrogen. The internal auridization of Mg-containing lead is a recent example [6]. It is based on the rapid diffusion of gold through the lead lattice, and on the relatively high affinity of lead for strongly electropositive metals.

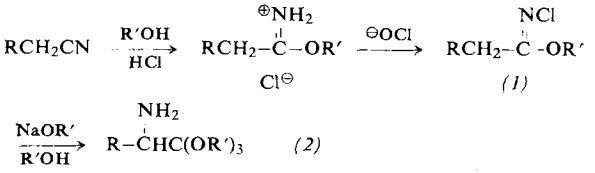
Recent Investigations of Psychotropic Compounds

By *J. Th. Hackmann* [*]

It is well known that environment and upbringing are very important for the individual. It is much more difficult to study the influence of neurohormones, and therefore less is known about it, although their significance is now better understood owing to the study of psychotropic compounds. It has been found that psychotropic compounds are often chemically related to neurohormones, as, for instance, psilocine, but in many cases, such as the active ingredient of hashish (cannabidiol), the corresponding neurohormone is not yet known.

The importance of the indole nucleus in psychotropic compounds has been repeatedly indicated. However, more attention should be paid to the presence of the 1-methylpiperidine ring (cf. scopolamine and 1-piperidyl glycolates) since this in particular is responsible for the apparent reality of hallucinations. The results often approach forms of mental disease and without doubt they are caused by biochemical disturbances in the brain (transmethylation).



Chemical compounds can influence, not only instincts, but also emotions, the source of which lies in the hypothalamus. It is of great importance to learn which compounds can cause the emotions by electrical stimulation of the selected region of the brain. Effects of this type can be achieved in all vertebrates; it is only necessary that the respective equivalent regions be stimulated electrically. Several plants are known whose extracts cause interesting effects; the organic chemist is recommended to study the constituents of *Solanum gayanum*, *Myrothamnus moschatus*, *Cineraria aspera*, *Latua venenosa*, *Hydnocarpus venenata*, *etc.*

It is remarkable that the drugs of Indian folk medicine have not been more intensively studied in spite of the success of *Rauwolfia serpentina*, for these drugs include, for instance, products that are claimed to increase memory and are thus used on mentally retarded children. Testing some of these products in rats has shown that these claims are indeed justified. A large and important field is thus open to study.

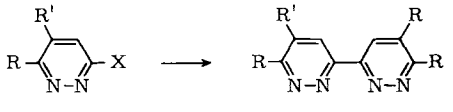
A general synthesis for α-amino acid ortho esters *(2)* is given by *W. H. Graham*: The nitrile is converted, *via* the imino ether, to the α-chloro imino ether *(1)*, which yields the α-amino acid ortho ester *(2)*:

The yields are good. The reaction temperature depends upon the acidity of the α-methylene proton. When R = C_6H_5, the reaction takes place at room temperature, and otherwise at 60—70 °C. With α-disubstituted acetonitriles the synthesis fails. The reaction is probably closely related to the Neber reaction. / Tetrahedron Letters *1969*, 2223 / —Ma.

[Rd 71 IE]

Tetracyanomethane *(1)* has been synthesized for the first time by *E. Mayer* by reaction of tricyanomethylsilver with cyanogen chloride in a bomb tube at 100 °C:

$$AgC(CN)_3 + ClCN \rightarrow \underset{(1)}{C(CN)_4} + AgCl$$



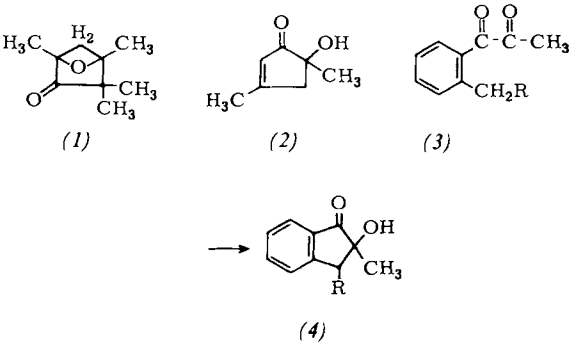
The crystalline compound *(1)* is readily soluble in aprotic solvents, sublimes at 60 °C, and decomposes at temperatures above 160 °C. As shown by the IR spectrum, *(1)* bears three equivalent CN groups (point group T_d). On alkaline hydrolysis, *(1)* behaves similarly to ClCN, which contains a positively charged CN group, to form the tricyanomethyl anion *(2)* and cyanate:

$$C(CN)_4 + 2\,OH^- \rightarrow \underset{(2)}{C(CN)_3^-} + OCN^- + H_2O$$

Compound *(2)* is also the main product of acid hydrolysis. Reaction of *(1)* with LiCl in acetonitrile gives tricyanomethyl-Li and ClCN, and should therefore prove useful as a cyanation agent. / Mh. Chem. *100*, 462 (1969) / —Ma.

[Rd 72 IE]

The synthesis of 3,3'-bipyridazine derivatives *(1)* has been accomplished by *H. Igeta, T. Tsuchiya, M. Nakajima,* and *H. Yokogawa*, by reaction of 3-halogenopyridazine derivatives with hydrazine hydrate (5—12 h) at room temperature in 5% ethanolic NaOH or KOH solution in the presence of $Pd/CaCO_3$ with vigorous stirring. 3-Chloropyridazine gives somewhat better yields than the bromine compound. Small amounts of by-products occur, which are formed by exchange of halogen for alkoxy or H. The dimeric compound



(1)

X = Cl, Br
R = H, CH_3, OCH_3, NH_2
R' = H, CH_3

cannot be obtained from 3-chloro-4-methylpyridazine. Compound *(1)* forms chelate compounds with Fe^{II}, Co^{II}, and Ni^{II}. / Tetrahedron Letters *1969*, 2359 / —Ma. [Rd 74 IE]

The photochemical conversion of unsaturated 1,2-diketones into cyclic compounds has been studied by *R. Bishop* and *N. K. Hamer*. Photolysis of β,γ- and γ,δ-unsaturated acyclic 1,2-diketones in pentane solution under an N_2 atmosphere with light of wavelength $\lambda > 380$ nm afforded 5-oxabicyclo-[2.1.1]hexan-2-ones, the double bond initially migrating over a cyclobutanol intermediate. For example, 4,4,5-trimethyl-5-hexene-2,3-dione yields 1,3,3,4-tetramethyl-5-oxabicyclo-[2.1.1]hexan-2-one *(1)* quantitatively. α,β-Unsaturated 1,2-diketones gave high yields of hydroxycyclopentenone derivatives. The irradiation of 5-methyl-4-hexene-2,3-dione in

(1) *(2)* *(3)* *(4)*

pentane with sunlight led to 3,5-dimethyl-5-hydroxy-2-cyclopenten-1-one *(2)*. *o*-Alkyl-substituted aryl-1,2-diketones such as *(3)* afforded 2-hydroxyindanones *(4)* in a similar way. / Chem. Commun. *1969*, 804 / —Ma. [Rd 75 IE]

The rate of association of lactams *(1)* in carbon tetrachloride has been investigated by *C. Y. S. Chen* and *C. A. Swenson* by measurement of the extinction of the N—H stretching vibrations in the region 3000—3500 cm^{-1}. The lactams *(1)*, $n = 1$—4, in a *cis*-configuration with reference to the peptide bond form cyclic dimers. The dissociation enthalpies of the dimers were found to be:

(1)

n	1	2	3	4
ΔH (kcal/mole)	6.37	5.90	5.52	6.33

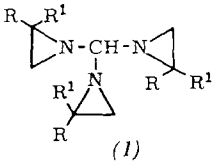
The higher enthalpies for *(1)*, $n = 1$ and 4, are explained by the lower and higher polarity of the carbonyl bond than in *(1)*, $n = 2$ and 3, which follows from the position of the CO stretching vibrations. These factors lead to a considerable energy gain during the dimerization. The lactam *(1)*, $n = 5$, exists both in the *cis*- and in the *trans*-form; the predominantly associated form is the cyclic dimer of the *cis*-form having a dissociation enthalpy of about 6 kcal/mole. / J. physic. Chem. *73*, 1363 (1969) / —Hz. [Rd 79 IE]

The kinetics of some reactions of difluorocarbene in the gas phase have been investigated by *W. J. R. Tyerman* by spectroscopic measurements in the absorption band of CF_2 at 249 nm. CF_2 was prepared by flash photolysis of $C_2F_4/NO_2/N_2$ mixtures. The molar decadic extinction coefficient of CF_2 at 249 nm is 7620 ± 400 l $mole^{-1}$ cm^{-1} at 298 °K. The dimerization of CF_2 in C_2F_4/N_2 and CF_2CFCl/N_2 mixtures was followed; the rate constant defined by

$$d[CF_2]/dt = -2\,k_1\,[CF_2]^2$$

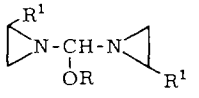
for the dimerization of CF_2 can be represented by $k_1 = (2.5 \pm 0.5) \times 10^6\ T^{1/2} \exp(-200 \pm 50)/T$ l mole^{-1} sec^{-1} in the temperature region 298–446 °K. At 298 °K the rate constant for the reaction of CF_2 with CFCl is about $(6 \pm 5) \times 10^8$ l mole^{-1} sec^{-1}. The rate constant expression $k_2 = 8.7 \times 10^4\ T^{1/2} \exp(-3200 \pm 625)/T$ l mole^{-1} sec^{-1} has been found for the formation of hexafluorocyclopropane from reaction of CF_2 with C_2F_4. / Trans. Faraday Soc. *65*, 1188 (1969) / —Hz. [Rd 80 IE]

The structure of dimethylgermane has been determined by *E. C. Thomas* and *V. W. Laurie* from the microwave spectrum in the region 8–35 GHz. All rotation transitions of the molecule are split into quartets by the internal rotation of the methyl groups; from the magnitude of the splitting the height of the potential well of the internal rotation was found to be 1182 ± 40 cal/mole. The C—Ge bond length is 1.950 ± 0.003 Å, the C—Ge—C angle has a value of 110.0 ± 0.5 °. Comparison of this almost tetrahedral angle with the angles in dimethylsilane (111.0 °) and propane (112.4 °) indicates that the interaction between the methyl groups practically disappears in the dimethyl compounds of the heavier elements of the fourth main group. The dipole moment of dimethylgermane is 0.616 ± 0.006 D. / J. chem. Physics *50*, 3512 (1969) / —Hz. [Rd 81 IE]



The polarographic behavior of cinnamaldehyde has been investigated by *D. Barnes* and *P. Zuman*. It can be established from the experimental results that the double bond is first hydrogenated and then the aldehyde is reduced, the cleavage of water from the aldehyde hydrate being the rate determining step for the second reaction. At intermediate pH values the hydrogenation of the C=C double bond can be resolved into several partial steps: in weakly acid solutions protonated cinnamaldehyde is reduced to a radical; in moderately alkaline solutions non-protonated aldehyde is reduced to a radical anion. These radicals can react (i) with each other with dimerization, (ii) with the starting material undergoing polymerization, and (iii) with mercury to form organomercury compounds. With monovalent cations in the range Li to tetraalkylammonium increasing amounts of adducts can be detected, which give rise to characteristic polarographic waves. / Trans. Faraday Soc. *65*, 1668, 1681 (1969) / —Hz. [Rd 83 IE]

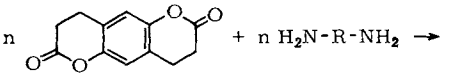
Lithium peroxide, LiO_2, has been prepared by *L. Andrews* by reaction of Li atoms with oxygen in matrices of inert gases or oxygen at about 15 °K. The IR spectra of LiO_2 species of various isotopic compositions show that the geometric structure of the molecule is an isosceles triangle with O—O = 1.33 Å, Li—O = 1.77 Å, and the angle O—Li—O = 44.1 °. The force constant of the O—O bond is 5.59 ± 0.05 mdyne/Å and thus corresponds with that in the O_2^- ion. Therefore, LiO_2 can also be considered as an isolated essentially ionic molecule $Li^+O_2^-$. At higher lithium concentrations Li_2O_2 is also formed in the matrix by addition of Li to LiO_2; a rhombic structure containing two equivalent Li and two equivalent O atoms can be ascribed to Li_2O_2. / J. chem. Physics *50*, 4288 (1969) / —Hz. [Rd 84 IE]



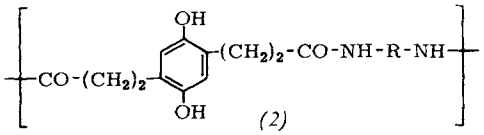
A Ti atom having coordination number 7 in a pentagonal-bipyramidal environment is present in the dinuclear complex μ-oxalatobis(oxalato)hexaquodititanium(III) · 4 H_2O, according to an X-ray structure analysis carried out by *M. G. B. Drew*, *G. W. A. Fowles*, and *D. F. Lewis*. The brown complex, which crystallizes in the space group $P\bar{1}$, has an almost pentagonal-bipyramidal configuration at the Ti atoms: the terminal bidentate C_2O_4 group (*d* TiO 2.08 to 2.09 Å), the bridging quadridentate C_2O_4 group (*d* TiO 2.16 to 2.19 Å), and one H_2O molecule (*d* TiO 2.08 Å) occupy the five equatorial positions, and two further H_2O molecules (*d* TiO 2.04–2.08 Å) are in the axial positions. The bridging C_2O_4 group is planar, while the terminal TiC_2O_4 unit deviates markedly from planarity. / Chem. Commun. *1969*, 876 / —HB. [Rd 89 IE]

Fibrous, pressure-induced sulfur is probably identical with the Ψ-sulfur investigated by *Prins*. According to an X-ray structure analysis carried out by *M. D. Lind* and *S. Geller*, it possesses a helix structure in which eight alternately left- and right-handed spirals are arranged along the *c* axis of the monoclinic unit cell ($a = 17.6$, $b = 9.25$, $c = 13.8$ Å, $\beta = 113$ °) in such a manner that ten S atoms in three turns form a period 13.8 Å long. All the spirals have a radius of 0.95 ± 0.003 Å and are close-packed. The crystals are yellow, and remain undecomposed for years when kept in air at room temperature. Crystal twinning gives the impression of an orthorhombic unit cell of twice the actual size. / J. chem. Physics *51*, 348 (1969) / —HB. [Rd 90 IE]

A simple synthesis of tris(aziridino)methane *(1)* is reported by *W. Funke*. Reaction of aziridines with dichlorocarbene, which is produced from chloroform and NaOH powder in benzene, affords *(1)*. The yields of tris(aziridino)-, tris(2-methylaziridino)-, and tris(2,2-dimethylaziridino)methane are 65, 43, and 30%, respectively. Compounds *(1)*, which are stable in the absence of air and moisture, polymerize in the presence of acids or alkylating agents. Bis(aziridino)alkoxymethanes *(2)* can be prepared by reaction of dichloromethyl methyl ether with aziridine in a suspension of NaOH in ether. Examples: *(2)*, R = CH_3, R^1 = H, 70% yield; C_2H_5, H, 50%; isopentyl, H, 82%; CH_3, CH_3, 57%. Compounds *(2)* are stable liquids exhibiting a less pronounced tendency to polymerize than *(1)*. Reaction of aziridine with chloroform-$NaOCH_3$ affords a mixture of tris(aziridino)methane, bis-



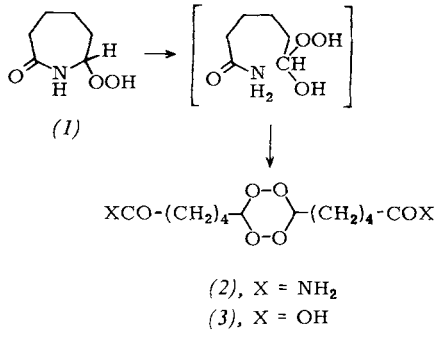
(1)



(2)

(aziridino)methoxymethane, and aziridinodimethoxymethane (25, 29, 12%). / Liebigs Ann. Chem. *725*, 15 (1969) / —Ma. [Rd 91 IE]

Redox polyamides *(2)* have been synthesized by *N. Nakabayashi* and *H. G. Cassidy* by condensation of the bislactone *(1)* with diamines such as hexamethylenediamine, piperazine, 4-aminoethylpiperidine, or 1,3-bis(4-piperidinyl)propane. The lactone function protects the OH groups until the onset



(1)

(2)

of polymerization, whereupon free hydroquinone hydroxyl groups appear. The polymer formed is oxidizable. / J. Polymer Sci. *7*, A-1, No. 5, 1275 (1969) / —Ma. [Rd 93 IE]

1,2,4,5-Tetroxane derivatives from ε-caprolactam hydroperoxide *(1)* have been obtained by *E. Höft, A. Rieche,* and *W. Schön.* Rapid treatment of *(1)* with 70—80% H_2SO_4 at room temperature and dilution with water leads to 3,6-bis-(carbamoylbutyl)-1,2,4,5-tetroxane *(2)*, m.p. 213—215 °C, in 88% yield. Reaction of *(2)* with hot 10% H_2SO_4 gives the dicarboxylic acid *(3)*, which can be converted into esters and

(1)

(2), X = NH_2
(3), X = OH

amides *via* the dichloride. The tetroxanes do not explode on impact or on overheating. They are suitable for use as polymerization initiators. / Liebigs Ann. Chem. *725*, 241 (1969) / —Ma. [Rd 92 IE]

The rotational isomerism of *m*-halogenobenzaldehydes has been studied by *G. A. Crowder* and *F. Northam* on the basis of the IR spectra. In the pure liquid compounds, the *cis*-O- and *trans*-O-isomers are present alongside each other; in the solid state, the chloro and bromo compound are present only as the lower-energy *cis*-O-isomer. *m*-Iodobenzaldehyde exists as the *trans*-O-isomer in the solid state; in the liquid state the energy difference between the rotamers is low. The greater stability of the *cis*-O-form of the chloro and bromo compounds is attributed to the inductive effect of the halogen: the H atom lying between the substituents carries a partial positive charge, thus leading to stabilization of the *cis*-O-form. / J. chem. Physics *50*, 4865 (1969) / —Hz. [Rd 94 IE]

The structure of B_2Cl_4 in the gas phase has been determined by *R. R. Ryan* and *K. Hedberg* by electron diffraction. In contrast to the solid state, in which the molecule is planar, the two BCl_2 planes are perpendicular to each other at equilibrium in the gas phase (symmetry D_{2d}). Structural data (at 251 °K): B—Cl = 1.750 Å; B—B = 1.702 Å; Cl—B—Cl = 118.65 °. Comparison of the diffraction maxima corresponding to the interatomic distances, which change on internal rotation about the B—B axis, with calculated values yielded a potential threshold $V_0 = 1.85$ kcal/mole for internal rotation according to the equation

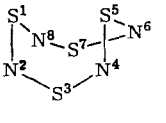
$$V = {}^1/_2\, V_0\,(1 - \cos 2\Theta)$$

J. chem. Physics *50*, 4986 (1969) / —Hz. [Rd 95 IE]

Formation and reactions of the ozonide ion in aqueous alkaline H_2O_2 have been studied by *V. R. Landi* and *L. J. Heidt* by flash photolysis. The O_3^- ion is recognized by an absorption maximum at 430 nm. In all cases the O_3^- absorption decayed by a first order process; the rate constant of the decay increases with the concentration of H_2O_2 and decreases with the concentration of OH^- and dissolved O_2. During the decay of O_3^- a relatively long-lived intermediate is formed, which was identified as ozone. The following reactions take place:

$$O_3^- = O_2 + O^- \quad k = (2.81 \pm 0.14) \times 10^3\ \mathrm{sec}^{-1}$$
$$O_2 + O^- = O_3^- \ (k_2) \quad k_2/k_3 = 3.6 \pm 0.3$$
$$O^- + HO_2^- = O_2^- + OH^- \ (k_3)$$
$$O_3^- + O_2^- + H_2O = O_3 + HO_2^- + OH^-$$

The increased stability of O_3^- at higher NaOH concentration is rationalized in terms of formation of the ion pair NaO_3, an equilibrium constant of 2.24±0.11 $mole^{-1}$ having been determined for this process. / J. Physic. Chem. *73*, 2361 (1969) / —Hz. [Rd 96 IE]



The solubility of Al_2O_3 in rutile has been studied at 1200 to 1426 °C on the basis of changes in the lattice constant *c* by *R. A. Slepetys* and *P. A. Vaughan.* The solubility increased with the temperature of annealing from 0.62 wt.-% Al_2O_3 at 1200 °C to 1.97% at 1426 °C. At temperatures below 1240 °C the dissolved phase in equilibrium is corundum and above this temperature it is Al_2TiO_5. The solubility of Al_2O_3 also increased on addition of Nb_2O_5. The density of a sample of rutile annealed at 1426 °C and containing 1.6% Al_2O_3 was 4.199 g cm^{-3} (pure rutile: 4.202 g cm^{-3}). These data are in accord with a solution model in which Al^{3+} and O^{2-} are incorporated into rutile lattice sites in the ratio of 1 : 2 and the excess of Al^{3+} occupy interstitial sites. Values of the enthalpy of solution of 35 kcal $mole^{-1}$ for Al_2TiO_5 and 100 kcal $mole^{-1}$ for Al_2O_3 were calculated from the temperature dependence of the solubility. The enthalpy of formation of Al_2TiO_5 in the temperature range around 1240 °C is thus calculated as —599 kcal $mole^{-1}$. / J. physic. Chem. *73*, 2156 (1969) / —Hz. [Rd 97 IE]

The vapor pressure and the crystal structure of metallic curium have been investigated by *P. K. Smith, W. H. Hale,* and *M. C. Thompson.* In the temperature range 1179 to 2068 °K and at pressures of 10^{-7} to 10^{-1} torr the vapor pressure equation

$$^{10}\log P\,(\mathrm{atm}) = (4.74 \pm 0.37) - (18060 \pm 590)/T\,(^\circ\mathrm{K})$$

was determined by an effusion method. The boiling point extrapolated to atmospheric pressure is 3540 °K. A hitherto unknown form of the metal having a face-centered cubic structure, the lattice constants 4.382 Å, and a density of 19.26 g cm^{-3} was identified. Comparison of these data with those found for related metals indicated that curium has a valence of 4 in this form. The entropy of melting of Cm is low (no figure can be given); this is a consequence of the relatively high entropy of solid Cm which contains contributions from transformations of several electronic configurations ($5f^6\ 6d^2\ 7s^3$ and $5f^7\ 6d\ 7s^2$). / J. chem. Physics *50*, 5066 (1969) / —Hz. [Rd 98 IE]

The vibrational spectra of S_4N_4 and S_2N_2 have been studied by *J. Bragin* and *M. V. Evans.* All the frequencies found in the case of S_4N_4 *(1)* could be assigned; the molecule has a cradle-like structure with the following bond lengths (in Å): S^1N^2 = 1.62; S^1S^5 = 2.58; S^1S^3 = 2.69, and the angles $N^2S^1N^8$ = 105 °; $S^1N^2S^3$ = 113 °; $S^1S^5N^4$ = 90 °. The four nitrogen

(1)

atoms form a plane. The calculated force constants show that repulsions between non-bonded atoms play a large role in S_4N_4. A planar rhomboidal structure with alternate S and N atoms is suggested for S_2N_2. Raman-active S—N frequency

of the class B_1g is not available for calculation of force constants in the case of S_2N_2 since the substance is too unstable to furnish interpretable spectra. / J. chem. Physics *51*, 268 (1969) / —Hz. [Rd 99 IE]

The electrical conductivity of CuCl at high pressure, as determined for tablets at 370—670 °K and 10—55 kbar is reported by *R. S. Bradley, D. C. Munroe,* and *P. N. Spencer.* A plot of the logarithm of the conductivity against $1/T$ at constant pressure is a straight line which changes its slope at 220 ± 20 °C. The slope, which can be regarded as a measure of the activation energy of the conduction process, falls in the low temperature range and rises in the high temperature region with increasing pressure, from which it may be concluded that electronic conduction predominates at lower temperatures and ionic conduction at higher temperatures. Doping with $CdCl_2$ up to 1 mole-% has little effect on the conductivity; doping with $CuCl_2$, on the other hand, causes a considerable increase in the conductivity; at higher pressures (40 kbar) electronic conductivity predominates in the whole range of temperatures investigated. Similar studies were carried out with CuCN, AgCN, AuCN. / Trans. Faraday Soc. *65*, 1912, 1920 (1969) / —Hz. [Rd 100 IE]

Solvent effects in the fluorescence and phosphorescence of indole are discussed by *C. M. Chopin* and *J. H. Wharton.* The relative quantum yields for fluorescence and phosphorescence change considerably on going from nonpolar to polar solvents, without any corresponding changes becoming apparent in the absorption spectrum. The authors assume, deviating from earlier interpretations, that isomerization from the first excited singlet state of indole to the corresponding state of 2*H*-indole can take place relatively easily; the triplet states of the two molecules also lie at very similar energies. Varying solvent stabilization of the excited states then affords a ready explanation of the observed anomalies in the emission spectra. / Chem. Physics Letters *3*, 552 (1969) / —Hz. [Rd 101 IE]

BOOK REVIEWS

Electrochemische Stromerzeugung (Electrochemical Production of Current). By *F. von Sturm.* Vol. 5 of "Chemische Taschenbücher", edited by *W. Foerst* and *H. Grünewald.* Verlag Chemie GmbH, Weinheim/Bergstrasse 1969. 1st Edit., ix + 189 pp., 83 illustrations, paper DM. 16.—.

The direct conversion of chemical into electrical energy has aroused much interest in the last decade because of the manifold requirements of our present technology and civilization. Although the thermodynamic and technical advantages of this type of energy production have been general knowledge for a very long time, there are still great difficulties preventing its realization in an economically rational manner. This has stimulated research into the use of new methods intended to supplement the classical established systems for conversion of electrochemical energy or to replace them by more efficient systems.

The pocketbook under review gives an excellent introduction to this type of problem. It begins with a brief sketch of the mode of action, construction, and limitations of classical primary and secondary batteries; this section also treats modern, alternative systems for such purposes. The main weight, however, is placed on the problems of fuel cells (about 2/3 of the text); the author attempts to delineate the trend of their development, placing the main emphasis on successful methods but without forgetting interesting sidelines even when there is no present prospect of their realization.

The presentation is clear and stimulating, and this well written introduction can be very warmly recommended.

H. Gerischer [NB 838 IE]

Statistische Elektrizität als Gefahr (The Dangers of Static Electricity). By *K. Haase.* Verlag Chemie GmbH., Weinheim/Bergstr. 1967. 1st Edit., 124 pp., 21 illustrations, DM 14.—.

Most of us have at one time or another picked up a static charge from a modern floor-covering, and were unpleasantly surprised by the resulting powerful sparks. Some of us may also have tried to use this phenomenon to ignite a gas burner or perhaps ether, and have found that this technique works all too readily.

Static may be encountered in industry with transmission belts and with spinning machines. Pneumatically conveyed materials can collect a high charge, as can insulating dusts on drying and unloading. Static electricity also builds up whenever insulating liquids or gases leave grounded equipment. It is therefore laudable that *K. Haase* should have written this readily understandable book on the dangers of static, a book that will be welcomed especially by process engineers and by those concerned with the design of new production plant.

The first section, occupying about a third of the book, describes the physical principles: electrostatics, charging up by charge separation, physics of the ignition of explosive mixtures. The second section deals with measurement techniques, including some specific methods of measurement for floors, shoe soles, and drive belts. In the last two sections the author discusses the ways of eliminating static electricity as a source of danger. This part is illustrated by 19 practical examples. The book ends with a bibliography, a formula index, and an alphabetical index.

Dreiringe mit zwei Heteroatomen. Oxaziridine – Diaziridine – Cyclische Diazoverbindungen (Three-membered Rings containing Two Hetero Atoms. Oxaziridines, Diaziridines, Cyclic Diazo Compounds). By *E. Schmitz.* Vol. 9 in the series "Organische Chemie in Einzeldarstellungen". Springer-Verlag, Berlin-Heidelberg-New York 1967. 1st Edit., xii + 179 pp., 5 illustr., bound DM 58.— / $ 14.50.

Since three-membered rings containing two hetero atoms were first synthesized in the 1950's, this monograph treats a very young area of organic chemistry, one, by the way, to whose rapid development the author has himself contributed decisive material. It is true that nitrones, hydrazones, diazomethane, and certain peroxides were earlier formulated as three-membered ring compounds, but all such structures were finally abandoned in favor of acyclic ones.

Each chapter is developed in accord with the historical course of discovery of its three-membered ring system. Treatment begins with the oxaziridines, the proof of whose structure was so important because, after a whole series of faulty interpretations, this provided the first certain occurrence of a three-membered hetero ring system. Oxaziridines are among the strongest organic oxidizing agents although they are themselves oxidized by peracids, a reaction from which an elegant synthesis of nitrosoalkanes in good yield has been developed.

This section is followed by one on diaziridines, whose ready accessibility and unusually varied modes of reaction do not merely make them interesting to the preparative organic chemist but have attracted general attention as having been developed in several directions for industrial production of hydrazine. The book closes with a description of diazirines, first prepared in 1960 and whose parent compound, cyclodiazomethane, was first obtained by *E. Schmitz* and *R. Ohme*. Reading this chapter, which contains a wealth of preparative and theoretical aspects (concerning, for example, the thermal decomposition or ring expansion) gives the impression also that here we are still quite at the beginning of promising developments. The theoretician will be particularly interested in a detailed analysis of the electron configurations and transitions of diazirines. The clarity of the writing and the intelligibility of this book are very welcome; it deals with the literature up to the middle of 1966; and it contains many UV, IR, and NMR spectroscopic data, as well as tables giving yields for most of the three-membered ring systems synthesized.

This book can be highly recommended and will doubtless take an important place in the library of the organic chemist.

J. Gosselck [NB 833 IE]

Steroid Reaction Mechanism. By *D. N. Kirk* and *M. P. Hartshorn*. Vol. 7 in the series "Reaction Mechanism in Organic Chemistry". Elsevier Publishing Company, Amsterdam-London-New York 1968. 1st Edit., xii + 474 pp., 57 illustrations, 31 tables, bound, Dfl. 85.—.

This book is a very useful adjunct to the well-known steroid monographs, *e.g. Fieser* and *Fieser*'s "Steroids" or *Djerassi*'s "Steroid Reactions".

After an introduction to conformational analysis a total of eleven chapters provide a comprehensive review of the manifold steroid reactions of present knowledge from the viewpoint of reaction mechanism, namely: 1, Steroids, Reaction Mechanisms and Conformational Analysis; 2, Reactions of Alcohols and Halides; 3, Steroid Olefins; 4, Steroid Ketones; 5, Solvolytic Reactions and Rearrangements of Steroid Derivatives; 6, Steroid Amines; 7, Reactions of Derivatives of Steroid Ketones; 8, Rearrangements of Epoxides; 9, Rearrangements involving Functional Groups; 10, Functionalization of Non-Activated Carbon Atoms; 11, Photochemical Reactions.

In addition to *ca.* 1300 references inclusive up to 1967, there is an appendix containing supplementary literature up to 1968. An alphabetic index of functional groups provides for rapid recovery of material on a desired subject.

The clear text, instructive formulas, and intelligible tables make understanding of the material easy even for the reader who is not familiar with the field. Since steroid examples are didactically excellent for treatment of much mechanistic organic chemistry, this book can be recommended also to the more advanced student. With few exceptions, *e.g.* Birch reduction of aromatic compounds, the reader will obtain an excellent and almost complete survey of the present state of steroid chemistry. The book fills a real gap; its publication is welcome and it is to be hoped that it attains wide circulation amongst those interested in this area.

R. Wiechert [NB 832 IE]

Rodd's Chemistry of Carbon Compounds, Vol. II: Alicyclic Compounds, Part C: Polycyclic Compounds Excluding Steroids. Edited by *S. Coffey*. Elsevier Publishing Company, Amsterdam-London-New York 1969. 2nd Edit., xvi, 481 pp., 155 figures, 64 tables, bound Dfl. 90.—[1].

The compilers of the new edition of Rodd's Chemistry of Carbon Compounds were faced with the problem of presenting the subject matter, which has grown immensely since the first edition was published in 1953, as concisely and as clearly as possible in the new edition. This problem has been brilliantly solved, though Volume II has unavoidably expanded from its original two parts to four. The present Part C corresponds roughly to the earlier part B, but no longer contains the steroids or the monocyclic and acyclic terpenoids. This is regrettable, since chemists working in the isoprenoid field will no longer have available to them a single reference book that covers the whole field.

Each of the six chapters begins with a brief discussion of the nomenclature of the class of compounds in question. This is followed by descriptions of general synthetic routes and occurrence, and sometimes the proof of the structure in the case of natural products. The individual substances are then discussed in the order hydrocarbons, alcohols, ketones, acids, *etc.* The literature is taken into account up to the beginning of 1966, and in some cases even up to 1968. The extended formulas are much better than in the first edition. A very welcome addition to the chapter on bicyclic monoterpenes is a section on the absolute configurations of these compounds. The book begins with the description of polycarbocyclic systems with separate rings and spiro compounds. This is followed by condensed cyclic systems and bridged ring compounds. The bicyclic monoterpenes of the thujane, carane, and pinane groups and the norbornane system are discussed at some length. Rapid development in the sesquiterpenoid field has entailed expansion of this chapter by almost 100% in relation to the first edition. A similar situation is found in the final chapter on di-, sester-, and triterpenoids. A four-page section on physical methods for the determination of the structure and configuration of natural products must necessarily be incomplete. A careful examination of this work will convince any reader that the best possible solution to the problem of a modern reference book has been found.

The volume can be wholeheartedly recommended, and should find a place in every library. *E. Klein* [NB 825 IE]

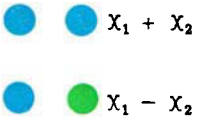
The Conservation of Orbital Symmetry [***]

By R. B. Woodward [*] and Roald Hoffmann [**]

1. Introduction

Of the various ways in which the phenomena of chemical bonding have been treated from the theoretical point of view, the molecular orbital method may fairly be deemed to have been the most fruitful in the hands of the organic chemist, and most adaptable to his needs. None the less, the method, with a few conspicuous exceptions, has been used mainly in the study of the static properties of molecules – in ground and excited states – and only rarely have its potentialities been explored in relation to reacting systems.

In 1965, in a series of preliminary communications [1–3], we laid down some fundamental bases for the theoretical treatment of all concerted reactions. The history of the genesis of these ideas has been described elsewhere [4]. The basic principle enunciated was that reactions occur readily when there is congruence between orbital symmetry characteristics of reactants and products, and only with difficulty when that congruence does not obtain – or to put it more succinctly, *orbital symmetry is conserved in concerted reactions.* This principle has met with widespread interest; the applications made of it, the tests which it has survived, and the corollary predictions which have been verified are already impressive. In this paper we develop our views at some length, survey some of the developments – in our hands and those of others – of the three years just past, and make some new projections.



2. Orbitals and Bonding

It is worth while to review the elementary aspects of the molecular orbital theory of bonding [5]. Molecular orbitals are constructed as combinations of atomic orbitals, and are then populated by electron pairs. When two equivalent atomic orbitals, χ_1 and χ_2, combine, they always yield a bonding combination and a corresponding antibonding orbital *(1)*.

(1)

The bonding combination is characterized by positive overlap, and by concentration of electron density in the region between the nuclei. By contrast, the antibonding combination exhibits negative overlap, and a nodal surface in the region between the nuclei. When χ_1 and χ_2 are *s* orbitals, the bonding combination is $\chi_1+\chi_2$, and the antibonding one $\chi_1-\chi_2$.

When χ_1 and χ_2 are p orbitals interacting in a σ manner, and oriented as shown in *(2)*

(2)

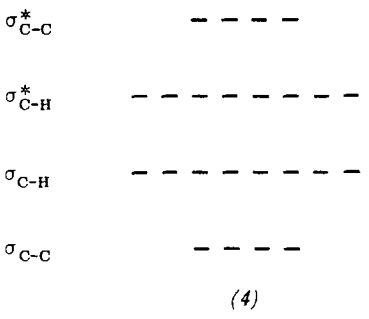
Throughout this paper, the phases of wave-functions are color-coded: positive = blue, negative = green. When phase relationships are not relevant, the orbitals are presented in solid gray.

the bonding combination is again $\chi_1+\chi_2$ and the antibonding combination $\chi_1-\chi_2$.

It is important to realize, however, that were the basis orbitals initially arbitrarily oriented in some other

(3)

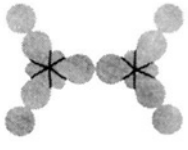
fashion, such as *(3)*, then, since $\chi_2=-\chi_2$, the bonding combination would be $\chi_1-\chi_2'$, and the antibonding one $\chi_1+\chi_2'$. It should also be kept in mind that multiplying an entire wave function by -1 does not affect its energy. Thus, overlap of minus with minus lobes is precisely equivalent to plus with plus lobes, and $-\chi_1-\chi_2$ is the *same* bonding orbital as $\chi_1+\chi_2$.



The description of σ bonds in hydrocarbons is simple. Each formal chemical bond engenders a σ and a σ^* orbital. The C–H and C–C cases are:

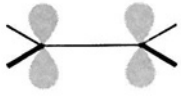
The molecular orbitals are represented in our drawings as the overlap of two hybrids of unspecified hybridization. It should be emphasized that this is only intended as an artistic mnemonic device: the only essential features of a σ orbital are that it is approximately cylindrically symmetrical around the bond axis, that it concentrates electron density in the region between the nuclei, and that there is no nodal plane between the atoms.

Our simple picture of bonding in, say, cyclobutane, shows four C–C σ levels, and eight C–H σ levels, each with a matching σ^* level *(4)*. The carbon 1*s* orbitals are not considered. Each of the σ levels is occupied by



(4)

two electrons. Spectroscopic studies indicate that the gap between occupied and unoccupied levels must be of the order of 10 electron volts.



The orbitals we have constructed are semi-localized. They are delocalized over only two atoms. Such orbitals are satisfactory for an analysis of some properties of the molecules – those which depend on all of the occupied molecular orbitals: bond lengths, energies, dipole moments. They are not the proper molecular orbitals of the molecule. The latter are completely delocalized, subject to the full symmetry of the molecule. For a discussion of physical properties depending on one or two specific molecular orbitals, such as spectra or ionization, it is absolutely necessary to construct these equivalent delocalized orbitals. The mechanics of delocalization will be described in Section 3.

In addition to σ bonds, the molecules of organic chemistry contain delocalized π orbitals. Thus, the electronic structure of ethylene is described as follows: There are four σ C–H bonds and a σ C–C bond *(5)*. Each

(5)

generates a σ and a σ^* level, and five pairs of electrons are placed in the σ levels. There remain two electrons and two atomic p orbitals perpendicular to the plane of the molecule *(6)*. These combine to give π and π^* orbit-

(6)

als, differentiated by the absence or presence of a node between the atoms (Figure 1).

There are two independent symmetry operations which may be used to classify these orbitals; the mirror plane m, perpendicular to the molecular plane and bisecting the molecule, and the two-fold rotation axis C_2, passing through the center of the carbon-carbon bond. It should be noted carefully that the symmetry properties

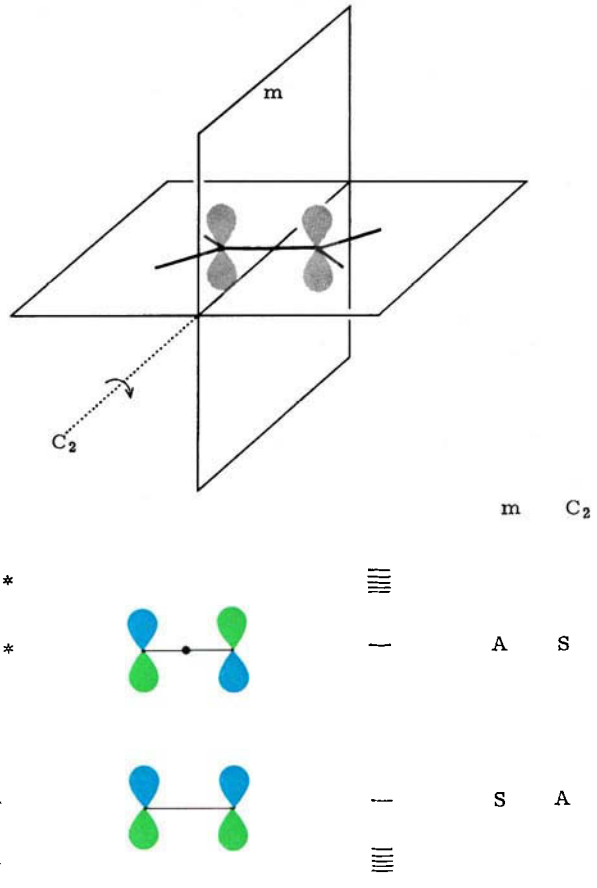


Figure 1. Molecular orbitals of ethylene and symmetry properties of the π and π^* orbitals. A = antisymmetric, S = symmetric. The horizontal bars indicate the relative orbital energies.

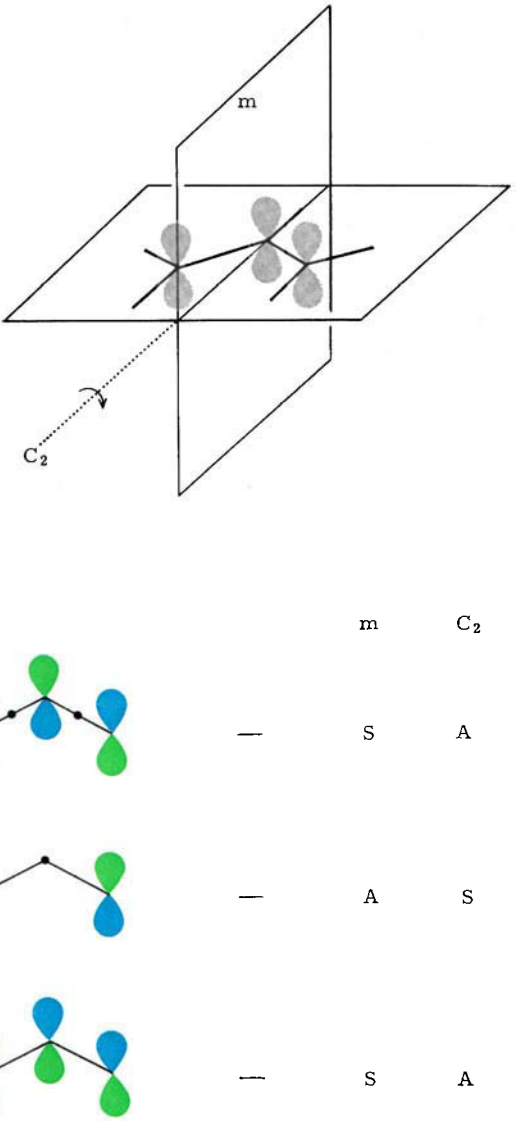
of the ethylene orbitals under each of the above operations are precisely opposite. Thus, the π orbital is symmetric (S) with respect to the mirror plane m, and antisymmetric (A) with respect to the rotation axis C_2.

The overlap between the two $2p_z$ orbitals is significantly less than that involved in σ interactions, and so the π bond is weaker than a σ bond, and the π and π^* levels are raised and lowered, respectively, from the sea of σ and σ^* levels (Figure 1).

The π molecular orbitals of the three-orbital allyl system are shown in Figure 2. Their nodal structure should be carefully noted. By virtue of their character as π orbitals, they all are antisymmetric under reflection in the plane of the allyl system. The lowest orbital, doubly occupied in the allyl cation, has no additional nodes. The middle, nonbonding orbital, which is singly occupied in the allyl radical, and doubly occupied in the anion, has a single nodal plane which precludes any contribution of the $2p$ orbital at the central carbon atom. The orbital of highest energy has two nodes.

The molecular orbitals of the four-orbital butadiene system are shown in Figure 3 for an *s-cis* arrange-



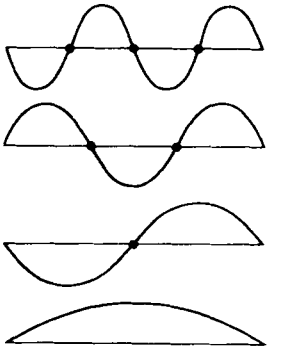


Figure 2. π molecular orbitals of the allyl system. A = antisymmetric, S = symmetric.

ment [6,7]. Note once again the nodal structure and the alternating symmetry properties. The correlation of higher energy with an increasing number of nodes is

(7)

[6] Throughout this paper molecular orbitals are symbolized in terms of the atomic orbitals whose interaction gives the actual molecular orbital; since we are in general interested only in nodal properties, we ignore the fact that the coefficients – and thus the relative sizes – of the resultant atomic orbital contributions are not all identical.

[7] The electronic structure of polyenes is perhaps the most highly developed branch of semi-empirical molecular orbital theory. A very good survey of the field is given in *L. Salem:* The Molecular Orbital Theory of Conjugated Systems. Benjamin, New York 1966. See also *A. Streitwieser:* Molecular Orbital Theory for Organic Chemists. Wiley, New York 1961.

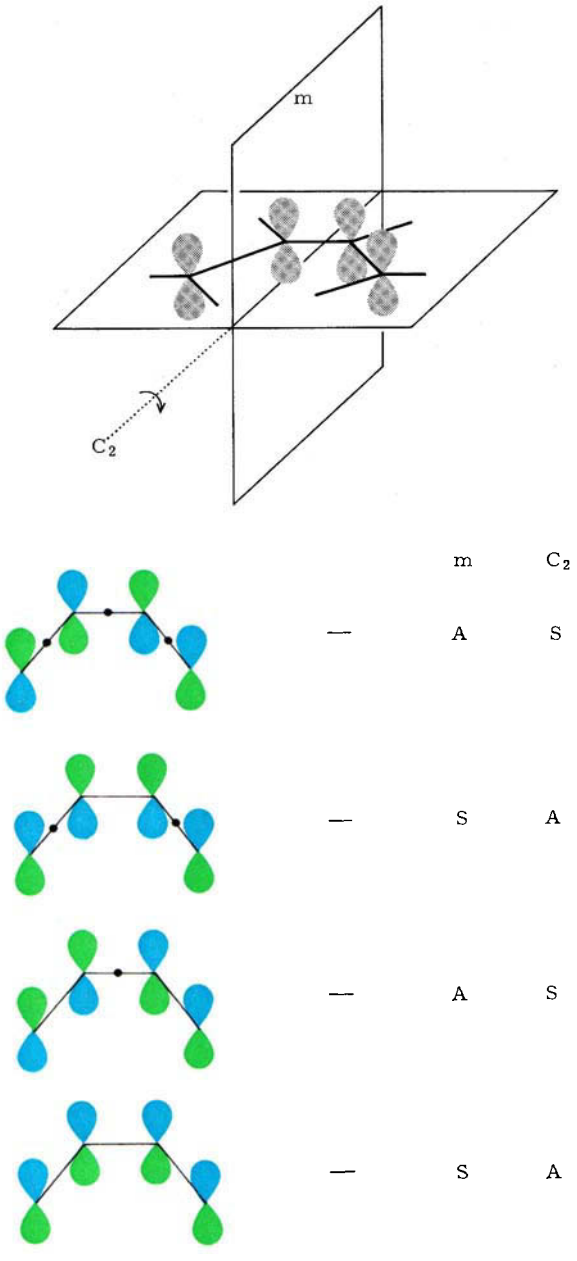

Figure 3. π molecular orbitals of *s-cis*-butadiene. A = antisymmetric, S = symmetric.

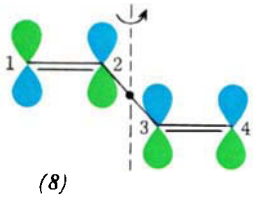
not an accident, but rather a general consequence of either classical or quantum mechanics. The envelopes of polyene orbitals coincide with the curve of the wave function of a particle in a one-dimensional box *(7)*. The lowest orbital has no nodes, the next higher one has one node, the next two, and so on until the highest orbital has the maximum number of nodes possible. The general expression for the k^{th} molecular orbital of a polyene or polyenyl system with n carbon atoms is

$$\Psi_k = \sum_{i=1}^{n} C_{ki}\,\Phi_i$$



where the Φ_i are the atomic orbitals numbered consecutively from one end. The coefficients are given by the expression [7]

$$C_{ki} = \sqrt{\frac{2}{n+1}}\sin\frac{\pi ki}{n+1}$$

The orbitals alternate in symmetry with increasing energy.

If n is even, there are $n/2$ bonding π orbitals and $n/2$ antibonding. If n is odd, there are $(n-1)/2$ bonding, $(n-1)/2$ antibonding, and one nonbonding orbital.

A final point of much importance is that no molecular orbital may be at the same time symmetric and antisymmetric with respect to any existing molecular symmetry element. Thus, the orbital *(8)* is symmetric un-

(8)

der rotation by 180 ° if atoms 2 and 3 are viewed, but antisymmetric if 1 and 4 are considered; it is not an acceptable molecular orbital of butadiene.

3. Correlation Diagrams

The united atom-separated atoms diatomic correlation diagrams first drawn in the early nineteen-thirties by *Hund* and *Mulliken* have an important place in theoretical chemistry [8]. In constructing such a diagram, one imagined the process of two atoms approaching each other from infinity. The energy levels of the separated atoms were placed in approximate order of energy on one side of the diagram. One then imagined the approach of the atoms through the physically realistic molecular region into the physically impossible process of nuclear coalescence. The energy levels of the resulting united atom were once again known. They were placed on the other side of the diagram. One then proceeded to classify the initial separated and the final united atom orbitals with respect to the symmetry maintained throughout the hypothetical reaction. Levels of like symmetry were connected, paying due attention to the quantum mechanical noncrossing rule – that is, only levels of unlike symmetry are allowed to cross (Figure 4).

In this way, from the relatively well-known level structures of the separated atoms and the united atom valuable information was obtained about the level structure of the intermediate region corresponding to the molecule. It was this kind of diagram which provided a

[8] *F. Hund*, Z. Phys. *40*, 742 (1927); *42*, 93 (1927); *51*, 759 (1928); *R. S. Mulliken*, Phys. Rev. *32*, 186 (1928); Rev. Mod. Phys. *4*, 1 (1932). See also *G. Herzberg*: The Electronic Structure of Diatomic Molecules. 2nd edition, Van Nostrand, Princeton 1950.

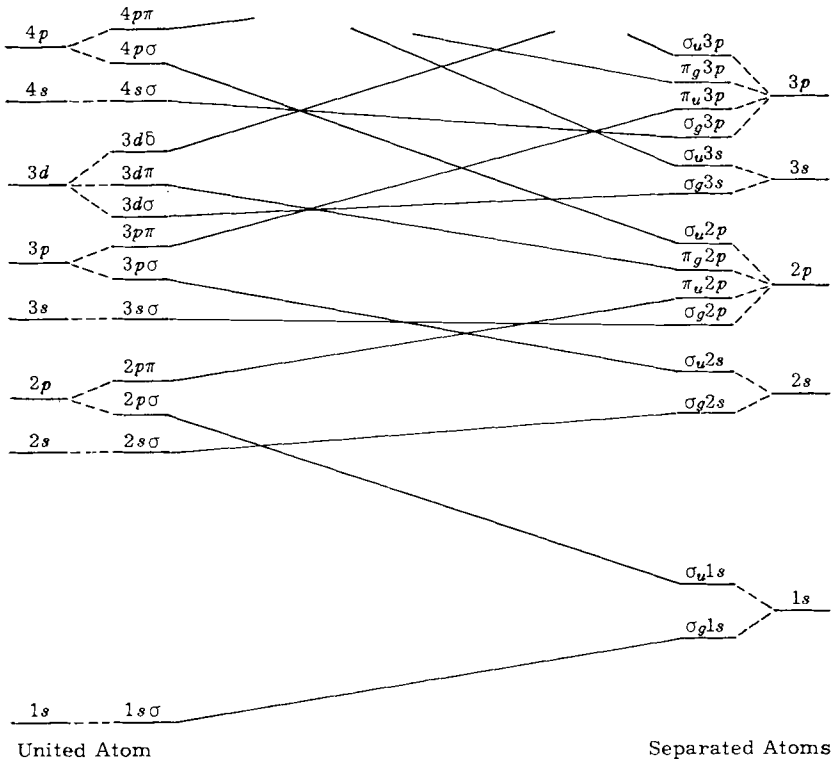


Figure 4. A typical atomic correlation diagram.

rationalization for the existence of the oxygen molecule as a ground-state triplet.

In an exactly analogous manner a correlation diagram may be drawn for a concerted reaction such as cycloaddition. On one side one writes down the approximately known energy levels of the reactants, on the other side those of the product. Assuming a certain geometry of approach one can classify levels on both sides with respect to the symmetry maintained throughout the approach, and then connect levels of like symmetry. Such a molecular correlation diagram yields valuable information about the intermediate region, which represents in this case the transition state for the reaction.

We would like to illustrate in some detail the construction of a molecular correlation diagram. The first example we choose is the maximum-symmetry approach of two ethylene molecules, leading to cyclobutane (Figure 5). As usual in theoretical discussions, maximum insight into the problem at hand is gained by simplifying the case as much as possible, while maintaining the essential physical features. In this instance we treat in the correlation diagram *only four* orbitals – the four π orbitals of the two ethylenes. In the course of the reaction these four π orbitals are transformed into four σ orbitals of cyclobutane. We may safely omit the C–H and the C–C σ bonds of the ethylene skeleton from the correlation diagram because, while they undergo hybridization changes in the course of the reaction, their number, their approximate positions in energy, and in particular their symmetry properties are unchanged.

The first step in the construction of a correlation diagram involves isolating the essential bonds and placing them at their approximate energy levels in reactants and products; the result is shown for the case at hand in Figure 6, in which the dashed horizontal line is the

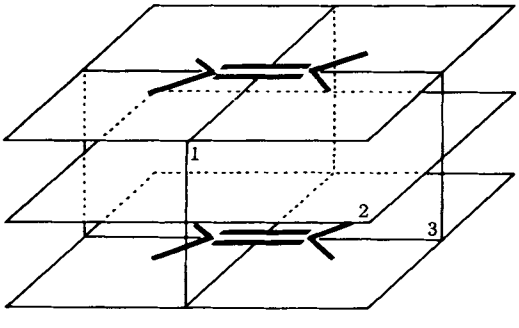

Figure 5. Parallel approach of two ethylene molecules.

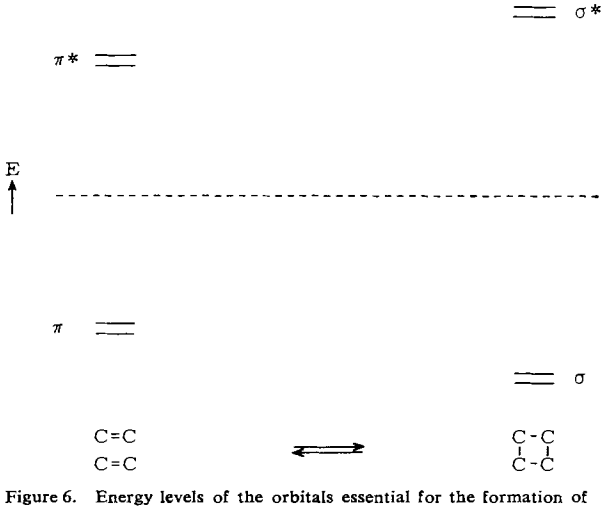

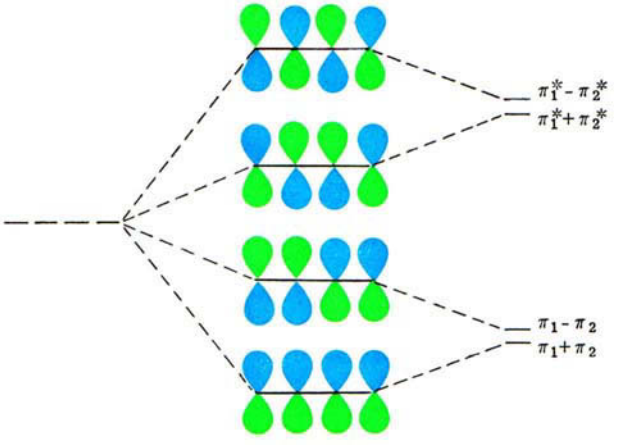

Figure 6. Energy levels of the orbitals essential for the formation of cyclobutane from two ethylene molecules in the geometry shown in Figure 5.

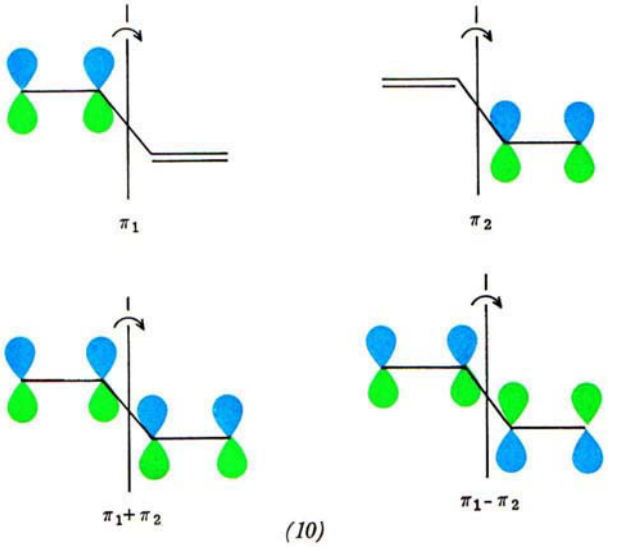
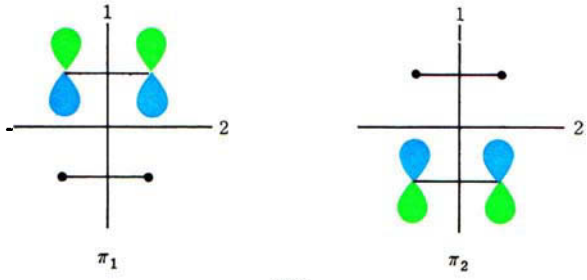


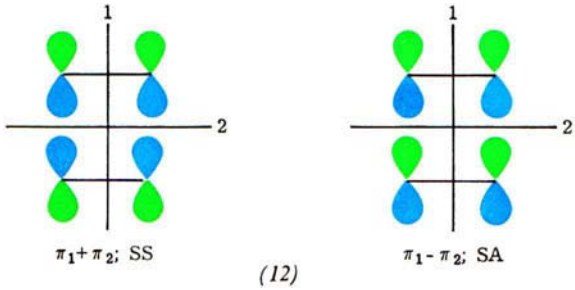
nonbonding level – approximately the energy of an electron in a free carbon 2*p* orbital. We have separated σ and σ^* by an energy greater than that between π and π^*; although there is little reason to question this assignment, it is important to emphasize that it is in no way essential to the subsequent argument. To assign an order of magnitude to the vertical energy scale we may take the distance between π and π^* as approximately 5 electron volts [7].

In the next step the proper molecular orbitals for the reactants and products are written down. A digression on constructing molecular orbitals for interacting systems is in order at this point. Consider an *s-trans*-butadiene. One way to derive the four molecular orbitals of butadiene is to allow all of the four atomic orbitals to interact as illustrated at left in *(9)*.



(9)

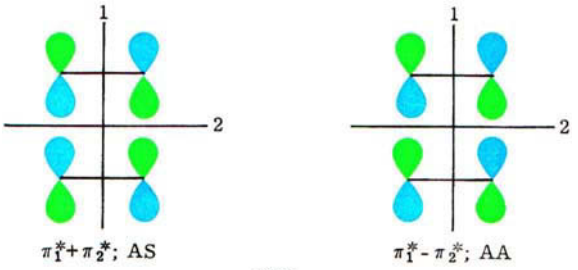
Yet another way is to view butadiene as arising from the interaction of two semi-localized double bonds. Consider the bonding π orbitals of the two ethylenes. While π_1 and π_2 are entirely satisfactory for a description of the isolated double bonds, they are not the proper combinations to use as molecular orbitals for butadiene. Molecular orbitals must be symmetric or antisymmetric with respect to any molecular symmetry element which may be present. In the case at hand the crucial symmetry operation is a 180° rotation around the two-fold axis. The obvious combinations to use, and ones which do satisfy the symmetry conditions, are $\pi_1 \pm \pi_2$ *(10)*. These, of course, turn out to be topologically identical with the two lowest-energy butadiene orbitals which were constructed by considering direct interaction of all four atomic orbitals.



(10)

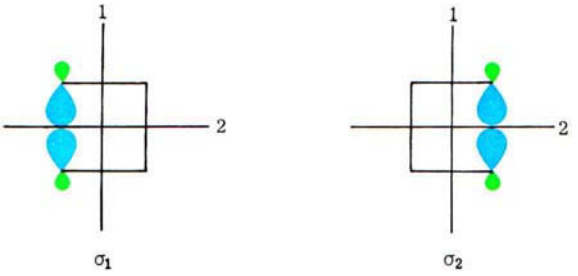
We are now prepared to treat the analogous problem of the molecular orbitals of two ethylenes approaching each other. Drawing orbital cross-sections in plane 3 (*cf.* Figure 5), diagram *(11)* represents localized π bonds of the two ethylenes. These are not the proper combinations to choose for a discussion of the orbitals of the complex of two ethylenes; they are not symmetric or antisymmetric under reflection in plane 2. Again the obvious combinations are $\pi_1+\pi_2$ and $\pi_1-\pi_2$ *(12)*.

(11)



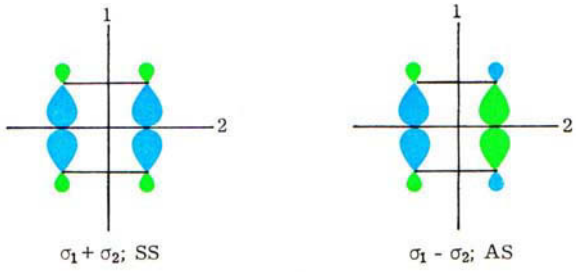
(12)

The first of these is symmetric with respect to reflection in both planes 1 and 2 (abbreviated as S_1S_2 or simply SS); the second is symmetric under reflection in plane 1, and antisymmetric under reflection in plane 2 (S_1A_2 or SA) [9]. Both orbitals, of course, are symmetric with respect to reflection in plane 3, and this trivial information need not be explicitly specified. At large separation between the ethylenes, $\pi_1+\pi_2$ and $\pi_1-\pi_2$ will be

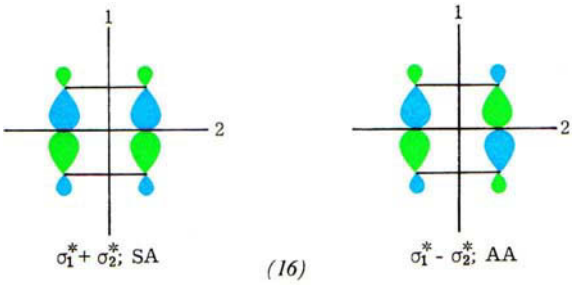


[9] We could, of course, label the levels with their proper symmetry designations, appropriate to the D_{2h} symmetry of the approach. We deliberately use the symmetric (S) and antisymmetric (A) labels since the nodal properties of the orbitals are then most clearly discernible.

degenerate, but at small separations $\pi_1+\pi_2$ will be at lower energy than $\pi_1-\pi_2$ since the former has fewer nodes. Similar combinations of antibonding molecular orbitals for the complex are shown in *(13)*.



(13)



One must next analyze the situation in cyclobutane in an entirely analogous way. Consider the localized σ bonds *(14)*. Again these do not satisfy all the symmetry operations of the cyclobutane molecule, and one must take the two combinations $\sigma_1\pm\sigma_2$ *(15)*; a similar procedure must be followed for the antibonding σ^* orbitals *(16)*.

(14)

(15)

(16)

We are now equipped to examine the correlation of the orbitals of reactants with those of the product (Figure 7). The direction in which the various levels will move may be obtained without detailed calcula-

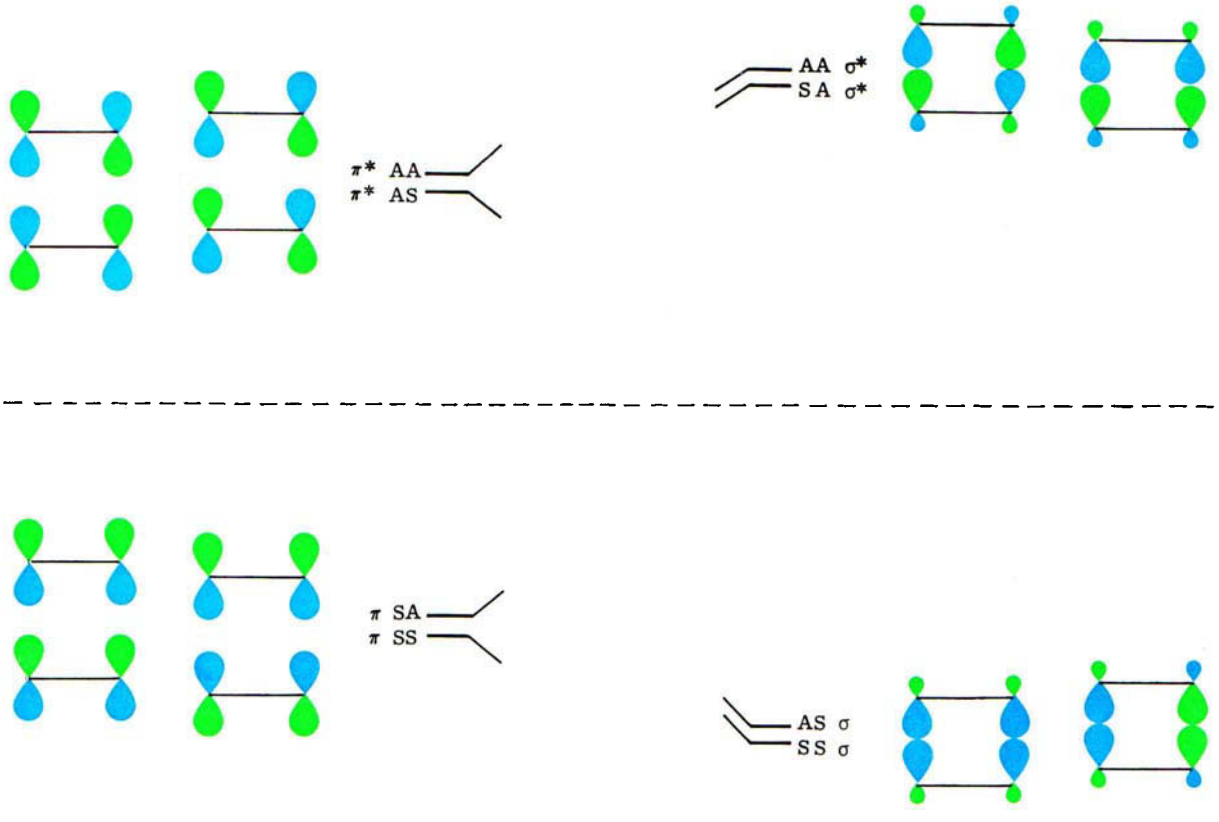


Figure 7. Initial displacements of orbital energy levels in the reaction: 2 ethylenes $\rightleftarrows$ cyclobutane.

tion, by examining in each case whether any level is bonding or antibonding along the reaction coordinate; in doing this one should keep in mind the definition of bonding or antibonding. Consider the two molecular orbitals for the hydrogen molecule, formed from two 1*s* orbitals (Figure 8). σ_g is bonding because electrons

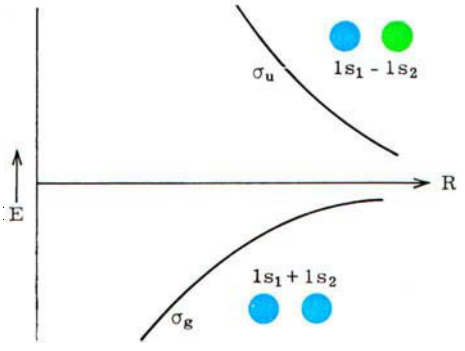

Figure 8. Formation of the bonding (σ_g) and antibonding (σ_u) molecular orbitals of the hydrogen molecule from two atomic 1*s* orbitals.

occupying it lie in the region between and are shared by the nuclei; σ_u is antibonding and at higher energy because the presence of a node between the nuclei isolates electrons populating the orbital in the regions of the individual terminal nuclei. There is another aspect of bonding or antibonding displayed in this schematic diagram: electrons placed in a bonding orbital bring the nuclei closer together (that is, for σ_g, $\partial E/\partial R > 0$), while electrons put into an antibonding orbital push the nuclei apart (that is, for σ_u, $\partial E/\partial R < 0$). Returning to the ethylene correlation diagram (Figure 7), we find that the lowest SS level of two ethylenes is bonding in the region of approach of the two molecules to each other and thus will be stabilized by interaction. The SA level has a node, and consequently is antibonding in the region of approach. At large distances the interaction is inconsequential, but as the distance between the reacting molecules diminishes, this orbital is destabilized and moves to higher energy. Similarly, the antibonding π^* AS orbital becomes bonding in the region of approach. It will thus be stabilized as the reaction proceeds, while the π^* AA orbital will be destabilized.

On the cyclobutane side both the σ levels, SS and AS, are bonding in the region where the cyclobutane is being pulled apart. Thus, they resist the motion – that is, they are destabilized along the reaction coordinate. On the other hand, the σ^* levels SA and AA are antibonding along the reaction coordinate and thus move to lower energy as the cyclobutane is pulled apart.

That these qualitative conclusions are correct may be seen from a completed correlation diagram in which levels of like symmetry are connected (Figure 9). The most obvious and striking feature of this diagram is the correlation of a bonding reactant level with an antibonding product level, and *vice versa*.

We now approach a central tenet of our treatment of concerted reactions. Clearly, *if orbital symmetry is to be conserved*, two ground-state ethylene molecules cannot

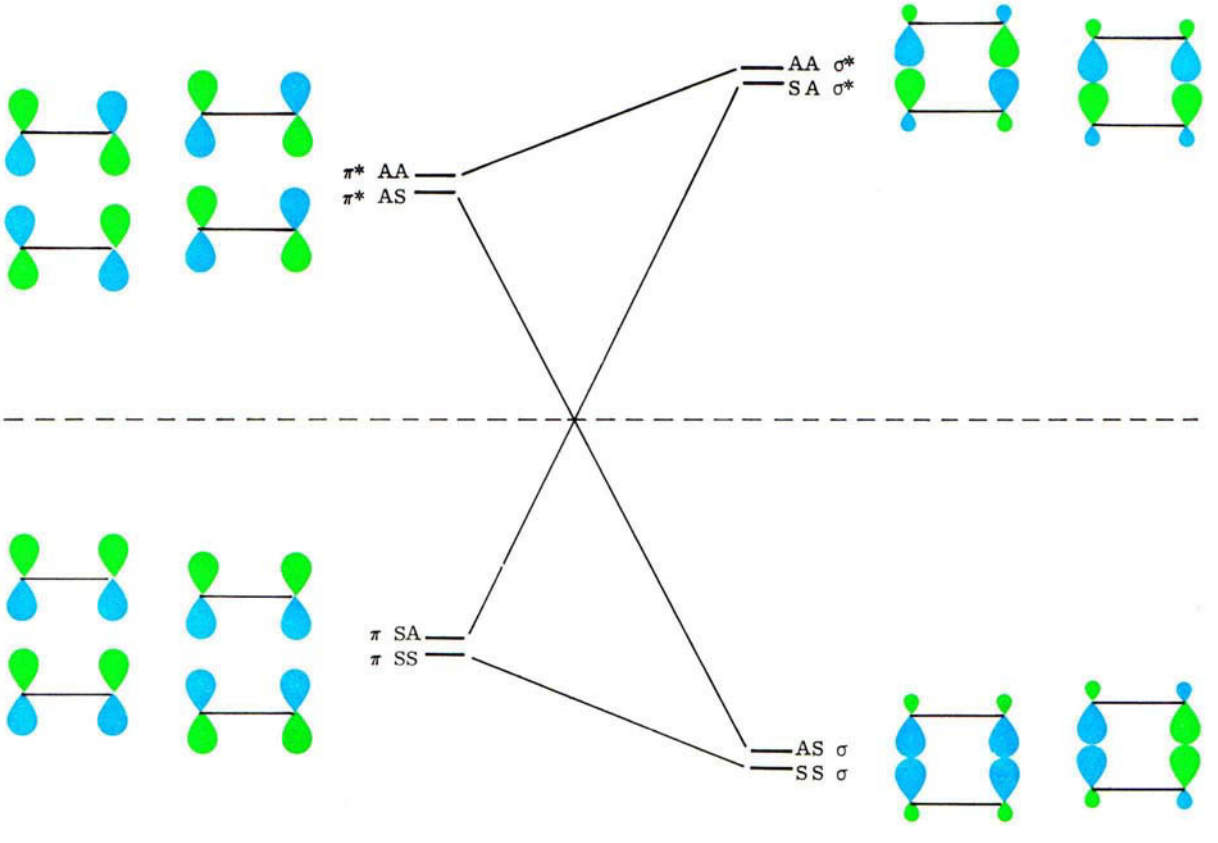

Figure 9. Complete correlation diagram for the formation of cyclobutane from two molecules of ethylene.

combine in a concerted reaction to give ground-state cyclobutane – nor can cyclobutane be decomposed in a concerted fashion to two ethylene molecules – through a transition state having the geometry assumed here. To put the matter in other words, there is a very large symmetry-imposed barrier to the reaction under discussion, in either direction. By the same token, there is no such symmetry-imposed barrier to the reaction of one molecule of ethylene with another, one of whose electrons has been promoted, say by photochemical excitation, to the lowest antibonding orbital. For these reasons we designate reactions of the first type *symmetry-forbidden*, and those of the second *symmetry-allowed.*

The matter may be further illuminated by inspection of the corresponding state diagram for the reaction (Figure 10). The ground state electron configuration of two ethylene molecules correlates with a very high-energy doubly excited state of cyclobutane; conversely the ground state of cyclobutane correlates with a doubly excited state of two ethylenes. Electron interaction

face combination of two ethylene molecules may be made by considering the energy required to raise two bonding electrons in the occupied bonding levels to the non-bonding level – perhaps 5 eV or about 115 kcal/mole.

The lowest excited state of two ethylenes, the configuration $(SS)^2(SA)^1(AS)^1$, correlates directly with the first excited state of cyclobutane. Consequently, there is no symmetry-imposed barrier to this transformation. This represents the course which is followed in many photochemical transformations. However, it should be emphasized that there are ambiguities in excited state reactions which do not exist in their simpler thermal counterparts. Thus, it may happen that the chemically reactive excited state is not that reached on initial excitation; in particular, singlet-triplet splittings for different excited states vary so widely that the symmetries of the lowest singlet and lowest triplet states may differ. Further, radiationless decay may be so efficient that the chemical changes subsequent to irradiation may be those of a vibrationally excited ground state. Finally,

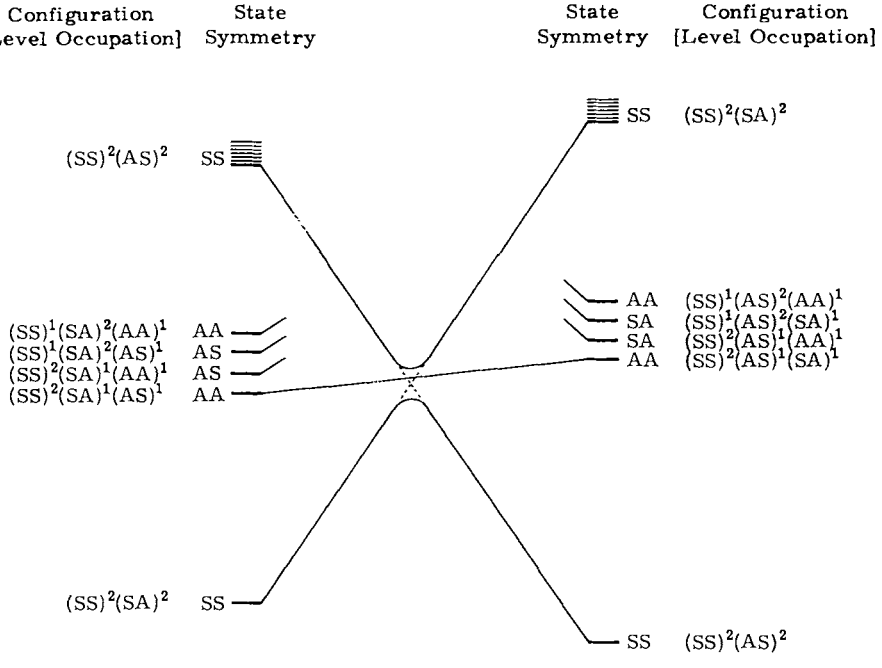

Figure 10. Electronic state diagram for the formation of cyclobutane from two molecules of ethylene. – Note that the symmetry of the states is obtained by multiplying the symmetry labels for each electron, following the rules [7]

$S \times S \longrightarrow S \longleftarrow A \times A$

$S \times A \longrightarrow A \longleftarrow A \times S$

Only singlet excited states are shown, and at this level of sophistication they should be regarded as degenerate in both reactants and products.

will prevent the resulting crossing, and force a correlation of ground state with ground state. But in the actual physical situation, the reaction still must pay the price in activation energy for the intended but avoided crossing. An order of magnitude estimate of the symmetry-imposed energy barrier to the concerted face-to-

the formation of a transition state for a given concerted reaction may be competitive with relaxation of the excited state component to an equilibrium geometry which renders the reaction geometrically impossible. It should be emphasized that none of these punctilios in any way vitiates the consequences of orbital symmetry

control. The principle of conservation of orbital symmetry remains applicable, *provided that the chemically reactive excited state is identified;* furthermore, the fact that the product state which correlates directly with the reactant state may lie higher in energy than the latter constitutes no special problem in orbital symmetry terms – though admittedly there is still much to be learned about the detailed physical nature of the processes accompanying the necessary energy cascade from electronically excited to ground states in such instances.

Many correlation diagrams differ sharply from that for the ethylene + ethylene reaction. Consider for example the prototype Diels-Alder reaction – the [4+2] cycloaddition of butadiene to ethylene. The most reasonable symmetric approach is characterized by a single plane of symmetry bisecting the two components (Figure 11).

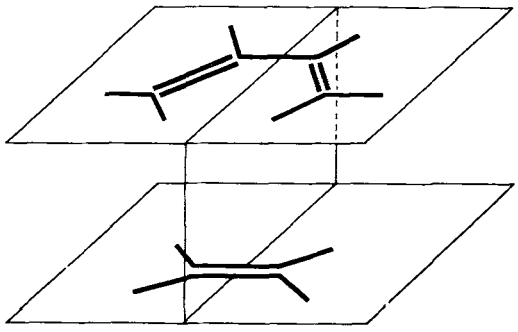

Figure 11. Symmetric approach of butadiene and ethylene in the Diels-Alder reaction.

The essential levels involved in the reaction are now six in number, and they are illustrated in the correlation diagram shown in Figure 12. The form of the four butadiene and two ethylene orbitals is self-evident. We have placed the ethylene π level between the two bonding diene orbitals, but the ordering is not consequential. On the product cyclohexene side note that one must construct delocalized σ bond combinations just as was done for cyclobutane.

The difference between this correlation diagram and that for the combination of two molecules of ethylene is striking. In this case every bonding level of reactants correlates with a bonding product level; there is no correlation which crosses the large energy gap between bonding and antibonding levels.

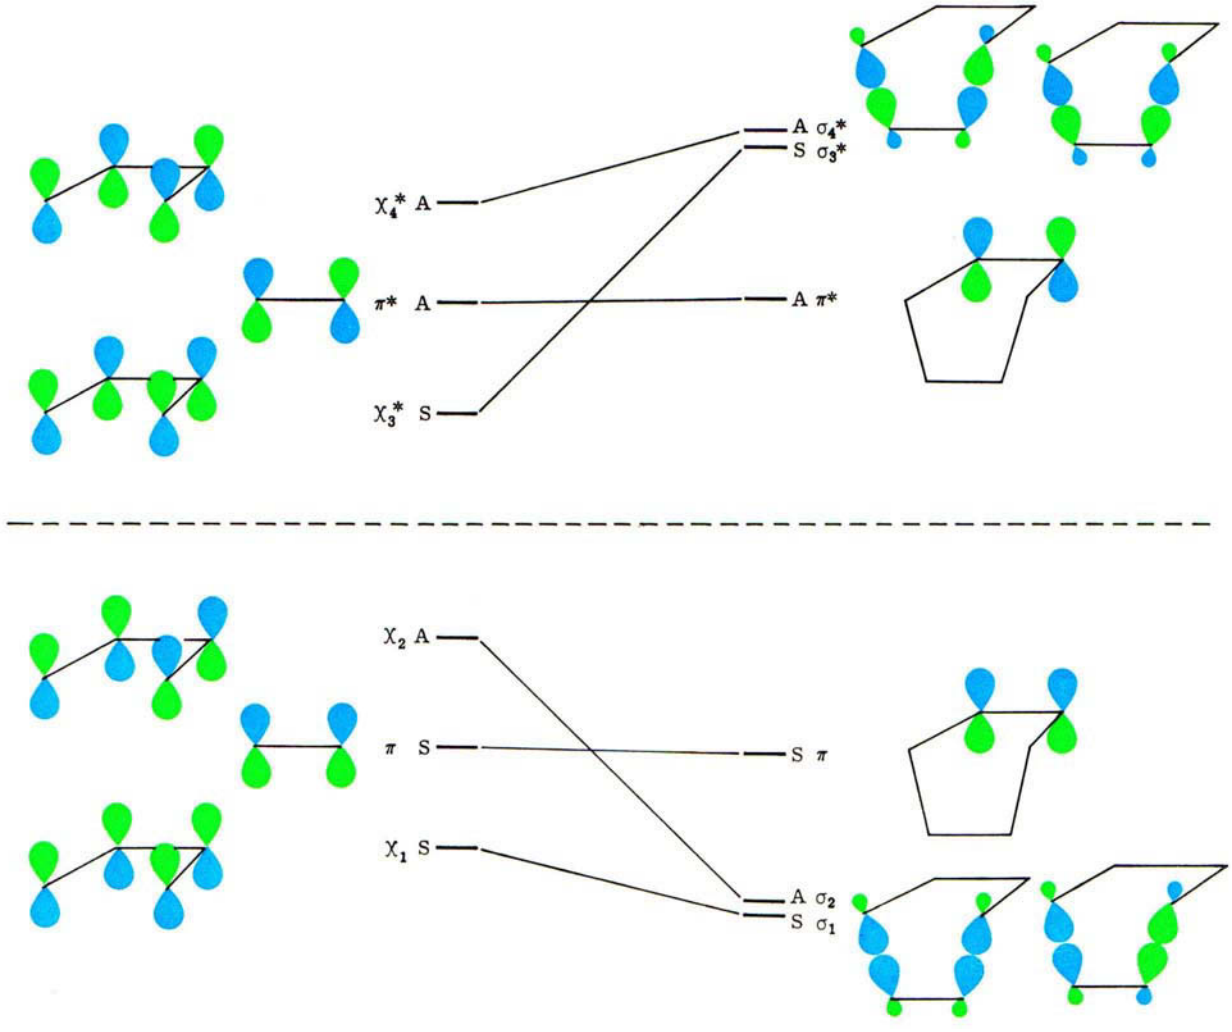

Figure 12. Correlation diagram for the Diels-Alder reaction of butadiene with ethylene.

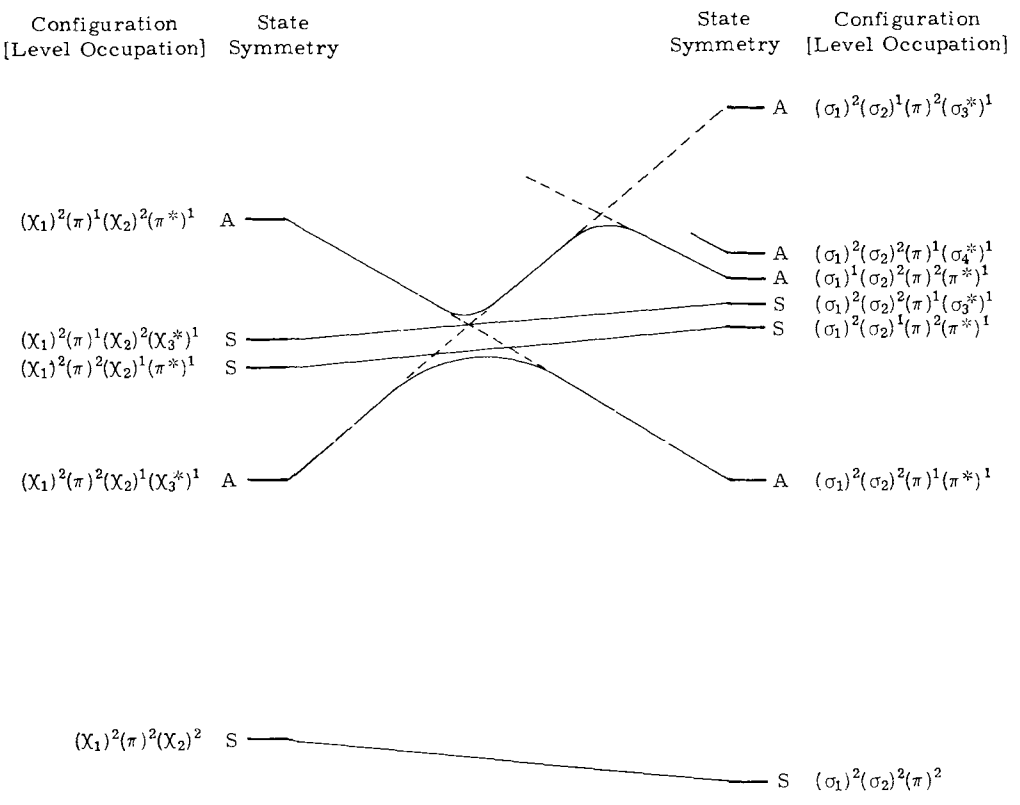

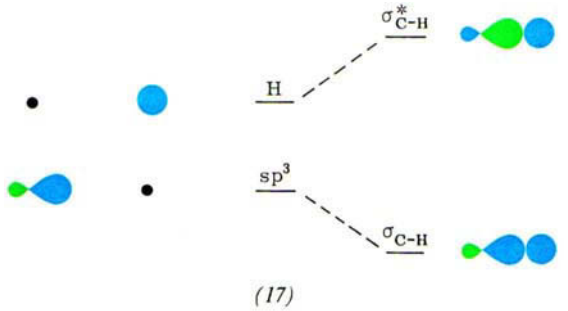

Figure 13. Electronic state diagram for the Diels-Alder reaction of butadiene with ethylene.

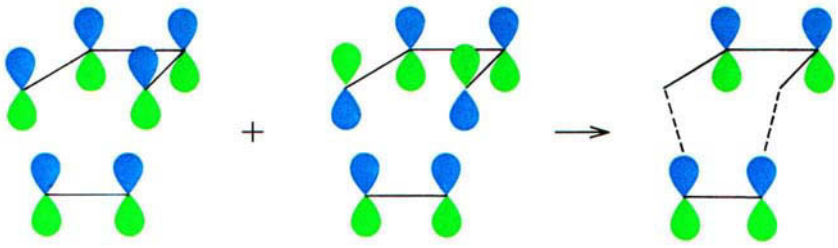
As before one may construct a state diagram (Figure 13). The ground state levels correlate directly, and the diagram implies that there is no activation energy at all for this thermal symmetry-allowed process. And indeed, *there is no symmetry-imposed barrier*, but of course there is an activation energy – experimentally found to approximate 20 kcal/mole – which arises from factors not simply related to orbital symmetry conservation; among them are energy changes accompanying rehybridization in the levels we have not included, and bond length extensions and contractions, as well as angle distortions.

The first excited state of the diene-ethylene complex does not correlate with the first excited state, $\pi \rightarrow \pi^*$, of cyclohexene. Consequently, in this case a symmetry-imposed barrier arises in the excited state process. These circumstances are perhaps most simply apprehended when it is realized that the first excited state is formed by promotion of an electron from an orbital decreasing in energy along the reaction coordinate to one increasing in energy.



The physical correlations of some levels may seem non-intuitive, but in each case they are realistic, and can be understood if followed through carefully in detail. For instance, it may seem strange that an ethylene π level becomes a π level of the cyclohexene. To understand this relationship one must allow the ethylene π level to interact with the two other symmetric levels – the lowest occupied and lowest unoccupied diene levels. An important general rule of quantum mechanics is relevant here[10]: if two levels of unlike energy interact, that of the lower energy will mix into itself some of the higher-energy wave function in a bonding way, but the higher level will mix into itself some of the lower one in an antibonding way. If more than two levels interact, their mixing can be analyzed as a superposition of such pair-wise interactions. The application of this rule is illustrated here for the formation of a C–H σ bond from a carbon sp^3 hybrid and a hydrogen 1*s* orbital *(17)*. In the case of butadiene + ethylene we

(17)

find that the olefin π level mixes into itself χ_1 in an antibonding way and χ_3 in a bonding way *(18)*. The diene contributions cancel at C-1 and C-4 of the buta-

[10] The rule follows directly from perturbation theory and the correlation of higher energy with increasing number of nodes in a wave function.

(18)

diene, but reinforce at C-2 and C-3. Thus, in the transition state this orbital is essentially half in the one and half in the other of the reacting moieties.

If one considers further cases of the general cycloaddition reaction of an m π-electron system with an n π-electron system to form two new σ bonds, while maintaining a plane of symmetry, it becomes evident that there are only two types of correlation diagrams:

a) those similar to that of the Diels-Alder reaction, with no correlation of bonding and antibonding levels, and characterized as symmetry-allowed for ground states and symmetry-forbidden for excited states;

b) those similar to that for the ethylene + ethylene combination, which display bonding-antibonding correlations, and are consequently symmetry-forbidden for ground states and symmetry-allowed for excited states.

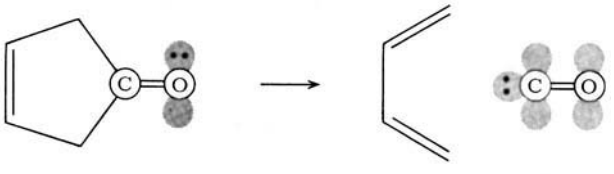
To derive a general rule, one may enumerate, say, bonding symmetric levels in reactants and products. If there are, for example, m π orbitals in a reactant, there will be $m/4$ symmetric bonding π orbitals if $m/2$ is even, or $(m+2)/4$ if $m/2$ is odd. That part of the product derived from this component will contain $(m-2)$ π orbitals, of which $m/4$ are symmetric bonding levels if $m/2$ is even, or $(m-2)/4$ if $m/2$ is odd. There are three possible cases (q_1 and q_2 are integers = 0, 1, 2 . . .):

Case	m	n	Total Symmetric Bonding π Levels	
			Before	After
1	$4q_1$	$4q_2$	q_1+q_2	q_1+q_2
2	$4q_1+2$	$4q_2$	q_1+q_2+1	q_1+q_2
3	$4q_1+2$	$4q_2+2$	q_1+q_2+2	q_1+q_2

Of the new bonding σ levels in the product, one is always symmetric; thus, for a thermal symmetry-allowed reaction, the total number of occupied symmetric π bonding levels in the reactants must exceed by one the number in the product; Case 2 satisfies this condition: for it,

$$m+n=4q_1+4q_2+2=4q+2.$$

Cases 1 and 3 necessarily lead to bonding-antibonding correlations; consequently, thermal reactions in which

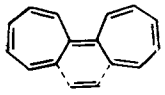


$$m+n=4q_1+4q_2 \text{ or } 4q_1+4q_2+4=4q$$

are symmetry-forbidden. In each case, of course, these rules are precisely reversed for reactions involving excited states. Further, it must be emphasized that these deductions apply only to cases in which the geometry of approach of the reacting molecules is that specified above; we shall demonstrate in the sequel that in some cases the same, and in others different, rules apply when the geometric relationships within the transition state are varied.

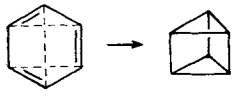
3.1. General Comments on the Construction of Correlation Diagrams

A crucial phase in the construction of a correlation diagram is the identification of pertinent σ and π levels and their delocalization to the full extent required by the transition state symmetry. The simplest procedure may be formulated as follows:



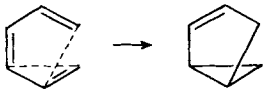
a) Identify all orbitals involved as σ, π, or n (nonbonded pair). Remember that for each σ and π level there will be corresponding σ* and π* levels; this is not the case for n orbitals. Thus, for the expulsion of carbon monoxide from cyclopentenone *(19)* the relevant orbitals are: in the cyclopentenone the C=C π and π* levels, two bonding C–C(O) σ levels and the corresponding σ* orbitals, and a lone pair on oxygen; in the products *(20)* and *(21)* the four diene π levels, two of which

(19) (20) (21)



are bonding, a new CO bond and its π* counterpart, and a new nonbonding pair level on the carbon atom of the carbon monoxide. Left out of consideration as non-essential are another oxygen lone pair and the remaining C=O π bond. Note that there exists an auto-

matic check in that the number of levels of each symmetry type on the right-hand side of a correlation diagram must equal that on the left.

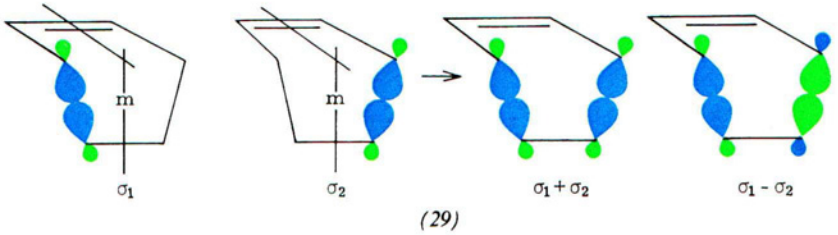


(22)

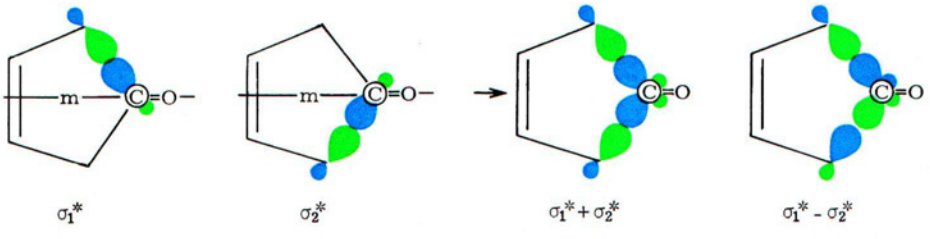
b) If a polyene system is present, the proper molecular orbitals of a polyene should be used. Thus, in the cycloaddition of a heptafulvalene *(22)*, one should consider the orbitals of a fourteen-membered polyene.

(23) (24)

For the cyclization of benzene *(23)* to prismane *(24)*, the proper orbitals on the left are those of benzene [*cf.* Section 6.4].



(25) (26)

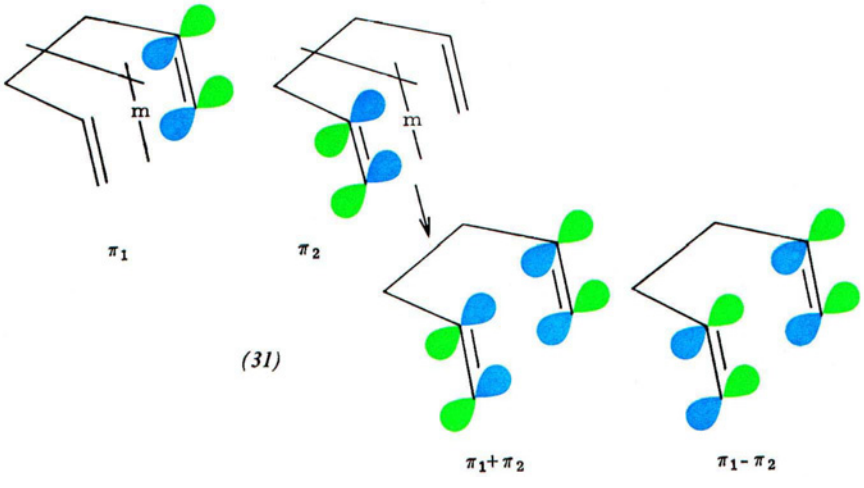


(27) (28)

bicyclo[2.2.0]hexene *(28)* must be treated as [4+2] and [2+2] cycloadditions respectively.

c) Mix all bonding σ orbitals which are not symmetric or antisymmetric with respect to every molecular symmetry element until they become so. For the vast majority of cases this process is one of identifying the symmetry-related orbitals, and forming their sums and differences. The procedure should then be repeated for σ* levels. As one example, consider the newly-formed σ bonds of a cyclohexene – the product of a [4+2] cycloaddition. The symmetry-related σ orbitals are

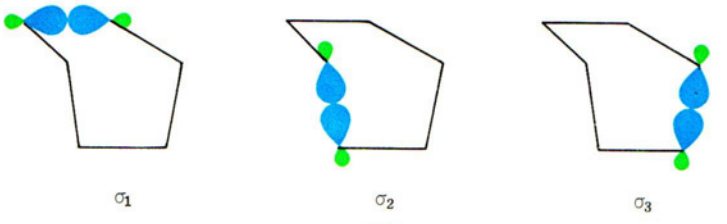
(29)



(30)

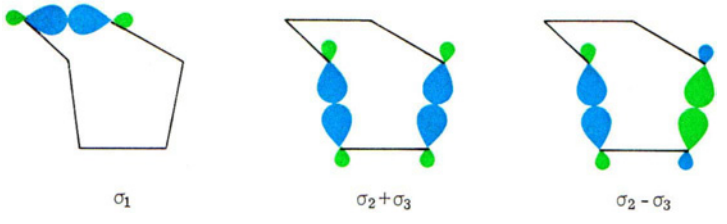
However, if only fragments of a polyene system participate in a reaction, the molecular orbitals of the component fragments must be used. Thus, the conversion of a hexatriene *(25)* to a bicyclo[3.1.0]hexene *(26)*, or to a

σ_1 and σ_2; they must be transformed as indicated in *(29)*, to $\sigma_1+\sigma_2$ and $\sigma_1-\sigma_2$.



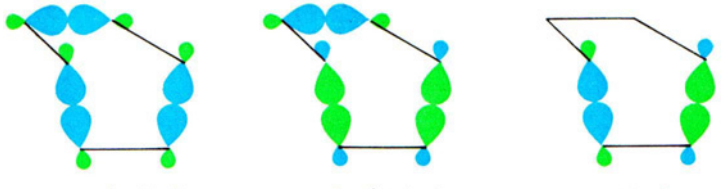
Again, consider the σ* orbitals of cyclopentenone *(30)*.

(31)



A similar mixing is required for nonconjugated π levels. Thus, in considering a [2+2] cycloaddition within a 1,5-hexadiene, leading to a bicyclohexane, the preparation of π orbitals is performed as shown in *(31)*.

d) A convenient, but not necessary, further step is to mix with each other all orbitals of a given symmetry. For example, consider the σ bonds of a [2+2+2] cycloreversion of a cyclohexane to three ethylenes. Assume a boat conformation of the cyclohexane. The three localized σ orbitals are σ_1, σ_2, and σ_3 *(32)*. The



(32)

only symmetry element in the transition state is a plane bisecting σ_1. The orbital σ_1 is symmetric under reflection in that plane, but σ_2 and σ_3 are not. Thus, in accordance with rule c) above, we should form the delocalized combinations $\sigma_2+\sigma_3$ and $\sigma_2-\sigma_3$. This yields a new set of symmetry-adapted orbitals *(33)*.

(33)

Now σ_1 and $\sigma_2+\sigma_3$ are symmetric with respect to the symmetry plane, and it is convenient to delocalize further by taking their sum and difference *(34)*.

(34)

More extensive delocalization (a secondary effect – but one which can be of chemical significance) would follow from mixing of σ_1^* and $\sigma_2^*-\sigma_3^*$ into $\sigma_2-\sigma_3$, and $\sigma_2^*+\sigma_3^*$ into the symmetric combinations.

3.2. Precautions in the Construction of Correlation Diagrams

There are several pitfalls in the construction and application of correlation diagrams. To avoid these the following precautions must be observed:

a) Each basic process must be isolated and analyzed separately. Otherwise the superposition of two forbidden but independent processes may lead one to the erroneous conclusion that the combined process is symmetry-allowed. Two wrongs do not make a right.

b) The symmetry elements chosen for analysis must bisect bonds made or broken in the process. Here there are two corollaries:

(i) a symmetry element of no use in analyzing a reaction is one with respect to which the orbitals considered are either all symmetric or all antisymmetric – obviously an analysis based on such elements only (such as plane 3 in the approach of two ethylenes [*cf.* Figure 5]) would lead to the conclusion that every reaction is symmetry-allowed;

(ii) if the only symmetry element is one which does not bisect any bonds made or broken, then the correlation diagram constructed on the basis of this element can only lead to the conclusion – often false – that a reaction is symmetry-allowed.

c) Each case must be reduced to its highest inherent symmetry. Thus, if there are heteroatoms in a polyene component, they are to be replaced by their isoelectronic carbon groupings. If there are substituents with trivial electronic demands they should be replaced by hydrogens. Heteroatoms do offer the possibility of new reactions by the inclusion of nonbonding pairs or by the availability of low-lying unoccupied orbitals. These types of interaction should be carefully analyzed.

To consider an example of a), take the formation of cubane from cyclooctatetraene in one step (Figure 14).

Construction of a correlation diagram (Figure 15) without regard to precaution a) would lead to the con-

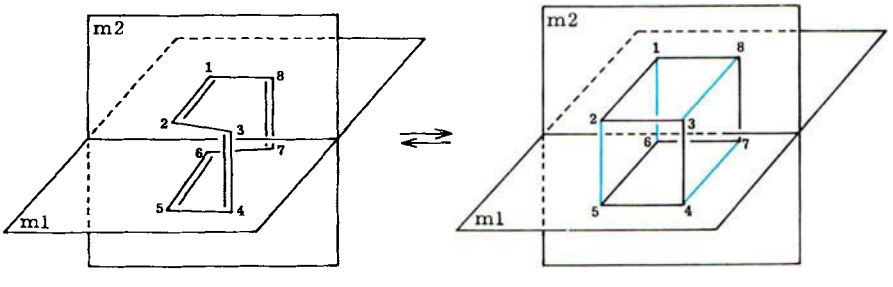


Figure 14. Formation of cubane from cyclooctatetraene in a concerted reaction.

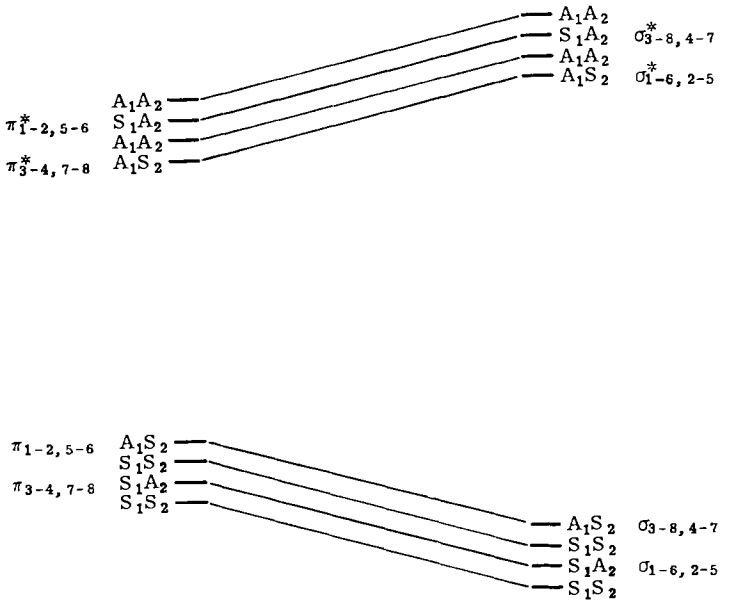

Figure 15. Incorrect correlation diagram for the formation of cubane from cyclooctatetraene.

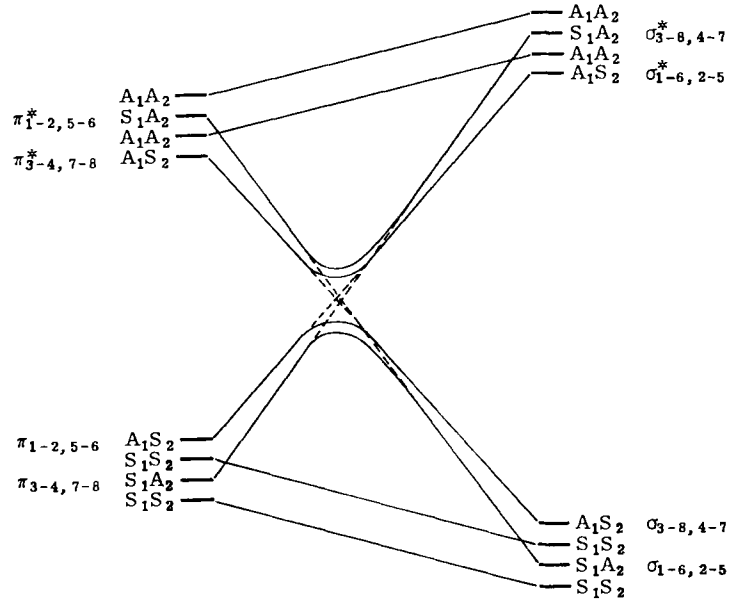

Figure 16. Correct correlation diagram for the formation of cubane from cyclooctatetraene. — Within any of the four groups of four closely spaced levels, those with both symmetric and antisymmetric labels, regardless of subscripts, are in fact degenerate, though shown here for clarity as differing slightly in energy.

clusion that this superposition of two [2+2] cycloadditions should be a symmetry-allowed thermal process.

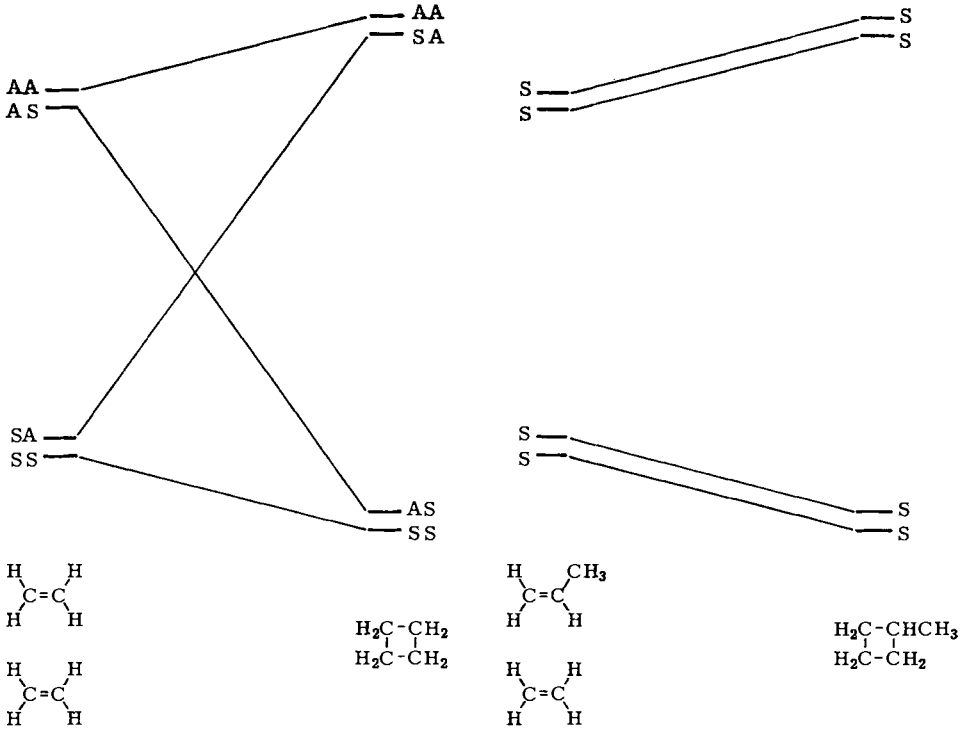
In fact the diagram should really appear as in Figure 16. The intended correlation of the S_1A_2 orbital formed from $\pi_{3-4,7-8}$ is to an antibonding S_1A_2 $\sigma^*_{3-8,4-7}$ orbital. A small perturbation links the 3-4,7-8 cycloaddition with the 1-2,5-6 process. The latter by an accident of symmetry is forming an S_1A_2 orbital of the cubane. The result is that the intended bonding-antibonding correlation is accidentally avoided. But the reaction is none the less symmetry-forbidden. In fact, whether a reaction is symmetry-allowed or forbidden is determined by the height of the electronic hill that reactant or product orbitals must climb in reaching the transition state; and the presence or absence of a hill is a function of the *intended* correlation, or the initial

slope of the levels. From this point of view, we see that in the case at hand the 3-4,7-8 combination is in no wise facilitated by the concurrent 1-2,5-6 process, and *vice versa.*

An example of type b) is provided by consideration of the conversion of butadiene *(35)* to bicyclobutane *(36)*. Here the only molecular symmetry element is a

(39) *(40)*

The rationale for point c) will become apparent on comparison of the correlation diagram for the face-to-face addition of ethylene to ethylene with that for ethyl-



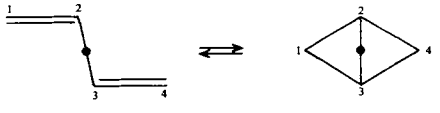


Figure 17. Left: Correlation diagram for the cycloaddition of two ethylene molecules. — Right: Incorrect correlation diagram for the cycloaddition of ethylene to propylene.

two-fold axis passing through a single bond which is not made or broken during the reaction. We will discuss this reaction in some detail in the sequel.

(35) *(36)*

Another instance is the case of two propylenes trading hydrogens [*(37)*→*(38)*], where only a center of symmetry (passing through no bonds) could be present.

(37) *(38)*

Still another example is the decomposition of pentalene to diacetylene and two acetylenes [*(39)*→*(40)*], where no element of symmetry bisects bonds broken or made.

ene to propylene. For the latter case there is, strictly speaking, no symmetry in the transition state. Thus, all levels are trivially symmetric and one might be tempted to draw the correlation diagram as shown at right in Figure 17.

The conclusion would be that methyl substitution had made the thermal [2+2] cycloaddition symmetry-allowed. This is incorrect. The proper level correlation diagram is shown in Figure 18.

Methyl substitution has in an absolute sense reduced all levels to the same symmetry. The level crossing has become impossible. But the perturbation is a very small one and so the crossing is barely avoided. A bonding level of reactants has still moved to high energy in the transition state. The corresponding state diagram differs trivially from that for ethylene + ethylene. The reaction remains symmetry-forbidden [11].

[11] A similar situation arises in other areas of chemistry. The n→π* transition in formaldehyde is electric-dipole forbidden. The source of the small intensity observed is still disputed. In the cases of acetaldehyde, or of unsymmetrically substituted ketones, the symmetry element which made the formaldehyde transition electric-dipole forbidden is removed. The transition becomes allowed. Does it therefore jump to a high intensity? Not at all; the intensity remains practically unchanged. This is because the *essential* symmetry, that of the local environment of the carbonyl group, is unchanged.

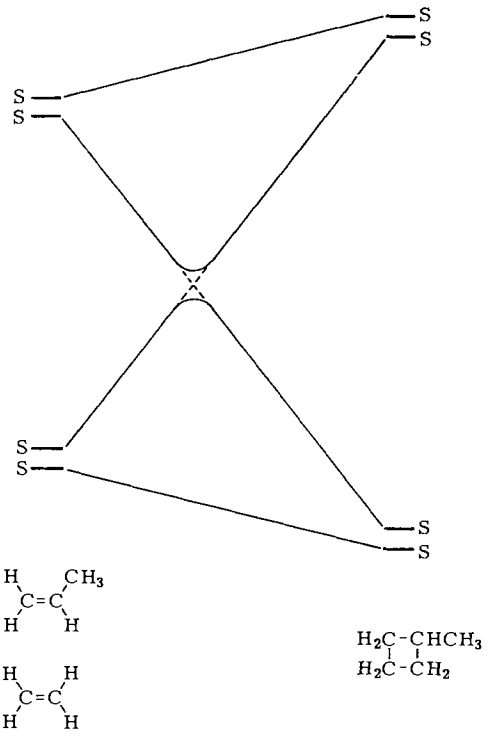

Figure 18. Correct correlation diagram for the cycloaddition of ethylene to propylene.

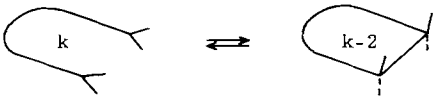
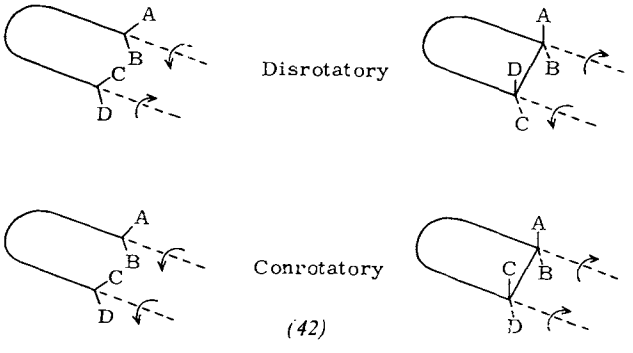


4. The Conservation of Orbital Symmetry

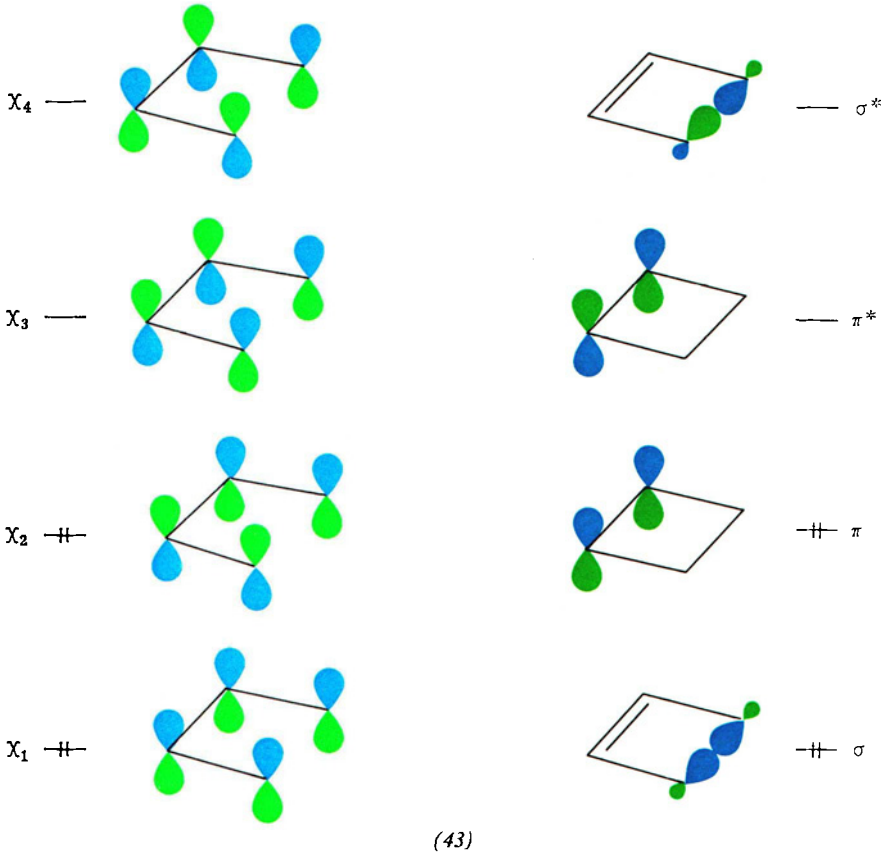
It is clear that the absence or presence of molecular symmetry in an absolute sense cannot be the ultimate source of the allowedness or forbiddenness of a reaction. Symmetry is discontinuous. It is either on or off, here or not here. Chemistry is obviously not like that. A slight perturbation, say substitution by a methyl group, may destroy total symmetry, but cannot be expected to change dramatically the mechanism of a reaction. The essential and decisive factor in making a reaction forbidden is that in the transition state there is at least one level that is no longer bonding, but at considerably higher energy. We have used symmetry as a crutch to aid us in denominating those high energy levels without doing the least bit of calculation. If symmetry is lacking, either as a result of trivial substitution, or more basically from the asymmetry of the components (*e.g.*, in the "ene" reaction), a reaction may still be analyzed by writing down the orbitals involved, allowing them to mix according to well-defined quantum mechanical principles and following the interacting orbitals through the reaction. High energy levels in the transition state may arise *pari passu* from real crossings or from intended but avoided ones. Such high energy levels will not be present if every bonding orbital of the product (reactants) is derivable from one bonding orbital of the reactants (product). For if a bonding orbital of the product is not derivable from any bonding orbital of reactants, it must be related to an antibonding reactant orbital. Whether or not it actually correlates to that antibonding orbital is dependent on the presence or absence of total symmetry; but even if the intended correlation is foiled, the level soars to high energy in the transition state.

In short, the most general, and at the same time physically most realistic view of orbital symmetry control of chemical reactions is obtained by specifying the relevant molecular orbitals of reactants, and observing their corresponding form in products, as reaction occurs *with conservation of orbital symmetry*. To illustrate our method at work we will first discuss some instances where correlation diagrams can be drawn, one of these in great detail, and then proceed to less symmetrical cases where no help may be expected from molecular symmetry.



5. Theory of Electrocyclic Reactions

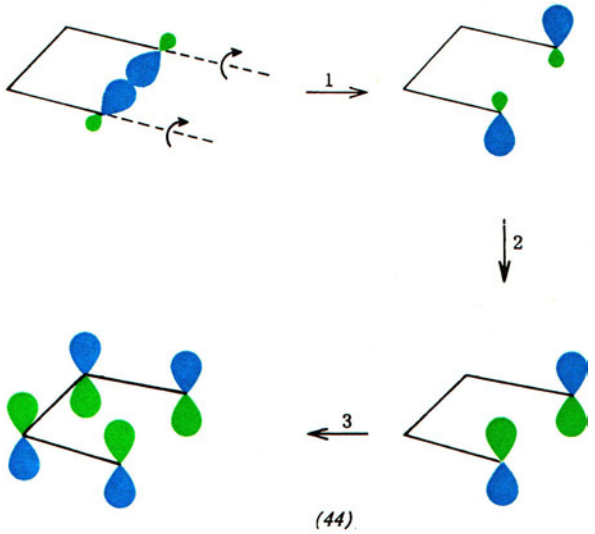
These intramolecular cycloadditions provided the stimulus for our study of molecular orbital symmetry and concerted reactions. We define as *electrocyclic* reactions the formation of a single bond between the termini of a linear system containing k π electrons, and the converse process *(41)*.



(41)

In such changes fixed geometrical isomerism imposed upon the open-chain system is related to rigid tetrahedral isomerism in the cyclic array. *A priori*, this relationship might be *disrotatory* or *conrotatory (42)*. In the former case the transition state is characterized by a plane of symmetry while in the latter a two-fold axis of symmetry is preserved.

(42)

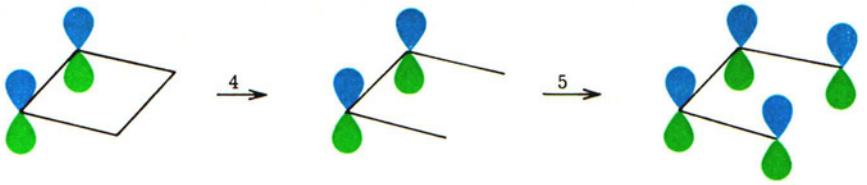


Consider the essential molecular orbitals in the conversion of cyclobutene to butadiene. These are the four π orbitals of the butadiene χ_1, χ_2, χ_3, χ_4, the π and π^* lev-

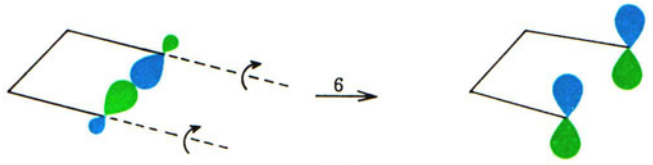
(43)

els of the cyclobutene double bond, and the σ and σ* orbitals of the single bond to be broken *(43)*.

Consider carrying out a conrotatory motion to completion on σ [step 1 in *(44)*] and follow through with a rehybridization (step 2). At this stage the orbital looks like a fragment of χ_2 (or χ_4) of butadiene and all that is needed is a growing-in (step 3) of orbitals at C-2 and C-3.



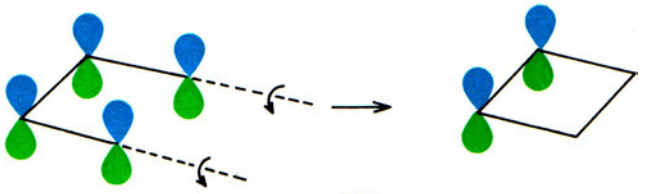
(44)



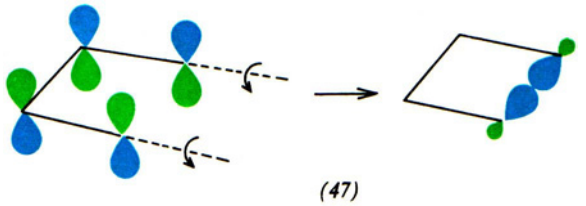
It should be kept in mind that in reality the steps 1, 2, and 3 will all be simultaneously proceeding along the reaction coordinate, and that the above factorization is only an aid to visualization. The growing-in of step 3 may seem like magic to those unfamiliar with molecular orbital manipulations. It is in fact a universal phenomenon, the detailed result in this case of mixing of π* with σ as the reaction proceeds. We have now followed σ through the reaction and correlated it with another bonding orbital, χ_2. Similarly we follow π through *(45)*. Note here that the growing-in step 5 is really a mixing of π with σ* (*cf.* step 6). π thus correlates with χ_1.

The correlations could of course have been obtained starting from butadiene. χ_1 by a conrotatory motion becomes π *(46)* and χ_2 is transformed into σ *(47)*.

In this analysis there appears a fading-away, in which extra nodes and contributions disappear. This is the precise reverse of the growing-in noted above and is again a result of mixing with higher orbitals of the proper symmetry. Very similar arguments lead to a correlation of σ* and χ_3, and of π* and $-\chi_4$ ($\equiv \chi_4$!). We have thus achieved a correlation of bonding levels of the reactant with bonding levels of the product, with conservation of orbital symmetry. The thermal reaction should be a facile one.



By contrast, consider now a disrotatory opening. The correlations are indicated in *(48)*. Both σ and π must correlate with χ_1 or χ_3 ($\equiv -\chi_3$!). But since only one can correlate with χ_1, the other must go up to χ_3, which is antibonding. Conservation of orbital symmetry requires in this case a high-lying transition state and the

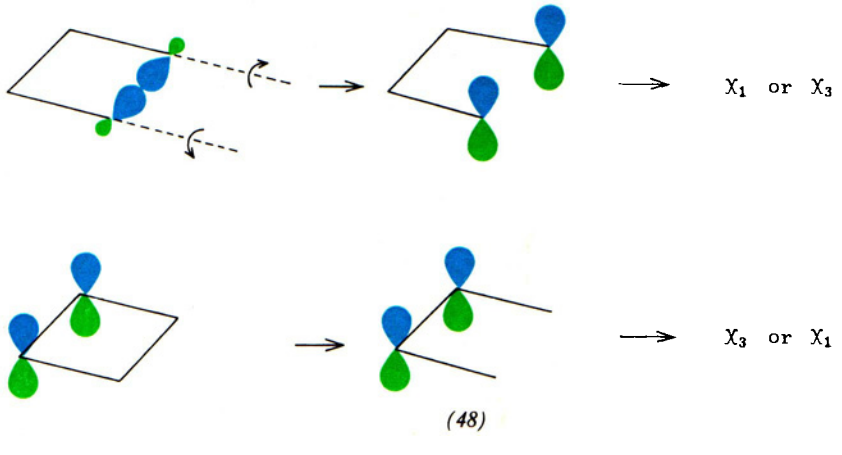


(45)

thermal reaction is symmetry-forbidden. Again the problem could have been approached from the other side *(49)*.

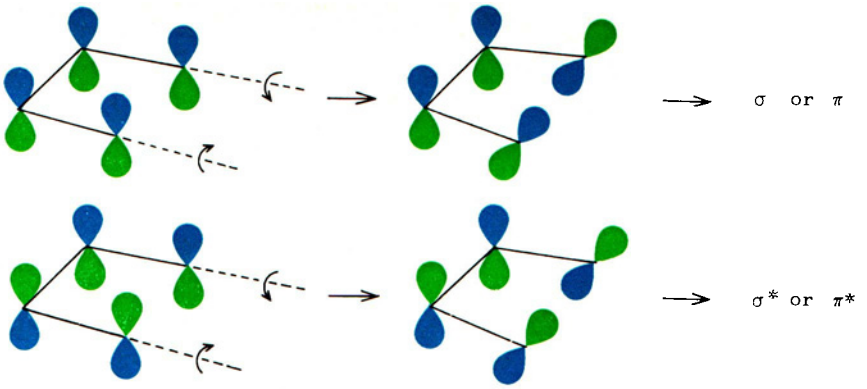
(46)

It is obvious that χ_2 is the troublesome orbital – it cannot transform into *any* bonding orbital of the cyclobutene, with conservation of orbital symmetry, in a disrotatory process.



(47)

What we have somewhat laboriously described in words is equivalent to the construction of two level correlation diagrams (Figure 19). It is clear that in the conrotatory process a two-fold rotation axis is maintained at all times whereas in the disrotatory motion an invariant plane of symmetry is present. These diagrams are clearly analogous to those discussed in section 3 (above) for combination reactions of π electron systems. Obviously the diagram for the conrotatory process is characteristic of a symmetry-allowed reaction, while the pattern for the disrotatory process is that of a symmetry-forbidden reaction.



We should emphasize at this point that this detailed stepwise analysis has been presented primarily for pedagogic reasons. The high molecular symmetry present in these cases would have permitted very simple direct derivation of the relevant correlation diagrams. But soon we will encounter cases of such low symmetry that the stepwise analysis is the only possible one.

The highest occupied orbitals play a dominant role in these correlations. Their importance is easy to justify. First, we think of them as containing the valence electrons of the molecule, most easily perturbed during incipient reaction. In this sense their role has been stressed in the important work of *Fukui*[12]. Second, if there is little symmetry in a molecule and if there is a bonding level which is intending to cross the energy

[12] *K. Fukui, T. Yonezawa*, and *H. Shingu*, J. chem. Physics *20*, 722 (1952); *K. Fukui, T. Yonezawa, C. Nagata*, and *H. Shingu, ibid. 22*, 1433 (1954); *K. Fukui* in *O. Sinanoğlu*: Modern Quantum Chemistry. Academic Press, New York 1965, Vol. 1, p. 49, and references therein.

(48)

(49)

gap to correlate to an antibonding level, then that level will usually be the highest occupied level. Consequently, its motion determines the course of the cor-

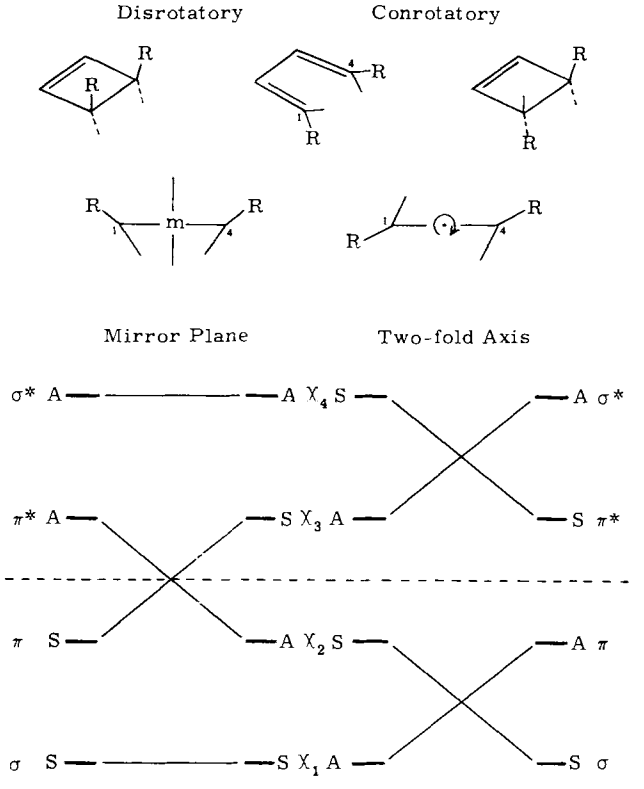


Figure 19. Correlation diagrams for the disrotatory and conrotatory conversion of cyclobutenes to butadienes.

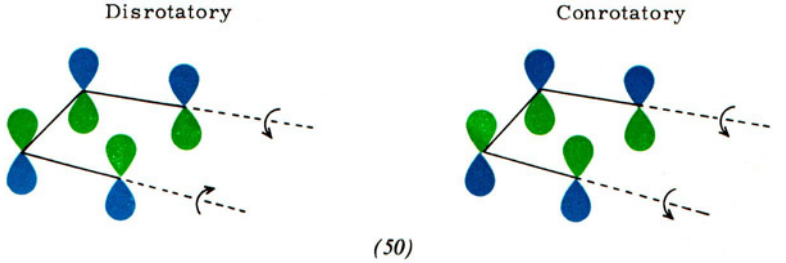


relation diagram and its initial slope is an important indication of whether the process is symmetry-allowed or forbidden. Consider the disrotatory and conrotatory motions as they affect χ_2 in butadiene *(50)*.

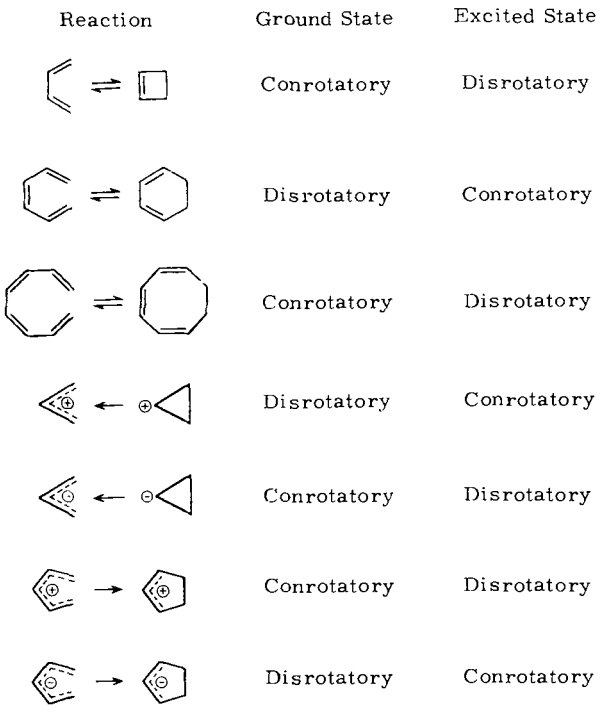
The disrotatory process pushes a plus lobe onto a minus lobe. Since one end of the molecule "feels" the phase of the wave function at the other end, this is an antibonding, destabilizing, repulsive interaction. The level moves up in energy along the reaction coordinate. Conrotatory motion brings a plus lobe onto a plus lobe (or minus on minus, which is equivalent). This is a bonding, stabilizing, attractive interaction terminating in the actual formation of the new σ bond.

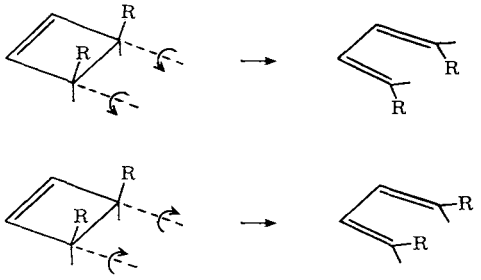
A warning note should be sounded here. The sense of orbital symmetry control of any concerted reaction can always be determined through inspection of the behavior of the highest occupied molecular orbital in the reacting system, but the analysis is often less simple than it is in the case of the butadiene → cyclobutene transformation. A temptation especially to be avoided in making such analyses is that of inadvertently placing more than two electrons in a single molecular orbital.

The general rules for electrocyclic reactions are very easily derivable from the nodal properties of polyenes and polyenyl ions: the thermal electrocyclic reactions of a k π electron system will be disrotatory for $k = 4q+2$, conrotatory for $k = 4q$ ($q = 0, 1, 2\ldots$); in the first excited state these relationships are reversed. Some of the consequences of the rules are summarized in Figure 20.

We turn next to a consideration of secondary factors which influence the actual composition of the products of an electrocyclic reaction. The first is steric control. For every reaction there are two conrotatory and two disrotatory motions which may or may not be distinguishable. Thus, the two conrotatory modes of opening

(50)





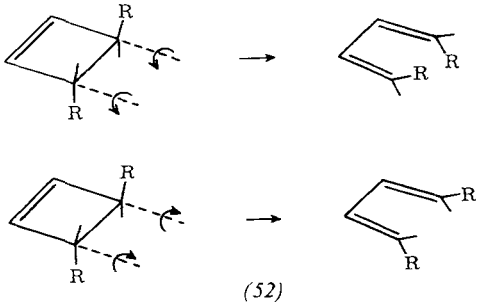


Figure 20. Conrotatory and disrotatory electrocyclic reactions.

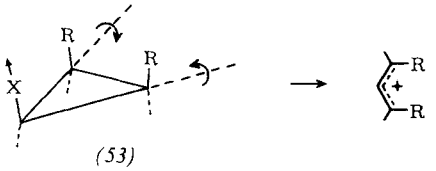
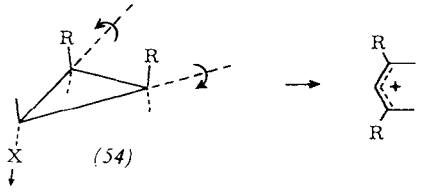
of a *cis*-dimethylcyclobutene are enantiomeric and lead to the same product, *cis,trans*-1,4-dimethylbutadiene *(51)*.



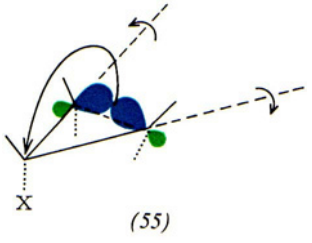
(51)

The two conrotatory motions for a *trans*-dimethylcyclobutene lead to two different isomers: *cis,cis*- and *trans,trans*-1,4-dimethylbutadiene *(52)*. In fact, the *trans,trans* product is found exclusively [13]; we attribute this to the unfavorable steric situation in the transition state leading to the *cis,cis* product.



(52)

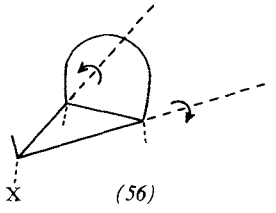
A most interesting subsidiary question in connection with the electrocyclic opening of a cyclopropyl cation to an allyl cation was first posed to us by *C. H. DePuy:* assuming that departure of a leaving group from a cyclopropane ring, and the bond-breaking electrocyclic reaction to give an allyl cation, are concerted, could there be a difference between the two *a priori* possible disrotatory modes, defined in relation to the position of the leaving group? Extended Hückel calculations provided the initial answer, which may be summarized by saying that the substituents on the same side of the three-membered ring as the leaving group rotate towards one another *(53)*, whereas those on the other side rotate apart *(54)*.



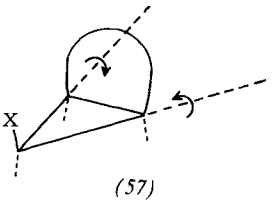
(53)

(54)

The result may be understood in qualitative terms when it is realized that as the 2,3 bond is broken by disrotatory outward rotation *(55)*, the electron density of that bond, which originally was more or less in the plane of the cyclopropane ring, shifts above the plane. It is then available for backside displacement of the leaving group – in other words, the reaction is a normal S_N2 displacement of the group X by the electrons of the backbone σ bond of the cyclopropane ring.



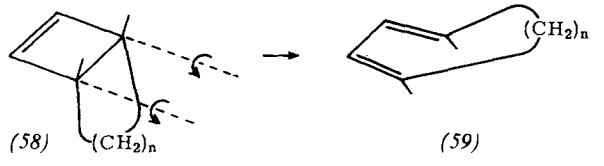
(55)



Several corollaries of these conclusions follow. If R in *(53)* or *(54)* is some bulky group then we should expect for steric reasons a faster solvolysis for compound *(54)*. On the other hand, when *cis* positions are linked by a short methylene chain, we should expect the opening of a compound such as *(56)* with leaving group *anti*

[13] *R. E. K. Winter*, Tetrahedron Letters *1965*, 1207.

to the ring to be severely disfavored, since the resulting rotation would lead to a *trans,trans*-allyl cation in a small ring. We should expect a facile opening only for a *syn* leaving group, as in *(57)*.



(56)

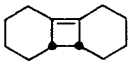
(57)

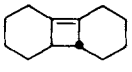
5.1. Electrocyclic Reactions Exemplified

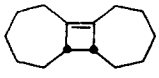
The conrotatory electrocyclic change of a cyclobutene to a butadiene is a very well-known process. Its stereochemistry was established some ten years ago [14] and its scope and energetics have been very carefully studied [15]. Satisfactory rationalization of the striking stereospecificity of the reaction was lacking until the orbital symmetry control of electrocyclic changes was discovered. Given that in the thermal reaction conrotatory displacement is symmetry-allowed, it follows that

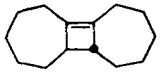
(58) *(59)*

a bicyclic cyclobutene containing a *cis*-fused methylene chain *(58)* leads to a cyclic *cis,trans*-diene *(59)*.



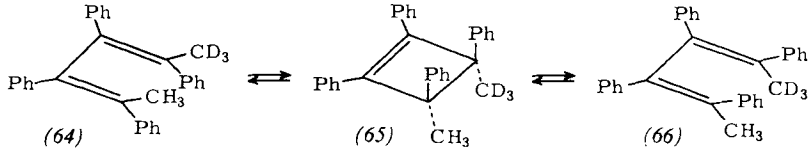






Such a *trans*-olefin becomes increasingly highly strained as the ring size diminishes. This trend is beautifully reflected in the temperatures at which the half-life of compound *(58)* is about 2 hours [16] as *n* is varied:

n	1	2	3	4	5	6
T(°C)	<100	195	>380	350	335	180



The half-life of *(58)* decreases for small *n* since, due to ring strain, the reaction itself becomes highly exothermic.

Molecules such as bicyclo[2.2.0]hexadiene and bicyclo[2.1.0]pentene clearly owe whatever stability they possess to the fact that the transformations, respectively to benzene and cyclopentadiene, are symmetry-forbidden.

Criegee and *Reinhardt* [17] have synthesized the laterally fused *cis*- and *trans*-cyclobutenes *(60)* – *(63)*. These exhibited dramatically different pyrolytic stabilities [18]. In the substances with *anti* backbones, the symmetry-imposed conrotatory motion leads to *cis* double bonds in the six- or seven-membered rings and the electrocyclic cleavage takes place readily. By contrast, the

		E_a (kcal/mole)	$k = 10^{-4}$ at °C
(60)		42	261
(61)		29	87
(62)		45	273
(63)		27	109

symmetry-allowed processes with the *syn* isomers would give substances containing a *trans* double bond in a six- or a seven-membered ring. Consequently, the

(64) *(65)* *(66)*

transformation occurs only at extreme temperatures; it might well proceed by a non-concerted mechanism.

The highly substituted butadienes *(64)* and *(66)* have been studied in a most ingenious and amusing experiment [19]. These substances are equilibrated through the intermediacy of the cyclobutene *(65)*. After fifty-one days at 124 °C, each cyclobutene molecule had faultlessly undergone 2.6×10^6 conrotatory openings, and a disrotatory mistake was yet to appear.

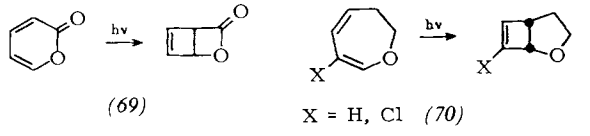
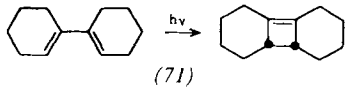
Some fascinating transformations of the *cis*- and *trans*-benzocyclobutenes *(67)* and *(68)* are readily explicable as electrocyclic reactions followed by Diels-Alder additions [20].



(67)

(68)

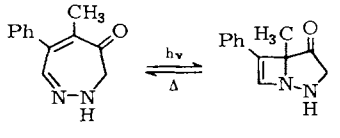
X = O, NR



There are numerous examples of photochemical cyclobutene-butadiene interconversions. In the great majority of cases the diene is part of a cyclic system and is thus constrained to undergo the symmetry-allowed disrotatory process. Some typical examples are the reactions *(69)* and *(70)* [21,22].

(69)

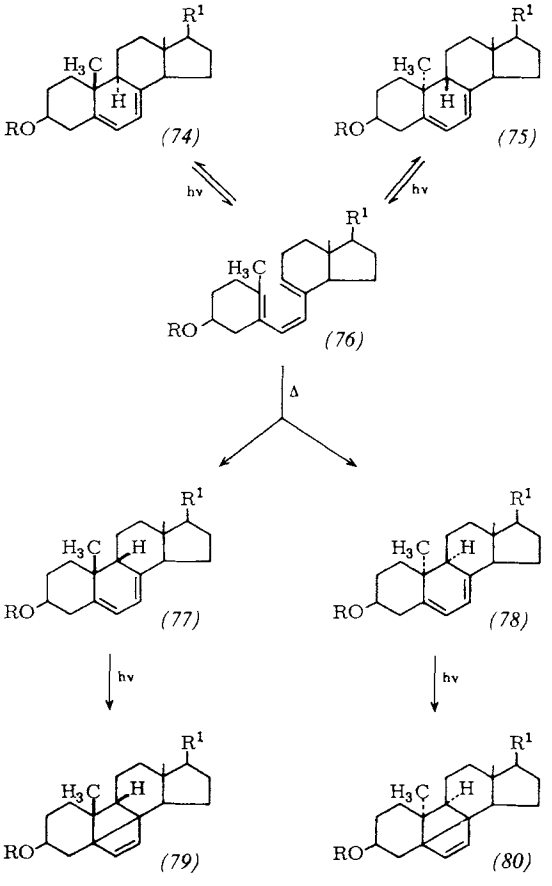
X = H, Cl *(70)*



One case with greater stereochemical freedom *(71)* has been observed [23] and fits our expectations.

(71)

Recently it has been confirmed that *trans,trans*-2,4-hexadiene undergoes photochemical cyclization to *cis*-dimethylcyclobutene [24]; the case is of special interest in that geometric constraints are absent.



The diazepinone *(72)* yields on photolysis the bicyclic isomer *(73)*, which reverts readily thermally to the starting compound [25]. The reversibility is easily understood once it is realized that direct *cis*→*trans* interconversion, an impossible process in fused carbocyclic systems, is simply an inversion at the nitrogen atom in *(73)*.

(72) *(73)*

The symmetry-allowed photochemical conrotatory cyclization of *cis*-hexatrienes, and the reverse reaction, were first recognized in studies in the vitamin D field. The conversions *(74)* – *(80)* – all symmetry-allowed – were established in an extensive series of elegant investigations [26].

Of particular interest is the fact that the cyclohexadienes *(77)* and *(78)*, prevented by insurmountable geometrical restraints from undergoing symmetry-allowed electrocyclic cleavage, are photoisomerized to the cyclobutenes *(79)* and *(80)*, in an alternative symmetry-allowed process.

(74) *(75)* *(76)* *(77)* *(78)* *(79)* *(80)*

A further example of the photochemical cyclohexadiene→hexatriene reaction has recently been studied [27].

A related reaction presumably also takes place in the photocyclization of *cis*-stilbenes *(81)* and similar com-

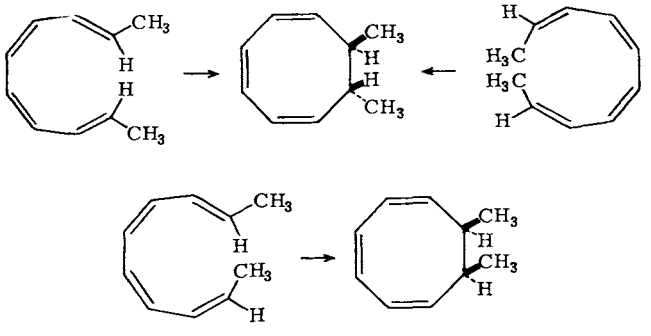
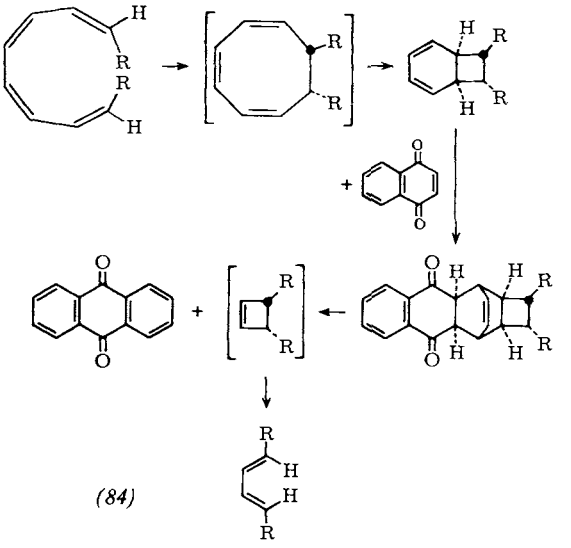
(81)



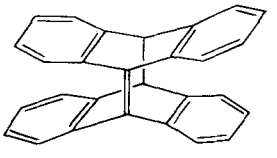
pounds [28], though the stereochemistry of the product has not been definitely established.

The earlier indications that the *thermal* cyclization of trienes was disrotatory [26] were confirmed by the study of simple model compounds *(82)* [29].



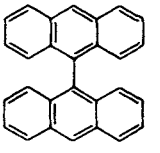
(82)

The electrocyclic closure *(83)* of a *cis,cis*-octatetraene should be thermally conrotatory, photochemically disrotatory. Though any conformation of a *cis,cis*-octatetraene is far from planarity, the nodal patterns in the orbitals are preserved. The predicted stereochemical course of the thermal reaction has been confirmed recently [30].



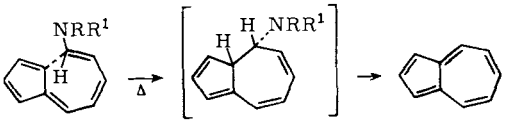
(83)

Some previous experiments can also be interpreted accordingly. Thus, in reactions *(84)* explored by *Meister* [31] the following sequence of symmetry-allowed changes can be adduced: an 8-electron conrotatory electrocyclic reaction, a 6-electron disrotatory reaction, a [4+2] cycloaddition, a reversion of the same, and a 4-electron conrotatory electrocyclic reaction.



(84)

The preparation of the fantastic hydrocarbon *(85)* by *Greene* [32] presents a situation of great interest, related to the octatetraene→cyclooctatriene electrocyclic conversion. Undoubtedly, the substance would suffer instantaneous transformation to its isomer 9,9′-bianthryl *(86)* – in fact, $t_{1/2} \approx 30$ minutes at 80 °C – were it not for the circumstances that the symmetry-allowed conrotatory transformation is opposed by a necessary concomitant, and difficult, twisting motion about the 9,9′ double bond, while the geometrically simpler disrotatory cleavage is symmetry-forbidden.



(85)

(86)

A ten-electron electrocyclic reaction may have been realized in the Ziegler-Hafner synthesis of azulene [33]. The crucial cyclization step is very probably a disrotatory electrocyclic reaction *(87)*.

(87)

There were some previous indications in the literature that the opening of cyclopropyl cations to allyl cations is a stereospecific process [34]. For instance, *Skell* and *Sandler* observed that the two epimers *(88)* and *(89)*

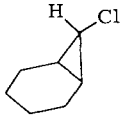
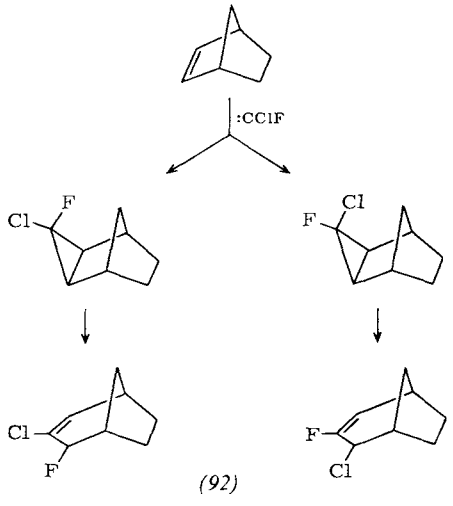
(88)



(89)

(structures not assigned) gave different solvolysis products. The hitherto mysterious phenomena are now readily explicable; the structures must be assigned as shown, since only loss of the *endo* halogen atoms can be concerted with the required disrotatory opening of the cyclopropane rings.

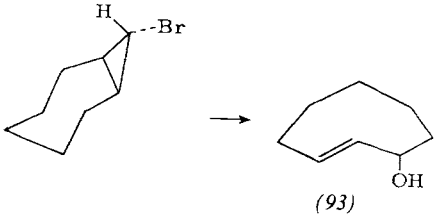
The first clear confirmations of our predictions for the electrocyclic opening were obtained in 1965. Whereas *(90)* undergoes solvolysis readily at 125 °C, its epimer *(91)* is recovered unchanged after prolonged treatment with acetic acid at 210 °C [35].



(90)

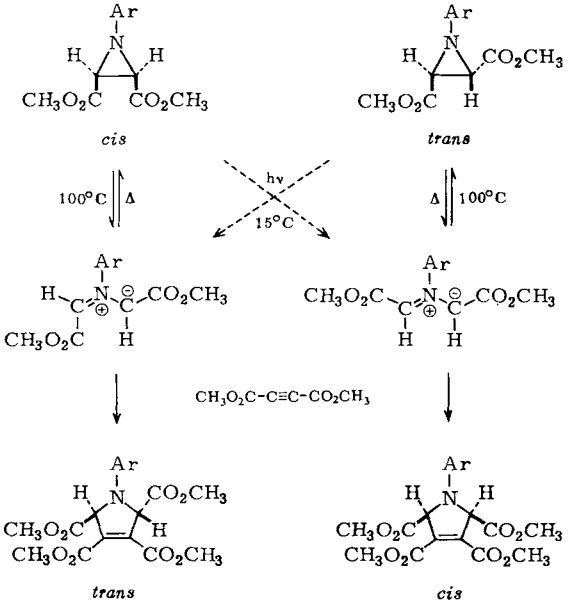
(91)

A detailed study of all methyl-substituted cyclopropyl tosylates clearly showed the steric effect of methyl groups forced against each other by the stereoelectronic factor [36].



(92)

[35] *S. F. Cristol, R. M. Segueira,* and *C. H. DePuy,* J. Amer. chem. Soc. *87,* 4007 (1965). Similar results were communicated to us by *W. Kirmse. Cf.* also the behavior on pyrolysis of the closely related chlorobicyclo[3.1.0]hexanes: *M. S. Baird* and *C. B. Reese,* Tetrahedron Letters *1967,* 1379.



[36] *P. v. R. Schleyer, G. W. Van Dine, U. Schöllkopf,* and *J. Paust,* J. Amer. chem. Soc. *88,* 2868 (1966); *U. Schöllkopf,* Angew. Chem. *80,* 603 (1968); Angew. Chem. internat. Edit. *7,* 588 (1968).

Since then, numerous further confirmations have appeared. We mention here only two of these. *Ghosez* and co-workers [37] observed the reactions *(92),* and *Whitham* has shown that solvolysis of *exo*-8-bromobicyclo[5.1.0]octane gives the expected *trans*-cyclooctenol *(93)* [38].

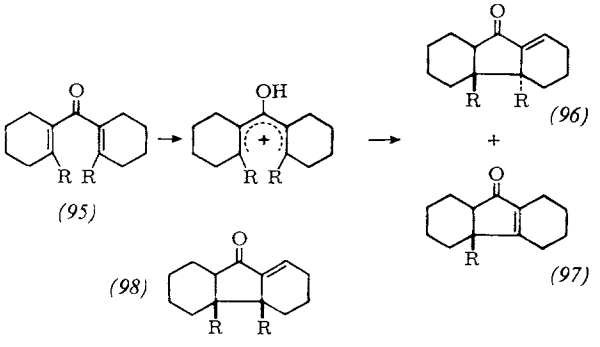
(93)

The electrocyclic cleavage of the cyclopropyl anion has not been tested directly in the parent case, but an isoelectronic example, drawn from aziridine chemistry, provides a striking confirmation of the conservation of orbital symmetry. The beautiful observations of *Huisgen, Scheer,* and *Huber* [39] are summarized in the diagram *(94)*.

