There is a third type of computer application to NMR spectroscopy in which the NMR signal contains the spectrum in a coded form dictated by the measuring method, and the computer, acting as a translator, represents an integral component of the spectrometer. This type of computer application includes the processing of pulsed spectroscopy which has become so important recently. The information here is present initially as an intensity *vs. time* diagram from the "free induction" of the nuclear resonance signal (FID), *i.e.* as an interferogram of all the resonance frequencies present. This has to be changed by Fourier transformation into the usual form of an intensity *vs. frequency* spectrum[10] with all the resonances differentiated by chemical shifts and spin-spin couplings. The new experimental technique of Fourier transform spectroscopy offers so many advantages in increased sensitivity and measuring speed[11, 11a], that it will certainly contribute to popularization of the computer in nuclear magnetic resonance spectroscopy[27].

Because of the astoundingly rapid progress in semiconductor technology, computers of sufficient capacity for this purpose have become so cheap that instead of costing many times more than a medium priced NMR spectrometer they cost only as much as a fairly expensive spectrometer accessory.

Further computer applications of this sort are the investigation of kinetics of fast reactions by examination of the line-broadening and its variation with temperature.

The development of uniform process control especially by optimizing the spectrometer adjustments (*e.g.* continuous control of field homogeneity) and the direct control of spectral recording by computer is also progressing. Small computers[12] are now on the market which have been programmed for this purpose.

[*] It should be noted that signal averaging computers of this kind, but now normally with 4 to 8 K channels, are still on the market [5]. They can no longer compete with genuine minicomputers of similar capacity with regard to price and flexibility, and are being increasingly replaced by the latter.

2. Experience with the Mülheim Computer System

2.1. On-line Data Acquisition and Direct Processing

From what has been said above it should be clear that the aid of a computer is indispensable if one wishes to completely exploit the capability of nuclear magnetic resonance spectroscopy. Thus the emphasis lies equally on the use of a computer as a digital recorder (on-line service)—with subsequent more or less extensive processing of the information produced by the spectrometer—as on the off-line use for spectrum simulation.

A large computer system[13], which allows both possibilities to be used equally well in a time-sharing configuration, is accordingly ideal for the solving of NMR problems. However, such an investment for this purpose alone cannot be considered.

The connection of many measuring instruments, user terminals, and peripheral instruments requires, among other things, a sophisticated operating system (monitor) with high core storage requirements. The prerequisite for suitable availability of a computer system for NMR spectroscopy, especially when extensive calculations such as those encountered in Fourier transform spectroscopy have to be performed, is that the operating system should not be over-extended. If this does happen, then reduction of the calculating capacity, increased susceptibility to trouble, and discontinuous operation can result.

The digital registration of a conventional spectrum (field or frequency sweep) takes place over one of the connections of the "slow" interface (Figure 1). This reduces the continous sequence of spectral signals produced by the spectrometer into a discrete series of sampled points to which the corresponding numerical values are then assigned by an analog/digital converter. The data acquisition program SELDAT picks up these values 20 times (or less) a second and feeds them into the computer for storage. Signal searching is then carried out with the program NMRAN which, in many respects, resembles the program GCAN. However, it also takes into account some special features of NMR spectra that impede signal searches and are not easy to handle in programming.

Thus a nuclear magnetic resonance spectrum, in contrast to a gas chromatogram, can begin directly with a signal. The baseline cannot therefore be assumed (for example from the first 20 points of the record) but must be found by the program: The bottom third of the lowest 6% of the points of a spectrum are discarded, and the remainder used for an extrapolation onto the maximum of a Gaussian curve. This forms the basis for a zero-line correction.

We consider such a complicated procedure necessary because NMR signals can show oscillations ("wiggles") following the peak. These may reach far below the true baseline and would falsify it. Since the additional danger exists of mistaking the wiggles for very sharp signals, a measure for the closeness of successive signals has to be included in the evaluation. On the other hand, very broad signals may appear in an NMR spectrum which must not be interpreted as the baseline. These can be dealt with by inclusion of a further parameter. Finally transmission errors ("spikes") must be eliminated in a special program section. If desired digital filtering[*] can be introduced here for smoothing or for increasing contrast.

A subsequent integration yields the intensities of the lines or the group of lines. As each nucleus contributes equally to the signals in which it shares the line groups can be normalized with regard to the number of nuclei present, provided their total number is known. Otherwise the signal intensities are allotted as percentages. Spectral records, determination of line positions, and integration are carried out in one operation, thus saving manpower.

For further computer processing, line positioning with high precision is necessary. This requires a strict correlation between measured frequency (abscissa) and storage address. The correlation is best guaranteed if the computer itself controls the frequency or field sweep, and possibly the recorder sweep, of the spectrometer. Such control could be carried out by computer-driven stepper-motors or D/A converters, or by direct digital control of a frequency synthesizer. All this, however, places a burden on the computer and one therefore frequently proceeds in the reverse manner: The *spectrometer* induces the acceptance of a data word, usually by means of the priority interrupt system.

The following method is a compromise which we are successfully employing at present. Our NMR instruments are 300 m away from the computer so that rapid transfer of digital data is a problem. The system we have devised relies on the precision of the internal computer clock and thus saves corresponding output units on the computer and the spectrometer. While not using rigid abscissa coupling, we are able to control the spectrometer by a stepper-motor whose driving pulses are taken from the correspondingly subdivided frequency of a highly stable counter crystal oscillator. The motor simultaneously drives the spectrometer recorder and a potentiometer connected to a highly linear voltage-regulated oscillator (VCO). However, the better solution of this problem at present (Figure 1) is the use either of a sweep ramp of an externally

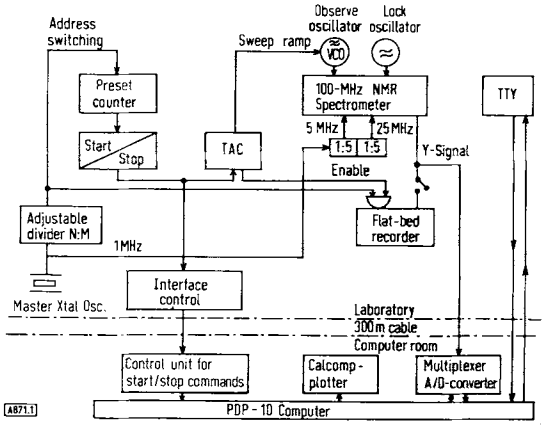

Fig. 1. Block diagram of our conventional NMR instrument (frequency sweep) in on-line operation.

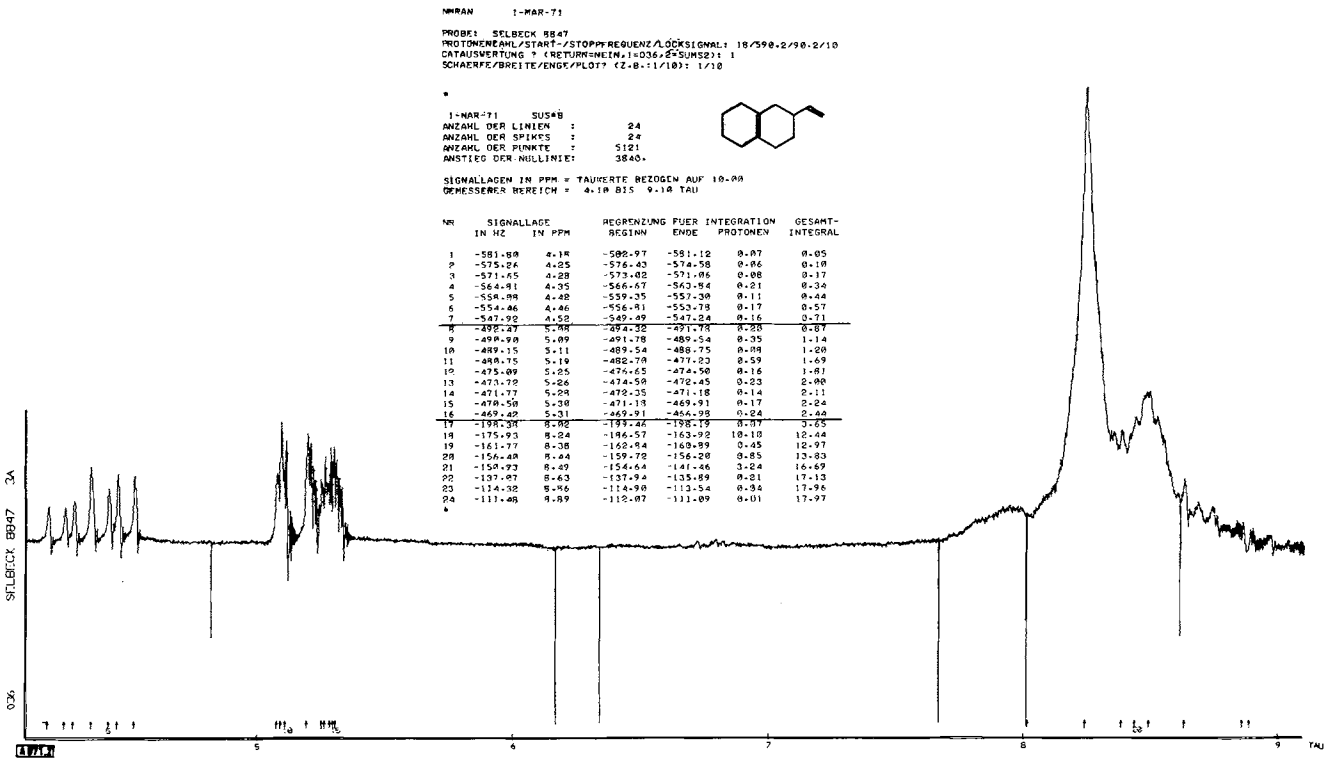
[*] Unlike electronic filtering, in which the back edge of the signal is strongly spread out, *supplemental* digital filtering operates symmetrically on the signal (*i. e.* on the amplitude, not on the phase, of its high frequency components). In this way the filter characteristics can be varied *after* recording as required.

controlled signal averaging computer (TAC) or of a suitably programmed D/A converter for an automatic recording routine. The necessary start and stop impulses for the computer are produced by the start- and final frequencies preselected at the coding switches which causes the triggering through a properly modified counter.

(NMRCAT). In contrast to the signal averaging computers discussed initally, a large computer system has the advantage of being able to distribute the spectrum over *many more* storage locations with *larger* word size. This means that even *long* spectra with *high* resolution can be registered, and that one is hardly limited in the number



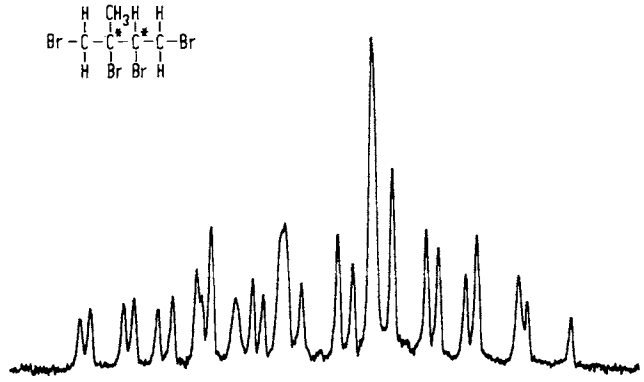


Fig. 2. Example of data acquisition and reduction: frequency range 500 Hz, data rate 10 points/s. Arrows on the abscissa mark line positions discovered by the program. Some spikes were not eliminated by the program. The uneven values on integration suggest an impurity in the sample (2-vinyl-1,2,3,4,5,6,7,8-octahydronaphthalene).

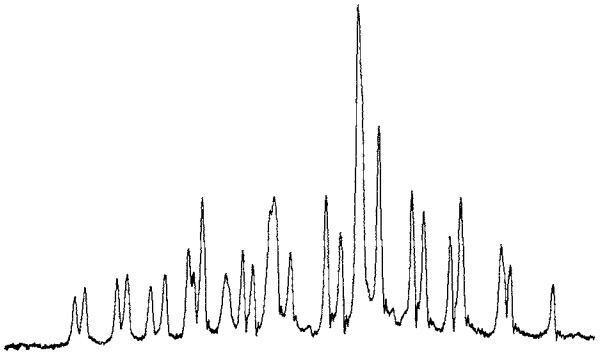

Figure 2 illustrates data processing by this method. The line positions recognized by the program NMRAN are marked by arrows on the computer diagram (consecutive program NMRPLT). The top of the list contains instructions regarding number of protons, start and stop frequencies, lock signal, *etc.*, and for the type of evaluation as mentioned above. The result, written either slowly by teleprinter in the laboratory or rapidly by line printer in the distant computer center, gives line separations in Hz from a standard line, and chemical shifts as τ or δ values. The standard line may be defined at a later time if desired. The integration proceeds in increments (*i.e.* separately for each line), at which point errors caused by signal overlap may enter, as well as cumulatively, in which defined line groups are evaluated without such errors. The processed spectrum remains on the disk file, and is ready for further processing. Its signals can be taken out by an evaluation program (NMRSIG) that searches for repeated line spacings and thus finds probable coupling constants. Also it sorts the signals into given ranges, thereby affording preliminary evidence about structural features. In its present form this program needs further improvement.

The program complex concerned with spectral data acquisition must also include an accumulation program of accumulations. ^{1}H-NMR spectroscopy thus becomes a micro method. However, it is primarily the possibility of being able to accumulate spectra thousands of times ($n \geqslant 1000$; sensitivity gain $S/N \approx \sqrt{n}$) that proves so advantageous for the recording of resonances of nuclei other than ^{1}H and ^{19}F. Because of their smaller gyromagnetic ratio and their frequently lower natural abundance, such "heteronuclei" possess considerably smaller detectabilities. In addition they exhibit very large chemical shifts and must therefore be recorded over a broad spectral range.

Figure 3 shows the possibility of data processing from a complex spectrum (the methyl signal has been omitted) recorded for a mixture of two racemates of diastereomers (two chirality centers)[15]. The spectral type of the isomers cannot therefore be very different, and an assignment of line groups to each racemate was therefore accomplished by a combination of searching for recurring line separations, and for the centers of gravity of the chemical shifts. The computer permits sufficiently accurate determination of the line positions and also yields a good estimate of the ratio of the two constituents from the calculated intensities of the single lines, even from such a complicated spectrum. An undertaking of this nature would be unthinkable

Fig. 3. Sections of the spectrum of a diastereomeric pair (1,2,3,4-tetrabromo-2-methylbutane). Above: recorder trace of the spectrometer. Below: computer diagram with evaluation sheet from the program GCAN (precursor of NMRAN, intensities in percentages of the total integral).

with normal analog integration. The figure shows the spectrum of the skeletal protons as recorded by the spectrometer (above), and the spectrum as acquired and plotted by the computer (below). A table of printed out values is also included.

An acceleration of data flow by more rationalized data acquisition and direct data reduction, although desirable for our considerable analysis throughputs on several instruments, can at present only be achieved to a limited extent. There are two bottlenecks which can only be partly bypassed. Firstly, much would be gained if the readiness of the spectrometer could be optimized automatically by the computer. This is particularly important for prolonged spectrum accumulation. A time-sharing computer of our type is not really suitable for process control[13]. Improvements in this direction such as have already been effected in special small computers[12] must therefore be put aside in our case (see Section 3, last paragraph).

Furthermore, the on-line *processing* of conventionally recorded spectra will remain difficult. Even on slow scanning of a spectrum, it is unavoidable that *sharp* lines will show strong wiggles whose maxima may be mistaken for further absorption lines. Even the program tricks described above prove inadequate when groups of very sharp lines predominate in the spectrum.

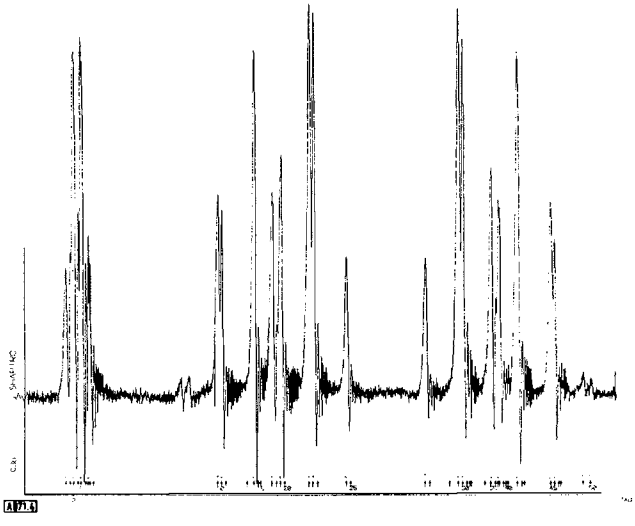

Fig. 4. 100-Hz section of the spectrum (100 MHz) of an eight-component mixture (here: signals of methyl formate and *o*-dichlorobenzene) with sharp lines. Computer diagram: data rate 20 points/s, sweep 0.2 Hz/s. Report see Figure 5.

Figures 4 and 5 illustrate this point with the aid of a typical example. The imperfection of the method is shown by the fact that 22 out of 24 lines were found correctly (×) (even with the considerable precision of ±0.03 Hz), but 28 arise from misinterpreted wiggles (/). A truly satisfactory solution is only to be expected on general application of Fourier transform spectroscopy which, owing to its principle of stationary operation, inherently gives spectra without wiggles.

2.2. Off-line Applications

Nuclear magnetic resonance spectra may show very complex splitting patterns which can no longer be analyzed by simple means. In the last ten years, a series of programs have been developed which can simulate spectra from a number of parameters (chemical shifts, coupling constants,

Fig. 6. Spectrum simulation with VARIOS. Below: measured 100-MHz spectrum with expanded section (center) of the olefin signal. Above: simulation with *three* (left), and *four* protons (right) in the allylic position. Parameters (S = chemical shift, J = coupling constant) in Hz.

programs to make allowance for step-wise variations of the initial values (VARIOS). In this way it is normally possible to recognize the spectral type and so to decide between structural alternatives, especially if the simulated spectra are drawn out with a plotter program (POMLUX). In addition to the spectrum POMLUX writes some frequency marks, the input parameters (see Figs. 6—9), and an identification label.

A871.7

Fig. 7. Structural differentiation by model calculation (LAME) between *cis*- and *trans*-1,1-dibromo-2,3-dimethylcyclopropane. Below: measured spectrum (100 MHz) (signal groups 1,2 = ring protons, 3,4 = methyl groups). Above: simulation with *cis* (left) and *trans* couplings (right). Especially noticeable effects are marked (by hand) with arrows.

If *precise* values are to be extracted from a measured spectrum, the iteration routines contained in a second part of the programs are used. These approximate the model spectrum to the measured one with regard to the line frequencies and sometimes also to intensities. It is intended to couple the feed-in of the measured spectra for the iteration program directly to the record evaluated by NMRAN.

A typical example of a qualitative evaluation (structural elucidation) by the computer is shown in Figure 6. It is concerned with deciding on the position of the double bond in the eight-membered ring of a bicyclo[6.3.0]-undecene. From the synthesis, there was a choice between the alternatives shown having three or four allylic protons. The spectrum of the olefin part was simulated using

For the sake of illustration a particularly successful model calculation on a 1,3-dioxane is indicated in Figure 8. Here even the "W" coupling over four bonds, $^4J(1,4)$, visible in the observed spectrum was verified by line broadening of groups 1 and 4 in the model spectrum. (The spectrometer resolution was better than the line widths of 0.5 Hz used in the simulation.)

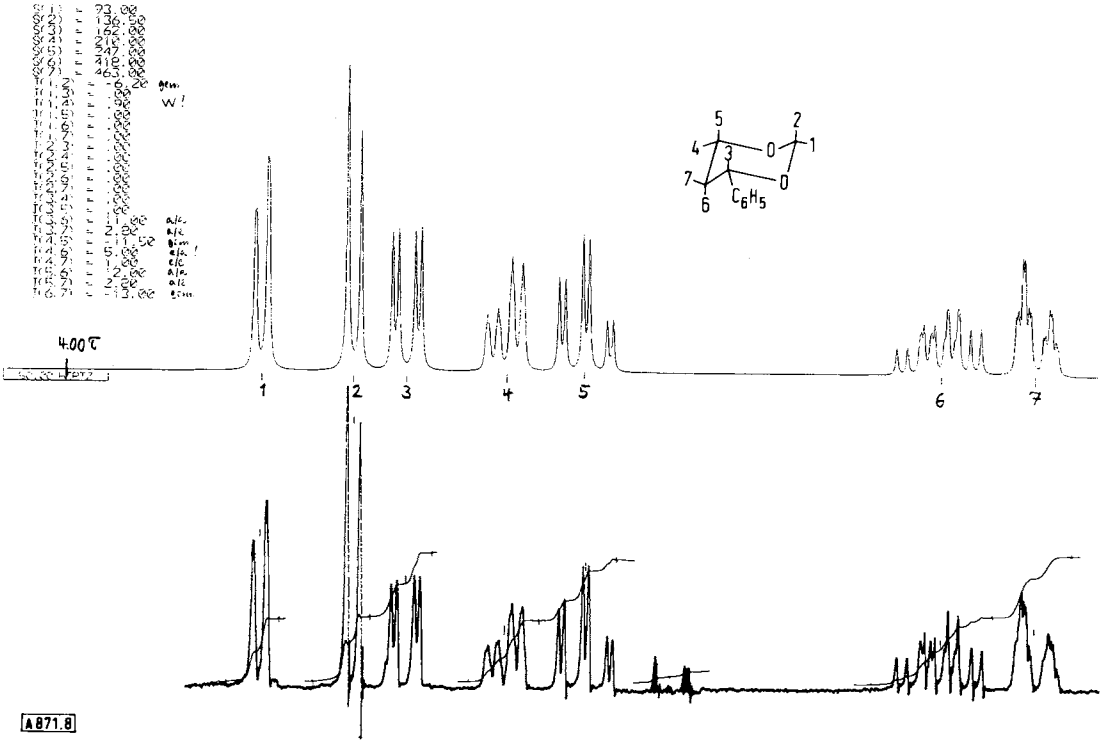

Fig. 8. Model calculation of the 100-MHz spectrum of 4-phenyl-1,3-dioxane. Below: measured spectrum. Above: simulation.

plausible coupling constants and chemical shifts. (No useful information could be obtained from the rest of the spectrum since the signals of the allylic protons are overlapped by the other ring protons.) The section on the left of the figure (three neighbors to the double bond) agrees well, as is evident from the comparison of the computer-simulated and plotted partial spectrum with the measured one (shown enlarged in the center).

A further example in which a model calculation elucidates the configuration of a compound is shown in Figure 7. It is known that in three-membered rings, *cis* vicinal protons have coupling constants between 8 and 12 Hz, while those in the *trans* configuration have constants less than 6 Hz. We had to determine the configuration of a 1,1-dibromo-2,3-dimethylcyclopropane[22]. Here the line pattern was complicated by the spin-spin interaction of the six closely neighbouring methyl protons, so that the coupling constants required to solve the problem could not be found directly. A model calculation with LAME[19] using the smaller coupling constant $J(1,2) = 5$ Hz ruled out the *trans* configuration. A calculation using $J(1,2) = 11$ Hz is however in convincing agreement with the experimental spectrum. The rather high value of 11 Hz can be explained by the known ability of neighboring halogen atoms to increase *cis* coupling constants considerably.

In Figure 9, an approximated spectrum is shown which was derived by an iteration program (LAOCOON[8]) using the method of least squares. Whenever the solution is to converge within a tolerable computing time, the application of an iteration program presupposes a successful model calcu-

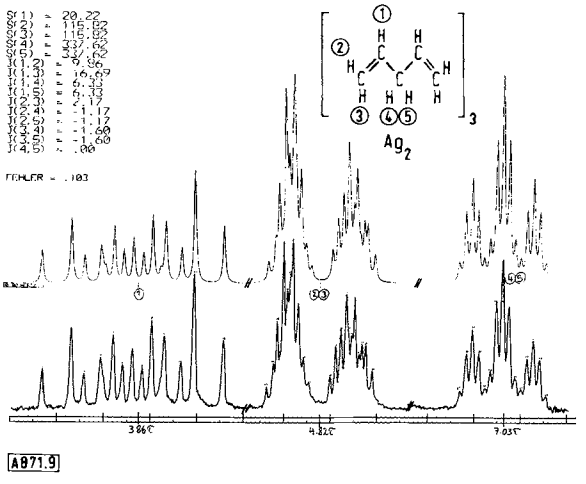

Fig. 9. Iteration with LAOCOON: 100-MHz spectrum of $Ag_2(CH_2CHCH_2CHCH_2)_3$. Below: measured spectrum. Above: best fit after 2 iterations (RMS error 0.103 Hz).

lation giving values closely approaching the real ones. This was a further reason for including automatic variation of critical parameters (VARIOS) in the simulation programs. Iteration then yields values for spin coupling and chemical shifts that are reliable enough for inclusion in tables of structural parameters in the literature. Well measured spectra are naturally essential for this purpose.

In these applications, data input normally represents a bottleneck and may give rise to errors. We have therefore modified our programs so that they can request the required data from the user (over TTY) in dialog form, thus increasing reliability, providing more flexibility, and allowing program use by less experienced persons.

2.3. The Computer as a Spectrometer Component

2.3.1. Fourier Transform Spectroscopy

One can obtain information about nuclear magnetic resonance in two complementary but different ways. The conventional manner of recording a spectrum is to scan slowly through the resonance positions by time-linear variation of the polarizing magnetic field H_0 or of the monochromatic HF measuring frequency. One can also, as was first accomplished *experimentally* by *Ernst* and *Anderson*[11], irradiate the sample (H_0 field constant) with one sufficiently broad high frequency band. All the resonances of a spectrum are then excited simultaneously. In practice irradiation is performed with short (microsecond range) intense HF square pulses having a frequency distribution given by $\sin \omega t/\omega t$. As a consequence a frequency band of several hundred to several thousand Hz at nearly constant amplitude is produced. The "free induction" signal of such an experiment is shown in Figure 12 (see also the interferogram shown in the upper left of Figure 15). It contains all the resonance frequencies superimposed upon one another and each decaying with its characteristic relaxation time, which is usually of the order of seconds ("time domain"). *Computational* frequency analysis (Fourier transformation) reproduces the spectrum in the familiar form ("frequency domain"). The result of a Fourier transformation by the computer is shown in Figure 10.

The trace—showing a 500-Hz section of a spectrum of an eight-component mixture (containing 30% v/v CCl_4) —was drawn out with the TTY plotter described below (see footnote [*] on p. 384). The spectrum originates from a single high frequency pulse, whose free induction decay (FID) was sampled for 5.7 s. The necessary phase correction was carried out automatically by a special program. In spite of the good resolution of the spectrometer, no wiggles are observed in the spectrum, so that in principle no difficulties exist in the application of the line search program. (Cf. remarks about Figure 5 in Section 2.1!)

The instrumentation (Figure 11) and computer programs will be described next:

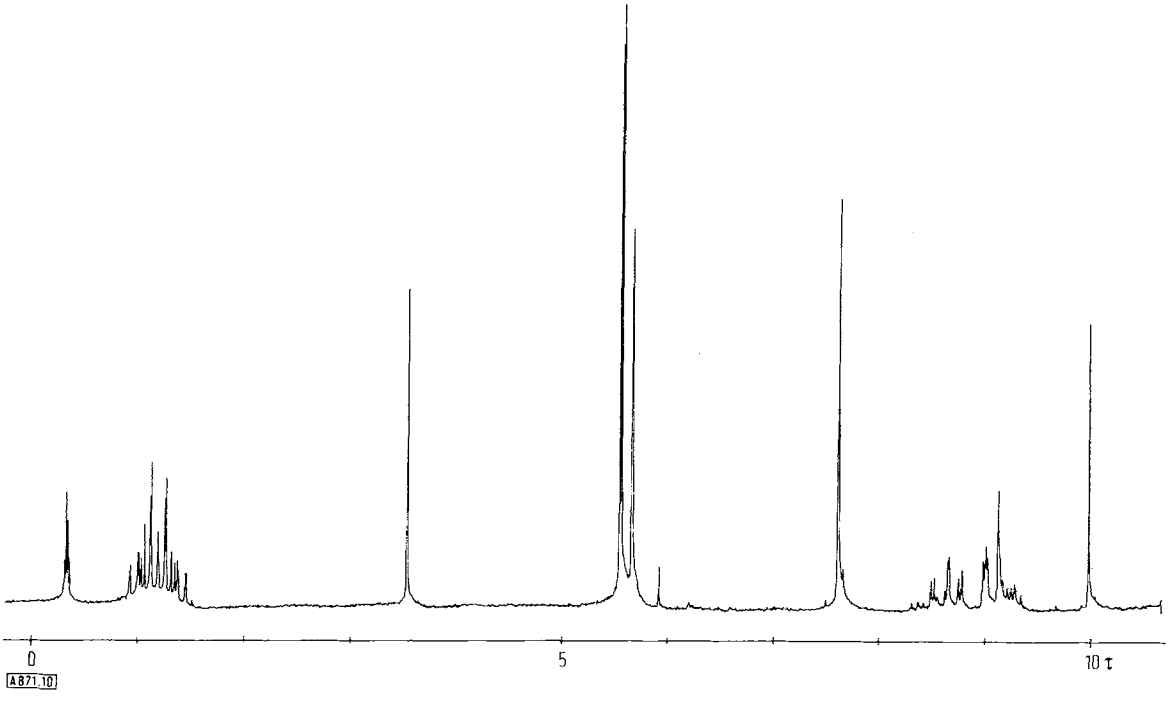

Fig. 10. Fourier transform spectrum (60 MHz) of a test sample after phase correction by the program PHASE. Signals from left to right are: Methyl formate (H),*o*-dichlorobenzene, dichloromethane, methyl formate (CH_3), methyl acetate (ester CH_3), methanol (CH_3), methyl acetate (acid CH_3), 3,3-diethylpentane, TMS. FID 5.7 s. Resolution: 4080 points/711 Hz.

For Fourier transform spectroscopy we use a multipurpose spectrometer of our own construction which can process three frequencies simultaneously. One frequency stabilizes the magnetic field on an external ^{19}F standard. The two other frequencies (ν_1, ν_2) are transmitted and received by doubly tuned networks matched to the probe coils. Thus the resonances of two kinds of nuclei can be observed simultaneously (cf. ^1H- and ^{31}P-FID of Fig. 12), or one nucleus may be observed while ν_2 is used for narrow- or broad-band double resonance experiments.

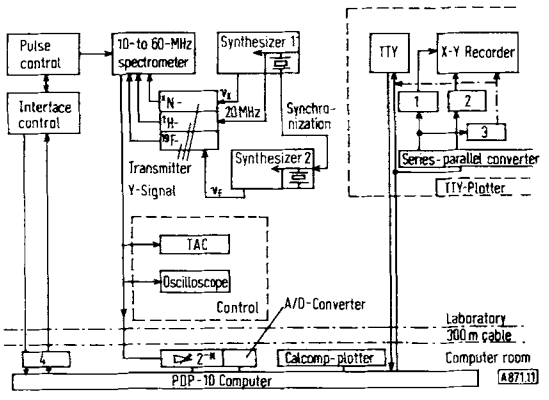

Fig. 11. Block diagram of our 14.1 kG multinuclei Fourier transform spectrometer system. See incriptions; 1, D/A converter for the ordinate (signal amplitude); 2, D/A converter for the abscissa (frequency and chemical shift respectively); 3, up/down control of the plotter pen; 4, control instrument for start/stop commands.

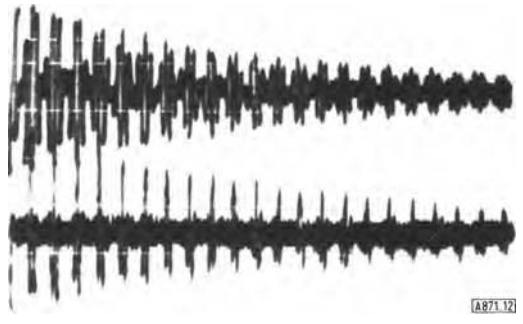

Fig. 12. Simultaneously recorded Fourier transform spectrum of $P(OCH_3)_3$. Above: Interferogram (FID) of ^1H resonance. Below: Interferogram (FID) of ^{31}P resonance. Pattern on double channel oscilloscope. Abscissa 2 s. From this $^2J_{H-P} = 10.7$ Hz. Irradiation: *ca.* 0.7 ppm off the centers of resonance.

(Examples of ^1H-$\{^{31}P\}$ experiments are shown in Figures 13 and 14.) The instrument also contains a pulse-programmer which is particularly important for spin-echo experiments and an automatic control circuit for activating fast signal sampling by the A/D-converter of the computer.

As mentioned earlier, if it is desired to measure heteroatoms with large chemical shifts, then the interface must be able to process high frequencies. For such measurements we require the "fast" interface of the computer with a maximum data rate of 20 kHz, which at present is alternatingly used for data acquisition from a rapid-scan mass spectrometer. The appropriate handling program TRADAT corresponds to the above mentioned slow acquisition program SELDAT. Like SELDAT and TRADAT, the very commonly used data accumulation program HSCAT is written in the assembler language of the PDP 10 (MACRO). The Fourier transformation is programmed in FORTRAN IV, either in the rapid version of *Cooley* and *Tuckey*[23] (FORT) or in a conventional transformation program (TRANS) of our own. Digital smoothing may also be appended (GLAETT). The method of measurement and the properties of the amplifier cause a phase rotation of the signal frequencies that varies over the whole spectrum. These phase changes are determined by the program AUTFA and correctly adjusted by the auxiliary program PHASE.