(94)

The 1,3-dipolar isomer of an aziridine is a 4 π electron molecule isoelectronic to allyl anion. The net inversion of stereochemistry observed in the thermal reaction would be extremely puzzling were it not the obvious consequence of a conrotatory opening, followed by a [4+2] cycloaddition.

The cyclization of pentadienyl cations to cyclopentenyl ions is a reaction extensively studied by *Deno* and by

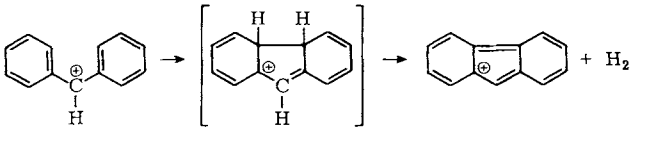


[37] *L. Ghosez, G. Slinckx, M. Glineur, P. Hoet,* and *P. Laroche,* Tetrahedron Letters *1967,* 2773. Related reactions with HCCl and HCBr are also observed: *C. W. Jefford, E. Huang Yen,* and *R. Medary, ibid. 1966,* 6317.

[38] *G. H. Whitham* and *M. Wright,* Chem. Commun. *1967,* 294.

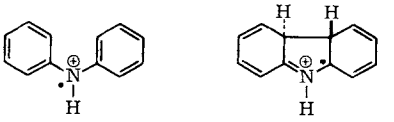
[39] *R. Huisgen, W. Scheer,* and *H. Huber,* J. Amer. chem. Soc. *89,* 1753 (1967).

Sorensen [40]. However, the nature of the sulfuric acid medium predominantly used in these studies precludes elucidation of the stereochemistry of the reaction; hydrogen and methyl shifts intervene before product isolation. Further, it is now clear that the well-known Nazarov reaction [41] involves an electrocyclic reaction within a pentadienyl cation; again, no information about the stereochemistry of the change was forthcoming from the very extensive early work.



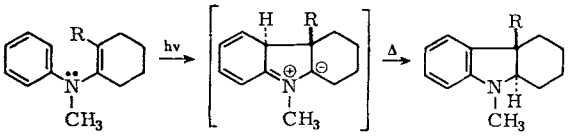
The stereochemistry of the reaction has now been established in recent studies at Harvard [42]. Treatment of dicyclohexenyl ketone *(95)*, R = H, with phosphoric

(95) *(96)* *(97)* *(98)*



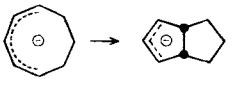
acid affords two ketones *(96)*, R = H, and *(97)*, R = H. Similarly, the substituted ketone *(95)*, R = Me, yields *(96)*, R = Me; in this case the process is not complicated by concomitant formation of a stereochemically uninformative product of type *(97)*. Thus, the predicted conrotatory course is cleanly followed in both cases. Moreover, the irradiation of *(95)*, R = H, yields a ketone *(98)* which is the product of disrotatory cyclization.

The opportunity for observing the excited state reactions of cations arises in mass-spectrometric studies. *Johnstone* and *Ward* [43] observed that the diphenylmethyl cation *(99)*, generated mass spectrometrically, cyclizes to a hydrofluorene species which loses *two* hydrogen atoms in a single step, and is therefore very



(99) *(100)*

probably the *cis* ion *(100)* – the expected product of the symmetry-allowed electrocyclization of the first excited state of the cation *(99)*. By contrast, the radical cation *(101)*, cyclizes to a hydrocarbazol species which loses hydrogen atoms one at a time, and is thus probably the *trans* ion *(102)* – again the result of the symmetry-allowed excited state process.



(101) *(102)*

Chapman [44] has observed photochemical cyclizations of the amines *(103)*. These are isoelectronic with pentadienyl anion, and their excited state closure should take a conrotatory course. The initially formed inter-

(103), R = H, CH_3 *(104)* *(105)*

mediate *(104)* apparently returns to the ground state and undergoes a hydrogen shift (a symmetry-allowed suprafacial [1,4] anionic shift – see Section 7) leading to the stable final product *(105)*.

(105a) *(105b)*

Very recently, the first example of the electrocyclic closure of a simple cyclopentadienyl anion has been observed [*(105a)*→*105b)*] [44a].

Winstein has studied an exceptionally interesting system in which nine- and ten-electron electrocyclic processes are operative [45]. When one electron is added to *cis*-bicyclo[6.1.0]nona-2,4,6-triene *(106)*, an ion-radical *(107)* is produced, clearly with symmetry-allowed

(106) *(107)*

disrotatory geometrical displacements. Moreover, yet another electron can be added, to give a ten-electron doubly charged anion. In spectacular contrast [46], addition of an electron to the isomeric *trans*-triene *(108)* is not accompanied by delocalization of the cyclopro-

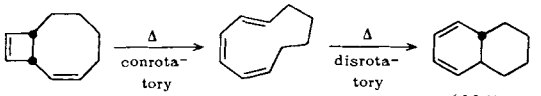
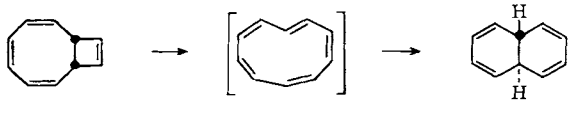
[46] *G. Moshuk, G. Petrowski*, and *S. Winstein*, J. Amer. chem. Soc. *90*, 2179 (1968).

pane electrons. In this case, the steric restraints present do not permit disrotatory displacements, and the seven-electron ion-radical *(109)* is produced.

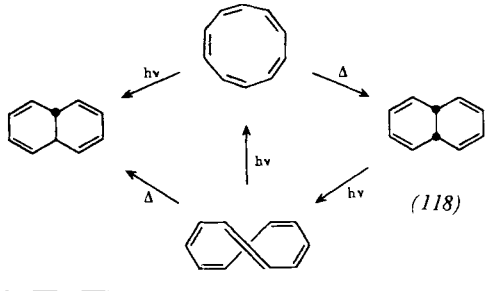


(108) *(109)*

The congeries of electrocyclic reactions *(110)–(116)* was studied by *Fonken* [47], who correctly assumed, but did not observe, the intermediacy of *(115)* in the transformation of *(114)* into *(116)*. In an independent investigation by *Radlick* [48] this course of events has been rigorously established.



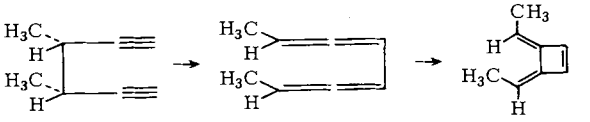
(110) *(111)* *(112)* *(113)*



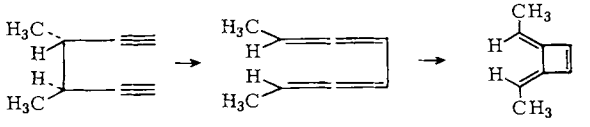
(114) *(115)* *(116)*

A similar sequence of electrocyclic reactions is provided by the pyrolysis of bicyclo[6.2.0]deca-2,4,6,9-tetraene to *trans*-9,10-dihydronaphthalene *(117)* [49].

(117)



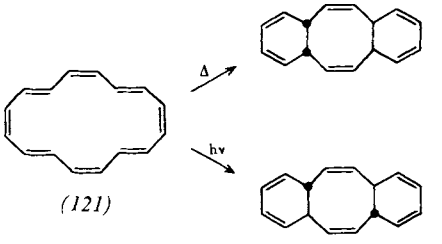
Trans-9,10-dihydronaphthalene is reported to be converted photochemically to a cyclodecapentaene (at –190 °C) which reverts thermally to the *cis*-9,10-dihydronaphthalene *(118)* [50]; in more recent studies the



(118)

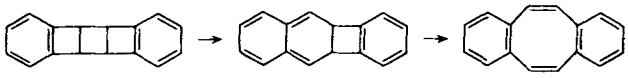
relationships shown in the diagram have been suggested [50a].

1,5-Alkadiynes undergo intramolecular rearrangement at elevated temperatures to give dimethylene cyclobutenes *(119)*, *(120)*. The observed stereospecificity [51] is



(119)

(120)



readily accounted for by the sequence of a symmetry-allowed [3,3] sigmatropic shift (see below, Section 7) and a four electron conrotatory electrocyclic reaction.

(121)

The recently synthesized [16]annulene isomerizes thermally and photochemically to two different isomers [52], the products of double disrotatory and double conrotatory closures, respectively.

Of very special interest is the recent discovery of metal catalysis of electrocyclic reactions. For example, the dibenzotricyclooctadiene *(122)* is reported to undergo

(122) *(123)* *(124)*

thermal isomerization to dibenzocyclooctatetraene *(124)* when heated at 180 °C for 4–5 hours [53]. But at room temperature, in the presence of silver ions, the isomerization is complete in 10 seconds [54]. A forbidden disrotatory opening [*(122)→(123)*] is here obviously made allowed by the extra orbitals and electrons available from the complexing metal ion. A similar dramatic reversal of the rules for cycloaddition and cyclore-

version reactions has been observed, and analyzed in terms of orbital symmetry conservation [55].

We now conclude our exemplification of electrocyclic reactions by alluding to two interesting, but as yet unrealized, possibilities. The valence tautomerism of cyclooctatetraene and bicyclo[4.2.0]octatriene is familiar [56]. The requisite disrotatory process may be achieved thermally by an opening of the six-membered ring of *(126)* or photochemically by cleavage of the cyclobutene ring. Since these electrocyclic changes might

(125) *(126)* *(127)*

be faster than bond switching in cyclooctatetraenes [57], it is possible that the alternatives might be experimentally observable.

The as yet unsynthesized cyclodeca-1,2,4,6,7,9-hexaene *(128)* can exist in *meso* and *d,l* modifications. Both stereoisomers should be nearly strainless. The molecules are, of course, valence tautomers of naphthalene *(129)*, and closure to naphthalene is formally an electrocyclic conversion of a hexatriene to a cyclohexadiene. The *meso* form *(130)* is in fact sterically

(128) *(129)*

well-disposed for disrotatory closure to naphthalene; since that indeed is the symmetry-allowed electrocyclic mode, it would be expected that *(130)* would have a

(130) *(131)*

very fragile grasp on existence. By contrast, the molecules of the *d,l* form [*cf. (131)*] have two interesting features. First, a model shows that an interesting conformational flipping can take place, without change of chirality. Second, the geometric circumstances are such that isomerization to naphthalene can be completed only by a symmetry-forbidden conrotatory closure. Consequently, the racemic compound might have reasonable thermal (but not photochemical) stability with respect to transformation into its aromatic isomer. By the same token, *(131)* is the product of the conrotatory cleavage of the 9,10 bond of the naphthalene molecule, and might well be among the products of photochemical transformation of the latter.

6. Theory of Cycloadditions and Cycloreversions

In our discussion of correlation diagrams we have already derived the selection rules for one type of simple two-component cycloaddition, namely, that which is *suprafacial* on each component. A suprafacial process is one in which bonds made or broken lie on the same face of the system undergoing reaction. For example, in an ethylenic *(132)* or cisoid diene system *(133)*, formation of bonds in the senses indicated by the arrows takes place in a suprafacial manner.

(132) *(133)*

A priori however, there are alternative, *antarafacial* processes, in which the newly formed or broken bonds lie on opposite faces of the reacting systems [58] [*cf. (134)* and *(135)*].

(134) *(135)*

We shall use the terms *supra* and *antara* to designate these geometrical alternatives in making general allusions to reaction types, and the letters s and a as subscripts in defining particular reactions. Thus, the cycloadditions mentioned above are *supra,supra* reactions, and the Diels-Alder reaction is a $[4_s+2_s]$ process [59].

A priori, there are in fact four possible modes of combination of the termini of two unlike components in a cycloaddition reaction. Each mode has a characteristic stereochemical consequence, displayed in Figure 21.

In using the principle of orbital symmetry con. ervation to determine whether any cycloaddition is symme-

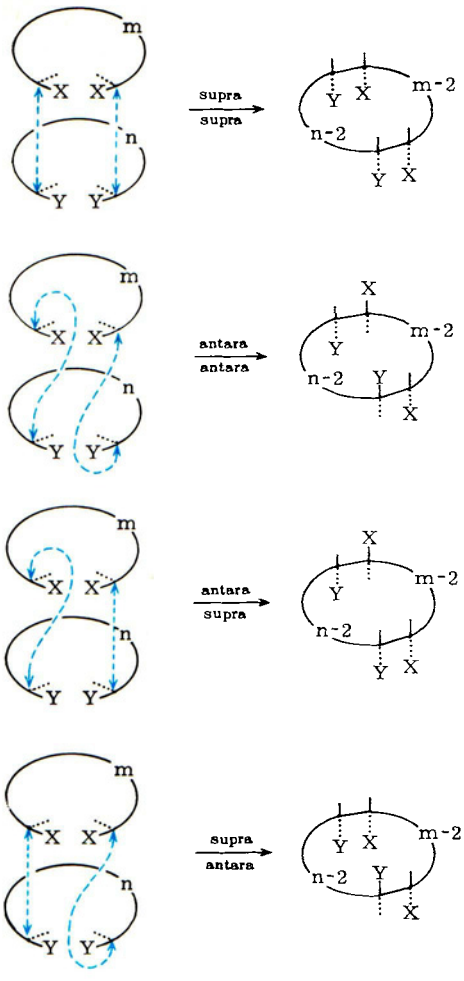
[55] *F. D. Mango* and *J. H. Schachtschneider*, J. Amer. chem. Soc. *89*, 2484 (1967); *H. Hogeveen* and *H. C. Volger*, *ibid. 89*, 2486 (1967).

[56] *E. Vogel*, *H. Kiefer*, and *W. R. Roth*, Angew. Chem. *76*, 432 (1964); Angew. Chem. internat. Edit. *3*, 442 (1964); *R. Huisgen* and *F. Mietzsch*, Angew. Chem. *76*, 36 (1964); Angew. Chem. internat. Edit. *3*, 83 (1964).

[57] *F. A. L. Anet*, *A. J. R. Bourn*, and *Y. S. Lin*, J. Amer. chem. Soc. *86*, 3576 (1964).

[58] The terms suprafacial and antarafacial were first used in our discussion of sigmatropic reactions; *cf.* ref. [3].

[59] We [Accounts of Chem. Res. *1*, 17 (1968)] and others have earlier used *cis* and *trans* to designate the geometrical relationships here denominated *supra* and *antara*. However, the use of *cis* and *trans* as nomenclatural qualifiers is firmly established, and their employment in different senses – often of necessity, simultaneously – can be cumbersome and confusing, especially in discussing multicomponent combinations.



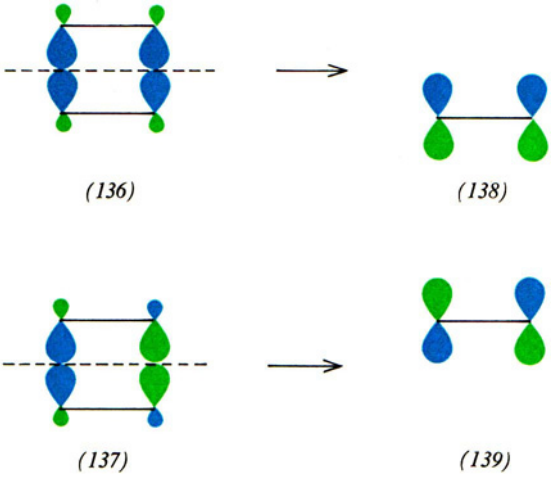


Figure 21. Stereochemical consequences of two-component cycloadditions. The diagrams are purely schematic, and do not reflect the actual geometry of the transition states, which of course differs markedly from case to case. Note that there are two possible *supra,supra* cases when *m* or *n*>2, differing in the mode of approach of the reactants [*exo* and *endo* additions]. Similar circumstances obtain in the other cases. When the two reactants are identical the *supra,antara* and the *antara,supra* processes are indistinguishable.

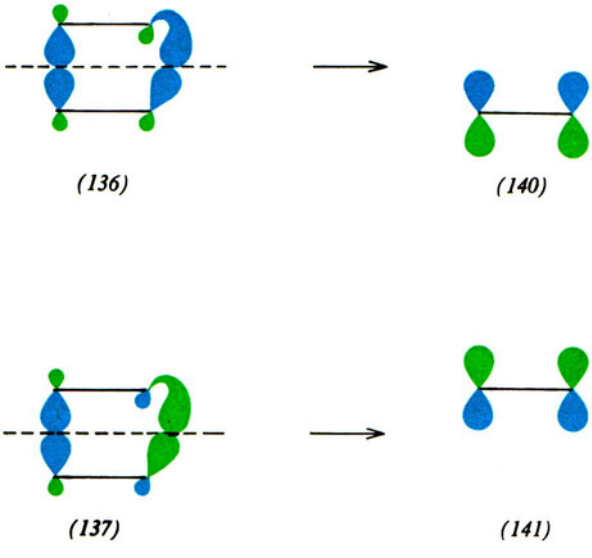
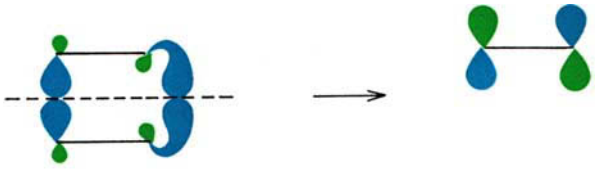
try-allowed or forbidden, a complete analysis requires that all orbitals – bonding and antibonding – be considered. But a simplified procedure is often useful. First, all relevant reactant electrons are placed in fully delocalized bonding σ molecular orbitals of the *product* of the cycloaddition under examination. Then, if the electrons occupying the σ orbitals can be moved into bonding orbitals of the products of the cycloreversion when the σ bonds are broken with symmetry conservation, the reaction is symmetry-allowed. When the system is one lacking any molecular symmetry, the signs of the orbital lobes are determined by point-to-point transference from an analogous symmetrical system involving the same numbers of orbitals of the same types.

We shall illustrate the procedure for all possible [2+2] reactions. In each case the four relevant electrons are first placed in pairs in the two generalized cyclobutane orbitals *(136)* and *(137)*.

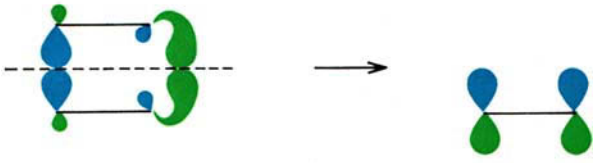


a) The $[2_s+2_s]$ process. When the σ bonds are cleaved, the two electrons in the orbital *(136)* can pass with symmetry conservation into a bonding orbital *(138)* of one ethylene molecule, but those in *(137)* can only enter an antibonding orbital *(139)* of the other ethylene.

The reaction is symmetry-forbidden.



b) The $[2_s+2_a]$ process. When the σ bonds are cleaved, the two electrons in the orbital *(136)*, now shown distorted in a purely formal manner, can pass with symmetry conservation into a bonding orbital *(140)* of one ethylene molecule, while those in *(137)* likewise pass into a bonding orbital *(141)* of the other ethylene.



The reaction is symmetry-allowed.

c) The $[2_a+2_a]$ process. When the σ bonds are cleaved, two electrons in the orbital *(136)*, again, but different-

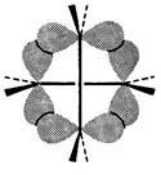
ly, distorted in a purely formal manner, can only enter an antibonding orbital *(142)* of one ethylene molecule, while those of *(137)* pass into a bonding orbital *(143)* of the other.

(136) *(142)*

(137) *(143)*

The reaction is symmetry-forbidden.

It will be noted that the analyses just completed reveal the existence of a concerted symmetry-allowed path for the combination of two ethylenic compounds to give a cyclobutane. What the simplified formal analysis does not render obvious is the actual geometry of approach for the allowed $[2_s+2_a]$ process, which clearly must differ from that of the symmetry-forbidden combinations. When one considers in detail the manner in which maximum overlap of the relevant orbital lobes may be achieved in the $[2_s+2_a]$ reaction, it is clear that the ethylenic components must approach one another orthogonally, as in *(144)*.



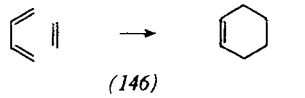
(144)

Bonding orbital of ethylene I + antibonding orbital of ethylene II

Bonding orbital of ethylene II + antibonding orbital of ethylene I

It is further worthy of comment that a complete correlation diagram may be constructed for the allowed $[2_s+2_a]$ reaction, using a two-fold axis of symmetry which passes through the midpoints of both of the ethylenic bonds. Similar circumstances obtain in the case of the $[2_a+2_a]$ reaction. In this case the geometry of approach is that shown in *(145)*, and the reaction is

(145)



forbidden in the ground state, as deduced above, but allowed for the excited state (*cf.* Figure 22). A final point of much importance is that the principle of conservation of orbital symmetry is valid, *whether or not a formal correlation diagram can be constructed.* For example, no pertinent correlation diagrams can be drawn for the concerted $[4_s+2_a]$ and $[6_s+2_a]$ combinations, but orbital symmetry analysis readily reveals that the former is forbidden and the latter allowed.

The generalized cycloaddition rules are now easily derived. In the addition of an m to an n-electron system the rules shown in Figure 22 must be observed for concerted processes (q is an integer = 1, 2, 3 . . .).

$m+n$	Allowed in Ground State Forbidden in Excited State	Allowed in Excited State Forbidden in Ground State
$4q$	m_s+n_a m_a+n_s	m_s+n_s m_a+n_a
$4q+2$	m_s+n_s m_a+n_a	m_s+n_a m_a+n_s

Figure 22. Selection rules for $[m+n]$ cycloadditions.

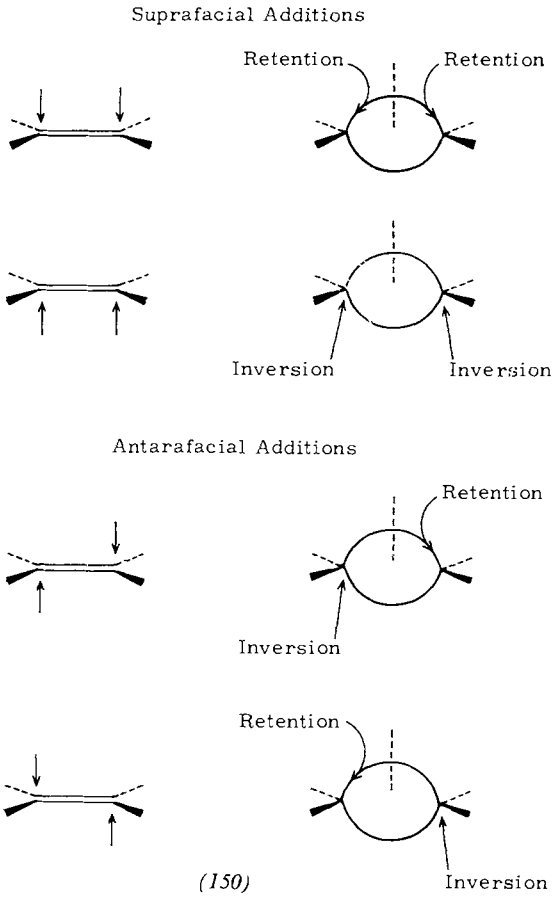
An important generalization is that these rules depend not on the total number of orbitals but on the number of electrons. Thus, the [4+2] case may be achieved in each of the ways shown by formulae *(146)–(149)*.

(146)

(147)

(148)

(149)



It should be noted also that *supra,antara* and *antara,antara* cycloadditions are not so unlikely as they might appear to be on simple steric grounds.

It remains to point out that σ *bonds can act as components in cycloaddition reactions.* In such cases, the following definitions are important:

a) A σ bond is considered to be involved in a cycloaddition reaction in a *supra* sense if configuration is retained, or inverted, at *both* of its termini in the course of reaction.

b) A σ bond is considered to be involved in a cycloaddition reaction in an *antara* sense if configuration is retained at one, and inverted at the other, terminus in the course of reaction.

The rationale underlying these important conventions will be apparent immediately upon consideration of additions to an ethylene molecule, regarded as containing two σ bonds *(150)*.

(150)

c) We adopt the simple and useful device of denominating the type of orbital involved in a concerted reaction by a subscript preceding the number of electrons in the relevant orbital. Thus

$\sigma 2_a$ $\pi 4_s$ *etc.*

In order to clarify and exemplify these matters, it may be pointed out that the electrocyclic transformation of cyclobutenes to butadienes may be regarded formally as a cycloaddition of a σ bond to a π bond, in either of two equivalent ways.

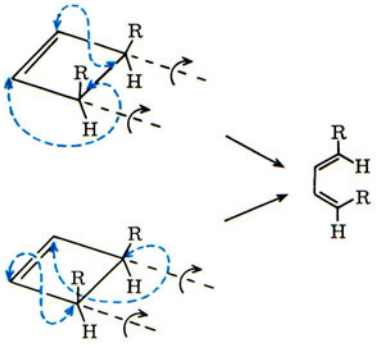


Figure 23. Electrocyclic conversion of cyclobutenes to butadienes as $[\sigma 2_s+\pi 2_a]$ cycloadditions.

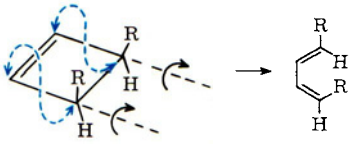
a) As shown in Figure 23: *suprafacial* on the σ bond, *antarafacial* on the π bond, *i. e.* $[\sigma 2_s+\pi 2_a]$.

b) As shown in Figure 24: *antarafacial* on the σ bond, *suprafacial* on the π bond, *i. e.* $[\pi 2_s+\sigma 2_a]$.



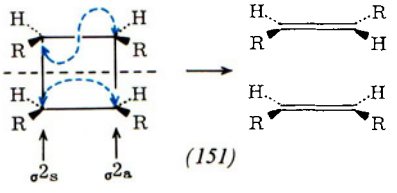


Figure 24. Electrocyclic conversion of cyclobutenes to butadienes as $[\pi 2_s+\sigma 2_a]$ cycloadditions.

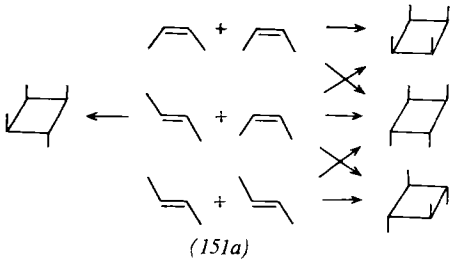
It will be observed that whichever formal view is taken, the conrotatory processes represent symmetry-allowed cycloaddition reactions; by contrast, the disrotatory analogues must be regarded as $[\pi 2_s+\sigma 2_s]$ or $[\pi 2_a+\sigma 2_a]$ reactions, which are, of course, symmetry-forbidden in ground states.

As a final illustration we may now characterize the concerted scission of cyclobutane as a $[\sigma 2_s+\sigma 2_a]$ process *(151)*.

(151)



6.1. Cycloadditions and Cycloreversions Exemplified

The [2+2] cycloaddition is one of the most widely observed photochemical reactions, with more than one hundred examples quoted in a recent review [60]. It is likely that many of these reactions are not concerted, probably as a consequence of the fact that competitive relaxation of a participant excited state occurs, with transformation to an equilibrium geometry in which the ethylene moieties are 90 ° out of coplanarity. Thus, *trans* fusions are common in many of the cycloadducts [61]; of course, it should be noted that *trans* fused products would result from concerted symmetry-allowed $[\pi 2_s+\pi 2_a]$ combinations of vibrationally excited ground-state molecules. Nevertheless, two striking examples of concerted symmetry-allowed photo-induced $[2_s+2_s]$ processes have recently been observed. Thus, irradiation of the neat *cis*- and *trans*-2-butenes, separately and in admixture, gives the results shown in *(151a)* [61a].

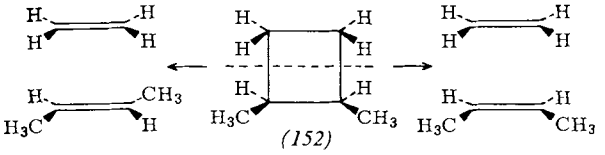
[61a] *H. Yamazaki* and *R. J. Cvetanović*, J. Amer. chem. Soc. *91*, 520 (1969).

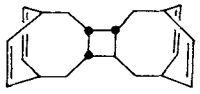


(151a)

Further, a pretty example *(151b)* of the photochemical $[\sigma 2_s+\sigma 2_s]$ reaction has been discovered [61b].

(151b)

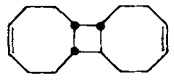
It is quite possible that the reversal of the simplest [2+2] cycloaddition, the pyrolysis of cyclobutane, is not a concerted process. The pre-exponential factor of the Arrhenius equation has been regarded as consistent only with a stepwise decomposition through a tetramethylene radical [62]. Further, the fact that pyrolysis of *cis*- or *trans*-dimethylcyclobutane *(152)* yields a mixture of *cis*- and *trans*-butenes, among other products [63], has been adduced in support of the diradical mechanism. Nevertheless, if the cycloreversion is concerted, it must be of the type $[\sigma 2_s+\sigma 2_a]$, and the same stereochemical result would be observed.



(152)

A beautiful example of the symmetry-allowed $[\pi 2_s+\pi 2_a]$ combination has been discovered by *Kraft* and *Koltzenburg* [64]. The olefin *(153)* dimerizes spontaneously to *(154)*.

(153)



(154)

Earlier observations [65] that *cis*, *trans*-cycloocta-1,5-diene *(155)* dimerizes spontaneously at room temperature to a cyclobutane are less illuminating, since the stereochemistry of the product – now predictable as *(156)* – has not been established.

(155)

(156)

It is worthy of note that when a double bond is twisted about its axis – as it must be in *(153)* and *(155)* – the concomitant orbital twisting is such as distinctly to favor the $[\pi 2_s+\pi 2_a]$ process.

A further very interesting point which emerges from a detailed consideration of the general case (Figure 25) is that the reaction-facilitating twisting motions generate systems of opposite chirality in the two ethylene components. Consequently, *we may predict that the optically active forms of the olefins (153) and (155) will dimerize less readily than the racemic substances.*

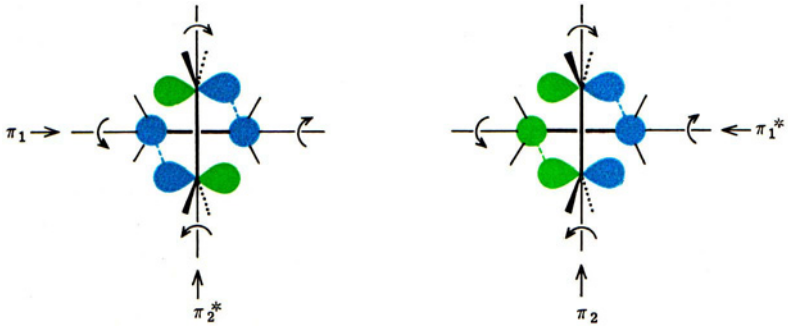


Figure 25. Combination of systems of opposite chirality in the $[\pi 2_s+\pi 2_a]$ cycloaddition of two ethylene molecules.

Bicyclobutanes are produced on irradiation of some substituted butadienes [66] as well as butadiene itself [67]. The bicyclobutanes are remarkably stable, considering their strain energy (*ca.* 69 kcal/mole). The activation energy for isomerization to butadiene is 41 kcal/mole [68,69]. The temptation arises then to consider the rearrangement of bicyclobutane to butadiene

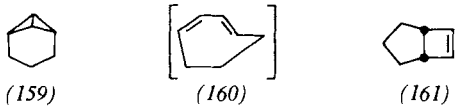
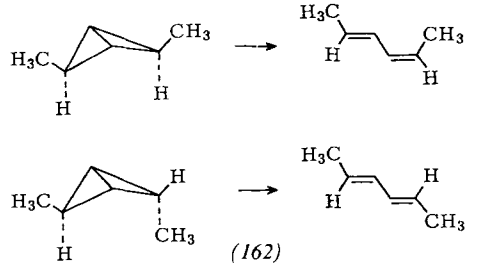
(157)



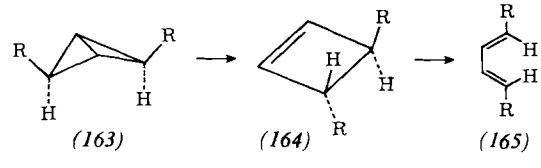
as a non-concerted process proceeding through a diradical intermediate *(157)*.

If, however, the reaction is a concerted one, it is clear that it must be a $[\sigma 2_s+\sigma 2_a]$ process, with the stereochemical consequences shown in *(158)* [70].



(158)

The evidence is now compelling that the reaction is in fact a concerted $[\sigma 2_s+\sigma 2_a]$ process. A first, indirect indication that such is the case, was provided by the observation that *(159)* is converted to *(161)* on pyrolysis [71]. The result is best accommodated by assuming the



(159) (160) (161)

intermediacy of *(160)*, which closes in a conrotatory fashion to the observed product. The decisive experiment was recently reported by *Closs* and *Pfeffer* [72]. Their results are summarized in *(162)*.

(162)

Remarkably, there exists in principle an alternative pathway relating bicyclobutane and butadiene, with precisely opposite stereochemical consequences. This route *[(163)→(164)→(165)]* entails the intermediacy of a cyclobutene, which then undergoes conrotatory cleavage to the product butadiene. Thermodynamically, the sequence is feasible [73]. In formal terms, the change may be described as involving successive symmetry-allowed $[\sigma 2_s+\sigma 2_a]$ and $[\sigma 2_s+\pi 2_a]$ reactions. The possibility that special substitution patterns – perhaps operating through attendant simple steric effects – may bring this path to light should not be dismissed.

(163) (164) (165)

The reader may find it illuminating to verify for himself the relationships displayed in Figure 26, which presents the stereochemical pattern for all possible symmetry-allowed processes relating bicyclobutanes, cyclobutenes, and butadienes.

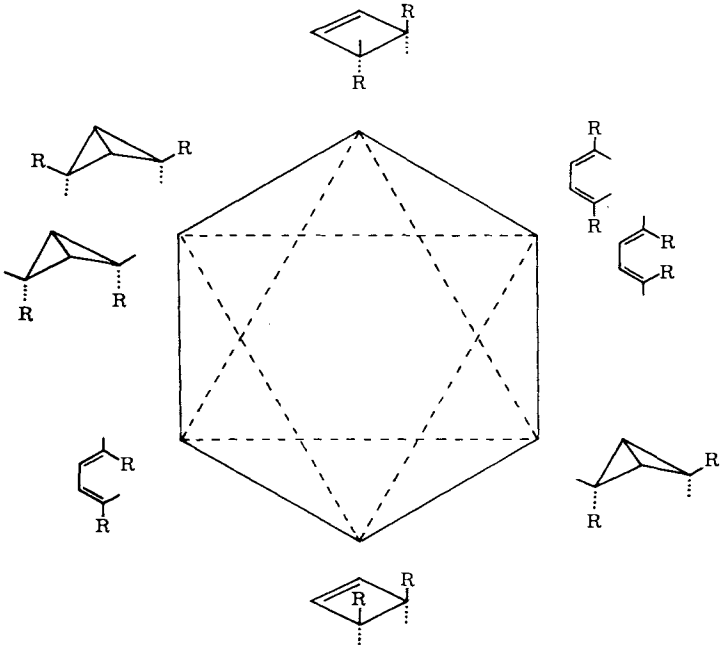


Figure 26. Symmetry-allowed processes relating bicyclobutanes, cyclobutenes, and butadienes. — Allowed ground state paths. --- Allowed excited state paths.

The number of known Diels-Alder reactions – the $[\pi 4_s+\pi 2_s]$ cycloadditions – is legion [74, 75]. Though a diradical mechanism has been advanced on numerous occasions [76], the overwhelming body of experimental facts is consistent only with a concerted mechanism [77].

There is a growing body of photochemical Diels-Alder reactions [78], but in most instances there is no evidence which provides information as to whether the reactions are concerted or not. However, it is very probable that concerted symmetry-allowed excited-state $[\pi 4+\pi 2]$ processes are involved in the ubiquitous conversion of

[70] Similar conclusions have been reached by *Wiberg* on the basis of semi-empirical MO calculations [*K. B. Wiberg*, Tetrahedron *24*, 1083 (1968)].

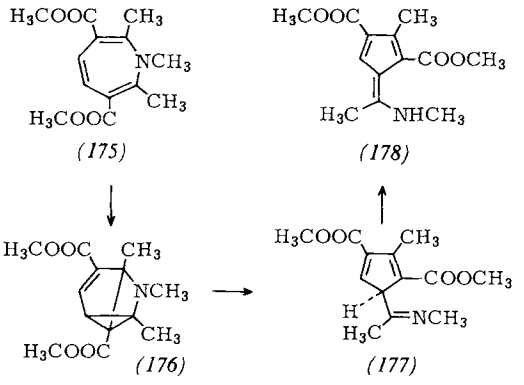
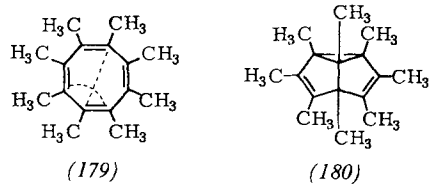
(166)

cis-hexatrienes *(166)* to bicyclo[3.1.0]hexenes [79]. If concerted, these reactions must be either $[\pi 4_s+\pi 2_a]$ or $[\pi 4_a+\pi 2_s]$ processes. Excluding the formation of a *trans* fused bicyclohexene, the stereochemical consequences of the allowed processes are seen from formulae *(167)–(171)*.



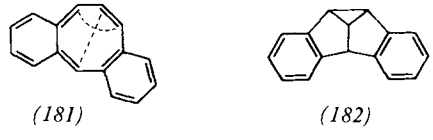
(167) *(168)* *(169)* *(170)* *(171)*

No reaction involving a substance sufficiently extensively labeled as to provide a test of these conclusions has been studied. In vitamin D_2 *(172)*, the top and bottom faces of the triene system are no longer equivalent, and the processes which lead in the general cases to enantiomers must in this instance afford different structures. In fact, irradiation of vitamin D_2 leads to two bicyclohexenes – suprasterol I *(173)* [80] and suprasterol II *(174)* [81]. These structures are precisely those which must result from concerted symmetry-allowed excited-state $[\pi 4_s+\pi 2_a]$ processes, but in the absence of further labeling at the starred atoms it is not possible to discern whether the $\pi 4$ system participates in the reactions in a suprafacial manner.



(172) *(173)* *(174)*

A proposed mechanism for the observed transformation of the azepine *(175)* into the fulvene *(178)* invokes the symmetry-allowed ground-state $[\pi 4_a+\pi 2_a]$ reaction *(175)→(176)* [82].



(175) *(178)* *(176)* *(177)*

At elevated temperatures, in the presence of base, octamethylcyclooctatetrasne *(179)* is smoothly converted to octamethylsemibullvalene *(180)* [83]. It seems possible that the base serves merely to protect the reactant from alternative acid-catalyzed changes, and that the reaction is a simple symmetry-allowed $[\pi 4_a+\pi 2_a]$ intramolecular cycloaddition. Further, *Pettit* [84] has made observations which are best interpreted by assuming that dibenzo[*a*,*c*]cyclooctatetraene *(181)* undergoes spontaneous transformation to *(182)*; the special points worthy of note in this case are that the $[\pi 4_a+\pi 2_a]$ reaction is favored both by concomitant loss of *o*-quinoid character as reaction proceeds, and by deviation in *(181)* from normal cyclooctatetraene geometry, induced by the fused six-membered rings. The difficulty of the $-[\pi 4_a+\pi 2_a]$ process [84a] in the absence of favorable steric constraints is shown by the fact that the ketone *(183)* fails to undergo cycloreversion to butadiene and

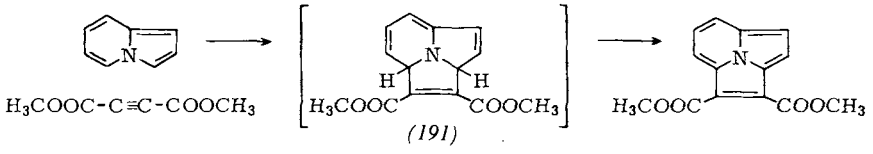
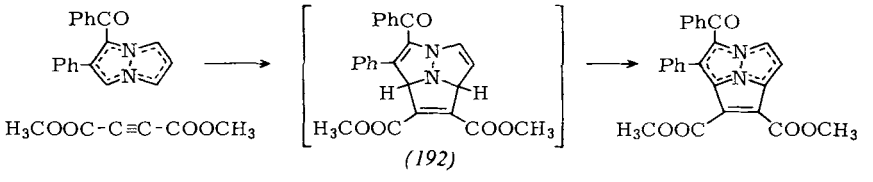
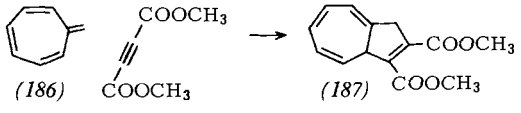
[84a] Here and in the sequel we use the device of placing a negative sign before the bracket whenever a reaction is characterized in terms of its products.



(185) even at 400 °C; the corresponding $-[\pi 4_s+\pi 2_s]$ reaction *(184)*→*(185)* takes place readily [85].

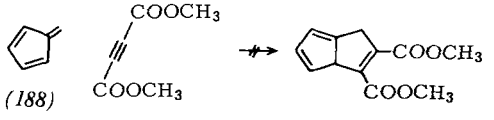


with the acetylenic ester, producing an azulene by way of an adduct *(190)*, as yet not isolated, which is the product of an [8+2] reaction [89].



Two unusual [8+2] cycloadditions, discovered by *Boekelheide* [90], are portrayed in *(191)* and *(192)*.

[6+4] Cycloadditions were unknown until our enunciation of the principle of orbital symmetry conservation stimulated the search for them. The cases *(193)*–*(198)* are now known.



[4+4] Cycloadditions are well known [86]. As yet, they have been encountered only in photochemical reactions, and no detailed stereochemical information is available.

[8+2] Cycloadditions have been relatively rarely observed. Heptafulvene *(186)* readily combines with dimethyl acetylenedicarboxylate [87] to give *(187)*, whereas fulvene *(188)* does not react in a similar sense (note that the $[\pi 6_s+\pi 2_s]$ combination is symmetry-forbidden). Similar reactions of calicenes have been observed [88]. Hexaphenylpentalene *(189)* also combines

[6+6] Cycloadditions of presumed *p*-xylylene intermediates are known [96], but no information is available about the detailed mechanism of the reactions. Irradiation of tropone in acidic solution gives a symmetrical dimer *(199)* [97], which is the product to be expected from a concerted symmetry-allowed excited-state $[\pi 6_s+\pi 6_s]$ combination; the unusual experimental conditions, and the fact that other photoinduced dimerizations of tropone may proceed in a non-concerted fashion [98] suggest caution in adopting the conclusion that the concerted process is in fact involved in the formation of *(199)*.

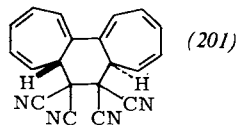
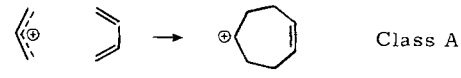
Heptafulvalene *(200)* combines with tetracyanoethylene to give the adduct *(201)*, whose structure has been firmly established by X-ray crystallographic



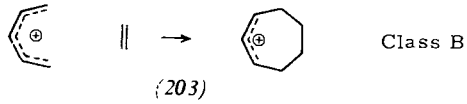
(199)

methods[99]. The adduct is the expected product of the symmetry-allowed ground-state $[\pi 14_a+\pi 2_s]$ process; it may be noted that the twisted shape of the heptafulvalene molecule sets the stage ideally for *antara* addition to the 14-electron system.

[99] *W. von E. Doering*, personal communication.



(200)

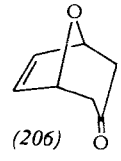


(201)

Cycloadditions involving ionic components are as yet not common. Ionic [4+2] cycloadditions may be realized in a number of different ways *[(202)–(204)]*.

(202) Class A

(203) Class B



(204) Class C

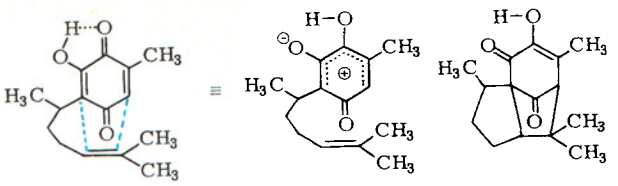
We may assign to class A the cycloaddition reactions of cyclopropanones *(205)*. It is not unlikely that cyclopropanones are in equilibrium with an isomeric dipolar species. The latter can act as a 2 π-electron system, and,

(205)

predictably, combines with dienes in $[\pi 4_s+\pi 2_s]$ processes – for example, with furans to give adducts of the type *(206)*[100].

(206)

Most recently, the direct combination of the 2-methylallyl cation *(207)* with cyclopentadiene and with cyclohexadiene, to give the bicyclic cations *(208)*, Z = $-CH_2-$ or $-CH_2-CH_2-$, has been demonstrated[101].



(207) *(208)*

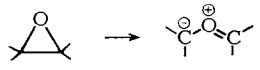
A remarkable cycloaddition of class B is that which occurs in the formation of the pipitzols *(210)* from perezone *(209)*[102].

[100] *R. C. Cookson, M. J. Nye*, and *G. Subrahmanyam*, J. chem. Soc. *C*, *1967*, 473; *1965*, 2009; *A. W. Fort*, J. Amer. chem. Soc. *84*, 2620, 2625, 4979 (1964); *N. J. Turro* and *W. B. Hammond*, *ibid.* *87*, 3258 (1965); *88*, 3672 (1966); *W. B. Hammond* and *N. J. Turro*, *ibid.* *88*, 7880 (1966).

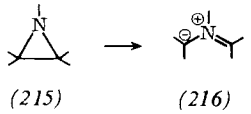
[101] *H. M. R. Hoffmann, D. R. Joy*, and *A. K. Suter*, J. chem. Soc. *B*, *1968*, 57.

[102] *F. Walls, J. Padilla, P. Joseph-Nathan, F. Giral*, and *J. Romo*, Tetrahedron Letters *1965*, 1577.

(209) (210)



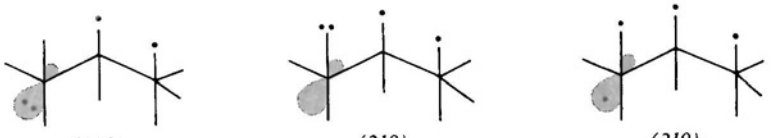
As yet, no simple instances of class C ionic [4+2] cycloadditions have been discovered. However, a very important and numerous group of reactions – the 1,3-dipolar additions [103] – may be placed in this class, since the 1,3-dipolar substances which participate in cycloaddition reactions, although formally neutral molecules, generally function as three-orbital 4π-electron species. *Huisgen*, whose own magnificent researches have transformed 1,3-dipolar addition from an obscure phenomenon, exemplified only by a few curiosities, into a major reaction-type, has presented excellent surveys of the field [103], and has analyzed the process in terms of orbital symmetry conservation [104]. Consequently, it is only necessary here to summarize briefly the major fundamental factors, and to allude to



(211) (212)

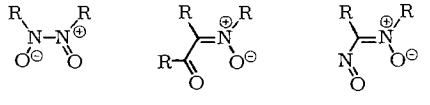
a few special points. The great majority of known participants in 1,3-dipolar addition reactions are isoelectronic either with ozone *(211)* or with nitrous oxide *(212)*, and unambiguously contain a three-orbital system occupied by four π electrons.

Another class of reactants is represented by labile molecules which undergo ready transformation into species containing the requisite 4-electron system, *e.g.* the carbonyl ylides *(214)* and the azomethine ylides *(216)* are produced by electrocyclic transformation of ethylene oxides *(213)* and ethylene imines *(215)*, substituted in such wise as to facilitate ring cleavage; the



(213) (214)

(215) (216)



symmetry-determined conrotatory course of these antecedent processes has already been discussed above (*cf.* Section 5).

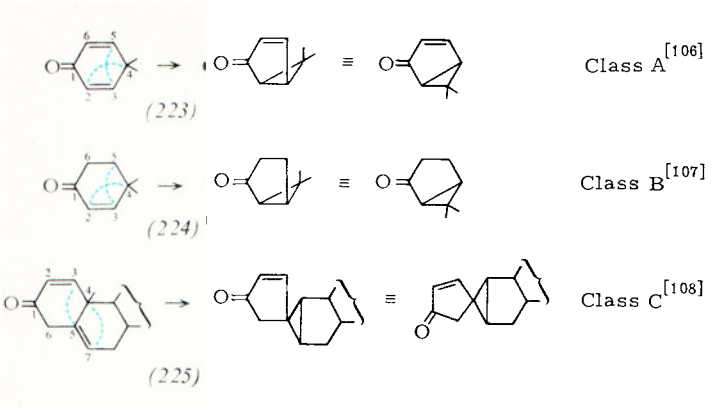
The situation in respect to the possibility of the participation, in concerted cycloaddition reactions, of fugitive species such as vinylcarbene and its isoelectronic analogues, presents interesting ambiguities. Such molecules may exist in three forms, differing in the number of π electrons occupying the allyl orbital. The first, *(217)*, containing two electrons in the allyl system, may be expected to combine with dienes in a [2+4] process, but independent reaction as a simple substituted carbene could supervene. The second, *(218)*, with four electrons in the allyl system, should undergo normal concerted combination with 2 π-electron molecules, while the third, *(219)*, is an analogue of triplet carbene. These systems have not been extensively studied; it may be expected that their electronic structures, and consequently the courses of their reactions will vary as the backbone atoms, and attached substituents, are varied.

(217) (218) (219)

Brief mention may be made of the possibility of analogues of 1,3-dipolar additions, in which larger numbers of electrons are incorporated in the π system of the dipolar component. As speculative examples, the *cis* form *(220)* of a dimeric nitroso compound, the α-ketonitrones *(221)*, and the α-nitrosonitrones *(222)*, all contain 6 π-electron systems, and concerted combination with dienes is symmetry-allowed.

(220) (221) (222)

A special word of caution should be added in relation to 1,3-dipolar additions. There may well be instances of such reactions in which the complementary polar character of the reactants is sufficiently extreme as to favor two-step combination, proceeding through a relatively stable dipolar intermediate.



6.2. [2+2] Cycloadditions in the Photochemistry of the Cyclohexadienones and Cyclohexenones

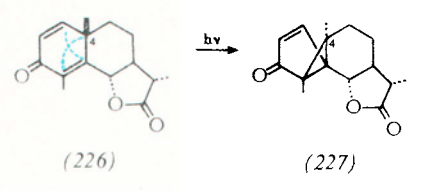
Following the pioneering work of *Barton*, *Jeger*, and their co-workers, the beautiful complexity of the photochemistry of cyclohexadienones and cyclohexenones has been most ably explored by *Chapman*, *Schaffner*, *Schuster*, *Zimmerman*, and their collaborators [105].

[103] *R. Huisgen*, Angew. Chem. *75*, 604 (1963); Angew. Chem. internat. Edit. *2*, 565 (1963); *R. Huisgen*, *R. Grashey*, and *J. Sauer*, in *S. Patai:* The Chemistry of Alkenes. Interscience, New York 1964, p. 739; *R. Huisgen*, Helv. chim. Acta *50*, 2421 (1967).

[104] *A. Eckell*, *R. Huisgen*, *R. Sustmann*, *G. Wallbillich*, *D. Grashey*, and *E. Spindler*, Chem. Ber. *100*, 2192 (1967).

[105] Two recent reviews serve as excellent guides to the elegant structural work accomplished. (a) *K. Schaffner*, Advances in Photochemistry *4*, 81 (1966); (b) *P. J. Kropp*, Organic Photochemistry *1*, 1 (1967).

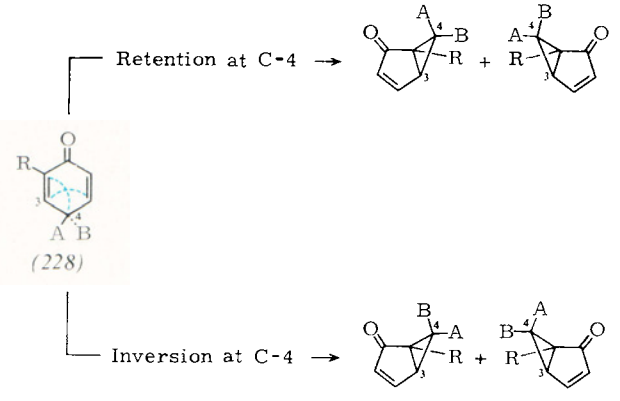
The primary isomerization processes which have been noted are of three types *(223)–(225)*.



It seems probable that all, and has been established that some, of these cases involve reactions proceeding through n,π* triplet states. It has also been clearly established that the quantum efficiency of the processes varies over a very wide range[109]. Detailed mechanisms have been proposed for these reactions[110]; the most elaborate and ingenious of these mechanisms is that suggested by *Zimmerman*[111].

We would like to examine the stereochemical constraints imposed by conservation of orbital symmetry on these transformations. These constraints are operative only if the reactions are concerted. We are aware of the elegant physical measurements which have been interpreted as supporting the proposed non-concerted mechanisms. But we regard it as worth while to stipulate the stereochemical imperatives associated with concerted paths from the starting materials to the observed products.

Formally, all of the reactions are $[\sigma 2+\pi 2]$ cycloadditions. If they are concerted changes within excited states, such cycloadditions must be $[\sigma 2_s+\pi 2_s]$ or $[\sigma 2_a+\pi 2_a]$ reactions.



In classes A and B suprafacial participation of double bond 2,3 is a stereochemical impossibility, since it leads to *trans* fused three- and five-membered rings. Consequently, these reactions must follow the $[\sigma 2_a+\pi 2_a]$ course, which requires antarafacial addition at double bond 2,3, and inversion at C-4. In class C the special constraint present in classes A and B is absent. Both $[\sigma 2_a+\pi 2_a]$ and $[\sigma 2_s+\pi 2_s]$ processes are feasible.

Antara addition at the double bond and inversion at the migrating saturated carbon atom is of course precisely what occurs in the classic conversion of santonin

(226) into lumisantonin *(227)*[112]. Unfortunately, in this case the alternative symmetry-forbidden change, taking place with retention at C-4, would lead to a sterically unlikely *trans* ring fusion; consequently, it might be argued that the observed path, though symmetry-allowed, would in any event be imposed by the geometry of the system.

The simplest labeling of the parent cyclohexadienone which would endow it with a center of chirality would also allow in principle a resolution of this question. Consider the consequences of retention or inversion at C-4 on such a chiral cyclohexadienone *(228)*[113]. Inversion or retention at C-4 can each be performed in

two distinct ways, depending on whether the addition at C-3 is on top or bottom. If A and B are different substituents these pathways become distinct, each with its own steric factors. It is thus likely that even a stereospecific process will yield two products in differing proportions. The products of inversion are diastereomeric, and enantiomeric to the products of retention. The actual course followed in the rearrangement of a simple chiral cyclohexadienone has not yet been determined,

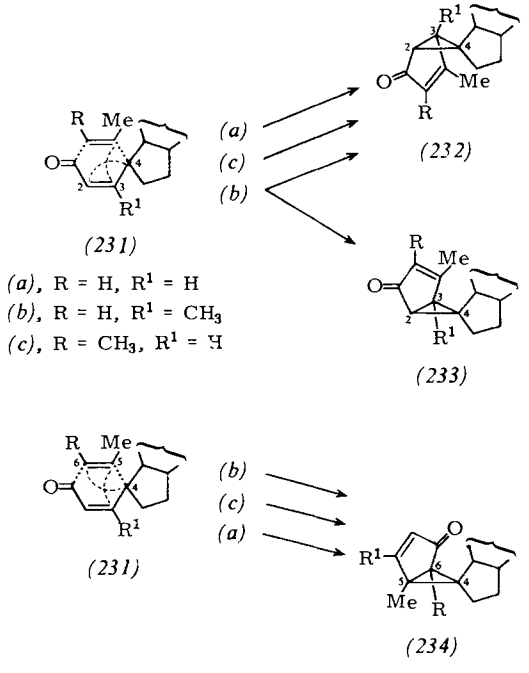
[113] Only the consequences of an addition on the double bond next to R are sketched. Of course the addition on the opposite side is feasible, and will double the number of possible products.

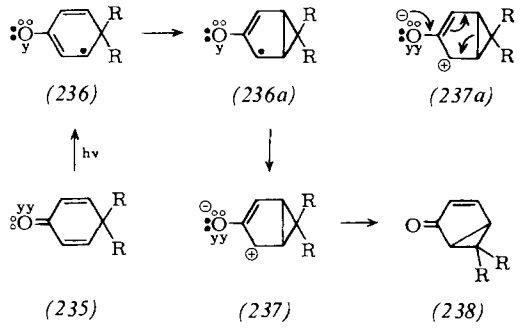


but is being studied by *Schuster*[114] who has independently recognized that the matter is one of great interest.

The versatile field of steroid derivatives appears already to have provided verifications of our predictions. The remarkably rich photochemistry of 1-dehydrotestosterone acetate and its methyl derivatives[115] begins with the now familiar conversion of a 2,5-cyclohexadienone *(229)* into a bicyclo[3.1.0]hexenone *(230)*, and thence to a new cyclohexadienone *(231)* of assigned

(229) *(230)* *(231)*

stereochemistry. On further photolysis *(231)* furnishes two or three isomers, depending on the pattern of substitution. The ingeniously assigned[115] structures of the products are shown in formulae *(232)–(234)*.

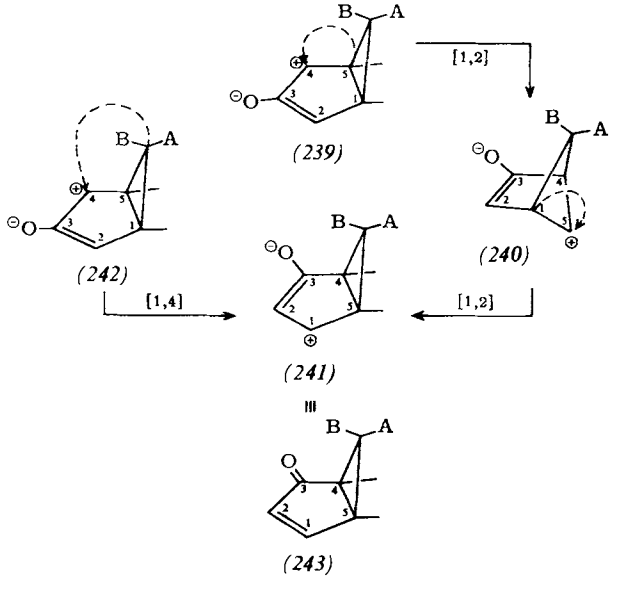


(231)

(a), R = H, R^1 = H
(b), R = H, R^1 = CH_3
(c), R = CH_3, R^1 = H

(232) *(233)* *(234)*

The molecules *(232)*, *(233)*, and *(234)* are all products of $[\pi 2_a + \sigma 2_a]$ processes, precisely as predicted from orbital symmetry considerations for concerted changes; it is especially to be noted that inversion must occur at C-4 during each of the photoisomerizations. For the substitution patterns *(a)* and *(c)* only one product *(232)* of the two which might result from symmetry-allowed changes involving the 2,3 double bond is observed. Similarly, only *(234)* is produced from *(a)* and *(c)* when the 5,6 double bond is implicated. In the case of *(b)*, three of the four possible products of symmetry-allowed processes have been isolated. Not one of the four products which might result from symmetry-forbidden or non-stereospecific processes has been found.

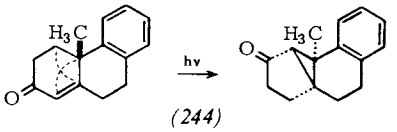


Unfortunately, the Zimmerman mechanism[111] for reactions of class A, illuminated with the insight afforded by orbital symmetry considerations, leads to precisely the same products which must be obtained in a concerted reaction. Formulae *(235)–(238)* show the basic mechanism suggested by *Zimmerman*[111].

(236) *(236a)* *(237a)*

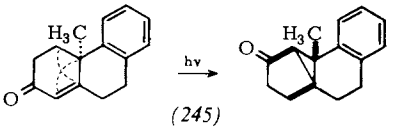
(235) *(237)* *(238)*

The final step, following bond reorganization [*(236)→(236a)*] (symmetry-allowed!) and demotion [*(236a)→(237)*] is formally a ground-state cyclopropylcarbinyl rearrangement; note that reversion of *(237)* to the original cyclohexadienone *(235)* [*cf.* arrows in *(237a)*] is symmetry-forbidden! There are actually two possibilities for the last step of this sequence. They are best described as [1,2n] sigmatropic shifts (*cf.* Section 7, below). The first process consists of two sequential [1,2] shifts [*(239)→(240)→(241)* ≡ *(243)*], while the second is a [1,4] rearrangement [*(242)→(241)* ≡ *(243)*]. Since [1,2] sigmatropic shifts must



(239) *(240)* *(242)* *(241)* *(243)*

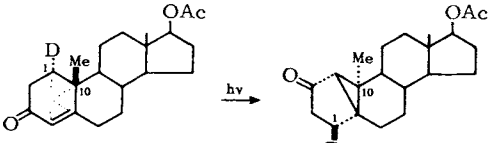
proceed with *retention*, but [1,4] shifts, if forced to be suprafacial, must proceed with *inversion* at the migrating carbon, it follows that the consequences of the two alternatives are stereochemically indistin-



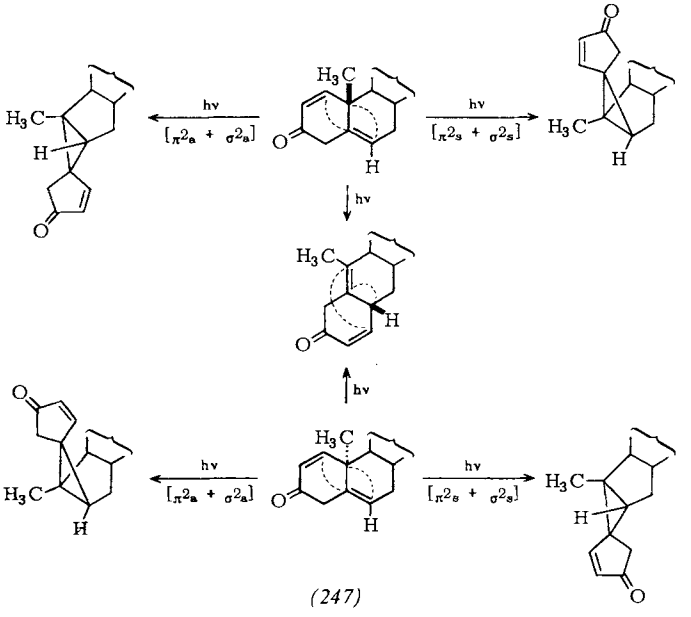
[114] *D. I. Schuster*, personal communication.

[115] *H. Dutler, M. Bosshard*, and *O. Jeger*, Helv. chim. Acta *40*, 494 (1957); *K. Weinberg, E. C. Utzinger, D. Arigoni*, and *O. Jeger*, *ibid. 43*, 236 (1960); *H. Dutler, C. Ganter, H. Ryf, E. C. Utzinger, K. Weinberg, K. Schaffner, D. Arigoni*, and *O. Jeger*, *ibid. 45*, 2346 (1962); *C. Ganter, F. Grzuter, D. Kägi, K. Schaffner*, and *O. Jeger*, *ibid. 47*, 627 (1964); *F. Frei, C. Ganter, D. Kägi, K. Kocsis, M. Miljković, A. Siewinski, R. Wenger, K. Schaffner*, and *O. Jeger*, *ibid. 49*, 1049 (1966).

guishable. Thus, for reactions of class A, either a totally concerted mechanism or a stepwise one involving concerted elements leads to the same stereochemical results. While the physical evidence adduced for the chronology proposed by *Zimmerman* is very impressive, we do not regard it as conclusive: either mechanism remains a possibility.



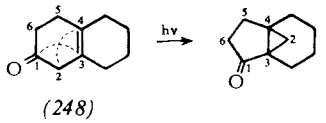
(244)



(245)

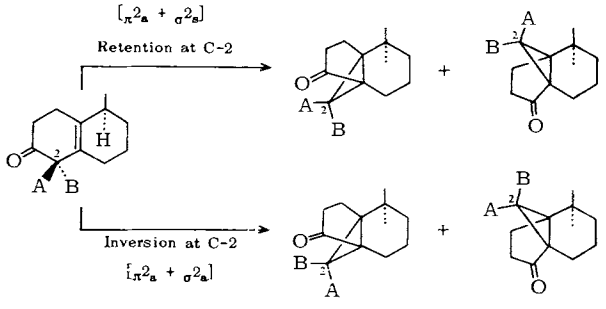
The photochemical rearrangement of cyclohexenones (the class B reactions) is a highly stereospecific process, and very probably follows a concerted course. Thus, *Chapman* found [116] retention of chirality in the reactions *(244)* and *(245)*.

(246)



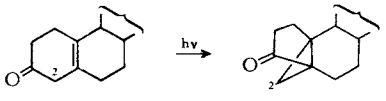
Belluš and *Schaffner* [117] studied the reaction with a very subtle probe; the isomerization of *(246)* proceeds with retention at C-1 and inversion at C-10. The inversion at C-10 is forced by the steric situation, but the retention at C-1 is not, and is clearly inconsistent with a radical fragmentation of the C(1)-C(10) bond.

(247)



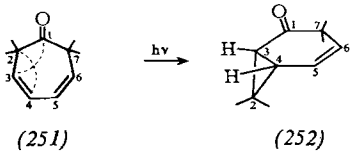
We turn now to reactions of class C. In this case there are no steric restraints operative against either the $[\pi 2_s+\sigma 2_s]$ or the $[\pi 2_a+\sigma 2_a]$ concerted processes. In the beautiful case *(247)* that has been studied [108] just the products predicted for the two allowed cycloadditions are found. But once again avoidance of *trans* fused rings would lead to the very same stereochemical consequences for stepwise processes.

There are two further photochemical transformations of enones which fall into the category of [2+2] cycloadditions. The first of these is an isomerization of a nonconjugated cyclohexenone *(248)* [118].



(248)

Formulae *(249)* show the consequences of the stereochemically feasible reactions *antara* on the double bond with options of retention or inversion at C-2.



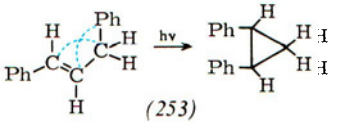
(249)

A steroidal derivative of this class has been photolyzed [118]. Of the two distinct possible products, only that one is produced whose cyclopropane ring is α-oriented *(250)*. Since labels are lacking at C-2, the primary question of retention or inversion is as yet unanswered. We predict that the reaction will be found to proceed with inversion at C-2. Similar circumstances obtain in the case of a further example *[(251)→(252)]* [119].

(250)

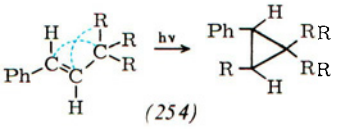
There appear to be a number of examples of photochemically induced $[\pi 2_a+\sigma 2_a]$ cycloadditions involving

(251) *(252)*



[116] *O. L. Chapman, J. B. Sieja,* and *W. J. Welstead, jr.*, J. Amer. chem. Soc. *88*, 161 (1966).

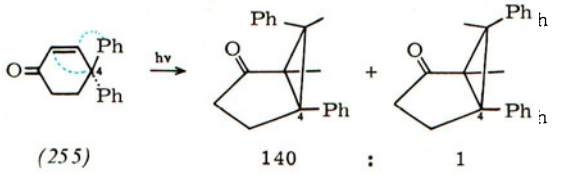
[117] *D. Belluš, D. R. Kearns,* and *K. Schaffner*, Helv. chim. Acta *52*, 971 (1969).



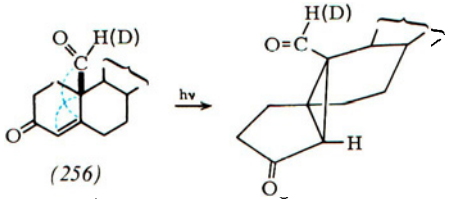
[118] *J. R. Williams* and *H. Ziffer*, Chem. Commun. *1967*, 194, 469; Tetrahedron *24*, 6725 (1968).

[119] *L. A. Paquette, R. F. Eizember,* and *O. Cox*, J. Amer. chem. Soc. *90*, 5153 (1968).

simple olefins and dienes. Thus, *Griffin* [120] observed unusual propylene→cyclopropane cyclizations accompanied by group migrations [*(253)*, *(254)*]. These could well be concerted transformations, but definitive stereochemical information is lacking.

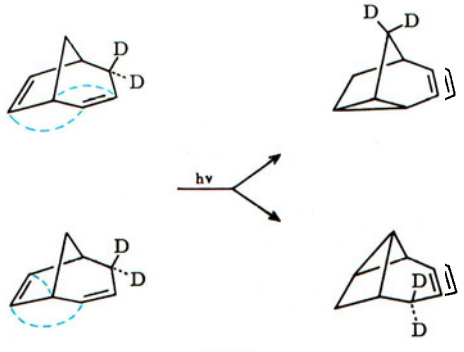


(253)



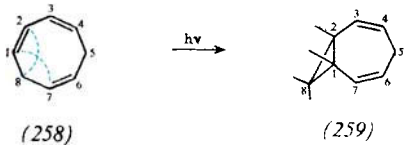
(254)

An instance of this type of reaction in which the stereochemical course has been established is available in the photolysis of 4,4-diphenylcyclohexenone *(255)* [121]. The predominant product is the result of an antarafacial addition on the double bond and inversion at C-4.



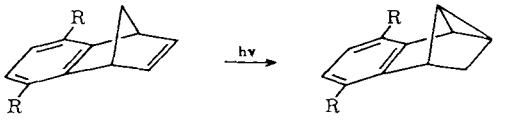
(255) 140 : 1

A probable further example of a $[\sigma 2_a + \pi 2_a]$ reaction has emerged in a recent study of the photolysis of 3,19-dioxo-4-androsten-17β-yl acetate *(256)* [122].



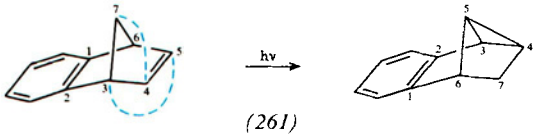
(256)

Still other possible $[\sigma 2_a + \pi 2_a]$ changes, constrained to proceed as such, are available in the case *(257)* studied by *Sauers* [123].

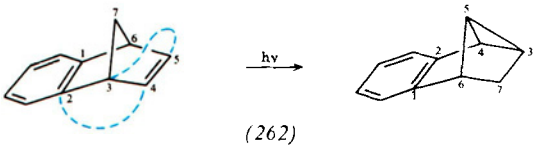


(257)

The formation of *(259)* on photolysis of cyclooctatriene *(258)* is also constrained to follow the $[\pi 2_a + \sigma 2_a]$ course, if concerted; it has been shown that the process occurs without a hydrogen shift [124].

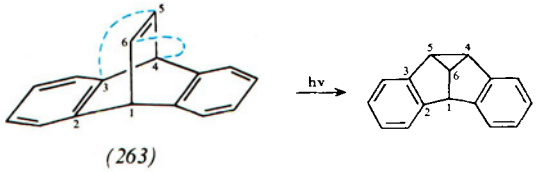


(258) *(259)*

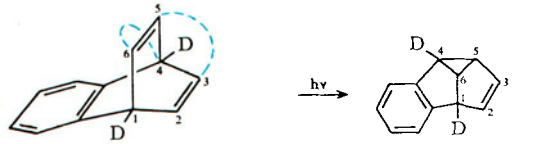


(260)

A related case *(260)* has been observed by *Edman* [125]. A concerted cycloaddition may involve either the σ bond at 3,7 *(261)* or that at 2,3 *(262)*. The concerted



(261)



(262)

nature of the reaction could be ascertained using a chiral reactant.

Still other reactions of this type are found in the conversion of a dibenzobicyclo[2.2.2]octatriene *(263)* to a dibenzosemibullvalene [126] and of a labeled benzobicyclo[2.2.2]octatriene *(264)* to a benzosemibullvalene [127]

We emphasize that neither of these cases need be concerted; indeed, there is evidence for a stepwise process in the corresponding reaction of the parent barrelene [128].

We must now examine the question of how a process shown to proceed through an excited triplet state of a molecule could possibly be concerted. We believe that orbital symmetry relationships dictate to a molecule in an excited state a certain set of motions, leading to reaction, which are facile, and another set of motions which are difficult. There is no necessity to reach the excited state of products. The symmetry-allowed motions are initiated in the excited state of the reactant. In their course they are accompanied by a radiationless transition to the ground-state of the product. While the physical rationale of such a transition is still lacking, the occurrence of such a process presents no more difficulty than does any other radiationless transition.

6.3. The [2+2+2] Cycloaddition Reaction

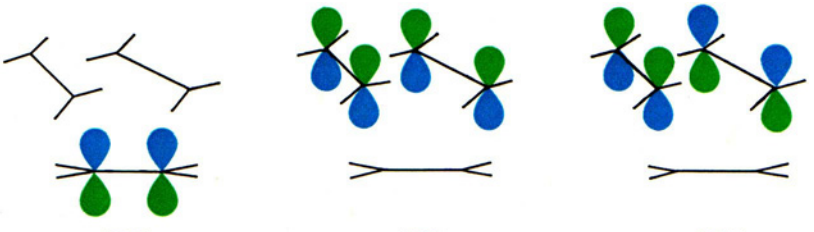
Further useful practice in the application of the principle of orbital symmetry conservation may be gained from a detailed consideration of the [2+2+2] concerted cycloaddition (or cycloreversion) reaction; the exercise is made the more valuable through the emergence from it of some new factors, and through the fact that it sets the stage for comparisons, in the sequel, which deepen our understanding of orbital symmetry conservation as a fundamental extension of our knowledge of the phenomenon of chemical bonding.

(265) (266) (267)

Let us consider the decomposition of cyclohexane, through a boat-shaped transition state, into three molecules of ethylene. First, we assign six electrons – those involved in the bonds to be broken – in pairs, to the generalized σ orbitals *(265)*, *(266)*, and *(267)* [*cf.* Section 3.1]. Note that the only symmetry element imposed by the geometry of the system is the mirror plane *m*, and that the orbitals shown are, as required, either symmetric or antisymmetric with respect to that element. *It is of especial importance in this case to observe the fundamental principle that unsymmetrical molecular orbitals are not permissible:* thus, the orbital *(268)* is not real, and must be expunged by addition to its equally unreal conjugate *(269)*. It is also worthy of

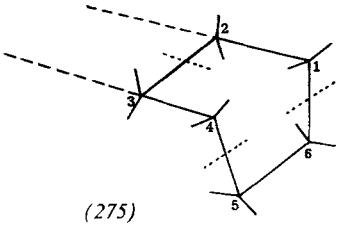
(268) (269)

note that the orbitals *(267)* and *(265)* may be replaced by their sum *(270)* and difference *(271)*, with no change in any conclusion which may be discovered from their use; but in general the most obviously informative practice is to make use of those designations



(270) (271)

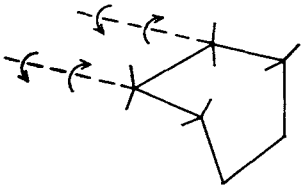
which most explicitly reveal the largest extent of delocalization in the generalized molecular orbitals – in this case *(265)* and *(267)*, rather than *(270)* and *(271)*. In any event, no other acceptable orbitals are available for the case at hand, and it is important to realize that in consequence there is no element either of arbitrariness or of ambiguity in the conclusions we shall reach.



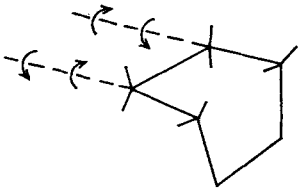
We next note that the six electrons in the π orbitals of the product ethylene molecules must be assigned to the generalized molecular orbitals *(272)*–*(274)*.

One further, and very important, factor must now be recognized. The geometrical relationships among starting material and products, as revealed by inspection of *(275)*, require that in the course of reaction, rotations about the axes 1,2 and 3,4 must take place, in such wise as to bring the substituent groups at C-1 and C-2 on the one hand, and those at C-3 and C-4 on the other, into the common planes in which they lie in the respective product ethylene molecules. *A priori*, on purely geometrical grounds, these displacements might be *conrotatory (276)* or *disrotatory (277)*, and there are, of

(272) (273) (274)



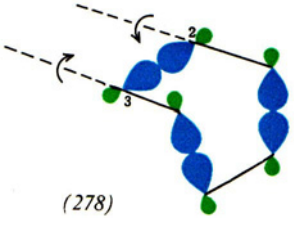
[128] *H. E. Zimmerman, R. W. Binkley, R. S. Givens,* and *M. A. Sherwin,* J. Amer. chem. Soc. *89*, 3932 (1967).



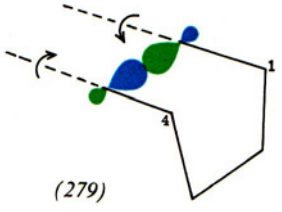
(275)

course, in each case two possibilities [arrows in *(276)* and *(277)*].

Now we are properly prepared to annihilate our cyclohexane molecule. We shall see that there are *two*,



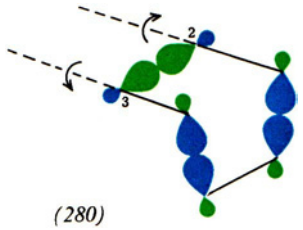
(276)



(277)

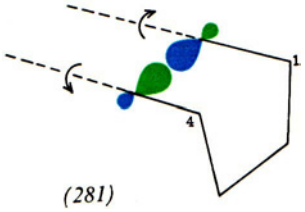
and only two, symmetry-allowed ways in which this decomposition may occur – given the transition state geometry we have chosen.

1. Let us first permit the two electrons in orbital *(265)* to enter orbital *(272)*, as of course they may do with conservation of orbital symmetry. It is then at once clear that the two electrons in orbital *(267)* must occupy orbital *(278)* of the product array – *and that of the rotational displacements adumbrated above, the inward disrotatory one (278)* must obtain. It remains only to place the remaining σ pair – those in the orbital *(266)*



(278)

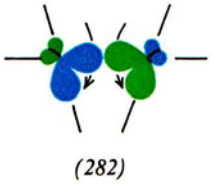
(279)



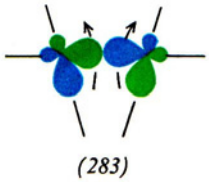
at the outset of reaction – into orbital *(274)* of the product assemblage; a special point here is that mixing of the occupied orbital *(266)* with the unoccupied antibonding backbone σ* orbital *(279)* is consistent with the same inward disrotatory motion about axes 1,2 and 3,4. The symmetry-allowed process which we have now depicted in full detail may be designated a $-[\pi 2_s+\pi 2_s+\pi 2_s]$ cycloreversion reaction. Naturally, a precisely analogous analysis applies to the reverse process – the symmetry-allowed $[\pi 2_s+\pi 2_s+\pi 2_s]$ cycloaddition reaction.

2. Alternatively, let us first permit the two electrons in orbital *(267)* to take up new positions in orbital *(272)* as cycloreversion proceeds Now those in orbital *(265)* have no choice but to enter orbital *(273)* of the product array. And, in sharp contrast to the case discussed above, the cleavage of the backbone bond (2,3) must be accompanied by *outward* disrotatory displacements *(280)*. As before, the remaining pair, occupying orbital

(280)



(266), takes up new positions in orbital *(274)*, and, as before, mixing of *(266)* with the unoccupied antibonding backbone σ* orbital *(281)* is consistent with the outward disrotatory motion required by the symmetry relationships between orbitals *(280)* and *(274)*. The process here delineated may be designated a symme-



(281)

try-allowed $-[\pi 2_s+\pi 2_a+\pi 2_a]$ cycloreversion reaction; it is the reverse of the allowed $[\pi 2_s+\pi 2_a+\pi 2_a]$ cycloaddition reaction.

Thus, we have found that there are two possible symmetry-allowed [2+2+2] cyclic processes which proceed through a transition state possessing a single plane of symmetry. Structural, steric, and entropy factors may favor one or the other of these paths in various special circumstances. Is one or the other favored by inherent stereoelectronic factors not so far delineated? Indeed, when one considers in greater detail the mixing of the antisymmetric bonding orbital *(266)* with the antisymmetric antibonding orbital *(279)* [or *(281)*], it is found that the *s*, *s*, *s* process is favored over the alternative *s*, *a*, *a* path. Thus, the dihedral angle between the relevant orbitals at the outset of reaction is represented in plan in *(282)* and *(283)*. The geometry of the alternatives indicates clearly that favorable, energy-lowering overlap will develop more readily from the motions depicted in *(282)*, and that the ascent to the transition state

(282)

(283)

will be considerably steeper for the *s*, *a*, *a* process of *(283)* [128a].

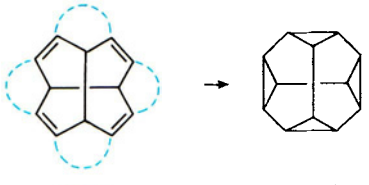
Several facets of the [2+2+2] reactions deserve further, if now briefer, consideration. The reader may wish to sharpen his apprehension of symmetry considerations through verifying for himself the propositions which follow:

a) There is a continuum of topologically equivalent symmetry-allowed thermal $[\pi 2_s+\pi 2_s+\pi 2_s]$ processes, whose transition states vary from that depicted above to one whose geometry resembles that of a chair cyclohexane ring.

b) There are two further symmetry-allowed thermal $[\pi 2_s+\pi 2_a+\pi 2_a]$ processes, topologically different from the one described above, which proceed through enantiomeric transition states possessing a two-fold axis of symmetry.

c) There are *no* symmetry-allowed thermal $[\pi 2_s+\pi 2_s+\pi 2_a]$ processes.

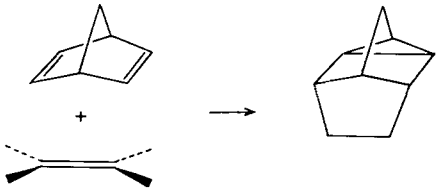
d) There are *no* symmetry-allowed thermal $[\pi 2_a+\pi 2_a+\pi 2_a]$ processes.



e) For reactions involving occupied antibonding levels – for example, reactions of molecules in photochemically excited states – there are no *s*, *s*, *s* or *s*, *a*, *a* symmetry-allowed [2+2+2] processes, but there are two allowed enantiomeric *s*, *s*, *a*, as well as two permitted, and also enantiomeric, *a*, *a*, *a* paths.

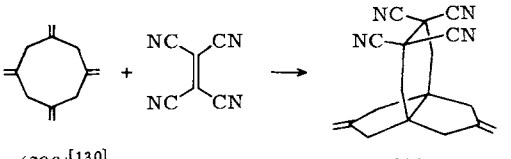
f) Every all-*antara* [2+2+2+. . .] combination is symmetry-forbidden in ground states, and symmetry-allowed for excited states in which the antibonding orbital of one participating ethylene unit is occupied.

Lest any might cavil at the discussion of processes which on casual consideration could appear to be so improbable of realization as only to merit summary dismissal, we may allude to the essentially strain-free, as yet unknown, molecules *(284)* and *(286)*, whose double bonds are so constrained by the frameworks in which they are embedded as to favor photochemical conversion to *(285)* and *(287)*, by the all-*antara* paths mentioned above.



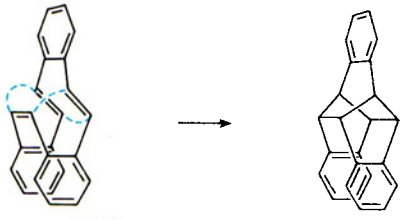
(284) *(285)*

(286) *(287)*

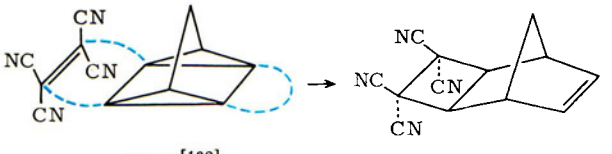


[128a] Since the above was written, this prediction has received elegant experimental confirmation: *J. A. Berson* and *S. S. Olin*, J. Amer. chem. Soc. *91*, 777 (1969).

It remains to exemplify some of the above processes through presentation of selected known cases. Most of those so far discovered fall in the symmetry-allowed thermal *s*, *s*, *s* class. Perhaps best known is the addition of olefins to bicycloheptadiene [129] [*(288)*→*(289)*].

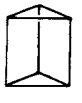


(288) *(289)*



Further examples in this group are the reactions *(290)*→*(291)*, *(292)*→*(293)*, and *(294)*→*(295)*.

(290) [130] *(291)*



(292) [131] *(293)*

(294) [132] *(295)*

To what does this fantastic molecule *(296)* owe its capacity to survive? In it there is stored at least ninety kilocalories of energy more than is contained in its iso-

(296)

mer benzene[133]; a graceful process of atomic displacements may readily be envisaged for the conversion of the one molecule into the other [*cf. (297)→(298)*]. Yet, no less than a further thirty-three

(297) *(298)*

kilocalories must be added to the already exorbitantly strained hexamethylprismane molecule in order to bring about its conversion to hexamethylbenzene[133]. To the mind uninformed by an appreciation of the limitations placed upon bond-breaking and bond-making processes by orbital symmetry relationships, the excess energy of the prismane molecule must have the aspect of an angry tiger unable to break out of a paper cage.

When we examine this situation in detail from the vantage point of the principle of orbital symmetry conservation, we shall see that there is no paper cage, but rather one quite properly barred to contain its tiger. First, we must construct the generalized molecular orbitals *(299)* into which must be placed the six electrons

(299)

of the three σ bonds which must be broken if prismane is to be converted to benzene.

Now, let us break the three σ bonds, *while conserving the symmetry imposed upon the orbitals of the prismane molecule by its geometry*; note that σ_2 and σ_2^*, of like symmetry, interact to produce a new pair, represented by the sum and the difference of the originals. The specified changes are shown in Figure 27.

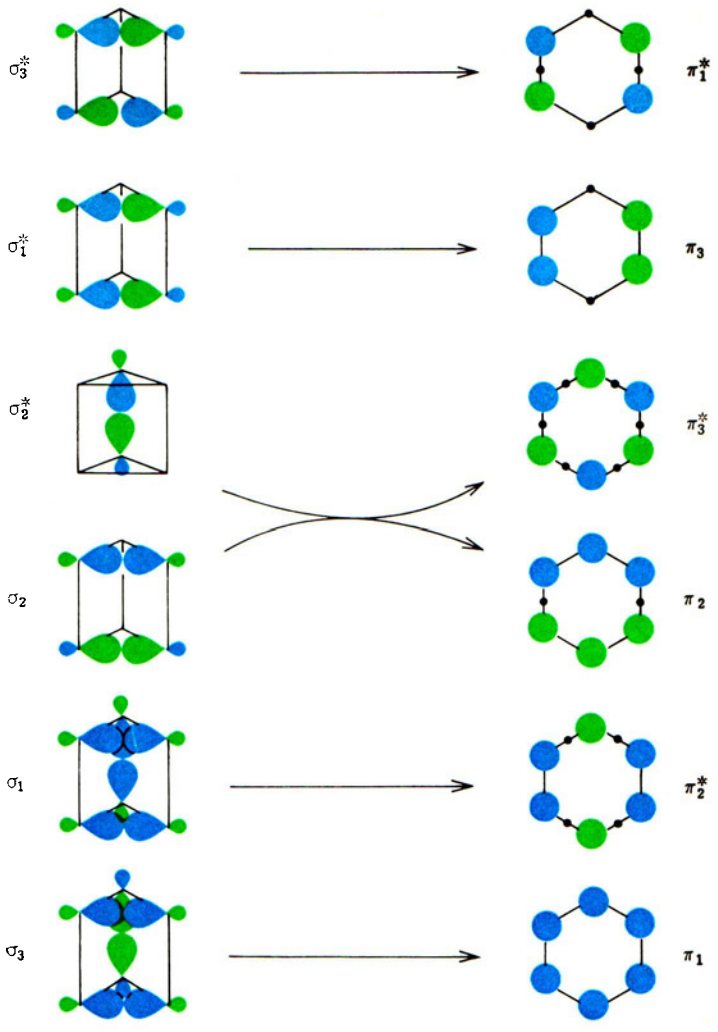

Figure 27. Formation of the π orbitals of benzene from σ orbitals of prismane.

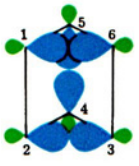
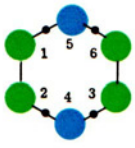
What are the new orbitals thus generated? They are precisely the molecular orbitals of the benzene molecule. But while two of the bonding σ orbitals of prismane (σ_2 and σ_3) have transformed into two bonding orbitals of benzene (π_2 and π_1), *the third becomes an antibonding orbital of the product* ($\sigma_1 \rightarrow \pi_2^*$). Physically, this correlation introduces an antibonding, energy-raising component into the transition state for the transformation. It is that component which makes the transformation of prismane into benzene symmetry-forbidden, and permits the former to exist.



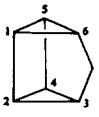
Further insight into the basic nature of symmetry-determined bonding relationships can be gained by amplifying our discussion of prismane in a number of ways. First, let us note that, in a formal sense, the transformation of prismane into benzene might be regarded as a $-[\pi 2_s + \pi 2_a + \pi 2_a]$ cycloreversion reaction [*(300)→(301)*]. We have seen in the preceding section that thermal reactions of that class are symmetry-allowed. What then excludes the prismane→benzene



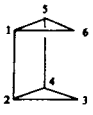
(300) *(301)*

[133] *J. F. M. Oth*, Angew. Chem. *80*, 633 (1968); Angew. Chem. internat. Edit. *7*, 646 (1968); Rec. Trav. chim. Pays-Bas *87*, 1185 (1968).

transformation from the symmetry-allowed class to which it might formally be assigned on casual inspection? When we scrutinize the offending bonding-antibonding correlation of the orbitals σ_1 *(302)* and π_2^* *(303)*, we see at once that it is the development of nodal, antibonding, energy-raising relationships at the 1,5, 5,6 , 2,4 , and 3,4 bonds, necessitated by the presence of the invariant framework σ bonds in the prismane molecule, which differentiates the prismane→benzene



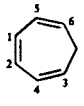
(302)



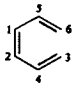
(303)

transformation from the general [2+2+2] cycloreversion reaction. When, as in the latter, those σ bonds are absent, these antibonding, energy-raising components are also absent.

The point may be illustrated further by considering certain molecules closely related to prismane. Consider first quadricyclene *(304)* and the tricyclohexane *(305)*.

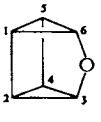


(304)

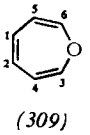


(305)

These molecules might at first sight be expected to be susceptible of symmetry-allowed transformation to cycloheptatriene *(306)* and hexatriene *(307)*, but analysis along the lines set down above shows that, as in the case of prismane, the presence of the framework σ bonds places the changes in the symmetry-forbidden category. It is worthy of note that, in fact, quadricyclene is not converted to cycloheptatriene, even at very high

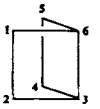


(306)



(307)

temperatures [134]. In that light, the oxygen analogue *(308)* is of special interest. In this case, the product of a $-[\pi 2_s+\pi 2_a+\pi 2_a]$ cycloreversion is oxepine *(309)*, and the orbital correlation analogous to that which leads in the other cases to an antibonding level, gives now the highest occupied ground-state level, which is probably weakly bonding. It is gratifying to note that derivatives of the oxa analogue are smoothly transformed to oxepines when heated [135,136].



(308)

(309)

Another relative of the prismane molecule is the bicyclo[2.2.0]hexane *(310)*. In this case, lacking as it does σ

(310)

(311)

bonds joining C-1 to C-5, and C-2 to C-4, no offensive nodes develop as the transition state for $-[\pi 2_s+\pi 2_a+\pi 2_a]$ cycloreversion is approached; consequently, the thermal transformation of *(310)* to ethylene and butadiene *(311)* is symmetry-allowed. In fact, it has not as yet been observed. When the unsubstituted bicyclohexane

(312)

(313)

itself is heated, it is converted to 1,5-hexadiene *(312)* [137] – either by a two-step mechanism involving an intermediate *(313)*, or by a symmetry-allowed $[\sigma 2_s+\sigma 2_a]$ path.

6.5. [2+2+2+2] Cycloadditions

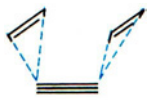
The $[\pi 2+\pi 2+\pi 2+\pi 2]$ cycloaddition reaction is symmetry-allowed:

a) For ground state reactants, when an *odd* number of components is involved in a suprafacial manner.

b) For reactions in which one component is in an excited state, when an *even* number of components is involved in a suprafacial manner.

Obviously, entropy factors render polymolecular reactions of this type very highly improbable. Just as obviously, this difficulty can be surmounted by the manoeuvre of building all the components into a single molecule, geometrically prepared for their eventual dispersal. Such examples have already been mentioned above [*(284)* and *(286)*].

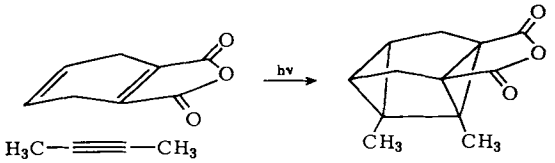
Symmetry-allowed many-component fragmentations are also opposed by a special factor; for each σ bond which is transformed into a π bond an endothermicity of some twenty kilocalories must be expected.



There are instances of $[\pi 2+\pi 2+\pi 2+\pi 2]$ cycloadditions masquerading as other processes. Consider for exam-

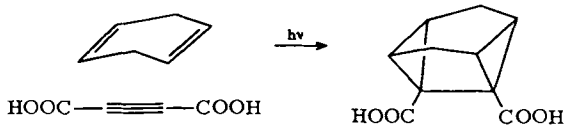
[134] *H. Prinzbach* and *J. Rivier*, Tetrahedron Letters *1967*, 3713.

[135] *H. Prinzbach, M. Argüelles*, and *E. Druckrey*, Angew. Chem. *78*, 1057 (1966); Angew. Chem. internat. Edit. *5*, 1039 (1966).



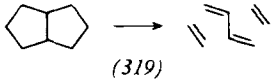
[136] *H. Prinzbach, P. Vogel*, and *W. Auge*, Chimia *21*, 469 (1967).

[137] *C. Steel, R. Zand, P. Hurwitz*, and *S. G. Cohen*, J. Amer. chem. Soc. *86*, 679 (1964).



(314)

ple the double cycloaddition of an acetylene to two ethylenes *(314)*. Examination of the orbitals reveals that the two acetylene π bonds are acting independently. At least two such reactions [*(315)→(316)* and *(317)→(318)*] have been observed [138,139].



(315) (316)

(317) (318)

An amusing fragmentation would be the reaction *(319)*; the analogous decomposition of pentalene to di-

(319)

acetylene and two acetylenes has been suggested in the literature as a theoretical possibility [140]; we now recognize this to be a symmetry-forbidden thermal process.

We defined as a sigmatropic change of order [i,j] the migration of a σ bond, flanked by one or more π electron systems, to a new position whose termini are $i-1$ and $j-1$ atoms removed from the original bonded loci, in an uncatalyzed intramolecular process. Thus, the well-known Claisen and Cope rearrangements are sigmatropic changes of order [3,3].

A priori, there are two topologically distinct ways of effecting a sigmatropic migration. These are illustrated in Figure 28 for the [1,5] shifts of a hydrogen atom. In the first, *suprafacial* process, the transferred hydrogen atom is associated at all times with the same face of the π system. In the second, *antarafacial* process, the migrating atom is passed from the top face of one carbon terminus to the bottom face of the other.

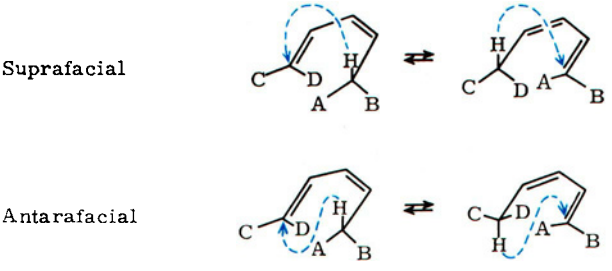


Figure 28. Suprafacial and antarafacial [1,5] shifts of a hydrogen atom.

For the analysis of these reactions correlation diagrams are not relevant since it is only the transition state and not the reactants or products which may possess molecular symmetry elements. We shall present several equivalent methods for analyzing these reactions.

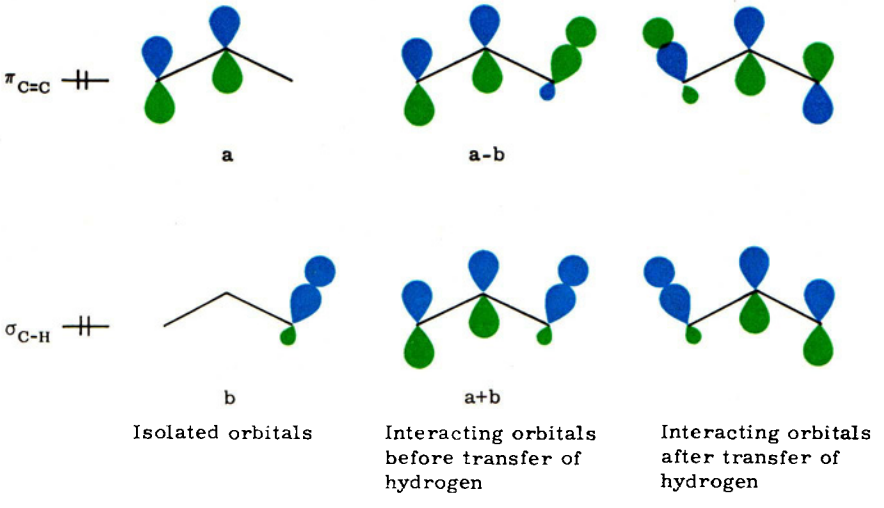

Figure 29. Conservation of orbital symmetry in a suprafacial [1,3] hydrogen shift.

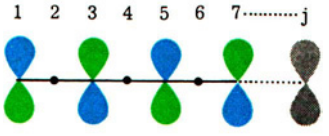
1. The use of the principle of *conservation of orbital symmetry* is here illustrated for the case of a supra-

[138] *R. Askani*, Chem. Ber. *98*, 3618 (1965).

[139] *M. Takahashi, Y. Kitahara, I. Murata, T. Nitta*, and *M. C. Woods*, Tetrahedron Letters *1968*, 3387.



[140] *H. C. Longuet-Higgins* in: Theoretical Organic Chemistry. The Kekulé Symposium. Butterworths, London 1959, p. 17.

facial [1,3] hydrogen shift. The relevant correlations are shown in Figure 29. Clearly, two electrons can enter a bonding orbital, either σ or π, of the product, but the other two must be placed either in a σ^* or a π^* orbital, if orbital symmetry is to be conserved. *The reaction is symmetry-forbidden.*

2. In the [1,j] sigmatropic migration of hydrogen within an all-*cis*-polyene framework [*(320)*→*(321)*], one may envisage the transition state as made up by the combination of the orbital of a hydrogen atom with those of a radical containing $2k+3$ π electrons. The highest oc-

$$\underset{(320)}{R_2\overset{1}{C}=\overset{2}{C}H\text{-}(CH=CH)_k\text{-}\overset{j}{C}HR_2} \rightarrow \underset{(321)}{R_2\overset{1}{C}H\text{-}(CH=CH)_k\text{-}CH=CR_2}$$

cupied orbital of the framework system is the nonbonding allylic orbital which possesses the symmetry shown in *(322)*. Consider a hydrogen atom bonding to

(322)

the termini of such systems. In order to avoid a high energy orbital in the transition state, it is required that positive overlap between the framework orbital and the migrating hydrogen orbital be maintained. The result is symmetry-allowed suprafacial migration for odd k, while the antarafacial path must be followed for even k.

3. Let us now examine the transition state from a different, but equivalent, viewpoint. First, we write down an explicit three-center bond involving the termini of the carbon chain and the migrating hydrogen atom. The three-center bond has the typical level pattern indicated in Figure 30. There remains a $2k+1$ π orbital system in the carbon chain. The molecular orbitals of

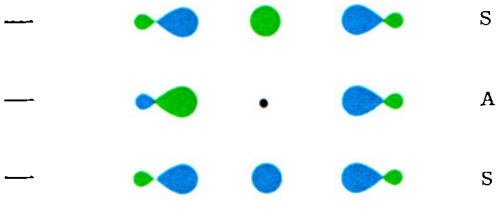


Figure 30. Orbital relationship in a three-center bond. Note that the symmetry labels are invariant whether a mirror plane or a two-fold axis of rotation is used as the basis for classification.

this remnant are next classified with respect to the symmetry element (two-fold axis or mirror plane) present in the transition state. There now arise two cases, differing in the symmetry of the nonbonding orbital of the remnant. In the first case (Figure 31) this orbital is antisymmetric and interacts strongly with the central orbital of the three-center bond. In the second case (Figure 32) the remnant orbital is symmetric and cannot interact in a similar way. The presence of the interaction

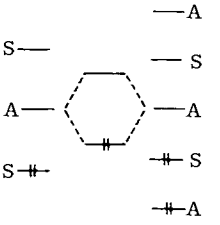

Figure 31. Interaction of nonbonding antisymmetric levels of three-center bond and remnant, for the antarafacial [1,7] shift of a hydrogen atom ($k = 2$).

typically stabilizes one level, and destabilizes the other. Now, since there are in all $2k+4$ electrons to be accommodated $-2k$ electrons in bonding polyenyl levels, and

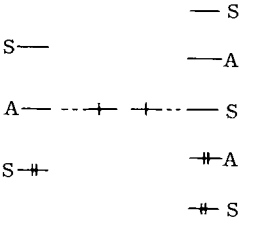

Figure 32. Noninteraction of nonbonding levels of three-center bond and remnant, for the suprafacial [1,7] shift of a hydrogen atom ($k = 2$).

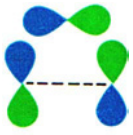
2 in the lowest orbital of the three-center bond – there remain 2 electrons to be placed in the lower component of this interacting pair. It follows that for the ground-state reaction, the first case is symmetry-allowed. Thus, in general, in order that the nonbonding orbital of the $(2k+1)$-orbital remnant π system shall be antisymmetric under the appropriate symmetry operation, these reactions must proceed through a transition state having a mirror plane when k is odd, or one having a two-fold axis when k is even.

For excited-state reactions, as in the cases of electrocyclic reactions and cycloadditions, the selection rules are precisely reversed, as compared with those for ground states.



For sigmatropic changes of order [i,j] in which both i and j are greater than 1, the migrating group of the above analyses consists of more than one atom, and appropriate topological distinctions must be made in

$i+j$	Ground State	Excited State
$4q$	antara-supra supra-antara	supra-supra antara-antara
$4q+2$	supra-supra antara-antara	antara-supra supra-antara

Figure 33. Selection rules for sigmatropic reactions of order [i,j] with i and $j > 1$.

relation to *both* π systems through which the σ bond is moving. The selection rules are summarized in Figure 33.

In the above treatment of [1,j] sigmatropic changes, we have considered only those cases in which a σ orbital of the migrating group interacts with a π system in the transition state, and migration occurs *with retention of configuration at the shifting site*. When the migrating group possesses an accessible π orbital and is not so substituted as to create an impossible steric situation in the transition state, alternative processes using that π orbital must be considered. Clearly, such changes *must proceed with inversion at the migrating center* [*cf. (323)*], and the selection rules are precisely reversed from those given in Figure 33.

(323)

A number of special points pertinent to sigmatropic changes should be noted.

a) Antarafacial processes are obviously impossible for transformations which occur within small or medium-sized rings.

b) Distortion of the carbon framework, with concomitant impairment of coupling within the π system, may render a symmetry-allowed process difficult or impossible of realization; for example, this factor makes the antarafacial process difficult or perhaps impossible in the [1,3] case, but is not an impediment for the [1,7] reaction.

c) A cyclopropane ring may replace a π bond in the framework system for a sigmatropic change.

d) Orbital symmetry arguments are applicable to sigmatropic changes within ionic species. Thus, the suprafacial [1,2] shift within a carbonium ion is symmetry-allowed and is very well known. The predicted [1,4] shift with inversion of the migrating group, within a but-2-en-1-yl cation has recently been observed. We may expect that the [1,6] shift within a hexa-2,4-dien-1-yl cation will take place through a readily accessible suprafacial transition state.

It remains to point out that the insights afforded by the discussions presented in the preceding sections allow us to view sigmatropic changes as cycloaddition reactions. Thus, the [1,3] sigmatropic process *(324)*→*(325)*

(324) *(325)*

is a $[\sigma 2+\pi 2]$ reaction, and the [3,3] sigmatropic rearrangement *(326)*→*(327)* is a $[\pi 2+\sigma 2+\pi 2]$ concerted cycloaddition.

(326) *(327)*

From this standpoint, let us now examine in detail the stereochemical aspects of the [1,3] sigmatropic change. We know that the symmetry-allowed processes must fall in either the $[\sigma 2_s+\pi 2_a]$ or the $[\sigma 2_a+\pi 2_s]$ class. All of the possibilities are shown in Figure 34. It is at once apparent that the first two alternatives depicted in Figure 34 are simply different ways of regarding one and the same physical process. Consequently, the analysis yields, as it must, precisely the conclusions reached in our prior discussions of sigmatropic reactions.

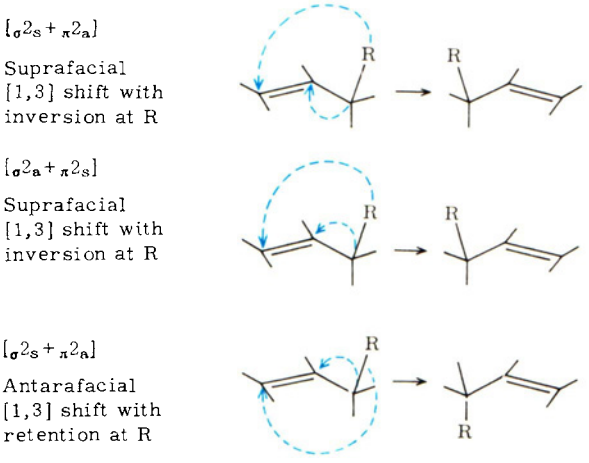


Figure 34. Stereochemical possibilities in sigmatropic [1,3] shifts.

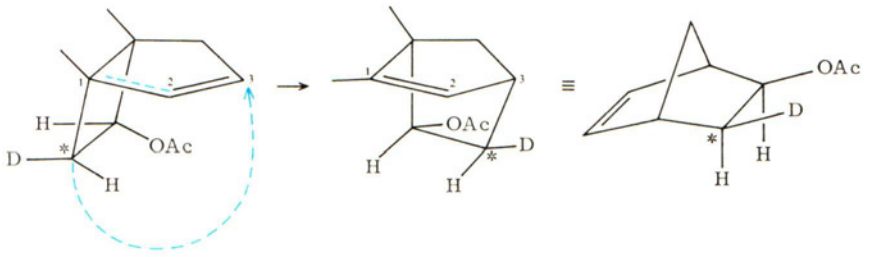
7.1. Sigmatropic Reactions Exemplified

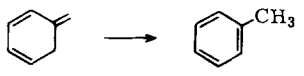
Few thermal uncatalyzed [1,3] shifts are known [141]. Those which formally might be considered in this category, such as the vinylcyclopropane→cyclopentene rearrangement, proceed with such high activation energies (*ca.* 50 kcal/mole) that the energy surface for concerted reaction cannot be far removed from that for alternative stepwise processes. None the less, *Berson* and *Nelson* [142] recently made the dramatic observation that *(328)* undergoes a concerted symmetry-allowed suprafacial [1,3] shift, *with inversion at the migrating center* [starred in *(328)*], to give *(329)*, at 307 °C.



The triene *(330)* owes its relative stability [143] to the requirement of a symmetry-forbidden [1,3] shift for an uncatalyzed rearrangement to toluene.

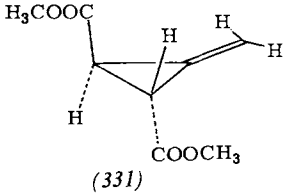
---

[141] For example, [1-^{14}C]-propylene does not rearrange to [3-^{14}C]-propylene: *B. Sublett* and *N. S. Bowman*, J. org. Chem. *26*, 2594 (1961).



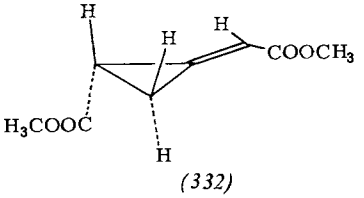
[142] *J. A. Berson* and *G. L. Nelson*, J. Amer. chem. Soc. *89*, 5303 (1967); *J. A. Berson*, Accounts Chem. Res. *1*, 152 (1968).

[143] *W. J. Bailey* and *R. A. Baylouny*, J. org. Chem. *27*, 3476 (1962).

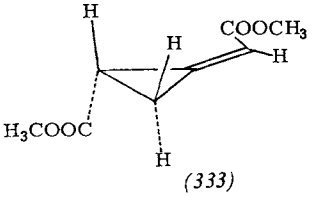


(328) (329)

The rearrangement of the ester *(331)* of Feist's acid is an especially interesting [1,3] sigmatropic transformation. Studies on the optically active substance have demonstrated that the reaction occurs with high stereospecificity [144]. Of the two *a priori* possible symmetry-allowed skeletal processes – [1,3] suprafacial migration with inversion at the migrating atom, and [1,3] antarafacial shift with retention – the latter is rendered inaccessible by the constraints imposed by the σ skeleton.

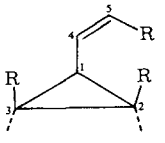


(330)

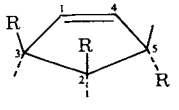


Since substituents are present, the allowed and accessible process may be realized in two electronically identical, but sterically different, ways. Consequently, we may predict that *(331)* must be transformed into *(332)* and/or *(333)*; the evidence is now conclusive [144] that the two isomers actually produced are the predicted ones.

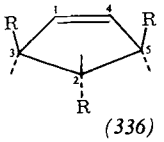
(331)



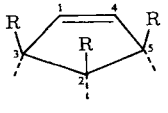
(332)



(333)



We have mentioned above that the activation energy for the vinylcyclopropane→cyclopentene conversion [145,146] is *ca.* 50 kcal/mole [146]. The bond-breaking process in cyclopropane itself requires an activation energy of 63 kcal/mole [147]; allylic stabilization has been estimated at *ca.* 13 kcal/mole [148]. Consequently, if full use be made of the available allylic stabilization energy in a diradical intermediate, a two step, non-concerted path for the conversion of vinylcyclopropane to cyclopentene is not thermodynamically unreasonable. Some preliminary studies have yielded results consistent with such a mechanism [149]. Nevertheless, in view of the recently established occurrence of symmetry-allowed concerted processes, despite extraordinarily unfavorable geometric constraints, it is worth while to consider the stereochemical consequences of the possible concerted processes for the vinylcyclopropane→cyclopentene change. Consider the maximally labeled derivative *(334)*; the symmetry-allowed reactions are:



(334)

(335)

(336)

(337)

a) an antarafacial [1,3] shift of bond 1,2 to C-5, with retention at C-2, leading to *(335)*;

b) a suprafacial [1,3] shift of bond 1,2 to C-5, with inversion at C-2, leading to *(336)*.

The isomer *(337)* cannot be produced in a symmetry-allowed process.

Photochemical [1,3] rearrangements, symmetry-allowed as suprafacial shifts, have been observed in a large number of cases [150].

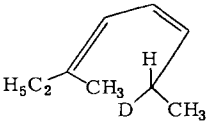
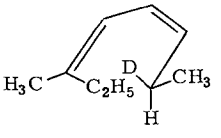
Specific thermal [1,5] shifts have been observed in a great number of cases [151]. The simplest case of a [1,5] shift in a 1,3-pentadiene was studied by *Roth* and *König* [152]. They compared the rearrangements of *(338)* and *(339)*, and observed a large kinetic isotope

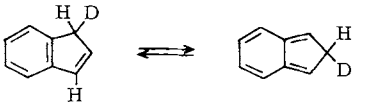


(338) *(339)*



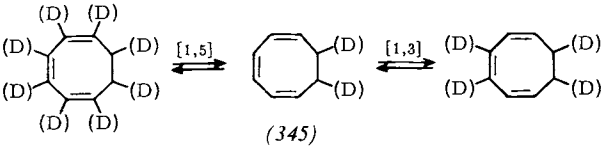
effect of 12.2 at 25 °C, consistent with a highly symmetrical transition state in a concerted process. The activation energy for the rearrangement is in the neighborhood of 35 kcal/mole. Direct confirmation of the concerted, suprafacial character of the [1,5] sigmatropic shift of a hydrogen atom has been most elegantly provided by the same investigators [153], who demonstrated the completely stereospecific conversion of *(340)* into *(341)* and *(342)*.

(340)



(341)

(342)



Numerous sequential stereospecific [1,5] shifts have been observed in cyclopentadienes and cycloheptatrienes [154–156].

Roth has beautifully shown the absolute preference for [1,5] over [1,3] shifts in cyclic systems. Thus, a [1,5] shift scrambles the deuterium label in *(343)* over all nonaromatic positions at elevated temperatures [155], despite the necessity of proceeding through the unstable isoindene *(344)*. In sharp contrast, the base-catalyzed reaction proceeds with a stereospecific [1,3] shift [157].

(343) *(344)*

Still another test for the possible occurrence of a thermal [1,3] shift proved negative [158]. The 7,8 dideuterium labeled cycloocta-1,3,5-triene *(345)*, through a series of reversible [1,3] sigmatropic shifts, involving the isomeric cycloocta-1,3,6-triene, would distribute the label statistically over all ring positions. On the other hand, a sequence of [1,5] shifts would place the label in positions 3, 4, 7, and 8 only; the latter result is experimentally observed.

(345)

Photochemical [1,5] shifts of as yet undetermined stereochemistry are known in open, but *not* in cyclic hydrocarbons [159] and in heterocycles [160].

Berson and *Willcott* [161] have observed a remarkable series of isomerizations of methyl-substituted cycloheptatrienes. Their results, summarized in Figure 35, are consistent with a sequence of [1,5] sigmatropic rearrangements and electrocyclic reactions. Our prediction is that the suprafacial [1,5] shifts must proceed

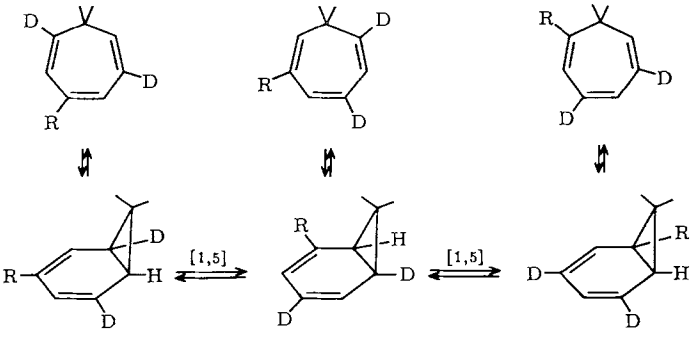


Figure 35. Isomerizations of methyl-substituted cycloheptatrienes through sequences of [1,5] sigmatropic rearrangements and electrocyclic reactions.

with retention at the shifting center. This condition implies that in each shift substituents on the cyclopropane ring pivot 180 °. The beautiful experimental test proposed but as yet not completed by *Berson* and *Willcott* [161] necessitates the pyrolysis of an optically active compound *(346)*. Symmetry-forbidden [1,5]

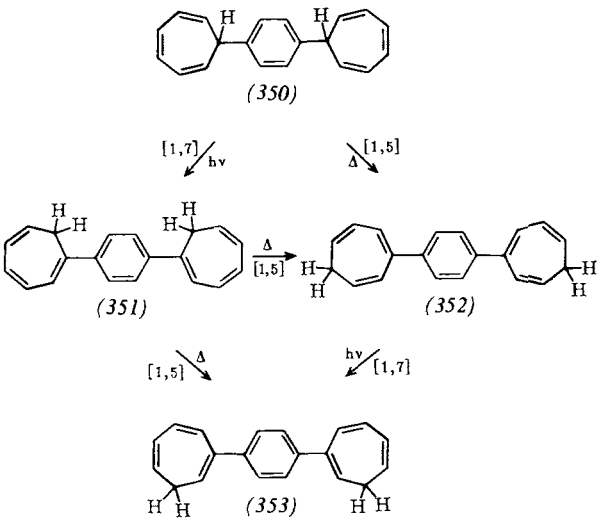
(346)

shifts with inversion – the course which would be followed were the principle of least motion determinative – would result in racemization, while the predicted shifts with retention would lead to no loss of optical activity (Figure 36).

Figure 36. Schematic top view of the possible placements of substituents on a cyclopropane ring migrating around a cyclohexadiene ring by a series of [1,5] sigmatropic shifts, with retention (left) or inversion (right). Note that for clarity the cyclopropane rings are assumed to be perpendicular to the plane of the page, and are not seen.

The Cope and Claisen rearrangements, both [3,3] sigmatropic shifts, are such common reactions that we could not possibly do justice to the many examples studied [162]. These rearrangements are allowed both in a *supra-supra* and an *antara-antara* manner. At first sight it would seem obvious that the transition state for the latter is sterically unattainable. And yet an *antara-antara* Cope rearrangement has been observed; *Mukai* [163]

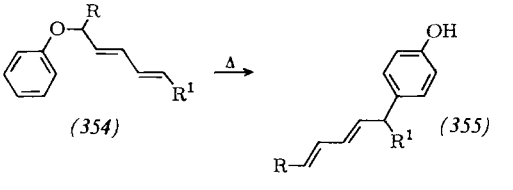


(347) (348) (349)

reported the stereospecific rearrangement of *(347)* to *(348)*. The case provides a striking instance of the manner in which framework restraints may operate to make otherwise difficultly accessible symmetry-allowed reactions possible [*cf.* the transition state *(349)*].

The antarafacial sigmatropic transformation of order [1,7] has been known for some time, in the precalciferol→calciferol interconversion [164].

In cycloheptatriene an antarafacial [1,7] shift is impossible. Consequently, [1,7] shifts within this system must be photochemically induced, or occur with inversion at the shifting site if thermal. A number of



sequences of such light-induced [1,7] rearrangements have been observed [165].

Murray and *Kaplan* [166] have observed the consistent sequence *(350)–(353)* of thermal [1,5] and photochemical [1,7] sigmatropic hydrogen shifts among the isomers of 1,4-di(cycloheptatrienyl)benzene.

Further fascinating examples of [1,7] shifts have been described by *Schmid* [166a].

A symmetry-allowed [3,5] sigmatropic rearrangement must be an excited state reaction if constrained to be suprafacial on both components. So far, there appears to have been observed one case only [167].

The first [5,5] sigmatropic shift has now been realized by *Fráter* and *Schmid* [168], in the facile stereospecific rearrangement of *(354)* to *(355)*.

(354) (355)

[1,2] Shifts in a carbonium ion are very common [169]. Stereospecific hydrogen or methyl shifts in benzenonium cations [170] may be regarded as [1,2] or [1,6] shifts.

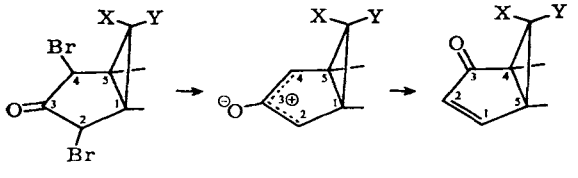
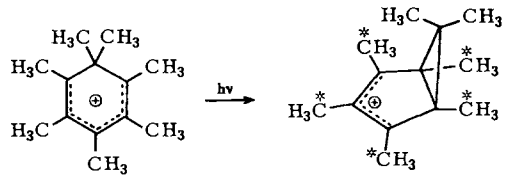
Sigmatropic reactions of order [1,4], *e.g.* migrations in a but-2-en-1-yl cation, have not been observed until recently, when *Swatton* and *Hart* reported the very rapid degenerate rearrangement *(356)* [171].



(356)

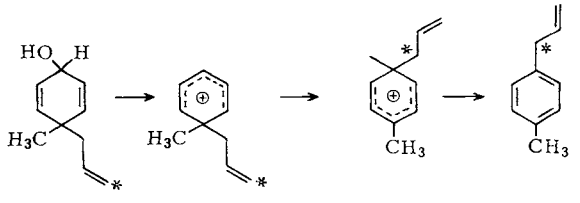
A [1,4] sigmatropic shift constrained to proceed suprafacially must take place with inversion at the migrating group. Note how this prediction contrasts with that for the [1,5] shift in the sterically very similar *(357)*.



(357)

The predicted inversion in a [1,4] sigmatropic shift has recently been verified by several groups. *Hill* [172], and *Zimmerman* [173] have demonstrated that such a process occurs in the Favorskii reaction of a bicyclo-[3.1.0]hexanone [*(358)*→*(359)*→*(360)*].

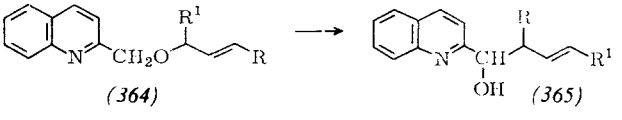
(358) *(359)* *(360)*



Further, *Hart* [174] has demonstrated that the rearrangement *(356)* previously discovered by him [171] indeed proceeds with inversion. The clearest demonstration of the nature of this rearrangement has been obtained by *Winstein* and *Childs* [175]. They generated various methylated bicyclo[3.1.0]hexenyl cations *(362)* in highly acidic media under conditions such that the nuclear magnetic resonance spectrum of the cation

(361) *(362)*

could be observed directly at various temperatures. The cations were generated by the symmetry-allowed photochemical disrotatory cyclization of the corresponding cyclohexadienyl cations *(361)* and were relatively stable, in consequence of the symmetry-imposed barrier to thermal reversion. As the temperature at which the measurements were made was raised, in the case of the heptamethyl compound *(362)* an averaging process took place; five methyl groups (marked by asterisks) became equivalent, while the other two methyl groups, which at low temperature gave distinct resonances, remained unaffected.



Several examples of [3,4] cationic sigmatropic reactions have recently become available through the elegant researches of *Schmid* [176]. In these dienol-ben-

(363)

zene, as well as the analogous dienone-phenol, rearrangements, the [3,4] sigmatropic reactions are competitive with equally allowed [1,2] and [3,3] shifts.

There also may be at hand some examples of [2,3] anionic sigmatropic reactions, in the Wittig rearrangement – the base-catalyzed transformation of benzyl ethers to alcohols. Thus, *Makisumi* and *Notzumoto* [177] observed the base-catalyzed conversion of *(364)* to *(365)*. Similar results on labeled 9-fluorenylallyl eth-

(364) *(365)*

ers were obtained by *Schöllkopf* [178]. The isoelectronic analogue [*(366)*→*(367)*], within formally neutral species, has been found to occur readily, and has been recognized as a very general reaction-type [179].

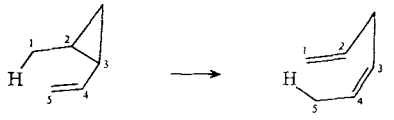
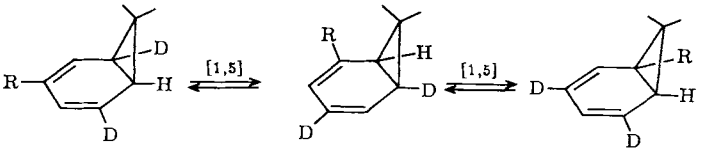
(366) (367)



We would expect that [1,2] anionic shifts should proceed with inversion at the migrating atom. Such shifts have been observed[180] in all-carbon systems, but stereochemical information is not available. The Stevens rearrangement involves the migration of an alkyl group from a quaternary ammonium atom to an adjacent carbanionoid center. The reaction is thus isoelectronic with a [1,2] carbanion rearrangement. It is definitely intramolecular[181], and migration proceeds with retention of configuration at the shifting carbon atom[182]. There is considerable argument concerning the mechanism of the reaction[180,182,183]. Ion-pair and diradical mechanisms have been suggested[182,183] which might circumvent the disagreement with the predictions for a concerted process.

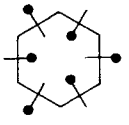
The perhaps bizarre alternative suggestion may be put forward that the metal ions always associated with such systems play a determinative role. If a metal ion is strongly associated with the carbanionoid center at the outset of reaction, and with the nitrogen atom when the migration has been concluded, the symmetry-allowed process depicted in *(368)* may be envisaged; in

(368)



this change, inversion occurs at nitrogen and at the carbanionoid carbon, and a *p* orbital of the metal is involved.

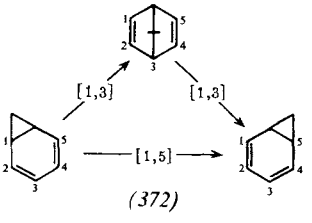
(369)



The homo [1,5] sigmatropic shift *(369)* is very well known[184].

The impetus for a general consideration of sequential sigmatropic shifts arose from the experimental observation by *Berson* and *Willcott* of a sequence of [1,5] sigmatropic shifts *(370)* in norcaradienes[161]. Such

(370)



processes must proceed *with retention* at the migrating carbon atom. The consequences of a sequence of motions with retention are sketched in *(371)*. The illustration is essentially a superposition of snapshots of all of

(371)

the possible positions of labels attached to the methylene carbon atom as it migrates around the six-membered ring (*cf.* Figure 36).

Now it is also conceivable, though energetically unlikely, that the methylene group might migrate by a sequence of [1,3] sigmatropic shifts, through norbornadiene intermediates *(372)*.

(372)

In that connection the following question may be asked: given that suprafacial [1,5] sigmatropic shifts must proceed with retention, and that [1,3] shifts must proceed with inversion if constrained to be suprafacial – is it true that a random sequence of [1,3] and [1,5]

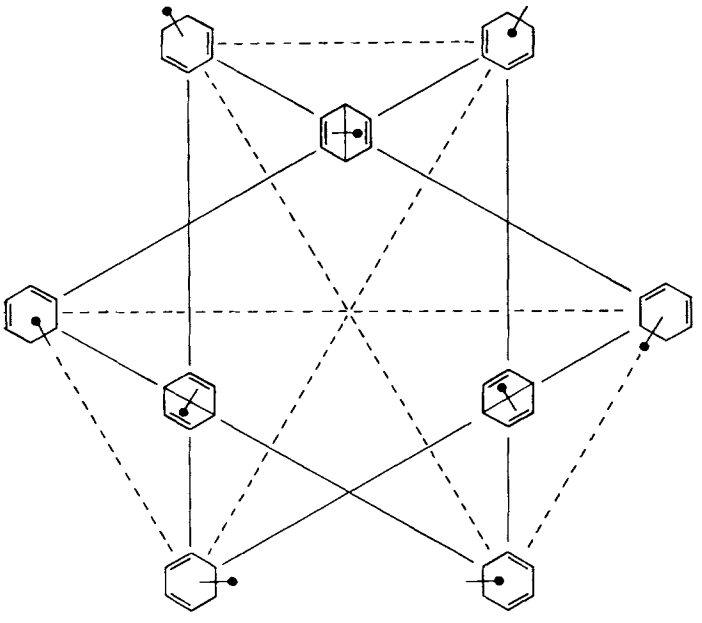
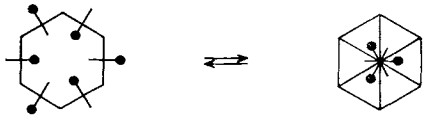
shifts will produce only the same labeling pattern as the previously analyzed sequence of [1,5] shifts [*cf. (371)*]? In this case the answer is yes, as shown by a diagram





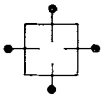


Figure 37. Sigmatropic [1,3] and [1,5] shifts in substituted norcaradienes and norbornadienes. — [1,3] shifts, ···· [1,5] shifts.

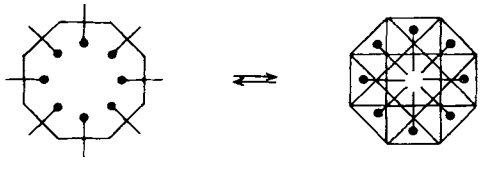
(Figure 37) relating all the possible species through all the possible paths. The information contained in Figure 37 is summarized in *(373)* and *(374)*.



(373) *(374)*

Similar questions may be posed for other [2n.1.0] bicyclic systems. For the [2.1.0] system, only [1,3] shifts are possible; the labeling pattern is summarized in *(375)*.

(375)

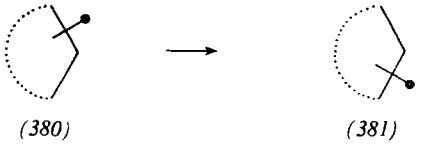
For the [6.1.0] system [1,3], [1,5], and [1,7] shifts are all possible. The diagram relating all isomers is very complicated, but its information content may be summarized in *(376)* and *(377)*. Here again any sequence of [1,3], [1,5], or [1,7] shifts which relates two isomers gives the same configuration as any other sequence.

(376) *(377)*

It may be shown that the results derived above represent a general topological property of [2n.1.0] bicyclic systems.

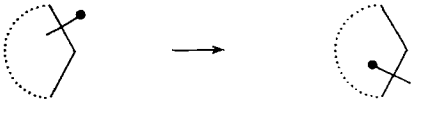
There are two parts to the proof. First, it is clear that a [1,5] shift with retention at a migrating center is indistinguishable from a sequence of *two* [1,3] shifts, each proceeding with inversion at the migrating center. Similarly, a [1,7] shift with inversion is stereochemically indistinguishable from a series of *three* [1,3] shifts, each with inversion. In general,

$$[1, (2q+1)] = [1,3]^q$$



Consequently, it is sufficient to consider a random sequence of [1,3] shifts in constructing a proof.

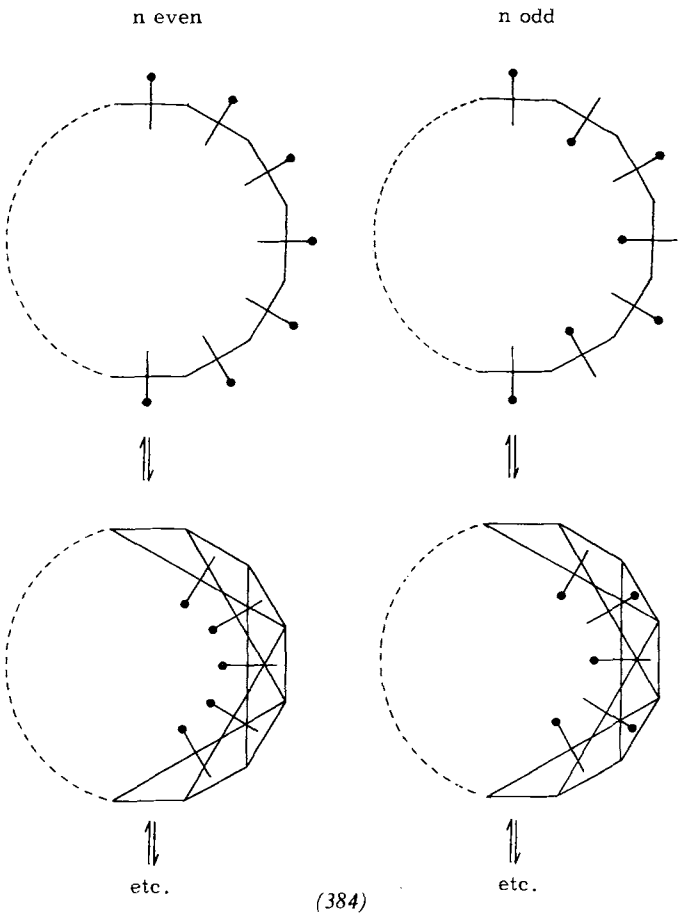
We will prove that in a bicyclo[(2n−2).1.0] system *every* possible sequence of [1,3] shifts which effects the transformation of *(378)* into *(379)* contains an odd number



(378) *(379)*

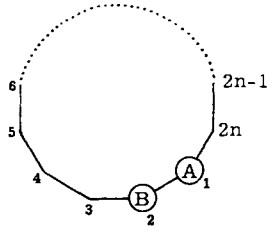
of such shifts if n is even, and an even number of shifts if n is odd. Thus, it will be shown that for n even, there is an odd number of inversions, *i. e.* one net inversion [*(380)*→*(381)*], whereas for n odd, there is net retention [*(382)*→*(383)*]. The cyclic symmetry of the rearrangement then generates the isomer relationships shown in *(384)*.

(380) *(381)*



(382) *(383)*

We now construct the mathematical problem equivalent to the rearrangement sequence. Consider a polygon *(385)* with $2n$ vertices, numbered sequentially clockwise from an arbitrary origin. Suppose markers, A and B, are placed at vertices 1 and 2, respectively, of this polygon. A game is then played, with the following set of rules:



a) A random number of moves of the markers to new vertices is performed sequentially.

b) In each move *either* A *or* B moves two positions clockwise or counterclockwise. Thus, if A is at position k, it can move to $k+2$ or $k-2$.

(384)

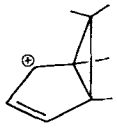
c) No hopping is allowed; *i.e.* if A is located at point k and B at $k-1$, the move of A from k to $k-2$ is forbidden and A has only the option of moving to $k+2$.

(385)

Theorem: Given the above rules of the game, *every possible sequence of moves* which begins with A at 1 and B at 2 and terminates with A at 3 and B at 2 comprises an even number of moves if n is odd, and an odd number of moves if n is even.

Before proceeding to the proof of this theorem, one should assure oneself that the above game and theorem are equivalent to the problem presented by the sequential rearrangements. The requisite identifications are that the ring of $2n$ atoms, around which the carbon atom moves, corresponds to the polygon, while the markers A and B represent the bonds from the vertices of the polygon to the migrating atom.

Proof: Define a distance, measured in number of sides of the polygon, between the markers A and B, beginning at B, and *measured clockwise*. Then if B is at 2 and A is at 1, the distance between the two is the maximum: $2n-1$. We now proceed to examine the number of steps it takes to reduce this distance between the markers to 1, with B at 2 and A at 3. First, we will examine the number of moves it takes to reduce the distance to 1, *when B may have moved to any vertex*. The initial move reduces the distance from $2n-1$ to $2n-3$. Every subsequent move can be classified as *effectual* or *ineffectual*. An effectual move makes the distance smaller than the previous minimum, an ineffectual move does not. All ineffectual moves come in pairs: for, if at some point the distance is j, and a move increases the distance to $j+2$, then another move is necessary to return it to j. Only effectual moves reduce the distance between A and B. Since each effectual move reduces the distance by 2, the total number of moves, for any sequence, necessary to reduce the distance from $2n-1$ to 1 is:



$$(2n-2)/2 = (n-1) + \text{some even number}$$
Effectual *Ineffectual*

So far we have deduced the number of moves necessary to reduce the distance to 1, but B may be at any even-numbered vertex. Now, A and B having been placed at *any* adjacent vertices, an even number of ineffectual moves will suffice to realize the final objective of placing B at position 2, and A at position 3. We have thus shown that the total number of necessary moves is:

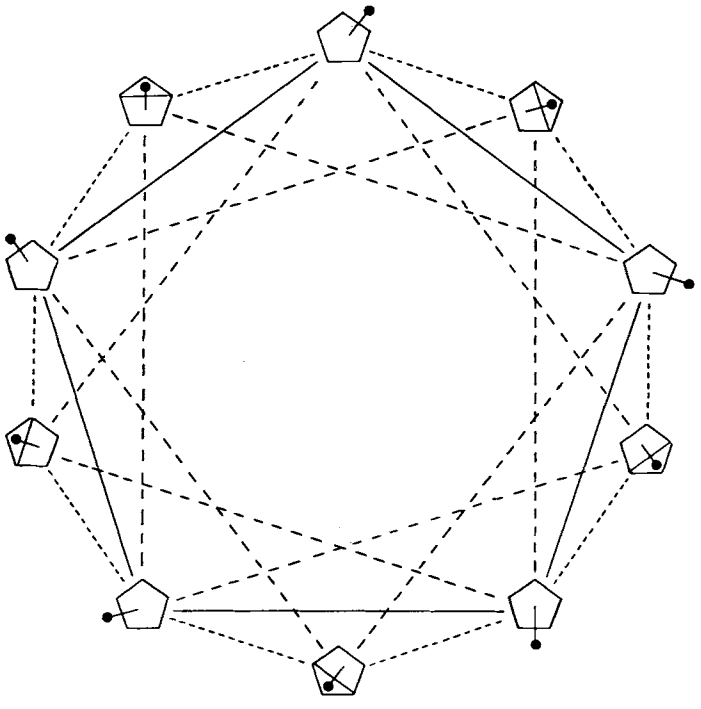
$$(n-1) + \text{some even number}$$

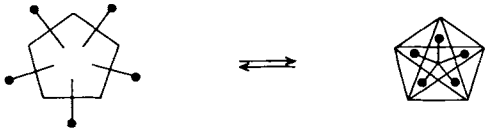
Consequently, the required number of moves is odd if n is even, and even if n is odd, which was to be proven.

For cationic sigmatropic rearrangements, the topological relationships can differ significantly from those just shown to be general for neutral species. We consider first the sigmatropic rearrangements of a bicyclo[3.1.0]hexenyl cation *(386)*. In this system [1,2],

(386)

[1,4], and [1,3] shifts may occur; experience indicates that ionic [1,2q] shifts should be much faster than the neutral [1,(2q+1)] rearrangements. Using the previous conventions, and observing the symmetry-imposed conditions that [1,2] shifts must occur with retention, while [1,3] and [1,4] migrations must take place with inversion, we obtain the interrelations shown in Figure 38. The relationships are summarized in *(387)* and *(388)*.





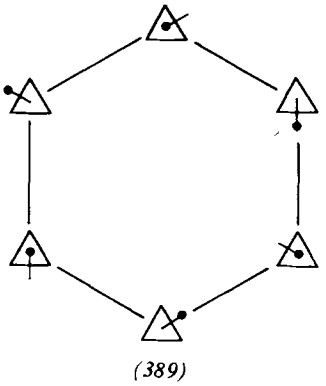


Figure 38. Sigmatropic [1,4], [1,2], and [1,3] shifts in the cation *(386)*. — [1,4] shifts, ····· [1,2] shifts, --- [1,3] shifts.

At this point it might appear that sequential sigmatropic reactions in cyclic polyenyl ions will always have the same consequences as in cyclic polyenes. *This is not*

(387) *(388)*

so. Consider the simplest system in which [1,2] shifts are possible – the rearrangements of the bicyclo-[1.1.0]butyl cation *(389)*. In sharp contrast to those in

(389)

each of the previous cases studied, this sequence produces apparent epimerization, *i.e.* a series of rearrangements can convert *(390)* into *(391)*. It may be readily

(390) *(391)*

seen that similar circumstances will obtain in (7, 11, ...)-membered rings – as well as in the three-membered case (*cf.* Figure 39).

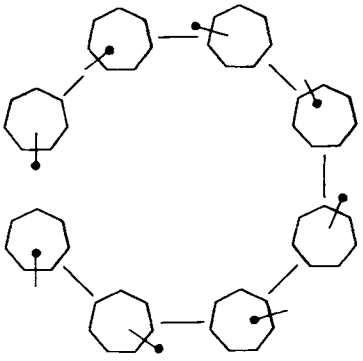

Figure 39. [1,6] Sigmatropic shifts in bicyclo[5.1.0]octadienyl cations.

The bicyclo[(2n+1).1.0] cation cases thus must be divided into two categories. In the first class, the [1,(2n+2)] sigmatropic shift proceeds with *retention* and epimerization must occur as a consequence of $2n+3$ such shifts; such is the case for [1,2], [1,6], [1,10], ... shifts, that is, in general for cases where n is even. The second category comprises those cases in which n is odd, the [1,(2n+2)] sigmatropic shift proceeds with *inversion*, and epimerization can never be realized through any number of symmetry-allowed migrations – as in the cyclic polyene cases.

8. Group Transfers and Eliminations

Consider the concerted reaction in which two hydrogen atoms are transferred from ethane to ethylene *(392)*, in a process suprafacial on both reactants. A

(392)

correlation diagram (Figure 40) is easily constructed for this reaction, utilizing the symmetry plane bisecting the two molecules; the process is clearly symmetry-allowed. In contrast is the diagram (Figure 41) for the

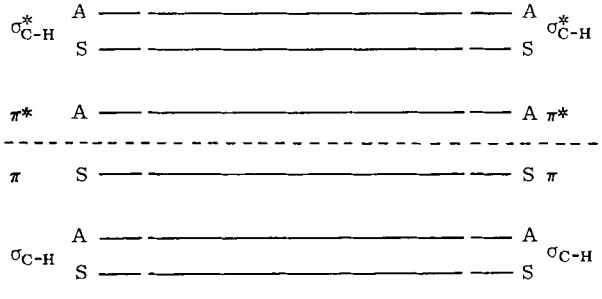

Figure 40. Correlation diagram for the concerted transfer of two hydrogen atoms from ethane to ethylene.

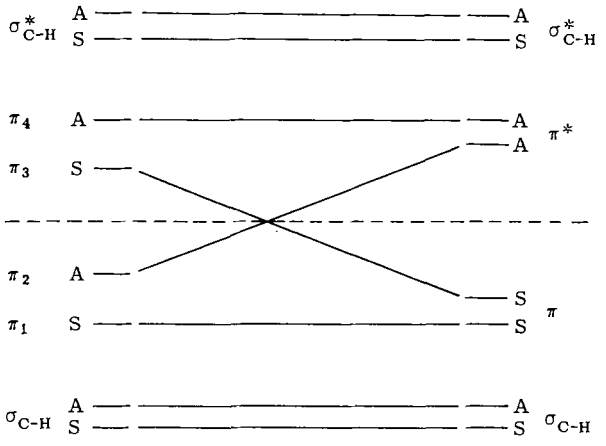
(393)

concerted transfer of two hydrogen atoms from ethane to the termini of butadiene *(393)*; the reaction is symmetry-forbidden.



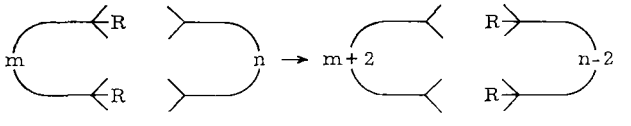


Figure 41. Correlation diagram for the concerted transfer of two hydrogen atoms from ethane to the termini of butadiene.

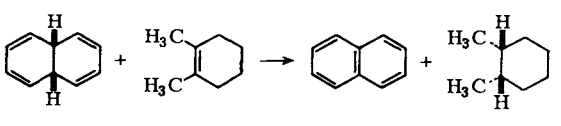


For the general case *(394)*, it is simple to derive the following selection rule: The double-group transfer is symmetry-allowed for ground states when

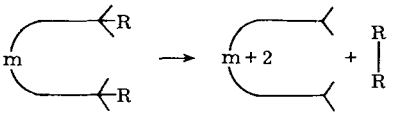
(394)

$m+n = 4q+2$, for excited states when $m+n = 4q$, where m and n are numbers of π electrons, and q is an integer (0, 1, 2, . . .). The rule applies also to a process antarafacial on both components, and is reversed for a process antarafacial on one component only. The rules must be appropriately modified if the possibility of inversion at R is real (*cf.* Section 11).

The best known example of this type of reaction, with $m = 0$, $n = 2$, is the transfer of hydrogen from diimide to olefins [185]. Hydrocarbon analogues also exist; for example, the reaction *(395)* was observed by *Doering* and

(395)

[185] Reviewed by *S. Hünig, H. R. Müller,* and *W. Thier,* Angew. Chem. *77*, 368 (1965); Angew. Chem. internat. Edit. *4*, 271 (1965); *E. J. Corey, D. J. Pasto,* and *W. L. Mock,* J. Amer. chem. Soc. *83*, 2957 (1961).



[186] *W. von E. Doering* and *J. W. Rosenthal,* J. Amer. chem. Soc. *89*, 4535 (1967).

Rosenthal [186]. A case with $m = 2$, $n = 4$ has also been observed *(396)* [187].

(396)

The rule derived above also applies to the limiting case with $n = 0$ – the concerted elimination *(397)*. We predicted, thus, that the concerted noncatalytic hydrogenation of a diene, or the reverse elimination, should be

(397)

1,4 rather than 1,2. At the time our predictions were made the literature appeared to contain only two relevant pieces of information:

a) 2,5-Dihydrofuran loses hydrogen in a unimolecular process with $E_a = 48.5$ kcal/mole and a negative entropy of activation, while 2,3-dihydrofuran does not react in this way [188].

b) 3,3,6,6-Tetramethyl-1,4-cyclohexadiene when pyrolyzed in pentane gave a much larger yield of ethane (and *p*-xylene) than could have arisen from a free radical chain reaction [189].

Subsequently, our predictions have been substantiated in a number of studies. *Baldwin* [190] in studying the elimination of hydrogen from an isotopically labeled cyclopentene found a greater than 10:1 preference for 1,4 over 1,2 elimination. *Ellis* and *Frey* [191], *Benson* and *Shaw* [192], and *Kellner* and co-workers [193] have independently studied the pyrolysis of 1,3 and of 1,4-cyclohexadiene. The latter decomposes unimolecularly to benzene and hydrogen with $E_a = 42.7$ kcal/mole; at the same temperatures the 1,3-cyclohexadiene is thermally stable and at higher temperatures it decomposes mainly by radical-chain processes. *Frey* has provided further interesting examples of concerted elimination of hydrogen; on the other hand, his evidence indicates that those processes which lead to the formation of methane or ethane proceed by radical-chain mechanisms [194].

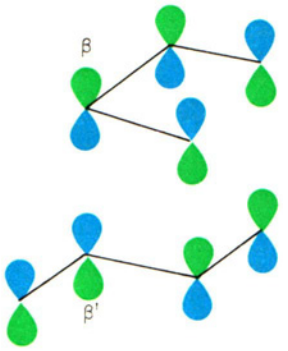
(398)

The concerted loss of two geminal groups *(398)*, provided that it proceeds through a transition state of C_{2v} symmetry (*cf.* Section 10.1), should be an excited state reaction, and thus compete with vicinal elimination [*(397)*, $m=0$] – also a symmetry-allowed excited state process. Both cases are known [195].

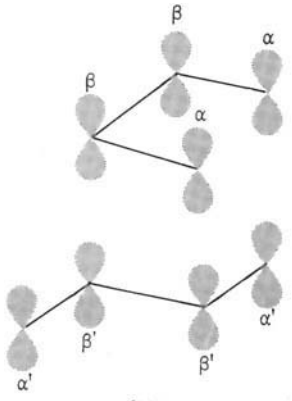
9. Secondary Effects



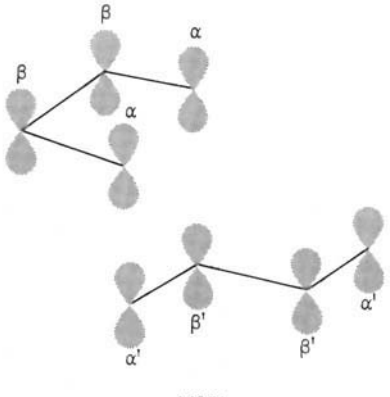
Orbital symmetry arguments may also be used to yield further insight into the origins of secondary conformational effects in concerted cycloaddition reactions.

Consider the Diels-Alder addition of butadiene to itself, as a concerted [$\pi 4_s + \pi 2_s$] cycloaddition reaction. *A priori*, this reaction might take place through either of two alternative transition states, *(399)* or *(400)*. The *endo* approach *(399)* is distinguished from the *exo* *(400)* mainly by the proximity of a β and a β′ orbital in the former. Any secondary interaction among occupied diene and dienophile molecular orbitals will contribute only in a very minor way to the total energy of the transition state, since such an interaction will increase the energy of some levels while decreasing the energy of others. The significant interactions will come from the symmetry-allowed mixing of unoccupied with occupied levels [196]. In the case at hand, inspection of diagrams *(401)* and *(402)* reveals at once that either possibility for such mixing leads to bonding, *i.e.* energy-lowering, interaction of the proximate β and β′ orbitals [197]. Thus, the *endo* transition state *(399)* for this [$\pi 4_s + \pi 2_s$] concerted cycloaddition reaction is stabilized *vis-à-vis* the *exo* alternative *(400)* by symmetry-controlled secondary orbital interactions.

(401)



Mixing of highest occupied "diene" orbital (top) with lowest unoccupied "olefin" orbital (bottom)



(402)

Mixing of lowest unoccupied "diene" orbital (top) with highest occupied "olefin" orbital (bottom)

The orbital symmetry relationships signalized here provide a simple quantum chemical basis for the large body of experience summarized in the Alder *endo* addition rule [198]. Our treatment differs from previous proposals, which have emphasized the roles of inductive

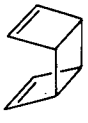
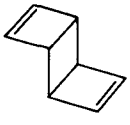
forces [199], electrostatic forces consequent upon charge transfer between diene and dienophile [200], and maximum accumulation of unsaturation [198]. In particular it is now clear that in some cases the orbital interactions among unsaturated centers involved in a concerted cycloaddition reaction will be such as to raise rather than lower, the energy of the *endo* transition state, and lead to a preference for *exo* addition, insofar as

(403)



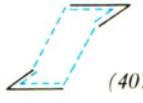
(404)



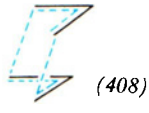
symmetry factors are dominant; inspection of the relevant orbital diagrams *(403)* and *(404)* for the symmetry-allowed $[\pi 6_s+\pi 4_s]$ combinations indicates that it is such a case.

This prediction was made prior to the discovery of [6+4] cycloadditions, and has since been confirmed [201]. By contrast, the symmetry-allowed $[\pi 8_s+\pi 2_s]$ and $[\pi 2_s+\pi 2_s+\pi 2_s]$ cycloadditions should resemble the [4+2] process and proceed by preference through *endo* transition states; there is already evidence for that preference in an example of the latter process [202].

The dimerization of cyclobutadiene is a special case of much interest, considered in the light of orbital symmetry relationships. If, as seems likely, there is substantial double bond localization in that highly reactive molecule, one can delineate, *a priori*, the possibilities of $[\pi 2_s+\pi 2_s]$, $[\pi 2_s+\pi 4_s]$, and $[\pi 4_s+\pi 4_s]$ cycloadditions. Our selection rules require a preference for the concerted $[\pi 2_s+\pi 4_s]$ process, and indeed evidence that this path is favored has been brought forward [203]. Examination



(405)



(406)

of secondary orbital interactions along the lines set down here reveals further that the *endo* process, leading to the *syn* dimer *(405)*, should be favored over the alternative *exo* combination, which would give the *anti* dimer *(406)*. The formation of both *syn* and *anti* dimers in reactions initiated with a variety of possible cyclobutadiene precursors has been reported, but in those experiments in which there was the greatest likelihood of the transitory existence of a free cyclobutadiene, the predicted *endo* process was observed [204].

The [3,3] sigmatropic shift in 1,5-hexadienes has been shown to proceed more easily through a four-center

(407)

(408)

chair-like transition state *(407)* than through the boat-like alternative *(408)* [205]. We suggest that orbital symmetry relationships may play a major role in determining that preference. A correlation diagram for the molecular orbitals involved in the rearrangement is illustrated in Figure 42. The levels are classified as symmetric or antisymmetric with respect to the mirror plane *m* in the boat-like transition state, or a two-fold rotation axis in the chair-like form. The scheme shown is for the former case, and the diagram for the latter is qualitatively similar. The correlation of reactant bonding levels with product bonding levels, characteristic of a symmetry-allowed thermal reaction, should be noted. At the half-way mark in the reaction the level ordering is recognizable as that of two strongly interacting allyl radicals. The actual behavior of the levels along the

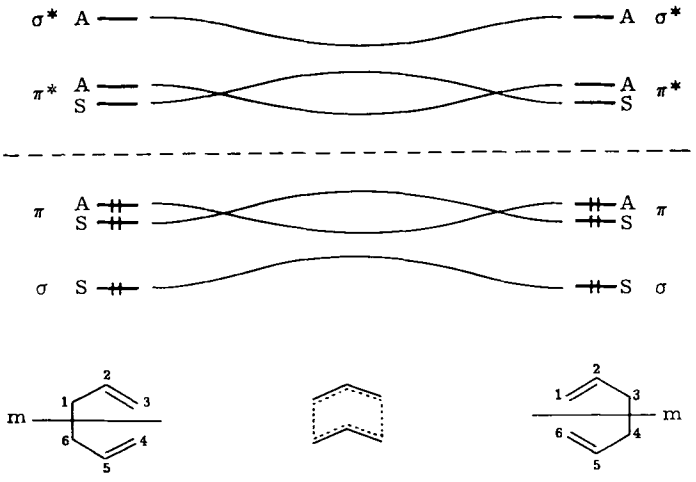

Figure 42. Correlation diagram for the [3,3] sigmatropic rearrangement of 1,5-hexadiene.

reaction coordinate is abstracted from extended Hückel calculations.