The graphical analog output on a Calcomp plotter is controlled by the program PLOTTC. The plotter allows all the calculated points to be quickly reproduced as a well-resolved spectrum. However, it is installed in the distant computer room and must be available to all users. For supervision in the laboratory, we therefore use a DAC interface, controlled by a TTY connection with an attached DIN A3 XY-recorder whose speed is limited by a teleprinter in parallel and whose resolution along both axes is only 512 points (9 bits). For this a routine PLOTTC and sub-routine TPLOT are used. Longer sets of data must be drawn out in sections (but see footnote [*] on p. 384!).

The advantages of Fourier transform spectroscopy are obvious. By suitable choice of pulse width, one can always work at maximum excitation when recording single spectra. Signal accumulation is particularly efficient because the very short sampling duration allows incomparably more records to be summed in a given time. A gain in sensitivity (signal to noise ratio) of two orders of magnitude is readily attainable. As the recording of *one* spectrum takes only seconds, kinetic phenomena extending over time intervals of 1—60 minutes can be observed by spectroscopy, and under certain conditions even very short-lived products can be detected. It may be supposed that if the computing time is too long the accomplishment of the transformation will be restricted. However, in our experience the usual time of execution (about 20 s with the fast Cooley-Tuckey algorithm) does

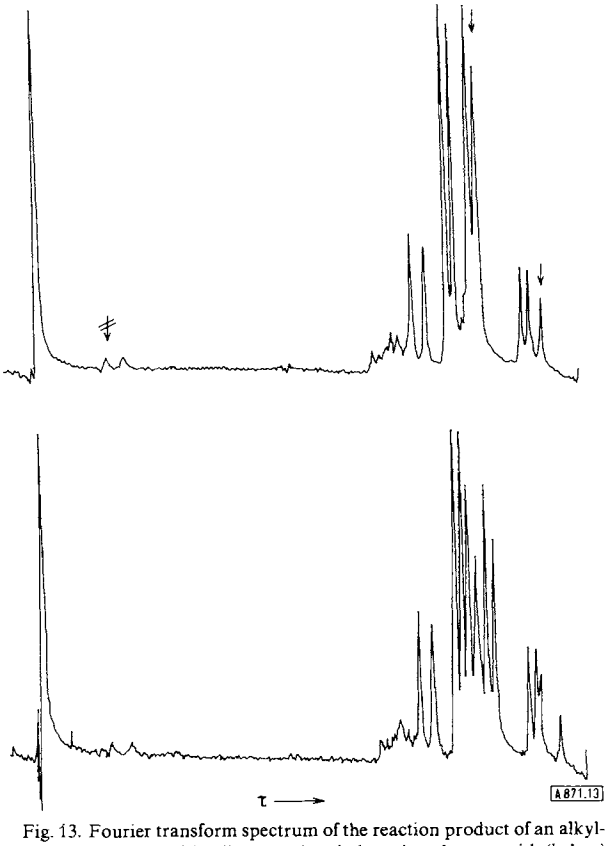

Fig. 13. Fourier transform spectrum of the reaction product of an alkylaluminum amide with triisopropylmethylenephosphorane with (below) and without (above) ^{31}P noise decoupling. Accumulated 20 and 3 times, respectively. Frequency range 500 Hz (for explanation see text). The arrows indicate the disappearance of the phosphorus coupling.

not give rise to problems, *e.g.* due to overflow of the memory.

The plotting of a transformed spectrum over a TTY recorder can take more than 20 minutes when performed under the conditions just mentioned[*]. This was the case for Figures 13 and 14. The spectrum shown in Figure 13 was recorded for the reaction product[24] of an alkylaluminum amide with triisopropylmethylenephosphorane. For the elucidation of the structure of the compound, it was important to know whether the doublet (marked with a crossed arrow) originated from ^{31}P coupling.

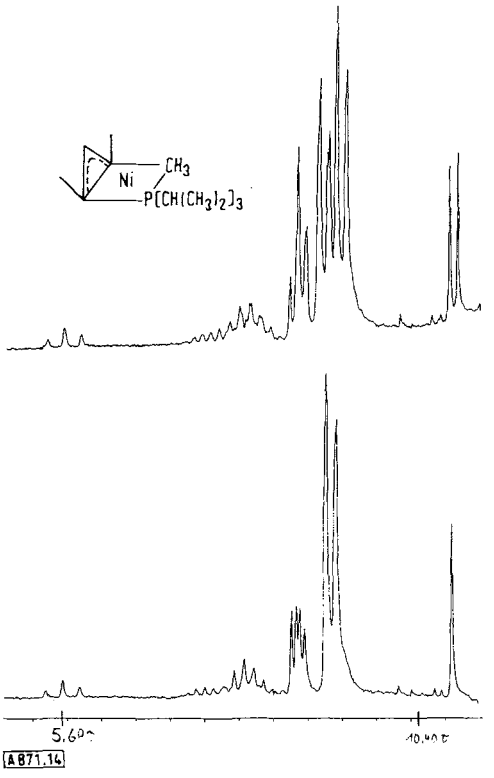

Fig. 14. Proton Fourier transform spectrum of a π-pentenylnickel complex with (below) and without (above) ^{31}P noise decoupling. Accumulated 30 and 10 times, respectively. Recording time: 2.4 s for each FID. Temperature −20°C.

Briefly the method was as follows: The region of phosphorus signals was searched for resonances with pulses while simultaneously applying spin-spin noise decoupling[26] of protons and signal accumulation. The sample gave only one phosphorus resonance which was then irradiated with a broad band. Under these conditions, the proton spectrum was pulsed and transformed. The figures show the spectra before (below) and after ^{31}P decoupling (above). The signal in question remains unchanged, and therefore does not derive from ^{31}P coupling. On the other hand the phosphorus coupling of the isopropyl signals and of the P-methylene signal (marked with arrows) are seen to disappear.

[*] In the meantime we have successfully obtained a resolution of 2^{13} (8 K) points in 12 minutes on a 60 cm flat-bed recorder by better use of the TTY code, other D/A-converters, and automatic switching to higher transfer speed (cf. Figure 10).

Another successful example of this kind is shown in Figure 14. ^{31}P decoupling made assignment straightforward. The sensitive substance[25], a π-pentenylnickel complex, was measured at low temperatures and served as a model for the assignment of a similar complex in which additional multiple splitting due to induced chirality completely obscured the line pattern.

The examples illustrate some special applications of Fourier transform spectroscopy to proton resonance at high resolution. The enormous increase in sensitivity attainable with this method, especially where an increase in signal concentration is obtained by the additional use of noise decoupling[26] and signal enhancement results from the *nuclear Overhauser effect*, makes this the method of choice for NMR spectroscopy of heteronuclei. Thus ^{13}C spectroscopy on samples with the natural isotopic abundance of only 1% has made remarkable progress despite the 6000-fold lower sensitivity compared to the case of ^{1}H-NMR[27]. However, it should not be forgotten that the nuclear Overhauser effect falsifies the relative signal intensities.

Figure 12 shows the ^{1}H and ^{31}P free induction of trimethyl phosphite, *simultaneously* displayed on an oscilloscope. The coupling constant $^{3}J_{PH}$ could easily be obtained by signal correlation[2]. Application of the method in this case would be trivial, but it is possible to think of more complicated cases for which the solution by this procedure could be of interest.

We also utilize the high sensitivity of Fourier transform spectroscopy for the detection and measurement of the ^{31}P chemical shifts of unstable transition metal complexes present in low concentrations because of their low solubility at reduced temperatures.

2.3.2. Treatment of Time-dependent Phenomena

Nuclear magnetic resonance spectra are known to be affected by rapid reactions such as ligand exchange, isomerization, and topomerization[27a] (time scale 10^2 to 10^5 μs). Changes in the number of lines and effects on the line width are possible consequences in the spectra. The transverse relaxation time T_2, whose reciprocal is a measure of the width of a spectral line, depends on the lifetime τ of the fluctuating molecular state of the chemically reacting species. Precise measurement of T_2 affords rate constants whose temperature dependence yields information about activation energy and enthalpy and entropy of reaction.

Basically two methods can be used to determine the kinetics of reactions on the NMR time scale[6, 28, 29], *viz.* the "line-shape" method and the spin-echo procedure.

The former includes the derivation of analytical expressions for the spectral pattern as functions of the different rate constants. These expressions can be very unwieldy when spin coupling is accounted for and can normally only be solved by computer[6, 29]. The observed spectra are compared with those computed either by inspection or by iteration procedures. The recent development of a so-called "direct"[31] method of calculating spectral patterns including line shapes by *Binsch et al.*[30] has made

the derivation of rate constants from spectra a very powerful method. The procedure (program DNMR 3)[32] simulates the whole spectrum, and besides having the advantage of providing spectral assignments it also yields the line shape parameters and thus kinetic data too. Since this method takes account of all lines, including those unaffected by the reaction, it is to a great extent free from systematic errors and is therefore generally applicable to NMR. Unfortunately the demand on core storage is well over 30 K, so that we use the method only occasionally. However, attempts are being made to reduce the program size by more than 9 K[33]. An iteration method has also been appended to the program[34].

3. Conclusion

The computer system of our institute is able to handle most of the qualitative requirements of the NMR spectroscopist satisfactorily. In daily practice, the dialog mode of computer usage made possible by time-sharing has been a definite advantage. Working in our laboratory we can easily write, or modify, our own programs, and adapt foreign programs. Moreover, we can simplify the data input and supervision of the execution of our programs, as well as initiate the start and control routines of the instruments operating on-line.

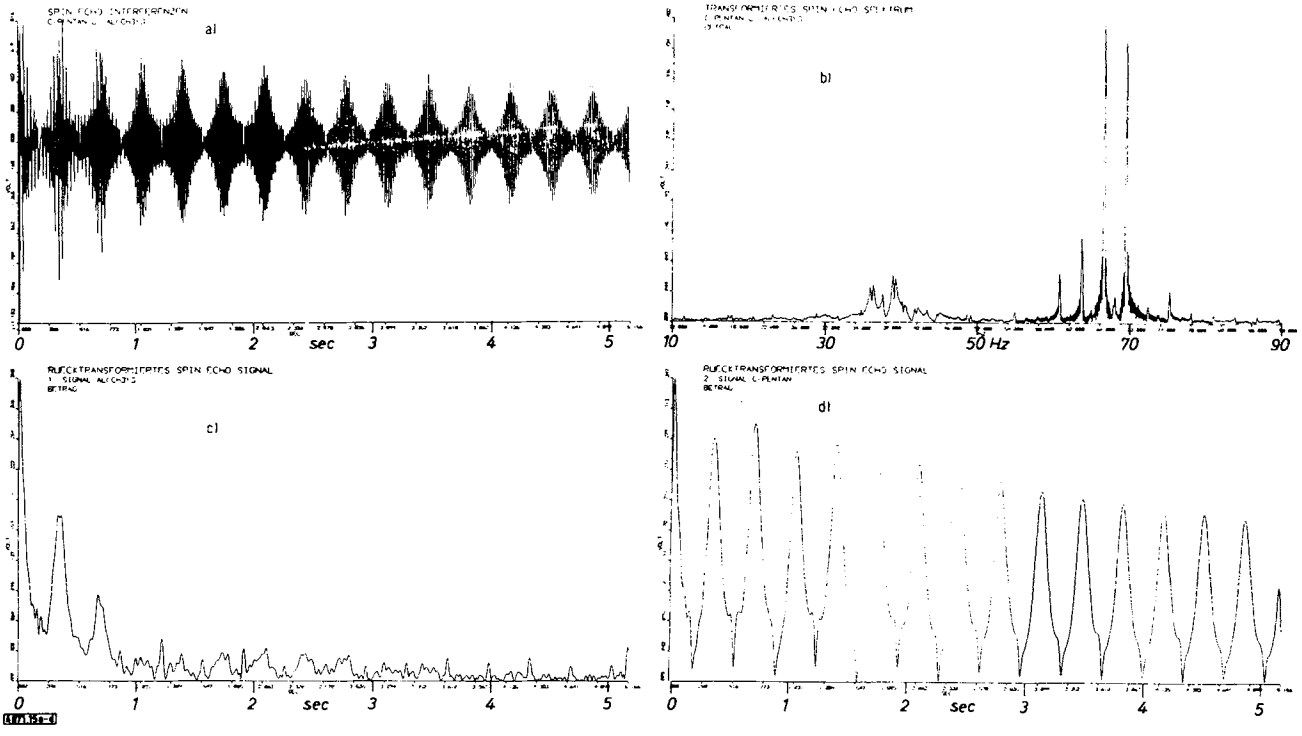

Fig. 15. 51.9% solution of $[Al(CH_3)_3]_2$ in cyclopentane as an example of simultaneous determination of two T_2 values differing considerably owing to methyl group exchange in $[Al(CH_3)_3]_2$. Recorded at 180°-pulse separation of $2\tau = 0.348$ s. Our sample gives $T_2 = 10.6$ s for cyclopentane, and 0.56 s for trimethylaluminum (from [38]). a) Spin echo interference pattern of cyclopentane and $[Al(CH_3)_3]_2$. b) Transformed spin-echo spectrum. c) Inverse transformation of the 1st signal (trimethylaluminum) of b. d) Inverse transformation of the 2nd signal (cyclopentane) of b.

(The line-shape method belongs to the type of applications described in Section 2.2.)

We have tried to master the extended application of the spin-echo method, as described by *Hahn*[35], *Carr* and *Purcell*[36], and *Meiboom* and *Gill*[37], to chemical kinetics. The spin-echo method is directly applicable only to single signals. A spin-echo record complicated by chemical shifts and/or coupling constants gives interferograms which are *a priori* not interpretable. Meanwhile, however, we have succeeded[38] in separating the signals by Fourier transformation, and reproducing the spin-echo trace for each line by inverse transformation of the frequency section of the signal groups for each line. This yields the transverse relaxation time T_2 (Figure 15). We hope in this way to be able to use the spin-echo method also for more complex systems.

The least problems are encountered on operation with the "slow interface" and the related programs. There are fundamental difficulties involved in writing an infallible evaluation program which limit the routine acquisition of spectra at slow scanning rates. In our view, *general* use of Fourier transform spectroscopy should make for completely computerized processing of the spectra once some minor difficulties with phase correction and the resulting integration error have been overcome.

For certain problems, however, the combined time-sharing and real-time processing of our computer system does not allow continuous work. Of course, some extensive programs such as relatively involved simulation and iteration programs or programs for dynamic nuclear magnetic resonance spectroscopy (DNMR), can be run off between 8 a.m. and 5 p.m. as long as they do not require

more than 28 K storage units. Larger problems must be dealt with outside these hours.

More serious is the computer processing of problems requiring long continuous operation, as for example with prolonged spectrum accumulation. Here each interruption of normal time-sharing operation (*e.g.* for routine checks) or machine failure can destroy the accumulated records. It is also difficult to apply automatic checks over short time intervals or to employ proportionality control, which is desirable for spectrometer optimization.

The greatest difficulties arise in the use of the "fast interface", which is always employed with pulsed spectroscopy. Access alternates with that by rapid mass spectroscopy[39] when the latter is coupled with gas chromatography. The interface can only be used for 2.5 to 3 s between successive mass spectrometer recordings since control of a combined GC/MS analysis requires a definite timetable and therefore has higher priority for access to the fast analog/digital converter. However, this rigid timetable is unacceptable for pulsed spectroscopy and restricts its efficiency considerably.

For the future, it will therefore be expedient to enlarge the system by inclusion of small satellite computers to relieve the central computer of limited problems concerned with process control, data transmission, and data acquisition and output, and thus allow unrestricted continuity of operation. The latter is especially important since uninterrupted, freely scheduled Fourier transform spectroscopy is accompanied by qualitative advantages such as further increases in sensitivity and selectivity by use of "driven equilibrium Fourier transform spectroscopy" (DEFT)[40] or other multiple pulse methods[40a]. We are attempting, therefore, to connect a small computer across a fast TTY input by means of a data coupler or directly at the input/output bus to the large machine. In our situation such an investment seems justified to rationalize the use of three large analytical instruments adapted for computer connection, two of which being able to perform Fourier transform spectroscopy.

We would like to thank Messrs. A. Iländer, A. Bischof, and H. Brenneke for their cooperation in electronic developments, and for the preparation of the instruments for connection to the computer.

Automated X-Ray Structure Determination as an Analytical Method

By Carl Krüger[*]

1. Introduction

The last few years have seen such rapid advances in X-ray structure analysis, even of complicated chemical compounds, that the method now appears able to provide the preparative chemist with a valuable service as a modern analytical technique. The main reason for this development is technological progress. Firstly, large, third-generation computers, which are necessary for the time-consuming evaluation of extensive data sets, have become available; secondly, the manufacturers of analytical instruments offer fast automatic diffractometers that are necessary for the collection of these data. The working schedule for the elucidation of the exact structure of a chemical compound by three-dimensional X-ray structural analysis is therefore divided into two parts:

1. Measurement of position and intensity for a large number of diffraction data from a single crystal

2. Evaluation of these data for subsequent solution of the structure and representation of the molecule and the contents of the unit cell of the crystal.

The first part of this report describes the operational features of our diffractometer system, while the second part deals with our computational approach to the solution of structural problems. Problems that have not yet been satisfactorily solved are indicated. It should be pointed out that ours is not the only system possible, but an optimal one for our computational and operational facilities.

2. Fully Automatic Single-Crystal Diffractometers

Construction and operation of modern single-crystal diffractometers have already been described in detail[1]. As a common feature, crystals having approximate dimensions of 0.1 to 0.6 mm are mounted on a carrier and oriented in a homogeneous, monochromatic X-ray beam in reflecting positions according to *Bragg*. The integrated intensity of a reflection is measured with a scintillation counter. During the course of one analysis of average difficulty, there are more than a thousand reflecting positions for a crystal and a corresponding number of intensity measurements must be performed.

Most of the available instruments orient the crystal into reflecting positions using the so-called "Eulerian cradle" which allows the crystal to be rotated about three or four axes into any position. Control of these movements in early instruments was accomplished using stepping motors driven by paper tape. This technique relies heavily on the availability of a computer for preparing the controlling tapes. Any changes in the measuring parameters during data collection (*e.g.* crystal misalignment) were tedious and necessitated preparation of a new controlling tape. This and other similar tasks may be more flexibly performed automatically by a process-control computer.

In principle this control could also be accomplished by a time-sharing computer in on-line operation. The advantages of such a mode would include the programming facilities available in a higher-level language (FORTRAN *etc.*), fast program change, and direct data transfer to external data storage devices of the computer. An alternative would be the utilization of a small process-control computer or "dedicated computer" (see ref. [2] for the advantages and disadvantages of these two systems).

In lengthy experiments, where a relatively large computer effort is required for control, the use of a small computer appears more suitable. A small computer is independent of servicing and breakdown periods of a naturally more sensitive, large computer system. It is useful, however, to link the small computer to a large computer for rapid transfer of programs and data. Thus the external storage capacities of a large computer become accessible, while still preserving a certain independence in the data collection system. The arrangement of our diffractometer system is shown in Figure 1.

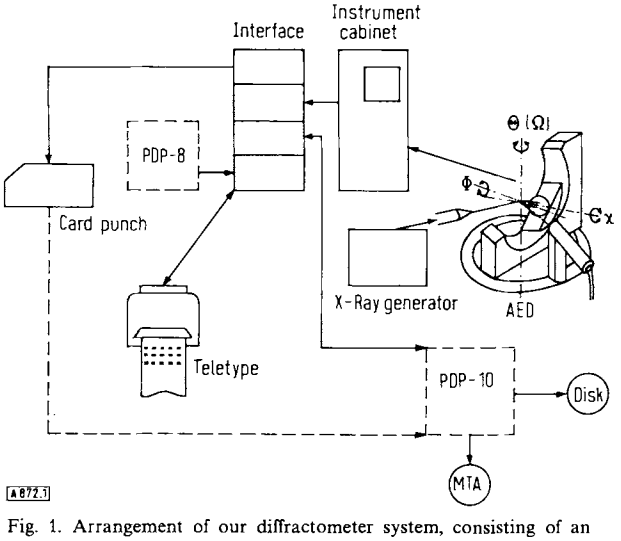

Fig. 1. Arrangement of our diffractometer system, consisting of an automatic, four-circle X-ray diffractometer, Kristalloflex 4 AED (Hoppe-Siemens), an interface, and a small computer (PDP 8) connected to a large computer (PDP 10). For further details see text.

A fully automatic four-circle diffractometer[*] (AED Siemens-Hoppe)[3] is controlled by a small PDP 8 computer (12-bit word length, 4 K memory and 32 s cycle time) using an interface linked to an IBM 026 card punch. An ASR 35

[*] In principle, all commercially available computer-controlled diffractometers can be used in the manner described here.

teletype is also connected *via* an additional link and can be used to communicate with the large computer. The connection between large and small computers is very important. For several technical reasons we chose to connect the small computer in the simplest possible manner, *i.e.* as a pseudo-teletype, which allows for selection of various data transfer rates[4][*].

This type of connection can be made without altering the operating system of the large computer. The normal data transfer rate permits operation of the teletype as a normal time-sharing terminal, but data-collection programs or data can be transferred ten times faster if desired. The experimentalist therefore enjoys the advantages of both systems.

Storage of data collection programs for a process-control computer in binary form on external devices of a large computer and loading them when needed has proved to be an optimal mode of operation. The time required for loading programs is ordinarily about two minutes. Programs which may be needed at the diffractometer in the course of the experiment may also be initialized on the large computer from the same teletype (*e.g.*, least-squares programs for cell dimensions or programs for generation of Miller indices with the corresponding angular values for the instrument).

Figure 2 gives the scheme of a routine X-ray analysis[5].

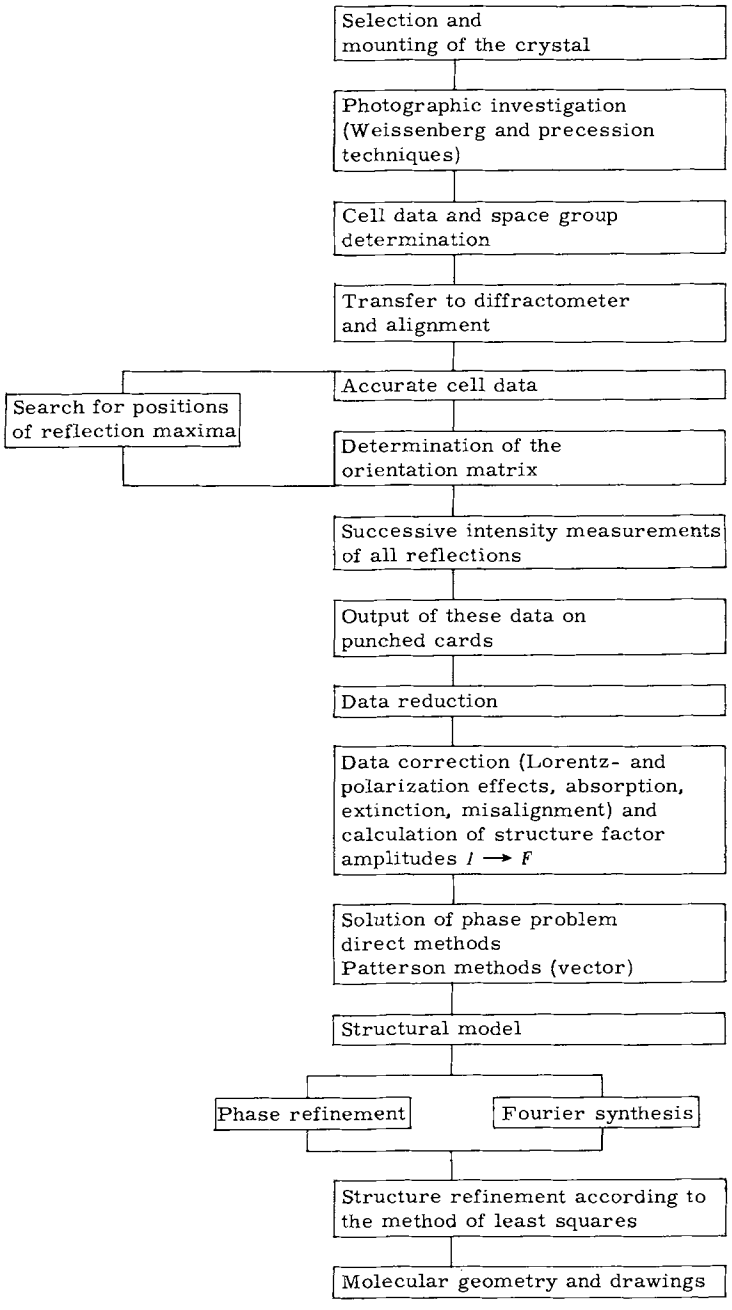

Fig. 2. Scheme of a routine automatic X-ray structural analysis.

After selection with the aid of a polarizing microscope, the crystal may be mounted on a goniometer head, if necessary under an inert gas atmosphere in a Lindemann glass capillary, centered, and adjusted optically. Determination of cell data and space group is performed by Weissenberg and precession photographic techniques, which also furnish information about the crystal quality and crystal symmetry. Crystal and goniometer head are transferred to the automatic diffractometer where the operations of centering and adjusting the crystal are computer controlled.

Crystal quality is again checked (Ω-scans, Φ-scans) before data collection. Accurate diffracting angles of several (*ca.* 50) high-angle reflections are then determined from the positions of the maxima obtained by computer controlled step-scan profiles using a receiving slit in front of the scintillation counter. These measured data are treated by the method of least squares and yield accurate unit cell parameters (± 0.001 Å) that are subsequently used for exact positioning of the crystal and counter for the determination of the intensities of the reflections.

Various programs for these operations are available for the small as well as the large computer and are accessible from the teletype. Experience has shown the availability of more than one computer system to be especially time-saving in such cases.

A possible alternative to the point-to-point search for reflections lies in the use of computer programs that determine optimum angular positions of accessible reflections within specified limits and record these values. From our experience we prefer the former method.

The actual data collection program of the controlling computer subsequently generates Miller indices of desired reflections within defined limits and excludes those that are systematically absent due to molecular arrangement (space group).

Every reflection is centered on the counter by movement of the "Eulerian cradle" and the integral intensity is determined by scanning in one angle. Each reflection has five measured values of which two are background measurements on each side of the peak (five-value measurement[6]).

There are also data collection programs employing difference filter measurement. Every reflection is scanned twice: once with a filter screening out the white radiation and a

[*] Alternatively, the diffractometer could be controlled by a small computer with an expanded memory (8 K) or a fast disk unit. These systems are relatively economical, but not in comparison to our system.

second time with another filter screening out the primary peak as well as the white radiation.

Additional characteristics of our measuring programs include the following: The scan-width for each reflection can be controlled as a function of the diffracting angle by the computer, thus reducing the overall measuring time. Furthermore, very strong reflections are scanned with attenuating filters automatically introduced into the primary beam and are marked accordingly. The intensity of a monitoring reflection is determined with a slit system at the end of a cycle (about 20 to 40 reflections) and indicates possible misalignment or decomposition of the crystal. Misalignment errors are reported. Output of the measured intensity as well as the diffractometer parameters for each reflection are printed out on the teletype and punched on cards. The remainder of the calculations for the structural analysis is done off-line on the large computer.

3. Determination of the Structure

After data collection the measured intensities are prepared for evaluation. The relevant program[7] utilizes the five measurements of each reflection, determines probable errors and indicates possible reasons, scales the data with respect to the initial monitoring reflection, and then writes the results onto a magnetic tape that is used for the actual data reduction. Most of our programs write data onto magnetic tapes that are subsequently read by other programs. Data reduction first corrects the measured intensities (I) for Lorentz and polarization effects and for absorption, and then converts them into the required amplitudes (structure factor amplitudes, F)[8].

The crucial and remaining problem of an X-ray crystal structure analysis is to derive the electron density distribution of the unit cell, which means computing the parameters that define the geometry and vibrational characteristics of the molecule. Given the measured amplitudes (structure factor amplitudes ($|F|$)) and the corresponding phases, this computation is relatively simple. However, the necessary phase angles (zero and π for centrosymmetric space groups) are neither known nor measurable.

The subsequent mathematical treatment of the structural analysis is divided into three parts:

1. Solution of the phase problem by finding parts of the molecule

2. Construction of the complete molecule

3. Adjusting the molecular parameters to the measured data.

For practical solutions to the phase problem the methods described in Sections 3.1 and 3.2 have been applied successfully.

3.1. Heavy Atom Method

In this method the larger electron density of a heavy atom is utilized to ascertain the spatial position of the heavy atom by Patterson methods with the squared amplitudes ($|F^2|$) and does not require any knowledge of the phases. A sufficient number of phases are then known so that a Fourier synthesis will establish the remainder of the molecule more or less completely.

Similar results are obtained by the convolution method[9]. The geometry of a known molecular fragment (*e.g.* one or more benzene rings) generates a vector set which is optimally adjusted to the observed vector set. Phases obtained from the located molecular fragment are then applied as a pseudo heavy atom.

3.2. Direct Methods

Direct methods[10] are structural solving processes which furnish structural models directly from structure factor amplitudes and not from information about heavy atoms *etc.* These methods employ statistical relationships between the phases of certain reflections (triple-product relationship). For centrosymmetric space groups there are computer programs that yield probable solutions by iterative techniques. This method is best applied to molecules with atoms of similar atomic number. The program set (FAME-MAGIC)[11] which we use works automatically in most centrosymmetric problems. Structures in acentric space groups require considerably more mathematical treatment, but computer programs for these situations are in an advanced testing stage in several laboratories.

Apart from these principal methods, crystal structures can also be solved by anomalous dispersion effects or by isomorphous replacement of heavy atoms where the space group symmetry remains the same. Another, "trial and error" method which adjusts a given model to the unit cell has received only limited attention.

4. Structural Refinement

After a sufficient part of the molecule has been ascertained, the complete construction of the unit cell is determined by successive Fourier and difference Fourier syntheses. Proposals have also been made for automation of this time-consuming part of structural analysis[12]. One method which appears very promising refines the occupancy factors of all atoms according to a third order polynomial equation (phase refinement). Also included in this refinement are positions which may eventually prove to be false. The method works in reciprocal space as well as real space[13] and is being automated.

The last step, which requires the most computer time, adjusts the atomic positions and vibrational parameters to the observed data by the method of least squares[8]. The subsequent calculation of inter- and intramolecular distances and planes or drawing of the molecule, as shown in several examples, requires comparatively less computing time.

The program system which we apply to structural determinations has been developed around the operational mode of the available computer. All of the necessary programs are stored on a disk unit and are individually accessible from a teletype at any time. Input data for these programs

can also be given from the teletype, while all other information is stored on mini-magnetic tapes or on disk units and are retrievable when needed. Systems for other computers work similarly, but input control for programs is generally by punched cards[14][*].

5. Examples

The following typical examples illustrate how efficient these present methods are in application to routine operations.

The drawings were prepared with a local modification of the program ORTEP[15] on an x-y plotter.

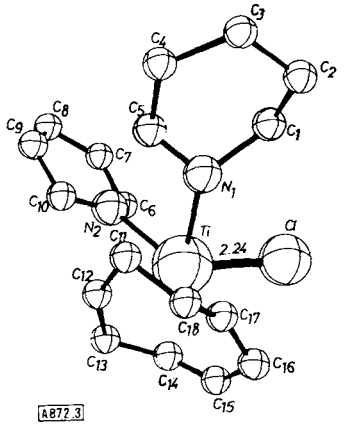

Fig. 3. Structure of a pyridine adduct to cyclooctatetraenechlorotitanium.

Figure 3 shows the geometrical arrangement of a pyridine adduct to a cyclooctatetraenechlorotitanium. The gross features of the structure were obtained by direct methods, even though the cyclooctatetraene fragment was disordered about the transition metal atom and the pyridine rings occupy two statistically disordered orientations. Several examples of similar disorder are known[16].

A further example indicates the present limits of our operation with respect to molecular size and is depicted in the stereoscopic drawing of Figure 4. This structure is a nitrogen adduct to bis(tricyclohexylphosphane)nickel(0) and is a molecule with 80 atoms[17].

In this analysis 5977 reflections were measured with the following cell data: $P2_1/n$, $a=21.83$, $b=16.54$, $c=21.24$ Å, $\beta=102.7°$, $Z=4$, d(X-ray)$=1.12$, d(observed)$=1.13$ g cm^{-3}. The positions of the heavy atoms were determined by direct methods; all subsequent C and N atom positions were established through ten cycles of phase refinement in direct space. The following refinement of the molecular parameters had to be divided into several parts, because the size of the problem far exceeded the capacities of the computer.