If the correlation diagrams are qualitatively similar for the boat and chair reactions, where does the observed preference come from? An explanation requires the construction of two further correlation diagrams (Figure 43), for the alternative hypothetical processes in which two allyl radicals approach each other from infinity, in parallel planes, oriented with respect to each other in the one case in a *quasi* boat relationship, and

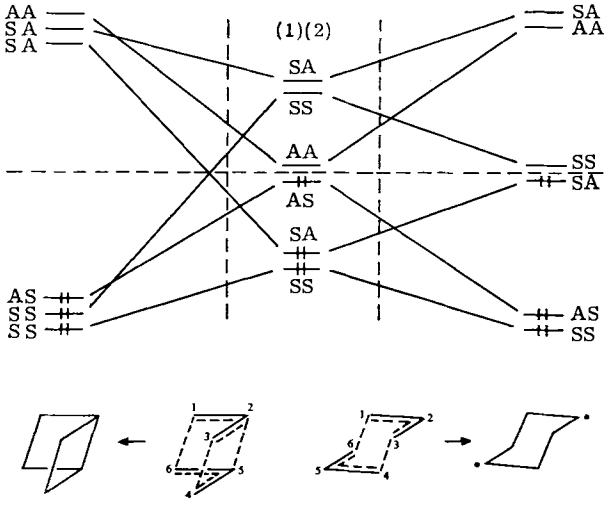

Figure 43. Correlation diagram for the approach of two allyl radicals from infinity in a *quasi* boat or a *quasi* chair relationship. (1) and (2) at the top of the center column refer to the symmetry elements present (see text).

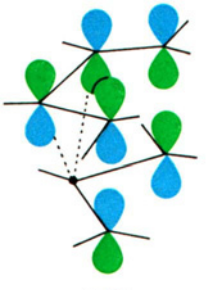
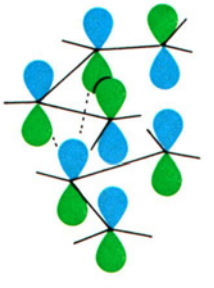
in the other in a *quasi* chair fashion. In each of these processes there are two symmetry elements:



a) in both, a mirror plane m_1, which passes through C-2 and C-5, and bisects the angles C(1)-C(2)-C(3) and C(6)-C(5)-C(4);

b) in the boat approach, a second mirror plane, m_2, parallel to and half-way between the planes of the approaching radicals, and in the chair approach a two-fold axis of symmetry, lying on the intersection of m_2 and the plane defined by C(1)-C(3)-C(4)-C(6).

To complete the correlations one must specify the end products of these hypothetical motions; these are a bicyclohexane in the boat approach, and a 1,4-cyclohexylidene biradical in the chair pathway. Among the occupied levels the critical difference in the two pathways is in the behavior of the occupied S_1A_2 level, which in the boat-like approach correlates to an antibonding σ orbital while in the chair-like process it goes over to a non-bonding biradical level. The crucial point of the argument now is that a reaction proceeding as in Figure 42 must pass at the half-way point through some point in a correlation diagram resembling one or the other of those shown in Figure 43, and that this point will be approximately the same horizontal distance, marked by dashed vertical lines, along the reaction coordinate in the two alternate pathways of Figure 43. Further, at any such point the chair-like transition state is at lower energy as a result of the difference in correlation properties of the occupied S_1A_2 orbital. The central conclusion is that orbital interactions involving C-2 and C-5 have a net antibonding, energy-raising effect. In this sense, the argument represents a further development of the simple orbital repulsion effect suggested by *Doering* and *Berry* [205].



It should be emphasized that the effects discussed here are, not unexpectedly, small ones, and that in systems possessing special geometrical restraints which necessitate a boat-like transition state, [3,3] sigmatropic changes take place with no special difficulty [206].

To present a final illustration of the procedure, in a case in which the result is not yet known, we consider the [4+2] cycloaddition of a butadiene to an allyl cation. The two significant interactions are shown in *(409)* and *(410)*. The secondary interactions in *(409)* must be negligible, while those in *(410)* are antibonding; a preference for the *exo* transition state is expected [206a].

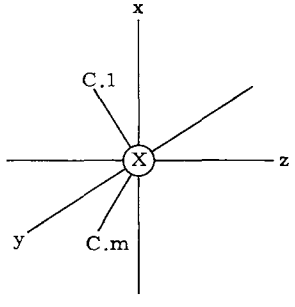
10. Divertissements!

In the previous sections, we have discussed and exemplified orbital symmetry control of the major general types of concerted organic reactions. We turn now to a discussion of two special types, each of which possesses fascinating unique features, and further illustrates the power of the principle of orbital symmetry conservation in understanding and predicting the detailed course of chemical transformations.

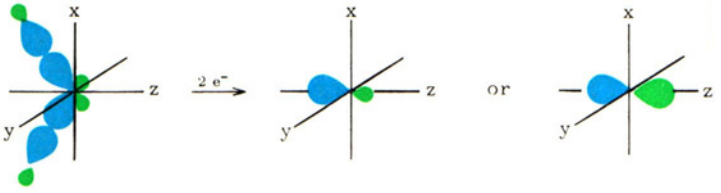
10.1. Cheletropic Reactions



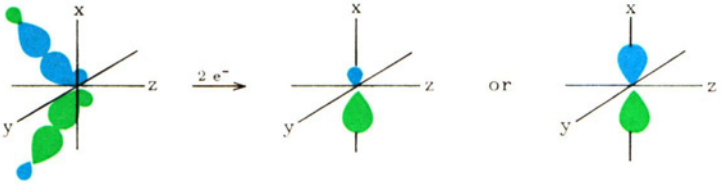
We define as *cheletropic reactions* those processes in which two σ bonds which terminate at a single atom are made, or broken, in concert.

Let us consider the cheletropic reaction *(411)*, in which a small molecule X(YZ. . .) and a polyene containing

(411)



an *m*-electron π system are produced. We shall examine the geometrical aspects of the reaction, with reference to an invariant coordinate system *(412)*, whose origin is always at X, and whose z axis bisects the line

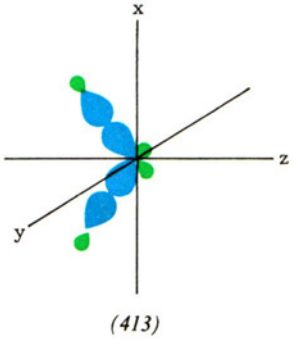


(412)

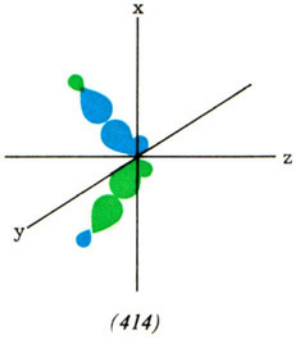
between C.1 and C.m. Thus, the σ bonds being broken lie in the xz plane, and their four electrons are distributed as usual, in pairs, in the two generalized orbitals *(413)* and *(414)*. Now, in general, two electrons must be delivered from these orbitals to each of the developing products, with conservation of orbital symmetry. A crucial point now emerges: the transfer of two electrons from the breaking σ bonds to new orbitals in the product molecule X(YZ. . .) may take place in either of two sharply distinct ways.

a) Two electrons from the symmetric orbital [*(413)* ≡*(415)*] may take up new positions in a z-symmetric lone pair orbital of X(YZ. . .), or enter a π system antisymmetric with respect to the xy plane.

(415)

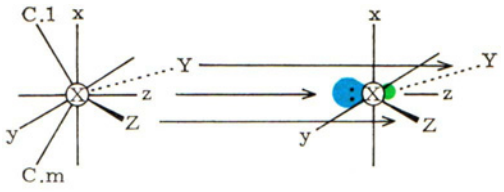


(416)



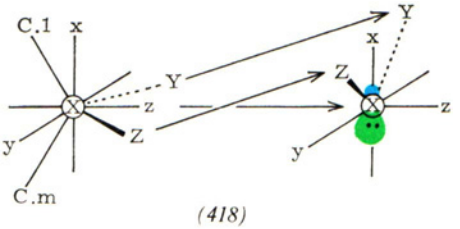
b) Two electrons from the antisymmetric orbital [*(414)* ≡*(416)*] may take up new positions in an x-symmetric lone pair orbital of X(YZ. . .), or enter a π system antisymmetric with respect to the yz plane.

In the light of this analysis, it is clear that the geometrical displacements at C.1 and C.m are dependent upon the detailed geometry of departure of X(YZ. . .), and in particular, on the sense of the displacements of the atoms YZ. . . which are attached to X. To illustrate this important point, we consider the departure of a bent molecule Y-X-Z, which as it develops must acquire a symmetric lone pair at the central atom X. The reaction may take place in either of two ways, depicted in *(417)* and *(418)*.



a) *Cf. (417)*: X acquires its needed lone pair from the symmetric σ orbital *(415)*, as X, Y, and Z depart co-lin-

(413)



(414)

(417)

early, all remaining in the yz plane. We shall designate such processes as *linear* cheletropic reactions. It

(418)

may be noted that in a formal sense, the product electron pair is participating in a *suprafacial* fashion, in that the two bonds from which the two electrons came lie on the same side of the nodal surface (approximated by the plane xy) of the product orbital which the pair occupies.

b) *Cf. (418)*: X acquires its needed lone pair from the antisymmetric σ orbital *(416)*, as X departs co-linearly, remaining in the yz plane, while Y and Z undergo displacements in both the x and z directions, with the result that the product molecule lies in the xy plane. We shall designate such processes as *non-linear* cheletropic reactions. In this case the product electron pair at X is participating in an *antarafacial* fashion, in that the two bonds from which the electrons came lie on opposite sides of the nodal surface (approximated by the plane yz) of the product orbital which the pair occupies.

It is now clear that in linear cheletropic reactions of the type *(411)*, two electrons must be delivered from the antisymmetric σ orbital [*(416)* ≡*(420)* ≡*(423)*] to the highest occupied π orbital of the polyene *(419)*. Consequently, the displacements at C.1 and C.m must be disrotatory when $m = 4q$ [*(420)*→*(421)*], and conrotatory when $m = 4q+2$ [*(423)*→*(424)*].

By contrast, if the fragmentation *(411)* follows the non-linear cheletropic path, two electrons must be delivered to the highest occupied π orbital of the polyene *(419)* from the symmetric σ orbital [*(415)* ≡*(422)* ≡*(425)*]. In this case, therefore, the displacements at C.1 and C.m must be conrotatory if $m = 4q$ [*(422)*→*(421)*], and disrotatory when $m = 4q+2$ [*(425)*→*(424)*].

The selection rules are summarized in Figure 44. In these cheletropic transformations there undoubtedly

	Allowed Ground State Reactions	
m	Linear	Non-linear
4*q*	Disrotatory	Conrotatory
4*q*+2	Conrotatory	Disrotatory

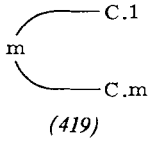


Figure 44. Selection rules for cheletropic reactions.

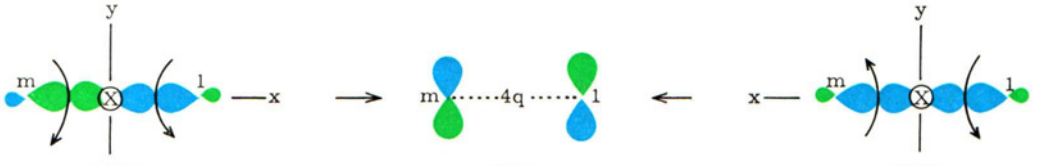
exists, for each ground state reaction, an excited state process characterized by reversed stereochemical features. However, the extruded small molecule X(YZ)... will frequently possess many occupied lone pair orbitals, and the accompanying possibility of numerous $n \rightarrow \pi^*$ states raises the possibility in any given case that excited state processes with the *same* stereochemical characteristics as the corresponding ground state transformation may be available.



Linear cheletropic fragmentations leading to the production of nitrogen or carbon monoxide represent reactions well-suited for the construction of formal correlation diagrams, which have been drawn by *Lemal* [207], and by *Baldwin* [208], as well as by us. For car-

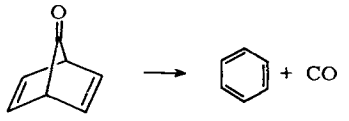
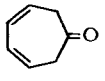
(419)



(420) (421) (422)

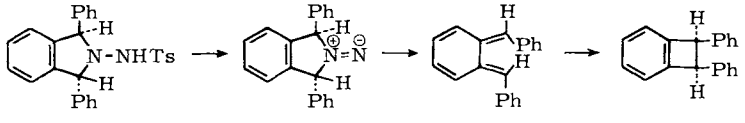


(423) (424) (425)

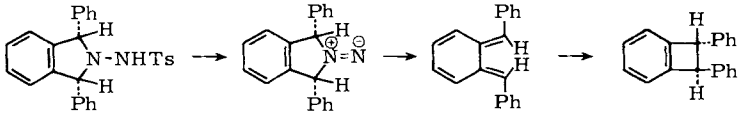
bon monoxide elimination no direct stereochemical results are available. It is clear, however, that cyclopent-3-en-1-ones ($m=4$) undergo decarbonylation readily, apparently in a concerted manner [208]. In this connection, the failure of attempts to prepare norbornadien-7-one *(426)*, may be contrasted with the stability of norbornanones [209].

(426)

A case with $m=6$ is represented by 3,5-cycloheptadienone *(427)*, which in one of the few known condensed-phase decarbonylations, undergoes photolysis to hexatriene and carbon monoxide [210].



(427)



(428)

The elimination of nitrogen from diazenes *(428)* has been carefully studied by *Lemal* [207]. The process is stereospecific and disrotatory, as predicted; the linear disrotatory path is clearly one involving less strain than the non-linear conrotatory alternative in this case.

(429)

(430)

Remarkable sequences [*(429)*, *(430)*] comprising disrotatory nitrogen eliminations, followed by conrotatory electrocyclic reactions have been revealed by *Carpino* [211].

The reversible, facile addition of sulfur dioxide [212] to dienes is well known [213]. The expected disrotatory course for the elimination of sulfur dioxide from a butadiene sulfone has been established [214]. The corresponding photochemical process is not completely stereospecific, but a clear preference for the conrotatory path is shown [215]. Sulfur dioxide also readily undergoes 1,6-addition to 3-*cis*-hexatrienes; the reverse process has recently been shown to proceed in a conrotatory fashion, and must therefore be classified as a linear cheletropic reaction [216].

Cheletropic reactions in which a three-membered ring is produced or destroyed, *e.g.* fragmentations of type *(411)* in which $m = 2$, are of special interest in that geometric factors require that they take place in a disrotatory, or suprafacial manner. Consequently, these transformations must occur by the non-linear cheletropic path.

The well-known [217] stereospecific combination of singlet carbenes with olefins to give cyclopropanes undoubtedly falls in the non-linear cheletropic class [218].

Cyclopropenones and cyclopropanones lose carbon monoxide thermally under mild conditions [219,220], and even more readily on irradiation [219,221]. Stereochemical information on the decarbonylation is lacking. It has, however, been clearly demonstrated that nitrogen is stereospecifically extruded in a disrotatory fashion from alkyl-substituted three-membered ring

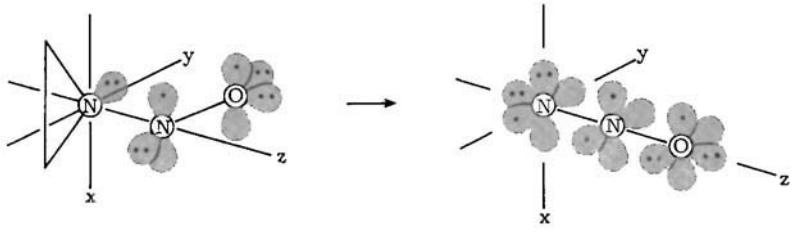
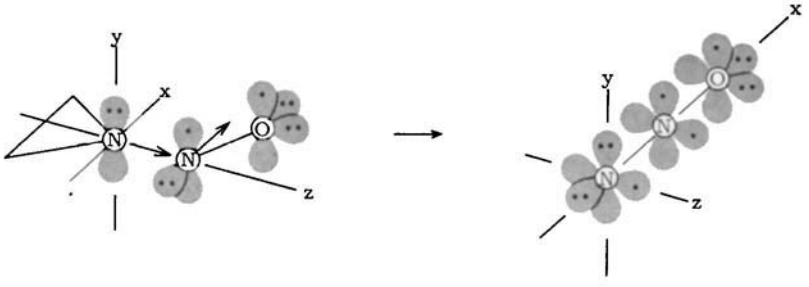
[221] *D. C. Zecher* and *R. West*, J. Amer. chem. Soc. *89*, 153 (1967).



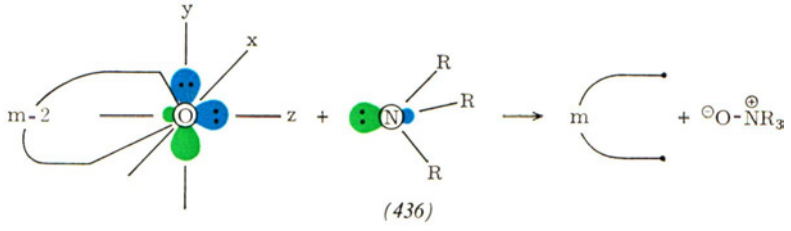
diazenes *(431)* [222]; this change must follow the non-linear path, with x-displacement of N-2 in the plane of the aziridine ring as reaction proceeds.



(431)

Sulfur dioxide is readily lost from episulfones in a stereospecific disrotatory manner [223,224]. In order to circumvent the problem which seemed to be posed by the fact that linear cheletropic fragmentation is symmetry-forbidden in this case, it has been suggested [224] that the reaction might proceed in a non-concerted way, through a discrete intermediate. It is now clear that the available evidence is also consistent with the view that the elimination follows the concerted symmetry-allowed non-linear cheletropic path [*cf. (418)*].

The observed ready elimination of nitrous oxide *(433)* from *N*-nitrosoaziridines [225] probably also follows the non-linear cheletropic path [*(432)*→*(433)*]; note that the $4\pi_y$ system remains intact throughout the reaction, and that an x-symmetric lone pair at nitrogen in *(433)* is derived from the bonding antisymmetric σ orbital of the aziridine ring. However, an interesting alternative should be considered. If the nitroso compound be allowed to achieve the conformation *(434)*, the unshared electron pair at the pyramidal aziridine nitrogen atom may become one of the z-symmetric lone pairs of nitrous oxide *(435)*, while the electron pair from the bonding antisymmetric σ orbital of the aziridine ring enters the $4\pi_x$ system. In view of the fact that the uncoupling of two electrons from the $4\pi_y$ system of *(432)* may require *ca.* 23 kcal/mole, as estimated from the barrier to rotation in *N*-nitrosoamines [226], it seems unlikely that the molecule will make use of this alternative symmetry-allowed process to destroy itself.

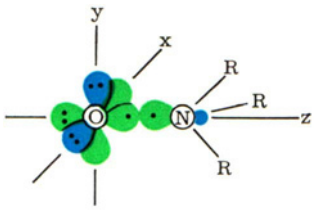


(434) *(435)*

(432) *(433)*

The hypothetical abstraction reaction *(436)* provides a further example of a cheletropic change. If the abstraction takes place in a *linear* fashion, the lone pair of the amine and the two oxygen lone pairs are transformed into the N-O bond and the z and y-axis unshared pairs of the *N*-oxide *(437)*. The remaining x-axis lone pair of the *N*-oxide must be taken from the antisymmetric σ orbital of the breaking carbon-oxygen bonds. Therefore, two electrons from the corresponding symmetric σ orbital must be delivered to the polyene product.

(436)



[222] *J. P. Freeman* and *W. H. Graham*, J. Amer. chem. Soc. *89*, 1761 (1967). However, the corresponding aryl-substituted case proceeds in a non-stereospecific manner (personal communication from *L. A. Carpino*).

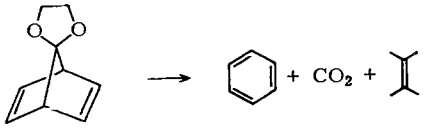
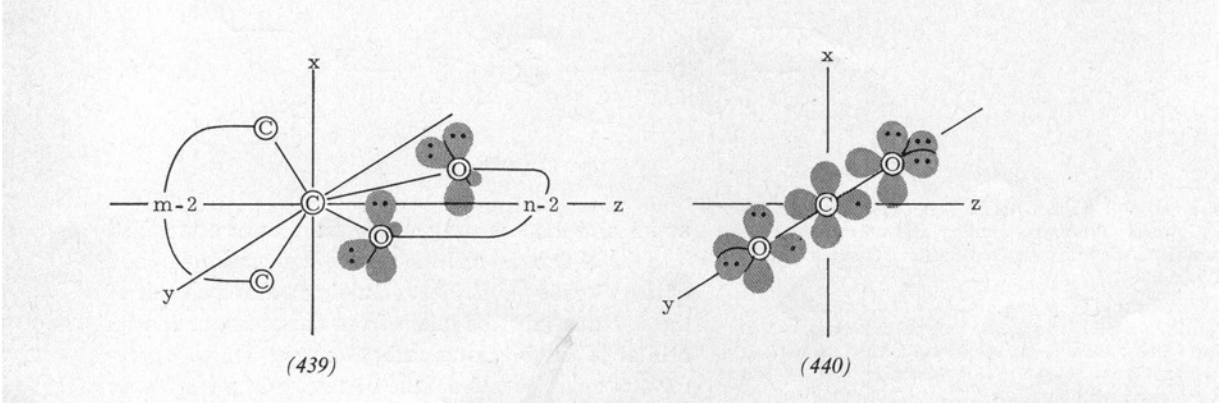
[226] *C. E. Looney*, *W. D. Phillips*, and *E. L. Reilly*, J. Amer. chem. Soc. *79*, 6136 (1957).



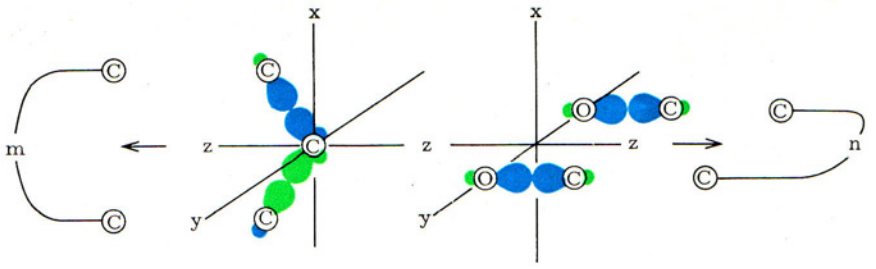
(437)

Consequently, the reaction must occur in a disrotatory sense when $m=4q+2$, or conrotatory when $m=4q$. If, on the other hand, the amine attacks in a *non-linear* manner, *i.e.* in the xz plane, but in the x direction, the stereochemical consequences are precisely reversed. A possible analogue of the linear reaction is available in the stereospecific abstraction of sulfur from the *cis*- and *trans*-butene episulfides by phosphines [227].



(441) (442) (443) (444)

A fascinating concatenation of a cheletropic fragmentation with a vicinal elimination is presented by the decomposition of a spiroketal to carbon dioxide and two olefins. As yet, the only known instances of the reaction involve ethylene ketals derived from substituted



(438)

norbornadienones (438) [228]. It is most interesting to examine the stereochemical aspects of the process in the general case (439); m and n represent the numbers of electrons in the π systems of the product polyenes. In addition to the four electrons which constitute the skeletal σ bonds, carbon dioxide (440) requires twelve electrons: eight of these populate two perpendicular 4π systems, in the xy and yz planes, respectively, while four occupy two y-symmetric lone pair orbitals. If the reaction under discussion follows the linear cheletropic path, it is clear that the eight lone pair electrons at the oxygen atoms of (439) pass smoothly into the y-symmetric lone pair orbitals and the $4\pi_{xy}$ system of carbon dioxide (440), with conservation of orbital symmetry. Further, the orbitals of the orthogonal $4\pi_{yz}$ system can only be filled by transferring two electrons from the symmetric C–C–C σ orbital (441) to the lowest occupied symmetric π_{yz} orbital (442), and two from the antisymmetric O–C–O σ orbital (444) to the highest occupied π_{yz} orbital (443). Therefore, the electrons occupying the antisymmetric C–C–C σ orbital (446) must be delivered to the highest occupied orbital of the polyene (445), while those in the symmetric O–C–O σ orbital (447) take up their new positions in the highest occupied orbital of the polyene (448). Consequently, the geometric displacements associated with the carbon-carbon bond cleavages will be disrotatory when $m=4q$, or conrotatory when $m=4q+2$; by contrast, the carbon-oxygen scissions will be associated with disrotatory displacements when $n=4q+2$, or conrotatory when $n=4q$. If the reaction follows the *non-linear* cheletropic path, the stereochemical consequences attendant upon the carbon-carbon bond cleavages will of course be reversed. Finally, it may be noted that if there is a minimum in the potential surface for the reaction, representing the intermediacy of a singlet carbene species (449), the analysis in terms of orbital symmetry conservation is unchanged.

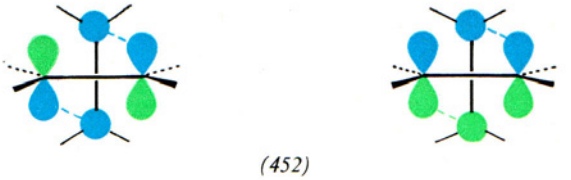
(445) (446) (447) (448)

(449)

(450)

(451)



It might appear that in respect to cheletropic reactions, the principle of orbital symmetry conservation is rather generous than discriminate. But that is not so. Cheletropic reactions are unusual in that the stereochemical imperatives imposed by orbital symmetry control upon one of the reactant sites leave no imprint upon the products. Consequently, verification of the predictions which can be made about the detailed course of cheletropic reactions cannot be achieved simply by examining the stereochemistry of the products, and awaits more sophisticated scrutiny.

10.2. Cycloaddition Reactions of Ketenes

The combination of ketenes with olefins to give cyclobutanes has long been known [229]. In recent years, the reaction has been subjected to very searching scrutiny, and the evidence is now conclusive that it is concerted. Thus, the reaction proceeds with a high negative entropy of activation [230], the dependence of rate on solvent polarity is modest [230,231], and stereometric relations in the reactants are maintained in the products [232] – the most striking instance being the formation of distinct adducts from the reactions of dichloroketene with the *cis*- and *trans*-cyclooctenes [233]. Most compelling is the observation that the reaction of ketenes with dienes – even those so constrained as to favor terminal addition – gives only cyclobutanes, and no cyclohexenes [234]. For example, cyclopentadiene and diphenylketene react to give *(450)*; no *(451)* is produced.

A concerted combination of ethylenes to give a cyclobutane must follow the $[\pi 2_s + \pi 2_a]$ path, and in the case at hand the facts demonstrate beyond question that the olefinic reactant participates in a suprafacial way. Is there a special factor in the structure of ketenes which disposes them to play an antarafacial role in cycloaddition reactions?

We have seen that the $[\pi 2_s + \pi 2_a]$ process involves orthogonal approach of the reacting species (*cf.* Section 6) – *i.e.* that the π systems must orient themselves as in

(452)

(452) – and we recognize that the path is not normally a readily accessible one, in the absence of special factors (*cf.* Figure 25, Section 6.1). For normal olefins, insurmountable difficulties would appear to be presented by steric hindrance factors, and by transition-state strain associated with framework distortions necessary to maintain effective orbital overlap.

Ketenes are powerful electrophiles. Chemically, the spearhead of their reactivity is the carbon atom of their especially reactive carbonyl group. This dominant aspect of the structure of ketenes, succinctly expressed in the valence-bond structure *(453)*, suggests that we analyze the combination of a vinyl cation *(454)* – *i.e.* a *vinylium* ion – with an olefin from the viewpoint of or-

(453)

(454)

bital symmetry conservation. The relevant orbital diagrams are *(455)* and *(456)*, and the significant differences *vis-a-vis* those for the simple olefin-olefin combination *(452)* are the substantially more favorable situation in respect to steric oppositions, and more especially, the presence of the orthogonal vacant *p* orbital in

[229] *Cf. H. Staudinger:* Die Ketene. Enke, Stuttgart 1912.

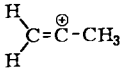
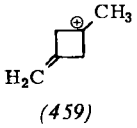
(455)



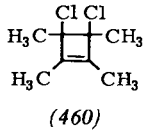
(456)

the vinylium ion [green in *(455)* and checkered in *(456)*]. *It is at once apparent that the latter special feature contributes two strong bonding interactions* [dotted lines in *(455)*] *which are absent from the* $[\pi 2_s+\pi 2_a]$ *reaction path for simple olefins.* It should be noted that the view presented is such that the *top* of the vacant *p* orbital is seen, and that it is the bottom of that orbital which is bonding to the occupied π system of the simple olefinic reactant [*cf. (455)*]. To put the matter in another way, the normal symmetry-allowed combination of a cation with an ethylene, in this unique situation sets the stage for and is coalescent with the $[\pi 2_s+\pi 2_a]$ cycloaddition reaction.

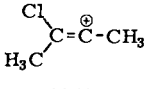


In the light of the analysis just presented, it is clear that a vinylium ion must be regarded as constituted *par excellence* for participation as the $\pi 2_a$ component in the concerted $[\pi 2_s+\pi 2_a]$ cycloaddition. Consequently, it is most gratifying to find that the predicted reaction has in fact been observed, though not hitherto recognized as such. Thus, *Griesbaum* [235] found that allene reacts with hydrogen chloride at −70 °C to give a mixture of the stereoisomeric dichlorodimethylcyclobutanes *(457)*; it is now clear that an initially-produced cation *(458)* combines with a molecule of allene by the

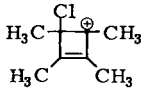
(457)



(458)

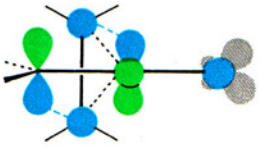


(459)

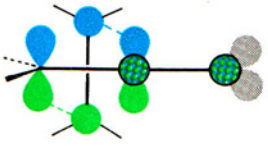


$[\pi 2_s+\pi 2_a]$ route to give *(459)*, which reacts with chloride ion and hydrogen chloride to afford the observed products. Further, the very useful, but surprising – indeed hitherto baffling – synthesis of 1,2-dichloro-1,2,3,4-tetramethylcyclobutene *(460)*, by treatment of 2-butyne with chlorine in the presence of boron trifluoride [236,237], is now readily explicable: $[\pi 2_s+\pi 2_a]$ combination of 2-butyne with the β-chlorovinylium ion *(461)* leads directly to the cyclobutenyl cation *(462)*, whose discharge by chloride ion yields *(460)*. These striking examples leave no doubt that vinylium ions possess in high degree the predicted capacity for concerted combination with $\pi 2_s$ systems.

(460)



(461)



(462)

And now we can answer emphatically in the affirmative the inquiry which launched the discussion just concluded. Ketenes, in their capacity as vinylium ylides *(453)*, are in fact ideally constituted to play an antarafacial role in reaction with $\pi 2_s$ systems, and it is that symmetry-allowed role which they exhibit in the many observed concerted combinations with olefinic systems. Of course, ketenes are not simple vinylium ions, but

(463)

(464)

detailed analysis reveals that the circumstances are not significantly altered in the more complicated case. Thus, for ketenes the relevant orbital diagrams are *(463)* and *(464)*. In this case the place of the vacant *p* orbital of the simple vinylium ion is taken by the unoccupied $\pi^*_{C=O}$ orbital of the ketene molecule [*cf. (463)*]; it is the exceptionally low-lying position of this orbital which accounts in molecular orbital terms for the high electrophilic reactivity of ketenes. As in the simpler case, there is no net change in bonding through interaction of the extra π system with the π* orbital of the $\pi 2_s$ component [*cf. (456)* and *(464)*]. Finally, it should be pointed out explicitly that interaction of the $\pi_{C=C}$ system of the ketene molecule with the antisymmetric lone pair orbital at the oxygen atom is essentially irrelevant to the matter at hand. This interaction, which is small in terms of energy in any event, creates three new allylic orbitals (Figure 45). Of these, two are occupied; the lower simply takes the place of the usual two-orbital π system [*cf. (464)* and *(456)*] and the electrons in the middle orbital return to their original lone pair status as reaction proceeds.

In the dimerization of ketenes – also regarded as concerted [238] – one of the ketene molecules exercises its unique potentiality as a $\pi 2_a$ component, while the other acts in normal $\pi 2_s$ fashion. In that connection it should be noted that the participation of a ketene as a $\pi 2_s$ component is not facilitated by the presence of the orthogonal $\pi_{C=O}$ system, nor is the interaction with the lone

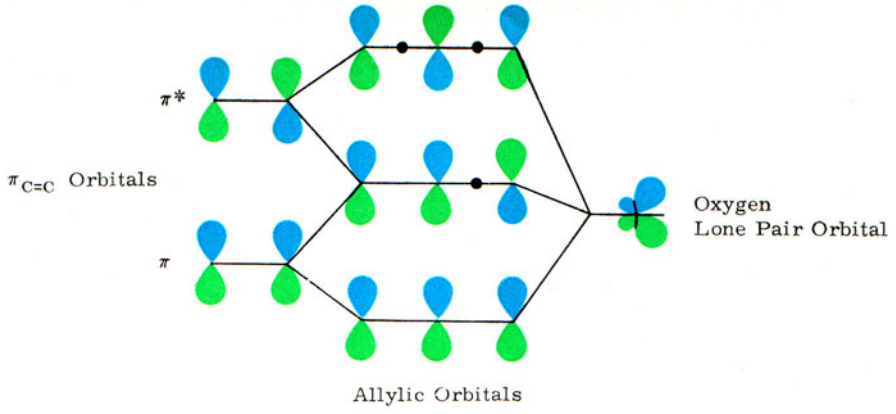

Figure 45. Allylic orbitals in the ketene molecule. — Note that as a consequence of the relative stability of the occupied atomic oxygen orbital, the node in the middle allylic orbital is not at the central atom, as it would be in a three-carbon system, and must be located between carbon and oxygen.

pair at oxygen expected to have a major effect. Thus, in participating in cycloaddition reactions as $\pi 2_s$ components, ketenes should not differ markedly from normal alkyl ethylenes. Consequently, in the reactions of ketenes with dienes, the normal symmetry-allowed $[\pi 4_s + \pi 2_s]$ reaction is not expected to be a ready one. Further, the $[\pi 4_s + \pi 2_a]$ reaction is of course symmetry-forbidden, and the presence of an orthogonal vacant *p* orbital, or low-lying $\pi^*_{C=O}$ system, cannot facilitate the $[\pi 4_a + \pi 2_a]$ process. Taken together, these circumstances account for the formation of cyclobutanones to the exclusion of cyclohexenones when ketenes react with simple dienes.

11. Generalized Selection Rules for Pericyclic Reactions

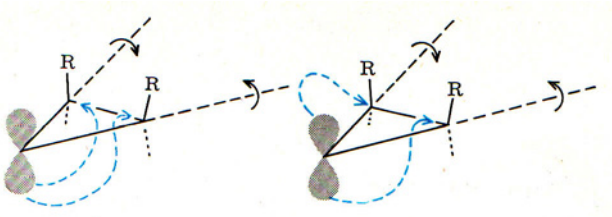
In our development of the theme of orbital symmetry control of concerted chemical changes, we have laid the basis for a general consideration of all *pericyclic* reactions – that is, reactions in which all first-order changes in bonding relationships take place in concert on a closed curve. Thus, we have discussed in detail the special characteristic features of several clearly differentiable reaction types. But we have also made it clear that the different classes have much in common. In particular, we have pointed out that electrocyclic reactions and sigmatropic changes can as well be treated as concerted intramolecular cycloaddition processes. Now, we develop further the important generalization that all pericyclic reactions may be categorized as concerted cycloaddition processes, and must obey the selection rules for such changes.

The selection rules for two-component cycloadditions [*cf.* Figure 22, Section 6] may easily be generalized by induction to include any number of components. In that way we derive the following general rule for all pericyclic changes:

A ground-state pericyclic change is symmetry-allowed when the total number of $(4q+2)_s$ *and* $(4r)_a$ *components is odd.*

Obviously, if the designated total is *even*, the reaction is symmetry-forbidden. Odd-electron systems generally conform to the pattern for even-numbered systems containing one more electron, and there is in general, corresponding to every ground-state reaction, a related excited-state process for which the rule is simply reversed.

In order to complete the generalized description of pericyclic reactions, it is necessary at this point to introduce one further, and final, convention. Clearly, when q or $r = 0$, a $4r$ component necessarily represents a single atomic orbital, and a $4q+2$ component may do so. That is to say, such a single orbital component may be vacant or occupied. Like any other component, single orbital components may participate in either a suprafacial or an antarafacial manner, and they require a special designation – a presubscript ω – consistent with the characterization of σ and π components, thus:



$$\omega 0_s \quad \omega 0_a \quad \omega 2_s \quad \omega 2_a$$

With the tools now at hand, it is a simple matter to classify any pericyclic reaction, and to determine whether it is symmetry-allowed. We shall now recapitulate the examples mentioned earlier, and exemplify the procedure in some new instances. Note that the dashed lines in all of the analyses represent bonding interactions in the transition state.

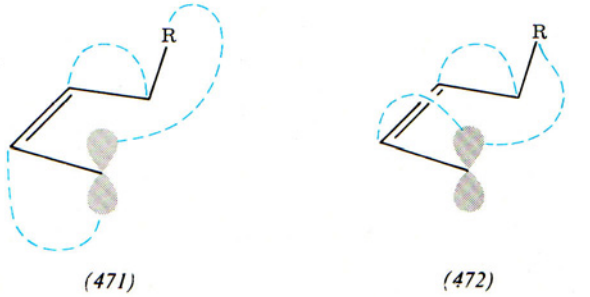
a) The conrotatory electrocyclic opening of cyclobutenes [*cf.* Figures 23 and 24, Section 6] may be regarded either as a $[\pi 2_s + \sigma 2_a]$ or a $[\pi 2_a + \sigma 2_s]$ process, and the general rule shows at once that it is symmetry-allowed.

b) The suprafacial [1,3] sigmatropic shift with inversion at the migrating center [*cf.* Figure 34, Section 7] may also be regarded as a symmetry-allowed $[\pi 2_s + \sigma 2_a]$ or a $[\pi 2_a + \sigma 2_s]$ change.

c) The disrotatory electrocyclic transformation of a cyclopropyl cation to an allyl cation may be regarded either as an $[\omega 0_s + \sigma 2_s]$ *(465)* or as an $[\omega 0_a + \sigma 2_a]$ *(466)* process, and is symmetry-allowed. Note that in a formal sense, when a single ω component is involved in a pericyclic reaction, the ω orbital moves to a new position, and one of the dashed lines used in the analysis vanishes in the product.

$[\omega 0_s+\sigma 2_s]$ (465) $[\omega 0_a+\sigma 2_a]$ (466)

d) The [1,2] sigmatropic shift within a cation cannot take place with inversion of the migrating group, since the $[\omega 0_a+\sigma 2_s]$ *(467)* and $[\omega 0_s+\sigma 2_a]$ *(468)* processes are symmetry-forbidden. Note that antarafacial bonding



$[\omega 0_a+\sigma 2_s]$ (467) $[\omega 0_s+\sigma 2_a]$ (468)

interaction between two atoms joined by a non-participating bond and bridged by a single atom is physically impossible. Thus, the $[\omega 0_s+\sigma 2_s]$ processes depicted in *(469)* and *(470)* both represent the symmetry-allowed but physically unrealizable antarafacial [1,2] sigmatropic shift with inversion at the migrating center.

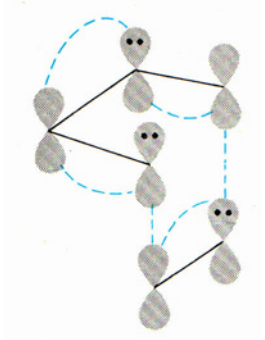
(469) (470)

e) The suprafacial [1,4] sigmatropic shift with inversion at the migrating center may be regarded, *i.a.*, as a symmetry-allowed $[\pi 2_a+\omega 0_a+\sigma 2_a]$ process *(471)*. All of the

(471) (472)

alternative formal classifications *(473)*, each of which represents a symmetry-allowed reaction, require inversion at R, and no allowed suprafacial process exists in which R migrates with retention; for example, the

$[\pi 2_s+\omega 0_a+\sigma 2_s]$
$[\pi 2_s+\omega 0_s+\sigma 2_a]$ *(473)*
$[\pi 2_a+\omega 0_s+\sigma 2_s]$



$[\pi 2_s+\omega 0_s+\sigma 2_s]$ pericyclic reaction depicted in *(472)* is obviously symmetry-forbidden.

f) The non-linear cheletropic extrusion of sulfur dioxide from an episulfone [*cf.* *(418)*, Section 10.1] is a symmetry-allowed $[\sigma 2_s+\sigma 2_a]$ reaction *(474)*, and the reverse process would be a $[\pi 2_s+\omega 2_a]$ change *(475)*.

(474) (475)

g) The Diels-Alder reaction is obviously a symmetry-allowed $[\pi 4_s+\pi 2_s]$ change, but it could be analyzed as an allowed $[\omega 0_s+\omega 2_s+\omega 0_a+\omega 2_a+\omega 0_s+\omega 2_s]$ process *(476)*.

(476)

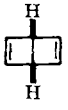
The example is included partly in a sportive spirit, but it does have the serious purposes of indicating that (i) the participation of any number and kind of ω components in a pericyclic reaction presents no occasion for difficulty in analyzing the process in terms of the general rule, and (ii) polarization of the bonds involved in a pericyclic reaction in no way alters the orbital symmetry control to which it is subject.

It should be emphasized that use of the general selection rule for pericyclic reactions must always be subject to the following precautions.

a) The geometry of each individual case must be examined on its merits in order to ascertain whether the process is physically realizable. We have already exemplified, in d) above, and in our discussion of the rearrangement of the ester of Feist's acid [*cf.* *(331)*, Section 7.1], situations in which formally symmetry-allowed processes are geometrically impossible.

b) In cases in which the reacting components are directly joined by non-participating bonds, forced ancillary off-circuit antibonding interactions may render an otherwise allowed reaction symmetry-forbidden. Thus, prismane cannot be converted to three isolated, non-interacting, ground state ethylene moieties by a $[\sigma 2_s+\sigma 2_a+\sigma 2_a]$ process. The geometric constraints imposed by the non-participant σ framework require that the ethylene moieties produced in such a reaction inter-

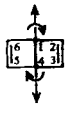
act strongly in an antibonding way, and the orbital symmetry-imposed electronic configuration of the array is in fact that of a doubly excited state of the actual product benzene [*cf.* Section 6.4]. Any case in which similar circumstances may be suspected should be subjected individually to complete analysis in the light of the principle of orbital symmetry conservation.



12. Violations

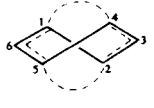
There are none!

Nor can violations be expected of so fundamental a principle of maximum bonding. All the more is it then important to give consideration to some reactions which might appear on casual inspection to contravene orbital symmetry conservation.



First, it should be emphasized explicitly here that a given symmetry-allowed concerted reaction need not necessarily represent the manner in which reacting molecules will actually comport themselves. Quite possibly another path, involving reactive *intermediates* of relatively low energy may be followed. The other side of this coin is that molecules may in some cases combine, or decompose, to give the very products which would result from symmetry-forbidden concerted processes. In these cases it is clear that the actual reaction path is a non-concerted one, involving discrete intermediates; indeed, the principle of orbital symmetry conservation is very useful in defining conditions in which such processes may be expected. Such are often the circumstances in the combination of ethylenes to give cyclobutanes. The direct, concerted $[\pi 2_s + \pi 2_s]$ combination is of course symmetry-forbidden, and the allowed $[\pi 2_s + \pi 2_a]$ reaction is realizable only in special circumstances. Nevertheless, there are a substantial number of instances, lacking the special prerequisites for the $[\pi 2_s + \pi 2_a]$ reaction, in which the combination of two ethylenic molecules leads to a cyclobutane [239]. And in such cases, the available evidence is compelling in favor of the view that discrete diradical or ionic intermediates are involved [240]; further, it is of obvious significance that such reactions are observed only when the reactant olefins are ornamented by substituents so constituted as to provide effective stabilization of the requisite intermediate.

It remains only to address a few final comments to the matter of symmetry-forbidden reactions which may occur in a concerted fashion. In principle, of course, given sufficient energy, and means of constraining molecules in energy-rich configurations, we could bring about any symmetry-forbidden reaction. A very powerful Maxwell demon could make a molecule of cyclobutane by grasping a molecule of ethylene in each hand, and – not without an impressive exhibition of his strength – forcing the two together face-to-face. He could seize a molecule of cyclobutene at its methylene groups, and tear it open in a disrotatory fashion to obtain butadiene. But without such demoniac intervention, molecules will very rarely comport themselves in like fashion – since reaction paths with lower energy surfaces than those associated with symmetry-forbidden processes will almost always be available. None the less, the possibility remains that molecules may be constructed within which no other such alternatives exist; then, provided that the molecule be sufficiently energized, the symmetry-forbidden path would necessarily be followed. Derivatives of *cis*-bicyclo[2.2.0]hexadiene *(477)* quite possibly exemplify such a process. These substances do undergo conversion to the corresponding



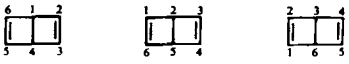
(477)

benzenoid isomers, with an activation energy in the neighborhood of 37 kcal/mole [241]. The simple disrotatory cleavage of the central bond is symmetry-forbidden, but *(477)* is already strained to the extent of *ca.* sixty kilocalories relative to benzene [242], and the addition of a further thirty-seven kilocalories may sufficiently energize the molecule as to overcome the prohibition against disrotatory cleavage. But even in this case, the possibility is not entirely excluded that events may take another course, and that the transformation may proceed through a discrete intermediate. For example, if the breaking of the central bond of *(477)* is accompanied by a quasi-conrotatory skewing distortion [*cf. (478)*] – a boat→twist-boat transformation – the result *(479)* is an array containing two skewed allyl radical systems [C(5)-C(6)-C(1) and C(2)-C(3)-C(4)], joined orthogonally at their termini. Were all bonding between C-1 and C-4 to be lost concurrently with these

(478)

(479)

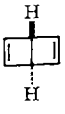
motions, the related symmetry-derived antibonding components in the transition state for conversion to benzene would vanish, and the process could continue



[239] An excellent review is available: *J. D. Roberts* and *C. M. Sharts*, Organic Reactions *12*, 1 (1962).

[240] *P. D. Bartlett, L. K. Montgomery*, and *B. Seidel*, J. Amer. chem. Soc. *86*, 616 (1964); *L. K. Montgomery, K. Schueller*, and *P. D. Bartlett, ibid. 86*, 622 (1964); *P. D. Bartlett* and *L. K. Montgomery, ibid. 86*, 628 (1964); *P. D. Bartlett*, Science *159*, 833 (1968).

[241] *J. F. M. Oth*, Angew. Chem. *80*, 633 (1968); Angew. Chem. internat. Edit. *7*, 646 (1968); Rec. Trav. Chim. Pays-Bas, *87*, 1185 (1968); *H. C. Volger* and *H. Hogeveen*, Rec. Trav. Chim. Pays-Bas *86*, 830 (1967).



[242] *W. Schäfer*, Angew. Chem. *78*, 716 (1966); Angew. Chem. internat. Edit. *5*, 669 (1966).

to completion by appropriate symmetry-allowed combinations of the isolated allyl radicals. Even if some 1,4 bonding is retained – and of course, were that the case, some 2,5 bonding would be generated – the corresponding symmetry-derived antibonding components in the transition state *(479)* will be smaller than those in the transition state for the simple symmetry-forbidden disrotatory cleavage; it is of special interest that if *(479)* should represent the transition state for the conversion of bicyclohexadienes to aromatic compounds, the former should be susceptible of isomerization in the sense *(480)*→*(481)*→*(482)*.

(480) *(481)* *(482)*

Finally, we emphasize the fact that *cis*-bicyclo-[2.2.0]hexadienes owe their remarkable durability to symmetry-imposed barriers, and, to introduce a light note, suggest that our fellow chemists estimate how long the isomer *(483)* – put together, perhaps, by our versatile demon – would survive.

(483)

13. Other Theoretical Work

In view of the fact that the principle of conservation of orbital symmetry has been found to be an exceptionally powerful predictive and interpretive tool, it is not surprising that a number of alternative theoretical approaches have been set forth. In all cases the central conclusions, of necessity, agree in all respects with our own. Reference should be made to the interesting contributions of *Fukui* [243], *Salem* [244], *Zimmerman* [245], *Dewar* [246], *Oosterhoff* and *van der Lugt* [247], and, of course, *Longuet-Higgins* and *Abrahamson* [248].

It is also appropriate here to mention some earlier studies relevant to and antecedent to our own. Correlation diagrams for the simplest chemical reactions are no novelty; some interesting applications are presented by *Laidler* [249]. Such diagrams were extensively used by *Griffing* [250], but were incorrectly interpreted. In an important paper by *Herzfeld* [251] it was shown that for a set of $2p$ orbitals the number of nodes in a molecular system is conserved as atoms are brought near each other, and that when the orbitals are alike no two states of different energy can have the same number of nodes. *Bader* [252] presented a novel and interesting discussion of some elementary reactions.

We have already mentioned the suggestion of *Oosterhoff* [253] that orbital symmetry might play a role in electrocyclic reactions. The advantages of a six-electron transition state were pointed out by *Syrkin* [254]. His papers, and those by *Balaban* [255] and *Mathieu* and *Valls* [256] are a rich source of references for possible concerted reactions.

Numerous reviews summarizing various aspects of the application of the principle of conservation of orbital symmetry have already appeared [257].

The frontier-electron theory was developed by *Fukui*, who has continued an intensive exploration of various methods of calculation pertinent to problems of chemical reactivity [258]. In some of our work we have utilized extended Hückel calculations [259] to confirm qualitative conclusions. The virtue of these approximate calculations lies in the fact that they may be applied to σ as well as π systems. The method was originally developed in collaboration with *Lipscomb* and owes much to previous work of *Longuet-Higgins* on boron hydrides.

Of special interest are several recent applications of orbital symmetry conservation in novel directions. The derivation of selection rules for the isomerization and substitution reactions of transition metal complexes [260], the suggestion that orbital symmetry is determinative in chemiluminescent reactions [261], and the analysis of the role of orbital symmetry in excited state energy transfer [262] merit particular attention.

14. Conclusion

We have now explicated the principle of conservation of orbital symmetry, and exemplified its use. It may perhaps be appropriate here to emphasize that the central content of the principle lies in the incontrovertible proposition that a chemical reaction will proceed the more readily, the more *bonding* may be maintained throughout the transformation. Consequently, we cannot doubt that the principle will endure, whatever the language in which it may be couched, or whatever greater precision may be developed in its application and extension.

Nor can it be doubted that extension will be made – both of a fundamental and of a detailed nature. Since every elementary step in *any* chemical reaction is a concerted process, correlative ideas must be applicable to *all* reactions. The exploration of applications in inorganic chemistry has barely been begun. And within the realm already delineated, only the imagination sets limits upon the number and variety of new and fascinating molecules which may be designed to favor reactions as yet undiscovered, but now known to be feasible.

Classification of Partition Reactions of Inorganic Cations

By H. Specker and A. Kettrup [*]

In partition reactions of inorganic cations, it is necessary to establish the composition of the extracted compounds. The methods used and the limits of their application are described and illustrated for the extraction of cobalt thiocyanates. The results obtained allow new analytical applications, e.g. the fractional extraction of Hg, Bi, Cd, In, and Zn.

1. Introduction

The aim of the present article is to describe the methods that provide information about the composition of an extracted species, as well as their application limits, using the extraction of cobalt thiocyanates as an example.

A general picture will also be given of the extraction of inorganic compounds with ketones and triesters of phosphoric acid as solvents. Extractions with diesters of phosphoric acid and with amines will not be discussed, since these systems were reviewed comparatively recently [1–3].

2. Methods of Determining the Compositions of Extracted Compounds

All the methods described below were originally developed for determination of the compositions of complexes in single-phase, particularly aqueous systems. The question of primary interest is that of the number n of ligands (*e.g.* halide ions) bound per central atom. In extractions with solvents that are capable of coordination, we also wish to know the number r of solvent molecules bound. If a definite compound, *e.g.* a halogenometalate

$$(A^+)_z[ML_n]^{z-} \cdot rS$$

is extracted over a wide concentration range, two series of measurements with suitable variations are generally sufficient to give the numbers of halide and solvent ligands.

The photometrically determined extinction value is very often used as a measure of the concentration of the complex formed in normal solution equilibria;

however, any other physical property that is definitely associated with the compound formed, *e.g.* the electric conductivity, may also be used. In partition measurements, the equilibrium reached in the extraction is fixed by the phase separation. In this case, provided that the total concentration of the element in question in the organic phase can be taken as equal to the concentration of the extracted complex and the blank extraction is not high, the inorganic components can be determined by a simple analysis of the organic phase. However, this will be possible in only a few cases.

2.1. Molar Ratio Method

The molar ratio method depends on the stoichiometric, *i.e.* quantitative reaction of the components forming the compound [4]. This means that in normal solution equilibria the complex formation constant K_n and in extractions the partition constant K_D, must be very large. In this method the concentration of one component of the complex, *e.g.* of the metal (C_M), is kept constant, while the concentration of the other, in this case of the ligand (C_L), is increased from one experiment to the next. In partition methods, the system is allowed to reach partition equilibrium after each addition of L, and the concentration of the complex in the organic phase is measured. This method gives satisfactory results when the partition constants are high; it has been used successfully to determine the number of solvent ligands in the system $UO_2(NO_3)_2 \cdot 2$ tributyl phosphate [5].

2.2. Logarithmic Method

This method for the investigation of solution equilibria, in particular of very weak complexes, which was first described by *Bent* and *French* [6], can be derived as follows. For a reaction

$$aM + nL \rightleftharpoons M_aL_n$$

we obtain

$$K = [M_aL_n]/([M]^a \cdot [L]^n)$$

Similarly, the heterogeneous partition constant (w = water, org = organic solvent) is given by

$$K_D = [M_aL_n\bullet_r]_{org} / \left([M]^a_w \cdot [L]^n_w \cdot [S]^r_{org}\right)$$

Introduction of the partition coefficient D gives

$$K_D = D / \left([L]^n_w \cdot [S]^r_w\right)$$

and hence, taking logarithms, we obtain

$$\log D = \log K_D + n \cdot \log [L]_w + r \cdot \log [S]_{org}$$

n, which will be referred to simply as the number of halide ligands, is determined by varying the halide concentration C_L while the concentrations of all other components, including that of the metal C_M, are kept constant. It is assumed that the components react to only a small extent. The equilibrium concentration can then be replaced by the total concentration: $[L] = C_L$, $[S] = C_S$, *etc.* Collection of the constant terms gives

$$\log D = A + n \cdot \log C_L.$$

n is the gradient of the straight line obtained by plotting the logarithm of the partition coefficient for M (metal) against the logarithm of the concentration C_L. The number r of solvent ligands can similarly be obtained by a series of measurements in which only the solvent concentration C_S in an inert solvent is progressively varied. Then

$$\log D = B + r \cdot \log C_S$$

Umland [7] applied the logarithmic method to two-phase systems for the determination of n for metal quinolinolates ("oxinates"). *Irving* [8], and even earlier *McKay* [9], used this method based on the above derivation for the first time to determine the numbers of coordinately bound solvent molecules (tributyl phosphate) in lanthanide nitrates and in uranyl nitrate respectively. According to *McKay*, in the determination of r, the solvent concentrations must be kept low in order to remain in the "ideal" range, *i.e.* $C_{TBP} < 0.186$ mole/l in the case of tributyl phosphate. The partition coefficients in this range are generally small, and are often very difficult to determine unless tracer methods can be used. This method for the determination of the number r of solvent ligands has therefore been confined so far to partition systems containing highly active esters of phosphoric acid. It can also be seen from the equations that the heterogeneous partition constants K_D can be calculated in this way, as was suggested by *Umland* [10].

2.3. Straight-Line Method

The straight-line method was developed by *Asmus* [11] for the investigation of medium-strong to weak complexes; the little-known method of *Edmonds* and *Birnbaum* [12] has a mathematically equivalent form.

[10] *F. Umland* and *K. U. Meckenstock*, Z. analyt. Chem. *173*, 211 (1960).

[11] *E. Asmus*, *U. Hinz*, *K. Ohls*, and *W. Richly*, Z. analyt. Chem. *178*, 104 (1960).

[12] *S. M. Edmonds* and *N. Birnbaum*, J. Amer. chem. Soc. *63*, 1471 (1941).

We applied the straight-line method for the first time to two-phase systems (purely empirically at first, and then mathematically) for the determination of the empirical formulas of extracted halogenometalate complexes and of the coefficients n and r [13]. In this method, increasing quantities of the component L (*e.g.* halide) are added to a constant preset quantity of M (cation); a quantity that is proportional to the quantity of complex ML_n formed is then measured. The results of the measurements are used to find functions that appear as straight lines in a suitably chosen system of coordinates only if a parameter is identical with n, or with n or r in the case of an extraction system. In a greatly simplified form, with all the constants and known quantities collected and represented by P' and P'' *Asmus*'s final equation can be written in the form:

$$\frac{1}{{}_{v}n(r)} = P' \cdot \frac{1}{m} - P''$$

where v is the volume (in ml) of the component L or solvent added, and m is the quantity that is proportional to the concentration of ML_nS_r (generally the extinction).

To determine n, increasing quantities of L are added to the aqueous solution, the extraction is carried out, and m is measured in the extract. To determine r, increasing quantities of the active solvent, *e.g.* tributyl phosphate, are added to the inert solvent, *e.g.* isooctane, while keeping all other parameters constant, and $1/v^r$ (r = 1,2,3,4....) is plotted as usual against $1/m$. K_D can be calculated here, like K_n in the single-phase systems, from the gradient $\tan\alpha$ of the straight line and the intercept Q on the ordinate [13]. The straight-line method is illustrated schematically in Figure 1.

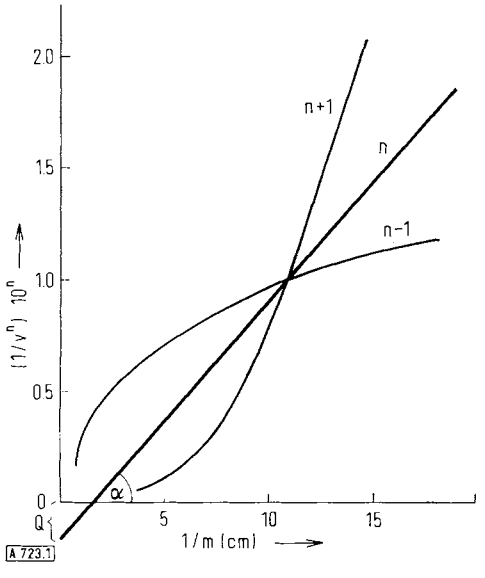

Fig. 1. Schematic illustration of *Asmus*'s straight line method.

[15] *P. Job,* C.R. hebd. Séances Acad. Sci. *180,* 928 (1925).

2.4. Continuous Variation Method

The most widely used method of determining the composition of a compound ML_n is the method devised by *Ostromisslensky* [14] and *Job* [15] on the basis of the principle of "continuous" variations. Equimolar solutions of the components M and L are mixed in quantities such that the total volume, and hence the total concentration C, remains constant:

$$(C_M + C_L) = C$$

$$C_M = C(1-x) \text{ and } C_L = C \cdot x$$

where $0 \leq x \leq 1$ (mole fraction of the component L). The concentration of the compound ML_n reaches a maximum when the ratio of the initial concentrations is exactly

$$C_L/C_M = x/(1-x) = n$$

This method is particularly suitable when $n = 1$; if n = 2,3, or even 4, it can be used only if one complex is formed and if its formation constant is sufficiently high. The improper use of this method has been referred to by several authors, particularly *Woldbye* [16], *Jones* [17], and *Asmus* [18].

In two-phase systems, the Job method is also subject to these limitations, but occasionally offers greater advantages. It has been used by *Pilipenko* [19] and by *Umland* [20] to determine the compositions of extracted chelates, and its theoretical validity for this purpose has been verified by *Irving* [21]. This method was later used successfully for the investigation of metal halides and halogenometalates [5]. It has also been used to find the number r of solvent ligands. Figure 2 illustrates the use of this method for the determination of r in the system ferric thiocyanate – tributyl phosphate, in one case with variation of iron in the aqueous phase and of tributyl phosphate in the organic, and in the

other with variation of thiocyanate in the aqueous phase and of tributyl phosphate in the organic. Both series of measurements lead to the conclusion that the extracted compound has the composition $Fe(NCS)_3 \cdot 3$ TBP.

2.5. Comparison of Spectra

The composition of the extracted compound can always be deduced from the absorption spectra when they agree with the spectra of metal halides or halogenometalates in solution or even with the spectra of single-phase equilibrium mixtures. Comparison of the absorption spectra of extracts and of model solutions can frequently also be used when the organic phase contains several compounds in equilibrium with one another instead of predominantly one compound. The methods described earlier can be used only with reservations, if at all, in such cases. If a series of recorded absorption spectra show one or more isosbestic points, *i.e.* points at which the extinction remains the same when the spectra change, there are only two absorbing compounds in equilibrium with each other. This special case frequently facilitates the interpretation of the spectra, and hence the calculation of the equilibrium.

2.6. Detection of Mononuclear Complexes

The most suitable method for determining whether mononuclear or polynuclear complexes are formed in solution is the logarithmic method (Section 2.2) proposed by *Bent* and *French* [6]. To find the number a of central atoms M in a dissolved complex having the empirical formula M_aL_n, the metal concentration C_M is varied in the presence of a constant high excess concentration of the component L and of all the other reactants present. The coefficient a is found as the gradient of the straight line obtained on plotting

$$\log C_{M_aL_n} = f(\log C_M)$$

For mononuclear complexes, therefore, it is always found that $\tan \alpha = a = 1$. The equation is also applicable to two-phase systems. The logarithm of the concentration of the complex in the extract is again plotted against the logarithm of the predetermined metal concentration in the aqueous phase (or more accurately the equilibrium concentration), and the slope of the straight line is determined:

$$\log C_{complex} = a \cdot \log C_M + \text{const.} \quad (C_M \gg C_{complex})$$

The partition coefficient D or $\log D$ may be plotted instead of $\log C_{complex}$. A line parallel to the abscissa is then obtained only if the extracted compound is mononuclear. The partition coefficient is then independent of the given concentration C_M of the central atom [22].

[22] *I. Nelidow* and *R. M. Diamond*, J. physic. Chem. *59*, 710 (1955).

Except in the typical polyacids and heteropolyacids, polynuclear complexes or polymers occur only at higher metal concentrations; the occurrence of these compounds is then synonymous in many cases with the formation of autocomplexes. Thus we have detected autocomplexes in the extraction of cobalt thiocyanates at high concentrations under certain conditions.

3. Determination of the Complex Constants in Solution

The formation constant of a complex is easy to determine if there is only one complexing equilibrium in solution. Suitable methods are the logarithmic method, the straight line method, and other known methods. It is equally easy to determine the constant K_D of a partition reaction having a single, definite course if the concentrations can be used instead of activities in the calculations. More complicated methods are required, on the other hand, to determine the constants of successive complexes quantitatively for step equilibria in a solution or in partition processes.

It is rarely possible to carry out a detailed quantitative treatment of such difficult situations in two-phase systems. We have tried to record the absorption spectra of cobalt thiocyanates in the pure extraction solvents (tributyl phosphate, cyclohexanone, isobutyl methyl ketone) in very different cation and anion concentration ranges, in order to apply the results to extracts and to compare them. The choice of methods for the investigation of the stepwise complex formation was limited by the almost total overlap of the spectra of successive cobalt complexes. The methods available are firstly *Bjerrum*'s method of corresponding solutions (calibration curve method) [23], secondly a variant of the spectroscopic method described by *Newman* and *Hume* [24], and thirdly two mutually complementary evaluation methods based on the presence of isosbestic points [25, 26]. The use of all the methods mentioned so far will be illustrated below for the extraction of cobalt thiocyanates.

4. Cobalt Thiocyanates in the Partition System

The analytical application of cobalt thiocyanate extraction has been known for 100 years [27]. Despite their ready accessibility for analytical and photometric investigations the composition of the blue cobalt halides extracted is not yet definitely known; this is true even of the aqueous solutions. Our measurements

[23] *J. Bjerrum*, Kgl. dansk. Vidensk. Selsk., *21*, 4 (1944).

[24] *L. Newman* and *D. N. Hume*, J. Amer. chem. Soc. *79*, 4551 (1957).

[25] *G. Werding*, Dissertation, Universität Münster 1963.

[26] *W. Libus*, *A. Ugniewska*, and *S. Minc*, Roczniki Chem. (Ann. Soc. chim. Polonorum) *34*, 29 (1960).

[27] *H. W. Vogel*, Ber. dtsch. chem. Ges. *8*, 1553 (1875).

have failed to confirm *Lehné*'s opinion [28], based on the spectra (ε_{max} = 150 l·mole^{-1} cm^{-1}, λ = 620 nm), that only $[Co(NCS)_4]^{2-}$ is present in aqueous 8.4 M ammonium thiocyanate solution. The spectra show clearly that $[Co(NCS)_3]^-$ must also be present at this concentration.

The classical method for the analysis of the organic phase leads to two definite results, when the "blank value" is taken into account, with an excess of cobalt ion and with an excess of ammonium thiocyanate (see Table 1). With an excess of cobalt, only $Co(NCS)_2$ is extracted with the three solvents mentioned, whereas with an excess of thiocyanate, TBP extracts the trithiocyanatocobaltate and the other solvents extract the tetrathiocyanatocobaltate. The blank extraction was reproducibly suppressed in every case by addition of an inert solvent (isooctane).

Table 1. Ratio NCS^- : Co^{2+} found by analysis of the organic phases.

	Tributyl phosphate	Cyclo-hexanone	Isobutyl methyl ketone
Constant NCS^- conc. (mole/l) (excess)	0.75	0.75	0.75
Increasing Co^{2+}conc. (mole/l)	0—0.1	0—0.07	0—0 09
NCS^-/Co^{2+} = n (corr.)	3.1	4.0	3.8
Constant Co^{2+} conc. (mole/l) (excess)	0.75	0.75	1.50
Increasing NCS^- conc. (mole/l)	0—0.07	0—0.07	0—0.025
NCS^-/Co^{2+} = n (corr.)	1.86	1.94	2.1

The molar ratio method does not give the desired result because of the limitations mentioned above. S-shaped curves of very little value are obtained. This method simply confirmed that the extraction does not proceed stoichiometrically and that several compounds are extracted at the same time. For the same reason, the logarithmic method also failed to give a definite result. Even *Asmus*'s straight line method was of no assistance in extractions from aqueous solutions containing thiocyanate, owing to the simultaneous extraction of several compounds. If, by analogy with the photometric determination of cobalt, the extraction is carried out with tributylammonium thiocyanate and *n*-butanol at pH = 6, only one thiocyanato complex is extracted, as is shown by the constant spectrum (ε_{max} = 625 nm). In this special case the conditions for both the straight line method and the logarithmic method are satisfied. It is clear from Figures 3 and 4 that the complex extracted is tetrathiocyanatocobaltate, and not the hexathiocyanato compound, as was originally assumed.

Like the analysis of the mixture, the determination of the number r of solvent ligands is difficult because of the succession of step equilibria. It is however possible to determine the coordinately bound solvent molecules either with an extremely large excess of ammonium thiocyanate or with an excess of cobalt. Under these conditions the compounds $[Co(NCS)_4]^{2-}$ and

[28] *M. Lehné*, Bull. Soc. chim. France *1951*, 76.

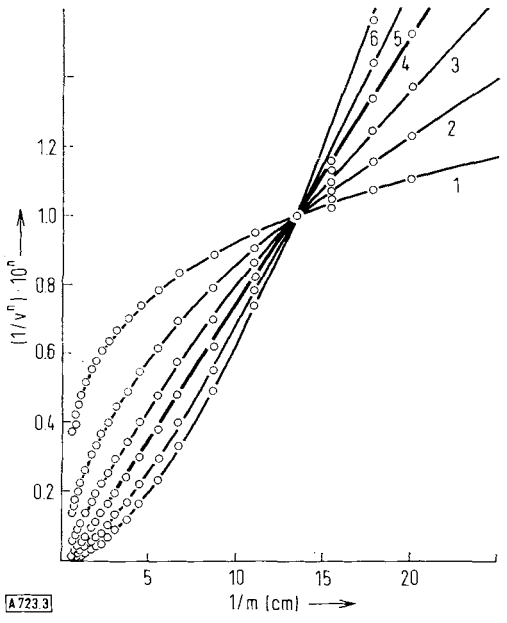

Fig. 3. Determination of the number n of thiocyanate ligands by the straight line method in the two-phase system: $(C_4H_9)_3NH^+$—Co^{2+}—NCS^-—H_2O/*n*-butyl acetate.

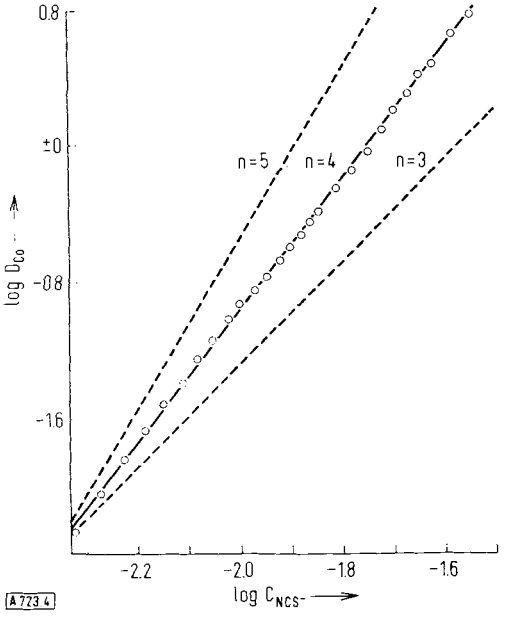

Fig. 4. Determination of the number n of thiocyanate ligands by the logarithmic method in the two-phase system: $(C_4H_9)_3NH^+$—Co^{2+}—NCS^-—H_2O/*n*-butyl acetate.

$Co(NCS)_2$ respectively are present. For the compound $NH_4[Co(NCS)_3]$, which is always present in the equilibrium when the concentrations of the components are comparable, r can only be estimated from the intermediate values. It was possible to show in preliminary experiments and from the absorption spectra that at a cobalt: thiocyanate molar ratio of 1:4 in the aqueous phase the trithiocyanatocobaltate is present in the tributyl phosphate extract to the extent of 85 %. The determination of the number of solvent ligands, however, was still confined to the tributyl phosphate-cobalt thiocyanate system, since very accurate analysis of the organic phases was not possible in the systems with cyclohexanone and isobutyl methyl ketone.

The results obtained by the logarithmic method with a large excess of thiocyanate are shown in Figure 5. The concentration of the active solvent (tributyl phosphate) was varied from 0 to 0.3 M in isooctane and plotted against the partition coefficient. All the series of experiments gave a slope of 4, *i.e.* the compound $(NH_4)_2[Co(NCS)_4]$ is coordinated with four molecules of tributyl phosphate.

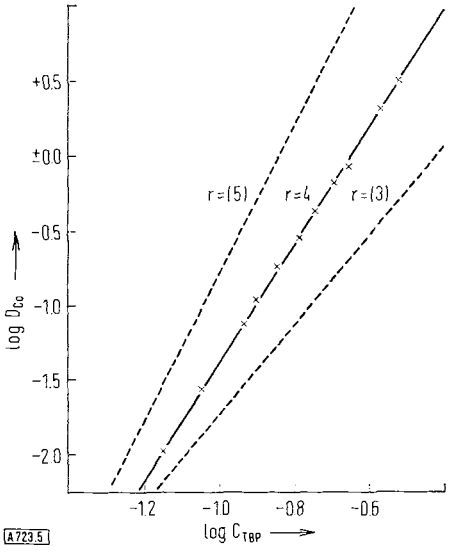

Fig. 5. Use of the logarithmic method for the determination of the number r of solvent ligands on tetrathiocyanatocobaltate.

The extracted compound $Co(NCS)_2$ has also been investigated by the logarithmic method. With low starting concentrations [0.1 mole/l of $Co(NCS)_2$], the slope is clearly 2, showing that the compound $Co(NCS)_2 \cdot 2$ TBP is present. At higher starting concentrations in the aqueous phase [1.6 mole/l of $Co(NCS)_2$] and under otherwise identical conditions the slope of the straight line is 3; intermediate concentrhtions give slopes of 2 to 3. It is very probable in this case that an autocomplex having the composition $Co_2(NCS)_4 \cdot 3$ TBP is being extracted, but we have not yet been able to obtain definite confirmation of this.

These extraction systems were also investigated by *Asmus*'s straight line method, which fully confirmed the results of the logarithmic method.

The continuous variation method was also used to obtain further confirmation of the numbers r of solvent ligands found so tar. The conditions for the use of this method are also satisfied, since one series of experiments can be carried out with an excess of cobalt and another with an excess of thiocyanate. The experiments with an excess of cobalt confirmed the compound $Co(NCS)_2 \cdot 2$TBP, while the experiments with an excess of thiocyanate confirmed the compound $(NH_4)_2[Co(CNS)_4] \cdot 4$TBP. The determination of the number r of solvent ligands on extraction of trithiocyanatocobalt was more difficult. This compound is never present alone in the extract. However, we were able to calculate from a large number of spectra that at a cobalt: thiocyanate ratio of 1:4 in the aqueous phase the trithiocyanato compound is present in the tributyl phosphate phase to the extent of 85 %. Under these conditions the logarithmic method gives a slope of 2.93. This leads to $r = 3$ for the number of solvent ligands, and to the compound $NH_4[Co(NCS)_3] \cdot 3$TBP.

To sum up, therefore, good agreement can be obtained by several methods even for the very complicated cobalt thiocyanate system.

The formation constants K_3 and K_4 in the following reactions were also calculated:

$$Co(NCS)_2 + NH_4NCS \overset{K_3}{\rightleftharpoons} NH_4[Co(NCS)_3]$$

$$NH_4[Co(NCS)_3] + NH_4SCN \overset{K_4}{\rightleftharpoons} (NH_4)_2[Co(NCS)_4]$$

Since we had available a large volume of experimental data and many absorption spectra, *Bjerrum*'s method of corresponding solutions, *Newman* and *Hume*'s method, and the method based on isosbestic points were used

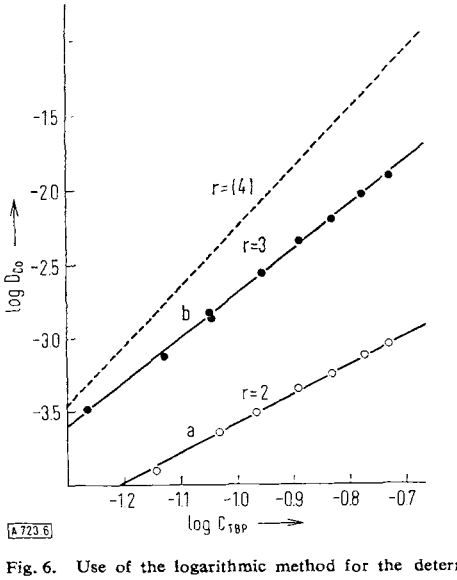

Fig. 6. Use of the logarithmic method for the determination of the number r of solvent ligands in the system Co^{2+}—NCS^-—H_2O/tributyl phosphate-isooctane. a) from 0.1 M $Co(NCS)_2$ solution; b) from 1.6 M $Co(NCS)_2$ solution.

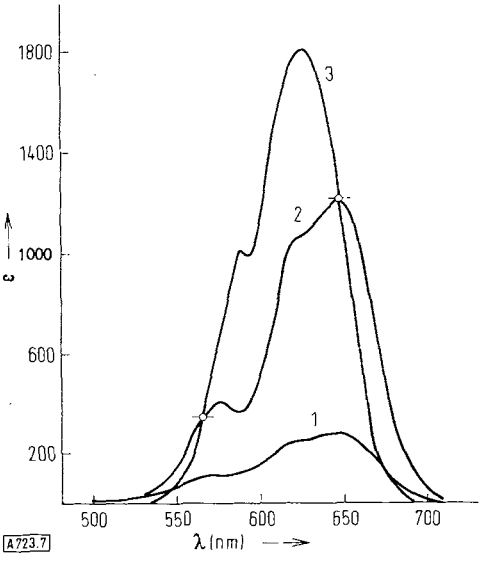

Fig. 7. Absorption spectra of cobalt thiocyanates in tributyl phosphate. Curve 1: spectrum of $Co(NCS)_2$; curve 2: spectrum of $NH_4[Co(NCS)_3]$; curve 3: spectrum of $(NH_4)_2[Co(NCS)_4]$. o = isosbestic points.

for the solvents tributyl phosphate, cyclohexanone, and isobutyl methyl ketone.

The results are shown in Table 2. The complex constants K_4 are greater by factors of 30 to 50 in cyclohexanone and in isobutyl methyl ketone than in tributyl phosphate. This provides quantitative confirmation that different compounds[29] are extracted by different solvents. The number of inorganic ligands

Table 2. Complex constants of cobalt thiocyanates in organic solvents.

	K_n	Tributyl phosphate	Cyclo-hexanone	Isobutyl methyl ketone
Bjerrum method	K_3	$2.5 \cdot 10^4$	$3.4 \cdot 10^4$	$2.4 \cdot 10^4$
	K_4	$1.9 \cdot 10^2$	$6.5 \cdot 10^3$	$7.1 \cdot 10^3$
Newman-Hume method	K_3	$2.4 \cdot 10^4$	$3.3 \cdot 10^4$	$2.5 \cdot 10^4$
	K_4	$2.0 \cdot 10^2$	$6.1 \cdot 10^3$	$7.0 \cdot 10^3$
Isosbestic point method	K_3	$3 \cdot 10^4$	—	—
	K_4	$1.9 \cdot 10^2$	—	—

is smaller with highly active solvents, *i.e.* inorganic ligands can be displaced by solvent molecules.

The percentage distribution of the thiocyanato complexes can also be calculated as a function of the ammonium thiocyanate concentration from the K_n values. In equilibrium with the aqueous phase, the compound $NH_4[Co(NCS)_3]$ occurs to extents of up to 85, 53, and 47 % respectively in tributyl phosphate, cyclohexanone, and isobutyl methyl ketone.

5. Investigation of Other Extraction Systems

As has been repeatedly mentioned, the application of the methods discussed to the system cobalt thiocyanate-organic solvent presents special difficulties. In studies on the extraction of other metals, which are based on the periodic system, the conditions for the use of these methods are much more favorable. The composition of the extracted species is shown in Table 3.

Table 3. List of compounds extracted (Cyclo = cyclohexanone, TBP = tributyl phosphate).

Central atom	Solvent (S)	Compound extracted	Ref.
CuI	TBP	$[Cu_2I_3]^- \cdot 3S$	[30]
Ag	Cyclo	$[Ag_2I_3]^- \cdot 2S$	[30]
	TBP	$[Ag_2I_3]^- \cdot 2S$	[30]
AuIII	TBP	$[AuCl_4]^- \cdot 3S$	[30, 31]
Zn	Cyclo	$ZnI_2 \cdot 2S$, $Zn(NCS)_2 \cdot 4S$, $[ZnI_3]^- \cdot 3S$, $[Zn(NCS)_3]^- \cdot 3S$	[32]
	TBP	$ZnCl_2 \cdot 2S$, $ZnI_2 \cdot 2S$, $Zn(NCS)_2 \cdot 4S$, $[Zn(NCS)_3]^- \cdot 3S$	[32]
Cd	Cyclo	$CdI_2 \cdot 2S$, $[CdI_3]^- \cdot 3S$	[32]
	TBP	$CdCl_2 \cdot 2S$, $CdI_2 \cdot 2S$, $Cd(NCS)_2 \cdot 4S$, $[Cd(NCS)_3]^- \cdot 3S$	[32]
Hg	Cyclo	$HgI_2 \cdot 2S$, $HgCl_2 \cdot 2S$, $Hg(NCS)_2 \cdot 4S$, $[HgI_3]^- \cdot S$, $[HgCl_3]^- \cdot S$, $[Hg(NCS)_3]^- \cdot 3S$	[32]
	TBP	$HgI_2 \cdot 2S$, $HgCl_2 \cdot 2S$, $Hg(NCS)_2 \cdot 4S$, $[HgI_3]^- \cdot S$, $[HgCl_3]^- \cdot S$, $[Hg(NCS)_3]^- \cdot 3S$	[32, 33]
Ga	Cyclo	$[GaCl_4]^- \cdot 2S$	[34]
	TBP	$[GaCl_4]^- \cdot 2S$, $Ga(NCS)_3 \cdot 3S$, $[Ga(NCS)_4]^- \cdot 2S$	[34]
In	Cyclo	$[InI_4]^- \cdot 2S$	[34]
	TBP	$[InCl_4]^- \cdot 2S$, $[InI_4]^- \cdot 2S$, $In(NCS)_3 \cdot 3S$, $[In(NCS)_4]^- \cdot 2S$	[34]
Tl	Cyclo	$[TlCl_4]^- \cdot 2S$, $[TlI_4]^- \cdot xS$, $TlI_3 \cdot xS$	[34]
	TBP	$TlCl_3 \cdot S$	[34]
Sc	TBP	$Sc(NO_3)_3 \cdot 3S$	[36]
Sn	TBP	$SnCl_4 \cdot 2S$	[37]

6. Analytical Uses

If the compound extracted is known, the equilibrium constants of partition reactions can be calculated. These K_D values in the dilute solution range are an accurate expression of the extracting powers of organic solvents, particularly if extracted compounds of the same formula type are compared, *e.g.* the complexes of the iodides of Group II triad metals with tributyl phosphate. Using total ionic strengths $I < 0.01$ and identical initial concentrations of the metal salt solution, the halide solution, the mineral acid, and the solvent, the quantities obtained are thermodynamic constants at a given temperature, and are preferable to partition coefficients obtained at arbitrary concentrations. These results can be transferred to the analytical concentration range ($I > 0.01$) only if the activity coefficients of all the components of a partition system are known. This is only rarely true of aqueous solutions, and is never true for organic solvents.

The partition coefficients found in the ideal solution range nevertheless agree well with the partition behavior of metals at high concentrations of the components of the aqueous and organic phases, and can therefore be used for the classification of inorganic partition reactions.

The constants were calculated by the logarithmic method (intercept on the ordinate) and by *Asmus*'s straight line method (intercept on the ordinate and slope) [11].

A selection of the K_D values obtained is given in Table 4; they reflect the observed partition behavior very satisfactorily. To supplement these results, the enthalpies of partition of some systems were measured [50, 51]. The partition constants and enthalpies of partition can, as one would expect, be correlated.

Table 4. K_D value and enthalpy of partition as a measure of the partition behavior of an element (TAP = triamyl phosphate; MIBK = isobutyl methyl ketone; for TBP and Cyclo, see Table 3.

	K_D-value		$-\Delta H_{293}$ (kcal/mole^{-1})
	Linear method	Log method	
$BiI_3 \cdot 3TBP$	$6 \cdot 10^8$	$4.3 \cdot 10^8$	6.8 ± 0.1
$BiI_3 \cdot 3TAP$	$4.5 \cdot 10^7$	$1.5 \cdot 10^7$	—
$BiI_3 \cdot 3$ Cyclo	$2.8 \cdot 10^4$	—	4.9 ± 0.15
$Li[BiI_4] \cdot 2MIBK$	$5 \cdot 10^1$	—	3.4 ± 0.1
$Fe(NCS)_3 \cdot 3TBP$	$1 \cdot 10^9$	$7.3 \cdot 10^8$	8.3 ± 0.2
$HgI_2 \cdot 2TBP$	$5.8 \cdot 10^{11}$	$7.3 \cdot 10^{11}$	10.1 ± 0.2
$HgI_2 \cdot 2$ Cyclo	—	$8.2 \cdot 10^8$	7.0 ± 0.1
$HgI_2 \cdot 2MIBK$	$1.1 \cdot 10^8$	$2.4 \cdot 10^8$	5.9 ± 0.1
$CdI_2 \cdot 2TBP$	—	$8 \cdot 10^4$	5.5 ± 0.2
$ZnI_2 \cdot 2TBP$	—	$1.5 \cdot 10^{-2}$	4.7 ± 0.2
$UO_2(NO_3)_2 \cdot 2TBP$	—	—	6.2 ± 0.2

[50] *A. Kettrup* and *H. Specker*, Z. analyt. Chem. *230*, 241 (1967).
[51] *A. Kettrup* and *H. Specker*, Z. analyt. Chem. *240*, 1 (1968).

Analytical uses can be predicted from the partition constants. An impressive example of this is the fractional extraction of mercury, bismuth, cadmium, zinc, and indium, which is shown in Figure 8.

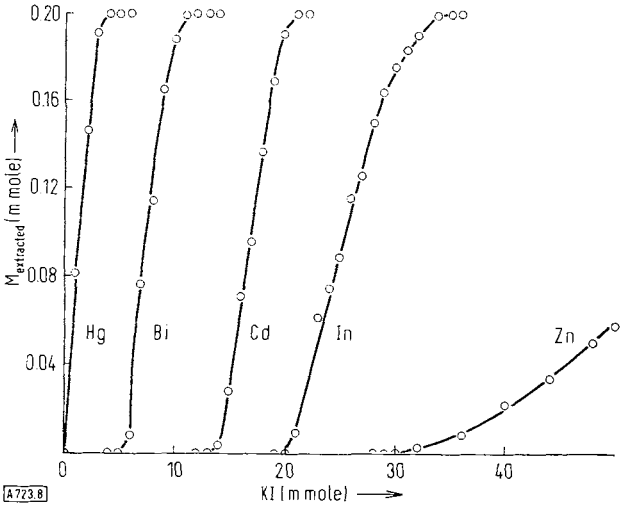

Fig. 8. Extraction sequence of some iodides with cyclohexanone as the solvent. Quantities present: 0.2 mmole of Hg^{2+}, Bi^{3+}, Cd^{2+}, In^{3+}, and Zn^{2+}.

HgI_2 and $[HgI_3]^-$ are extracted with high partition constants; this is the basis of a very selective extractive separation of mercury from nearly all other elements [52]. Trace elements in bismuth can be concentrated in the same way [53]. This principle is also used for the concentration of traces in pig iron and steels in the extraction of the chlorides with tributyl phosphate [54]. The problem of the determination of very low tin contents ($<10^{-3}$ %) in steels has also been solved in this way [37]. In principle, the partition constants can be used to find the practical partition coefficients, and hence the degree of partition [13], if only one compound is extracted with a high partition constant and if the anionic ligand is introduced in the aqueous phase or the active solvent in the organic phase.

We thank the Deutsche Forschungsgemeinschaft and the Stifterverband für die Deutsche Wissenschaft (Hibernia AG and Scholven-Chemie) for their support of our work over several years.

Elemento-Organic Amines and Imines

By O. J. Scherer[*]

Amines with mixed substituents containing two or three El–N bonds[**] are relatively stable if one or two of these bonds are $(CH_3)_3$ Si–N bonds. IR and ^1H–NMR studies indicate that the (p → d)π bond components of the element-nitrogen bonds steadily decrease from silicon, phosphorus, and sulfur toward their higher homologs. Because of the differences in the polarities of the element-nitrogen bonds, these substances can be used for selective insertion and cleavage reactions. The reaction of metalated N-silyl-aminoarsines with methyl chloride as well as the reaction of metalated N-trimethyl(IVa)-element-substituted amino-tert-butylphosphines with halogenotrimethyl(IVa)element compounds open new, simple routes for the conversion of elemento-organic amine systems into imine systems. The problem of reversible and irreversible $(CH_3)_3$El ligand migration (1,3 shift) is discussed for trimethyl(IVa)element-substituted benzamidines, diaminophosphines, aminoiminophosphoranes, sulfinamides, and aminosulfimines.

1. Introduction

Whereas compounds of nitrogen with its five neighboring elements have mostly been known for a long time and have been extensively studied, compounds of nitrogen with the other nine elements in the portion of the periodic system shown were very much an unexplored field until about ten years ago.

C	N	O
Si	P	S
Ge	As	Se
Sn	Sb	Te
Pb	Bi	Po

The often extreme sensitivity of element-nitrogen compounds of this type to moisture and oxygen, their not infrequent extreme thermal instability, and their toxicity (particularly that of the heavier homologs) may have been major causes of the striking neglect of this field of study.

To permit the investigation and discussion of the thermal stabilities, reactivities, bonding, and ligand migration reactions of elemento-organic nitrogen compounds containing different hetero atoms, it was first necessary to synthesize many model substances [1].

It was found very useful in many cases to attach one or two trimethylsilyl groups to the nitrogen atom, possibly because the bulky trimethylsilyl ligand provides favorable steric conditions, and may also strengthen the σ bond by (p → d)π bonding [2] with the "lone" pair of electrons on the nitrogen.

2. Bis(organoelement)-Substituted Amines with Two Different Hetero Atoms

2.1. IVa/IVa Elements

If two hydrogen atoms in ammonia or a primary amine are imagined to be replaced by the organoelement ligands X and Y, we formally obtain the following class of compounds:

R = H, alkyl, aryl
X,Y = organoelement ligand

Compounds of this type [*e.g. (2), (4), (9)*, and *(10)*] with different group IVa elements are best synthesized by double decomposition of lithium *N*-methyl-*N*-trimethyl(IVa)elementamides [*e.g. (1), (3)*, and *(5)*] with halogenotrimethyl(IVa)element compounds. The "lithium methylamide" derivatives can be prepared

Table 1. Physical properties of the compounds *(2)*, *(4)*, *(9)* and *(10)*.

Compound		B.p. (°C/torr)	Ref.
(2a)	$(CH_3)_3SiN(CH_3)Si(CH_3)_3$	147/760	[3, 13]

both by metalation [eq. (a)] and by cleavage of element-nitrogen bonds [eq. (b) and (c)] (for examples see Table 1).

$(CH_3)_3Si-N(CH_3)-H + RLi \rightarrow (CH_3)_3Si-N(CH_3)-Li + RH$ (a) [3]
$R = CH_3$, n-C_4H_9 *(1)*

(1) + $(CH_3)_3ElCl \rightarrow (CH_3)_3Si-N(CH_3)-El(CH_3)_3 + LiCl$
El = Sn *(2c)*, Pb *(2d)* *(2)* (a') [3]

$[(CH_3)_2Ge-N(CH_3)]_3 + 3\ CH_3Li \rightarrow 3\ (CH_3)_3Ge-N(CH_3)-Li$ (b) [4]
(3)

(3) + $(CH_3)_3ElCl \rightarrow (CH_3)_3Ge-N(CH_3)-El(CH_3)_3 + LiCl$
(4) [4]
El = Si *(4a)*, Ge *(4b)*, Sn *(4c)*, Pb *(4d)*

$(CH_3)_3Sn-N(CH_3)-Sn(CH_3)_3 + CH_3Li \rightarrow (CH_3)_3Sn-N(CH_3)-Li + (CH_3)_4Sn$ (c) [5]
(5)

(5) + $(CH_3)_3ElCl \rightarrow$ *(2c)*, *(4c)* + LiCl [5]
El = Si, Ge

$(CH_3)_3Si-NC(CH_3)_3-Li$ has also been allowed to react with $(CH_3)_3ElCl$ compounds (El = Ge, Sn, Pb) in accordance with eq. (a') [6].

Owing to the ease with which *N*-methyl-*N*-trimethylsilylamine can be obtained from chlorotrimethylsilane and methylamine, *(1)* has been the most widely used compound for syntheses of this type.

(1) + $(CH_3)_2SiCl_2 \rightarrow (CH_3)_3Si-N(CH_3)-Si(CH_3)_2-Cl + LiCl$ [5, 7]
(6)

(6) + 2 $RNH_2 \rightarrow (CH_3)_3Si-N(CH_3)-Si(CH_3)_2-N(R)-H + RNH_2 \cdot HCl$
R = H, CH_3 *(7)* [5, 7]

(7) + n-$C_4H_9Li \rightarrow (CH_3)_3Si-N(CH_3)-Si(CH_3)_2-N(R)-Li + n$-$C_4H_{10}$
R = H [8a], CH_3 [5, 7] *(8)*

(8) + $(CH_3)_3ElCl \rightarrow (CH_3)_3Si-N(CH_3)-Si(CH_3)_2-N(R)-El(CH_3)_3 + LiCl$
(9)

R = CH_3, El = Ge *(9b)* [5], Sn *(9c)* [7], Pb *(9d)* [5];
R = H, El = Ge [8a]

n *(1)* + $(CH_3)_{4-n}SnX_n \rightarrow (CH_3)_{4-n}Sn[N(CH_3)-Si(CH_3)_3]_n + n\ LiX$ [9]
$n = 1 \rightarrow 4$; X = Cl, Br *(10)*

Organo(IVa)element derivatives of ammonia, *e.g. (7)*, R = H, are difficult to prepare, since the compounds R_3El-NH_2 required as starting materials are thermally stable only if R is a bulky ligand. With R = CH_3, El = Si [10] or Ge [11], the monoorgano(IVa)element derivative $(CH_3)_3El-NH_2$ immediately condenses to give $[(CH_3)_3El]_2NH$ and NH_3, whereas the tin analog gives only the tertiary amine [12].

$3(CH_3)_3SnNH_2 \rightarrow 2\ NH_3 + [(CH_3)_3Sn]_3N$

The simplest member of the silicon series [13] is triethylsilylamine. The metalation of this compound with *n*-butyllithium and substitution of the product with chlorotrimethylgermane [14] presents no difficulties.

$(C_2H_5)_3Si-NH_2 + n$-$C_4H_9Li \rightarrow (C_2H_5)_3Si-NH-Li + n$-$C_4H_{10}$
(11)

(11) + $(CH_3)_3GeCl \rightarrow (C_2H_5)_3Si-NH-Ge(CH_3)_3 + LiCl$
(12)

As is shown in Section 4, *(12)* is the key substance for the synthesis of elemento-organic amines containing three different hetero atoms.

Nearly all elemento-organic amines with two different hetero atoms are water-clear, moisture-sensitive liquids that can be purified by vacuum distillation. The lead compounds *(2d)*, *(4d)*, and *(9d)*, which exhibit remarkable thermal stability, also deserve special mention, since comparable plumbylamines with an alkyl group in place of the ligand $(CH_3)_3El$ are extremely unstable, even when the lead atom carries bulky groups [15]. The sensitivity to water, as expected, increases rapidly from the silicon compound to the lead compound. Among the *N*-silylated stannylamines *(10)* the water sensitivity is least for *(10d)*, which can even be handled in air for short periods. This special behavior is probably due to steric effects, the tin atom being shielded from nucleophilic attack by the four *N*-methyl-*N*-trimethylsilylamino groups.

Comparison of the ^1H-NMR spectra of the compounds *(2)*, *(4)*, and *(9)* reveals the following relations (see Table 2):

$\delta(CH_3)_3Si$ [*(2)*], $\delta(CH_3)_3Ge$ [*(4)*], and $\delta(CH_3)_2Si$ [*(9)*]

unlike $\delta CH_3(N^1)$, are displaced to higher fields on transition from El = Si to its higher homologs. Whereas the hetero atom has no appreciable influence on $J_{^{13}CH(Si)}$ and $J_{^{13}CH(Ge)}$, $J_{^{13}CH(N^1)}$ decreases slightly from El = Si to El = Pb. These results indicate that the (p $\rightarrow$ d)π strengthening of the El–N bond decreases from silicon to its higher homologs. If the $(CH_3)_3Si-N(CH_3)$ group is attached instead of CH_3 to the silicon atom in class *(2)*, the hetero atom El in

[a] = $J_{^{117,119}Sn-C-H}$; [b] = $J_{^{117,119}Sn-N-C-H}$; [c] = $J_{^{207}Pb-C-H}$; [d] = $J_{^{207}Pb-N-C-H}$; [e] = $\delta(CH_3)_3Ge$; [f] = $J_{^{13}CH(Ge)}$.

(9) now has a pronounced influence only on $\delta(CH_3)_2Si$ and $\delta CH_3(N^1)$, while $\delta(CH_3)_3Si$ and $\delta CH_3(N^2)$, the signals of the ligands situated farther away from El, show practically no measurable change.

In the *N*-silylated stannylamines *(10)*, δCH_3(Si) and δCH_3(Sn) show an almost linear displacement to lower fields as the number *n* of methyltrimethylsilylamino groups is increased, whereas δCH_3(N) is practically unaffected by *n*. The increases in the coupling constants $J_{^{117,119}Sn-C-H}$ and $J_{^{117,119}Sn-N-C-H}$ are greatest for the transitions $n = 2 \rightarrow 3$ and $n = 3 \rightarrow 4$ respectively. It should be mentioned that $J_{^{117,119}Sn-N-C-H}$ for *(10d)* $n = 4$, is greater than $J_{^{117,119}Sn-C-H}$ for *(2c)* and *(10b)*, $n = 2$. The values of 63.8 and 66.8 Hz are considerably higher than those of the class of unsilylated compounds $[(C_2H_5)_2N]_nSn(CH_3)_{4-n}$ [16].

The elemento-organic amines containing different hetero atoms differ in the polarities of the element-nitrogen bonds; a selective "insertion reaction" of a 1,2-dipole should therefore be favored. It is known from examples in the literature [17] that even the Si–N bond, which is the least polar in this group, reacts smoothly with most 1,2-dipoles. *N*-Methyl-*N*-trimethylsilyl-*N*-trimethylstannylamine *(2c)* and methyl or phenyl isocyanate react under mild conditions (low temperature, high dilution, and a slight excess of *(2c)*) to form 1:1 adducts *(13)* [18].

$$(CH_3)_3Si-\underset{\displaystyle CH_3}{\underset{|}{N}}-Sn(CH_3)_3 + R-N=C=O \qquad R = CH_3,\ C_6H_5$$

(2c)

$$\rightarrow (CH_3)_3Si-\underset{\displaystyle CH_3}{\underset{|}{N}}-\underset{\displaystyle O}{\underset{\|}{C}}-\underset{\displaystyle R}{\underset{|}{N}}-Sn(CH_3)_3$$

(13)

Whereas insertion of the isocyanate into the Si–N bond cannot be absolutely ruled out in the case of $R=CH_3$, the absence of $J_{^{117,119}Sn-N-C-H}$ coupling for *(13)*, $R=C_6H_5$, indicates addition to the more polar Sn–N bond for this substance at least. A moderate excess of isocyanate leads to mixtures of products as a result of further "insertion reactions" while a larger excess leads to trimerization of the isocyanate [18]. Benzonitrile, which does not react with the Si-N bond of $(CH_3)_3Si-N(CH_3)-H$ [19], forms a benzamidine derivative with $(CH_3)_3Sn-N(CH_3)_2$ [20]. *(2c)* gives no indication [19] of reaction in accordance with eq. (d), even under more forcing conditions (several hours at higher temperatures).

$$(CH_3)_3Si-\underset{\displaystyle CH_3}{\underset{|}{N}}-Sn(CH_3)_3 + C_6H_5-C\equiv N \qquad \text{(d)}$$

(2c)

$$\not\rightarrow C_6H_5-C\begin{matrix}\overset{\displaystyle N-Sn(CH_3)_3}{\|}\\ \underset{\displaystyle N-Si(CH_3)_3}{|}\\ \underset{\displaystyle CH_3}{}\end{matrix}$$

(14)

The difference in the reactions of $(CH_3)_3Sn-N(CH_3)_2$ and *(2c)* is due either to steric effects or to decreased basicity in the latter compound as a result of the $(p \rightarrow d)\pi$ bond to the silicon atom.

2.1.1. Elemento-Organic Benzamidines

Elemento-organic benzamidines *(16)* [19–23] containing different group IVa elements are obtained by addition of lithium *N*-alkyl-*N*-trimethylsilylamides to

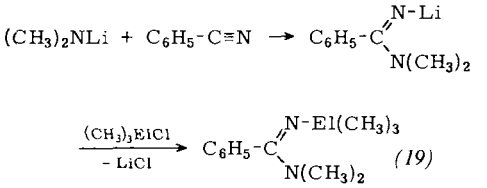
El = Si; R = CH_3 *(16a)*, C_2H_5 *(16b)*, El = Ge *(16c)*, Sn *(16d)*, Pb *(16e)*, R = CH_3

benzonitrile followed by reaction with chlorotrimethyl(IVa)element compounds [eq. (e)][19].



The compounds *(16)* are moisture-sensitive liquids that can be distilled in an oil-pump vacuum. They are rapidly split at the element-nitrogen bond by water and alcohol to form the free base (which was identified as the hydrochloride). Owing to the proximity of the two nitrogen atoms to each other, these compounds are ideal models for the investigation of ligand migration reactions. The isomers *(17)* and *(18)* of *(16)* must also be considered.

(17) *(18)*

(16) can be discussed only if one assumes the occurrence of either metal-proton coupling across five bonds or shortening of the coupling path by additional coordinate bonding of Sn and Pb to the singly-bonded amidine nitrogen atom. This coupling can be explained much more simply if *(16d)* and *(16e)* are formulated as the isomers *(17)*.

An answer to the question of the predominant isomer is provided by the *N'*-trimethyl(IVa)element-substituted *N,N*-dimethylbenzamidines *(19)*, which can be obtained from lithium dimethylamide, benzonitrile, and $(CH_3)_3ElCl$ (El = Si, Ge, Sn)[19].

El = Si *(19a)*, Ge *(19b)*, Sn *(19c)*

The fact that no coupling with the CH_3N group ($J_{117,\,119Sn-N-C-H} = 0$) is observed in the ^1H–NMR spectrum of *(19c)* may be taken as strong evidence that the benzamidines *(16c)*–*(16e)* are in the isomeric form *(17)*. This is supported by the fact that for all $(CH_3)_3El$ groups bound to the imine nitrogen atom,

Table 3. ^1H–NMR data (in Hz) for the benzamidine derivatives *(16)* and *(19)* (in CCl_4, TMS as internal standard) [19]. δC_6H_5(m) is omitted.

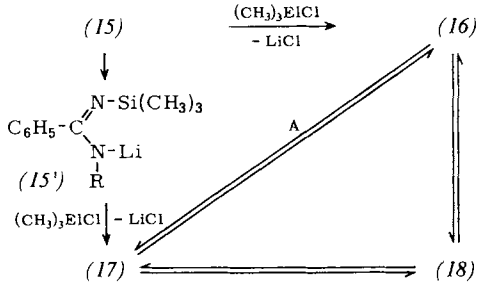
(16c)	−154.0		+16.5	−25.5				
(16d)	−154.0		+15.5	−17.5	55.0/57.0	28.5/29.7		
(16e)	−161.0		+17.5	−64.5			69.0	32.0
(19a)	−171.5		+17.0					
(19b)	−169.0			+ 6.0				
(19c)	−169.5			+ 9.5	52.5/55.0			

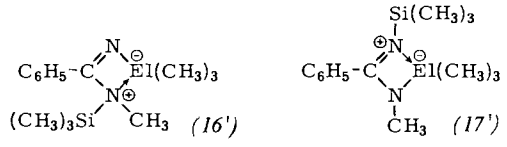
The ^1H–NMR spectra of *(16a)* and *(16b)* (Table 3) exhibit in addition to the expected phenyl and *N*-methyl resonances, a broad signal in the trimethylsilyl region at 35 °C (even at high dilution), which splits into two singlets of equal area at about −30 °C. This observation points to a reversible intramolecular migration (1,3 shift) of the two trimethylsilyl ligands.



Despite frequent modification of the preparation conditions, silicon derivatives always contain small quantities of a "by-product"; on the basis of its IR and ^1H–NMR spectra and its element analysis, it is concluded that this product has the structure of the isomer *(18)* [19]. The two isomers are not in equilibrium with each other, at least after the reaction at room temperature, as is shown by the fluctuation of the quantity of *(18)*.

Unlike the bis-silylated compounds *(16a)* and *(16b)*, the compounds *(16c)*, *(16d)*, and *(16e)* are entirely in the form of one isomer. Since the ^1H–NMR spectra of *(16d)* and *(16e)* also exhibit $J_{117,119Sn-N-C-H}$ and $J_{207Pb-N-C-H}$ coupling respectively, the structure the resonance is distinctly displaced toward higher fields. The difference between the chemical shifts of trimethylelement ligands attached to the amine and to the imine nitrogen atoms of the benzamidine is about 30 Hz (Table 3).

The ligand arrangement required in *(17)* does not conflict with the reaction path proposed in eq. (e) if one considers the reaction scheme 1 for the formation of *(16a)*–*(16e)*.

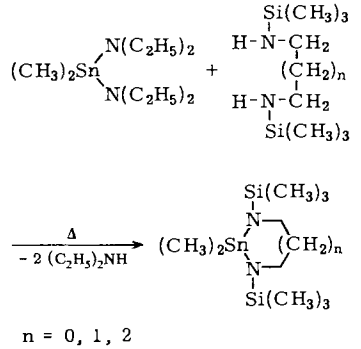


a) Adduct *(15)* does not react, as required by eq. (e), in the form *(15)*, but in the form *(15')*, to give *(17)*. This explanation is not convincing, since *(15)* and $(CH_3)_3SiCl$ on the one hand and lithium methylamide, benzonitrile, and chlorotrimethylsilane (but not chlorotrimethylstannane) on the other give mixtures of isomers [19]. The formation of *(15')* by insertion of benzonitrile into the Si–N bond of $(CH_3)_3Si-N(CH_3)-Li$ was ruled out by the reaction of $(CH_3)_3Si-N(CH_3)-H$ with benzonitrile.

b) Though reaction (e) takes place as indicated, *(16c)*–*(16e)* unlike *(16a)* and *(16b)*, undergo an irreversible ligand ex-

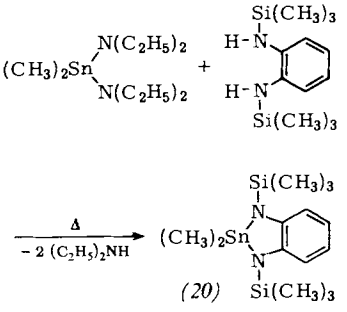
Scheme 1. El = Si—Pb; R = CH_3, C_2H_5.

change (step A in Scheme 1). The tendency of the elements Ge, Sn, and Pb (unlike Si) to increase their coordination number above four may be the driving force for the rearrangement of *(16)* into *(17)*. Unlike in *(16')*, a gain in energy due to further limiting resonance structures is possible in the modified form *(17')* of *(17)*



The tendency of silicon to achieve the greatest possible (p → d)π bond strengthening would also oppose the substitution on the imine nitrogen.

Nothing definite can be said at present about the mechanism of this ligand exchange reaction. The ability of the organo-(IVa)element substituents to migrate is probably strongly influenced by the mutual proximity of the two nitrogen atoms and the ease of displacement of the π electrons inside the amidine skeleton. Since *(16a)* and *(16b)* give isomer mixtures, it must be assumed that here at least the rearrangement from *(16)* to *(17)* does not proceed *via (18)*, but that a synchronous mechanism must be considered for the ligand migration (cf. Section 2.2.1).



2.1.2. Heterocycles

Bis[organo(IVa)element] combinations in which one hetero atom forms part of a ring while the other is exocyclic can be obtained by synthetic variants of transamination with cyclization [24a].

n = 0, 1, 2

It is interesting to note that with CH_3 instead of the $(CH_3)_3Si$ group, only the six-membered analogs can be prepared [24a] (polymerization occurs with the five-membered rings [24]). This is a very clear illustration of the stabilizing influence of the trimethylsilyl ligand. The *N*-silylated stannabenzimidazolidine *(20)* is obtained by this method from *N,N'*-bis(trimethylsilyl)-*o*-phenylenediamine and bis(diethylamino)dimethylstannane [24a].

2.2. IVa/Va Elements

Phosphorus-nitrogen compounds with a $(CH_3)_3Si$ group on the nitrogen are obtained almost exclusively by cleavage of bis-silylated amines with phosphorus halides [25]. Attempts to prepare these compounds in the same way as their analogs with IVa elements, *i.e.* from lithium *N*-methyl-*N*-trimethylsilylamide *(1)* and methylphosphorus halides, have been unsuccessful [26]. Reactions of *(1)* with methylhalogeno and trihalogeno compounds of arsenic, antimony, and bismuth, on the other hand, have been successful [27a].

$$n\,(CH_3)_3Si{-}NCH_3{-}Li + (CH_3)_{3-n}ElX_n \;\underset{(1)}{\rightarrow}\; [(CH_3)_3Si{-}NCH_3]_n\,El(CH_3)_{3-n} + n\,LiX \qquad (21)$$

El = As, n = 1–3, X = Cl, Br; El = Sb, n = 1–3, X = Cl, Br; El = Bi, n = 1–3, X = Br

As-(*N*-Methyltrimethylsilylamino)dimethylarsine*(21a)* is also formed by cleavage of an As–N bond of *N,N*-bis(dimethylarsino)methylamine with methyllithium and reaction of the lithium *N*-methyl-*N*-dimethylarsinoamide *(22)*, formed in accordance with eq. (f) with chlorotrimethylsilane [27b]. Methyllithium cleaves the As–N bond of *(21a)* only under more forcing conditions (approx. 70 °C) [3].

$$(CH_3)_2As{-}N(CH_3){-}As(CH_3)_2 + CH_3Li \rightarrow \underset{(22)}{(CH_3)_2As{-}N(CH_3){-}Li} + As(CH_3)_3 \qquad (f)$$

$$(22) + (CH_3)_3SiCl \rightarrow (CH_3)_2As{-}N(CH_3){-}Si(CH_3)_3 + LiCl \qquad (21a)$$

A new, simple route to the relatively little-investigated class of iminoarsoranes is provided by the reaction of an *N*-metalated aminoarsine with methyl chloride [40a].

[24] a) *O. J. Scherer, J. Schmidt, J. Wokulat,* and *M. Schmidt,* Z. Naturforsch. *20b*, 183 (1964); b) *C. H. Yoder* and *J. J. Zuckerman,* J. Amer. chem. Soc. *88*, 4831 (1966).

[25] Cf. *e.g. O. J. Scherer,* Organometallic Chem. Reviews, Part A *3*, 281 (1968).

[27] a) *O. J. Scherer, P. Hornig,* and *M. Schmidt,* J. organometallic Chem. *6*, 259 (1966); b) *O. J. Scherer* and *M. Schmidt,* Angew. Chem. *76*, 787 (1964); Angew. Chem. internat. Edit. *3*, 702 (1964).

$$[(CH_3)_3C]_2As{-}NLi{-}Si(CH_3)_3 \xrightarrow[-LiCl]{CH_3Cl} [(CH_3)_3C]_2As(CH_3){=}N{-}Si(CH_3)_3$$

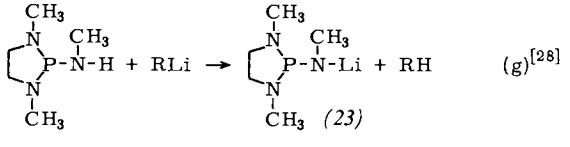
Nearly all compounds *(21)* are colorless liquids, whose sensitivity to oxygen and moisture decreases with increasing n and increases from the arsenic to the bismuth compounds. Like the tin derivative *(10c)*, the compounds with $n = 3$ melt around room temperature.

On comparison of the chemical shifts of the homologous series $(CH_3)_3Si{-}N(CH_3)El(CH_3)_2$, $[(CH_3)_3Si\text{-}N(CH_3)]_2ElCH_3$, and $[(CH_3)_3Si\text{-}N(CH_3)]_3El$, El = As to Bi, it is found that $\delta CH_3(Si)$ and $\delta CH_3(N)$ vary in the same direction as for corresponding compounds with El = IVa elements (Section 2.1).

$[(CH_3)_3Si{-}N(CH_3)]_nEl(CH_3)_{3-n}$ compounds with El = As to Bi, $n = 1-3$, like the comparable tin compounds *(10)*, show a shift of $\delta CH_3(Si)$ toward lower field strengths with increasing n; $\delta CH_3(N)$, on the other hand, is differently influenced (Table 4).

The spectra, like those of the IVa element compounds, can be interpreted by assuming a decrease in the (p → d)π-strengthening of the El–N bond from El = As to Bi.

Synthesis of compounds of the type *(21)* with aminophosphines instead of amines of group IVa elements leads surprisingly readily to compounds having this desired combination of IVa and Va elements, in which the thermal stability of the primary and secondary aminophosphines, compounds which have not been extensively studied, is increased by suitable ligands on the phosphorus atom, *e.g.* the $(CH_3)_3C$ group [28–31a].



$$[(CH_3)_3C]_2P{-}NH{-}Sn(CH_3)_3 \ (26c) \xrightarrow{\Delta} \begin{cases} \rightarrow 1/2\ [(CH_3)_3C]_2P{-}N[Sn(CH_3)_3]_2 + 1/2\ [(CH_3)_3C]_2P{-}NH_2 & (i) \\ \rightarrow [(CH_3)_3C]_2P(H){=}N{-}Sn(CH_3)_3\ (27) & \\ \rightarrow [(CH_3)_3C]_2P[Sn(CH_3)_3]{=}NH\ (28) & (j) \end{cases}$$

It should be mentioned that the tin derivative (26c) unlike most stannylamines with NH bonds [12a], does not undergo dismutation at high temperatures [eq. (i)].

A type of "Michaelis-Arbuzov rearrangement" into one of the two possible iminophosphoranes *(27)* or *(28)* [eq. (j)] is not observed even when *(26c)* is heated at 150 °C for 20 hours.

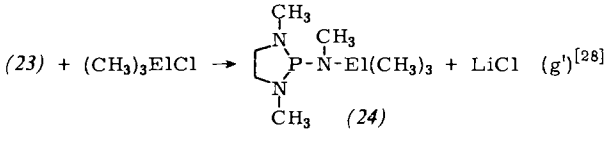


Table 4. Physical properties and ^1H–NMR data (in Hz) of the compounds *(21)* (in CCl_4, TMS as internal standard).

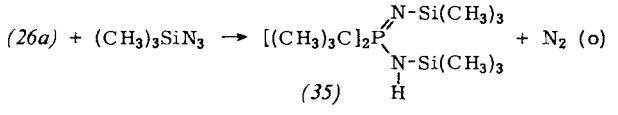
The aminoiminodiazaphospholidine derivative *(33)* is formed not only from *(24a)*, but also on reaction of *(24')* with two moles of trimethylsilyl azide [28].

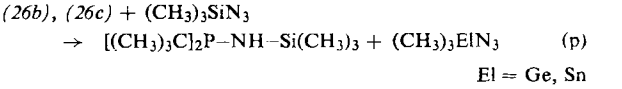
(m)

On the other hand, if the two phosphorus atoms in *(24')* are separated by the -N(CH$_3$)-(CH$_2$)$_2$-N(CH$_3$)- group, the P–N bond is not broken [28].



N-Organo(IVa)element-substituted aminophosphines *(26)* are almost quantitatively oxidized to *P*-chloroiminophosphoranes *(34)* by carbon tetrachloride [29,30]

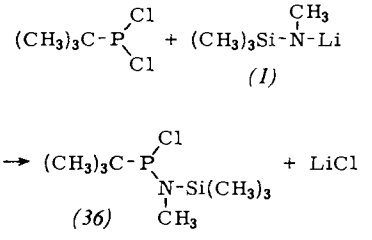
(n)



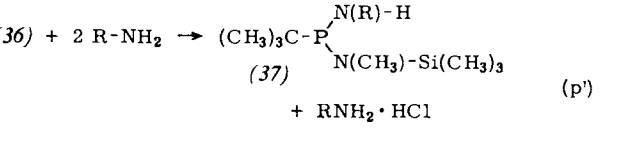
El = Si *(34a)*, Ge *(34b)*, Sn *(34c)*

Whereas oxidation with trimethylsilyl azide leads, in the case of the silicon compound *(26a)* [eq. (o)] [30], to the desired compound,

(o)



the reactions with *(26b)* and *(26c)* lead merely to cleavage [eq. (p)] of the Ge–N or Sn–N bond; this is a clear indication of the pseudohalogen character of trimethylsilyl azide [30].

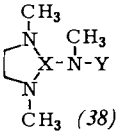


(p)

El = Ge, Sn

(1) On reaction of (CH$_3$)$_3$Si–N(CH$_3$)Li *(1)* with *tert*-butyldichlorophosphine instead of with methylphosphorus halides [26], it is even possible to displace the chlorine atoms successively [32].

(36) is an important starting material for the synthesis of diaminophosphines with different ligands on the amino groups [32].



(p')

R = *e.g.* H *(37a)*, CH$_3$ *(37b)*

(37a) does not exist in the isomeric form expected from eq. (p'). The "more symmetrical" isomer (CH$_3$)$_3$CP[NHSi(CH$_3$)$_3$](NHCH$_3$) has been formed by an irreversible (CH$_3$)$_3$Si/H ligand exchange [32].

At this point we shall discuss the ^{1}H–NMR spectra of compounds that illustrate the influence of the hetero atom and of the oxidation state of the phosphorus on the P–N(CH$_3$) coupling constant. The models *(24)*, *(31)*–*(33)*, and *(38)* satisfy these requirements (Table 5).

X = P, P-CH$_3$, P=S, P=N-Si(CH$_3$)$_3$
Y = (CH$_3$)$_3$El, El = Si → Sn

Table 5. ^{1}H–NMR data (in Hz) for the compounds *(24)*, *(26)*, and *(31)*–*(34)* (in benzene, TMS as external standard).

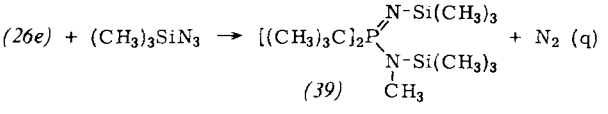
			− 5.0 (s) }						
(26a)			+21.2 (d)	−28.5 (d)			0.6	11.0	[30]
(26b)			+12.0 (d)	−33.9 (d)			0.3	10.9	[30]
(26c)			+16.3 (s)	−36.2 (d)			0	10.7	[30]
(26d)			−29.3 (s)	−41.2 (d)			0	10.8	[30]
(34a)			+11.5 (d)	−47.2 (d)			0.5	17.3	[30]
(34b)			0.0 (s)	−49.0 (d)			0	17.0	[30]
(34c)			+ 5.5 (s)	−58.4 (d)			0	16.7	[30]

[a] δ CH$_3$(P)—144.5 (d), $J_{^{31}PCH}$ = 14.5 Hz (in CDCl$_3$); [b] $J_{^{31}P=NSiCH}$ = 0.35 Hz; $J_{^{117,119}Sn-C-H}$ and $J_{^{207}Pb-C-H}$ were not given; [c] R = −N(CH$_3$)−(CH$_2$)$_2$−N(CH$_3$)−; δ CH$_2$(R) possesses, with the exception of *(31)* [δ CH$_2$(R)—224.0 (d), $J_{^{31}PNCH_2(R)}$ = 8.8 Hz] a multiplet structure.

In *(38)*, the oxidation state of the phosphorus has little influence, and the ligand Y has practically none, on the coupling $J_{^{31}PNCH_3(R)}$ of the phosphorus with the protons of the ring CH_3N group. The coupling constant $J_{^{31}PNCH_3}$ of the phosphorus with the protons of the CH_3N bridge, on the other hand, shows a distinct dependence both on X and on Y. The constant increases from X = P^{III} to X = P^{V} [*e.g.* *(24a)* → *(32)*; 3.3 → 14.5 Hz]; $J_{^{31}PNCH_3(R)}$ remains practically unchanged (12.5 → 12.2 Hz). The influence of the hetero atom Y on the coupling constant $J_{^{31}PNCH_3}$ can be observed in the compounds *(24a)* → *(24c)*, since it increases from 3.3 to 7.3 Hz. In *(33)*, long-range coupling of the phosphorus is found only with the protons of the trimethylsilyl group bound to the imine nitrogen atom ($J_{^{31}P=NSiCH_3}$ = 0.35 Hz)[28].

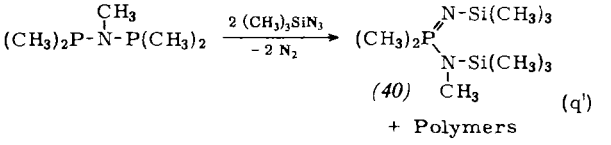


Whereas $J_{^{31}PCCH}$ for $[(CH_3)_3C]_2P-NH-El(CH_3)_3$ *(26a)–(26c)* is practically unaffected by the ligand El on the nitrogen atom, the long-range coupling $J_{^{31}PNElCH_3}$ decreases from 0.6 to 0 Hz [*(26a)–(26c)*]. As expected, $J_{^{31}PCCH}$ of the compounds *(26a)–(26c)* containing trivalent phosphorus increases on oxidation to the pentavalent phosphorus compounds *(34a)–(34c)*. The only sign of the influence of the hetero atom is a small linear decrease. $J_{^{31}PNElCH}$ is observed only for the silicon derivative *(34a)*.

Though the chemical shift varies with concentration when benzene is used as the solvent, $\delta CH_3(N)$ and $\delta CH_3(N_R)$ show the same tendency toward lower fields for El = Si → Sn as in corresponding IVa/IVa combinations.

2.2.1. *N,N'*-Bis(organoelement)-Substituted Aminoiminophosphoranes

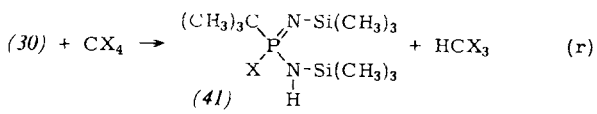
Like the benzamidines *(16)*, the structurally related aminoiminophosphoranes *(39)* are suitable for the study of ligand migration processes.



The first compound was obtained from triphenylsilyl azide and diphenylphosphine[33]. Other possible routes to these compounds are the oxidation of aminophosphines with silyl azides[28,30,31a] [eq. (q), cf. eq. (1), (m), (o)],

(26e) + $(CH_3)_3SiN_3$ → $[(CH_3)_3C]_2P(N\text{-}Si(CH_3)_3)(N(CH_3)\text{-}Si(CH_3)_3)$ + N_2 (q)

(39)

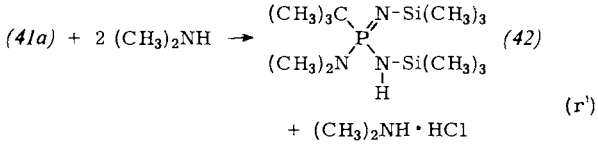


the cleavage of a P–N bond in diphosphinoamines[28, 34] [eq. (q'), cf. eq. (m)] with silyl azides,

$(CH_3)_2P(CH_3)N\text{-}P(CH_3)_2$ $\xrightarrow[-2\,N_2]{2\,(CH_3)_3SiN_3}$ $(CH_3)_2P(N\text{-}Si(CH_3)_3)(N(CH_3)\text{-}Si(CH_3)_3)$ + Polymers (q')

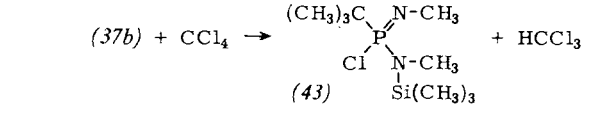
(40)

the reaction of *N,N'*-organoelement-substituted diaminophosphines with tetrahalogenomethanes[31a,32] [eq. (r), cf. eq. (n)], and the oxidation of stannylphosphines with phenyl azide[36].



(30) + CX_4 → $(CH_3)_3C(N\text{-}Si(CH_3)_3)P(X)(N(H)\text{-}Si(CH_3)_3)$ + HCX_3 (r)

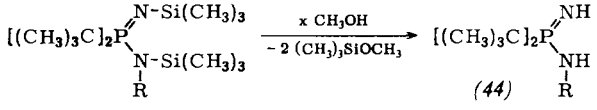
(41)



X = Cl *(41a)*, Br *(41b)*

(41a) contains a reactive P–Cl bond, as is shown by the reaction with dimethylamine[31a,32],

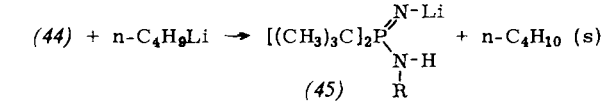
(41a) + 2 $(CH_3)_2NH$ → $(CH_3)_3C(N\text{-}Si(CH_3)_3)P(N(CH_3)_2)(N(H)\text{-}Si(CH_3)_3)$ *(42)* + $(CH_3)_2NH \cdot HCl$ (r')



A number of other aminoiminophosphoranes *(43)* and *(46)* containing only one trimethyl(IVa)element group can be synthesized both in analogy with eq. (r) from *(37b)* and carbon tetrachloride[32]

(37b) + CCl_4 → $(CH_3)_3C(N\text{-}CH_3)P(Cl)(N(CH_3)\text{-}Si(CH_3)_3)$ + $HCCl_3$

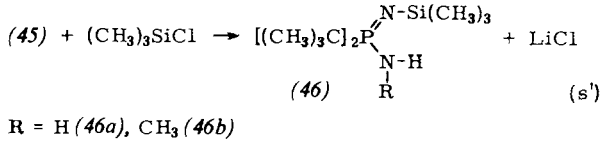
(43)



and by alcoholysis of *N,N'*-bis(trimethylsilyl)aminoiminophosphoranes, metalation with *n*-butyllithium, and reaction with *e.g.* chlorotrimethylsilane [eq. (s)][30,35].

$[(CH_3)_3C]_2P(N\text{-}Si(CH_3)_3)(N(R)\text{-}Si(CH_3)_3)$ $\xrightarrow[-2\,(CH_3)_3SiOCH_3]{x\,CH_3OH}$ $[(CH_3)_3C]_2P(NH)(N(H)R)$

(44)



R = H *(44a)*, CH_3 *(44b)*

(44) + $n\text{-}C_4H_9Li$ → $[(CH_3)_3C]_2P(N\text{-}Li)(N(H)R)$ + $n\text{-}C_4H_{10}$ (s)

(45)

R = H *(45a)*, CH_3 *(45b)*

(45) + $(CH_3)_3SiCl$ → $[(CH_3)_3C]_2P(N\text{-}Si(CH_3)_3)(N(H)R)$ + LiCl (s')

(46)

R = H *(46a)*, CH_3 *(46b)*

The tautomeric form with the trimethylsilyl group on the amine nitrogen atom can be definitely ruled out for *(46)* on the basis of IR and ^1H–NMR studies[35].

The trimethylstannyl ligand can be introduced instead of trimethylsilyl in compounds of the type *(43)* by means of the multistep synthesis shown in scheme 2[32].

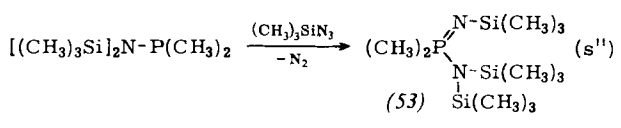
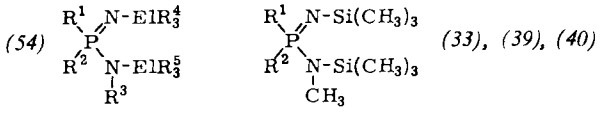
[36] *H. Schumann* and *A. Roth*, J. organometallic Chem. *11*, 125 (1968).



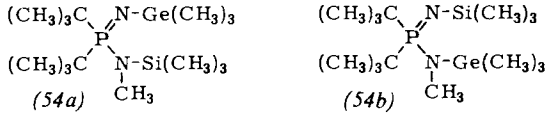
Scheme 2.



Attempted reactions of the metalation products of *(35)* and *(42)* with chlorotrimethylsilane have been unsuccessful evidently on steric grounds[31a,32]. The amide *(52)* is dimeric in benzene, as is shown by cryoscopic molecular weight determinations. Its ^{1}H–NMR spectrum contains only one sharp signal for the "differently bound" trimethylsilyl ligands (in various solvents and at high dilutions). These facts are best explained by the structure *(52a)* for the molecule in solution[31a,31b,32].

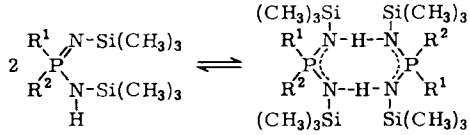
(52) *(52a)*

However, reaction of impure bis(trimethylsilyl)aminodimethylphosphine[37] [prepared from $[(CH_3)_3Si]_2NNa$ and $(CH_3)_2PCl$; see also section 3.2] with trimethylsilyl azide gives the first triply silylated aminoiminophosphorane *(53)*[31a,32].



On the basis of the general formula *(54)*, we find a number of important questions in connection with reversible and irreversible migration processes:

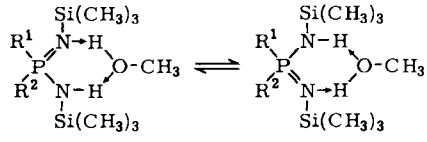
1. How do the ligands R^1, R^2, and R^3 influence the ability of the R^4_3El and R^5_3El groups to migrate?



2. What part is played here by the ligands R^4 and R^5, and what part by the hetero atom El?

3. What happens if the R^4_3El group and R^3 are replaced by CH_3?

Compounds of the type *(33)*, *(39)*, and *(40)*, unlike benzamidine *(16a)*, do not exhibit migration of the trimethylsilyl groups (even at high temperatures) in any of the four examples studied $R^1 = R^2 = -N(CH_3)-(CH_2)_2-N(CH_3)-$ *(33)*[28]; $R^1 = R^2 = (CH_3)_3C$ *(39)*[30]; $R^1 = R^2 = CH_3$ *(40)*[34], and $R^1 = R^2 = C_6H_5$[8b]. In compounds containing different hetero atoms, the two isomeric forms [*(54a)* and *(54b)* in this case] are stable even at 150 °C[35].

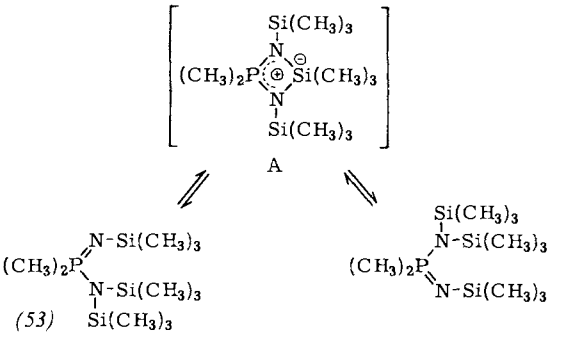


If the CH_3 group in the bis-silylated compounds *(33)*, *(39)*, and *(40)* is replaced by a proton, *(35)* is obtained with $R^1 = R^2 = (CH_3)_3C$[30], and *(42)* with $R^1 = (CH_3)_3C$, $R^2 = (CH_3)_2N$[31a,32]. A reversible intermolecular proton exchange can be detected in both compounds

(35), (42)

The NMR spectra in both cases contain one signal for the "differently bound" trimethylsilyl groups at high concentrations in benzene, and two trimethylsilyl signals at lower concentrations[30,31a,32]. Coalescence of the two signals can be observed by the addition of catalytic quantities of methanol [but not traces of amine, *e.g.* $(CH_3)_2NH$].

If tetrahydrofuran is used as the solvent for *(35)*[30], and acetone for *(42)*[32] (tetrahydrofuran gives no splitting in this case) instead of benzene, the spectrum both in concentrated and in dilute solution contains two $(CH_3)_3Si$ signals, which do not merge even on heating or an addition of small quantities of methanol. This supports the assumption that the formation of hydrogen bonds (detectable by IR spectroscopy[30]) with the solvent[38] takes precedence over the intermolecular proton exchange in this case.



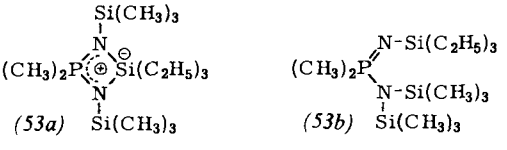
The proton exchange also stops when the $(CH_3)_2N$ group in *(42)* is replaced by the halogen atoms Cl *(41a)* and Br *(41b)*. Since the IR spectrum contains no evidence of hydrogen bonding to the halogen[32],

[37] *O. J. Scherer*, unpublished.

[38] Cf. *e.g. H. Suhr*: Anwendung der kernmagnetischen Resonanz in der organischen Chemie. Springer, Berlin 1965, p. 111 ff.

this difference in the behavior of *(41a)* and *(41b)* on the one hand and *(35)* and *(42)* on the other can perhaps be attributed to inductive effects.

A reversible intramolecular 1,3-trimethylsilyl migration occurs when the proton is replaced by the $(CH_3)_3Si$ ligand [31a, 31c, 32]. This migration, which has a low activation energy, can be "frozen in" at about −20 °C.

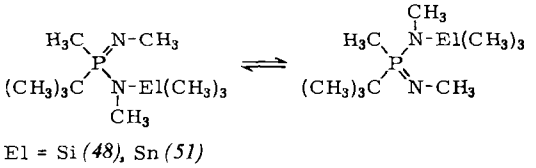


A

(53)

The replacement of a $(CH_3)_3Si$ group on the amine nitrogen atom by the $(C_2H_5)_3Si$ group in *(53)* leads to a compound *(53a)* [8b] that shows no splitting of the $(CH_3)_3Si$ signal in the NMR spectrum even at −55 °C and at high dilution. This observation is open to several interpretations:

1. The reversible intramolecular migration proceeds too rapidly even at −55 °C.

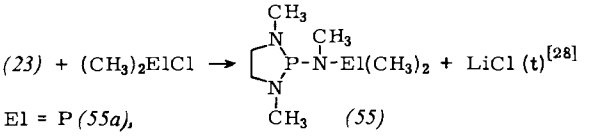


2. The substance is in the form of an "inner" symmetrical complex with pentacoordinated silicon (corresponds to transition state A).

(53a) *(53b)*

3. Both trimethylsilyl groups are bound to the amino nitrogen atom (this assumption is supported by the P=N band in the IR spectrum), and give no 1,3 migration in this isomeric form *(53b)*.

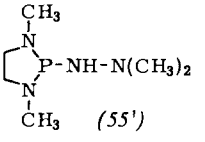
The driving force for the formation of *(53b)* may be the preference for the formation of sterically "balanced" molecules [cf. compound *(37a)*]. If the model compounds mentioned are modified in such a way that only one trimethyl(IVa)element ligand is now bound to the amine nitrogen atom [32], *(48)* exhibits a reversible intramolecular 1,3 migration of the $(CH_3)_3El$ ligand, which stops at −55 °C and can be readily detected by the splitting of the CH_3N doublet (NMR) into two doublets [32]. $\delta CH_3(N)$ for *(51)* consists of only one doublet down to −55 °C, even at high dilution. The absence of $J_{^{117},^{119}Sn-N-C-H}$ coupling (which would be expected for a pentacoordinated Sn atom with a trigonal bipyramidal arrangement, even with fast pseudorotation) indicates that even at this temperature the system is "stereochemically nonrigid".



El = Si *(48)*, Sn *(51)*

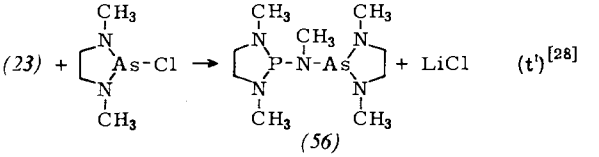
All the results support the hypothesis that reversible intramolecular $(CH_3)_3M$ ligand migration in organo-(IVa)element-substituted aminoiminophosphoranes appears to be favored whenever, instead of a new isomeric form [*e.g.* *(53b)* or $R^1R^2P(=NCH_3)(N[Si(CH_3)_3]_2)$ for the compounds *(33)*, *(39)*, and *(40)*], an identical molecule [as a transition state, a molecule with identical *N* ligands (*e.g.* A)] can be postulated as an intermediate.

2.3. Va/Va Elements

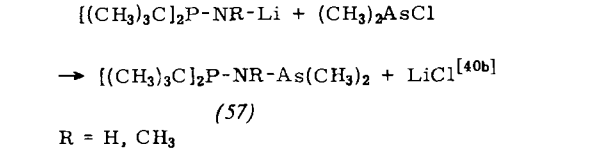


Compounds containing the atomic grouping $R_2P-NR^1-ElR^2_2$ (El = As → Bi) are at present known only in the form of aminophosphinoarsines $(CF_3)_2P-NR-As(CF_3)_2$, R=H, CH_3 [39].

Novel compounds of this type can be prepared by reaction of the lithium *N*-phosphinoamides *(23)* and *(25)* mentioned in equations (g) and (h) with dimethyl-(Va)element halides or 2-chloro-1,3-dimethyl-1,3,2-diazaarsenolane [27b] eq. (t') (cf. Table 6).



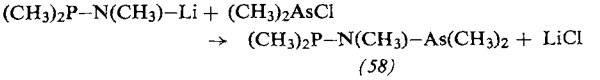
(23) + $(CH_3)_2ElCl$ → *(55)* + LiCl (t) [28]



El = P *(55a)*,
As *(55b)*, Sb *(55c)*

(55')

(23) + → *(56)* + LiCl (t') [28]



$[(CH_3)_3C]_2P-NR-Li + (CH_3)_2AsCl$

→ $[(CH_3)_3C]_2P-NR-As(CH_3)_2$ + LiCl [40b]

(57)

R = H, CH_3

The parent compound from which these alkyl-substituted products are derived, *i.e. As,As*-dimethyl-(*N*-dimethylphosphino-*N*-methylamino)arsine *(58)*, can also be prepared in this way [34].

(58)

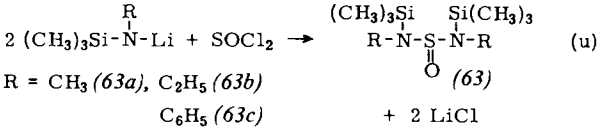
(58)		−154.0 (d)	−60.5 (d)	−60.3 (d)		6.3	0.70	6.25	[34]

[a] R = $-N(CH_3)-(CH_2)_2-N(CH_3)-$, δ CH_2(R) possesses multiplet structure in all cases.

Like the compounds *(24a)–(24c)*, the compounds *(55)* exhibit an increase in $J_{^{31}PNCH_3}$ from El = P to El = Sb (3.4–8.9 Hz), while $J_{^{31}PNCH_3(R)}$ remains practically unchanged. Unlike *(24a)*, the first member *(55a)* shows no long-range coupling $J_{^{31}PNElCH}$ (this is also true of the reference substance *(55')* [41]). The long-range coupling is however observed for the arsenic and antimony compounds *(55b)* and *(55c)* respectively. Comparison of the compounds *(55b)* and *(58)* reveals that the ligand on the phosphorus does not appreciably influence the coupling constants and chemical shifts of the $-N(CH_3)-As(CH_3)_2$ residue.

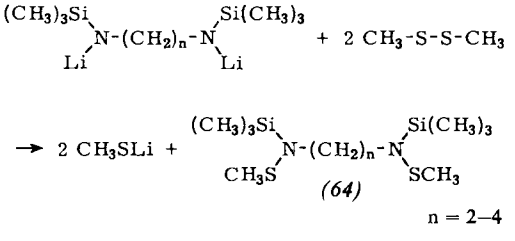


2.4. IVa/VIa Elements

Bis(organoelement)-substituted amines with this combination of elements are confined to the elements silicon and sulfur. Until recently these compounds were nearly always synthesized by heterolysis of *N*-silylated nitrogen compounds with sulfur halides [25]. We found that lithium *N*-alkyltrimethylsilylamides add smoothly to *N*-phenylthionylimide (*N*-sulfinylaniline) to give *(59)* [42].

R = Alkyl

Substitution of the 1:1 adducts *(59)* with chlorotrimethylsilane gives *N,N'*-disilylated sulfinyldiamides *(60)*, which split off hexamethyldisiloxane at temperatures above 100 °C. The resulting sulfur *N*-alkyl-*N'*-aryldiimides *(62)* can be isolated in this way in a fairly pure state. The pure compounds are however obtained when *(59)* is allowed to react with chlorotrimethylstannane or aluminum chloride instead of with chlorotrimethylsilane. Since the decomposition of *(61)* into *(62)* is accompanied by almost exclusive formation of trimethylsiloxytrimethylstannane, this must be taken as evidence of an intramolecular decomposition. *N,N'*-Dimethyl-*N,N'*-bis(trimethylsilyl)-sulfinyldiamide *(63a)*, which can be synthesized in accordance with eq. (u),



(u)

forms colorless crystals immediately after distillation; on storage in a stoppered flask at room temperature, these crystals slowly decompose into hexamethyldisiloxane and sulfur *N,N'*-dimethyldiimide [42b].

^{1}H–NMR spectroscopic measurements show that *(63a)* has decomposed to an extent of about 40 % after three days, and about 80 % after three weeks. Further enrichment of the thermally very unstable $CH_3N{=}S{=}NCH_3$ [43] is impossible at room temperature. Attempts to prepare the ethyl and phenyl derivatives *(63b)* and *(63c)* in accordance with eq. (u) showed that both suffer partial decomposition (detectable by NMR spectroscopy) during the reaction. Sulfur *N,N'*-diphenyldiimide is obtained by this method in a yield of 40 %.

Organo(IVa/VIa)element-substituted amines can also be obtained by nucleophilic cleavage of sulfur-sulfur bonds (for detailed discussion cf. Section 3.3), as is shown by the reaction of dimethyldisulfane with metalated *N,N'*-bis(trimethylsilyl)alkylenediamines [44].

n = 2–4

Selective hydrolysis or alcoholysis of the Si–N bond to form the silicon-free aminosulfanes $CH_3S-NH-(CH_2)_n-NH-SCH_3$ cannot be achieved with *(64)* (the compounds are recovered unchanged). More vigorous reaction conditions (*e.g.* acid or alkaline hydrolysis) lead at higher acid or base concentrations to simultaneous cleavage of the S–N bond. This may be regarded as evidence of the unusual stability of this class of substances toward hydrolysis.

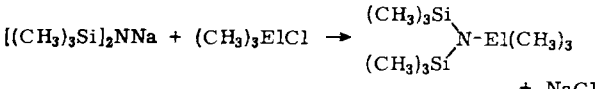
3. Tris(organoelement)-Substituted Amines with Two Different Hetero Atoms

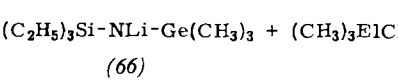


3.1. IVa/IVa Elements

Tris(organoelement)-substituted amines can be derived from the ammonia molecule in the same way as bis(organoelement)-substituted amines.

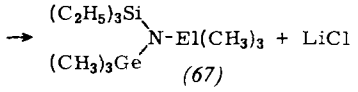
X,Y = organoelement ligand

An excellent starting material for the synthesis of bis(trimethylsilyl)trimethyl(IVa)element-substituted amines *(65)* [45] is sodium bis(trimethylsilyl)amide, which was synthesized by *Wannagat* [46] (Table 7).



El = Ge *(65b)*, Sn *(65c)*, Pb *(65d)* *(65)*

Table 7. Physical properties and spectra of the compounds *(65)* (in CCl_4, TMS as internal standard).



Compound	B.p.(°C/torr)	M.p.(°C)	δ CH_3(Si)	$J_{^{13}CH(Si)}$ (Hz)	ν_{as} SiN(Si) (cm^{-1})	Ref.

(65b)	54—56/1	29—32	— 7.2	118.0	931	[45b]
(65c) [b]	58—59/1	20—22	— 5.0	118.0	950	[45b]
(65d) [c]	85—87/3		0	118.0	970	[45b]

[a] El = Si. [b] $J_{117,\,119SnCH}$ = 54.0/56.5. [c] $J_{^{207}PbCH}$ = 67.0.

(65c) is also formed from bis(trimethylsilyl)amine and *N,N*-diethyltrimethylstannylamine [47]. Alkoxy derivatives are also known in the germanium series [48]. Lithium *N*-triethylsilyl-*N*-trimethylgermylamide *(66)* [14] has proved valuable as a starting material for the synthesis of the compounds *(67)* with a new IVa/IVa element combination [8b].

(67)

El = Si, Ge

$[(CH_3)_3Sn]_2NSi(CH_3)_3$ can be obtained both from lithium bis(trimethylstannyl)amide [12d] and chlorotrimethylsilane [though the product always also contains *(65c)*] and by substitution of impure sodium trimethylsilylamide with chlorotrimethylstannane [49].

The compounds *(65)* differ very markedly in their behavior toward protonic solvents. *(65b)*, like *(65a)*, El = Si, is surprisingly resistant to moisture. This behavior, which is unusual for alkylgermanium-nitrogen compounds, is probably due to steric factors. *(65c)* and *(65d)* react immediately with water at the Sn–N and Pb–N bonds respectively.

The tris(organoelement)-substituted amines are suitable for the study of the relative inductive effects of the IVa elements (cf. also [51]). This effect can either

El = Ge → Pb

weaken (–I effect, A) or strengthen (+I effect, C) the Si–N bonds, which are strengthened in the symmetrically substituted derivative (B) by equal sharing of the formally "lone" pair of electrons on the nitrogen atom. IR (increase in the frequency of the antisymmetric SiN(Si) stretching vibration for El = Si → Pb) and ^{1}H-NMR spectra (shift of δCH_3(Si) to higher field strengths for El = Si → Pb; $J_{^{13}CH(Si)}$ remains constant), as can be seen from Table 7, indicate strengthening of the Si–N bond by the incorporation of the hetero atom El, *i.e.* a + I effect (C):

$(CH_3)_3Pb > (CH_3)_3Sn > (CH_3)_3Ge > (CH_3)_3Si$

As in the case of the bis(organoelement)-substituted amines with different hetero atoms, these observations can be taken as evidence that (p → d)π strengthening of the El–N bond is of minor importance for the higher homologs of silicon [52]. Two other classes of compounds, *i.e.* the heterosiloxanes, which were studied by *Schmidbaur* [53] and the trimethyl(IVa)-element azides, which were investigated by *Thayer* and *West* [54], exhibit the same relations.

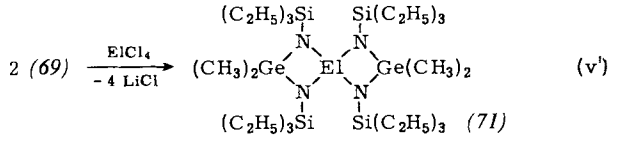
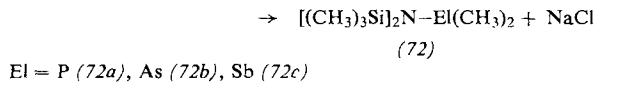
3.1.1. Heterocycles

Cyclic amines of this type with two different hetero atoms were described by *Fink* [55] in the form of the four-membered heterocycles *(68)*.



El = B *(68a)*, P *(68b)*

Starting with metalated bis(*N*-triethylsilylamino)dimethylgermane *(69)* [14], it is possible to synthesize not only the derivatives *(70)* [*e.g.*(v)] but also spiranes *(71)* [eq. (v')] [8b].

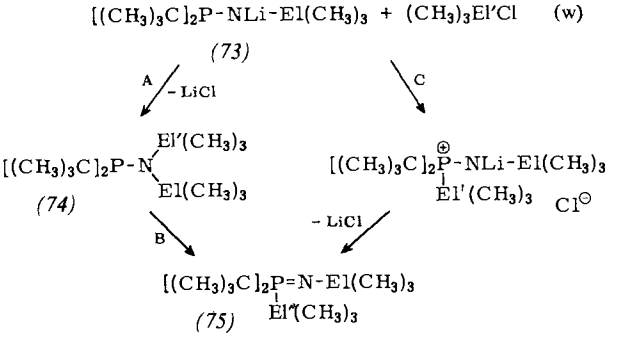


El = Si *(70a)*, Ge *(70b)*

El = Si *(71a)*, Ge *(71b)*

3.2. IVa/Va Elements

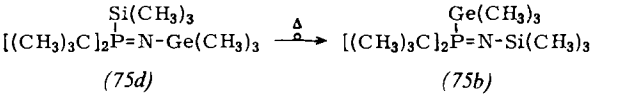
Attempts to obtain definite *N*-silylated phosphorus-nitrogen compounds by reaction of PCl_3 [56] or variously substituted phosphorus chlorides with sodium bis(trimethylsilyl)amide have been successful only in the case of chlorodiphenylphosphine [57]. Whereas bis(trimethylsilyl)aminodimethylphosphine *(72a)* [31a,32] cannot be obtained in the pure state (detectable by NMR spectroscopy) in accordance with,



El = P *(72a)*, As *(72b)*, Sb *(72c)*

the analogous reactions with chlorodimethylarsine [58] and chlorodimethylstibine [1] present no difficulties. In view of the incompleteness of the class of substances *(72)*, we shall not discuss their ^1H–NMR spectra in detail [δCH_3(Si) is slightly displaced toward higher field strengths from *(72b)* to *(72c)*; −10.0 → −8.5 Hz]. *(72a)*, unlike *(72b)*, gives the triply silylated amino-iminophosphorane *(53)* on oxidation with trimethylsilyl azide [eq. (s')]. Unlike bis(trimethylsilyl)-amine [58], *(72b)* does not react with excess chlorodimethylarsine to give tris(dimethylarsino)amine $[(CH_3)_2As]_3N$.

3.2.1. *N,P*-Bis(organoelement)-Substituted Iminophosphoranes



Attempts to prepare compounds of the type *(72)* by the reverse route, *i.e.* by substitution of *N*-silylated lithium *N*-phosphinoamides *(73)* in accordance with eq. (w) led us to the first *N,P*-bis(organo(IVa)element)-substituted iminophosphoranes *(75)* [29,30], but gave no amines *(74)*.

El = El' = Si *(75a)*; El = Si, El' = Ge *(75b)*;
El = Si, El' = Sn *(75c)*; El = Ge, El' = Si *(75d)*;
El = El' = Ge *(75e)*; El = Ge, El' = Sn *(75f)*.

The fact that *(75b)* is obtained from $[(CH_3)_3C]_2P$–NLi–$Si(CH_3)_3$ and chlorotrimethylgermane, and *(75d)* from $[(CH_3)_3C]_2P$–NLi–$Ge(CH_3)_3$ and chlorotrimethylsilane shows that the reaction is actually an addition (path C) and not a substitution (path A). If *(74)* were the intermediate, the end product should be the same in both cases, *i.e.* *(75)*.

As was found by *Schmitz-Du Mont* and *Jansen* [59], on the other hand, substitution occurs on reaction of $(C_6H_5)_2P$–NK–$Si(CH_3)_3$ with chlorotrimethylsilane. *(75d)* rearranges irreversibly into the isomer *(75b)* when heated at 120–130 °C for several hours; so far as we know, this is the first example of isomerism of an iminophosphorane.

It is not yet known whether this rearrangement proceeds intermolecularly or intramolecularly [*(74)* would presumably occur as an intermediate in the latter case]. The stronger tendency of silicon, as compared with its heavier homologs, to form (p → d)π bond components may be the driving force of this ligand exchange. Another decisive factor may be the more favorable energy balance resulting from the conversion

[55] *W. Fink*, Angew. Chem. *78*, 803 (1966); Angew. Chem. internat. Edit. *5*, 760 (1966).

[56] *U. Wannagat*, Angew. Chem. *75*, 173 (1963); Angew. Chem. internat. Edit. *2*, 161 (1963).

[57] *H. Nöth* and *L. Meinel*, Z. anorg. allg. Chem. *349*, 225 (1967).

[58] *O. J. Scherer* and *M. Schmidt*, Angew. Chem. *76*, 144 (1964); Angew. Chem. internat. Edit. *3*, 137 (1964).

[59] *O. Schmitz-Du Mont* and *W. Jansen*, Angew. Chem. *80*, 399 (1968); Angew. Chem. internat. Edit. *7*, 382 (1968).

of Ge–N and Si–P bonds into Si–N and Ge–P bonds.

All the iminophosphoranes *(75)* are sublimable solids, and their sensitivity to moisture decreases in the following order:

(75f) ⩾ *(75e)* > *(75d)* > *(75c)* ⩾ *(75b)* > *(75a)*

The increased reactivity of the El′–P as compared with the El–N bond is clearly shown in the alcoholysis [eq. (x)] and in the reaction with carbon tetrachloride [eq. (x′)], which leads in quantitative yield to the *P*-chloroiminophosphorane *(34a)* prepared earlier in accordance with eq. (n).

$$[(CH_3)_3C]_2\overset{Si(CH_3)_3}{\overset{|}{P}}{=}N{-}Si(CH_3)_3 \quad (75a)$$

$$\xrightarrow[-(CH_3)_3SiOCH_3]{CH_3OH} [(CH_3)_3C]_2\overset{H}{\overset{|}{P}}{=}N{-}Si(CH_3)_3 \quad (76) \quad (x)$$

$$[(CH_3)_3C]_2\overset{C}{\overset{|}{P}}{-}NH{-}Si(CH_3)_3 \quad (26a)$$

$$(75a) \xrightarrow[-(CH_3)_3SiCCl_3]{CCl_4} [(CH_3)_3C]_2P(Cl){=}N{-}Si(CH_3)_3 \quad (34a) \quad (x')$$

The alcoholysis of *(75a)* suggests that iminophosphoranes of the type *(76)*, or at least these model substances, are unstable and rearrange into the thermodynamically more stable isomeric aminophosphine (NH → PH tautomerism has so far been observed only in cyclotriphosphazenes [60]).

3.3. IVa/VIa Elements

Sulfur-sulfur bonds can be broken both electrophilically [61] and nucleophilically [61,62].

Sodium bis(trimethylsilyl)amide not only reacts with chlorosulfanes [63], S_8 [64], and dithiocyanogen [65] to form *N*-silylated aminosulfanes having the composition

$$[(CH_3)_3Si]_2N{-}S_n{-}N[Si(CH_3)_3]_2 \qquad n = 1 \rightarrow 4$$

but also readily cleaves a wide range of disulfane derivatives [eq. (y)] [44,66].

This cleavage of disulfanes confirms the observation that the ease of nucleophilic cleavage of sulfur-sulfur

$$[(CH_3)_3Si]_2NNa + R{-}S{-}S{-}R \rightarrow [(CH_3)_3Si]_2N{-}S{-}R + RSNa \quad (y)$$

(77)

R = CH_3 *(77a)*, C_2H_5 *(77b)*, *n*-C_4H_9 *(77c)*, C_6H_5 *(77d)*, $C_2H_5OC(O)$ *(77e)*, $C_6H_5C(O)$ *(77f)*, *i*-$C_3H_7OC(S)$ *(77g)*, $(CH_3)_2NC(S)$ *(77h)*, $(C_6H_5CH_2)_2NC(S)$ *(77i)*, $(C_2H_5O)_2P(S)$ *(77j)*.

bonds increases as the substituent R becomes more strongly electron-attracting [44]. If the cleavage of dialkyldisulfanes (very few anions $A^{\ominus}$ cleave dimethyl- or diethyldisulfane) is taken as a measure of the nucleophilic strength of $A^{\ominus} = N[Si(CH_3)_3]_2^{\ominus}$, it can be seen that sodium bis(trimethylsilyl)amide is one of the strongest nucleophilic agents. If the disulfane derivative in eq. (y) is replaced by dimethyldiselenane, the reaction yields bis(trimethylsilyl)aminomethylselenane *(78)* [44].

$$[(CH_3)_3Si]_2N{-}Se{-}CH_3 \quad (78)$$

Comparison of the ^1H–NMR and IR spectra of *(78)* with those of the analogous sulfur compound *(77a)* shows that the replacement of sulfur by selenium leads to slight changes in $\delta CH_3(Si)$ and $\nu_{as}SiN(Si)$, the chemical shift being displaced to higher field strengths [*(77a)* –10.7, *(78)* –9.2 Hz], and the antisymmetric SiN(Si) stretching vibration to higher wave numbers [*(77a)* 935, *(78)* 940 cm^{-1}]. These observations are in good agreement with the results obtained for tris(organo(IVa/IVa)element)-substituted amines. However, the differences are more pronounced than for the latter (cf. Section 3.1).

A distinct weakening of the "thiophilic character" in alkali metal silylamides can be achieved by introduction of electron-attracting substitutents on the silicon atom. $[(i\text{-}C_3H_7O)_3Si]_2NNa$ cleaves only the sulfur-sulfur bond of the particularly reactive diethyl dithiodiformate [44].

$$[C_2H_5OC(O)S]_2 + [(i\text{-}C_3H_7O)_3Si]_2NNa \rightarrow [(i\text{-}C_3H_7O)_3Si]_2N{-}S{-}C(O){-}O{-}C_2H_5 + C_2H_5OC(O)SNa$$

(79)

Many of the *N*-silylated aminosulfanes are surprisingly insensitive to water. Their chemical behavior toward thionyl chloride is interesting. In most cases cleavage of the Si–N and not of the S–N bond occurs, even under very mild conditions [67].

$$[(CH_3)_3Si]_2N{-}S{-}R \xrightarrow[-2\,(CH_3)_3SiCl]{SOCl_2} R{-}S{-}N{=}S{=}O \quad (80)$$

R = CH_3 *(80a)*, C_2H_5 *(80b)*, $CH_2{=}CH{-}CH_2$ *(80c)*, C_6H_5 *(80d)*, $C_6H_5C(O)$ *(80e)*, $C_2H_5OC(O)$ *(80f)*, *i*-$C_3H_7OC(S)$ *(80g)*.

This provided the first preparative route to the *N*-alkylsulfenylthionylimides, as well as to many other derivatives of this class of compounds [67,68].

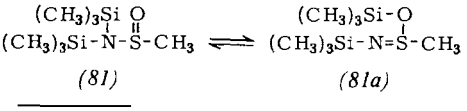
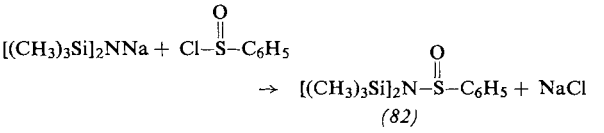
3.4. Ligand Migration Processes in *N*-silylated Sulfinamides and Aminosulfimines

Fluxional organometallic molecules (particularly transition element compounds) have recently been intensively studied [69]. Whereas amides I [70], thioamides [71], ureas [72], and amidines (skeleton IV) are used to study the 1,3 migration of $(CH_3)_3El$ ligands attached to nitrogen for elements of group IVa, aminophosphine oxides II [73] and aminoiminophosphoranes V for elements of group Va, *N*-silylated sulfinamides III and aminosulfimines VI should be suitable for this purpose in the case of group VIa (Scheme 3).



Scheme 3. The free valences on the N represent $(CH_3)_3El$ ligands.

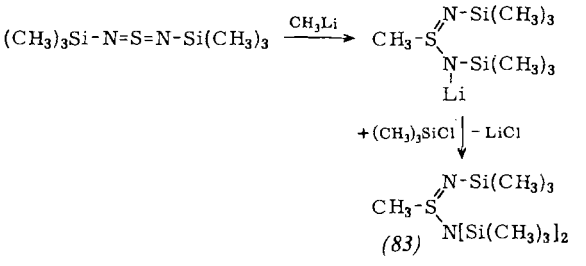
Methyllithium adds to the double bond system of *N*-sulfinyltrimethylsilylamine. The 1:1 adduct reacts further with chlorotrimethylsilane to give the bis-silylated sulfinamide *(81)* [74].



(81)

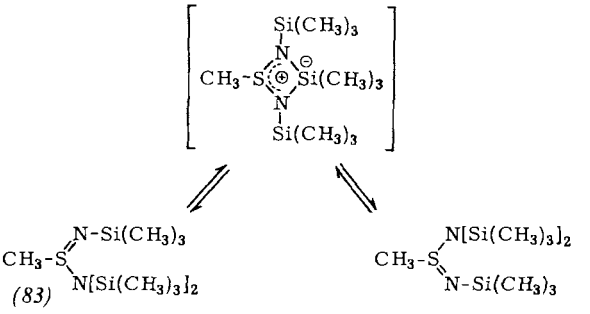
The ^1H–NMR spectrum of *(81)* (in CCl_4 solution and undiluted at 35 °C contains three $(CH_3)_3Si$ and two CH_3S signals. Whereas coalescence of the silyl and sulfenyl signals occurs at about 100 °C, the spectrum resumes its original form when the specimen is cooled to 35 °C again. This shows that *(81)* is in equilibrium with its imine tautomer *(81a)* at 35 °C [about 60 % of *(81)* and 40 % of *(81a)*], this equilibrium being displaced even more in favor of the amine form *(81)* on further cooling to −50 °C.

(81) *(81a)*



If the CH_3 group on the sulfur atom is replaced by C_6H_5, no amine-imine tautomerization is observed between about −50 and 100 °C.

(82)

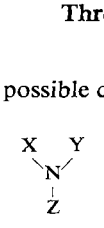


The difference in the behavior of *(81)* and *(82)* is probably due to an increase in the electron density on the oxygen atom as a result of the inductive effect of the methyl group.

1,2-Addition of methyllithium is also possible in the case of sulfur bis(trimethylsilyl)diimide [75].

(83)

N,N',N''-Tris(trimethylsilyl)-*S*-methylaminosulfimine *(83)*, like the analogous aminoiminophosphoranes, exhibits dynamic properties.



(83)

The ^1H–NMR spectrum contains one $(CH_3)_3Si$ signal at 35 °C, even at high dilution, two at about −50 °C, and three at about −80 °C.

It may be concluded from these observations that the reversible intramolecular $(CH_3)_3Si$ ligand migration indicated in the formulas stops at about −50 °C [75]. The additional splitting of the signal due to the amine-bound $(CH_3)_3Si$ groups at about −80 °C can be interpreted as resulting from hindered rotation about the S–N bond.

4. Tris(organoelement)-Substituted Amines with Three Different Hetero Atoms

The number of possible combinations for the formula

X, Y, Z = organoelement ligand

[69] For example, *F. A. Cotton*, Accounts chem. Res. *1*, 257 (1968).

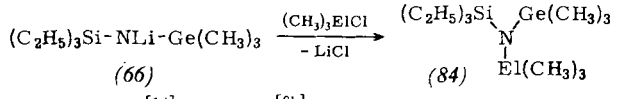
[71] *K. Itoh*, *K. Matsuzaki*, and *Y. Ishii*, J. chem. Soc. (London) *C 1968*, 2709.

[72] a) *J. F. Klebe*, *J. B. Bush jr.*, and *J. E. Lyons*, J. Amer. chem. Soc. *86*, 4400 (1964); b) *I. Matsuda*, *K. Itoh*, and *Y. Ishii*, J. chem. Soc. (London) *C 1969*, 701.

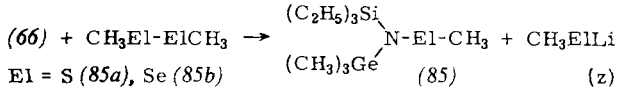


[73] *M. Meyer zur Heyde*, Tetrahedron Letters *1969*, 1425.

[74] *O. J. Scherer* and *R. Schmitt*, Tetrahedron Letters *1968*, 6235.

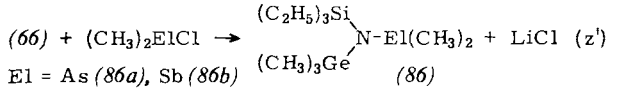
[75] *O. J. Scherer* and *R. Schmitt*, J. organometallic Chem. *16*, P 11 (1969).

which would appear to be large "on paper", is limited in practice, since only one synthetic route has so far led to the desired result. The starting material is a primary elemento-organic amine that has no great tendency toward condensation and whose element-nitrogen bond is not unstable toward organolithium compounds.



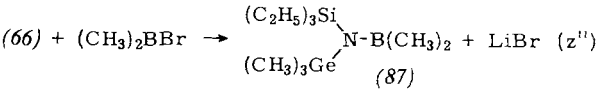
These conditions are satisfied by *N*-triethylsilylamine and aminodi-*tert*-butylphosphine derivatives with elements of the second short period. The choice of the second ligand is also limited, since the element-nitrogen bond in this compound also must resist cleavage during the metalation. In tris(organoelement)-substituted amines with three different homologs from one group of the periodic system, only an element from the first long period is possible.

El = Sn *(84a)*[14], Pb *(84b)*[8b]

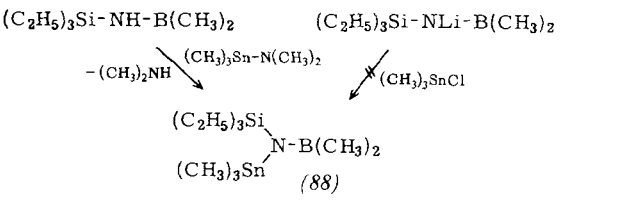


(84a) and *(84b)* are the first stable ammonia derivatives with three different homologs of carbon [8a, 8b, 14].

The introduction of the third ligand is practically free from any restrictions, as is shown by the following reactions [eq. (z), (z'), and (z'')]:

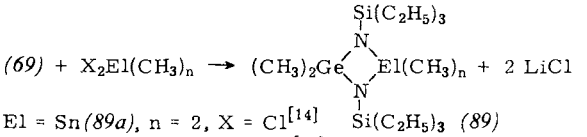


El = S *(85a)*, Se *(85b)*

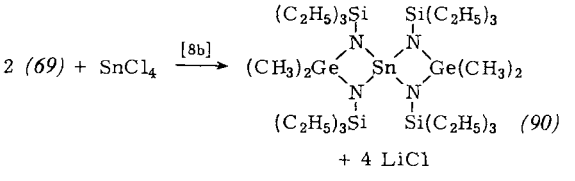


Like sodium bis(trimethylsilyl)amide, *(66)* also cleaves chalcogen-chalcogen bonds [8b] [eq. (z)]. The reaction of this compound with dimethyl(Va)element-halogen compounds presents difficulties only in the case of chlorodimethylphosphine [8b].

El = As *(86a)*, Sb *(86b)*



In addition to tris(organoelement)-substituted amines with IVa/VIa and IVa/Va combinations, IVa/IIIa combinations are also possible [8b].



It should be noted that in the case of *(88)*, the desired result cannot be obtained by double decomposition [76], but only by transamination.

The variety of possibilities offered by this interesting field of elemento-organic nitrogen compounds with different hetero atoms is finally illustrated by the syntheses of two heterocycles [8b].

El = Sn *(89a)*, n = 2, X = Cl [14]
El = B *(89b)*, n = 1, X = Br [8b]

Reductive Cleavage of Bonds by Complexes of Zerovalent Transition Metals

By *H. Schott* and *G. Wilke*[*]

We have observed that in nickel(0) complexes — hereafter symbolized as [Ni⁰] — the nickel atoms render possible the ready cleavage of certain bonds. For example, ethylenebis(triphenylphosphine)nickel and benzoyl peroxide react spontaneously in benzene solution according to the following equation:

$$[Ni^0] + C_6H_5{-}C(=O){-}O{-}O{-}C(=O){-}C_6H_5 \rightarrow Ni^{II}(C_6H_5CO_2)_2$$

Dialkyl peroxides, *e.g.* di-*tert*-butyl peroxide or ascaridol, likewise undergo reaction with cleavage of the O—O bond.

$$[Ni^0] + R{-}O{-}O{-}R \rightarrow Ni^{II}(OR)_2$$

A simple, pure nickel alkoxide has been prepared for the first time in this way from di-*tert*-butyl peroxide and bis(cycloocta-1,5-diene)nickel. (The compounds prepared by reaction of nickel halides with alkali metal alkoxide are always contaminated with basic products[1].)

The blue di-*tert*-butoxynickel *(1)* is completely insoluble in the commonly used solvents. It decomposes at about 100 °C with separation of nickel, as has also been observed in the case of nickel-aluminum ethoxide[2]. 75 % of the *tert*-butoxy groups give rise to *tert*-butanol, the remainder decomposing into compounds having a lower number of carbon atoms — *inter alia*, butane, butene, propane, propene, acetone, methane, and CO_2. If compound *(1)* is decomposed in the presence of suitable electron donors, complexes containing zerovalent nickel are again formed, *e.g.*

$$\underset{(1)}{Ni[OC(CH_3)_3]_2} + 4\,P(OC_6H_5)_3 \xrightarrow{120\,^\circ C} Ni^0[P(OC_6H_5)_3]_4\,(80\%) + \text{decomposition products}$$

If the reaction is carried out under similar conditions and in the presence of butadiene, catalysts are obtained which facilitate the formation of cycloocta-1,5-diene or cyclododeca-1,5,9-triene.

The reaction of nickel(0) complexes with organic disulfides, *e.g.* dibenzyl disulfide or di-β-naphthyl disulfide, proceeds in analogous fashion to the O—O cleavage described above:

$$[Ni^0] + R{-}S{-}S{-}R \rightarrow Ni(SR)_2$$

Possibly, the synthesis of bis(trityl)nickel[3] previously reported by us also involves such a bond cleavage; however, one must take into consideration in this case that the trityl radical already in solution can react with the nickel(0).

$$[Ni^0] + (C_6H_5)_3C{-}C(C_6H_5)_3 \rightarrow Ni[C(C_6H_5)_3]_2$$

In the reductive cleavage described, the various Ni⁰ compounds exhibit widely differing reactivities. While O—O cleavage is possible with all known Ni⁰ compounds — including $Ni(CO)_4$ — only complexes containing olefinic ligands — *e.g.* cycloocta-1,5-diene — are suitable for the preparation of bis(trityl)nickel. Further examples involving bond cleavage by nickel(0) are the formation of π-allylnickel bromide from tetracarbonylnickel and allyl bromide (cleavage of a C—Br bond) reported by *Fischer* and *Bürger*[4] and the preparation of a nickel(I) phosphide from a nickel(0) complex and triphenylphosphine (cleavage of a P—C bond) *via* a non-isolable phenylnickel diphenyl phosphide as described by *Herrmann*[5].

Other transition metal(0) complexes also react with di-*tert*-butyl peroxide. *Hagihara* and *Yamazaki*[6] have prepared tetra-*tert*-butoxychromium from di-*tert*-butyl peroxide and dibenzenechromium. We have found that both $Fe(CO)_5$ and $Co_2(CO)_8$ react with di-*tert*-butyl peroxide — to give tri-*tert*-butoxyiron and tri-*tert*-butoxycobalt respectively.

Representative procedure:

Di-*tert*-butyl peroxide (8 ml) in toluene (120 ml) is allowed to react with an ethylene-saturated solution of ethylenebis(triphenylphosphine)nickel in toluene (250 ml) for 5 h at 110 °C. The reaction mixture is then filtered, and the residue is washed with toluene and ether and finally dried. Yield: 2.3 g (87 %) of $Ni[OC(CH_3)_3]_2$. The filtrate contains 7 g (98 %) of triphenylphosphine oxide.

A New Reaction of *N*-Vinylcarbazole with Disulfur Dichloride

By *J. Pielichowski*[*]

Disulfur dichloride is known to react with olefins to give bis(β-chloroalkyl) sulfide and sulfur[1,2]. On reaction of *N*-vinylcarbazole with disulfur dichloride hardly any sulfur separates but gaseous chlorine is evolved.

In this case the disulfur dichloride causes polycondensation to a polymer having a molecular weight of about 1300 (ebullioscopic). The polymer contains two atoms of sulfur per molecule of *N*-vinylcarbazole and only little chlorine (about 2 %) probably in the end groups. The course of the reaction depends primarily on the concentration of the two reagents.

The structure of the polymer follows from its IR spectrum after polarographic reduction (solvent: dimethylformamide) of the disulfide groups to sulfide groups (νS—S = 400—500 cm^{-1} [3]). The other absorption bands confirm the presence of carbazole and ethyl groups (values: 720, 750, and 2880 cm^{-1}).

Procedure

N-Vinylcarbazole (5 g) is dissolved in CCl_4 (100 ml); S_2Cl_2 (3 g) is passed into the solution, which is then allowed to stand for 12 h. An olive-green polymer (8 g) is obtained which is boiled for 1 h with a 10% aqueous solution of Na_2SO_3. After filtration, the residue is washed and dried to give a brown powder (yield 7.5 g, m.p. 190—220 °C, solubility in dioxane: 1 g/100 ml, in toluene: 0.5 g/100 ml).

The Interaction between the Lone Pairs in Azomethane[1]

By *E. Haselbach, J. A. Hashmall, E. Heilbronner*, and *V. Hornung* [*]

The extent of the interaction between the lone pairs n_1 and n_2 of the *trans* azo group in aromatic and aliphatic azo compounds has long been a subject of debate. On the basis of electronic spectra and theoretical studies, values between 0 and 7 eV have been derived [2] for the splitting of the levels of the two linear combinations

$$n_+ = \frac{1}{\sqrt{2}}(n_1 + n_2),\ (A_g);\quad n_- = \frac{1}{\sqrt{2}}(n_1 - n_2),\ (B_u)$$

We now wish to report on the result obtained by photoelectron spectroscopy [3] on *trans*-azomethane *(3)* [4]. The photoelectron spectra of *trans*-2-butene *(1)* and of *trans-N*-ethylidenemethylamine *(2)* were taken as a basis for comparison.

(1) *(2)* *(3)*

The π-ionization potential, π-IP, (all values refer to the relevant band maxima; vertical ionization) is shifted toward higher values on successive replacement of C atoms by N atoms: π-IP *(1)* = 9.11 eV; π-IP *(2)* = 10.66 eV; π-IP *(3)* = 11.84 eV. In the case of *(1)* and *(3)*, the corresponding band shows a marked vibrational fine structure with a splitting of 0.17 and 0.15 eV, respectively. (Characteristic stretching frequencies of the un-ionized double bonds in the ground state: *(1)* C=C : 0.21 eV [5]; *(3)* N=N : 0.17 eV [6].) The σ-ionization potentials also shift toward higher values along the series *(1)*, *(2)*, *(3)*, the envelope of the σ bands essentially retaining its form.

The band occurring at 9.49 eV in the spectrum of *(2)* therefore has to be assigned to the ionization of one of the lone pair electrons in the orbital n.

In the spectrum of *(3)*, the first band lies at 8.98 eV, *i.e.* at a lower value than in the spectrum of *(2)*. This is indicative of a strong splitting of the orbitals n_+ and n_-, the relevant band being assigned — on the basis of theoretical calculations — to ionization from n_+ : n_+-IP = 8.98 eV. The band corresponding to ionization from the energetically lower orbital n_- is found at 12.3 eV. It partly overlaps with the π-band at 11.84 eV; the potential for the n_- ionization can therefore only be given to within 0.2 eV: n_--IP = 12.3 ± 0.2 eV. These values give

$$\Delta = n_-\text{-IP} - n_+\text{-IP} = 3.3 \pm 0.2\ \text{eV}$$

for the desired splitting.

Semi-empirical SCF—MO calculations by the MINDO/1 technique [7] show qualitative agreement with the experimental results, as regards both the assignment of the bands and the magnitude of the observed shifts and splittings. In particular, a splitting of Δ (calculated) = 2.2 eV is predicted for *(3)*; it is relatively insensitive to changes of the angle C—N=N in the range 110 to 130 °.

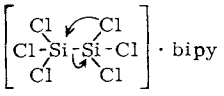
Formation of a Silylene Complex by Base-Catalyzed Decomposition of Hexachlorodisilane

By *D. Kummer* and *H. Köster* [*]

A yellowish white stable 1 : 1 adduct [1,2] is formed on reacting hexachlorodisilane with 2,2′-bipyridine (bipy) in pentane, whereas in tetrahydrofuran (THF) the reaction mixture rapidly turns green, even at 25 °C. On investigating this reaction (with Si_2Cl_6 and bipy in a molar ratio of 1 : 3) we have now been able to isolate $SiCl_2 \cdot 2$ bipy *(1)* and thus gain the first direct proof of a base-catalyzed disproportionation of Si_2Cl_6 proceeding *via* an $SiCl_2$ intermediate (cf. [3]).

$$Si_2Cl_6 + 3\ \text{bipy} \xrightarrow[25\,^\circ C]{\text{THF}} \underset{(1)}{SiCl_2 \cdot 2\ \text{bipy}} + \underset{(2)}{SiCl_4 \cdot \text{bipy}}$$

Both reaction products are formed quantitatively and separate out as a green precipitate. At other molar ratios of Si_2Cl_6 and bipy (1 : 1 to 1 : 3), 1 mole of *(2)* is always formed per mole of Si_2Cl_6 since *(2)* is much less soluble than *(1)*, *e.g.*:



$$Si_2Cl_6 + 2\ \text{bipy} \rightarrow SiCl_4 \cdot \text{bipy} + \frac{1}{2}\ SiCl_2 \cdot 2\,\text{bipy} + \frac{1}{2n}(SiCl_2)_n$$

$$Si_2Cl_6 + \text{bipy} \rightarrow SiCl_4 \cdot \text{bipy} + \frac{1}{n}(SiCl_2)_n$$

In the latter case the precipitate is almost colorless. The compound formally represented as $(SiCl_2)_n$ has not been investigated. Compound *(1)* is slightly soluble in benzene [4] and can be separated from the practically insoluble *(2)* by extrac-

tion. The composition of both substances has been confirmed by analysis and by X-ray powder diagrams. The debyeogram of *(1)* is identical with that of the $SiCl_2 \cdot 2$ bipy prepared according to *Herzog*[4] from $SiCl_4 \cdot$ bipy and $Li_2 \cdot$ bipy.

According to our investigations, compound *(1)* is formed by way of an α-elimination.

During the rearrangement an intermediate can be detected which, according to ^1H–NMR spectra, corresponds to the product of slow decomposition of $(Cl_2CH_3Si)_2 \cdot$ bipy in its structural features[1]; the disproportionation reactions of Si_2Cl_6 and of $(Cl_2CH_3Si)_2$ are, therefore, of the same type. Since previously reported results on the disproportionation of $[CH_3O(CH_3)_2Si]_2$[3] indicated a different reaction route, further investigations will have to be carried out in order to ascertain to what extent the reaction path found by us is valid in other base-catalyzed disproportionations of disilane.

Dichlorosilylene-bis(2,2′-bipyridine) (1)

Si_2Cl_6 (3.60 g, 13.4 mmoles) is condensed under reduced pressure into a solution of bipy (6.26 g, 40.2 mmoles) in THF (100 ml). After warming to 25 °C, the almost colorless reaction mixture (solution and white precipitate) turns dark green within a few minutes. After 6 hours' standing the solution is filtered by suction and the dark green residue is extracted with benzene (100 ml) at 30 °C until the extraction liquid is colorless (in this case 25 days). The extraction is accelerated if carried out at 40—50 °C. 4.2 g of *(1)* was isolated from the concentrated extract and a further 0.8 g from the original reaction solution; thus a total yield of 5.0 g (90%) of *(1)* was obtained. 4.7 g of a pale green colored extraction residue remained (calc. for *(2)* 4.37 g). Since the products are extremely sensitive to moisture and oxygen all operations were carried out in an all-glass apparatus fitted with break-seals.

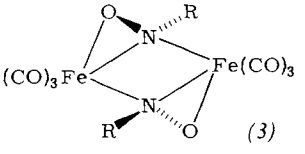
The Crystal Structure of Bis(tricarbonyl-2-methyl-3-chloronitrosobenzeneiron)

By *M. J. Barrow* and *O. S. Mills*[*]

A series of tricarbonylnitrosobenzeneiron complexes[1] results from the γ or UV irradiation of nitrobenzenes in the presence of pentacarbonyliron. Colligative properties suggested that both monomeric and dimeric forms exist dependent on the particular nitrobenzene precursor. The authors were unable, on the basis of the IR and UV spectroscopic data, to establish unequivocally the molecular structure and later Mössbauer studies[2] have shown that if the complexes are dimeric, then both iron atoms must have identical environments. Most of the complexes precipitate as fine powders from which it is difficult or impossible to obtain crystals large enough for single-crystal X-ray analysis and we have examined the only compound which, as far as we know[3], has yielded suitable crystals, *i.e.* that formed from 2-methyl-3-chloronitrobenzene.



This complex $(C_{10}H_6ClFeNO_4)_n$, mol. wt. = $n \times 295.5$, crystallizes in the monoclinic space group $P2_1/c$ (No. 14, C_{2h}^5) with $a = 18.26$, $b = 7.25$, $c = 8.71$ Å, $\beta = 90.85°$, $V = 1151$ Å^3, $d_{calc} = 1.71$ gcm^{-3} ($Z = 4$ or 2 for $n = 1,2$ respectively). The structure, solved by conventional Fourier methods (1008 reflections, present $R = 0.11$), establishes that this complex is a dimer. The space group requires that the dimer be centrosymmetric, in accord with the Mössbauer observations. The mass spectrum, taken at 70 eV, showed a peak at the *m/e* for the parent monomeric ion with low intensity peaks at values up to 50% greater and suggests that the dimeric molecules are probably easily dissociated.

The structure (cf. formula *(3)*) contains two novel features. The tricarbonyliron units are bridged by the two nitrosobenzene groups but only the nitrogen atoms are bonded to

(1) *(2)*

R = 2-CH_3-3-Cl-C_6H_3

(3)

both iron atoms. The central Fe—N—Fe—N ring is hence strictly planar and has edges of length 2.00 (3) Å, a value close to those found in other nitrogen-bridged bis(tricarbonyliron) complexes, 1.96—2.02 Å[4–8]. The NO group is placed unsymmetrically between the iron atoms. The oxygen atom is 1.91 Å from one iron yet is more than 2.7 Å away from the second iron. The former distance is less than that found in bis(μ-phenyloxycarbenetricarbonyliron)[9] 1.97, triacetylacetonatoiron[10] 1.99, and tris(*N*-nitrosophenylhydroxylamine)iron[11] 2.00 Å in which the bonds have some covalent character. The Fe—O and Fe—N distances can be discussed in terms of structures *(1)* and *(2)* written with either two sigma bonds or with interaction through the π-electrons of the NO group to the metal. The N—O distance, at present 1.39 Å, is one of the largest values yet recorded and favors representation *(2)*.

Hitherto, all carbon- or nitrogen-bridged iron complexes have shown metal-metal distances which can be interpreted in terms of Fe—Fe bonds and the question has been raised as to whether or not these Fe—Fe bonding distances are inevitable consequences of the presence of the bridging atoms, *i.e.* is the Fe—Fe distance determined by the requirement of the angle subtended at the bridge atom *or* is it the involvement of a metal-metal bond, with some optimum separation, which determines the angle subtended? Nitrogen-bridged compounds have been associated with the shortest distances reported between zerovalent iron atoms, 2.37—2.43 Å[4–8]. The present value, 3.13 Å, proves conclusively that these shorter separations cannot exclusively be due to the presence

of the bridge nitrogen atoms. We interpret the distance in this example as involving a null bond and indeed no bond need be invoked to account for the diamagnetism. The situation can be compared to that in bis(diaryldiazomethane)tris-(tricarbonyliron) in which a non-bonded separation of 3.06 Å is reported [12]. The angle subtended at the nitrogen atom by the iron atoms is 100°, some 25—30° larger than those found in complexes which involve metal-metal bonds.

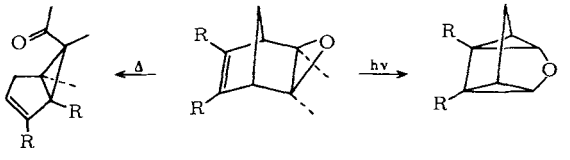
5-Acetyl-1,2,3,4,5-pentamethylbicyclo[2.1.0]-pentene

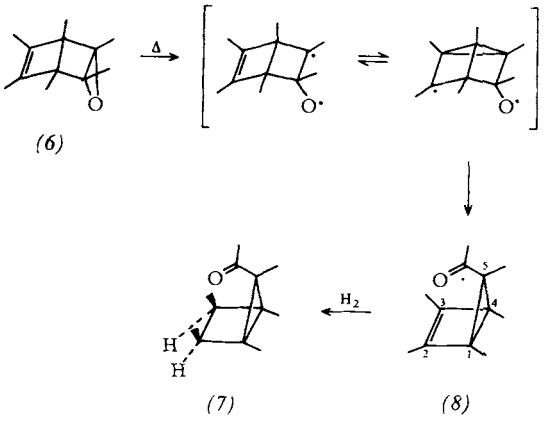


By *M. Klaus, H. Prinzbach,* and *H. Achenbach* [*]

We have attempted to imitate the ethylene/cyclopropane → cyclopentane photoisomerization, realized several times for *(1)* → *(2)* when X = CR_2 [1], with the analogous ethylene/oxirane substrates, *i.e. (1)* → *(2)* where X = O.

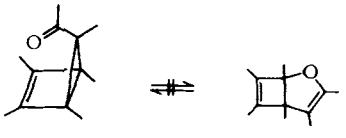
(1) *(2)*

As a first example we recently described the conversion *(4)* → *(5)* [2].



(3) *(4)* *(5)*

Attempts to convert the epoxide *(6)* [4] of hexamethyl(Dewar benzene) [5] — which probably exists in the *endo*-form [3] — into hexamethyloxaquadricyclane [6] have so far been without success [7]; however, we found that pyrolysis of *(6)* led to the very stable bicyclo[2.1.0]pentene derivative *(8)*, as expected in view of the conversion of *(4)* into *(3)* [8].



When *(6)* was heated (190 °C, 9 h) in a well-cleaned Teflon vessel, a mixture of products (*ca.* 90%) was isolated by distillation and this could be separated by fractional distillation followed by column chromatography (silica gel, cyclohexane/ethyl acetate 8 : 2) into hexamethylbenzene (5%), 5-acetylpentamethylcyclopentadiene (the product of acid-catalyzed isomerization [3,4]) (3—7%), 2,3,4,5,6,6-hexamethyl-2,4-cyclohexadienone (69%) [9], and *(8)* (16%).

The bicyclic product *(8)* is stable up to at least 210 °C [10]. In the presence of Pd/C it absorbs 1 mole of hydrogen selectively, to give *(7)*. Isomerization to 5-acetylpentamethylcyclopentadiene [4] is not effected by passing HCl into a CCl_4 solution of *(8)* or by addition of acetic or sulfuric acid.

(6) *(7)* *(8)*

The structures of *(7)* and *(8)* were confirmed in particular by the spectroscopic data. Molecular ions that appeared with medium intensity in the mass spectrum of *(8)* occurred only very weakly in that of *(7)*; with both compounds elimination of C-2 and C-3 led to a very intense peak at *m/e* = 124 (weak metastable peaks at *m/e* = 85 and 85.5, respectively); the species corresponding to this peak can pass by loss of a methyl

radical into the fragment ion m/e = 109 (acetyldimethylcyclopropenyl cation) (metastable signal at m/e = 96).

The C=O stretching bands at 1686 and 1696 for *(8)* and *(7)*, respectively, are typical of cyclopropyl ketones [11]. The NMR spectrum of *(7)* suggests that the two quartets observed for *(8)* are to be assigned to the methyl groups on C-1 and C-4. The asymmetry due to hindered rotation around C-5/C=O is no longer effective for the methyl protons on C-2 and C-3 [12]. There is no indication of an equilibrium *(8)* $\rightleftarrows$ *(9)* between 30 and 120 °C [13].

The *endo*-orientation is assigned to the acetyl group only for mechanistic reasons, but the *exo*-hydrogenation of *(8)* to give *(7)* is made probable by an earlier example [14].

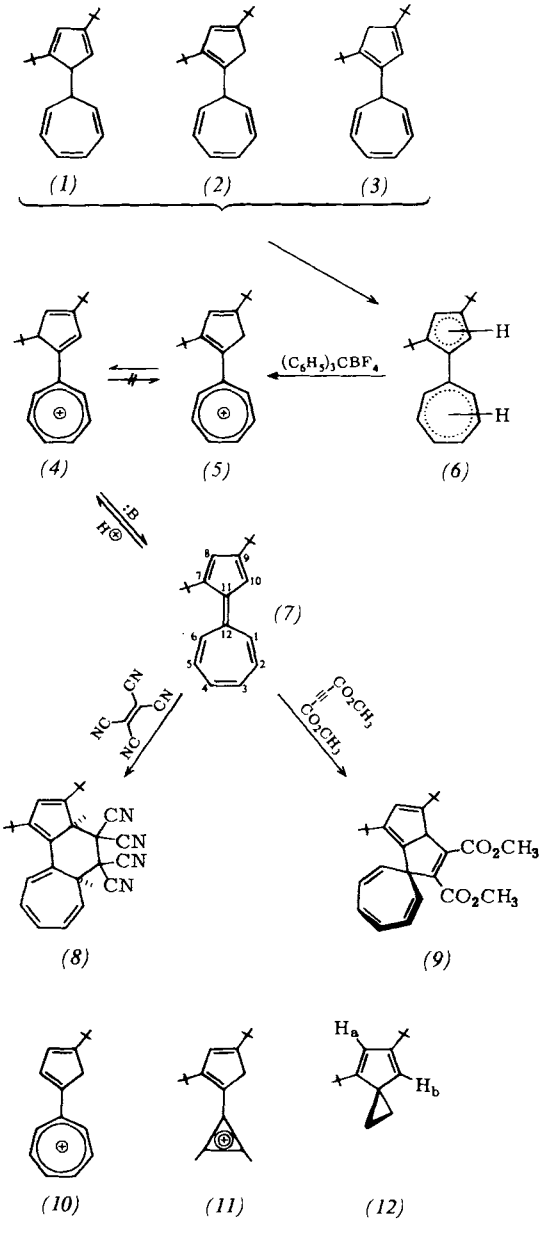
7,9-Di-*tert*-butylsesquifulvalene: Its Synthesis and Cycloadditions [**] [1]



By *H. Prinzbach* and *H. Knöfel* [*]

We have prepared 7,9-di-*tert*-butylsesquifulvalene *(7)*, which, unlike other sesquifulvalene derivatives [2], undergoes [12 + 2] cycloaddition.

Treatment of lithium 1,3-di-*tert*-butylcyclopentadienide [3] (0.1 mole in 200 ml of anhydrous ether at −50 °C) with tropylium bromide (0.1 mole) precipitates a mixture of the dihydrosesquifulvalenes *(1)*, *(2)*, and *(3)* (b.p. 104–109 °C/10^{-3} torr; 70–75%) [4]. When heated at 165 °C for 30 min *(1)*–*(3)* isomerize to the complex mixture *(6)* which is formed by several sigmatropic H shifts in the five- [5] and the six-membered ring [6]. As expected, hydride elimination from *(6)* by trityl tetrafluoroborate [7] (0.8 equivalent of trityl salt in CH_2Cl_2 at 0–5 °C) to give the cyclopentadienyltropylium salts *(4)* and *(5)* is very rapid; the non-planar π-system *(5)* rearranges slowly to *(4)*. This compound *(4)* can be isolated as red needles, m.p. 165 °C, by precipitation from ether and can be purified by prolonged extraction with ether. We have been able to prepare the conjugate acids *(10)* and *(11)* analogously [8].

Adding a CH_2Cl_2 solution of *(4)* to a vigorously stirred mixture of trimethylamine with benzene or with CCl_4 at 0–5 °C liberates the base *(7)*; repeated concentration to at most a 10^{-3} M solution and renewed addition of benzene or CCl_4, followed by filtration through an Al_2O_3 column (basic, IV) leads to solutions of pure *(7)* in these solvents. If light and air are excluded, *(7)* is stable in *ca.* 10^{-2} M solution at 0 °C for several days, and also for a short time (NMR) in 10^{-1} M solution. As expected [2], protonation gives *(4)* preferentially.

When benzene solutions of *(7)* and tetracyanoethylene are mixed, the deep red solution at once fades to yellow. The 1 : 1 adduct *(8)* is precipitated from benzene/CCl_4 as pale yellow needles, m.p. 104–106 °C. However, *(7)* and dimethyl acetylenedicarboxylate in boiling benzene (4 h) give a yellow 1 : 1 adduct *(9)*.

[a] TMS as internal standard, coupling constants in Hz. To aid comparisons, the numbering of *(7)* is retained for all the compounds.
[b] In CH_2Cl_2. [c] In ethanol. [d] In CF_3COOH.
[e] BuH = *tert*-Butyl-H. [f] In CCl_4. [g] In $CDCl_3$.

The new compounds (Table) have been characterized by elemental analysis, spectroscopic data, and differing reactions.

Useful comparative data for the UV and NMR results for the sesquifulvalene *(7)* and the conjugate acid *(4)* were available from previous experiments[2,9]. The hypsochromic shift of the longest-wavelength maximum of *(7)* relative to that in unsubstituted sesquifulvalene (λ_{max} = 391 nm in isooctane) is preliminarily interpreted as due to the increased departure from planarity. Very considerable localization of the double bonds in *(7)* is indicated, by, *inter alia*, the size of the coupling constants $J^{8,10}$ (2.3 Hz) [cf. *(12)* τ = 3.80 (H^a, D); 4.81 (H^b, D); J^{ab} = 2.2 Hz (in CCl_4)][8].

The apparently very long wavelength of the first UV maximum of *(4)* is also well fortified by analogies [cf. *(10)*][8,10]. The *cis*-configuration in the [12 + 2] adduct *(8)* is postulated on the basis of the Woodward-Hoffmann rules. There are also several analogies for the quite different direction of addition of dimethyl acetylenedicarboxylate that gives *(9)*[11]. We are testing on 8-*tert*-butylsesquifulvalene the hypothesis that the ester, like tetracyanoethylene, first attacks as an electrophile at C-10 and then closes the ring with C-12, and not with C-1, so as to avoid steric compression between H-6 and the neighboring *tert*-butyl group.

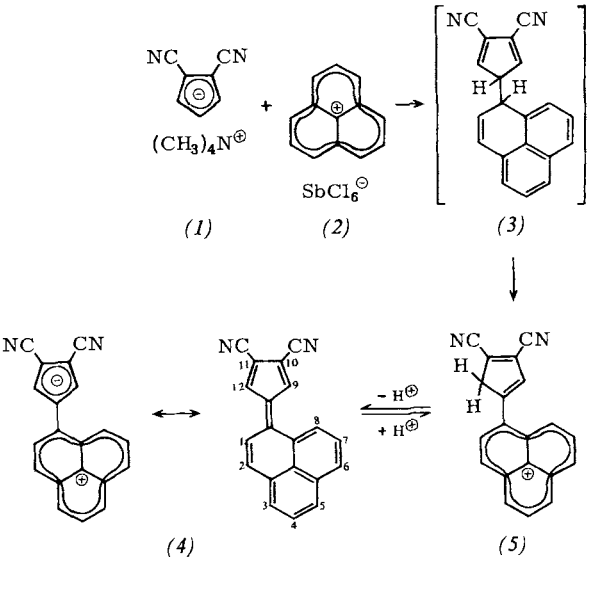
10,11-Dicyanopentaphenafulvalene[**][1]

By *H. Prinzbach* and *E. Woischnik*[*]

Attempts to extend the series of "mixed" fulvalenes (calicene, sesquifulvalene, fidecence[2]) to combinations containing the phenalene cation or anion have long remained without success[3]. Only a few "phenafulvalenes" stabilized by powerful acceptor groups[4] or dimethylamino-substituted vinylogs[5] have been obtained pure and characterized.



In the dicyano compound *(4)* we have prepared a stable, comparatively simple derivative with the $6\pi + 12\pi$ system[6].

Treatment of the dicyanocyclopentadienyl salt *(1)*[7] with the phenalenium salt *(2)*[8] yields the dihydro product *(3)*, but this reacts so rapidly with *(2)* to give *(5)* or with loss of $HSbCl_6$ to give *(4)* that no attempt was made to isolate the intermediate stages *(3)* and *(5)*. Because *(4)* is so reactive and especially because it decomposes readily in contact with various chromatographic carrier materials, reaction conditions were chosen which made it unnecessary to separate or purify the product because it could be separated directly from the reaction medium in a pure state. In the absence of air, pure crystalline *(4)* can be kept for some days without decomposition.

In agreement with the low basicity of 14,14-dicyanophenafulvene[4] the equilibrium *(4)*⇄*(5)* in CF_3COOH (*ca.* 5% solution) lies largely towards *(4)* (H/D exchange in CF_3COOD at positions 9 and 12 requires several days); however, *(4)* is protonated in 80% sulfuric acid almost wholly to the orange conjugate acid *(5)* which, nevertheless, is not very stable in this medium; *(4)* is largely regenerated by adding water rapidly[9].

The structures *(4)* and *(5)* are proved by the results of elemental analysis and the spectroscopic data[10].

(4), *m/e* = 278 (M^+). IR (KBr), ν = 2205, 1609, 1558, 1508, 1489, 1474, 1312, 1205, 928, 767 cm^{-1}. UV, λ_{max} (CH_3CN) =

587 nm (ε = 23400), 394 (sh, 4500), 368 (5100), 348 (sh, 4700), 300 (sh, 12600), 287 (13800), 270 (12000).

The first band displays strong positive solvatochromism: 555 nm (C_6H_{12}), 560 (CCl_4), 569 (C_6H_6), 579 ($CHCl_3$), 585 (CH_2Cl_2), 585 (C_2H_5OH), 587 (CH_3CN), 596 (CF_3COOH).

NMR (220 MHz, CF_3COOH), τ = 1.67 (1, D, J = 8.1 Hz; H^8), 1.78 (1, D, $J \approx$ 8 Hz; H^6), 1.82 (1, D, $J \approx$ 7 Hz, H^5), 2.01 (1, D, J = 7.2 Hz; H^3), 2.10–2.35 (2, M; H^7, H^4), 2.22 (1, D, J = 9.5 Hz; H^2), 2.41 (1, D, J = 9.5 Hz; H^1), 2.94 (2, S; H^9, H^{12}).

(5), UV, λ_{max} (80% H_2SO_4) = 528 nm (sh, ε = 7900), 458 (16100), 401 (16300), 327 (8300), 314 (8100), 226 (27200).

NMR (60 MHz, 80% H_2SO_4), τ = 0.95–1.35 (5, D + T), 1.80–2.20 (3, D + T), 3.15 (1, S), 5.85 (2, br. S).

The signals at τ = 3.15 and 5.85 disappear in 80% D_2SO_4/D_2O; presumably the proton adds at both positions H-9 and H-12 of *(4)*.

Insufficient solubility prevented exact determination of the dipole moment of *(4)*. As judged from the chemical shifts of the protons that are not influenced by anisotropic effects, the electron density at the carrier carbon atoms of the phenalene skeleton is always less than in phenalenone and comparable with conditions in 14,14-dicyanophenafulvene.

10,11-Dicyanopentaphenafulvalene (4):

A CH_2Cl_2 solution of *(1)* (760 mg, 4 mmoles; in 100 ml) is added dropwise to a slurry of finely powdered *(2)* (4.0 g, 8 mmoles) in CH_2Cl_2 (80 ml) at 0 °C during *ca.* 30 min with stringent exclusion of oxygen and moisture. The solution changes rapidly from red to deep violet; it is stirred for 4 h at 30 °C, then the $(CH_3)_4NSbCl_6$ is filtered off under N_2, and the filtrate is concentrated to a quarter of its volume. On storage, 10,11-dicyanopentaphenafulvalene *(4)* separates as bluish-black crystals with a reddish surface sheen; they are almost pure and melt at 255–258 °C (yield 380–400 mg, 34–36%).

Photochemical [2π + 2σ] Cycloadditions in Tetracyclo[3.3.2.0^{2,4}.0^{6,8}]decene Systems[**][1]

By *H. Prinzbach*, *M. Klaus*, and *W. Mayer*[*]

We recently showed that photochemical [2π + 2π] cycloaddition can occur also in the bicyclo[2.2.2]octadiene skeleton and that in monohomobarrelene *(2)* this [2π + 2π] addition *(2)*→*(3)* leaves no opportunity for the [2π + 2σ] addition *(2)*→*(1)* to occur[2].

We have now realized such [2π + 2σ] additions in the two tetracyclenes *(5a)* and *(5b)* obtained[3] from *(2)*. On direct irradiation, *(5a)* and *(5b)* isomerize to the "trishomobenzene" derivatives *(6a)* and *(6b)*, respectively, the reaction being very smooth (86–96% yield) and probably occurring through the excited singlet state[4]. There was no convincing evidence of competitive formation of *(4a)* or *(4b)*[5]. This selective cycloaddition between the excited maleic chromophore and the *exo*-three-membered ring[6] underlines the importance, noted earlier, of stereoelectronic factors in such [2π + 2σ] additions.

The structures were proved by elemental analyses and spectral data (Table). For comparison we synthesized the 1-pyrazolines *(7a)*, m.p. 183.5–184.5 °C, and *(7b)*, m.p. 177 to 178 °C, and also the novel "trishomobarrelenes" *(8a)*, m.p. 93–94.5 °C, and *(8b)*, m.p. 173.5–174.5 °C[7].

The *endo*-position[8] of X in *(5)* is expected because of the directing influence of the cyclopropane ring in *(2)*, but it could not be proved by $J^{a,d}$ because of the approximately equal interplanar angles a–C–C–d^{exo} and a–C–C–d^{endo}; however, the considerable paramagnetic shift of δH^e on transition from *(5a)* to *(7a)* or *(8a)* (τ = 9.06, 7.98, and 8.15, respectively) is in favor of placing H^e[9] above the C=C plane in *(5a)*.

Compound M.p. (°C)	UV [a] (nm; ε)	NMR (τ); J (Hz) [b]								CO_2CH_3	Molecular ion at m/e[c]

(5a) 89–89.5	sh 239 (3100)	6.59 (M) [d] $\Sigma J_{a,b} + J_{a,b'} = 3.5$ $\Sigma J_{a,d} + J_{a,d'} = 4.0$		8.78 (bM) $J_{b,c} = 7.3$ $J_{b,c'} = 3.5$		9.22 (bM) $J_{c,c'} = 6.1$ $J_{c,b} = 7.3$	8.21 (M) $J_{c',c} = 6.1$ $J_{c',b} = 3.5$	8.58 (M) $J_{d,e} = 2.9$		9.06 (T) $J_{e,d} = 2.9$	6.29 (S, 6) 6.46 (S, 3)	
(6a) 117–117.5	$\varepsilon_{220} = 550$	8.08 [e] $J_{a,b} = 8.5$		7.60 (M) $J_{b,a} = 8.5$ $J_{b,c} \approx 7$		7.71 (M) $J_{c,c'} = 13.5$ $J_{c,b} \approx 7$	8.27 (D) $J_{c,c'} = 13.5$	8.17 (M) $J_{d,e} = 3.7$ $J_{d,a} \approx 1.3$		8.42 (T) $J_{e,d} = 3.7$	6.27 (S, 3) 6.30 (S, 6)	306
(5b) 87–88	sh 233 (3600)	6.50 (M) [d]		8.74 (M) $J_{b,c} = 7.5$ $J_{b,c'} = 3.5$		9.33 (M) $J_{c,b} = 7.5$ $J_{c,c'} = 6$	8.43 (M) $J_{c',c} = 6$ $J_{c',b} = 3.5$	7.02 (M)			6.30 (S)	
(6b) 103–104	$\varepsilon_{220} = 410$	7.96 [e] $J_{a,b} = 8.5$		7.50 (M) $J_{b,a} = 8.5$ $J_{b,c} \approx 7$		7.62 (M) $J_{c,c'} = 14.5$ $J_{b,c} \approx 7$	8.23 (D) $J_{c',c} = 14.5$	6.59 (M)			6.31 (S)	250

[a] In C_2H_5OH. [b] Measured at 100 MHz [*(5)*] and 220 MHz [*(6)*]. We thank Drs. *W. Brügel* and *H. Friebolin* for the 220 MHz spectra. [c] We thank Dr. *H. Moll* for the mass spectra. [d] In CCl_4. [e] In $CDCl_3$.

The *endo*-position of the epoxide ring in *(5b)* is rendered probable by absence of long-distance coupling $J^{b,d}$ (the H^d signal becomes a sharp singlet on decoupling of $H^{a,a'}$; the $H^{d,d'}$ multiplet suffers no change at all on irradiation of $H^{b,b'}$).

The direction of cycloaddition of *(5)* to give *(6)* follows from, *inter alia*, the changes of $J^{c,c'}$ and $J^{d,e}$; the $J^{c,c'}$ value [6.1 Hz in *(5a)*, 6.0 Hz in *(5b)*], which is typical for geminal cyclopropane coupling, increases to the values 13.5 Hz in *(6a)* and 14.5 Hz in *(6b)* [10] which are reasonable for geminal cyclopentane protons, whilst $J^{d,e}$ retains the values normal for *trans*-vicinal cyclopropane protons [2.9 Hz in *(5a)*, 3.7 Hz in *(6a)*].

$J^{a,b}$ $J^{b,c}$, and $J^{c,c'}$ for the photoproducts *(6)* agree well with the coupling constants evaluated for the related tetracyclo[3.3.0.$0^{2,4}$.$0^{6,8}$]octane skeleton [11].

The attachment of the pyrazoline ring shown in *(7)* and consequently the similar orientation of all the three-membered rings in *(8)* are based on the criteria that were determinative for addition of X to *(2)*.

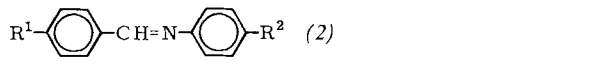
A Liquid-crystalline (Nematic) Phase with a Particularly Low Solidification Point

By *H. Kelker* and *B. Scheurle* [*]

We have prepared a chemically homogeneous, stable, nematogenic substance that is still liquid at room temperature: *N*-(*p*-methoxybenzylidene)-*p*-*n*-butylaniline *(2k)*. This melts at 20 °C to a mobile, turbid, pale yellowish liquid with all the properties of a nematic phase; its clarification point is approximately 41 °C. Comparison with homologous and isomeric compounds [1] enables its transition temperatures and other physical properties to be discussed in relation to constitution. The optical and electrooptical properties that characterize some higher-melting liquid-crystalline substances are also observed with *(2k)*.



Our investigations started from the finding that in the azomethine series *(1)* there is a very obvious melting-point minimum at the butyric ester (R^1 = *n*-propyl) [2]. The melting

(1), R^1 = n-Alkyl

point of the butyrate is 50 °C and the clarification point 112 °C. According to *Weygand* alkyl chains are all to be regarded as "wing groups"; examples are *n*-alkyldiphenylpyridazines and *p*-butylbenzoic acid.

Comparison of compounds containing an azoxy, azo, or azomethine group shows that the homologous azomethines have the lowest clarification point. There are, however, no general rules for melting-point series, least of all for the initial members of homologous series. We synthesized azomethines of series *(2)* by the known method, condensation of an aromatic aldehyde with an alkylaniline. [*(2a)* [3] and *(2b)* [4] are known.] From the series of solidification and clarification points it could not be deduced with certainty that the butyl

(2)

	R^1	R^2	M.p. (°C)	Transition point (°C), behavior
(a)	CH_3O	H	60–63 [3]	isotropic

derivatives *(2k)* and *(2l)* would have the desired properties [**].

Compounds *(2k)* and *(2l)* were prepared by condensing *p*-methoxy- and *p*-ethoxy-benzaldehyde with *p*-*n*-butylaniline. After the usual working up procedure, *(2l)* was recrystallized several times from ethanol; *(2k)* was obtained in about 80% yield by distillation in a high vacuum. *Gabler* [5], who briefly mentions this type of compound, prepared only members with longer alkoxy chains R^1 (C_8 and C_9) and $R^2 < C_4H_9$, and these also showed as few peculiarities as did the Schiff base *(2m)* which is isomeric with *(2k)*.

Since *(2k)* is readily accessible, physical properties can be studied for this compound which would be hard to study without special apparatus (thermostat) for higher-melting compounds. For instance, we were able to demonstrate the "dynamic scattering" effect [6] for *(2k)*, the phenomenon that forward scattering of incident light is increased in an electric field; this effect is utilized industrially for display of numbers, *etc.* By use of *(2k)* it is also possible to demonstrate strain figures on plastics or glass at room temperature. Here we are clearly dealing with "epitaxy" effects such as have been utilized in the manufacture of polarization films [7].

(2k) can also be used as solvent for *Saupe*'s technique of NMR spectroscopy [8] (direct spin-spin coupling in the nematic phase).

Finally it was of interest to prepare cholesteric mixed phases containing *(2k)* and to study their possible use in thermotopography [9,10]. It is known that nematic phases become cholesteric on addition of optically active cholesteric substances. Use of *(2k)* had the result that the typical cholesteric reflection color appeared but that this was not shifted towards the violet on increase in temperature as is characteristic of many mixtures and for mixtures of various proportions. In mixtures of *(2k)* with cholesteryl benzoate, methyl carbonate, nonanoate, or oleate, a cholesteric phase is formed on cooling below the clarification point; this shows a reflection color which depends on the composition but which remains almost unchanged over a wide temperature range. The color shifts slightly towards the violet before it vanishes at 0 °C. These experiments were carried out on cover slips with the reverse side blackened and placed on a Kofler hot stage.

The mixtures behave like binary mixtures when $\beta > \beta_0$ [9]. [β_0 is the composition of a binary cholesteric mixture at which the relation between reflection color and temperature changes sign.] Above β_0 the wavelength of the reflected light shifts to red with increase in temperature, and to blue with decrease in temperature. Whereas the mixtures of *(2k)* and cholesteryl oleate are stable for weeks, the three other esters rapidly crystallize out.

Polyethylene Glycol for Fractionation and Crystallization of L-Asparaginase

By *O. Wagner*, *K. Bauer*, *E. Irion*, *E. Rauenbusch*, *W. Kaufmann*, and *A. Arens* [*]

Clinical trials of the antilymphoma effects of L-asparaginase (EC 3.5.1.1.) of type II from *E. coli* [1] required large amounts of high-purity preparations of the enzyme. After acetone treatment of the cells the intracellular enzyme can be extracted with water and precipitated with acetone. The crude asparaginase thus obtained contains 12–18 units/mg of protein [2]. We have found that an exceptionally selective fractionation leading to highly pure preparations that crystallize spontaneously may be accomplished by use of a 50% aqueous solution of polyethylene glycol (average molecular weight 1550) [3].

Precipitation of the asparaginase from aqueous solutions at low salt concentrations with polyethylene glycol is largely independent of pH. The fractionation can be refined by addition of urea (3 moles/l) and by precipitation in the region of the isoelectric point (I.P.) at pH = 5 (see Table 1).

Table 1. Fractionation of L-asparaginase (asparaginase A) from *E. coli* ATCC 9637; 3000 l culture broth. A 10% enzyme solution was used for each of the fractionations 1–3.

	Polyethylene glycol (%)	Yield (g)	Spec. activity (units/mg protein)	Total activity (units)	Yield (%)
Crude enzyme	–	380	17	4960000	100
1. pH = 8.5 3 mole/l urea	17–33	81	63	4210000	85
2. pH = 5.1	8–12	22.8	137	2780000	56
3. pH = 5.1	3.8–7.0	6.7	248	1530000	31

Asparaginase preparations containing more than 180 units/mg can be crystallized by careful precipitation with polyethylene glycol at the I.P. Well-formed crystals (needles) can be grown particularly readily by precipitation with a mixture of polyethylene glycol (50 g) (average molecular weight 6000), water (25 ml), and methanol (25 ml). The crystalline asparaginase obtained in this manner has a specific activity of 280 units/mg of protein [4] which cannot be increased by further recrystallization.

The L-asparaginase from strain 9637 and strain 11303 differ in their migration rates on electrophoresis. Crystalline L-

asparaginase (asparaginase B) from strain ATCC 11303 is equally well obtainable by slight variations of the fractionation limits (see Table 1). The L-asparaginases obtained by this technique[5] from the crude asparaginases of the two strains of bacteria are identical with those purified by column chromatographic procedures.

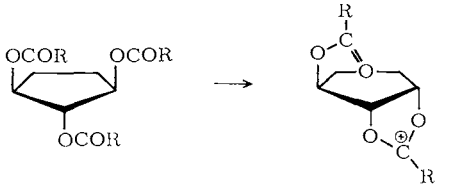
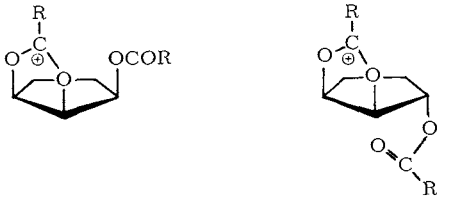
Valence Isomerism in Acyloxonium Cations of 1,2,3-Triols. Simple Synthesis of Acyloxonium Salts[1]

By *H. Paulsen* and *H. Behre*[*]

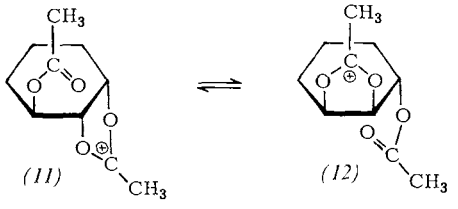
We have found that reaction of 1,2- or 1,3-diol esters *(1)* and *(3)* with $SbCl_5$ in CH_2Cl_2 serves as a simple, general method for the preparation of acyloxonium salts[2,3] of types *(2)* and *(4)*. The reaction obviously proceeds by way of neighboring group participation and loss of a carboxylate ion, since only the *trans* form of diesters of cyclic diols undergoes reaction; thus, we have prepared acetoxonium salts from the acetates of *trans*-1,2-cyclopentanediol (56%); *trans*-1,2-cyclohexanediol (25%); *trans*-1,3-cyclopentanediol (40%); *trans*-1,3-cyclohexanediol (59%). These salts crystallize out at different rates, varying from a few minutes at room temperature to 24 hours at 40 °C, depending on the neighboring group activity and stereochemistry of the compound in question. The following compounds *(2)* and *(4)* (arranged according to decreasing reactivity) have been prepared from *(1)* and *(3)*: Compound *(2)*, R = CH_3 (55%, 5 min. at 20 °C), C_2H_5 (55%, 5 min. at 20 °C), *tert*-butyl (60%, 5 min. at 20 °C), C_6H_5 (65%, 1 h at 20 °C), *p*-$C_6H_4CH_3$ (56%, 24 h at 40 °C), *p*-$C_6H_4OCH_3$ (70%, 48 h at 40 °C); compound *(4)*, R = CH_3 (48%, 3 h at 40 °C), C_6H_5 (51%, 5 h at 40 °C), *p*-$C_6H_4CH_3$ (67%, 12 h at 40 °C), *p*-$C_6H_4OCH_3$ (69%, 48 h at 40 °C). In each case the fastest reactions are those involving the acetyl and pivaloyl compounds.



(1), n = 1 *(2)*, n = 1
(3), n = 2 *(4)*, n = 2



(5a), R = CH_3 *(6a)*, R = CH_3
(5b), R = $(CH_3)_3C$ *(6b)*, R = $(CH_3)_3C$



Esters of cyclic triols form acyloxonium salts if, like *(7)*, they contain *trans*-diol groups — a salt of *(5a)* is formed from glycerol triacetate. The cation *(5a)* is interesting since it can undergo rearrangement *via* a *trans* opening reaction into the cation *(6a)*, which is identical in structure with *(5a)*. The

(9a), R = CH_3 *(10a)*, R = CH_3
(9b), R = $(CH_3)_3C$ *(10b)*, R = $(CH_3)_3C$

(11) *(12)*

NMR spectrum of *(5a)* in CD_3NO_2 at room temperature contains a sharp acetoxonium methyl signal (τ = 6.95) at low field strength and a normal acetyl methyl signal (τ = 7.84). On increasing the temperature both signals become broader and finally coalesce at 105 °C. Referred to the NMR timescale a rapid reversible rearrangement *(5a)* ⇌ *(6a)* takes place. The rearrangement can be observed still better in the case of the pivaloxonium ion *(5b)* since the frequency difference of both *tert*-butyl signals is smaller and the coalescence temperature (87 °C) consequently lower, so that fewer decomposition reactions interfere with the investigation. The rearrangement *(5)* ⇌ *(6)* can be considered as valence isomerism of a cation. (The $\Delta G^{\ddagger}$ values determined for this rearrangement are given in Table 1.)

Esters of (1,3/2)-cyclopentanetriol *(7)* can react with $SbCl_5$ to give the acyloxonium cation *(8)* or *(9)*. The triacetate *(7a)* yields *(8a)* only. *(8a)* exhibits a rapid valence isomerization *(8a)* ⇌ *(10a)* at higher temperatures (see Table 1). The tri-

Table 1. $\Delta G^{\ddagger}$ values determined by NMR spectroscopy for the rearrangement of acyloxonium cations. T_c = coalescence temperature; solvent: CD_3NO_2.

	Signal	T_c (°K)	$\Delta\nu$ (Hz)	$\Delta G^{\ddagger}$ (kcal/mole)
(5a) ⇌ *(6a)*	CH_3	≈378	53.5	18.7
(5b) ⇌ *(6b)*	$(CH_3)_3C$	360	21.8	18.4
(8a) ⇌ *(10a)*	CH_3	365	54.0	18.0
(8b) ⇌ *(10b)*	$(CH_3)_3C$	348	22.3	17.8
(11) ⇌ *(12)*	CH_3	≈368	43.0	18.4

pivalate, on the other hand, affords *(8b)* (43%) and *(9b)* (57%). The ion *(8b)* exhibits a rapid rearrangement *(8b)* ⇌ *(10b)* (see Table 1) whereas the ion *(9b)* does not. The salt *(9b)*, from which (1,2,3/0)-cyclopentanetriol is easily accessible, can be obtained by crystallization from a mixture of the hexachloroantimonates of *(8b)* and *(9b)*. The cation *(11)* also exhibits a rapid valence isomerization *(11)* ⇌ *(12)* (see Table 1). *(11)* is best prepared as the tetrafluoroborate by removal of hydride from 3-*O*-acetyl-1,2-*O*-ethylidene-(1,2/3)-cyclohexanetriol with $(C_6H_5)_3C^{\oplus}BF_4^{\ominus}$.

4-Acetoxymethyl-2-methyl-1,3-dioxolan-2-ylium hexachloroantimonate (5a)

$SbCl_5$ (4.5 ml) is dissolved in CH_2Cl_2 (5 ml) and then added dropwise with stirring at −10 °C to a solution of glycerol triacetate (7.7 g) in anhydrous CH_2Cl_2 (7 ml). After 24 h at room temperature the acetoxonium salt *(5a)* crystallizes (yield 50%, m.p. 145—148 °C).

Cyclorearrangement of 3,4,5-Tri-*O*-acetyl-(1,2,4/3,5)-cyclopentanepentol-1,2-*O*-acetoxonium Tetrafluoroborate

By *H. Paulsen* and *H. Behre* [*]

In acyloxonium salts of 1,2,3-triols a rapid valence isomerism takes place between the two possible dioxolanylium cations [1]. The $\Delta G^{\neq}$ value of this rearrangement is lower in the case of (1,2/3)-cyclopentanetriol derivatives than it is in the case of glycerol or (1,2/3)-cyclohexanetriol compounds, since the neighboring group reaction [2] in the cyclopentane ring is apparently sterically favored. As was to be expected, we have found that a total valence isomerization takes place in the cyclopentanepentol system.

Penta-*O*-acetyl-(1,2,4/3,5)-cyclopentanepentol reacts heterogeneously with $SbCl_5$. We therefore prepared 3,4,5-tri-*O*-acetyl-1,2-*O*-ethylidene-(1,2,4/3,5)-cyclopentanepentol *(1)* by reaction of the free pentol [3] with acetaldehyde diethylacetal and subsequent acetylation. [*(1)* consists of 65% of the *exo* form (m.p. 120 °C) and 35% of the *endo* form (m.p. 110 °C)]. The acetal *(1)* reacts with $(C_6H_5)_3C^{\oplus}BF_4^{\ominus}$ in CH_3CN with loss of hydride [4] to give the $BF_4^{\ominus}$ salt of *(2)*. By successive neighboring group reactions the cation *(2)* can be converted into a second cation that is structurally identical with *(2)*. The prerequisites for a neighboring group reaction are fulfilled at each stage of the conversion. After ten conversion steps the starting material is re-formed.

The NMR spectrum of the acetoxonium salt *(2)* in CD_3CN at room temperature contains an acetoxonium methyl signal at low field strength with $\tau = 7.13$ (3H) and two signals due to normal methyl groups at $\tau = 7.90$ (6H) and $\tau = 7.95$ (3H). At 80 °C all signals are considerably broadened, thus indicating that at this temperature the rearrangement is rapid according to the NMR time scale. Careful integration of the changed methyl signals shows that all the acetyl methyl groups participate in the process; this can be considered as proof that the substance undergoes rearrangement in the manner mentioned. The exact coalescence temperature cannot be determined since *(2)* rapidly decomposes at temperatures above 80 °C. The value of $\Delta G^{\neq}$ can be estimated as being approximately 18 kcal/mole by extrapolation and comparison with the heating curves of the acetoxonium salts of 1,2,3-triols.

We have also examined whether "jumping" takes place during the cyclic rearrangement, *i.e.* whether a C-atom can be "jumped over" *via* 1,3-neighboring group reaction. If this were the case then other isomers of cyclopentanepentol would have to be formed. GLC analysis of the hydrolyzed reaction mixture showed that other isomeric cyclopentanepentols [5] are formed in amounts of 3%.

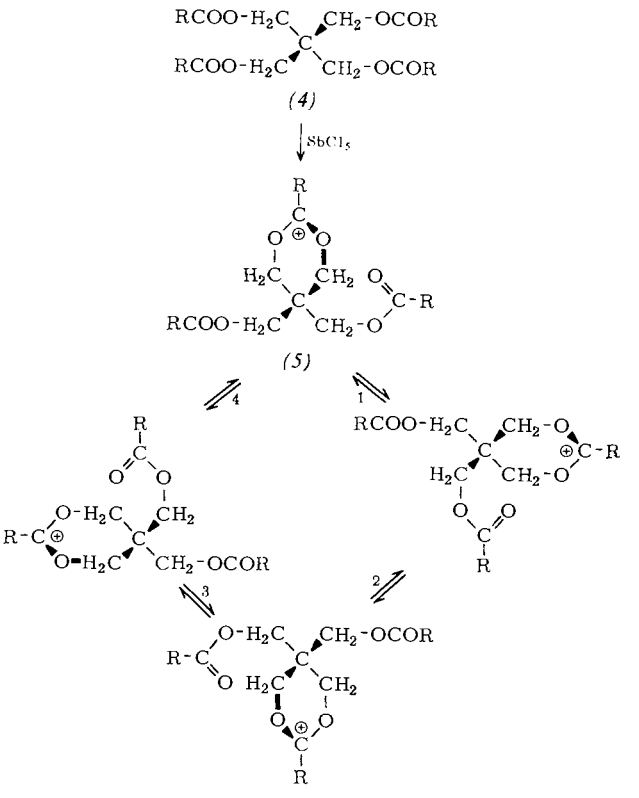
Cyclorearrangement of Di-*O*-pivaloylpentaerythritol-*O*-pivaloxonium Hexachloroantimonate

By *H. Paulsen, H. Meyborg,* and *H. Behre*[*]

1,2-Diol esters react faster with $SbCl_5$ to give an acyloxonium salt containing a five-membered ring than do 1,3-diol esters to give such a salt having a six-membered ring. The reaction of 1,2,4-butanetriol esters with $SbCl_5$ permits direct comparison of the stabilities of dioxolanylium and dioxanylium salts and shows that the five-membered ring is the more stable since a salt of *(1)* is formed preferentially (90%).



(1) *(2)* *(3)*

R = $(CH_3)_3C$

Valence isomerization should, however, occur in the case of acyloxonium salts of 1,3,5-triols. Since the above findings indicate that this conversion should have a higher $\Delta G^{\ddagger}$ value than in the case of 1,2,3-triols[1] we have directed our attention to the more readily investigatable pivalic esters. On heating with $SbCl_5$ in CH_2Cl_2 (20 h), 1,3,5-pentanetriol tripivalate affords the salt of *(2)* in 61% yield. At room temperature, the NMR spectrum of *(2)* in CD_3CN contains two sharp *tert*-butyl signals, that at lower field (τ = 8.64) being assigned to the group attached to the dioxanylium ring and the other (τ = 8.81) to the normal pivaloyl group. Coalescence of the two signals occurs at 110 °C (solvent $C_6H_5NO_2$), apparently due to a fast reversible 1,3-neighboring group reaction *(2)* ⇌ *(3)*. The $\Delta G^{\ddagger}$ value of 19.3 kcal/mole is 0.9–1.0 kcal/mole higher than the value found for the valence isomerization of the glycerolpivaloxonium salt[1].

As with cyclopentanepentol[2], a system can also be found for the dioxanylium ion in which a cyclorearrangement with total valence isomerization is observed. Pentaerythritol tetrapivalate *(4)* affords the monopivaloxonium salt *(5)* (2-*tert*-butyl-5,5-bis(pivaloyloxymethyl)-1,3-dioxan-2-ylium hexachloroantimonate) in 35% yield on heating with one mol. equiv. of $SbCl_5$ in CH_2Cl_2. As shown in the reaction scheme, *(5)* can undergo a 1,3-neighboring group reaction to give an ion which is structurally identical with the starting ion. Four rearrangement steps suffice to regenerate the starting material. Rearrangement takes place in a spiral manner about the central tetrahedral carbon atom.

The NMR spectrum of the pivaloxonium salt *(5)* at room temperature in CD_3NO_2 shows a 9-proton signal (τ = 8.51)

R = $(CH_3)_3C$

for the *tert*-butyl group attached to the dioxanylium ring and an 18-proton signal (τ = 8.77) for the two pivaloyl groups. In addition, a downfield singlet (τ = 4.82, 4H) is observed for the methylene protons of the dioxanylium ring, and another singlet at τ = 5.72 for the remaining methylene protons. The signals due to the *tert*-butyl groups and those of the methylene groups coalesce when the solution is heated to 110 °C and 122 °C respectively. This observation can be regarded as proof that *(5)* does undergo rearrangement in the manner indicated above. The coalescence temperature of 110 °C ($\Delta\nu$ = 20.0 Hz) for the *tert*-butyl groups gives a value of $\Delta G^{\ddagger}$ = 19.3 kcal/mole for the rearrangements.

General Meeting of the Gesellschaft Deutscher Chemiker 1969

This year's General Meeting was held at Hamburg (Germany) from 15th to 20th September. A selection of abstracts of the lectures and discussions that took place on this occasion is given below. Only work that has not yet been published or presented for publication is included. The abstracts are listed in the alphabetical order of authors' names.

From the lectures:

Effective Charge and Specific Energy Loss of Fission Fragments in Metal Absorbers

By *H. Albrecht* (lecturer) and *H. Münzel*[*]

It is important for users of heavy-ion accelerators to know the energy loss and the effective charge of heavy ions as a function of their energy and mass. To obtain experimental data for the range 100—150 atomic weight units, dE/dx measurements were carried out for fission fragments in thin aluminum, silver, and gold foils. The fission source was a ^{252}Cf preparation. Both the mass and the energy of the fission products could be determined by the use of two semiconductor counters with 180° geometry. The specific energy loss was then calculated by comparison of measurements with and without absorbers.

An attempt was also made to determine the effective charge of the fragments and to obtain information about recharging processes in the absorber material by measurement of the deflection of the fission products in a magnetic field of 10000 oersted with the aid of position-sensitive detectors.

Influence of Foreign Atoms on the Formation and Structure of Boron Modifications and Boron-Rich Borides

By *E. Amberger* (lecturer) and *K. Ploog*[*]

On pyrolysis of very pure boron halides (BCl_3, BBr_3) on hot (900—1300 °C) substrate surfaces (Ta, SiC, BN) in an atmosphere of hydrogen, we obtained monocrystalline α-rhombohedral and II-tetragonal boron and also microcrystalline β-rhombohedral boron and compact vitreous deposits of amorphous boron in a reproducible synthesis. We are now engaged in the determination of the as yet unknown, very complicated structure of II-tetragonal boron (space group $P4_122$; $a = 10.12$; $c = 14.14$ Å; $d = 2.36$ g/cm³), which has now been obtained for the first time in the monocrystalline state, though it has been known in the microcrystalline form since 1959.

If small quantities of foreign gases (*e.g.* CH_4, $CHBr_3$, CI_4, N_2) are introduced under conditions that would otherwise lead exclusively to the formation of II-tetragonal boron, the well known I-tetragonal boron structure is formed instead. The foreign atoms C and N are incorporated into the lattice. The I-tetragonal structure [theoretical formula of "I-tetragonal boron": $(B_{12})_4B_2$] has been found in the following boron-rich borides, which have now been synthesized for the first time: $(B_{12})_4B_2C_2$, $(B_{12})_4B_2C$, and $(B_{12})_4B_2N_2$.

In media containing no foreign atoms, I-tetragonal boron is never formed at 900 to 1300 °C. It is therefore very doubtful whether it is in fact possible to prepare pure "I-tetragonal boron, $(B_{12})_4B_2$". In any case, the addition of foreign gases to the boron halide-hydrogen mixture is a simple and reliable method for the reproducible synthesis of the I-tetragonal lattice.

NMR Spectroscopic Investigation of the Complex Formation in the Extraction of Uranium and Plutonium with Organophosphorus Compounds

By *R. v. Ammon*[*]

The nuclear fuels uranium and plutonium are often purified by solvent extraction with organophosphorus compounds. Some of the complexing equilibria involved have been studied by NMR spectroscopy. The types of nuclei that are suitable for this purpose are those situated close to the coordination center, *i.e.* the phosphoryl group of the organophosphorus compound. Thus they are the α-CH_2 protons of the alkyl group, the hydrogen bond proton, and the phosphorus atom. The extracting agents are tri-*n*-butyl phosphate (TBP) and tri-*n*-octylphosphine oxide (TOPO) in an inert diluent. HNO_3 and H_2O are extracted as well as uranyl nitrate and plutonium(IV) nitrate.

HNO_3. The ^1H resonance confirms the presence of the compound TBP·HNO_3 or TOPO·HNO_3. The ^{31}P resonance, together with the ^1H resonance, also indicates the nature of the bonding of a second molecule of HNO_3 to the 1:1 adduct; with TBP it is bound by hydrogen bonds to the nitrate oxygen atoms, while with the more basic TOPO, both HNO_3 molecules are bound to the phosphoryl group.

Uranyl nitrate [$UO_2(NO_3)_2$]. NMR shifts of ligand nuclei in uranyl complexes are mainly determined by the magnetic anisotropy of the uranyl group. Therefore the pronounced shift of the signal due to the rapidly exchanging HNO_3 and H_2O protons to lower field shows that when the uranium content in the organic phase is low, water is coordinated directly to the uranyl group, probably in the complexes TBP·$UO_2(NO_3)_2$·H_2O and TOPO·$UO_2(NO_3)_2$·H_2O. The complexes $UO_2(NO_3)_2$·2 TBP and $UO_2(NO_3)_2$·2 TOPO are formed only at higher uranium concentrations.

Pu(IV) nitrate [$Pu(NO_3)_4$]. Because of its paramagnetism, Pu^{IV} causes a pseudo-contact shift of the α-CH_2 protons to a higher field strength. From the sign of this shift it can be qualitatively concluded that the principal axis of symmetry of the complex $Pu(NO_3)_4$·2 TBP cannot pass through the plane formed by the central atom and the TBP ligands, but that there must be a twofold rotation axis normal to this plane.

NMR spectroscopy is thus found to be a valuable aid in the investigation of complex formation reactions of this type, even when the central atoms of the complexes are paramagnetic.

Studies on the Course of a Chloramine Oxidation of Hydroxyproline

By *W. Arneth*[*]

There are two principal methods for the determination of hydroxyproline, which differ basically only in the substance used to oxidize the hydroxyproline to a chromogen that can be converted into a dye with *p*-dimethylaminobenzaldehyde. Dilute hydrogen peroxide is used in one case, and buffered chloramine solution in the other. Whereas the course of the peroxide oxidation of hydroxyproline is known, nothing is known as yet about the processes that take place during a chloramine oxidation.

The two reactions appear to be different. In the peroxide method, the excess of oxidizing agent must be removed *completely* by heating before dye formation. In the chloramine method, on the other hand, it appears from the procedure that this can be achieved by acidification of the reaction mixture. We have found, however, that even after acidification the chloramine is still almost completely unchanged, and so cannot interfere with the determination. The conditions in a chloramine oxidation cannot, therefore, be the same as those prevailing during a peroxide oxidation. This is confirmed by the observation that on oxidation with peroxide, even a few μg of hydroxyproline yields steam-volatile products that give a color with *p*-dimethylaminobenzaldehyde whereas about one hundred times as much hydroxyproline is required to obtain the same result in a chloramine oxidation.

A similar situation is found in the detection of pyrrole, the end product of the peroxide oxidation, with mercury(II) chloride solution. When hydroxyproline is oxidized with peroxide, a few μg are sufficient to give a milky turbidity on steam distillation into $HgCl_2$ solution, whereas more than twenty times as much hydroxyproline is required in a chloramine oxidation. After the oxidation with chloramine, some oxidation products can be detected by thin layer chromatography, but none of these is identical with the pyrrolecarboxylic acid that can be readily isolated from the reaction solution after a peroxide oxidation.

It can be concluded from the results obtained so far that the chloramine oxidation of hydroxyproline proceeds differently from the peroxide oxidation.

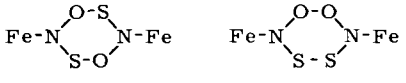
Radiochemical Investigations on High-Energy Nuclear Reactions of Tantalum

By *B. Neidhart, R. U. Trabitzsch,* and *K. Bächmann* (lecturer)[*]

Tantalum was bombarded with high-energy protons (19 GeV and 580 MeV), and the cross-sections (σ) and ranges (*R*) of lanthanides, Rb, Sr, Y, and Zr were determined by radiochemical methods. Mass yield curves were constructed from the cross sections. At 580 MeV the σ values of products with mass numbers of 82 to 88 are about 0.5 mb, whereas the cross sections in this mass range increase to about 6 mb at 19 GeV. In the lanthanide range, the σ values increase steeply from ≈0.4 to 70 mb with increasing mass number, whereas at 19 GeV the cross sections in this mass range remain approximately constant at ≈18 mb up to atomic mass numbers of 165, and increase only above this mass number.

The distribution of the Rb isotopes was studied in detail. Preferential formation of neutron-deficient products was observed. The isotopic distribution curve shows a maximum at mass number 83 for 580 MeV and at mass number 82.5 for 19 GeV.



Comparison of the range of Rb isotopes at 580 MeV ($R \approx 8$ mg/cm²) and 19 GeV ($R \approx 3$ mg/cm²) shows that the ranges of neutron-deficient products are considerably lower than those of neutron-excess ones. The ranges of the lanthanides are smaller than those of rubidium isotopes and exhibit a much smaller dependence on energy.

The Structure of the Reaction Product of $Fe[(CN)_5NO]^{2-}$ with S^{2-} Ions

By *E. J. Baran* (lecturer) and *A. Müller*[*]

Although the reaction of pentacyanonitrosylferrate(II) and sulfide ions ("Gmelin reaction") is generally known as an important reaction for the detection of sulfur, there is no definite proof of the structure of the red-violet reaction product, whose anion is nearly always formulated as the pentacyanomonothionitroferrate(II) ion $[Fe(CN)_5NOS]^{4-}$ *(1)*. We have carried out a spectroscopic investigation of the solid formed on reaction in methanol. The frequencies obtained by model calculations in which reasonable assumed force constants were used for *(1)* are not, however, compatible with the experimental vibrational spectrum. This spectrum suggests that the reaction product is probably a dimeric compound $Na_8[Fe(CN)_5NOS]_2 \cdot 4H_2O$ *(2)*.

(2a) *(2b)*

The question whether the grouping *(2a)* or *(2b)* is present cannot be definitely answered. Earlier kinetic measurements can also be reconciled with dimerization.

(2) is analytically pure and amorphous to X-rays. The IR spectrum contains the following principal absorption bands (in cm^{-1}): 3400 = ν (OH), 1620 = δ (HOH), 2050 = ν (CN), 672 and 655 = δ (CN), 435 = ν (FeC), 1140, 1005, 962 and 575 = ring vibrations (?). The presence of two or more non-equivalent iron atoms can be ruled out on the basis of the Mössbauer spectrum of the ^{57}Fe nuclei. As expected, the spectrum is similar to that of $Na_4[Fe(CN)_5NO_2]$ *(3)*. It follows that the π back-bonding strength $Fe \overset{\sigma}{\underset{\pi}{<}} L$ in *(2)* and *(3)* should be approximately equal.

The electronic spectrum of the solid contains a strong band at 580 nm, which is responsible for the characteristic color, and two weaker bands at 390 and 305 nm. Since the electronic spectrum of the aqueous solution is not identical with that of the solid, it is possible that a different species exists in solution.

On reaction of $[Fe(CN)_5NO]^{2-}$ with other compounds containing sulfur (*e.g.* thioacetamide and thiourea), color reactions very similar to the Gmelin reaction are observed. Spectroscopic investigation of the solid reaction products showed however that no related compounds are formed.

Ligand Recoil in Hexahalo Complexes of Re^{IV} and Rh^{III} and the Production of Practically Carrier-Free ^{36}Cl

By *R. Bell* (lecturer) and *G. Stöcklin*[*]

The chemical consequences of (n,γ)- and (n,2n)-processes on the halogen ligands of crystalline complexes of the type $K_2[ReX_6]$ (X = F, Cl, Br, I) and $K_3[RhCl_6]$, respectively,

have been investigated. The resulting radiohalogen appears mainly in two products, *i.e.* as labeled parent compound (retention) and as free halide (yield), *e.g.*:

The radiohalide yield is independent of the type of nuclear process, *i.e.* of recoil energy and range. However, it shows a distinct dependence on the nature of the ligand. From the fluoro to the iodo complex, the yield decreases in the order of the Re–X bond energies (F^-: 17.5 %; Cl^-: 15.6 %; Br^-: 12.2 %; I^-: <2 %). It is smaller for the less stable hexachlororhodate than for the corresponding rhenium complex.

Thermal annealing, which was investigated at 80, 120, 160, and 200 °C, leads to a decrease in the halide fraction and to temperature-dependent plateau values. The observed reformation of the labeled parent complex can be explained by a halogen isotope exchange in the solid state (see abstract by *Rössler* and *Upadhyay* in this collection).

With respect to the enrichment of ^{36}Cl ($T_{1/2}$ = 3.1×10^5 a), which is difficult to obtain in high specific activities, the dose dependence of the chloride yield was investigated in the $K_2[ReCl_6]$-system. The yields of $^{38}Cl^-$ and $^{36}Cl^-$ remained constant over a wide range of radiation dose (10^{13} to 10^{20} n/cm^2). Practically carrier-free ^{36}Cl activities in the mCi range can thus be obtained.

Information about the reactions of recoil halogen atoms in the solid and the retention processes was obtained by intermolecular competition experiments using $K_2[ReCl_6]/K_2[ReBr_6]$ mixed crystals (1:1). In the case of the Br recoil component, it could be shown by electrophoretic separation of the chlorobromo complexes that the radiobromine (apart from that in the form of bromide) occurs practically only in the monosubstituted parent compounds, *i.e.* as labeled hexabromo complex and as monobromopentachloro complex ($^*Br^-$: 12 %; $[ReBr_5{}^*Br]^{2-}$: 50 %; $[ReCl_5{}^*Br]^{2-}$: 30 %; other complexes with mixed ligands: each < 2 %).

These results again confirm that the environment of the recoil atom after the nuclear process is not a molten zone in the sense of the "hot spot" model, as has already been shown for the recoil of the Re central atom[1]. Furthermore, it becomes obvious that the reactions of the recoil halogens in the solid are simple ligand exchange reactions involving substantially intact complexes.

Breakdown of Sugars during the Ripening of Camembert: Enzymatic Determination of D-Lactose, D-Glucose, and D-Galactose

By *G. Berner*[*]

During the ripening and storage of cheese products, many compounds undergo transformations as a result of metabolic processes. We used enzymatic sugar determinations to follow the breakdown of D-lactose, D-glucose, and D-galactose in samples of Camembert over a period of 30 days after the salt-bath treatment. D-Lactose was hydrolyzed with β-galactosidase, and the resulting D-glucose was determined. After 30 days, D-lactose and D-galactose can no longer be detected, whereas the D-glucose content increases steadily during storage.

The rates of breakdown of the sugars in the interior and in the outside layer of Camembert are different. The accuracy of the enzymatic analyses was tested by the admixture technique.

The High-Temperature Ammonolysis of UF_4

By *H. J. Berthold* (lecturer) and *H. G. Hein*[*]

The reaction of UF_4 in a stream of NH_3 begins at 890–900 °C with reduction to UF_3 by the hydrogen present. If the gas stream contains sufficient NH_3 for ammonolysis to occur, the UF_3 is then converted *via* crystalline $U(NH_2)F_2$ into higher uranium nitride $UN_{1.90}$.

The vacuum degradation of $U(NH_2)F_2$ in a mass spectrometer between 600 and 900 °C results in elimination of hydrogen fluoride to give U(NH)F, which loses further HF to give UN when pumping is continued for about half an hour.

The ease of elimination of hydrogen fluoride and the detection of the existence of crystalline U(NH)F suggest that the ammonolysis of $U(NH_2)F_2$ also proceeds mainly *via* the intermediate U(NH)F. The UN formed by elimination of HF from U(NH)F is thermodynamically unstable at 900 °C in the presence of nitrogen, and changes immediately into higher uranium nitride $UN_{1.90}$. It cannot therefore be isolated as an intermediate in the ammonolysis.

$U(NH_2)F_2$ crystallizes in the orthorhombic system (Z = 2) with the lattice constants a = 3.89 Å, b = 4.02 Å, and c = 5.70 Å (all values ± 0.01 Å).

The diffraction diagram of U(NH)F indicates a face centered cubic structure (CaF_2 type) with a = 5.532 ± 0.003 Å.

The $UN_{1.90}$ formed as the final product in the ammonolysis of UF_4 or UF_3 at 900 °C is the highest stable uranium nitride known at present. It has a cubic primitive lattice with a = 10.605 ± 0.001 Å and its structure may be described as a defect CaF_2 structure with ordered nitrogen vacancies. The nitride fits in with the known nitrides UN, α-UN_x ($1.5\leq x<1.8$), β-UN_x ($1.33<x\leq1.47$), and the unstable UN_2 (CaF_2 type, a = 5.414 Å), which was first observed by us in other investigations, as a new "γ phase". According to our previous results, the range of existence of γ-UN_x is given by $1.8\leq x\leq1.9$.

Nitrides of the γ phase with compositions $UN_{1.80-1.86}$ are formed on nitriding of uranium metal or uranium nitrides with NH_3 between 500 and 1000 °C.

Unlike the ordered γ-$UN_{1.90}$, however, these nitrides have disordered structures, and of the superstructure lines of the cubic primitive γ phase, only the two strongest lines 12.2.0 and 12.2.2 are generally just visible in their diffraction diagrams. The nitrides are frequently described in the literature as having a CaF_2 structure.

$UN_{1.90}$ can be readily degraded under vacuum at 1000 °C to UN, which can be used as a nuclear fuel for fast breeder reactors.

Carrier-Free Separation of ^{131}Cs from Irradiated Barium Salts by Countercurrent Electrolysis

By *B. A. Bilal*[*]

On neutron activation of barium, the nuclide ^{131}Ba is formed from the isotope ^{130}Ba by (n, γ) reaction. ^{131}Ba is unstable, and disintegrates by electron capture with a half-life of 12 d into ^{131}Cs, which also changes by electron capture, with a half-life of 9.7 d, into ^{131}Xe.

If an aqueous solution of an irradiated barium salt (barium acetate) is subjected to countercurrent electrolytic separation[1,2], the submicro quantity (order of magnitude 10^{-13} mole) of ^{131}Cs formed by the radioactive decay can be continuously isolated without a carrier.

The relative difference in the mobilities of the components Cs and Ba is 22 % in very dilute solutions. This value, which increases with increasing concentration, allows a fast and complete separation of the Cs/Ba mixture.

The separation chamber[3] consists of two parallel vertical cooling plates held a constant distance apart (1—2 mm) and firmly cemented to the lower edges and the two sides. Depressions at corresponding points form the electrode compartments and the reservoir compartment. Nylon gauze diaphragms are gripped in the facing grooves.

By suitable choice of the current strength and the flow rate of the countercurrent electrolyte (2 M acetic acid), it is possible to obtain a steady state with the desired concentration of the mixture (cf. [1] which was at first regarded as homogeneous. The components now separate, until they finally occupy adjacent zones. Since the quantity of ^{131}Cs to be separated is extremely small, the Cs zone at all the possible concentrations would be so vanishingly small that it would be practically impossible to separate the Cs from the Ba. A third component (in this case NH_4 ions) whose mobility is intermediate between those of Cs and of Ba is therefore added to the mixture. The NH_4 ions form a zone adjacent to the Ba zone. The more mobile Cs ions penetrate through the ammonium zone and accumulate in the cathode compartment. In order to remove the ammonium acetate it is sublimed off under vacuum at 160 °C after the solution has been evaporated to dryness.

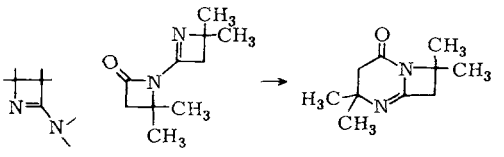
Preparation and Properties of β-Lactim Ethers

By *D. Bormann*[*]



The alkylation of β-lactams (azetidin-2-ones) *(1)* in the absence of bases leads to 2-alkoxyazetinium salts *(2)*, which are converted by deprotonation into β-lactim ethers (2-alkoxyazetines) *(3)*.

(1) *(2)* *(3)*

β-Lactim ethers are organic bases, the reactivities of which differ with their degree of substitution. As azaenol ethers, they contain two reactive centers, *i.e.* the nitrogen and the C atom 2. Reaction with acylating agents gives *N*-acyl adducts, some of which change into *N*-acylazetidin-2-ones.

Nucleophiles react with the C atom 2 of β-lactim ethers, though the reaction is slower than with the larger-ring lactim ethers (γ-butyrolactim ether or ε-caprolactim ether). Thus the reaction of *(3)* with strongly nucleophilic amines leads to elimination of alcohol and formation of 2-aminoazetines *(4)*.

(4) *(5)* *(6)*

Thermally stable β-lactams, such as β,β-dimethyl-β-lactam, react similarly. This compound condenses with β,β-dimethyl-β-lactim ether to form azetinylazetidinone *(5)*, which can be rearranged to the tetrahydropyrimidine derivative *(6)*.

Radionuclides as a Source of Energy

By *H.-J. Born*[*]

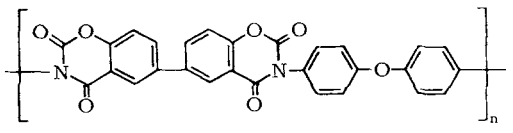
The conversion of radiation energy from radionuclides is becoming increasingly important, particularly in maintenance-free sources of electric current, both for space travel and for terrestrial purposes.

In the conversion *via* thermal energy, which is the most important process at present, electric current is produced with the aid of thermocouples, thermionic diodes, or even a turbine or a piston machine. Photoelectric radionuclide batteries, on the other hand, convert the radiation first into light and then, with the aid of photoelectric cells, into electrical energy.

The choice of the conversion process and of the radionuclide depends on the power, life, stability, screening, space, and weight requirements and on the required purity of the nuclide.

The data of the nuclides may be regarded as criteria of their usefulness. Thus whereas about 2270 Ci of ^{147}Pm are required for one watt (thermal), only 30 Ci of ^{238}Pu are required for the same power. The power density, based on the radionuclide in question in the form of the usual compound with no foreign additives, but including the radiation of any radioactive daughter products, is, *e.g.*, about 2 W_{th}/cm^3 for the β-emitting ^{147}Pm, but 1530 W_{th}/cm^3 for the α-emitting ^{228}Th, which has a similar half-life, together with its numerous α-emitting daughter products. Impurities reduce this power density.

The availabilities of the nuclides vary considerably and are continuously changing with the steady development of nuclear technology. Despite the great abundance of β-emitting fission products, the α-emitters among the transuranium elements are taking the lead in this respect. This is partly because special separation stages for the isolation of transuranium elements can be incorporated at relatively low cost into the new concentration plants being planned.



The use of preparations having very high specific powers in the form of alloys or mixed oxides and their observation will increase our knowledge of radiation damage and hence of the condensed phase in general.

Polybenzoxazinediones, a Class of Heat-Resistant Polymers

By *L. Bottenbruch*[*]

Poly-1,3-benzoxazine-2,4-diones such as *(1)* can be prepared by several methods from *p,p'*-dihydroxybiphenyl-*m,m'*-dicarboxylic acids.

(I)

Reaction of esters of these acids with diamines yields highly polymeric polyamides, whose cyclization by reaction with carbonic acid derivatives such as phosgene or diesters of carbonic acid leads to the polybenzoxazinedione. The reaction of esters of these acids with diisocyanates gives polyurethanes, which cyclize when heated, with loss of the monohydroxy compound and formation of polybenzoxazinediones.

Quantitatively cyclized polymers of uniformly high molecular weight can be prepared surprisingly readily by reaction of diphenyl esters of dihydroxybiphenyldicarboxylic acids with diisocyanates in dimethyl sulfoxide with tertiary amines as catalysts. If a solution of equimolar quantities of the diester and the diisocyanate in dimethyl sulfoxide is heated to about 90 °C with the addition of a little tertiary amine, a fast reaction takes place, as can be seen from the rapid increase in the viscosity of the reaction solution. The polybenzoxazinedione is formed quantitatively with elimination of phenol, and can be precipitated from the solution.

Polybenzoxazinediones have been prepared *e.g.* with the following compounds as starting materials: hydroquinonedicarboxylic acid; resorcinoldicarboxylic acid; dihydroxybiphenyldicarboxylic acid; and methylenedisalicylic acid; as well as phenylene diisocyanate; biphenyl diisocyanate; naphthylene diisocyanate; diphenylmethane diisocyanate; diphenylpropane diisocyanate; and diphenyl ether diisocyanate.

Some polybenzoxazinediones dissolve in industrial solvents such as dimethylformamide, dimethylacetamide, *N*-methylpyrrolidone, and cresol, and can be made into films and fibers by conventional methods using solutions in these solvents.

Films of a polybenzoxazinedione prepared from dihydroxybiphenyldicarboxylic acid ester and diphenyl ether diisocyanate are characterized by high mechanical strength, high tear propagation resistance, and constant mechanical properties between −180 °C and +300 °C. The films also exhibit good long-term thermal stability. No embrittlement occurs within one year at 235 °C. At 275 °C, the elongation falls to 5 % after 6 weeks. The electrical properties are good, and, like the mechanical properties, they are constant over a wide temperature range. Fibers or films can be drawn at very high temperatures, and their mechanical strength is then many times that of the undrawn material. The films are stable towards concentrated acids, dilute bases, and most solvents, but they are unstable towards strong bases.

"Peraromatic" polybenzoxazinediones can be used as starting materials for heat-resistant films and fibers.

Structural Chemistry of Ternary Sulfides Containing Alkali and Transition Metals

By *W. Bronger* [*]

Little is known as yet about ternary sulfides having the general composition $A_xM_yS_z$, where A = alkali metal and M = transition metal, in contrast with the corresponding oxides. The first detailed glimpses into this field have been provided by investigations carried out in recent years, which were concerned mainly with the structure of compounds containing 3d transition metals.

The 3d-element sulfides whose existence has been confirmed and which have been investigated in some detail are listed in the table. Sulfides containing heavier transition metals are known only for molybdenum [1a], palladium [1b], and platinum [1c].

Cr	Mn	Fe	Co	Ni	Cu
$NaCrS_2$					
$KCrS_2$	$K_2Mn_3S_4$	$KFeS_2$		$K_2Ni_3S_4$	KCu_4S_3
	$Rb_2Mn_3S_4$	$RbFeS_2$	$Rb_2Co_3S_4$	$Rb_2Ni_3S_4$	$RbCu_4S_3$
	$Cs_2Mn_3S_4$	$CsFeS_2$	$Cs_2Co_3S_4$	$Cs_2Ni_3S_4$	

The chromium(III) compounds listed have a structure in which the alkali metal and chromium atoms, which are arranged in alternating layers, are octahedrally surrounded by sulfur (α-$NaFeO_2$ type) [2]. The manganates(II) and cobaltates(II) [3] also have layer structures. In this case, sulfur tetrahedra surrounding transition metal atoms are joined by their edges. The structures of the alkali metal thioferrates(III) [4] are characterized by chain linkage of the iron atoms *via* edges of the surrounding sulfur tetrahedra. The arrangement of the alkali metal atoms in $CsFeS_2$ is responsible for a unique type of structure.

The structure of the alkali metal nickel sulfides is not yet known. However, their magnetic behavior, like that of the palladium compounds of the same type, point to planar coordination of Ni^{2+} and Pd^{2+} [1b]. The structure of $Cs_2Pd_3S_4$ [5] confirms this. The palladium atoms, again in a layer structure, are surrounded by sulfur rectangles joined up by their edges to give a two-dimensional arrangement. Finally, in the copper compounds listed in the table, the Cu atoms, which are situated inside sulfur tetrahedra, are incorporated into double layers [6].

In general it can be seen from the structures of these ternary sulfides that they are intermediate between the more alloy-like binary transition metal sulfides and the more salt-like complexes of the transition metals.

Influence of the Central Metal on the Hydrogenation of the Porphin System

By *J. W. Buchler* (lecturer) and *H. H. Schneehage* [*]

Whereas a magnesium-porphin complex is specifically hydrogenated *in vivo* to chlorophyllide a, this process has not yet been achieved *in vitro*. Following investigations by *Closs* [1], *Mauzerall* [1], and *Inhoffen* [1], we are studying the dependence of the "reductive protonation" (addition of electrons in an anhydrous medium followed by protonolysis) on the central metal M in metal octaethylporphins (P)M.

$$(P)M \xrightarrow{2e^{\ominus}} (P)M^{2\ominus} \underset{-2X^{\ominus}}{\overset{2HX}{\rightleftharpoons}} (PH_2)M \quad \circ\!\!\rightarrow (H_2P)M$$

We found (see Table 1) that the initial products are α,γ-dihydroporphins $(PH_2)M$, which do not rearrange with M = Mg, and in other cases, depending on the strength of the acid HX, rearrange slowly into chlorins $(H_2P)M$.

$(PH_2)M$ $(H_2P)M$

Table 1. Variation of M and HX.

$M^{n\oplus}$	HX	Result
$Mg^{2\oplus}$	CH_3OH	demetalation
$Zn^{2\oplus}$	CH_3OH	rearrangement
$Zn^{2\oplus}$	CH_3COOH	demetalation
$Al^{3\oplus}$ or $Sn^{4\oplus}$	CH_3OH	no rearrangement
$Al^{3\oplus}$ or $Sn^{4\oplus}$	HCl	rearrangement

The air-sensitive α,γ-dihydroporphins $(PH_2)M$ were characterized in the form of their methyl derivatives, which were obtained from (P)M by reductive methylation[1]. From the data in Table 1 and other observations we derive the working hypothesis that the rearrangement $(PH_2)M \rightarrow (H_2P)M$, and hence the formation of chlorins, proceeds best under conditions of partial demetalation of $(PH_2)M$. With magnesium as the central metal, this state might be reached under particularly mild conditions, and this could be one aspect of its importance in chlorophyll. For M = Zn, it was found that *cis*- and *trans*-octaethylchlorins[2] are formed in roughly equal quantities.

Phthalocyanine and Perfluorophthalocyanine Complexes of Thorium, Protactinium, Uranium, and Neptunium

By *F. Lux, D. Brown, D. Dempf* (lecturer), *R. D. Fischer*, and *W. Hagenberg* [*]

Bis(phthalocyaninato)thorium(IV) ($ThPc_2$) and -uranium(IV) (UPc_2) have already been described[1]. On extension of the group of compounds to other actinides, $PaPc_2$ and $NpPc_2$ were first detected radiochemically;

$$^{232}ThPc_2(n,\gamma)\,^{233}ThPc_2 \xrightarrow[t_{1/2}=22.1\ min]{\beta^-} {}^{233}PaPc_2;\ \beta^-,\ t_{1/2} = 27.4\ d$$

$$^{238}UPc_2(n,\gamma)\,^{239}UPc_2 \xrightarrow[t_{1/2}=23.5\ min]{\beta^-} {}^{239}NpPc_2;\ \beta^-,\ t_{1/2} = 2.35\ d$$

The existence of the protactinium and neptunium compounds is shown by the observation that the specific activities of ^{233}Pa and ^{239}Np remain constant in the sublimates obtained on repeated resublimation of the irradiated $ThPc_2$ and UPc_2.

Another proof for the existence of $NpPc_2$: Uranium tetraiodide was prepared from neutron-irradiated, and hence ^{239}Np-containing, uranium metal, and was used as starting material for the preparation of UPc_2[1]; the ^{239}Np behaves in practically the same way as uranium.

Weighable quantities of bis(phthalocyaninato)protactinium(IV) ($PaPc_2$) were prepared in the same way as the thorium and uranium compounds from PaI_4 and phthalodinitrile. PaI_5 may also be used as a starting material. This is surprising since Pa^V can otherwise be converted into Pa^{IV} only with very strong reducing agents. $PaPc_2$, like $ThPc_2$ and UPc_2, can be sublimed without decomposing and is stable in air, whereas protactinium(IV) compounds are generally extremely sensitive to oxygen and moisture.

In the preparation of the MPc_2 complexes (M = Th, Pa, U), the electron donor-acceptor complexes (EDA complexes) $MPc_2 \cdot I_2$ are formed as intermediates. The sandwich configuration of the bis(phthalocyaninato) complex is thus formed immediately; by analogy with $SnPcI_2$[2], a monophthalocyaninatoactinide diiodide should have been expected as the first stage. The EDA complexes are also formed from MPc_2 and iodine in 1-chloronaphthalene. The black, completely insoluble compounds lose iodine at 250 °C. For EDA complexes of aromatic hydrocarbons with iodine, the excitation energy for the EDA band is a linear function of the ionization energy of the hydrocarbon. The EDA band of the $MPc_2 \cdot I_2$ complexes (λ_{max} = 530 nm) fits well into this system.

$ThPc_2$ and UPc_2 were the first actinide compounds having the sandwich configuration, and $PaPc_2$ is the only protactinium compound of this type known at present. Single crystals of $ThPc_2$ and UPc_2 have been grown, and structural determinations are in progress.

The IR spectrum from 400 to 4000 cm^{-1} for $PaPc_2$ is practically indentical with the corresponding spectra of $ThPc_2$ and UPc_2[1], and is characteristic of metal phthalocyanines. The electronic spectrum of $ThPc_2$ and UPc_2, like that of most phthalocyanatometal complexes, shows only *one* band between 600 and 700 nm[1]. In the spectrum of $PaPc_2$ this band is split.

It may be assumed from the IR spectra of the MPc_2 complexes between 4000 and 10000 cm^{-1} (absence of f-f transitions) and from their ESR spectra that the compounds have a center of symmetry.

Thorium tetraiodide reacts with perfluorophthalodinitrile at 240 °C to give a perfluorophthalocyaninato compound having the composition $ThPc^fI$. Thus in contrast to the reaction with phthalodinitrile, a monoperfluorophthalocyaninato compound is formed. In this compound thorium has the formal oxidation number III. It has been found by mass spectrometry that bis(perfluorophthalocyaninato)thorium(IV) ($ThPc^f_2$) is formed from the $ThPc^fI$ by thermal decomposition (molecular weight from mass spectrometry: 1830 ± 2). These compounds are the first known examples of the existence of the perfluorophthalocyanine ring[3].

Independent Yields of Iodine Isotopes in Low-Energy Fission Reactions

By *H. O. Denschlag* (lecturer) and *S. M. Qaim*[*]

Fissionable material in aqueous solution was irradiated for a short time (approximately 50 msec) in a reactor or with a neutron generator. The samples were then ejected from the irradiation position by means of a special pneumatic tube system[1]. The fission iodine was separated from its genetic precursors – tin, antimony, and tellurium – within 2 sec by ion exchange on AgCl layers. From the ratio of iodine in the AgCl layer to iodine subsequently formed from the precursors in the filtrate, it was possible to calculate what fraction of the iodine isotopes ^{133}I, ^{134}I, and ^{135}I is formed directly by fission and what fraction is formed indirectly by decay of precursors (fractional independent and secondary yields, respectively)[2,3]. The fractional iodine yields were measured for the fission of ^{233}U, ^{235}U, and ^{239}Pu with thermal neutrons and for the fission of ^{232}Th with epi-Cd reactor neutrons and 14 MeV neutrons.

The results of the measurements provide interesting information on the charge distribution in the formation of fission products in the region of the closed nuclear shell with 82 neutrons ($^{135}_{53}$I, $^{134}_{52}$Te, and neighboring elements). The charge distribution is generally described by two parameters: Z_p, the most probable nuclear charge in an isobaric chain and σ, the width parameter of the Gaussian charge dispersion curve about the maximum value Z_p. It was possible to calculate both parameters for chain 135 in the fission of ^{233}U, ^{235}U, and ^{239}Pu, since experimental values of the fractional xenon yields[4] were also available. The width of the charge dispersion curve is $\sigma = 0.58 \pm 0.11$, in agreement with the value $\sigma = 0.59 \pm 0.06$ found outside the region of closed shells[5]. On the other hand, the Z_p values calculated from the experimental yields with $\sigma = 0.59$ show a fine structure, which can be understood as resulting from the tendency to achieve $N = 82$. The fine structure is particularly noticeable if the charge distribution curve is plotted as described by *Wahl*[5], but using the latest values for the evaporation of prompt neutrons from the fission fragments[6,7]. From the position of the fine structure and from the fact that the complementary fission fragment in the fission of ^{233}U exhibits an effect of the same type[8], we conclude that the existence of the 82-neutron shell influences both the division of the compound nucleus and the subsequent prompt neutron emission.

Mass-Spectrometric Investigation of Poly-*S*-phenyl-*S'*-vinylmethylenedisulfones

By *H. Diefenbach* (lecturer), *H. Ringsdorf*, and *U. J. Zahorszky*[*]

S-Phenyl-*S'*-vinylmethylenedisulfone *(1)* has been polymerized with azodiisobutyronitrile and K-*tert*-butoxide in dioxane and DMF. The polymers *(2)* and *(3)* obtained by the free-radical and anionic methods differ in several of their properties. Owing to the acidity of the active methylene group and the strong tendency of the vinylsulfonyl group to enter into additions, an addition mechanism with proton migration is conceivable for the anionic polymerization of *(1)*.

(1) *(2)* *(3)*

The difference in structure was detected by mass spectrometry. Whereas the pyrolysis of the free-radical polymer *(2)* in the mass spectrometer yields CH_3—SO_2—C_6H_5 (m/e = 156) and SO_2 (m/e = 64), that of the anionic polymer *(3)* leads mainly to C_6H_5—S—S—C_6H_5 (m/e = 218).

Novel Reactions of Hexachlorobutadiene

By *K. Gorzny, K. Grübel*, and *H. Drawe* (lecturer)[*]

The transfer of radiation-chemical syntheses from the preparative to the industrial scale involves economic and engineering considerations. The search for cheap products that are difficult to react by conventional methods led us to hexachlorobutadiene (HCB). HCB, which was formerly thought to be inert, occurs in large quantities as a waste product in the industrial production of chlorinated hydrocarbons.

We have so far carried out the following specific radiation syntheses with HCB:

1. The reaction with phosphites yields new phosphonates of the type

$$Cl_2C{=}CCl{-}CCl{=}CCl{-}P(O)(OR)_2$$

These are being tested for use as polymerization additives, and are to be produced on a pilot plant scale.

2. When elemental white phosphorus is dissolved in HCB, γ-irradiation yields a reactive red phosphorus that contains only about 50% of P. The possibility of preparing low molecular weight organophosphorus compounds from this reactive phosphorus is being investigated.

3. It has been shown for the example of cyclohexane (we synthesized 1,1,2,3,4-pentachloro-4-cyclohexyl-1,3-butadiene) that one Cl atom of HCB can in principle be replaced by a hydrocarbon group.

4. The radiation-chemical synthesis of telomers of styrene has also been achieved with HCB. Even small additions of HCB increase the overall polymerization rate of styrene; the molecular weight simultaneously shows a marked decrease. Since the reaction is completely suppressed by the addition

of diphenylpicrylhydrazyl, it must be free-radical in nature. In view of the observed dependence of the relative polymerization rate on the mole fraction of the mixtures, energy transfer is assumed to occur from styrene to HCB. This assumption is supported by the fact that the energy transfer is eliminated by the addition of quenchers (such as anthracene).

Problems in the Blocking of Thiol Groups in Polypeptides

By *G. Ebert* (lecturer) and *Chr. Ebert*[*]

The investigation of keratin fibers often requires the reduction of the —S—S— bridges and blockage of the resulting SH groups. Examples of reagents used for this purpose are monoiodoacetate, monoiodoacetamide, *N*-ethylmaleimide, phenylmercury hydroxide, and methyl iodide. Most of these blocking agents contain hydrophilic, ionic, or polar groups and are also very much larger than the substituted H atom. Owing to interactions of the blocking groups with one another and with the amino acid side chains, as well as to steric effects, an additional change in the conformation of the protein molecules, which depends on the blocking agent, may occur.

The small, apolar CH_3 group (introduced by CH_3I, as suggested by *Harris*) appears to minimize disturbances of this type. A check showed, however, that a considerable proportion of the initially formed SCH_3 groups are further methylated to give the dimethylsulfonium salt of cysteine, which loses $(CH_3)_2S$ to give peptide-bound dehydroalanine. The double bond in this compound reacts to only a small extent with ε-amino groups of adjacent lysine units to give lysinoalanine, but even slight crosslinking of this nature can appreciably change the properties of the protein.

The order-disorder transition of partly reduced keratin fibers that had been blocked with CH_3I and ICH_2COO^- has been investigated by differential calorimetry and by shrinkage measurements. Very pronounced differences were found in the temperature at which the process occurred, the amount of heat absorbed, and the cooperativity of the process. These quantities are distinctly lower for the protein fibers in which ionic groups have been introduced to block the SH groups; this points to a considerable change in the conformation of the protein, in the sense of a decrease in order.

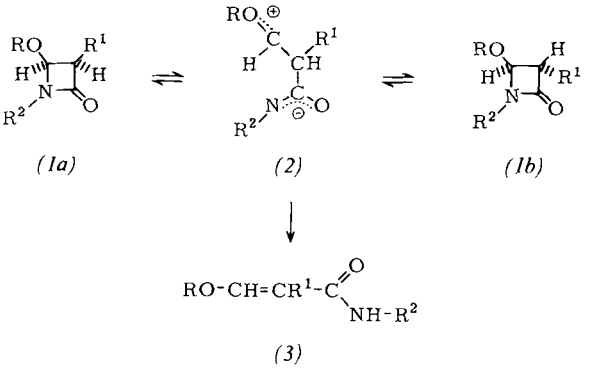
Mechanism of the Formation and Isomerization of β-Lactams



By *F. Effenberger* (lecturer) and *G. Prossel*[*]

Kinetic and stereochemical studies on the reaction of enol ethers with sulfonyl isocyanates lead to a deeper understanding of polar 2 + 2 cycloadditions.

The isocyanate adds stereospecifically to *cis*- and *trans*-enol ethers to give the β-lactams *(1)*.

The isomerization *(1a)* ⇌ *(1b)* and the irreversible formation of *(3)* proceed *via* the polar intermediate *(2)*. The isomerization rate is determined by the ring strain in *(1)* and the stabilization of *(2)*.

Information about the transition state of this cycloaddition can be obtained from the relative stabilities of the enol ethers used and of the β-lactams formed, the reaction rates in various solvents, and the activation parameters.

ESR-Spectroscopic Investigation of Radiation-Induced Electron Transfer Processes in Aqueous Solutions

By *K. Eiben*[*]

Radiation-induced electron transfer reactions in aqueous solutions have been studied directly by an *in-situ* ESR technique. The focused beam of a 2.8 MeV electron accelerator was directed toward a flat quartz cell centered in the ESR resonator. An aqueous solution was passed through the cell, and a stationary concentration of radicals (> 10^{-7} mole/l) was maintained in the solution during irradiation[1].

The hydrated electrons (e^-_{aq})[2] and H-atoms formed as intermediates in the radiolysis of water [eq. (1)] have been detected by this method.

$$H_2O \rightsquigarrow H;\ e_{aq};\ OH;\ H_3O^+;\ H_2;\ H_2O_2 \qquad (1)$$

In N_2O-saturated (approximately 2×10^{-2} mole/l) aqueous solutions which contained an aliphatic alcohol (approximately 10^{-1} mole/l), the primary radicals produced according to reaction (1) are converted quantitatively into hydroxyalkyl radicals [eq. (2)—(4)].

$$e^-_{aq} + N_2O \xrightarrow[-N_2]{} O^- \overset{+H_3O^+}{\rightleftharpoons} OH \quad p_K = 11.9 \qquad (2)$$

$$OH + CH_3OH \xrightarrow[-H_2O]{} {}^{\bullet}CH_2OH \overset{+OH^-}{\rightleftharpoons} {}^{\bullet}CH_2O^- \quad p_K = 10.9 \qquad (3)$$

$$H + CH_3OH \xrightarrow[-H_2]{} {}^{\bullet}CH_2OH \overset{+OH^-}{\rightleftharpoons} {}^{\bullet}CH_2O^- \quad p_K = 10.9 \qquad (4)$$

The ESR spectra of these hydroxyalkyl radicals disappear when suitable acceptors for an electron transfer [reaction (5) or (6)] are added to the aqueous solution in concentrations of 10^{-3}—10^{-4} mole/l.

$$CH_3NO_2 + R\dot{C}HOH \xrightarrow{H_2O} CH_3\dot{N}O_2^- + RCHO + H_3O^+ \qquad (5)$$

$$C_6H_5NO_2 + R\dot{C}HO^- \rightarrow C_6H_5\dot{N}O_2^- + RCHO \qquad (6)$$

The electron transfer reactions (5) and (6) yield the anion-radicals of several aliphatic and aromatic nitro compounds and the ketyl radicals of acetophenone and benzophenone [eq. (7)]. They were identified by their ESR spectra.

$$R^1R^2C{=}O + R\dot{C}HO^- \rightarrow R^1R^2\dot{C}{-}O^- + RCHO \qquad (7)$$

The dependence of the electron transfer on the dissociation and structure of the hydroxyalkyl radicals has also been studied. Hydroxyisopropyl, for example, is a more effective

electron donor than hydroxymethyl in acidic and neutral solutions, whereas the ionized hydroxyalkyl radicals do not differ in this respect in alkaline solutions.

The Reaction of Diborane and Boranecarbonyl with Nitrogen-Oxygen Compounds

By *U. Engelhardt* [*]

Attempts to prepare a hypothetical trihydridonitrosylborate (cf. [1]), $Na[H_3BNO]$, from diborane and "nitrosylsodium" $(NaNO)_x$ [2] gave sodium tetrahydridoborate as the principal product. When carried out without additional solvents as a heterogeneous solid-gas reaction or in suspension in liquid diborane at −100 to −130 °C, the reaction remains incomplete even after reaction times of several weeks (approximately 1/4 of the theoretically expected amount of diborane is consumed).

A small quantity of an unidentified compound, which is extremely sensitive to shock, is formed, and is obtained as a mixture with unreacted starting material and sodium tetrahydridoborate. The solid reaction products that remain when the unreacted diborane is pumped off give no gaseous decomposition products when slowly warmed to room temperature (similar results in suspension in pentane). If the solid starting material is suspended in ether and allowed to react with diborane at −78 to −110 °C, N_2O and H_2 are formed during the reaction and during subsequent warming to room temperature. The residue contains $Na[BH_4]$ as the only identified product containing a BH bond. The diborane consumption in these reactions is about 1 BH_3 per NaNO formula unit.

N_2O does not form a complex with diborane in the homogeneous gas phase between −105 °C and room temperature, as can be seen from pV/T curves. NO is also inert. It reacts slowly with diborane only at +90 °C with formation of H_2, N_2O, and H_3BO_3. The reaction becomes explosive at +120 °C.

Since boranecarbonyl decomposes primarily into CO and BH_3 even below room temperature, this compound seemed to be a particularly suitable starting material for the formation of borane complexes of the nitrogen-oxygen compounds at low temperatures. The required boranecarbonyl was partly prepared by a new method in normal glass apparatus without the use of pressure.

A gaseous mixture of diborane and carbon monoxide is heated on a hot finger at 200 °C, and the BH_3CO formed is simultaneously condensed in the bottom of the vessel at −150 °C. Attempts to prepare BH_3CO directly from $Na[BH_4]$ CO, and acid, on the other hand, have been unsuccessful. Boranecarbonyl begins to react with NO even at −135 °C with liberation of CO. Investigations in a low temperature IR cell showed that N_2O is formed even at this low temperature. A white coating of H_3BO_3 is also formed. The intermediate formation of BH_3NO could not be detected by IR spectroscopy. At higher temperatures (up to room temperature) the reaction with a large excess of NO leads almost quantitatively to N_2O, CO, and H_3BO_3. Mass spectra of a gaseous reaction mixture of BH_3CO and excess NO at very low pressures contained intense signals at mass numbers 28 (CO), 44 (N_2O), 26 ($^{11}B_2H_4$, $^{11}B^{10}BH_5$, $^{10}B_2H_6$), and 27 ($^{11}B_2H_5$ *etc.*). Very weak signals are also found at mass numbers 43 and 45, which can be interpreted as $^{10}BH_3{}^{14}N^{16}O$ and $^{11}BH_2{}^{14}N^{16}O$, and $^{11}BH_3{}^{15}N^{16}O$ (together with $^{14}N^{15}N^{16}O$) respectively. The species $^{11}BH_3{}^{14}N^{16}O$ (mass number 44) formed from the most abundant isotopes is, if present, masked by the N_2O, which has the same mass number and is always present.

Investigations on mixtures of N_2O with BH_3CO at room temperature in an IR gas cell have shown that the components do not react with each other. The boranecarbonyl decomposes quantitatively into B_2H_6 and CO in the course of several days with or without N_2O.

Hydroformylation of Unsaturated Compounds with Carbonyltrialkylphosphinerhodium Catalysts

By *B. Fell* (lecturer) and *W. Rupilius* [*]

It is well known that the hydroformylation of an olefin is accompanied by double-bond isomerization, as a result of which even a compound having a definite double-bond position gives not only the aldehydes (or alcohols) corresponding to the olefin, but a mixture of all theoretically possible positional isomers. If the cobalt catalyst normally used is replaced by a complex carbonyltrialkylphosphinecobalt catalyst, even reactions with olefins having internal double bonds lead preferentially to the unbranched aldehyde.

In contrast with the cobalt-catalyzed reaction, the rhodium-catalyzed hydroformylation is accompanied by slight double-bond isomerization. This is completely suppressed by the use of a catalyst combination of a rhodium compound and excess trialkylphosphine. It is important to maintain a molar ratio of rhodium to phosphine of at least 1:50 to 1:60.

It is even possible with this catalyst system to hydroformylate compounds that formerly failed to undergo the reaction, owing to the formation of other products, *e.g.* allyl alcohol or 2-butene-1,4-diol, as a result of double-bond isomerization. 1,5,9-Cyclododecatriene reacts smoothly to form the tris-hydroformylated product. Other dienes and polyenes with isolated double bonds react similarly. The most important success achieved with this catalyst system was the first double hydroformylation of conjugated dienes such as 1,3-butadiene or 1,3-pentadiene.

Determination of the Branching Ratio in the Disintegration of ^{242}Am

By *H.-J. Born, R. Gasteiger* (lecturer), *G. Höhlein*, and *W. Weinländer* [*]

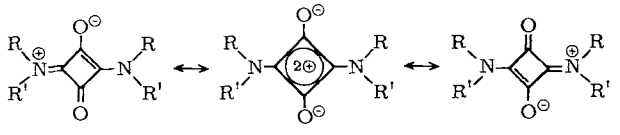
In connection with the production of heavy nuclides by neutron irradiation of ^{241}Am, it is important to know the decay ratio of the resulting ^{242}Am, which decays by β^- emission into ^{242}Cm and by E. C. into ^{242}Pu.

Since the values in the literature exhibit considerable scatter, this ratio was redetermined by measurements on the two plutonium isotopes ^{238}Pu and ^{242}Pu. Unlike other methods, the method used here avoids sources of error such as losses on

prolonged irradiation as a result of fission and neutron capture, and inaccuracies in the determination of the neutron flux and in the absolute measurement of activities.

The most important requirement is a clean separation of the Pu isotopes formed from Am and Cm; the requirements concerning the decontamination of Am (factor 10^{-9}) are particularly rigorous, since the α energies of ^{241}Am and ^{238}Pu are practically identical. Ion-exchange separation satisfied the requirements for the purity of the Pu fraction only when anion exchangers and cation exchangers were combined.

The activity ratio of the Pu isotopes was determined by α spectroscopy, the α preparations being prepared electrolytically.



It was found that the ratio in the decay of the isotope ^{242}Am is β^-/E.C. = 4.8 ± 0.1.

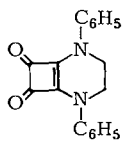
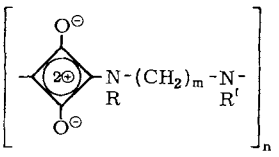
Condensation Products of Squaric Acid with Primary and Secondary Amines

By *J. Gauger* (lecturer) and *G. Manecke* [*]

Condensation of 1,2-dihydroxycyclobutenedione (squaric acid) with primary or secondary amines gave squaric acid 1,3-diamides *(1)*, which, as derivatives of 1,3-diaminocyclobutenediylium diolate, form a new class of intramolecular salts.



(1) R = H, Alkyl; R' = H, Alkyl, Aryl



These compounds contain the resonance-stabilized cyclobutenediylium diolate system, which makes them very stable both chemically and thermally because of its quasi-aromatic character.

The structure of the squaric acid 1,3-diamides *(1)* was proved by synthesis of 1,3-bis(2,4,6-trimethylphenylamino)cyclobutenediylium diolate (exclusion of ring substitution in the aromatically substituted compounds) and by IR, NMR, and mass-spectroscopic measurements.

The chelating ability of the 1,3-diaminocyclobutenediylium diolates with donor groups in the *o*-position of the phenyl ring was investigated, the copper chelates of these compounds were prepared, and the Cu^{2+}: ligand ratio in these chelates was found to be 2:1. In the dialkali metal compounds of the three isomeric 1,3-bis(nitrophenylamino)cyclobutenediylium diolates, the deeply colored alkali metal salts of the *o*- and *p*-nitro compounds contain a novel quinoid dye system, in which the cyclobutenediylium diolate grouping is in resonance interaction with the aromatic nuclei and the nitro groups *via* N atoms. The *m*-nitro compound, on the other hand, gives a much weaker color deepening with alkali, since no resonance *via* quinoid structures is possible in this case.

(2)

(3)

(3a), R = C_6H_5; m = 2
(3b), R = H, alkyl; m = 6, 8, 10
(3c), R = H, alkyl; *p*-phenylene- or *p*-biphenylylene- in place of $-(CH_2)_m-$

Condensation of squaric acid with *N,N'*-diphenylethylenediamine led to the cyclic compound *(2)* and the chain polycondensate *(3a)*.

We were also able to prepare the polycondensation products *(3b)* and *(3c)*.

Synthesis and Characterization of Amphoteric and Novel Weakly Basic Ion Exchangers with Strictly Uniform Structures

By *P. Gergs* (lecturer) and *G. Manecke* [*]

The amphoteric ion exchangers synthesized so far by copolymerization of aziridinylalkanecarboxylic acid esters with bisaziridinyl compounds followed by hydrolysis of the ester groups were not uniform in structure [1].

By copolymerization of dimethyl benzene-1,3- (or -1,4-)bis-(3-aziridinylpropionate) *(1)* [2] with methyl 3-aziridinylpropionate *(2)* followed by hydrolysis of the ester groups, we have obtained an amphoteric ion exchanger whose structure

(1) *(2)*

is perfectly uniform with respect to the functional groups. Crosslinking occurs only *via* the benzene rings built into the polymer chains. It was shown by elemental analysis that the composition of the hydrolyzed copolymer corresponds to the ratio of the components in the copolymerization. The occurrence of side reactions and degradation reactions during the copolymerization or hydrolysis can be ruled out. A crosslinker content of 25–30 mole-% has been found to be particularly suitable. The copolymers are light yellow, and exhibit excellent chemical and mechanical stability. They have good swelling properties; because of their amphoteric character, their swelling minimum occurs at pH = 3–4. The complexing properties of the copolymers have been examined with heavy metal ions (Cu^{2+}, Ni^{2+}, Zn^{2+}). 5 mequiv of Cu^{2+}/g of resin were taken up at pH = 6. The metal ions can be quantitatively eluted with acids.

Column-chromatographic separations of metal ions and of amino acids and peptides have also been tried on the new amphoteric ion exchangers. Good separations were obtained in some cases.

We have also prepared copolymers from aziridine and the crosslinking substances mentioned. These copolymers are novel weakly basic exchangers having very good chemical and mechanical stabilities, which form complexes with heavy metal ions and can be used for the column-chromatographic separation of weakly acidic amino acids.

Unstable Carbonium Ions

By *R. Gleiter*[*]

Charge stabilization by interaction with neighboring groups is practically impossible in the phenyl cation and in bicyclic hydrocarbons carrying a positive charge on the bridgehead.

The possibility of a π-σ-π interaction[1] for the stabilization of these ions will be discussed here. In this type of interaction, two π orbitals are coupled *via* a σ bond. If the two π orbitals contribute only two electrons to the bond, the system is stabilized.

It was assumed in the calculation that the ion has a singlet ground state and has the same geometric structure as the parent hydrocarbon. As a measure of the stabilization, the energy required to remove a hydride ion from the hydrocarbon was calculated. In the presence of hetero atoms, the inductive effect leads to destabilization.

Results: In the case of the phenyl cation, hetero atoms such as N in the *ortho* position have a destabilizing effect, while in the *meta* position they have a stabilizing effect (approx. 0.1 eV). Vinyl and cyclopropyl groups have a stabilizing effect both in the *ortho* and in the *meta* position (approx. 0.1 eV). Of the three possible pyridyl cations, only the 4-pyridyl cation exhibits stabilization (0.25 eV). Among the bicyclic compounds, those having the quinuclidine structure are stabilized, whereas molecules derived from 1-azanorbornane are destabilized.

Preparation and Polycondensation Reactions of Aromatic Diamines Containing Siloxane Chains

By *G. Greber* (lecturer) and *D. Lohmann*[*]

By condensation of permethylated α,ω-dichloropolysiloxanes with 4-[*N,N*-bis(trimethylsilyl)amino]phenylmagnesium bromide or 4-[*N,N*-bis(trimethylsilyl)amino]phenyllithium and by addition of corresponding siloxanes with H instead of Cl to *N*-trimethylsilyl-4-allylaniline or 4-allyl-*N,N*-bis(trimethylsilyl)aniline, we have synthesized siloxane-modified *N*-silylated aromatic diamines *(1)*, *(2)*, and *(3)*, which can be converted into the free diamines *(4)* by hydrolysis or alcoholysis

(1), $R^1 = R^2 = (CH_3)_3Si$, m = 0, n = 1 - 3
(2), $R^1 = (CH_3)_3Si$-, R^2 = H, m = 3, n = 1 - 3
(3), $R^1 = R^2 = (CH_3)_3Si$, m = 3, n = 1 - 3
(4), $R^1 = R^2$ = H, m = 0 or 3, n = 1 - 3

The polycondensation of the fully silylated diamines *(1)* and *(3)* with acyl chlorides of dicarboxylic acids leads to loss of chlorotrimethylsilane and formation of interesting polyamides that are silylated on the amide groups, and which are soluble in benzene and tetrahydrofuran. On removal of the trimethylsilyl groups by hydrolysis, these give siloxane-modified, high-melting polyamides, which are soluble only in the typical polyamide solvents and are stable up to about 400 °C.

The fully silylated diamines *(1)* and *(3)* surprisingly also undergo polycondensation with pyromellitic dianhydride to give soluble and fusible polyimides having decomposition points between 430 and 500 °C. In contrast with the usual process, hexamethyldisiloxane is eliminated in this case instead of water, so that no hydrolytic degradation of the polyamidic acid molecules can occur.

Siloxane-modified polyimides having comparable properties can also be obtained by polycondensation of ordinary aromatic diamines with dianhydrides containing siloxane chains. Dianhydrides of this type are formed on reaction of α,ω-bis(4-trimethylsiloxyphenyl)siloxanes with trimellitic 1,2-anhydride 4-chloride, with elimination of chlorotrimethylsilane.

Soluble and fusible polymeric Schiff bases that are stable up to about 500 °C were obtained by polycondensation both of the free amines *(4)* and of the tetrasilylated diamines *(1)* and *(3)* with terephthaldialdehyde.

The thermal stability values indicated were determined in the presence of atmospheric oxygen by thermogravimetric analysis.

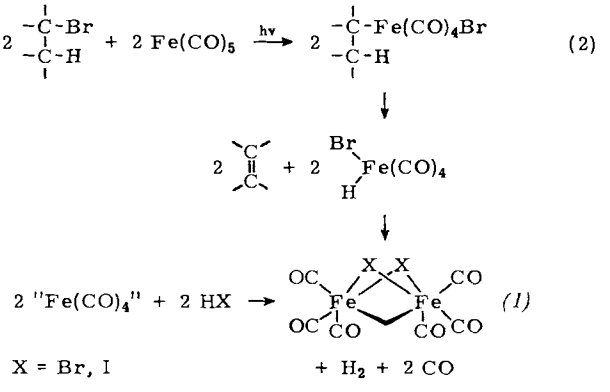
Photochemical and Thermal Reactions of Carbonyliron Compounds with Halogenoalkanes and Halogenoalkenes

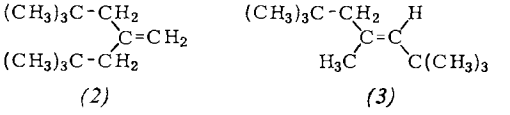


By *E. Koerner von Gustorf, F.-W. Grevels* (lecturer), and *J. C. Hogan*[*]

Organic halogen compounds with no readily abstractable β hydrogen can be photochemically dimerized by dehalogenation by $Fe(CO_5)$ [eq. (1)]. Alkyl halides with hydrogen in the

$$Fe(CO)_5 + 2\,RX \xrightarrow{h\nu} R_2 + FeX_2 + 5\,CO \qquad (1)$$

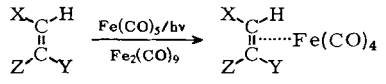
R = *e.g.* cycloheptatrien-7-yl



β position, such as *tert*-butyl bromide, react in accordance with eq. (2).

(2)

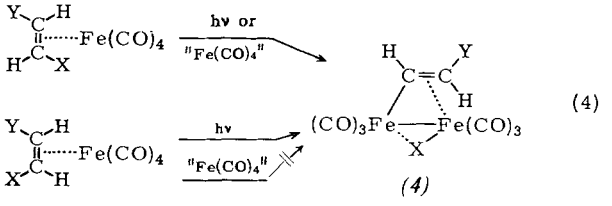
The novel dinuclear di-μ-halogenobis(tricarbonyliron) compounds *(1)* are also formed from "$Fe(CO)_4$" [from the photolysis of $Fe(CO)_5$ or from $Fe_2(CO)_9$] and hydrogen halide.



$Fe(CO)_5$ and *tert*-butyl bromide react photochemically to give isobutylene, which is converted mainly into the trimers *(2)* and *(3)*. Exposure of bromotricarbonyl-2-methallyliron or tricarbonyl(trimethylenemethyl)iron in *tert*-butyl bromide

(2) *(3)*

and isobutylene to light leads practically exclusively to *(2)* and *(3)*.



Halogenoethylenes react in accordance with eq. (3) to give the corresponding $Fe(CO)_4$ complexes.

(3)

X = F, Cl, Br, I; Y = H, Cl, Br, I; Z = H, Cl, Br, I

According to IR studies, the olefinic ligands are normally arranged equatorially in the trigonal-bipyramidal $Fe(CO)_4$ complexes, but appear to assume axial positions in the *trans*-1,2-dihalogenoethylene complexes. The carbon-halogen bond in the latter compounds is particularly reactive (cf. *e.g.* scheme (4)).

(4)

(4)

X = Cl, Br, I; Y = F, Cl, Br, I

(4) reacts with alcohols to give tetracarbonyliron complexes of acrylic esters, and tetracarbonyl-2-butene-1,4-dione-1,4-diyliron is formed in acetic acid. Both reactions probably proceed *via* an unstable acetylene complex.

Quantitative Determination of Impurities in Boron Carbide by Neutron Activation Analysis

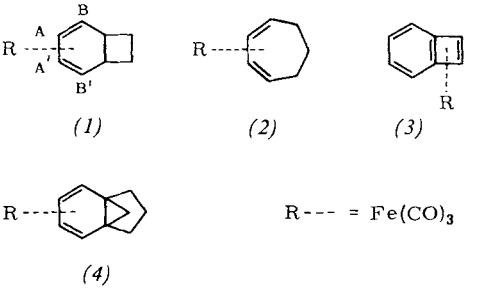
By *W. Gückel* (lecturer) and *H.-J. Born*[*]

When boron carbide is used in reactor technology, the nature and quantity of the impurities present should be accurately known. Chemical methods of trace analysis and spectral methods are of little value because of the great chemical and mechanical resistance of boron carbide. Activation analysis, on the other hand, offers a sensitive and non-destructive analytical procedure. However, the large cross section of boron for thermal neutrons presents considerable difficulties in activation and in the quantitative evaluation.

The first of three activation methods examined uses only nuclear reactions initiated by fast neutrons. This avoids the inhomogeneous activation of the sample caused by thermal neutrons and resonance neutrons. Since short-lived nuclides are formed in most cases, these investigations were carried out in the fast rabbit system of the Munich experimental reactor. The detection sensitivities that could be obtained in this way were unfortunately relatively low.

In the second method, thermal neutrons and resonance neutrons are used, and activation is practically confined to the surface of the sample. A correction factor is calculated to compensate for self-absorption effects. Good sensitivities could be obtained with this method, but it has the disadvantage that information about the sample as a whole must be deduced from the state of the surface layer.

In the third method, the inhomogeneous activation by thermal neutrons is avoided by irradiation behind a cadmium filter. The (n,γ) activations due to resonance neutrons are practically homogeneous in small specimens. The impurities throughout the volume of the specimen are found in this way, but the detection sensitivities are lower than with surface activation.



The trace content (ppm range) of Na, Al, Si, Sc, V, Mn, Cr, Fe, Co, and As were determined quantitatively. In some boron carbide specimens that had been purified by repeated zone melting, it was still possible to detect very small quantities (ppb range) of Na, Sc, Mn, and Co.

NMR-Spectroscopic Studies on Olefin-Tricarbonyliron Complexes

By *H. Günther* (lecturer) and *R. Wenzl*[*]

The ^1H—NMR spectra of the tricarbonyliron complexes of bicyclo[4.2.0]octa-2,4-diene *(1)*, 1,3-cycloheptadiene *(2)*, benzocyclobutadiene *(3)*, and tricyclo[4.3.1.$0^{1,6}$]deca-2,4-diene *(4)* have been analyzed. The protons in the unsaturated part of the compounds give spectra of the AA'BB' type, which

(1) *(2)* *(3)* *(4)*

are perturbed by long-range coupling with protons on saturated C atoms, but can be calculated without difficulty (see Table).

Table: τ-values (in ppm) and coupling constants J (in Hz) for the olefinic protons in *(1)*–*(4)*

	$\tau_{AA'}$	$\tau_{BB'}$	J_{AB}	$J_{AB'}$	$J_{AA'}$	$J_{BB'}$
(1)	5.06	6.92	6.59	1.62	4.23	0.20
(2)	5.25	7.34	7.61	1.13	4.83	0.44
(3)	5.51	6.62	6.77	1.50	4.06	0
(4)	3.42 [a]	3.56 [a]	8.61	0.68	6.77	1.57

[a] assignment uncertain.

In the diene systems of *(1)* and *(2)*, the vicinal coupling constants are lower than the corresponding values in the free olefins. For J_{AB}, the change can be explained according to the equation [1]

$$^3J = -35.10\, R_{\mu,\nu} + 56.65$$

by the increase in the C—C distance $R_{\mu,\nu}$ in the complex. This correlation fails, however, for $J_{AA'}$. Other factors such as changes in the valence and dihedral angles and a substituent effect of the $Fe(CO)_3$ group must therefore be effective. The dependence of the ^3J values on the ring size as observed for cyclic olefins is confirmed in the complexes.

In *(3)*, the ^3J values exhibit considerably larger alternation in the six-membered ring than in benzocyclobutene (J_{AB} = 8.61, $J_{AA'}$ = 6.77 as against J_{AB} = 7.36, $J_{AA'}$ = 7.78 Hz), for which the strain effects are roughly comparable. It can therefore be concluded that partial bond fixation in the six-membered ring of *(3)* has occurred. This interpretation is supported by the magnitudes of the long-range coupling

constants ($J_{AB'}$ = 0.68, $J_{BB'}$ = 1.57 Hz). In the $Fe(CO_3)$ complex of anthracene analyzed by *H. Klose*[2], on the other hand, the complex formation evidently leads to isolation of a diene system. The NMR parameters in the uncomplexed part of the molecule are similar to those in naphthalene.

The norcaradiene complex *(4)* analyzed by *W. Bleck*[3] gives "normal" values for the H,H coupling constants, showing that the ligand is an olefin. On the other hand, a special bonding type evidently exists in the corresponding tricarbonylchromium complex, since the three-membered ring must also be involved in complex formation in this case.

Homogeneous Precipitation of Halometalates from Anhydrous Acetic Acid

By *H. D. Hardt* (lecturer), *M. Fleischer*, and *G. Streit*[*]

Many heavy metals can be precipitated from solutions in glacial acetic acid *e.g.* in accordance with

$$M(CH_3COO)_2 \xrightarrow{CH_3COX} [MX_3]^- \xrightarrow{K^+,NH_4^+,\ etc.} Y[MX_3],\ Y_2[MX_4],\ etc.$$

M = metal, Y = cation, X = halogen

as halometalates, and the conditions for successive precipitations and/or heterogeneous transformations of the primary precipitate can be fixed by conductometric control. From solutions of trichlorocobaltate(II), for example, $NR_4[CoCl_3]$, $R=CH_3$, precipitates first, and changes on further addition of NR_4^+ into $(NR_4)_2[CoCl_4]$ (both compounds with tetrahedral crystal fields).

Precipitation with ammonium ions, on the other hand, after primary precipitation of $NH_4[CoCl_3]$ (blue, octahedral crystal field, hexagonal: a = 6.97 Å, c = 6.02 Å), leads directly to the pentachlorocobaltate, whose tetrahedral coordination is deduced from the reflection spectrum, and which should therefore be formulated as $NH_4^+\cdot(NH_4)_2[CoCl_4]\cdot Cl^-$. It decomposes thermally at 150 °C to give $NH_4[CoCl_3]$, which changes at 205 °C into $CoCl_2$.

This method can be used for the preparation of thermally unstable double salts, and yields *e.g.* the colorless tetramethylammonium trichlorochromate(II), $NR_4[CrCl_3]$.

Without the addition of alkali, acetic acid solvates of the corresponding halides, *e.g.* $CoCl_2 \cdot {}^1/_2CH_3COOH$ and $CrCl_2 \cdot {}^3/_2CH_3COOH$, are generally obtained; in the case of the chromium(II) halides, the dimeric solvate $Cr_2(CH_3COO)_4\cdot 2CH_3COOH$, which is structurally identical with $Cu_2(CH_3COO)_4\cdot 2\ CH_3COOH$, is formed[1].

Whereas the chlorochromate(III) ion in acetic acid solution exhibits characteristic splitting of the ${}^4A_{2g} \rightarrow {}^4T_{2g}$ transition, which points to C_{4v} symmetry, this splitting is absent from the reflection spectra of pentahalochromates(III), *e.g.* $(NR_4)_2[CrCl_5]\cdot CH_3COOH$, precipitated from such solutions. Their structure should therefore be characterized by practically regular octahedral crystal fields and probably by chains of $[CrX_6]$ units.

By comparison of the powder diffraction diagrams of the primary precipitates in the reaction medium with those of the dry samples, it is possible to decide whether acetic acid solvates are formed. Whereas the alkali metal halometalates (*e.g.* $K[CoCl_3]$, $NH_4[CoCl_3]$, $NH_4^+\cdot(NH_4)_2[CoCl_4]\cdot Cl^-$) generally precipitate out without solvation, acetic acid solvates of the pentahalogenochromates(III) are formed when they are precipitated as salts of organic nitrogen bases. The absorption due to the ${}^4A_{2g} \rightarrow {}^4T_{2g}$ transition, which occurs at 500–550 nm, shows a systematic red shift which increases with the cation in the order $K^+ < NH_4^+ < Rb^+ < Cs^+ = (NR_4)^+$.

Fatty Acids and Hydrocarbons from Extracts and Distillates of Bituminous Shales

By *W. Heller*[*]

The *Posidonomya shales* of Swabia have repeatedly attracted attention because of their bitumen content, though this is low. Where the shale material lies close to the surface, small smouldering fires often occur when the field is set alight. The object of the present investigations is to throw some light on the composition of the bituminous substance. The fats [triglycerides (neutral fats), esters of fatty acids, and free fatty acids] and hydrocarbons were examined. Even in bitumen extracted under mild conditions, the fatty acids are present mainly in the free state, but only in very small quantities. Triglycerides are, however, also present, and these were determined by methods for the determination of neutral fats. They are mainly derived from C_4 to C_8 fatty acids; there are no esters of long-chain fatty acids present. Micro methods are required for the detection of the individual fat fractions.

The gas chromatograms of the Posidonomya shale extracts show clearly that C_{15} und C_{17} *n*-hydrocarbons predominate. These can be definitely attributed to the corresponding physiologically important fatty acids, which have been decarboxylated in the sediment. Gas-chromatographic investigations on many petroleums lead to similar results. The strikingly high C_5 signal is very probably due to carbohydrates.

The aromatic components include benzene and its derivatives, particularly toluene, as well as polynuclear aromatic hydrocarbons such as anthracene, benzopyrene, phenanthrene, and pyrene. However, the aromatic hydrocarbons are present in much smaller quantities than the *n*-hydrocarbons.

Properties of the Si—Si Bond

By *E. Hengge*[*]

It is well known that double Si—Si bonds using p orbitals cannot be formed. This agrees with the behavior of other elements with principal quantum numbers n = 3 and > 3. Strengthening of bonds by $(p \rightarrow d)_\pi$ bonding, such as occurs with phosphorus, sulfur, chlorine, *etc.*, is impossible for silicon because of lack of electrons.

The strength of the Si—Si bond nevertheless differs with the substituents. The force constant fSiSi in the hexahalogenodisilanes increases rapidly from iodine to chlorine. The strong influence of the substituents on the SiSi force constant can also be seen in a series of disilane derivatives with mixed substituents (methylchloro-, methylmethoxy-, and methyldimethylaminodisilanes), the value of the force constant changing in the order:

$$CH_3 < H < I \approx C_6H_5 < Br < Cl < OCH_3 < N(CH_3)_2$$

It is clear, therefore, that the strength of the Si—Si bond increases with the electron density on the silicon, which suggests that the additional bonding component is due to this increased electron density, presumably with participation of d states.

On the other hand, shifts in the UV spectrum in the sense of this series cannot be accurately detected. Bathochromic shifts occur preferentially on asymmetric substitution.

Comparable effects are also found for cyclic silanes. Several derivatives of cyclopentasilane (phenyl, methyl, methoxy, iodo, and butyl derivatives, as well as derivatives with mixed substituents) showed no appreciable shifts in the UV spectrum. Corresponding to the strong bathochromic shift of chain silanes with increasing chain length, however, bathochromic shifts into the visible region occur on polycondensation of rings.

The chemical properties of the Si—Si bond also change with the bond strength, though additional factors connected with the nature of the reaction must naturally also be considered in this case. Thus the Si—Si bond reacts preferentially with Grignard reagents only if the bond is asymmetrically substituted, if ring strain is present, or if additional halogen atoms are present on the Si.

Activation Analysis of Boron and some Elements of the Rare Earths by Means of Prompt Neutron Capture γ Radiation

By *R. Henkelmann* (lecturer) and *H.-J. Born* [*]

The prompt γ quanta are emitted 10^{-14} to 10^{-12} seconds after neutron capture from the excited state of the intermediate nucleus, with liberation of the bonding energy of the neutron (6–8 MeV). The transition to the ground state generally proceeds *via* numerous intermediate states, so that very complex γ spectra are produced.

The prompt γ radiation is useful mainly for macroscopic analyses, and is suitable for trace determinations of only a few elements. The method can be used to advantage for the detection of elements whose determination by measurement of the (n,γ) reaction products is difficult either because no suitable γ spectrum exists or because the half-lives involved are too extreme. The method depends on the thermal neutron flux available and the reaction cross sections of the isotopes investigated. The isotope having the highest cross section and having a high abundance often forms a stable reaction product (B, Cd, Sm, Gd, Se, *etc.*).

Since the spectra contain very large numbers of lines, a planar Ge(Li) crystal of volume 13 cm^3 is used together with a 1600 channel pulse-height analyzer to record the γ spectra. The resolution of the detector is about 4.2 keV for the 661.6 keV line of ^{137}Cs. Owing to the low response probability of the detector for high-energy γ quanta, only the spectra in the region 0—1 MeV are recorded for analysis.

The γ spectra of 20 elements have been recorded, and the detection limits for these elements have been calculated from the spectra and checked experimentally. At the neutron flux of 1.5×10^7 n cm^{-2} sec^{-1} available, the detection limits for the elements B, Cd, Eu, Gd, and Sm are about 1 μg, those for Dy, Er, Hg, In, and Sc are about 10 μg, and those for all other elements are higher. This method can be used for the determination of lanthanides in minerals and boron in metals.

Complex Formation Between Unsaturated Nitriles and Carbonylmetal Compounds

By *M. Herberhold* (lecturer) and *H. Brabetz* [*]

In solution cyanoolefins can add to the complex fragment $[C_5H_5Mn(CO)_2]$ formed photolytically ($\lambda > 300$ nm) from $C_5H_5Mn(CO)_3$. The question whether the cyanoolefin is coordinated *via* the olefinic π system [as in $C_5H_5Mn(CO)_2C_2H_4$] or *via* the free electron pair on the nitrogen atom of the cyano group [as in $C_5H_5Mn(CO)_2(NC—C_6H_5)$] depends both on the reaction conditions and on the steric conditions at the C=C double bond.

Direct irradiation of $C_5H_5Mn(CO)_3$ in the presence of acrylonitrile [1] or crotononitrile in benzene/hexane leads predominantly to π-complex formation. Coordination *via* the cyano group predominates when $C_5H_5Mn(CO)_3$ is irradiated in THF followed by displacement of the ether ligand in $C_5H_5Mn(CO)_2(OC_4H_8)$ by acrylonitrile or crotononitrile. Cinnamonitrile and fumarodinitrile form intensely red "nitrile complexes"; in both cases, the coupling constant of the olefinic protons in the ^1H—NMR spectrum points to a free *trans* double bond: $C_5H_5Mn(CO)_2(NC\text{-}CH'=CH\text{-}C_6H_5)$, $\tau = 5.47$ (C_5H_5 protons/s), 2.64 (1H/d), 3.81 (1H′/d) $J_{H,H'} = 16$ Hz; $C_5H_5Mn(CO)_2(NC—CH=CH—CN)$, $\tau = 5.39$ (C_5H_5 protons/s), 3.48 and 3.64 (2H/AB system with center at $\tau = 3.56$) $J_{A,B} = 16.5$ Hz; measurement in $[D_6]$-acetone. Tetracyanoethylene (TCNE), on the other hand, appears to be π-bonded through the olefinic double bond.

$C_5H_5Mn(CO)_2L$ compounds containing π-bonded cyanoolefins (L) exhibit a shift of the cyclopentadienyl proton signal toward lower field in the ^1H—NMR spectrum (in $[D_6]$-acetone), as compared to the corresponding complexes of σ-bonded nitriles. The shift is dependent on the number of cyano groups: $\tau(C_5H_5) = 5.35$ ($L = C_2H_4$), 5.10 ($CH_2=CH\text{-}CN$), 5.17 and 5.19 ($CH_3CH=CH—CN$), 4.84 (NC—CH=CH—CN), 4.48 (TCNE).