In view of this situation, the resulting computing time for the anisotropic refinement of the vibrational parameters

indicated termination of the refinement at the agreement value of $R=0.11$. Figure 5 shows the geometry for an important section of the molecular grouping $P_2Ni—N{\equiv}N—NiP_2$.

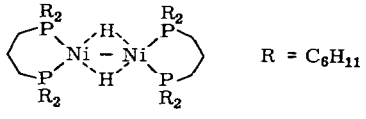

Fig. 7. Structure of di-μ-hydridobis[1,3-trimethylenebis(dicyclohexylphosphane)nickel] *(Ni-Ni)* and structural formula.

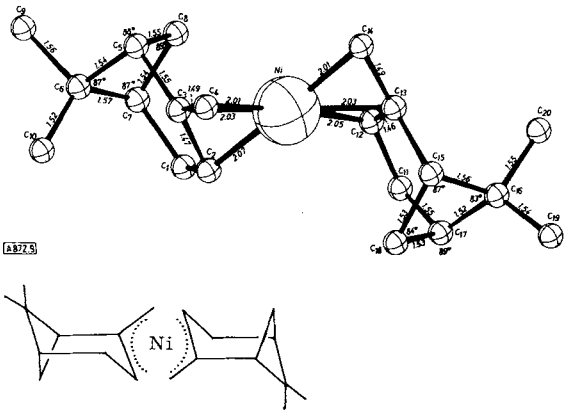

Fig. 9. Structure of bis(π-pinenyl)nickel and structural formula.

symmetry axis can be seen parallel to the *c* axis. The molecular structure is also illustrated stereoscopically in Figure 9 and Figure 10.

The last example, the structure determination of a compound prepared by the displacement of one carbonyl from $Ni(CO)_4$ by the ylide tricyclohexylethylidenephosphorane, will also illustrate the costs incurred by a three-dimensional structural analysis. The molecular arrangement is shown in Figure 11[20].

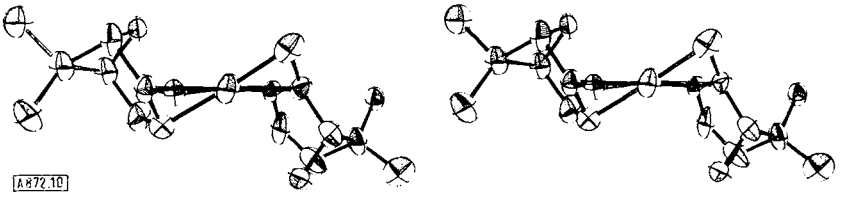

Fig. 10. Stereoscopic drawing of bis(π-pinenyl)nickel.

From Figure 6 it is evident that the effective stability of this compound is primarily dependent on the molecular nitrogen being enclosed by the cyclohexyl rings. This steric arrangement is also evident in the dihedral angle of 96.7° between P—Ni—P planes (see also Fig. 4).

A similar torsion (116.7°) between opposite P—Ni—P groups can also be observed in di-μ-hydridobis[1,3-trimethylenebis(dicyclohexylphosphane)nickel] *(Ni-Ni)* (Fig. 7[18]). The bond distance of the complexed nitrogen is slightly lengthened (0.01 Å) compared to that in the free state.

Another form used to illustrate the molecular parameters with the plotter program ORTEP is shown in Figure 8 for the unit cell of bis(π-pinenyl)nickel[19]. A two-fold screw

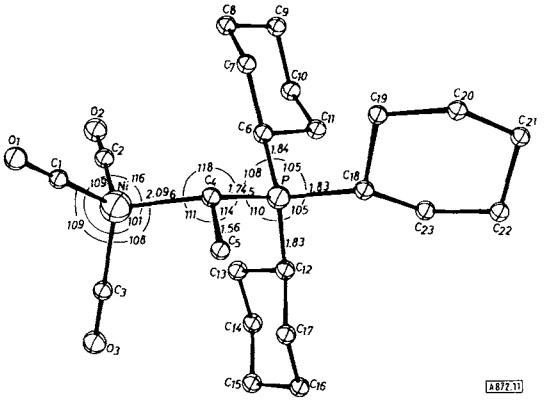

Fig. 11. Structure of the compound $(CO)_3Ni{-}CH(CH_3){-}P(C_6H_{11})_3$.

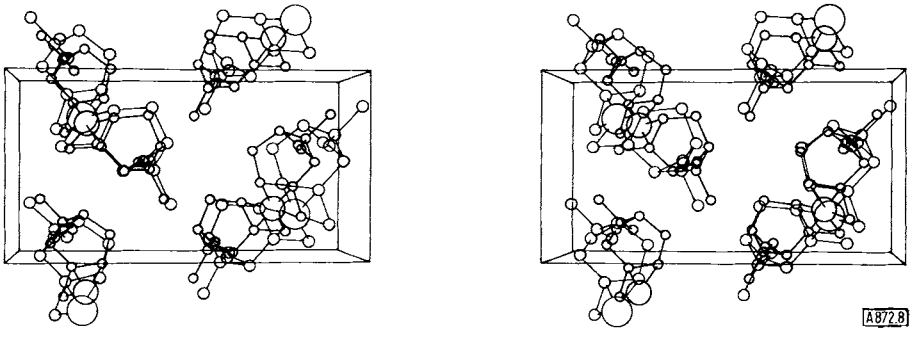

Fig. 8. Stereoscopic drawing of the unit cell of bis(π-pinenyl)nickel. *a* axis horizontal, *b* axis vertical.

The formation of a sigma Ni—C bond between the sp^3 carbon (C4) of the ylide and the transition metal is of interest. This bond is noticeably longer than several other σ-Ni—C bonds[17, 21] which we have recently investigated (Figs. 12 and 13). The phosphorus-carbon distance is relatively short, although longer than that found in free ylides[22], but is similar to the P—C distance found in phosphonium compounds[23].

According to our present experience three-dimensional structural analyses of average difficulty (approximately 50 atoms per molecule maximum) can be completed in a minimum of four weeks. Certain unforeseen difficulties that may occur during the analysis can increase this time to two or three months. Of course the minimal time is based on the availability of a large computer and an automatic data collection system. Approximately a week for each part of the analysis—preliminary investigation, data collection, structure determination, and refinement (±0.01 Å)—has been assumed.

The cost of such an analysis is largely dependent on the expenditures for computer time and man-hours required. Depending upon the problem this may be between DM 20000 and DM 200000. It clearly follows that routine X-ray structural analyses should be applied only in situations where less expensive methods do not provide sufficient information.

Application of Computers to MO Theory and Chemical Kinetics

By Günther von Bünau[*]

1. Introduction

The rapid development of electronic computers in recent years has led to the situation where the methods and ideas of theoretical chemistry can be applied in ever-increasing degrees to the problems facing the experimentalist. Whenever it is suspected that observed phenomena may be traced back to molecular properties the question arises of the possibility of a calculation delivering a quantitative statement about the structure, stability, and reactivity of the molecule. There is little doubt today that such a calculation must ultimately return to the quantum mechanical theory of molecules, *i.e.* solution of the Schrödinger equation. Nevertheless, it is not yet clear to many chemists how relatively simple it is to carry out their own quantum mechanical calculations with programs and computers already available. The FORTRAN texts of some standard programs (for example, Hückel[1] and CNDO[2]) have already been published in books. Many other programs of importance to theoretical chemistry can be readily obtained from the Quantum Chemistry Program Exchange Project (QCPE) of the University of Indiana (Chemistry Department, Bloomington, Indiana 47401, USA). (In Germany the QCPE programs are distributed by the Deutsches Rechenzentrum in Darmstadt.) Moreover, most computing centers have program libraries already containing QCPE and other programs of interest to chemists. Comprehensive descriptions and directions with respect to input data exist for all well-tested programs.

The purpose of this article is, therefore, to give the experimental chemist a feeling for the nature of the programs which are available for the solution of his problems and for the input data necessary for molecular calculations. First, we consider programs for the calculation of the coordinates of the atomic nuclei in a molecule. These coordinates represent the most important input data for most quantum mechanical calculations and are also important in calculation of reaction kinetic frequency factors (Section 2). For an understanding of the differences among the numerous quantum mechanical models, it is also necessary to analyze the Schrödinger equation and discuss the various possibilities for its approximate solution (Section 3). A few simple MO theory examples calculated at the Max-Planck-Institut für Kohlenforschung in Mülheim will then be described in detail to illustrate these points (Section 4). Following this, a few special methods from reaction kinetics will be discussed which allow the estimation of activation energies of H atom transfer reactions (BEBO method, Section 5.1) and the calculation of the energy-dependence of unimolecular decompositions (quasi-equilibrium theory, Section 5.2). Finally, the phenomenological treatment of complicated kinetic systems with the aid of a computer will be mentioned (Section 6).

2. Coordinate Calculations

The coordinates of the atoms in a molecule may always be determined by the usual methods of vector calculations since the bond angles and distances are either known or are varied in the calculation. For larger molecules, the accomplishment of this task can be very tedious and is better left to a computer[3,4]. The program KOORD, a variation of QCPE 136, in use at Mülheim not only calculates the atomic coordinates of a molecule in any orientation, but also derives quantities such as: center of mass coordinates, principal moment of inertia, rotational partition function, and spectroscopic rotational constants. In addition, KOORD also calculates the translational partition function from the molecular mass and draws projections of three-dimensional molecular models (Fig. 1).

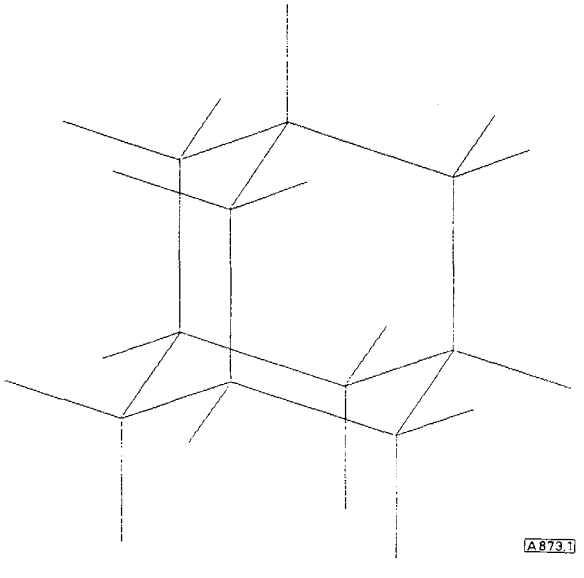

Fig. 1. Plotter drawing of the adamantane molecule (projected stick model).

Program KOORD requires about 12000 core locations. The Mülheim computer requires 0.38 s to determine the 24 coordinates of the ethane molecule; only 0.46 s are necessary for determination of the 78 coordinates of adamantane. Thus, in general, the computational time is small compared to the time required for the output of the computer calculation with a rapid line printer or plotter.

With certain assumptions, the coordinate calculations may also be used to estimate the frequency factors for

reaction rate constants. For instance, in the sense of the Eyring theory, the rate constant k_r of a bimolecular reaction

$$A + B \rightleftharpoons AB^{\ddagger} \rightarrow \quad (1)$$

may be written as

$$k_r = \frac{kT}{h} \times \frac{Q^*}{Q_A \times Q_B} \exp\left(-\frac{\Delta E_A}{RT}\right) \quad (2)$$

where k is the Boltzmann constant, T the absolute temperature, and h Planck's constant. Q_A, Q_B, and $Q^{\ddagger}$ represent the partition functions of the molecules A, B, and $AB^{\ddagger}$ respectively, and can be written as products of the translational, rotational, and vibrational partition functions. At sufficiently low temperatures, the contribution from the vibrational partition function is small so that the total partition function may be taken from the coordinate calculation. Correspondingly, the frequency factor

$$A = \frac{kT}{h} \times \frac{Q^*}{Q_A \times Q_B} \quad (3)$$

of a bimolecular reaction may always be estimated from the coordinate calculation if the vibrational partition functions may be neglected or cancel out of the ratio of the total partition functions of the transition and initial states.

3. Molecule Theory

In the quantum mechanical theory of molecules, each molecule is assigned a function of state Ψ which may be found by solution of a Schrödinger equation set up especially for that molecule. The state function is necessarily quite complex since, according to the axioms of quantum mechanics, all measurable properties of molecules can be extracted from Ψ by subjecting it to some characteristic computational procedure.

The energy of a molecule is of prime interest. Given the approximation that the total energy of the molecule be represented as a sum of energies of translational, rotational, vibrational, and electronic motion, it is possible to solve the separated Schrödinger equations for each type of motion. It is especially significant for quantum chemistry that the separate treatment of the molecular electronic state is in general a very good approximation (Born-Oppenheimer approximation, Section 3.1). The real basis of the MO theory is, however, the orbital approximation (Section 3.2) which is familiar to the chemist from the special case of the electron configurations of atoms (*e.g.* $1s^2 2s^2 2p^2$ for the ground state of the C atom). For the practical calculation of the electronic Ψ function, the complicated molecular orbitals are written as linear combinations of simpler "basis orbitals" (Section 3.3). Sometimes, only the molecular orbitals of the valence electrons are calculated by application of empirical parameters (Section 3.4).

3.1. Born-Oppenheimer Approximation

Every quantum mechanical description of a molecule consisting of N atoms and n electrons presupposes the calculation of the (total) wavefunction Ψ of the molecule. Ψ is a function of the atomic and electronic coordinates and the time t; Ψ^2 is the probability density for finding the system in a given configuration. In principle, Ψ can be determined by solution of the Schrödinger equation

$$H\Psi = -\frac{\hbar}{i} \cdot \frac{\partial}{\partial t} \Psi \quad (4)$$

where $i = \sqrt{-1}$ and the operator H represents

$$H = -\frac{\hbar^2}{2m} \sum_k^n \nabla_k^2 - \sum_k^n \sum_\nu^N \frac{Z_\nu e^2}{r_{k\nu}} + \sum_{k<l} \frac{e^2}{r_{kl}} - \frac{\hbar^2}{2} \sum_\nu^N \frac{1}{M_\nu} \nabla_\nu^2 + \sum_{\nu<\mu} \frac{Z_\mu Z_\nu e^2}{R_{\mu\nu}} \quad (5)$$

Here, ∇_k^2 is the Laplacian operator for the k^{th} electron

$$\nabla_k^2 = \frac{\partial^2}{\partial x_k^2} + \frac{\partial^2}{\partial y_k^2} + \frac{\partial^2}{\partial z_k^2} \quad (6)$$

$\hbar = h/2\pi$, h is Planck's constant, m is the mass and e the charge of the electron, $r_{k\nu}$ the distance between the k^{th} electron and the ν^{th} nucleus, r_{kl} the distance between electrons k and l, $R_{\mu\nu}$ the distance between atomic nucleii μ and ν of charge Z_μ and Z_ν respectively.

Physically, the terms on the right hand side of eq. (5) can be interpreted as follows:

1. The kinetic energy of the electrons
2. The potential energy of the electrons in the field of the atomic nucleii
3. The mutual electrostatic repulsion of the electrons
4. The kinetic energy of the nucleii
5. The mutual electrostatic repulsion of the nucleii

In addition to these terms, the complete Hamiltonian operator H must contain further terms which consider the interactions of the electrons with external fields (*e.g.* in ESR) and nuclear spins (*e.g.* in NMR), and relativistic effects (*e.g.* for high energy molecular beams). A description of the explicit forms of such terms may be found in ref[5]. The calculation of such weak interactions as well as the time dependence of Ψ are accessible only with the help of quantum mechanical perturbation theory. There, we presume a knowledge of the wave functions of the unperturbed system, which may be taken from the Schrödinger equation for the stationary molecular states.

$$H\overset{0}{\Psi} = E\overset{0}{\Psi} \quad (7)$$

E is the total energy of the molecular state under consideration. Apart from the special cases already mentioned, all quantum mechanical methods of calculation are ultimately based on eq. (7). Equation (7) cannot be solved exactly and must be further simplified before an approximate solution can be found for chemically interesting cases. The numerous

approximation techniques employed in the last few decades are based on various physical models, the most important of which is the Born-Oppenheimer approximation[6].

The Born-Oppenheimer approximation is based on the fact that the electrons, owing to their several-thousand-fold smaller masses, move much faster than the nuclei. The electrons thus adjust to any change in position of the nuclei (*e.g.* the vibrations of the nuclei about their equilibrium positions) so rapidly that relaxation effects can be ignored. This approximation corresponds to the possibility of separating the last two terms in eq. (5) and solving separated Schrödinger equations for nuclear and electronic motion.

3.2. Orbital Approximation

In the orbital approximation, the total electronic wave function is represented as a product of one-electron wave functions ψ_i

$$\Psi_{el} = \psi_1(1)\,\psi_2(2)\cdots\psi_n(n) \tag{8}$$

Since the electrons are indistinguishable, Ψ_{el} must be invariant (except for a change of sign) on exchange of electron coordinates (Pauli principle). Equation (8) does not meet this criterion but linear combinations of such products can be found which do fulfil the Pauli principle. For this purpose, the individual electrons are usually assigned a spin function and only products of the same total spin are combined.

In the case of filled shells (*i.e.* each occupied orbital is filled with two electrons of opposite spin), the orbital approximation implies that Ψ_{el} is a solution of the Hartree-Fock equation:

$$\left[-\frac{\hbar^2}{2m}\nabla_k^2 - \sum_{\nu}^{N}\frac{Z_\nu e^2}{r_{k\nu}} + \sum_l (2J_l - K_l)\right]\psi_k = E_k\psi_k \tag{9}$$

where

$$J_l(1) = \int \frac{e^2\psi_l^2(2)}{r_{12}}\,d\tau_2; \quad K_l(1)\psi_k(1) = \left[\int \frac{e^2\psi_k(2)\psi_l(2)}{r_{12}}\,d\tau_2\right]\cdot\psi_l(1)$$

The electron repulsion term of the Schrödinger equation is approximated in the Hartree-Fock treatment by an expression which considers only an average repulsion, *i.e.* the repulsion of an electron appears in the calculation as the interaction of one electron with the average field generated by all other electrons. Since the total distribution of the electrons can only be obtained from the unknown Ψ function or its square, the expression in brackets in eq. (9), *i.e.* the Hartree-Fock operator, assumes the solution in advance. In this case, an iterative procedure must be used in which an electron configuration is assumed, the Hartree-Fock equation solved, and a new electron distribution obtained and so on, until the electron distribution no longer changes, *i.e.* becomes self-consistent.

The orbital approximation is the starting point for almost all quantum mechanical calculations.

In the usual description outlined here, introduction of the spin quantum number merely leads to a certain algebraic form of the linear combination representation of Ψ_{el}. However, the Hartree-Fock equation no longer contains the spin. The assignment of a spin quantum number may be practical in this connection, but from the standpoint of the theory it is both questionable and dispensable[7].

Since only Ψ^2 and not Ψ is an observable quantity, the statistical (Thomas-Fermi) method should be mentioned here for completeness. The statistical treatment is based on the continuous density distribution of an electron gas as opposed to the Schrödinger equation. It is important only for atoms. Application of the theory to molecules is problematical and difficult[8-10].

3.3. Linear Combination Methods

For practical application of the Hartree-Fock equation to molecular systems a more precise specification of the molecular orbitals ψ_k is necessary. Linear combination expressions are the most simple to handle in a calculation.

$$\psi_k = \sum_l c_{kl}\phi_l \tag{10}$$

It is reasonable that the "basis functions" ϕ_l should be so chosen that they approximate as well as possible the form of the molecular orbitals in the neighborhood of the individual centers. Starting with various physical models, this approximation can be carried out in many different ways. Thus, for example, the ϕ_l can be assigned the analytic form of the hydrogen atomic orbitals:

$$\phi_l \sim P_k(r)\exp\left(-\frac{\alpha r}{k}\right) \tag{11}$$

where $P_k(r)$ is a polynomial in r for which r^{k-1} is the highest power of r occurring. Slater orbitals have a simpler form than the hydrogen orbitals

$$\phi_l \sim r^{k-1}\exp\left(-\frac{\alpha r}{k}\right) \tag{12}$$

in that they contain only one power of r. However, both the hydrogen and the Slater functions cause problems in the calculation of integrals of the type

$$\int \phi_k^*(1)\phi_l^*(1)\frac{e^2}{r_{12}}\phi_m(2)\phi_n(2)\,d\tau \tag{13}$$

This difficulty is avoided by application of orbitals having the analytic form of a Gaussian function

$$\phi_l \sim \exp(-\alpha r^2) \tag{14}$$

A disadvantage of the Gaussian-orbital method is, however, that many basis functions are necessary in order to approximate an atomic orbital. Thus, for example, for representation of a p orbital at least two Gaussian functions are needed:

p Function Gaussian group

It is better to combine four or more Gaussian functions for the representation of a p-function.

3.4. Semiempirical Approximations

Further simplifications result if, instead of all of the electrons, only valence electrons are considered; moreover, only certain integrals are calculated at all while the others are neglected. Thus, the neglect of integrals with differential overlap is a characteristic of many semiempirical methods, *e.g.* integrals of the type in eq. (13) are set equal to zero if $n \neq m$ or $l \neq k$. In the remaining integrals, empirically determined values are put in to compensate for the neglected integrals.

In the simplest semiempirical approximations, the Hückel methods, the explicit or simplified form of the Hartree-Fock operator no longer enters into the calculation and all quantities are empirically determined (π electron theory) or are reduced to the calculation of overlap integrals (extended Hückel theory, EHT). The Hückel methods yield molecular orbital functions which are not self-consistent.

In deciding what to neglect and what to calculate, which basis orbitals and empirical quantities to use, one has a broad range of possibilities which correspond to definite physical models. For identification of these models a large number of code names have been adopted in the literature (see Table 1) whereby the basic object of simplifying the Schrödinger equation is threatening to blossom into a black art. Fundamentally, one would naturally prefer a model that implies the most precise solution of the Schrödinger equation. The performance of an "*ab initio*" calculation (*i.e.* a calculation starting with the Hartree-Fock equation and using no empirically obtained quantities) would often demand an immoderately large expenditure of computer time or would often exceed the capacity of a given computer.

For practical application, therefore, the semiempirical methods have instead received increased attention in recent years, in spite of their notorious theoretical in-

Table 1. Code names of quantum chemical approximations [a].

Code	Explanation
AMO	Alternating MO method, accounts for electronic repulsion in particular by assigning electrons with differing spins to different orbitals [14]
AO	Atomic orbital
ASMO	Antisymmetrized molecular orbitals, *i.e.* molecular orbitals which fulfil the Pauli principle. In this case the total wave function changes sign when the coordinates of two electrons are interchanged (the wave function is antisymmetric with respect to interchange)
BO	Bond orbital
CI	Configuration interaction method, uses a generalized product expression for the wave function (see eq. 8) to account for differences between the Hartree-Fock and the Schrödinger equation
CNDO	Semiempirical, SCF method with complete neglect of differential overlap (see [15])
DO	Differential overlap, *i.e.* consideration of products $\psi_i(1)\,\psi_j(1)\,d\tau_i$ (even if $i \neq j$) in the integration of the Hartree-Fock equation
EHM, EHT	Extended Hückel method (theory) [16]. Iterative variation: IEHM [17]
FEM	Free electron model, treats the molecule as a potential well in which the electrons move freely subject to quantum mechanical boundary conditions
GO, GTO	Gaussian orbital (Gauss-type orbital)
GF	Group functions, mostly two-electron functions which are used in place of atomic orbitals as the basis of a linear combination method [18, 19]
HMO	Hückel-MO method
INDO	Semiempirical SCF method, intermediate neglect of differential overlap [20]
KGO	Constellations with Gauss orbitals, special CI method for use with Gauss orbitals [21]
LC	Linear combination method, for example LCAO: Linear combination of atomic orbitals, correspondingly LCBO, LPGO, LCPO, *etc.*
MC	Multi-configuration method (for example, MCSCF [22]), special form of the CI method
MINDO	Modified INDO method [23]
NO, NSO	Natural orbitals, natural spin orbitals, one-electron functions which facilitate an optimum consideration of configuration interaction [24, 25]
NPSO	Non-paired spatial orbital method [26, 27]
PO	Pars orbital, orbital of a group of atoms within a molecule [28]
PPP	Pariser-Parr-Pople method [29, 30], self-consistent, π-electron method which partially considers electron repulsion, also called P^3 method
SCF	Self-consistent field method, carries out the iterative solution of the complete or approximated Hartree-Fock equation
STO	Slater orbital (Slater-type orbital)
VB	Valence bond method, occasionally also called Heitler-London-Slater-Pauling (HLSP) method
ZDO	Zero differential overlap

[a] The list could be extended almost indefinitely.

Table 2. Selected programs from the Mülheim computing center [a].

Program	Quantum-chemical approximation	Number of valence electrons	Memory requirements $k=1000$ core locations	Computing time (s)
HUCKF	Hückel-MO method (π electron theory with ω-variation and forced convergence)			
SCFCON	Pariser-Parr-Pople method with configuration interaction	triplet 30 singlet 80	38 k	naphthalene 131 (10 electrons)
HMOV	Extended Hückel method with Slater orbitals for 1s, 2s, and 2p valence electrons	98	36 k	ethane 12 (14 electrons)
SCCC-MO	Extended Hückel method with arbitrary basis orbitals and consideration of all valence electrons including 4s, 4p, 3d (maximum 30). Iterative calculation of self-consistent partial charges possible	60	38 k	ethane 29
CNINDO	Semiempirical variation of SCF method (similar to QCPE 141) for open and filled shells	80	38 k	ethane 20
CNDO-CI	Variation of CNINDO with configurational interaction	60	38 k	
CNDO-LS	Perturbation theoretical consideration of spin-orbit coupling within the framework of the CNDO approximation	60	38 k	
MOLVAR	CNDO method with automatic minimization with respect to an arbitrary number of parameters	60	38 k	
SCFAT	Hartree-Fock method for atoms with closed shells			

[a] Tested FORTRAN IV versions, available upon request from *F. Mark* (MPI für Kohlenforschung, Abt. Strahlenchemie, Mülheim). Most of the programs listed here have been developed or adapted (from QCPE programs) for use on the PDP 10 computer by *F. Mark* and his group.

adequacies. This is not only due to the fact that the semiempirical methods require less computer time but also that the "quantum chemical interpolation" of calculable molecular properties is often all that the chemist needs if he is more interested in general trends than numerical values. In the scope of this paper it will suffice to illustrate in simple examples a few typical applications of semiempirical calculations.

In Table 2, the semiempirical techniques currently in use at Mülheim are shown. From the given computation times and the core space requirements one can easily see the characteristic dilemma of quantum chemistry: the calculation expense increases with increasing theoretical rigor. The computation time increases greatly with the size of the molecule (approximately with the third power of the number of valence electrons).

The results of MO theory discussed below were obtained with the extended Hückel method. This method is especially easy to interpret and may be easily applied to excited and ionized species[11] whose treatment by more rigorous methods is still difficult.

4. Examples of the Application of MO Theory

MO calculations yield numerical values for the orbital energies E_k (second line in the example shown in Table 3). In the ground state the 14 valence electrons of ethane pair-wise occupy the seven lowest levels (of which some are degenerate, *i.e.* have the same energy), for which a total electronic energy of $E=-243.673$ eV results. For each E_k there is a corresponding set of coefficients of the linear combination of the orbital function, ψ_k (in the column under E_k), the square of which represents the partial charge distribution in the molecular orbital. From Figure 2 and the coefficients of the two a_{1g} orbitals

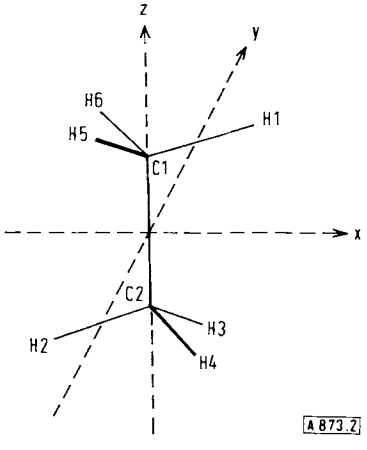

Fig. 2. Coordinate system for ethane and numbering of the atoms (see Table 3).

it can be seen that the a_{1g} orbitals provide the main contribution to the C—C bonding in ethane. In the $2a_{1g}$ MO, for example, the $2p_z$ (C) atomic orbitals con-

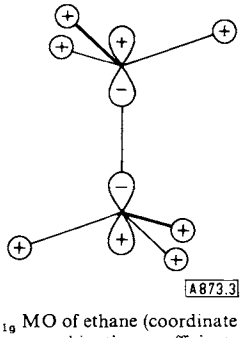

Fig. 3. Schematic representation of the $2a_{1g}$ MO of ethane (coordinate system as in Fig. 2). In this MO the linear combination coefficients (+0.5626 and −0.5626 in Table 3) of the p_z basis orbitals localized on C1 and C2 dominate. These orbitals have the same sign in the space between the C atoms and contribute substantially to the C—C bonding energy (the small contribution of the 2s orbitals on C1 and C2 is neglected in the drawing). Correspondingly it is seen that the $2a_{1g}$ MO is C—H bonding.

structively add in the overlapping region of the bond axis (Fig. 3). Correspondingly it follows from Table 3 that the highest occupied (degenerate) $1e_g$ MO is C—C (π) antibonding and C—H bonding, that also the low-lying a_{2u} orbital is C—C (σ) antibonding, and so on. These antibonding contributions are more than compensated by bonding contributions, so that overall bonding MOs

Table 3. Molecular orbitals ψ_k of ethane: Eigenvalues E_k (orbital energies), linear combination coefficients c_{kl} (see eq. (10)), and MO bonding energies for the occupied and lowest unoccupied (in the ground state) orbitals of ethane (see Fig. 2 and 3).

result (MO bonding energy negative; numerical values in eV).

The electronic excitation (raising of an electron from $1e_g$ to the $2a_{2u}$ orbital, unoccupied in the ground state) as well as ionization (removal of an electron from the $1e_g$ MO) leads to a degenerate state which according to the Jahn-Teller principle[12] must assume a conformation of lower symmetry. It is, therefore, pointless to retain the D_{3d} symmetry for calculations on excited or ionized ethane.

As an illustration, let us consider two distorted conformations of the ethane molecule which are distinguished by the 1,1 and 1,2 approach of the H atoms (Fig. 4). Such conformations can be considered as models for the transition states for elimination of molecular H_2 which plays an important part in the vacuum UV photolysis of ethane[13]. The EHT calculation indicates that for both excited and ionized ethanes the transition state for 1,1 elimination is energetically preferred to that for 1,2 elimination. As yet it has been experimentally shown only

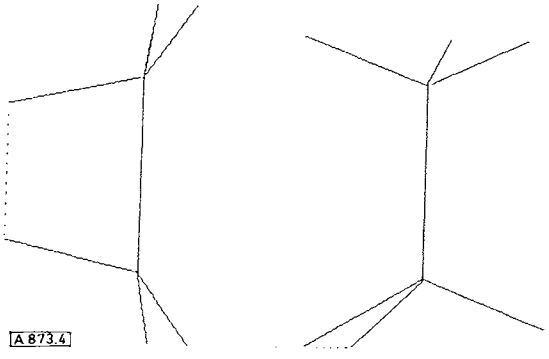

Fig. 4. Plotter drawing of the transition state for the 1,2 (left) and 1,1 (right) elimination of an H_2 molecule from ethane. The dotted lines correspond to an H···H distance of 1.1 Å (compared to *ca.* 1.78 Å in undistorted ethane).

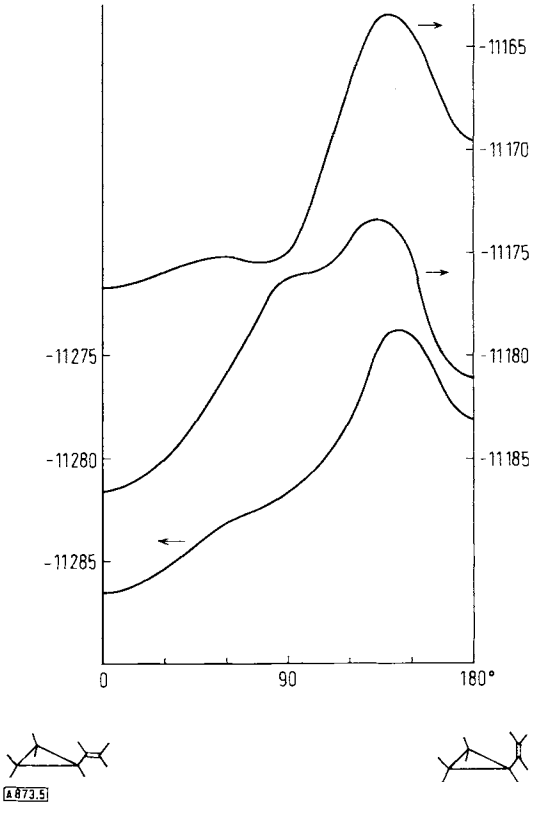

Fig. 5. Total electronic energy (kcal/mol) of vinylcyclopropane (from extended Hückel theory) as a function of the torsional angle about the C—C_2H_3 bond: ground state (lowest curve, left ordinate) first and second excited states (middle and upper curves respectively, right ordinate).

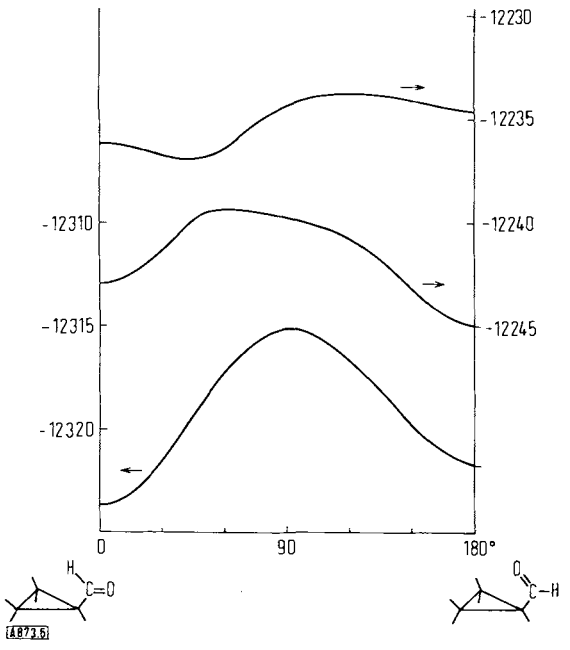

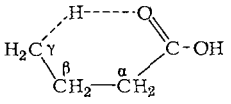

Fig. 6. Total electronic energy (kcal/mol) of cyclopropanecarbaldehyde as a function of the torsional angle about the C—CHO bond for the ground state (lower curve, left ordinate) and the first and second excited states (middle and upper curves, respectively, right ordinate).

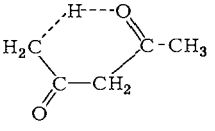
in the case of electronic excitation that 1,1 elimination occurs preferentially.



Since EHT calculations (like most other semiempirical methods) do not yield good values for equilibrium bond distances, one can only expect reasonable results from model calculations with given fixed bond distances (*e.g.* in an assumed transition state) if the comparison is limited to sufficiently similar systems. However, this situation frequently occurs in practice.

Calculations of activation energies for conformational changes also number among the applications of MO theory to reaction kinetics. As an example we may consider the rotational barriers of vinylcyclopropane and cyclopropanecarbaldehyde which have been the objects of various spectroscopic and theoretical investigations in recent years[31-34]. Of special interest was the question of the importance of π-electron conjugation between the double bond and the cyclopropane ring. It is possible to answer this question by calculating the total MO energy as a function of the angle of rotation about the C—C_2H_3 and C—CHO bonds respectively for the ground and first excited states. If electron conjugation is important, then an increase in the rotational barrier is expected with electronic excitation (similar to the case of butadiene). The results of such calculations are shown in Figures 5 and 6, in which the torsional angle 0° belongs to the *trans*-conformation. It is apparent that the rotational barrier for vinylcyclopropane is somewhat increased by excitation (analogous to butadiene) whereas for cyclopropanecarbaldehyde the barrier is lowered. Conjugation effects are therefore only important in the former case.

Mass spectrometry of organic molecules offers a broad, hardly touched field of application for MO theory[35,36]. Analysis of conformational changes and charge distributions in the dissociating ions is common in the literature of this field. Thus, for example, it is assumed that in the McLafferty rearrangement of the butyric acid ion a proton migrates from the γ position to the carbonyl group in a six-membered transition state

whereupon the C—C bond between the α and β C-atoms is broken and ethylene is eliminated. It is *a priori* not possible to decide which of these two steps determines the rate of the overall reaction. EHT calculations for several conformations of the transition state show that the proton migration and not the dissociation of the C—C bond determines the activation energy of the rearrangement.

Moreover, the EHT calculation explains why in the analogous case of 2,4-pentadione the McLafferty rearrangement assumes only minor importance. In this case it is calculated that the activation energy for the H transition is substantially greater than for butyric acid and the energy of the C_α-C_β bond in the rearranged ion is even slightly stronger than in the initial state.

5. Calculation of Reaction Rate Constants

Since the Schrödinger equation contains the time as well as the coordinates of all the atomic nuclei of a system, every imaginable reaction kinetic situation must in principle be reducible to this basis. A practical way of doing this is to solve separated Schrödinger equations for the individual states of motion (see Section 3) and to consider the statistical distribution of energy states, *i.e.* to ascertain the partition functions previously mentioned (Section 2). (The explicit time-dependence of the Schrödinger equation is only important in special cases, for example for radiative transitions between electronic states.) For many important (and most thermal) reactions the electronic partition function is equal to one, *i.e.* only *one* electronic state is occupied during the entire reaction (adiabatic reaction). The application of the Schrödinger equation to this state then requires the calculation of the electron energy E as a function of the coordinates of all nuclei of the reacting system. In the simplest case, dissociation of a diatomic molecule, E is dependent on only *one* coordinate, the internuclear distance (which is therefore also the reaction coordinate), and may be graphically portrayed as a potential curve. In general, however, E is a many-dimensional potential energy surface on which the special route of least energy expense is singled out as the reaction coordinate. The activation energy of

the reaction is determined by the saddle point along the reaction coordinate.

Considering the difficulties which arise in an MO theoretical calculation of the electronic energy for only one nuclear configuration of a given molecule it is obvious that the calculation of the activation energy in general represents a formidable computational task. Simplifications are possible in cases where the reaction coordinate is known, for example the rotation about a bond or other elementary isomerizations (Section 4). In other cases plausible theoretical models exist which determine the reaction coordinate. Two important models of this type for which tested programs exist in the Mülheim computing center will be described in the following sections.

5.1. BEBO Method

The BEBO method[*] allows the calculation of activation energies and reaction rate constants in the important special case of H atom transfer reactions[37]:

$$AH + B \rightleftarrows A\cdots H\cdots B \rightarrow A + HB \qquad (15)$$

In this model it is taken that the bond HB is partially formed during the reaction before the A—H bond is completely broken: The reaction coordinate is defined by assuming conservation of bond order, *i.e.* the sum of the bond orders of A ··· H and H ··· B should be equal to one along the reaction coordinate.

Application of this concept assumes further that a well-defined relationship exists between bond order and bond length on the one hand and bond energy and bond order on the other. Such relationships are verified by a great amount of empirical material so that it is possible to express the potential energy V along the reaction coordinate as a function of experimental single bond distances R_i and energies E_i:

$$V = f(E(A—H), E(H—B), R(A—H), R(H—B), R(A—B)) \qquad (16)$$

The maximum of V along the reaction coordinate corresponds then to the potential energy of activation V^*, which must be corrected for the zero point energies of the initial and transition states in order to obtain the theoretical value for the observable activation energy.

In the BEBO approximation, the transition state for the H atom transfer is interpreted as a linear triatomic species; one of the four normal vibrations of the transition state is omitted since it corresponds to the reaction coordinate. The remaining three normal vibrations represent a stretching and two degenerate bending modes for which at small amplitudes a parabolic potential can be assumed. The frequencies of these vibrations are then given directly by the masses of A and B and the force constants (*i.e.* the second derivatives of the potentials with respect to the corresponding normal coordinates).

The BEBO method suggests itself for application in all cases where the necessary data are already available. Starting with experimental single bond lengths determined by various methods[39] and *Pauling*'s single bond energies[38], the calculated activation energies shown in Table 4 are obtained; where available, literature values are shown for comparison. (In Table 4 the value 0 is given for those cases in which the potential V does not show a maximum along the reaction coordinate.) Since zero-point energies are not taken into account in Table 4, these values may be further improved. On the other hand, the BEBO values appear more questionable the smaller they become since the theoretical prerequisites of the normal coordinate

Table 4. Potential energy of activation, V^* in kcal/mole, calculated by the BEBO method. Values in parentheses taken from [40].

analysis are no longer fulfilled. On the whole, comparison between experimental activation energies and calculated V^* values shows a very satisfactory agreement.

Table 5. Kinetic isotope effects at room temperature for H abstraction by radicals, calculated by the BEBO method.

Reaction 1:	$C_2H_6+C_2H_5$	$C_2H_6+C_2H_3$	$C_2H_6+C_2H$	$C_2H_4+C_2H_3$	$C_2H_4+C_2H$	$C_2H_2+C_2H$
Reaction 2:	$C_2D_6+C_2D_5$	$C_2D_6+C_2D_3$	$C_2D_6+C_2D$	$C_2D_4+C_2D_3$	$C_2D_4+C_2D$	$C_2D_2+C_2D$
k_1/k_2	28.9	23.9	5.5	29.7	10.4	32.1

A special application of the BEBO method is the calculation of kinetic isotope effects which, among others effects, must be considered in mechanistic investigations of reactions in radiation chemistry. As the examples in Table 5 show, the kinetic isotope effect is large and is determined essentially by the quantum mechanical tunnel effect. An experimental confirmation of the calculated values in Table 5 has yet to be provided.

For the application of the BEBO method the computation expense is relatively small. The Mülheim program requires only 8000 storage locations; the computing times are typically of the order of 10 s and are slightly dependent on the temperature of the system considered.

5.2. Quasi-equilibrium Theory of Mass Spectra

At low pressures—for example in a mass spectrometer, and also in gas reactions—the rate constant k of a unimolecular decomposition depends not only on the activation energy E_A of the decomposition reaction but also on the internal energy E of the molecule. The theory of mass spectra formulated by *Rosenstock, Wallenstein, Wahrhaftig,* and *Eyring*[41] assumes that the rate at which energy supplied to the molecule (for example by electron impact or photoionization) is distributed over all the vibrational degrees of freedom is always large compared to the rate of decomposition. There then exists a quasi-equilibrium distribution of states which can be ascertained by the methods of statistical mechanics. For the energy-dependent rate constant *Rosenstock et al.* derived the expression

$$k(E) = \frac{s}{h} \frac{W^*(E-E_A)}{\rho(E)} \qquad (17)$$

where s is a symmetry factor (number of equivalent decomposition paths), $W^*(E-E_A)$ the number of states of the activated complex with energy greater than E_A, and $\rho(E)$ the density of states between E and $E+dE$. W^* and ρ depend in a complicated manner on the normal vibrations of the molecule, which for application of the theory must be known input parameters.

The program available at Mülheim (QET) is essentially an adapted version of the original IBM program written by *Vestal*[42]. It may be applied to molecules with up to 100 degrees of freedom and a total of 25 primary, secondary, and tertiary decomposition modes and delivers information on: breakdown spectra of ions, intensities of metastable ions, kinetic energies of fragments, and temperature dependence of mass spectra. As an illustration, the breakdown graphs of ions from methane are shown in Figure 7.

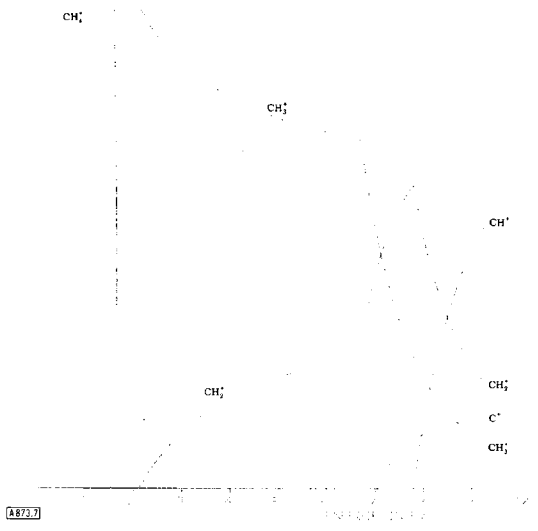

Fig. 7. Breakdown graph for the methane ion (plotter drawing) from the quasi-equilibrium theory (relative ion intensity as a function of the energy content of the molecule in excess of the ionization energy). Each vertical line (E = constant) defines a "mono-energetic mass spectrum" (sum of the intensities = 1).

For each point of the energy scale (corresponding to energy in excess of the ionization energy supplied to the methane molecule) the graph shows an intensity distribution of fragments of the methane ions (the intensities are normalized to unit sum). Thus it may be seen from Figure 7 that CH_4^+ with an energy content higher than 1.7 eV is completely decomposed into CH_3^+. Since CH_4^+ corresponds to the most intense line in the mass spectrum of methane it is clear that, in general, only a small fraction of the usual 70 eV carried by the ionizing electrons is transferred to the methane molecule.

The QET program requires *ca.* 33000 core locations and a relatively large expense in computer time which increases sharply with the size of the molecule and the number of decomposition reactions. About 4 minutes computing time is required to calculate the mass spectrum of ethane (with ten decomposition reactions).

6. Integration of Kinetic Equation Systems

A computing problem *par excellence* is the evaluation of data resulting from pulse radiolysis studies. Pulse radiolytic systems are characterized by a large number of parallel and consecutive reactions all having similar rate constants. Thus it is not possible to neglect several reactions in com-

parison to a rate determining step as is often done in reaction kinetics. Instead, one must solve numerically the total system of coupled, nonlinear differential equations which corresponds to the chemical reaction system. Since the raw data (changes in optical density as a function of time) as a rule do not have the desired exactness, the evaluation can only be carried out through comparison with model calculations and not by computational search for an unknown reaction scheme involving the measured values.

For adapting a given reaction scheme to the measured data, programs are generally used which achieve an optimum determination (in the sense of the least squares method) of the rate constants and activation energies from concentration *vs.* time measurements. Starting with estimated values of the rate constants the system of differential equations is solved iteratively; after each iteration an improvement of the estimated values is made. The technique was applied in the elucidation of thermal isomerization in the cyclodecatriene series[43].

I thank Dr. F. Mark for several important suggestions and Dr. P. Potzinger for critically reading the manuscript.

Glossary of Some Computer Terms

A/D converter (Analog-to-Digital converter)—a device for converting an analog value (usually an electrical voltage) into a numerical representation.

Batch operation—programs are processed sequentially, possibly in parallel running "batch streams" ("multiprogramming batch"). No interactive work.

Bit—a digit position in the binary number system; derived from "*b*inary dig*it*".

Byte—a group of binary positions (bits) treated as a unit. Most byte-oriented computers work with 8-bit bytes. One character (letter or number) is stored in a byte. Word-oriented computers (for example, the PDP10) sometimes offer instructions which permit working with variable-length bytes.

Byte instructions—computer instructions which manipulate bytes.

Channel status—the current state of the parameters characteristic for data acquisition, for example, "active", "inactive", data rate, run-time.

Closed-loop operation—experimental parameters are controlled by the computer during an experiment by analyzing measured values.

Core image—the momentary state of a program in memory during program execution.

Contact scanner—a device which enables the computer to determine the state of on-line instruments and register related signals (for example, start and stop signals).

Conversational time-sharing operation—a time-sharing system (see definition) which permits a programmed dialog between the user and the computer.

Data buffer—temporary storage for accumulating data. The use of data buffers allows a more rational handling of data.

Data rate—transfer rate of data, expressed in words, bits, bytes, data points, *etc.*, per unit time.

Data reduction—decreasing the extent of information of measured data to an amount or form essential to a problem.

D/A converter (Digital-to-Analog converter)—see A/D converter.

Dedicated system—a system in which a computer is used strictly for the data acquisition and processing for one single instrument (or a group of instruments of the same type, for example several chromatographs).

Disk—a magnetic data storage medium. Several magnetic disks can be grouped in a stack on a rotating axis. One distinguishes between a fixed-head disk (one read/write head per concentric path) and a movable-head disk (one head per surface).

Enable—a condition which exists when several switching signals yield a "true" value in an AND function.

Failsafe system—a computer system which is safeguarded against failures of hardware and software components.

Floating-point instructions—instructions for processing data coded in floating-point format, that is, data expressed as an exponent and a mantissa.

Hardware—the material part of a computer system.

High-level programming language—allows the user to express algorithms in a computer independent form; a problem oriented as opposed to computer oriented form of expression. FORTRAN and BASIC are two such languages.

"Integrated" instrument—an instrument with a "built-in" computer; sometimes also called an "instrument computer".

Interactive time-sharing operation—see conversational time-sharing operation.

Interface—an electronic adapting unit between instrument and computer.

Interrupt system—an arrangement whereby brief interruptions of the running program are permitted if a data word (or byte) is to be transferred to or from a peripheral unit.

Job—a sequence of tasks for the computer which are initiated by a user at a terminal (or by submission of a deck of cards).

K—abbreviation for $2^{10}=1024$. For example, a core memory capacity of 32 K words corresponds to $32 \times 1024 = 32768$ words.

Line-driver—a unit which allows the program-controlled opening and closing of circuits, and therefore the control of on-line instruments.

Monitor—see operating system.

Multi-mini system—a computer system which is made up of several small computers. One of them can function as the central processor and all of the others are connected to it. The small computers can also be organized in a network fashion.

Multiplexer—a device used if a data path is to be switched among several instruments; in on-line systems a multiplexer is used with an A/D converter common to several instruments.

Off-line operation—the computer processes jobs which, in contrast to on-line operation, have no real-time requirements.

On-line operation—the computer is directly coupled to analytical instruments.

Operating system, monitor—an executive or controlling program which regulates the progress of computer operation, that is, the distribution of computing time, the allocation of core storage, and the use of peripheral units for the different jobs.

Periphery—the "exterior" devices of the computer such as card readers, magnetic tapes, and line printers.

Priority levels—a graduated hardware interrupt system allows not only program interruption, but permits a data

transfer between the computer and its periphery according to speed requirements and real-time demands; data transfers in progress on lower priority levels are interrupted if an interrupt signal is received for a level of higher priority. Besides such hardware priority levels, there are also software priority levels in the form of different queues, in which the programs to be run are placed, depending on their instantaneous status, requirements, size, *etc.*

Process-control computer—a computer which is used for supervision and control of experiments, manufacturing processes, and so on.

Random access—a programmed reading or writing of data on a storage medium independent of where the data is actually stored. Possible with magnetic disks, drums, and core storage, but not with magnetic tapes, paper tapes, *etc.*, that have to be read or written serially.

Real-time data acquisition—the computer takes data from an analytical instrument in real-time, that is (with a delay of a few microseconds) during the measurement.

Satellite computer—a subordinate (small) computer for handling tasks given to it by a central computer.

Software—computer programs; one distinguishes between "system software" (necessary for operation or the support of the operation) and "application software" (problem-oriented programs).

Swapping operation—movement of programs (in the form of their core images) between disk or drum units and core storage, should total core capacity be insufficient to hold all currently active programs.

Teletype—a company product designation which has become a common term to mean any input/output typewriter-like device used as a computer terminal.

Terminal—data station (for example, teletype, display device) which allows the user to communicate with the computer.

Text editor—a program for the creation and correction of programs and data sets by type-in from a terminal.

TI correction—correction of intensity distortions caused by pressure changes during the running of a mass spectrum.

Time-sharing system—a system which allows several users to work with the computer simultaneously.

TTY—an abbreviation for teletype (see definition).

An Alternative Approach to the Nomenclature of Cyclic Conjugated Polyolefins, together with some Observations on the Use of the Term "Aromatic"

By Douglas Lloyd and D. R. Marshall[*]

So much ambiguity and disagreement has arisen concerning the usage of the word 'aromatic' that it might be better to discontinue the use of this term.

1. Introduction

The term 'aromatic' is remarkable in organic chemistry for the variety of meanings and interpretations which have been ascribed to it in more than a century of use. Perhaps even more remarkable is the fact that although this word is one of the commonest used by chemists, it has no firmly defined meaning and different individuals may mean very different things by the term. This indeterminacy stems to a large extent from its checkered history with ever-changing meaning.

In recent years a number of definitions, some more satisfactory and explicit than others, have been made but on the whole each individual tends to use the term to suit his own preconceived ideas. Furthermore, the avidity with which contemporary chemists use this magic term was commented on by a speaker at a recent symposium on "Aromaticity, Pseudoaromaticity, Antiaromaticity"[1] who described it as the modern chemists' equivalent of being possessed by devils.

2. Original Meaning and Changes in Meaning of the Term "Aromaticity"

The term 'aromatic' was first applied by chemists in the early part of the nineteenth centry to describe compounds which had an aromatic odour and which had been isolated

St. Andrews Fife (Scotland)
Dr. D. R. Marshall
Department of Chemistry, University College of North Wales
Bangor Caernarvonshire (Wales)

from many volatile vegetable oils. Its meaning was thus the same as the everyday non-scientific meaning.

It was soon noticed that many of these 'aromatic' compounds contained relatively more carbon than the so-called 'aliphatic' organic compounds which had been obtained from fats, and they were described by *Kekulé* in the 1860's as "Kohlenstoffreichere Verbindungen"[2]. When it was recognized that these carbon-rich compounds were derivatives of benzene, the term 'aromatic' was appropriated to convey a structural meaning instead of its hitherto purely descriptive meaning, namely a derivative of benzene.

When *Kekulé* first proposed the cyclohexatriene structure for benzene[2], he commented on the particular stability of this ring-system and in effect defined aromatic compounds as benzene derivatives.

Kekulé's use of the word 'aromatic' was thus based on *structural features*, but almost at once the suggestion was made by *Erlenmeyer*[3] that the concept of aromaticity should be based on *properties* of compounds and encompass substances of similar behavior rather than those with a common structural feature. Thus the seeds of mid-twentieth century confusion about the meaning of the term were sown over a hundred years ago and almost as soon as the structure of benzene was elucidated. The possibility of these two alternative interpretations has subsequently bedeviled organic chemistry.

When *Armit* and *Robinson*[4] formulated the concept of the 'aromatic sextet' in 1925 they also made the observation that aromatic compounds were characterized by "reduced unsaturation and the tendency to retain the type", as shown, for example, by their tendency to undergo substitution rather than addition reactions. Here aromaticity is clearly being considered in terms of the properties of compounds rather than in structural terms.

Hückel's rule, propounded in the 1930's[5], which states that "amongst fully conjugated, planar, monocyclic polyolefins only those possessing $(4n+2)$ π-electrons, where n is an integer, will have special electronic stability", also implies a relationship between aromatic character and properties, in particular the stability of compounds. Both *Armit* and *Robinson*, and *Hückel*, introduced another factor by associating aromaticity with particular electronic structures.

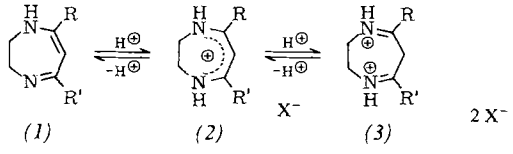
Aromaticity had thus been correlated with structural features, with chemical reactivity (or lack of it), with electronic structures or with stability, the latter term being capable of further sub-divisions of interpretation.

3. Some Modifications in Nomenclature

Until more recent times this ambiguity of definition was not of great import, for the compounds which had aromatic properties or stability were benzene derivatives and whatever fundamental definition was used, the same set of compounds was being described. In fact 'aromatic compound' was in effect a synonym for 'benzene derivative'. The only difficulty encountered was with certain five-membered ring heterocyclic compounds, which in some, but not all, respects resembled benzene derivatives in their properties, and of course, did not have a benzene-like structure.

Following the stimulus supplied by the appreciation of the significance of Hückel's rule, a plethora of so-called 'non-benzenoid aromatic compounds' has been described[6]. These compounds resemble benzene in having closed cyclic conjugated systems of electrons but they do not have the particular structural feature of benzene derivatives, namely the six-membered ring. Nor do they necessarily have the properties which until recent decades were considered as characteristic of aromatic systems, for example the ability to undergo electrophilic substitution reactions, or a resistance towards oxidizing agents.

Not surprisingly the tropylium cation, accepted as an example of a non-benzenoid aromatic structure in the terms of Hückel's rule, does not react with electrophiles. For example no exchange of deuterium for hydrogen is observed either on prolonged treatment with concentrated deuteriosulfuric acid or with a solution of aluminum bromide in deuteriobromic acid, conditions under which benzene undergoes hydrogen/deuterium exchange almost instantaneously[7]. At the other end of the scale, [18]annulene, an example of a non-benzenoid aromatic hydrocarbon, decomposes in a short time on standing[8], and only undergoes electrophilic substitution under carefully defined conditions[8, 9]. Indeed not even all benzene derivatives are typically 'aromatic' in their chemical behavior.



Confusion has been made worse by the introduction of further terms indicating modified aromaticity such as 'pseudo-aromatic'[10] and 'anti-aromatic'[11, 12]. An anti-aromatic system has been defined as one in which electron delocalization considerably raises the energy of the molecule[11, 12], and has been applied to cyclic peripherally conjugated polyolefins. The results of kinetic measurements on hydrogen-deuterium exchange in a number of cyclopropene derivatives have been interpreted on this basis[12, 13]. A typical property of anti-aromatic compounds is the paramagnetic ring-current observed in annulenes and dehydroannulenes having $4n$ π-electrons[14].

Pseudo-aromatic molecules have been defined[15] as those with non-totally symmetric ground states, a symmetry criterion which, for molecules with only peripheral conjugation, also applies to those having $4n$ π-electrons. It had been frequent practice to describe all non-aromatic cyclic conjugated systems as pseudo-aromatic but this term does not draw attention to the destabilization which may be observed in $4n$ π-electron systems.

We have contributed to this list of terms denoting modified aromaticity by attempting to make a definition[16] of the term 'quasi-aromatic'[17] as follows: "We propose that molecules should be called quasi-aromatic only if they contain an acyclic conjugated π-electron system and show chemical properties typical of aromatic compounds, especially reaction by substitution with retention of type. A significant mesomeric stability is implied"[16]. This definition was rightly criticized by *Marchand*[18] who said that there was a need to resolve the meaning of aromaticity in some suitable physical terms before introducing such extra terms as quasi-aromatic.

3.1. The Example of 2,3-Dihydro-1,4-diazepinium Salts

We had used the term "quasi-aromatic" to describe the behavior of 2,3-dihydro-1,4-diazepinium salts *(2)*. These compounds have proved to be excellent substrates for the

(1) *(2)* *(3)*

examination of 'quasi-aromatic' character. The ring structure serves to fix the conjugated system in a favorably stable conformation. On the other hand it is clear that the ring cannot be 'aromatic' in the classic structural sense because the conjugation does not extend all round the ring, part of which is formed of sp^3-hybridized carbon atoms. Since these dihydrodiazepinium salts have been the subject of an intensive chemical investigation by us[19], we have used this system specifically to provide examples to support our arguments. Other complementary examples might be taken, for example, from the chemistry of the corrins[20], which contain the same kind of conjugated system included within a larger ring structure, or of open-chain analogs, namely the salts of α,ω-diazapolymethines[20a], or of the transition-metal chelates of β-diketones[21, 22, 23a]. (It had been argued that the latter compounds might have complete cyclic conjugated systems involving the metal atom[22] but later workers are not in agreement with this interpretation[23]. An excellent review of the position concerning these chelates has recently been given by *H. Musso et al.*[23a].)

2,3-Dihydro-1,4-diazepinium salts possess an extremely stable electronic system which resists breakdown and are characterized by a great "tendency to retain the type"[4]. Their stability constants (with respect to the diamines and dicarbonyl compounds formally derived from them by hydrolysis) are high, mostly $\sim 10^6$—10^9[24]. The monocation *(2)* is the predominant species over a very wide pH range, for the pK_a values for the equilibrium with the related bases *(1)* are usually ~13—14[25, 26], while only in >70% sulfuric acid do the dications *(3)* predominate over the monocations[27]; this suggests an effective resonance energy of 20—30 kcal/mol.

The chemical similarity of the dihydrodiazepinium salts to benzenoid compounds is demonstrated by the ease with which they undergo typical 'aromatic' substitution reactions. Thus they are readily halogenated[28], and nitrated[29, 30], and, although they are cations, couple with diazonium ions[31]. The resultant 6-nitrodihydrodiazepinium salts can be reduced to typically 'aromatic' amines[30, 32]—for example with nitrous acid they form diazonium salts[30, 32].

All of these chemical properties and reactions are just those which have always been firmly associated with what have been called aromatic compounds, yet, as stated previously, in no classical structural sense can dihydrodiazepinium salts be considered to be aromatic compounds. This illustrates nicely the pitfalls of trying to use chemical reactivity as an index of 'aromaticity'.

Other definitions of aromaticity in terms of some particular properties appear commonly to include some subjective judgment to decide where the boundary between 'aromatic' and 'non-aromatic' shall be drawn. In fact in many cases hitherto, compounds have been described as aromatic without any real definition.

A structural definition, restricting its usage to that prevalent in most text-books of general organic chemistry, namely as a synonym for 'benzenoid' would be unambiguous but it is questionable if such a tautological exercise has any value.

The present attitude towards 'aromaticity' is coming to resemble a medieval theological disputation and the time has come when a reformation (or a counter-reformation) is needed.

4. New Suggestions and Definitions

We suggest that because of this confusion and lack of common consent as to its meaning[33], it would be better if the use of the term 'aromatic' were discontinued, save perhaps with its general and original connotation of 'perfumed', and that it should pass with other technical terms which have outlived their precision and usefulness, into the realm of the historian of chemistry.

The term "arenes", presently defined as "the generic name of monocyclic and polycyclic hydrocarbons"[34] should be specifically restricted to benzenoid hydrocarbons; "aryl" derivatives should be similarly defined. We also repeat our suggestion[35] that it is preferable to denote derivatives of benzene as "benzenoid" rather than "aromatic". This word is unambiguous. Alternatively "aryl" could be used as long as its meaning is rigorously defined as suggested[*].

We would also suggest that cyclic conjugated systems in general should be termed simply as either *Hückel* or *anti-Hückel* (or for the larger annulenes *non-Hückel*) systems[**], these terms replacing, respectively, what is probably the most general present-day usage of "aromatic" and "anti-aromatic", namely the energetic criterion, as defined, for example, by *Breslow*[12] and *Dewar*[36]. This replacement is however necessary just because of the lack of a universally recognized usage or meaning of the troublesome term "aromatic".

The terms benzenoid or aryl would thus refer to structural features and the terms Hückel or anti-Hückel (or counter-Hückel) to ground-state stability.

---

[*] Professor *M. Cais* (private communication) has suggested that the continued use of terms such as "benzene-like" or "benzenoid-like" might be helpful in discussing and comparing properties of non-benzene derivatives with those of benzene; for example it might be useful to talk about the benzene-like properties of ferrocene.

[**] There may be semantic, and indeed more than semantic, objections to the use of the term 'anti-Hückel', since Hückel theory did not embrace any concept of conjugative destabilization of $(4n)$-π-electron systems. However, since the name of Hückel is so firmly associated with the stability of $(4n+2)$-π-electron systems, it seems worthwhile to maintain this association. If $(4n)$-π-electron systems show opposite properties, it would then seem reasonable to denote this by "opposite to Hückel", *i. e.* anti-Hückel. An alternative and probably preferable term would be "counter-Hückel".

Since for more than a century "aromatic" also embraced a characteristic sort of reactivity, namely the tendency to undergo substitution rather than addition reactions, we consider that it would be useful to have a specific term to mean "the tendency to retain the type"[4]. We suggest as possible words to describe such behavior either *regenerative* or *meneidic*. The former word is descriptive of the process which takes place—the original electronic system is regenerated after being temporarily lost in the transition state; the latter word is of Greek origin (from *menein*, to stay, persist, remain; and *eidos*, type, form)[37]. Thus benzene normally behaves as a regenerative or meneidic system; ethylene does not.

The terms regenerative or meneidic need not necessarily be confined to electrophilic substitution reactions. Pyridines and nitrobenzenes show their regenerative or meneidic character equally well in their substitution reactions with nucleophiles. Similarly the various carboxyl derivatives, acids, esters, amides, *etc.* show regenerative or meneidic character in their reactions. The terms might also be considered to embrace substitution at sp^3-hybridized as well as at sp^2-hybridized atoms, but it is intended that they should be restricted to the latter and to what have been described as S_A (for substitution through association) reactions[38], wherein a new bond is formed before the old bond breaks. Any loosening of this restriction would destroy the convenience of the term by making it less specific in its meaning.

We thus propose this change in nomenclature, wherein we differentiate between structural features, ground-state properties, and chemical reactivity. These three factors had all at different periods been regarded as criteria for aromaticity. Unfortunately these criteria are not always compatible and compounds may not satisfy them all equally well, and it becomes a matter of opinion whether or not a compound is "aromatic". For this reason and the consequent wide diversion in the interpretation of the term we suggest that its use should be discontinued.

We propose that the terms *arenes*, *aryl*, and *benzenoid* be used to denote a *structural* feature, namely the presence of a benzene ring, *Hückel* and *anti-Hückel* (or *counter-Hückel*) to refer to *ground-state properties*, and either *regenerative* or *meneidic* to refer to *chemical reactivity*, namely the tendency of an unsaturated molecule to react by substitution rather than addition[*].

In keeping with these suggestions we would, for example, describe 2,3-dihydro-1,4-diazepinium salts as compounds which, although they are not Hückel compounds, are none the less examples of molecules having regenerative or meneidic character.

We wish to acknowledge the contribution which discussions with friends, especially Dr. A. R. Butler of the University of St. Andrews and Professor J. R. Nunn of Rhodes University, Grahamstown, made to the form of this paper. Some of the material presented in the paper formed part of a lecture delivered by Douglas Lloyd at a symposium which has been published (1971) by the Israel Academy of Sciences and Humanities[39].