The force constant $k(C\equiv O)$ of the $C\equiv O$ stretching vibrations [2] in the IR spectrum is related linearly, to a first approximation, to the position of the C_5H_5 proton signal in the ^1H—NMR spectrum. If the cyanoolefin is coordinated *via* the free electron pair on the nitrogen atom of the nitrile group, the C_5H_5 proton signal always appears in the region $\tau \approx 5.35$-5.50. This is also characteristic of complexes of *p*-substituted benzonitrile of the type $C_5H_5Mn(CO)_2(NC\text{-}C_6H_4\text{-}Z)$ ($Z = CH_3O$, CH_3, H, CN, NO_2).

In compounds such as $(TCNE)Cr(CO)_5$ [3], the coordinated cyanoolefin partly retains its π-acid character. This is in agreement with the assumption that this compound is a true π-olefin complex.

Structure of Dimeric Dimethylaminodimethylaluminum

By *H. Hess* (lecturer), *A. Hinderer*, *S. Steinhauser* (deceased), and *J. Weidlein* [*]

Dimeric dimethylaminodimethylaluminum has been investigated by X-ray analysis and molecular spectroscopy. The compound crystallizes in the monoclinic space group $P\ 2_1/a$ with the lattice constants $a = 12.85$, $b = 8.15$, $c = 7.63$ Å, $\beta = 117.7°$ and with 2 molecules in the unit cell. The structure was deduced from 711 reflection data *via* Patterson,

Fourier, and difference Fourier syntheses and refined by the method of least squares to an R value of 5.9% (anisotropic temperature factors, hydrogen atoms included). The molecules form planar, square 4-membered rings of alternating Al and N atoms. The following mean bond lengths were found: Al—N = 1.96, Al—C = 1.96 and N—C = 1.49 Å. In agreement with the centrosymmetry of the molecules, as found by crystallography, the IR and Raman spectra satisfy the alternative selection rules.

Scavenger Experiments on the Mechanism of the Radiolysis of Ethylbenzene

By *H. Heusinger* (lecturer) and *H. Hofer* [*]

In the radiolysis of ethylbenzene, styrene (G = 0.031) and the possible side-chain dimers C_6H_5—$CH(CH_3)$—$CH(CH_3)$—C_6H_5 (G = 0.046), C_6H_5—CH_2—CH_2—$CH(CH_3)$—C_6H_5 (G = 0.0002), and C_6H_5—$(CH_2)_4$—C_6H_5 (G = 0.0001) were quantitatively determined.

Scavengers for free radicals and quenchers for excited states were used to clarify the mechanism. These investigations showed that styrene is formed independently of 2,3-diphenylbutane by elimination of molecular hydrogen from ethylbenzene. Various reaction paths must be considered for the formation of 2,3-diphenylbutane. Styrene and 2,3-diphenylbutane can account for only about 25% of the radiolytic liberation of hydrogen.

Technological Observations in the Hardening of Varnishes with Electron Beams

By *H. Hinrichs* (lecturer) and *K. Wasem* [*]

The hardening of varnishes with electron beams at room temperature has attracted great interest, particularly since the varnish films harden thoroughly in seconds with practically no evolution of heat, and high throughputs are possible in continuous operations. The process is particularly recommended for the hardening of varnish films on heat-sensitive materials such as wood, paper, cardboard, plastics, and textile fibers.

The coating materials must be oligomers or synthetic resins with polymerizable double bonds activated by neighboring groups, which crosslink under the influence of the high-energy ionizing electron radiation.

These synthetic resins are adjusted to the desired working viscosity with polymerizable monomers such as styrene or esters of acrylic or methacrylic acids. The reactivity of a varnish system that can be hardened with electron beams depends both on the synthetic resin and on the monomer. The ratio of the quantities of synthetic resin and monomer is also of decisive importance for the tack-free hardening of a varnish film.

When the irradiation is carried out in air, the predominantly free-radical polymerization process is inhibited by oxygen, and the film surface remains tacky in many varnish systems. If the hardening is carried out under an inert gas (*e.g.* nitrogen), the surface crosslinking is improved and the radiation dose is reduced by 50—70 %.

Pigments do not interfere with the hardening process, provided that they are not affected by the radiation. Radiation-hardened, pigmented varnishes generally exhibit good gloss and smoothness. As expected, their solvent resistance and surface hardness are better than those of clear varnishes.

Determination of Medium-Heavy Elements by γ-Excited X-Ray Fluorescence

By *M. Hollstein* [*]

The use of γ-excited X-ray fluorescence for the quantitative determination of medium-weight elements was investigated. The X-ray spectrometer used was a high-resolution semiconductor detector-preamplifier system in conjunction with a ^{241}Am source and conventional multichannel pulse-height analysis electronics. The energy resolution of the spectrometer was about 1 keV (FWHM) for photon energies of 8—60 keV.

The contents of alloying components in the concentration range 0.04—9 % in a series of NBS standards were determined by direct measurements. It was found that a non-destructive analysis can be carried out in a few minutes with an accuracy of a few percent and a sensitivity of approximately 1×10^4 counts min^{-1} $\%^{-1}$. The detection limit is about 0.01 %.

Automatic Determination of Sulfur Dioxide in Atmospheric Air

By *J. G. Hoogland* (lecturer), *H. Zeedijk*, and *H. J. Brouwer* [*]

Highly sensitive methods are required for the analysis of gaseous impurities in the atmosphere. The impurities, which are often present in sub-ppm concentrations, must be recorded automatically for control purposes [1]. Since a fully automatic system capable of operating for 3 months or more without supervision was required, the coulometric titration of sulfur dioxide in KBr solution containing Br_2 [2] was chosen as the method.

After 3 years of development, the automatic measuring system is now in production [**] and is intended for a measuring network covering the whole of the Netherlands. The first section is being constructed in the industrial area at Rotterdam [3]. The SO_2 absorbed in the KBr/H_2SO_4 electrolyte containing Br_2 forms sulfate and bromide. The decrease in the bromine concentration leads to a decrease in the potential of a Pt electrode; an electrolysis current is produced electronically between two auxiliary electrodes. The electrolysis current liberates bromine at the anode until an equilibrium is reached in which the titration current is proportional to the SO_2 content in the air.

Even when the air sample contains no SO_2, the bromine concentration decreases as a result of evaporation. It is important to keep the resulting "zero current" (*i.e.* the bromine concentration in the solution) small, but in such a way that the other properties of the apparatus are not adversely affected. This is possible in dilute sulfuric acid, in which SO_2 and Br_2 react rapidly.

The potential measurement used for adjustment of the bromine concentration does not obey the Nernst law in the operating range (bromine concentration $< 10^{-7}$ mole/l), but is influenced by atmospheric oxygen and dissolved SO_2. This dissolved SO_2 displaces the operating point during the titration, so that the bromine concentration shows practically no decrease, and even increases in certain circumstances. It is thus possible to select a very low bromine concentration in the rest state.

High and Low Coordination Numbers in Compounds of the Elements of Group IVa

By *F. Huber* (lecturer), *H.-J. Haupt*, and *E. Schönafinger* [*]

Organolead compounds $R_{4-n}PbX_n$ react with salts MX to give the complex anions $[R_3PbX_2]^-$, $[R_2PbX_3]^-$ (R = C_6H_5, CH_3; X = Cl, Br, $OCOCH_3$), and $[RPbX_4]^-$ (R = C_6H_5; X = $OCOCH_3$), which can exhibit considerable thermal stability provided that the ionic radius of M is sufficiently large [Cs^+, $(C_6H_5)_4P^+$, $(C_6H_5)_4As^+$]. (Some analogous tin compounds are also known.) R_3GeX and R_2GeX_2 (R = C_6H_5, X = Cl, Br, I), on the other hand, do not react with salts of bulky cations, and the reaction of $C_6H_5GeCl_3$ with $[(C_6H_5)_4El]Cl$ (El = P, As) leads to dismutation into $GeCl_4 \cdot 4\,[(C_6H_5)_4El]Cl$ and $(C_6H_5)_4Ge$. Organochlorosilanes $R_{4-n}SiCl_n$ (n = 1, 2, 3; R = C_6H_5, CH_3), like $SiCl_4$, react with $[(C_6H_5)_4P]Cl$ to give $SiCl_4 \cdot 4\,[(C_6H_5)_4P]Cl$.

In the presence of salts having cations not suitable for the formation of stable anionic organolead complexes, the inert pair effect causes R_2PbX_2 to give PbX_2 and RX, and $(CH_3)_3Pb$-hal to dismutate to $(CH_3)_4Pb$ and $Pbhal_2$ (hal = Cl, Br).

The new compounds $(CH_3)_3SiCl \cdot 3(C_6H_5)_3PO$, $RSiCl_3 \cdot 3(C_6H_5)_3PO$ (R = C_6H_5, CH_3), and $SiCl_4 \cdot 4(C_6H_5)_3PO$ have ionic structures (*e.g.* $CH_3SiCl_3 \cdot 3(C_6H_5)_3PO = [CH_3SiCl\{(C_6H_5)_3PO\}_3]Cl_2$), and so exhibit no unusual coordination numbers (in solution up to 5).

The same is true of $R_3SiCl \cdot phen$ (R = C_6H_5, CH_3), $(C_6H_5)_2SiCl_2 \cdot phen$, $SiCl_4 \cdot 2$ phen, and presumably also $C_6H_5SiCl_3 \cdot 3$ phen (phen = 1,10-phenanthroline).

In studies on the coordination of organoelement compounds in solution, UV spectroscopic and conductometric measurements showed that organolead compounds interact strongly with the solvent. Thus in solutions of R_2PbX_2, dissociation leads exclusively to complex ions with coordination numbers ≥ 3. In solvents having pronounced donor functions, *e.g.* pyridine or acetone, complexes of the type $R_2PbX_2 \cdot 4$ donor occur in equilibria in these complex species, the central atom (the ligand distance being not uniform) having a coordination number of 8 in the limiting case. $(C_6H_5)_2PbI_2$ in benzene forms EDA complexes with solvent molecules, these complexes being detected by dipole measurements.

A High-Spin Isomer of ^{179}Hf

By *N. Kaffrell* (lecturer), *W. Herzog*, and *N. Trautmann* [*]

The existence of high-spin isomers for neutron-rich lutetium and hafnium nuclides in the region of mass numbers 177, 178, and 180 led us to look for isomeric states at mass number 179. On irradiation of enriched ^{179}Hf and ^{180}Hf with 14 MeV neutrons, a hitherto unknown component having a half-life of 25.3 ± 0.3 d was found. After irradiation of natural hafnium nitrate with 14 MeV neutrons, we separated lutetium and hafnium by partition between HDEHP [**] and 0.2 N hydrofluoric acid; the characteristic γ lines of the 25 d component could then be detected only in the Hf fraction.

Further investigation of the γ radiation with high-resolution Ge(Li) detectors and γ–γ coincidence measurements with two semiconductor detectors allowed the construction of a decay scheme. Of the twelve identified γ lines at 122.6, 146.3, 170.0, 192.7, 217.3, 236.5, 257.6, 268.9, 316.6, 362.7, 410.0, and 453.8 keV, eleven γ transitions can be fitted in the energy-level diagram of a rotational band based on the [624↑] ground state of ^{179}Hf.

The isomeric state could be a three-quasiparticle state of configuration p[514↑], p[404↑], n[624↑] with spin and parity of $J^\pi = 25/2^-$. This state is depopulated by a 257.6 keV γ transition, the multipolarity of which is assumed to be E3 on the basis of the indirectly determined conversion coefficient; this can be reconciled with the assignment of $J^\pi = 25/2^-$ for the isomeric state. Another γ transition (approx. 21 keV) that should be present according to the decay scheme could not be observed in the γ spectrum. Since this transition should be of type M2, its absence is understandable in view of the very high conversion coefficient.

To further clarify the assignment and to obtain carrier-free samples, attempts were made to prepare ^{179m}Hf by the reactions ^{181}Ta (γ, pn) ^{179}Hf and $^{181}Ta(d,\alpha)$ ^{179}Hf. When the irradiation had been completed, tantalum and hafnium were separated by partition between tributyl phosphate and 12 N nitric acid.

Gas-Chromatographic Determination of the Purity and Polarization-Optical Quality Testing of Molecular Single Crystals of High Quality

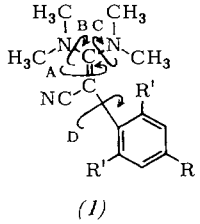
By *N. Karl* [*]

For the investigation of semiconductor properties (particularly the mobilities and lifetimes of charge carriers), for the study of optical processes (particularly the singlet and

triplet exciton migration, fluorescence, and phosphorescence) and ESR of triplet excitons in crystals of organic compounds containing π-electron systems, *e.g.* naphthalene, anthracene, and fluorene, the requirements regarding the chemical purity of the crystals, special doping, and crystallographic quality have been steadily increasing in recent years.

Chemical purities of less than 1 ppm in all impurities, and of the order of magnitude of 0.01 ppm in special impurities, can often be achieved by zone melting and by crystal growth from the melt or by sublimation. The best crystals are of "optical" quality.

If a good separation can be achieved, gas-chromatographic analysis permits the determination of impurities and doping component concentrations down to the ppm range. The main problem is the detection of very similar substances that are difficult to separate. The systems thionaphthene (benzo[*b*]-thiophene)-naphthalene and phenazine-anthracene were investigated as typical examples. The former system can be quantitatively determined on a 5 m × 3/8" column with 20% LiCl on Chromosorb P—NAW at 150 °C down to about 50 ppm of thionaphthene in naphthalene with a flame ionization detector. Anthracene decomposes on this column. The phenazine-anthracene separation can be achieved on a 1.5 m × 1/8" column with 10% XE-60 on Chromosorb W-AW-DMCS at 140 °C. The detection limit for phenazine in anthracene is also about 50 ppm. The gas-chromatographic determination of the distribution coefficients is in progress.



The crystallographic quality of aromatic single crystals can be judged conveniently from the interference diagrams obtained in monochromatic polarized convergent light. (These diagrams can also be used for the accurate orientation of the crystals.)

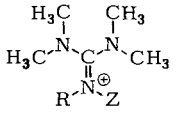
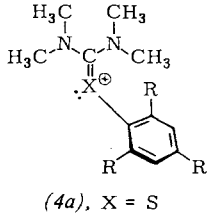
NMR Studies on Rotation and Inversion at Double Bonds

By *H. Kessler* [*]



The thermal *cis-trans* and *syn-anti* isomerizations in the compounds *(1)*—*(4)* are being studied by means of the temperature dependence of the NMR spectra.



(1)

(2)

(3)

(4a), X = S
(4b), X = O

In the ketene aminals *(1)* (R′ = H, R = H, F, Cl, Br, $COOCH_3$, $COCH_3$, CN, NO_2), up to 4 rotation barriers (A, B, C, D) can be determined, and their values can be correlated with the Hammett σ_p constants of the substituent R. The Hammett reaction constants can be determined on the assumption that the activation entropy $\Delta S^{\neq}$ is zero. Their values are $\rho_A = +2.75$ (correlation coefficient $r = 0.99$) for the rotation about the CC double bond (A) in 1,2,4-trichlorobenzene as solvent; $\rho_B = -0.96$ ($r = -0.98$) and $\rho_C = -1.35$ ($r = -0.96$) for rotation about the two CN single bonds (B, C) in $CDCl_3$, and $\rho_D = -0.82$ ($r = 0.79$) for the rotation about the C-aryl bond (D) observed for R = $COOCH_3$, $COCH_3$, CN, NO_2 in $CDCl_3$. It is shown in the case of the *p*-bromo compound *(1)*, R′ = H, R = Br, that the rotation about the CC double bond becomes easier with increasing polarity of the solvent. On the other hand, the polarity has no measurable effect on the rate of inversion at the double-bonded nitrogen atom in the guanidines *(2)* [1]. This is however affected by protic solvents (CD_3OD, $CDCl_3 + CF_3COOH$) owing to protonation on the indicated unshared electron pair. In the guanidinium salts *(3)*, on the other hand, rotation about the CN double bond can be observed [1].

The *syn-anti* isomerization in the thiuronium salts *(4a)* [2] becomes more difficult with increasing size of the substituents R in the order R = H, CH_3, i-C_3H_7, which allows the conclusion that the isomerization at the CS double bond follows the rotation mechanism and does not involve inversion at sulfur.

Separation of Alkaline Earth Metals on Cellulose Columns

By *H. Klamberg* (lecturer) and *W. Lohr* [*]

All six elements of Group IIa of the periodic system can be separated from one another quickly and reliably by paper chromatography. This method, in which the best results are obtained with methanol:water:concentrated hydrochloric acid = 80:10:10 vol-% as the solvent, and which allows easy detection of the elements in the presence of one another even in microgram quantities in UV light following treatment of the chromatogram with 8-hydroxyquinoline, was applied some time ago to thin layer chromatography using acid-washed cellulose powder as the layer material.

This separation method represents the starting point for development of a process for the rapid separation of beryllium, magnesium, calcium, strontium, and barium on cellulose columns and subsequent quantitative photometric determination. The columns used are 8 cm long and have diameters of about 12 mm. The adsorbent used was ultrafine cellulose powder No. 223 U manufactured by Binzer, Hatzfeld. To minimize the analysis time, the operation is carried out slightly above atmospheric pressure.

The samples for analysis are introduced at the top of the column by means of a microliter pipet (methanol:water:concentrated hydrochloric acid — 53:27:20 vol-% as eluent). For the quantitative determination, an ammoniacal solution of phthalein purple (Merck, Darmstadt) is added to the column eluate by means of a metering pump, and the complexes formed with magnesium, calcium, strontium, and barium are determined photometrically (flow-through cell, 578 nm). Beryllium, which leaves the column first, is determined indirectly by the formation of a carbonato complex and the reaction of the simultaneously liberated protons with the metal indicator. The extinctions of the eluate flowing continuously through the photometer are registered by a pen-type recorder and the resulting maxima are used, after calibration, for the quantitative determination of the elements.

Chemical Lasers: Physicochemical and Technological Possibilities

By *K. L. Kompa* [*]

Chemical lasers are based on the occurrence of IR chemiluminescence in chemical reactions. Reactions known so far extend from photodissociations *via* bimolecular substituons to eliminations. Since their discovery (1965), lasers of this type have attracted interest as accurate probes for the investigations of the energy distribution in elementary chemical reactions and as gas lasers, sometimes with very high optical gain, that are independent, in principle at least, of auxiliary external energy sources. The latter aspect, for which fast, branched chain reactions such as occur *e.g.* in F_2/H_2 explosions are preferentially used, has received special attention in recent Russian work. We have followed the former aspect using the "pumping step" [1]

$$F + H_2(D_2) \rightarrow HF(DF)\ (v > 0) + H(D)$$

for the investigation of the vibrational and rotational energy distribution in the hydrogen fluoride or deuterium fluoride molecules formed and for the study of energy transfer processes. The fluorine atoms can be produced by flash photolysis of inorganic fluorides such as the hexafluorides of uranium, molybdenum, or tungsten, xenon tetrafluoride, antimony pentafluoride, or oxygen difluoride. Considerable demands are made on the flash photolysis equipment used in regard to time resolution (<1 μsec) and the possibility of vacuum UV photolysis.

The laser emission in these reaction systems takes place in $v = 3 \rightarrow 2$, $v = 2 \rightarrow 1$, and $v = 1 \rightarrow 0$ P branch transitions of HF or DF. The experimentally determined optical amplification of these emission lines can be used, together with the Patel equation [2], to determine the occupancies of the vibrational-rotational states involved in the emission. An interfering factor here, however, is the competition of very fast radiationless vibrational deactivation. The extent of this deactivation has been approximately determined by experiments on time-dependent energy storage in the hydrogen fluoride molecules by controlled switching of the laser resonator (q switching) at predetermined times during or after the pumping process. Experiments with a frequency-selective monochromatic resonator were also used for the investigation of coupling phenomena between the molecular energy states involved. When the parameters determined in this way are known, it should be possible to obtain correct amplification data and to determine state populations, which can be correlated with detailed reaction rate constants.

Molecular Weight Distribution in Synthetic Resins

By *W. König* [*]

The technological properties and applications of macromolecular substances is largely determined by the shape, size, and size distribution of the molecules. The typical synthetic resins for coatings differ from high polymers in their structure and molecular dimensions. Various simultaneous or successive chemical reactions are usually involved in the formation of synthetic resins. The resulting molecules differ not only in their size but also in their chemical structure. The question of the molecular distribution was studied in this work with the aid of gel permeation chromatography.

Under certain conditions, gel chromatography gives elution curves that give a direct indication of the distribution characteristics of the resin. By calibration of the chromatographic system with suitable monodisperse substances, it is possible to use the data obtained from the elution curves for the construction of molecular distribution curves.

The resins studied included rosin derivatives, such as rosin itself, ester gum, modified phenolic resins, maleic resins, drying and nondrying alkyd resins of various structures, and cyclized rubbers. The resins had average molecular weights of about 1000 to 3000 and molecular weight distributions of from a few hundred to a few thousand or tens of thousands.

For the esterified rosin derivatives, irrespective of the nature of the modification by maleic acid or phenol, a pronounced maximum in the distribution curve always corresponds to the molecular weight of the pure glycerol or pentaerythritol ester of the resin acid. This maximum is followed on the high molecular weight side by plateaus or shoulders whose heights and widths depend on the modification. A separate maximum in the low molecular weight range is sometimes found for the free resin acids.

Preparation and Electrical Properties of Polymers with Conjugated Polyene Structures Containing Aromatic, Substituted Aromatic, or Thiophene Rings

By *G. Kossmehl* (lecturer), *M. Härtel*, and *G. Manecke* [*]

Polymers containing arylene and vinylene units having the general structure

$$-[-Ar-CH=CH-Ar^1-CH=CH]_n-$$

(Ar = *p*-phenylene units, 2-nitro-, 2,5-dimethoxy-, or 2,5-dichloro-*p*-phenylene units; Ar^1 = *p*-phenylene or 2,5-thienylene units) were prepared, generally in good yields, from bis-Wittig salts and dialdehydes of the benzene or thiophene series.

We also prepared polymers containing *m*- and *o*-phenylene and containing 9,10-anthrylene units.

All the polymers were examined for crystallinity by X-ray methods, and their electrical conductivities were also investigated. Clear relations were found between the chemical structure, the crystallinity, and the electrical conductivity; for example, polymers containing *p*-phenylene units conduct electricity less efficiently than the polymers whose *p*-phenylene units have been replaced by 2,5-thienylene units.

Oligomers having the general formula

$$Ar^1-[-CH=CH-Ar^2-]_n-CH=CH-Ar^3$$

$Ar^1 = Ar^3$ = phenyl or 2-thienyl; Ar^2 = *p*-phenylene or 2,5-thienylene

with $n = 1, 2, 3$, and 5 were synthesized as model substances, and their spectral, X-ray, and electrical properties were compared with those of the corresponding polymers.

Rapid Volatilization of Arsenic, Antimony, Selenium, and Tellurium as Hydrides from Mixtures of Fission Products

By *J.-V. Kratz* (lecturer), *H. Folger*, and *G. Herrmann* [*]

The radioactive tracer method was used for a systematic study of the optimum conditions for the volatilization of arsenic, antimony, selenium, and tellurium as hydrides from solutions of fission products. The hydride separations proceed

fastest on introduction of 1.6 g of zinc powder in 2 ml of concentrated hydrochloric acid with carrier quantities of about 10^{-4} mmole. Yields of 75—90 % were obtained for all four hydride-forming elements within one second. The decontamination factors for non-volatile fission products are greater than 10^3. For the investigation of short-lived fission products, the experimental procedure was fully automated in connection with the fast rabbit system of a TRIGA reactor[1]. The hydride mixture is separated on liquid or solid adsorbents; the arsenic and antimony fraction can be counted as early as 2 seconds after the end of irradiation, and the selenium and tellurium fractions after 5 seconds.

New delayed neutron precursors were detected in the selenium and tellurium fractions by neutron counting[2]. From selenium separations at various times after the end of irradiation and by counting the bromine daughters the half-lives of ^{87}Se and ^{88}Se were found to be 5.9 ± 0.2 and 1.7 ± 0.5 s respectively. Both isotopes are themselves weak neutron precursors with neutron yields of 0.35 ± 0.12 and 0.32 ± 0.16 neutrons/10^4 fissions respectively. Direct and indirect neutron measurements on the tellurium fraction gave half-lives of 20 ± 1 s and 3.5 ± 0.5 s for ^{136}Te and ^{137}Te respectively, and neutron yields of approximately 1.2 and approximately 0.7 n/10^4 fissions.

The fast separations made it possible to record γ spectra of short-lived isotopes of the hydride-forming elements. Using Ge(Li) semiconductor detectors, it was possible to confirm not only the known γ rays of $^{132-133}$Sb, $^{81-84}$Se, $^{131-134}$Te and their daughter products, but also to characterize γ rays of 11s-^{134}Sb, 33.7s-^{85}Se, 16.7s-^{86}Se, 16.6s-^{135}Te, 20.9s-^{136}Te, and 3.5 s-^{137}Te. The half-lives and mass assignments were confirmed in some cases by the growth of known γ rays of the daughter products, *e.g.* 1565 keV (^{86}Br) with $T_{1/2} \approx 16.1$ s, 1313 and 1321 keV (^{136}I) with $T_{1/2} \approx 21.6$ s precursor half-life.

Fast Separation of Fission Halogens by Recoil Reaction with Methane

By *K.-L. Kratz* (lecturer) and *G. Herrmann*[*]

The recoil-induced formation of volatile methyl halides when the fission products are stopped in methane was used for the separation of the halogens in the gas phase. The other fission products, present as aerosols, can be quantitatively retained either electrostatically or with a membrane filter.

The experimental procedure was fully automated in order to allow the determination of short-lived isotopes of iodine and bromine. Polyethylene capsules containing a uranium target and CH_4 as the stopping gas were subjected to pulse irradiation in the Mainz TRIGA reactor and transported rapidly to the separating apparatus by means of compressed air in a fast pneumatic tube system. The fission product/gas mixture is flushed out of the irradiation capsule with the carrier gas N_2 or CH_4 through two hypodermic needles (flow rate approximately 27 l/min) and forced through several successive adsorption vessels to achieve chemical separation. The adsorption vessels are then transported to the neutron detectors. In the most favorable case, 0.5 s elapses before the measurements can be started, *i.e.* isotopes with half-lives down to 0.2 s can be determined.

To test the selectivity of the separation, the contamination by the elements Se, Sb, and Te, which are known to form volatile compounds with CH_4 or H_2 that would pass through the aerosol filter, was determined by comparison of γ spectra of unseparated and separated samples recorded with semiconductor detectors. This fraction was found to be ≤ 1–3 %. To ensure that the halogens are decontaminated from inert gases and their daughter products, some of which are themselves neutron emitters, neutral adsorbents such as Sterchamol and silica gel with a few wt-% of $AgNO_3$, AgCl, KI or $KBrO_3$ are used. For further separation of the halogens from one another, iodine and bromine traps are filled with different adsorbents and use is made of the difference in the boiling points of methyl iodide (42.3 °C) and methyl bromide (4.5 °C). The iodine compound is retained in the first adsorption vessel, which is packed with Sterchamol/$AgNO_3$ and heated to 80 °C, while the more volatile methyl bromide is found mainly in the second trap, which contains silica gel/AgCl.

The half-lives and the contributions to the individual delayed neutron periods of the isotopes $^{87-91}$Br and $^{137-141}$I were determined by simultaneous measurement of the neutron decay curves.

Alkylations with Tertiary Oxonium Salts

By *R. Kreher* (lecturer), *H. Hennige, G. Vogt,* and *A. Bauer*[*]

The trialkyloxonium tetrafluoroborates, which were introduced into preparative organic chemistry by *H. Meerwein*[1,2] exhibit surprisingly high selectivity despite their high chemical reactivity.

3-Arylisoindolin-1-ones are alkylated on the oxygen of the cyclic amide grouping by trialkyloxonium tetrafluoroborates to give the 1-alkoxy-3-arylisoindoleninium tetrafluoroborates. Deprotonation of these products yields 1-alkoxy-3-arylisoindolenines, which are of interest as tautomers of the hitherto unknown 1-alkoxy-3-arylisoindoles.

The *N*-alkylated isoindolin-1-ones also undergo *O*-alkylation with tertiary oxonium salts to give 1-alkoxy-*N*-alkylisoindoleninium tetrafluoroborates, which can also be prepared independently from 1-alkoxyisoindolenines by *N*-alkylation. Deprotonation yields the extremely reactive 1-alkoxy-*N*-alkylisoindoles.

The alkylation of 1,3-dimethyl-6*H*-cyclohepta[*c*]pyrrol-6-one takes place selectively on the oxygen of the vinylogous amide grouping. Deprotonation of the resulting oxonium-imonium salts yields 6-alkoxy-1,3-dimethyl-2-azaazulenes, which are easily accessible in this way.

Pyrazolin-5-ones with a cyclic acid hydrazide group are also alkylated on the oxygen of the carbonyl function; *N*-alkylation is also observed to an extent that depends on the substituents[3]. In the case of acyclic hydrazides the alkylating agent preferentially attacks the more strongly basic nitrogen atom in the β position. The isoelectronic *N*-alkoxybenzanilides are alkylated on the oxygen of the carbonyl function. Hydrolysis of the resulting oxonium-imonium salts leads to alkyl benzoates and, surprisingly, azobenzene.

The trialkyloxonium tetrafluoroborates are found in every case to be excellent alkylating agents for ambifunctional compounds.

Polymerization Reactions on Pigment Surfaces

By *K. Hamann* and *R. Kroker* (lecturer)[*]

The interactions between pigments and binders have until now been studied by investigation of the adsorption and desorption of low molecular weight and macromolecular substances on solid particles. A new line of investigation concerned with polymerization reactions on pigment surfaces has attracted interest in recent years. The object of these investigations is to bond macromolecules in which the pigment is embedded as firmly as possible to the pigment surface, by joint covalent bonds if possible.

An anionic copolymerization of ethylene carbonate and phthalic anhydride is initiated by sodium benzoate. The initiator molecules are incorporated into the polyester chains as end groups.

If the sodium benzoate is replaced by the sodium salt of a copper-phthalocyaninemonocarboxylic acid pigment, covalent bonds can be formed during the polymerization between copper-phthalocyanine and the polyester chains.

The polymerization is carried out in bulk at 200 °C. The reaction products isolated include, in addition to surface-treated pigments, soluble blue polyesters. These products were investigated analytically, thermogravimetrically, and IR-spectroscopically for characterization purposes.

The surface-treated pigments consist of about 15 to 40 % polyester. The soluble blue polymers have a number average molecular weight of 2000 to 4000, and contain up to 5 % of copper-phthalocyanine.

Optimum Irradiation Conditions for the Production of Radionuclides with a Cyclotron

By *J. Lange* (lecturer) and *H. Münzel*[*]

For the optimum production of radionuclides and for the optimum use of the particle accelerator it is necessary to know the excitation function of the nuclear reaction in question. However, since this is frequently unknown, the irradiation conditions must be fixed arbitrarily in many cases. An investigation was therefore carried out to establish whether unknown excitation functions can be estimated in such cases from experimental data. It was found that the influence of the atomic number of the target nucleus on the shape, position, and maximum cross section of the excitation functions qualitatively corresponds to theoretical expectations. We were able to develop a method for the estimation of unknown excitation functions. The yields for the irradiation of thick targets were calculated for all elements using the estimated excitation functions.

The Reaction between Phosphorus Pentoxide and Silicon Nitrides

By *I. Fränz* and *W. Langheinrich* (lecturer)[*]

Thin films of vitreous silicon nitride as produced from silane and ammonia can serve as diffusion masking layer in the fabrication of semiconductor planar devices. Phosphorus pentoxide acts on the silicon nitride at temperatures about 1200 °C in technical phosphorus diffusion processes. If oxygen is also present, the IR absorption spectrum of the diffused wafer contains the absorption peak of silicon dioxide at 1100 cm^{-1}, and the absorption of phosphorus pentoxide, recognized from the peak at 1335 cm^{-1}, as well as the absorption peak of silicon nitride at 900 cm^{-1}. The determination of the phosphorus concentration profiles after neutron irradiation of the samples shows that a homogeneous phosphorus glass containing 7—8 moles of SiO_2 per mole of P_2O_5 has been formed. Thus it appears that only the oxygen reacts with silicon nitride to form silicon dioxide, which then forms a glass with phosphorus pentoxide:

$$5\ Si_3N_4 + 15\ O_2 + 2\ P_2O_5 \rightarrow 15\ SiO_2 + 2\ P_2O_5 + 10\ N_2$$

This reaction is about 100 times as fast as the reaction in pure oxygen; this points to intermediate participation of the phosphorus pentoxide.

The intermediate product can be detected if the reaction is investigated in the absence of oxygen. The product is again a thin vitreous layer that is sharply separated from the underlying unreacted silicon nitride, and which has uniform phosphorus concentration, as is shown by tracer experiments with ^{32}P. The phosphorus concentration in these layers is appreciably higher than in the first case. The IR absorption in the NaCl range showed that the glass also contains silicon dioxide and phosphorus pentoxide. The second reaction product is indicated by the intense smell of phosphine which can be detected when the samples are chemically sectioned. Silicon phosphide must have been formed and can be detected by means of its absorption band at 475 cm^{-1}.

$$3\ Si_3N_4 + 4\ P_2O_5 \rightarrow 5\ SiO_2 + 4\ SiP + 2\ P_2O_5 + 6\ N_2$$

In the presence of oxygen the thickness of the silicon nitride layer that has been converted into phosphorus glass varies linearly with time. This indicates that the rate-determining step is probably not a diffusion-controlled process inside the phosphorus glass layer.

Adsorption of Protactinium, Zirconium, and Niobium on Silica Gels and Vycor Glass from Solutions in Hydrochloric Acid[**]

By *M. Laser*[*]

The high-temperature chlorination of irradiated ceramic uranium-thorium breeder elements leads, on subsequent fractional condensation of the chlorides, to a uranium fraction that contains all the protactinium and considerable quantities of zirconium, niobium, ruthenium, molybdenum, tellurium, and other fission products. The fine purification of this fraction is effected by solvent extraction of the solution of the chlorides (Chlorinex process). However, it is first necessary to remove the protactinium. This is achieved by adsorption on silica gel or Vycor glass, a special glass containing 96.3 % of SiO_2.

Most of the protactinium is adsorbed on silica gel and Vycor glass from hydrochloric acid solution (optimum 4 M). Variation of the acid concentration has only a small effect.

Approximately 1–3 % of the protactinium is in a non-adsorbable form. This percentage is practically unaffected by variation of the acid concentration or of the temperature.

The adsorption mechanism is not yet known. It is probable, however, that at least two types of bonds are superimposed, since only part of the adsorbed protactinium can be desorbed by elution with oxalic acid.

The adsorption of niobium increases rapidly with increasing acid concentration, and so varies in the same direction as the precipitation of hydrated niobium pentoxide by strong acids.

In the case of zirconium, on the other hand, the adsorption decreases with increasing HCl concentration, and reaches a constant value for about 6 M hydrochloric acid.

Simultaneous separation of the protactinium, zirconium, and niobium, which would lead to a large reduction in the radiation level in the subsequent solvent extraction, is very difficult, since the optimum adsorption conditions for zirconium and niobium are very different. Nevertheless, the adsorption of more than 90 % of the zirconium/niobium activity has been achieved in a single pass.

The Vycor glass and the silica gels investigated differ only slightly in their adsorption behavior. The differences can be attributed mainly to the different surface areas of the products.

Comparison of Organometallic Complexes of Aluminum and those of Some Transition Metals

By *H. Lehmkuhl* (lecturer) and *J. Čuljković* [*]

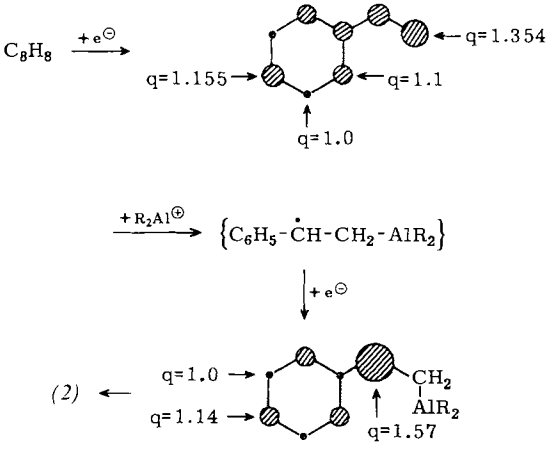
Potassium reacts with dialkylaluminum chloride in THF at −80 °C as follows:

$$2\,K \xrightarrow[-80°C]{THF} 2\,K^{\oplus} + 2e^{\ominus}_{solv.}$$

$$\xrightarrow[-2KCl]{2R_2AlCl/THF} R_2AlO(CH_2)_4AlR_2 \cdot THF$$

whereas aluminum is lost at +20 and +60 °C, with formation of a trialkylaluminum-tetrahydrofuran adduct. The cleavage of THF or the formation of Al are suppressed in the presence of benzene, naphthalene [1], or anthracene; the dihydroarene-diyl-bis(dialkylaluminum)-tetrahydrofuran adducts, *e.g. (1)* are formed instead.

$$2\,M + 2\,R_2AlCl + C_{14}H_{10} \xrightarrow[-2\,MCl]{THF} \text{H, AlR}_2\cdot\text{THF; H, AlR}_2\cdot\text{THF} \quad (1)$$



M = Na, K; with benzene only M = K; R = CH_3, C_2H_5

The analogous reactions with trialkylaluminums lead to equimolar mixtures of alkali metal tetraalkylaluminates and alkali metal dialkyldihydroarenediylaluminates [2]. The stability of the complexes increases with increasing electron affinity of the aromatic hydrocarbon. Olefins with similarly low reduction potentials (styrene, stilbene), 1,3-diolefins (butadiene [3], isoprene, myrcene, 1,3-cyclooctadiene), and electron-attracting alkynes (tolan) can react with alkali metal and trialkylaluminum to give the alkali metal dialkylaluminate complexes with hydrocarbons, *e.g. (2)*.

The course of the reaction and the products can be interpreted on the basis of HMO models of the initial hydrocarbons and their anions for all the systems investigated so far. The hydrocarbon anion is formed first, and a dialkylaluminum cation from the electrolytic dissociation equilibrium [4] then adds on in the position of highest charge order. This gives a new

$$2\,K + 2\,R_3Al + C_8H_8 \xrightarrow{THF} K^{\oplus}\left[\text{styrene-CH(AlR}_2\text{)-CH}_2\right]^{\ominus} + K^{\oplus}[AlR_4]^{\ominus} \quad (2)$$

π-electron system having a higher electron affinity, which rapidly takes over an electron from further alkali metal; the new carbeniate anion changes into an aluminate ion by formation of an Al—C bond. On the basis of HMO charge orders q, we obtain *e.g.* for the reaction of styrene, the following picture:

Organometallic complexes of transition metals were used for comparison in every case.

The Thermal Dimerization of *cis-trans*-1,5-Cyclooctadiene

By *J. Leitich* [*]

Racemic *cis,trans*-1,5-cyclooctadiene dimerizes at room temperature in the dark by combination of two *trans* double bonds to form a cyclobutane ring. This reaction yields three stereoisomers, *i.e. trans-trans (syn) (1)*, *trans-cis (2)*, and *trans-trans (anti) (3)*, in proportions of about 10:4:1.

(1) *(1a)*

In *(1)* and *(3)*, the *trans* configurations of the reacting centers have been retained, while in *(2)* one inversion has taken place. The doubly inverted isomers are not formed (detection limit 0.1 %); the only by-products are about 3 % of *cis,cis*-1,5-cyclooctadiene and varying quantities of polymers. The rate of formation and the proportions of the dimers are independent of light or catalytic effects, and are practically independent of the solvent ($k_{cyclohexane}/k_{dimethylformamide} = 2.1$), and the proportions are practically independent of the temperature. Kinetic parameters [for *(1)* in DMF between 30 and 50 °C]: reaction order: 2; $\Delta H^{\neq} = 17.0 \pm 1.0$ kcal/mole; $\Delta S^{\neq} = -31 \pm 3$ e. u.

(R)-(−)-*cis,trans*-1,5-cyclooctadiene on the other hand, forms (+)-*(2)* and (+)-*(3)* in a ratio of 1:2.9 with no *(1)*.

Racemic *trans*-cyclooctene also forms small quantities of the analogous saturated dimers *(1a)*, *(2a)*, and *(3a)* in a ratio of 2:6:1 at 150 °C, together with polymers and isomers.

The question whether the *trans* or *cis* linkage is energetically more stable for an eight-membered ring condensed to a four-membered ring has also been investigated on the basis of equilibrium positions in the cyclobutanone and benzocyclobutene systems. The energy difference in the case of the saturated eight-membered ring is small: $c_c^{equ}/c_t^{equ} = 1$ and 3 respectively; in the case of the 5-*cis*-unsaturated eight-membered ring, on the other hand, the *trans* arrangement is clearly preferred ($c_t^{equ}/c_c^{equ} > 100$).

These observations lead to the following conclusions concerning the course of the reaction: The dimerization begins in every case with the formation of one bond to give a biradical intermediate (rate-determining step). Closure of the second bond with retention of all configurations then occurs so fast that monoinversion can compete only if it leads to an energetically more favorable end product [*(2a)* but not *(2)*], or if the reacting double bond is more highly twisted (as in *cis,trans*-1,5-cyclooctadiene). Nevertheless, it is concluded that a specific factor favoring monoinversion is operative which is not steric in origin and therefore must be stereoelectronic. Thus, the extent of formation of *(2)* and *(2a)* shows that the predictions of the Woodward-Hoffmann rules have some validity even in disconcerted cycloadditions.

Determination of Copper, Lead, and Cadmium in Different Concentration Ratios by Various Voltammetric Methods

By *B. Lendermann* (lecturer), *H. Monien*, and *H. Specker*[*]

The determination of trace elements by voltammetric methods is influenced by the presence of other electro-active ions. The permissible excess concentrations of accompanying elements depend decisively on the electrochemical behavior both of the trace and of the excess element, as well as on the voltammetric method used.

In the determination of copper, lead, and cadmium in the systems Cu—Pb, Pb—Cd, and Pb—Cd—Cu, the concentration ratios at which one of the elements can still be determined in the presence of others without the measurement signal being affected and the determination limits for increasing excess concentrations are shown. The measurements were carried out with a conventional direct current polarograph, with a Davis cathode ray polarograph, and by inverse voltammetry on a hanging mercury drop electrode and on a carbon-paste electrode. By comparison of the results it is possible to estimate which method is most suitable for the analysis problem in question.

Purification of Contaminated Exhaust Gases in the Combustion of Irradiated HTGR Graphite Nuclear Fuel Elements

By *M. F. Lepold*[*]

To remove graphite ballast, the reprocessing of HTGR nuclear fuel elements[1] is preceded by combustion at about 1000 °C. The exhaust gas consists of about 65—75 % vol-% of CO_2, 15—25 vol-% of CO, and 5—10 vol-% of O_2, and contains all the fission products that are volatile during the combustion. It is first prepurified by passage through sintered metal filters and fiber-glass filters, and is then converted into a gas consisting of more than 99.7 vol-% of CO_2 on a catalyst. The component CO or O_2 that is present in the smaller amount is added before the mixture is brought into contact with the catalyst.

^{131}I and ^{106}Ru are filtered out of this gas on active charcoal. At 80 °C and with a linear flow rate of the carbon dioxide of 5.2 cm/s, a decontamination factor $D \geq 10^5$ can be achieved for ^{106}Ru and ^{131}I, provided that the required bed depth of 4 cm can be displaced in the sense of a gas-solid chromatograph under the influence of the flowing carbon dioxide. The active charcoals examined have BET surface areas of between 950 and 2500 m^2/g; the capacity for iodine is 1.1 to 2.9 g per g of active charcoal at 80 °C when the CO_2 is saturated with I_2.

To separate the fission inert gases (concentration of the order of magnitude of 1 mg/Nm^3), CO_2 is reversibly fixed on a 5 Å molecular sieve zeolite, the interstitial volume of which is filled with argon, and which takes up fission inert gases. The argon and the accompanying fission inert gases are removed from the zeolite packing by flushing the interstitial volume with CO_2 after CO_2 saturation of the molecular sieve zeolite has been reached. The CO_2 desorbed by the molecular sieve zeolite is substantially free from activity, the decontamination factor for ^{85}Kr from CO_2 being 6×10^3, whereas the argon enriched with ^{85}Kr, as a concentrated gaseous waste, is fixed on active charcoal at −78 °C in aluminum cylinders. When the cylinders are warmed to room temperature, the internal pressure increases to 7 atm. The capacity of the molecular sieve zeolite for CO_2 between the extremes (25 °C, 600 torr during adsorption and 150 °C, 1 torr during desorption) is 20 % of the weight of the zeolite packing.

A pilot plant for the continuous purification of 2.5 Nm^3 of CO_2 per hour has been constructed in the hot cell at Jülich on the basis of these results.

Absorption of Carbon Dioxide in Buffered Arsenite Solutions

By *A. Löwe* (lecturer), *N. Neth*, and *K. Dialer*[*]

The absorption, or more precisely the reaction, of carbon dioxide in water is accelerated by arsenite ions. This fact is utilized in industry for CO_2 washing in the "Vetrocoke" process. Apart from this application, the absorption system offers the interesting possibility of measuring specific interfacial areas in absorbers. For this purpose the catalyst concentration, which is pH-dependent, must be kept as nearly constant as possible by means of a buffer, to counter depletion phenomena in the absorption boundary layer. If, as is obvious, a carbonate buffer is used, the degree of dissociation of the arsenious acid at a buffer ratio (carbonate/bicarbonate) of 1, according to the thermodynamic equilibrium constants, is higher than 90 %.

Investigations on the equilibria in arsenite solutions with carbonate buffers have, however, shown that calculations based on thermodynamic constants, or using constants determined as a function of the ionic strength with large excesses of neutral salts (NaCl, KCl), lead to incorrect results for the compositions of the solutions.

The degrees of dissociation of arsenious acid are much lower in some cases than was formerly thought. Moreover, the hydrolysis constant of arsenite changes very rapidly with the degree of dissociation and with small additions of neutral salts. The specification of ionic strengths or buffer ratios, particularly if they are based on weighed portions, are

therefore of little value for the characterization of these absorption solutions.

The hydrolysis constant of the carbonate increases with increasing carbonation of a given solution, while that of the arsenite decreases. This is fortunate in view of the boundary layer depletion, since change is essentially confined to the buffer ratio, whereas the catalyst concentration remains practically constant.

In line with these results, kinetic measurements in a film absorber with various CO_2 pressures and contact times gave no indication of boundary layer depletion. For accurate evaluation of the measurements, it was necessary to make allowance for the fact that the "end effects" depend on the absorption rate, and cannot be predetermined by physical absorption measurements.

The Lattice Vibration Spectra of Heavy Metal Thiospinels

By *H. D. Lutz*[*]

The *IR* absorption spectra of the thiospinels $MnCr_2S_4$, $FeCr_2S_4$, $CoCr_2S_4$, $ZnCr_2S_4$, $ZnAl_2S_4$, $CdCr_2S_4$, $HgCr_2S_4$, $CrGa_2S_4$, $CrIn_2S_4$, $MnIn_2S_4$, $FeIn_2S_4$, $CoIn_2S_4$, $NiIn_2S_4$, and $CdIn_2S_4$ have four generally very sharp absorption maxima in the regions 300–450, 230–350, 170–300, and 70–120 cm^{-1}, which correspond to the four IR-active vibrations of the type F_{1u}.

The vibration forms[1] of the lattice vibrations of the spinel lattice show that all the atoms in the unit cell are involved in each one of the IR-active vibrations. The modes of the IR-inactive vibration types can be rigorously separated on the basis of their symmetry properties into vibrations of $M^{II}S_4$ tetrahedra and vibrations of $M_4^{III}S_4$ cubes. The assignment of the absorption maxima to the IR-active vibrations was based on the influence of the mass of the atoms on the position of the vibrations, the ratios of the wave numbers of the maxima for corresponding oxo- and thiospinels, and the intensity of the vibrations.

The two short-wavelength, very intense lattice vibrations are displaced toward higher wave numbers from $MnCr_2S_4$ to $ZnCr_2S_4$, despite the increase in the mass of the metal atoms. This points to a marked increase in the force constant, which is connected with a corresponding decrease in the CrS and SS distances in the lattice, and an increasing compression of the $M^{II}S_4$ tetrahedra.

In the spectra of the indium thiospinels, which crystallize with the inverse spinel structure, the shortest-wavelength vibration is more intense than the next; this is the reverse of the relation found in the spectra of the normal chromium thiospinels. This reversal of the intensities of the two short-wavelength maxima can be interpreted as resulting from the replacement of the M^{II} ions in the tetrahedral positions by ions of higher valence.

The α Radiation of $^{228}Ac(MsTh_2)$. A New α Branching in the Thorium Decay Series

By *F. Lux* (lecturer) and *N. Kaubisch*[*]

On the basis of the theories of α decay, α branching with a decay energy of about 4.6 MeV and a branching ratio of 0.8×10^{-8} or 3.5×10^{-8} has been estimated for $^{228}Ac(MsTh_2)$, a member of the thorium decay series.

For experimental checking, we had available a sample of 8 mCi of $^{228}Ra(MsTh_1)$, which also contained 10 mCi of ^{226}Ra. In the radiochemical separation and purification of ^{228}Ac, the ^{226}Ra had to be removed very carefully, since its 4.78 MeV α radiation would have interfered with the α-spectroscopic detection of the assumed α radiation of ^{228}Ac. The following decontamination factors (*DF*) had to be reached: 10^9 for radium, 10^5 for lead as $^{212}Pb(ThB) + ^{214}Pb(RaB)$ and for bismuth as $^{212}Bi(ThC) + ^{214}Bi(RaC)$, and 10^2 for $^{228}Th(RdTh)$. The following tracers were used for the evaluation of the separation process: ^{226}Ra, ^{140}La for ^{228}Ac, ^{228}Ac, ^{212}Pb, ^{212}Bi, $^{234}Th(UX_1)$. The separation and purification of ^{228}Ac was carried out in three steps.

1. Treatment of the ^{228}Ra sample by precipitation of $Ba(Ra)(NO_3)_2$ with fuming nitric acid; the radium content of the ^{228}Ac remaining in solution is reduced by a DF of 10^3.

2. Fine purification of the ^{228}Ac: Addition of thorium carrier, thorium hydroxide precipitation (quantitative coprecipitation of ^{228}Ac) with CO_2-free ammonia, single reprecipitation, DF for radium 10^4. Ion exchange separation (modification of the method given by *Cabell*[1]): Column 7.5×100 mm, cation exchange resin Dowex 50 WX8, 200–400 mesh, 60 °C. Application of preparation: 5 ml of 2 N HCl. Elutions: 10 ml of 2 N HCl (elution of lead and bismuth), 50 ml of 1.5 N HNO_3 (elution of radium), 10 ml of 3 N HNO_3, 20 ml of 6 N HNO_3 (elution of actinium). DF: for radium 10^2, for lead and bismuth 10^5 each, for thorium 10^4.

3. Preparation for α-spectroscopy: Electrolysis in nitric acid solution (pH = 2) after *Iyer et al.*[2], electrolysis time 30 min. The platinum cathode leaves with the actinium deposited on them are heated. Leaf diameter 16 mm, preparation diameter 10 mm. Total separation time 135 min, yield of ^{228}Ac 45 %.

The α spectra were recorded with the aid of a silicon semiconductor detector. The measuring chamber[3] was built between the pole pieces of a homogeneous electromagnet (magnet of a Varian ESR spectrometer) to deflect the interfering β radiation due to ^{228}Ac in the 9150 oersted magnetic field. The α line of ^{228}Ac was expected to appear on the low-energy flank of the 5.34 and 5.42 MeV α lines of ^{228}Th, which is formed in ^{228}Ac as a daughter product. A computer analysis was accordingly required to show that the α spectrum of the ^{228}Ac preparation contains an α line of energy 4.27 ± 0.04 MeV, which had not previously been observed for ^{228}Ac and its secondary products, and which must be assigned to the ^{228}Ac. Comparison of this line with that of ^{228}Th gives an α branching ratio of ^{228}Ac of $(5.5 \pm 2.2) \times 10^{-8}$.

Attempts were made to separate the ^{224}Fr resulting from the α decay of ^{228}Ac by α recoil and to identify it by decay measurements in an anticoincidence counter. The result was negative under the experimental conditions used. Therefore the half-life of ^{224}Fr seems to be considerably smaller than 2 min, which is the detection limit in the ^{232}Th-spallation experiments conducted by *Butement* and *Robinson*[4].

Preparation, Structure, and Properties of Barium Phosphides

By *K.-E. Maass*[*]

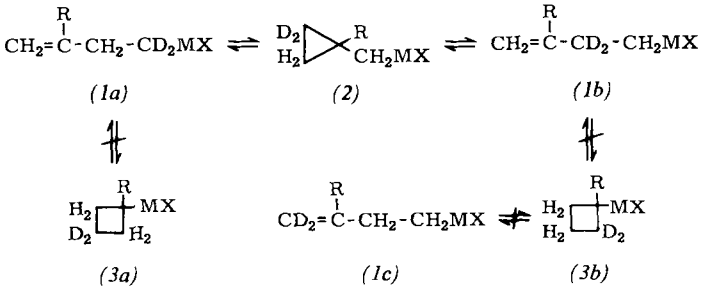
We investigated the binary barium-phosphorus system at temperatures above 500 °C under 1 atm of argon. The phosphides were prepared from barium metal chips and red phosphorus vapor.

A melting point of higher than 3000 °C repeatedly given for the compound Ba_3P_2 since 1956 was found to be incorrect; Ba_3P_2 melts at 1340 °C. X-ray powder photographs show that Ba_3P_2 crystallizes in the Th_3P_4 structure and in the narrower sense in the anti-Ce_2S_3 type.

Very short metal-metal distances (3.81 Å) are found. The discussion of the atomic distances and coordinations leads to the conclusions that phosphorus as the anion does not carry the full negative charge of P^{3-}, the phosphorus-barium bond may be regarded as substantially ionic, and metallic bonds exist between the barium atoms, *i.e.* the substance exhibits mixed ionic-metallic bonding.

In addition to the stoichiometric compound Ba_3P_2, which is not formed preferentially in the system, there are seven other barium phosphides, which have been gathered together in a provisional phase diagram. The polyphosphide with the highest phosphorus content is BaP_3. All the phosphides are black and have a metallic luster, which decreases with increasing P content. Ba_3P_2 has a specific resistance of approximately 10^5 ohm·cm at room temperature. With the exception of BaP_3, all the phosphides decompose in air and in water and acids with loss of phosphines.

The insolubility of BaP_3 and the viscous softening of BaP_2 and $BaP_{1.82}$ suggest that the compounds are highly polymeric.



The phosphides of the alkaline earth metals occupy a distinct intermediate position between the sulfides and silicides in the transition from predominantly ionic bonding in the sulfides to predominantly metallic-covalent bonding in the silicides, magnesium phosphide exhibiting a closer relation to the sulfides, while the barium-phosphorus system shows a closer resemblence to the silicide systems.

Kinetics of the Rearrangement of Allylcarbinyl Anions (3-Butenide Ions)

By *A. Maercker* (lecturer) and *K. Weber*[*]

In contrast with the unsubstituted allylcarbinyl Grignard compounds *(1)*, R = H, MX = MgBr, for which equilibration *(1a)*⇌*(1b)* can be readily followed by NMR spectroscopy even at room temperature[1], the rearrangement of the 3-substituted analogs *(1)*, R = C_6H_5, CH_3, MX = MgBr, proceeds at a comparable rate only at 80 °C. The β-deuterated Grignard compound *(1b)* is favored in the equilibrium ($K_p^{80\,°C} = 1.27 \pm 0.07$) because of a thermodynamic secondary isotope effect. The postulated cyclopropylcarbinyl intermediate *(2)* cannot be detected either chemically or by NMR spectroscopy. Rearrangement to give the four-membered ring *(3a)* or *(3b)* cannot be observed; nor can migration of the deuterium into the vinyl positions *(1c)*. A cyclobutyl intermediate *(3b)* in the equilibrium can therefore definitely be ruled out, even for R = C_6H_5.

(1a) *(2)* *(1b)*

(3a) *(1c)* *(3b)*

The rate of the equilibration *(1a)*⇌*(1b)* depends not only on the structure of the organic residue but also on MX, the solvent, the concentration, and the magnesium bromide content of the solution. Thus the rearrangement takes place more rapidly in diethyl ether than in tetrahydrofuran (THF). This is true of the Grignard and dialkylmagnesium compounds. The addition of small quantities of hexamethylphosphoramide to ethereal Grignard solutions leads to acceleration, whereas in the case of dialkylmagnesium compounds the presence of dioxane both in diethyl ether and in THF retards the rearrangement. The reaction rate is found to increase with increasing concentration and on addition of magnesium bromide. The transition from the alkylmagnesium bromide to the dialkylmagnesium compound in diethyl ether also leads to a distinct acceleration of the rearrangement.

The lithium compound *(1a)*, R = CH_3, MX = Li, rearranges particularly rapidly; in this case the establishment of the equilibrium can be followed even at 0 °C in diethyl ether. Since the by-products formed by decomposition of the ether influence the rearrangement rate, accurate kinetic measurements cannot be carried out over a long period. In nearly every case investigated, the rearrangement of the organomagnesium compounds exhibits a reaction order of <1; this indicates the participation of associates, presumably ate complexes, in the equilibria preceding the rearrangement.

Cyclobutadienes from Cyclobutenedicarboxylic Anhydrides

By *G. Maier* (lecturer), *U. Mende*, and *G. Fritschi*[*]

The photolysis of cyclobutenedicarboxylic anhydrides[1] appears to be a generally applicable method for the production of cyclobutadienes and cyclopentadienones.

(1) *(2)* *(3)*

	(1a)	*(1b)*	*(1c)*	*(1d)*	*(1e)*	*(1f)*	*(1g)*[2]
R^1	H	H	H	CH_3	CH_3	Cl	H
R^2	H	H	CH_3	CH_3	CH_3	Cl	H
R^3	H	CH_3	CH_3	CH_3	Cl	CH_3	$C(CH_3)_3$
R^4	H	CH_3	CH_3	CH_3	Cl	CH_3	$C(CH_3)_3$

On irradiation (low pressure Hg lamp) in a 2-methyltetrahydrofuran matrix at −196 °C, the unsubstituted anhydride *(1a)* remains practically unchanged, whereas the anhydrides *(1b)*—*(1g)* suffer photolysis. A yellow color appears, and very quickly disappears when the organic glass is warmed. All the observations indicate that the cyclobutadienes *(2b)*—*(2g)* and the cyclopentadienones *(3b)*—*(3g)* are frozen in as the monomers under the irradiation conditions. The steric hindrance of two *tert*-butyl groups is insufficient for appreciable stabilization of *(2g)* and *(3g)*.

Studies of Plutonium Dioxide by Chemical Analysis[1]

By *E. Mainka* (lecturer) and *A. v. Baeckmann*[*]

Very accurate and comprehensive chemical analyses are necessary for the supervision and control of fissionable material. To determine the accuracies that can be achieved under the conditions of routine analyses, the results for 160 samples were evaluated statistically. These samples were analyzed both in Hanford (USA) and by us in connection with the acceptance of the plutonium dioxide intended for the fast zero-energy unit at Karlsruhe.

The results show that the mass spectrometric determination of the isotope composition with respect to ^{239}Pu and ^{241}Pu, which is important for checking the material and for its value, was carried out with an accuracy of about 0.05%. The chemical determination of the plutonium contents gave an agreement of about 0.2%.

It is however interesting to note that our results were nearly always lower than those obtained at Hanford. Since we obtained the same results both gravimetrically and oxidimetrically, a systematic error on our part can be ruled out.

It must be mentioned that the material to be analyzed differs in its hygroscopicity according to its previous treatment. It was possible in one case in particular to explain the differences in the analyses on the basis of water absorption by the sample.

The hygroscopic behavior of the sample material is therefore the critical point to which special importance must be assigned in the sampling. We believe that this is the explanation of the systematic error.

Trace impurity determinations were also carried out on these samples at both laboratories by emission spectroscopy. The object of this investigation was to establish that the material corresponded to the given specifications. It was also important to obtain an estimate of the purity. Comparison of the values for up to 17 elements that were present as trace impurities gave an agreement of within 25% in most cases. Considerable differences were, however, sometimes found for the elements Al, Ca, Si, and Na. It is still necessary to check whether this could be due to inhomogeneity of the samples. Nevertheless, it may be said that these differences had no effect on the acceptance, since all the values were within the specification.

Oxidation Kinetics of $NbSi_2$ and $MoSi_2$ at High Temperatures

By *E. Fitzer, K. Matthias* (lecturer), and *K. Wild*[*]

The resistance of $MoSi_2$ and $NbSi_2$ to oxidation in air at 1 atm between 1300 and 1700 °C is due to the formation of a vitreous SiO_2 surface film. The subsequent growth of the SiO_2 film is due to the fact that the oxygen diffusing through the SiO_2 selectively oxidizes the silicon from the hard material at the SiO_2/silicide phase boundary with formation of SiO_2 glass and an intermediate layer of a silicide having a lower silicon content. The rate-determining process in this selective oxidation of Si is the transport of oxygen through the SiO_2.

Conditions for the occurrence of this technically interesting kind of oxidation can be deduced from thermodynamic and kinetic considerations, and their validity has been checked in the cases of molybdenum silicides and niobium disilicide. The required oxidation kinetics for these silicides were quantitatively determined by thermogravimetric measurements. The weight changes due to uptake of oxygen could be used to find the growth of the SiO_2 layer, since the areas of the samples were known. The layer thicknesses found in this way were checked by layer thickness measurements on optical and electron micrographs.

X-ray studies and concentration measurements using an electron beam microprobe were used for the detection of the selective oxidation of silicon with formation of SiO_2 glass and silicides with lower silicon contents. Using a color picture technique it was also possible to show qualitatively the chemical composition of the layers in a single electron-scan photograph.

The satisfactory agreement of the theoretical calculations and the experimental checks in the establishment of the temperature range and the range of O_2 partial pressures for the technically interesting selective oxidation of Si in the molybdenum silicides and in niobium disilicide suggest that the oxidation behavior of other silicides can be estimated purely from characteristic material values.

Preparation of Plutonium-238 from Americium-241

By *A. J. Blair, H. Ihle, H. Michael* (lecturer), and *A. Neubert*[*]

^{238}Pu can be obtained in macroscopic quantities by two methods: (i) from ^{237}Np by neutron capture and β decay, and (ii) from ^{241}Am by neutron capture, β decay, and subsequent α decay of the resulting ^{242}Cm. When prepared from ^{237}Np, the ^{238}Pu formed contains small quantities of ^{236}Pu (n, 2n; γ, n-reaction), as well as heavy plutonium isotopes[1]. ^{236}Pu is an isotopic impurity, which, owing to the γ activity of its daughter nuclei, affects the use of ^{238}Pu as an energy source for medical purposes (heart pacemakers, artificial hearts), even when present in very small concentrations[2]. ^{236}Pu should not be formed in measurable quantities in the production of ^{238}Pu from ^{241}Am.

Samples of 10, 50, and 100 μg of ^{241}Am were irradiated in the BR2 high-flux reactor (Mol, Belgium). Plutonium, americium, and curium were separated from one another and from the fission products by four ion-exchange separations. On the first column, americium, curium, and fission products were eluted with 8 N HCl from the anion exchanger AG 1—X4. The Pu^{IV}, which remains on the column under these conditions, is then reduced to Pu^{III} with HI and eluted. On the second column, the majority of the fission products, excluding the lanthanides, are eluted before the trivalent actinides with 1 N HCl from the cation exchanger AG 50W-X4. The actinide-lanthanide group separation is carried out on the third column at 80 °C with 12 M LiCl as the eluent and AG 1-X4 as the ion exchanger. Americium and curium are then separated on AG 50W-X4 with α-hydroxyisobutyric acid.

The radiochemical purity and the isotopic composition of the plutonium, americium, and curium fractions are examined by α analysis and mass spectrometry. The experimentally observed yields of the individual actinide nuclides are compared with the yields obtained by calculation for the formation of the various nuclides on neutron irradiation of ^{241}Am.

After completion of the chemical separation, the plutonium formed by α decay of the curium fraction is separated by anion exchange. Its isotope composition is determined by α analysis and mass spectrometry.

The Analysis of Actinides Separated in a Mass Separator

By *A. J. Blair* and *H. Michael* (lecturer) [*]

In order to determine by emission spectroscopy the chemical impurities in actinide nuclide samples which have been separated in an electromagnetic mass separator, it is advantageous to separate them first from the actinide element. This can be carried out with a number of cation-exchange resin-hydrochloric acid systems [1, 2]. Many elements can be quantitatively separated from lanthanides by elution with 1.75 N HCl from Dowex 50W—X8 [3]. We have measured the partition coefficients of the elements Cs, Ba, Pm, Am, Cm, Cu, Au, Cd, Ta, Cr, W, Re, and Pt in this system. Complete separation, however, of the heavy alkaline earth metals from the actinides is not possible under these conditions. Therefore the partition coefficients of Sr, Ba, Y, Pm, Am, and Cm were determined in the system AG 50W—X4, 1.00 N HCl. Of all the elements examined, only the trivalent lanthanides could not be separated from the trivalent actinides. Contamination by lanthanides is not to be expected in actinides separated in a mass separator.

The partition coefficients K_d were determined by column experiments. If v is the volume of the eluate up to the elution maximum and V is the column volume, then

$$K_d = v/V$$

In the separation and determination of the impurities, the eluate collected up to the beginning of the elution of the actinides was analyzed.

To check the completeness of the separation and the recovery of the contaminating elements, samarium was used as stand-in for trivalent actinides. The elution position was determined radiometrically with ^{153}Sm. 12 elements expected to occur as typical impurities were added to the samples. The impurities were completely separated from the samarium by elution from the cation exchanger AG 50W—X4 with 1.00 N HCl, and were determined by emission spectroscopy. To within the limits of error of the emission-spectrographic analysis, the quantities found in the eluate agreed with those used.

The method allows a simple quantitative separation of nearly all impurities, with the exception of the lanthanides, from the trivalent actinides.

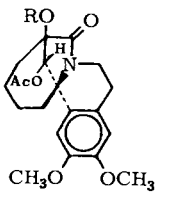
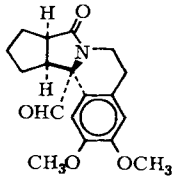
A Reversible Skeletal Rearrangement in the *trans*-Erythrinane Ring System

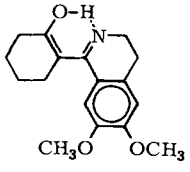


By *S. Mohr* (lecturer), *A. Mondon*, *G. Vilhuber*, and *Chr. Fischer* [*]

trans-Diol-*trans*-erythrinanelactam *(1a)* reacts exclusively at the tertiary alcohol function on monoacetylation or monomesylation to give *(1b)* and *(1c)*. Vigorous acetylation of *(1a)*, on the other hand, leads to rearrangement of the *trans*-erythrinane skeleton and formation of the diacetate *(2a)* with the10-azatetracyclo[10.4.1.0^{1,10}.0^{2,7}]heptadeca-3,5,7(2)-triene skeleton.



The rearrangement is reversed by hydrolysis, which leads back to the diol *(1a)*. The monomesylate *(1c)* also rearranges to give the mesylate acetate *(2b)*. On Zemplén hydrolysis,



(1a), R = H
(1b), R = Ac
(1c), R = Ms

(2a), R = Ac
(2b), R = Ms

(3)

(4)

(2b) fragments to give the tertiary aldehyde *(3)*. The carboxylic acid corresponding to *(3)* is decarboxylated in concentrated sulfuric acid, with further substantial rearrangement to give the dihydroisoquinoline derivative *(4)*, the structure of which has been verified by independent synthesis.

Preparation and Structural Chemistry of Mixed Oxo-Thio-Seleno Metalates

By *A. Müller* (lecturer) and *E. Diemann* [*]

By introduction of H_2S or H_2Se into aqueous solutions of $MoO_2S_2^{2-}$, $WO_2S_2^{2-}$, $MoO_2Se_2^{2-}$, and $WO_2Se_2^{2-}$ [*(1)* to *(4)*], it is possible to prepare the following compounds in the form of colored crystals in the presence of CsCl: Cs_2MoOS_3, Cs_2WOS_3, Cs_2MoOSe_3, Cs_2WOSe_3, Cs_2MoOS_2Se, Cs_2WOS_2Se, $Cs_2MoOSSe_2$, and Cs_2WOSSe_2.

The preparation depends on the facts that the more electronegative oxygen is replaced in the ions *(1)* to *(4)* in the first reaction step, and that the cesium salts are relatively sparingly soluble. All the salts indicated dissolve in water to give a deep color and have characteristic electronic spectra. The high extinction coefficients are indicative of M—X π bonds (M = Mo, W; X = O, S, Se). Characteristic ranges can be given for the ν (MX) stretching vibrations: ν (MO): 800 to 900 cm^{-1}, ν (MS): 450—480 cm^{-1}, ν (MSe): $\approx$ 300 cm^{-1}.

The bond orders estimated from the bond force constants according to *Siebert* also point to delocalized π bonds. Corresponding force constants have very similar values in different ions. The X-ray data were determined from single-crystal and powder photographs. All the compounds indicated above crystallize in the rhombic system with the space group D_{2h}^{16}-Pnma. The lattice constants vary only very slightly: a: 9.7—10.1 Å, b: 7.2—7.6 Å, c: 12.2—12.5 Å. The axial ratios are practically constant, $a : b : c \approx 1.35 : 1 : 1.67$. The similarity of the lattice dimensions and reflection intensities to those of other substances crystallizing with the β-K_2SO_4 structure suggests that these compounds crystallize in the pseudo-β-K_2SO_4 structure. The constant axial ratio a/b is particularly characteristic of such a structure.

Investigation of Lattice Defects from the Diffusion Behavior of Argon in Neutron-Irradiated Potassium Chloride

By *F. W. Felix* and *M. Müller*[*] (lecturer)

Simple interstitial diffusion was formerly postulated for the movement of argon in potassium chloride. Later calculations by *Norgett* and *Lidiard*[1] showed that the measured activation energy of 0.4—0.6 eV[2,3] is too high in relation to that calculated for interstitial diffusion (0.14 to 0.2 eV). The increase in the activation energy is satisfactorily explained by assuming an additional interaction with cation vacancies, which hinder the diffusion of the inert gas through interstitial sites.

A value of $\Delta H = 1.28$ eV has been found for the binding energy of argon in vacancies. The defects resulting from the irradiation also interact with the inert gas and hinder its diffusion. The values found for the binding energy of these irradiation defects with the argon are $\Delta H = 1.9$ eV for a neutron dose of $\Phi t = 5.16 \times 10^{14}$ cm^{-2} and $\Delta H = 1.44$ eV for a neutron dose of $\Phi t = 3.09 \times 10^{17}$ cm^{-2}.

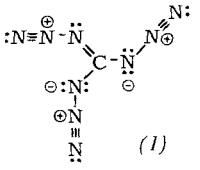
The Crystal Structure of Triazidocarbonium Hexachloroantimonate



By *Ulrich Müller*[*]

Triazidocarbonium hexachloroantimonate, $[C(N_3)_3]^+SbCl_6^-$, is formed by reaction of antimony azide tetrachloride, $[SbCl_4N_3]_2$, with CCl_4[1]. Its vibration spectrum in both the solid and dissolved states contains 3 bands each for the symmetric and antisymmetric azide stretching vibration, so that the $C(N_3)_3^+$ ion does not have the point symmetry C_{3h} that seems probable at first sight. The crystal structure determination of $[C(N_3)_3]SbCl_6$ shows that the point symmetry C_3 is a good approximation for the $C(N_3)_3^+$ ion and that the deviation from C_{3h} is relatively small.

Single-crystal photographs showed a monoclinic unit cell of space group $P2_1c$ with four formula units, the lattice constants being $a = 9.27$, $b = 10.96$, $c = 15.30$ Å, and $\beta = 113.4°$. The structure was solved by three-dimensional Patterson and Fourier syntheses and refined by the method of least squares to an R value of 6.8% for the 1070 observed reflections. The structure consists of almost strictly octahedral $SbCl_6^-$ ions (average SbCl distance 2.353 Å) and propeller-like $C(N_3)_3^+$ ions assembled in such a way that each ion is surrounded by 8 nearest oppositely charged ions, so that there is some resemblance to the CsCl type. The geometry of the $C(N_3)_3^+$ ion is shown in the diagram, where the numbers with signs indicate the distance of the atom in question from the plane through the strictly planar $C(\alpha\text{-}N)_3$ basic skeleton (all distances in Å).

An unusually large difference is found between the two N—N distances in each of the three non-linear azido groups: The α-N—β-N bond must be formulated as a single bond, and the β-N—γ-N bond as a triple bond. The C—N bond lengths correspond to a bond order of 1.33, and thus compare with those in guanidinium salts. The bonding in the $C(N_3)_3^+$ ion can thus be represented by three resonance forms *(1)*.

(1)

The charge distribution leads to electrostatic interactions between the N atoms of adjacent azido groups within the $C(N_3)_3^+$ ion and between the β-N atoms and one of the neighboring $SbCl_6^-$ ions, which has three Cl atoms oriented toward the β-N atoms of the $C(N_3)_3^+$ ion. These interactions influence the geometry of the $C(N_3)_3^+$ ion.

Isolation of ^{242}Cm for Use in a Radionuclide Battery

By *W. Müller*[*]

The nuclides ^{238}Pu, ^{242}Pu, ^{241}Am, and ^{242}Cm were isolated from samples of ^{241}Am that had been exposed to an integral flux of 1×10^{21} n/cm^2 in the BR2 reactor. At the beginning of the isolation, after a cooling time of about 250 days, 1 g of ^{242}Cm (> 3 kCi) and several grams of plutonium and americium were present.

On the basis of results obtained with samples that had been irradiated for longer times, a separation method based on ion exchange was chosen: The aluminum-encased irradiation samples were dissolved in NaOH, and plutonium (^{238}Pu and ^{242}Pu in a mass ratio of 3.6 : 1) and part of the fission products were removed from the mixture of trivalent actinides and lanthanides with 8 N HCl on Dowex 1X8. Americium and curium were separated from the lanthanides with 10 M LiCl. The decontamination factors of the principal fission products were around 10^3. The mixture of transplutonium elements (^{242}Cm, ^{241}Am) was precipitated from 0.1 N HNO_3 with oxalic acid; the oxalates were decomposed to oxides under nitrogen at 800 °C.

4.3 g of the oxide mixture with a curium content of 450 mg was sealed in a double-walled platinum capsule, transferred from the hot cell into a glove box shielded with 25 cm of water, and introduced into a thermoelectric converter.

Structure and Conductivity of Organic Polymers

By *H. Naarmann*[*]

The polymeric organic semiconductors known at present cover a conductivity range of 16 orders of magnitude, from the insulators with specific electric conductivities of about

10^{-14} siemens/cm to *e.g.* products with graphite-like structures and values up to about 10^{+2} siemens/cm.

A distinction is made between (i) polymers with conjugated double bonds, (ii) polymers with hetero atoms in which the conjugation chain is interrupted by hetero atoms such as —S—, —O—, or —NR—, (iii) polymers with rings containing metals or with metal atoms in the chain, (iv) charge-transfer complexes, and (v) semiconducting plastics by electrically conducting additives.

Taking into account the relatively large intermolecular distances in organic substances, the mobility [μ] of the charge carriers *i.e.* π electrons, despite the possibility of overlap of π-electron clouds, is about 10^2 to 10^{-6} [$cm^2\ volt^{-1}\ s^{-1}$], *i.e.* distinctly lower than those of metals (10^3) or of inorganic semiconductors (10^3 to $10^{-3}\ cm^2\ volt^{-1}\ s^{-1}$). The following methods can be used to influence the conductivity of organic semiconductors:

1. Increasing the degree of polymerization, *i.e.* increasing the chain length, which is accompanied in every case by a deepening of color and an increase in conductivity.

2. Increasing the pressure. The energy barriers for the electron transition are lowered; depending on the type of semiconductor, the conductivity is found to increase by about 2 powers of ten per 1000 atm.

3. Raising the temperature. The specific electric conductivity and the thermal activation energy E are related as follows:

$$\sigma = \sigma_0\, e^{-E/2kT}$$

(σ = measured conductivity, k = Boltzmann constant, T = temperature in °K).

4. Irradiation (possibly in the presence of sensitizers). The conductivity is increased by 1—3 orders of magnitude. On exposure, *e.g.* to a tungsten filament lamp, a rapid increase in current ("primary photoelectric current") is observed, followed by a slower further increase ("secondary photoelectric current"). When the light is switched off, the primary photoelectric current quickly collapses, whereas the secondary photoelectric current decays with a half life of about 50 seconds. At higher light intensities, the primary photoelectric current increases proportionately.

5. Complex formation (formation of charge-transfer complexes). Conductivity increases of 1—3 orders of magnitude can be achieved by addition of monomeric electron acceptors (or donors) to polymeric electron donors (or acceptors).

The control of conductivity and the production of conducting, readily processable systems (as lacquers) by polymeric charge-transfer complexes in particular offers new possibilities for the production of products with values of 10^{+2} to 10^{+3} siemens/cm, corresponding to the specific electric conductivities of inorganic semi-conductors. Particularly suitable combinations are those in which electron-rich polyolefins are used as donors with polysulfonium picrates as acceptors. These systems and also polymers with added graphite, silicon, or metals such as arsenic or bismuth exhibit the thermoelectric force effect with values of between 4 and 250 μV/°C. The sign of the thermoelectric voltage shows that the conduction is of the p type.

Calorimetric Temperature Measurements in Plasma Jets

By *R. Neubeck* [*]

Chemical reactions in plasma jets are gaining fresh importance as cheap electrical power becomes available from nuclear power plants. The term "plasma" refers here to partly ionized gases at high temperatures (2000—15000 °K), such as are formed by heating in an electric arc. To understand chemical processes in such plasmas, it is necessary, among other things, to know the local temperature distribution. This was formerly determined mainly by spectroscopic methods. These methods require expensive apparatus, and the accuracy attainable is frequently not very high. On the other hand, a special calorimetric method developed by *J. Grey* (Princeton, USA) has proved very suitable for temperature measurements in subsonic plasma flows.

In this method, a double-jacketed copper probe cooled with pressurized water and having an outside diameter of 1.5 mm is used, so that the local distribution of the temperature in plasma jets can be determined. To minimize errors due to radiation and thermal conduction, the measurement involves two steps. In the first no plasma gas is sucked through the inner tube of the probe, and only an external heat flow occurs from the plasma to the cooling water. A certain quantity of gas is then sucked through the inner tube so that an internal heat flow to the cooling water occurs as well as the external flow. The difference between the two measured quantities of heat gives the enthalpy of the plasma gas at the stagnation point of the probe by means of a simple heat balance if the gas enthalpy at the exit from the probe is known. The temperature can be calculated from the enthalpy. The stagnation pressure is measured at the same time as the enthalpy and used, with the Bernoulli equation, to find the linear velocity. From the velocity, the enthalpy, and the density calculated from the temperature, it is possible to determine the radial distribution of the mass and energy flow density.

The argon and nitrogen plasma jets used in the measurements are characterized by strong radial and axial temperature and velocity gradients. The mass flow density distributions obtained point to a swirl flow in the plasma jet. The local temperature measurements show that the hot plasma jet mixes very poorly with cold secondary gases.

Finally it is also possible to calculate the local equilibrium concentration from the temperature and mass flow density distributions.

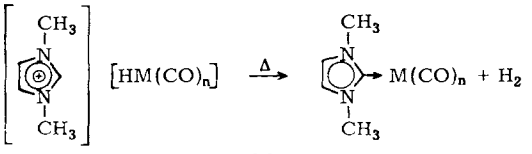
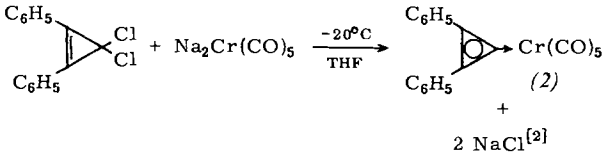
Nucleophilic Cyclic Carbenes as Complex Ligands on Transition Metals



By *K. Öfele* [*]

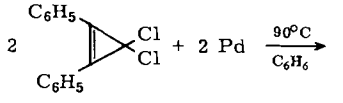
A series of transition metal complexes with various cyclic carbenes have been prepared by three new methods.

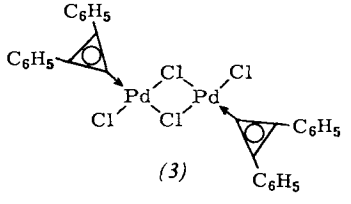
The pentacarbonylchromium and tetracarbonyliron complexes of *N,N'*-dimethylpyrazolin-3-ylidene, 2,4-dimethyl-1,2,4-triazolin-3-ylidene, 1,4-dimethyltetrazolin-5-ylidene, and *N*-methylthiazolin-2-ylidene corresponding to *(1)* were formed in a similar manner in various yields.



(2) and *(3)* are the first metal complexes in which a carbene that is not stabilized by hetero atoms is present as a ligand. Information about the bonding in *(2)* was provided by an X-ray structure determination [3].

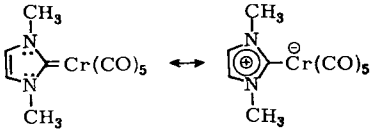
All the complexes mentioned are perfectly stable in air and are characterized by high thermal and chemical stabilities, as is particularly noticeable on comparison of *(3)* with most of the organometallic Pd compounds prepared previously. The carbene ligands act as strong donors in every case. *(1)* and *(2)* do not undergo catalytic hydrogenation even at high pressures. It is interesting to note that all the Cr complexes and all the Fe complexes of type *(1)* with different heterocyclic carbene ligands have almost identical properties.





M = Cr, n = 5[1]
M = Fe, n = 4

(1)



2 NaCl[2]

(3)

The behavior of these new transition metal complexes is evidently determined by the fact that the ligands are more or less aromatic in character, in accordance with (4).

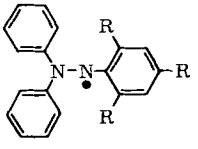
Reactions of Thermalized Electrons in the Gas Phase

By *D. Perner* (lecturer) and *R. N. Schindler*[*]

Investigations on the reactivity of electrons in the gas phase have been carried out by two methods. In one experiment, the reactions of the electrons are followed by means of a microwave interferometer. A pulsed source giving 600 kV electrons is used for ionization. The arrangement permits the measurement of 10^{11} to 5×10^{13} electrons/cm^3 and their variation with time at a time resolution better than 10^{-7} s.

To obtain information that will be of interest to the radiation chemist, the experiments are carried out at pressures of up to 200 torr. At the electron and ion densities produced in this arrangement, which are relatively high for radiation-chemical conditions, combination of the ions with the electrons predominates in most cases. Rate constants are given not only for recombination reactions but also for the reaction of electrons with typical electron scavengers such as O_2 and SF_6.



In a second experiment electrons are produced by photoionization of amines or NO in a windowless flow system with an inert gas as a carrier gas, and measured by EPR spectroscopy. This arrangement is suitable for the determination of rate constants for the reaction of electrons with substrate molecules

Stable Triarylhydrazyls Containing no Nitro Groups as Polymerization Inhibitors

By *G. Peschk* (lecturer) and *D. Braun*[*]

Until recently, only stable triarylhydrazyls containing nitro groups such as diphenylpicrylhydrazyl *(1)* were known. When these compounds are used in studies of the kinetics of polymerization (*e.g.* for the determination of the rate of decomposition of free-radical forming inititators[1] and of the initiation rate[2]) relatively large errors occur, since in addition to the radical function the nitro groups present in the molecule also have a more or less strongly pronounced retarding effect on the reaction[3]. With the synthesis of new triarylhydrazyls containing no nitro groups, *e.g.* α,α-diphenyl-β-[2,4,6-tris(methoxycarbonyl)phenyl]hydrazyl *(2)*[4] and α,α-diphenyl-β-(2,4,6-tricyanophenyl)hydrazyl *(3)*, which was prepared independently by *Bretschneider* and *Wallenfels*[5] and by the present authors, compounds have become available that are better suited for kinetic purposes.

(1), R = NO_2
(2), R = $COOCH_3$
(3), R = CN

The hydrazyl *(2)* reacts in a strictly stoichiometric ratio with the free radicals formed by decomposition of initiators as well as with growing macroradicals, and so approaches the status of an ideal inhibitor.

Compounds of type *(1)* do not completely inhibit polymerization, as was determined by combining the ESR spectroscopic measurement of the consumption of the inhibitor radicals with the dilatometric determination of the chemical conversion. Compounds *(2)* and *(3)*, on the other hand, inhibit the polymerization reaction until they are completely consumed without affecting the subsequent polymerization, while the secondary reaction products of *(1)* formed during the induction period exhibit a strong retarding effect.

Whereas the decomposition of the initiator azoisobutyronitrile in the presence of oxygen yields peroxy radicals, which cleave the N—N bond of the hydrazyl, the products formed in the absence of oxygen are mainly substitution products of the hydrazyl, from which hydrazines are formed by hydrogen transfer. Products that can be reoxidized to hydrazyls are present after polymerization in this case.

Preparation and Properties of Mixed Sulfides of the 4f Transition Elements

By *H. Pink* [*]

Ternary chalcogenides $M^{II}M_2^{III}X_4$ having various combinations of elements M^{II} and M^{III} with X = O or S have been known in large numbers for a long time. However, substances in which M^{III} is a lanthanide and M^{II} is Eu^{II} or an element of group IIa are relatively new.

These compounds are often prepared from the elements or by solid state reactions from the binary compounds. For example, the series $SrLn_2S_4$ (Ln = lanthanide) can be prepared by prolonged heating of SrS and Ln_2S_3. For the mixed sulfides $EuLn_2S_4$, EuS and Ln_2S_3 must first be prepared separately.

We found in an earlier investigation [1] that analytically pure and phase-pure europium(II) sulfide can be obtained in accordance with

$$Eu_2(C_2O_4)_3 \xrightarrow[T]{H_2S} 2\,EuS + 2\,H_2C_2O_4 + 2\,CO_2 \qquad (1)$$

from the oxalate, which is readily obtainable by precipitation of Eu^{3+} with $C_2O_4^{2-}$.

The precipitation of oxalate is well known as an accurate method of determination in the analytical chemistry of lanthanides. We have now precipitated the mixed oxalates from solutions containing Eu^{3+} and Ln^{3+} in a molar ratio of 1 : 2 and treated the resulting precipitates in accordance with eq. (1).

The products are dark brown to reddish brown powders whose composition corresponds to the empirical formula $EuLn_2S_4$. X-ray structure investigation shows that a change in structure from the cubic Th_3P_4-type to the orthorhombic $CaFe_2O_4$-type takes place with increasing atomic weight of Ln between Gd and Tb. The ratio of Eu^{2+} : Eu^{3+} was determined by the Mössbauer method from the isomerization shift of the 21.6 keV γ radiation of ^{151}Eu; the effective magnetic moments and the paramagnetic Curie temperatures were determined from susceptibility measurements between 4.2 and 500 °K.

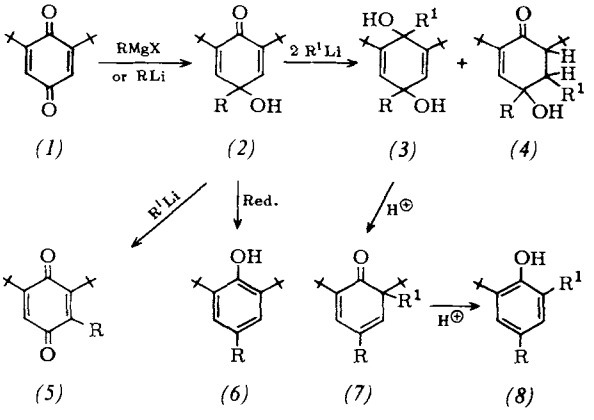
Use of Gas Chromatography for the Study of the Interaction Forces between Binders and Solvents in Paint Films

By *M. Schneider* and *K.-H. Reichert* (lecturer) [*]

Paint films may be regarded as multi-component systems composed of binders, pigments, and a series of different volatile and non-volatile substances. The interaction forces between the various components in the film are of great importance to the film properties. For example, the interactions between binders and solvents affect the film-forming process, which is responsible for a number of properties of the final paint film.

In order to investigate the relationship between different film properties and the interaction forces, attempts were made to obtain a suitable index for binder-solvent interactions using a gas-chromatographic technique. For this purpose the binders were applied to finely powdered inert support materials and were used in ordinary separating columns for the gas chromatographic measurement. On the resulting binder columns retention volumes of solvents were measured, which are dependent on the equilibrium distribution of the solvents between the carrier gas and the stationary binder phase, and are therefore closely related to the free energy of vaporization of the solvents from the corresponding binder phase.

Comparative studies on solvents of several homologous series on different binder systems have shown that the retention volumes of the solvents at adequate temperatures can be used as a measure of the interaction with the corresponding binder. For a given polar binder, the interaction forces generally decrease with decreasing polarity of the solvent, *e.g.* esters > aromatic hydrocarbons > aliphatic hydrocarbons.



Binders can also be characterized according to their interactions with solvents by comparison of the retention volumes of polar and apolar solvents. It is possible by this method to distinguish not only binders of completely different types, *e.g.* urea resins and cyclized rubber, but also chemically very similar binders such as copolymers with different compositions. On vinyl chloride-vinyl acetate copolymer systems, for example, the interaction with polar solvents was found to increase with the acetate content of the copolymer.

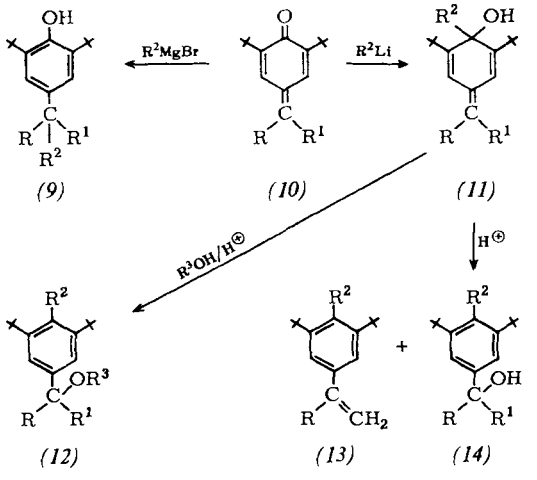
Reactions of Organolithium Compounds with Sterically Hindered Quinones, Quinols, and Quinonemethides

By *A. Rieker* [*]



Experiments were carried out to establish whether the sterically hindered carbonyl group in 2,6-di-*tert*-butyl-substituted quinones, quinols, and quinonemethides undergo 1,2-addition with organolithium compounds.

R = C_6H_5

The reaction of *(2)*, R = C_6H_5, with 1 equivalent of R^1Li, R^1 = C_6H_5, CH_3, in ether at 30 °C leads after 12 hours and working up in air to 47% of the quinone *(5)*, R = C_6H_5, presumably as a result of 1,2-migration. With two equivalents of R^1Li (4 hours, 60 °C, diethyl ether or di-*n*-butyl ether, hydrolysis at pH > 7), on the other hand, the 1,2-addition products *(3)* are obtained, *e.g.* R = $C(CH_3)_3$, R^1 = CH_3: 90% (yield); R = $C(CH_3)_3$, R^1 = 4-$CH_3C_6H_4$: 50%; R = $C(CH_3)_3$, R^1 = C_6H_5: 46%; R = C_6H_5, R^1 = CH_3: 92%; R = C_6H_5, R^1 = 4-$CH_3C_6H_4$: 59%; R = R^1 = C_6H_5: 56%; R = R^1 = CH_3: 85%; R = CH_3, R^1 = 4-$CH_3C_6H_4$: 38%. The 1,4-addition products *(4)* are formed in smaller quantities. The proportion of *(4)* increases at higher concentrations, *e.g.* approximately 0.7 M, R = $C(CH_3)_3$, R^1 = C_6H_5: 60% of *(4)*. Similarly, the reaction of the quinone *(1)* with two equivalents of R^1Li also yields *(3)*; reactions with one equivalent of RLi or RMgX, on the other hand, leads only to *(2)*, R = C_6H_5, 2-, 3-, 4-$CH_3C_6H_4$, 2-, 3-, 4-$CH_3OC_6H_4$, 4-$C_6H_5C_6H_4$, 4-$(CH_3)_3C$—C_6H_4, 2,4,6-$(CH_3)_3C_6H_2$, 4-BrC_6H_4, α-naphthyl, β-naphthyl, cycloheptyl, in yields of 50—80%. The quinols *(2)* can be reduced to the phenols *(6)* in very good yields with Zn/HCl.

The diols *(3)* react with acids to give 2,4-cyclohexadienones *(7)*, which lose isobutylene to give the phenols *(8)* in yields of up to 90%. This reaction can be followed directly by UV and NMR spectrometry. In the case R = C_6H_5 and R^1 = 4-$CH_3C_6H_4$, *(7)* can be isolated as such.

Quinonemethides *(10)* generally give 1,6-adducts, *e.g.* *(9)*, R = R^1 = R^2 = CH_3 with Grignard compounds, whereas reaction with R^2Li leads preferentially to 1,2-adducts, *e.g.* *(11)* R = R^1 = CH_3, R^2 = C_6H_5; R = R^1 = R^2 = C_6H_5 (90%); R = H, R^1 = R^2 = C_6H_5 (57%). The adducts *(11)* are converted into the alcohols *(14)* by acids, and into the ethers *(12)* by acid and alcohol. For R = R^1 = CH_3 and R^2 = C_6H_5, styrene *(13)*, R = CH_3, R^2 = C_6H_5, is formed as well as *(14)* from *(11)*. It is therefore concluded that 1,2-addition predominates in the reactions of the 2,6-di-*tert*-butylated compounds *(2)*, *(1)*, and *(10)* with organolithium compounds, despite strong steric hindrance.

Solid State Exchange Between Radiohalide and Ligands in Doped Hexahalo Complexes of Re^{IV} and Rh^{III}

By *K. Rössler* (lecturer) and *S. R. Upadhyay*[*]

Model experiments on ligand exchange in the solid state were carried out in hexahalo-complexes of Re^{IV} and Rh^{III} to obtain information on the annealing mechanism of recoil halogen produced by nuclear processes in the same systems (cf. abstracts *Bell* and *Stöcklin* in this collection).

Compounds of the type $K_2[ReX_6]$ and $K_3[RhX_6]$ (X = F, Cl, Br) were doped by coprecipitation with practically carrier-free radiohalides ($*X^-$ = $^{38}Cl^-$, $^{82}Br^-$, $^{131}I^-$). At temperatures between 80 and 250 °C it could be observed that the radiohalide-ions rapidly entered the ligand sphere, *e.g.*:

$$*X^- + K_2[ReCl_6] \rightarrow Cl^- + K_2[ReCl_5*X]$$

The identity of the products was confirmed by high-voltage electrophoresis.

Like the thermal annealing of recoil halogens in the corresponding systems, this solid state exchange proceeds approximately in accordance with first order kinetics and leads to temperature-dependent plateaus.

For a given matrix, the exchange velocity decreases with varying dopants in the sequence $^{38}Cl^- > {}^{82}Br^- > {}^{131}I^-$ *e.g.* (at 200 °C):

$^{38}Cl^-/K_2[ReCl_6]$: $k = 18.2\times10^{-2}$ min^{-1},
$^{82}Br^-/K_2[ReCl_6]$: $k = 5.0\times10^{-2}$ min^{-1},
$^{131}I^-/K_2[ReCl_6]$: $k = 3.0\times10^{-2}$ min^{-1}.

For the same dopant, the exchange velocity is higher in the hexabromo complex than in the hexachloro complex *e.g.* (at 200 °C):

$^{38}Cl^-/K_2[ReCl_6]$: $k = 18.2\times10^{-2}$ min^{-1},
$^{38}Cl^-/K_2[ReBr_6]$: $k = 48.0\times10^{-2}$ min^{-1};
$^{82}Br^-/K_2[ReCl_6]$: $k = 5.0\times10^{-2}$ min^{-1},
$^{82}Br^-/K_2[ReBr_6]$: $k = 36.5\times10^{-2}$ min^{-1}.

The exchange proceeds faster in the rhodium complexes than in the corresponding rhenium systems. These results can be attributed to steric and bond-energy effects.

The remarkable agreement of velocity constants and activation energies from the solid state exchange with those from thermal annealing of recoil atoms suggests that a very similar mechanism is operative in both cases. The very low activation energies (E_A = 3.5 kcal/mole for $^{38}Cl^-/K_2[ReCl_6]$ and E_A ≈ 7 kcal/mole for $^{82}Br^-/K_2[ReBr_6]$) indicate that the overall formalism of a first order reaction hides more complex processes. As a possible mechanism a lattice-defect promoted migration of ligand vacancies is suggested.

Helix Formation in Oligopeptides of L-Proline

By *M. Rothe* (lecturer), *R. Theysohn*, *K.-D. Steffen*, *Hj. Schneider*, *M. Zamani*, and *M. Kostrzewa*[*]

We have prepared the hitherto unknown oligo-L-prolines up to the heptadecapeptide (n = 2–17) and co-oligopeptides of proline and glycine, such as H(Pro-Gly-Gly)$_n$OH with n = 1–8, by the conventional *p*-nitrophenyl ester method and by *Merrifield*'s method in a monodisperse and electrophoretically pure state. The properties of these compounds as collagen models[1] have been investigated.

Conformational studies by spectroscopic comparison (ORD, CD, IR, UV, NMR) with the corresponding polypeptides showed that helix formation starts with triproline[2].

Specific rotation measurements showed that beginning with this degree of polymerization, two conformations are present as in polyproline, *i.e.* a right-handed helix with *cis*-peptide linkages (form I) and a left-handed helix with trans-peptide linkages (form II). These conformations are stabilized in certain solvents, and can be interconverted by changing the solvents, as is shown by mutarotation in water to more negative final values (formation of form II) and in the opposite sense in *n*-propanol (back to form I).

The differences in specific rotation values increase rapidly to more than 400° at the decapeptide (in water). Beginning with hexaproline, forms I and II can be isolated and give conformation-dependent IR and CD spectra. It has thus become possible for the first time to prepare definite linear peptides with *cis*-peptide linkages. Their optical rotatory properties are similar to those of cyclotri-L-prolyl, in which, for steric reasons, only *cis*-peptide linkages are possible. The conformation of this 9-membered ring has been studied by CD and NMR spectroscopy.

The properties of the free and N-blocked[3] (*e.g.* *tert*-butyloxycarbonyl and benzyloxycarbonyl) oligoprolines approach those of the polymers as the chain length increases (with a marked change between the dipeptide and the tripeptide). The typical IR bands of polyproline I and polyproline II appear for the first time in the spectrum of pentaproline; N-blocked tetraprolines exhibit spectra nearly related to that of polyproline II.

In CD measurements in water, a weak positive and a strong negative Cotton effect is observed beginning with triproline (at 226 and 197 nm, respectively). They are shifted to higher wavelengths with increasing n, and at heptaproline the posi-

tions of the Cotton effects of polyproline II (230 and 205 nm, respectively) have practically been reached.

In the co-oligopeptides with glycine, on the other hand, no ordered structures are present even in the octatripeptide (24 amino acid residues).

IR and Raman Spectroscopic Studies on the Structure of TlF

By *A. Ruoff*[*]

In X-ray studies, *J. A. A. Ketalaar*[1] could not distinguish between the space groups Fmmm, Fmm, and F222 for the crystal structure of TlF, whereas *Alcock*[2] reported the space group to be Pm2a. However, since *Alcock* precipitated his products from aqueous solutions, it is not certain whether this was TlF or a hydrate of TlF. Using the method of factor group analysis, we obtained the selection rules given in the table for the IR and Raman spectra.

	No. of vibrations		
	IR and Raman active	Raman active only	IR active only
F mmm	—	—	3
F mm	3	—	—
F 222	3	—	—
Pm 2a	17	4	—
found	3	—	—

The spectra thus give the space group Fmm or F222. In the latter case, TlF would have the zinc blende structure. This would appear very unlikely because of the ratio of the ionic radii. The vibration frequencies can be readily correlated with the Tl—F distances by the Badger rule[3], since ν_1, ν_2, and ν_3 belong to different species. This correlation provides further confirmation of the space group Fmm, and allows an approximate determination of the position of the F atom (which is difficult to localize by X-ray methods). The following result is obtained:

Fmm Tl: 0; 0; 0; F: 0;0; 0.46

The Tl has a coordination number of 5+1 in this arrangement. This structure is similar to those of SnO, (isoelectronic) red PbO, and BiO^+.

A relatively sharp band in the IR spectrum at 474.5 cm^{-1}, which has no counterpart in the Raman spectrum, is very probably due to monomeric TlF, the content of which in the lattice may be estimated as about 5–10%.

Cyclization of Long-Chain Trienoic Carboxylic Acids with Alkali

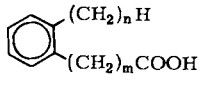
By *A. N. Sagredos* (lecturer), *J. D. von Mikusch*, and *V. Wolf*[*]

The cyclization of 9-*cis*,12-*cis*,15-*cis*-octadecatrienoic acid (linolenic acid), which has been observed to take place even under the conditions of alkali isomerization at 180 °C, is preceded by conjugation of the triene system. With tung oil, 80% of which consists of the glycerides of α-eleostearic acid (9-*cis*,11-*trans*,13-*trans*-octadecatrienoic acid) cyclization accordingly proceeds more rapidly than with linseed oil. However, since linolenic acid, which is present in linseed oil to the extent of about 54%, isomerizes to give a mixture of conjugated dienoic and trienoic acids, it was surprising to find that linseed oil gives a more uniform cyclization product than tung oil.

To elucidate the course of the reaction, 9-*trans*,12-*trans*,15-*trans*-octadecatrienoic acid (linolenelaidic acid) and 9-*trans*, 11-*trans*,13-*trans*-octadecatrienoic acid (β-eleostearic acid) as well as the above mentioned oils were treated with 6.5% KOH-glycol solution for 25 minutes at 180 °C, and the composition of the resulting isomeric cyclohexadiene derivatives was determined after aromatization, special attention being paid to the length of the side chains.

Cyclization of the *cis*,*cis*,*cis*-triene (linolenic acid) led primarily to compound *(1)*, $n = 3$, $m = 8$, whereas the three trienes with central *trans* double bonds gave mixtures of *(1)* with $n = 2$, 3, and 4 (from linolenelaidic acid) and $n = 3$, 4, and 5 (from the other trienes).

(1), n + m = 11



It may be concluded from these observations that the primary reaction is an ionic isomerization (allylic shifts and *cis-trans* rearrangements) of the trienecarboxylic acids into conjugated isomers. The ring-forming conjugated trienes with a central *cis* double bond subsequently cyclize by a multi-center mechanism leading to the cyclohexadiene derivatives.

Aromatization of C_{18} Alkylcyclohexadienecarboxylic Acids

By *A. N. Sagredos*, *H. Scharmann* (lecturer), and *V. Wolf*[*]

In the presence of alkali, C_{18} trienoic carboxylic acids form alkylcyclohexadienecarboxylic acids after ionic isomerization. This cyclization is assumed to proceed by a multi-center mechanism. Aromatic carboxylic acids *(1)* are formed in a secondary reaction.

(1), n + m = 11.

It was shown by spectroscopic studies that all the isomers with $n = 0$–11 occur in the product. The mass-spectrometric fragmentation behavior in this series of isomers exhibits characteristic differences when n and m vary. Homologous ω-phenylalkanecarboxylic acids, alkanecarboxylic acids, alkylbenzenes and alkanes have been detected as by-products of this aromatization. The distribution of the homologous compounds shows a distinct dependence on the positions of the double bonds in the initial trienoic carboxylic acid. A

free-radical reaction and a base-catalyzed disproportionation of the initially formed alkylcyclohexadienecarboxylic acids is proposed.

Oxidative Addition of Organic Anions to Olefins — Oxidative Dimerization of Olefins

By *H. Schäfer*[*]

Organic anions can be oxidatively added to unactivated double bonds at a platinum anode[1].

We have achieved the addition of the following anions (R^-) to olefins such as styrene, vinyl ethyl ether, butadiene, cyclooctene or cyclohexene: sodium salts of 1,3-dicarbonyl compounds, of aliphatic nitro compounds, and of nitriles; also Grignard compounds and sodium azide.

The electrolysis products can be readily explained if the following possibilities are assumed for the stabilization of the free-radical primary adducts *(1)*: (a) abstraction of hydrogen from the allyl position of the olefin to form alkyl *(2)* and alkenyl derivatives *(3)*, (b) dimerization, (c) mixed coupling, and (d) oxidation to give cations *(4)*, which are either solvolyzed or (in the case of 1,3-dicarbonyl compounds) intramolecularly cyclized to give tetrahydrofuran *(5)* or dihydrofuran *(6)* derivatives. Sodium azide leads by paths (a), (b), and (c) to monoazido-, 1,2-, and 1,4-diazidoalkanes, whose reduction yields the corresponding amines.

If the electrolysis is carried out on graphite instead of platinum anodes, these additions are almost completely suppressed and the dimers of the olefins are formed instead[2]. This oxidative dimerization of olefins allows the one-step preparation of 1,4-dimethoxybutane or butadiene derivatives from olefins and the coupling of aldehydes or ketones *via* the enol ethers to give 1,4-dicarbonyl compounds. The reaction is assumed to proceed by oxidation of the olefin to a radical-cation, which gives 1,4-dimethoxybutane and butadiene derivatives by dimerization and by S_N1 and E1 reactions respectively.

Reactions of Electrophiles with Phosphonium Salts in the Absence of Auxiliary Bases

By *G. P. Schiemenz* (lecturer) and *J. Becker*[*]

Phosphonium salts are CH acid compounds. Under the influence of bases, the cations lose a proton from the α-position with respect to the phosphorus; the resulting carbanions react with many electrophiles. An auxiliary base has always been used in the past for the production of the carbanions. This should really be superfluous. The phosphonium cation is necessarily associated with an anion, which should be able, under suitable conditions, to take over the function of the base; this is particularly true of the fluoride ion, which is strongly nucleophilic in aprotic polar solvents. Phosphonium salts would then be both CH acids and bases.

Phosphonium fluorides were prepared in methanol solution from the bromides or chlorides on an ion exchanger charged with fluoride. The crystalline fluorides could be isolated in the case of cations of relatively low acidity; they have the typical properties of phosphonium salts: conductivity and molecular weight determinations showed that they are largely dissociated in polar solvents, but associated into ion pairs and higher aggregates in chloroform. In their NMR spectroscopic behavior they surprisingly show a greater similarity in $CDCl_3$ to the iodides than to the chlorides, possibly because of solvation of the anion. The α-proton signals appear as a doublet, *i.e.* deprotonation could not be detected in this way. In acetonitrile, however, they react with *p*-nitrobenzaldehyde in a sort of Wittig reaction to give good yields of olefins.

The reaction also takes place with more strongly acidic phosphonium salts, but the deprotonation to form the ylide takes place so readily that the fluorides can no longer be isolated. Mere evaporation of the methanolic solution often leads quantitatively to the ylide, *e.g.* in the case of triphenyl-*p*-nitrobenzylphosphonium fluoride, whose pale yellow methanol solution is stable for several months, the ylide is recognizable by its deep red color. Since the ylides here are not formed in a basic medium, they are stable for long periods; the phosphonium fluorides are regenerated by atmospheric moisture. The special role of the fluoride ion is seen in the NMR spectrum of acetonyltriphenylphosphonium salts in acetonitrile. The bromide has a doublet for the CH_2 protons; in the fluoride, the $^{31}P-^{1}H$ coupling is broken down by deprotonation-protonation equilibria. The particularly acidic cyanomethyltriphenylphosphonium cation enters into Wittig reactions even as the bromide.

The carbonyl olefination occasionally fails if one of the reactants is sensitive to the added base; for example, aldehydes may preferentially undergo the Cannizzaro reaction. The new variant, in which the reaction is not carried out in a basic medium, should be helpful in such cases. Moreover, the materials required do not include the auxiliary base, but consist entirely of substances of which groups are found in the desired products.

Mechanism of the Anionic Catalysis of the Decomposition of Nitramide in the Light of New Views on Acid-Base Catalysis

By *Hermann Schmid*[*]

The elucidation of the course of general acid-base catalysis in the mutarotation of α-glucose in aqueous solution[1] also

leads to new views on the course of general base catalysis in the decomposition of nitramide ($H_2N{-}NO_2$) in aqueous solution. The entropy change ΔS_2 in the reaction of the hydrated anion $A^- \cdots H_2O$ with the hydrated oxonium ion $H_2O \cdots H_3O^+$ to give the hydrated acid $AH \cdots OH_2$ can be calculated from the catalysis coefficients of the anion (k_{A^-}) and of water (k_W) in the acid-base catalysis of the mutarotation of α-glucose with the same activation enthalpy:

$$\Delta S_2 = R \ln (k_{A^-}/k_W)$$

The entropy change ΔS_1 in the opening of the hydrogen bond $AH \cdots OH_2$ can also be calculated from the catalysis coefficients of the acid (k_{HA}) and of water (k_W) in the acid-base catalysis of the mutarotation of α-glucose with the same activation enthalpy:

$$\Delta S_1 = R \ln (k_{HA}/k_W)$$

In the general base catalysis of the decomposition of nitramide by anions such as formate, acetate, propionate, benzoate, primary phosphate, and hydroxide, on the other hand, the entropy change

$$\Delta S = R \ln (k_{A^-}/k_W)$$

corresponds to the entropy change in the reaction of $A^- \cdots H_2O$ with $H_2O \cdots H_3O^+$ to give the unhydrated acid AH.

This equation is interpreted as meaning that the anionic reaction, like the mutarotation of α-glucose, is preceded by the transfer of a proton from the nitramide (or from its tautomer respectively) to the water molecule of the hydrated anion $A^- \cdots H_2O$. The resulting H_3O^+ reacts with A^-, because of the immediate proximity of the two, without further activation enthalpy and with an entropy change of only ΔS. In contrast with the general acid-base catalysis of the mutarotation of α-glucose, this reaction leads not to $AH \cdots OH_2$ but only to AH.

The entropy change for the breaking of the hydrogen bonds

$$H_2O \cdots H{-}O{-}H \cdots H_2O$$

can thus be calculated from the OH^- catalysis of both reactions. This entropy value agrees with that found by *Walrafen* from the Raman spectrum of water. The Brönsted equation is replaced by the linear relation of ΔS_1 and ΔS_2 to the logarithm of the base constant K_B[1]. In comparison with

$$\Delta S_2 = \beta R \ln K_B$$

it is

$$\Delta S = R \ln K_B$$

β is therefore equal to 1. The deviations from this relationship are clarified by thermodynamics.

Elucidation of the Mechanism of the Reaction of Epoxides with Carboxylic Acids by Kinetic Studies and Model Analysis Using a Digital Computer [1]

By *W. W. Schmitt* [*]

The primary step in the acid-catalyzed reaction of α-epoxides with carboxylic acids (hydroxyalkylation), which leads to 1,2-diol esters, was subjected to a comprehensive kinetic analysis in an inert solvent without additional catalysts.

The systems studied were propylene oxide + benzoic, formic, acetic, and chloroacetic acid.

From the kinetic results, it was possible to distinguish two parallel paths leading to the same reaction product β-hydroxypropyl ester, since it was found *e.g.* that the reaction order with respect to the acid component, independent of the system and temperature, showed sliding transitions from 1.0 to 2.0, the order with respect to epoxide converging to zero.

From these results and independent spectrometric observations, it was shown that both steps take place from a fast H-association equilibrium that precedes the actual reaction, the "true" reactants of the individual steps still being unknown at that time because of interplay of dimerization and association equilibria of the acids.

All but two of the formal reaction possibilities were eliminated as nonsense reactions by a selection strategy with the aid of a digital computer, so that the following quantitative interpretation can be given.

The parallel elementary steps of the process are the unimolecular reaction by rearrangement of the epoxide-acid associate and the bimolecular reaction of two epoxide-carboxylic acid associates with one another which are described by time equations of the type

$$v_R = -(dx/dt) = k_1 \times c_a + k_2 \times c_a^2$$

where c_a is the equilibrium concentration of the associate in question.

The rate constants for the two steps were determined for all systems by congruence analysis, and the "true" activation entropies were calculated from the dependence on T. In agreement with the unimolecular reaction course, $\Delta S^{\neq}$ values of about —40 e.u. were obtained for k_1.

The purely associate-controlled reaction course is contrary to ionic A and S_N mechanisms described earlier for the systems investigated. The Brønsted law is formally satisfied with $\alpha = 1$; it seems necessary, however, to reformulate its applicability as a criterion of catalysis in non-aqueous systems.

Dependence of the Stress Birefringence of Rubber-Elastic Substances on Temperature and Degree of Swelling

By *J. Schwarz* [*]

It follows from the *Kuhn-Grün* statistical theory of photoelasticity that the birefringence exhibited by an amorphous rubber-elastic substance at constant deformation is independent of temperature. It also follows that the photoelastic coefficient, *i.e.* the ratio of the birefringence to the stress, remains constant when these substances are swollen in solvents, provided that a correction is applied to allow for the possible change in the average refractive index of the material on swelling.

We found that for crosslinked polybutadiene and crosslinked styrene-butadiene copolymer (26% styrene), the birefringence at constant deformation decreased by 23 and 12% respectively with rising temperature between 0 and 75 °C.

The corrected photoelastic coefficients of the polymers also decreased on swelling in carbon tetrachloride, the maximum decreases being 35 and 30% respectively.

Deviations from the predictions of the simple theory are to be expected if the mean conformation of the polymer, *i.e.* that of the main chains and that of side groups, changes with temperature and degree of swelling. The addition of optically anisotropic solvent molecules to the polymer during swelling can also cause deviations; in order to prevent this, carbon tetrachloride was used as the swelling medium.

In the case of polybutadiene it is certain that the decrease in birefringence with rising temperature and with swelling is not due to side group effects; this is also fairly certain in the case of the styrene-butadiene copolymer.

This decrease must therefore be due to an effect of the mean conformation of the main chains. It can be concluded that in amorphous polymers, instead of complete randomness, certain positions of chain segments in relation to one another are preferred as a result of the interaction forces, and this leads to a short-range order in the sense that the chains tend to be roughly parallel to one another. This deviation from randomness should decrease or disappear entirely with rising temperature and with swelling of the polymers.

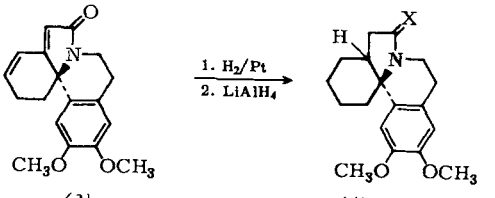
Synthesis of *trans*-Erythrinanes

By *P.-R. Seidel* (lecturer) and *A. Mondon* [*]

All the erythrinanes described prior to 1960 have been shown to belong to the *cis* series (with respect to the linkage of rings A and B) [1]. *trans*-Erythrinanes were unknown until now, though models of these compounds can be readily constructed.

A *trans*-linked erythrinane derivative has been obtained on the preparative scale for the first time from the enol lactam *(1)* by oxidation with $Pb(OAc)_4$. The reaction product can be separated by fractional crystallization into two isomeric "double molecules" *(2)* (m.p. 240 and 270 °C).



These compounds, which are no longer enolizable, are remarkably readily hydrogenated. They smoothly take up 3 moles of H_2, and after hydrogenolysis of the enol ether linkage, they both give *cis*-15,16-dimethoxy-7β-hydroxy-erythrinan-8-one, which is obtained directly under the same

(1) *(2)*

conditions from *(1)*. This confirms the existence of *cis,trans*-isomeric erythrinane derivatives.

trans-Erythrinanes that are not substituted on C-7 are obtained by hydrogenation of the diene lactam *(3)* with Pt in methanol or glacial acetic acid. The known *cis* base *(5a)* and the new *trans* base *(5b)* are obtained by chromatographic separation of the lactams *(4a)* and *(4b)* and reduction with $LiAlH_4$.

(3)

(4), X = O
(5), X = H_2
(a), *cis*; *(b)*, *trans*

Proof of the structure is provided by the UV and mass spectra, which are identical for the two steroisomers. The NMR spectra of the *trans* series show a strong deshielding effect for the aromatic proton on C-14. For chemical proof of the configuration, the quaternary ammonium bases of *(5a)* and *(5b)* were subjected to Hofmann degradation until the chirality center on C-6 was eliminated. The two stereoisomers gave the same biphenyl derivatives after three steps.

Pharmacological studies on the isolated, chronically enervated rat diaphragm showed no difference in activity between *(5a)* and *(5b)* and their optical antipodes. The curare-like action of the erythrinanes is thus neither structure-specific nor configuration-specific [2].

Preparative Scope of the Reduction of Higher Transition Metal Chlorides in Anhydrous Methanol

By *H. J. Seifert* [*]

In solution in methanol containing HCl, VCl_3 can be electrolytically reduced to V^{2+}, and $TiCl_4$ to Ti^{3+}.

$ZrCl_4$ is not reduced in pure methanol; the alcoholysis equilibrium is displaced toward the formation of methoxy compounds by discharge of the H^+ ions. The reduction of WCl_6 is concentration-dependent: in dilute solution it yields trivalent tungsten, while in concentrated solutions, reduction plus alcoholysis lead to green $W_2Cl_4(OCH_3)_4 \cdot 2\,CH_3OH$.

Reduction of $VOCl_3$ at a controlled potential yields a solution of $VOCl_2$.

Solid methanol adducts have been isolated from the resulting solutions in some cases. Complexes with other organic ligands have also been prepared by displacement reactions and investigated.

Determination of Trace Elements in Plastics by Neutron Activation and Gamma Spectrometry

By *H. Sorantin* [*]

To assess the suitability of a plastic for special applications *e.g.* in electrical engineering, nuclear engineering, and medicine, the nature and quantity of the trace elements present must be accurately known.

Since the concentration of foreign elements is very low, neutron activation analysis was chosen because of its sensitivity and the fact that no interfering activations of the matrix with neutrons occur, except in Teflons and PVC's.

A further advantage of the selected method was the elimination of any errors due to the escape of volatile compounds during ashing or due to reagents used in chemical procedures. In a series of commercially available plastics 23 elements could be identified, after neutron activation, by their radioisotopes. The quantitative analysis covered 16 elements (Na, Cl, Ca, Se, Cr, Mn, Fe, Cu, Zn, Sc, Br, Sb, Au) and ranged from 10^{-4} to 10^3 ppm [1].

Behavior of Neptunium and Plutonium in Various Oxidation States on a Cation Exchanger

By *S. Specht* (lecturer), *G. Höhlein*, and *H.-J. Born* [*]

Plutonium in mineral acid solutions can exist simultaneously in four oxidation states: Pu^{3+}, Pu^{4+}, PuO_2^{2+}, and in a very low equilibrium concentration as PuO_2^{+}. The proportions of the valence states can be altered by disproportionation and radiolysis; in solutions with pH $\geq$1.5, part of the Pu^{IV} may be present in the colloidal state. Neptunium exhibits similar behavior though to a lesser degree; the oxidation states Np^{4+}, NpO_2^{+}, and NpO_2^{2+} are again readily obtainable.

In an attempt to find the simplest possible method for the separation and identification of microconcentrations of Pu^{III}, Pu^{IV}, Pu^{VI}, and the colloidal component, as well as of Np^{IV}, Np^{V}, and Np^{VI}, the behavior of these species on the cation exchanger AG50WX8 was investigated with HCl as the eluent. This investigation was based on work by *Diamond*, *Street*, and *Seaborg*.

The arrangement used consisted of chromatographic columns [1] developed by the present authors and operated by hose pumps and tubular plastic scintillators [2], which were used for the continuous monitoring of the α-activity in the solutions. The elution curves could be recorded automatically in this way.

The partition coefficients and the separation factors of the individual ions and the HETP values of the columns were determined as a function of the acid concentration. We found that the ions containing plutonium in various valence states were best separated in the range 1N–3N HCl and could be definitely identified on the basis of the position of the band. Pu^{III} and Pu^{IV} could not, however, be separated in the region around 6N HCl, and could be separated only with difficulty in the range up to 12N HCl. Colloidal plutonium always appears as a relatively sharp band after the first three column volumes.

In the case of neptunium the separation conditions are more favorable. Thus the oxidation states of synthetic mixture can be eluted with 1 N HCl in the order Np^{V}, Np^{VI}, Np^{IV} with separation factors of *ca.* 3 and 5. The separation factors increase with decreasing acid strength. Np^{IV} and Np^{VI} cannot be separated by elution with 4–5 M HCl for at this acid strength these two oxidation states of Np exhibit the same elution behavior.

The HETP values of the ion exchange columns used increase considerably with increasing acid concentration, and this again makes it advisable to carry out the separations in the dilute acid range.

Addition of Mixed Epoxides in the High Pressure Range

By *E. Staude* [*]

The addition of ethylene oxide-propylene oxide mixtures to β-phenoxyethanol (monophenyl monoethylene glycol) has been investigated using sodium phenoxide as the catalyst at pressures up to 1000 atm. The four possible competing reactions were investigated kinetically as single reactions. The basic addition of epoxide proceeds in bulk by a multi-center reaction. If the reaction product has an end group similar to that of the initial alcohol, the reaction rate above an epoxide-alcohol ratio of 1 depends only on the concentration of the catalyst. On the other hand, when a secondary alcohol is formed from a primary alcohol and a corresponding epoxide or *vice versa*, the OH component also appears in the kinetic equation.

This means that it is not possible to calculate the dimensionless reactivity parameter normally used to describe a copolymerization reaction. The incorporation of the monomer into the product can however be determined *via* the relative rates as a function of the initial monomer composition. Closed expressions are given for the overall conversions of the two monomers. Since the constants of the individual reactions of ethylene oxide at high pressures cannot be determined for experimental reasons, the effect of pressure on these reactions can be determined *via* the kinetic equation set up for the overall conversions in mixed reactions. An increase in pressure leads to an increase in the ethylene oxide conversion. The high negative activation volume rules out an ionic reaction.

The Phase Behavior of Ethylene-Polyethylene Mixtures (under the Conditions used in the Industrial High-Pressure Synthesis of Polyethylene)

By *R. Steiner* (lecturer) and *K. Horle* [*]

The occurrence of a phase separation is of considerable importance for the control of the industrial high-pressure polymerization of ethylene, since the separation into a monomer phase and a polymer phase can not only influence the kinetics

of the reaction, but can also lead to deposition of polymer films on the inside wall of the reactor.

The phase behavior of ethylene-polyethylene mixtures has therefore been investigated in the range 1200—2000 atm and 180—240 °C by an optical method [1], the measurement being carried out during the polymerization to avoid measuring errors due to delayed dissolution of the polymer [2]. The principle of this method is that the intensity of light passing through the reaction mixture is very strongly reduced in the two-phase region by scattering, and a switch from light to dark consequently occurs on phase separation. A special micro-stirrer vessel with two opposing pressure-resistant sapphire windows 3 mm in diameter was constructed for this investigation. This reactor can be operated continuously and is connected on the one hand to a compression system and on the other to product separators and analytical equipment.

Since the polymer concentration in the reaction mixture cannot be specified in advance, but is determined by the pressure, temperature, and initiator concentration, the conversion was determined by weighing the polymer collected, or, if the reaction time was insufficient for such a determination, was calculated from kinetic equations [3].

The results show that a miscibility gap occurs, and extends into the industrially interesting range above 1500 atm. At constant temperature, the phase separation curves have an upper critical phase separation point above which polyethylene and ethylene are miscible in all proportions. This critical phase separation point is displaced toward lower pressures and higher polymer concentrations with rising temperature. The displacement is however limited, since polyethylene and ethylene decompose at excessively high temperatures, and the polymer crystallizes at excessively low temperatures. No dependence of the phase separation curves on the average molecular weight could be detected in the range investigated.

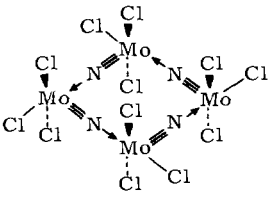
The Crystal Structure of Molybdenum Nitride Trichloride, $MoNCl_3$

By *J. Strähle* [*]



Molybdenum nitride trichloride crystallizes in the triclinic system (space group $P\bar{1}$) with four formula units per unit cell and with the lattice constants $a = 9.14$, $b = 7.67$, $c = 8.15$ Å, $\alpha = 108.8°$, $\beta = 99.3°$, and $\gamma = 108.6°$. The crystal structure was deduced with the aid of three-dimensional Patterson and Fourier syntheses and refined by the method of least squares to an R value of 5.8% (1600 reflections, MoKα-radiation).

$MoNCl_3$ molecules are present in the crystal structure, but these are strongly associated *via* nitrogen bridges to form tetramers. The tetramers are in turn loosely linked *via* chlorine bridges and form undulating layers parallel to (010). Each Mo atom is surrounded by four Cl and two N atoms to give a strongly distorted octahedron. The individual molecules, which are strictly speaking asymmetric, have a pseudo-reflection plane containing one Cl atom and the Mo and N atoms. The association of the four molecules of the unit cell to give the tetrameric unit is such as to give approximately the point symmetry 4/m (pseudo-reflection plane m parallel to $(03\bar{1})$). The Mo atoms form approximately a square with the N atoms on its sides.

Angles: Mo(1)-N(1)-Mo(2′) = 167.3°, Mo(2)-N(2)-Mo(1) = 178.1°.

Mo-N-distances: Mo(1)-N(1) = 1.64 Å, N(1)-Mo(2′) = 2.20 Å; Mo(2)—N(2) = 1.67 Å, N(2)-Mo(1) = 2.14 Å

These data point to the bonding scheme indicated for the tetrameric unit.

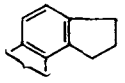
Metal-Catalyzed Aromatization of Unsaturated C_{18} Carboxylic Acids

By *H. J. Strauss* (lecturer), *W. R. Eckert*, and *J. D. von Mikusch* [*]



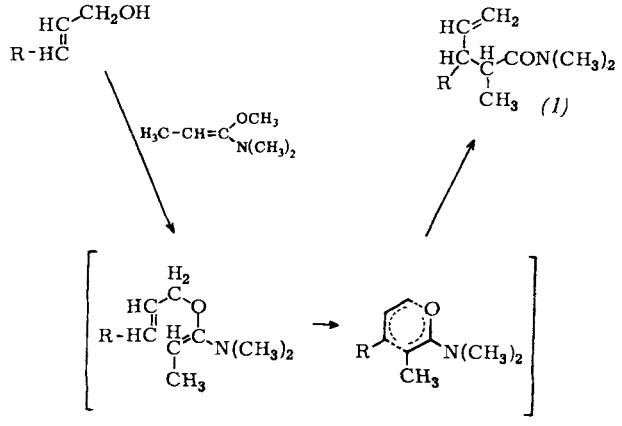
When unsaturated fatty acids are heated with palladium or platinum catalysts, aromatic fatty acids are formed, as is shown for the methyl esters of linseed oil fatty acids, tung oil fatty acids, linoleic acid, oleic acid, and elaidic acid. The aromatic fatty acids are isolated by treating the product with urea to remove straight-chain fatty acids by adduct formation. They consist essentially of the 11 isomers *(1)* having $n = 0$—10. The products *(2)* and *(3)* are also observed.

(1), n + m = 10

(2), n + m = 8

$R^1 = CH_3$ or C_2H_5
$R^2 = (CH_2)_7COOH$ or $(CH_2)_6COOH$

(3), R^1 and R^2



The course of the reaction with time has been studied for the methyl esters of linseed oil fatty acids and of oleic acid with Pd/C as the catalyst at 270 °C. Rapid *cis-trans* isomerizations and double bond shifts occur at first, as shown by IR and UV spectroscopy as well as by oxidation of the unsaturated straight-chain carboxylic acids. The aromatization involves dehydrogenation, the hydrogen being taken up by an unsaturated C_{18} carboxylic acid. Polyunsaturated acids first yield aromatic fatty acids of all types and octadecenoic acids. The monoenoic carboxylic acids are subsequently disproportionated at 270 °C, leading to the formation of aromatic fatty acids *(1)* and stearic acid. If the aromatization is carried out at 180 °C, monoenoic acids remain in the final product.

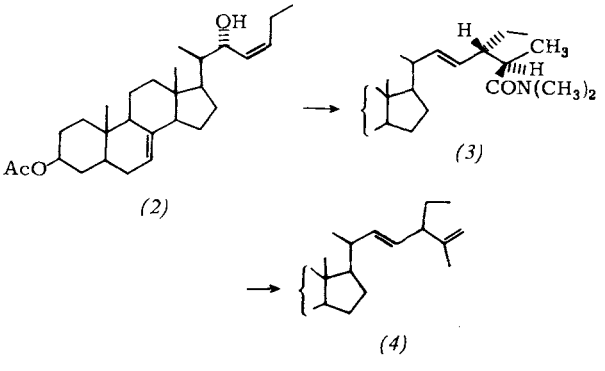
Formation of Amides by Claisen Rearrangement of Ketene *O,N*-Acetals; Stereochemistry



By *W. Sucrow* (lecturer) and *B. Girgensohn* [*]

We have recently applied the rearrangement of allylketene *O,N*-acetals, which was studied by *Eschenmoser* [1], to methylketene *O,N*-acetal in the synthesis of santolinatriene [2]. The reaction leads predominantly to one of the two epimers of *(1)*, R = $(H_3C)_2C{=}CH$

With 2-buten-1-ol as a model (R = CH_3), it can be shown that the rearrangement proceeds stereoselectively. *trans*-Butenol gives mainly (about 85%) *erythro-(1)*, while *cis*-butenol gives mainly (about 90%) *threo-(1)* (recognizable from the NMR spectra, confirmed by Lemieux degradation and hydrolysis to the dimethylsuccinic acids). Since the configuration of the ketene *O,N*-acetal double bond is unknown, this result can be explained either by a chair-form transition state (cf. [3], ketene acetal then having the Z configuration), in which both methyl groups would be quasi-axial with *cis*-butanol as the starting material, or by a boat-form transition state (ketene acetal then having the E configuration).

In the synthesis of the sterol side chain of *(4)*, the rearrangement proceeds practically stereospecifically. The Δ^{23}-*cis*-steroid alcohol *(2)* forms a practically uniform amide *(3)*, which has the *threo* configuration if the rearrangement mechanism corresponds to that of butenol. The configuration of the alcohol group in *(2)* (probably 22 β_F) must be transferred to C-24 of *(3)*, according to model considerations. Reduction with $LiAlH_4$ and Cope degradation gives the sterol of natural configuration as in pumpkins. The epimeric alcohol of *(2)* leads to the 24-epimeric sterol *(4)*.

Temperature Dependence of the Reaction Rate of Enzymes

By *G. Talsky* (lecturer) and *W. Müller* [*]

The investigation of the temperature dependence of the reaction rates of a series of native and modified enzymes with their substrates, including lipase [1], xanthine oxidase [2] urease [3], papain [4], trypsin [5], chymotrypsin [5], and ribonuclease showed that the deviations observed in the Arrhenius diagram, *i.e.* the curvature of the line or two intersecting straight lines, can be resolved into a trend line if measurement is carried out over sufficiently small temperature intervals. It is therefore impossible to give a uniform experimental activation energy for an enzyme substrate system over a large temperature range in the absence of larger amounts of buffers and salts; it is necessary instead to distinguish in addition to practically linear sections, temperature ranges in which temperature anomalies occur.

The ranges of anomalous temperature behavior can be displaced or made to disappear by variation of the reaction medium. The results led to the conclusions that enzymes exist in more than one active conformation, and that these conformations can change into one another within a few degrees. Assuming an equilibrium between pairs of active forms of the enzyme and a cooperativity of 80–100 interactions per enzyme molecule, the experimental course of the curve can be satisfactorily calculated. The anomalous temperature behavior is demonstrated for the case of the systems ribonuclease A/cyclic cytidine phosphate and RNase/ribonucleic acid.

Preparation and Investigation of Zirconium Phosphate Exchangers Exhibiting Separation Properties for Lanthanides and Actinides

By *J. Treplan* (lecturer) and *H.-J. Born* [*]

In the search for ion exchangers having high resistances to radiation, attempts were made to vary *Amphlett*'s method in such a way as to give products having the highest possible ion exchange capacity for the trivalent actinides and lanthanides.

Particular attention was paid to fixing the conditions for the preparation so that reproducible products could be produced. The chemical and physical properties of the zirconium phosphate preparations obtained by variation of the conditions were investigated.

A capacity of 0.12 to 1.81 mequiv/g was found at pH = 4 for the trivalent ions (test substance Eu^{3+}). The capacity for monovalent elements is between 0.19 and 2.3 mequiv/g. These values were also confirmed by potentiometric titration.

The partition ratios of some lanthanide and actinide elements in the system zirconium phosphate-HCl were determined in batch experiments, the dependence of the partition ratios on the acid strength corresponding to the theoretical values. It was found advantageous to use higher temperatures.

To elucidate the structure of the product the ratio Zr : phosphate was first determined. The gravimetric and activation analysis method gave a ratio of 1 : 2 which agrees with the

structure suggested by *Blumenthal*. The loss on drying and the change in capacity were determined for the various preparations at 30, 45, 75, and 105 °C, as were the losses on heating between 105 and 1000 °C. Solubility studies with hydrochloric acid at various concentrations gave an average loss of 6% when the exchanger was in the NH_4^+ form.

Preliminary values for the radiation resistance of the preparations was obtained by γ irradiation in the Munich research reactor. Surprisingly, it was found that for radiation times of up to 16 hours at a dose rate of 10^8 rad/h, the capacity for Cs^+ increased by up to 30%, depending on the irradiation time. The capacity for europium on the other hand reaches a maximum, also corresponding to an increase of about 30%, after irradiation for 4 hours, and then falls back to its original value.

Quantitative Separation of Several Fission Products with Ion Exchangers

By *H. Völler* (lecturer), *H.-J. Born*, *G. Höhlein*, and *W. Weinländer*[*]

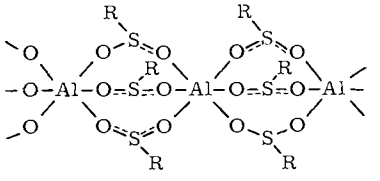
A process is described in which several fisson products from neutron-irradiated ^{241}Am can be separated with the aid of ion exchangers in a single separation step and determined spectroscopically.

A simple combined ion-exchange separation unit with an anionic first column (Dowex 1X8, 200—400 mesh) followed by a cationic column, (Aminex, marketed by Biorad Laboratories, grain size 15 μm) was designed. With a view to operation in a glove box, this method involves only a few, uncomplicated steps. Extensive investigations on elution conditions and their parameters as well as on operating procedures were therefore necessary. For the optimization of the separation steps, series investigations were carried out, *e.g.*, on the influence of the grain size of the exchanger, the flow rate of the eluate, the activity in the columns, and the construction of the columns. The separation method has been tested with a mixture of the radionuclides ^{95}Zr, ^{95}Nb, ^{106}Ru, ^{110m}As, ^{137}Cs, ^{115}In, ^{115}Cd, ^{133}Ba, ^{154}Eu, and ^{140}La in tracer quantities.

^{95}Zr and ^{95}Nb were quantitatively absorbed, together with most of the ^{106}Ru (up to 98%), in the strong oxalic acid solution on the anion exchanger. The other nuclides pass quantitatively and are retained on the following cationic column. Zirconium and niobium can be selectively desorbed from the anion exchanger with a mixture of very dilute oxalic acid and dilute nitric acid. The ruthenium in the anion column appears in the eluate with dilute sodium hydroxide solution or very concentrated hydrochloric acid, sodium hydroxide solution being preferred because of its more favorable elution band (greater symmetry, smaller width). A group separation of the monovalent, divalent, and trivalent cationic fission products is carried out on the Aminex column with nitric acid. Owing to the small grain diameter of the Aminex resin, the elution bands of the nuclides are very narrow, and a relatively good separation of the elements within the individual groups is possible with suitably chosen elution conditions.

Owing to the large quantity of the target material ^{241}Am in relation to the fission products, a broad americium band, which overlaps with neighboring elution bands, occurs in the lanthanide-actinide group. This is avoided by oxidation of the Am to Am^V, whose elution band appears sooner.

The elements of the important lanthanide group are separated on the cation exchanger Aminex by the "pH gradient method" with α-hydroxyisobutyric acid.



The investigations were carried out in a glove box, which was fitted with a gamma- and an alpha(beta)-through flow measuring device for following the elutions and with special devices that allow the removal of the resulting nuclide fractions without contamination for spectroscopy.

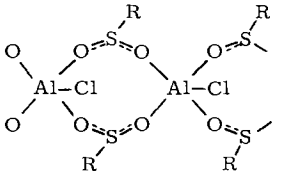
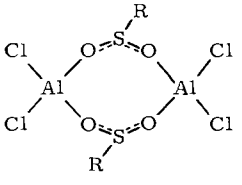
Cleavage of Aluminum-, Gallium-, and Indium-Carbon Bonds with SO_2, CO_2, COS and CS_2



By *J. Weidlein*[*]

The reaction of trialkylaluminum or its ether adducts with gaseous or liquid SO_2 leads to alkanesulfinates of aluminum. All three Al—C bonds are broken with strong evolution of heat. The products are pure white, highly polymeric solids, which are completely insoluble in organic solvents and whose hydrolysis leads in good yields to alkanesulfinic acids, which can otherwise be obtained only with difficulty[1]. On the basis of the IR spectra, the structure *(1)* with hexacoordinate Al atoms and —O—SR—O— bridges can be postulated.



(1)

Halogen- or pseudohalogen-monosubstituted dialkylaluminums (R_2AlX with R = CH_3, C_2H_5 and X = Cl, Br, SCN) react with SO_2 to form white hygroscopic solids, which are insoluble in apolar solvents but dissolve readily in liquid sulfur dioxide. Alkylaluminum dihalides ($RAlHal_2$ with R = CH_3, C_2H_5 and Hal = Cl, Br) can be converted by SO_2 into highly viscous, colorless, thermally very unstable, and hygroscopic oils, which also dissolve in organic solvents (dimeric in benzene). The IR and Raman spectra of the compounds are compatible with the structures *(2)* and *(3)*.

(2)

(3)

The reactions of trialkylgallium[2] and trialkylindium with SO_2 lead to the cleavage of only one metal-C bond. The products are dimeric, liquid or solid dialkylmetalalkanesulfinates, which are soluble in organic solvents, and whose vibration spectra (IR and Raman) as well as ^1H-NMR measurements point to 8-membered ring skeletons similar to *(3)*, presumably with only slight undulation. Halogen-substituted organogallium and organoindium compounds do not react with SO_2.

Gaseous CO_2 (at normal pressure and elevated temperatures) can cleave only one metal-carbon bond in Al-, Ga-, and In-trialkyls. Whereas only dimeric dialkylmetallocarboxylic acid derivatives are formed in the case of Ga and In, with Al trimeric and more highly associated oligomers can be isolated. Dimeric molecules are the sole products of reaction of the trialkyls (or their addition compounds with ether) with the amount of pure carboxylic acid calculated for exchange of one alkyl group for a RCOO group. (Formation of one mole of alkane.) IR, Raman, and ^1H-NMR spectra show that the

eight-membered parent system of the dimeric dialkylcarboxylic acid compounds of Al, Ga, and In is isosteric with the ring system of the dialkylsulfinates of Ga and In.

Cleavage of the metal-carbon bond in the trialkyls of Al, Ga, and In can also be achieved with COS and CS_2. The thermally unstable and hygroscopic solids formed in this reaction can be assigned a structure analogous to the SO_2 and CO_2 "insertion compounds" on the basis of physical measurements.

Experience in the Isolation of ^{242}Cm in the Kilocurie Range

By *H.-J. Born, G. Höhlein, D. Pabst, B. Schütz, S. Specht, H. Völler*, and *W. Weinländer* (lecturer) [*]

A method for the separation of ^{242}Cm on the kilocurie scale from neutron-irradiated americium targets has been developed and tested. It was particularly important to prepare the curium free from impurities and to obtain the ^{241}Am and the plutonium isotopes quantitatively. After dissolution of the aluminum irradiation capsule with 8 N NaOH followed by filtration, the oxides of Am, Cm, Pu and the fission products are dissolved in 12 N HCl. Approximately 0.1 N I^- is added to ensure that the Pu is trivalent after dissolution.

The solution is then pumped through an anion exchanger (AG 21 K); Zr (Kd $\approx$ 100) and Nb (Kd $> 10^4$) are completely adsorbed while Ru (Kd $\approx$ 20—30) is partly adsorbed. The remaining ions pass through the exchanger.

After subsequent dilution the entire solution is pumped through a cation exchanger. Most of the monovalent ions largely pass through immediately. The rest of the monovalent ions, the divalent ions, and the remainder of the Ru are then eluted with 1 N H_2SO_4. In order to bring the plutonium into the tetravalent state traces of NO_2^- are added to the sulfuric acid. 9 N HCl (20% methanol) is then used for desorption of Pu^{IV}, Am^{III}, and Cm^{III}, while the lanthanides still remain on the column. The Pu^{IV} is quantitatively removed from the solution by adsorption on a second anion exchange column. After concentrating the solution and adjusting its acid strength to 1 N, the solution, containing mainly Am and Cm together with traces of lanthanides, is adsorbed on top of a cation column, and then Am and Cm are separated with α-hydroxyisobutyric acid. This step had been checked earlier with approximately 100 Ci of ^{242}Cm.

The separation process was tested and optimized in inactive runs. The "hot" experiment showed that great difficulties were created by the radiolysis of the solvent and of the ion exchanger. Since cation exchangers are completely destroyed by a dose of 10 Wh/g, and anion exchangers by much smaller doses, special attention must be given to this point. However, the decomposition of the solvent and the consequent formation of gas bubbles, which interferes in particular with the operation of the anion exchanger, is even worse. In the case of the cation exchanger this problem could be largely overcome by the addition of methanol.

The Cm fraction obtained is then converted into the oxide by readsorption on a cation exchanger followed by ashing of the exchanger bed at about 800—1000 °C. The Cm is obtained as the oxide in a very clean state; yield about 90%.

ESR Studies on the Mechanism of the Radiolysis of Polystyrene

By *J. Wilske* (lecturer) and *H. Heusinger* [*]

The formation of free radicals and radical-pairs in polystyrene under the action of ionizing radiation has been investigated as a function of temperature.

It has been shown that the radical-pairs formed in polystyrene do not consist of radicals that were accidently formed close together; on the contrary, the two radicals are formed almost simultaneously as a result of the same primary act of absorption. The average distance between these radicals is about 20 Å; this distance remains approximately constant as the dose is increased.

The following reactions, which were proposed by *Voevodskii* [1] and *Libby* [2], are possible for the formation of these radicals:

$$R_aH^+ + e^- \rightarrow R_a^\bullet + H_{kin}$$
$$R_bH + H_{kin} \rightarrow R_b^\bullet + H_2$$
$$R_aH^+ + R_bH \rightarrow R_aH_2^+ + R_b^\bullet$$
$$R_aH_2^+ + e^- \rightarrow R_a^\bullet + H_2$$

In the first case the closely adjacent radicals R_a and R_b are formed by the reaction of a "hot" hydrogen atom, and in the second case by an ion-molecule reaction.

When polystyrene is heated to 20 °C, the radical-pairs recombine in a first order reaction. It is assumed that this involves chain cross-linking:

$$R_a^\bullet + R_b^\bullet \rightarrow R_aR_b$$

The formation of free radicals and of radical-pairs at −196 °C is not influenced by the addition of pyrene. Even when the polystyrene is warmed to 20 °C, the free-radical concentration remains independent of the pyrene content; the recombination of the radical-pairs is also unaffected by pyrene.

On irradiation at 20 °C, the free radical formation decreases by a factor of 10 at a pyrene content of 3% in the polystyrene, whereas the formation of chain crosslinks is independent of the pyrene content.

To explain these results, it must be assumed that the free radical formation proceeds by two different mechanisms at high and low temperatures. At high temperatures (20 °C) the radicals are formed mainly *via* excited states of the polystyrene (energy transfer to pyrene possible), while at low temperatures they are formed *via* ionized states.

Polymers from Tetracyano Compounds

By *D. Wöhrle* (lecturer) and *G. Manecke* [*]

We have examined several possibilities for the synthesis of conjugated polymers from tetracyano compounds and compared the semiconductor properties of these polymers.

Some of the monomeric tetracyano compounds have poor electric conductivities; tetracyanobenzene, tetracyanothiophene, tetracyanofuran, and tetracyanoethylene: $\sigma_{300\,°K} < 10^{-15}$ ohm^{-1} cm^{-1}. Other monomers, on the other hand, exhibit good semiconductor properties, *e.g.* some bis(*cis*-1,2-dicyanoethylene-1,2-dithiolato)metalates [1] such as *(1)*, for which $\sigma_{300\,°K} = 5.0 \times 10^{-2}$ ohm^{-1} cm^{-1}.

Polymers having hemiporphyrazine-like structures [2] have been synthesized by reaction of the tetracyano compounds

Cu^{2+} *(1)*

with diamines such as 2,6-diaminopyridine. In the presence of metal salts at higher temperatures, tetracyano compounds give polymers with phthalocyanine-like structures[3,4]. The reaction of the tetranitriles in basic reaction media, *e.g.* in quinoline, led at high temperatures to polymers with a triazine-like structure[4].

The products in every case were perconjugated, dark, infusible polymers, mostly characterized by good electric properties: $\sigma_{300\,°K} = 3.9 \times 10^{-2}$ to 7.2×10^{-14} ohm^{-1} cm^{-1}. In the case of the polymeric phthalocyanines it was found that the conductivities increase with increasing aromatic character of the polymer unit from furan *via* thiophene to benzene. It was also possible, for polymeric phthalocyanines containing different metals, to describe the influence of the ionization potential of the metal on the conductivity.

The phthalocyanines are better conductors than the hemiporphyrazines, since the phthalocyanine system is more strongly aromatic, and so exhibits a stronger electronic ring current, than the hemiporphyrazine system. In the case of the highly conducting polymers obtained from the bis(*cis*-1,2-dicyanoethylene-1,2-dithiolato)metalates, the nature of the metal atom has no great influence.

Energy and Isotope Dependence of the Chemical Behavior of Molybdenum Recoil Atoms in Hexacarbonylmetal Compounds Following Nuclear Reactions

By *E. Henrich* and *G. Wolf* (lecturer)[*]

As has been shown by numerous investigations, the chemical behavior of recoil atoms produced by nuclear reactions can be influenced by the recoil energy, and also varies from isotope to isotope of an element. In most experiments, recoil atoms having different energies have been produced by different nuclear reactions (n, γ; n, 2n; γ, n reactions). However, these reactions always led to different isotopes of an element, so that the energy effect and the isotope effect could not be clearly separated. To avoid this, a series of target elements (Mo to In) were bombarded with 600 MeV protons. Both ^{90}Mo and ^{93m}Mo were formed together with other products. The recoil energies of these two species varied with the mass number of the target element.

The targets were irradiated in close contact with hexacarbonylmetal compounds so that some of the recoiling Mo atoms could penetrate into the carbonyl. A selective reaction took place between some of the Mo recoil atoms and the catcher, with formation of hexacarbonylmolybdenum, which could be separated from the other products, together with the catcher, by sublimation or extraction.

The yield of this reaction was always the same for a given isotope irrespective of the target, *i.e.* irrespective of the recoil energy within the limits considered. Moreover, the ^{93m}Mo yield was always about 10% higher than the ^{90}Mo yield, irrespective of the target. Similar results were obtained on irradiation of hexacarbonylmolybdenum with fast neutrons having energies of up to 50 MeV, in which the same Mo isotopes are formed.

This energy-independent isotope effect is explained as follows: ^{90}Mo is still in an excited nuclear state after being slowed down in the catcher, and some of the bonds already formed are broken again as a result of its decay by γ emission or electron conversion. ^{93m}Mo, on the other hand, has no nuclear level that is sufficiently long-lived to cause such a delayed effect.

Radio Frequency Polarographic Studies on Semiconductors and Reactor Materials

By *I. Büker* and *G. Wolff* (lecturer)[*]

Modern polarographic methods have recently assumed increasing importance alongside emission spectroscopy, mass spectrometry, and activation analysis for the trace analysis of semiconductor materials and of light metals and steels used as structural materials for modern reactors[1]. One of these new methods, in which the detection of the polarization current is based on the rectification effect caused by the non-linearity of the current-voltage curve, is radio frequency polarography.

It is possible with the aid of the rectification technique to reach detection limits of a few 10^{-9} to 1×10^{-8} mol/l for metal ions. Accordingly, with suitable preparation of the sample material and careful choice of the electrolyte, impurities in the solids can be detected down to the range of 5—10 ppb, *i.e.* 5 to 10×10^{-9} g of impurity/g of sample. In the electrochemical technique used here a very simple preparation of the sample is often sufficient, so that the introduction of impurities with impure chemicals is largely avoided. On the other hand, the method requires a fairly accurate knowledge of the relations between signal size, signal position, and double layer parameters. Thus an optimum detection limit is obtained, *e.g.*, only if the high frequency amplitude over the double layer is accurately adjusted to suit the ion being analyzed. Another factor that has an important effect on the step height is the pH value of the electrolyte, which must be kept within very narrow limits in some cases, particularly in the analysis of light metal.

If due attention is paid to all these points, this method is as effective as the others mentioned above.

Inverse-Voltammetric Determination of Tin and Lead in the Presence of each Other

By *K. Zinke* (lecturer) and *H. Monien*[*]

The determination of tin and lead in the presence of each other is difficult both by the hanging mercury drop and by the dropping mercury electrode, since the electrochemical properties of the two elements differ only slightly. The elements can, however, be determined in the presence of each other by the use of the carbon paste electrode. Lead is determined by oxidation at an electrolysis potential of +1.4 V. The PbO_2 formed accumulates on the electrode surface and redissolves on subsequent reduction with a current wave. The

current maxima are proportional to the quantity of Pb deposited. In a tartrate-buffered electrolyte, 20—100 ng of Pb/ml can be determined in this way in the presence of a 100-fold excess of tin.

Another possible method of concentration is the adsorption of a metal-dye complex on the electrode surface. In this case there is no need to apply a potential to the carbon electrode. Tin is determined *via* the oxidation of a tin-dye complex, which is adsorbed on the electrode surface after the electrode has been in the solution to be analyzed for 5—10 minutes. On subsequent scanning of the anode potential, an oxidation signal that is proportional to the quantity of tin adsorbed is obtained at +0.720 V. Out of several complexing agents that react with Sn but not with Pb, hematein has proved to be particularly suitable. The complexing agent dissolved in dioxane reacts at pH 3.7 to 4.0 both with Sn^{2+} and with Sn^{4+} ions to form a precipitate. A method is described for the determination of 10—100 ng of Sn/ml in the presence of a 10^5-fold excess of lead and zinc with a relative standard deviation of 7%. The permissible excess of Fe^{3+} is 10^3, of Cu^{2+} is 10^2, and of Sb^{3+} is 10. In a standard Pb alloy containing 0.005% of Sn, the Sn could be determined with a relative standard deviation of about 5%. [VB 212 IE]

SELECTED ABSTRACTS

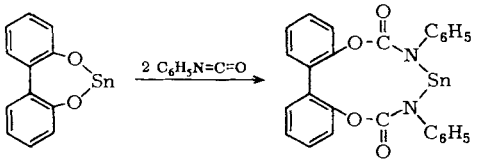
The first allowed triplet-triplet absorption band of benzene has been detected by *R. Astier* and *Y. H. Meyer* at 430 nm. It was detected in the flash photolysis of a 3×10^{-2} M solution of benzene or hexadeuteriobenzene (425 nm) in methanol-ethanol (1:3) in a 20 cm cell at about 100 °K. By simultaneous measurement of the lifetimes of the phosphorescence and the 430 nm absorption at various temperatures it was established that a triplet-triplet absorption was involved. The extinction coefficient of the 430 nm band may be of the order of 10^4. / Chem. Physics Letters *3*, 399 (1969) / —Hz. [Rd 82 IE]

The reactions of disulfur dinitride with antimony pentachloride and with boron trihalides have been studied by *R. L. Patton* and *W. L. Jolly*. A solution of S_2N_2 in CH_2Cl_2 reacts with an excess of $SbCl_5$ to give the diadduct *(2)*, which is converted into the monoadduct *(1)* by further S_2N_2. Compound *(1)* adds $SbCl_5$ to form the diadduct *(2)*, any excess of S_2N_2 dimerizing to S_4N_4. *(1)* (orange needles) melts at 108—109 °C (decomp.) in a sealed tube and sublimes in a vacuum at 60 to 70 °C; *(2)* (yellowish crystals) melts at 130—131 °C with decomposition. The IR spectra show that the S_2N_2 ring remains intact in both compounds; in *(1)* it is planar or folded, and in *(2)* planar. S_2N_2 reacts with *(1)* in CH_2Cl_2 to give the known compound $S_4N_4SbCl_5$, containing the eight-membered S_4N_4 ring, as well as $(S_4N_4SbCl_5)_x$.