Received: February 22, 1971 [A 874 IE]
revised: September 20, 1971
German version: Angew. Chem. *84*, 447 (1972)

[*] It has also been suggested [40] that molecules showing diamagnetic, paramagnetic and no ring-currents be called, respectively, *diatropic*, *paratropic*, *atropic*. Although, in general, diatropic and paratropic molecules would be the same ones that we call *Hückel* and *Counter-Hückel*, this nomenclature refers specifically to magnetic properties, whereas Hückel and Counter-Hückel refer fundamentally to energetic properties.

Metal Ion Function in Carbonic Anhydrase

By R. H. Prince and P. R. Woolley[*]

The purpose of this review is to present an up-to-date account of the chemistry of the metal ion in the enzyme carbonic anhydrase. The interest lies in how the study of the metal may lead to deductions concerning the chemistry of the enzyme's action and in the way that metalloenzyme chemistry seems to demand a new appraisal of some aspects of the established chemistry of metal complexes.

1. Preliminary Consideration: The Properties of Metal Complexes

1.1. The Free Metal Ion

The gross features of coordination chemistry can be rationalized in terms of the quantum-mechanical picture of the metal ion built up by placing electrons in hydrogen-like orbitals. The electrons of a free ion in the ground state possess characteristic energy and charge distribution. These lead to a conception of ionic radius, net charge, and, in conjunction with excited states, polarizability. These three attributes are manifested in the metal ion's coordination chemistry as maximum coordination number, polarizing power, Lewis acid strength, stereochemical behavior, reactivity, *etc* (cf. for example ref. [1a]).

1.2. The Complexed Metal

Consider a metal ion M chelated by a ligand of fixed geometry L_c which leaves at least one open coordination site. This can be occupied by a ligand L'.

$$M + L_c \rightarrow ML_c$$

$$ML_c + L' \rightarrow L'ML_c$$

The complexation of M by L_c will modify the properties of M as compared either with the free ion or with the solvated ion. In addition, the properties of L_c and L' will be modified by coordination. The first, obvious change in the metal ion will be a reduction in the remaining number of vacant or solvated inner-sphere coordination sites when L_c is bound. Complexation of L_c will also result in a change of charge; overall, if L_c bears a net charge, and in the charge localized on the metal ion. This will be substantially reduced compared with the charge on the free ion, and will result in a rearrangement of electronic energies. If the complexation takes place in solution, the effect on charge localized upon the metal ion will correspond to the difference between complexation by L_c and by solvent molecules.

A change in local charge and in electronic energy in the metal ion will result in other changes; in polarizing power, which decreases as local charge decreases; in polarizability and redox potential[*]; and consequently in Lewis acid strength and hardness/softness of the metal towards L', and the inertness and stability of the M—L' bond.

1.3. The Complexed Ligands

There are three relevant comparisons: i) complexed L_c with free or solvated L_c; ii) complexed L' with free or solvated L'; and iii) the complex $L'ML_c$ with the complex L'M·solvent (*i.e.*, the effect of L_c upon the interaction between M and L').

[*] Dr. R. H. Prince and Dr. P. R. Woolley
University Chemical Laboratory
Lensfield Road
Cambridge CB2 1EW (England)

[*] Generally the former increases and the latter becomes more negative as the ligand's donor power increases.

i) Complexation of L_c will often induce a modification of its chemical reactivity; it will probably result in restrictions upon the stereochemical flexibility of L_c; and if L_c bears a negative charge then neutralization will occur—this will be most effective if the centers of negative charge are the donor atoms themselves, as in the case of carboxyl groups.

ii) The effect of complexation on L′ will be basically similar to the effect on L_c, although as L′ is monodentate it will, other things being equal, be more labile than L_c. The kind of modifications of reactivity which the metal ion might bring about are well known. They include the enhancement of almost any process which would bring more negative charge towards the metal ion, such as ligand deprotonation, or susceptibility to nucleophiles or to reducing agents.

iii) In what ways could $L'ML_c$ differ from L′M·solvent? One is the nature of the microenvironment of the M—L′ interaction; for example in a polar situation the chelating ligand could exclude polar molecules from the region of the M—L′ bond, thus intensifying electrostatic interactions; or, in a nonpolar solvent, the reverse could occur. Another way in which L_c could significantly affect the properties of the M—L′ bond is by changing the properties of M described above: hardness, acid strength, *etc.* The M—L′ bond would be sensitive to this, and also to the geometry of the arrangement of donor atoms of L_c around M.

2. Carbonic Anhydrase: Structure and Catalytic Reactivity

Carbonic anhydrase (CA) is a hydrolytic enzyme which catalyzes the hydration and hydrolysis of many carbonyl and related systems: various slightly different forms occur in different organisms. The simplest reaction catalyzed is the hydration of carbon dioxide[1]

$$CO_2 + OH^- \rightleftharpoons HCO_3^-$$

Other reactions are catalyzed less effectively, *e.g.* the hydration of many aldehydes[2]

$$CH_3CHO + H_2O \rightleftharpoons CH_3CH(OH)_2$$

the hydrolysis of esters[3]

$$CH_3COOAr + OH^- \rightarrow CH_3COO^- + HOAr$$

of certain sultones[4], and of 2,4-dinitrofluorobenzene[5]. Each of these reactions involves bond cleavage, and most of their nonenzymatic pathways involve a transition complex in which the coordination number at an electrophilic center has increased by one oxygen atom.

The catalytic power of carbonic anhydrase is very high: its turnover number (*i.e.* under saturation conditions) for CO_2 hydration is around 10^6 s^{-1}[6]; the spontaneous hydration rate is 7.0×10^{-4} s^{-1} so that carbonic anhydrase enhances the rate by a factor of 10^9. The hydroxide-catalyzed rate constant is 8×10^3 l mol^{-1} s^{-1}[6, 7]. For other substrates the acceleration is less dramatic but still considerable. Detailed tabulations of the extensive biochemical and chemical literature on carbonic anhydrase already exist[8] and will not be repeated: results will be summarized here which are concerned with the metal ion's function, and only the most recent work is cited.

2.1. Catalytic Effects and Inhibition

Carbonic anhydrase kinetics follow the Michaelis-Menten pattern in most cases, and some typical K_m and k_2 values are shown in Table 1.

It will be observed from the Michaelis and inhibition constants (Table 2) that with the exception of CO_2 the strongest binding at the active site is associated with large, conjugated molecules. This probably reflects a high degree of hydrophobic character around the active site, though this is by no means conclusive as there is evidence for the preferential association of aromatic molecules with the polar surface, rather than with the interior, of certain micelles[9]. The extremely strong binding of sulfonamides has not yet been explained, and the requirement for an aryl (rather than, say, benzyl) sulfonamide with unsubstituted nitrogen must be due to a need for very accurate matching of enzyme's and inhibitor's stereoelectronic topography, consistent with the

Table 1. Kinetic parameters of some CA-catalyzed reactions (data from refs. [2, 3, 6, 8] and literature cited therein). The kinetic regime followed is the Michaelis-Menten scheme:

$$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P$$

(E = enzyme, S = substrate, P = product). The experimental constants are k_2 and $K_m = \frac{k_2 + k_{-1}}{k_1} \approx \frac{k_{-1}}{k_1}$ (K_m in mol/l $\times 10^{-3}$, k_2 in s^{-1}).

CA Form	CO_2 Hydration			HCO_3^- Dehydration			CH_3CHO Hydration			pNPA [b] Hydrolysis		
[a]	pH	K_m	k_2	pH	K_m	k_2	pH	K_m	k_2	pH	K_m	k_2
HCAB	6.30	6.3	5.2×10^3							7.0	5.2	0.8
	7.55	1.0	2.2×10^4	7.05	32	2.3×10^4				9.0	5.8	2.1
HCAC	6.30	18.0	2.8×10^5							7.0	22.0	37
	7.55	9.3	6.3×10^5	7.05	68	3.7×10^5				9.0	24.0	55
BCA	6.30	12.5	1.8×10^5				7.08	650	700	7.44	1.4	0.13
	7.55	12.5	7.1×10^5	7.05	[c]		7.64	610	880	8.22	8.6	1.1

[a] HCAB and HCAC are human carbonic anhydrase, forms B and C respectively. BCA is bovine carbonic anhydrase.
[b] pNPA = *p*-nitrophenyl acetate.
[c] $k_{enz} = k_2/K_m = 8.9 \times 10^6$ (l mol^{-1} s^{-1}).

Table 2. Inhibition constants of some sulfonamide inhibitors $R—SO_2NH_2$ [55]. $K=([E][I])/[EI]$; E = enzyme, I = inhibitor.

R		K (mol/l)
C_6H_5		4.6×10^{-7}
p-$CH_3—C_6H_4$		1.0×10^{-7}
p-$H_2N—C_6H_4$		9.0×10^{-7}
α-Naphthyl		1.6×10^{-7}
β-Naphthyl		1.0×10^{-7}
o-$HOOC—C_6H_4$		5.3×10^{-7}
$NC—CH_2—CH_2$		380×10^{-7}
$C_6H_5—CH_2$		150×10^{-7}
highly conjugated, aromatic	typically	0.08×10^{-7}
$R—SO_2—NHR'$	typically	6000×10^{-7}

suggestion[10] that an enzyme should bind certain substrate-analogs more strongly than substrates. There is considerable evidence that sulfonamide and other ionizable inhibitors bind as anions[22], and the Hammett relationship has been used to show that sulfonamide binding involves an *increase* of residual negative charge on the donor nitrogen[11]. While the anionic inhibitors could bind to zinc, in fact the order of inhibitor binding strength does not follow the order of binding to free Zn^{2+} in aqueous solution, but does follow quite well the lyotropic series (see Table 2a)[43].

Table 2a. Inhibition of CA [43] and complexation of Zn^{2+} (aq) [54] by small anions.

Anion	$K=[E][I]/[EI]$ (mol/l)	Anion	$K=[Zn^{2+}][I]/[ZnI^+]$ (mol/l)
F^-	0.4	ClO_4^-	very large
Cl^-	0.05	NO_3^-	10^7
CH_3COO^-	0.03	I^-	10
Br^-	0.02	Br^-	1
NO_3^-	0.01	Cl^-	1
I^-	0.002	SCN^-	0.07
ClO_4^-	0.001	F^-	0.05
SCN^-	0.0007	CH_3COO^-	0.03

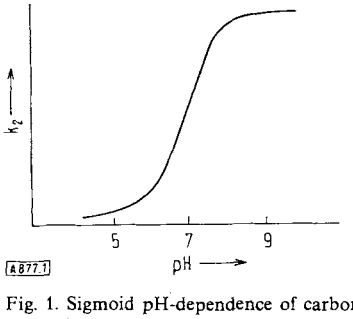

Fig. 1. Sigmoid pH-dependence of carbonic anhydrase. (The scale of the ordinate depends on the substrate.)

The turnover number of carbonic anhydrase plotted against pH invariably yields a sigmoid curve, corresponding to an increase in activity in increasingly alkaline solutions. These curves all contain a point of inflection between pH 6.9 and 8.0, showing that carbonic anhydrase has a group ionizing in this region. On the basis of the established ionization behavior of proteins, this pK_a might be attributed to the terminal NH_2 group of the polypeptide chain, or to an imidazole nitrogen in a histidine residue; another possible origin of this pK_a is the ionization of a zinc-bound water molecule. The ionizing group is clearly intimately linked with the active site.

2.2. Constitution and Structure of Carbonic Anhydrase

Recent chemical analysis[12] has shown unambiguously that carbonic anhydrase consists of protein and one zinc ion only. X-ray structural work is in progress, but for practical reasons has been very slow[13]. A study at 5.5 Å resolution has shown that:

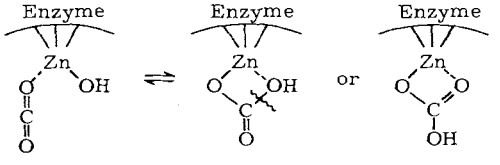
i) The molecule is roughly ellipsoidal, $40\times45\times55$ Å.

ii) The zinc is near the center of the molecule, and its coordination site communicates with the surrounding medium *via* a "cleft" in the molecule.

iii) The one SH group is 14 Å from the zinc, implying by default that the zinc ligating groups must bind through N and O.

iv) Sulfonamide inhibitors bind by projecting into the cleft, and binding onto or close to the zinc ion.

A further study at higher resolution which when complete should yield the atomic coordinates of human carbonic anhydrase, form C (HCAC), has given the following preliminary results[14]:



v) In the region of the active site all the peptide N—H and C=O groups are paired off, so that the protein in this region must be relatively hydrophobic.

vi) The zinc ion appears to be ligated by *three* protein groups, imidazole nitrogen, in an approximately tetrahedral arrangement, with the fourth coordination site open to the surrounding medium.

vii) In the cleft near the zinc atom, the surrounding water molecules appear to be ordered.

3. Metal-Centered Investigations

In 1949 *Smith* put forward a general theory of action of hydrolytic enzymes[15], as it had been recognized that many of these enzymes contained a metal ion which seemed to be essential for catalytic function. According to his hypothesis "... the M—S complex is bound to protein in such a manner as to produce an electronic deformation at the sensitive bond. The real catalysis is then acidic or basic by the Brønsted mechanism". *Smith* cites carbonic anhydrase as the simplest example of his theory, the "sensitive bond" being the C—OH bond in bicarbonate.

By implication, *Smith* allows the protein part of the enzyme no role except perhaps that of a template to ensure that only the correct substrate is attacked. This is a weakness in his theory, since the sheer size of the enzyme suggests that it is more than simply a molecule which can bring Zn, CO_2, and OH^- together. However, the theory did emphasize the

role of the metal and its coordination sphere, and this at least can be put to experimental test. In the following discussion evidence will be adduced to criticize the hypothesis that the enzyme's activity depends upon the existence of a zinc-bound hydroxyl group.

3.1. Apocarbonic Anhydrase

The means to investigate the role of zinc in carbonic anhydrase came when *Lindskog*[16] first succeeded in removing reversibly the very tightly-bound zinc ion under conditions mild enough to avoid denaturation. The equilibrium

$$E - Zn + n\,o\text{-phen} + H^+ \rightleftharpoons EH + Zn(o\text{-phen})_n^{2+}$$

was set up and driven to the right using dialysis to remove the $Zn(o\text{-phen})^{2+}$. The apoenzyme was catalytically almost inactive, and most of the activity was restored by adding zinc ions in the molar ratio 1:1. The slight residual activity of apoCA is not significant, as the polar groups on the enzyme's exterior should promote slight general acid/base catalysis. Its gross structure, as revealed by sedimentation[16] and ORD[17], is the same as that of ZnCA, although it denatures more rapidly. This implies that the zinc's function is probably not merely to organize the protein's tertiary structure, so that it must be concerned directly with the active site.

3.2. Displacement of Zinc by Other Metals

The preparation of new derivatives of carbonic anhydrase has been attempted by adding equimolar or excess quantities of Co^{2+}, Ni^{2+}, Fe^{2+}, Cu^{2+}, Cd^{2+}, Pb^{2+}, Hg^{2+}, Be^{2+}, Mg^{2+}, Ca^{2+}, Ba^{2+}, and Fe^{3+}[16, 17]. The replacement of one metal by another in compounds of unknown structure provides a valuable probe into the nature of the metal coordination subject to the guarded assumption that the coordination site is the same for the different metals. This assumption is tentatively supported in the case of carbonic anhydrase by *Coleman*'s observation[17] that the various metallo-CA's do not incorporate radioactive zinc.

A metalloenzyme can be studied by varying the metal ion only, and if the thermodynamic, magnetic, kinetic, and spectral properties of the different metalloenzymes thus obtained are compared with the properties of simple coordination compounds of the metal ions concerned, it is frequently possible to extract information[19] about the coordination in the enzyme.

3.2.1. Activity of Metallocarbonic Anhydrases

Typical results[20] show the following trend of activities, corrected for any remaining zinc and for the residual activity of apoCA: native CA, 100%; Zn^{2+} + apoCA, 94%; Co^{2+} + apoCA, 50%; other metal ions + apoCA, 0%. Only Zn^{2+}CA and Co^{2+}CA are significantly active.

3.2.2. Inhibitor Binding

This shows a clear correlation with activities (Figure 2). The apoenzyme and the inactive MCA's bind acetazolamide[*] weakly, in contrast to the active enzymes ZnCA and CoCA which bind acetazolamide 10^2 to 10^3 times more strongly and are inhibited by it. This suggests very strongly that the sulfonamide group and the metal ion interact. The X-ray data, the fact that sulfonamides bind as anions, the fact that other inhibiting anions cannot bind unless their concentration is great enough to displace the more strongly bound sulfonamide, and the UV spectral evidence (see Section 3.2.3) all support the notion of a metal-inhibitor bond. Therefore when an inhibitor binds to carbonic anhydrase it alters the coordination of the zinc or cobalt, possibly displacing a group already bound, in such a way that reaction can no longer take place. The sigmoid (as opposed to hyperboloid) binding curves of acetazolamide do show that the inhibitor is displacing something, rather than simply adding to the enzyme.

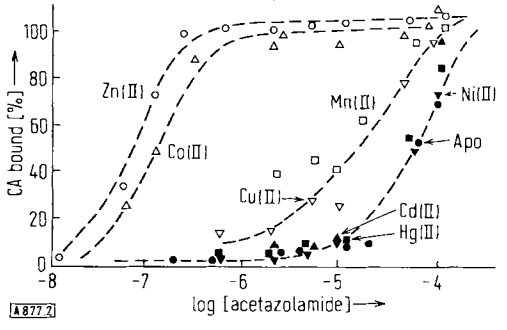


Fig. 2. Acetazolamide binding to metal-substituted carbonic anhydrase. (From ref. [18].)

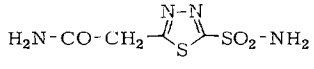
3.2.3. Stoichiometry, Kinetics, and Thermodynamics of Metal Ion Binding

A commonplace feature of coordination chemistry is the neutralization of basic ligand groups upon complexation, with liberation of protons if complexation occurs at pH values below the pK of these groups. However *Lindskog*[21] showed that in carbonic anhydrase the reverse took place, *viz.*, at pH 6:



$$Zn^{2+} + \text{apoCA} \rightarrow \text{ZnCA} + (1.3 \pm 0.15)\,H^+$$

at pH 9:

$$Zn^{2+} + \text{apoCA} \rightarrow \text{ZnCA} + (2.2 \pm 0.1)\,H^+$$

The zinc is therefore inducing a further ionization upon binding and the proximity of the ionizing group to the zinc ion in ZnCAl will be reflected in the perturbation of the

[*] 5-Sulfamoyl-1,3,4-thiadiazol-2-acetamide. The trivial name is derived from 5-acetamido-1,3,4-thiadiazole-2-sulfonamide.

ligand field at zinc as the pH passes from 6 to 9. This cannot be examined with ZnCA, but it should be reflected in the d-d electronic spectrum of CoCA. In fact the visible spectrum of CoCA has an acid and an alkaline form[21], and well-defined isosbestic points show that the pH-dependent equilibrium is between two forms only. These are related by an ionization with a pK_a around 7.1, and the spectra show that in both forms the coordination is irregular (Figure 3).

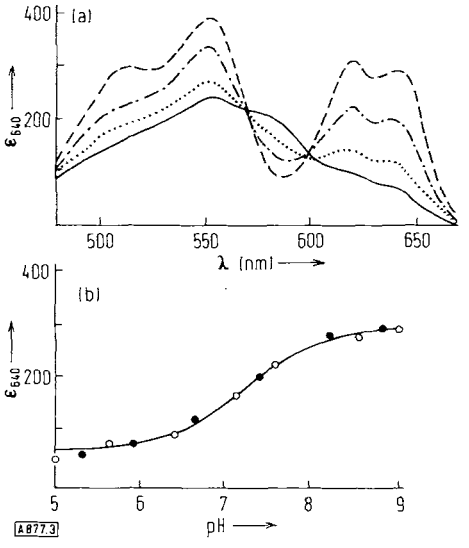


Fig. 3. Visible spectra of cobalt-carbonic anhydrase a) in acidic (——) and increasingly alkaline solution (· · · · ·, – · – · –, – – – –); b) extinction at various pH values (from ref. [21]).

This ionization pK_a is destroyed not only by removal of zinc but also by inhibitors, as shown by *Coleman*[22]. The binding of anionic inhibitors is accompanied at low pH by the release of protons and at high pH by release of hydroxide ions; if E^- and EH are the two forms of the holoenzyme and I^- the inhibiting anion, then in acid:

$$HI + EH \rightarrow EH{\cdot}I + H^+$$

and in alkali:

$$I^- + E^- \xrightarrow{+H_2O} EH{\cdot}I + OH^-$$

The amounts of H^+ or OH^- liberated as a function of pH were successfully related to the pK_a values of the inhibitor and the enzyme. It will be noted that the pK_a values associated with activity, inhibition, and metal-dependent ionization are roughly the same, suggesting that the same group may be involved.

The kinetics and thermodynamics of the binding of zinc by carbonic anhydrase have been investigated[23,24] and Table 3 shows the second-order rate constants, activation parameters, and thermodynamic constants of binding. These are compared with those for smaller ligands of various coordination numbers. Both rate process and equilibrium are entropy-dominated, in spite of a smaller opposing enthalpy. The entropy terms are substantial, and the only ligand comparable in this respect is CDTA (cyclohexenediamine tetraacetate), a formally hexadentate ligand. While it is most unlikely that apocarbonic anhydrase is hexadentate (which illustrates the danger of overinterpreting an observed behavioral similarity between an enzyme and a proposed model), the similarity between carbonic anhydrase and CDTA is very probably a consequence of the same cause: the expulsion of a large number of water molecules. The effect in the case of CDTA is due to charge neutralization, and in carbonic anhydrase the binding of the metal may also result in charge neutralization in the active site region.

Further evidence for this may be cited (see literature quoted in ref. [24]): the difference UV spectrum of ZnCA minus apoCA is similar to the difference spectra produced when a tyrosine or a tryptophan derivative is transferred from water to a less polar solvent. This similarity suggests that one or more tyrosine and/or tryptophan groups are in a more polar environment in the apoenzyme than in the holoenzyme. Other workers concluded on the basis of studies with fluorescent sulfonamides that the active site of the native enzyme is nonpolar. It is interesting to note that recent structural work on a number of enzyme systems shows the active site to be located in a nonpolar environment[24a].

The positive binding enthalpy supports a small coordination number, so that during the reaction more M—L bonds are broken than formed, as expected if the zinc is three or four coordinate (aquated zinc is hexacoordinate). The metals whose binding results in an active enzyme are those with

Table 3. Rate and equilibrium parameters for the reaction M + apoCA → MCA (data from refs. [23, 24, 53, 54]).

M	Ligand	k (l mol^{-1} s^{-1})	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$ (e.u.)	ΔH (kcal/mol)	ΔS (e.u.)
Zn	typical small unidentate	10^{7-8}				
Zn	typical small bidentate (bipyridyl)	10^6	+6	−9	−10	+8
Zn	typical small tridentate (terpyridyl)	10^6	+8	−4		
Zn	apoCA, pH 5.5	$<10^4$	+21	+28	+3.9	+61
Zn	apoCA, pH 7.0	10^4	+21	+30	+9.8	+88
Co	apoCA, pH 7.0				+9.4	
Ni	apoCA, pH 7.0				+3.2	
Cu	apoCA, pH 7.0				+3.4	
Cd	apoCA, pH 7.0				+4.4	
Zn	CDTA (cyclohexene-diamine tetraacetate)				+4.7	+82

the most endothermic binding to carbonic anhydrase. This is consistent with the Irving-Williams sequence of stabilities ($Co < Ni < Cu > Zn$) and *if* the five metals Zn, Co, Cd, Cu, and Ni all bind at the same site it may be responsible for the activity pattern. *Dennard* and *Williams*[19] have pointed out that a catalytically active metal must not bind too strongly to its apoenzyme or it will lose coordination flexibility.

3.3. Spectroscopic and Magnetic Studies

The d-d transition in CoCA has been extensively studied. Basically three kinds of spectrum are obtained from CoCA: One each in acid and in alkaline solution and one for inhibited forms (Fig. 4). Their interpretation is difficult; they show that the coordination cannot be simple. The spectrum of $CoCA \cdot CN^-$ is similar to that of $[CoCl_4]^{2-}$, suggesting tetrahedral coordination, although this is not conclusive; irregular six-coordinate Co^{2+} complexes are known which give very similar spectra[25].

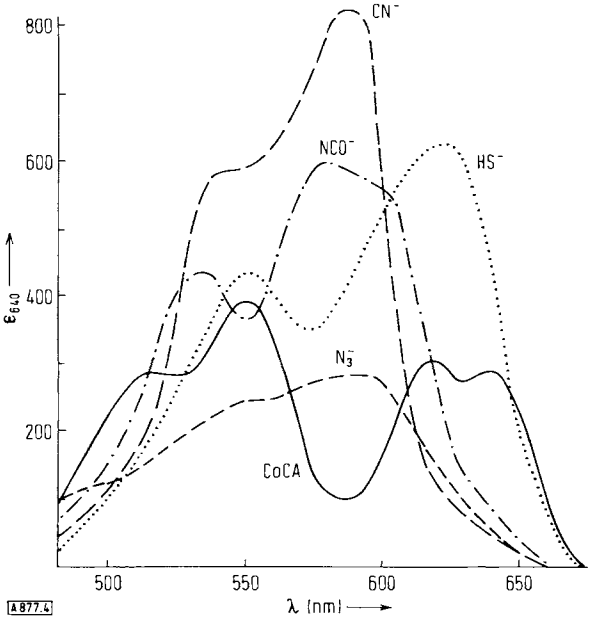

Fig. 4. Visible spectra of cobalt-carbonic anhydrase in alkaline solution in the presence of inhibiting anions (from ref. [21]).

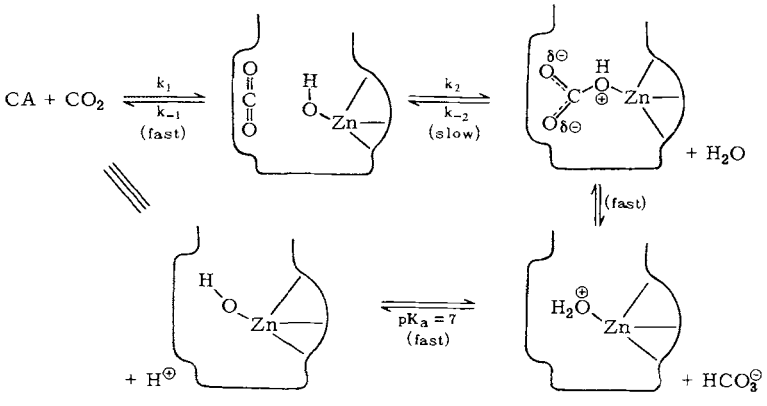
Optical rotatory dispersion (ORD) studies have been carried out by *Coleman* on HCAB[17]. Zn-, Co-, and apoCA have similar ORD spectra in the UV, implying that they have the same gross protein conformation. The visible region of the CoCA ORD is featureless, in spite of the d-d transition, which means that the Co site in HCAB is optically inert. *Coleman* postulated a square-planar binding of cobalt, with the additional coordination of H_2O or OH^-, which are not strong enough ligands to destroy the approximate symmetry. In fact the tetrahedral coordination of cobalt with two equivalent donors would be an equally good explanation, and in the light of X-ray data seems preferable. Inhibitors give rise to a visible-ORD spectrum in CoCA, explicable as resulting from the displacement of H_2O or OH^- by a ligand higher in the spectrochemical series. Furthermore, CuCA binds cyanide less tightly than CoCA, which may reflect the greater destabilization of trigonal or tetragonal Cu^{2+} by the addition of an axial ligand.

A ^{35}Cl-NMR study of ZnCA in chloride solutions showed that the zinc in bovine carbonic anhydrase (BCA) has at least one, and probably only one, open coordination site. *Ward*[26] showed by line-broadening that the chloride ions in the $CA—Cl^-$ complex are bound directly to zinc, the consequent high electric field gradient resulting in rapid quadrupole relaxation. Titration by cyanide, which displaces chloride, gave the number of chlorides bound. Chloride binding was pH-dependent, and the pK of carbonic anhydrase measured thereby was in turn sensitive to the concentration of chloride, being 6.2 at $[Cl^-]=0$ and 9.3 at $[Cl^-]=0.5$ mol/l. Extension of this work to human and horse carbonic anhydrases shows that the more active forms have a lower zero-chloride pK_a and a higher molar relaxivity than the less active forms. If the pK_a is that of ionizing zinc-bound water, then it is not surprising that the stronger polarization of ligand water (higher field) is accompanied by a greater molar relaxivity (higher field gradient), both of which could result from an increased positive charge on the zinc ion. It would however be more surprising if the more highly polarized hydroxide ion were the better nucleophile, and this may hint that if the hydroxide mechanism is correct then the activity of carbonic anhydrase is due to other factors as well.

An investigation[27] of solvent proton relaxation by the paramagnetic Co^{2+} ion in CoCA reveals a strong, pH-dependent, inhibitable relaxivity associated with the active site. The relaxivity was less at low pH, and the acid form of the enzyme possessed the same molar relaxivity as the inhibited form. It was concluded that a rapidly-exchanging, cobalt-bound hydroxide could be displaced by inhibitors, or prevented from exchanging by protonation (p$K_a \approx 7$). For the rapidly-exchanging form several parameters were calculated: r_{Co-H} (if OH^-) = 2.5 Å; r_{Co-H} (if OH_2) = 2.8 Å; proton residence time $\approx 10^{-5}$ s. The interatomic distances calculated are too small for anything except Co—O—H, and although better agreement with the expected distance ($r_{Co-H} = 2.85$ Å) is obtained assuming $Co—OH_2$ rather than $Co—OH^-$, the difference thus obtained from a technique giving $\left\langle \frac{1}{r^6} \right\rangle$ is probably insignificant.



Further evidence for the zinc-hydroxide/zinc-water species is found in the kinetic pattern of sulfonamide substitution[28], which upon analysis resembles the pattern of ligand substitutions of 3d metal-ion inner-sphere complexes; after an outer-sphere pre-equilibrium the rate constant of inner-sphere complex formation is independent of the nature of the substituent, depending only upon the rate at which inner-sphere sites are vacated by water molecules.

Some work carried out by *Riepe* and *Wang*[29] should be mentioned, because although not directly related to the zinc ion it provides key evidence in the problem of substrate binding. Based on delicate difference infrared spectroscopy, their work indicated that while CO_2 is *not* bound directly to zinc, its isoelectronic analog N_3^- is so bound. However, the binding of N_3^- and of CO_2 are mutually exclusive,

which suggests that CO_2 is bound in a position very close to the zinc ion, where it is accessible to bound ligands. In addition, *Riepe* and *Wang* showed that the binding constant of azide ion decreased with increasing pH and did not level off, implying that the azide ion is displaced specifically by OH^- rather than by another deprotonated group.

4. The Mechanistic Role of Zinc

The results presented above provide extremely good evidence that the zinc ion in all forms of carbonic anhydrase is coordinated by protein and water. While none shows beyond all doubt that the pK_a around 7 recurrent in carbonic anhydrase chemistry is due to the ionization of one zinc-bound water molecule, it is hard to offer an alternative explanation, particularly of the UV-spectral and relaxation data. The existence of this zinc-aquo complex seems a necessary condition for the activity of carbonic anhydrase. In view of the evidence that CO_2 is bound close to but not onto zinc, a mechanistic scheme of the kind shown is very plausible[30].

Does this stand up to quantitative examination? From CO_2 hydration data for alkaline BCA, $k_2 = 8 \times 10^5\ s^{-1}$, while $K_m = (k_{-1} + k_2)/k_1 = 0.0124\ l\ mol^{-1}$[6]. Since k_2 is pH-dependent while K_m is not, probably $k_{-1} \gg k_2$. Assuming a lower limit of $k_{-1} = 10\ k_2$, the lower limit for k_1 is $6 \times 10^8\ l\ mol^{-1}\ s^{-1}$. This is close to the diffusion-controlled limit, and therefore requires a fairly open active site, which is consistent with the observed binding of larger, aromatic substrates and inhibitors.

Table 4. Comparison of k_2 for CA (rate of breakdown of the enzyme-substrate complex) with $50\ k_{OH^-}$ (hypothetical rate of breakdown of the substrate when surrounded by hydroxide ions).

Substrate	$k_2\ (s^{-1})$	$50\ k_{OH^-}\ (s^{-1})$
CO_2	10^6	0.4×10^6
CH_3CHO	10^3	200×10^3
Pyridinecarbaldehydes	10^2	2500×10^2
p-Nitrophenyl acetate	10	50×10

If the reaction step with rate k_2 corresponds to attack by a hydroxide ion, then it can be compared with the rate of attack by free hydroxide (Table 4). Only in the case of CO_2 is k_2 unreasonably high, which implies that the catalytic action of carbonic anhydrase is not due solely to the provision at the active site of "free" hydroxide at relatively low pH.