(1)

(2)

In CH_2Cl_2, S_2N_2 reacts with BCl_3 to yield $S_4N_4BCl_3$, $S_2N_2(BCl_3)_2$, and $(S_2N_2BCl_3)_x$. At 0 °C, the diadduct corresponding to *(2)* affords the monoadduct, which gives the diadduct on renewed addition of BCl_3 at −78 °C. $SbCl_5$ can displace BCl_3 from $N_2S_2BCl_3$ to yield $N_2S_2(SbCl_5)_2$ *(2)*. The sole product formed on reaction of BF_3 and N_2S_2 is $S_4N_4BF_3$./ Inorg. Chem. *8*, 1389, 1392 (1969) / —Kr. [Rd 85 IE]

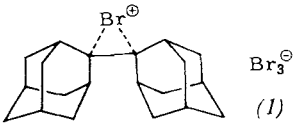


Dichlorodimethylpentanedionatoantimony(v) *(2)* (and two similar stable methylantimony(v) complexes) have been prepared by *N. Nishii, M. Shindo, Y. Matsumura*, and *R. Okawara* at low temperature from chlorodimethylstibine, sulfuryl chloride, and Na pentanedionate (Na-acac).

$$(CH_3)_2SbCl + SO_2Cl_2 \rightarrow \underset{(1)}{(CH_3)_2SbCl_3} \xrightarrow{\text{Na—acac}} (CH_3)_2SbCl_2(acac)$$

(2), m.p. 176 °C (decomp.)

The stable trichlorodimethylantimony(v)-DMSO, m.p. 147.5 °C, crystallizes on addition of DMSO to a solution of the unstable compound *(1)* in methanol. Trichloromethylpentanedionatoantimony(v) was obtained from CH_3SbCl_2, SO_2Cl_2, and 2,4-pentanedione (m.p. 110—111 °C). / Inorg. nuclear Chem. Letters *5*, 529 (1969) / —Kr. [Rd 86 IE]



Phenyl isocyanate inserts into the tin^{II}-oxygen bond, as has been found by *P. G. Harrison* and *J. J. Zuckerman*. These authors obtained grayish-white *(2)*, which decomposes at ≈300 °C, in 97% yield after refluxing 5,7-dioxa-6-stanna^{II}-dibenzo[*a,c*]cycloheptene *(1)* (prepared from SnO and 2,2-dihydroxybiphenyl) in toluene for 50 hours. *(2)* appears to be

(1) *(2)*

the only compound known having an Sn^{II}-N bond. No final distinction can be made between *(2)* and an alternative form containing the —O—C(=NC$_6$H$_5$)—O—Sn grouping [instead of —O—CO—NC$_6$H$_5$—Sn— as in *(2)*] on the basis of the IR or Mössbauer spectrum. / Inorg. nuclear Chem. Letters *5*, 545 1969) / —Kr. [Rd 87 IE]

The isolation of the stabilized bromonium compound *(1)* has been accomplished by *J. Strating, J. H. Wieringa*, and *H. Wynberg*. Compound *(1)*, which is a comparatively stable yellow substance, precipitates on treatment of biadamantylidene with bromine in CCl_4, and could not be recrystallized owing to its insolubility. If the suspension is heated to 40 °C

(1)

with a KI solution, bromine and the hydrocarbon are liberated again. This finding, together with the empirical formula and the fact that no bromine-substitution products are present (mass and IR spectrum), suggested the bromonium structure. / Chem. Commun. *1969*, 907 / —Kr. [Rd 88 IE]

The reactions of methyl radicals with silane, disilane, phenylsilane, and their Si-deuterated analogs, which proceed *via* H or D abstraction, have been studied by *O. P. Strausz, E. Jakubowski, H. S. Sandhu,* and *H. E. Gunning*. The methyl radicals were produced by photolysis of azomethane and the product distributions determined by mass spectrometry and gas chromatography. Silanes are more reactive than hydrocarbons; the activation energies of the reactions are lower, while the pre-exponential factors are equal. The reactions

$$CH_3^{\bullet} + CH_4 = CH_4 + CH_3^{\bullet} \quad (1)$$

and

$$CH_3^{\bullet} + SiH_4 = SiH_3^{\bullet} + CH_4 \quad (2)$$

are compared as an example: the activation energies are 14.65 kcal mole^{-1} for eq. (1) and 6.99 kcal mole^{-1} for eq. (2); the logarithms of the pre-exponential factors are 11.83 cm^3 mole^{-1} s^{-1} for eq. (1) and 11.80 cm^3 mole^{-1} s^{-1} for eq. (2). / J. chem. Physics *51*, 552 (1960) / —Hz. [Rd 102 IE]

Trimethyltin isothiocyanate is reported by *R. A. Forder* and *G. M. Sheldrick* to consist of zig-zag chains containing linear S · · · Sn—N—C—S units arranged along the *z* axis of the orthorhombic unit cell (a = 13.20, b = 10.28, c = 12.01, all ±0.01 Å; Z = 8; $d_{calc.}$ = 1.82 g/cm^3), the bond angle at the S atom being 97 ± 2 °. The C_3Sn unit is almost planar with d SnC = 2.13 ± 0.03 Å. The interatomic distances are S · · · Sn 3.13 ± 0.02, SnN 2.15 ± 0.06, NC 1.15 ± 0.07, and CS 1.64 ± 0.07 Å; the bond lengths in the NCS group lie between those in HN=C=S and CH_3S—C≡N and thus suggest resonance of the kind

$$=S\cdots Sn-N=C=S\cdots Sn-N= \leftrightarrow -S-\overset{\ominus}{Sn}-\overset{\oplus}{N}\equiv C-S-\overset{\ominus}{Sn}-\overset{\oplus}{N}\equiv$$

which requires no contributions from $(p\rightarrow d)_\pi$ bonding to explain the stereochemistry. / Chem. Commun. *1969*, 1125 / —HB. [Rd 104 IE]

The IR spectrum of CO in zeolites has been subjected to investigation by *P. J. Fenelon* and *H. E. Rubalcava*. It can be deduced from the differences between the spectra of pure $^{12}C^{16}O$ and a mixture of $^{12}C^{16}O$ and $^{13}C^{16}O$ that CO can rotate relatively freely in the cavities of Na zeolites (diameter of cavity in Na zeolite 11.4 Å, effective diameter of the rotating CO molecule approx. 4.5 Å). The spectrum corresponds approximately to that of CO gas at 50 atm. In Ca zeolites, where considerably stronger adsorption forces occur, the spectrum resembles that of liquid CO. It can be interpreted if a relatively high threshold potential is assumed for the rotation. / J. chem. Physics *51*, 961 (1969) / —Hz. [Rd 107 IE]

The conductivity of aqueous electrolyte solutions in shock waves has been studied by *S. D. Hamann* and *M. Linton*. The molar conductivity of KCl does not change significantly in shock waves up to 140 kbar; although the temperature jump should increase the mobility of K^+ and Cl^-, this effect is cancelled by the simultaneous increase in the density. On the other hand, the conductivities of KOH and HCl are increased several-fold, signifying that the additional mobilities of H_3O^+ and OH^- increase by a factor of 3 to 4 under shock-wave conditions. The ionic product of water is estimated as 0.09×10^{-6} mole^2 g^{-2} at a shock-wave pressure of 133 kbar. A careful extrapolation permits the assumption that water is almost completely dissociated at 200 kbar and then possesses properties similar to a fused salt. A discontinuity in the compressibility curve of water in the region around 150—200 kbar lends further support to such a concept. / Trans. Faraday Soc. *65*, 2186 (1969) / —Hz. [Rd 108 IE]

BOOK REVIEWS

Carbene, Carbenoide und Carbenanaloge (Carbenes, Carbenoids, and Carbene Analogs). By *W. Kirmse*. Vol. 7 of "Chemische Taschenbücher", edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie GmbH., Weinheim/Bergstr. 1969. 1st Edit., 260 pp., 4 figs., 26 tables, paperback DM 18.—.

One of the focal points of organic chemical research during the past decade has been the detection of short-lived intermediates and this has simultaneously given a new impulse to preparative work. This intimate mixture of theory and practice is illustrated in *Kirmse*'s book on Carbenes, Carbenoids, and Carbene Analogs. The author is an expert and successful research worker in the outlined field and has mastered his task in the concise style required by a pocket book.

He begins with an introduction to the theory of particles containing bivalent carbon, passes to their reactivity in the gas phase (where carbenes have been demonstrated beyond dispute), and then turns to their reactions in solution. Here there is a high probability that occurrence of carbenes must be taken into account, so far as they are produced by photolysis or thermolysis of diazo compounds. Their characteristic reactions are set out briefly and clearly with a large number of examples.

The critical basis for the probability of production of carbenes or carbenoids is also presented. This is important for the evaluation of reaction mechanisms with carbenoids prepared by different methods, particularly those which are organometallic. The next chapter concerning intramolecular reactions introduces the reader to the role of carbenes and carbenoids in synthetic planning, to the extent that one recognizes that they permit access to unusual ring structures which are otherwise scarcely obtainable. — In the preparative section, the synthesis of cyclopropane derivatives is given prominence. These structures are able, in turn, to give interesting transformations, either during the process of formation or thereafter. The final chapter deals with carbene analogs. Fascinating studies are described here concerning the reactivity of carbon in the vapor phase and of the nitrenes. The chemistry of these species corresponds in many respects to that of carbenes.

The art of omission, which will not please everyone, is here well warrented. The essential points (literature up to 1968 inclusive) have been clearly brought out by the author. Apart from some misprints, the book can be warmly recommended to all scientists, particularly to organic and organometallic chemists.

G. Wittig [NB 827 IE]

Organometallic Chemistry. By *P. L. Pauson*. Edward Arnold (Publishers) Ltd. Maidenhead 1967. 1st Edit., 202 pp., stitched 30s., bound 50s.

According to the author, who is Freeland Professor of Chemistry at the University of Strathclyde, Glasgow, this book is intended, not for specialists, but as a general introduction for advanced students.

A general, very concise introductory section on structure, bonding, and thermochemical data is followed by skillfully

presented chapters dealing with methods of preparation, properties, and reactions of organic compounds of metals of the main groups and of the triads. In the chapter on catalytic processes, insufficient attention is given to exchange and reorientation phenomena in intermediate complexes, *i.e.* the dynamic aspects of the metal-catalyzed reactions. The reader making his first contact with organometallic chemistry may find the book difficult to read because of the large numbers of individual facts mentioned in some sections.

P. Heimbach [NB 826 IE]

Experimental Methods in Catalytic Research. By *R. B. Anderson.* In the series "Physical Chemistry". Academic Press, New York-London 1968. 1st Edit., xii + 498 pp., numerous illustrations and tables, bound, $ 22.50.

In the past four decades methods have been developed for studying the alteration to molecules activated on a catalyst and the physicochemical properties required in a catalyst for specific processes of heterogeneous catalysis. A series of such experimental methods is described in this book. Since an introduction into the theory and the experimental bases of these methods requires very varied experience, *R. B. Anderson* has recruited several well-known scientists with special experience to present the extensive material in eleven chapters.

In the first chapter *Anderson* himself describes the study of the kinetics of catalytic reactions in 40 pages. The 2nd chapter, by *W. B. Innes*, concerns physical adsorption and chemisorption, also the determination of surface area and pore structure of the catalyst (49 pages). In the 3rd chapter, comprising 65 pages, *P. M. Gundry* and *F. C. Tompkins* treat the determination of surface potentials and their use for problems in catalysis. The 4th chapter, by *R. S. Hansen* and *N. C. Gardner*, provides a summary, in 45 pages, of field electron and field ion microscopy. The 5th chapter is devoted to chemisorption in ultra high vacuum systems; here, in 45 pages, *R. S. Hansen* and *V. J. Mimeault* describe flash desorption spectrometry and give a brief section on evaporated films and electronic action between their surface and adsorbed foreign molecules. Diffraction of slow electrons is treated in chapter 6 (20 pages) by *H. E. Farnsworth*. In the 7th chapter *T. J. Gray* concerns himself with measurement of semiconduction and photoconduction and the catalyst properties connected therewith (34 pages). The study of vibration and electronic spectra of adsorbed molecules is described by *G. Blyholder* in chapter 8 (36 pages). In chapter 9, *W. S. Goldstein* devotes 38 pages to the measurement of the acidity of catalyst surfaces. In the 32 pages of chapter 10, *L. J. E. Hofer* describes the magnetochemical methods and their use in research on catalysis. *R. J. Kokes* presents electron spin resonance and its use in problems of catalysis (37 pages).

The older methods of investigating catalysts by diffraction of X-rays and fast electrons are not reported, nor are applications of the electron probe microanalyzer, X-ray absorption, or the Mössbauer effect, or the study of electrode reactions. Each chapter is provided with a list of references, treating English-language literature up to about 1966 but (with three exceptions) the German only up to 1960.

As a whole the book gives a useful comprehensive survey of modern physicochemical methods for research on catalysis.

R. Suhrmann [NB 831 IE]

Solid Phase Peptide Synthesis. By *J. M. Stewart* and *J. D. Young.* W. H. Freeman and Co., San Francisco-London 1969. 1st Edit., xi + 103 pp., 28 illustrations, bound 48s.

Within a few years of the first publication, solid-phase peptide synthesis, often called Merrifield synthesis after its discoverer *Bruce Merrifield*, has achieved a firm place in most laboratories concerned with the synthesis of peptides or proteins. The culmination to date is the synthesis, by *Merrifield* and *Bernd Gutte* early in 1969, of an enzyme preparation with ribonuclease activity. As is now well known, the principle of this method is to build a linear peptide by chain-lengthening, unit by unit, from the carboxyl end while keeping the peptide chain anchored covalently, *e.g.*, by an ester bond, to a solid phase until the synthesis is complete. Sequence-pure peptides, *i.e.* peptides with the desired sequence throughout, can, however, be obtained only if each peptide bond is formed in 100% yield and if the selective protecting groups on the *N*-terminal amino acid are completely removed while the side-chain functions remain protected until the end of the synthesis.

Merrifield syntheses have split chemists working on peptide synthesis into two camps: one group hopes for rapid solution of all the synthetic problems by the new method and sees the time coming when sequence-pure peptides will be synthesized automatically in gram quantities; the other considers it impossible in principle to prepare sequence-pure peptides with more than a definite but as yet undetermined number of amino acid units.

The present is thus a very opportune time for *Stewart* and *Young*'s book. It will help everyone wanting to synthesize peptides by the Merrifield method, not only by explaining the theoretical basis of each operation (pages 1—26) but also by providing clear experimental details (pages 27—70) for this method. The book is written with exemplary clarity and the illustrations are of excellent quality. It is directed in the first place to those interested in solid-phase synthesis, but the Reviewer recommends this "Gattermann of peptide synthesis" to everyone with any interest in amino acids and peptides. Although we already have excellent textbooks and reference works for peptide chemistry, such as those by *Bodansky* and *Ondetti* (1966) and *Schröder-Lübke* (1965, 1966), we must nevertheless welcome a laboratory book that covers the literature between those dates and the beginning of 1968 and describes, *e.g.*, in detail *Sakakibara*'s method for removal of almost all protecting groups by means of hydrofluoric acid.

This unrestricted recommendation is not weakened by mention of the very fragmentary citation of European literature; this can be remedied in the next edition if Merrifield specialists will heed the author's request to keep them informed of new papers.

Acid-Catalyzed Cyclodimerizations *via* Vinyl Cations as Intermediates[1]

By K. Griesbaum[*]

The electrophilic addition of hydrogen chloride and bromide to allene and of hydrogen bromide to methylacetylene at −70 °C leads not only to the simple Markownikoff adducts but also to cis- and trans-1,3-dihalo-1,3-dimethylcyclobutanes. These cyclodimerizations, which evidently proceed via vinyl cations, have opened up new short routes for the synthesis of cyclobutane-, cyclobutene-, and bicyclobutane derivatives starting from substrates that are industrially readily accessible.

1. Introduction

Vinyl cations have long been considered to be species of particularly high energy and thus unstable. This view, which has even been presented in recent textbooks[2], is probably based on the inertia of vinyl halides toward silver nitrate in alcoholic solution[3].

In recent years, however, other methods have been used to verify the existence of vinyl cations. Though they have not yet been definitely detected as such by spectroscopic methods in solution, there are now convincing arguments for their occurrence as intermediates in many reactions. Examples of such reactions are the solvolysis of arylvinyl-[4a] and cyclopropylvinyl halides[4b], vinyltrifluoromethanesulfonates[4c], and homoallenyl-[4d] and homopropargyltosylates and -bromosulfonates[4e], the nitrosation of some vinylamines[5], and particularly some electrophilic additions to alkynes[6–9] and to allene[10].

2. Electrophilic Cyclodimerization of Allene and Methylacetylene with Hydrogen Bromide

The addition of acids to allene is a particularly suitable example for the necessity of a re-appraisal of ideas on the reputed instability of vinyl cations. Unlike in the addition to alkynes, two reaction paths, *i.e.* one *via* the vinyl cation *(1)* and one *via* the alkyl cation *(4)*[11], are possible in this case. However, all the hitherto studied electrophilic additions of compounds of the type HX to allene have proceeded in such a way

[3] This reaction is inadequate as a test for the existence of vinyl cations, since it would necessitate the cleavage of a very strong vinyl chloride bond. The preferential protonation of allene at one of the termini of the cumulative system by acids could, on the other hand, suggest the opposite conclusion, *i.e.* that vinyl cations are formed preferentially. Hence, it is not sufficient to consider only one parameter, but both the kinetic and the thermodynamic factors must be taken into account.

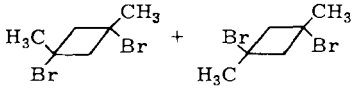
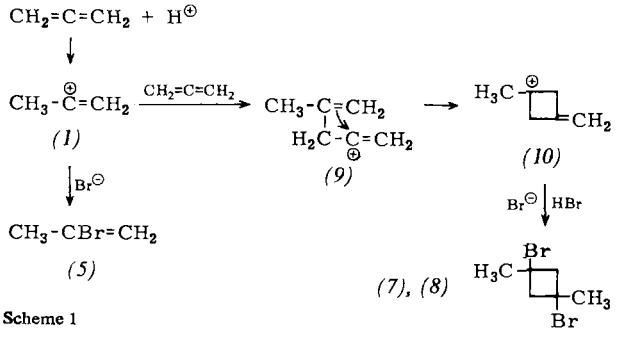
[10] For a review of these reactions, see *K. Griesbaum*, Angew. Chem. *78*, 953 (1966); Angew. Chem. internat. Edit. *5*, 933 (1966).



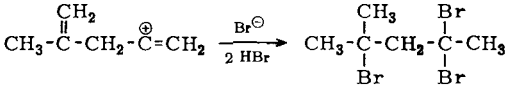
[11] The incipient cation *(4)* is not a resonance stabilized allyl cation but a primary cation, owing to the perpendicular arrangement of the two double bonds in allene.

that it is possible to formulate a vinyl cation intermediate *(1)*.



Whereas it has long been assumed that only the simple Markownikoff adducts *(2)* and *(3)* are formed in these additions, we have found that the reaction of hydrogen bromide with allene at −70 °C and in the dark yields a mixture of adducts containing four components instead of the expected two. These were the Markownikoff adducts 2-bromopropene *(5)* and 2,2-dibromopropane *(6)* as well as the previously unknown *cis*- and *trans*-1,3-dibromo-1,3-dimethylcyclobutanes *(7)* and *(8)* [12].

A free-radical cyclodimerization to form *(7)* and *(8)* was unlikely in view of the reaction conditions and it could be definitely ruled out on the basis of detailed investigations [13]. A second possibility was the radical-induced or electrophilically induced head-to-tail cyclization of the 2-bromopropene *(5)* formed in the free-radical and electrophilic additions of hydrogen bromide to allene. It was also possible to rule out this reaction path by model experiments.



We therefore assumed that this was the first case of a purely acid-induced [14] cyclodimerization *via* vinyl cations, which possibly proceeds by the following steps (Scheme 1):

Scheme 1

In the first step, allene is protonated at a terminal carbon atom to form the 2-propenyl cation *(1)*. Cation *(1)* can either react further with the nucleophile Br^- to give the Markownikoff adduct *(5)* or it can alkylate another molecule of allene to form the new vinyl cation *(9)* [15a]. This intermediate *(9)* cyclizes as indicated by the arrow to give the presumably more stable tertiary cation *(10)* [15b]. The cyclic dibromide *(7)*, *(8)* is finally formed by attack of bromide and addition of hydrogen bromide to *(10)*.

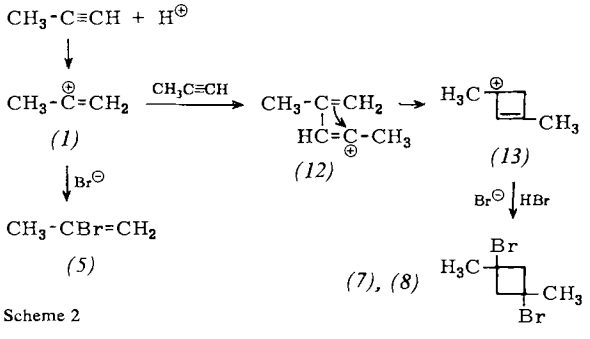
To obtain experimental evidence for this postulated reaction course, it would be necessary *e.g.* to try to intercept the dimeric vinyl cation *(9)* by formation of acyclic adducts such as *(11)*.

It is quite conceivable that the reaction leads not to a true intermediate of the form *(9)*, but directly to the tertiary cation *(10)* *via* a transition complex between the vinyl cation *(1)* and allene. It is also uncertain whether the observed isomer ratio reflects the stereochemical course of the reaction or merely a post-isomerization.

Despite their incompleteness, these views have proved to be a useful working hypothesis for the further investigation of these cyclodimerizations. The next substrate to be considered was methylacetylene, the protonation of which should give the same 2-propenyl cation *(1)* as the protonation of allene:

[12] *K. Griesbaum*, J. Amer. chem. Soc. *86*, 2301 (1964).

[13] *K. Griesbaum, A. A. Oswald*, and *D. N. Hall*, J. org. Chemistry *29*, 2404 (1964).



[14] When this work was being carried out we knew of only one example of a cyclodimerization *via* vinyl cations, *i.e.* the boron trifluoride-catalyzed cycloaddition of chlorine to 2-butyne with formation of dichlorotetramethylcyclobutene: *R. Criegee* and *A. Moschel*, Chem. Ber. *92*, 2181 (1959). Further examples of catalytic cycloadditions, leading to four-membered rings *via* vinyl cations have been reported in the interim, *e.g.* the one-step synthesis of hexamethyl(Dewar-benzene) from 2-butyne: *W. Schäfer* and *H. Hellmann*, Angew. Chem. *79*, 566 (1967); Angew. Chem. internat. Edit. *6*, 518 (1967).

[15] These reaction steps have analogs in the chemistry of alkyl cations: a) Competition between the combination of an intermediate cation with a nucleophile on the one hand and the alkylation of an olefin on the other has been reported for the addition of hydrogen bromide to propene, which leads not only to 2-bromopropane but also to bromohexane: *F. R. Mayo* and *M. G. Savoy*, J. Amer. chem. Soc. *69*, 1348 (1947); b) There have been several recent reports of intramolecular cyclization reactions of unsaturated cationic intermediates bearing their positive center in a β position with respect to the double- or triple bond: *M. Hanack, I. Herterich*, and *V. Vött*, Tetrahedron Letters *1967*, 3871; *M. Hanack* and *I. Häffner*, *ibid.* *1964*, 2191.

On the basis of earlier reports, there was little likelihood of a cyclodimerization of methylacetylene with hydrogen bromide. This reaction had been very thoroughly investigated by *Kharasch* in connection with the discovery of the free-radical addition of hydrogen bromide. At that time only the simple Markownikoff adducts *(5)* and in particular *(6)* were found in the nucleophilic reaction [16].

However, re-examination of this reaction with the aid of modern analytical methods showed that methylacetylene is also partly cyclodimerized by hydrogen bromide; at −70 °C we obtained about 9% of *cis*- *(7)* and 32% of *trans*-1,3-dibromo-1,3-dimethylcyclobutane *(8)* in addition to *(5)* and *(6)* [17].

It is not yet certain whether the cyclodimerization of methylacetylene follows a path of its own (Scheme 2) or whether it proceeds *via* an acid-catalyzed isomerization to allene and subsequent cyclodimerization in accordance with Scheme 1. This question could probably be answered by the use of deuterium bromide as the addend. If the two reactions follow different routes each methyl group of the 1,3-dibromo-1,3-dimethylcyclobutane formed by cyclodimerization of allene and each methylene group of that formed by the cyclodimerization of methylacetylene should contain one deuterium atom

Scheme 2

Irrespective of these as yet unanswered questions concerning the reaction course, however, the cyclodimerization of methylacetylene provided a much better economic basis for the one-step synthesis of substituted reactive cyclobutane derivatives. Both allene and methylacetylene are still very expensive in the pure state, whereas stabilized mixtures (*i.e.* mixtures to which propane and propene have been added to reduce the explosion hazard) of allene and methylacetylene are available in large quantities as welding gas [18]. Enriched mixtures of these two substrates can probably be also obtained by work-up of the C_3 streams that occur in the thermal cracking of petroleum. Since in such mixtures the two isomers are often present in the ratio of their thermodynamic equilibrium, in which methylacetylene strongly predominates [19], it is advantageous for the overall yield that both substrates give roughly the same quantity of cyclodimerization product.

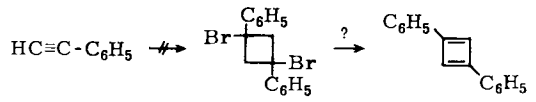
3. Scope and Limitations of Electrophilic Cyclodimerizations *via* Vinyl Cations

Following the extension of the cyclodimerization to methylacetylene, we examined the question whether the reaction also proceeds with hydrogen chloride and hydrogen iodide.

The reaction of hydrogen chloride with allene at −78 °C had been reported to proceed at a significant rate only in the presence of catalysts, and to lead exclusively to the two Markownikoff adducts *(14)* and *(15)* in the presence of bismuth trichloride [20]. In contrast, we obtained a mixture of four components both in the presence of bismuth trichloride and in the much slower uncatalyzed reaction. These products were the two simple Markownikoff adducts 2-chloropropene *(14)* and 2,2-dichloropropane *(15)* and the two cyclodimerization products *cis*- *(16)* and *trans*-1,3-dichloro-1,3-dimethylcyclobutane *(17)* [21]. The extent to which cyclodimerization had occurred was again strongly dependent on the reaction temperature. Only about 2% of cyclodimerization products were obtained at room temperature, whereas up to 30% were formed at −70 °C. Since the low-temperature reaction with HCl, even in the presence of a catalyst, is much slower than the reaction of allene with HBr, the hydrochlorination is less suited for the preparation of cyclobutane derivatives than the hydrobromination.



No cyclodimerization products were found in the reactions of hydrogen iodide with allene and with methylacetylene [21]. This is quite understandable, since the iodide ion is a better nucleophile than the bromide or chloride ions [22], and can thus direct the reaction exclusively in the direction of the simple Markownikoff adduct.

The reaction of phenylacetylene with hydrogen bromide appeared interesting in connection with the cyclobutadiene problem. On dehydrobromination of the expected 1,3-dibromo-1,3-diphenylcyclobutane *(18)* the double bonds should, apart from ring cleavage reactions, be introduced into the four-membered

(18)

ring system, since no escape reactions giving exocyclic double bonds are possible.

However, the additions under the usual conditions for cyclodimerization gave only the normal Markownikoff adducts. It is not certain whether the cyclization is prevented in this case by steric factors or by the nature of the intermediate benzyl-vinyl cation. If, for example, the failure of cyclization were due to an enhanced stability of the vinyl cation owing to resonance stabilization, it should be possible to influence the reaction course by suitable *p*-substitution. It is also possible that on grounds of the geometry of the transition state, the cyclodimerization may depend on the occurrence of not strictly linear vinyl cations. For benzyl-vinyl cations a strictly linear structure has been postulated [8].

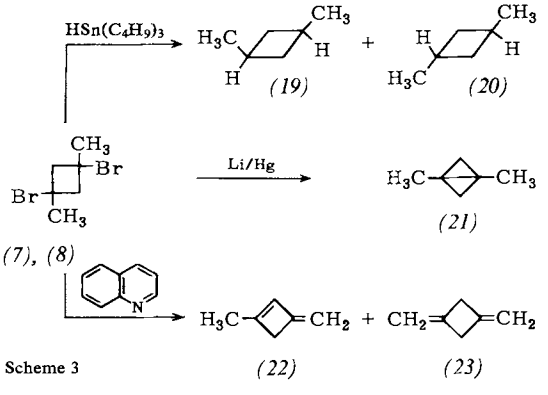
The higher homologs of allene can be used only to a limited extent, if at all, for such cyclodimerizations, since with increasing substitution by alkyl groups, alkyl cations are formed in preference to vinyl cations as intermediates, so that the higher allenes are protonated at the central carbon atom of the cumulative system [20]. Hence, apart from unsubstituted allene, the choice of substrates is limited to substituted acetylenes.

A possible extension of the preparative use of electrophilic cyclodimerizations was indicated during the investigation of the methylacetylene-hydrogen bromide reaction. Depending upon the source of methylacetylene the gas chromatogram of the crude product mixture contained a signal whose retention time was longer than that of the isomeric 1,3-dibromo-1,3-dimethylcyclobutanes. Investigation by combined gas chromatography and time-of-flight mass spectroscopy showed that the substance corresponding to the signal has the typical molecular-ion triplet (*m/e* = 254, 256, 258) and the fragment-ion doublet (P—Br: *m/e* = 177, 175) of a dibromide [23]. The mass spectrum also pointed to a trimethyl compound. Analysis of the batches of methylacetylene used for the experiments in question showed that they contained small quantities of 2-butyne. We therefore suspect that the by-product was one of the possible isomeric dibromotrimethylcyclobutanes, which may have been formed by co-cyclization of methylacetylene and 2-butyne.

The influence of catalysts on the cyclodimerization by acids has only received a cursory study thus far. Preliminary investigations have shown that boron trifluoride increases not only the rate of the hydrogen bromide-methylacetylene reaction but also the selectivity of the cyclodimerization. The results were, however, inconclusive because of partial resinification of the reaction product.

[23] *J. H. Beynon*: Mass Spectrometry and its Application to Organic Chemistry. Elsevier, Amsterdam 1960, p. 299.

[24] The reactions described in the following were carried out with a mixture of about 10% of *cis*- and 90% of *trans*-1,3-dibromo-1,3-dimethylcyclobutane as it was obtained from the cyclodimerization reaction.



4. Chemistry of the 1,3-Dibromo-1,3-dimethylcyclobutanes[24]

Following the synthesis of the 1,3-dibromo-1,3-dimethylcyclobutanes *(7)* and *(8)*, we carried out a number of experiments mainly in order to support the structure assignments which were initially based purely on spectroscopic data, by conversion of these compounds into known cyclobutane derivatives (Scheme 3). During the course of this work it became evident that 1,3-dihalocyclobutanes, with their tertiary halogen substituents, are fairly reactive and should have a variety of uses.

When the dibromide was heated with an excess of tributyltin hydride, a mixture of *cis*- *(19)* [25] and *trans*-1,3-dimethylcyclobutane *(20)* [25] was obtained in 58% yield. During this reaction, the *cis-trans* ratio changed from 10 : 90 in the starting bromide to 30 : 70 in the reduction product. This is understandable if (as is assumed for such reactions [26]) the reaction proceeds *via* free-radical intermediates.

When the dibromide is stirred at room temperature with a suspension of 2% of lithium amalgam in dioxane, the bicyclic dehalogenation product 1,3-dimethylbicyclo[1.1.0]-butane *(21)* is formed with a selectivity of $> 85\%$ [27, 28].

Dehydrobromination of the dibromide with quinoline [29] at approximately 200 °C gave a mixture of the two dienes 1-methyl-3-methylenecyclobutene *(22)* [25, 30] and 1,3-dimethylenecyclobutane *(23)* [25] (ratio 80 : 20, respectively) in a yield of about 50%.

Scheme 3

These preliminary results demonstrate that cyclodimerizations leading to reactive cyclobutane derivatives are not only of mechanistic interest, but may also open up new paths for the synthesis of compounds that have hitherto only been obtainable either *via* roundabout routes [25] or in considerably smaller yields [28] and with greater effort.

Organogermyl, Organostannyl, and Organoplumbyl Phosphines, Arsines, Stibines, and Bismuthines

By H. Schumann[*]

The preparation, properties, and reactions of the compounds named in the title are described, with particular reference to the possible participation of $(p\rightarrow d)_\pi$ components in the bonding between the group IVB and the group VB elements.

1. Introduction

A problem that is still of great interest in the field of covalent inorganic compounds is the nature of the bonding between silicon and oxygen. It is not yet generally accepted that the unexpected stability of this bond is due to decisive contributions from $(p\rightarrow d)_\pi$ double-bond components. A deeper insight into the nature of the bond should, however, be obtainable by comparison of the physical and chemical properties of such covalent silicon compounds with the properties of similar covalent compounds of the silicon homologs germanium, tin, and lead. The investigations should concentrate on the one hand on tin as one of the bonding partners and on the other on the homologous elements of oxygen and nitrogen. We have already reviewed the most important organometallic compounds containing bonds between germanium, tin, or lead and sulfur, selenium, or tellurium [1]. Covalent compounds of the group IV elements mentioned with phosphorus, arsenic, antimony, and bismuth are reported in the present article. These compounds were unknown until a few years ago.

2. Organogermyl, Organostannyl, and Organoplumbyl Phosphines

2.1. Synthesis

Only two phosphines with organometallic substituents were known in 1962. These were triethylstannyldiphenylphosphine, which was prepared in 1959 by *Kuchen* and *Buchwald* [2], and tris(trimethylstannyl)-phosphine, which was described in 1960 by *Bruker et al.* [3].

In analogy with the reactions of sulfur, selenium, and tellurium with tetraorganostannanes [4–7], organostannyl phosphines of various degrees of polymerization were obtained from tetraphenylstannane and phosphorus in a sealed tube above 220 °C [8–10]. Triphenylphosphine and alloy-like tin phosphides were also formed.

Diphenyltin and triphenylphosphine are formed first between 220 and 230 °C, and combine to form the addition complex diphenyltin-triphenylphosphine *(1a)*. Though this complex cannot be isolated, its existence can be demonstrated by the formation of the stable oxidation products diphenyltin oxide and triphenylphosphine oxide [11]. When the temperature is raised, the complex *(1a)* rearranges into the stable isomer triphenylstannyldiphenylphosphine *(2a)*, which in turn is dephenylated by excess phosphorus. At 230 to 250 °C, for example, cyclic trimeric diphenylstannylphenylphosphine is formed. Between 250 and 280 °C and with an excess of phosphorus, low molecular weight compounds of this type undergo cleavage of further P–C and Sn–C bonds to form highly polymeric organostannyl phosphines; however, these can be isolated only in the form of their oxidation products (Table 1). Above 280 °C, all the Sn–C bonds are broken; the end products of the degradation of phosphorus by tetraphenylstannane are triphenylphosphine and tin metal.

Table 1. Oxidation products isolated as secondary products of the reaction of $Sn(C_6H_5)_4$ with P_x (between 250 and 280 °C) ($R = C_6H_5$).

Structural units of: Organostannylphosphine	Structural units of: Organotin phosphonate or phosphate	Degradation products
		R_2SnO $RP(O)(OH)_2$
		$RSn(O)OH$ H_3PO_4
		SnO_2 $R_2P(O)OH$ H_3PO_4
		$RSn(O)OH$ $R_2P(O)OH$ $RP(O)(OH)_2$
		$RSn(O)OH$ $RP(O)(OH)_2$
		$RSn(O)OH$ $RP(O)(OH)_2$ H_3PO_4

organophosphines (in the presence of triethylamine as a hydrogen halide acceptor) has been found to be very specific. Owing to the instability of the products, rigorous exclusion of moisture and oxygen is necessary. Thus triorganogermanium, triorganotin, or triorganolead halides react with diorganophosphines to give products of the type *(2)* [12–16a], while with monoorganophosphines [12, 16–17a] and with phosphine [12, 16, 16a, 18, 19] they form compounds such as *(3)* and *(4)*.

$$R_3MX + R'_2PH \xrightarrow[-[(C_2H_5)_3NH]X]{+(C_2H_5)_3N} R_3M{-}PR'_2 \quad (2)$$

$$2\,R_3MX + R'PH_2 \xrightarrow[-2[(C_2H_5)_3NH]X]{+2(C_2H_5)_3N} (R_3M)_2PR' \quad (3)$$

$$3\,R_3MX + PH_3 \xrightarrow[-3[(C_2H_5)_3NH]X]{+3(C_2H_5)_3N} (R_3M)_3P \quad (4)$$

When diorganometal dihalides are used, the reaction with diorganophosphines yields monomeric compounds of the type *(5)* [12–14], and the reaction with monoorganophosphines yields oligomers of the type $(R_2M{-}PR')_n$ [21]. Cyclic trimers of this type can be isolated in yields of up to 85% with suitable experimental conditions [20]. On the other hand, bis(chlorodiphenylgermyl)phenylphosphine *(3a)* is formed almost quantitatively from diphenylgermanium dichloride and phenylphosphine. With dipotassium phenylphosphide in monoglyme/ether, the two ring systems *(3b)* and *(3c)* are formed in a ratio of 3 : 1: monopotassium phenylphosphide leads almost exclusively to *(3b)*. The same mixture of *(3b)* and *(3c)* is also formed on reaction of *(3a)* with $K_2PC_6H_5$ or $KHPC_6H_5$ [21].

$$2\,R_2GeCl_2 + RPH_2 \xrightarrow[-2[(C_2H_5)_3NH]Cl]{+2(C_2H_5)_3N} R_2Ge(Cl){-}P(R){-}GeR_2(Cl) \quad (3a)$$

$$5\,R_2GeCl_2 + 5\,K_2PR \xrightarrow[-10\,KCl]{} \text{(3b)} + \text{(3c)}$$

$$2\,R_2GeCl_2 + 2\,KHPR \xrightarrow[-2\,KCl,\,-2\,HCl]{} \text{(3b)}$$

$R = C_6H_5$

The reactions of diorganometal dihalides with phosphine itself also give polymeric organometal phosphines, but in this case containing the structural units $R_2M\langle$ and $\rangle P$ [21].

In the special case of the reaction of diphenyltin dichloride with phosphine, small quantities of a benzene-soluble compound *(6)* were isolated as well as high polymers; an adamantane skeleton has to be proposed for this compound [21].

$$R_2MX_2 + 2\,R'_2PH \xrightarrow[-2[(C_2H_5)_3NH]X]{+2(C_2H_5)_3N} R_2M(PR'_2)_2 \quad (5)$$

$$3\,R_2MX_2 + 3\,R'PH_2 \xrightarrow[-6\,[(C_2H_5)_3NH]X]{+6\,(C_2H_5)_3N} \text{(6)}$$

$$6\,R_2SnCl_2 + 4\,PH_3 \xrightarrow[-12\,[(C_2H_5)_3NH]Cl]{+12\,(C_2H_5)_3N} \text{(6)}$$

$R = CH_3, C_4H_9, C_6H_5$, $R' = C_6H_5$

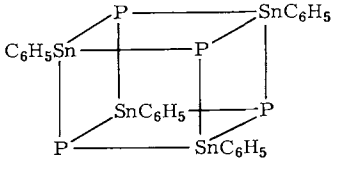
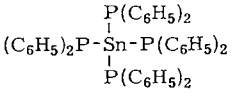
Phenyltin trichloride reacts with diphenylphosphine to form monomeric tris(diphenylphosphino)phenylstannane *(7)* [12] and with phenylphosphine to give a phenylstannylphosphine *(8)* (yield 5%) having the composition $(C_6H_5Sn)_2(PC_6H_5)_3$, together with high polymers of unknown structure. The IR and ^{31}P-NMR spectra [21] of *(8)* indicate a bipyramidal structure with three phosphorus atoms in equatorial positions and two tin atoms in axial positions.



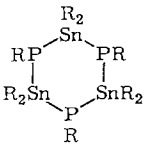
(7)



(8)

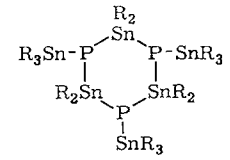
Methyltin and butyltin trichlorides give only highly polymeric reaction products with phosphine. On the other hand, small quantities of a tetrameric phenylstannylphosphine *(9)* having a cubane structure can be isolated from the polymer mixture obtained from phenyltin trichloride and phosphine [22]. Finally, tin tetrachloride reacts with diphenylphosphine to give tetrakis(diphenylphosphino)stannane *(10)* [12].

(9)



(10)

In addition to this versatile method, other syntheses for phosphines with organometallic constituents have also been developed in recent years. Examples of such syntheses are the reactions of organo-germanium or organotin halides with alkali metal organophosphides [2,3,8,12–14,17a,19,21,23–25] and of triphenylstannyllithium and phenylchlorophosphines [8,23,26,27]:



$$R_{4-n}MX_n + n\ LiPR'_2 \rightarrow R_{4-n}M(PR'_2)_n + n\ LiX, \quad M = Ge, Sn$$

$$n\ R_3SnLi + R'_{3-n}PCl_n \rightarrow (R_3Sn)_nPR'_{3-n} + n\ LiCl, \quad R = C_6H_5$$

Care must however be taken in the last reaction to ensure that the phosphorus chloride in question is present in excess right to the end of the reaction. Otherwise the initially formed monomeric reaction products are attacked by the strongly nucleophilic triphenylstannanide ion in a manner that has not yet been fully clarified, with formation of polymeric cyclic phenylstannylphosphines such as *(11)* and *(12)* [23].

(11) R = C_6H_5

(12)

Reactions of this type have also allowed the preparation of a trigonal bipyramidal phenylgermylphosphine of the type *(8)* and a heptameric phenylgermylphosphine $(C_6H_5GeP)_7$ from phenylgermanium tribromide and $K_2P(C_6H_5)$ or Na_3P respectively [21].

Organophosphines also react with organotin oxides [28, 29] and with organogermylamines [13,14,17a,19,30,31, 34] and organostannylamines [32,33] with liberation of water or amine and formation of corresponding metal phosphines.

Phosphines in which the phosphorus atoms carry different organometallic residues are also obtainable [16a,35]. Thus bis(triphenylstannyl)phenylphosphine is split by butyllithium in benzene solution with formation of butyltriphenylstannane and lithium phenyltriphenylstannylphosphide *(13)*. This product, which cannot be isolated, reacts with triphenylgermanium bromide and triphenyllead chloride to form the compounds *(14)* or *(15)* with mixed substituents Lithium bis(triphenylstannyl)phosphide, which is obtained in the same way as *(13)* from tris(triphenylstannyl)phosphine and butyllithium, reacts similarly.

$$[(C_6H_5)_3Sn]_2PC_6H_5 + LiC_4H_9 \rightarrow (C_6H_5)_3SnC_4H_9 + \underset{(13)}{(C_6H_5)_3Sn(C_6H_5)P\text{-}Li}$$

2.2. Physical Properties

Apart from the alkylgermyl and alkylstannyl derivatives which are liquid under normal conditions, all the known phosphines of this type are colorless to light yellow crystalline solids (Table 2). They dissolve readily, and without decomposing, in aromatic hydrocarbons and in some ethers, such as tetrahydrofuran. Aliphatic hydrocarbons such as pentane, or methylcyclohexane are excellently suited for recrystallization.

Table 2. Organogermyl, organostannyl, and organoplumbyl phosphines.

The thermal stability of these compounds varies considerably. Thus organogermyl and organostannyl phosphines generally decompose only above 200 °C in an uncontrollable manner, whereas organoplumbyl phosphines decompose at very low temperatures with deposition of lead. Trimeric dimethylstannylphenylphosphine *(16)* is also thermally unstable, and decomposes above 130 °C to give bis(trimethylstannyl)-phenylphosphine *(17)*, cyclopenta(phenylphosphane) *(18)*, and tin [20].

$$\underset{(16)}{[(CH_3)_2Sn\text{–}PC_6H_5]_3} \xrightarrow{\Delta} \underset{(17)}{[(CH_3)_3Sn]_2PC_6H_5} + \underset{(18)}{(C_6H_5P)_5} + Sn$$

The vibration spectra of the organometal phosphines mentioned (Table 3) should contain, in addition to the vibrations of the methyl groups and the substituent-dependent and substituent-independent vibrations of the phenyl rings, a skeletal vibration ν M–P for compounds of symmetry C_s and three skeletal vibrations ν_{as} M–P–M, ν_s M–P–M, and δ M–P–M for compounds of symmetry C_{2v} as IR- and Raman-active vibrations. Four-particle molecules of the type M_3P with a planar arrangement of the atoms, corresponding to the symmetry D_{3h}, should give four skeletal vibrations, *i.e.* one symmetrical and one antisymmetrical stretching vibration, and two bands in the long-wave region of predominantly deformation character. The symmetrical stretching vibration is IR-inactive. With a trigonal pyramidal arrangement (symmetry C_{3v}), the nature and number of the vibrations remain the same, but the symmetrical stretching vibration is also IR-active. The fact that all four skeletal vibrations do in fact occur both in the IR and in the Raman spectra of the tris(triorganoelement)-substituted phosphines thus clearly shows the pyramidal structure of these molecules and indicates the absence of strong $(p\rightarrow d)_\pi$ multiple bond components [16a, 39–41].

The long-wave shifts of the frequencies ν M–P, ν_{as} and ν_s M_2P or M_3P, and δ M_2P or δ M_3P on replacement of M = Ge by Sn and Pb are due to the increase in the mass of the triorganoelement groups in the same direction. The differences $\nu_{as} - \nu_s$ (M–P–M) increase from 24 cm^{-1} for $[(C_6H_5)_3Ge]_2PC_6H_5$ to 41 cm^{-1} for the analogous tin compound, and 35 cm^{-1} for the corresponding lead derivative. This indicates an increase in the angle at the phosphorus due to the increase in the bulk of the triphenylelement unit.

The chemical shifts of the singlets that are found in every case as expected in the ^{31}P-NMR spectra (Table 4) [40,41] have surprisingly high positive values, which are exceeded only by the value for white phosphorus (δ = 462 ± 2 ppm [40]). It is also found that the δ values vary in the series $[(C_6H_5)_3Sn]_3P$,

$[(C_6H_5)_3Sn]_2PC_6H_5$, $(C_6H_5)_3SnP(C_6H_5)_2$, $P(C_6H_5)_3$ in a manner that indicates the absence of $(p\rightarrow d)_\pi$ bond components between phosphorus and tin. As expected, however, the variation of the δ values in such series of compounds is determined, not by one variable, but by several parameters that act with or against one another. The ^{31}P-$^{117,119}Sn$ coupling constants, which are absolutely essential for a conclusive discussion of the situation, are not yet known. Pure $p_\sigma(P)-(sp^3)_\sigma(Si)$ bonds are assumed for similar organosilylphosphines on the basis of detailed ^{31}P-NMR spectroscopic measurements [42].

2.3. Chemical Properties and Reactions

2.3.1. Oxidation

The sensitivity of organogermyl, organostannyl, and organoplumbyl phosphines toward oxygen [43] depends mainly on the number and nature of the organic residues used to block the unwanted valences of the metal. Alkyl compounds are more sensitive than the corresponding phenyl derivatives toward oxygen. The attack of oxygen is slowest on tetrakis(diphenylphosphino)stannane *(10)* and tris(triphenylstannyl)phosphine, whereas all the other organometal phosphine derivatives investigated can be safely handled only in oxygen-free atmospheres. The oxidation, either on simple exposure to air or (always quantitatively) with hydrogen peroxide in ethanol, proceeds in accordance with the general equation

$$\gtrdot M-\ddot{P}\lessdot + O_2 \rightarrow \gtrdot M-O-\overset{O}{\overset{\|}{P}}\lessdot$$

with the formation of organometal phosphinates. The possible intermediates phosphine oxide *(20)* or phosphinite *(19)* have never been isolated in this reaction.

Even when *C,N*-diphenylnitrone, 1,2-dihydroisoquinoline *N*-oxide, or benzonitrile oxide is used as a specific oxidizing agent, triphenylstannyldiphenylphosphine for example is entirely oxidized to the final stage, *i.e.* to the phosphinate.

Attempted independent syntheses of one of the two intermediates of this oxidation in particular were unsuccessful in the case of triphenylstannyl diphenylphosphinite *(19a)*, which is extremely sensitive to oxygen, whereas triphenylstannyldiphenylphosphine oxide *(20a)* escapes isolation by immediate rearrangement into the isomeric phosphinite [43].

$$(C_6H_5)_3SnOLi + (C_6H_5)_2PCl \xrightarrow{-LiCl} (C_6H_5)_3Sn-O-\ddot{P}(C_6H_5)_2 \quad (19a)$$

$$(C_6H_5)_3SnLi + (C_6H_5)_2P(O)Cl \xrightarrow{-LiCl} (C_6H_5)_3Sn-P(O)(C_6H_5)_2 \quad (20a)$$

$$(C_6H_5)_3Sn-O-\ddot{P}(C_6H_5)_2 + 1/2\,O_2 \rightarrow (C_6H_5)_3Sn-O-P(O)(C_6H_5)_2$$

(19a), m.p. 120 °C — *(21a)*, m.p. 360 °C

Thus all the compounds described in the literature as organostannylphosphine oxides are in fact probably the corresponding phosphinates *(21)* as has already been stated by a number of authors [44–49].

These results and the fact that organotin phosphinites *(19)* remove oxygen even from organostannanols to form organotin phosphinates [28] suggest the following oxidation course:

The organometal phosphines first add one oxygen atom to form the phosphine oxides. The strengthening of the metal-phosphorus bond is lost with the blockage of the originally free electron pair on the phosphorus. This bond is accordingly broken, and the phosphine oxide gives a phosphinite in a reverse Arbusov rearrangement. The subsequent addition of a second oxygen atom to the now restored lone pair of the electrons on the phosphorus leads to the formation of phosphinates. Since the second oxygen is added more

M = Ge, Sn, Pb *(20)* *(19)* *(21)*

rapidly than the first, only the phosphinates are obtained as stable end products in every case. Triphenylstannyldiphenylphosphine reacts similarly with elementary sulfur to give *(21b)*, whereas bis(triphenylstannyl)phenylphosphine and tris(triphenylstannyl)phosphine give, not the expected thiophosphates but only their decomposition products, *i.e.* bis(triphenylstannyl) sulfide and polymeric phenylphosphorus sulfides or P_2S_5 [43].

$$4\,(C_6H_5)_3Sn{-}P(C_6H_5)_2 + S_8 \rightarrow 4\,(C_6H_5)Sn{-}S{-}P(S)(C_6H_5)_2$$
(21b), m.p. 128–130 °C

2.3.2. Hydrolysis

Perphenylated organogermyl, organostannyl, and organoplumbyl phosphines are not hydrolyzed in the absence of air, probably because of insufficient wetting by water [1]. In alkyl-substituted compounds the metal-phosphorus bond is broken with formation of phosphines and germoxanes, stannanols, or plumbanols [1]. All known organometal-substituted phosphines are decomposed in this way by alcoholic sodium hydroxide solutions. The structure of the phosphine can be readily deduced from the degradation products (Table 1).

2.3.3. Polar Insertion Reactions

The metal-phosphorus bond of organogermyl and organostannyl phosphines can be broken by 1,2-dipolar reagents [50, 51, 31]. For example carbon disulfide is inserted between germanium and phosphorus in triethylgermyldiethylphosphine and between tin and phosphorus in triphenylstannyldiphenylphosphine to form triethylgermyl diethylphosphinodithioformate *(22a)* and triphenylstannyl diphenylphosphinodithioformate *(22b)* respectively.

$$(C_2H_5)_3Ge{-}P(C_2H_5)_2 + CS_2 \rightarrow (C_2H_5)_3Ge{-}S{-}C(S)P(C_2H_5)_2$$
(22a)

$$(C_6H_5)_3Sn{-}P(C_6H_5)_2 + CS_2 \rightarrow (C_6H_5)_3Sn{-}S{-}C(S)P(C_6H_5)_2$$
(22b)

COS, Cl_2CS, $(NH_2)_2CS$, C_6H_5NCO, and C_6H_5NCS also react as 1,2-dipoles to give the compounds shown in Table 5. Cleavage with CO_2, on the other hand, has been observed only in analogous organosilyl phosphines [52].

Table 5. Reaction products from organogermyl and organostannyl phosphines with 1,2-dipolar reagents.

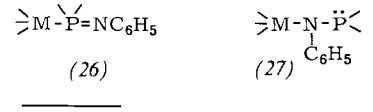
(23)

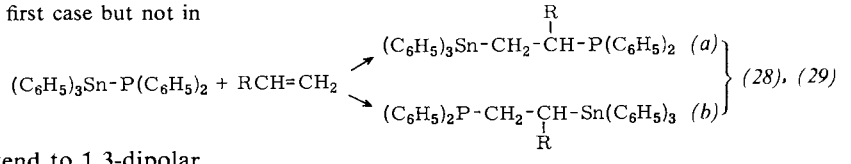
$Sn[P(C_6H_5)_2]_4$ also reacts, though very slowly, with CS_2 and phenyl isocyanate with cleavage of all four tin-phosphorus bonds; $[(C_6H_5)_3Sn]_3P$, on the other hand, does not undergo this cleavage. The difference in the behavior of these two stannyl phosphines again points to the participation of the lone pair of electrons on the phosphorus in the tin-phosphorus bond.



Whereas there are four lone pairs of electrons available on the phosphorus atoms of $Sn[P(C_6H_5)_2]_4$ to strengthen the bonds to a single tin atom, so that full use is not made of them, the lone pair of the single phosphorus atom in $[(C_6H_5)_3Sn]_3P$ is completely "exhausted" by participation in three tin-phosphorus bonds. Thus the electrophilic attack by 1,2-dipolar reagents is successful in the first case but not in the second.

This reaction principle does not extend to 1,3-dipolar reagents. Thus, whereas organostannyl phosphines are merely oxidized by nitrones and nitrile oxides [43] and do not react with nitrilimines and diazomethane, organic azides such as phenyl azide break the bonds between phosphorus and the group IVA elements mentioned to form novel iminophosphoranes such as *(24)* and *(25)* [17].

(24a), M = Sn, decomp. pt. 170 °C
(24b), M = Pb, m.p. 173–178 °C
(25a), M = Sn, m.p. 160 °C
(25b), M = Pb, decomp. pt. 40 °C

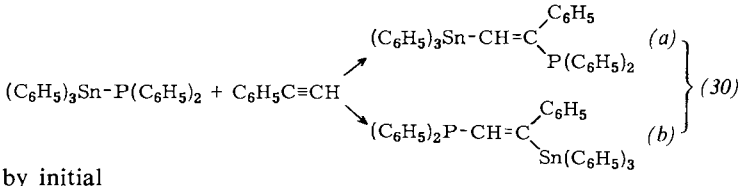


The reactions may be assumed to proceed by initial formation of an iminophosphorane of the type *(26)*, which is unstable (with *tert*-butyl residues on the phosphorus and a trimethylsilyl group on the nitrogen, *N,P*-organometal-substituted iminophosphoranes of this type have now been isolated [58]), and rearranges into an aminophosphine of the type *(27)* which takes up a further phenylimine residue to form the stable end product. The fact that reactions of this type proceed rapidly with mono-, slowly with bis-, and immeasurably slowly with tris-organometal-substituted phosphines again points to participation of the lone pair of P electrons in the M–P bond.

(26) *(27)*

2.3.4. Addition to Olefinic Double Bonds

Triphenylstannyldiphenylphosphine reacts with allyl chloride and with styrene to form chloromethyltriphenylstannylethyldiphenylphosphine *(28)* and phenyltriphenylstannylethyldiphenylphosphine *(29)* respectively [59]; the products in both cases are in two isomeric forms, which have not been separated.



(28), *(29)*

(28a, b), R = $ClCH_2$, m.p. 39 °C
(29a, b), R = C_6H_5, m.p. 59 °C

The reaction with phenylacetylene stops at the stage of the phenyltriphenylstannylethylenediphenylphosphine *(30)* in the forms *(a)* and *(b)*, even when a large excess of triphenylstannyldiphenylphosphine is present [59].

By analogy with hydrostannation [60], this reaction may be assumed to proceed by a free-radical mechanism. This is supported both by the considerable increase in the yield on addition of catalytic amounts of azodiisobutyronitrile and by the simultaneous formation of different isomers. In the reaction of triethylgermyldiethylphosphine with phenylacetylene, two *cis* and two *trans* isomers could be detected by ^{1}H-NMR spectroscopy [31]. Acrylonitrile adds triethylgermyldiethylphosphine [31] and trimethylstannyldiphenylphosphine [61] exclusively to the olefinic double bond, while vinylogous carbonyl compounds such as mesityl oxide, acrolein, or cinnamaldehyde insert their carbonyl function between the tin and the phosphorus in a polar reaction with trimethylstannyldiphenylphosphine to give compounds of the type *(31)*, with no attack on the olefinic double bond [61].

2.3.5. Phosphonium Salt Formation

Organogermyl, organostannyl, and organoplumbyl phosphines, unlike organosilyl phosphines [62], do not form stable phosphonium salts. Organogermyl phosphines [13,14], and organostannyl phosphines [12] react with Lewis acids only at very low temperatures to give addition products, which quantitatively decompose on warming, with cleavage of the Ge–P or Sn–P bond.

$$(CH_3)_3Sn\text{–}P(C_6H_5)_2 + 2\ CH_3I \rightarrow (CH_3)_3SnI + [(C_6H_5)_2\overset{\oplus}{P}(CH_3)_2]I^{\ominus}$$

Tris(trimethylstannyl)phosphine and trimethyltin chloride also fail to give stable tetrakis(trimethylstannyl)phosphonium chloride [63].

As has been shown by NMR spectroscopy, exchange merely occurs with the trimethylstannyl groups on the phosphorus atom. A 1 : 1 mixture of tris(trimethylstannyl)phosphine and trimethyltin chloride gives only one singlet signal for all the trimethylstannyl protons in the ^{1}H-NMR spectrum, even at −60 °C, whereas the original doublet signal of the stannyl phosphine is no longer found. Since cryoscopic molecular weight determinations and IR spectra clearly show that the two components are present together in such mixtures, the ^{1}H-NMR spectrum must be interpreted as resulting from a very rapid exchange of the $(CH_3)_3Sn$ groups *via* an extremely short-lived pentacoordinate state of the phosphorus.

Similar exchange reactions, though in some cases with formation of new end products, occur between tris(trimethylsilyl)-, tris(trimethylgermyl)-, tris(trimethylstannyl)-, or tris(trimethylplumbyl)phosphine and trimethylchlorosilane, trimethylgermanium chloride, trimethyltin chloride, trimethyllead chloride, trimethylstannyldimethylamine, and bis(trimethylstannyl) sulfide.

$$[(CH_3)_3M]_3P + 3\ (CH_3)_3M'Cl \rightleftarrows [(CH_3)_3M']_3P + 3\ (CH_3)_3MCl$$

M and M′ = Si, Ge, Sn, Pb.

With M = Si and M′ = Ge, Sn, or Pb because of the high tendency of $(CH_3)_3SiCl$ to be formed, and with M = Ge or Sn and M′ = Pb because of the fast thermal decomposition of the $[(CH_3)_3Pb]_3P$ present in equilibrium, this exchange proceeds quantitatively in the direction of the upper arrow; for M = Ge and M′ = Sn and for M = Sn and M′ = Ge, on the other hand, all four possible reaction products can be detected together.

2.3.6. Synthesis of Oligomeric Phenylphosphines

The reaction of organostannyl phosphines with phenylphosphorus or phenylarsenic chlorides leads to stable products containing two, three, or four directly linked phosphorus atoms and compounds in which a phosphorus atom is linked to one, two, or three arsenic atoms [64]. Thus the reaction of tris(trimethylstannyl) phosphine with diphenylphosphorus or diphenylarsenic chloride leads to elimination of trimethyltin chloride and formation of tris(diphenylphosphino)-phosphine or tris(diphenylarsino)phosphine:

$$[(CH_3)_3Sn]_3P + 3\ (C_6H_5)_2ElCl \rightarrow [(C_6H_5)_2El]_3P + 3\ (CH_3)_3SnCl$$

El = P, As

Similarly, diphenylphosphorus and diphenylarsenic chlorides react with bis(trimethylstannyl)phenylphosphine to give the compounds *(32a)* and *(32b)* respectively.

$$[(CH_3)_3Sn]_2PC_6H_5 + 2\ (C_6H_5)_2ElCl \rightarrow [(C_6H_5)_2El]_2PC_6H_5 + 2\ (CH_3)_3SnCl$$

(32a), El = P; *(32b)*, El = As

Compounds of this type, of which bis(diphenylphosphino)phenylphosphine [65] and tris(diphenylphosphino)arsine [66] have also been obtained by other routes, are colorless when pure, crystalline, and soluble in ether, cyclohexane, and aromatic hydrocarbons. Their structure has been verified by IR, Raman, and ^{31}P-NMR spectra (Table 6). Their sensitivity to oxygen

decreases as the number of phenyl groups bound to the central P atom increases. $[(C_6H_5)_2P]_3P$ decomposes very rapidly into triphenylphosphine, tetraphenyldiphosphane, and $(C_6H_5P)_n$.

2.3.7. Transition Metal Complexes

It can be concluded from the chemical and physical properties already mentioned that the lone pair of electrons on the phosphorus in organometal-substituted phosphines makes a certain contribution to the phosphorus-metal bond in the sense of a $(p\rightarrow d)_\pi$ interaction. The phosphines discussed should therefore exhibit little or no tendency to occur in transition metal complexes as σ donors.

By reaction of tetracarbonylnickel with tris(trimethylsilyl)-, tris(trimethylgermyl)-, tris(trimethylstannyl)-, and tris(trimethylplumbyl)phosphines and with tris(*tert*-butyl)phosphine in tetrahydrofuran at room temperature, however, it is possible to synthesize nickel(0) complexes such as *(33)*, in which tertiary organometal-substituted phosphines with tetracoordinate phosphorus are present for the first time as ligands together with carbon monoxide [67,67a].

El = C, Si, Ge, Sn, Pb *(33)*

The complexes are formed quantitatively as colorless crystals, which unlike the starting phosphines, are surprisingly stable to atmospheric oxygen but are often thermally very unstable.

The considerable increase in the coupling constant $J_{^1H-C-El-^{31}P}$ that is always found on transition from the free phosphines (C = 9.80 Hz, Si = 4.62 Hz, Ge = 4.00 Hz, Sn = 1.95 Hz, Pb = 0 Hz) to the complexes (Table 7) confirms the increase in the s character of P–El bonds on transition from the substantially p^3-hybridized P atom in the free phosphines to the sp^3 state in the complexes. The slight shift of the ν_{as} PEl_3 band observed on comparison of the IR spectra of the free phosphines and of the complexes show that the element-phosphorus bonds are only slightly weakened by the complex formation. The stability of the complexes to oxygen supports the hypotheses that on oxidation of organometal-substituted phosphines, the attack of the oxygen takes place on the "lone" pair of electrons on the phosphorus, which is blocked in the complexes by coordination with nickel and is thus no longer available for electrophilic attack.

These phosphines containing tris(trimethylelement) groups also react with hexacarbonylchromium [67a,68],

Complexes in which phosphines with organometal groups are present as polydent ligands have also been reported [70, 71].

3. Organogermyl-, Organostannyl-, and Organoplumbylarsines

3.1. Synthesis

The first organometallic compounds containing covalent bonds between arsenic and an element of group IVB, apart from a mention in a patent [72], were obtained in 1964 by *Jones* and *Lappert* [32, 33] and by *Schumann* and *Schmidt* [73].

$$(CH_3)_3Sn{-}N(CH_3)_2 + (C_6H_5)_2AsH \rightarrow (CH_3)_3Sn{-}As(C_6H_5)_2 + (CH_3)_2NH$$

$$3\,(C_6H_5)_3SnLi + AsCl_3 \rightarrow [(C_6H_5)_3Sn]_3As + 3\,LiCl$$

A large number of organostannyl arsines and some organogermyl and organoplumbyl arsines were prepared slightly later by *Campell, Fowles*, and *Nixon* [74] and by *Schumann et al.* [75–77]. Organogermanium, organotin, and organolead halides, as well as tin tetrachloride, react with sodium diphenylarsenide in liquid ammonia to form organometal-substituted diphenylarsines in which one to four diphenylarsine residues are bonded to the element in question.

$$R_{4-n}SnCl_n + n\,NaAs(C_6H_5)_2 \rightarrow R_{4-n}Sn[As(C_6H_5)_2]_n + n\,NaCl$$

R = C_2H_5, C_3H_7, C_4H_9, C_6H_5; n = 1, 2, 3, 4

$$(C_6H_5)_3MCl + NaAs(C_6H_5)_2 \rightarrow (C_6H_5)_3MAs(C_6H_5)_2 + NaCl$$

M = Ge, Pb)

Another series of compounds, in which one to three triphenylstannyl residues are bonded to arsenic, can be prepared by the reaction of triphenylstannyllithium with phenylarsenic chlorides or arsenic trichloride in tetrahydrofuran [75].

$$n\,(C_6H_5)_3SnLi + Cl_nAs(C_6H_5)_{3-n} \rightarrow n\,LiCl + [(C_6H_5)_3Sn]_nAs(C_6H_5)_{3-n}$$

n = 1, 2, 3

The yields of organostannyl arsine are generally low, since side reactions such as condensation and transmetalation cannot be eliminated despite adherence to special experimental conditions. Organostannyl arsines can on the other hand be obtained without by-products by reaction of organotin halides with organoarsines or AsH_3 in benzene in the presence of triethylamine as a hydrogen chloride acceptor [76].

$$n\,R_3SnCl + R'_{3-n}AsH_n \xrightarrow[-n[(C_2H_5)_3NH]Cl]{+n(C_2H_5)_3N} (R_3Sn)_nAsR'_{3-n}$$

R, R' = CH_3, C_6H_5; n = 1, 2, 3

The analogous tris(triorganogermyl)- and tris(triorganoplumbyl)-arsines can be synthesized in the same way [18] or by reaction of trimethylgermyldimethylamine with AsH_3 [19].

$(C_6H_5)_2Sn[As(C_6H_5)_2]_2$, $C_6H_5Sn[As(C_6H_5)_2]_3$, and $Sn[As(C_6H_5)_2]_4$ can also be prepared by reaction of the corresponding tin halides with $KAs(C_6H_5)_2$ in

liquid ammonia [76]. Methylstannyl and methylarsine derivatives of this type cannot be synthesized by this method; they undergo dismutation with methyl shift to give $Sn[As(C_6H_5)_2]_4$ and $(CH_3)_3Sn-As(C_6H_5)_2$ or $Sn(CH_3)_4$ and $(CH_3)_2As-As(CH_3)_2$. The organogermyl-, organostannyl-, and organoplumbylarsines known at present are listed in Table 8.

3.2. Physical Properties

The organogermyl-, organostannyl-, and organoplumbylarsines largely correspond to the homologous phosphorus compounds in their physical properties. Thus alkylgermyl- and alkylstannylarsines are colorless liquids that can be distilled without decomposing under reduced pressure, while the corresponding phenyl compounds and the organoplumbylarsines are colorless to light yellow solids. They dissolve readily and without decomposition in organic solvents such as tetrahydrofuran, diethyl ether, or aromatic hydrocarbons. Their thermal stability is generally higher than that of their phosphorus analogs. The IR (Table 9) and the (so far only incompletely measured) Raman spectra again indicate the pyramidal structure of the compounds. Some of the ^{1}H-NMR spectra of some organometal-substituted arsines have been recorded [19, 76, 78, 104], but no theoretical information has been deduced from the results.

3.3. Chemical Properties and Reactions

Arsines containing organometal groups are sensitive to oxygen. They are oxidized in air at various rates to give isolable metal arsinates of the type *(38)* [78a] (Table 10).

$$\gtrless M-\ddot{A}s\lessgtr + O_2 \longrightarrow \gtrless M-O-\overset{O}{\overset{\|}{A}}s\lessgtr \qquad M = Ge, Sn, Pb$$

(38)

Table 10. Organometal arsinates.

Compound	M.p. (°C)	Ref.
$(C_6H_5)_3Ge-O-As(O)(C_6H_5)_2$	178	[77]
$(CH_3)_3Sn-O-As(O)(CH_3)_2$	157–158 (decomp.)	[78a]
$(CH_3)_3Sn-O-As(O)(C_6H_5)_2$	192–195	[78a]
$(C_2H_5)_3Sn-O-As(O)(C_6H_5)_2$	166–167	[74]
$(C_3H_7)_3Sn-O-As(O)(C_6H_5)_2$	204–205	[74]
$(C_4H_9)_3Sn-O-As(O)(C_6H_5)_2$	196–198	[74]
$(C_6H_5)_3Sn-O-As(O)(CH_3)_2$	181–183 (decomp.)	[78a]
$(C_6H_5)_3Sn-O-As(O)(C_6H_5)_2$ *(38a)*	323–324	[74, 75, 78a]
$(C_6H_5)_2Sn[OAs(O)(C_6H_5)_2]_2$ *(38b)*	330	[75]
$C_6H_5Sn[OAs(O)(C_6H_5)_2]_3$ *(38c)*	180 (decomp.)	[75]
$(C_6H_5)_3Pb-O-As(O)(C_6H_5)_2$	280 (decomp.)	[77]

Compounds of this type have been prepared independently from organotin halides and diphenylarsinic acid in the presence of triethylamine as a proof of their structure [74, 75].

$$(C_6H_5)_{4-n}SnCl_n + n\ HO-As(O)(C_6H_5)_2 \xrightarrow[-n[(C_2H_5)_3NH]Cl]{+n(C_2H_5)_3N} (C_6H_5)_{4-n}Sn[O-As(O)(C_6H_5)_2]_n \quad (38)$$

$n = 1, 2, 3$

The products of the type *(38)*, which are found to be identical, are colorless crystals of which only the dimeric [74] alkylstannyl derivatives dissolve in organic solvents. Oxygen-free water does not attack organostannylarsines, as is shown by the synthesis of a compound of this type in water [104]. Hydrogen peroxide breaks the Sn–As bond of methylstannylarsine derivatives [78a], the nature of the cleavage product providing evidence of the constitution of the starting arsine. Polar reagents such as methyl iodide split the Sn–As bond more slowly than the Sn–P bond to form organotin iodides and tetraorganoarsonium iodides [74, 78a].

Triphenylstannyldiphenylarsine and bis(triphenylstannyl)phenylarsine react with phenyl azide to form the new organotin-substituted aminoiminoarsines *(39)* and *(40)* respectively [78b].

Tris(triphenylstannyl)arsine, on the other hand, is not attacked by phenyl azide even in boiling benzene.

$$(C_6H_5)_3SnAs(C_6H_5)_2 + 2\ C_6H_5N_3 \longrightarrow (C_6H_5)_3Sn-\overset{\overset{NC_6H_5}{\|}}{N}-As(C_6H_5)_2 + 2\ N_2$$

$$\quad\quad\quad

The high formation tendency of trimethyltin chloride allows the use of organostannylarsines for the synthesis of interesting oligomeric phenylarsines, in which up to four arsenic atoms are linked to one another [64] (Table 6). Thus tris(trimethylstannyl)arsine reacts with diphenylphosphorus or diphenylarsenic chloride to form tris(diphenylphosphino)arsine or tris(diphenylarsino)arsine. Bis(diphenylphosphino)phenylarsine and bis(diphenylarsino)phenylarsine can be prepared similarly from diphenylphosphorus or diphenylarsenic chloride and bis(trimethylstannyl)phenylarsine. Diphenylphosphinodiphenylarsine *(41)* can be synthesized from trimethylstannyldiphenylarsine and diphenylphosphorus chloride.

$$[(CH_3)_3Sn]_nAs(C_6H_5)_{3-n} + n\,(C_6H_5)_2ElCl \rightarrow [(C_6H_5)_2El]_nAs(C_6H_5)_{3-n} + n\,(CH_3)_3SnCl$$

El = P, As; n = 3, 2

$$(CH_3)_3SnAs(C_6H_5)_2 + (C_6H_5)_2PCl \rightarrow (C_6H_5)_2PAs(C_6H_5)_2 + (CH_3)_3SnCl \quad (41)$$

With diphenylantimony or diphenylbismuth chlorides and with methylphosphorus or methylarsenic chloride the separation of trimethyltin chloride has also been observed, but the oligomeric phenylarsinostibines or phenylarsionobismuthines and oligomeric methylphosphinoarsines or methylarsinoarsines could not be isolated, presumably because of their low stability.

A number of recent investigations [71,79] show that organometal-substituted arsines can be bonded to transition metals as complex ligands.

4. Organogermyl-, Organostannyl-, and Organoplumbylstibines

4.1. Synthesis

Organogermyl-, organostannyl-, and organoplumbylstibines, as expected, are very similar to the analogous arsenic compounds. Useful synthetic routes were again offered by the reactions of organometal halides with $NaSb(C_6H_5)_2$ [74,77,80], Li_3Sb [81,82], or SbH_3 [18] in liquid ammonia or benzene, or the reaction of triphenylstannyllithium with $(C_6H_5)_2SbCl$, $C_6H_5SbCl_2$, or $SbCl_3$ in tetrahydrofuran [73,80].

The last of these reactions gives the desired compounds only in unsatisfactory yields, since transmetalation and condensation occur at the same time.

Stibines of the type $(R_3M)_3Sb$ (M = Si, Ge, Sn) are obtained in a very elegant manner from triethylstibine and triethyl- or triphenylsilane, -germane, or -stannane with elimination of ethane. Stibines of the type *(42)* can also be obtained by displacement reactions [83–85].

$$3\,R_3MH + (C_2H_5)_3Sb \rightarrow (R_3M)_3Sb + 3\,C_2H_6$$

M = Si, Ge, Sn; R = C_2H_5, C_6H_5

$$[(C_2H_5)_3M]_3Sb + 3\,(C_2H_5)_3M'H \rightarrow [(C_2H_5)_3M']_3Sb + 3\,(C_2H_5)_3MH \quad (42)$$

M = Si, M′ = Ge, Sn; M = Ge, M′ = Sn

Finally, trimethylstannyldibutylstibine is formed as a by-product in the presumably free-radial hydrostannation of ethynyldibutylstibine with trimethylstannane [86].

$$(C_4H_9)_2Sb{-}C{\equiv}CH + (CH_3)_3SnH \rightarrow (C_4H_9)_2Sb{-}Sn(CH_3)_3 + C_2H_2$$

4.2. Physical and Chemical Properties

Organometal-substituted stibines (Table 11) are colorless liquids or crystalline solids that dissolve readily and in the monomeric state in aromatic hydrocarbons or tetrahydrofuran. They can be recrystallized from aliphatic hydrocarbons in the absence of oxygen. Oxygen-free water does not attack phenylstannylstibines, presumably because of their non-wettability. On the other hand all these compounds are sensitive to oxygen. As in the oxidation of the analogous phosphorus and arsenic compounds, two oxygen atoms are initially taken up per metal-antimony bond, but in this case the oxidation does not lead to definite products [74,80], since antimony-carbon bonds are evidently also oxidatively broken in this case. Small quantities of $AlBr_3$ catalyze the thermal decomposition

$$R_3MCl + NaSb(C_6H_5)_2 \rightarrow R_3MSb(C_6H_5)_2 + NaCl$$

of $[(C_2H_5)_3Sn]_3Sb$ to form $Sn(C_2H_5)_4$, Sn, and Sb. The cleavage of organostannylstibines with methyl iodide [74], benzoyl peroxide [84], and organohalides [84] has also been investigated.

5. Organogermyl-, Organostannyl-, and Organoplumbylbismuthines

In contrast with the organometal compounds of phosphorus, arsenic, and antimony, which have now grown considerably in number, the number of organogermanium-bismuth and organotin-bismuth compounds (Table 12) is very small. No compounds containing covalent lead-bismuth bonds are known as yet. Apart

Table 12. Organogermyl- and organostannylbismuthines.

Compound	M.p. (°C)	B.p. (°C/torr)	Ref.
$[(CH_3)_3Ge]_3Bi$		114–116/0.1	[88]
$[(C_2H_5)_3Ge]_3Bi$		167–168/2.5	[84, 85, 87]
$[(C_2H_5)_3Sn]_3Bi$	160–170 (decomp.)		[84, 85, 87]
$[(C_6H_5)_3Sn]_3Bi$	138–142 (decomp.)		[73, 83]

from a passing reference to the use of triethylstannyldiphenylbismuthine as an antioxidant in lubricants [72], *Schumann* and *Schmidt* [73] were the first to report the successful synthesis of small quantities of tris(triphenylstannyl)bismuthine from triphenylstannyllithium and bismuth chloride in tetrahydrofuran. *Creemers* [83] increased the yield to more than 75% by reaction of triethylbismuthine with triphenylstannane.

$$3\,(C_6H_5)_3SnLi + BiCl_3 \rightarrow [(C_6H_5)_3Sn]_3Bi + 3\,LiCl$$

$$3\,(C_6H_5)_3SnH + Bi(C_2H_5)_3 \rightarrow [(C_6H_5)_3Sn]_3Bi + 3\,C_2H_6$$

Tris(triethylgermyl)bismuthine and tris(triethylstannyl)bismuthine [84,85,87], as well as the extremely sensitive tris(trimethylgermyl)bismuthine [88], have also been synthesized.

$$3\,(C_2H_5)_3MH + Bi(C_2H_5)_3 \rightarrow [(C_2H_5)_3M]_3Bi + 3\,C_2H_6$$

M = Si, Ge, Sn

$$3\,(C_2H_5)_3SnH + [(C_2H_5)_3Ge]_3Bi \rightarrow [(C_2H_5)_3Sn]_3Bi + 3\,(C_2H_5)_3GeH$$

$$3\,(CH_3)_3GeCl + Na_3Bi \xrightarrow[\text{in } NH_3]{} [(CH_3)_3Ge]_3Bi + 3\,NaCl$$

The compounds with M = Ge or Sn, whose chemical properties have not yet been extensively studied, decompose at about 100 °C into hexaorganodigermanes or hexaorganodistannanes and bismuth. In the presence of catalytic amounts of $AlCl_3$, they decompose at even lower temperatures into tetraethylgermane or tetraethylstannane, germanium or tin, and bismuth. All the substances are sensitive to oxygen.

6. Comparisons

The starting point for the consideration of bonding in covalent compounds between elements of groups IVB and VB was the comparison of silicon-nitrogen compounds [89] with analogous silicon-oxygen compounds. In investigations of this nature, strong $(p\rightarrow d)_\pi$ double-bond components were discussed for both the Si–O and the Si–N bonds. The evidence presented to support the hypothesis of such strengthening of the Si–N bond was above all the planar structure of the trisilylamine [90], on which strong doubt has now been cast [91].

The possibility of $(p\rightarrow d)_\pi$ bond strengthening has also been investigated for the homologs of the silicon-nitrogen compounds. Thus $(p\rightarrow d)_\pi$ double-bond components were postulated not only for organostannylamines [92–94] but also for trisilylphosphine, for which a planar structure was thought to have been found [95]. Views on this point have also been reversed since then [96]. Other investigations [42,62] refute such a hypothesis. Thus trimethylsilyldiethylphosphine reacts with ethyl iodide to give a stable phosphonium salt, which melts without decomposition at 122 °C [97]. HI [97], $(BH_3)_2$, BF_3, BCl_3, and BBr_3 [98] also add as Lewis acids to the lone pair of electrons on the

phosphorus in silylphosphines or monogermylphosphines [105].

Similar contradictions can be found for organogermyl-, organostannyl-, and organoplumbylphosphines. The course of the oxidation and the unsuccessful attempts at specific syntheses of organostannylphosphine oxides or organostannylphosphonium salts lead one to attribute the stability of the tin-phosphorus bond to a necessary $(p\rightarrow d)_\pi$ contribution, since the Sn–P bond is broken as soon as the lone pair of electrons on the phosphorus is engaged. The 1,2-dipolar additions of carbon disulfide and phenyl isocyanate also support this hypothesis, since $Sn[P(C_6H_5)_2]_4$ is accessible to these reactions, whereas no electrophilic attack of these 1,2-dipoles on $[(C_6H_5)_3Sn]_3P$ is observed.

This interpretation of the covalent bond appears to be opposed by the vibration spectra, which can be interpreted only in terms of a pyramidal structure of the compounds, though it should be pointed out that it is by no means certain that $(p\rightarrow d)_\pi$ double-bond components must be associated with a planar structure of the molecule [99,100]. The reactions of the tris(trimethylmetal)-substituted phosphines with carbonyl compounds of the transition metals also show very clearly that it is possible to use the lone pair of electrons on the phosphorus for coordinate bonding without breaking the original $P-M^{IV}$ bonds.

As regards the stability of compounds of elements of groups IVB and VB, the investigations carried out so far show clearly that the most stable molecules are obtained with approximately equal covalent radii of the bonding partners [84,85,87,101].

In the light of our present knowledge, the hypothesis of the participation of the lone pair of electrons of phosphorus, arsenic, antimony, and bismuth in the bond with silicon, germanium, tin, or lead seems quite feasible. The final decision should be left to detailed physicochemical studies and structure analyses.

Crystal Structure Analysis by Neutron Diffraction II[**]

By G. Will[*]

This second part of the article "Crystal Structure Analysis by Neutron Diffraction" deals with the diffraction of neutrons by magnetically ordered crystals. Neutron diffraction is at present the only reliable method for the determination of the magnitude, direction, and spatial distribution of magnetic moments in crystalline substances. Since the magnetic moments are essentially due to the unpaired electrons, the distribution of these electrons in the crystal can be measured in this way.

1. Introduction

An important application of neutron diffraction is the determination of magnetic spin structures in crystals in the magnetically ordered state. The neutron, or rather its magnetic moment, acts as a probe, by means of which the spatial electron spin distribution in the crystal can be measured in atomic dimensions. Neutron diffraction is at present the only method that allows the reliable determination of the magnetic environmental relations between the individual atoms or ions and of the long-range order of the spin. The investigation of magnetism and the use of constantly improving magnetic materials has now become so important that the chemist engaged in the preparation and analysis of such compounds must also be familiar with the magnetic properties and their investigation.

[**] Part II: Neutron Diffraction and Magnetic Structures. – Part I: Neutron Diffraction at Atomic Nuclei [1].

2. Physical Principles

The neutron has a magnetic moment of $\mu_n = -1.91319$ nuclear magnetons (μ_N), and can therefore enter into magnetic dipole-dipole interaction with the magnetic moments of the atoms. The interaction with the magnetic moments of shell electrons that are situated in incomplete shells, and which therefore produce a resultant magnetic moment, is particularly important. The interaction with the magnetic moments of the atomic nuclei, on the other hand, is weaker by a factor of about 2000, and can be detected only under certain conditions; this interaction can be disregarded in the present connection.

The elastic scattering of the thermal neutrons by crystals consists essentially of two components having approximately equal orders of magnitude (scattering lengths between 10^{-12} and 10^{-13} cm):

1. nuclear scattering due to interactions between the neutron and the atomic nuclei [1];

2. magnetic scattering due to a classical dipole interaction between the magnetic moment of the neutron and the magnetic moments of the shell electrons.

The observed intensity of a diffracted neutron beam from a crystal is made up additively from these two components.

$$I = I_{\text{nucl}} + I_{\text{magn}} \tag{1}$$

Since the intensities in general are proportional to the squares of the crystallographic structure factors, we can write

$$|F|^2 = |F|^2_{\text{nucl}} + q^2 \cdot |F|^2_{\text{magn}} \tag{2}$$

$\mathbf{q}$ = magnetic interaction vector (see eq. (6)), F = crystallographic structure factor.

$$F_{\text{nucl}} = \sum_j b_j \cdot e^{2\pi i(hx_j + ky_j + lz_j)} \tag{3a}$$

$$F_{\text{magn}} = \sum_j p_j \cdot e^{2\pi i(hx_j + ky_j + lz_j)} \tag{3b}$$

The structure factor in X-ray diffraction, for comparison, is

$$F_{\text{x-ray}} = \sum_j f_j^R \cdot e^{2\pi i(hx_j + ky_j + lz_j)} \tag{3c}$$

where f_i^R are the *X-ray atomic scattering factors*, which describe the spatial distribution of *all* the electrons around the atomic nuclei. The nuclear scattering amplitudes, which are independent of the scattering angle, are represented by b_j; p_j are the angle-dependent magnetic scattering amplitudes.

The magnetic scattering of neutrons was discussed by *Halpern* and *Johnson* [2], and later in an extended form by *Trammell* [3] and *Blume* [4]. According to these authors the magnetic scattering amplitude p_j is given by

$$p_j = p_j(\boldsymbol{k}) = -\frac{e^2\mu_n}{mc^2} \cdot S_j \cdot f_j(\boldsymbol{k}) \tag{4a}$$

$$= 0.539 \cdot 10^{-12} \cdot S_j \cdot f(\boldsymbol{k}) \text{ cm}.$$

e,m = charge and mass of the electron

μ_n = magnetic moment of the neutron (in μ_N)

S_j = spin quantum number of the atom j

$f_j(\boldsymbol{k})$ = corresponding *magnetic form factor*

$$\boldsymbol{k} = \frac{4\pi \sin\Theta}{\lambda} \cdot \boldsymbol{\epsilon}$$

$\boldsymbol{\epsilon}$ = scattering vector (unit vector)

2Θ = scattering angle (Θ = Bragg angle)

Where the orbital moment cannot be neglected, eq. (4a) becomes

$$p_j(\boldsymbol{k}) = -\frac{e^2\mu_n}{mc^2} \cdot \frac{1}{2}\left[L_j^J \cdot f_j^L(\boldsymbol{k}) + 2\,S_j^J \cdot f_j^S(\boldsymbol{k})\right] \tag{4b}$$

with L^J and S^J, the projections of these quantum numbers on the vector $\mathbf{J}$.

$f_j(\boldsymbol{k})$ are now *magnetic form factors*, which describe the spatial distribution of the *unpaired electrons*. When the orbital moments are not negligible, separate form factors f^L and f^S must be used for the orbital and spin moments; this is so *e.g.* for lanthanides.

The magnetic scattering of neutrons is particularly interesting when the spins, in other words the individual magnetic moments, undergo a transition into an ordered state, *i.e.* when collective magnetism arises. Neutron diffraction is at present the only method by which the long-range order of the magnetic moments and their relative and absolute orientation can be determined. The neutron diffraction experiments provide information about:

1. the existence of collective magnetism;

2. the transition temperature (Curie or Néel temperature, T_C or T_N);

3. the nature of the magnetism: paramagnetism, ferromagnetism, antiferromagnetism, or ferrimagnetism;

4. the size of the magnetic unit cell;

5. the distribution of the magnetic atoms (or ions) in the sublattice and their relative orientation;

6. the absolute orientation of the moments with respect to the crystal axes;

7. the magnitude of the magnetic moments of the individual atoms or ions;

8. the magnitude and direction of the internal fields (by application of an external magnetic field);

9. the temperature dependence of the magnetization;

10. the local distribution of the magnetic moment density in the crystal, *i.e.* in the case of 3d electrons, the local distribution of the 3d electron density (covalency effects).

3. Examples of Applications

3.1. Antiferromagnetic Structure of MnO

The method and the derivation of the results is best illustrated with the aid of examples. MnO was the first substance whose antiferromagnetic structure was established by neutron diffraction [5]. This experiment provided evidence of the very existence of antiferromagnetic order. The same magnetic order as in MnO has also been found in NiO [6] and in EuTe [7]. Though FeO [6] and CoO [6,8] assume an order with the same spin-sign sequence as MnO, the moments have a different orientation in relation to the crystal axes (Table 1).

Table 1. Magnetic properties of 3d metal oxides and Eu-chalcogenides.

	MnO	FeO	CoO	NiO
T_N (°K)	122	198	291	523
Symmetry below T_N	rhombohedral $\alpha < 60°$	rhombohedral $\alpha > 60°$	tetragonal $c/a < 1$	rhombohedral $\alpha < 60°$
Direction of magnetic moment	(111)	[111]	[$\bar{1}\bar{1}$7]	(111)

	EuO	EuS	EuSe	EuTe
Magnetic order	ferro	ferro	antiferro	antiferro
T_C resp. T_N (°K)	77	16.5	4.6 [a]	7.8

[a] According to *G. Busch, P. Junod, R. G. Morris,* and *J. Muheim,* Helv. physica Acta *37*, 637 (1964). Considerable uncertainty still exists concerning the magnetic behavior and even the transition temperatures. Thus *Busch et al.* found a second transition at 3.8 °K, which could be confirmed by recent neutron diffraction experiments.

Magnetic order manifests itself in the appearance of coherent scattering. Collective magnetism can therefore be recognized immediately if two neutron diffraction diagrams are recorded, one above and one below the Curie or Néel temperature, the difference diagram, representing the magnetic scattering, then being found by subtraction.

$$I_{magn} = I^{T<T_N}_{magn+nucl} - I^{T>T_N}_{nucl} \qquad (5)$$

Figure 1 shows a recent neutron diffraction diagram of MnO recorded by the author, and Figure 2 shows the antiferromagnetic structure derived from this diagram. MnO crystallizes in a face-centered cubic cell with the NaCl structure. The space group extinction rules for the nuclear scattering are therefore

h,k,l = even: $F = b_{Mn} + b_O = -3.7 + 5.77 = 2.07f$

h,k,l = odd: $F = b_{Mn} - b_O = -3.7 - 5.77 = -9.47f$

The nuclear scattering lengths are $b_{Mn} = -3.7\,f$ and $b_O = 5.77\,f$ ($1\,f = 1$ fermi $= 10^{-13}$ cm; cf. also [11]). When MnO powder is cooled in a cryostat, new reflections that point to magnetic order of the spins are observed below $T_N = 122$ °K. These new reflections can be indexed as $h/2$, $k/2$, $l/2$ where all the indices h, k, l are odd. Integer Miller indices are obtained by multiplication by 2; this means that to describe the magnetic arrangement of the spins in the crystal, the unit cell dimensions must be doubled in all three directions. The dimensions of the magnetic unit cell are thus double the dimensions of the chemical unit cell (see Fig. 1):

$$a_{magn} = 2 \cdot a_{nucl}$$
$$b_{magn} = 2 \cdot b_{nucl}$$
$$c_{magn} = 2 \cdot c_{nucl}$$

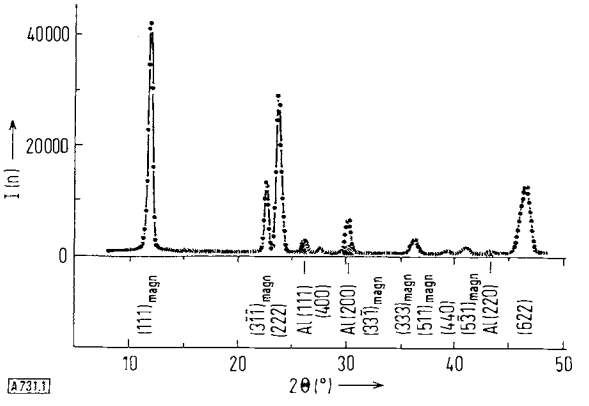

Fig. 1. Neutron-diffraction diagram of antiferromagnetically ordered MnO recorded at 4.2 °K. Owing to the doubling of the unit cell in the magnetically ordered state, all the reflections of the magnetic scattering have odd indices; all the nuclear scattering reflections have even indices. The reflections (222) and (622) (= h, k, l odd × 2) are strong, and the reflections (400) and (440) (h, k, l even × 2) are weak, corresponding to the intensity conditions for a face-centered cubic lattice (NaCl structure) and considering the negative sign of the nuclear scattering length of manganese.

The magnetic phase transition is associated with a crystallographic phase transition. Below 122 °K, in the antiferromagnetic range, MnO crystallizes with a rhombohedral unit cell, though the angle α differs only very slightly from 90°. At 4.2 °K, $a_{nucl} = b = c = 4.415$ Å and $\alpha = 90.6°$.

The magnetic order can now be deduced from the size of the magnetic unit cell together with the observed extinction rules for the magnetic reflections (MnO: h, k, l even not observed). For MnO, this gives an antiparallel orientation of the spins along the three crystal axes: ↑↓↑↓↑↓. Since only the relative orientation is expressed, the situation can be described by a sign sequence: $+-+-+-\ldots$. This gives the antiferromagnetic structure as shown in Figure 2. It consists of ferromagnetic (111) planes in which all the spins are parallel, with an antiferromagnetic sequence of such (111) planes normal to the plane in the [111] direction.

The absolute orientation and the magnitude of the magnetic moments can be determined from the intensities of the individual reflections. The quantity q^2 from eq. (2) is used for this purpose.

q is known as the magnetic interaction vector, and represents a relation between the direction of the

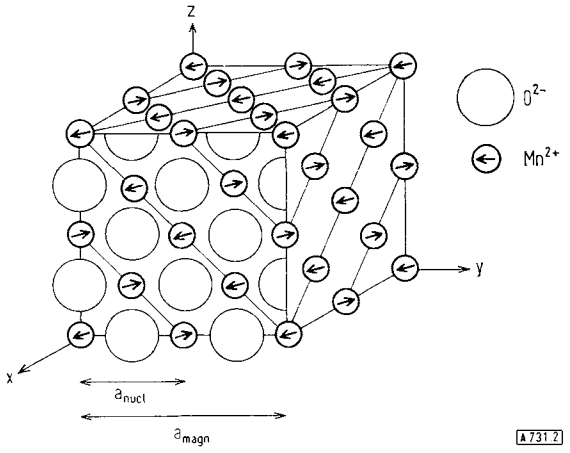

Fig. 2. Antiferromagnetic structure MnO. The spins lie in the (111) planes, and all the spins are parallel within the same (111) plane. The same magnetic structure is also found in NiO and EuTe.

magnetic moments, described by a unit vector $\boldsymbol{\varkappa}$, and the orientation of the reflecting crystal plane *h k l*, described by the scattering vector $\boldsymbol{\epsilon}$ (unit vector), which is normal to the plane *hkl* (cf. Fig. 3).

$$\mathbf{q} = \boldsymbol{\epsilon}(\boldsymbol{\epsilon} \cdot \boldsymbol{\varkappa}) - \boldsymbol{\varkappa} \tag{6}$$

Multiplication gives

$$q^2 = 1 - (\boldsymbol{\epsilon} \cdot \boldsymbol{\varkappa})^2 = \sin^2\alpha \tag{7}$$

where α is the angle between $\boldsymbol{\epsilon}$ and $\boldsymbol{\varkappa}$.

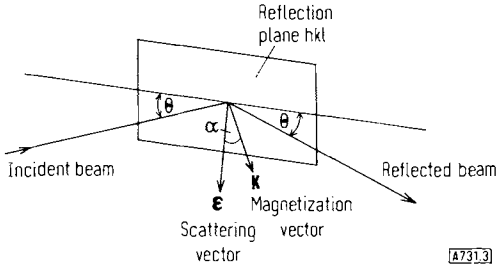

Fig. 3. Vector relation between incident neutron beam, diffracted beam, orientation of the reflecting plane, and the magnetization direction. The scattering intensity is proportional to $\sin^2\alpha$, *i.e.* the intensity has a maximum when the magnetic moments lie in the reflecting plane *hkl*.

Since the orientation of the various crystallites in a powder is random, limits are placed on the determination of the angle α from powder measurements. Thus it can be shown that for cubic crystal symmetry, $\langle q^2 \rangle$ = constant = $^2/_3$, and is thus independent of the orientation. In a cubic crystal therefore, the orientation of the spins in relation to the crystal axes cannot be determined from powder measurements. In crystals with rhombohedral, tetragonal, or hexagonal symmetry, the orientation of the spins can be given in relation to the unique axis of the crystal system, *i.e.* in relation to [111] in rhombohedral crystals and in relation to the *c* axis in tetragonal or hexagonal crystals.

For MnO, and also for EuTe, the measured intensity *ratios* show that the magnetic moments lie in the (111) planes as shown in Figure 2. Within the (111) plane the orientation cannot be determined from powder data.

The magnitude of the magnetic moment at the individual ions can be calculated from the absolute intensities using eq. (4a) or (4b). The determination of the absolute scale is rather easy in neutron diffraction studies, since the always-present nuclear scattering reflections can be used as an internal standard.

3.2. Investigations on Europium Chalcogenides

The special importance of the chalcogenides EuO, EuS, EuSe and EuTe is that they allow the direct study of the magnetic exchange forces as a function of the interionic distance in a series of simple compounds. They are of general interest because they represent the first ferromagnetic insulators that have been found which are optically transparent in the visible part of the spectrum. The compounds crystallize in the simple, parameter-free NaCl structure, which is particularly convenient for theoretical considerations. The magnetic properties of these compounds are shown in Table 1, and Figure 4 shows the exchange interactions as a function of the lattice constants. Since the Eu–Eu distances are directly reflected in the lattice constants, it is possible to combine the lattice constants and the magnetic behavior and estimate from them the exchange interactions. The strong ferromagnetic interaction J_1 between the nearest-neighbor Eu ions in EuO and EuS is responsible for the ferromagnetic behavior of both compounds. In EuTe, the antiferromagnetic interaction J_2 between next-nearest neighbors is distinctly greater than J_1; EuTe therefore behaves antiferromagnetically. Our neutron diffraction studies [7] have shown an antiferromagnetic order of the second kind in EuTe, which means that the compound has the same spin configurations as MnO (Fig. 2).

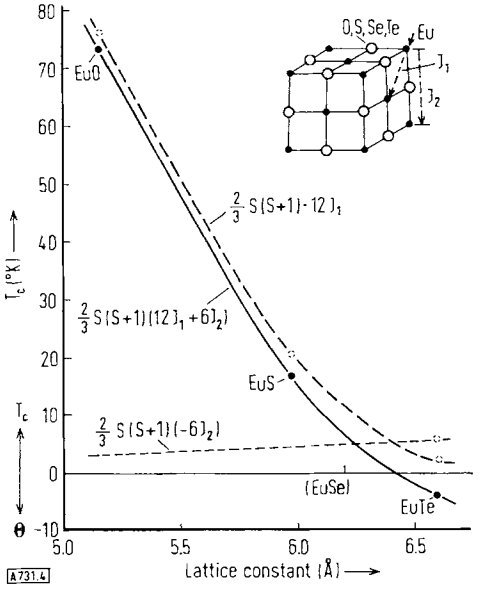

Fig. 4. Plot of the magnetic interactions J_1 and J_2 in europium chalcogenides as a function of the lattice constants.

The results for the magnetic properties of EuSe are contradictory. The magnetic structure may be influenced by small quantities of impurities or Eu^{3+} ions. A neutron diffraction study by *Pickart* and *Al-*

perin [9] showed that the sample used by these authors had a complicated antiferromagnetic structure, but that this structure could be changed into a ferromagnetic order by even a small external magnetic field of about 1700 Oe. EuSe was therefore not taken into account for the dependence of the exchange forces J_1 and J_2 in Figure 4.

3.2.1. Sublattice Magnetization and Exchange Interactions

In a face-centered cubic lattice, each ion has twelve nearest neighbors (nn) at a distance $\sqrt{2}/2\,a_0$ along the face diagonals [110] and six next-nearest neighbors (nnn) at a distance a_0 along the axes [100]. In the order of the second kind, as the antiferromagnetic order observed in MnO is called, each Mn^{2+} ion has six parallel and six antiparallel nearest neighbors and six antiparallel next-nearest neighbors (Table 2).

Table 2. Neighborhood relations in face-centered cubic lattices.

Neighbors	ferro-magnetic	antiferromagnetic	
		1st kind	2nd kind
nn	12 p	4 p, 8 ap	6 p, 6 ap
nnn	6 p	6 p	6 ap

When the magnetic order and the transition temperatures have been determined they can be used together with *Weiss*'s molecular field theory to derive the Heisenberg exchange interactions. *Heisenberg*'s view of ferromagnetism is based on the idea that the exchange interactions between two atoms i and j are responsible for the orientation of the magnetic moments. The magnetic exchange energy is described by a Hamiltonian operator $\mathfrak{H}$.

$$\mathfrak{H} = -2 \sum_{i>j} \cdot J_{i,j}\, \mathbf{S}_i \cdot \mathbf{S}_j \qquad (8)$$

$\mathbf{S}_i$ and $\mathbf{S}_j$ are spin operators $J_{i,j}$ is the exchange integral between the atoms i and j. Since the theory of exchange interactions is based on *ad-hoc* assumptions and the exchange integrals themselves cannot be calculated J must be determined experimentally if one wishes to understand the magnetic behavior of the substances. However, other interactions such as magnetic dipole-dipole coupling or the effects of anisotropy energies must generally be taken into account in addition to the exchange interactions. Measurements on simple structures such as the parameter-free structures of the NaCl type are therefore of great interest for the theory of magnetism. The series MnO, FeO, CoO, NiO and EuO, EuS, EuSe, EuTe have been extensively investigated; the oxides of the 3d transition metals are all antiferromagnetic, while a transition from ferromagnetism to antiferromagnetism is observed in the europium chalcogenides (cf. Table 1).

The exchange parameters J can be derived from the experimental data by means of relations from *Weiss*'s molecular field theory [10]. The following relations are valid:

$$\Theta = T_C = {}^2/_3\, S(S+1)\,[\,12J_1 + 6J_2] \qquad (9a)$$
$$T_{N_1} = {}^2/_3\, S(S+1)\,[-\,4J_1 + 6J_2] \qquad (9b)$$
$$T_{N_2} = {}^2/_3\, S(S+1)\,[\;\;0 - 6J_2] \qquad (9c)$$
$$T_{N_3} = {}^2/_3\, S(S+1)\,[-\,4J_1 + 2J_2] \qquad (9d)$$

T_C is the ferromagnetic Curie temperature; for antiferromagnetic crystals, Θ is the paramagnetic or asymptotic Curie-Weiss temperature, which follows from the Curie-Weiss law. For EuTe it was found that $\Theta = -7.5\,^\circ K$, and this together with the experimentally found Néel point $T_{N_2} = 7.8\,^\circ K$ [7] gives eq. 9a and 9b (order of the second kind):

$$J_2 = -(0.12 \pm 0.01)\,^\circ K; \quad J_1 = (0.025 \pm 0.025)\,^\circ K$$

(Energies are obtained by multiplication by $k = 1.38 \times 10^{-16}$ erg $^\circ K^{-1}$).

EuTe thus has a negative nnn exchange interaction, which is responsible for the antiferromagnetic orientation of the spins, and which is about five times as great as the positive direct nn exchange interaction.

Important information about the sublattice magnetization is obtained from the temperature behavior of the magnetic scattering. Figure 5a shows the temperature dependence of the magnetic scattering for the (111) reflection of EuTe. It is found from this that $T_N = 7.8\,^\circ K$. For comparison with the temperature dependence of magnetization as given by *Brillouin*, the observed intensity I_{rel} is normalized to I/I_0 and plotted against the normalized temperatures T/T_N. These normalized values are shown in Figure 5b; it can be seen that the experimental values do not agree with the theoretical Brillouin curve for a system having spin 7/2.

Both Mn^{2+} ($3d^5$) in MnO and Eu^{2+} ($4f^7$) in EuTe are in pure S states. There are therefore no orbital moment components to be taken into account. The dipole interactions are also negligibly small in these crystals, and the magnetic anisotropy energy is large only within the (111) planes while it is small perpendicular to these planes, *i.e.* in the direction of the antiferromagnetic coupling. The relations are therefore simple and the deviation of the experimental points from the Brillouin curve is surprising at first.

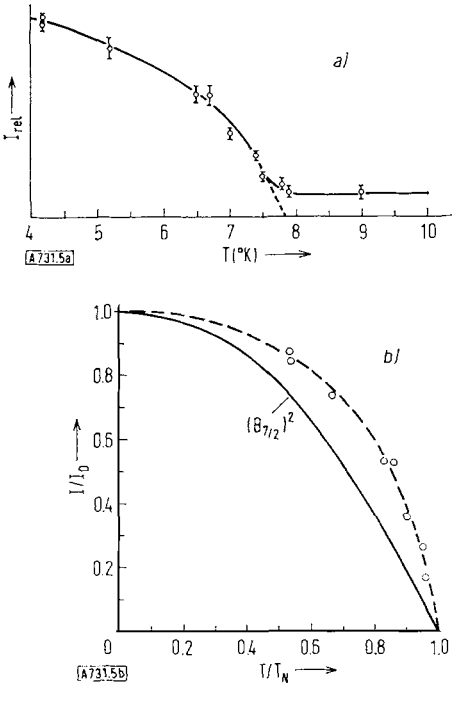

Fig. 5. Temperature dependence of the (strongest) magnetic reflection (111) in EuTe.

(a) Dependence of the intensity on temperature: The (111) reflection disappears at $T_N = 7.8\,^\circ K$; EuTe is in a paramagnetic state above this temperature.

(b) Intensity and temperature normalized to I_0 and $T_N \cdot I = f(T)$ thus becomes universal, and should follow the Brillouin function for spin S = 7/2 (continuous curve). The observed dependence, on the other hand, corresponds to a curve (broken) that was calculated by insertion of a biquadratic term of about 1% into the Hamiltonian exchange function.

[9] *S. J. Pickart* and *H. A. Alperin*, J. Physics Chem. Solids *29*, 414 (1968).

[10] *J. S. Smart*, Physic. Rev. *86*, 968 (1952).

To explain the discrepancy, *Rodbell, Jacobs, Owen,* and *Harris*[11] introduced a biquadratic contribution into the normally linear exchange interaction.

$$\mathfrak{H} = -2 \sum_{i>j} \{ J (\mathbf{S}_i \cdot \mathbf{S}_j) - j (\mathbf{S}_i \cdot \mathbf{S}_j)^2 \} \qquad (10)$$

If this biquadratic term is taken into account in the calculation of the Brillouin function, a very satisfactory agreement with the experimental point (broken curve in Fig. 5b) is obtained. Similar deviations of the experimental points from the Brillouin curve were found for MnO and NiO, and a biquadratic exchange term could also be detected for these crystals.

The biquadratic component amounts to about 1 % of J, and is therefore very small (in EuTe, j was found to be ≈ 0.001 °K). It is only rarely of such importance as in MnO and EuTe, and is generally overshadowed by the much larger exchange contributions of the dipole interaction and the magnetic anisotropy. It would therefore be wrong to try to explain every deviation from a Brillouin function by a biquadratic component of the exchange interaction.

3.3. Ferrimagnetic Structure of Ferrites

Reference was made in the first part of this article to the important role of neutron diffraction in the investigation of ferrites having the general composition $[X^{2+}(Y^{3+})_2(O^{2-})_4]$[1]. Since X and Y are normally adjacent elements in the periodic system they can be difficult or even impossible (*e. g.* in the case of $MnFe_2O_4$) to distinguish by X-rays. The neutron scattering powers of elements of adjacent atomic numbers on the other hand are generally quite distinct; neutron diffraction thus permits a definite identification of the ions.

X and Y in the ferrites are usually 3d transition elements. The analysis of the magnetic scattering of neutrons below the ordering temperature T_N also gives the ionization states of the ions and their distribution over the lattice sites. A classical example is the investigation of magnetite $Fe_3O_4 = [Fe^{2+}(Fe^{3+})_2(O^{2-})_4]$. Fe^{2+} and Fe^{3+} differ in their spin quantum numbers, S=2 and S=5/2 respectively, and consequently also have different magnetic scattering powers, p = 1·09 and $1{\cdot}36\times10^{-12}$ cm respectively. Neutron scattering at room temperature[12] gave an inverse spinel structure for magnetite with Fe^{3+} in the tetrahedral (or A) sites while the octahedral (or B) sites are uniformly occupied by Fe^{2+} and Fe^{3+}. The neutron diffraction data also show that the moments of the ions in the A and B sites are antiparallel to one another, so that the resultant magnetic moment corresponds to the moment of one Fe^{2+} ion per Fe_3O_4 formula unit. Fe_3O_4 is an example of ferrimagnetism postulated by *Néel*[13]. The magnetic structure is shown in Figure 6; the magnetic unit cell has the same dimensions as the chemical unit cell.

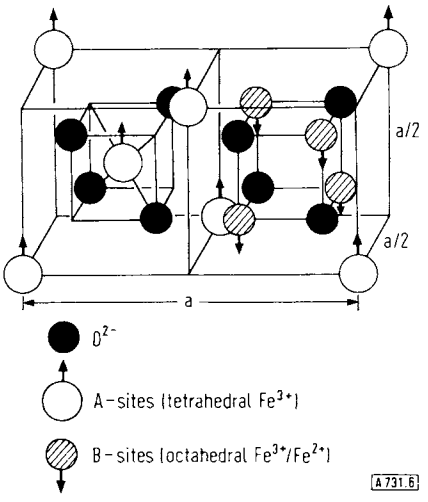

Fig. 6. Magnetic structure of magnetite at room temperature $[Fe^{2+}(Fe^{3+})_2(O^{2-})_4]$. Magnetite crystallizes with the spinel structure. One quarter of the unit cell is shown.

Magnetite exhibits a second magnetic phase transition, which was elucidated by an elegant experiment. Below 110–120 °K (the exact temperature depends on impurities in the crystals) the crystals exhibit a sudden change in electric conductivity and in magnetization. To explain this, *Verwey et al.*[14] postulated a crystallographic phase transition from the cubic spinel structure to an orthorhombic structure, combined with ordering of the Fe^{2+}/Fe^{3+} ions on the octahedral sites.

Hamilton[15] was able to confirm this hypothesis by neutron diffraction with a synthetic Fe_3O_4 single crystal. In this crystal, ordering of the iron ions on the octahedral sites (now in an orthorhombic unit cell) takes place at 119 °K. The Fe^{3+} ions form simple chains parallel to the a axis, while the Fe^{2+} ions are arranged perpendicular to these in chains parallel to the b axis. The orthorhombic a and b axes correspond to the cubic [110] face diagonals (Fig. 7). All the magnetic moments in the structure below 119 °K are parallel or antiparallel to the orthorhombic c (= cubic) axis. The experimental detection of this order is based

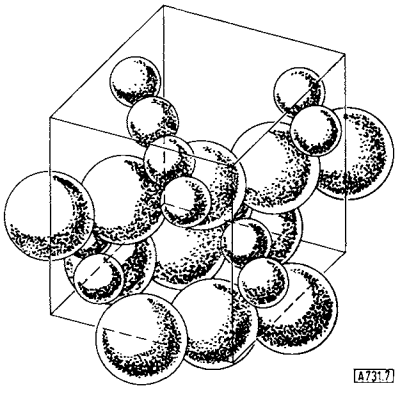

Fig. 7. Distribution of Fe^{2+} ions (large spheres) and Fe^{3+} ions (small spheres) in magnetite on the octahedral sites below the second magnetic transition at 119 °K. The ions, which are randomly distributed above this temperature (Fig. 6), now form mutually perpendicular ordered chains.

on the appearance of the (002) reflection on neutron diffraction; this reflection is proportional to the difference in the scattering powers $p(Fe^{3+})-p(Fe^{2+})$, and is forbidden for the cubic random distribution.

3.4. Magnetic Behavior of Solid Solutions in the Ternary System Fe_2O_3–Cr_2O_3–Al_2O_3

The sesquioxides α-Fe_2O_3, Cr_2O_3, Ti_2O_3, V_2O_3 and Al_2O_3 all crystallize hexagonally in the corundum structure, but only the crystals of α-Fe_2O_3 and Cr_2O_3 exhibit magnetic long-range order of the spins; no long-range order of the magnetic moments could be detected by neutron diffraction in Ti_2O_3 and V_2O_3, despite the observed anomalies in the temperature dependence of the magnetic susceptibility.

the sign sequence (+−+−). (When Fe_2O_3 is cooled below about −23 °C, the spins flip from the (111) plane into the [111] direction. This phase transition has not however been found in any solid solutions; if it does exist it does so only in a very narrow range around pure Fe_2O_3.)

Since the oxides discussed here form solid solutions, information on the magnetic interactions, and hence on the conditions for the various magnetic structures, should be obtainable from the magnetic properties of the solid solutions. Thus *Cox et al.* [18] found that in the system Fe_2O_3–V_2O_3, the magnetic structure of α-Fe_2O_3 persists up to a V_2O_3 content of 60 %. A particularly interesting phase in the system Fe_2O_3–Ti_2O_3 is a solid solution having the the composition $FeTiO_3$, in which there is a completely ordered distribution of the Fe^{2+} and Ti^{4+} ions over the A and B sites [19].

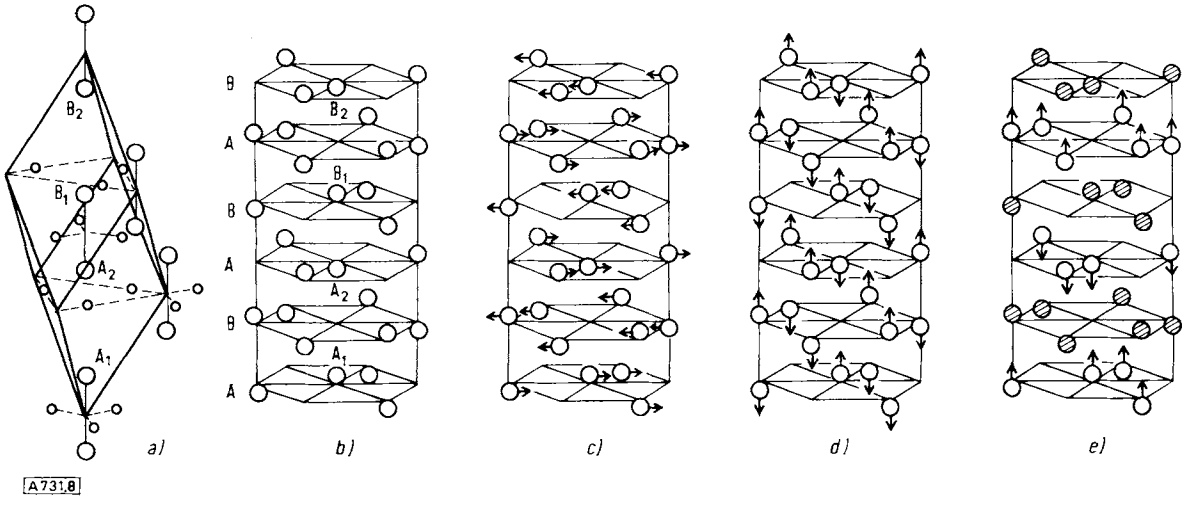

Fig. 8. Crystalline and magnetic structures of some sesquioxides.
a) Corundum structure — rhombohedral cell. Large circles = metal ions, small circles = oxygen ions.
b) Corundum structure — hexagonal representation. Only the metal ions, are shown.
c) Magnetic structure of α-Fe_2O_3 at 25 °C.
d) Magnetic structure of Cr_2O_3.
e) Magnetic structure of $FeTiO_3$. Open circles = Fe^{2+}, shaded circles = Ti^{4+}.

α-Fe_2O_3 and Cr_2O_3 have the same crystal structure, but quite different spin structures [16, 17] (Fig. 8). In Fe_2O_3, the spins lie in the hexagonal basal plane at 25 °C; the spins are parallel within a plane, and the planes are arranged in antiparallel sequence along the hexagonal *c*-axis. (In a rhombohedral description of the unit cell, we have ferromagnetic (111) planes in an antiferromagnetic sequence along [111].) The structures are described by the atomic positions A_1, A_2, B_1, and B_2. The spins in these positions in α-Fe_2O_3 then have the sign sequence (++−−).

In Cr_2O_3, on the other hand the spins are directed parallel to rhombohedral [111]; an antiferromagnetic arrangement exists within the individual (111) planes. In the rhombohedral [111] direction, the spins have

$FeTiO_3$ has an antiferromagnetic structure, in which ferromagnetic (111) planes form an antiparallel sequence in the [111] direction. These ferromagnetic planes are separated by layers of non-magnetic Ti^{4+} ions. The sign sequence can be given purely formally as (+−00); the spins themselves are oriented parallel and antiparallel to [111].

Complicated magnetic behavior is expected, and observed [20], in the solid solutions of the system Fe_2O_3–Cr_2O_3, since here we have interaction of two magnetic structures with opposite spin directions and different orders. A neutron diffraction study showed that the magnetic structure from 100 to 35 mole-% of Fe_2O_3 is that of α-Fe_2O_3, while at 10 to 0 mole-% of Fe_2O_3 it is that of Cr_2O_3. The transition temperature decreases with increasing Cr content: Fe_2O_3: T_N = 965 °K; Fe_2O_3–Cr_2O_3 (40:60 mole-%): T_N = 400 °K. Between 35 and 10 mole-% of Fe_2O_3, there is a helical structure described as an "umbrella structure", *i.e.* an arrangement in which the spins lie on cones, adjacent spins being turned through an angle α that is different

[18] *D. E. Cox, W. J. Takei, R. C. Miller*, and *G. Shirane*, J. Physics Chem. Solids *23*, 863 (1962).

[19] *G. Shirane, S. J. Pickart, R. Nathans*, and *Y. Ishikawa*, J. Physics Chem. Solids *10*, 35 (1959).

[20] *D. E. Cox, W. J. Takei*, and *G. Shirane*, J. Physics Chem. Solids *24*, 405 (1963).

by 180° in relation to one another. Both α and the apex angle of the cone vary with the Cr content. The orientation of the axis of the cone in the crystal also changes. The axis of the cone is initially (above 35 % Fe_2O_3) perpendicular to the *c* axis, *i.e.* parallel to the collinear moments in Fe_2O_3, the (half) apex angle of the cone being 19°. The apex angle increases to 77° at 20 % Fe_2O_3, and then decreases again. The orientation of the cone switches into the direction of the *c* axis at about 15 % Fe_2O_3; it then corresponds to the collinear moments in Cr_2O_3. The investigations were recently carried on by *Scharenberg* [21] and extended to include the presence of non-magnetic aluminum ions. Dilution of the magnetic lattice in this way yields valuable information concerning the range of the exchange forces and the stability of the magnetic structures. The results of these measurements can be seen in the magnetic phase diagram of Fe_2O_3–Cr_2O_3–Al_2O_3 (Fig. 9), from which the ranges of the various structure types are immediately recognizable.

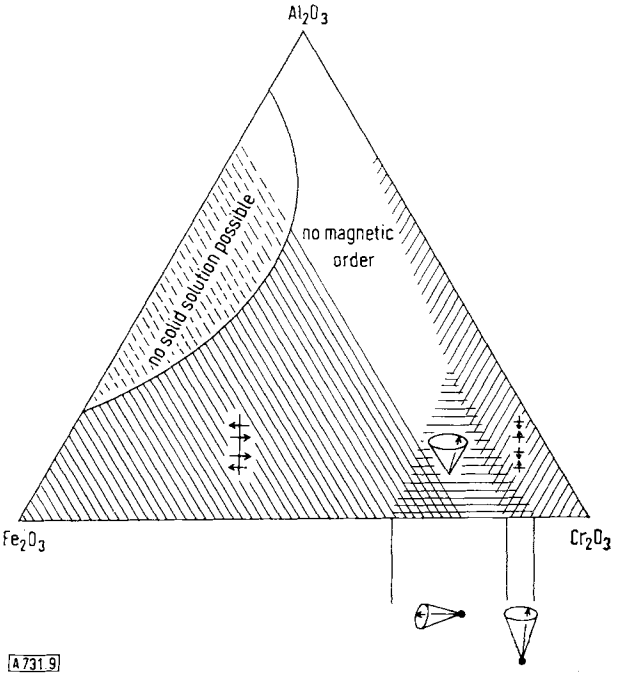

Fig. 9. Magnetic phase diagram of the ternary system Fe_2O_3–Cr_2O_3–Al_2O_3. In the regions with double shading, the crystals have two magnetic transitions: paramagnetic state $-T_{N_1}$ (magnetic collinear structure) $-T_{N_2}$ (magnetic spiral structure).

3.5. Determination of Covalent Bond Components in Antiferromagnetic Salts from Neutron Diffraction Data

In most antiferromagnetic salts of the 3d transition metals, *e.g.* $LaCrO_3$ or $KMnF_3$, the 3d metal ion is surrounded octahedrally by six ligands. The orbitals of the ligands are of s or p character, and give bonding and antibonding orbitals with the five d orbitals of the central ion. Only the antibonding orbitals are of interest for the consideration of the magnetic properties. The bonding orbitals have such low energy levels in the complexes discussed here that these levels are all doubly occupied by electrons. Only the higher antibonding orbitals are singly occupied, and are thus responsible for the magnetic behavior. We follow the procedure used by *Hubbard* and *Marshall* [22] and consider first a simple antiferromagnetic chain of p and d orbitals as shown in Figure 10.

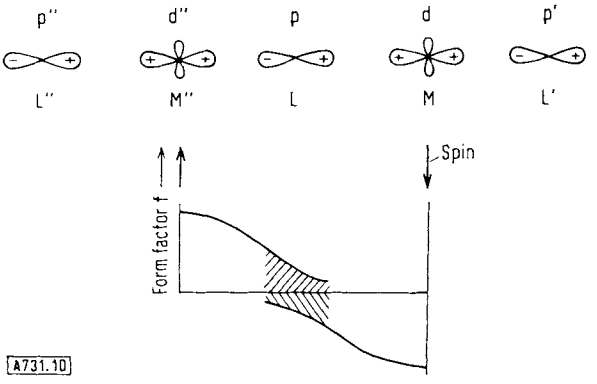

Fig. 10. Schematic diagram of the orbitals of an antiferromagnetic chain and the overlap of the form factors of 3d electrons. In the case of antiferromagnetic orientation of the spins, interference extinction occurs in the neutron diffraction in the region of the ligands.

L = ligand ion, M = metal ion. Owing to the antiferromagnetic order, the spins, and hence also the spin densities and the form factors, have opposite signs in M and M''.

The magnetically active orbital of M can no longer be described simply by d orbitals, but we have to take into account the admixture of p orbitals (covalency).

$$\psi_M(\mathbf{r}) = N \{ d(\mathbf{r}) - A \cdot p(\mathbf{r}) + A \cdot p'(\mathbf{r}) \} \qquad (11)$$

A are the admixture parameters and N is a normalization factor. S_σ is the overlap integral between p and d

$$1/N^2 = 1 - 4A \cdot S_\sigma + 2A^2 \qquad (12)$$

orbitals. This can be used to find the moment density $D(\mathbf{r})$ around M; if overlap between p and p' is neglected, we obtain for $D(\mathbf{r})$

$$\begin{aligned} D(\mathbf{r}) = {} & d^2(\mathbf{r}) \{ 1 + 4A \cdot S_\sigma - 2A^2 \} \\ & - 2A \{ d(\mathbf{r}) \cdot p(\mathbf{r}) - d(\mathbf{r}) \cdot p'(\mathbf{r}) \} \\ & + A^2 \{ p^2(\mathbf{r}) + p'^2(\mathbf{r}) \} \end{aligned} \qquad (13)$$

The first term containing $d^2(\mathbf{r})$ is confined to the magnetic ion M. The second term describes the overlap density between p and d orbitals, and is also confined to the immediate neighborhood of M. The third term, on the other hand, describes a density distribution, which lies exclusively at the position of the ligands; the distance from L to the neighboring metal ion M'' is the same as the distance from M. The analogous density due to the ion M'' at the position L is roughly equal to the contribution due to M, but is of opposite sign in antiferromagnetic substances. This means that $A^2p^2(\mathbf{r})$ and $A^2p'^2(\mathbf{r})$ cancel out with the analogous contributions from M and M''. It is

[21] *W. Scharenberg*, Dissertation, Universität Bonn 1968.

[22] *J. Hubbard* and *W. Marshall*, Proc. physic. Soc. *86*, 561 (1965).

clear therefore that in a neutron diffraction experiment on an antiferromagnetically ordered crystal, only the contributions of the first two terms in eq. (13) are observable in the Bragg maximum.

$$\mu(\mathbf{r})_{obs} = d^2(\mathbf{r}) \{ 1 + 4A \cdot S_\sigma - 2A^2 \} - 2A \{ d(\mathbf{r}) \cdot p(\mathbf{r}) - d(\mathbf{r}) \cdot p'(\mathbf{r}) \} \quad (14)$$

Thus whereas the integration of eq. (13) gives 1, integration of eq. (14) merely gives

$$\mu(\mathbf{r})_{obs} = \int \mu(\mathbf{r})\, d\mathbf{r} = 1 - 2A^2 \quad (15)$$

Calculation of the magnetic moments μ_{obs} (*e.g.* according to eq. (4)) from the measured diffraction intensity gives a value that is smaller by $2A^2$ than the true moment μ_0.

It is therefore possible, in principle at least, to determine the covalent part in antiferromagnetic complexes of this type from neutron diffraction data. The effects are naturally very small, and the measurements are therefore laborious and require a number of precautions to eliminate possible sources of error such as, for example, "$\lambda/2$ contamination" of the neutron beam (cf. [1]).

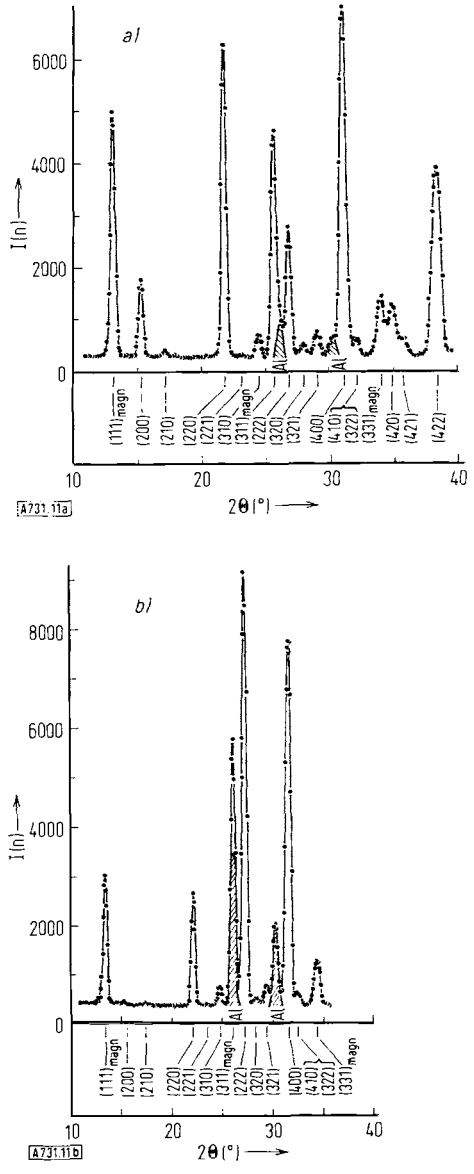

Fig. 11. Neutron diffraction diagram of a) $LaFeO_3$ and b) $LaCrO_3$, recorded at 4.2 °K in the antiferromagnetic state.

We have carried out neutron diffraction experiments of this type on $LaCrO_3$, $LaFeO_3$, and $LaMnO_3$ as well as on a series of fluorites having the composition KMF_3 (M = 3d transition elements), and have actually been able to detect this effect in $LaCrO_3$ and $LaFeO_3$ [23]. Figure 11 shows the neutron diffraction diagrams of $LaFeO_3$ and $LaCrO_3$.

On application to the three-dimensional crystal structure, considerations analogous to those used for equations (11) to (15) lead to the following relations (A = covalency coefficient) [22].

$$\mu_{obs}/\mu_0 = \begin{cases} 1 - 3(A_\sigma^2 + A_\delta^2) & Ni^{2+} \\ 1 - 4A_\pi^2 & Cr^{3+} \\ 1 - 1.2(A_\sigma^2 + 2A_\pi^2 + A_\delta^2) & \begin{cases} Mn^{2+} \\ Fe^{3+} \end{cases} \end{cases}$$

The evaluation of our measurements on powder specimens is concentrated mainly on the first magnetic reflection (111) at small scattering angles, where reliable theoretical assumptions regarding the form factor can be made. This means that the observed deviations in the values of the form factor can be entirely attributed to the covalency of the bond, and not *e.g.* to a possible asymmetric charge distribution. The measurements were hampered by a very small coherent nuclear scattering contribution to the magnetic scattering. This nuclear scattering component is the result of the distortion of the perovskite-like crystal structure from the ideal (cubic) perovskite structure; it must be determined separately by a crystal structure analysis [24]. However, this contribution can only increase the effect and cannot decrease it. $LaCrO_3$ and $LaFeO_3$ crystallize in a perovskite-like structure, in which each cation is octahedrally surrounded by antiparallel oriented neighbors. The magnetic structure of $LaMnO_3$ is different: each Mn^{3+} ion has two parallel and four antiparallel neighbors. The unfavorable ratio 2 : 4 of parallel to antiparallel neighbors decreases the effect; we feel, that for this reason, among others, we were unable to detect the covalency parameters in $LaMnO_3$.

Table 3 also shows the results of measurements on NiO [25], MnO [26], and MnF_2 [27]. Results of nuclear magnetic resonance measurements [28] are given for comparison.

The values for Fe^{3+} and Mn^{2+} both of which have the $3d^5$ configuration are particularly interesting. It is

Table 3. Covalency parameters in some antiferromagnetic salts of 3d elements.

Ion	From NMR measurements		From neutron diffraction measurements	
	Compound	Covalency coefficients (%)	Compound	Covalency coefficients (%)
Ni^{2+}	$KNiF_3$	$A_\sigma^2 + A_S^2 = 4.32$	NiO	$A_\sigma^2 + A_S^2 = 6.0$
Cr^{3+}	K_2NaCrF_6	$A_\pi^2 = 4.7$	$LaCrO_3$	$A_\pi^2 = 4.6$
Fe^{3+}	Fe^{3+} in $KMgF_3$	$A_\sigma^2 - A_\pi^2 = 3.3$ $A_S^2 = 0.76$	$LaFeO_3$	$A_\sigma^2 + 2A_\pi^2 + A_S^2 = 10.0$
Mn^{2+}	$KMnF_3$	$A_\sigma^2 - A_\pi^2 = 0.18$ $A_S^2 = 0.52$	MnF_2 MnO	$A_\sigma^2 + 2A_\pi^2 + A_S^2 = 3.3$ 5.5
Mn^{3+}			$LaMnO_3$	no effect found

possible to determine A_σ^2 and A_π^2 (in %) individually by a combination of NMR and neutron diffraction data

Fe^{3+}: $A_\sigma^2 = 5.4$ $A_\pi^2 = 2.1$
Mn^{2+} in $MnF_2(MnO)$: $A_\sigma^2 = 1.2\ (1.8)$ $A_\pi^2 = 1.0\ (1.6)$

3.6. Determination of the Local 3d Spin Density Distribution in Crystals[29]

The magnetic form factor f can be deduced from the measured magnetic scattering with the aid of eq. (4). It is then possible by Fourier transformation of the diffraction data to calculate the spatial distribution of the magnetic moments in the crystal. The result is a diagram of the density distribution of the magnetic moments around the centers of the atoms similar to the electron density distribution obtained in X-ray structure analyses. If we confine our considerations to the 3d elements, where the crystal fields are strong compared with the spin-orbital coupling, so that the orbital moments are generally suppressed, then the magnetic moment density from the neutron diffraction data directly describes the spin density, and hence the density of the unpaired (outer) electrons, which are responsible for the chemical bonding.

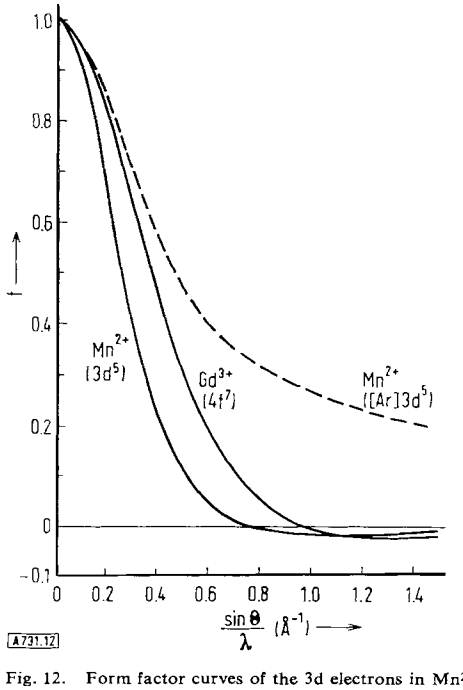

Fig. 12. Form factor curves of the 3d electrons in Mn^{2+} and of the 4f electrons in Gd^{3+} for the magnetic scattering of neutrons [the form factor curve of Mn^{2+} (with all electrons) for the diffraction of X rays is also given for comparison].

[29] For a review see *e.g. G. Will*, Z. angew. Physik *24*, 260 (1968).

Since the outer electrons are on average farther from the nucleus than the mean total electron density that determines the X-ray diffraction, the magnetic form factor, which is a shape factor in the present example of the 3d electrons, falls off much more rapidly than the X-ray form factor. This is illustrated in Figure 12 for Mn^{2+} (the magnetic form factor of Gd^{3+} is also shown for comparison). In the lanthanides the unpaired electrons (4f electrons) are on average denser at the nucleus; the fall-off of the form factor is therefore rather less. Mn^{2+} and Gd^{3+} are in an S state with electronic configurations $3d^5$ and $4f^7$ respectively, and the electron distribution is spherically symmetrical.

Whereas the electron distribution around the nucleus can be taken as spherically symmetrical on the whole in X-ray structure analysis, the distribution of the outer bonding electrons, which are "seen" by the neutrons, is generally not spherically symmetrical. Consequently, the "form factor curves" for neutron diffraction are not smooth curves; the experimental points are scattered more or less widely about an average curve. Figure 13 shows form factor values for

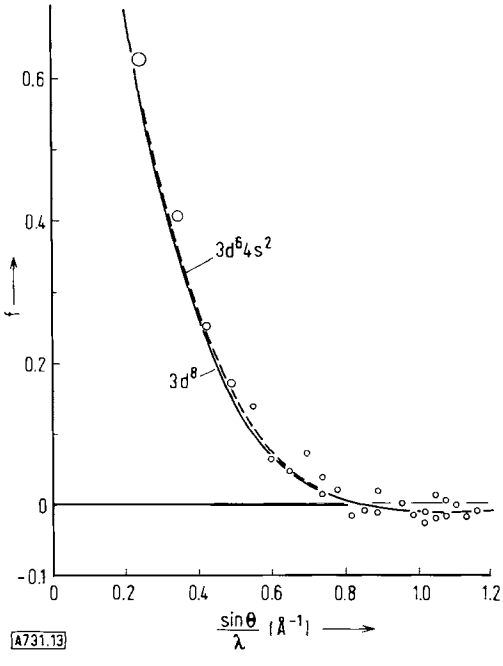

Fig. 13. Experimental magnetic form factor values (circles) found for elementary iron with polarized neutrons, compared with theoretical curves for various electronic configurations.

elementary iron in the ferromagnetic state measured with polarized neutrons, together with the theoretical spherically symmetrical electronic configurations for comparison. The deviations of the experimental points from the spherical symmetry curves are real (*e.g.* outside the error limits), and are a direct measure of the asymmetric distribution of the 3d electrons (the size of the circles corresponds approximately to the experimental accuracy).

The resolution in the density diagram is found to depend on the number of reflections measured, and is determined by the $\sin\Theta/\lambda$ range. A resolution of 1 Å corresponds roughly to $\sin\Theta/\lambda = 0.3$ to 0.4 $Å^{-1}$ (1 Å $\approx 0.66\ \lambda/2\sin\Theta$); to obtain a resolution of 0.25 Å, therefore, measurement up to $\sin\Theta/\lambda = 1.2\ Å^{-1}$ is necessary. The deviations of the electron density distribution from spherical symmetry are particularly evident in the region around 0.8 $Å^{-1}$; on the other hand, the magnetic form factors are very small between $\sin\Theta/\lambda = 0.8$ and 1.2 $Å^{-1}$ so that the determination of the 3d electron distribution necessitates the accurate measurement of very small quantities. It is interesting to note the change in the sign of the form factor curves from $+f$ to $-f$ at about $\sin\Theta/\lambda = 0.8\ Å^{-1}$ as a result of the limited spread of the 3d electrons (the maximum is situated about 0.35 to 0.40 Å from the center of the nucleus).

The usual technique of diffraction of unpolarized neutrons is generally inadequate for the reliable determination of the form factors and hence the 3d electron densities. Much more accurate measurements are possible with polarized neutrons.

The neutron has a spin of 1/2, and can occur in the energetically different spin states + 1/2 and −1/2. Both spin states normally occur with equal probability in a neutron beam (unpolarized neutrons). With a suitable experimental arrangement (Fig. 14), however, it is possible to obtain a neutron beam that contains only neutrons in a single spin state (polarized neutrons). A polarized neutron beam of this type is obtained *e.g.* by Bragg reflection from a "polarization monochromator" (nowadays nearly always a single crystal having the composition $Co_{0.92}Fe_{0.08}$ which is magnetized in an external field). Approximately 99 % of the neutrons in the resulting beam are in the same spin state. The direction of the spin vector is described by a unit vector $\pm\ \boldsymbol{\lambda}$, which is referred to the external magnetic field. The neutron beam can be converted from one spin state into the other by superposition of a low frequency field on the polarized beam ("flipper").

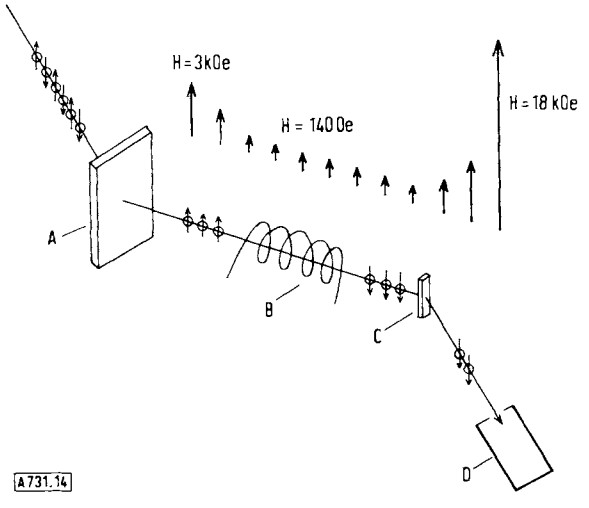

Fig. 14. Schematic representation of the experimental arrangement for measurements with polarized neutrons. A: Polarization monochromator ($Co_{0.92}Fe_{0.08}$); B: "flipper"; C: test crystal; D: counter.

The conditions for the polarization of the neutrons are obtained by insertion of eq. (3a) and (3b) in eq. (2). The structure factor F can then be expressed in the general form

$$F = \sum_j \{\ b_j + (\mathbf{q}_j \cdot \boldsymbol{\lambda})\, p_j\ \} \cdot e^{2\pi i (hx_j + ky_j + lz_j)} \qquad (16)$$

The vectors $+\boldsymbol{\lambda}$ and $-\boldsymbol{\lambda}$ are present in equal proportions in a beam of unpolarized neutrons; the scattered intensity is proportional to F^2 and therefore to $b^2 + p^2$; the cross term $(\mathbf{q}\boldsymbol{\lambda})$ thus becomes zero [eq. 2]. For polarized neutrons, on the other hand, we have *e.g.* $+\boldsymbol{\lambda} = 1$ and $-\boldsymbol{\lambda} = 0$. Eq. (16) now leads to a phase dependence of the nuclear scattering on the magnetic scattering. The resultant intensity is proportional to $(b + p)^2$:

polarized neutrons: $I \sim (b + p)^2$

unpolarized neutrons: $I \sim b^2 + p^2$

The requirement for the polarization monochromator is therefore simply $b = p$. In this case we have for an unpolarized neutron beam $I_{(+\lambda)} = (b + p)^2 = 2b^2$ and $I_{(-\lambda)} = (b - p)^2 = 0$.

To detect very small scattering contributions p, therefore, it would be necessary with unpolarized neutrons to measure a term p^2 whose square is small and a term b^2 whose square is large, whereas for polarized neutrons there is a linear relation between p and b. Another advantage of polarized neutrons lies in the measuring technique itself. For the accurate determination of p one need only determine accurately the ratio p:b; the method is therefore on a relative scale, and is thus independent of systematic errors (such as the determination of an absolute scale or of the temperature factor, which is known to cause a decrease in the scattering intensity with increasing scattering angle, similar to the decrease in the form factor itself.) In measurements with polarized neutrons, one simply determines the polarization ratio P by recording first I^+ with neutrons having $\boldsymbol{\lambda} = +1$, and then I^- with neutrons having $\boldsymbol{\lambda} = -1$.

$$P = \frac{I^+}{I^-} = \frac{(b + p)^2}{(b - p)^2} \qquad (17)$$

This leads to very accurate values of p, and hence of f.

The limits of the method can also be found very readily from eq. (17). To obtain a difference between I^+ and I^-, coherent overlap of neutron scattering and magnetic scattering must occur in the reflections. Investigations so far have been concentrated on ferromagnetic crystals, where this condition is always satisfied. This is not generally the case in antiferromagnetic crystals, and measurement with polarized neutrons is fundamentally impossible for *e.g.* MnO or NiO, where the neutron scattering reflections and the magnetic reflections are rigorously separated because the magnetic unit cell is twice as large as the chemical unit cell, and the crystallographic extinction rules separate the two sets of reflections exactly.

Detailed investigations have been carried out on the ferromagnetic elements iron [30], nickel [31], and hexagonal cobalt [32], as well as on Pd-0.01 Fe [33], Fe_3Al [34], and some Fe–Rh alloys [35]. A Fourier synthesis with the experimental data as amplitudes gives the electron density distribution of the unpaired electrons. If only the difference values of the experimental points from the spherically symmetrical average curve are used as amplitudes, the deviation of the electron distribution

from spherical symmetry is obtained directly. Figure 15 shows the result of such a difference Fourier synthesis using the values for iron from Figure 13. An interesting feature of this spin density distribution is the extended negative areas, which represent a density distribution of spins of opposite sign, *i.e.* antiferromagnetic orientation. The negative polarization is assigned to the 4s conduction electrons that uniformly fill the entire crystal with the opposite spin direction.

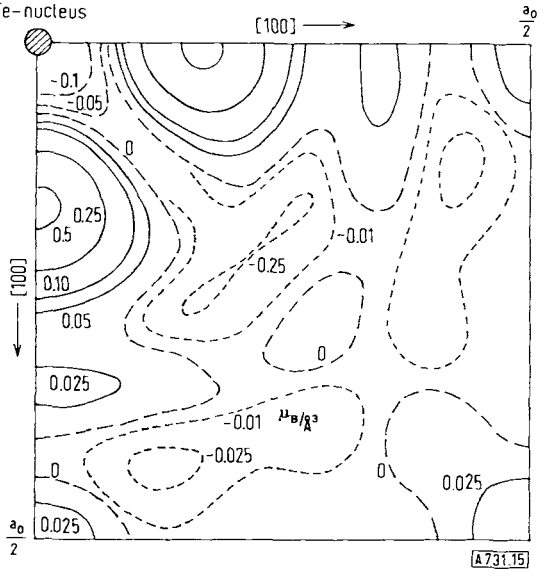

Fig. 15. Deviation of the spin density distribution from spherical symmetry in an iron crystal (difference Fourier diagram). The extended negative regions are due to the negatively polarized 4s electrons which form a uniform antiferromagnetic background in the otherwise ferromagnetic crystal (3d electrons). The maxima therefore essentially denote an additional 3d electron density; a distinct concentration of the 3d electrons along the crystal axes is evident. This distribution is characteristic of the e_g symmetry of the 3d electrons.

The e_g or t_{2g} character of the electron distribution can be deduced from the observed concentration of the electron density in certain directions in the crystal. Iron crystallizes in a body-centered cubic lattice. The five-fold degenerate 3d energy levels are split by the crystal field into two states with e_g symmetry and three states with t_{2g} symmetry. Owing to the octahedral symmetry of the environment of the iron atoms, the energies of the e_g levels are higher than those of the t_{2g} levels. The observed electron concentration along the cubic [100] axes (Fig. 15) thus points to e_g symmetry of the electron distribution. Careful numerical evaluation of the experimental data [30], in which a small component of the orbital moment and 4s electron contributions were taken into account, gave +2.39 μ_B for positive magnetization and −0.21 μ_B for negative magnetization. Assuming that Hund's rule is valid, therefore, there are 7.6 electrons in the 3d band and 0.4 electrons in the conduction band. The electronic configuration in ferromagnetic elementary iron should thus be $3d^{7.6}\ 4s^{0.4}$. Of the 7.6 electrons, 53% are in an e_g symmetry state (along the cube axes) and 47% in a t_{2g} symmetry state (along the cube diagonals).

Exactly the opposite situation is found in nickel, which crystallizes in a face-centered cubic lattice; 19% of the 3d electrons are in e_g levels and 81% in t_{2g} levels (the distribution for spherical symmetry is 40% e_g, 60% t_{2g}). The electron distribution obtained by analysis of the neutron diffraction data are: $3d_{spin} = 0.656\ \mu_B$, $3d_{orbital} = +0.055\ \mu_B$; for 4s conduction electrons, one finds $-0.105\ \mu_B$.

Table 4. Character of the electron distribution in some 3d elements and 3d–4d alloys.

3.7. The Magnetic Structure of Oxygen

Finally, brief mention should be made of a neutron diffraction study on solid oxygen, which showed an antiferromagnetic order [36]. Crystalline oxygen exists in three phases:

α-O_2 (0–24 °K); β-O_2 (24–44 °K); γ-O_2 (44–54 °K).

The γ phase has 8 molecules in a cubic unit cell. The β phase has one molecule in a rhombohedral cell, the molecule probably being oriented along the trigonal axis. The structure of the α phase is unknown. The symmetry is presumably monoclinic. Magnetic measurements on gaseous, liquid, and solid γ oxygen indicate two unpaired electrons in a $^3S_1$ state [37]; the susceptibility indicates an anti-ferromagnetic order at low temperatures. In the neutron diffraction experiments on solid β- and α-oxygen, the diagram of α-O_2 did in fact contain two additional lines at small scattering angles, which must be attributed to an antiferromagnetic order in α-O_2. Since the magnetically ordered spins are due to unpaired p-electrons which have a relatively large spread, the magnetic form factor falls off very rapidly, with the result that the detection of magnetic reflections become difficult ($f = 0.5$ for $\sin\Theta/\lambda = 0.2\ Å^{-1}$). No magnetic long-range order was observed for β-O_2. The magnetic and neutron diffraction data (maximum of the diffuse scattering at $\sin\Theta/\lambda = 0.1\ Å^{-1}$), however, indicate an antiferromagnetic short-range order in β-O_2.

Small Charged Heterocycles

By D. R. Crist and N. J. Leonard[*]

The synthesis and important reactions of stable aziridinium salts are described in this article. The more stable azetidinium salts, which undergo similar reactions, have also been studied. Polar and dipolar cycloadditions produce heterocycles by ring expansions that can be represented as ③$^{\oplus}$ + 2→⑤$^{\oplus}$, ③$^{\oplus}$ + 3→⑥$^{\oplus}$, *and* ④$^{\oplus}$ + 3→⑦$^{\oplus}$.

1. Introduction

Small rings are of interest not only for theoretical reasons but also because of new industrial and biological applications. This is particularly true of aziridine derivatives, which find use as alkylating agents [1], chemical mutagens [2], insect chemosterilants [3], models for pharmacological studies [4], and in polymerizations [5]. Moreover, stable aziridinium salts are now more readily available owing to new synthetic methods and suppression of decomposition reactions [6]. This review will be limited to the synthesis and reactions of isolable three- and four-membered heterocycles that bear a positive charge. This definition of scope excludes a) cations related to the cyclopropyl skeleton [7], b) acid-catalyzed reactions of ethylene oxides [8] and sulfides [9] that proceed through non-isolable cations, and c) α- and β-lactams [10, 11] that are uncharged in their stable forms.

Aziridinium and azetidinium salts are more stable than their oxygen or sulfur analogs because of the greater basicity of nitrogen. The driving force for most reactions of these salts is the release of the strain energy inherent in a small ring [12]. Both aziridinium and azetidinium systems give more stable ring-opened or ring-expanded products. In the presence of nucleophiles the initial reaction produces an amino group, which is itself a good nucleophile. This property leads to varied and useful reactions. Differences between the systems relate to ease of formation and stability: the aziridinium ion is formed more readily owing to an entropy effect but is also considerably more reactive.

2. Aziridinium Salts

2.1. Aziridinium Salts as Reactive Intermediates

In order to explain the biological effects, abnormal reactivity, and rearrangements of β-haloethylamines, aziridinium ions were frequently postulated and, in certain cases, could be isolated. For example, picrylsulfonate salts having biological activity similar to the starting material could be isolated from aged solutions of nitrogen mustards [13] and other β-haloethylamines [14]. The postulate of aziridinium ions such as *(1)* as the physiologically active component was consistent with kinetic studies [15].

In the presence of various nucleophiles, chloride ion formation occurs at a rate independent of the nature or concentra-

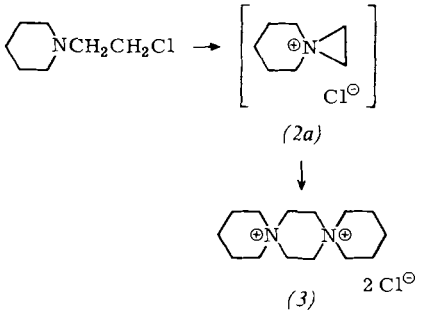
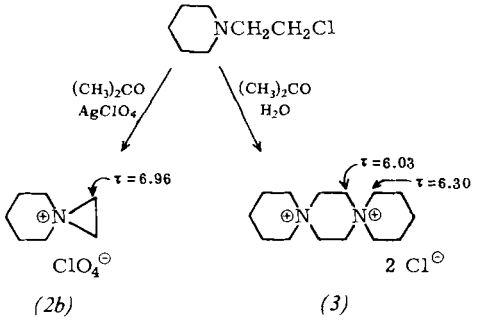
(1)

tion of the nucleophile. A complete kinetic analysis including all products is consistent with *(1)* as an essential intermediate, and NMR methods have enabled direct observation of an increasing aziridinium ion concentration and subsequent dimerization [16].



Early workers observed rearrangements of the following type [17].

The rearrangement occurs with α-bromo-β-(tertiary-amino) ketones ($R^2 = COC_6H_5$) [18] in a reaction recently observed [19] to be stereospecific. For cyclic amines, this rearrangement can cause ring expansions [20] or contractions [21].

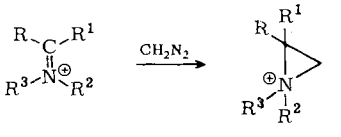


An early claim [22] to the isolation of *(2a)* as a salt appears erroneous [23], since the reaction conditions would have favored formation of piperazinium salt *(3)*.

(2a) *(3)*

Unambiguous proof that the isolated product was dimeric comes from the independent synthesis [24] of salts corresponding to both *(2b)* and *(3)* and the demonstration that the original reaction conditions gave a product consistent only with structure *(3)*.

(2b) *(3)*



The upfield NMR shift of aziridinium ring protons relative to unstrained $-\overset{\oplus}{N}-CH_2-$ is similar to the upfield shift of cyclopropane protons and is diagnostic of an aziridinium ring. The first authentic isolated aziridinium salt is probably the picrylsulfonate reported by *Golumbic*, *Fruton*, and *Bergmann* [13a]; however, in this and later cases [25] low solubility hindered further study.

2.2. Synthesis of Stable Aziridinium Salts

The success of new synthetic methods for the isolation of aziridinium salts depends to a large extent on a judicious choice of solvent and nucleophiles involved. In the absence of adequate reactivity and spectral data or molecular weight determinations, the possibility that the product is dimeric should be recognized.

2.2.1. Reaction of Diazomethane with Iminium Salts

The most general preparation of stable aziridinium salts is by the reaction of diazomethane with an iminium perchlorate or tetrafluoroborate [*] in methanol/ether, acetonitrile, acetone, or, preferably, methylene chloride at 0 °C [26].

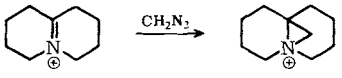
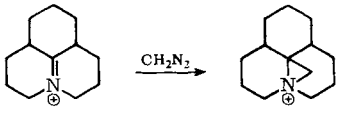
[*] Unless otherwise indicated, the aziridinium salts discussed here have tetrafluoroborate or perchlorate as the counter ion.

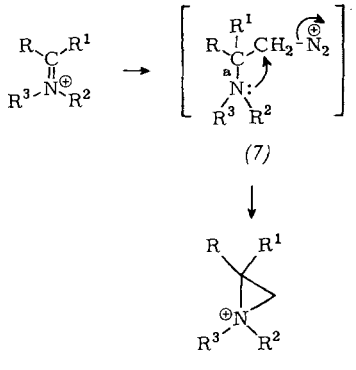


[26] *N. J. Leonard* and *K. Jann*, J. Amer. chem. Soc. *82*, 6418 (1960); *84*, 4806 (1962).

Numerous examples show that a wide range of *N*-alkyl and *C*-alkyl or -aryl substitution is allowed [27]. In a few cases, however, low product stability can lead to further reaction, such as thermal rearrangement of *N,N*-dibenzylaziridinium salts [28] or dimerization of the product when R = H, R^1 = aryl [29]. Other diazoalkanes also react with iminium salts to give products with a higher degree of substitution [26]. First discovered [26] with salt *(4)*, this preparative method has been extended [30] to bi- and tricyclic systems by similar reactions of the endocyclic iminium salts *(5)* and *(6)*.



(4)



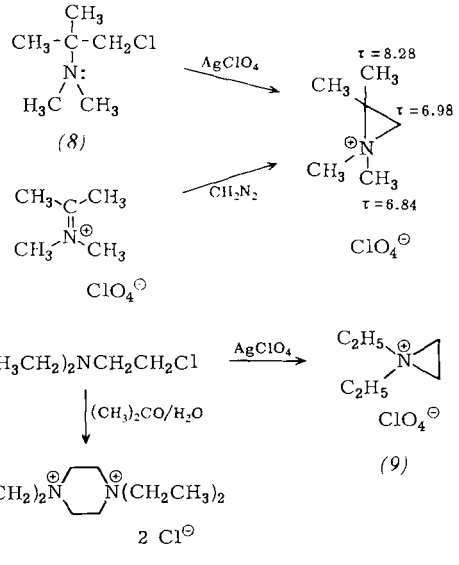
(5)

(6)

The mechanism of addition probably involves initial attack of diazomethane [31] at the highly electrophilic carbimino position [6] of the iminium salt. The timing of subsequent steps is uncertain, but the reaction can be considered in simplified form as a stepwise process analogous to diazomethane addition to ketones to give epoxides [32]. This is suggested by the preliminary finding that the reaction is not completely stereospecific.

(7)

Mixtures of *N*-ethyl-*N*-methylisobutylideneammonium tetrafluoroborate containing 65, 35, and 14% of the *cis* isomer (obtained by fractional crystallization), in reaction with diazomethane gave aziridinium salts containing 42, 25, and 21% *cis* isomer, respectively [33]. *N*-Ethylisobutylideneammonium tetrafluoroborate containing 100% *trans* isomer (presumed on a steric basis and consistent with NMR data) gave 13% of the *cis* product.



A reasonable explanation of these data is that the reaction intermediate involves diazonium or derived carbonium ions which can equilibrate by rotation about a bond [a in *(7)*]. Since the product distribution resembles that of the starting material, ring closure of the initial adduct *(7)* appears to be more rapid than rotation about bond a in the limited number of cases examined.

In those few cases where ring expansion has also been observed [34, 35], the intermediacy of *(7)* or the derived carbonium ion is indicated, and $C \rightarrow C^{\oplus}$ migration can apparently compete with $N \rightarrow C^{\oplus}$ ring closure.

Most starting iminium salts can be prepared from the enamines or, in a modified procedure, directly from the ketone and amine perchlorate in the presence of a trace of free amine [36].

2.2.2. Reaction of β-Haloethylamines with Silver Perchlorate

This method, conceptually like the original reactions in which aziridinium ions were postulated, differs in that the reaction is carried out in the absence of good nucleophiles and under conditions where halide loss is

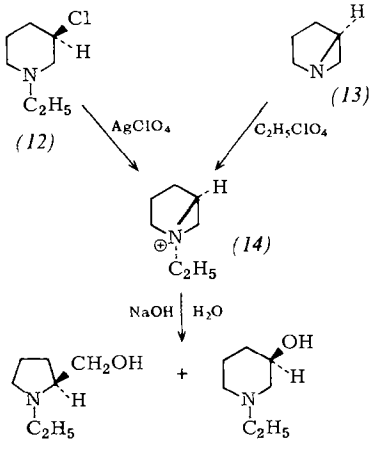
irreversible[24,37]. It also appears to be general, limited only by the availability of the starting amine. Treatment of the chloroamine *(8)* with silver perchlorate gives the same product as the diazomethane reaction with the iminium salt. The reactive intermediate *(9)* postulated in early kinetic studies[15c] was isolated in 94% yield by this method.

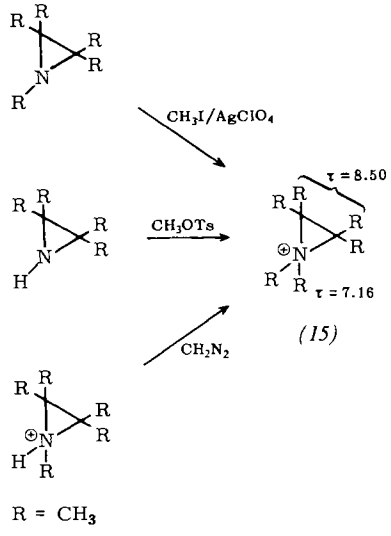
The product showed characteristic NMR absorption at τ 6.93 and was found to be monomeric, whereas the piperazinium salt, formed on standing in acetone-water, showed absorption at τ 6.03. In the rearrangement of α-bromo-β-(tertiary-amino) ketones, *threo* and *erythro* forms produced isomeric aziridinium intermediates which could be assigned structures *(10)* and *(11)*, respectively, by NMR[37]. From the assignment it could be concluded that these haloamines proceed stereospecifically to the aziridinium intermediate as suggested earlier[19].



(10)

(11)

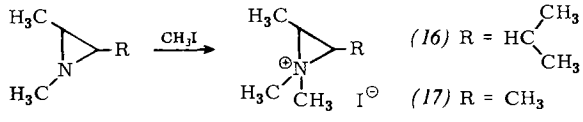
A similar stereospecific reaction sequence has been reported[38] for the chloromethylpyrrolidine-chloropiperidine system. Thus *(12)* reacts with silver perchlorate to give the same product as that obtained by alkylation of 1-azabicyclo[3.1.0]hexane *(13)*. Both the aziridinium salt *(14)* and the chloropiperidine give the same product mixture on alkaline hydrolysis. Moreover the entire process is stereospecific, since 95 ± 5% retention of configuration is observed in the conversion of *(12)* into the hydroxypiperidine, thereby ruling out a dissociated carbonium ion intermediate.



(12) *(13)* *(14)*

2.2.3. Quaternization

A promising method for quaternization[24] appears to be the use of alkyl halides in the presence of silver perchlorate[39]. Even the highly strained 1-ethyl-1-azoniabicyclo[3.1.0]hexane salt *(14)* prepared in this manner withstood ring opening when perchlorate was the only nucleophile present[38].



This procedure provides a route to hexamethylaziridinium salts *(15)*, which can also be obtained by alkylation with methyl tosylate or by the method of diazomethane insertion into an $N^{\ominus}$–H bond[40,41].

(15)

Some aziridinium salts have been synthesized by direct alkylation but the method seems to depend upon steric hindrance to subsequent reactions. This is indicated by the fact that the iodide *(16)* could be crystallized[42] while *(17)* decomposed on attempted crystallization[43].

Steric effects probably account for the unusual stability of the aziridinium iodides made in this manner from imines of cycloheptene[44], cyclooctene[45], cyclodecene[45], and cyclo-

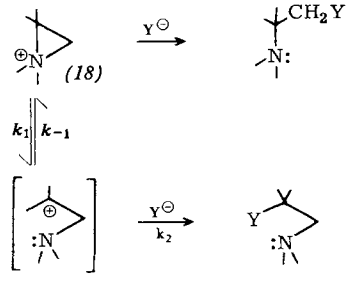
dodecene[46]. In several of these cases, structures are known by X-ray analysis[46,47]. In general, the initial reaction of an aziridine with alkyl halides is followed by ring opening by the nucleophilic counter ion[22,48]. Furthermore, alkylation at elevated temperatures can lead to thermal rearrangement of the desired product, as shown by recent work[49] which disproved a patent claim for simple alkylation in refluxing benzyl chloride[50].

2.2.4. Protonation of Aziridines

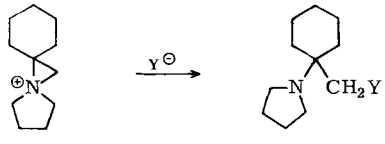


Certain aziridinium salts containing $^{\oplus}$N–H have been isolated, but such isolation seems to depend upon special circumstances such as product insolubility, low temperature isolation, steric hindrance to displacements, or non-nucleophilic counter ions. Thus hydrochlorides[51] and poly-nitro or-halogenophenolates[52] have been isolated by precipitation from the reaction medium at low temperature. Use of non-nucleophilic acids such as picric[53] and picrylsulfonic acids[51c] and 1,1-dinitroethane[54] enabled isolation of salts due to low solubility. A recent development of considerable synthetic potential in this area is the use of tetrafluoroboric acid[55].

This method avoids the usual difficulty attendant upon protonation: facile ring opening by nucleophile or solvent[56]. Competitive S_N1 and S_N2 reactions can occur, with the dominant process determined by the particular substrate and nucleophile[57]. A recent example of the opening of a steroidal aziridine to give exclusively a *trans* diaxial product has been reported[58].

2.3. Reactions of Stable Aziridinium Salts

The most important reactions of aziridinium salts, including solvolysis, nucleophilic attack, dipolar additions, and thermal rearrangements, are shown in Scheme 1. These reactions can be classified, to some extent arbitrarily, as direct displacements by nucleophiles or as reactions of aminocarbonium ions. Whether the second process is S_N1 depends on the



Scheme 1

relative rates of k_{-1} *vs* k_2 [$Y^{\ominus}$], and this point is under current investigation. However, for the purposes of this review reactions will be discussed in these terms on the basis of product analysis. In either case, as mentioned earlier, a reactive electrophile is converted into a good nucleophile (the $-NR_2$ group).

2.3.1. Direct Displacements

It has long been known that aziridinium ions react readily[13a] with thiosulfate to give Bunte salts[59], a reaction which can be used for quantitative analysis[60]. Good nucleophiles cause ring opening with attack at the less hindered carbon atom in the manner of S_N2 reactions[61].

Y = CN, OCH_3, N_3, OAc, C_6H_5O

A related process is the tendency of aziridines under cationic catalysis to dimerize or polymerize, depending upon the nature of the solvent, nucleophiles present, and aziridine substitution[62]. After formation of *(19)*, the reaction can take two courses: Reaction with an

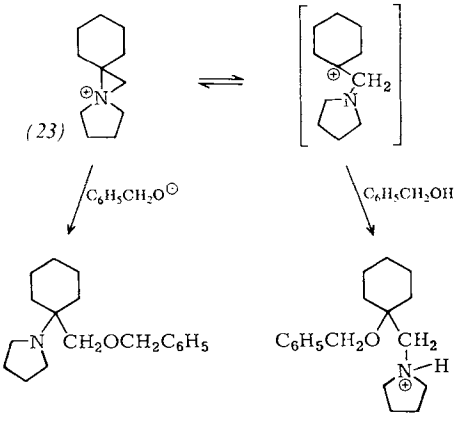
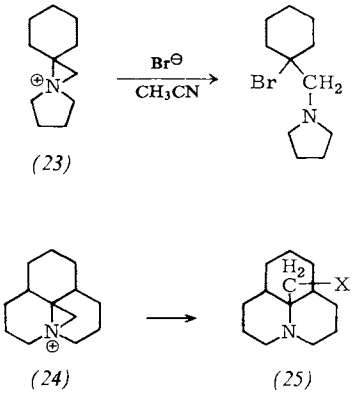
excess of aziridine leads to polymer, while reaction with $X^{\ominus}$ will cause ring opening and subsequent closure to dimer. By suitable choice of anion and solvent, quantitative yields of either polymer or dimer can be achieved.

2.3.2. Aminocarbonium Ion Reactions

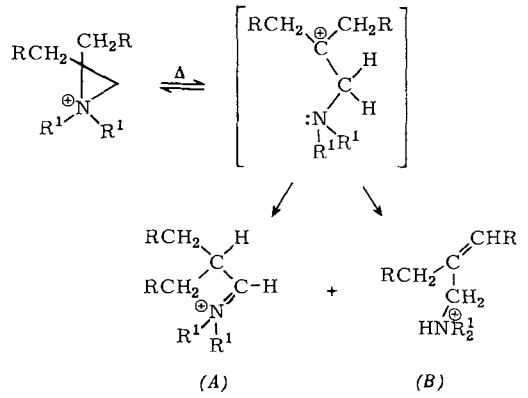


The tendency of an aziridinium salt to react as an aminocarbonium ion is shown by the reaction of *(20)* with chloride ion at C-2 [24]. A reasonable interpretation is that reaction proceeds through the more stable of two possible carbonium ions. In an S_N2-type process, nucleophilic attack would have occurred at the less hindered C-3. Solvolysis under neutral conditions also gives products derived from an aminocarbonium ion [26], in contrast to the direct displacement when alkoxide ions are present.



If the original aziridinium C–N$^{\oplus}$ bond is endocyclic, the reaction of such an aminocarbonium ion with solvent can bring about a ring expansion, as illustrated by the alcoholysis of *(21)* [30]. This reaction has been extended to bicyclic compounds such as *(22)* to effect double ring expansion.

As with typical S_N1 and S_N2 reactions, competition between the two mechanisms occurs, and changing reaction conditions or substrates can reverse the preferred pathway. For example, *(23)* undergoes an aminocarbonium ion reaction under neutral solvolysis conditions but an S_N2 reaction occurs with alkoxide [63].

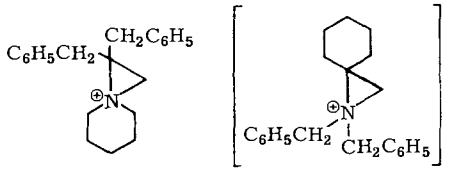


As an illustration of the case in which the same reaction conditions give either type of product, depending on the substrate [30], the perchlorate of *(23)* with lithium bromide in acetonitrile reacts as an aminocarbonium ion while *(24)* undergoes displacement to give *(25)* (X = Br). The more rigid carbon skeleton in the tetracyclic case probably resists the ring flattening and expansion necessary to form a *tert*-carbonium ion at the central bridgehead. Thus it is not surprising that *(24)* also produces the ether derivative *(25)* (X = OCH_3) on methanolysis.

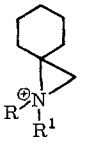
2.3.3. Thermal Rearrangements

Aziridinium salts containing the ring carbon grouping $-CH_2-CR_2-$ undergo thermal rearrangements in the

[63] *N. J. Leonard, E. F. Kiefer,* and *L. E. Brady,* J. org. Chemistry *28*, 2850 (1963).



(A) (B)

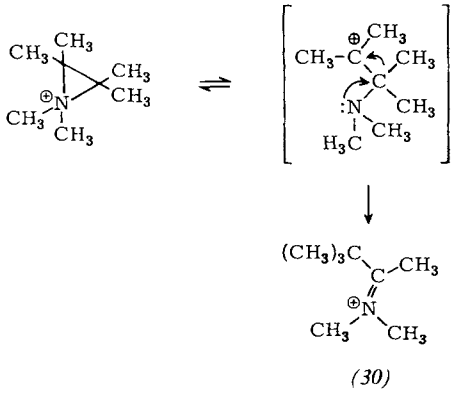


melt and in inert solvents to give iminium salts or a mixture of iminium and alkenylammonium salts [6, 28].

Thermal stability and product ratio depend markedly on the aziridinium structure. Work is in progress to delineate steric and electronic effects on the rearrangement.

At this stage, comparison of the stability of sterically similar salts *(26)* and *(27)* suggests that the dominant effect is electronic. While *(26)* is stable below its m.p. (139 °C), *(27)* is too labile to be isolated; reaction of the appropriate iminium salt with diazomethane gives only rearrangement products [28]. Increasing the number of *N*-benzyl substituents through the series

(26) *(27)*

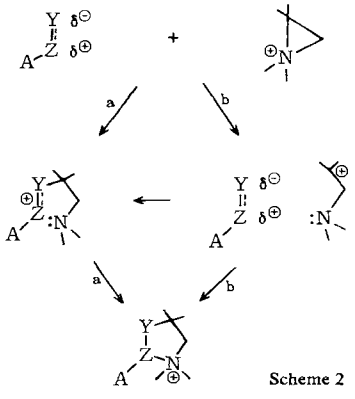


(28) R = R^1 = C_2H_5

(29) R = $CH_2C_6H_5$

R^1 = C_2H_5

(28), *(29)*, and *(27)* also increases product ratio *(B)*/*(A)* with values 25/75, 51/49, and 82/18, respectively [35]. A possible mechanism involves formation of



(30)

the more stable aminocarbonium ion followed by hydrogen migration to give products.

Also consistent with this mechanism is the rearrangement of hexamethylaziridinium perchlorate to give *(30)*, which can be interpreted as a Wagner-Meerwein methyl shift in the proposed intermediate [28].

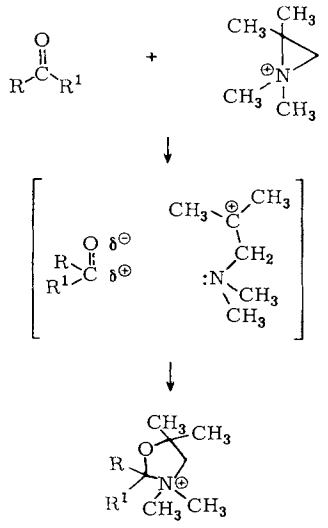
2.3.4. Polar and Dipolar Additions

By considering the ring system as an aminocarbonium ion one can see the bifunctional nature of aziridinium ions and intuitively might expect additions to polar and dipolar species (Scheme 2).

Scheme 2

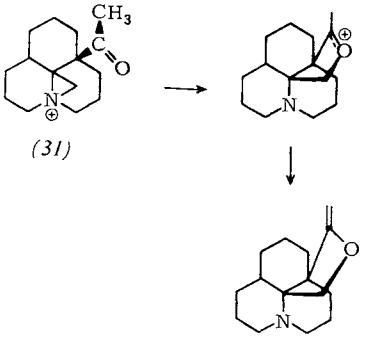
Here a three-membered ring is expanded to a five-membered ring, both bearing positive charges. This process has been conveniently written [27] as ③⊕ + 2→⑤⊕. This description is consistent with *Huisgen*'s [64] recent definitions in which a cycloaddition step is classified according to the number of new σ-bonds formed, with subdivisions determined by the number of ring members involved. An electronic description, on the other hand, awaits theoretical calculations similar to those reported for trimethylene and related 1,3-dipoles [65].

Whether the reaction is stepwise (path a) or concerted (path b) is a difficult question currently under discussion in the case of 1,3-dipolar cycloaddition [66]. Work on the kinetics and stereospecificity of the cycloaddition [67] represented in Scheme 2 should help in elucidating the mechanism. For reasons of clarity and ability to rationalize simultaneous solvolysis and thermal rearrangements, these ring expansions will be illustrated in terms of aminocarbonium ion intermediates, though it is hoped the reader will bear in mind the mechanistic ambiguities.



The first ③⊕ + 2→⑤⊕ expansions were observed with aldehydes [63] and ketones [27]. Structures of the oxazolidinium salt products were consistent with reaction

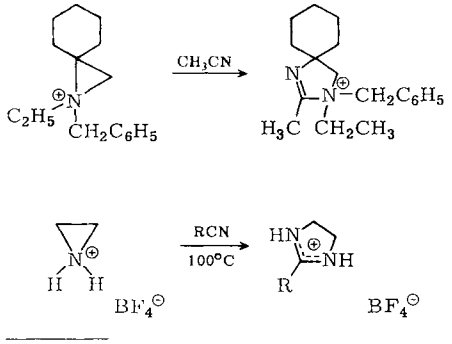
[64] *R. Huisgen*, Angew. Chem. *80*, 329 (1968); Angew. Chem. internat. Edit. *7*, 321 (1968).



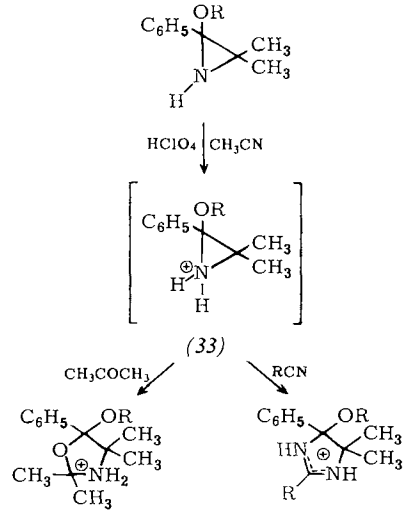
[65] *R. Hoffmann*, J. Amer. chem. Soc. *90*, 1475 (1968).

[66] a) *R. A. Firestone*, J. org. Chemistry *33*, 2285 (1968); b) *R. Huisgen*, *ibid. 33*, 2291 (1968).

[67] The definition of "cycloaddition" [64] includes both concerted and stepwise processes. In the present case, aziridinium ions are considered polar species since they bear a full positive charge even when ring-opened; "polar additions" are those in which the second species can be represented without formal charge separation, while "dipolar additions" are those in which this species requires charge separation in all its formal structures.

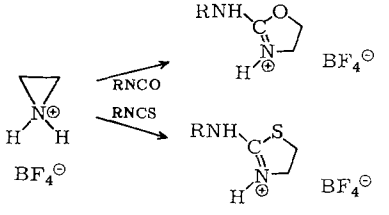


of the electronegative atom at the more stable carbonium ion center as shown. Generality was demonstrated by successful reaction of various aziridinium perchlorates with aromatic aldehydes, aryl and alkyl ketones, and cycloalkanones. If sterically prevented from 1,2-addition, a carbonyl group can function as a weak nucleophile [*(31)*→*(32)*][68,69].

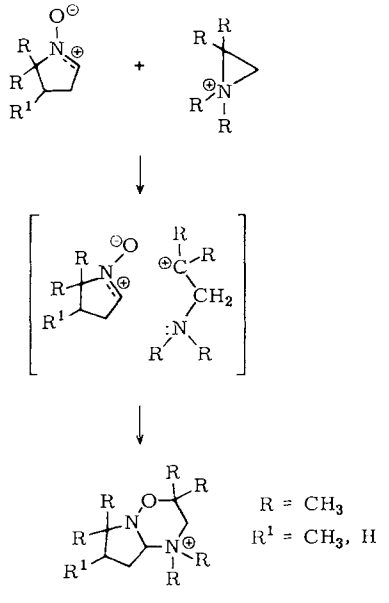


(31)

(32)



The same type of ring expansion occurs with nitriles and substituted[70] or unsubstituted aziridinium ions[71] to give imidazolium salts. Alkoxy ring substituents do not interfere with the expansion; thus the cation *(33)*, formed by protonation, can also undergo ring expansion with nitriles and ketones[72]. The same



(33)

reaction conditions can cause analogous reactions with oxiranes, as previously observed in the presence of tin chloride[73].

Isocyanates and isothiocyanates also undergo 1,2-polar addition to aziridinium tetrafluoroborate[74] to give another type of ③⊕ + 2→⑤⊕ process.

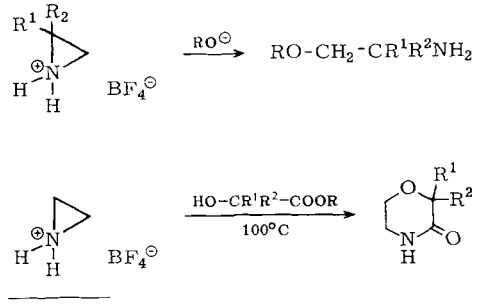
A 1,3-dipolar addition has been carried out[75] with aziridinium perchlorates and nitrones to give the novel heterocyclic system *(34)*. These reactions constitute a ③⊕ + 3→⑥⊕ conversion.

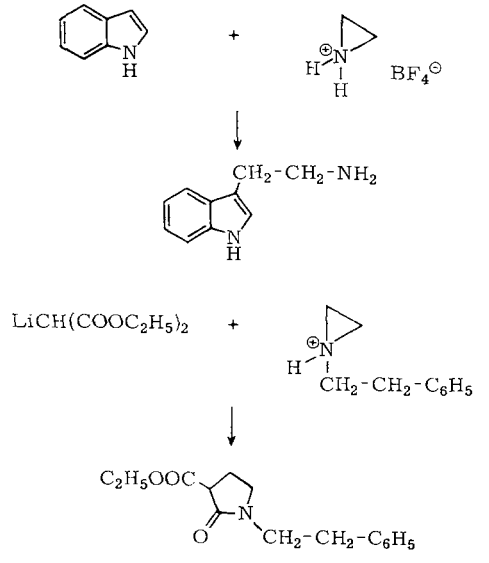
2.4. Synthetic Utility of Aziridinium Salts

Since the ready availability of aziridines is a decisive factor in this connection, the following synthesis starting from olefins should play an important role[76].

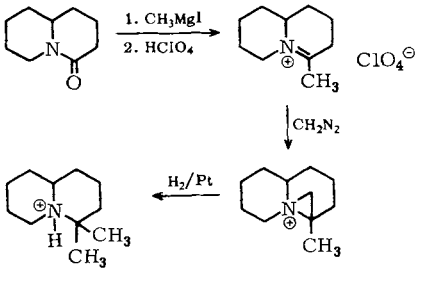
Ring expansions by solvolysis or by 1,2-polar and 1,3-dipolar additions can lead to complex heterocyclic ring systems in good yields. These ③⊕ + 2→⑤⊕ and ③⊕ + 3→⑥⊕ expansions parallel the extremely useful Diels-Alder synthesis of carbocyclic systems. The addition of diazomethane to iminium salts occurs so readily, even at low temperature, that side reactions with carbonyl groups do not interfere. Thus the steroidal aziridinium salt *(35)* was obtained in 70% yield[77].



(35)



The proper combination of sequences involving enamines, iminium salts, and aziridinium ion reactions can be very useful in alkaloid synthesis. An example of direct displacement by hydride was reported in a β-benzomorphan synthesis[78].



Amino ethers can be prepared by alkoxide displacement on aziridinium ions[55]. An extension of this reaction is the preparation of oxalactams by similar alkylation of hydroxy esters, with subsequent ring closure[1d]. Side reactions leading to linear polyamides limited yields to the 27–34% range.

C-Alkylation of indole by aziridinium ions gives tryptamine. With 2-methylindole, the 3-aminoethyl product was formed in 80–90% yield[1d]. Diethyl lithiomalonate reacts with *N*-(2-phenylethyl)aziridine only in the presence of an excess of malonic ester, which suggests reaction of an aziridinium ion[1e].

Hydrogenation causes reductive cleavage of a C–N⊕ aziridinium bond[26]. This reaction has been used as a synthetic route to introduce *gem*-dimethyl substitution α to nitrogen[79].

3. Azetidinium Salts

Although azetidinium salts are quite stable, their literature is not so extensive as that for aziridinium compounds since some are difficult to synthesize and they appear to have less biological activity[80]. Many of the syntheses and reactions are directly analogous to those described above for aziridinium salts.

The earliest example of an azetidinium salt was reported by *Gabriel*[81]. However, it was possible that the vigorous conditions used in its formation had caused dimerization. The original claim was proved valid by preparation of authentic, monomeric *(36)* under

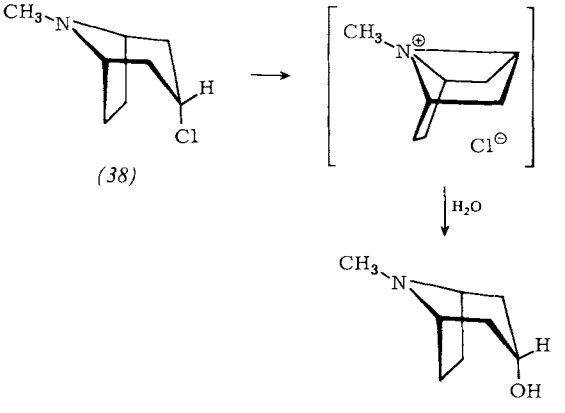
the action of silver perchlorate [82] and conversion of *Gabriel*'s chloride to the same salt.

(36)

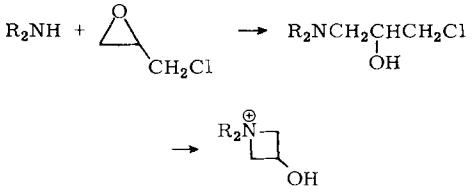
3.1. Azetidinium Salts as Reactive Intermediates



To explain an enhanced rate of substitution in the γ-chloroamine *(37)* relative to neopentyl chloride, *Wheatley* and *Cheney* postulated [83] reaction through the azetidinium ion.

(37)

Similarly an azetidinium ion intermediate was invoked [84] to account for retention of configuration in the solvolysis of tropanyl chloride *(38)*. The epimeric chloride underwent fragmentation with loss of chloride, as predicted by *Grob*'s stereoelectronic fragmentation rules [85].

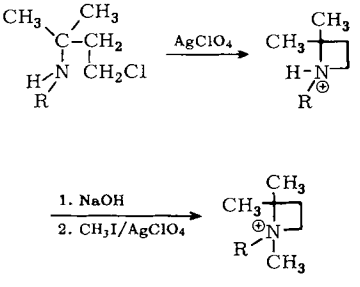


(38)

3.2. Synthesis of Azetidinium Salts

Direct alkylation of 1-alkylazetidines leads to isolable azetidinium salts. Precursors can be obtained by cyclization of secondary amines having a suitable leaving group in the γ-position or by reduction of β-lactams and malonimides [11].

The cyclization procedure has recently been extended to the synthesis of 3,3-disubstituted azetidinium salts [86] previously obtained by an indirect route [87]. A second mode of preparation is the direct cyclization of tertiary amines [11]; thus a monomeric [89] 3-hydroxyazetidinium chloride was synthesized from a secondary amine and epichlorohydrin [88].



The main synthetic problem lies in the sluggishness of cyclization which permits side reactions such as fragmentation, elimination, and polymerization. In these competitive processes, the steric requirements of substituents are an important factor [90]. As illustrated for a sulfonamido anion, the conformation preceding cyclization is given by *(39)* while that for fragmentation is given by *(40)*. With this large *N*-substituent, form *(40)* is less important than for simple amines and

(39) *(40)*

cyclization is favored. Symmetrical *gem*-substitution on either C-2 or C-3 should have little effect on the rate of cyclization but should increase product stability [91]. *threo*-Substituents should have little effect on cyclization *vs.* fragmentation.

A modification of the cyclization procedure [82] for a primary chloride uses silver perchlorate. The first step is complete after one day at room temperature. Nearly

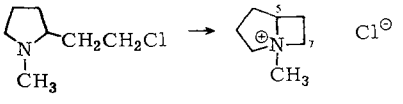
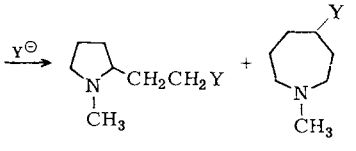
quantitative yields show that side reactions are eliminated at the low reaction temperature. This procedure has also been used to prepare bis(azetidinium) salts [92].

3.3. Reactions of Azetidinium Salts

3.3.1. Nucleophilic Ring Openings



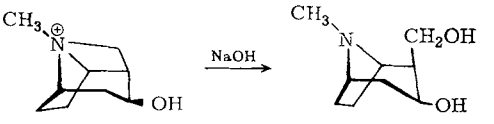
The reaction of monocyclic azetidinium salts represented by *(41)* with various nucleophiles [$(CH_3)_3CSNa$, R_2NH, R_3N, KOC_6H_5, KCN] has been investigated by *Gaertner* [93]. Although ring opening occurs readily in these cases, the chloride *(41)* does not react with refluxing methanol as do the aziridinium perchlorates.



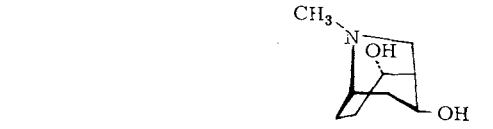
(41) *(42)*

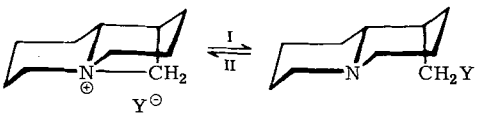
It might be expected that the resultant tertiary γ-amino derivatives *(42)* could cyclize to the starting material, and this does happen with a compound of type *(42)* [Cl instead of $SC(CH_3)_3$]. Equilibrium constants for cyclization of the alcohols were *ca.* 50 times greater than for the corresponding acetates.

Nucleophilic ring openings occur in bicyclic systems as well, and can lead to a rearrangement [94] analogous to the chloromethylpyrrolidine-chloropiperidine system (see Section 2.2.2). Since the same product ratio was found starting from the γ-chloroamine *(43)* and



(43) *(44)*

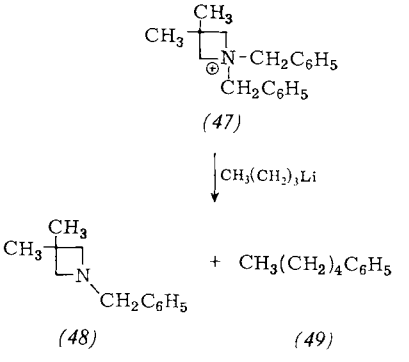




the independently synthesized *(44)*, it seems likely that *(43)* first undergoes an internal nucleophilic displacement to give the ion *(44)*. Reaction of $Y^{\ominus}$ at C-5 of *(44)* would then lead to ring expansion and at C-7 to direct substitution.

Similar ring opening displacements also occur in tricyclic systems such as *(45)* [95] and *(46)* [95–97]. In the latter case, a ring-chain isomerization was observed in which the product mixture depended on the nucleophile as indicated [96].

(45)



(46) I, Y = Br, I, CN, OCH_3
II, Y = OTs

A related process is dimerization and ultimately polymerization in which free azetidines act as nucleophiles. This reaction is not so important as in the aziridinium series, and while the *N,N*-dimethylazetidinium salt polymerizes fairly rapidly, the diethyl salt is relatively stable [98].

An exception to nucleophilic ring openings is the reaction of *(47)* with *n*-butyllithium at the benzylic position to give *(48)* and *(49)* along with rearrangement products [99].

(47) *(48)* *(49)*

3.3.2. Base-Catalyzed Eliminations and Rearrangements

Azetidinium salts containing α-methyl groups have been found [82, 100] to undergo an elimination reaction in contrast to the nucleophilic substitution observed in the bicyclic systems described above. Part of this difference may be due to facility of an E2 mechanism [101], since, as indicated for *(50)* [82] in Scheme 3, any of the six hydrogens of the methyl groups can lie

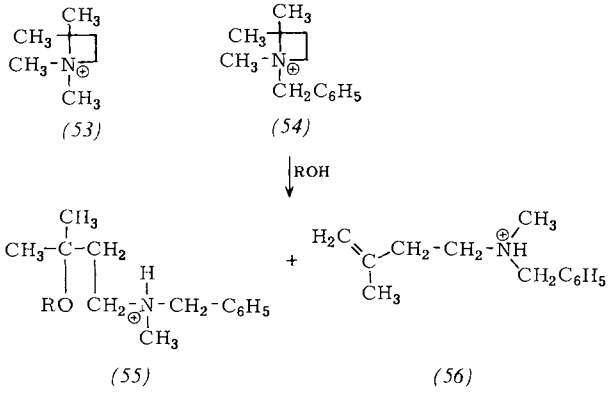
(50)

Scheme 3

in the *trans* coplanar arrangement of atoms required by this mechanism [102]. The similarity of ground and E2 transition state geometries, together with the inherent ring strain, may decrease the free energy of activation for elimination sufficiently so that no other processes can compete.

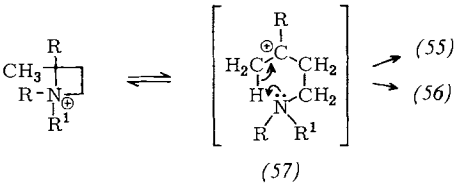


With a strong base such as phenyllithium or potassamide, ring opening of *(51)* occurs as the major reaction along with formation of a minor amount of a Stevens rearrangement product *(52)* [103]. It is possible that an ylide → ring-opened carbene mechanism is operative for this strained system.

(51) (52)

3.3.3. Reactions Proceeding *via* Aminocarbonium Ions

Azetidinium ions are less susceptible to S_N1-like ring openings than aziridinium salts, as illustrated by the complete failure of *(53)* to undergo solvolysis [82,104] or ring expansion [82], despite *gem*-dimethyl assistance to such reactions. The more reactive *N*-benzyl salt *(54)*, however, gave two products resulting from cleavage of the $N^{\oplus}$–C-2 bond [82]. This is particularly interesting in view of the lengthened C-2–N distance



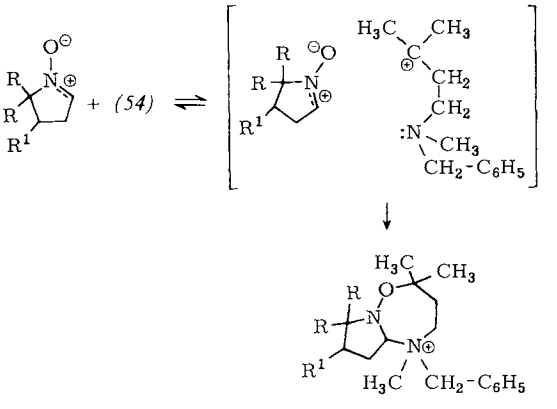
(53) (54) (55) (56)

[103] *A. G. Anderson* and *M. T. Wills*, J. org. Chemistry *33*, 536 (1968).

[104] Attempted methanolysis of a 3-hydroxyazetidinium salt was also unsuccessful [93].

(1.60 Å as determined by X-ray analysis [105]). Olefin *(56)*, formed initially about one-third as fast as *(55)*, was the sole product of attempted ring expansions with acetone or acetonitrile.

This reaction can be rationalized in terms of competitive S_N1 and E1 mechanisms involving the aminocarbonium ion intermediate *(57)*.

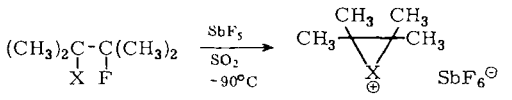


(57)

Kinetic control of product formation by a facile intramolecular hydrogen transfer could explain the absence of ring expansion or internal olefinic products. Alternatively the olefin may be formed by an E2 mechanism in which a catalytic amount of base transfers hydrogen from methyl to nitrogen.

3.3.4. Dipolar Additions

As mentioned above, azetidinium salts do not undergo 1,2-polar additions with acetone or acetonitrile. However, if the azetidinium $N^{\oplus}$–C bond is sufficiently reactive toward polar cleavage, as provided by the *N*-benzyl group in *(54)*, 1,3-dipolar addition with nitrones of the type ④$^{\oplus}$ + 3 → ⑦$^{+}$ can occur [82].



4. Other Heterocycles

Halonium ions have frequently been postulated as reaction intermediates [106]. Recent evidence suggests that these species may be stable in strong acid media [107]. A solution of *(57a)* in SbF_5–SO_2 shows only one NMR absorption peak, strongly suggestive of conversion into the symmetrical species *(58)*.

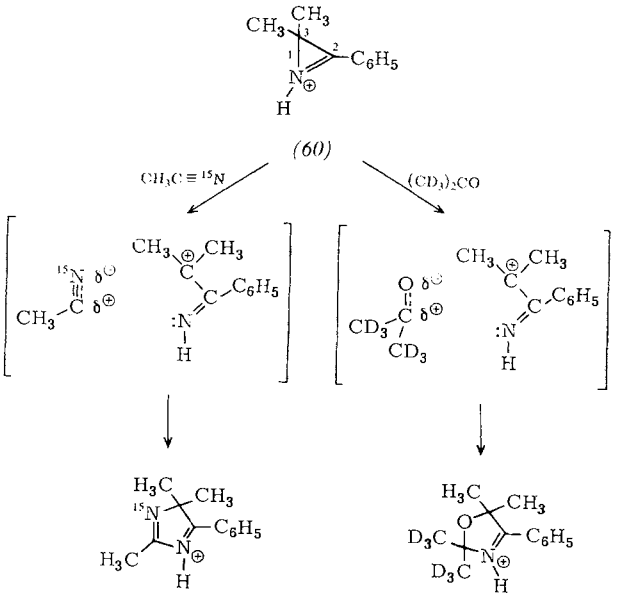
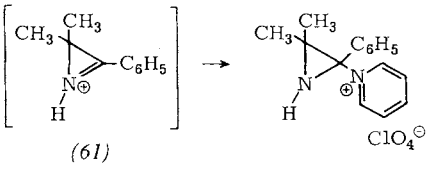
[107] *G. A. Olah* and *J. M. Bollinger*, J. Amer. chem. Soc. *89*, 4744 (1967); for a review see *G. A. Olah* and *C. U. Pittman, Jr.* in *V. Gold*: Advances in Physical Organic Chemistry. Academic Press, New York 1966, Vol. 4, p. 305.

(57a), X = Cl, Br, I *(58)*

Episulfonium picrylsulfonates derived from cyclooctene have been prepared by various methods[108]. As with aziridinium salts, unusual stability may result from fusion to a medium-sized ring. The reaction of dimethyl sulfide with *(59)* causes ring opening to *trans* product.



(59)



The azirinium perchlorate *(60)*, formed *in situ* with perchloric acid, undergoes 1,2-polar addition to acetone and nitriles[72]. As before, the question of the reaction sequence is unsettled, and only concerted-type processes are shown (Scheme 4).

Mechanistic ambiguities arising from molecular symmetry have been clarified by isotopic labeling experiments. Chemical degradation of products followed by NMR or mass spectral analysis showed the isotope distribution indicated in Scheme 4. These results require that in both cases reaction proceeds by $N^{\oplus}$–C-3 bond cleavage of the starting azirinium ion.

Unlike the case of aziridinium salts, nucleophiles can add to the unsaturated bond of the 1-azirinium cation, as observed in the reaction of the free azirine with pyridinium perchlorate[72]. With anilinium perchlorate[109] and with perchloric acid in methanol[72], the initially formed cation *(61)* undergoes 1,2-bond cleavage after addition of the nucleophile. It is probable that rearrangements of 1-azirines in the presence

Scheme 4

(61)

of acyl chlorides[110], acid anhydrides[111], and carboxylic acids[111] are also initiated by formation of azirinium cations.

COMMUNICATIONS

Vinyloxytrimethylsilanes as Silylating Agents

By *M. Donike* and *L. Jaenicke*[*]

We have found that vinyloxytrimethylsilanes *(1)*[1,2] are suitable as silylating agents. The course of this group transfer reaction resembles that of chemical and of biological acylation and phosphorylation with enol esters.

In order to verify this hypothesis we investigated IR spectroscopically the reaction of *n*-butyl alcohol with excess of *(1a)*. No noticeable reaction takes place in the absence of catalysts. Addition of catalytic amounts of trimethylchlorosilane immediately induces a slightly exothermal reaction leading to the formation of *n*-butyl trimethylsilyl ether. Compounds *(1b)*, *(1e)*, and a mixture of *(1c)* and *(1d)* behave similarly.

(1) *(2)*

R, R^1 = $-(CH_2)_4-$, R^2 = H
R = R^1 = C_2H_5, R^2 = H
R = C_2H_5, R^1 = R^2 = H
R = R^1 = CH_3, R^2 = H
R = CH_3, R^1 = R^2 = H
X-H = R-OH, R-SH, $R-NH_2$, R-COOH

To establish which functional groups can be silylated with vinyloxytrimethylsilane we carried out reactions with typical silylable compounds and *(1e)* (see Table 1). Compound *(1e)*

Table 1. Reaction of 2-trimethylsiloxypropene *(1e)* with silylable compounds X—H [a].

X—H	Rel. Yield (%) [a]	X—H	Rel. Yield (%) [a]
n-Butanol	99	*N*-Methylacetamide	0
Stearyl alcohol	99	Mercaptoethanol	5
Palmitic acid	98	Propylene ethanol	52
Thiophenol	86	*n*-Butylamine	0 [b]
Phenol	96	Diethylamine	0
Hydroquinone	97	Phenylamine	40
Catechol	97	Ephedrine	0 [c]
Resorcinol	99		

[a] In each case 10 mg of X—H was dissolved (or suspended) in acetonitrile (1 ml) and treated with compound *(1e)* (0.4 ml) and trimethylchlorsilane (0.02 ml). Comparable suspensions were treated with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide (0.42 ml). After 30 mins' heating at 80 °C the conversion was determined gas chromatographically and the yields calculated with reference to 100% conversion in the comparison suspension.

[b] Formation of a Schiff base.

[c] Formation of an oxazolidine.

was chosen because its volatility (b.p. 94 °C) makes it particularly suitable for use in gas chromatographic investigations (cf. Table 2). Moreover, *(1e)* is readily accessible by reaction of *N*-methyl-*N*-trimethylsilylacetamide[2] with dry acetone in a hydrocarbon in absence of moisture.

Table 2. Retention indices, according to *Kovats* [4], of silylating agents on 10% UCW 98 (methylvinylsilicone rubber).

Silylating agent	Retention index
Trimethylchlorosilane	560
2-Trimethylsiloxypropene *(1e)*	691
N-Methyl-*N*-trimethylsilyl-trifluoroacetamide	779
Hexamethyldisilazane	798
N,N-Diethyltrimethylsilylamine	806
N,N-Bis(trimethylsilyl)trifluoroacetamide	858
N-Methyl-*N*-trimethylsilylacetamide	908
O,N-Bis(trimethylsilyl)acetamide	888

Carboxyl, monofunctional aliphatic hydroxyl, and phenol groups react with *(1e)*, somewhat slowly compared with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide[3], but nevertheless completely to give the trimethylsilyl esters or ethers *(2)*.

Vicinal functions, *e.g.* α-amino acids, 1,2-diols, and β-mercaptoalcohols lead to heterogeneous products. Primary amines condense to Schiff bases whereas secondary and tertiary amines do not react even after prolonged heating. Secondary α-hydroxy amines readily yield oxazolidines.

Results of previous investigations have shown that although *(1e)* is not so generally applicable as silylamides its high volatility nevertheless offers many advantages in chromatographic analysis, particularly in trace analysis, of lower carboxylic acids and alcohols.

Effect of Crystalline Form on the Air-Oxidation of Steroidal 11β-ols to 11-ones

By *G. Brenner, F. E. Roberts, A. Hoinowski, J. Budavari, B. Powell, D. Hinkley*, and *E. Schoenewaldt*[*]

We have observed the spontaneous air-oxidation of crystalline hydrocortisone-21-*tert*-butylacetate *(1a)* to cortisone *tert*-butylacetate and have extended our study to encompass a variety of 11β-hydroxy-steroid-21-esters. A recent report[1] of a similar oxidation of crystalline *(2)* prompts preliminary publication of our results.

(1)

(2)

(1a), R = CO–CH_2–$C(CH_3)_3$
(1b), R = CO–$(CH_2)_4CH_3$
(1c), R = CO–$(CH_2)_{14}CH_3$
(1d), R = CO–$(CH_2)_2$-cyclo-C_5H_9
(1e), R = CO–$C(CH_3)_3$
(1f), R = CO–CH_3
(1g), R = CO–C_2H_5

Samples of crystalline *(1a)* stored for 1—2 years have been found to contain up to 40% of the readily isolated 11-ketonic cortisone TBA and a 15-year-old sample was found to have oxidized to the extent of 80%. Thin layer chromatograms, X-ray patterns, IR and NMR spectra showed that only starting material and oxidation product were present. The oxidation is easily duplicated in thermally accelerated tests and can be measured by NMR using the shift of the 18-methyl singlet from 9.04 τ (11β-ol) to 9.33 τ (11-one). The reaction requires molecular oxygen and produces water. It is accelerated by heat, greatly accelerated by free-radical initiators or by UV light, and is quenched by free-radical inhibitors. No impurity could be found responsible for the reaction.

Similar evidence of air-oxidation to the 11-ketone was found in old samples of *(1a)*—*(1d)* and, to a markedly lesser degree, prednisolone *tert*-butylacetate. In baffling contrast, 15—17 year-old samples of *(1e)*—*(1g)* and 9α-fluorohydrocortisone *tert*-butylacetate were completely free of 11-ketonic products nor could oxidation be induced in steroids of this group under the most drastic conditions of thermal and photolytic initiation in the solid state.

The finding that polymorphic modifications of hydrocortisone- and prednisolone *tert*-butylacetate could be prepared that were likewise inert to air-oxidation permits formulation of a generalization with predictive value relating oxidative-susceptibility to the type of crystalline form. Esters in this series are commonly encountered in one or more of three types of crystal form:

Type A: A form in which the crystallizing solvent(s) is held within the crystal in non-stoichiometric proportion and which can be completely desolvated in vacuum without change in X-ray pattern.

Type B: A stoichiometric solvate. Desolvation is accomplished only at elevated temperature and is accompanied by changes in the X-ray pattern.

Type C: A non-solvated form.

We find that all steroid esters subject to air-oxidation are of type *A*; all steroid esters resistant to oxidation are of types *B* or *C*.

To validate this generalization, type *C* crystals were prepared and found to be inert to photolytic oxidative conditions under which the *A* forms were extensively oxidized (see Table 1).

Table 1. Dependence of oxidation on crystal form. Thermal oxidation at 100 °C, photolytic oxidation at 50 °C

[a] At 80 °C, conversion into Type C.

The air-oxidation of 11β-hydroxy steroids has also been demonstrated in solution (dimethylacetamide, 100 °C, 1600 psig air). Thus no chemical barrier to oxidation need be invoked for steroids stable in the crystalline state.

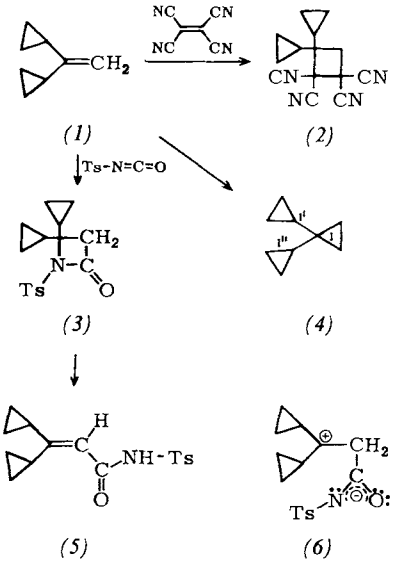
Cycloadditions to 1,1-Dicyclopropylethylene[1]



By *F. Effenberger* and *W. Podszun*[*]

While the stabilization of cationic centers by alpha cyclopropyl groups has been verified in many instances[2, 3], to the best of our knowledge nothing is known about the influence of cyclopropyl groups, as substituents, on the reaction mechanism of multiple bonds. The α-cyclopropylcarbonium ions[4] that may be formed are capable of rearrangement, thus providing additional information as to a polar or a more concerted mechanism of cycloaddition.

We have therefore investigated the reaction of 1,1-dicyclopropylethylene *(1)* with electrophiles. Reaction of *(1)* with tosyl isocyanate in ether at 0 °C leads to the formation of the β-lactam *(3)* (yield 50%, m.p. 93 °C; IR: $\nu_{C=O}$ = 1788 cm^{-1}). In boiling benzene, *(3)* rearranges to the acrylamide *(5)* (yield 100%, m.p. 98 °C; IR: $\nu_{C=O}$ = 1704 cm^{-1}, ν_{NH} = 3276 cm^{-1}) which is possible *via* the dipole *(6)* only. If the reaction of *(1)* with tosyl isocyanate is carried out at 20 °C, a mixture of *(3)* and *(5)* is formed.

Tetracyanoethylene reacts with *(1)* at 20 °C to give the cyclobutane derivative *(2)*. When the reactants are mixed in benzene the solution turns blood-red, indicating π-complex formation. Attempts at thermal isomerization of *(2)* into a substitution product corresponding to the amide *(5)* failed. On prolonged standing in [D_6]-DMSO, the intensity of the cyclopropyl proton signals decreases, possibly by rearrangement of a carbonium ion dipole corresponding to *(6)*.

The reactivity of compound *(1)* towards diphenylketene is much lower than towards tosyl isocyanate. Comparison with corresponding cycloadditions to enol ethers[5] shows that, relative to the R—O group (which exerts a greater mesomeric

effect), the cyclopropyl group favors cycloadditions *via* polar transition states over more concerted processes.

Simmons-Smith reaction [CH_2I_2, Zn(Cu)] with *(1)* affords the interesting compound 1,1-dicyclopropylcyclopropane *(4)* in moderate yields; *(4)* can be separated from the reaction mixture by gas chromatography [^{1}H-NMR: τ ≈ 8.95 (m/2H on $C^{1'}$ and $C^{1''}$); ≈9.8 (m/8H on $C^{2'}$, $C^{3'}$, $C^{2''}$, $C^{3''}$); 10.0 (s/4H on C^2 and C^3)].

A Simple New Synthesis of 2-Thiopyrimidine Nucleosides[**]

By *H. Vorbrüggen*, *P. Strehlke*, and *G. Schulz*[*]

2-Thiopyrimidine nucleosides have hitherto been available only by multistep syntheses[1]. Two recently published direct syntheses starting from 2-thiopyrimidine derivatives and acylated halo sugars using the mercury salt method[2] and the *Hilbert-Johnson* procedure[3] respectively prompt us to report a very simple general synthesis of 2-thiopyrimidine nucleosides and a 6-aza analog *via* the silyl modification of the *Hilbert-Johnson* method[4, 5].

				β	199–202	−82.5	75	187–188	+6.5	7.7 [f] $J_{AX} + J_{BX}$ = 12 Hz	220 (4.18) 278 (4.23)	242 (4.40) 265 (4.20) shoulder
(c)	H	N	2,3,5-Tri-*O*-benzoyl-ribofuran-osyl chloride	78	173	−35.5	87	197–198	−96.6	6.95 [d] 2.5	218 (4.13) 269 (4.26)	236 (4.14) 267 (4.30)

[a] $c = 0.5$ in $CHCl_3$. [b] $c = 0.5$ in H_2O. [c] Crude yields: crystalline α-anomer 35%, β-anomer 11.5%. [d] D_2O at 90 °C. [e] D_2O at 30 °C. [f] [D_5]-Pyridine at 30 °C.

Treating 2-thiouracils with hexamethyldisilazane in anhydrous dioxane gave the *O,S*-bis(trimethylsilyl) derivatives *(1)* in almost quantitative yield. These derivatives react with acylated halo sugars in anhydrous benzene containing one equivalent of silver perchlorate[6] at 25 °C [*(1a)* and *(1c)* 60 min; *(1b)* 30 min] to provide the acylated 2-thionucleosides *(2)*, usually in good yield. Saponification with 0.01–0.02 N $NaOCH_3$ in anhydrous methanol or methanolic ammonia leads finally to the free 2-thiopyrimidine nucleosides *(3a)* and *(3b)*, as well as the 6-aza analog *(3c)*[7], usually in excellent yield. Elemental analyses and physical data are in accord with structures *(2)* and *(3)*. In the case of tribenzoylribofuranosyl chloride, only the β-D-ribofuranosides were obtained. Their configuration was proved not only by their NMR data but in the case of *(3a)* also by oxidation with $NaOH/H_2O_2$[8], whereupon we isolated a 70% yield of crystalline uridine, which was identified by comparison of its IR spectrum (KBr) and thin-layer chromatogram with authentic material.

All the 2-thiouridines, when compared with the uridines, showed a characteristic deshielding of the 1′-H in the NMR spectrum of up to one δ unit[9].

Further applications of this new method, *e.g.* synthesis of 2-thiocytidines, are being investigated[10].

Synthesis of Hall's Methyl 2-Thiouridine-5-acetate from Yeast-tRNA[1]

By *H. Vorbrüggen* and *P. Strehlke*[*]

Using our new method of preparing 2-thionucleosides[1] we have synthesized the methyl 2-thiouridine-5-acetate *(1)* recently isolated from yeast-tRNA by *Hall et al.*[2].

From diethyl 2-formylsuccinate, thiourea, and potassium carbonate in water we obtained ethyl 2-thiouracil-5-acetate, m.p. 185–187 °C, which with hexamethyldisilazane afforded the *O,S*-bis(trimethylsilyl) derivative in excellent yield. With tri-*O*-benzoyl-D-ribofuranosyl chloride and silver perchlorate in benzene (15 min, 24 °C) the silyl derivative gave a 78% yield of crystalline ethyl 2′,3′,5′-tri-*O*-benzoyl-2-thiouridine-5-acetate, m.p. 118–120 °C, $[\alpha]_D = -83°$ ($c = 0.5$ in $CHCl_3$). Hydrolysis and simultaneous transesterification with 0.02 N-sodium methoxide in anhydrous methanol (16 h, 24 °C) afforded a 74% yield of *Hall*'s methyl 2-thiouridine-5-acetate *(1)*, m.p. 195–196 °C (from 4 : 1 CH_3OH/H_2O), $[\alpha]_D = +19.8°$ ($c = 0.5$ in H_2O), $\delta_{H-1'} = 6.67$ ppm ($J = 2.5$ Hz at 90 °C in D_2O), which was shown to be identical with the natural product by m.p., UV and mass spectra, and thin-layer chromatography[3,4].

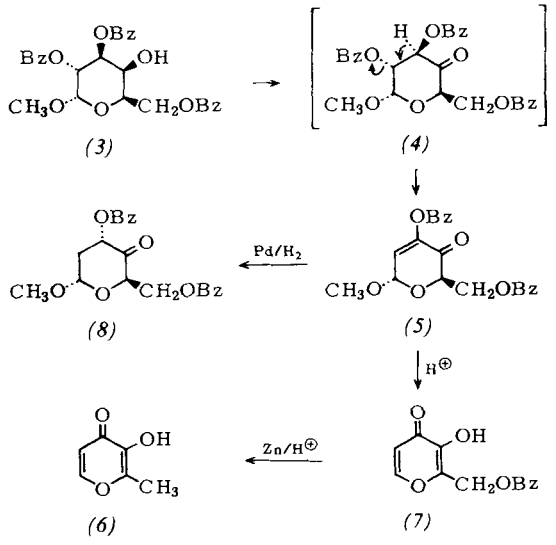
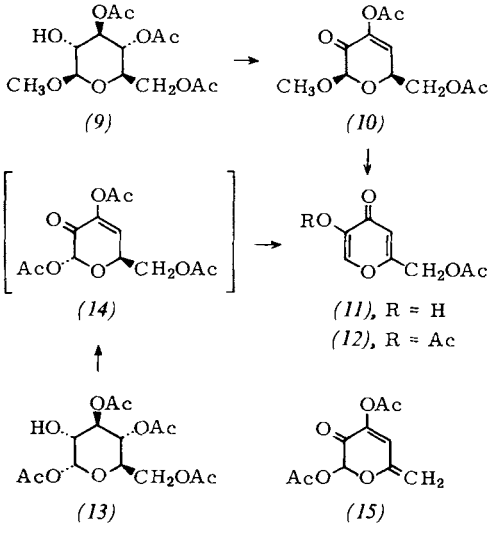
Intermediates in the Formation of γ-Pyrones from Hexose Derivatives: A Simple Synthesis of Kojic Acid and Hydroxymaltol



By *F. W. Lichtenthaler* and *P. Heidel*[*]

Sugar enolones of types *(1)* and *(2)* have been postulated as hypothetical intermediates in the formation of, respectively, kojic acid from acylated ald-2-uloses[1] and hydroxymaltol from the 3-*C*-formyllyxose portion of the antibiotic hydroxystreptomycin[2]. We have prepared enolones of these types in a simple manner, by oxidation of partially acylated aldopyranosides with dimethyl sulfoxide and acetic anhydride; their ready conversion into γ-pyrones supports the earlier mechanistic considerations and provides the simplest chemical synthesis to date of kojic acid and hydroxymaltol.

(1) *(2)*



When methyl 2,3,6-tri-*O*-benzoyl-α-D-galactopyranoside *(3)*[3] is oxidized by dimethyl sulfoxide-acetic anhydride, a new product[4] can be detected[6] already after 2 hours alongside *(3)* (approx. 70%) and the ketone *(4)*. The amount of the new product increases as the reaction proceeds and after 24 hours constitutes the sole reaction product (apart from benzoic acid). Working up gives needles, m.p. 127 to 128 °C, $[\alpha]_D^{25} = +70°$ ($CHCl_3$). Combustion analysis, the molecular weight determined by mass spectrometry, decoloration of bromine water and permanganate solution, and the isolation of benzoic acid (78% calc. on 1 equivalent) indicate that this is an unsaturated dibenzoate; failure to react with 2,4-dinitrophenylhydrazine, an enone *R*-band in the circular dichroism plot at 342 nm ($\Delta\varepsilon = -2.15$ in dioxane)[7], and the NMR data (4 Hz doublets for H^3 and H^2 at $\tau = 3.26$ and 4.58; ABC system for H^6 and C-6–CH_2 around $\tau = 5.2$ in $CDCl_3$) prove conclusively the presence of a conjugated enone, (2*S*, 6*R*)-4-benzoyloxy-6-(benzoyloxymethyl)-5,6-dihydro-2-methoxy-2*H*-pyran-5-one *(5)*. Thus oxidation of the free hydroxyl group in *(3)* is accompanied under the reaction conditions by an acid-catalyzed β-elimination of benzoic acid [*(4)* → *(5)*], which has analogies in the elimination under similar conditions of phosphoric acid from nucleotides[8] and of acetic or benzoic acid from acylated aldulosides[9].

(3) *(4)* *(5)* *(6)* *(7)* *(8)*

Hydrogenation over 10% palladium-charcoal in methanol-ethyl acetate (40 min) converts *(5)* quantitatively into methyl 3,6-di-*O*-benzoyl-2-deoxy-α-D-*erythro*-hexopyranoside *(8)*, which was characterized as a pure syrup by combustion analysis, by spectral data (νCO at 1740 and 1720 cm^{-1}, quartet for H^1 and H^3 at $\tau = 4.81$ and 4.12, respectively, with $J_{1,2} = 5.5$ and 7.0, as well as $J_{2,3} = 7.5$ and 13.0 Hz), and as 2,4-dinitrophenylhydrazone, needles, decomp. 191–193 °C. The enolone *(5)* is stable towards weak acids such as acetic acid; however, strong acids such as trifluoroacetic acid convert it, with spontaneous hydrolysis of the 2-methoxyl and 4-benzoyloxyl group[10], into the more stable γ-pyrone, 2-(benzoyloxymethyl)-3-hydroxy-4*H*-pyran-4-one *(7)*, m.p. 136–139 °C (89% yield); this structure followed unambiguously from the NMR data (OH singlet at $\tau = 0.49$, 5.5 Hz doublet for H^6 and H^5 at $\tau = 1.84$ and 3.55, CH_2 singlet at $\tau = 4.63$) and by conversion into maltol *(6)*[11] by zinc and hydrochloric acid[12].

As in the case of *(3)*, oxidation of methyl 3,4,6-tri-*O*-acetyl-β-D-glucopyranoside *(9)*[13] by dimethyl sulfoxide and acetic anhydride occurs with β-elimination of acetic acid from the 2-keto compound that is the primary product, leading thus to (2*S*, 6*R*)-4-acetoxy-2-(acetoxymethyl)-6-methoxy-5,6-dihydro-2*H*-pyran-5-one *(10)*, m.p. 139–142 °C, in 47% yield, and this is converted immediately on dissolution in trifluoroacetic acid into monoacetylkojic acid *(11)*[14], m.p. 135 to 136 °C, in 82% yield.

(9) *(10)* *(14)* *(11)*, R = H *(12)*, R = Ac *(13)* *(15)*

The enolone *(14)* expected on oxidation of 1,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside *(13)*[15] could, however, not be isolated. Owing to the greater lability of the 1-acetoxyl than of the 1-methoxyl group of *(10)*, the weakly acidic oxidation conditions suffice for formation of the γ-pyrone system; diacetylkojic acid *(12)*[14] results and is isolated in 74% yield. Accordingly, the product obtained by *Perlin* and co-workers[9b] on oxidation of *(13)* by DMSO–SO_3 and considered to be the conjugated 3,5-dienone *(15)* is more correctly formulated as *(12)*[16,17].

(2S,6R)-4-Benzoyloxy-6-(benzoyloxymethyl)-5,6-dihydro-2-methoxy-2H-pyran-5-one (5)

The glycoside *(3)* (3.0 g, 6.0 mmoles) in DMSO (20 ml) is treated with acetic anhydride (10 ml) and set aside at room temperature for 2 days, then stirred into ice-water. The oil that separates is taken up in chloroform, dried over Na_2SO_4, freed from solvent, and treated with methanol, whereupon it

crystallizes. Recrystallization from ethanol gives 1.2 g (52%) of *(5)* as colorless needles, m.p. 127–128 °C, $[\alpha]_D^{25} = +70°$ ($c = 1$ in $CHCl_3$).

[16] Structure *(15)* is already refuted by previous NMR data [9b] (2H singlet for the methylene protons of an enol ether). These data agree with those for diacetylkojic acid except for one signal [singlet at $\tau = 2.95$ instead of $\tau = 3.52$ for H-3 in *(12)*].

[17] Note added in proof: The formation of diacetylkojic acid on dimethyl sulfoxide oxidation of *(13)* has also been demonstrated by *G. J. F. Chittenden* (personal communication and Carbohydrate Res., in press).

3-Nitro-2-azachromone (4*H*-1,2-Benzoxazin-4-one): Structure of the Presumed *p*-Nitrophenylnitroacetylene[1]

By *H. G. Viehe*, *V. Jäger*, and *F. Compernolle* [*]

After appearance of our communication on the synthesis of the first nitroacetylene[1] we learnt[2] that in 1903 *Wieland* and in 1960 *Novikov et al.* regarded a compound $C_8H_4N_2O_4$ *(1)*[3] as *p*-nitrophenylnitroacetylene *(2)* on the basis of elemental analysis and molecular-weight determination. We can confirm the formation of *(1)*; its chemical and physical properties can be brought into accord only with the structure *(3a)* of a 2-azachromone.

A melting point of about 140 °C without decomposition is, in our experience with nitroacetylenes, unthinkable for a compound such as *(2)*. The NMR spectrum of *(1)* shows four neighboring aromatic protons and, together with the analytical data, indicates a fused heterocycle.

In accord with formulation *(3a)*, compound *(1)* has in its IR spectrum strong CO and NO_2 absorption bands at 1676[4], 1550, and 1352 cm^{-1} and other strong bands at 1613, 1565, 1460, 1040, 813, and 771 cm^{-1}, but does not have the strong C≡C absorption characteristic of nitroacetylenes[1]. The UV spectrum of *(1)* in methanol has maxima at 242 nm (log ε = 3.90), 256.5 (3.83 shoulder), and 321.5 (3.76). In the mass spectrum, fragment ions appear at *m/e* = 192, 165, 146, 120, 118, 92, 90 (base peak), 64, and 63. The position of the metastable peaks proves the following degradation paths:

192 → 165 (−HCN)
192 → 146 (−NO_2) → 118 (−CO) → 90 (−CO)
and 146 → 90 (−2CO); 90 → 64 and 63 (−CN and −HCN, resp.)

Treatment of *(1)* with carbonyl reagents does not lead to corresponding derivatives; instead, treatment with phenylhydrazine in ethanol and a little acetic acid gives ethyl salicylate. Alkaline degradation with 2 N-KOH at room temperature affords salicylic acid. *(1)* reacts neither with concentrated sulfuric acid in the cold nor with 20% aqueous H_2SO_4 in THF under reflux, but with 90% H_2SO_4 at 100 °C affords 1,2-benzisoxazole-3-carboxylic acid[6].

Dilute alcoholic hydrochloric acid in THF at room temperature replaces the nitro group of *(1)* by Cl. This corresponds to a nucleophilic substitution and shows the relation to nitrolic acids $RC(NO_2)=NOH$, which are converted into hydroxamic acids by concentrated HCl[7].

These results leave *(3a)* and *(3b)* as the only possible formulations of *(1)* and the chlorine derivative, and this is confirmed by the mass spectrum of *(3b)*.

The compound $C_8H_4N_2O_4$ *(1)* designated as *p*-nitrophenylnitroacetylene is thus to be considered as a derivative of the barely known 4*H*-1,2-benzoxazin-4-ones (2-azachromones)[8].

Hydrogen Tetrahalogenobis(*N,N*-dimethylacetamide)aurates(III)

By *M. Ziegler, P. Barth,* and *H. Winkler* [*]

Addition of *N,N*-dimethylacetamide (DMA) to aqueous solutions (≧ 8%) of hydrogen tetrahalogenoaurates(III) affords less readily soluble, crystalline complexes: $H[AuCl_4(DMA)_2]$ *(1a)*, yellow, m.p. 66 °C; $H[AuBr_4(DMA)_2]$ *(1b)*, dark red, m.p. 79 °C. These adducts are not only soluble in water or alcohol, but, in contrast to the starting compounds $H[AuHal_4]$, they also dissolve extremely readily in aliphatic halogenohydrocarbons which can therefore be used for their extraction.

Elemental analysis and IR- and ^{1}H-NMR spectra show the new compounds to correspond to formula *(1)*.

(1)

Since no bands are registered above 3000 cm^{-1} in the IR spectrum, proton coordination at the nitrogen, as, for example, is found in the ammonium salt $[HN(C_4H_9)_3][AuCl_4]$ with νNH = 3150 cm^{-1} ($[DN(C_4H_9)_3][AuCl_4]$, νND = 2395 cm^{-1}), would appear unlikely. On the other hand, broadened bands (width up to 200 cm^{-1}) around 812 cm^{-1} would indicate hydrogen bonding of the kind —CO · · · H · · · OC— [1]. The formulation *(1)* is confirmed by the intensity ratio of the ^{1}H-NMR signals $H^a : H^b : H^c$ = 6 : 12 : 1 (H^c : acetamide = 1 : 2); the δH^c values ($CDCl_3$; TMS as external standard) of —17.45 [*(1a)*] and —17.05 ppm [*(1b)*] are extreme values within the range of diamagnetic shifts expected.

The exclusive decrease of the H^c values by competing proton exchange is indicative of solvent reactions of compound *(1)* with aliphatic halogenohydrocarbons, *e.g.*, CH_2Cl_2; a concomitant increase in δH(methylene) from —1.88 to about —10 ppm is also observed.

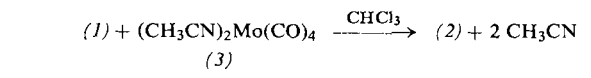
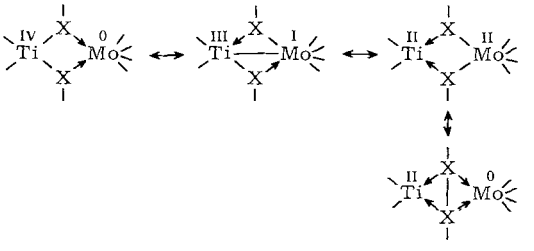
Titanium-Molybdenum Complexes with Chalcogen Bridging Ligands



By *H. Köpf* and *K. H. Räthlein* [*]

Bi- and tri-nuclear germanium(or tin)-chromium complexes joined by sulfur bridging atoms have recently [1] been prepared by direct introduction of organometallic sulfides as ligands replacing CO in hexacarbonylchromium.

We have applied this synthetic method to organotitanium chalcogenides by treating the potentially bidentate ligands



bis(phenylchalcogeno)bis(cyclopentadienyl)titanium(IV) *(1a)* (X = S) [2] and *(1b)* (X = Se) [3] with equimolar amounts of hexacarbonylmolybdenum in tetrahydrofuran under UV irradiation [4] for 3 hours at room temperature. This afforded the doubly bridged, binuclear complexes *(2a)* and *(2b)*, which, after concentration of the dark reaction solutions in a vacuum, were isolated as bluish-black crystals that were soluble in organic solvents, sensitive to air and solvolysis, yet thermally stable up to 200 °C in the absence of air. The complexes *(2)* from bis(acetonitrile)tetracarbonylmolybdenum(0) [5] *(3)* were formed particularly smoothly in chloroform without irradiation:

The IR spectra of *(2)* showed four CO stretching vibrations for the carbonyl skeleton of symmetry C_{2v} as well as the characteristic π-C_5H_5 and C_6H_5 bands. The molecular weight determined in benzene was in accord with the monomeric *cis*-structure *(2)* formulated.

The oxidation state of the metals concerned in the diamagnetic compounds *(2)* can no longer be stated unambiguously. Several limiting forms may participate in the ground state (non-bonding electron pairs and terminal ligands are omitted), viz:

In fact the τC_5H_5 values in the ^{1}H-NMR spectra indicate for the complexes *(2)* a considerably greater shielding of the cyclopentadienyl protons in comparison with *(1)*. This is not in accord with the decrease in the electron density on titanium that is to be expected from an increase in the donor function of the chalcogen atoms X to molybdenum [6], but it can be readily explained as due to electron back-donation from molybdenum and/or a chalcogen-dichalcogen redox system to the unoccupied ψ_0-orbital of Ti^{IV} [7]. The increase in the mobility of the electrons in the TiX_2Mo ring follows also from the bathochromic shift in the visible absorption from reddish-violet (539 nm; in chloroform) for *(1a)* to blue (also 618 nm) for *(2a)*.

Bis(cyclopentadienyl)diphenoxotitanium(IV) *(1c)* (X = O) [9] reacts with hexacarbonylmolybdenum or *(3)* under analogous conditions but instead of giving *(2c)* it splits off two further CO groups and affords the yellow, relatively stable, trinuclear tetrasubstitution product *cis*-$[(C_5H_5)_2Ti(OC_6H_5)_2]_2Mo(CO)_2$ *(4)*. The *cis*-structure of *(4)* (symmetry C_2) follows from the appearance of two IR frequencies in the carbonyl region and two ^{1}H-NMR signals of equal intensity that can be assigned to two pairs of C_5H_5 groups in different surroundings. The pale red color of the solutions, unchanged from that of *(1c)*, and the position of the τC_5H_5 values for *(4)* indicate that in this case mesomerism is not important. The effect of mesomerism on the ground state thus increases from O to Se, the limiting structure with diphenyldichalcogenide bridges acquiring additional weight in the same series.

Di(μ-phenylthio)bis(cyclopentadienyl)titaniumtetracarbonylmolybdenum (2a)

A solution of *(1a)* (396 mg, 1 mmole) in chloroform (20 ml) is added dropwise within 30 minutes to a stirred suspension of *(3)* (290 mg, 1 mmole) in chloroform (10 ml) under nitrogen. The red solution becomes deep blue. After 2 hours'

further stirring and filtration most of the solvent is removed in a vacuum. The bluish-black leaflets precipitated are washed with a little cold chloroform and dried in a vacuum. After dissolution in, and recovery from, chloroform the yield is 51% (310 mg). *(2b)* (66%, 460 mg) is obtained analogously from *(1b)* (1 mmole, 490 mg); and *(1c)* (364 mg, 1 mmole) affords *(4)* (260 mg, 59%), a yellow powder, on dissolution of the crude product in carbon disulfide, concentration, and rubbing of the residue with methanol.

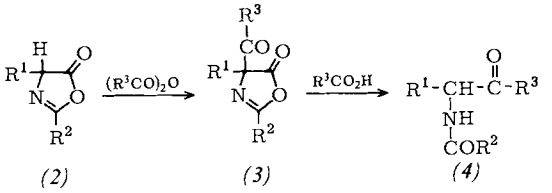
N,N-Dimethyl-4-pyridinamine, a Very Effective Acylation Catalyst

By *W. Steglich* and *G. Höfle* [*]



We have found that *N,N*-dimethyl-4-pyridinamine *(1)* [1], alone or mixed with triethylamine, is a superlative acylation catalyst, much superior to pyridine [2].

(1)

O-Acylations: Acylation of tertiary alcohols is considered to be difficult [3]. For example, *tert*-butyl alcohol and 1-methyl-1-cyclohexanol are not acylated by acetic anhydride and pyridine [4]. Yet acetylation in the presence of an equivalent amount of *(1)* is complete after 10 hours at room temperature (NMR kinetics). For preparative purposes it suffices to add catalytic amounts of *(1)* and to bind the acid formed by triethylamine. [Example: 1-Methyl-1-cyclohexanol (11.4 g, 0.1 mole), acetic anhydride (20 ml, 0.21 mole), triethylamine (20 ml, 0.15 mole), and *(1)* (0.5 g, 4.1 mmoles); after 14 hours at room temperature 86% of acetate; analogously, 60% of *tert*-butyl acetate. The amounts of acetate formed by pyridine and/or triethylamine are less than 5%.]

C-Acylations: The Dakin-West reaction [5] was chosen as example, its most important step being the pyridine-catalyzed acylation of the 5-oxazolone *(2)* to the 4-acyl-5-oxazolone *(3)* [6,7].

(2) *(3)* *(4)*

(a), $R^1 = R^3 = CH_3$, $R^2 = C_6H_5$
(b), $R^1 = C_6H_5$, $R^2 = R^3 = CH_3$

Here *(1)* accelerates this reaction much more than pyridine does. For example, acetylation of *(2a)* to *(3a)* with pyridine requires about 6 hours [7], but with 0.05 part of *(1)* only 3 minutes are needed. At the same time the decarboxylative ring fission is greatly accelerated, so that the Dakin-West reaction can be carried out at room temperature.

Analogously to *(4a)* (see below), 2-phenylglycine afforded *N*-(1-phenylacetonyl)acetamide *(4b)* in good yield after 13 hours' stirring. Further, conversion of oxazolones into *(4)* by carboxylic acids [7,8] is effected smoothly at room temperature under catalysis by *(1)*; for example, *(2a)* (0.97 g, 5.55 mmoles), glacial acetic acid (0.32 ml, 5.55 mmoles), and *(1)* (40 mg, 0.33 mmole) in methylene chloride give 73% (0.80 g) of *(4a)* after one day.

N-(1-Methylacetonyl)benzamide (4a)

N-Benzoylalanine (3.9 g, 20 mmoles) and *(1)* (0.1 g, 0.82 mmole) are stirred with acetic anhydride (4 ml, 42 mmoles) and triethylamine (4 ml, 0.29 mmole). Lively evolution of CO_2 and slight warming occur. After 30 min glacial acetic acid (30 ml) is added, then the solution is set aside for 30 min, concentrated in a vacuum, shaken with 2 N NaOH, and extracted with ether. Shaking the ethereal phase with 1 N-HCl, drying, and evaporation gives 78% (3.0 g) of *(4a)*, m.p. 63 °C (m.p. in [9] is 69 °C).

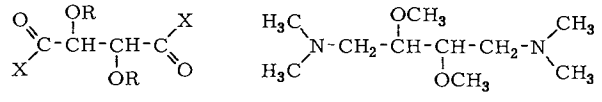
Asymmetric Solvent Catalysis; *N,N,N′,N′*-Tetramethyl-2,3-dimethoxy-1,4-butanediamine, a New Chiral Medium



By *D. Seebach, H. Dörr, B. Bastani,* and *V. Ehrig* [*]

Chiral bifunctional [1] ethers [2] (2,3-dimethoxybutane) and amines [3] (sparteine) can be used forasymmetric syntheses [4] of, *e.g.*, alcohols *(2)* from aldehydes and organometallic reagents (asymmetric catalysis by coordination bonding).

(1), M = Li, Mg *(2)*
X = OR, NR_2

Experiments so far have been done with a ratio (*r*) of chelating agent to metal derivative of $r = 1$ in an inert solvent (benzene or hexane); the optical yield (*p*) reached a maximum of 6% with M = Li [3]. We have found that *p* can be raised appreciably if the asymmetric addend is not only the complexing agent ($r = 1$) but also the solvent (r = up to 20). As

(3a), X = OC_2H_5, R = H DAB
(3b), X = $N(CH_3)_2$, R = H
(3c), X = $N(CH_3)_2$, R = CH_3

chiral medium [5] we used *N,N,N′,N′*-tetramethyl-2,3-dimethoxy-1,4-butanediamine (DAB), which is readily obtained from diethyl tartrate *(3a)*.

Table 1. Optical yields *p* obtained on addition of butyllithium to benzaldehyde, leading to 1-phenyl-1-pentanol [a], in DAB-pentane (20 mmolar batches; aldehyde added after dilution with pentane). Also, for comparison, the same reaction in ether and in presence of (−)-sparteine [b] and (−)-2,3-dimethoxybutane (DMB) [c].

No.	Temp. (°C)	DAB/BuLi (*r*)	Pentane/DAB (vol.) approx.	*p* (%)
1	0	2	6	8.5
2	− 78	0.25	60	6.2
3	− 78	0.5	30	8.5
4	− 78	1	13	9.5
5	− 78	2	6	14.8
6	− 78	2.5	5	15.2
7	− 78	3	4	15.6
8	− 78	4	2.5	15.2
9	− 78	8	1.2	20.2
10	− 78	15	0.5	20.6
11	−120	2	8	22.3
12	−120	4	2.6	25.0
13	−130	9	1.2	33.0
			Ether/DAB	
14	− 78	2	5	12.5
		Sparteine/BuLi	Hexane/ Sparteine	
15	− 70	1	11	5.8 [3]
16	− 78	3	4.5	13.3
		DMB/BuLi	Hexane/DMB	
17	− 78	3	10	3.9

[a] (+)-DAB, (−)-sparteine, and (−)-DMB led in all cases to (+)-alcohol of (*R*) configuration. As value for the optically pure carbinol we took $[\alpha]_D = 17.5°$ (homogeneous) or $[\alpha]_D = 31.3°$ ($c = 13$ in C_6H_6) [8]

[b] $[\alpha]_D = 5.62°$ (homogeneous).

[c] $[\alpha]_D = 3.71°$ (homogeneous), from (+)-tartaric acid.

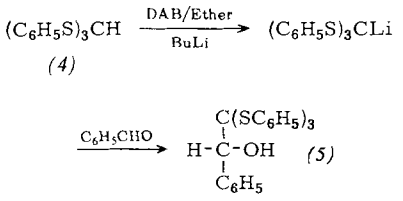
Conversion into the diamide *(3b)* [$NH(CH_3)_2$—CH_3OH; m.p. 184.2–185.0 °C; $[\alpha]_D = 42.7°$ ($c = 3.0$ in C_2H_5OH)], esterification to give *(3c)* [$(CH_3)_2SO_4$, NaH—THF; m.p. 63.2–63.5 °C; $[\alpha]_D = 115.7°$ ($c = 3.1$ in C_6H_6)], and reduction ($LiAlH_4$—THF) affords a 65% overall yield of (*S,S*)-(+)-DAB from natural (+)-tartaric acid and of (*R,R*)-(−)-DAB from (−)-tartaric acid [b.p. 62–63 °C/3 torr; $n_D^{20} = 1.4343$; $d^{20} = 0.896$; $[\alpha]_D = 14.65°$ (homogeneous); dipicrate, m.p. 151.2–152.0 °C, $[\alpha]_D = 20.5°$ ($c = 3.5$ in $(CH_3)_2CO$)] [6].

Nos. 2–10 in Table 1 show that the optical yield on addition of butyllithium to benzaldehyde increases with increasing content of DAB in the medium up to $r = 2$, then remains constant up to $r = 4$, and with $r = 8$ increases again; on cooling down to −130 °C (compare nos. 1, 5, and 11, nos. 8 and 12, and nos. 9 and 13) we obtained values of *p* up to 33% [7].

DAB solidifies to a glass at about −30 °C but can be stirred at very low temperatures if small amounts of pentane are added (column 4 of Table 1); mixtures with butyllithium are clear and homogeneous.

The optical yield decreases only slightly if ether is used for dilution instead of pentane (Table 1, nos. 14 and 5).

Table 2. Optical yields *p* on addition of organometallic compounds to carbonyl compounds in the presence of (+)-DAB (solvent: pentane for RLi, ether for Mg derivatives).



Carbonyl compound	R-metal	Temp. (°C)	DAB/ R-metal	$[\alpha]_D$ (*c*, solv.) [a]	*p* (%)
C_6H_5—CHO	$CH_3Li/LiBr$ (Ether)	−100	3	−0.76 (16, CH_3OH)	1.7
CH_3—CHO	BuLi (Hexane)	−120	2	+1.6 (4, C_2H_5OH)	14
C_2H_5—CHO	BuLi (Hexane)	−120	2	+1.6 (10, C_2H_5OH)	19
$(CH_3)_2CH$—CHO	BuLi (Hexane)	−120	2	+6.1 (5, C_2H_5OH)	22
C_6H_5—CHO	$(CH_3)_2CHLi$ (Hexane)	−120	4	+6.6 (7.5, Ether)	14
C_4H_9—CHO	C_6H_5Li (Benzene/ Ether)	− 78	2	+2.4 (13, C_6H_6)	7.8
$(C_6H_5)_2CH$—CHO	C_6H_5Li (Benzene/ Ether)	− 78	3	−11.1 (9, C_2H_5OH)	10
$CH_3COC_2H_5$	C_6H_5Li (Benzene/ Ether)	− 78	3	+0.6 (−)	3.3
C_6H_5—CHO	*n*-C_4H_9MgI	− 78	3	−2.0 (13, C_6H_6)	6.5
C_6H_5—CHO	$(n\text{-}C_4H_9)_2Mg$	− 78	2	−2.5 (7, C_6H_5)	8

[a] For rotations of optically pure products see [8b, 10].

Table 2 gives further examples comprising other carbonyl and other organometallic compounds. Optically active compounds result in all these cases. The optical yields vary greatly; from the absolute configurations of the favored antipodes produced it appears that there is no single mechanism concerned [9].

Asymmetrically solvated lithium derivatives besides those shown in Table 2 can be obtained by metalation with butyllithium in DAB-hexane or -ether. For instance, when butyllithium is added to the orthotrithioformic ester *(4)* [11] in ether-(+)-DAB [ratio DAB: (4) = 4 : 1] at −78 °C, an insoluble mass is formed on the wall of the flask but this redissolves on subsequent additon of benzaldehyde. The (*R*)-mandelic acid derivative *(5)* [12], $[\alpha]_D = +23°$ ($c = 5$ in CH_2Cl_2), is formed in 91% yield.

Experimental (see Table 1, no. 13): (+)-DAB (20 ml, 90 mmoles) and pentane (20 ml) under argon at −80 °C are treated with butyllithium (10 mmoles; 2.7 M in hexane) and stirred with a mechanical Teflon overhead stirrer. The pentane bath is caused to solidify (−130 °C) by addition of liquid nitrogen. The contents of the flask assume the consistency of honey. Benzaldehyde (10 mmoles) in pentane (5 ml)

is then added during 5 min, this causing formation of a precipitate. After the addition, the mixture sometimes soldifies and cannot be stirred. It is allowed to warm slowly, at −50 °C it is treated with water (2 ml), then acidified by addition of 17% HCl with cooling and transferred in pentane to a separatory funnel. The aqueous phase is extracted with pentane. The pentane phases are united, washed with dilute HCl, $NaHCO_3$ solution, and water, and dried over Na_2SO_4. Distillation affords 1-phenyl-1-pentanol (1.21 g, 74%;pure on gas chromatography), b.p. 81 °C/0.8 torr, $[\alpha]_D = +5.74°$ (homogeneous), $[\alpha]_{365} = +17.75°$. To regenerate the DAB (90%, with no loss of activity) the hydrochloric acid solutions are collected, saturated with KOH, and extracted continuously with ether or benzene.

[11] *D. Seebach*, Angew. Chem. *79*, 468 (1967); Angew. Chem. internat. Edit. *6*, 442 (1967).

[12] The optical yield could not be determined since the hydrolysis [11] leading to (*R*)-(−)mandelic acid was accompanied by partial racemization.

1,4-Addition of 2-Lithio-1,3-dithianes to Substituted ω-Nitrostyrenes

By *D. Seebach* and *H. F. Leitz* [*]

Metalated 1,3-dithianes *(1)* [M = Li, Mg, Mg/Cu^I, Zn, or Cd], which have proved their value as nucleophilic acylating agents[1], add to α,β-unsaturated carbonyl compounds exclusively at the 1,2-positions (*i.e.*, to the C=O group), giving compounds *(2)* [1b,2].

	R^1	R^2	R^3	*(4)* [3] Yield (%)[a]	M.p. (°C)
(a)	H	4-CH_3O	H	25	89.6–91.0
(b)	H	2,5-$(CH_3O)_2$-4-CH_3	H	90	143.1–144.2
(c)	H	4-CH_3O	CH_3	50	132.8–134.2
(d)	H	2,5-$(CH_3O)_2$-4-CH_3	CH_3	70	155.0–156.1
(e)	CH_3	4-CH_3O	H	25	81.0–82.0
(f)	C_6H_5	4-CH_3O	H	90	93.1–94.2
(g)	C_6H_5	2,5-$(CH_3O)_2$	H	72	138.2–139.2

[a] Yields are not optimal in all cases.

We have now found that 1,4-addition occurs if the nitrostyrenes *(3)* are added slowly to the 2-lithio-1,3-dithianes *(1)* (both in THF at −78 °C); after hydrolysis we isolated the 2-(2-nitroalkyl)-1,3-dithianes *(4)*. The structure of products *(4)* [3] was established chemically (elemental analysis, preparation of optically active *(4)* [4] and reduction to primary amines) and by spectroscopy; the IR spectrum contains no C=N, b–H, or N–H bands. ^{1}H-NMR data [3] (in $CDCl_3$, TMS as internal std., 60 MHz) were as follows for two examples: *(4a)*, τ = 2.78 and 3.14 ($H^{h,i}$/2d), J_{hi} = 8.5 Hz; τ = 4.92 (H^c/dd), J_{cd} = 13 Hz, J_{bc} = 5.5 Hz; τ = 5.28 (H^d/dd), J_{bd} = 9 Hz; τ = 5.72 (H^a/d), J_{ab} = 7.5 Hz; τ = 6.14 (H^b/ddd); τ = 6.22 (3 H^g/s); τ = 7.2 (4 H^e/br. m); τ = 8.4 (2 H^f/br. m). *(4c)*, τ = 4.76 (H^c/dq), J_{bc} = 9 Hz, J_{cd} = 6.5 Hz; τ = 5.52 (H^a/d), J_{ab} = 6 Hz; τ = 6.58 (H^b/dd); τ = 8.35 (3 H^d/d); other signals as for *(4a)*.

We consider the 1,4-addition unusual for the following reasons: (1) Nitrostyrenes, like other oxidizing agents, could lead to radical dimerization of lithiodithianes [1b]; (2) high yields on 1,4-addition to nitroolefins have been obtained only with strongly CH-acidic compounds [5a]; (3) with Mg-, Zn-, and Cd-alkyl and -aryl compounds, competing 1,2-addition reduces the yields [5b]; and (4) organolithium compounds in particular favor 1,2-addition to α,β-unsaturated electrophiles, which would lead to hydroxylamines in the present case [5c].

trans,cis,cis,cis-Cyclononatetraenyl Anion, a New Aromatic 10 π System

By *G. Boche*, *D. Martens*, and *W. Danzer*[*]

Woodward and *Hoffmann*[1] predicted that thermal ring opening of the cyclopropyl anion to the allyl anion would proceed in a conrotatory fashion. *Huisgen et al.*[2] have been able to detect the expected thermal conrotation and photochemical disrotation in the isoelectronic aziridine/azomethine ylide system.

Katz and *Garratt*[3] have prepared potassium *cis,cis,cis,cis*-cyclononatetraenide *(3)* in essentially quantitative yield[4] by reaction of *anti*-9-methoxy-*cis*-bicyclo[6.1.0]nona-2,4,6-triene *(1)* with potassium in tetrahydrofuran. Orbital symmetry considerations[1,5] would, however, suggest that the cyclopropyl anion *(2)* undergoes conrotatory ring opening to give potassium *trans,cis,cis,cis*-cyclononatetraenide *(4)*.

(1) *(2)* *(3)* *(4)*

We have, therefore, reinvestigated the course of the reaction in [D_8]-THF at −40 °C by NMR spectroscopy and, after complete consumption of *(1)*[6], a spectrum was obtained that indicates the presence of only 4 ± 2% of *(3)* (sharp signal at τ = 2.87). The chemical shifts observed clearly indicate that the remaining signals cannot be assigned to the potassium cyclopropanide compound *(2)* but to the aromatic potassium *trans,cis,cis,cis*-cyclononatetraenide *(4)*: The six protons H^3—H^8 absorb between τ = 3.0 and 3.6; the signal due to H^2 and H^9 appears as a broadened doublet (J = 15 Hz) centered at τ = 2.73, and H^1 absorbs as a triplet at τ = 13.52 (J = 15 Hz).

As, for example, in the case of the aromatic annulenes[7], the delocalization of the π electrons in *(4)* in an external magnetic field gives rise to a ring current which shifts the NMR signals of the protons situated outside the ring (H^2—H^9) downfield, and that of the inner proton H^1 upfield[8]. If *(2)* were present, six olefinic protons ($H^{2'}$—$H^{7'}$) and three cyclopropyl-anion protons[9] ($H^{1'}$, $H^{8'}$, $H^{9'}$) would be observed. The ring opening *(2)*→*(4)*[10], which is fast even at −40 °C, profits from formation of the 10π aromatic compound *(4)*. On the other hand, ring opening does not occur at a measurable rate in the aziridine/azomethine ylide system until the temperature has been raised to 100 °C[2a]. None of the isolable cyclopropyl anions is known to undergo ring opening[1,5,9].

Potassium *trans,cis,cis,cis*-cyclononatetraenide *(4)* can be stored for days at −40 °C in a closed vessel. However, conversion to the all-*cis* compound *(3)* takes place when the reaction mixture is stirred at room temperature.

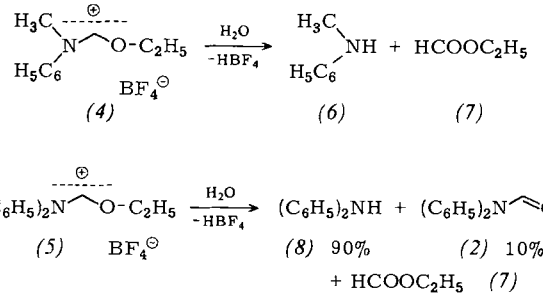
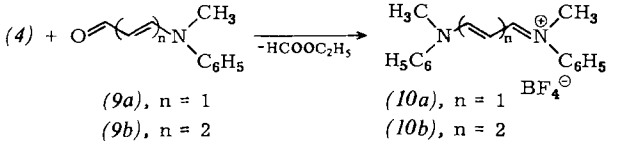
C–N Fission of *O*-Alkylated Formamides[1,2]

By *H. G. Nordmann* and *F. Kröhnke*[*]



We have prepared the *O*-alkylated formamides ethoxy-*N*-(methylanilino)- *(4)* and ethoxy-*N*,*N*-(diphenylamino)-methylium tetrafluoroborate *(5)* by alkylation of *N*-methylformanilide *(1)* and diphenylformamide *(2)*, respectively, with triethyloxonium tetrafluoroborate *(3)*[3,4].

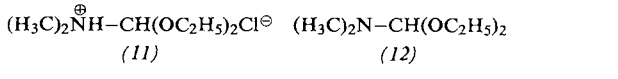
(1), R^1 = CH_3 *(3)* *(4)*, R^1 = CH_3
(2), R^1 = C_6H_5 *(5)*, R^1 = C_6H_5



These products *(4)* and *(5)* are crystalline substances that are relatively insensitive to atmospheric moisture and can be recrystallized from acetonitrile-ether. Their structure has been proved by analyses and NMR spectra. A characteristic feature is that introduction of the positive charge shifts the formyl-H signals from 8.27 to 8.48 ppm [*(1)*→*(4)*] and from 8.55 to 8.82 ppm [*(2)*→*(5)*] (δ values; in $CDCl_3$; TMS as internal standard).

(4) reacts with an excess of water at room temperature to give *N*-methylaniline *(6)* and ethyl formate *(7)* almost quantitatively; but, in this reaction, *(5)* gives diphenylamine *(8)* (90%), diphenylformamide *(2)* (10%), and ethyl formate

(7) (analysis by NMR spectroscopy and gas chromatography).



At room temperature in methylene chloride the salts *(4)* and *(5)* transfer the amino group almost quantitatively to vinylogous amides *(9)* and similar carbonyl compounds. *E.g.*, the symmetrical vinylogous amidinium salts *(10)* can be prepared in this way.

(9a), n = 1 *(10a)*, n = 1
(9b), n = 2 *(10b)*, n = 2

The above results accord with the ready hydrolytic fission of the C—N bond in *O*-alkylated and *O*-acylated vinylogous amides and in the vinylogous formimidoyl chlorides. This C—N fission is the basis for formation of symmetrical amidinium salts from vinylogous amides in an alkylating or acylating medium (the "symmetry reaction"), as well as for the synthesis of β-chlorovinyl aldehydes [2].

Analogously, dimethylformamide diethyl acetal hydrochloride *(11)* suffers hydrolysis of the C—N bond by *Meerwein*'s method [4], giving the hydrochloride of the leaving amine quantitatively. However, *Bredereck* [5] found that dimethylformamide diethyl acetal *(12)* [which on dissociation in an inert solvent gives an *O*-alkylated formamide similar to *(4)* and *(5)*] undergoes mainly C—O fission on hydrolysis, *i.e.*, dealkylation to dimethylformamide.

(11) *(12)*

Ethoxy-N-(methylanilino)methylium tetrafluoroborate (4)

(3) (19 g, 100 mmoles) is treated with *(1)* (14.86 g, 110 mmoles = 13.50 ml) with exclusion of moisture and ice-cooling, and the mixture is stirred at room temperature. *(4)* crystallizes within 30 min from the ether layer (ice-cooling). The product is filtered off and washed with dry ether until colorless and dry. It must be kept in a desiccator over P_2O_5. Yield: 25.1 g (100%). For purification, *(4)* is dissolved in dry acetonitrile at room temperature, treated with active charcoal, and precipitated with anhydrous ether at 0 °C [2 ml of acetonitrile/10 ml of ether/1 g of *(4)*], forming colorless, narrow leaflets, m.p. 104—106 °C (unsharp; in a sealed tube). *(5)* is prepared analogously, forming colorless rods, m.p. 92—94 °C (unsharp).

N-Methyl-[3-(N'-methylanilino)propenylidene]anilinium tetrafluoroborate (10a)

(4) (2.51 g, 10 mmoles) is dissolved in anhydrous methylene chloride (10 ml) and treated with *(9a)* (1.61 g, 10 mmoles), and the mixture is stirred at room temperature for 2 hours with exclusion of moisture. The orange solution obtained is cooled in ice and treated with ether (50 ml) whilst being rubbed. The yellow *(10a)* crystallizes and is collected and washed with ether (yield 3.10 g, 92%). For purification it is dissolved in acetonitrile at room temperature and treated with ether with rubbing until a permanent turbidity is produced [6 ml of acetonitrile/100 ml of ether/1 g of *(10a)*]. Lemon yellow rods, m.p. 149—151 °C, are obtained.

A New Peroxide Rearrangement: *cis*-4,5-Epoxy-2-pentenal from 1,4-Epidioxy-2-cyclopentene

By *K. H. Schulte-Elte, B. Willhalm*, and *G. Ohloff* [*]

1,4-Epidioxy-2-cyclopentene *(2)* is formed by 1,4-addition of singlet oxygen to cyclopentadiene *(1)* and can be isolated at —100 °C [1]. In an attempt to prepare *(2)* by dye-sensitized photo-oxidation of *(1)* in alcoholic solution and in presence

of polymerization inhibitors at temperatures above 0 °C we obtained, surprisingly, the hitherto unknown compound *cis*-4,5-epoxy-2-pentenal *(3)* in 58% yield [b.p. 35 °C/0.1 torr; $n_D^{20} = 1.4933$; $d_4^{20} = 1.04$; IR: 762, 1635 cm^{-1} (*cis*-CH=CH—); 1675, 2730, 2850 cm^{-1} (—CHO); NMR (CCl_4 + $CDCl_3$/TMS): 9.92 ppm (1H/m, —CHO); 6.1 ppm (2H/m, *cis*-CH=CH—); 4.17 ppm (1H/m, oxiranyl proton); 3.12 and 2.71 ppm (2H/2 × 2d, oxiranyl protons, J = 4.5 and 5.5, and 2.3 and 5.5 Hz resp.)]. *cis*-1,2,3,4-Diepoxycyclopentane *(4)* [2] (7%) and polymeric compounds (30%) were formed at the same time.

1-Hydroxy-2-cyclopenten-4-one *(6)* (b.p. 70 °C/0.1 torr; $n_D^{20} = 1.4882$; $d_4^{20} = 1.02$), which was previously obtained [1] as an isomerization product from *(2)*, was not formed in this reaction. In alkaline alcoholic solution [3], however, it was formed in 20% (maximum) yield. The prerequisites for the preparation of *(6)*, therefore, are that the synthesis is carried out rapidly, at or below room temperature, and at a pH of 8—10.

In the presence of triphenylphosphine, compound *(3)*, which is stable in the pure state, rearranges almost quantitatively at room temperature to the *trans* isomer *(5)* [b.p. 36 °C/0.1 torr; $n_D^{20} = 1.4931$; $d_4^{20} = 1.08$; IR: 923, 972, 1638 cm^{-1}

(*trans*-CH=CH); 1680, 2720, 2810 cm^{-1} (—CHO); NMR (CCl_4 + $CDCl_3$/TMS): 9.46 ppm (1 H/m, —CHO); 6.41 ppm (2 H/m, *trans*-CH=CH—); 3.53 ppm (1 H/m, oxiranyl proton); 3.06 and 2.70 ppm (2 H/2 × 2d, oxiranyl protons, J = 4.5 and 5.5, and 2.3 and 5.5 Hz resp.)].

As dienophiles, compounds *(3)* and *(5)* exhibit about the same reactivity as crotonaldehyde. Thus the adduct from 2,3-dimethylbutadiene can be obtained in 82% yield merely by heating the components in benzene. Heating *(3)* and *(5)* in dilute hydrochloric acid leads to smooth formation of furfuryl alcohol, while their reduction with $NaBH_4$ in ethanol yields a mixture of *trans*-2-pentene-1,4-diol (b.p. 127 °C/ 12 torr; n_D^{20} = 1.4740; d_4^{20} = 1.02) and *trans*-2-pentene-1,5-diol (b.p. 132 °C/12 torr; n_D^{20} = 1.4712; d_4^{20} = 1.038) in a ratio of 3:1.

The purely thermal isomerization of *(2)* to *(3)* represents a new type of rearrangement of peroxides of the 3,6-dihydro-1,2-dioxin[4,5] or 1,2-dioxolane type[6]. This smooth rearrangement, which is not influenced by solvents or radical inhibitors, is presumably an electrocyclic four-center reaction. Alkyl derivatives of 1,4-epidioxy-2-cyclopentene can isomerize in a similar way[7].

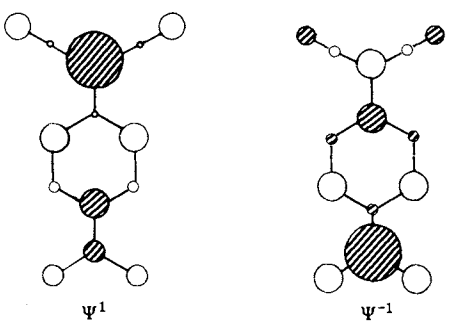
Azaquinodimethanes[1]

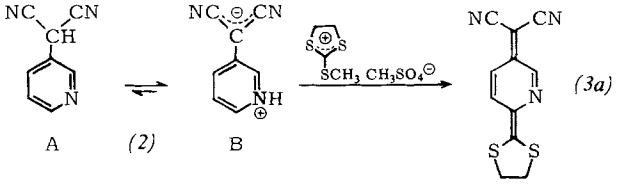
By *H.-U. Wagner* and *R. Gompper*[*]



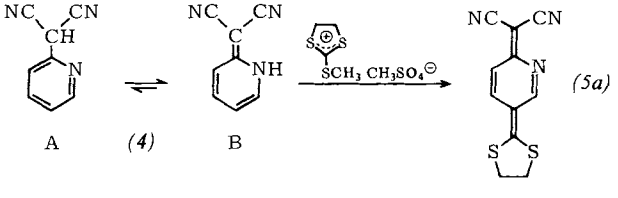
The "push-pull" substituted quinodimethanes of type *(1)* are characterized by intense, longwave absorption bands in the visible region[2]. According to the simple HMO model these bands correspond to an electron transition from the highest occupied molecular orbital, Ψ^1, to the lowest unoccupied orbital, Ψ^{-1}. This transition is polarized in the direction of

A *(1a)* B

the two-fold axis of the molecule and associated with a charge shift from the dicyanomethylene to the dimercaptomethylene[3]. The polarization is also reversed at positions 2 and 3: During the transition from Ψ^1 to Ψ^{-1} the electron density at position 2 increases, whereas at position 3 it decreases (Fig. 1).



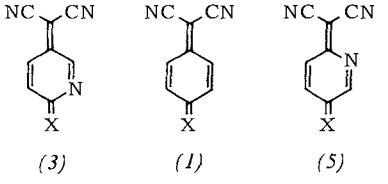
It is to be expected, therefore, that when the carbon is replaced by the more electronegative nitrogen, the Ψ^1 level is lowered much more than the Ψ^{-1} level. The lower energy difference should be characterized by a bathochromic shift of the longwave band. The converse is true for position 3.



Ψ^1 Ψ^{-1}

Fig. 1. Molecular orbital diagrams. The diameters of the circles correspond to the linear combination coefficients. HMO parameters: h_N = 0.8, h_S = 1.0, k_{C-CN} = 0.8, k_{C-S} = 0.7, $k_{C=N}$ = 1.8. The shading denotes negative sign. The ethylene bridge in the dithiolane ring is not considered in the π process.

The desired azaquinodimethanes of types *(3)* and *(5)* can be prepared from the pyridylmalonodinitriles *(2)* and *(4)* respectively and a dithiolanylium salt [cf. the synthesis of *(1a)*[4,5]].



A *(2)* B *(3a)*

A *(4)* B *(5a)*

The pyridylmalonodinitriles *(2)* and *(4)* were synthesized from the corresponding acetonitriles by direct introduction of cyano group using cyanates (cf. the cyanation of malonodinitrile[6]). According to the IR spectra, compounds *(2)* and *(4)* (solid in KBr) are present in the tautomeric forms B. Both compounds exhibit intense NH bands at 3150—3100 cm^{-1} and very strong cyanide bands (*(2)* at 2190 and 2140, *(4)* at 2200 and 2170 cm^{-1}). These doubly split cyanide bands, which are also found in the spectra of *(1a)* and the azaquinodimethanes mentioned in Table 1, are characteristic of strongly conjugated dicyanomethylene groups (cf.[4]). The high melting points [*(2)* at 246—248 °C, *(4)* at 245—250 °C; cf. phenylmalonodinitrile, m.p. 68 °C] are indicative of highly polar compounds.

	640		

[a] Measured in chloroform. The solubility is so low that a determination of the extinction was considered inpracticable. The bands generally show pronounced partial vibration bands. The figures quoted denote the maxima of the individual parts of the bands.
[b] Log ε about 4.7.

The reactions of *(2)* and *(4)* with 2-methylthio-1,3-dithiolanyl methyl sulfate are carried out in boiling pyridine under reflux. The azaquinodimethanes *(3a)* and *(5a)* precipitate from the hot solution as bluish-black, very fine needle-like crystals. The azaquinodimethanes *(3b)*–*(3e)* and *(5b)*–*(5e)* (see Table 1) are prepared in an analogous manner. The structures of the new compounds were determined by elemental analysis, and IR and UV spectroscopy.

As shown in Table 1, aza substitution in position 2 leads to the expected bathochromic shift — in position 3 to a hypsochromic shift. According to the HMO models for quinodimethanes containing a π-cyclic donor X, the shifts in these systems should be slightly greater in magnitude than in *(3a)* and *(5a)*. Since, however, the position of the maxima depends largely on the shape of the bands, and the 0–0 transition cannot be determined unequivocally, these fine differences cannot be interpreted quantitatively. All systems exhibit weakly negative solvatochromism (longwave bands: λ_{CHCl_3}–λ_{CH_3CN} about 10–30 nm). According to *Förster*[7] this points to a diminution of the polarity on electron excitation, *i.e.* the non-polar resonance structure A makes a greater contribution to the excited state than to the ground state. The HMO model also shows that the overall polarity of the molecule is lowered by transition of an electron to the oppositely polarized molecular orbital Ψ^{*-1} [8].

Azaphosphatriptycene[**]

By *D. Hellwinkel* and *W. Schenk*[*]

In an extension of our work on organic derivatives of main-group elements in higher coordination states, which owe their marked stability to the bidentate 2,2′-biphenylylene group[1], we set about preparing compounds of this type containing tridentate ligands. Since 2,2′,2″-triiodotriphenylmethane and 1,1,1-tris(2-iodophenyl)ethane[2] have hitherto proved preparable only in insufficient yields we resorted to tris(*o*-bromophenyl)amine *(1a)* as starting material, this compound being formed in 50–54% yield, m.p. 185.5 to 186 °C, on reaction of bis(*o*-bromophenyl)amine[3] with *o*-dibromobenzene, potassium carbonate, and copper bronze.

(1a), X = Br
(1b), X = Li

(2)

Tris(*o*-lithiophenyl)amine *(1b)*, which is prepared from *(1a)* and *n*-butyllithium and is sparingly soluble in ether, reacts with triphenyl phosphite in ether/THF to give colorless crystals of azaphosphatriptycene *(2)*, m.p. 255–255.5 °C, in 30% yield.

The relatively high proportion of doubly and trebly charged ions is particularly conspicuous in the mass spectrum of *(2)* (Table 1); such ions have also been observed in the mass spectrum of triptycene itself[4].

Table 1. Molecular ions and most important fragment ions of *(2)* (singly, doubly, and trebly charged ions are listed under one another together with their relative intensities).

M	M − H	M − 2H	M − 3H	M − 4H
273	272	271	270	269
(67%)	(100%)	(4%)	(9.3%)	(1.6%)
$136^1/_2$	136	$135^1/_2$	135	$134^1/_2$
(10%)	(10%)	(7.8%)	(10.5%)	(2.1%)
91	$90^2/_3$	$90^1/_3$	—	$89^2/_3$
(0.2%)	(0.1%)	(0.1%)		(0.1%)

The ^{31}P-NMR signal of *(2)* appears at an astonishingly high field strength: $\delta^{31}P$ = +80 ppm ($CHCl_3$); +79 ppm (THF) (85% H_3PO_4 as external standard)[5]. This suggests that the lone pair on phosphorus has a high s character and therefore that the CPC bond angle must be in the region of 90°[6]. Such a value, *i.e.* 93°, is also calculated from the formulas developed by *Parks*[7], which correlate bond angles, chemical shift of the phosphorus, and differences in electronegativity for the participating atoms in tertiary phosphines. The second value of 104.5° obtained on solution of the resulting quadratic equation can be neglected as implausible[2].

Interestingly, the UV spectrum of *(2)* (ethanol): λ_{max} = 216.5 nm (log ε = 4.31); shoulder at 245 nm (log ε = 3.35); ($CHCl_3$): λ_{max} = 247.5 nm (log ε = 3.57), shoulder at 279 nm (log ε = 2.94) shows little resemblance to that of azatriptycene[8].

Reaction of *(2)* with methyl iodide in a bomb tube affords *P*-methylazaphosphoniatriptycene iodide : decomposition point 279–285 °C; τ = 6.68 (CH_3), J_{HCP} = 15.6 Hz; $\delta^{31}P$ = +4.75 ppm (CF_3COOH). In this compound the phosphorus is more strongly shielded than in triphenylmethylphosphonium iodide (τ = 7.19 (CH_3); J_{HCP} = 13.6 Hz; $\delta^{31}P$ = −19.4 ppm), whereas the methyl protons absorb at lower field strength. This is again compatible with the concept that the Pσ orbital bonded to the methyl group possesses relatively high s character which leads to an electron density that is

higher than normal (pure sp^3 valence) on phosphorus and lower on the methyl group.

Reaction of *(2)* with bromine and subsequent hydrolysis gives the *P*-oxide: decomposition point 300—301 °C, ν P=O = 1250 cm^{-1}; λ_{max} = 220.5 nm (log ε = 3.98), shoulder at 238 nm (log ε = 3.67) (ethanol).

Compounds of type *(2)* [9] are of interest with regard to higher valencies of the bridgehead atoms, since it is possible that unusual molecular geometries can be realized with the aid of the rigid nitrilo-2,2′,2″-triphenyl system.

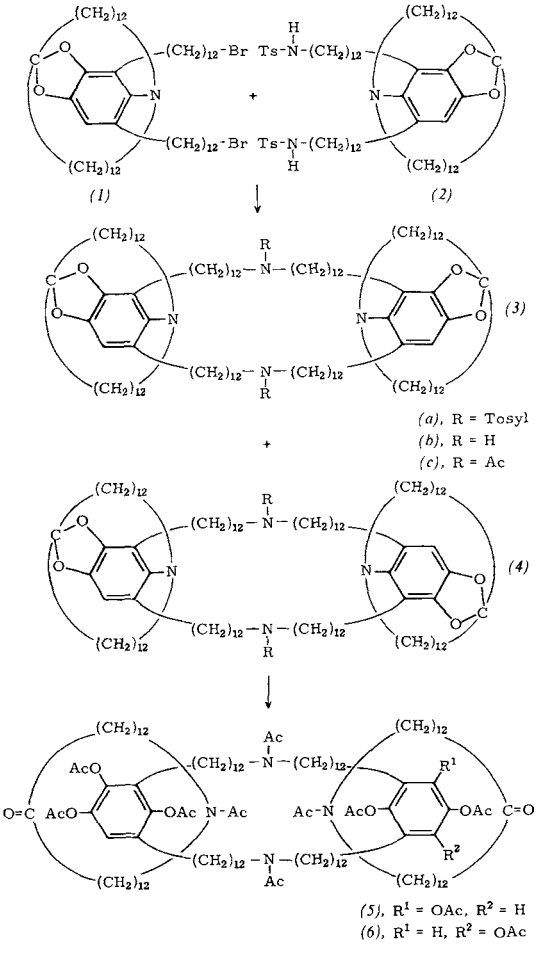
[3]-Catenanes[1] [**]



By *G. Schill* and *C. Zürcher* [*]

We have prepared catenanes from three rings joined after the manner of links in a chain by an extension of the principle of the directed synthesis [2].

Reaction of the diansa-dibromo compound *(1)* [3] with *p*-toluenesulfonamide in the presence of sodium hydride in anhydrous dimethylformamide [4] yields the ditosyl derivative *(2)* in 74% yield. Subsequent cyclization of *(2)* with *(1)* in the molar ratio 1 : 1 in anhydrous dimethylformamide [5] at 100 to 120 °C in highly diluted solution with potassium carbonate [6] affords a 38% yield of a mixture of the *cis-trans* isomeric cyclization products *(3a)* and *(4a)* which cannot be separated by thin-layer chromatography. On removal of the tosyl groups by reaction with sodium in anhydrous butanol [7] to form *(3b)* and *(4b)* and subsequent acetylation with pyridine/acetic anhydride we obtained a mixture of the [3]-pre-catena compounds *(3c)* and *(4c)*.

The mass spectrum [8] of *(3c)* + *(4c)* contains the molecular ion as base peak at *m/e* 1720 and a peak due to the doubly charged molecular ion at *m/e* 860 having an exceptionally high relative intensity of 91%. (The isotopic peaks at *m/e* 1721 and 860.5, whose intensities exceed those of the peaks at 1720 and 860, are neglected.) The spectrum exhibits a remarkably low degree of fragmentation. Although groups of peaks occur at intervals of 14 mass units, as in the spectra of saturated long-chain hydrocarbons, the relative intensity of the highest peak is only 20%. Other di- and tri-ansa compounds have also been observed to behave similarly.

The chemical bonds between the doubly-bridged systems are broken in a manner similar to that used in earlier experiments [2]. We isolated a 32% yield (calculated with respect to *(3c)* and *(4c)*) of a mixture of the two [3]-catena compounds

(5) and *(6)* as a colorless oil that appears homogeneous on thin-layer chromatography.

The results of elemental analysis, the IR spectrum (CO frequencies of the phenolic acetyl groups at 1780 cm^{-1}, of the keto groups at 1720 cm^{-1}, of the *N*-acetyl groups at 1650 cm^{-1}), and the molecular weight as determined by vapor pressure osmometry are in agreement with the structures given for *(5)* and *(6)*.

The NMR spectrum (in $CDCl_3$, TMS as internal standard) shows the following signals: τ = 3.03 (aryl protons); τ = 6.78 ($-CH_2-N-$ protons); τ = 7.68, 7.71, 7.76 (*O*-acetyl protons); shoulder at τ = 7.64 (benzylic and $-CH_2-\overset{\overset{O}{\|}}{C}-$ protons.

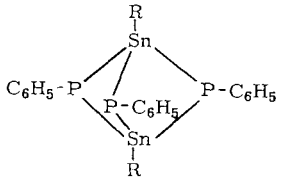
Organometal-Substituted Phosphines having a Cage-Like Structure[**]

By *H. Schumann* and *H. Benda*[*]

Di- and trifunctional organometal halides react with phosphine, alkali-metal phosphides, or alkali-metal organophosphides to give not only polymeric but also oligomeric organometallophosphines having a cage-like structure. Thus we recently reported on the synthesis of *closo*-tetrakis(phenylstannylphosphine)[1].

If a benzene solution of phenyltrichlorosilane or phenyltrichlorogermane and a suspension of dipotassium phenylphosphide in monoglyme/ether are simultaneously added under argon to a 2 : 1 mixture of diethyl ether/monoglyme, a *ca.* 60% yield of colorless *closo*-tetrakis(phenylsilyl)hexakis(phenylphosphine) *(1)* or pale-yellow *closo*-tetrakis(phenylgermyl)hexakis(phenylphosphine) *(2)* is obtained alongside potassium chloride and small amounts of insoluble polymers.



(1), R = C_6H_5, M = Si
(2), R = C_6H_5, M = Ge

The crystals of *(1)* and *(2)* are soluble in benzene, sensitive to oxygen, and decompose, without melting, above 125 °C with blistering; their homogeneity was established by thin-layer chromatography[2]. Complete elemental analyses, the cryoscopically determined molecular weight, and the IR spectra [*(1)*: νSi—P at 406, 348, and 326 cm^{-1}; *(2)*: νGe—P at 390, 334, and 309 cm^{-1}] confirm the adamantane-type structure, which has also been found for the corresponding organosilyl[3], organogermyl[4], and organostannyl[5] sulfides.

By contrast, the reaction of butyl- or phenyl-trichlorostannane with phenylphosphine in the presence of triethylamine affords a *ca.* 25% yield of benzene-soluble *closo*-bis(butylstannyl)tris(phenylphosphine) *(3)* or *closo*-bis(phenylstannyl)tris(phenylphosphine) *(4)*, together with polymeric products.

(3), R = n-C_4H_9
(4), R = C_6H_5

The colorless compounds *(3)* and *(4)* are sensitive to air and melt at 89—91 °C (decomp.) and 133—135 °C, respectively. The trigonal-bipyramidal structure is in accord with the cryoscopically determined molecular weights, the results of elemental analyses, the ^{31}P-NMR spectra[6] [*(3)* shows a singlet at +5.2 ppm], as well as the IR spectra[7] [νSn—P at 375, 328, 305 (*(3)*), and 362, 320, 296 cm^{-1} (*(4)*)].

Procedure:

(1) and *(2)*: Phenyltrichlorosilane (4.2 g, 0.02 mole) or phenyltrichlorogermane (5.1 g, 0.02 mole) is dissolved in benzene; one third of the solution is transferred, together with ether (60 ml) and monoglyme (30 ml), to a three-necked flask that has been flushed out with dry argon. The remaining two thirds of the solution is then added dropwise and simultaneously with a suspension of dipotassium phenylphosphide (0.03 mole) in monoglyme (50 ml), over a period of 4h with stirring. After six hours' stirring, half of the solvent is removed under reduced pressure, the solution is filtered, and the filtrate is concentrated until it becomes oily. Repeated extraction with petroleum ether and methylcyclohexane, dissolution in benzene, and fractional precipitation with pentane/methylcyclohexane affords almost pure crystals, which can be recrystallized from toluene/methylcyclohexane.

(3) and *(4)*: Solutions of butyltrichlorostannane (5.7 g, 0.02 mole) or phenyltrichlorostannane (6.0 g, 0.02 mole), phenylphosphine (3.3 g, 0.03 mole), and triethylamine (6.1 g, 0.06 mole) in benzene are simultaneously added dropwise at the same rate to benzene (150 ml) under dry argon. The resulting precipitate is removed after six hours' stirring. On fractional precipitation with pentane/methylcyclohexane, the clear concentrated benzene solution yields a product that proves pure on thin-layer chromatography.

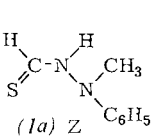
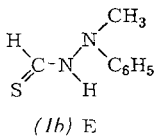
Rotational Isomerism of N^2-Methyl-N^2-phenylthioformohydrazide[1]



By *W. Walter* and *H. Weiss*[*]

A number of N^2,N^2-dialkylthioformohydrazides exhibit betaine-thioacyl tautomerism[2,3]. In the case of N^2,N^2-diethylthioformohydrazide it was assumed[3] that an additional rotational isomerism (E—Z isomerism) occurs in solutions of thioacyl tautomers, as is generally observed in thioamides[1]. We report here on N^2-methyl-N^2-phenylthioformohydrazide *(1)*, which does not form a betaine and permits direct observation of the rotational isomerism. The compound crystallizes in two forms having different melting points and exhibiting different IR- and UV spectra.



In carbon tetrachloride an equilibrium is rapidly set up between *(1a)* and *(1b)* [about 10% *(1a)*: 90% *(1b)*]. Nevertheless, the bands could be assigned to the two isomers by comparison with those of the rotational isomers of thioamides[4].

Since rapid isomerization occurs in solution the signals of both forms, *i.e.* of *(1a)* and *(1b)*, appears in the ^{1}H-NMR spectrum. In $CDCl_3$ the formyl proton of the E form *(1b)* couples with the N—H proton to give an AB system. The coupling constant is of the same order of magnitude as in N^2,N^2-diethylthioformohydrazide[3] and in thioamides[5],

and thus confirms the assignment given. A coupling with the formyl proton of *(1a)* was not observed. Deuteration eliminated the coupling in *(1b)*. The ratio of isomers is also about 9 : 1 under NMR conditions. The lower value of the NH stretching vibration of *(1b)* in KBr indicates the presence of a cyclic dimer, which can be formed from *(1b)* but not from *(1a)* [5].

(1a) Z

(1b) E

	(1a) Z	*(1b)* E
M.p.	114—115 °C	86—87 °C
IR (KBr) (ν-NH)	3270 cm^{-1}	3120 cm^{-1}
in CCl_4 $<10^{-3}$ M (ν-NH)	3322 cm^{-1}	3300 cm^{-1}
UV ($CHCl_3$) λ_{max}	252 nm	275 nm
ε_{max}	8.2×10^3	3.6×10^3
^{1}H-NMR —NH	τ = 1.09	AB J_{AB} = 12 Hz, τ_A = 1.10
—CH (in $CDCl_3$)	τ = 0.62	AB J_{AB} = 12 Hz, τ_B = 0.57
D—N—CH	τ = 0.65	τ = 0.60

The isomerization can be followed by IR spectroscopy. The rate constants for equilibrium and the free activation enthalpies of *(1b)* for equilibrium starting from *(1b)* of 4.9×10^{-3} s^{-1} ($\Delta G^{\neq}$ = 21.0 ± 0.2 kcal/mole) and from *(1a)* of 4.9×10^{-4} s^{-1} ($\Delta G^{\neq}$ = 22.4 ± 0.2 kcal/mole) were determined on the basis of a first order reaction. The values for secondary thioformamides [5] are of the same oder of magnitude, but somewhat higher.

N^2-Methyl-N^2-phenylthioformohydrazide (1)

A solution of *N*-methyl-*N*-phenylhydrazine (0.05 mole) in triethylamine (30 ml) is added dropwise and slowly with vigorous stirring to a solution of *O*-ethyl thioformate (0.5 mole) in triethylamine (15 ml); the reactants are kept ice cold during the addition and the reaction mixture is stirred for a further hour. The solvent is then removed by means of a rotatory evaporator and the residual oil is treated with petroleum ether. A crude crystalline product precipitates (yield 91%). Recrystallization from nitromethane yields *(1a)* as broad yellow crystals (m.p. 114—115 °C). *(1a)* is dissolved in an excess of chloroform and allowed to stand at room temperature for five hours. After removal of solvent in a rotatory evaporator, the crude product is recrystallized from nitromethane. Compound *(1b)* is obtained as colorless needles, m.p. 86—87 °C. The melt crystallizes at 90—95 °C and melts once again at 113—114 °C, *i.e.* when *(1b)* has once again rearranged to *(1a)*.

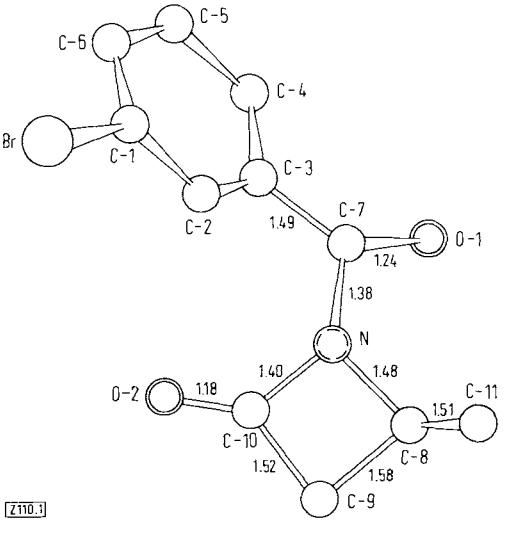
X-Ray Structure Analysis and Absolute Configuration of (+)-1-*m*-Bromobenzoyl-4-methylazetidin-2-one

By *E. F. Paulus, D. Kobelt*, and *H. Jensen* [*]

The enantiomers of optically active β-lactams can be obtained by separation from their racemic mixtures [1]. Thus, *rac*-4-methylazetidin-2-one, m.p. –12.4 °C, yields enantiomers having m.p. +26.7 °C and $[\alpha]_D^{21}$ = + or –8.22° (melt). On hydrolysis the levorotatory form is converted into (*S*)-(+)-β-aminobutyric acid [2]; the (*S*)-configuration can therefore be ascribed to the (–)-4-methylazetidinone [3]. While carrying out an X-ray determination of the steric features of the β-lactam ring we attempted a confirmation of the absolute configuration at the same time.



In order to do this it was necessary to introduce an anomalously scattering atom (for $Mo_{K\alpha}$ rays) into the molecule. This was achieved by acylation of (–)-4-methylazetidinone with *m*-bromobenzoyl chloride in ethyldiisopropylamine. (+)-1-*m*-Bromobenzoyl-4-methylazetidin-2-one, m.p. 88 °C, $[\alpha]_D^{22}$ = +255.0° (*c* = 3 g/100 ml; methanol), crystallizes in the space group $P2_12_12_1$ with *a* = 11.86 ± 0.01, *b* = 9.41 ± 0.01, *c* = 9.80 ± 0.01 Å; *Z* = 4; $d_{x\text{-ray}}$ = 1.63, d_{exp} = 1.61 g/cm³ (suspension method).

The intensities of the X-ray reflections were measured with a single-crystal diffractometer [7]. Of the 1834 reflections recorded, 643 had a statistical error of measurement of <10%, 505 an error of between 10 and 50%; these 1148 reflections were used in the structural analysis.

The heavy atom method was used for the determination of the phases for a Fourier synthesis of the electron density. A complication encountered was that the *x*-coordinate of the bromine atom was about 0.5. In the first Fourier synthesis, therefore, both molecular configurations appeared at the same time.

The atomic parameters of both configurations were refined by the method of least squares (full matrix). The *R*-factor ($R = [(\Sigma w(|F_o| - |F_c|)^2) / (\Sigma w |F_o|^2)]^{1/2}$ for the (*S*)-configuration is 6.05% and for the (*R*)-configuration 7.49%. According to *Hamilton* [4], the probability for the (*S*)-configuration is greater than 99.9%. The difference between the *R*-factors of both configurations is therefore unusually great [4,5]. Thus the (*S*)-configuration is proved by X-ray analysis.

The figure shows a projection of the molecule on the "best" plane of the β-lactam ring. The nitrogen of the four-membered ring is only 0.08 Å above the C(7)—C(8)—C(10) plane, thus indicating that the N—C(7) bond is turned about 7.7° out of the N—C(8)—C(10) plane. The planes N—C(9)—C(10) and N—C(8)—C(9) are at an angle of 2.1°. This slight deviation of the four-membered ring from planarity is near the limit of significance (average standard deviation of bond angles: 0.8°).

Z110.1

The "best" plane through C(3)—C(7)—O(1)—N is at an angle of 18° to the β-lactam ring, and at an angle of 41° to the benzene ring. The lactam ring and benzene ring are inclined at an angle of 56° to each other.

The deviation of the molecule from the favorable planar resonance form appears to be due to steric factors. The hydrogen atom on C(2) approaches to within 2.75 Å of O(2), that on C(4) to within 2.71 Å of O(1); on the other hand the sum of the van der Waals radii in both cases is 2.7 Å.

A few characteristic bond lengths (in Å) are given in the Figure (average standard deviation: 0.015 Å). Particularly striking is the large distance between C(8) and C(9), which has also been observed in another β-lactam[6]. The C(10)—O(2) distance is unusually small for a carbon-oxygen double bond; this is also apparent from the carbonyl stretching vibration at 5.62 μm.

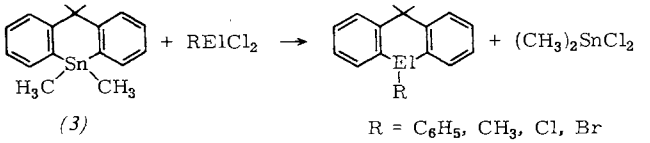
9-Arsaanthracene[**]



By *P. Jutzi* and *K. Deuchert*[*]

Compounds con taining an arsenic-carbon (p—p)π bond ought not to be particularly stable because of unfavorable orbital overlapping; hence, the recent synthesis of arsamethinecyanines[1] serves as the only unequivocal evidence for the existence of this type of bonding, even though (As_{4p}—C_{2p})π bonds had already been formulated in the 1920's[2,3]. 9-Arsaanthracene *(1)* ought to be formed by intramolecular loss of HCl from 9-chloro-9,10-dihydro-9-arsaanthracene *(2)*.

(2) *(1)*

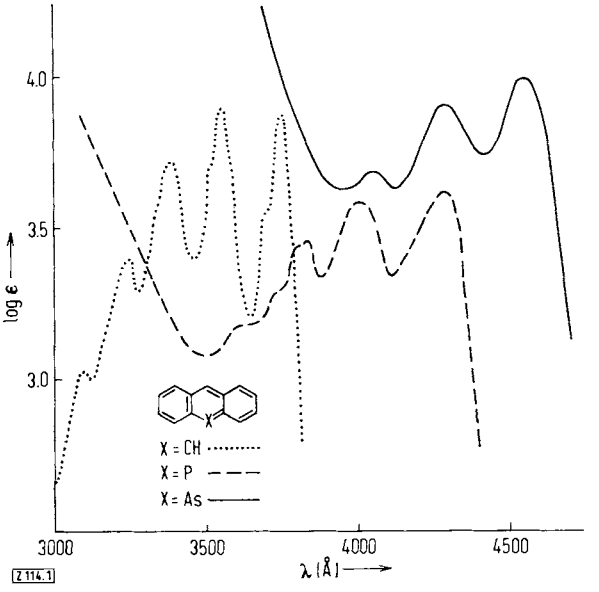
Derivatives of dihydroanthracene having elements of the fifth main group as substituents in position 9 can generally be prepared by reaction of 9,9-dimethyl-9,10-dihydro-9-stannanthracene[4] *(3)* with element halides[5].

(3)

R = C_6H_5, CH_3, Cl, Br
El = P, As, Sb

Compound *(2)* can be prepared in this way in yields of up to 75%; a stoichiometric mixture of *(3)* and $AsCl_3$ is heated with stirring for 3 hours at 120 °C, $(CH_3)_2SnCl_2$ is sublimed off under vacuum (oil pump), and *(2)* is recovered and purified by distillation (m.p. 96 °C, b.p. 140 °C/0.03 torr).

Attempts were made to eliminate HCl from *(2)* by reaction with *tert*-butyllithium, triethylamine, and 1,5-diazabicyclo-[5.4.0]undec-5-ene[6] *(4)* in cyclohexane, benzene, and tetrahydrofuran; the characteristic electron excitation spectrum of each of the deep-yellow colored solutions was taken as a measure of the presence of *(1)*. According to our observations the most favorable conditions for reaction of *(2)* with *(4)* are achieved in THF saturated with argon. A solution of *(4)* (0.82 g) in THF (10 ml) is added dropwise and slowly to an ice-cold solution of *(2)* (1.49 g) in THF (90 ml); the reaction mixture immediately becomes cloudy and turns yellow in color. Reaction is complete within one hour. The precipitate (1.5 g), which contains the hydrochloride of *(4)* and polymers, is removed by filtration. The filtrate exhibits the spectrum shown in the diagram.



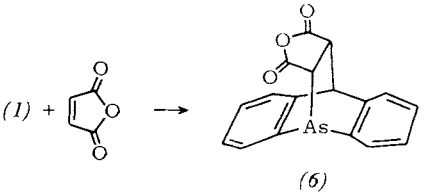


Fig. 1. UV spectra of anthracene (in cyclohexane), 9-phosphaanthracene *(5)* (in toluene), and 9-arsaanthracene *(1)* (in THF)[**]. The heights of the curves for *(5)* and *(1)* are in arbitrary units.

Comparison of the UV spectra of 9-phosphaanthracene[7] *(5)* and *(1)* reveals an almost superimposable structure of the absorption bands, the surprisingly large bathochromic shift in the spectrum of *(1)* (longwave absorption at λ = 454 nm) is possibly due to the low electronegativity of the heteroatom (χ_P = 2.5; χ_{As} = 2.1[8]). Furthermore, the relative intensities and spacing of the absorption maxima in the spectra of *(1)* and *(5)* are very similar to the ^1L_a band of anthracene.

We have not, as yet, been able to isolate compound *(1)*, which, like its phosphorous analog *(5)*[7], also proves to be unstable; polymerization occurs, with foaming, on removal of the solvents. The stability in solution is strongly solvent dependent (THF > benzene > cyclohexane). Decomposition takes place in the presence of oxygen or HCl. The yellow solution immediately decolorizes on addition of maleic anhydride, the Diels Alder adduct *(6)*, m.p. 248 °C, being formed in 70% yield. The structure of *(6)* follows from ebullioscopic determination of molecular weight, IR and ^{1}H-NMR spectroscopy, and elemental analysis.

(6)

The elimination of the HCl from *(2)* can be verified under mass spectrometric conditions: The stable ion $(1)^+$ (m/e = 240, I = 80%; corresponding metastable ion at m/e = 210) is formed in a one-step fragmentation from the molecular ion (m/e = 276, I = 20%). The occurrence of the doubly positively charged 9-arsaanthracene ion ($m/2e$ = 120) is characteristic of aromatic compounds.

Dibenz[*b,e*]arsenine (9-Arsaanthracene)[**]

By *H. Vermeer* and *F. Bickelhaupt*[*]

Tricyclic aromatic compounds containing arsenic as heteroatom have already been the subject of many reports[1,2]. However, the suggested structures of these molecules have remained somewhat doubtful, firstly because of inadequate structural proof and secondly because of their unusual properties compared with those of their phosphorous analogs[3]. We have, therefore, tried to prepare dibenz[*b,e*]arsenine (9-arsaanthracene) *(1)* as an authentic member of this type of compound by elimination of HCl from 5-chloro-5,10-dihydrodibenz[*b,e*]arsenine (9-chloro-9,10-dihydro-9-arsaanthracene) *(2)*[4,5]. The UV system of *(2)* does not contain an absorption maximum between 290 and 700 nm so that the arsonium chloride structure discussed by *Gump* and *Stoltzenberg*[4] can be ruled out.

(1)

In the mass spectrum[6] of *(2)* there are signals due to the ions $(2)^+$ (m/e = 278, 1.9%; m/e = 276, 5.6%), $(1)^+$ (m/e = 240, 92.9%), fluorene$^+$ (m/e = 166, 100%), fluorenyl$^+$ (m/e = 165, 92.9%), and $(1)^{2+}$ ($m/2e$ = 120, 15.7%). The transitions $(2)^+ \rightarrow (1)^+$ (*Jennings'* method[7]) and $(1)^+ \rightarrow$fluorenyl$^+$ (metastable ion at m/e = 113.5, calc. 113.54) take place in one step. In contrast to the analogous ion of dibenzo[*b,e*]phosphorin [$(3)^+$][3], the aromatic ion $(1)^+$ does not give the strongest peak.

Solutions of *(2)* (*ca.* 100 mg) in toluene, ether, or dimethylformamide (*ca.* 10 ml) immediately turn yellow on addition of a suitable base (triethylamine or 1,5-diazabicyclo[5.4.0]-undec-5-ene (DBU); 5—15% excess) and (except in dimethylformamide) a precipitate is formed (consisting mainly of the hydrochloride of the base; yield 85—95%).

The formation of *(1)* was deduced from the characteristic UV spectrum[**], which corresponded to the spectra of anthracene and *(3)*; as expected the long-wavelength maximum of *(1)* is shifted bathochromically with respect to that of *(3)*.

Not surprisingly, *(1)* is less stable than *(3)*; the UV absorption of the dissolved compound disappeared during the isolation, *e.g.* on evaporating the solution at room temperature. The yield is highest (*ca.* 8%[8]) in the system dimethylformamide/DBU but the stability is the lowest (decrease in extinction at 451 nm to about 30% in 20 min). This instability of *(1)* increases the doubt surrounding the validity of the structure suggested for the arsenic compounds mentioned above.

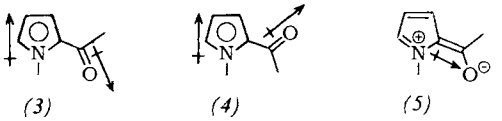
Conformational Studies in Pyrrole Chemistry

By *R. A. Jones* [*]

Extensive participation of the zwitterionic limiting forms *(1a)* and *(2a)* in the structure of 2-formylpyrrole hinders rotation about the C—C bond between the formyl group and the pyrrole ring, so that two conformers can exist.



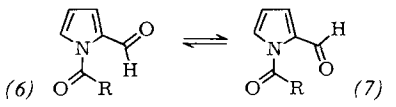
(1a) *(1b)*

(2a) *(2b)*

A study [1] of the dipole moment of 2-formylpyrrole [*(1)* or *(2)*, R = H] showed that the conformer *(1)* is the more stable. Further indications were obtained from IR [2] and NMR studies [3]. The NMR spectra show that the formyl-proton couples with the proton on C-5 [4]. Application of the zigzag rule [5,6] indicates the predominance of structure *(1)*. Coupling with the proton on C-4 was not observed.

Spectroscopic comparison of the 1-alkyl-2-formylpyrroles [7] [*(1)* or *(2)*, R = CH_3, C_2H_5, iso-C_3H_7, *tert*-C_4H_9] shows that the predominating conformation remains unchanged through the series in spite of the increasing size of the alkyl group. The IR and UV spectra can be interpreted only if the carbonyl group is twisted slightly out of the plane of the pyrrole ring. The effect of this twist on the coupling constants between the formyl-proton and the proton on C-5 is not known [6], but a diminution of this constant is to be expected. Since there is no coupling between the formyl-proton and the proton on C-4 it must be concluded that 1-butyl-2-formylpyrrole also exists in form *(1)*.

These results can be explained by dipole-dipole interaction [*(3)* and *(4)*]. This would lead to the energy content of system *(3)* being less than that of system *(4)*. Studies of the dipole



(3) *(4)* *(5)*

moment show that the "resonance moment" *(5)* is also important, but exact values are not available [8].

The formyl group of 1-formylpyrrole can rotate freely at 40 °C [9].

Spectroscopic examination of 1-ethoxycarbonyl-2-formylpyrrole and 1-acetyl-2-formylpyrrole shows that an equilibrium exists between *(6)* and *(7)*, the conformers *(6)* predominating to the extent of 70%, and assumption of dipole-dipole interaction is in agreement with these results.

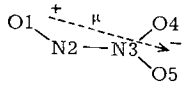
SELECTED ABSTRACTS

The preparation of transition metal complexes by simultaneous condensation of vaporized atoms of the elements Cr, Fe, Co, and Ni with an excess of ligand has been achieved in good yields in gram quantities by *P. L. Timms*. Thus Cr, Fe, Co, and Ni react with PF_3 to give $Cr(PF_3)_6$, $Fe(PF_3)_5$, along with $(PF_3)_3Fe(PF_2)_2Fe(PF_3)_3$, $Co_2(PF_3)_8$, and $Ni(PF_3)_4$. Co-condensation of Cr and benzene gives a 60% yield of dibenzenechromium, that of Fe and Ni with cyclopentadiene gives ferrocene and π-cyclopentadienyl-π-cyclopentenylnickel. Fe and benzene yield a highly reactive product which explodes at temperatures above −50 °C and which affords cyclohexane in the presence of H_2, and ferrocene in the presence of cyclopentadiene. / Chem. Commun. *1969*, 1033 / —HB. [Rd 103 IE]

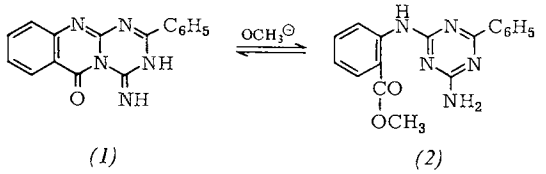


The fluorescence and phosphorescence of biacetyl in the gas phase at low pressures has been studied by *C. S. Parmenter* and *H. M. Poland* with a view to gaining information about the kinetics of the singlet-triplet transition. The quantum yields of both kinds of emission were independent of pressure between 0.1 and 40 torr on excitation with light of the wavelength 4358 Å; it therefore follows that, under these conditions, collisions play no part in the transition to the triplet system. The phosphorescence quantum yield decreased below 0.1 torr; it was shown that this is extensively or exclusively due to radiationless deactivation of triplet molecules by collision with the walls. Those excited singlet molecules that are not deactivated by fluorescence all undergo transition to the triplet state, the rate constant amounting to 10^{-8} s^{-1}; direct radiationless deactivation of the excited singlet to the ground state can be neglected. / J. chem. Physics *51*, 1551 (1969) / —Hz. [Rd 105 IE]

The ESR spectrum of the acetonyl radical $CH_3-CO-\dot{C}H_2$ has been investigated by *G. Golde, K. Möbius*, and *W. Kaminski*. The radical was generated by photolysis of an aqueous solution of acetone to which H_2O_2 had been added. The temperature dependence of the ESR spectrum shows that the rotation of the $\dot{C}H_2$ group about the C—C bond is hindered: analysis of the spectrum at various temperatures afforded the

Arrhenius parameters $E_a = 9.4 \pm 0.5$ kcal/mole and $\log k = 12.9 \pm 0.3$ for this rotational movement. This result can be interpreted in terms of a certain degree of delocalization of the spin density of the radical electron over the rest of the molecule. / Z. Naturforsch. *24a*, 1214 (1969) / —Hz.

[Rd 106 IE]

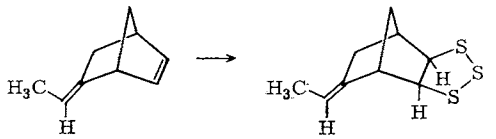


The molecular geometry of dinitrogen trioxide has been determined by *A. H. Brittain, A. P. Cox*, and *R. L. Kuczkowski* from the microwave spectrum. The main difficulty encountered in the measurements was that N_2O_3 is 99.5% dissociated to NO and NO_2 at the pressures (10^{-2} to 10^{-1} torr) used in microwave spectroscopy, even at temperatures as low as —78 °C. The spectra of N_2O_3 containing certain percentages of ^{15}N and ^{18}O yield the following data: N2—N3 = 1.864 Å; N2—O1 = 1.142 Å; N3—O4 = 1.202 Å; N3—O5 = 1.217 Å; O1—N2—N3 = 105.1 °; O4—N3—N2 = 112.7 °;

O5—N3—N2 = 117.5 °. The molecule is planar; the frequency of the twisting vibration about N2—N3 is 124 ± 25 cm^{-1}. The dipole moment amounts to 2.12 D and acts in a direction at 9.1 ° to N2—N3; the negative end of the dipole lies at the nitro group. / Trans. Faraday Soc. *65*, 1963 (1969) / —Hz.

[Rd 109 IE]

The triazino[2,1-*b*]quinazoline system has been synthesized for the first time by *J. T. Shaw* and *J. Ballentine*. The acid-catalyzed cyclization of K dicyanobenzamidine with methyl anthranilate (refluxed in anhydrous methanol in the presence of pyridine and benzenesulfonic acid) yields compound *(1)*, a derivative of the new ring system, m.p. 342—343 °C (DMF).



(1) *(2)*

Compound *(1)* is cleaved by $NaOCH_3$ to the ester *(2)*, which regenerates *(1)* when heated to a temperature in excess of its melting point. Several tautomers of *(1)* are possible. The NH and the phenyl group could be exchanged. / Chem. Commun. *1969*, 1040 / —Ma.

[Rd 111 IE]

A selective, stereospecific insertion of sulfur into olefins such as norbornene has been described by *T. C. Shields* and *A. N. Kurtz*. If sulfur is activated by NH_3 or aniline in the presence of an amide such as DMF as promotor and subsequently heated to 110 °C with norbornene, 5-ethylidenenorbornene

(1) *(2)*

(1), or similar compounds, *exo*-3,4,5-trithiatricyclo[5.2.1.$0^{2,6}$]-decane or the 8-ethylidene derivative *(2)* is obtained in 86 or 71% yield. Up to 99% DMSO or an excess of amide can serve as solvent. The addition occurs exclusively at the double bond of the ring. / J. Amer. chem. Soc. *91*, 5415 (1969) / —Ma.

[Rd 112 IE]

New luminescence experiments on azulene are the subject of a report by *P. M. Rentzepis*. Azulene and its derivatives occupy a special place among all organic compounds owing to the fact that under normal conditions they only fluoresce from the second excited singlet state. Excitation with extremely short laser pulses (several 10^{-12} s) has now revealed emission from the first excited singlet state S_1 (maximum at about 750 nm) and the lowest triplet state T_1 (maximum at about 1100 nm). The fluorescence from S_1 has a decay time less than 10^{-10} s and a quantum yield of about 10^{-7}. Phosphorescence from T_1 could only be observed at 77 °K with a decay time of 10^{-6} s. / Chem. Physics Letters *3*, 717 (1969) / —Hz.

[Rd 117 IE]

BOOK REVIEWS

Die Nomenklatur in der organischen Chemie (The Nomenclature of Organic Chemistry). By *W. Holland*. Verlag Harri Deutsch — Zurich-Frankfurt/M. 1969. 1st Edit., 190 pp., stitched, DM 34.80.

As stated in the introductory remarks, the author set himself the task, not merely of giving the nomenclature rules current today, but also of describing the older usages. The book does indeed contain numerous references to previous proposals for, and usages in, nomenclature, so that the original literature can still be understood by the reader. However, as a guide and help in the formation of names for organic compounds — and that is what it should be — the book cannot be unreservedly recommended because of the various contradictions it contains. For instance, on p. 46 methoxycarbonyl is correctly recommended in place of the older designation carbomethoxy, yet on p. 36 only carbobenzoxy (with the abbreviation Cbo) is given for the amino acid protecting group and not benzyloxycarbonyl (with the abbreviation Z). In the explanation of the ring fusion principle on pages 87—88 the instruction is recorded whereby the parent compound shall chosen to be as large as possible and the anneland as small as possible, but a contradiction to this is met on page 89 where in the explanation of numbering round the outer ring the example naphth[2.1-*a*]anthracene should correctly be named benzo[*b*]chrysene [RRI 6379]. And the list of such contradictions could be considerably extended. Also it is not evident why in the tables aromatic compounds are drawn sometimes with and sometimes without double bonds.

Ilse Spaeth [NB 837 IE]

Kunststoff-Handbuch, Band IV: Polyolefine (Plastics Handbook, Vol. 4: Polyolefins). Edited by *R. Vieweg, A. Schley*, and *A. Schwarz*. Carl Hanser Verlag, München 1969. 1st Edit., xxi + 976 pp., 795 illustrations, 106 tables, linen DM 270.—; on subscr. to the complete work (12 vol.) DM 216.—.

The rate of production of polyolefins has grown faster than that of any other thermoplastic, so that appearance of the present volume[1] should receive a warm general welcome,

[1] Cf. Angew. Chem. *81*, 542 (1969); Angew. Chem. internat. Edit. *8*, 468 (1969).

especially as the expanding area of application of polyolefins is in particular need of a review volume such as this.

The book is divided into the main sections Preparation, Properties, Fabrication, and Application of Polyolefins. It treats mainly the polymers of ethylene, propene, and isobutene; diolefins and mixed polymers of ethylene and propene, and of ethylene and vinyl acetate, leading to elastomers, are mentioned only marginally, and these should perhaps be treated in greater detail in the next edition because their importance is increasing.

The Ziegler low-pressure polymerization process, polymers obtained by that process, and modified polyolefins have ample space devoted to them, but the low-pressure polymerization process developed by Phillips Petroleum, and the high-pressure polymerization of ethylene by which most polyethylene is produced, are perhaps treated too briefly. The preparation of olefins themselves will not necessarily be looked for in a plastics Handbook.

The polymerization of ethylene and propene by means of Ziegler catalysts is presented in great detail, yet intelligibly and clearly, and this permits rapid and successful orientation even though there is unfortunately no reference later than 1960. The part dealing with the properties of polyethylene contains a wealth of material on the structure, on the thermal, mechanical, and electrical properties, and on the behavior towards chemical reagents. Detailed tables make it easier to find individual facts. The chapter on fabrication is very successful, presenting in full all the important methods of working polyolefins, such as extrusion, injection molding, calendering, powder sintering, and flame spraying, as well as procedures for dealing with semimanufactured material, each supported by good illustrations.

The largest part of the book is rightly devoted to application of polyolefins. This very properly recognizes the changes introduced by polyolefins in the most varied fields, *e. g.* packaging, building, agriculture, craft and vehicle construction, plant construction, and the household.

High praise should be awarded to the editors for their having engaged first-class experts for the individual sections; these authors have provided the reader with an excellent presentation in word and picture. In an area in a state of such dynamic development it is tolerable that there are small gaps here and there; for instance, it would have been good to be told something about methylpentene polymers (TPX) and about production of foams from polyolefins. The book contains a large number of references and good tables and indexes, and it can be warmly recommended to all who are interested in polyolefins, both for their study and for rapid information.

O. Horn [NB 839 IE]

Index Pharmacorum. Synonyma, Struktur und Wirkung der organisch-chemischen Arzneistoffe (Synonyms, Structure, and Action of Organic Drugs). By *H. Ippen.* Published on behalf of the Deutsche Forschungsgemeinschaft. Georg Thieme Verlag, Stuttgart, 1968. xxviii + 693 pp., bound, DM 130.—.

A problem familiar to all whose work concerns drugs is the fact that identical medications are often on sale in different countries with different trademarks, and the same substance may even be available under several protected trade names in one country, with the result that the unequivocal identification of a medication is extremely difficult. Added to this is the difficulty that by using trade names in scientific publications, one runs the risk of conflict with commercial interests. The chemical nomenclature for drugs, on the other hand, is often too clumsy and not readily understood by the non-chemist. Non-protected free names have therefore been introduced. Thus, in the USA there arose the "Generic Names", in England the "Approved Names", in Scandinavia the "Nordiske Farmakope-Naevn", in France the "Dénominations Communes", to which were added, after 1950, the "International Non-Proprietary Names" of the World Health Organization. None of these drug nomenclature systems, however, is anywhere near complete and their use in scientific publications is haphazard. The identification of a drug from its name consequently requires many aids, which are not available everywhere, and is often very time-consuming.