The dehydration of bicarbonate shows a similar kinetic pattern, although in the case of BCA[6] the enzyme cannot be saturated, so that the $E—HCO_3^-$ complex must be very unstable. *Caplow*[31] studied the catalysis by hypobromous acid of the dehydration reaction, and concluded that a concerted electrophilic displacement must be occurring:

$$HO—Br + HO—CO_2^- \rightarrow HO^- + Br—OH + CO_2$$

The bromine atom acts as a Lewis acid. This is consistent with the kinetic scheme above for dehydration: displacement of zinc-bound water would result in the formation and immediate breakdown of a zinc-bicarbonato complex.

This proposed reaction course leads to a number of questions.

i) Can the very low pK_a of $Zn—OH_2$ in carbonic anhydrase be accounted for?

ii) Can the rapid proton transfer be incorporated into the scheme?

iii) Can the unusual order of inhibitor binding be explained?

iv) Why is carbonic anhydrase so specific in its requirement for Zn^{2+} or Co^{2+}?

Before discussing these problems, it would be germane to introduce some of the concepts useful in enzyme chemistry. The basic assumption is of course that the groups in the enzyme molecule obey the chemical principles governing the behavior of small molecules in aqueous solution. Catalysis by enzymes is remarkable on two accounts: the very large accelerations observed, and the high, sometimes absolute, substrate specificity. Many ideas have been put forward to explain these, some differing only in detail[32]. The basic lines of explanation usually involve appeal to one or more of the following concepts.

i) The lock-and-key picture, according to which substrates are specifically bound as their stereoelectronic topography complements that of the enzyme's substrate-binding site. Specific binding by metal-ion centers in enzymes applies, as one would expect, largely to electron-donating substrates such as anions, O_2, and CO. There are many instances of this[33]. In such cases the influence of the protein on the

metal cannot be very important, as long as the metal has enough coordination sites to bind the substrate, and a sufficiently high ligand exchange rate in the vacant sites. The latter is a function of donor power as well as geometry of the protein[34].

ii) The bringing together (approximation) of reacting groups so as to increase the collision frequency and/or raise the steric probability factor. Approximation of reacting groups is, at its simplest, an effective increase in their concentration at the active site and hence of collision number, but in many cases[35] it is an inadequate explanation of reactivity bestowed upon normally very inert substrates. In the case of carbonic anhydrase, as discussed above, it is barely adequate; it requires an unreasonably high effective concentration of OH^- at the active site. It is also inadequate to explain the greatly reduced activation energy of the catalyzed reaction[36]. Furthermore the attribution of the nucleophilicity of free OH^- to zinc-bound OH^- is implausible.

For many reactions the electronic activation energy is a sensitive function of angle of attack, and the Arrhenius plot gives "averaged" values; it has recently been suggested that enzymes could act by constraining the substrates to meet in a fixed orientation corresponding to an activation energy much lower than that observed in free solution. This procedure is called "orbital steering"[37]. In the case of carbonic anhydrase such an explanation cannot be ruled out.

iii) The strained-molecule hypothesis. Essentially, the enzyme-to-substrate binding distorts the substrate in the direction of reaction, resulting in a lower activation energy with respect to the ground-state enzyme-substrate complex. Involvement of metal in the formation of an enzyme-substrate complex in which the substrate is strained is very plausible, because of the ability of metals to form labile bonds to donors in which the donor atoms or groups are electronically and/or geometrically strained. The postulated ionizing water molecule in carbonic anhydrase is such a donor. The polarizing power of $[(H_2O)_5Zn]^{2+}$ is illustrated by comparing the pK_a of H_2O, $(H_2O)_5ZnOH_2^{2+}$, and H_3O^+; they are 15.7, 10.5[*], and -1.7. Thus the polarizing power of the pentacoordinate zinc ion is less than that of a proton, as would be expected. In carbonic anhydrase the same pK_a drops to about 7.1, which is a substantial change.

iv) The "unusual medium" theory pictures the enzyme as providing an unusual medium, distinct from the aqueous environment, in which the catalyzed reaction takes place. There is considerable evidence that the interior of an enzyme is much less polar than its exterior. It was predicted[39] that this would stabilize the conformation of the enzyme molecule, and this has been borne out by X-ray structure-determination. In the now classic example of lysozyme[40] the enzyme contains a "groove" on its surface. The substrate binds to this groove and the catalyzed reaction then occurs in the nonpolar interior of the enzyme. Such a theory would account for the very large size of many enzyme molecules compared with their substrates.

[*] This figure is derived from the tabulated pK of 9.7 [38, 43, 54] by applying a statistical correction, effectively to reduce the number of ionizable protons from twelve to two.

The idea of an unusual environment at the active site of metalloenzymes has been pursued by *Vallee* and *Williams*[41], who point out that many enzymes containing metal ions possess unusual properties, notably in their UV and ESR spectra and redox potentials. Such anomalies are not observed in biological molecules where the metal is inactive, and are frequently destroyed when the enzyme is inhibited or denatured. The unusual features of metalloenzymes are attributed to the metal's possessing a coordination geometry of a kind not found with simpler ligands; such a geometry is imposed upon the metal by the protein, whose conformation is already fixed. This would modify the properties of the metal ion with regard to coordination by further ligands, as discussed in Section 1. In carbonic anhydrase the environment of the zinc/cobalt may be "unusual" in three respects: in the conformation imposed by it upon the ion; in its apolarity; and in the ordering of water molecules around it. (It is, of course, not unexpected that water molecules should be relatively ordered around an apolar surface in an aqueous solution[42].)

In what way is the coordination of zinc abnormal? If the total coordination number is four (3 protein, 1 water) then the residual charge on the zinc could be greater than if the zinc were hexacoordinate, although since the donor atoms are nitrogens of imidazole rather than oxygens of water this is not conclusive. A higher residual charge on zinc would decrease the pK_a of coordinated water. However, a shift of 3.5 units is large, and further enhancement could be due to the nonpolar nature of the environment around the zinc: ionization would be encouraged if it resulted in better attainment of overall charge-neutrality.

One supposed difficulty in all mechanistic schemes so far proposed for carbonic anhydrase is that the zinc hydroxo complex loses hydroxide to the substrate and regains water, which then ionizes. In the CO_2 hydration (turnover $10^6\ s^{-1}$) the zinc-bound water must therefore ionize at least at this rate. However, if the pK_a of the water is 7.0 and the maximum diffusion-controlled protonation rate is 10^{10} $l\ mol^{-1}\ s^{-1}$, then the predicted maximum deprotonation rate is $10^{10}/10^7 = 10^3\ s^{-1}$.

The suggestion that a nearby histidine residue might assist in deprotonation is not plausible, chiefly because chemical methods designed to detect such a group have only succeeded in one of the less active forms of carbonic anhydrase. However, if the nonpolar active site is surrounded by a region of ordered water molecules then two possibilities arise:

i) The true pK_a of $ZnOH_2$ is even less than 7, which increases the maximum deprotonation rate (the difference between the true and observed pK_a would then have to be explained as due to an equilibrium constant between protons solvated in the ordered region and in bulk phase).

ii) The diffusion-controlled limit for proton transfer is greatly increased, as in ice[42a], with a simultaneous increase in the maximum rate of deprotonation.

The idea of ordered water at the active site may also explain the observed inhibitor binding order[43], which follows the lyotropic series[44] (see Table 2a). The binding of anions and the associated spectral changes in $Co^{II}CA$ show that the

inhibitors do bind to the metal; but the order of binding constants is more easily explicable if the thermodynamic drive for binding comes from the easy assimilation of the anions into an ordered water structure. Such a stabilization of anions bound at the active site could also assist in lowering the pK_a of the zinc-bound water.

From the inorganic point of view, the most remarkable feature of the catalytic power of carbonic anhydrase is the absolutely specific need for Zn^{2+} or Co^{2+}. No other metal imparts significant activity to apoCA, so it is likely that Zn^{2+} and Co^{2+} have more than one property crucial for the hydrolytic mechanism.

Table 5. Selected properties of metal ions (see text).

Metal	Ionic radius (Å) [a]	Water exchange rate $\log_{10}k$ (s^{-1}) [53]	Imidazole assocn. const. $\log_{10}K$ ($l\ mol^{-1}$) [54]
Mn^{2+}	0.80	7.6	1.65
Fe^{2+}	0.76	6.5	—
Co^{2+}	0.71	6.4	2.23
Ni^{2+}	0.69	4.4	3.27
Cu^{2+}	0.92	9.9	4.26
Zn^{2+}	0.72	7.5	2.57
Cd^{2+}	0.95	—	2.80

[a] Cf. ref. [45], p. 45.

One can compare the properties of zinc and cobalt ions with those of other ions, and ionic size, inner-sphere water exchange rate, and strength of binding to imidazole are shown in Table 5. None of these points to any special behavior on the part of zinc and cobalt ions, though they are clearly very similar.

The best explanation seems to lie in the metal's *coordination flexibility*, and in this respect Zn^{2+} and Co^{2+} do indeed stand out[45]. This is illustrated in Table 6, which compares the stability constants for various metals binding to two chelating ligands, one of which gives, with two waters, an octahedral complex, while the other can only do this with some strain.

Table 6. Stability constants of chelates (see text).
$L^1 = H_2N(CH_2CH_2NH)_3H$,
$L^2 = N(CH_2CH_2NH_2)_3$, $K_i = \frac{[ML_i]}{[M][L_i]}$ (data from ref. [54]).

M	$\log_{10}K_1$	$\log_{10}K_2$	$\log_{10}\frac{K_2}{K_1}$
Mn^{2+}	5.0	5.7	0.7
Fe^{2+}	8.0	8.7	0.7
Co^{2+}	11.0	12.7	1.7
Ni^{2+}	14.1	14.8	0.7
Cu^{2+}	20.5	18.7	−1.8
Zn^{2+}	11.9	14.5	2.6
Cd^{2+}	10.8	12.3	1.5
Hg^{2+}	25.3	26	0.7

It would thus seem possible that the essential property of zinc and cobalt ions is that they can bind to imidazole in a nonoctahedral disposition. Other metals, binding more strongly to imidazole, could impose an octahedral geometry upon the donor atoms and seriously distort the active site. It is of interest in this connection that imidazole has recently been shown[46] to give, under similar conditions, both octahedral (hexakis) and tetrahedral (tetrakis) complexes with Co^{2+}. On the simple basis of coordination flexibility one would also expect Cd^{2+} and Mn^{2+} to activate apoCA. Neither should manifest coordination-selective ligand-field stabilization energy (LFSE), and Cd^{2+} is a recognized analog of Zn^{2+}[45]. In fact neither is active in carbonic anhydrase, which shows that some factor as yet unexplained operates in carbonic anhydrase, particularly as cobalt/zinc enzymes such as carboxypeptidase[47] and alkaline phosphatase[48] are partly activated by Cd^{2+} and Mn^{2+}.

The study of carbonic anhydrase has therefore raised the issue of the properties of metals in systems where the coordination environment is fixed by the ligand rather than by the metal. The postulated mechanism based on an active coordinated water molecule requires (i) that the acid-dissociation of this molecule should be thermodynamically and kinetically very much easier than the corresponding dissociation in the free aquated zinc ion, and (ii) that the hydroxo complex should be a very strong nucleophile. This certainly requires quantitative investigation since to satisfy both (i) and (ii) requires a metal ion whose polarizing power is large but not too large.

The sensitivity of the rate of complexation of L′ to the nature of L_c has been shown to depend on the metal ion[49]; the rate of the reaction

$$ML_c + L' \xrightarrow[-H_2O]{k_{assoc.}} L_cML'$$

does not depend upon L_c if $M = Mg^{2+}$, but does depend upon L_c if M is the more polarizable Mn^{2+}, Cu^{2+}, or Zn^{2+}. Interestingly, in one instance the patterns of variation of $k_{assoc.}$ (as L_c was changed) were found[50] to be the same for Zn^{2+} and Co^{2+} but different for Ni^{2+}.

Very little is known about the nucleophilicity of metal-bound water or hydroxide, although there have been some recent indications that Cr^{III}—OH and Co^{III}—OH are good nucleophiles; *Buckingham et al.*[51] showed that the complex

$$N_4Co^{III}(OH)\cdot NH_2—CH_2—CONR_2$$

undergoes very rapid intramolecular hydrolysis of the amide group, while *Earley et al.*[52] showed that the reaction

$$[N_5Cr^{III}OH]^{2+} + CO_2 \rightarrow [N_5Cr^{III}OCO_2]^+ + H^+$$

is at least 10^4 times as fast as the reaction[*]

$$H_2O + CO_2 \rightarrow HCO_3^- + H^+$$

We are very grateful to Drs. K. K. Kannan and A. Liljas for providing pre-publication results on the X-ray structure of CA.—P. R. W. acknowledges with thanks the award of a Research Studentship by the Science Research Council of the U. K.

[*] *Note added in proof* (April 24, 1972): The kinetics of the hydration of CO_2 have been reinvestigated by *Khalifah* [56]. and he reports that the Michaelis constants for CO_2 hydration by human carbonic anhydrases band C are pH-independent, in contrast to the earlier work (Table 1). This brings human carbonic anhydrase into line with bovine carbonic anhydrase (Table 1).
A nitroxide spin-labeled sulfonamide has been used [57] to examine the active site of bovine CA. Analysis of the ESR signal of the nitroxide radical suggested that the part of the cavity at a distance of 11 Å from the zinc ion is not non-polar but is in fact highly polar. Any conclusion based on the assumption that the amino acid residues around the cavity are entirely nonpolar must therefore be called into question, pending the complete mapping of the molecule by X-ray crystallography.
Using model systems involving zinc, we have investigated two problems raised by the chemistry of CA—the extent to which simpler organic systems can cooperate with zinc ions to catalyze the reactions of carbonyl compounds [58], and the question of the pK_a of zinc-bound water.

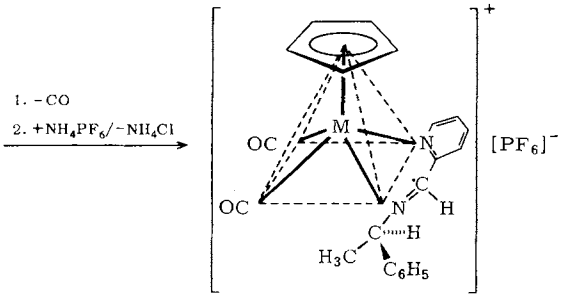
Optically Active Molybdenum and Tungsten Complexes with Tetragonal-pyramidal Configuration[1]

By *Henri Brunner* and *Wolfgang A. Herrmann*[*]



Compounds of the type $C_5H_5M(CO)_2LX$ (M = Mo or W) have square-pyramidal structures with the C_5H_5 ligand at the apex of the pyramid[2-4]. Interconversion of *cis-trans*-isomers can be followed by NMR spectroscopy[5-7]. Bidentate ligands LL, replacing the two substituents L and X, necessarily occupy *cis*-positions and *cis-trans*-isomerizations are excluded. With asymmetric chelate ligands LL' compounds of the type $C_5H_5M(CO)_2LL'$ should occur in enantiomeric forms; however, since derivatives with coordination number 5 generally isomerize readily, only a few compounds of five-ligated phosphorus have as yet been isolated in optically active form[8,9]. Whereas these compounds usually undergo rapid pseudorotation, we now report optically active molybdenum and tungsten complexes with surprisingly stable tetragonal-pyramidal configuration.

When tricarbonylchloro(π-cyclopentadienyl) complexes of molybdenum *(1)* or tungsten *(2)* are treated with the Schiff base of pyridin-2-aldehyde and (−)-α-phenylethylamine *(3)*, one CO group is replaced and the Cl ligand is displaced into the outer coordination sphere. Thus are formed the cationic complexes *(4a, b)* and *(5a, b)*, respectively, as chlorides that contain asymmetric Mo or W atoms.

(1), M = Mo
(2), M = W

(3)

(4a, b)
(5a, b)

In this reaction the bidentate Schiff base *(3)* functions on the one hand as a ligand lowering the symmetry and on the other as an optically active agent for resolution of the racemate. After conversion of the chlorides into hexa-

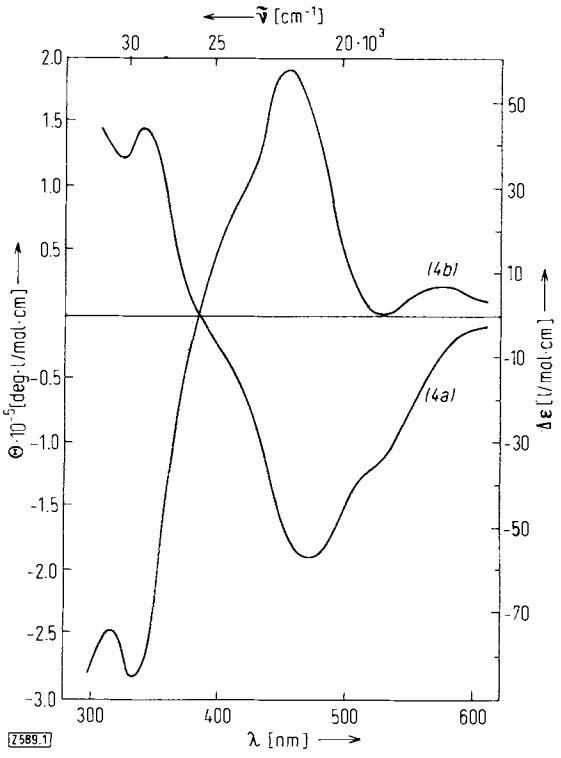

Fig. 1. CD spectra of the diastereoisomeric molybdenum complexes *(4a)* and *(4b)* in acetone.

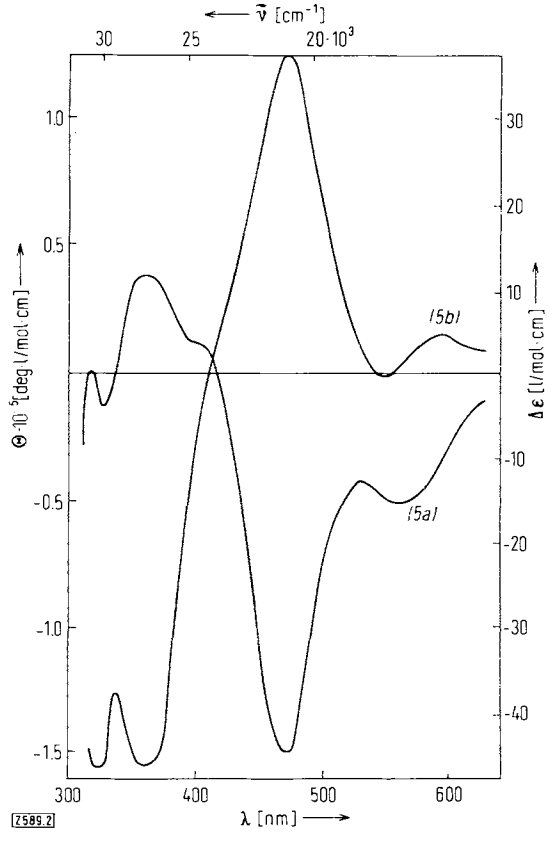

Fig. 2. CD spectra of the diastereoisomeric tungsten complexes *(5a)* and *(5b)* in acetone.

fluorophosphates the diastereoisomers can be separated on the basis of their differing solubilities by repeated fractional crystallization from an acetone/methylene chloride/ethanol mixture (20:3:1). It is remarkable that of the diastereoisomeric pair *(4a, b)* it is the levorotatory (at 436 nm) isomer *(4b)*, but of *(5a, b)* the dextrorotatory isomer *(5a)*, that is preferentially enriched in the sparingly soluble fraction. The absolute configurations are not known.

In the solid state and in solution the diamagnetic salt-like complexes *(4a)*, *(4b)*, *(5a)*, and *(5b)* are configurationally stable at room temperature. However, the complexes decompose slowly under the action of atmospheric oxygen and of light, with slight increase in the specific conductivity. Two strong CO bands appear in the carbonyl region of the IR spectra of these compounds. The ^{1}H-NMR spectra show, besides the signals of the chelate ligand, a sharp singlet due to the protons of the cyclopentadienyl ring. The complexes are deep red with a metallic sheen and dissolve readily in acetone or dimethyl sulfoxide, but very slightly in water or apolar solvents.

Figures 1 and 2 show the CD spectra of the complexes *(4a)*, *(4b)* and *(5a)*, *(5b)*, respectively. The diastereoisomeric pairs give approximate mirror images over parts of their CD curves.

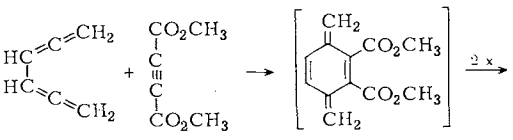
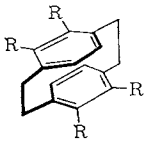
A Simple Synthesis of [2.2]Paracyclophanes



By *Henning Hopf*[*]

Dedicated to Professor R. Criegee on the occasion of his 70th birthday



Addition reactions to 1,2,4,5-hexatetraene (biallenyl) *(1)*[1] are of interest because this acyclic C_6H_6 hydrocarbon contains one conjugated and two cumulated diene systems. To find out whether [2+2]-cycloaddition to the allene groups or [2+4]-cycloaddition to the "inner" double bonds is favored[2], we have treated *(1)* with dienophiles; we report here the reaction of biallenyl *(1)* with dimethyl acetylenedicarboxylate *(2)*.

Warming a solution of equimolar amounts of *(1)* and *(2)* in benzene for 9 hours at 65 °C, followed by removal of the solvent and recrystallization from benzene affords very shiny crystalline scales (m.p. 213—215 °C, uncorr.; yield 32%), to which structure *(4a)* may be assigned on the basis of the following data.

[*] Dr. H. Hopf
Institut für Organische Chemie der Universität
75 Karlsruhe, Richard-Willstätter-Allee 2 (Germany)

(1) *(2)* *(3)*

(4a), R = CO_2CH_3
(4b), R = H
(4c), R = CH_2OH
(4d), R = CO_2H

(4e), -R-R- =

According to the mass spectrum *(4a)* is a dimer of the 1:1 adduct of *(1)* and *(2)*[3]. The IR spectrum (KBr) shows intense bands at 1724, 1264, 1127, and 1107 cm^{-1} ($COOCH_3$) accompanied by weaker absorption maxima at 3000, 1577, 1553, 869, 788, and 725 cm^{-1} [Ar—H; the aromatic bands of the parent hydrocarbon *(4b)* appear at 3030, 1575, 930, 893, and 725 cm^{-1} [4, 5]]. The NMR spectrum [($CDCl_3$/TMS), $\tau = 3.10$ (4H/s), 6.15 (12H/s), and 6.78 ppm (8H/AA'BB'—M)] shows the shift of the aromatic protons to higher field characteristic of [2.2]paracyclophane systems [*(4b)*: $\tau = 3.63$ (s) and 6.95 (s)[6]]. The unstructured UV spectrum (ethanol) with bands at $\lambda_{max} = 302$ ($\varepsilon = 2080$) and 213 nm (42000) also indicates the [2.2]paracyclophane structure of *(4a)* [*(4b)*: $\lambda_{max} = 302$ (160), 284 (250), and 224 nm (25000)[4, 7]].

(4a) withstands several hours' heating at 250 °C without change and thus presumably exists in the *anti*-conformation shown. The *syn*-isomer should, by analogy to results of *Reich* and *Cram*[8], be less stable and rearrange to *(4a)* at high temperatures.

Formation of the tetraester *(4a)* from *(1)* and *(2)* can be most simply explained as occurring through the intermediate quinodimethane derivative *(3)*. Such intermediates are formed in several other syntheses of [2.2]paracyclophanes[5, 9a, 9b] but from cyclic precursors. This is evidently the first case of formation of a quinodimethane from acyclic precursors by 1,4-cycloaddition.

Pure biallenyl is not necessary for preparation of *(4a)*: the C_6H_6 hydrocarbon mixture obtained by dimerization of propargyl bromide[10], which contains about 40% of *(1)*, can be treated directly with *(2)* since the other C_6H_6 isomers—mainly 1,2-hexadien-5-yne (propargylallene)—do not react with *(2)* under the conditions stated. Thus this

Total Synthesis of [α,γ-$^{14}C_2$]Uroporphyrin III

By *Burchard Franck, Dietrich Gantz,* and *Fritz Hüper*[*]

Uroporphyrin III *(6)* and its hexahydro derivative, uroporphyrinogen III *(4)*, have been discussed as biosynthetic precursors of the biologically important tetrapyrroles heme, chlorophyll, and vitamin B_{12}[1]. Specifically ^{14}C-labeled uroporphyrin III and uroporphyrinogen III have not previously been available for testing of these proposals by feeding experiments[2]. We report here a procedure for the total synthesis of [α,γ-$^{14}C_2$]uroporphyrin III as its octa-

A = —CH_2—CO—
Ps = —CH_2—CH_2—CO— *(6)*, A—OH, Ps—OH instead of A—OCH_3, Ps—OCH_3

methyl ester *(5)* which is stable and is the appropriate depot compound for feeding experiments. This compound readily yields uroporphyrinogen III by hydrolysis and reduction.

The α- and γ-methine groups were selected for specific ^{14}C-labeling. First, the radioactivity can then be introduced during the last stage of a *convergent synthesis*[4] which is superior to linear approaches in the number of steps and yield; and, secondly, the corresponding C atoms of important products biosynthesized from *(4)* can be selectively isolated for localization of radioactivity[5, 6].

The dipyrrylmethanes *(1)* and *(3)* were obtained by, respectively, 13- and 11-stage syntheses modelled on work by *MacDonald*[7] and by *Treibs*[8]. Only the Vilsmeier reaction with [^{14}CO]dimethylformamide/$POCl_3$ came into consideration for converting *(1)* into the radioactive dialdehyde *(2)* for subsequent acid-catalyzed ring closure to a porphyrin. In other syntheses of aldehydes the requisite large excess of radioactive formylating agent reduces the radioactive yield considerably. Even in the Vilsmeier reaction of *(1)* the radioactive dimethylformamide must be used in, admittedly smaller, excess (in contrast to the procedure usual in isotope labeling) in order to allow the dipyrrylmethane, which is valuable because of its tedious preparation, to react in optimal yield. This being done, the ^{14}C-labeled dialdehyde *(2)* is obtained from *(1)* in a weight yield of 92.5% and a radioactive yield of 17%. Condensation of the radioactive dialdehyde *(2)* with the dipyrrylmethane *(3)* in glacial acetic acid in presence of hydriodic acid, and subsequent oxidation by air and methylation by methanol/HCl, afforded radioactive crystalline uroporphyrin III octamethyl ester *(5)*, m. p. 258—261 °C (258 to 260 °C[7]) in 52% yield based on *(2)*.

[(^{14}CHO)^2]Dipyrrylmethanedicarbaldehyde (2)

[^{14}CO]Dimethylformamide[9] (140 mg, 1.9 mmol, 2.5 mCi) in anhydrous CH_2Cl_2 (0.2 ml) was treated successively, with ice-cooling, with $POCl_3$ (0.18 ml, 2.0 mmol), and dropwise with a solution of the dipyrrylmethane *(1)* (100 mg, 0.22 mmol) in anhydrous CH_2Cl_2 (1 ml) and $POCl_3$ (0.05 ml, 0.54 mmol). This reaction mixture was kept for 1 h at 20 °C, then warmed for 1 h at 50 °C whereupon the CH_2Cl_2 distilled off; the mixture was then cooled again to 0 °C, dissolved in ice-water (100 ml) and treated with sodium acetate until its reaction was weakly alkaline. After three days the precipitated product was filtered off, washed with water, and recrystallized from 60% ethanol, yielding the dialdehyde *(2)* (103 mg, 92.5%; 0.43 mCi, 17%).

[α,γ-$^{14}C_2$]Uroporphyrin III octamethyl ester (5)

A solution of *(2)* (99 mg, 0.19 mmol, 0.15 mCi) and *(3)* (77.6 mg, 0.19 mmol) in glacial acetic acid (120 ml) was treated with 56% HI (0.6 ml) in glacial acetic acid (28 ml)[7]. After 20 min sodium acetate (1.9 g) in glacial acetic acid (28 ml) was added to the deep red reaction mixture, air was bubbled through and after 24 h the dark brown precipitate was collected. This was dissolved in 5% methanolic HCl and kept for 24 h at 20 °C, ice-water was added, and the mixture was extracted with $CHCl_3$. The dried residue from the $CHCl_3$ extract was purified by layer chromatography ($CHCl_3$ + 1% of CH_3OH; silica gel, E. Merck) and recrystallization from $CHCl_3$/acetone, affording *(5)* (92.5 mg, 52%; 0.079 mCi).

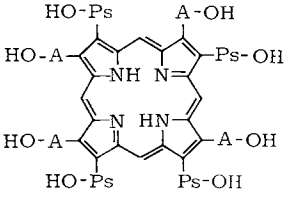
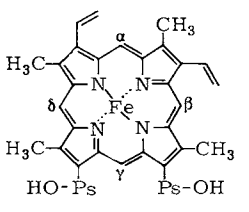
On the Biosynthesis of Heme and Vitamin B_{12} from [α,γ-$^{14}C_2$]Uroporphyrinogen III

By *Burchard Franck, Dietrich Gantz, Franz-Peter Montforts*, and *Franz Schmidtchen*[*]

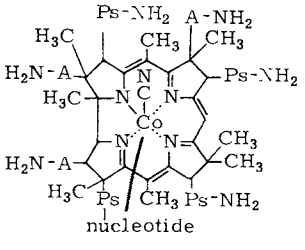


According to mechanistic considerations[1] and some experimental findings[2], uroporphyrinogen III *(3)* and its dehydrogenation product, uroporphyrin III *(4)*, come into consideration as biosynthetic precursors of the biologically important tetrapyrroles heme *(6)* and vitamin B_{12} *(8)*. Uroporphyrinogen III itself arises from eight molecules of 5-aminolevulic acid *(1)* by way of the monopyrrole, porphobilinogen *(2)*[3]. The biosynthesis of heme *(6)* and vitamin B_{12} *(8)* is substantially confirmed up to the porphobilinogen *(2)* stage by isotope experiments.

(1) *(2)*



(3)



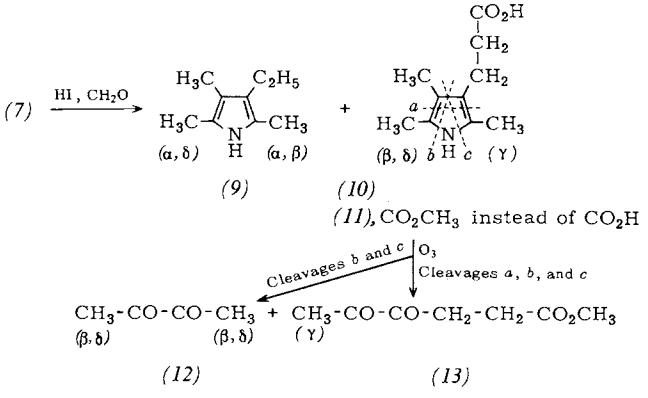
(4)

(5), OCH_3 instead of OH

(6)

(7), Fe instead of Fe(Cl)

(8)



A = $-CH_2-CO-$

Ps = $-CH_2-CH_2-CO-$

There has not hitherto been any proof, by feeding experiments with radioactively labeled precursors, of the biosynthetic intermediates assumed for the conversion of porphobilinogen *(2)* into the above tetrapyrroles *(6)* and *(8)*. By using specifically ^{14}C-labeled [α,γ-$^{14}C_2$]uroporphyrinogen III *(3)*, which has now become available[4], we have been able to show that this biosynthetic unit is converted with high incorporation and without isomerization into the blood pigment heme *(6)*, but not into vitamin B_{12} *(8)*.

Eight batches (each 20 ml) of duck's blood, hemolyzed by freeze-thawing[5], were incubated for 48 h at 32 °C with various amounts (0.22—1.19 mmol) of [α,γ-$^{14}C_2$]uroporphyrinogen III *(3)*[6] having a specific radioactivity amounting to 0.79 mCi/mmol. These batches were worked up separately. When freed quantitatively from porphyrins without metal atom and purified to constant radioactivity, the hemin *(7)* obtained had a mean radioactivity of 1.65 μCi/mmol, corresponding to 0.21% specific incorporation[7]. The absolute incorporations[8] lay between 33 and 61%.

A specific degradation was carried out to show that the ^{14}C radioactivity of the isolated hemin *(7)* resided only in the α- and γ-methine groups and that the biosynthesis of *(7)* from [α,γ-$^{14}C_2$]uroporphyrinogen III was thus direct and unaccompanied by isomerization[9]. Methylating fission of *(7)* by 67% hydriodic acid and paraformaldehyde in glacial acetic acid/H_3PO_2[10] afforded radioactive phyllopyrrole *(9)* and radioactive phyllopyrrolecarboxylic acid *(10)* which contained the α-, β-, and δ- or β-, γ-, and δ-methine-C atoms, respectively, in their α-methyl groups as indicated in the formula. Ozonolysis of the methyl phyllopyrrolecarboxylate *(11)* in $CHCl_3$, which occurs with participation of resonance structures[11] at *a*, *b*, and *c*, yielded inactive biacetyl *(12)*[12] and radioactive methyl 4,5-dioxohexanoate *(13)*[12] with the β- and δ-, or

γ-methine-C atoms, respectively, in the methyl groups. The relative amounts of labeled C atoms (see Table), calculated from the specific radioactivities found for the degradation products *(9)* and *(11)*—*(13)*, show that only the α- and γ-methine groups of heme were radioactive. The inactivity of the biacetyl *(12)*, which contains only the β- and δ-methine-C atoms, excludes labeling at these positions.