On behalf of the Deutsche Forschungsgemeinschaft, therefore, *H. Ippen* undertook to collect, in dictionary form, all defined organic substances that are, or have been, used as curative agents or as aids in the treatment, diagnosis, or investigation of illness. The following information is given for each one:

1. The non-protected name(s), with special indication of the names recommended or suggested by the World Health Organization.

2. The chemical designation of the compound according to the Beilstein and the "Chemical Abstracts" systems;

3. Officinal names insofar as they form part of the "Pharmakopoea Internationalis", the "Deutsche Arzneibuch", the "British Pharmacopoeia", or the "Pharmacopeia of the United States";

4. Trade names with the name of the firm holding the trademark;

5. Action and indications (only for some of the substances and only in keyword form);

6. The structural and molecular formulas.

The drugs are arranged either according to the organ system chiefly affected or according to indications. The arrangement within these groups has been determined mainly by chemical considerations. In addition to this very clear division of the book, two indexes (indications and substance groups, as well as a comprehensive 100 page index of synonyms) make the use of the work easier.

One can scarcely imagine the pains the author must have taken in compiling this dictionary, not only in bringing the wealth of information together, but also in checking its reliability. Whoever uses this book however, — the pharmacist, the pharmaceutical chemist, the pharmacologist, or the doctor — will thank the author for his trouble, for here is an aid as useful as it is long overdue. Not only will it be welcomed by information scientists, but its usefulness will also be put to the proof daily by practising doctors and dispensing pharmacists.

H. Grünewald [NB 842 IE]

Comprehensive Biochemistry. Edited by *M. Florkin* and *E. H. Stotz.* Vol. 23: Cytochemistry. Elsevier Publishing Company, Amsterdam-New York-London 1968. 1st Edit., xii + 167 pp., 32 illustr., 21 tables, bound Dfl. 35.—.

A cell surrounded by a membrane is composed of a nucleolus and cytoplasm in which can be detected cell compartments also separated by membranes of various types. This general type of structure is found in different but exact forms in microorganisms, plants, and animals. The physiological cell functions and the molecular processes characteristic of physicochemical regulation and biological control of the individual organelles are bound to complex highly organized structures; in this book they are collected in a section "Chemical Biology" that applies to all the molecular units and functions treated in the earlier sections.

Once more, competent authors have combined a review of the literature with their own observations and present a very valuable and useful reference work for the various features of structure and function of the cell. Each section deals with isolation, morphology, chemical composition, biochemical function, and enzymology, individual sections referring to the cell nucleus (*G. Siebert*), the nucleolus (*H. Busch*), lysosomes (*A. L. Tappel*), animal (*R. Coleman* and *J. B. Finean*) and bacterial cell membranes (*M. R. Salton*). Chapters are 30—40 pages in length and contain the literature up to the middle of 1966; in some cases appendices are provided covering further results up to the date of closure of the vol-

ume, showing the rapid development in this area of physiological biochemistry — there are as many references from the last year as from all previous years. The material is provided not only in the text but also impressively by good electron-optical illustrations and intelligible tables. The problems of the structure of membranes and the possibility of artefact formation are reported critically; current views on the homogeneity of membranes and on passive and active transport mechanisms are discussed with clarity. Thus this volume of "Comprehensive Biochemistry"[1] is an essential and welcome review of the biological-chemical requirements of dynamic biochemistry and is an important member within the general plan of this excellent series.

L. Jaenicke [NB 829 IE]

Quantitative Problems in the Biochemical Sciences. By *R. Montgomery* and *C. A. Swanson*. W. H. Freeman and Co., San Francisco-London 1969. 1st Edit., xiii + 308 pp., 51 illustr., 33 tables, bound 24 s.

Biochemistry ceased long ago to be a descriptive and qualitative science which the exact-thinking chemist regarded sceptically. On the contrary, it now makes full demands on the application of physicochemical procedures and ideas and is beyond doubt the most exact branch of biology. Moreover, the student who turns to biochemistry cannot learn too soon that the living organism does not play fast and loose with entropy; and he must not shy away from equipping himself with the necessary mathematical ability if he is to obtain more than a smell of physical chemistry; he needs to be in a position to formulate his observations mathematically, to discuss his experimental results in physical terms, and to evaluate meaningful reaction parameters; in short, to apply and make full use of the *modus operandi* of fundamental physical chemistry.

Unfortunately there are not nearly enough physical chemists with sufficient biological knowledge — and still fewer who will take the trouble — to provide courses or books that enable the student to train himself in the necessary experimental and mental work. The book under review here attempts to fill that gap. The approach used is didactically sound and full allowance is made for any missing elementary knowledge; so it begins with exercises in calculating exponentials and logarithms, discussing curves and equations, and dimensional analysis. There follow stoichiometric calculations, problems in the physics of solutions, chemical equilibria, hydrogen ion concentration and buffers, redox potentials, chemical energetics and kinetics, bringing in the most fundamental parts of enzyme kinetics (the Michaelis-Menten equation is discussed in different connections in three places, but without cross-references). The concluding chapters are more analytical and procedural: spectrophotometry and radiochemistry.

Each chapter begins with a short introduction that suffices to explain the methods of calculation involved; but a textbook of physical chemistry is needed for a deeper understanding of the problems set. Some examples are first worked out in full, then new problems are set whose solutions are given in an Appendix, and finally problems from experimental biochemistry are put up for discussion, with literature references but without a solution's being provided; answering these last problems without recourse to the cited paper demands thought, critical ability, and experience, as well as a good textbook of biochemistry, but these exercises are exceptionally stimulating for those with the necessary application and interest.

The book is excellently suited for seminars that follow courses or lectures if guidance from a person with some experience is available. For personal use alone it requires more character than is commonly met. *L. Jaenicke* [NB 828 IE]

Clinical Pharmacology. By *M. Shepherd*, *M. Lader*, and *R. Rodnight*. In the series "Modern Medicine". The English University Press, Ltd., London 1968. 1st Edit., xi + 306 pp., bound 50s.

A psychiatrist, a pharmacologist, and a biochemist have undertaken to present a scientific field that has fundamentally changed both the treatment of mental patients and the outward appearance of mental hospitals during the past 15 years. The three authors have apparently collaborated in writing the individual chapters of this monograph, much to the benefit of its uniform quality.

In the first part methods are described for evaluating the clinical usefulness of psychotropic drugs by both animal and human experiments. Then the individual drugs are discussed in regard to their absorption, distribution within the organism, metabolism, pharmacology proper, effect on behavior, clinical effects, and side effects. Following a brief treatment of sedatives and hypnotics as well as central stimulants of longstanding use, and of lithium, which has come into widespread use in the treatment of mania during recent years, the comprehensive chapter deals with tranquilizers, especially phenothiazine derivatives, *Rauwolfia* alkaloids, and butyrophenone derivatives. Among the drugs with antidepressant action preferential consideration is given to the monoamine oxidase inhibitors while the tricyclic compounds of the imipramine type having far greater clinical importance are treated much more briefly.

Other chapters deal with recent developments in the field of sedatives and hypnotics, stimulants, and anti-Parkinson drugs. Chemicals producing psychosis-like states are also briefly considered, *i.e.* lysergic acid diethylamide (LSD 25) and mescaline, the concept of psychotomimetic drugs also being defined. A long chapter is devoted to the biochemical effects of psychotropic drugs and current hypotheses in this field are mentioned. Finally the ways along which psychopharmacological research should develop in the future are discussed.

The present book is notable for the authors' strict adherence to proven facts; though giving due consideration to all the hypotheses so abundant in this field the authors refrain from committing themselves to any particular one. Almost 1300 references, mostly to the English literature, open the reader's way into the field of psychopharmacology.

From the title of this work one may get the impression that the book is a clinical work addressed mainly to the clinician. This is not the case; not only does the book contain the information the clinician should know when administering these drugs, but it is also so clearly written and readily intelligible as to enable even the educated layman to familiarize himself with the whole field of psychopharmacology without any difficulty. It may be considered an irony of fate that the first mention of chlorpromazine, the compound that practically brought psychopharmacology into being, refers to an incorrect structural formula. *G. Quadbeck* [NB 830 IE]

Photoluminescence of Solutions. By *C. A. Parker*. Elsevier Publishing Co., Amsterdam-London-New York 1968. 1st Edit., xvi + 544 pp., 188 illustrations, 53 tables, bound Dfl. 85.—.

Unlike absorption spectrophotometry, emission methods in the field of molecular spectroscopy are far from having become a general tool in the analytical laboratory. This is clearly due to the greater experimental demands of the latter, particularly in respect of quantitative results. Although the recording of Raman spectra will become possible for a wide circle of interested chemists by application of lasers, the possible applications of fluorescence and phosphorescence spectroscopy have as yet been rarely exploited. The present book will help to remedy the situation.

The book is divided into the following chapters: 1, Basic Principles and Definitions (68 pages). The fundamentals of fluorescence and phosphorescence, polarization phenomena

and scattering effects are described. 2, Kinetics of Photoluminescence (58 pages). The important aspects of excitation and quenching processes are treated, as well as delayed fluorescence. 3, Apparatus and Experimental Methods (174 pages). In this chapter the author gives an excellent and full description of the technique necessary for measurement of luminescence. Each component of the luminescence spectrometer is described in detail. In the part dealing with methods, the main emphasis is placed on measurement of the light beam, correction of luminescence spectra and measurement of lifetime and quantum yield. 4, Special Topics and Applications (93 pages). Here the author has selected problems with which he is familiar, such as intersystem crossing efficiency, protolytic reactions in the excited state, excimers, and delayed fluorescence; but solvent effects and applications of polarization measurements are treated only briefly. 5, Application to Analytical Chemistry (105 pages). The use of luminescence methods in determination of molecular structure are described, also qualitative and quantitative investigation of organic and inorganic compounds and of the elements alone and in admixture. The book closes with a list of references and a detailed keyword index.

According to the foreword, the book is intended to fulfil a double purpose: first, to teach students the fundamentals and, secondly, to serve the specialist as a reference book. The second aim seems to be met in chapters 3—5. The author's great experience makes itself felt in the description of methods and apparatus; for instance, correction of emission and excitation spectra, not yet generally applied, are described in detail. However, when reading the results of luminescence spectroscopy recorded in the book one must not expect a review of the present state of knowledge, for the author has intentionally confined himself to his own specialist partial field.

As an introduction to the fundamentals the book can be recommended only subject to restrictions. That the author has refrained from quantum-chemical considerations is no disadvantage in principle, since specialist books exist in that area. This has, however, been taken too far, so that some fundamentals, such as the Frank-Condon principle cannot be clearly presented. A number of quantum-chemical ideas, such as charge-transfer state, nodal plane, and transition moment, are used without exact explanation. Further, the way in which certain basic relations are presented is open to a series of objections; for instance, polarization effects and the relation of lifetime to quantum yield are very sketchily explained; also more space should have been devoted to the solvent effect when treating the "Luminescence of Solutions".

The good points of the book are undoubtedly the sections on apparatus and methods. As a monograph it fills a gap in this respect, and it can be very warmly recommended to chemists, biochemists, and others interested in the application of luminescence spectroscopy. *H. Stegemeyer* [NB 835 IE]

Principles of Organometallic Chemistry. By *G. E. Coates, M. L. H. Green, P. Powell,* and *K. Wade.* Methuen & Co. Ltd., London 1968. 1st Edit., x + 259 pp., numerous illustrations, bound 38 s.

This is an abbreviated presentation of the principles of the organometallic chemistry of metals of the main and subgroups, based on the two-volume third edition of the same authors' "Organometallic Compounds".

In this abbreviation the authors wished above all to provide students with easy access to this rapidly developing branch of chemistry. The authors have been extremely successful in limiting themselves to the most important matters; they often use skillfully chosen figures to replace much text, though it is also good that the cost of preparation of some of the key compounds is also discussed. The relation of theory and physical studies (in particular X-ray structure studies) is well done. The book is very carefully and clearly printed. Because of its low price every student of chemistry can afford it. *P. Heimbach* [NB 840 IE]

Lehrbuch der Physikalischen Chemie – in elementarer Darstellung (Textbook of Elementary Physical Chemistry). By *J. Eggert, I. Hock,* and *G.-M. Schwab.* S. Hirzel Verlag, Stuttgart 1968. 9th revised Edition, 935 pp., 248 figures, 125 tables, bound DM 72.—.

The size of the present 9th edition of *J. Eggert*'s Textbook of Physical Chemistry differs only slightly from that of the 8th edition, which was published in 1960. The division into nine chapters has also been retained: "Principles of the Atomistic and Energetic Approach"; "Atoms"; "Molecules"; "Aggregation States"; "Chemical Thermodynamics"; "Electrochemistry"; "Colloid Chemistry"; "Chemical Kinetics"; and "Photochemistry". Nevertheless, substantial portions of the book have been completely revised and brought up to date. For instance, the section on the wave-mechanical theory of nonpolar bonding in the chapter on "Molecules" has been enlarged, and a section has been added on electron spin resonance, nuclear magnetic resonance, and the Mössbauer effect. The reworking and expansion of the chapter on "Aggregation States", in particular of the section on solids, also deserves mention. The main subjects dealt with here are methods of structure determination, ligand field theory, and the structure of organic substances. The chapter on "Chemical Thermodynamics" has been to some extent rearranged into a clearer and more logical form. One finds a highly interesting – and important – concession to current events in the changes and additions introduced in the sections on "Production of Extreme Temperatures" and "Thermodynamics of Space Flight". Apart from these more extensive changes from the 8th edition, the authors have introduced a large number of improvements in the interest of a concise and up-to-date presentation of the facts.

In the Preface the authors pose the question whether the field of physical chemistry still constitutes a scientifically homogeneous entity, or whether it has already broken up into independent parts roughly corresponding to the individual chapters of the book. The reviewer is in complete agreement with the authors when they suggest that the teaching profession should not split up the subject in this way but should continue to present physical chemistry as an entity for as long as possible; after all, an understanding of one of its constituent fields very often throws light on the principles of others.

In a comprehensive textbook of physical chemistry the treatment accorded to each individual subject should of course reflect the importance of that subject. On that score the book lays itself open to criticism. In a number of the chapters the reader is confronted with such a mass of detail that there is a danger of its obscuring his appreciation of the whole. On the other hand, at least a brief introduction to statistical thermodynamics, and certainly a more detailed treatment of wave mechanics, would have been welcome. This would admittedly have involved a departure from the somewhat elementary mathematical treatment, chosen in accordance with the intention professed in the title. However, in view of the importance that bonding theory now has for both organic and inorganic chemists, a student will in any case have to be taught enough of the mathematical treatment to enable him to go on to the specialized literature without undue difficulty. The same comment applies to the chapter on "Chemical Thermodynamics".

The constantly recurring problem of whether a course in physical chemistry should begin with a discussion of thermodynamics or the structure of matter is skilfully resolved by first presenting an elementary description of the ideas and procedures of thermodynamics, the kinetic theory of gases, and quantum mechanics. The subsequent treatment of the atom, the molecule, and aggregation states can be built up in the first place on information already familiar, on experience, and on intuition. Thus the somewhat more abstract thermodynamics is postponed till the second half of the book.

The very fact of the publication of the 9th edition of a work that first appeared 42 years ago testifies to its usefulness to the chemistry student. The beginner especially will be greatly

helped by the elementary approach, the detailed descriptions and explanations of the fundamental laws, and the formulas and diagrams. The copious marginal notes help toward an understanding of the relationships between the laws and also make it easier to find a particular explanation.

The print, the illustrations, and the tables are a model of clarity, and the overall presentation is outstandingly good.

G. Wedler [NB 843 IE]

Principles of Organic Synthesis. By *R. O. C. Norman*. Methuen & Co. Ltd., London 1968. 1st Edit. xiii + 722 pp., numerous illustrations and tables, bound £ 5.5.0.

The author sets out to provide the student who already posesses a basic knowledge of organic chemistry with all he needs to know for planning and carrying out organic syntheses. The book consists of two parts:

The first contains several chapters dealing with physical organic chemistry; for example, chemical thermodynamics, molecular structures, chemical kinetics, and reaction mechanisms, as well as a chapter on stereochemistry.

The second, appreciably larger part of the book deals with organic chemistry proper, and is arranged according to reaction type. It has chapters on formation of carbon-carbon bonds with organometallic reagents, formation of aliphatic carbon-carbon bonds by base-catalyzed condensations, formation of aliphatic carbon-carbon bonds by acid-catalyzed condensations, formation of aliphatic carbon-carbon bonds by four-center reactions, formation of carbon-nitrogen bonds, electrophilic aromatic substitutions, aromatic diazonium salts, molecular rearrangements, free-radical reactions, oxidations, reductions, syntheses of heterocyclic compounds, syntheses of natural products.

The selection and arrangement of the material in both parts of the book are very sound. It is particularly commendable that, despite a strict limitation of the material, all the important reactions have been included. The numerous structural formulas included in the text contribute substantially to the readability and take into account the reaction mechanisms. The book's usefulness is enhanced by the references to review literature and the sets of questions given at the end of each chapter. It must be said, however, that the bibliography might have been more comprehensive.

This book will be welcomed both by advanced students and by industrial chemists. A point that has puzzled the reviewer is the choice of title. With regard to its content the book differs little from other modern textbooks of organic chemistry that are subdivided according to reaction type, rather than according to the class of substance.

H. Stetter [NB 846 IE]

Analogcomputer in Chemie und Biologie. Eine Einführung. (Analog Computers in Chemistry and Biology. An Introduction.) By *H. Röpke* and *J. Riemann*. Springer-Verlag, Berlin-Heidelberg-New York 1969. 1st Edit., vii, 184 pp., 198 figs., bound DM 38.—.

Following an introduction to the mathematical treatment of problems in reaction kinetics, the authors outline the mode of operation of operational-amplifier analog computers. Simple examples are used to explain the construction of analog computer circuits. Computing circuits are given for 47 model examples, and the results obtained with them are shown. The last section deals with the use of analog computers for special problems, mainly from the authors' own field. A comprehensive bibliography on the kinetics of chemical reactions and the principles and applications of analog computers completes the book.

The authors deliberately concentrate on application problems, and the sections on the basic construction of analog computers (Sections 6 and 7) are accordingly kept very short. It would in fact have been preferable, from the point of view of chemists and biologists, to go into greater detail here to enable the book to fulfill its purpose as an introduction to analog computer techniques. It would not have taken much more space to derive the working equations of the adder and of the integrator in order to allow the reader to obtain a clear understanding of the basic procedure and to apply it correctly to the other parts of the computer.

Frequent use is made of symbols whose meaning is not defined, *e.g.* symbols for operational amplifiers with other inputs besides the direct input. The discussions of Figure 32, 38, 40, and 42 are incomprehensible for this reason. In other circuits (adder, integrator, potentiometer), the symbols should have been placed immediately adjacent to the circuit, and not in a summarizing table that appears only many pages later.

The numerous model examples, which make up two thirds of the book, are excellently chosen to give a clear grasp of the method of operation and to encourage its application to other kinetic problems. The book is therefore a valuable aid to anyone who is interested in the use of analog computers.

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ABSOLUTE configuration, of bacteriochlorophyll-a (SC) 610 [G.E. *81*, 626 (1969)]

X-Ray structure analysis and ~ of (+)-1-m-bromobenzoyl-4-methylazetidin-2-one (SC) 990 [G.E. *81*, 1048 (1969)]

Absorbers, Effective charge and specific energy loss of fission fragments in metal ~ (CR) 889 [G.E. *81*, 908 (1969)]

Absorption spectra of small polar molecules in an apolar solvent (LA) 83

Acetic acid, Homogeneous precipitation of halometalates from anhydrous ~ (CR) 901 [G.E. *81*, 920 (1969)]

Acetonyl radical, ESR spectrum (LA) 993

5-Acetyl-1,2,3,4,5-pentamethylbicyclo-[2.1.0]pentene (SC) 880 [G.E. *81*, 899 (1969)]

Acid chlorides, Vilsmeier reaction of ~ capable of fragmentation (SC) 71 [G.E. *81*, 36 (1969)]

Addition to the C≡N bond of cyanates (SC) 607 [G.E. *81*, 623 (1969)]

Acid hydrates, Crystal structures (SC) 136 [G.E. *81*, 116 (1969)]

Acrylate, Solution properties of random copolymers of methyl methacrylate and *n*-butyl ~ (CR) 390 [G.E. *81*, 340 (1969)]

Actinides, Analysis of ~ separated in a mass separator (CR) 914 [G.E. *81*, 933 (1969)]

Preparation and investigation of zirconium phosphate exchangers exhibiting separation properties for lanthanides and ~ (CR) 926 [G.E. *81*, 946 (1969)]

Actinium, The α-radiation of $^{228}Ac(MsTh_2)$. A new α branching in the thorium decay series (CR) 911 [G.E. *81*, 930 (1969)]

Actinomycin D, Repression of RNA synthesis (LA) 463

Activation energy, Meaning and use of the Arrhenius ~ (FP) 438 [G.E. *81*, 446 (1969)]

Acylation, Methods and possibilities of nucleophilic ~ (FP) 639 [G.E. *81*, 690 (1969)]

Acylation catalyst, N,N-Dimethyl-4-pyridinamine, a very effective ~ (SC) 981 [G.E. *81*, 1001 (1969)]

5-Acylnorbornenes, Photocyclization (LA) 289

Acyloxonium Cations, Valence isomerism in ~ of 1,2,3-triols, simple synthesis of acyloxonium salts (SC) 886 [G.E. *81*, 905 (1969)]

Acyloxonium Salts, Cyclorearrangement of 3,4,5-tri-O-acetyl-(1,2,4/3,5)-cyclopentanepentol-1,2-O-acetoxonium tetrafluoroborate (SC) 887 [G.E. *81*, 906 (1969)]

Cyclorearrangement of di-O-pivaloylpentaerythritol-O-pivaloxonium hexachloroantimonate (SC) 888 [G.E. *81*, 907 (1969)]

Adamantane, Recent developments in the chemistry of ~ and diamondoid molecules (CR) 529 [G.E. *81*, 539 (1969)]

1-(1-Adamantyl)-3-tert-butylaziridinone (LA) 153

Adsorption, of protactinium, zirconium, and niobium on silica gels and Vycor glass from solutions in hydrochloric acid (CR) 908 [G.E. *81*, 928 (1969)]

Aflatoxin B, Various molds produce ~ on foodstuffs (LA) 291

Aldehydes, Electrochemical oxidation of ~, formic acid, and carbon monoxide at tungsten carbide electrodes in 2 N sulfuric acid (SC) 757 [G.E. *81*, 748 (1969)]

New methods for the oxidation of ~ to carboxylic acids and esters (LA) 85

New ~ synthesis from dihydro-1,3-oxazines (LA) 394

Synthesis of α-hydroxy ~ (LA) 462

Alkaline earth metals, Separation on cellulose columns (CR) 905 [G.E. *81*, 924 (1969)]

Alkenylamines, Alkyl and aryl α-chloro ~ (SC) 454 [G.E. *81*, 468 (1969)]

Intramolecular motions in ~ and hydrazones (CR) 528 [G.E. *81*, 540 (1969)]

Cu-catalyzed oxidation (LA) 394

Alkoxy-o-benzoquinones (LA) 151

Alkylating agent, tert-Butyl acetate as ~ (SC) 521 [G.E. *81*, 496 (1969)]

Alkylations, with tertiary oxonium salts (CR) 907 [G.E. *81*, 926 (1969)]

Alkyl azides, New synthesis (SC) 134 [G.E. *81*, 148 (1969)]

Allylcarbinyl anions, Kinetics of rearrangement of ~ (3-butenide ions) (CR) 912 [G.E. *81*, 931 (1969)]

N,N'-Alkylenedimaleimides, Intramolecular photocycloaddition (SC) 213 [G.E. *81*, 224 (1969)]

Alkylidenetriphenylphosphoranes, Main and secondary reactions between ~ and isothiocyanates (SC) 762 [G.E. *81*, 750 (1969)]

Alkynes, Synthesis from enol esters (FP) 429 [G.E. *81*, 437 (1969)]

Cyclization of ~ (FP) 727 [G.E. *81*, 717 (1969)]

Formation of benzindenes on photolysis of phenylsubsubstituted diazocyclopentadienes in ~ (SC) 446 [G.E. *81*, 426 (1969)]

Catalytic mixed oligomerization of butadiene and ~ (SC) 753 [G.E. *81*, 744 (1969)]

Reaction with boron monofluoride (LA) 83

Reaction with difluoroamine (LA) 288

Alkynylamines, Cycloaddition to ketenes (SC) 72 [G.E. *81*, 33 (1969)]

Reactions with iminium salts (SC) 675 [G.E. *81*, 702 (1969)]

Allene alcohols, New synthesis (LA) 532

Allene oxide, 2-tert-Butyl-3-(2,2-dimethylpropylidene)oxirane (LA) 394

Allenes, Thermally unstable ~ and related compounds (CR) 150 [G.E. *81*, 157 (1969)]

Allosteric enzymes, Evolution (CR) 78 [G.E. *81*, 39 (1969)]

Allosteric properties of yeast pyruvate kinase (CR) 79 [G.E. *81*, 40 (1969)]

Alloys, Structure of molten ~ in relation to their properties (CR) 460 [G.E. *81*, 433 (1969)]

Internal oxidation and related phenomena in ~ (CR) 775 [G.E. *81*, 792 (1969)]

Allyl radical, Catalytic oxidation of olefins via an ~ (SC) 601 [G.E. *81*, 571 (1969)]

Aluminum compounds, 1,1,3-Trimethylisopropylindenium tetrachloroaluminate (SC) 281 [G.E. *81*, 292 (1969)]

Structure of dimeric dimethylaminodimethylaluminum (CR) 902 [G.E. *81*, 922 (1969)]

Comparison of organometallic complexes of aluminum and those of some transition metals (CR) 909 [G.E. *81*, 928 (1969)]

Cleavage of aluminum-, gallium-, and indium-carbon bonds with SO_2, CO_2, COS, and CS_2 (CR) 927 [G.E. *81*, 947 (1969)]

Solubility of Al_2O_3 in rutile (LA) 778

Americium, Determination of the branching ratio in the disintegration of ^{242}Am (CR) 897 [G.E. *81*, 916 (1969)]

Preparation of plutonium 238 from ~ 241 (CR) 913 [G.E. *81*, 933 (1969)]

Amides, O-Acylated vinylogous ~ (SC) 756 [G.E. *81*, 747 (1969)]

Formation of ~ by Claisen rearrangement of ketene O,N-acetals; stereochemistry (CR) 926 [G.E. *81*, 945 (1969)]

Amidines, Preparation of cyclic ~ by reduction of dinitriles with $LiAlH_4$ (SC) 457 [G.E. *81*, 431 (1969)]

Amines, Elemento-organic ~ and imines (FP) 861 [G.E. *81*, 871 (1969)]

Condensation products of squaric acid with primary and secondary ~ (CR) 898 [G.E. *81*, 917 (1969)]

Preparation and polycondensation reactions of aromatic di-~ containing siloxane chains (CR) 899 [G.E. *81*, 918 (1969)]

Amino acids, General synthesis for α-~ ortho esters (LA) 776

Analytical methods for the investigation of ~, peptides and proteins (Book Review) 621

3-Aminoacrolein, Single-step synthesis of pyridines from ~ and carbonyl compounds (SC) 765 [G.E. *81*, 785 (1969)]

Aminobenzenes, Mechanism of oxidative dimerization (SC) 280 [G.E. *81*, 261 (1969)]

Aminophosphine, Prototopic system ~/iminophosphorane (SC) 614 [G.E. *81*, 572 (1969)]

Aminoquinazolines, New synthesis (SC) 73 [G.E. *81*, 84 (1969)]

Ammonolysis, New products of ~ of phosphorus pentachloride (SC) 615 [G.E. *81*, 573 (1969)]

High-temperature ~ of UF_4 (CR) 891 [G.E. *81*, 910 (1969)]

Analysis, Modern ~ (FP) 733 [G.E. *81*, 723 (1969)]

Aniline, ESR spectra of radical anions of N-trimethylsilyl derivatives of ~ and p-phenylenediamine (SC) 767 [G.E. *81*, 786 (1969)]

[12]Annulene, Two new valence isomers (SC) 69 [G.E. *81*, 33 (1969)]

Anorganikum (Book Review) 466

Anthraquinonecarboxylic acids, Structure and biosynthesis of the ergot pigments (FP) 251 [G.E. *81*, 269 (1969)]

Antigens, Semisynthetic and synthetic macromolecules in immunochemical research (CR) 388 [G.E. *81*, 338 (1969)]

Antimalarial drugs, Metabolic transformation (CR) 285 [G.E. *81*, 295 (1969)]

Antimony compounds, Rapid volatilization of arsenic, antimony, selenium, and tellurium as hydrides from mixtures of fission products (CR) 906 [G.E. *81*, 926 (1969)]

Crystal structure of triazidocarbonium hexachloroantimonate (CR) 915 [G.E. *81*, 934 (1969)]

Dichlorodimethylpentanedionatoantimony (LA) 930

Antimony pentachloride, Reactions of disulfur dinitride with ~ and with boron trihalides (LA) 930

Antioxidants (FP) 547 [G.E. *81*, 555 (1969)]

Aromatic systems, New ~ (CR) 219 [G.E. *81*, 229 (1969)]

Aromatization, Metal-catalyzed ~ of unsaturated C_{18} carboxylic acids (CR) 925 [G.E. *81*, 945 (1969)]

~ of C_{18} alkylcyclohexadienecarboxylic acids (CR) 920 [G.E. *81*, 940 (1969)]

Arrhenius activation energy, Meaning and use (FP) 438 [G.E. *81*, 446 (1969)]

9-Arsaanthracene (SC) 991 [G.E. *81*, 1051 (1969)]

Dibenz[b,e]arsenine (~) (SC) 992 [G.E. *81*, 1052 (1969)]

Arsenic compounds, Rapid volatilization of arsenic, antimony, selenium, and tellurium as hydrides from mixtures of fission products (CR) 906 [G.E. *81*, 926 (1969)]

Arsenite, Absorption of carbon dioxide in buffered ~ solutions (CR) 910 [G.E. *81*, 930 (1969)]

Arsines, Organogermyl, organostannyl, and organoplumbyl phosphines, ~ stibines, and bismuthines (FP) 937 [G.E. *81*, 970 (1969)]

L-Asparaginase, Polyethylene glycol for fractionation and crystallization of ~ (SC) 885 [G.E. *81*, 904 (1969)]

Association, Rate of ~ of lactams (LA) 776

Asymmetric solvent catalysis; N,N,N′,N′-tetramethyl-2,3-dimethoxy-1,4-butanediamine, a new chiral medium (SC) 982 [G.E. *81*, 1002 (1969)]

Asymmetric synthesis, Reactions in chiral crystals (SC) 608 [G.E. *81*, 628 (1969)]

Partial ~ of substituted benzylidenecycloalkanes (SC) 763 [G.E. *81*, 751 (1969)]

Atomic radius, Crystal structure and ~ of metallic radium (LA) 290

Aurates, Hydrogen tetrahalogenobis-(N,N-dimethylacetamide)-~ (III) (SC) 980 [G.E. *81*, 1047 (1969)]

1-Azabicyclo[1.1.0]butanes, Synthesis and properties (SC) 70 [G.E. *81*, 35 (1969)]

Azaferrocene, Optically active 2-methyl-~ (SC) 135 [G.E. *81*, 150 (1969)]

Azaphosphatriptycene (SC) 987 [G.E. *81*, 1049 (1969)]

8-Azapurines, Hydrolysis of 6-methylthio-~ to thiol esters of 1,2,3-triazolecarboxylic acids (SC) 132 [G.E. *81*, 115 (1969)]

Azaquinodimethanes (SC) 986 [G.E. *81*, 1004 (1969)]

Azetidinium salts, Small charged heterocycles (FP) 962 [G.E. *81*, 953 (1969)]

Azibenzil, Formation of cycloadducts (LA) 153

Azides, New synthesis of alkyl ~ (SC) 134 [G.E. *81*, 148 (1969)]

Aziridinedicarboxylic esters, Azomethine ylides from ~ (SC) 602 [G.E. *81*, 619 (1969)]

Aziridinium salts, Small charged heterocycles (FP) 962 [G.E. *81*, 953 (1969)]

Aziridinone, 1-(1-Adamantyl)-3-tert-butyl-~ (LA) 153

2H-Azirine, Synthesis and reactions of a ~ unsubstituted on C-3 (SC) 772 [G.E. *81*, 787 (1969)]

Azo compounds, New method for the preparation of α,β-unsaturated ~ (SC) 459 [G.E. *81*, 467 (1969)]

ESR spectra of radical anions of aliphatic ~ (SC) 755 [G.E. *81*, 745 (1969)]

Combination reaction during the thermal decomposition of aliphatic ~ in the presence of oxygen (CR) 389 [G.E. *81*, 339 (1969)]

Azodicarboxylate, Structure and reactivity of the betaine derived from triphenylphosphine and dimethyl ~ (SC) 513 [G.E. *81*, 534 (1969)]

Azomethane, Interaction between the lone pairs in ~ (SC) 878 [G.E. *81*, 897 (1969)]

Azomethine ylides, from aziridinedicarboxylic esters (SC) 602 [G.E. *81*, 619 (1969)]

Configuration of a cis-disubstituted ~ (SC) 604 [G.E. *81*, 621 (1969)]

Differing 1,3-dipolar activity of cis-trans isomeric ~ dicarboxylic esters (SC) 604 [G.E. *81*, 621 (1969)]

Azulene, New luminescence experiments on ~ (LA) 994

BACTERIOCHLOROPHYLL-a, Absolute configuration (SC) 610 [G.E. *81*, 626 (1969)]

Barium phosphides, Preparation, structure, and properties (CR) 911 [G.E. *81*, 931 (1969)]

Barium salts, Carrier-free separation of ^{131}Cs from irradiated ~ by counter-current electrolysis (CR) 891 [G.E. *81*, 910 (1969)]

Bases, Reactions with aromatic nitro compounds (FP) 120 [G.E. *81*, 136 (1969)]

Benzene, Preparation by pyrolysis of cis- and trans-1,3-hexadien-5-yne (SC) 680 [G.E. *81*, 704 (1969)]

Spectroscopic and photochemical properties of ~-chloroform mixtures at low temperatures (LA) 395

The first allowed triplet-triplet absorption band of ~-s (LA) 930

Benzindenes, Formation on photolysis of phenyl-substituted diazocyclopentadienes in alkynes (SC) 446 [G.E. *81*, 426 (1969)]

Benzocyclopropene, New synthesis (SC) 446 [G.E. *81*, 426 (1969)]

Benzoquinones, Alkoxy-o-~ (LA) 151

Benzo[b]thiophenes, Ring contraction of 1-thiochromans (SC) 456 [G.E. *81*, 424 (1969)]

Benz[d]-[1,3]oxathiole, Single-step synthesis of 5-hydroxy-~-2-ones (LA) 289

4H-1,2-benzoxazin-4-one, 3-Nitro-2-azachromone (~): structure of the presumed p-nitrophenylnitroacetylene (SC) 979 [G.E. *81*, 999 (1969)]

Benzylidenecycloalkanes, Partial asymmetric synthesis of substituted ~ (SC) 763 [G.E. *81*, 751 (1969)]

Beryllium compounds, Association of bis-(trimethylsilyl)amidolithium and methyl(trimethylsilanolato)beryllium in the solid state (SC) 378 [G.E. *81*, 398 (1969)]

Biacetyl, The fluorescence and phosphorescence of ~ (LA) 993

Bicyclo[6.4.0]dodeca-2,4,6,9,11-pentaene, Two new valence isomers of [12]annulene (SC) 69 [G.E. *81*, 33 (1969)]

Bicyclo[2.1.0]pentene, 5-Acetyl-1,2,3,4,5-pentamethyl-~ (SC) 880 [G.E. *81*, 899 (1969)]

Biochemistry, Comprehensive ~ (Book Review) 397

Biopharmaceutics, Sorption promotors (FP) 699 [G.E. *81*, 757 (1969)]

3,3′-Bipyridazine derivatives, Synthesis (LA) 776

2,2′-Bipyridine adducts of disilanes (SC) 599 [G.E. *81*, 574 (1969)]

Birch reductions of trimethylsilyl substituted aromatic compounds controlled by (Si←C_π) interactions (SC) 525 [G.E. *81*, 538 (1969)]

Birefringence, Dependence of the stress ~ of rubber-elastic substances on temperature and degree of swelling (CR) 923 [G.E. *81*, 942 (1969)]

Bis(carbon monoxide) (LA) 221

Bis(chlorosulfur)nitrogen cation (SC) 598 [G.E. *81*, 568 (1969)]

Bis(cyclooctatetraene)titanium, Crystal structure (SC) 765 [G.E. *81*, 785 (1969)]

Bis(dimethylamido)bis(N-fluorosulfonylimido)sulfur (SC) 674 [G.E. *81*, 705 (1969)]

10,10-Bis(dimethylamino)nonafulvene (SC) 593 [G.E. *81*, 564 (1969)]

Bis(diphenylboryl)diimine (SC) 755 [G.E. *81*, 745 (1969)]

Bis(N-fluorosulfonylimido)sulfur, and ~ difluoride, (SC) 510 [G.E. *81*, 494 (1969)]

Bis(N-fluorosulfonylimido)sulfur difluoride, and bis(N-fluorosulfonylimido)-sulfur (SC) 510 [G.E. *81*, 494 (1969)]

Bismuthines, Organogermyl, organostannyl, and organoplumbyl phosphines, arsines, stibines, and ~ (FP) 937 [G.E. *81*, 970 (1969)]

Bis(pentadienyl)dinickel (SC) 677 [G.E. *81*, 708 (1969)]

Crystal structure of ~ (SC) 678 [G.E. *81*, 708 (1969)]

Bis(sulfinylamido)mercury(II) (SC) 376 [G.E. *81*, 330 (1969)]

Bis(tricarbonyl-2-methyl-3-chloronitrosobenzeneiron, Crystal structure (SC) 879 [G.E. *81*, 898 (1969)]

1,2-Bis(trifluoromethyl)disulfane 1,1-difluoride, Trifluoromethylfluorosulfane and ~ (SC) 773 [G.E. *81*, 789 (1969)]

N,N-Bis(trifluoromethyl)hydroxylamine, Reactions (LA) 222

3,5-Bis(trifluoromethyl)-1,2,4,6-thiatriaza-2,5-cyclohexadiene-1,1-dione (SC) 510 [G.E. *81*, 493 (1969)]

Bis(trimethylsilyl)monoperoxosulfate (SC) 450 [G.E. *81*, 430 (1969)]

Bis(triphenylphosphine)oxygenplatinum(0) (LA) 152

Bonding, Spectroscopic investigation of various phosphorus-sulfur bonds (FP) 328 [G.E. *81*, 343 (1969)]

Boranes, Alkali-metal tetraorganylborates from triorganyl-~ (SC) 275 [G.E. *81*, 261 (1969)]

Diphenylborane derivatives containing boron-tin bonds (SC) 515 [G.E. *81*, 530 (1969)]

Alkylation of diazoacetonitrile and ethyl diazoacetate with organo-~ (LA) 153

Production of the ~ and Related Research (Book Review) 224

Borates, Alkali-metal tetraorganyl-~ from triorganylboranes (SC) 275 [G.E. *81*, 261 (1969)]

Boron, Activation analysis of ~ and some elements of the rare earths by means of prompt neutron capture radiation (CR) 902 [G.E. *81*, 921 (1969)]

Chemistry of ~ and its Compounds (Book Review) 224

Boron carbide, Quantitative determination of impurities in ~ by neutron activation analysis (CR) 900 [G.E. *81*, 919 (1969)]

Boron compounds, Influence of foreign Atoms on formation and structure of boron modifications and boron-rich borides (CR) 889 [G.E. *81*, 908 (1969)]

Reaction of diborane and boranecarbonyl with nitrogen-oxygen compounds (CR) 897 [G.E. *81*, 916 (1969)]

Boron dichloride, Structure in the gas phase (LA) 778

Boron monofluoride, Reaction with alkynes (LA) 83

Boron trihalides, Reactions of disulfur dinitride with antimony pentachloride and with ~ (LA) 930

Borylating agents, Boryl sulfonates (LA) 619

Boryl sulfonates, A new group of borylating agents (LA) 619

Boundary layer, The boundary between fluid phases as a barrier for the passage of molecules (CR) 391 [G.E. *81*, 401 (1969)]

Bromine compounds, The adduct $BrF_3 \cdot SbF_5$ (LA) 685

(+)-1-m-Bromobenzoyl-4-methylazetidin-2-one, X-Ray structure analysis and absolute configuration of ~ (SC) 990 [G.E. *81*, 1048 (1969)]

Bromonium compound, Isolation of a stabilized ~ (LA) 930

Bromotrichloromethane, Photolysis (LA) 463

Butadiene, Catalytic mixed oligomerization of ~ and alkynes (SC) 753 [G.E. *81*, 744 (1969)]

3-Butenide ions, Kinetics of the rearrangement of allylcarbinyl anions (~) (CR) 912 [G.E. *81*, 931 (1969)]

tert.-Butyl acetate as alkylating agent (SC) 521 [G.E. *81*, 496 (1969)]

CADMIUM compounds, Determination of copper, lead, and cadmium in different concentration ratios by various voltammetric methods (CR) 910 [G.E. *81*, 929 (1969)]

Organic compounds of zinc and cadmium (Book Review) 292

Cage structure, Organometal-substituted phosphines having a cage-like structure (SC) 989 [G.E. *81*, 1049 (1969)]

Californium(III) compounds, Preparation and properties (LA) 618

Californium(III) oxide fluoride (LA) 290

ε-Caprolactam hydroperoxide, 1,2,4,5-Tetroxane derivatives from ~ (LA) 778

Carbanions, Mono-, bis-, and tris(phenylseleno)methyllithium (selenium-stabilized ~) (SC) 450 [G.E. *81*, 465 (1969)]

Carbenes, Carbene/carbenoid problem (SC) 760 [G.E. *81*, 781 (1969)]

Hindered rotation about the C–O bond in methoxy(methyl)carbene ligands (SC) 761 [G.E. *81*, 780 (1969)]

Nucleophilic cyclic ~ as complex ligands on transition metals (CR) 916 [G.E. *81*, 936 (1969)]

~, carbenoids, and carbene analogs (Book Review) 931

Carbenoid, Carbene/~ problem (SC) 760 [G.E. *81*, 781 (1969)]

Carbides, Refractory ~ (Book Review) 464

Carbohydrates, Synthesis of rare sugars (FP) 401 [G.E. *81*, 415 (1969)]

Carbon compounds, Rodd's chemistry of ~ (Book Review) 780

Carbon dioxide, Absorption of ~ in buffered arsenite solutions (CR) 910 [G.E. *81*, 930 (1969)]

Carbonium Ions, Unstable ~ (CR) 899 [G.E. *81*, 918 (1969)]

~ (Book Review) 155

Carbon monoxide, Electrochemical oxidation of aldehydes, formic acid, and ~ at tungsten carbide electrodes in 2 N sulfuric acid (SC) 757 [G.E. *81*, 748 (1969)]

IR spectrum of ~ in zeolites (LA) 931

Syntheses with ~ (Book Review) 397

Carbonylation, New catalysts for low-pressure ~ (LA) 153

Carboxylic acids, Cyclization of long-chain trienoic ~ with alkali (CR) 920 [G.E. *81*, 940 (1969)]

Aromatization of C_{18} alkylcyclohexadiene-~ (CR) 920 [G.E. *81*, 940 (1969)]

Elucidation of the mechanism of the reaction of epoxides with ~ by kinetic studies and model analysis using a digital computer (CR) 922 [G.E. *81*, 942 (1969)]

Metal-catalyzed aromatization of unsaturated C_{18} ~ (CR) 925 [G.E. *81*, 945 (1969)]

Electrolytic decarboxylation of vicinal di-~ (LA) 83

New methods for the oxidation of aldehydes to ~ and esters (LA) 85

Catalase and peroxidase activity of Cu^{2+} complexes (FP) 167 [G.E. *81*, 161 (1969)]

Catalysis, Catalytic activity of transition metal compounds in the liquid-phase oxidation of hydrocarbons (FP) 97 [G.E. *81*, 91 (1969)]

Asymmetric solvent ~; N,N,N′,N′-tetramethyl-2,3-dimethoxy-1,4-butane-diamine, a new chiral medium (SC) 982 [G.E. *81*, 1002 (1969)]

Mechanism of the anionic ~ of the decomposition of nitramide (CR) 921 [G.E. *81*, 941 (1969)]

Coordination chemistry (CR) 283 [G.E. *81*, 262 (1969)]

New catalysts for low-pressure carbonylation (LA) 153

~ reviews (Book Review) 468

Experimental methods in catalytic research (Book Review) 932

Catalytic oxidation of olefins via an allyl radical (SC) 601 [G.E. *81*, 571 (1969)]

[3]-Catenanes (SC) 988 [G.E. *81*, 996 (1969)]

Cations, Classification of partition reactions of inorganic ~ (FP) 853 [G.E. *81*, 888 (1969)]

Cation radicals in vinyl polymerization (CR) 387 [G.E. *81*, 337 (1969)]

Cell nucleus, Point of attack of cortisol in the ~ (CR) 80 [G.E. *81*, 41 (1969)]

Cellulose, Separation of alkaline earth metals on ~ columns (CR) 905 [G.E. *81*, 924 (1969)]

Cellulose fibrils, Structure (CR) 384 [G.E. *81*, 334 (1969)]

Cell wall, Structural components of the ~ of E. coli (CR) 77 [G.E. *81*, 37 (1969)]

Cesium, Carrier-free separation of ^{131}Cs from irradiated barium salts by countercurrent electrolysis (CR) 891 [G.E. *81*, 910 (1969)]

Charge transfer, Products of ~ on collision of H^+, H_2^+, and He^+ with H_2, N_2, O_2, CO_2, H_2O, NH_3, and CH_4 (LA) 530

Chloramine oxidation, Studies on the course of ~ of hydroxyproline (CR) 890 [G.E. *81*, 908 (1969)]

Chlorine, Influence of ~ as substituent on the course of 1,3-dipolar cycloadditions of diazoalkanes (SC) 210 [G.E. *81*, 189 (1969)]

Ligand recoil in hexahalogeno complexes of Re^{IV} and Rh^{III} and the production of practically carrier-free ^{36}Cl (CR) 890 [G.E. *81*, 909 (1969)]

1-Chlorobenzotriazole (LA) 85

N-Chlorochloroformimidoyl chloride from cyanogen chloride and chlorine (SC) 606 [G.E. *81*, 572 (1969)]

Structural investigations on semi-crystalline polyethylene and ethylene-propylene ~ (CR) 390 [G.E. *81*, 340 (1969)]

Copper(I) chloride, Electrical conductivity at high pressure (LA) 779

Copper complexes, Catalase and peroxidase activity of Cu^{2+} complexes (FP) 167 [G.E. *81*, 161 (1969)]

Copper compounds, Determination of copper, lead, and cadmium in different concentration ratios by various voltammetric methods (CR) 910 [G.E. *81*, 929 (1969)]

Corrin synthesis, New type of ~ (FP) 343 [G.E. *81*, 301 (1969)]

Cortisol, Point of attack in the cell nucleus (CR) 80 [G.E. *81*, 41 (1969)]

Critical temperatures, Simple method for the determination of the ~ of volatile liquids (LA) 152

Crystalline form, Effect of ~ on the air-oxidation of steroidal 11β-ols to 11-ones (SC) 975 [G.E. *81*, 1046 (1969)]

Crystallization, Stimulation of ~ of polymers by nucleating agents of high molecular weight (CR) 386 [G.E. *81*, 335 (1969)]

Crystallography, Physico-chemical ~ (Book Review) 686

Crystals, Reactions in chiral ~ (SC) 608 [G.E. *81*, 628 (1969)]

Crystal structure, Analysis by neutron diffraction I (FP) 356 [G.E. *81*, 307 (1969)]

~, Analysis by neutron diffraction II (FP) 950 [G.E. *81*, 984 (1969)]

~ of two acid hydrates (SC) 136 [G.E. *81*, 116 (1969)]

~ of 4-thiouridine (SC) 139 [G.E. *81*, 121 (1969)]

$Ni_5(C_5H_5)_4S_4$, a pentanuclear metal complex containing a square-planar nickel(0) atom (SC) 144 [G.E. *81*, 152 (1969)]

~ of zirconium(IV) chloride (SC) 146 [G.E. *81*, 120 (1969)]

Association of bis(trimethylsilyl)amidolithium and methyl(trimethylsilanolato)beryllium in the solid state (SC) 378 [G.E. *81*, 398 (1969)]

Technetium(VII) oxide (SC) 381 [G.E. *81*, 328 (1969)]

~ of bis(tricarbonyl-2-methyl-3-chloronitrosobenzeneiron) (SC) 879 [G.E. *81*, 898 (1969)]

~ of $PCl_4(NCH_3)_2CCl$ (SC) 455 [G.E. *81*, 430 (1969)]

~ of pentacarbonyl(2,3-diphenylcyclopropenylidene)chromium(0) (SC) 515 [G.E. *81*, 536 (1969)]

~ of uridine 2',3'-O,O-cyclophosphorothioate (SC) 595 [G.E. *81*, 566 (1969)]

~ of perchloro[4]radialene (SC) 597 [G.E. *81*, 567 (1969)]

~ of bis(pentadienyl)dinickel (SC) 678 [G.E. *81*, 708 (1969)]

~ of methyltrimethylsiloxomercury (SC) 679 [G.E. *81*, 707 (1969)]

~ of bis(cyclooctatetraene)titanium (SC) 765 [G.E. *81*, 785 (1969)]

~ and molecular structure of 1,1-dimethoxy-2,4,6-triphenylphosphorin (SC) 769 [G.E. *81*, 783 (1969)]

X-Ray structure analysis and absolute configuration of (+)-1-m-bromobenzoyl-4-methylazetidin-2-one (SC) 990 [G.E. *81*, 1048 (1969)]

X-ray structural analysis of alkylthiostannic acids (monoalkyl sesquisulfides) (CR) 288 [G.E. *81*, 297 (1969)]

~ of molybdenum nitride trichloride $MoNCl_3$ (CR) 925 [G.E. *81*, 945 (1969)]

~ of triazidocarbonium hexachloroantimonate (CR) 915 [G.E. *81*, 934 (1969)]

~ and atomic radius of metallic radium (LA) 290

Vapor pressure and ~ of metallic curium (LA) 778

Curium, Isolation of ^{242}Cm for use in a radionuclide battery (CR) 915 [G.E. *81*, 935 (1969)]

Experience in the isolation of ^{242}Cm in the kilocurie range (CR) 928 [G.E. *81*, 948 (1969)]

Vapor pressure and crystal structure (LA) 778
Cyanates, Addition of acyl chlorides to the C≡N bond of ~ (SC) 607 [G.E. *81*, 623 (1969)]
Cyanogen chloride, Reaction with silver cyanate (SC) 444 [G.E. *81*, 423 (1969)]
N-Chlorochloroformimidoyl chloride from ~ and chlorine (SC) 606 [G.E. *81*, 572 (1969)]
Cyanogen fluoride, Simple preparation (SC) 601 [G.E. *81*, 627 (1969)]
8-Cyanoheptafulvalene, Synthesis (LA) 531
8-Cyanoheptafulvene, Photo-oxygenation (SC) 673 [G.E. *81*, 702 (1969)]
Cybernetics, Fundamental Concepts of ~ (Book Review) 533
Cycloadditions, with polar intermediates (FP) 312 [G.E. *81*, 348 (1969)]
Small charged heterocycles (FP) 962 [G.E. *81*, 953 (1969)]
~ of ketenes to ynamines (SC) 72 [G.E. *81*, 33 (1969)]
Influence of chlorine as substituent on the course of 1,3-dipolar ~ of diazoalkanes (SC) 210 [G.E. *81*, 189 (1969)]
Intramolecular photo-~ of N,N'-alkylenedimaleimides (SC) 213 [G.E. *81*, 224 (1969)]
Stereospecific synthesis of 5,6-dihydro-4H-1,3-oxazines via polar 1,4-~ (SC) 602 [G.E. *81*, 576 (1969)]
Photochemical [2π + 2σ] ~ in tetracyclo[3.3.2.$0^{2,4}$.$0^{6,8}$] decene systems (SC) 883 [G.E. *81*, 902 (1969)]
~ to 1,1-Dicyclopropylethylene (SC) 976 [G.E. *81*, 1046 (1969)]
Formation of cycloadducts (LA) 153
Cyclobutadiene, Formation of 1,2-dimethyl-~ on photolysis of dimethylcyclobutenedicarboxylic anhydride (SC) 132 [G.E. *81*, 114 (1969)]
~-s from cyclobutenedicarboxylic anhydrides (CR) 912 [G.E. *81*, 932 (1969)]
Cyclobutadienocyclopentadienide ion, Detection (LA) 531
Cyclobutane, Acid-catalyzed cyclodimerizations via vinyl cations as intermediates (FP) 933 [G.E. *81*, 966 (1969)]
Cyclodimerizations, Acid-catalyzed ~ via vinyl cations as intermediates (FP) 933 [G.E. *81*, 966 (1969)]
2-Cyclohexen-5-yne-1,4-dione, Formation (LA) 684
cis,cis,cis,cis-1,3,5,7-Cyclononatetraene (SC) 594 [G.E. *81*, 565 (1969)]
trans,cis,cis,cis-Cyclononatetraenyl anion, a new aromatic 10 π system (SC) 984 [G.E. *81*, 1003 (1969)]
cis,cis-1,3-Cyclooctadiene, Photolysis (LA) 462
cis,trans-1,5-Cyclooctadiene, Thermal dimerization (CR) 909 [G.E. *81*, 929 (1969)]
Cyclopentadienones, Synthesis of substituted ~ by ring contraction (SC) 275 [G.E. *81*, 260 (1969)]
Cyclophane, New synthesis (SC) 274 [G.E. *81*, 258 (1969)]
Cyclopropanone, Reaction of 2,2-dimethyl-~ and 1,1-dimethoxyethylene (LA) 289
Cyclopropene, Thermal dimerization (LA) 220
Cyclopropylnitrenium chloride, N-Methyl-1-phenyl-~ (LA) 620
Cyclopropyloxirane (SC) 75 [G.E. *81*, 86 (1969)]
1-Cyclopropylvinyl cation (LA) 621
Cyclosilane-d_{18}, a new ^{1}H-NMR standard for measurements up to 200 °C (SC) 380 [G.E. *81*, 394 (1969)]
Cyclosilazanes, Isomerizations of N-silylated ~ (SC) 521 [G.E. *81*, 499 (1969)]
Cytochemistry (CR) 77 [G.E. *81*, 37 (1969)]
Comprehensive Biochemistry (Book Review) 995

DEACTIVATION of excited states (FP) 261 [G.E. *81*, 279 (1969)]
9-Decalylium ion, Conformers (LA) 84
Decarboxylation, Electrolytic ~ of vicinal dicarboxylic acids (LA) 83
Dehydrobenzoquinone, Formation (LA) 684
Dephosphorylation, New method for the ~ of ribonucleoside 2'- or 3'-phosphates (LA) 531
Depsipeptides, Topochemical investigations on peptide systems (FP) 492 [G.E. *81*, 523 (1969)]
Deuterium compounds, Homogeneous catalyzed H–D-exchange in polycyclic aromatic compounds (LA) 685
Dewar-benzene, 1,2,3,4-Tetrachloro-5,6-dimethyl-~ (SC) 759 [G.E. *81*, 749 (1969)]
α,γ-Diazabicyclanes, Synthesis of ortho-condensed ~ containing a bridge-head nitrogen atom (SC) 69 [G.E. *81*, 34 (1969)]
Diazadiphosphetidine, 1,3-Di(tert-butyl)-2,4-dichloro-~ (SC) 752 [G.E. *81*, 743 (1969)]
6,7-Diazatricyclo-[3.2.2.$0^{2,4}$]non-6-ene, Synthesis and pyrolysis (LA) 393
Diazenes, tert-Butyl-α-hydroxyalkyl-~ from tert-butyl-~ (SC) 451 [G.E. *81*, 465 (1969)]
Diaziridine imine (SC) 448 [G.E. *81*, 428 (1969)]
Reversible valence isomerization of ~-s (SC) 449 [G.E. *81*, 429 (1969)]
Diaziridines, Separation of invertomers (diastereoisomers) of ~ (SC) 212 [G.E. *81*, 224 (1969)]
Three-membered rings containing two hetero atoms (Book Review) 779
Diazoacetate, Alkylation of diazoacetonitrile and ethyl ~ with organoboranes (LA) 153
Diazoacetonitrile, Alkylation of ~ and ethyl diazoacetate with organoboranes (LA) 153
Diazoalkanes, Influence of chlorine as substituent on the course of 1,3-dipolar cycloadditions of ~ (SC) 210 [G.E. *81*, 189 (1969)]
α-Diazocarboxylic acid, Preparation of a free ~ (LA) 619
Diazo compounds, Three-membered rings containing two hetero atoms (Book Review) 779
Diazocyclopentadienes, Formation of benzindenes on photolysis of phenyl-substituted ~ in alkynes (SC) 446 [G.E. *81*, 426 (1969)]
Diazomethane, Catalyzed reactions with vinyloxirane (SC) 75 [G.E. *81*, 86 (1969)]
Novel reaction of ~ (LA) 620
Diazonium salts, Aryldiimine as an intermediate during reduction of ~ with tetrahydridoborate (SC) 370 [G.E. *81*, 392 (1969)]
Dibenz[b,e]arsenine, 9-Arsaanthracene (SC) 991 [G.E. *81*, 1051 (1969)]
~ (9-Arsaanthracene) (SC) 992 [G.E. *81*, 1052 (1969)]
Dibenzo[a,e]cyclooctene complexes of chromium and molybdenum (SC) 374 [G.E. *81*, 331 (1969)]
Dibenzo[lm,yz]hexacene (LA) 462
2,3-Dibromocyclononene, cis- and trans-~ (LA) 84
7,9-Di-tert-butylsesquifulvalene, synthesis and cycloadditions (SC) 881 [G.E. *81*, 900 (1969)]
Dichloromaleimides, Novel pigments from ~ (SC) 751 [G.E. *81*, 742 (1969)]
Dictionary, of organic compounds (Book Review) 86
Practical ~ of medicine and related subjects (Book Review) 87, 222
~ of science and technology, English-German (Book Review) 154
The ABC of biology (Book Review) 223
10,11-Dicyanopentaphenafulvalene (SC) 882 [G.E. *81*, 901 (1969)]
1,1-Dicyclopropylethylene, Cycloadditions to ~ (SC) 976 [G.E. *81*, 1046 (1969)]
5,6-Didehydro-11,12-dihydrodibenzo-[a,e]cyclooctene (SC) 447 [G.E. *81*, 427 (1969)]
Dielectric properties, Variation of ~ of weakly polar liquids (LA) 530
1,2-Diethylidenecyclobutane, Preparation and properties (SC) 206 [G.E. *81*, 186 (1969)]
Diethyllysergamide, Interactions with calf thymus DNA (LA) 684
Difluoroamine, Reaction with acetylenes (LA) 288
Difluorocarbene, Kinetics of some reactions (LA) 776
1,3-Dihalogenoisoindenones, Reactivity (SC) 606 [G.E. *81*, 623 (1969)]
N,N'-Dihalogenosulfur diimides, N-Halogenoimidosulfur difluorides and ~ (SC) 771 [G.E. *81*, 785 (1969)]
Dihydro-1,3-oxazines, Stereospecific synthesis of 5,6-dihydro-4H-1,3-oxazines via polar 1,4-cycloaddition (SC) 602 [G.E. *81*, 576 (1969)]
New aldehyde synthesis from ~ (LA) 394
Diimine, Aryl-~ as an intermediate during reduction of diazonium salts with tetrahydridoborate (SC) 370 [G.E. *81*, 392 (1969)]
Bis(diphenylboryl)-~ (SC) 755 [G.E *81*, 745 (1969)]
ESR spectra of radical anions of aliphatic azo compounds: tert-butyl and trimethylsilyl derivatives of ~ (SC) 755 [G.E. *81*, 745 (1969)]
Diketones, Are β-~-metal complexes aromatic? (SC) 147 [G.E. *81*, 150 (1969)]
Photochemical conversion of unsaturated 1,2-~ into cyclic compounds (LA) 776
Dimerization, Mechanisms of oxidative ~ of aminobenzenes (SC) 280 [G.E. *81*, 261 (1969)]
Oxidative ~ of olefins (SC) 518 [G.E. *81*, 532 (1969)]

1,1-Dimethoxy-2,4,6-triphenylphosphorin, Crystal and molecular structure (SC) 769 [G.E. *81*, 783 (1969)]

Dimethyl azodicarboxylate, Structure and reactivity of the betaine derived from triphenylphosphine and ~ (SC) 513 [G.E. *81*, 534 (1969)]

1,2-Dimethylcyclobutadiene, Formation of ~ on photolysis of dimethylcyclobutenedicarboxylic anhydride (SC) 132 [G.E. *81*, 114 (1969)]

1,2-Dimethyl-1,2-diphenyl-1,2-disilacyclohexane (LA) 222

Dimethylgermane, Structure (LA) 777

N,N-Dimethyl-4-pyridinamine, a very effective acylation catalyst (SC) 981 [G.E. *81*, 1001 (1969)]

Dinitriles, Preparation of cyclic amidines by reduction of ~ with $LiAlH_4$ (SC) 457 [G.E. *81*, 431 (1969)]

Dinitrodiazomethane, Preparation by nitration of nitrodiazomethane (SC) 612 [G.E. *81*, 577 (1969)]

Dinitrogen trioxide, The molecular geometry of ~ (LA) 994

1,3,2-Dioxaphosphor^{V}-inane-2-thione, Stereospecific synthesis of cis-2-α-hydroxy-4-methyl-~ (SC) 511 [G.E. *81*, 495 (1969)]

Diphenylborane derivatives containing boron–tin bonds (SC) 515 [G.E. *81*, 530 (1969)]

(Diphenylphosphino)dithioformates, Alkali-metal ~ and (diphenylthiophosphinyl)-dithioformates (SC) 202 [G.E. *81*, 183 (1969)]

(Diphenylthiophosphinyl)dithioformates, Alkali-metal (diphenylphosphino)dithioformates and ~ (SC) 202 [G.E. *81*, 183 (1969)]

Diquinones, Formation of linear polycyclic ~ (LA) 618

1,2-Disilacyclohexane, 1,2-Dimethyl-1,2-diphenyl-~ (LA) 222

Disilanes, 2,2'-Bipyridine adducts (SC) 599 [G.E. *81*, 574 (1969)]

Diradicals, Formal ~ which should have singlet ground states (SC) 214 [G.E. *81*, 225 (1969)]

Disc Electrophoresis (Book Review) 686

Dissociation constants of some phosphoric acid derivatives (LA) 395

Disulfene (SC) 73 [G.E. *81*, 36 (1969)]

Disulfides, New method for the formation of S–S bonds (SC) 518 [G.E. *81*, 532 (1969)]

Convenient synthesis of ~ (SC) 677 [G.E. *81*, 706 (1969)]

Disulfur dichloride, New reaction of N-vinylcarbazole with ~ (SC) 877 [G.E. *81*, 896 (1969)]

Disulfur dinitride, Reactions with antimony pentachloride and with boron trihalides (LA) 930

8H-1,3,5,6-Dithiadiazocin-2-one, Optically active (SC) 758 [G.E. *81*, 749 (1969)]

1,3-Dithianes, 1,4-addition of 2-lithio-~ to substituted ω-nitrostyrenes (SC) 983 [G.E. *81*, 1047 (1969)]

Dithieno[3,4-b,3',4'-e]-[1,4]-dithiine (SC) 598 [G.E. *81*, 570 (1969)]

Dithiocarbamates, New preparation of thioformamides and ~ (SC) 141 [G.E. *81*, 154 (1969)]

Dithioformates, Alkali-metal (diphenylphosphino)-~ and (diphenylthiophosphinyl)-~ (SC) 202 [G.E. *81*, 183 (1969)]

1,4-Divinylazetidin-2-ones, Cope rearrangement of ~ (CR) 922 [G.E. *81*, 942 (1969)]

Drugs (Book Review) 291

Index Pharmacorum (Book Review) 995

EINSTEINIUM compounds, First crystalline ~ (LA) 463

Electricity, Danger of Static Electricity (Book Review) 779

Electrochemical oxidation of aldehydes, formic acid, and carbon monoxide at tungsten carbide electrodes in 2 N sulfuric acid (SC) 757 [G.E. *81*, 748 (1969)]

Electrochemistry, Electrochemical production of current (Book Review) 779

Electrochromism and solvatochromism (FP) 177 [G.E. *81*, 195 (1969)]

Electrocrystallization of metals under ideal and real conditions (FP) 108 [G.E. *81*, 101 (1969)]

Electrolysis, Carrier-free separation of ^{131}Cs from irradiated barium salts by countercurrent ~ (CR) 891 [G.E. *81*, 910 (1969)]

~ and hydrocarbons from extracts and distillates of bituminous shales (CR) 901 [G.E. *81*, 920 (1969)]

Introduction to the chemistry and biochemistry of ~ and their glycerides (Book Review) 86

Ferrocene, Optically active 2-methylaza-~ (SC) 135 [G.E. *81*, 150 (1969)]

Fertilizers, Oligomeric and polymeric nitrogen-phosphorus compounds (CR) 617 [G.E. *81*, 578 (1969)]

Fibroin, Investigations on the structure (CR) 388 [G.E. *81*, 338 (1969)]

Field ionization mass spectrometer, Determination of the structures of organic molecules and quantitative analyses with the ~ (FP) 623 [G.E. *81*, 662 (1969)]

Fission fragments, Effective charge and specific energy loss of ~ in metal absorbers (CR) 889 [G.E. *81*, 908 (1969)]

Flavonoids, New investigations of the biosynthesis of ~ (CR) 392 [G.E. *81*, 403 (1969)]

Flavors, Natural and synthetic ~ (Book Review) 686

Fluorescence, The ~ spectrum of estrone (LA) 530

The ~ and phosphorescence of biacetyl (LA) 993

Unusually large Stokes shifts and ~ decay times (LA) 530

Solvent effects in the ~ and phosphorescence of indole (LA) 779

Fluorination, Conjugated additions in hydrogen fluoride (FP) 349 [G.E. *81*, 321 (1969)]

Fluorine compounds, Conjugated additions in hydrogen fluoride (FP) 349 [G.E. *81*, 321 (1969)]

Fluorinated inorganic radicals (CR) 217 [G.E. *81*, 190 (1969)]

The adduct $BrF_3 \cdot SbF_5$ (LA) 685

Fluoroformamidine, Derivatives of N^2-(trifluoromethyl)-~ (LA) 462

Fluorosulfinic acid, Esters with lower alcohols (LA) 289

Fluoroxenon pentafluoroorthotellurate (SC) 373 [G.E. *81*, 330 (1969)]

Food chemistry, Handbook of ~ (Book Review) 153, 622

Formamides, C–N Fission of O-alkylated ~ (SC) 984 [G.E. *81*, 1004 (1969)]

Formamidines, Trisubstituted ~ (SC) 142 [G.E. *81*, 154 (1969)]

Formic acid, Electrochemical oxidation of aldehydes, ~, and carbon monoxide at tungsten carbide electrodes in 2 N sulfuric acid (SC) 757 [G.E. *81*, 748 (1969)]

α-(Formylamino)acrylic esters from α-metalated isocyanoacetic esters and carbonyl compounds (SC) 672 [G.E. *81*, 701 (1969)]

10-Formyltetrahydrofolate:NADP oxidoreductase, Physiological role and regulation (CR) 80 [G.E. *81*, 41 (1969)]

Fragmentation, Mechanisms and stereochemistry of heterolytic ~ (FP) 535 [G.E. *81*, 543 (1969)]

Vilsmeier reaction of acid chlorides capable of ~ (SC) 71 [G.E. *81*, 36 (1969)]

Fructose metabolism, Embryonic developments of the enzymes of ~ (CR) 78 [G.E. *81*, 39 (1969)]

D-GALACTOSE, Breakdown of sugars during ripening of Camembert: Enzymatic determination of D-Lactose, D-Glucose, and ~ (CR) 891 [G.E. *81*, 910 (1969)]

Gallium compounds, Cleavage of aluminum-, gallium-, and indium-carbon bonds with SO_2, CO_2, COS, and CS_2 (CR) 927 [G.E. *81*, 947 (1969)]

Galvinoxyl, Structure (LA) 464

Gamma spectrometry, Determination of trace elements in plastics by neutron activation and ~ (CR) 924 [G.E. *61*, 943 (1969);

Gas chromatography, Use for the study of interaction forces between binders and solvents in paint films (CR) 918 [G.E. *81*, 938 (1969)]

Genomes, Studies on adenovirus type 12: Relations between the virus- and host ~ (CR) 81 [G.E. *81*, 87 (1969)]

2-Germaacetate, Potassium ~ (LA) 222

Germyl compounds, Organogermyl, organostannyl, and organoplumbyl phosphines, arsines, stibines, and bismuthines (FP) 937 [G.E. *81*, 970 (1969)]

D-Glucose, Breakdown of sugars during ripening of Camembert: Enzymatic determination of D-lactose, ~, and D-galactose (CR) 891 [G.E. *81*, 910 (1969);

Glycerides, Introduction to the chemistry and biochemistry of fatty acids and their ~ (Book Review) 86

Gold compounds, Preparation and properties of $AuTe_2I$ (SC) 145 [G.E. *81*, 148 (1969)]

Graphite, Preparation of pure 2nd and 3rd phase ~-iron(III) chloride inclusion compounds and of ~-iron(III) bromide inclusion compounds (SC) 382 [G.E. *81*, 333 (1969)]

Adsorption of hexafluorobenzene on graphitized carbon black (LA) 619

Preparation of synthetic ~ by low-temperature pyrolysis of methane (LA) 684

Grignard reactions, Stereochemical course of ~ at asymmetric sulfur (SC) 612 [G.E. *81*, 619 (1969)]

Group theory for chemists, physical chemists, and mineralogists (Book Review) 396

HABER, The Story of Fritz ~ (Book Review) 687

Hafnium, A high-spin isomer of ^{179}Hf (CR) 904 [G.E. *81*, 923 (1969)]

m-Halogenobenzaldehydes, Rotational isomerism (LA) 778

N-Halogenoimidosulfur difluorides and N,N'-dihalogenosulfur diimides (SC) 771 [G.E. *81*, 785 (1969)]

N-(Halogenosulfonyl)urethanes, Action of phosphorus pentachloride on ~ (SC) 136 [G.E. *81*, 119 (1969)]

Halogens, Fast separation of fission ~ by recoil reaction with methane (CR) 907 [G.E. *81*, 926 (1969)]

Halometalates, Homogeneous precipitation of ~ from anhydrous acetic acid (CR) 901 [G.E. *81*, 920 (1969)]

N-Halosulfinylamines (SC) 376 [G.E. *81*, 331 (1969)]

Handbook of Chemistry and Physics (Book Review) 86, 87

The Merck Index (Book Review) 87

Healing, Tissue hyaluronidase and ~ of wounds (CR) 79 [G.E. *81*, 39 (1969)]

Heat transport, Simultaneous mass and ~ with wall reactions (CR) 220 [G.E. *81*, 230 (1969)]

Helix formation in oligopeptides of L-proline (CR) 919 [G.E. *81*, 939 (1969)]

Heptafulvalene, Synthesis of 8-cyano-~ (LA) 531

Heptafulvene, Photo-oxygenation of 8-cyano-~ (SC) 673 [G.E. *81*, 702 (1969)]

Heterolytic fragmentation, Mechanisms and stereochemistry (FP) 535 [G.E. *81*, 543 (1969)]

Heterosesquifulvalenes (FP) 478 [G.E. *81*, 518 (1969)]

Hexachlorobutadiene, Novel reactions (CR) 895 [G.E. *81*, 914 (1969)]

Hexachlorodisilane, Formation of a silylene complex by base catalyzed decomposition of ~ (SC) 878 [G.E. *81*, 897 (1969)]

Hexacyanopalladate(IV), Potassium ~ (SC) 600 [G.E. *81*, 575 (1969)]

trans-1,3-Hexadien-5-yne, Preparation of benzene by pyrolysis of cis- and ~ (SC) 680 [G.E. *81*, 704 (1969)]

Hexafluorobenzene, Adsorption on graphitized carbon black (LA) 619

Hexakis(trideuteriomethyl)-1,3,5-trisilacyclohexane, a new ^1H–NMR standard for measurements up to 200 °C (SC) 380 [G.E. *81*, 394 (1969)]

Hexaoxadiamantanes (LA) 395

Hyaluronidase, Tissue ~ and healing of wounds (CR) 79 [G.E. *81*, 39 (1969)]

Hydrates, Crystal structures of two acid ~ (SC) 136 [G.E. *81*, 116 (1969)]

Hydration structure and intermolecular interaction in polyelectrolytes (FP) 499 [G.E. *81*, 507 (1969)]

Hydrazide, Rotational isomerism of N^2-methyl-N^2-phenylthioformo-~ (SC) 989 [G.E. *81*, 1050 (1969)]

Hydrazine, Oxidation by molybdenum(VI) (LA) 152

Hydrazones, Intramolecular motions in enamines and ~ (CR) 528 [G.E. *81*, 540 (1969)]

Hydrazyls, Stable triaryl-~ containing no nitro groups as polymerization inhibitors (CR) 917 [G.E. *81*, 937 (1969)

Hydrido complexes and alkyl(aryl)-hydrido complexes of nickel (SC) 519 [G.E. *81*, 534 (1969)]

Hydridophosphinetris(trifluorophosphine)cobalt(I) (SC) 140 [G.E. *81*, 120 (1969)]

Hydrocarbons, Catalytic activity of transition metal compounds in the liquid-phase oxidation of ~ (FP) 97 [G.E. *81*, 91 (1969)]

Fatty acids and ~ from extracts and distillates of bituminous shales (CR) 901 [G.E. *81*, 920 (1969)]

Hydroformylation of unsaturated compounds with carbonyltrialkylphosphine-rhodium catalysts (CR) 897 [G.E. *81*, 916 (1969)]

Hydrogenation, Influence of the central metal on ~ of the porphin system (CR) 893 [G.E. *81*, 912 (1969)]

Hydrogen fluoride, Hexameric ~ (LA) 621

Hydrogen shifts, Aromatic [1,7]- and [1,5]-sigmatropic ~ (LA) 620

Hydrogen sulfide, Malonodithioamide from dimethylaminomalonodinitrile and ~ (SC) 750 [G.E. *81*, 741 (1969)]

α-Hydroxy aldehydes, Synthesis (LA) 462

Hydroxylamine, Reactions of N,N-bis-(trifluoromethyl)-~ (LA) 222

Hydroxymaltol, Intermediates in the formation of γ-Pyrones from hexose derivatives: a simple synthesis of kojic acid and ~ (SC) 978 [G.E. *81*, 998 (1969)]

cis-2-Hydroxy-4-methyl-1,3,2-dioxaphosphorinane-2-thione, Stereospecific synthesis (SC) 511 [G.E. *81*, 495 (1969)]

Hydroxyproline, Studies on the course of chloramine oxidation of ~ (CR) 890 [G.E. *81*, 908 (1969)]

Hypervalent molecules (FP) 54, 131 [G.E. *81*, 68 (1969)]

ILMENITE, New method for the production of titanium compounds having low iron content from ~ (LA) 532

Iminium salts, Reactions with ynamines (SC) 675 [G.E. *81*, 702 (1969)]

Imines, Elemento-organic Amines and ~ (FP) 861 [G.E. *81*, 871 (1969)]

Iminophosphorane, Prototropic system aminophosphine/~ (SC) 614 [G.E. *81*, 572 (1969)]

Immunogenicity, Semisynthetic and synthetic macromolecules in immunochemical research (CR) 388 [G.E. *81*, 338 (1969)]

Inclusion compounds, Preparation of pure 2nd and 3rd phase graphite-iron-(III) chloride inclusion compounds and of graphite-iron(III) bromide inclusion compounds (SC) 382 [G.E. *81*, 333 (1969)]

Indenium tetrachloroaluminate, 1,1,3-Trimethylisopropyl-~ (SC) 281 [G.E. *81*, 292 (1969)]

Indium complexes, Tris(trimethylsilyl)-indium (SC) 140 [G.E. *81*, 122 (1969)]

Trichlorobis(triphenylphosphine)indium (LA) 621

Indium compounds, Cleavage of aluminum-, gallium-, and indium-carbon bonds with SO_2, CO_2, COS, and CS_2 (CR) 927 [G.E. *81*, 947 (1969)]

Indole, Solvent effects in the fluorescence and phosphorescence of ~ (LA) 779

Inorganic chemistry, Physical methods in advanced ~ (Book Review) 399

~ (Book Review) 533

Inosatriamines, New route to ~ and triamino sugars (SC) 211 [G.E. *81*, 221 (1969)]

Inversion, NMR studies on rotation and ~ at double bonds (CR) 905 [G.E. *81*, 924 (1969)]

Invertomers, Separation of ~ (diastereoisomers) of diaziridines (SC) 212 [G.E. *81*, 224 (1969)]

Iodine, Independent yields of ~ isotopes in low energy fission reactions (CR) 895 [G.E. *81*, 914 (1969)]

Iodine dioxide trifluoride, Tetrafluoroorthoperiodic acid and ~ (SC) 768 [G.E. *81*, 753 (1969)]

Ion Exchangers, Synthesis and characterization of amphoteric and novel weakly basic ~ with strictly uniform structures (CR) 898 [G.E. *81*, 917 (1969)]

Behavior of neptunium and plutonium in various oxidation states on a cation exchanger (CR) 924 [G.E. *81*, 944 (1969)]

Preparation and investigation of zirconium phosphate exchangers exhibiting separation properties for lanthanides and actinides (CR) 926 [G.E. *81*, 946 (1969)]

Quantitative separation of several fission products with ~ (CR) 927 [G.E. *81*, 945 (1969)]

n-Ionization potential, Determination of the ~ of 2-trimethylsilylpyridine by photoelectron spectroscopy (SC) 524 [G.E. *81*, 537 (1969)]

Iridium compounds, Existence of RuC, IrC, and PtB (LA) 151

Iron compounds, Preparation of pure 2nd and 3rd phase graphite-iron(III) chloride inclusion compounds and of graphite-iron(III) bromide inclusion compounds (SC) 382 [G.E. *81*, 333 (1969)]

Stable salts containing the unusual anions $[Fe(CN)_5NO]^{3-}$ and $[Fe(CN)_5NOH]^{2-}$ (SC) 383 [G.E. *81*, 399 (1969)]

Magnetic non-equivalence of methylene protons and gem-methyl groups in asymmetric iron complexes (SC) 616 [G.E. 570 (1969)]

Radiochemical investigation of the coordination state of iron in the dinuclear iron(III)-1,10-phenanthroline complex ion (SC) 767 [G.E. *81*, 788 (1969)]

Crystal structure of bis(tricarbonyl-2-methyl-3-chloronitrosobenzeneiron) (SC) 879 [G.E. *81*, 898 (1969)]

Structure of the reaction product of $Fe[(CN)_5NO]^{2-}$ with S^{2-} ions (CR) 890 [G.E. *81*, 909 (1969)]

Photochemical and thermal reactions of carbonyliron compounds with halogenoalkanes and halogenoalkenes (CR) 899 [G.E. *81*, 918 (1969)]

NMR-spectroscopic studies on olefin-tricarbonyliron complexes (CR) 900 [G.E. *81*, 919 (1969)]

Ring expansion in organo -~ (LA) 84

Molecular geometry of tricarbonylcyclobutadieneiron (LA) 532

Iron(III)oxide, Solid-state reaction with zinc oxide (LA) 290

Iron(II) sulfate, Application of the Mössbauer effect to investigation of the solid state reaction of ~ with potassium cyanide (SC) 600 [G.E. *81*, 627 (1969)]

IR spectroscopy, IR and Raman spectroscopic studies on the structure of TlF (CR) 920 [G.E. *81*, 939 (1969)]

Isocyanates, Phosphorus ~ (FP) 421 [G.E. *81*, 407 (1969)]

Thermal rearrangement of phenylazomethyl ~ (SC) 456 [G.E. 81, 469 (1969)]

Rearrangement of N-halogeno-β-lactams – A simple synthesis of β-bromoalkyl ~ (CR) 904 [G.E. *81*, 923 (1969)]

Isocyanide dihalides, Reactions of ~ and their derivatives (FP) 20 [G.E. *81*, 18 (1969)]

Isocyanoacetic esters, α-(Formylamino)-acrylic esters from α-metalated ~ and carbonyl compounds (SC) 672 [G.E. *81*, 701 (1969)]

Isoindenones, Reactivity of 1,3-dihalogeno-~ (SC) 606 [G.E. *81*, 623 (1969)]

Isothiazoles, Synthesis of substituted ~ from isoxazoles (LA) 393

Isothiocyanates, Direct conversion of aromatic nitro compounds into ~ (SC) 760 [G.E. *81*, 782 (1969)]

Main and secondary reactions between alkylidenetriphenylphosphoranes and ~ (SC) 762 [G.E. *81*, 750 (1969)]

Isotope distribution, Determination of the ~ in labeled compounds (Book Review) 466

Isotope effects, Vapor pressure ~ (FP) 689 [G.E. *81*, 770 (1969)]

Isoxazoles, Synthesis of substituted isothiazoles from ~ (LA) 393

Isoxazol-4-ine derivatives (LA) 393

JUVENILE hormone, Synthesis of the (±) ~ of the giant silkworm moth Hyalophora cecropia L. (SC) 271 [G.E. *81*, 258 (1969)]

KETENES, Cycloadditions to ynamines (SC) 72 [G.E. *81*, 33 (1969)]

Ketene O,N-acetals, Formation of amides by Claisen rearrangement of ~; stereochemistry (CR) 926 [G.E. *81*, 945 (1969)]

Ketones, Are β-di-~-metal complexes aromatic? (SC) 147 [G.E. *81*, 150 (1969)]

Photochemical conversion of unsaturated 1,2-di-~ into cyclic compounds (LA) 776

Kinetics, Azomethine ylides from aziridinedicarboxylic esters: ~ of the cis-trans isomerization and of the ring opening (SC) 602 [G.E. *81*, 619 (1969)]

~ of some reactions of difluorocarbene (LA) 776

Kojic acid, Intermediates in the formation of γ-pyrones from hexose derivatives: a simple synthesis of ~ and hydroxymaltol (SC) 978 [G.E. *81*, 998 (1969)]

LACTAMS, Mechanism of formation and isomerization of β-~ (CR) 896 [G.E. *81*, 915 (1969)]

Rearrangement of N-halogeno-β-~ – a simple synthesis of β-bromoalkyl isocyanates (CR) 904 [G.E. *81*, 923 (1969)]

New rearrangement of β-~ (LA) 220

Rate of association of ~ (LA) 776

Lactim, Preparation and properties of β-~ (CR) 892 [G.E. *81*, 911 (1969)]

β-Lactone, New synthesis (LA) 531

D-Lactose, Breakdown of sugars during ripening of Camembert: Enzymatic determination of ~, D-glucose, and D-galactose (CR) 891 [G.E. *81*, 910 (1969)]

Lanthanide complexes, 2,4,6-tri-α-pyridyl-1,3,5-triazine (LA) 462

Lanthanides, Preparation and investigation of zirconium phosphate exchangers exhibiting separation properties for ~ and actinides (CR) 926 [G.E. *81*, 946 (1969)]

Lasers, Chemical ~: Physicochemical and technological possibilities (CR) 906 [G.E. *81*, 925 (1969)]

Lattice defects, Investigation of ~ from the diffusion behavior of argon in neutron-irradiated potassium chloride (CR) 915 [G.E. *81*, 934 (1969)]

Lead compounds, Determination of copper, lead, and cadmium in different concentration ratios by various voltammetric methods (CR) 910 [G.E. *81*, 929 (1969)]

Inverse-voltammetric determination of tin and lead in the presence of each other (CR) 929 [G.E. *81*, 950 (1969)]

Lewis acids, Stable organic ~ (CR) 461 [G.E. *81*, 469 (1969)]

Lichen substances, Biosynthesis (FP) 240 [G.E. *81*, 233 (1969)]

Ligands, New sulfur-containing macrocyclic hexadentate ~ (LA) 152

Liquid crystals, A liquid-crystalline (nematic) phase with a particularly low solidification point (SC) 884 [G.E. *81*, 903 (1969)]

Liquids, Physics of ~ (CR) 681 [G.E. *81*, 710 (1969)]

Variation of the dielectric properties of weakly polar ~ (LA) 530

2-Lithio-1,3-dithianes, 1,4-addition of ~ to substituted ω-nitrostyrenes (SC) 983 [G.E. *81*, 1047 (1969)]

Lithium compounds, Association of bis(trimethylsilyl)amidolithium and methyl(trimethylsilanolato)beryllium in the solid state (SC) 378 [G.E. *81*, 398 (1969)]

Mono-, bis-, and tris(phenylseleno)methyllithium (selenium-stabilized carbanions) (SC) 450 [G.E. *81*, 465 (1969)]

Reactions of organo-~ with sterically hindered quinones, quinols, and quinonemethides (CR) 918 [G.E. *81*, 938 (1969)]

Lithium superoxide (LA) 777

Lone Pairs, Interaction between the ~ in azomethane (SC) 878 [G.E. *81*, 897 (1969)]

Luminescence, New ~ experiments on azulene (LA) 994

Photoluminescence of solutions (Book Review) 996

Luciferin, New synthesis (LA) 531

Lysergamide, LSD interacts with calf thymus DNA (LA) 684

Lysozymes (FP) 227 [G.E. *81*, 224 (1969)]

MACROMOLECULAR chemistry, Reviews (Book Review) 225

Macromolecular colloquium (CR) 384 [G.E. *81*, 334 (1969)]

Macro-zwitterions, Formation in ionic polymerizations (CR) 386 [G.E. *81*, 336 (1969)]

Magnesium compounds, New method for the preparation of organo-~ of pyridine (SC) 279 [G.E. *81*, 293 (1969)]

Magnesium oxide, Surface species formed on adsorption of methanol and ethanol vapor on ~ (LA) 152

Increase in the catalytic activity of ~ powder (LA) 395

Magnetic properties of trinuclear complexes of quadridentate Schiff bases (LA) 152

Magnetic structure, Crystal structure analysis by neutron diffraction II (FP) 950 [G.E. *81*, 984 (1969)]

Malaria, Metabolic transformation of antimalarial drugs as a basis for the development of new active substances (CR) 285 [G.E. *81*, 295 (1969)]

Maleimides, Intramolecular photocycloaddition of N,N'-alkylenedi-~ (SC) 213 [G.E. *81*, 224 (1969)]

Novel pigments from dichloro-~ (SC) 751 [G.E. *81*, 742 (1969)]

Malonodinitrile, Malonodithioamide from dimethylamino-~ and hydrogen sulfide (SC) 750 [G.E. *81*, 741 (1969)]

Malonodithioamide from dimethylaminomalonodinitrile and hydrogen sulfide (SC) 750 [G.E. *81*, 741 (1969)]

Manganese compounds, Optical activity at an asymmetrical manganese atom (SC) 382 [G.E. *81*, 395 (1969)]

Marine chemistry (Book Review) 534

Mass spectrometry, Determination of the structures of organic molecules and quantitative analyses with the field ionization mass spectrometer (FP) 623 [G.E. *81*, 662 (1969)]

Investigation of poly-S-phenyl-S'-vinylmethylenedisulfones (CR) 895 [G.E. *81*, 914 (1969)]

Mass transport, Simultaneous heat and ~ with wall reactions (CR) 220 [G.E. *81*, 230 (1969)]

Melts, Raman spectra (LA) 618

Membranes, Transport phenomena in ~ (FP) 42 [G.E. *81*, 56 (1969)]

Transport of double- and triple-stranded ribopolynucleotides through cellular ~ (CR) 80 [G.E. *81*, 41 (1969)]

Chemical and enzymic reactions on the ~ of Ehrlich ascites tumor cells and their consequences for metabolism and permeability (CR) 81 [G.E. *81*, 38 (1969)]

Mercury compounds, Bis(sulfinylamido)-mercury(II) (SC) 376 [G.E. *81*, 330 (1969)]

Preparation of the compounds R_3El-Hg-ElR_3 (El = C, Si, Ge, Sn) and their synthetic applications (SC) 611 [G.E. *81*, 625 (1969)]

Crystal structure of methyltrimethylsiloxomercury (SC) 679 [G.E. *81*, 707 (1969)]

Merrifield polypeptide synthesis, 3-Nitrophthalic anhydride as blocking agent in the ~ (SC) 764 [G.E. *81*, 782 (1969)]

Mesoionic systems, Mesoionic 3-methylene-1,2,4-triazoles (SC) 133 [G.E. *81*, 115 (1969)]

Metalates, Preparation and structural chemistry of mixed oxo-thio-seleno ~ (CR) 914 [G.E. *81*, 934 (1969)]

Metal-metal bonds, Planar complexes containing ~ (FP) 35 [G.E. *81*, 10 (1969)]

Metals, Electrocrystallization under ideal and real conditions (FP) 108 [G.E. *81*, 101 (1969)]

Methacrylate, Solution properties of random copolymers of methyl ~ and n-butyl acrylate (CR) 390 [G.E. *81*, 340 (1969)]

Methallyl chloride, Methylenecyclopropane from ~ (SC) 205 [G.E. *81*, 186 (1969)]

Methane, Fast separation of fission halogens by recoil reaction with ~ (CR) 907 [G.E. *81*, 926 (1969)]

Preparation of synthetic graphite by low-temperature pyrolysis of ~ (LA) 684

Methanol, Surface species formed on adsorption of ~ and ethanol vapor on magnesium oxide (LA) 152

Methoxycarbene, Formation (LA) 532

2-Methylazaferrocene, Optically active ~ (SC) 135 [G.E. *81*, 150 (1969)]

Methylcyclopropane, Microwave spectrum (LA) 83

trans-2-Methylcyclopropanol from 1-methylcyclopropene (SC) 205 [G.E. *81*, 185 (1969)]

1-Methylcyclopropene, trans-2-Methylcyclopropanol from ~ (SC) 205 [G.E. *81*, 185 (1969)]

Methylenecyclopropane from methallyl chloride (SC) 205 [G.E. *81*, 186 (1969)]

Methylene groups, Thermal oxidation of N-vicinal ~ in polyamides (SC) 215 [G.E. *81*, 226 (1969)]

5-Methylenetetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]non-8-ene, Photoisomerization of derivatives (SC) 209 [G.E. *81*, 222 (1969)]

3-Methylene-1,2,4-triazoles, Mesoionic ~ (SC) 133 [G.E. *81*, 115 (1969)]

4-Methyl-1-pentene, Optical activity and conformation in solution of copolymers of optically active α-olefins with styrene and ~ (CR) 387 [G.E. *81*, 337 (1969)]

N-Methyl-1-phenylcyclopropylnitrenium chloride (LA) 620

Methyl radicals, Reactions of ~ (LA) 931

α-Methylstyrene, Dimerization products in H_2SO_4 (LA) 153

6-Methylthio-8-azapurines, Hydrolysis of ~ to thiol esters of 1,2,3-triazole-carboxylic acids (SC) 132 [G.E. *81*, 115 (1969)]

Methyltrimethylsiloxomercury, Crystal structure (SC) 679 [G.E. *81*, 707 (1969)]

Microseparation of phases in swollen gels and its investigation by light scattering (CR) 389 [G.E. *81*, 339 (1969)]

Microwave spectrum of methylcyclopropane (LA) 83

Mitochondria, Biogenesis of ~; pathway of the synthesis of mitochondrial phospholipids (CR) 79 [G.E. *81*, 40 (1969)]

Mixed-function oxygenases, Studies on the mechanism of ~ (CR) 219 [G.E. *81*, 229 (1969)]

Molecular biology (Book Review) 292

Molecular models, Framework ~ (Book Review) 293

Molecular orbital theories of bonding in organic molecules (Book Review) 225

Molecular spectra, Theory of ~ (Book Review) 396

Molecular weight distribution in synthetic resins (CR) 906 [G.E. *81*, 925 (1969)]

Molybdenum Complexes, Titanium-~ with chalcogen bridging ligands (SC) 980 [G.E. *81*, 1000 (1969)]

Molybdenum compounds, Tetracarbonyldiphosphanemolybdenum(0) (SC) 372 [G.E. *81*, 330 (1969)]

Dibenzo[a,e]cyclooctene complexes of chromium and molybdenum (SC) 374 [G.E. *81*, 331 (1969)]

Tetrasulfide chelate of molybdenum (SC) 375 [G.E. *81*, 332 (1969)]

Hexapotassium μ-thiobis(hexacyanomolybdate(IV)) (SC) 753 [G.E. *81*, 752 (1969)]

Oxidation kinetics of $NbSi_2$ and $MoSi_2$ at high temperatures (CR) 913 [G.E. *81*, 932 (1969)]

Energy and isotope dependence of the chemical behavior of molybdenum recoil atoms in hexacarbonylmetal compounds following nuclear reactions (CR) 929 [G.E. *81*, 949 (1969)]

Oxidation of hydrazine by molybdenum(VI) (LA) 152

Molybdenum nitride trichloride, Crystal structure of $MoNCl_3$ (CR) 925 [G.E. *81*, 945 (1969)]

Monoperoxosulfate, Bis(trimethylsilyl)-~ (SC) 450 [G.E. *81*, 430 (1969)]

Mössbauer effect, Application of the ~ to investigation of the solid state reaction of iron(II) sulfate with potassium cyanide (SC) 600 [G.E. *81*, 627 (1969)]

Mutations, Hereditary DNA alterations (FP) 12 [G.E. *81*, 1 (1969)]

NATURAL PHILOSOPHY, Introduction to ~ (Book Review) 224

Nematic crystals, A liquid-crystalline (nematic) phase with a particularly low solidification point (SC) 884 [G.E. *81*, 903 (1969)]

Neptunium compounds, Phthalocyanine and perfluorophthalocyanine complexes of thorium, protactinium, uranium, and neptunium (CR) 894 [G.E. *81*, 913 (1969)]

Behavior of neptunium and plutonium in various oxidation states on a cation exchanger (CR) 924 [G.E. *81*, 944 (1969)]

Neurons, Transmitter mechanisms in isolated ~ (CR) 287 [G.E. *81*, 291 (1969)]

Neurosciences (Book Review) 86

Neutron activation analysis, Quantitative determination of impurities in boron carbide (CR) 900 [G.E. *81*, 919 (1969)]

~ of boron and some elements of the rare earths by means of prompt neutron capture radiation (CR) 902 [G.E. *81*, 921 (1969)]

Determination of trace elements in plastics by neutron activation and gamma spectrometry (CR) 924 [G.E. *81*, 943 (1969)]

Neutron diffraction, Crystal structure analysis by ~ I (FP) 356 [G.E. *81*, 307 (1969)]

Crystal structure analysis by ~ II (FP) 950 [G.E. *81*, 984 (1969)]

Nickel compounds, $Ni_5(C_5H_5)_4S_4$, a pentanuclear metal complex containing a square-planar nickel(0) atom (SC) 144 [G.E. *81*, 152 (1969)]

Hydrido and alkyl(aryl)hydrido complexes of nickel (SC) 519 [G.E. *81*, 534 (1969)]

Bis(pentadienyl)dinickel (SC) 677 [G.E. *81*, 708 (1969)]

Crystal structure of bis(pentadienyl)dinickel (SC) 678 [G.E. *81*, 708 (1969)]

Complexing behavior of stannanide ions: tetrakis(trichlorostannanido)niccolate(0) (SC) 679 [G.E. *81*, 704 (1969)]

Niobium compounds, Adsorption of protactinium, zirconium and niobium on silica gels and Vycor glass from solutions in hydrochloric acid (CR) 908 [G.E. *81*, 928 (1969)]

Oxidation kinetics of $NbSi_2$ and $MoSi_2$ at high temperatures (CR) 913 [G.E. *81*, 932 (1969)]

Nitramide, Mechanism of the anionic catalysis of the decomposition of ~ (CR) 921 [G.E. *81*, 941 (1969)]

α-Nitration, Base-induced ~ of sulfonamides (LA) 290

Nitrenium chloride, N-Methyl-1-phenylcyclopropyl-~ (LA) 620

Nitriles, Preparation of cyclic amidines by reduction of di-~ with $LiAlH_4$ (SC) 457 [G.E. *81*, 431 (1969)]

Complex formation between unsaturated ~ and carbonylmetal compounds (CR) 902 [G.E. *81*, 921 (1969)]

Polymers from tetracyano compounds (CR) 928 [G.E. *81*, 949 (1969)]

New analytical method for the quantitative determination of tertiary ~ (LA) 684

Nitroacetylenes (SC) 273 [G.E. *81*, 259 (1969)]

3-Nitro-2-azachromone (4H-1,2-Benzoxazin-4-one): structure of the presumed p-nitrophenylnitroacetylene (SC) 979 [G.E. *81*, 999 (1969)]

Nitro compounds, Reactions of aromatic ~ with bases (FP) 120 [G.E. *81*, 136 (1969)]

Direct conversion of aromatic ~ into isothiocyanates (SC) 760 [G.E. *81*, 782 (1969)]

α-Nitro epoxides, Nitrooxiranes (LA) 463

Nitrogen, Non-enzymatic activation of molecular ~ (FP) 650 [G.E. *81*, 679 (1969)]

Salt-like organic complex containing molecular ~ (SC) 203 [G.E. *81*, 183 (1969)]

Nitrogen compounds, Separation of invertomers (diastereoisomers) of diaziridines. Slow inversion at tervalent nitrogen atoms (SC) 212 [G.E. *81*, 224 (1969)]

Oligomeric and polymeric phosphorus ~ (CR) 617 [G.E. *81*, 578 (1969)]

Nitrogen monoxide, ESR spectrum (LA) 532

Nitromethane, New rearrangements during the reaction of pyrylium salts with ~ (SC) 370 [G.E. *81*, 392 (1969)]

Nitrooxiranes (LA) 463

3-Nitrophthalic anhydride as blocking agent in Merrifield polypeptide synthesis (SC) 764 [G.E. *81*, 782 (1969)]

p-Nitrophenylnitroacetylene, 4H-1,2-benzoxazin-4-one: structure of the presumed ~ (SC) 979 [G.E. *81*, 999 (1969)]

ω-Nitrostyrenes, 1,4-Addition of 2-lithio-1,3-dithiane to substituted ~ (SC) 983 [G.E. *81*, 1047 (1969)]

Nitrous oxide, Catalytic reduction by dinitridohydridotris(triphenylphosphine)cobalt (LA) 394

NMR spectroscopy, Temperature dependence of the NMR spectrum of a soluble Ziegler-Natta catalyst (SC) 217 [G.E. *81*, 228 (1969)]

"Cyclosilane-d_{18}", a new ^1H-NMR standard for measurements up to 200 °C (SC) 380 [G.E. *81*, 394 (1969)]

Sodium 3-trimethylsilyltetradeuteriopropionate, a new water-soluble standard for ^1H- ~ (SC) 381 [G.E. *81*, 395 (1969)]

Magnetic non-equivalence of methylene protons and gem-methyl groups in asymmetric iron complexes (SC) 616 [G.E. *81*, 570 (1969)]

Proton magnetic resonance studies on polysaccharide derivatives (SC) 766 [G.E. *81*, 791 (1969)]

Investigation of binding of inhibitors to ribonuclease by ~ (CR) 392 [G.E. *81*, 402 (1969)]

Scope of NMR studies on paramagnetic compounds (CR) 460 [G.E. *81*, 433 (1969)]

Investigation of complex formation in extraction of uranium and plutonium with organophosphorus compounds (CR) 889 [G.E. *81*, 908 (1969)]

Studies on olefintricarbonyliron complexes (CR) 900 [G.E. *81*, 919 (1969)]

Studies on rotation and inversion at double bonds (CR) 905 [G.E. *81*, 924 (1969)]

^{19}F-NMR spectra of 3-substituted 2-chloro-1,1,2-trifluorocyclobutanes (LA) 530

Nobel lectures, Physiology or medicine 1901–1921 (Book Review) 154

Nomenclature, Names and structures of organic compounds (Book Review) 155

~ of organic chemistry 994 (Book Review)

Nonafulvene, 10,10-Bis(dimethylamino)-~ (SC) 593 [G.E. *81*, 564 (1969)]

Norbornenes, Photocyclization of 5-acyl-~ (LA) 289

Norcaradiene, Spiro derivative (SC) 76 [G.E. *81*, 83 (1969)]

Stable spiro-~ (SC) 76 [G.E. *81*, 83 (1969)]

Nuclear fuels, Purification of contaminated exhaust gases in the combustion of irradiated HTGR graphite ~ (CR) 910 [G.E. *81*, 929 (1969)]

Separation of rare earths from ceramic ~ (LA) 85

Nuclear quadrupole resonance, Calculation of the "optical electronegativity" of transition metal ions from ~ coupling constants (SC) 137 [G.E. *81*, 117 (1969)]

Nucleic acids, Hereditary DNA alterations (FP) 12 [G.E. *81*, 1 (1969)]

Chemical investigations of the molecular origin of biological radiation damage (FP) 578 [G.E. *81*, 581 (1969)]

Transfer ribonucleic acids (FP) 711 [G.E. *81*, 645 (1969)]

Synthesis of Hall's methyl 2-thiouridine-5-acetate from yeast-tRNA (SC) 977 [G.E. *81*, 998 (1969)]

Transport of double- and triple-stranded ribopolynucleotides through cellular membranes (CR) 80 [G.E. *81*, 41 (1969)]

Synthesis of coding polynucleotides with repeating base sequences (CR) 387 [G.E. *81*, 336 (1969)]

Characterization of tRNA and of aminoacyl-tRNA synthetase (LA) 291

Repression of RNA synthesis by actinomycin D is reversible (LA) 463

Nucleophilic acylation, Methods and possibilities (FP) 639 [G.E. *81*, 690 (1969)]

Nucleophilic substitutions with pyrimidine nucleoside N^3 sodium salts (SC) 609 [G.E. *81*, 576 (1969)]

Nucleosides, Nucleophilic substitutions with pyrimidine nucleoside N^3 sodium salts (SC) 609 [G.E. *81*, 576 (1969)]

Simple new synthesis of 2-thiopyrimidine ~ (SC) 976 [G.E. *81*, 997 (1969)]

Synthesis of Hall's methyl 2-thiouridine-5-acetate from yeast-tRNA (SC) 977 [G.E. *81*, 998 (1969)]

Nucleotides, New method for the dephosphorylation of ribonucleoside 2'- or 3'-phosphates (LA) 531

OCTAZETHRENE, Dibenzo[lm,yz]-hexacene (LA) 462

Oils, Analysis of mineral ~ and synthetic ~ by radiometric methods (Book Review) 533

Olefins, Photochemical ~-oxirane cyclodimerization (SC) 276 [G.E. *81*, 289 (1969)]

Oxidative dimerization of ~ (SC) 518 [G.E. *81*, 532 (1969)]

Catalytic oxidation of ~ via an allyl radical (SC) 601 [G.E. *81*, 571 (1969)]

New ~ reactions (CR) 148 [G.E. *81*, 155 (1969)]

NMR studies on rotation and inversion at double bonds (CR) 905 [G.E. *81*, 924 (1969)]

Oxidative addition of organic anions to ~ – Oxidative dimerization of ~ (CR) 921 [G.E. *81*, 940 (1969)]

New synthesis of alkenes from vic-dicarboxylic acids (LA) 290

Selective, stereospecific insertion of sulfur (LA) 994

Oligomerization, Catalytic mixed ~ of butadiene and alkynes (SC) 753 [G.E. *81*, 744 (1969)]

Optical activity at an asymmetrical manganese atom (SC) 382 [G.E. *81*, 395 (1969)]

~ and conformation in solution of copolymers of optically active α-olefins with styrene and 4-methyl-1-pentene (CR) 387 [G.E. *81*, 337 (1969)]

Phosphorus isocyanates (FP) 421 [G.E. *81*, 407 (1969)]

Phosphorus pentachloride, Action on N-(halogenosulfonyl)urethanes (SC) 136 [G.E. *81*, 119 (1969)]

New products of ammonolysis of ~ (SC) 615 [G.E. *81*, 573 (1969)]

Phosphorus pentoxide, Reaction between ~ and silicon nitrides (CR) 908 [G.E. *81*, 927 (1969)]

Phosphorus ylids, New evidence for a (p→d) π effect at silicon (SC) 372 [G.E. *81*, 329 (1969)]

Photochemistry, Mechanistic organic ~ (FP) 1 [G.E. *81*, 45 (1969)]

Photochemical [2π + 2σ] cycloadditions in tetracyclo[3.3.2.$0^{2,4}$.$0^{6,8}$]decene systems (SC) 883 [G.E. *81*, 902 (1969)]

Coordination chemistry (CR) 283 [G.E. *81*, 262 (1969)]

~ of thiacycloalkan-3-ones (LA) 221

Photochemical conversion of unsaturated 1,2-diketones into cyclic compounds (LA) 776

Photocurrent, Regularity of the electronic work function (LA) 222

Photocyclization of 5-acylnorbornenes (LA) 289

Photocycloaddition, Intramolecular ~ of N,N′-alkylenedimaleimides (SC) 213 [G.E. *81*, 224 (1969)]

Photoelectron spectroscopy, Determination of the n-ionization potential of 2-trimethylsilylpyridine by ~ (SC) 524 [G.E. *81*, 537 (1969)]

Photography, Investigation of superadditivity in photographic development by current-voltage curves at a silver electrode (SC) 281 [G.E. *81*, 293 (1969)]

Principles of photographic processes involving silver halides (Book Review) 685

Photoisomerization of derivatives of 5-methylenetetracyclo[4.3.0.$0^{2,4}$.$0^{3,7}$]non-8-ene (SC) 209 [G.E. *81*, 222 (1969)]

Photoluminescence of solutions (Book Review) 996

Photolysis, Formation of 1,2-dimethylcyclobutadiene on ~ of dimethylcyclobutenedicarboxylic anhydride (SC) 132 [G.E. *81*, 114 (1969)]

Formation of benzindenes on ~ of phenyl-substituted diazocyclopentadienes in alkynes (SC) 446 [G.E. *81*, 426 (1969)]

~ of cis,cis-1,3-cyclooctadiene (LA) 462

~ of gaseous bromotrichloromethane (LA) 463

Photo-oxygenation of 8-cyanoheptafulvene (SC) 673 [G.E. *81*, 702 (1969)]

Photoreactions of 5-phenylpyrazolines (LA) 85

Phthalocyanine, and perfluorophthalocyanine complexes of thorium, protactinium, uranium, and neptunium (CR) 894 [G.E. *81*, 913 (1969)]

Position of the inner H atoms in ~ (LA) 620

Physical chemistry, Textbook of ~ (Book Review) 997

Physical methods in advanced inorganic chemistry (Book Review) 399

Pigments, Novel ~ from dichloromaleimides (SC) 751 [G.E. *81*, 742 (1969)]

Pigment surfaces, Polymerizations on ~ (CR) 908 [G.E. *81*, 926 (1969)]

Plasma jets, Calorimetric temperature measurements in ~ (CR) 916 [G.E. *81*, 936 (1969)]

Plastics, Determination of trace elements in ~ by neutron activation and gamma spectrometry (CR) 924 [G.E. *81*, 943 (1969)]

The chemistry of ~ (Book Review) 466

Plastics handbook (Book Review) 468, 994

Platinum(III) bromide – a new structural type of AB_3 compounds (SC) 672 [G.E. *81*, 706 (1969)]

Platinum compounds, Planar complexes containing metal-metal bonds (FP) 35 [G.E. *81*, 10 (1969)]

Existence of RuC, IrC, and PtB (LA) 151

Reaction of bis(triphenylphosphine)-oxygenplatinum(0) (LA) 152

Plumbyl compounds, Organogermyl, Organostannyl, and organoplumbyl phosphines, arsines, stibines, and bismuthines (FP) 937 [G.E. *81*, 970 (1969)]

Plutonium, Heptavalent ~ (SC) 279 [G.E. *81*, 294 (1969)]

Preparation of ~- 238 from americium 241 (CR) 913 [G.E. *81*, 933 (1969)]

Plutonium compounds, NMR spectroscopic investigation of complex formation in extraction of uranium and plutonium with organophosphorus compounds (CR) 889 [G.E. *81*, 908 (1969)]

Behavior of neptunium and plutonium in various oxidation states on a cation exchanger (CR) 924 [G.E. *81*, 944 (1969)]

Plutonium dioxide, Studies on ~ by chemical analysis (CR) 913 [G.E. *81*, 932 (1969)]

Plutonium handbook – a guide to the technology (Book Review) 155

Polarography, Radio frequency polarographic studies on semiconductors and reactor materilas (CR) 929 [G.E. *81*, 949 (1969)]

Polarographic behavior of cinnamaldehyde (LA) 777

Polyamides, Thermal oxidation of N-vicinal methylene groups in ~, a reaction dependent on conformation (SC) 215 [G.E. *81*, 226 (1969)]

Polar super-~ (CR) 384 [G.E. *81*, 334 (1969)]

Redox ~ (LA) 777

Polybenzoxazinediones, a class of heat-resistant polymers (CR) 892 [G.E. *81*, 911 (1969)]

Polyelectrolytes, Hydration structure and intermolecular interaction in ~ (FP) 499 [G.E. *81*, 507 (1969)]

Polyethylene, Polymerization of ethylene with methyltitanium trichloride and methyltitanium dichloride (CR) 387 [G.E. *81*, 337 (1969)]

Structural investigations on semicrystalline ~ and ethylene-propylene copolymers (CR) 390 [G.E. *81*, 340 (1969)]

The phase behavior of ethylene-~ mixtures (under the conditions used in the industrial high pressure synthesis of ~) (CR) 924 [G.E. *81*, 944 (1969)]

Polyethylene glycol for fractionation and crystallization of L-asparaginase (SC) 885 [G.E. *81*, 904 (1969)]

Polymerizations, Formation of macrozwitterions in ionic ~ (CR) 386 [G.E. *81*, 336 (1969)]

Recent results on the kinetics of anionic ~ (CR) 389 [G.E. *81*, 339 (1969)]

~ on pigment surfaces (CR) 908 [G.E. *81*, 927 (1969)]

Polymerization inhibitors, Stable triarylhydrazyls containing no nitro groups as ~ (CR) 917 [G.E. *81*, 937 (1969)]

Polymers, Determination of the compatibility of ~ in solution (CR) 384 [G.E. *81*, 334 (1969)]

Temperature dependence of the thermal conductivity of amorphous high ~ (CR) 385 [G.E. *81*, 335 (1969)]

Stimulation of crystallization of ~ by nucleating agents of high molecular weight (CR) 386 [G.E. *81*, 335 (1969)]

Optical activity and conformation in solution of copolymers of optically active α-olefins with styrene and 4-methyl-1-pentene (CR) 387 [G.E. *81*, 337 (1969)]

Interpretation of coils and structure in the aggregated polymer state (CR) 389 [G.E. *81*, 339 (1969)]

Polybenzoxazinediones, a class of heat-resistant ~ (CR) 892 [G.E. *81*, 911 (1969)]

Molecular weight distribution in synthetic resins (CR) 906 [G.E. *81*, 925 (1969)]

Preparation and electrical properties of ~ with conjugated polyene structures containing aromatic, substituted aromatic, or thiophene rings (CR) 906 [G.E. *81*, 925 (1969)]

Structure and conductivity of organic ~ (CR) 915 [G.E. *81*, 935 (1969)]

Dependence of the stress birefringence of rubber-elastic substances on temperature and degree of swelling (CR) 923 [G.E. *81*, 942 (1969)]

~ from tetracyano compounds (CR) 928 [G.E. *81*, 949 (1969)]

Polyolefins, Plastics handbook, Vol. 4: ~ (Book Review) 994

Polyoxymethylenes (CR) 528 [G.E. *81*, 502 (1969)]

Polypeptide synthesis, 3-Nitrophthalic anhydride as blocking agent in Merrifield ~ (SC) 764 [G.E. *81*, 782 (1969)]

Poly(phenylene oxide), New synthesis of a linear ~ (SC) 379 [G.E. *81*, 400 (1969)]

Polysaccharides, Proton magnetic resonance studies on ~ derivatives (SC) 766 [G.E. *81*, 791 (1969)]

ORD and CD measurements on substituted ~ (CR) 386 [G.E. *81*, 336 (1969)]

Polystyrene, ESR studies on the mechanism of the radiolysis of ~ (CR) 928 [G.E. *81*, 948 (1969)]

Polytetrafluoroethylene, Radiation damage in oriented ~ caused by a pulsed electron beam (LA) 618

Porphin, Influence of the central metal on hydrogenation of the ~-system (CR) 893 [G.E. *81*, 912 (1969)]

Potassium chloride, Investigation of lattice defects from the diffusion behavior of argon in neutron-irradiated ~ (CR) 915 [G.E. *81*, 934 (1969)]

Potassium cyanide, Application of the Mössbauer effect to investigation of the solid state reaction of iron(II) sulfate with ~ (SC) 600 [G.E. *81*, 627 (1969)]

Potassium 2-germaacetate (LA) 222

Potassium hexacyanopalladate(IV) (SC) 600 [G.E. *81*, 575 (1969)]

Potassium nitrosobissulfate as specific oxidizing agent in organic chemistry (CR) 218 [G.E. *81*, 190 (1969)]

Precipitation reactions (FP) 188 [G.E. *81*, 206 (1969)]

Preparative methods, Standard methods of practical chemistry (Book Review) 154

L-Proline, Helix formation in oligopeptides of ~ (CR) 919 [G.E. *81*, 939 (1969)]

Propellane diones, One-step synthesis of pentalane and propellane ketones (LA) 84

Propylene oxide, Addition of mixed epoxides in the high pressure range (CR) 924 [G.E. *81*, 944 (1969)]

Protactinium compounds, Tetrakis(cyclopentadienyl)protactinium(IV) (SC) 202 [G.E. *81*, 182 (1969)]

Phthalocyanine and perfluorophthalocyanine complexes of thorium, protactinium, uranium, and neptunium (CR) 894 [G.E. *81*, 913 (1969)]

Adsorption of protactinium, zirconium, and niobium on silica gels and Vycor glass from solutions in hydrochloric acid (CR) 908 [G.E. *81*, 928 (1969)]

Protease inhibitors, Isolation with water-insoluble enzyme resins (LA) 291

Proteins, Analytical methods for the investigation of amino acids, peptides, and ~ (Book Review) 621

Psychotropic compounds, Recent investigations of ~ (CR) 775 [G.E. *81*, 753 (1969)]

Pteridine, New ~→purine transformation (SC) 608 [G.E. *81*, 624 (1969)]

Pulse radiolysis at high pressure (SC) 512 [G.E. *81*, 496 (1969)]

Purine, Structure of the ~ precursor in riboflavin biosynthesis (SC) 371 [G.E. *81*, 393 (1969)]

New pteridine→~ transformation (SC) 608 [G.E. *81*, 624 (1969)]

Pyridines, Aromatic and heterocyclic 3,4-disubstituted ~ (SC) 74 [G.E. *81*, 85 (1969)]

New method for the preparation of organomagnesium compounds of ~ (SC) 279 [G.E. *81*, 293 (1969)]

Determination of the n-ionization potential of 2-trimethylsilyl-~ by photoelectron spectroscopy (SC) 524 [G.E. *81*, 537 (1969)]

Single-step synthesis of ~ from 3-aminoacrolein and carbonyl compounds (SC) 765 [G.E. *81*, 785 (1969)]

N,N-Dimethyl-4-pyridinamine, a very effective acylation catalyst (SC) 981 [G.E. *81*, 1001 (1969)]

n-(2,5)-Pyridinophanes (LA) 221

Pyrimidine, Chemical investigations of the molecular origin of biological radiation damage (FP) 578 [G.E. *81*, 581 (1969)]

Nucleophilic substitutions with ~ nucleoside N^3 sodium salts (SC) 609 [G.E. *81*, 576 (1969)]

Pyrimidine nucleosides, A simple new synthesis of 2-thio-~ (SC) 976 [G.E. *81*, 997 (1969)]

Pyrimido[4,5-d]pyrimidine, Synthesis (SC) 383 [G.E. *81*, 396 (1969)]

γ-Pyrones, Intermediates in the formation of ~ from hexose derivatives (SC) 978 [G.E. *81*, 998 (1969)]

Pyrrole, Conformational studies in ~ chemistry (CR) 993 [G.E. *81*, 1006 (1969)]

Pyruvate decarboxylase, Studies on the mode of action, coenzyme binding, and structure of yeast ~ (CR) 82 [G.E. *81*, 87 (1969)]

Pyruvate kinase, Allosteric properties of yeast ~ (CR) 79 [G.E. *81*, 40 (1969)]

Pyrylium salts, New rearrangements during the reaction of ~ with nitromethane (SC) 370 [G.E. *81*, 392 (1969)]

QUANTITATIVE PROBLEMS in the biochemical sciences (Book Review) 996

Quinazolines, New synthesis of amino-~ (SC) 73 [G.E. *81*, 84 (1969)]

Quinols, Reactions of organolithium compounds with sterically hindered quinones, ~, and quinonemethides (CR) 918 [G.E. *81*, 938 (1969)]

Quinones, Reactions of organolithium compounds with sterically hindered ~, quinols, and quinonemethides (CR) 918 [G.E. *81*, 938 (1969)]

Formation of linear polycyclic di-~ (LA) 618

Quinonemethides, Reactions of organolithium compounds with sterically hindered quinones, quinols, and ~ (CR) 918 [G.E. *81*, 938 (1969)]

Quinoxaline di-N-oxide, New syntheses of ~ and phenazine di-N-oxides (SC) 596 [G.E. *81*, 569 (1969)]

[4]RADIALENE, Crystal structure of perchloro-~ (SC) 597 [G.E. *81*, 567 (1969)]

Radiation damage, Chemical investigations of the molecular origin of biological ~ (FP) 578 [G.E. *81*, 581 (1969)]

~ in oriented polytetrafluoroethylene caused by a pulsed electron beam (LA) 618

Radical anions, ESR spectra of ~ of aliphatic azo compounds (SC) 755 [G.E. *81*, 745 (1969)]

ESR spectra of ~ of N-trimethylsilyl derivatives of aniline and p-phenylenediamine (SC) 767 [G.E. *81*, 786 (1969)]

Radical cations, Reversible redox systems with stable ~ (CR) 286 [G.E. *81*, 295 (1969)]

Radicals, Formal di-~ which should have singlet ground states (SC) 214 [G.E. *81*, 225 (1969)]

New free-~ reactions with phosphorins (SC) 770 [G.E. *81*, 784 (1969)]

Fluorinated inorganic ~ (CR) 217 [G.E. *81*, 190 (1969)]

Reactions of organotin ~ (CR) 287 [G.E. *81*, 296 (1969)]

Stable triarylhydrazyls containing no nitro groups as polymerization inhibitors (CR) 917 [G.E. *81*, 937 (1969)]

Reactions of methyl ~ (LA) 931

Advances in free ~ chemistry (Book Review) 85

Radiochemistry, Radiochemical investigation of the coordination state of iron in the dinuclear iron(III)-1,10-phenanthroline complex ion (SC) 767 [G.E. *81*, 788 (1969)]

Investigations on high-energy nuclear reactions of tantalum (CR) 890 [G.E. *81*, 909 (1969)]

Quantitative separation of several fission products with ion exchangers (CR) 927 [G.E. *81*, 945 (1969)]

Fundamentals of ~ and reactor chemistry (Book Review) 396

Radiochemical dictionary of the elements and their isotopes (Book Review) 533

Radiolysis, Scavenger experiments on the mechanism of ~ of ethylbenzene (CR) 903 [G.E. *81*, 922 (1969)]

ESR studies on the mechanism of the ~ of polystyrene (CR) 928 [G.E. *81*, 948 (1969)]

Radionuclides as a source of energy (CR) 892 [G.E. *81*, 911 (1969)]

Optimum irradiation conditions for production of ~ with a cyclotron (CR) 908 [G.E. *81*, 926 (1969)]

Radium, Crystal structure and atomic radius of metallic ~ (LA) 290

Raman spectra of melts (LA) 618

Raman spectroscopy, IR and Raman spectroscopic studies on the structure of TlF (CR) 920 [G.E. *81*, 939 (1969)]

Rare earths, Organometallic sandwich complexes (CR) 774 [G.E. *81*, 754 (1969)]

Separation of ~ from ceramic nuclear fuels (LA) 85

Reactor chemistry, Fundamentals of radiochemistry and ~ (Book Review) 396

Rearrangements, Sigma-pi ~ of organotransition metal compounds (FP) 410 [G.E. *81*, 453 (1969)]

New ~ during the reaction of pyrylium salts with nitromethane (SC) 370 [G. E. *81*, 392 (1969)]

Thermal ~ of phenylazomethyl isocyanates (SC) 456 [G.E. *81*, 469(1969)]

Cyclo-~ of 3,4,5-tri-O-acetyl-(1,2,4/3,5)-cyclopentanepentol-1,2-O-acetoxonium tetrafluoroborate (SC) 887 [G.E. *81*, 906 (1969)]

Cyclo-~ of Di-O-pivaloylpentaerythritol-O-pivaloxonium hexachloroantimonate (SC) 888 [G.E. *81*, 907 (1969)]

New peroxide ~; cis-4,5-epoxy-2-pentenal from 1,4-epidioxy-2-cyclopentene (SC) 985 [G.E. *81*, 1045 (1969)]

~ of N-halogeno-β-lactams – A simple synthesis of β-bromoalkyl isocyanates (CR) 904 [G.E. *81*, 923 (1969)]

Kinetics of ~ of allylcarbinyl anions (3-butenide ions) (CR) 912 [G.E. *81*, 931 (1969)]

A reversible skeletal ~ in the transerythrinane ring system (CR) 914 [G.E. *81*, 933 (1969)]

Cope ~ of 1,4-divinylazetidin-2-ones (CR) 922 [G.E. *81*, 942 (1969)]

Formation of amides by Claisen ~ of ketene O,N-acetals; stereochemistry (CR) 926 [G.E. *81*, 945 (1969)]

New ~ of β-lactams (LA) 220

Receptors on the surface of human thrombocytes (CR) 81 [G.E. *81*, 38 (1969)]

Recoil atoms, Energy and isotope dependence of the chemical behavior of molybdenum ~ in hexacarbonylmetal compounds following nuclear reactions (CR) 929 [G.E. *81*, 949 (1969)]

Recoil reaction, Fast separation of fission halogens by ~ with methane (CR) 907 [G.E. *81*, 926 (1969)]

Redox polyamides (LA) 777

Redox systems, Reversible ~ with stable radical cations (CR) 286 [G.E. *81*, 295 (1969)]

Reductive cleavage of bonds by complexes of zerovalent transition metals (SC) 877 [G.E. *81*, 896 (1969)]

Respiratory chain phosphorylation, "Decoupling" of oxidative phosphorylation (LA) 463

Rhenium compounds, Ligand recoil in hexahalogeno complexes of Re^{IV} and Rh^{III} and the production of practically carrier-free ^{36}Cl (CR) 890 [G.E. *81*, 909 (1969)]

Solid state exchange between radiohalide and ligands in doped hexahalo complexes of Re^{IV} and Rh^{III} (CR) 919 [G.E. *81*, 939 (1969)]

Rhodium complex containing CO_2 ligands (LA) 619

Rhodium compounds, Ligand recoil in hexahalogeno complexes of Re^{IV} and Rh^{III} and the production of practically carrier-free ^{36}Cl (CR) 890 [G.E. *81*, 909 (1969)]

Hydroformylation of unsaturated compounds with carbonyltrialkylphosphine-rhodium catalysts (CR) 897 [G.E. *81*, 916 (1969)]

Solid state exchange between radiohalide and ligands in doped hexahalo complexes of Re^{IV} and Rh^{III} (CR) 919 [G.E. *81*, 939 (1969)]

Riboflavin, Structure of the purine precursor in ~ biosynthesis (SC) 371 [G.E. *81*, 393 (1969)]

Ribonuclease, Investigation of binding of inhibitors to ~ by NMR spectroscopy (CR) 392 [G.E. *81*, 402 (1969)]

Ring contraction, Synthesis of substituted cyclopentadienones by ~ (SC) 275 [G.E. *81*, 260 (1969)]

~ of 1-thiochromans to benzo[b]thiophenes (SC) 456 [G.E. *81*, 424 (1969)]

Ring expansion, Solvolytic ~ in a transition metal (SC) 143 [G.E. *81*, 153 (1969)]

~ in organoiron compounds (LA) 84

~ by insertion of SO_3 (LA) 289

Carbocyclic ~ reactions (Book Review) 398

Rotation, Hindered ~ about the C–O bond in methoxy(methyl)carbene ligands (SC) 761 [G.E. *81*, 780 (1969)]

NMR studies on ~ and inversion at double bonds (CR) 905 [G.E. *81*, 924 (1969)]

Rotational isomerism of N^2-methyl-N^2-phenylthioformohydrazide (SC) 989 [G.E. *81*, 1050 (1969)]

Rotational isomers, Intramolecular motions in enamines and hydrazones; separation of ~ (CR) 528 [G.E. *81*, 540 (1969)]

~ of m-halogenobenzaldehydes (LA) 778

Rotational spectra, Molecular structure from ~ (CR) 393 [G.E. *81*, 401 (1969)]

Rotaxanes (LA) 394

Ruthenium compounds, Existence of RuC, IrC, and PtB (LA) 151

A linear RuNRu bridge (LA) 621

Rutile, Solubility of Al_2O_3 in ~ (LA) 778

SANDWICH COMPLEXES, Rare earth organometallic ~ (CR) 774 [G.E. *81*, 754 (1969)]

Schiff bases, Magnetic properties of trinuclear complexes of quadridentate ~ (LA) 152

Selenium compounds, Rapid volatilization of arsenic, antimony, selenium, and tellurium as hydrides from mixtures of fission products (CR) 906 [G.E. *81*, 926 (1969)]

Preparation and structural chemistry of mixed oxo-thio-seleno metalates (CR) 914 [G.E. *81*, 934 (1969)]

Selenophosphinic acids, Metal complexes of thiophosphinic and ~ (FP) 89 [G.E. *81*, 127 (1969)]

Semiconductors, Radio frequency polarographic studies on ~ and reactor materials (CR) 929 [G.E. *81*, 949 (1969)]

Sesquifulvalene, Hetero analogs (FP) 478 [G.E. *81*, 518 (1969)]

7,9-Di-tert-butyl-~: Synthesis and cycloadditions (SC) 881 [G.E. *81*, 900 (1969)]

Shales, Fatty acids and hydrocarbons from extracts and distillates of bituminous ~ (CR) 901 [G.E. *81*, 920 (1969)]

Shock waves, The conductivity of aqueous electrolyte solutions in ~ (LA) 931

Sigma-pi rearrangements of organotransition metal compounds (FP) 410 [G.E. *81*, 453 (1969)]

Sigmatropic hydrogen shifts, Aromatic-[1,7]- and [1,5]-~ (LA) 620

Silanes, 2,2'-Bipyridine adducts of di-~ (SC) 599 [G.E. *81*, 574 (1969)]

Vinyloxytrimethylsilanes as silylating agents (SC) 974 [G.E. *81*, 995 (1969)]

Silazanes, Isomerizations of N-silylated cyclo-~ (SC) 521 [G.E. *81*, 499 (1969)]

Silepins, 6,7,8,9-Tetrahydro-5H-benzo[d]-~ (LA) 288

Silica gel, Adsorption of protactinium, zirconium, and niobium on ~ and Vycor glass from solutions in hydrochloric acid (CR) 908 [G.E. *81*, 928 (1969)]

Exceptionally reactive form of ~ (LA) 464

Silicon compounds, Divalent silicon intermediates (FP) 469 [G.E. *81*, 485 (1969)]

New evidence for a (p → d)π effect at silicon (SC) 372 [G.E. *81*, 329 (1969)]

Organosilicon chemistry (CR) 526 [G.E. *81*, 500 (1969)]

Properties of the Si–Si bond (CR) 901 [G.E. *81*, 920 (1969)]

Oxidation kinetics of $NbSi_2$ and $MoSi_2$ at high temperatures (CR) 913 [G.E. *81*, 932 (1969)]

New four-membered inorganic ring systems (LA) 289

Novel silicon anion (LA) 532

Silicon nitrides, Reaction with phosphorus pentoxide (CR) 908 [G.E. *81*, 927 (1969)]

Siloxane, Preparation and polycondensation reactions of aromatic diamines containing ~ chains (CR) 899 [G.E. *81*, 918 (1969)]

Silver carbonate, Selective oxidative coupling of phenols by ~ / celite (SC) 444 [G.E. *81*, 423 (1969)]

Silver cyanate, Reaction of ~ with cyanogen chloride (SC) 444 [G.E. *81*, 423 (1969)]

Silver electrode, Investigation of superadditivity in photographic development by current voltage curves at a ~ (SC) 281 [G.E. *81*, 293 (1969)]

Silver oxide, Anodic oxidation of Ag_2O to AgO (LA) 221

Silylating agents, Vinyloxytrimethylsilanes as ~ (SC) 974 [G.E. *81*, 995 (1969)]

Silyl compounds, Tris(trimethylsilyl)indium (SC) 140 [G.E. *81*, 122 (1969)]

Birch reductions of trimethylsilyl substituted aromatic compounds controlled by (Si ← C_π) interactions (SC) 525 [G.E. *81*, 538 (1969)]

Silylene complex, Formation of a ~ by base catalyzed decomposition of hexa-

chlorodsilane (SC) 878 [G.E. *81*, 897 (1969)]

Silylenes, Divalent silicon intermediates (FP) 469 [G.E. *81*, 485 (1969)]

Single crystals, Gas-chromatographic determination of the purity and polarization-optical quality testing of molecular ~ of high quality (CR) 904 [G.E. *81*, 924 (1969)]

Kinetics of the evaporation of sodium chloride from the (100) faces of ~ (LA) 221

Space-charge layers in surface-proximate regions of ~ of zinc oxide (LA) 291

Sodium chloride, Kinetics of the evaporation of ~ from the (100) faces of single crystals (LA) 221

Solid state reaction, Application of the Mössbauer effect to investigation of the ~ of iron(II) sulfate with potassium cyanide (SC) 600 [G.E. *81*, 627 (1969)]

~ of zinc oxide with iron(III) oxide (LA) 290

Solvatochromism, Electrochromism and ~ (FP) 177 [G.E. *81*, 195 (1969)]

Solvent catalysis, Asymmetric ~ ; N,N,N′,N′-tetramethyl-2,3-dimethoxy-1,4-butanediamine, a new chiral medium (SC) 982 [G.E. *81*, 1002 (1969)]

Solvent effects in the fluorescence and phosphorescence of indole (LA) 779

Solvent extraction, Coordination chemistry (CR) 283 [G.E. *81*, 262 (1969)]

Solvents, Chemistry in non-aqueous ionizing ~ (Book Review) 224

Water-like ~ (Book Review) 464

Solvent effects in organic chemistry (Book Review) 465

Sorption promotors in biopharmaceutics (FP) 699 [G.E. *81*, 757 (1969)]

Spinels, Lattice vibration spectra of heavy metal Thio-~ (CR) 911 [G.E. *81*, 930 (1969)]

Spiro[3.3]hepta-1,5-diene, Synthesis (LA) 290

Spironorcaradiene, Spiro derivative of norcaradiene (SC) 76 [G.E. *81*, 83 (1969)]

Stable ~ (SC) 76 [G.E. *81*, 83 (1969)]

Squaric acid, Condensation products with primary and secondary amines (CR) 898 [G.E. *81*, 913 (1969)]

Stannanide ions, Complexing behavior of ~: tetrakis(trichlorostannanido)niccolate(0) (SC) 679 [G.E. *81*, 704 (1969)]

Stannic acids, X-ray structural analysis of alkylthio-~ (monoalkyl sesquisulfides) (CR) 288 [G.E. *81*, 297 (1969)]

Stannyl compounds, Organogermyl, organostannyl, and organoplumbyl phosphines, arsines, stibines, and bismuthines (FP) 937 [G.E. *81*, 970 (1969)]

Stationary phase, New ~ for chromatography (SC) 453 [G.E. *81*, 464 (1969)]

Steroids, Effect of crystalline form on the air-oxidation of steroidal 11β-ols to 11-ones (SC) 975 [G.E. *81*, 1046 (1969)]

Microbial transformations of ~ (Book Review) 464

~ reaction mechanisms (Book Review) 780

Stibines, Organogermyl, organostannyl, and organoplumbyl phosphines, arsines, ~, and bismuthines (FP) 937 [G.E. *81*, 970 (1969)]

Stoichiometry, Problems for introductory university chemistry (Book Review) 534

Stokes shifts, Unusually large ~ and fluorescence decay times (LA) 530

Stress birefringence, Dependence of the ~ of rubber-elastic substances on temperature and degree of swelling (CR) 923 [G.E. *81*, 942 (1969)]

Sugars, see Carbohydrates

Sulfene, Di-~ (SC) 73 [G.E. *81*, 36 (1969)]

Sulfenyl chlorides, Thiiranium ions as reaction intermediates (FP) 482 [G.E. *81*, 475 (1969)]

Sulfides, Organometal ~ as ligands in pentacarbonylchromium(0) complexes (SC) 271 [G.E. *81*, 256 (1969)]

Structural chemistry of ternary ~ containing alkali and transition metals (CR) 893 [G.E. *81*, 912 (1969)]

Preparation and properties of mixed ~ of the 4f transition elements (CR) 918 [G.E. *81*, 937 (1969)]

Sulfinylamide, Bis(sulfinylamido)mercury-(II) (SC) 376 [G.E. *81*, 330 (1969)]

Sulfinylamines, N-Halo-~ (SC) 376 [G.E. *81*, 331 (1969)]

Sulfonamides, Base-induced α-nitration of ~ (LA) 290

Sulfones, Mass-spectrometric investigation of poly-S-phenyl-S′-vinylmethylenedi-~ (CR) 895 [G.E. *81*, 914 (1969)]

Formation of cycloadducts (LA) 153

Sulfur, A selective, stereospecific insertion of ~ (LA) 994

Fibrous, pressure-induced ~ (LA) 777

Sulfur compounds, Spectroscopic investigation of various phosphorus-sulfur bonds (FP) 328 [G.E. *81*, 343 (1969)]

Thiiranium ions as reaction intermediates (FP) 482 [G.E. *81*, 475 (1969)]

New mode of formation of sulfur-containing heterocycles (SC) 272 [G.E. *81*, 257 (1969)]

Tetrasulfide chelate of molybdenum (SC) 375 [G.E. *81*, 332 (1969)]

Bis(N-fluorosulfonylimido)sulfur and bis(N-fluorosulfonylimido)sulfur difluoride (SC) 510 [G.E. *81*, 494 (1969)]

Stereochemical course of Grignard reactions at asymmetric sulfur (SC) 612 [G.E. *81*, 619 (1969)]

Bis(dimethylamido)bis(N-fluorosulfonylimido)sulfur, a covalent compound containing the SN_4 group (SC) 674 [G.E. *81*, 705 (1969)]

New sulfur-containing macrocyclic hexadentate ligand (LA) 152

Ring expansion by insertion of SO_3 (LA) 289

New aromatic heterocycles containing tetravalent sulfur (LA) 462

Oxidation of sulfur hexafluoride by oxygen (LA) 532

Vibrational spectra of S_4N_4 and S_2N_2 (LA) 778

Sulfur dioxide, Automatic determination in atmospheric air (CR) 903 [G.E. *81*, 922 (1969)]

Superadditivity, Investigation of ~ in photographic development by current-voltage curves at a silver electrode (SC) 281 [G.E. *81*, 293 (1969)]

Superpolyamides, Polar ~ (CR) 384 [G.E. *81*, 334 (1969)]

Synthetic methods of organic chemistry (Book Review) 292

TANTALUM, Radiochemical investigations on high-energy nuclear reactions of ~ (CR) 890 [G.E. *81*, 909 (1969)]

Technetium(VII) oxide (SC) 381 [G.E. *81*, 328 (1969)]

Technical chemistry, Ullmann's encyclopedia of ~ (Book Review) 465

Tellurium compounds, Preparation and properties of $AuTe_2I$ (SC) 145 [G.E. *81*, 148 (1969)]

$FXeOTeF_5$: A derivative of xenon difluoride (SC) 373 [G.E. *81*, 330 (1969)]

Rapid volatilization of arsenic, antimony, selenium, and tellurium as hydrides from mixtures of fission products (CR) 906 [G.E. *81*, 926 (1969)]

Temperature measurements, Calorimetric ~ in plasma jets (CR) 916 [G.E. *81*, 936 (1969)]

Testosterones, Synthesis from estrogens (SC) 376 [G.E. *81*, 396 (1969)]

Tetracarbonyldiphosphanemolybdenum-(0) (SC) 372 [G.E. *81*, 330 (1969)]

Tetracyanomethane (LA) 776

Tetracyclo[3.3.2.$0^{2,4}$.$0^{6,8}$]decene, Photochemical [2π + 2σ] cycloadditions in ~ systems (SC) 883 [G.E. *81*, 902 (1969)]

Tetrafluoroorthoperiodic acid and iodine dioxide trifluoride (SC) 768 [G.E. *81*, 753 (1969)]

6,7,8,9-Tetrahydro-5H-benzo[d]silepins (LA) 288

Tetrahydropyran, New synthesis (LA) 530

Tetrakis(cyclopentadienyl)protactinium-(IV) (SC) 202 [G.E. *81*, 182 (1969)]

Tetrakis(trichlorostannanido)niccolate(0) (SC) 679 [G.E. *81*, 704 (1969)]

Tetraphosphorus trisulfide, Transition-metal complexes (LA) 620

Tetrasulfide chelate of molybdenum (SC) 375 [G.E. *81*, 332 (1969)]

Tetrazolinyl radical, Crystalline ~ (SC) 520 [G.E. *81*, 496 (1969)]

Tetroxane, Investigations on the epitactic and topotactic polymerization of trioxane and ~ (CR) 390 [G.E. *81*, 340 (1969)]

1,2,4,5-~ derivatives from ε-caprolactam hydroperoxide (LA) 778

Thallium compounds, IR and Raman spectroscopic studies on the structure of TlF (CR) 920 [G.E. *81*, 939 (1969)]

Thermal conductivity, Temperature dependence of the ~ of amorphous high polymers (CR) 385 [G.E. *81*, 335 (1969)]

Thiacycloalkan-3-ones, Photochemistry (LA) 221

6-Thia-2-phosphonia-1,3,5,8-tetra-azabicyclo[2.2.2]oct-4(5)-ene chloride, Synthesis of a derivative (SC) 278 [G.E. *81*, 291 (1969)]

1,2,4,6-Thiatriaza-2,5-cyclohexadiene-1,1-dione, 3,5-Bis(trifluoromethyl)-~ (SC) 510 [G.E. *81*, 493 (1969)]

Thiazolo[3,2-a]pyridinium salts, Synthesis of new ~ (SC) 74 [G.E. *81*, 84 (1969)]

Thiirane S-oxide, Molecular geometry (LA) 291

Thiiranium ions as reaction intermediates (FP) 482 [G.E. *81*, 475 (1969)]

1-Thiochroman, Ring contraction to benzo[b]thiophenes (SC) 456 [G.E. *81*, 424 (1969)]

Thioformamides, New preparation of ~ and dithiocarbamates (SC) 141 [G.E. *81*, 154 (1969)]

New synthesis of ~ (SC) 278 [G.E. *81*, 291 (1969)]

Thiol groups, Problems in the blocking of ~ in polypeptides (CR) 896 [G.E. *81*, 915 (1969)]

Thiophosphinic acids, Metal complexes of ~ and selenophosphinic acids (FP) 89 [G.E. *81*, 127 (1969)]

Thiophosphoric acid, Geometric isomerism in cyclic five- and six-membered mono-~ derivatives (SC) 511 [G.E. *81*, 494 (1969)]

2-Thiopyrimidine nucleosides, A simple new synthesis (SC) 976 [G.E. *81*, 997 (1969)]

Thiospinels, Lattice vibration spectra of heavy metal ~ (CR) 911 [G.E. *81*, 930 (1969)]

Thiostannic acids, X-ray structural analysis of alkyl-~ (monoalkyl sesquisulfides) (CR) 288 [G.E. *81*, 297 (1969)]

4-Thiouridine, Crystal structure (SC) 139 [G.E. *81*, 121 (1969)]

2-Thiouridine-5-acetate, Synthesis of Hall's methyl ~ from yeast-tRNA (SC) 977 [G.E. *81*, 998 (1969)]

Thorium compounds, Phthalocyanine and perfluorophthalocyanine complexes of thorium, protactinium, uranium, and neptunium (CR) 894 [G.E. *81*, 913 (1969)]

Thorium decay series, The α-radiation of $^{228}Ac(MsTh_2)$. A new α branching in the ~ (CR) 911 [G.E. *81*, 930 (1969)]

Thrombocytes, Receptors on the surface of human ~ (CR) 81 [G.E. *81*, 38 (1969)]

Tin compounds, Diphenylborane derivatives containing boron-tin bonds (SC) 515 [G.E. *81*, 530 (1969)]

Inverse-voltammetric determination of tin and lead in the presence of each other (CR) 929 [G.E. *81*, 950 (1969)]

Phenyl isocyanate inserts into the tin^{II}-oxygen bond (LA) 930

Trimethyltin isothiocyanate (LA) 931

Tin radicals, Reactions of organo-~ (CR) 287 [G.E. *81*, 296 (1969)]

Titanium compounds, Temperature dependence of the NMR spectrum of a soluble Ziegler-Natta catalyst (SC) 217 [G.E. *81*, 228 (1969)]

Crystal structure of bis(cyclooctatetraene)titanium (SC) 765 [G.E. *81*, 785 (1969)]

Polymerization of ethylene with methyltitanium trichloride and methyltitanium dichloride (CR) 387 [G.E. *81*, 337 (1969)]

New method for the production of ~ having low iron content from ilmenite (LA) 532

Ti atom having coordination number 7 (LA) 777

Titanium-molybdenum complexes with chalcogen bridging ligands (SC) 980 [G.E. *81*, 1000 (1969)]

α-Tocopherol, Energy content of the primary oxidation products of ~ (LA) 151

Topochemical investigations on peptide systems (FP) 492 [G.E. *81*, 523 (1969)]

Topotactic reactions, Chemical applications of electron microscopy: ~ (CR) 460 [G.E. *81*, 470 (1969)]

Transition metal chlorides, Preparative scope of the reduction of higher ~ in anhydrous methanol (CR) 923 [G.E. *81*, 943 (1969)]

Transition metal compounds, Catalytic activity of ~ in the liquid-phase oxidation of hydrocarbons (FP) 97 [G.E. *81*, 91 (1969)]

Sigma-pi rearrangements of organo-~ (FP) 410 [G.E. *81*, 453 (1969)]

Comparison of organometallic complexes of aluminum and those of some transition metals (CR) 909 [G.E. *81*, 928 (1969)]

Transition metal intermediates in organic synthesis (Book Review) 534

Transition metals, Reductive cleavage of bonds by complexes of zerovalent ~ (SC) 877 [G.E. *81*, 896 (1969)]

Transmitter mechanisms in isolated neurons (CR) 287 [G.E. *81*, 291 (1969)]

Transport, ~ phenomena in membranes (FP) 42 [G.E. *81*, 56 (1969)]

~ of double- and triple-stranded ribopolynucleotides through cellular membranes (CR) 80 [G.E. *81*, 41 (1969)]

Simultaneous ~ of mass and heat with wall reactions (CR) 220 [G.E. *81*, 230 (1969)]

Boundary between fluid phases as a barrier for the passage of molecules (CR) 391 [G.E. *81*, 401 (1969)]

Triamino sugars, New route to inosatriamines and ~ (SC) 211 [G.E. *81*, 221 (1969)]

Triazole, Hydrolysis of 6-methylthio-8-azapurines to thiol esters of 1,2,3-~-carboxylic acids (SC) 132 [G.E. *81*, 115 (1969)]

Mesoionic 3-methylene-1,2,4-~-s (SC) 133 [G.E. *81*, 115 (1969)]

Triazino[2,1-b]quinazoline system (LA) 994

Tribenzoxepin, Optically active (SC) 68 [G.E. *81*, 32 (1969)]

Tribromine cation, in $[Br_3]^+[AsF_6]^-$ (SC) 517 [G.E. *81*, 531 (1969)]

Tricarbonylcyclobutadieneiron, Molecular geometry (LA) 532

Tricarbonylcyclopentadienylchromium, Dinuclear complexes containing the ~ group (SC) 520 [G.E. *81*, 498 (1969)]

cis-Tricarbonyltris(phosphine)chromium-(0) (SC) 377 [G.E. *81*, 397 (1969)]

Trichlorobis(triphenylphosphine)indium (LA) 621

Tricyclo[6.4.0.$0^{2,7}$]dodeca-3,5,9,11-tetraene, Two new valence isomers of [12]-annulene (SC) 69 [G.E. *81*, 33 (1969)]

Tricyclo[3.2.1.$0^{1,5}$]octane (LA) 290

Triyclo[3.3.0.$0^{2,6}$]octane (LA) 151

N^2-(Trifluoromethyl)fluoroformamidine, Derivatives (LA) 462

Trifluoromethylfluorosulfane and 1,2-bis-(trifluoromethyl)disulfane 1,1'-difluoride (SC) 773 [G.E. *81*, 789 (1969)]

Trimethylenemethane (CR) 218 [G.E. *81*, 191 (1969)]

2-Trimethylsilylpyridine, Determination of the n-ionization potential of 2-trimethylsilylpyridine by photoelectron spectroscopy (SC) 524 [G.E. *81*, 537 (1969)]

3-Trimethylsilyltetradeuteriopropionate, Sodium ~, a new water-soluble standard for ^{1}H-NMR (SC) 381 [G.E. *81*, 395 (1969)]

Trimethyltin isothiocyanate (LA) 931

Trioxane, Investigations on the epitactic and topotactic polymerization of ~ and tetroxane (CR) 390 [G.E. *81*, 340 (1969)]

Triphenylenes, Synthesis of symmetrically substituted ~ (LA) 221

Triphenylphosphine, Structure and reactivity of the betaine derived from ~ and dimethyl azodicarboxylate (SC) 513 [G.E. *81*, 534 (1969)]

Triptycene, Azaphospha-~ (SC) 987 [G.E. *81*, 1049 (1969)]

2,4,6-Tri-α-pyridyl-1,3,5-triazine, Lanthanide complexes (LA) 462

Tris(aziridino)methane, Simple synthesis (LA) 777

Tris(trimethylsilyl)indium (SC) 140 [G.E. *81*, 122 (1969)]

Tropylium ring, Planar ~ (LA) 621

Trypsin inhibitor from pig pancreas (CR) 150 [G.E. *81*, 122 (1969)]

Tumor cells, Chemical and enzymic reactions on the membranes of Ehrlich ascites ~ and their consequences for metabolism and permeability (CR) 81 [G.E. *81*, 38 (1969)]

Tungsten carbide electrodes, Electrochemical oxidation of aldehydes, formic acid, and carbon monoxide at ~ in 2 N sulfuric acid (SC) 757 [G.E. *81*, 748 (1969)]

Tungsten(IV) oxide bromide (SC) 142 [G.E. *81*, 149 (1969)]

URANIUM compounds, NMR spectroscopic investigation of complex formation in extraction of uranium and plutonium with organophosphorus compounds (CR) 889 [G.E. *81*, 908 (1969)]

High-temperature ammonolysis of UF_4 (CR) 891 [G.E. *81*, 910 (1969)]

Phthalocyanine and perfluorophthalocyanine complexes of thorium, protactinium, uranium, and neptunium (CR) 894 [G.E. *81*, 913 (1969)]

Urethanes, Action of phosphorus pentachloride on N-(halogenosulfonyl)-~ (SC) 136 [G.E. *81*, 119 (1969)]

Uridine2',3'-O,O-cyclophosphorothioate, Crystal structure (SC) 595 [G.E. *81*, 566 (1969)]

VALENCE ISOMERIZATION, Reversible ~ of diaziridine imines (SC) 449 [G.E. *81*, 429 (1969)]

~ in acyloxonium cations of 1,2,3-triols, simple synthesis of acyloxonium salts (SC) 886 [G.E. *81*, 905 (1969)]

Vapor pressure, Isotope effects (FP) 689 [G.E. *81*, 770 (1969)]

~ and crystal structure of metallic curium (LA) 778

Varnishes, Technological observations in the hardening of ~ with electron beams (CR) 903 [G.E. *81*, 922 (1969)]

Vibrational spectra, Lattice ~ of heavy metal thiospinels (CR) 911 [G.E. *81*, 930 (1969)]

~ of S_4N_4 and S_2N_2 (LA) 778

Vilsmeier reaction of acid chlorides capable of fragmentation (SC) 71 [G.E. *81*, 36 (1969)]

N-Vinylcarbazole, New reaction of ~ with disulfur dichloride (SC) 877 [G.E. *81*, 896 (1969)]

Vinyl cations, Acid-catalyzed cyclodimerizations via ~ as intermediates (FP) 933 [G.E. *81*, 966 (1969)]

Vinyl ethers, Chemistry of enol ethers (FP) 295 [G.E. *81*, 374 (1969)]

Vinylogous amides, O-Acylated ~ (SC) 756 [G.E. *81*, 747 (1969)]

Vinyloxirane, Catalyzed reactions of diazomethane with ~ (SC) 75 [G.E. *81*, 86 (1969)]

Vinyloxytrimethylsilanes as silylating agents (SC) 974 [G.E. *81*, 995 (1969)]

Vinyl polymerization, Cation radicals in ~ (CR) 387 [G.E. *81*, 337 (1969)]

Virus, Studies on adeno-~ type 12: Relations between the ~- and host genomes (CR) 81 [G.E. *81*, 87 (1969)]

Vitamin E, Energy content of the primary oxidation products of α-tocopherol (LA) 151

Voltammetry, Determination of copper, lead, and cadmium in different concentration ratios by various voltammetric methods (CR) 910 [G.E. *81*, 929 (1969)]

Inverse-voltammetric determination of tin and lead in the presence of each other (CR) 929 [G.E. *81*, 950 (1969)]

WALL REACTIONS, Simultaneous transport of mass and heat with ~ (CR) 220 [G.E. *81*, 230 (1969)]

Wave mechanics of atoms, molecules, and ions (Book Review) 688

XENON, Conversion of liquid ~ into a metal-like state (LA) 83

Xenon compounds, $FXeOTeF_5$: derivative of xenon difluoride (SC) 373 [G.E. *81*, 330 (1969)]

$Xe(OTeF_5)_2$, Xenon bis(pentafluoro-orthotellurate) (SC) 523 [G.E. *81*, 536 (1969)]

$FXeOSO_2F$, $FeXeOClO_3$, $Xe(OSO_2F)_2$, and $Xe(OClO_3)_2$ (LA) 685

X-Ray fluorescence, Determination of Medium-Heavy Elements by γ-Excited ~ (CR) 903 [G.E. *81*, 922 (1969)]

X-Ray spectroscopy of the chemical bond in oxides (CR) 391 [G.E. *81*, 400 (1969)]

YNAMINES, see Alkynylamines

Yohimbane ring system, New two-stage synthesis (SC) 445 [G.E. *81*, 425 (1969)]

ZEOLITES, IR spectrum of CO *in* ~ (LA) 931

Ziegler-Natta catalyst, Temperature dependence of the NMR spectrum of a soluble ~ (SC) 217 [G.E. *81*, 228 (1969)]

Zinc compounds, Organic compounds of zinc and cadmium (Book Review) 292

Zinc oxide, Solid-state reaction of ~ with iron(III) oxide (LA) 290

Space-charge layers in surface-proximate regions of single crystals of ~ (LA) 291

Zirconium(IV) chloride, Crystal structure (SC) 146 [G.E. *81*, 120 (1969)]

Zirconium compounds, Adsorption of protactinium, zirconium, and niobium on silica gels and Vycor glass from solutions in hydrochloric acid (CR) 908 [G.E. *81*, 928 (1969)]

Zirconium phosphate exchangers, Preparation and investigation of ~ exhibiting separation properties for lanthanides and actinides (CR) 926 [G.E. *81*, 946 (1969)]