For investigation of vitamin B_{12} biosynthesis a 1-l liquid culture (cornsteep/glucose[14]) of *Propionibacterium shermanii* (ATCC 9617) was used which was kept anaerobically (N_2) for the first three days and then aerobically (100 ml of O_2 per min) for four days. To this were added, in two equal portions on the first and the second day, 4.29 μmol of [α,γ-$^{14}C_2$]uroporphyrinogen III of specific radioactivity 0.79 mCi/mmol. Later the vitamin B_{12} (6.6 mg) formed was determined microbiologically[15] and, after addition of inactive vitamin B_{12} and isolation the specific radioactivity was measured. For the undiluted vitamin this amounted to 0.017 μCi/mmol, corresponding to a specific incorporation of $<0.0025\%$, which is no longer significant[16].

[16] After conclusion of our feeding experiments *G. Müller* and *W. Dieterle*, Hoppe-Seylers Z. physiol. Chem. *352*, 143 (1971), announced that, using a biosynthetically obtained mixture of uniformly ^{14}C-labeled uroporphyinogens I and III and cell suspensions of *Propionibacterium shermanii*, they too observed no incorporation into the corrin ring of vitamin B_{12}.

X-Ray Structure Analysis of a Benzocyclopropene Derivative

By *Ernst Carstensen-Oeser*, *Berthold Müller*, and *Heinz Dürr*[*]

A benzene ring is appreciably deformed when annelated to a strained small ring. Previous NMR spectroscopic studies and calculations[1–3] for benzocyclopropene *(1)* indicated angular deformation of the kind shown in *(2)*[3] and changes in bond lengths in the six-membered ring that suggested a preference for the mesomeric limiting structure *(3)*[1,2].

(1) *(2)* *(3)* *(4)*

To determine these effects quantitatively we have carried out an X-ray structure analysis of a benzocyclopropene. Dimethyl 2,5-diphenylbenzocyclopropene-1,1-dicarboxylate *(4)*[4] is particularly suitable for this purpose: it crystallizes in well formed colorless needles of m. p. ≥ 175 °C.

The crystals are monoclinic, space group $P2_1/a$; $a=22.15\pm0.01$, $b=7.91\pm0.01$, $c=10.92\pm0.01$, $\beta=99.2\pm0.1°$; $Z=4$. The intensities of 3542 reflections were measured on an automatic diffractometer. We determined the sign of 297 reflections with the largest E values by triple product methods[5].

The structural model obtained by E-Fourier synthesis was refined to an R value of 7.7%.

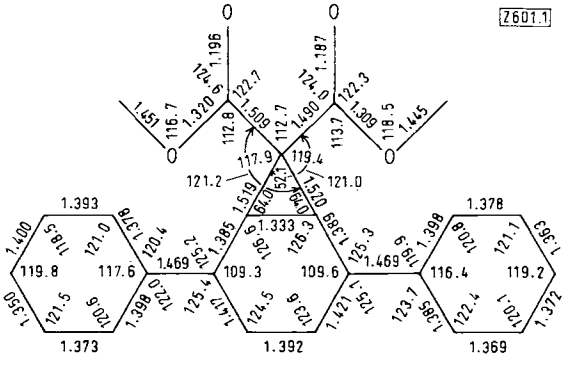

Fig. 1. Bond lengths and angles of *(4)*. The maximal values of all standard deviations amounted to 0.008 Å or 0.5°.

The result of the investigations (Fig. 1) confirmed the angular deformation shown in *(2)*. These changes in bond lengths and angles caused by the annelated strained ring must be viewed in comparison with those in *p*-terphenyl, for which a very accurate X-ray structure analysis has been carried out[6]. The bond lengths give *no* evidence for the Kekulé structure *(3)*. The unsaturated three-membered

ring has the same interatomic distances as in cyclopropene[7].

The benzocyclopropene system is not quite planar; the three-membered and the six-membered ring form an angle of $1.5 \pm 0.5°$. The planes of the two phenyl substituents in the crystal are twisted by 3.1° and 8.2° from the plane of the benzene ring in the benzocyclopropene system.

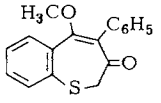
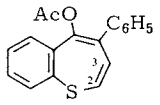
Synthesis of Stable 1-Benzothiepins[1]



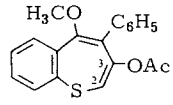
By *Hans Hofmann, Bernd Meyer*, and *Peter Hofmann*[*]

Stable 3-benzothiepins have been known for some time[4]. Attempts to prepare similar stable 1-benzothiepins have so far been successful only in one case [compound *(6)*][5]; in all other experiments only products of further reaction were isolated[6]. This is difficult to explain when it is remembered that 1-benzoxepin and 3-benzoxepin, for instance, are about equally stable and have approximately the same resonance energy[7]. We have therefore worked out methods of preparing 1-benzothiepins and have carried out an HMO analysis of the ring system.

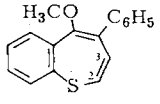
In the 1-benzoxepin series the synthetic route through the enol derivatives of seven-membered ring 1,3-diketones permits use of extremely mild reaction conditions[5, 8]. Analogously, we have prepared the substituted 4-phenyl-1-benzothiepins *(3)*—*(5)* from the ketones *(1)*[8] and *(2)*[9].



(1)



(2)



Acetylation of *(1)* with acetic anhydride in triethylamine in presence of 4-dimethylaminopyridine[10] at −15 °C afforded 5-acetoxy-4-phenyl-1-benzothiepin *(3)*. Analogous acetylation of *(2)* gave 3-acetoxy-5-methoxy-4-phenyl-1-benzothiepin *(4)*. Methylation of *(1)* with dimethyl sulfate and potassium *tert*-butoxide in tetrahydrofuran at 0 °C, followed by chromatography of a benzene solution on silica gel and rubbing with a little methanol, led to 5-methoxy-4-phenyl-1-benzothiepin *(5)*[11] (see Table).

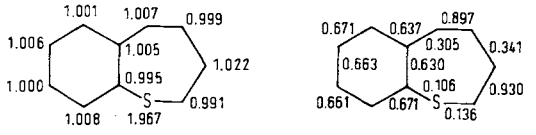
In the UV spectra the striking feature is the characteristic extensions of the long-wave absorption maxima which, as for the corresponding 1-benzoxepins, extend into the visible region[1]. The chemical shifts of H-2 and H-3 accord very well with the values calculated from the shielding constants[12]. In the ^{1}H-NMR spectra of analogous 1-benzoxepins H-3 appears upfield from H-2! This is in agreement with the calculated π-electron densities, which in 1-benzothiepins are larger in position 2 but smaller in position 3 than for 1-benzoxepins.

The starting point for our HMO calculations was the following finding: our HMO calculation[14] carried out on a non-planar model of 1-benzoxepin and the SCF—MO data published by *Dewar et al.*[7] gave results in good agreement for the bonding and the π-electron densities. Also, the values given by *Dewar et al.*[15] for 3-benzothiepin accord acceptably with the result of our calculation for a non-planar model of 3-benzothiepin. We have therefore carried out a HMO calculation on the same basis for 1-benzothiepin. We assumed a flat boat as the favored conformation of the hetero ring[16]; the following torsion angles φ between the p_z orbitals of the centers of the model[18] can then be estimated from a Dreiding model[17]:



[*] Prof. Dr. H. Hofmann, Dipl.-Chem. B. Meyer [2], and Dipl.-Chem. P. Hofmann [3]
Institut für Organische Chemie der
Universität Erlangen-Nürnberg
852 Erlangen, Henkestrasse 42 (Germany)

bonds 1-2 and 1-11, $\varphi = 60°$; bonds 3-4 and 5-6, $\varphi = 45°$. In the calculations for these bonds the angle-corrected β values were taken from the relation[19]

$$\beta_{ik}(\varphi_{ik}) = \cos\varphi_{ik}\beta_{ik}(\varphi = 0)$$

The parameters for the hetero atom, h_{-S-} (0.5) and k_{C-S} (0.43), are taken from data of *Häfelinger*[20]; only 3p participation is assumed for sulfur. In this way we obtained the results shown in Fig. 1:

Z602.1

Fig. 1. π-Electron densities (left) and π-bond orders for 1-benzothiepin.

The total π-electron energy amounts to $12\alpha + 13.514\beta$, with ΔE between HOMO and LUMO (Highest Occupied; Lowest Unoccupied MO) $= 0.987\beta$[21].

1-Benzothiepin therefore contains an almost unperturbed benzene portion with approximately equal π-bond orders, and a heterocyclic seven-membered ring with localized, slightly conjugated double bonds, definite single bonds and a lone pair located almost exclusively on the sulfur. The lengths of the two C—S bonds amount to 1.742 and 1.763 Å[22]. Thus the C—S single bonds are as long as usual; together with the low π-electron energy and the irreversible elimination of sulfur, they cause the appreciably lower thermal stability of 1-benzothiepins compared to analogous 1-benzoxepins. The 1-benzothiepins prepared so far appear not to differ significantly in stability from the 3-benzothiepins.

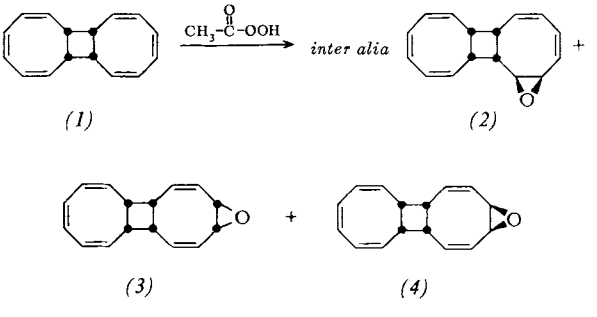
Oxa[17]annulenes[1][**]

By *Gerhard Schröder*, *Günter Plinke* and *Jean F. M. Oth*[*]

Dedicated to Professor R. Criegee on the occasion of his 70th birthday



If we replace a —CH=CH— group in an annulene by a hetero atom with a lone pair we arrive at a heteroannulene[2]. Viewed thus, furan and pyrrole are, respectively, oxa- and aza-[5]annulenes, and oxonines[3] and azonines[4] are, respectively, oxa- and aza-[9]annulenes.

Oxa[17]annulenes are isoelectronic with aromatic [18]-annulenes[5]. Two questions interested us particularly about these higher-membered heteroannulenes, namely:

1. What is their π-electron structure?

2. Can configurational isomers be isolated or does a rapid mutual interconversion of configurational isomers occur such as has been observed with many higher-membered carbocyclic annulenes[6]?

Dimeric cyclooctatetraene *(1)* of m. p. 53 °C[7] is a suitable starting material for preparation of oxa[17]annulenes. On epoxidation of *(1)* in chloroform by peracetic acid at 30 °C there are formed, besides bisepoxides, an asymmetric epoxide *(2)* and two symmetrical epoxides *(3)* and *(4)*. Separation and purification of *(2)*—*(4)* is accomplished by column chromatography (SiO_2; pentane/ether 30:1) (see Table 1).

The position of the epoxide ring relative to the cyclobutyl protons in *(2)*—*(4)* was determined from the paramagnetic shift of individual proton resonance signals as observed

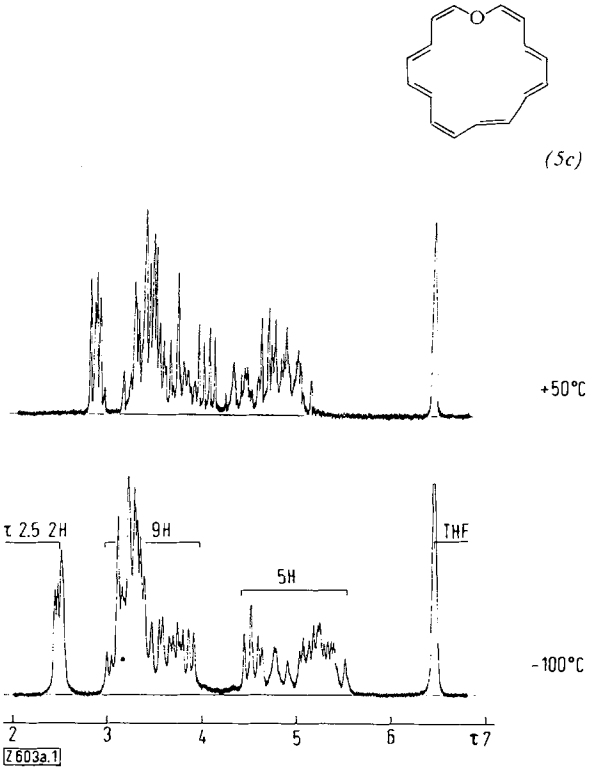
Table 1. Data for compounds *(2)*—*(4)*.

Cpd. [9]	Yield (%) [a]	M.p.(°C)	^{1}H-NMR, τ in ppm [b]	UV, λ in nm (ε) [c]
(2)	≈45	43–44	4.25 (10 H/m) 6.6 (5 H/m) 7.75 (1 H/m)	λ_{sh}224 (7050) λ_{sh}250 (2050)
(3)	≈3	88	4.3 (10 H/sharp m) 6.6 (6 H/sharp m)	λ_{sh}249 (1800)
(4)	≈1	86–89	4.5 (10 H/m) 6.5 (2 H/m) 7.0 (4 H/m)	λ_{max}250 (1600)

[a] Referred to the amount of *(1)* used.
[b] 60-MHz spectrum, in CCl_4, with TMS as internal standard.
[c] In ether.

in the presence of tris(tetramethylheptanedionato)europium[8].



Photolysis of the epoxides *(2)*—*(4)* by a low-pressure UV lamp at −80°C in ether opened a route to the oxa[17]-annulenes *(5a)*—*(5c)*. These three products differ only in the sequence and individual number of *cis*- and *trans*-

double bonds. On catalytic hydrogenation they give the same colorless crystalline monocyclic ether *(6)* (see Table 2).

(5a) is formed almost exclusively from *(2)*, and practically pure *(5c)* from *(4)*. *(3)* affords, besides a little *(5c)*, a mixture that is inseparable by column chromatography and recrystallization and whose NMR spectrum contains all the signals of *(5a)* plus absorption bands that we ascribe to *(5b)*. *(5a)*, *(5a)*/*(5b)*, and *(5c)* are crystalline red compounds that can be purified by column chromatography (SiO_2; pentane/ether 30:1) and recrystallization; they are thermally stable (unchanged when warmed at 60°C) but very sensitive to oxygen.

The NMR spectra of *(5a)*, *(5a)*/*(5b)*, and *(5c)* are very complicated. They are slightly temperature-dependent, which mirrors a certain amount of conformational mobility in the ring. We find no convincing evidence for marked π-electron delocalization in the NMR spectra[10]. The available spectroscopic data do not permit any firm statement about the configurations of the oxa[17]annulenes. Provisionally we suggest the *cis,trans,trans,trans,cis,trans,-cis*-configuration for *(5c)*.

We return now to our original questions:

1. The oxa[17]annulenes with $(4n+2)$ π-electrons are best described as polyolefins.

Table 2. Data for compounds *(5a)*, *(5c)*, and *(6)*.

Cpd. [9]	Yield	M.p.(°C)	^{1}H-NMR, τ in ppm	UV, λ in nm (ε) [c]
(5a)	≈33% from *(2)* ≈ 2% from *(4)*	162 (dec.)	2.5 (1 H/d; J = 12.5 Hz) 3.1–4.1 (10 H/m) 4.1–5.8 (5 H/m) [a]	λ_{max} 304 (34000) λ_{max} 403 (6500)
(5c)	≈ 1.5% from *(2)* ≈ 2% from *(3)* ≈40% from *(4)*	160 (dec.)	2.5 (2 H/two d; J = 6 and 7 Hz) 3.0–4.0 (9 H/m) 4.4–5.5 (5 H/m) [a]	λ_{max} 315 (58000) λ_{max} 407 (7100)
(6)	≈80% from *(5)*	20	6.7 (4 H/pseudo-t; J = 5 Hz) 8.7 (28 H/m) [b]	—

[a] 100-MHz spectrum, in CS_2/[D_8]-THF, at −100°C, with TMS as internal standard.
[b] 60-MHz spectrum in CCl_4, at 40°C, with TMS as internal standard.
[c] In ether.

2. In contrast to higher-membered carbocyclic annulenes[6], configurational isomers can be isolated that are not thermally interconvertible. At +10°C light from a low-pressure UV lamp isomerizes *(5a)*, partially to *(5c)*, but *(5c)* is almost unaltered by irradiation at −80 to +10°C.

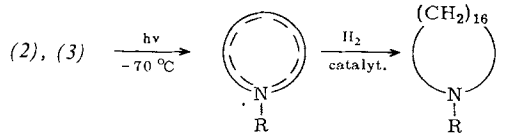
Aza[17]annulenes[1,2][**]

By *Gerhard Schröder, Günter Heil, Herbert Röttele*, and *Jean F. M. Oth*[*]

Dedicated to Professor R. Criegee on the occasion of his 70th birthday.

Aza[17]annulenes are of interest for the same reasons as are oxa[17]annulenes[1].



In analogy to epoxidation[1], the reaction of *(1)* in CH_2Cl_2 at 20 °C with *N*-(ethoxycarbonyl)nitrene [from *N*-(*p*-nitrobenzenesulfonyloxy)urethane and triethylamine[3]] gives an asymmetric adduct *(2)* and two symmetrical

According to their NMR spectra, *(2)* is an asymmetrical molecule, but *(3)* and *(4)* are symmetrical molecules. The steric orientation of the aziridine ring in *(2)* follows from comparison of the NMR spectrum with that of the analogous epoxide[1]. The aziridine ring in *(3)* can only be in the *anti*-position with respect to the cyclobutyl protons because with the *syn*-arrangement [*(4a)*] a Cope rearrangement (in the sense of the arrows shown) would set in, leading to *(4)*. This is the only way in which we can interpret the formation of *(4)*. This rearrangement has a precursor: the adduct of cyclooctatetraene and *N*-(ethoxycarbonyl)nitrene isomerizes when warmed, in which process a Cope rearrangement leads to ethyl 4-azabicyclo[5.2.0]nona-2,5,8-triene-4-carboxylate[4]. The doublet at τ = 3.15 and the pseudodoublet at τ = 5.20 in the NMR spectrum of *(4)* are particularly striking; they correspond in shape and chemical shift to the signals ascribed to the protons in α- and β-positions relative to the nitrogen in ethyl 4-azabicyclo[5.2.0]nonatriene-4-carboxylate[4].

[**] This work was supported by the Badische Anilin- & Soda-Fabrik AG and the Deutsche Forschungsgemeinschaft.

On photolysis of the aziridines *(2)* and *(3)* in ether at −70 °C, using a low-pressure UV lamp, there are formed the aza[17]annulenes *(5a)*—*(5c)*. Under the same conditions the compound *(4)* yields extremely unstable products that we have been unable to isolate and identify.

R = $C(=O)-O-C_2H_5$ *(5a), (5b), (5c)* *(6)*

(5a), *(5b)*, and *(5c)* differ only in the sequence and individual number of *cis*- and *trans*-double bonds. On their catalytic hydrogenation the same liquid monocyclic urethane *(6)* is obtained (see Table 2).

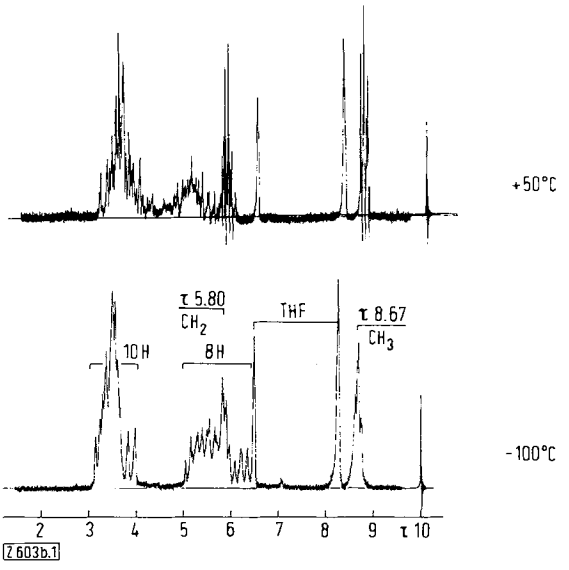

Table 2. Data for compounds *(5a)/(5b)*, *(5c)*, and *(6)*.

Cpd. [5]	Yield	M.p. (°C)	^{1}H-NMR, τ in ppm	UV, λ in nm (ε)

[c] 60-MHz spectrum, in CCl_4, at 40 °C, with TMS as internal standard.
[d] In cyclohexane.
[e] In ether.

(5a)—*(5c)* can be separated from other reaction products by column chromatography (SiO_2; pentane/ether 30:1) and recrystallization (from pentane/ether 1:1). Photolysis of *(2)* at −70 °C and subsequent column chromatography and recrystallization give an inseparable mixture of two aza[17]annulenes *(5a)* and *(5b)*; the aza[17]-annulene *(5c)* is obtained from *(3)*. Preliminary investigations show that irradiation of *(2)* at −100 °C affords almost pure *(5a)*. An NMR spectroscopic comparison of samples obtained by photolysis of *(2)* at −70 and −100 °C show that *ca.* 20% of *(5b)* accompanies the *(5a)* in the sample obtained at −70 °C. *(5a)/(5b)* and *(5c)* are crystalline, red, thermally stable up to at least 80 °C and extremely sensitive to air.

The NMR spectra of *(5a)/(5b)* and *(5c)*, like those of the oxa[17]annulenes[1], are very complicated. Temperature-dependence of the signals is only feeble. There is no definite indication of π-electron delocalization[6]. We do not feel able to make definite statements about the configurations of the aza[17]annulenes on the basis of the spectroscopic data.

Like the oxa[17]annulenes[1], the aza[17]annulenes *(5a)/(5b)* and *(5c)* are best described as polyolefins. Here again configurational isomers can be isolated that are not interconvertible thermally.

A study of the aza[13]annulenes that have meanwhile been synthesized[7] will undoubtedly contribute to a better understanding of questions raised here.

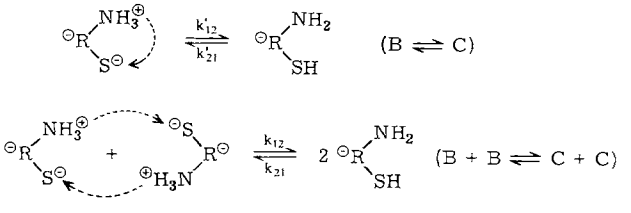
Studies of Intramolecular Proton Transfer to Cysteine and Related Compounds by Relaxation Kinetics[**]

By *Günter Maass* and *Frens Peters*[*]



The dissociative behavior of amino acids such as cysteine and related compounds containing more than two proton donor-acceptor functions has been repeatedly investigated[1-3]. Whereas the carboxyl-proton is removed in acid solution, the amino- and thiol-protons of cysteine are liberated in about the same weakly basic media. It is, however, not possible, without further assumptions, to assign the potentiometrically determined pK values pK_{II} and pK_{III} to individual "microscopic" pK values of the two groups[1] that are linked by the relations $K_{II}=K_1+K_2$ and $1/K_{III}=1/K_3+1/K_4$.

For the dissociative behavior of cysteine and analogous di- and poly-basic acids a simple reaction scheme is usually given[4] according to which the protonated species A passes into the deprotonated form D with loss of two protons by way of B or C. We have found that this scheme must be supplemented by a direct proton transfer between B and C, whose equilibrium constant is related to the other micro-

scopic constants by $K_5=K_1/K_2=K_4/K_3$. This proton transfer can be demonstrated directly by investigation of the chemical relaxation by means of ultrasound absorption measurements[5, 6]. Similar proton transfer reactions are known for cysteamine $HS(CH_2)_2NH_2$.

The proton exchange between the two functional groups may occur intra- or inter-molecularly:

The pH values were so chosen that the concentrations of forms B and C were maximal and those of forms A and D were low. Under these conditions the reciprocal of the relaxation time for the two parallel reactions:

$$1/\tau = 2(k_{12}\gamma_B + k_{21}\gamma_C)c_0 + (k'_{12} + k'_{21})$$

($\bar{c}_B=\gamma_B c_0$, $\bar{c}_C=\gamma_C c_0$: equilibrium concentrations of B and C, respectively) gives a straight line when plotted against the initial concentration c_0 (Fig. 1).

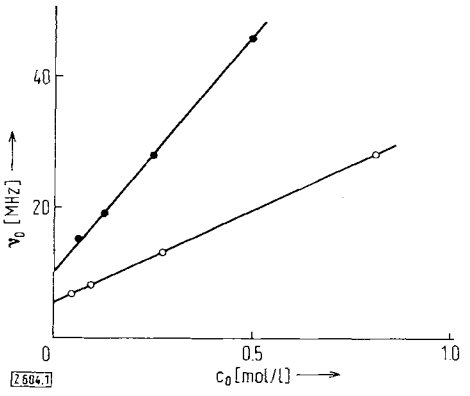


Fig. 1. Dependence of the relaxation frequencies on concentration. ● = Glutathione (pH = 9.05); ○ = cysteamine (pH = 9.7).

Thence, by extrapolation to low concentrations the time constants for the intramolecular proton transfer can be calculated. For cysteamine one thus obtains $1/\tau'=k'_{12}+k'_{21}=3.0\times10^7\ s^{-1}$ and for glutathione $1/\tau'=6.2\times10^7\ s^{-1}$. If the intramolecular proton exchange is fast compared with the intermolecular process the first terms can be neglected and the reciprocal relaxation time becomes independent of concentration; this condition is fulfilled for cysteine.

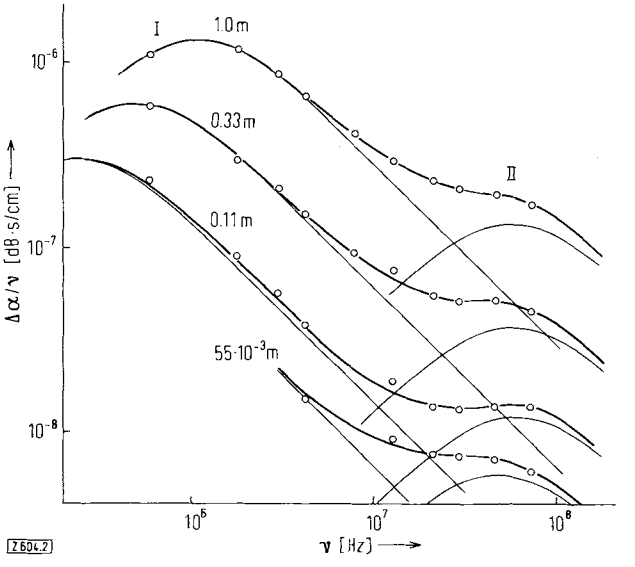

Fig. 2. Sound absorption spectra of aqueous cysteine solutions at pH = 9.5.

The sound absorption spectrum (Fig. 2) shows a rapid contribution, independent of concentration (effect II), and a second one (effect I) that is slower by an order of magnitude and can be ascribed to the intermolecular reactions. In this case, because of the markedly differing time constants, the two effects can be treated as uncoupled. For cysteine the sum of the velocity constants for intramolecular proton exchange between the thiol and the amino group has the value $1/\tau'=3.6\times10^8\ s^{-1}$.

Direct calculation of the individual velocity constants k'_{12} and k'_{21}, and thus the microscopic pK values, from the

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 75).

relaxation measurements requires a knowledge of the equilibrium constants K_5. However, the microscopic constants can be determined by combination of potentiometric and spectrophotometric titrations[1] only under the limiting assumption that the absorption by the deprotonated thiol group is independent of the prevailing degree of protonation of the amino group. This assumption can be tested by kinetic methods if the reaction volume $\Delta V(=V_B-V_C)$ is known and provided that it can be decided upon which side the equilibrium lies. It is then possible to determine $K_5=\bar{c}_B/\bar{c}_C=\gamma/(1-\gamma)$ unambiguously by measuring the maximal sound absorption amplitude $(\Delta\alpha/\nu)_{max}=\text{const.}\gamma(1-\gamma)\Delta V^2$.

However, it can be shown that for the systems studied, the intramolecular proton exchange between neighboring groups is faster by two or three orders of magnitude than the protolysis (or hydrolysis) reactions[7] (see Table):

$$B + H^+ \rightleftharpoons A \rightleftharpoons C + H^+$$
or $B \rightleftharpoons D + H^+ \rightleftharpoons C$ [7]

Table. Relaxation times for the intramolecular proton transfers.

Compound	τ [s]
Cysteine	2.8×10^{-9}
Homocysteine	4.4×10^{-8}
Penicillamine	4.9×10^{-8}
Glutathione	1.6×10^{-8}
Cysteamine	3.3×10^{-8}

This means that the direct proton exchange between the two functional groups with interchange of hydrogen bonds can occur appreciably more easily than the corresponding reactions of the free protons or hydroxide ions.

These results are of particular interest for enzyme reactions in which mutually reacting groups are brought into close contact by rapid structural interchanges (10^{-7} s). They show that the individual steps of intramolecular proton transfer are as fast as, or faster than, the structural changes.

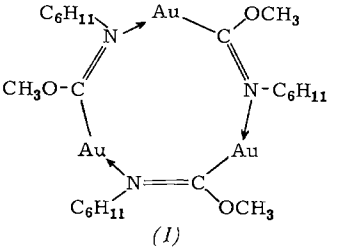
Trimeric 1-(Cyclohexylimino)methoxymethylgold(I), A New Type of Organometallic Compound

By *Giovanni Minghetti* and *Flavio Bonati*[*]



No organometallic compound corresponding to the general formula $[R-N=C(OR')-]_nM$ has hitherto been known.

[*] Dr. G. Minghetti and Prof. Dr. F. Bonati
Istituto di Chimica Generale dell'Università
I-20133 Milano, via Venezian 21 (Italy)

Such a compound ($R=C_6H_{11}$; $R'=CH_3$, $M=Au$, $n=1$) is formed (as trimer) when methanolic potassium hydroxide solution (157 mg/18.9 ml) and then, with stirring, cyclohexyl isocyanide (305 mg) are added to a suspension of chloro(triphenylphosphane)gold(I) in methanol. After 0.5 h the suspension is concentrated to half volume in a water-pump vacuum. The white precipitate is recrystallized from chloroform/methanol (m.p. $\approx$190 °C with gradual decomposition and violet coloration above 160 °C).

The ^{1}H-NMR spectrum, in $CDCl_3$, measured from $\tau=-10$ to $+30$ ppm, contains only signals that can be assigned to the cyclohexyl ($\tau=5.7$ and 8.3 ppm) and the methoxyl group ($\tau=5.99$ ppm). No N—H, O—H, or $-\overset{\oplus}{N}\equiv\overset{\ominus}{C}-$ stretching vibration was observed in the IR spectrum, but only $-\overset{|}{C}=N-$ and $=\overset{|}{C}-OCH_3$ stretching vibrations at 1535 (vs, br.) and 1130 (s) cm^{-1}, respectively. The compound is non-conducting in methylene chloride. The molecular weight in chloroform amounted to 1031 and is independent of concentration (0.81 – 3.1 wt.-%).

These findings and the position of the $-\overset{|}{C}=N-$ stretching vibration indicate a formula of type *(1)*.

(1)

If aromatic isocyanides are used instead of cyclohexyl isocyanide, monomeric (not trimeric) ligand-stabilized compounds such as $[(C_6H_5)_3P]AuC(=N-C_6H_4-CH_3)OCH_3$ are formed[1].

Except for the unstable cyclopentadienylgold(I) and $[C_6H_5-C\equiv C-Au]_x$, the compound *(1)* described here is the only organogold(I) compound[2] that does not require stabilization by ligands such as phosphanes or isocyanides.

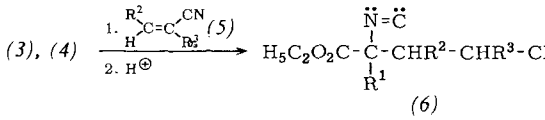
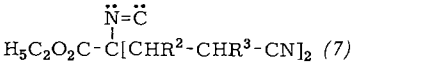
Ethyl γ-Cyano-α-isocyanoalkanoates from α-Metalated Ethyl Isocyano-acetates or -propionates and Acrylonitriles[1]

By *Ulrich Schöllkopf* and *Paul-Hermann Porsch*[*]



γ-Cyano-α-isocyanoalkanoic esters *(6)* deserve attention because they have several reactive centers and can react in many ways, *e.g.* by hydrolysis of the isocyano group to yield α-amino-γ-cyanoalkanoates. They are obtained by

[*] Prof. Dr. U. Schöllkopf and Dipl.-Chem. P.-H. Porsch
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)



cyanoethylating, for example, ethyl isocyanoacetate *(1)* ($R^1 = H$) or isocyanopropionate *(2)* ($R^1 = CH_3$) in ethanol with sodium ethoxide as catalyst at ≈30 °C. Essential intermediates are the α-metalated isocyanoalkanoic esters *(3)* or *(4)* which add to the double bond of acrylonitrile *(5)*. The adducts *(6)* result by protonation.

(6b)	H	C_6H_5	H	103/0.02	–	31 [b]
(6c)	CH_3	H	H	99/0.15	–	43 [c]
(6d)	CH_3	CH_3	H	100/0.15	–	53 [c]
(6e)	CH_3	C_6H_5	H	–	110 [f]	31 [c]
(6f)	CH_3	H	CH_3	94/0.05	–	86 [c]
(7a)		H	H	175/0.1	44–46 [g]	55 [b]
(7b)		H	CH_3	–	50–52 [h]	50 [b]
(7c)		CH_3	H	173/0.1	–	41 [b] [e]

[a] Molar ratio, *(1)* or *(2)*:*(5)* = 2:1.
[b] Molar ratio, *(1)* or *(2)*:*(5)* = 1:2.
[c] Molar ratio, *(1)* or *(2)*:*(5)* = 1:1.
[d] Amount of bis adduct = about 30% of the weight of monoadduct.
[e] Amount of monoadduct = about 30% of the weight of bis adduct.
[f] From cyclohexane.
[g] From ethanol/cyclohexane.
[h] From ethanol/water.

Bis adducts of type *(7)* can be formed from isocyanoacetic esters *(1)* because the anions from compounds *(6)* can react further with acrylonitrile *(5)* when $R^1 = H$. In experiments to date, acrylonitrile *(5)* ($R^2 = R^3 = H$) and methacrylonitrile *(5)* ($R^2 = H$, $R^3 = CH_3$) afford only the bis adducts—even when an excess of isocyanoacetic ester is used—whereas, for example, crotononitrile and cinnamonitrile give monoadducts of type *(6)* as isolable products.

Compounds *(6)* and *(7)* can be hydrolyzed by 2N hydrochloric acid in ethanol to γ-cyano-α-(*N*-formylamino) esters *(8)* and *(9)*, respectively, the nitrile group remaining intact.

If the cyanoethylation of ethyl isocyanopropionate *(2)* ($R^1 = CH_3$) is carried out at 65 °C with an equimolar amount of sodium ethoxide, the 3-cyanopyrroline-5-carboxylic esters *(11)* or, if $R^3 = H$, *(12)* result; they are formed by way of the anions *(10)*.

(10) *(11)*

(12) *(13)*

The 1-pyrrolines *(11)* can be reduced to 3-cyanoproline ethyl esters (ethyl 4-cyanopyrrolidine-2-carboxylates) *(13)* by catalytic hydrogenation in ethanol over palladium on activated charcoal.

Ethyl γ-cyano-α-isocyano-β-methylbutyrate (6a)

A solution (1 ml) of sodium ethoxide (prepared from 5 g of sodium in 100 ml of anhydrous ethanol) was added to one of ethyl isocyanoacetate[2] (11.3 g, 0.1 mol) in anhydrous ethanol (30 ml). Then a solution of crotononitrile (3.35 g, 50 mmol) in anhydrous ethanol (15 ml) was added dropwise over 30 min, the temperature not rising above 30 °C. The mixture was kept at room temperature for 15 h, then neutralized with glacial acetic acid, and the solvent was removed in a vacuum (bath-temperature max. 80 °C). The residue was dissolved in methylene chloride (50 ml) and washed three times with water (20 ml portions), and the organic phase was dried with sodium sulfate and evaporated. This residue afforded 50% (4.5 g) of a 1:1 diastereoisomeric mixture *(6a)*. IR spectrum (film): 2250 (ν_{CN}), 2140 ($\nu_{N=C}$), 1750 cm^{-1} (ν_{CO}); NMR spectrum ($CDCl_3$): τ = 5.46 (d, $J_{\alpha,\beta} \approx 4$ Hz), 5.60 (d, $J_{\alpha,\beta} \approx 4$ Hz), 8.58 (d, $J \approx 7$ Hz), 7.43 ppm (m). The distillation residue contained *ca.* 1.5 g of the bis adduct *(7c)*.

4-Ethoxycarbonyl-4-isocyano-3,5-dimethylheptanedinitrile (7c):

A mixture of crotononitrile (13.4 g, 0.2 mol) and ethyl isocyanoacetate (11.3 g, 0.1 mol) in anhydrous ethanol (30 ml) is added to a mixture of anhydrous ethanol (30 ml) and sodium ethoxide solution (2 ml; from 5 g of sodium and 100 ml anhydrous ethanol) during *ca.* 30 min at such a rate that the temperature does not exceed 30 °C. Working up is as described above. Fractional distillation of the crude product afforded 3 g of monoadduct *(6a)* and 10 g (41%) of *(7c)*. IR spectrum (film): 2260 (ν_{CN}), 2140 (ν_{NC}), 1740 cm^{-1} (ν_{CO}); NMR spectrum ($CDCl_3$): τ = 8.60 (m), 7.52 (m), 5.64 (q), 8.73 ppm (m).

4-Ethoxycarbonyl-4-formylamino-3,5-dimethylheptanedinitrile (9), $R^2 = CH_3$, $R^3 = H$

A mixture of *(7c)* (3.5 g), concentrated hydrochloric acid (1 ml), and 96% ethanol (15 ml) was stirred at room temperature until (2.5 h) the isocyanide band was no longer present in the IR spectrum, neutralized with 10% potassium hydroxide solution, and worked up as usual, affording 3 g of *(9)*, $R^2 = CH_3$, $R^3 = H$, as a colorless oil. IR spectrum (film): 3360 (ν_{NH}), 2250 (ν_{CN}), 1730 (ν_{CO}), 1680 ($\nu_{amide\ I}$), 1520 cm^{-1} ($\nu_{amide\ II}$).

Ethyl 3-cyano-4,5-dimethyl-2-pyrroline-5-carboxylate (12), $R^2 = CH_3$

A solution of ethyl isocyanopropionate[2] (6.35 g, 50 mmol) and crotononitrile (3.35 g, 50 mmol) in anhydrous ethanol

(15 ml) was added with stirring and cooling (water-bath) to a solution of sodium (1.15 g, 50 mmol) in anhydrous ethanol (40 ml); the mixture was stirred at 65 °C until the isocyanide band was no longer present in the IR spectrum (1.5—2 h), and was then neutralized with glacial acetic acid. Working up as described above afforded 54% (5.2 g) of *(12)*, $R^2=CH_3$, b. p. 106 °C/0.1 torr. IR spectrum (film): 3370 (ν_{NH}), 3095 ($\nu_{H-C=C}$), 2190 (ν_{CN}), 1730 (ν_{CO}), 1600 cm^{-1} ($\nu_{C=C}$); NMR spectrum (CCl_4): $\tau=3.08$ (d, $J_{2,4}=3$ Hz), 4.47 (s), 5.82 (q), 6.9 (m), 8.7 ppm (m).

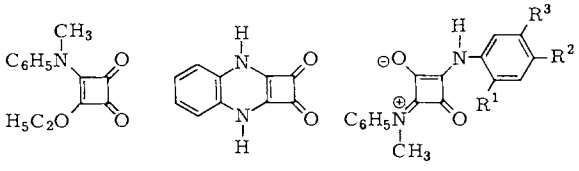
New Routes to Squaric 1,3-Diamides

By *Siegfried Hünig* and *Hermann Pütter*[*]

Squaric acid *(2a)* reacts with amines, when heated in alcohols or DMF, to give 1,3-diamides *(3)*[1], but 1,2-diamides *(1)*[2] are formed from squaric esters, *e.g. (2b)*. This rule is broken by feebly reactive amines. Only the 1,3-diamide *(3)* ($R^1=o$-$NO_2C_6H_4$, $R^2=H$)[1] can be isolated (65%) from *o*-nitroaniline and *(2b)* (4.5 h, 180 °C)[3].



(1) *(2a)*, R = H; *(2b)*, R = C_2H_5 *(3)* *(4)* *(5)*

The isomer of type *(1)* results, however, from *o*-nitroaniline and the dichloride *(4)* (40 min, 150 °C, 54%). The isomeric amides differ characteristically in their IR spectra[1,2].

Mainly the ester amide *(6)* is formed from *(2b)* and *N*-methylaniline (1:2) in ethanol (3 h, reflux). However, *(3)* ($R^1=C_6H_5$, $R^2=Me$) is formed in *n*-butanol (3 h, reflux, 56%); even in absence of solvent (1 h, reflux, 1:13) 70% of *(3)* is obtained. This indicates a direct reaction *(2b)* → *(3)* since the rearrangement *(1)* → *(3)* occurs only under catalysis by protons[1b,3]. The isomeric 1,2-diamide *(1)* ($R^1=C_6H_5$, $R^2=CH_3$) is conveniently obtained by alkylation of *(1)* ($R^1=C_6H_5$, $R^2=H$)[2a] by methyl iodide and K *tert*-butoxide in DMF (1 h, 20 °C, 43%).

Considerable importance attaches to the finding that when the 1,3-diamides *(3)* are heated with an excess of an amine R^3R^4NH for 3—20 min with or without a solvent at 150—200 °C the amino groups are exchanged, giving *(5)*. The reaction is smooth if the entering amine is more strongly basic (nucleophilic) than the leaving amine. This method is an advantageous extension of the usual method of heating a squaric acid salt with the amine[1] and makes aliphatic 1,3-diamides, *e.g. (5d)* and *(5f)*, accessible without the difficulties previously described for the case of *(5d)*[1e] (Table 1).

(6) *(7)*

	(8a)	*(8b)*	*(8c)*
R^1	NO_2	H	Cl
R^2	H	NO_2	H
R^3	H	H	Cl

The amide *(5c)* which is important as starting material for a squaric amidine[5] can only be prepared in this way; *o*-phenylenediamine closes the ring with either *(2a)* or *(2b)*, yielding the 1,2-diamide *(7)*. The compound hitherto described as *(5)*[6a] has another structure[1e,6b]. We have confirmed also that it is impossible to reduce the nitro group of *(3)* ($R^1=o$-$NO_2C_6H_4$, $R^2=H$) to an amino group[1e].

The reduced reactivity of *N*-methylaniline is evident here too: even if the leaving amine of *(3)* is favorable, only one

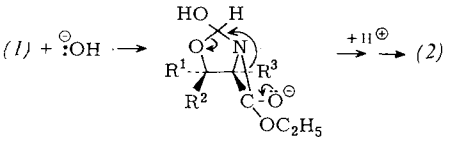
Ethyl α-Formylamino-β-hydroxy-acid Esters (β-Substituted *N*-Formylserine Esters) from Ethyl 2-Oxazoline-4-carboxylates[1]

By *Dieter Hoppe* and *Ulrich Schöllkopf*[*]

Ethyl 2-oxazoline-4-carboxylates *(1)* are obtained conveniently and in good yields from ethyl isocyanoalkanoates and carbonyl compounds in weakly basic alcoholic media[2]. Their conversion into ethyl α-formylamino-β-hydroxy-acid esters *(2)* can be accomplished almost quantitatively by warming 1 mol of *(1)* with 2—3 mol of water and 0.03 mol of triethylamine (if necessary, with addition of a little ethanol).

Alkaline hydrolysis is unusual for 2-oxazolines[3]; it can be achieved with the compounds *(1)* under relatively mild conditions, probably because the negative charge arising on the nitrogen atom when a hydroxide ion attacks C-2 is taken over by the carbonyl group at position 4 in the neighboring group effect.



(1) *(2)*

(2)	R^1	R^2	R^3	Hydrolysis (h) [a]	Yield (%) [b]
(a)	H	H	H	0.1	90 [c]

[*] Dr. D. Hoppe and Prof. Dr. U. Schöllkopf
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

The plane in which the ethoxycarbonyl group lies must therefore be perpendicular to that of the five-membered ring, and this is hindered particularly by *cis*-substituents on the ring. This consideration explains satisfactorily the various times required for the hydrolyses (cf. Table).

Water-soluble α-formylamino-β-hydroxy-acid esters *(2)* are isolated by removing the excess of water in a vacuum and distilling the residue or taking it up in carbon tetrachloride or ether and awaiting crystallization; sparingly soluble esters *(2)* are precipitated by water. These esters can be converted into α-amino-β-hydroxy acids (β-substituted serines) by heating them with 5N hydrochloric acid.

N-Formylthreonine ethyl ester (2b)

Ethyl *trans*-5-methyl-2-oxazoline-4-carboxylate[2] (5.4 g, 34 mmol), water (1.8 g), and triethylamine (0.1 g, 0.1 mmol) are heated for 30 min at 100 °C. The water is then distilled off at 1 torr and 80 °C (bath-temperature), ether (10 ml) is added, and the solution is left at 0 °C for crystallization. This yields *(2b)* (3.9 g, 68%), m.p. 74 °C (from 2:1 carbon tetrachloride/chloroform). NMR spectrum (in $CDCl_3$): $\tau = 5.4$ (m/C-2-H and C-3-H), 5.6 (—OH), 8.75 ppm (d/$J = 7$ Hz, $-CH_3$).

(2b) was converted by 5N HCl into threonine. *allo*-Threonine was not detectable either by IR spectroscopy or by thin-layer chromatography.

erythro- and threo-N-Formyl-2-methyl-3-phenylserine ethyl ester (2h)[4, 5]

Ethyl 4-methyl-5-phenyl-2-oxazoline-4-carboxylate[2] (*cis*:*trans* = 2.5:1) (4.7 g, 20 mmol), water (1.0 ml), ethanol (2.5 ml) and triethylamine (0.1 g) were heated under reflux for 6 h at 100 °C. The solvent was distilled off at 100 °C in a water-pump vacuum and the residue was chromatographed on silica gel (200 g; 0.05—0.2 mm; column diameter 3 cm) with ethyl acetate/chloroform (6:4). The fractions (each 20 ml) were investigated by thin-layer chromatography (silica gel F 1500 LS 254, Schleicher and Schüll; above solvent). Removing the solvent at water-pump vacuum from the fractions containing the faster migrating substance ($R_F = 0.26$) gave *erythro-(2h)* as a residual viscous oil (2.8 g, 56%) that slowly crystallized from ether/pentane (2:1) at −10 °C (m.p. 74 °C). NMR spectrum ($CDCl_3$): $\tau = 4.15$ and 4.85 (d/$J = 8.5$ Hz, —CHOH), 8.35 (s/$-CH_3$)[5], 5.77 and 8.72 ppm ($-OCH_2-CH_3$)[5].

Concentration of the fractions containing the slower migrating component ($R_F = 0.19$) and of the mixed fractions afforded an oil (1.5 g) that, when treated with ether (10 ml), yielded crystals of *threo-(2h)* (1.0 g, 20%), m.p. 105 °C. NMR spectrum ($CDCl_3$): $\tau = 5.0$ (—CHOH), 8.6[5] and 8.73 (s/$-CH_3$), 5.75 and 5.90[5], as well as 8.70 and 8.83[5] ($-OCH_2-CH_3$). Since the relative intensities

of the groups of signals change in CD_3OD we assume that the signal splitting is caused by competition between intra- and inter-molecular hydrogen-bridge formation.

A Squaric Diamidine and an Aza Analog of Biphenylene[**]

By *Siegfried Hünig* and *Hermann Pütter*[*]

The replacement of oxygen in squaric acid by nitrogen has hitherto been extended only to provide 1,2-[1] and 1,3-diamides[1]. We here describe the first squaric acid diamidine.

All previous attempts to introduce further amino groups into the 1,2-diamide *(2)*, *e.g.*, by *o*-phenylenediamine *(3)*,

[*] Prof. Dr. S. Hünig and Dipl.-Chem. H. Pütter
Institut für Organische Chemie der Universität
87 Würzburg, Landwehr (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie. DECHEMA, and the Badische Anilin- & Soda-Fabrik as well as by Chemische Werke Hüls who supplied squaric acid derivatives.

failed[3]. On the other hand, the 1,3-diamide[4] *(1)* has now been shown to be a useful starting material. When *(1)* is heated in polyphosphoric acid a dark green reaction mixture is formed from which a green (poly?)phosphate *(4a)* of indefinite composition is precipitated by water. Thence perchloric acid produces the extremely sparingly soluble green diperchlorate *(4b)*[5] (dec. from 295 °C; IR[6]: 3150, 1610, 1550, 1460, 1100, 1040, 780 cm^{-1}). *(4)* can be regarded as a highly stabilized cyclobutadienyl dication.

When stirred in DMF suspension in absence of air, *(4b)* changes without visible alteration into the equally very sparingly soluble diamidine *(5)*[5] (m. p. from 210 °C → *(6)*, 318 °C; [IR[6]: 3150—2800, 1610, 1580, 1510, 1460, 1420, 1230, 750 cm^{-1}]. Localization of the two H atoms in one hetero ring is unlikely since in our experience[3] structures of benzocyclobutadiene character[7] like *(7)* are avoided. The structure of the skeleton of *(4)* and *(5)* follows from the smooth oxidation to yellow quinoxalino[2',3':1,2]-cyclobuta[3,4-*b*]quinoxaline *(6)* [λ_{max} (CH_3CN) = 443 (61 700), 413 (24 200), 280 nm (50 000); m. p. 324 °C], which can be reduced back to *(5)*. Structure *(6)* is indicated by: a) the mass spectrum ($M^+ = 256$); b) an IR spectrum (1505, 1360, 1055, 760 cm^{-1}) containing few bands and no NH band but with an intense band at 760 cm^{-1} characteristic of *o*-disubstituted benzenes[8]; c) NMR signals only in the aromatic region where they are of AA'BB' type [(D_6-DMSO): $\delta = 7.86$, 8.06 ppm; $J_{AB} = 8.50$, $J_{AB'} = 1.50$, $J_{BB'} = 6.00$ Hz]. *(6)* can be described in the limiting formula *(6α)* as a cyclobutadiene annelated to two quinoxaline systems and is the first example[9] of a cyclobutadiene stabilized by incorporation into pyrazine rings.

Compound *(8)*[10] described a long time ago has a different structure[11]. Even very recent attempts to synthesize *(8)* have failed[12].

yield mainly the cyclic C_8H_{12}-hydrocarbons *(2)* and *(3)*[2]. Contrary to previous findings[3], *(1)*, which is completely stable up to 150 °C, was found to cyclodimerize between 200 and 250 °C to the two dispirooctanes *(3)* and *(4)*; higher oligomers are also formed.

Analogous cyclodimerizations were previously successful only with the substituted methylenecyclopropanes bicyclopropylidene[4] and (dichloromethylene)cyclopropane[5].

The efficiency of the dispirooctane synthesis depends greatly on the reaction conditions (cf. Table 1). The highest yields of *(3)*/*(4)* mixture so far obtained were 76% with 20% conversion after about 5 h at 230 °C.

(3) and *(4)* were identified by spectroscopy after separation by preparative gas chromatography. The main product is the previously unknown dispiro[2.0.2.2]octane *(4)*. Dispiro[2.1.2.1]octane *(3)* has recently been obtained catalytically from *(1)*[2].

Spectroscopic data for *(4)*: Mol. wt. (mass spectr.) 108; characteristic fragments 93, 91, 80, 79, and 54. IR spectrum (neat), 3060 ($\nu_{CH\Delta}$) and 1000 cm^{-1} (δ_Δ).—^{1}H-NMR spectrum (100 MHz, neat), $\tau = 7.81$ (s/4H), 9.74 (m/4H), and 9.85 ppm (m/4H).

Dispirooctanes (3) and (4)

(1) (32 g, 0.59 mol) is shaken for 5 h at 230 °C in an autoclave (200 ml; V4A steel; $p_{max} = 68$ atm.). After release of pure (GC) *(1)* (24.8 g; trap at −78 °C), working up gives a pale yellow liquid (6.7 g) from which colorless hydrocarbons (5.1 g, 76%) of b. p. 118—120 °C containing *(3)* (7.1%) and *(4)* (77.4%) (gas chromatography) are obtained; impurities (GC/MS) are mainly two compounds C_8H_{12} (4.0 and 5.3%); an unidentified viscous oily residue (1.6 g, 6.1%) remains.

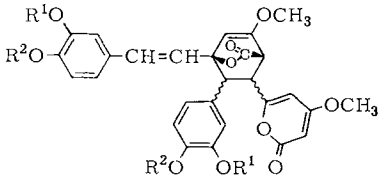
A Light-induced [2 + 4]-Cyclodimerization in the Crystalline State[**]

By *Hans Achenbach, Wolfgang Karl*, and *Egmont Schaller*[*]

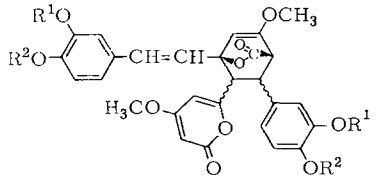


During work on the constituents of kava root (*Piper methysticum* Forst.)[1] we synthesized the known compound 5-hydroxy-3-methoxy-7-[3-methoxy-4-methoxymethoxyphenyl]-2,4,6-heptatrienoic acid δ-lactone *(1)*[2]. If the yellow needles of *(1)* [m. p. 121—123 °C (from methanol); $\lambda_{max} = 355$ nm] are exposed to daylight at room temperature, a compound *(3)* that is very sparingly soluble in methanol is formed during a few days.

Unlike *(1)*, the isomer *(2)* is stable to light.

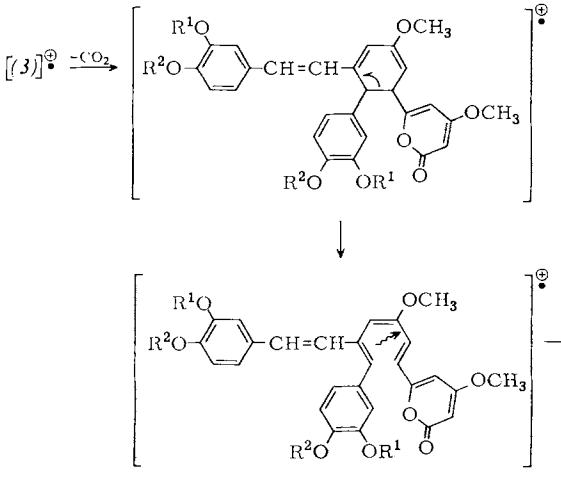
(1), $R^1 = CH_3$, $R^2 = CH_2OCH_3$
(2), $R^1 = CH_2OCH_3$, $R^2 = CH_3$

The structure of the photoproduct *(3)* [m. p. 191—193 °C; $M^+ = 636.2197$ (dimer); $\lambda_{max} = 260$ nm; $\nu_{CO} = 1725$, 1685 cm^{-1}] is based mainly on the following arguments:

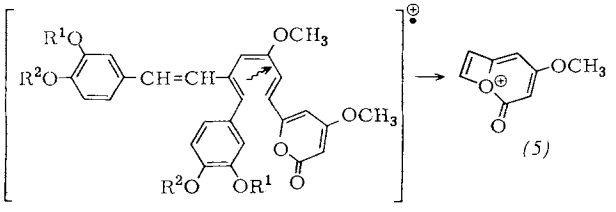


(3), $R^1 = CH_3$, $R^2 = CH_2OCH_3$

1. When heated in boiling xylene for 6 h, *(3)* decomposes almost quantitatively to *(1)*, which contraindicates a cyclobutane formulation.



2. The NMR spectrum shows only two olefinic protons (AB system, $J = 16$ Hz), whose signals disappear on catalytic hydrogenation to the dihydro compound. Thus only one styryl double bond participates in the dimerization.



[*] Doz. Dr. H. Achenbach, Dipl.-Chem. W. Karl, and E. Schaller
Chemisches Laboratorium der Universität
78 Freiburg, Albertstr. 21 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

(4), $R^1 = CH_3$, $R^2 = CH_2OCH_3$

3. In the mass spectrum of *(3)* the relatively weak molecular ion splits off CO_2 preferentially ($m/e = 592$; base peak). Thus the double bond system in one of the δ-lactone rings from *(1)* must have been altered. The position of the unchanged lactone ring can also be deduced from the mass-spectrometric fragmentation: formation of an observed fragment *(5)* at $m/e = 151.0393$ cannot be explained plausibly from the alternative structure *(4)*.

(1) did not dimerize to *(3)* under the conditions of the Diels-Alder reaction (xylene, 80 and 100 °C, up to 18 h). Also on irradiation of *(1)* with UV light (Hg-lamp, pyrex filter, $CHCl_3$ solution) a reaction could not be observed.

Whereas photo-induced [2+2]-cyclodimerizations in the crystalline state are known[3], photo-induced [2+4]-cyclodimerizations have been observed only in isolated cases together with other types of dimerizations and in liquid phase only[4].

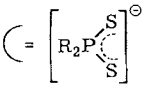
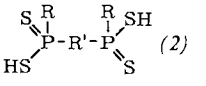
Coordination-Polymeric Metal Complexes of Bifunctional Dithiophosphinic Acids and Their Use as Adsorbents in Chromatography



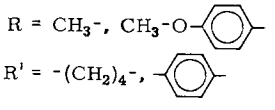
By *Wilhelm Kuchen, Jürgen Delventhal,* and *Helmut Keck*[*]

We have previously reported that planar Ni(II) and tetrahedral Co(II) dithiophosphinato complexes can add certain Lewis bases readily and reversibly to form octahedral complexes of type *(1)*[1-3].

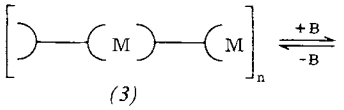
After the recent discovery of an elegant synthesis of bifunctional dithiophosphinic acids of type *(2)* in our



(1)

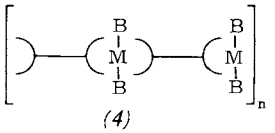


M = Co^{II}, Ni^{II}

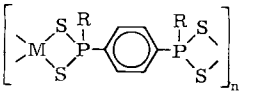


B = Pyridine, pyrazine, thiophene, etc.

laboratories[4,5] our attention was directed toward the complexing properties of these acids. We hoped thus to obtain coordination polymers of the composition *(3)* which should be able to expand their coordination



(2)



(3)

(4)

sphere reversibly to give the adducts *(4)*. These products would then be, *inter alia*, specific adsorbents for particular Lewis bases.

To prepare coordination polymers of type *(3)* we united aqueous solutions of the metal salts and the sodium salt of *p*-phenylenebis(methoxyphenyldithiophosphinic acid)[5] in the presence of CCl_4 and allowed the vigorously stirred mixture to react for several hours at room temperature.

(5a), M = Zn^{II}
(5b), M = Cd^{II}
(5c), M = Co^{II}
(5d), M = Ni^{II}
(5e), M = Pd^{II}

(5), R = CH_3-O-C$_6$H$_4$-

The coordination polymers $[ML]_n$ then separated in *ca.* 90% yields, being of type *(5)* or, for the chromium(III) complex, of type $[CrL_{1.5}]_n$ *(6)*. They are solids, insoluble in water or organic solvents, and very stable thermally and chemically; some of them are deeply colored. Magnetic and electron-spectroscopic findings show that the metal ion in *(6)* has octahedral, in *(5c)* tetrahedral, and in *(5d)* and *(5e)* planar coordination geometry.

[*] Prof. W. Kuchen, Dipl.-Chem. J. Delventhal, and Dipl.-Chem. H. Keck
Institut für Anorganische Chemie der Universität
4 Düsseldorf, Ulenbergstrasse 127/129 (Germany)

On treatment of *(5b)*, *(5c)*, or *(5d)* with Lewis bases, *e.g.* secondary or tertiary amines, adducts are formed, in some cases with change of color, corresponding in the case of pyridine to compounds *(4)* in stoichiometry.

The specific adsorbing power of such compounds was studied in detail for the Co(II) and Ni(II) complexes. For this purpose, *(5c)* and *(5d)*, mixed with an inert material, were packed into columns to which pentane solutions of the Lewis bases were then added. The separations effected were determined by gas chromatography of the pentane eluates.

It was thus shown that the complexes *(5c)* and *(5d)* are able to adsorb different amines to differing extents, so that, *e.g.* the strongly adsorbed pyridine can thus be separated from diethyl-, triethyl- and tributyl-amine, and diethylamine separated from tributylamine. Further, by use of *(5c)* a triethylamine/tributylamine mixture can also be separated.

The column packing can be regenerated by protic solvents such as a mixture of methanol/benzene and dilute acetic acid. *Ca.* 90% of the theoretical capacity could be reached experimentally with pyridine.

The "Sulfoxide Bond"[1]

By *Hans Bock* and *Bahman Solouki*[*]

In the sulfoxides[2] R^1—SO—R^2 such as

(1)

it is assumed from the short distance d_{SO} that a S=O double bond exists and from the pyramidal C_s conformation that there is an electron pair n_S on sulfur. Since the sulfur is surrounded by a total of ten valence electrons, the π_{SO} system is formulated with a 3d orbital. CNDO/2 calculations including the 3d orbitals[3] give the correlation diagram shown in Figure 1 for the five highest occupied molecular orbitals of dimethyl sulfoxide within the CSC- and CSO-angular range 90—120°.

[*] Prof. Dr. H. Bock and Dipl.-Chem. B. Solouki
Chemische Institute der Universität
6 Frankfurt 70, Ludwig-Rehn-Str. 14 (Germany)

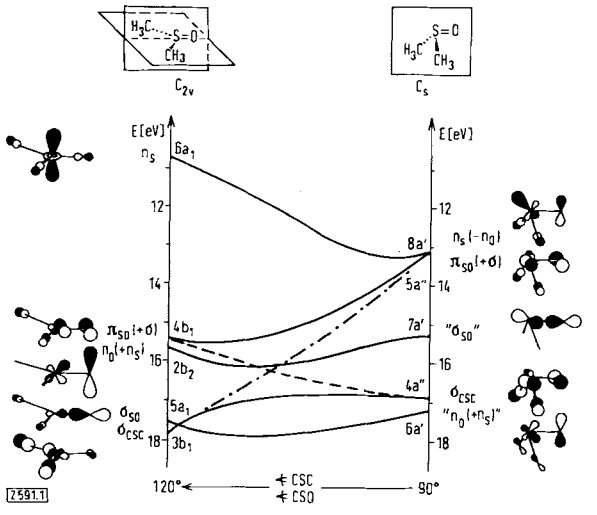

Fig. 1. Correlation diagram for dimethyl sulfoxide.

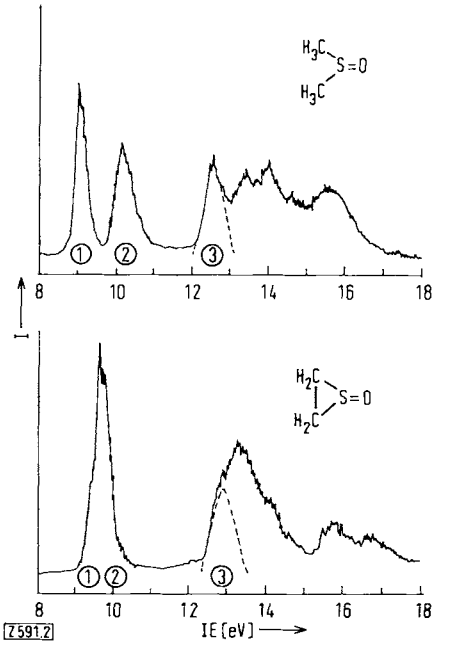
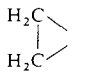
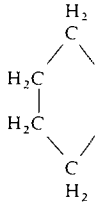
From the CNDO/2 orbitals shown in Fig. 1 it is clear that characterization is difficult because of the electron delocalization over the whole molecular skeleton: as the central angle ∢ CSC is decreased, the n_S electron pair is stabilized by increasing admixture of n_O and σ contributions, and the second-highest $\pi_{SO}(+\sigma)$ orbital is destabilized by further decrease of the π contribution. Successive molecular orbitals can be crudely characterized as $n_O(+n_S)$, σ_{SO}, and σ_{CSC}; the correlation of symmetry equivalent orbitals, $4b_1 \rightarrow 5a''$ and $3b_1 \rightarrow 4a''$, follows the non-crossing rule[4].

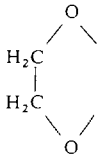
According to the correlation diagram (Fig. 1) it is to be expected that, for example, in dialkyl sulfoxides with a central CSC angle $\lesssim 90°$, the sulfur electron pair $n_S(-n_O)$ and the $\pi_{SO}(+\sigma)$ orbital will fortuitously be energetically equal. This expectation is confirmed by comparison of the photoelectron (PE) spectra of dimethyl sulfoxide and ethylene sulfoxide (Fig. 2).

The assignment of the dimethyl sulfoxide spectrum according to the calculated orbital sequence—









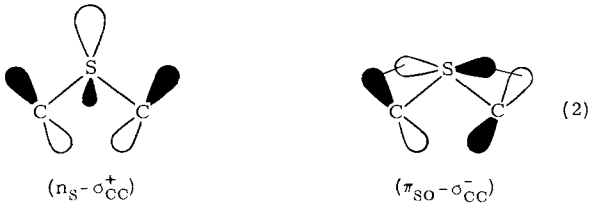


Fig. 2. PE spectra of dimethyl sulfoxide and ethylene sulfoxide.

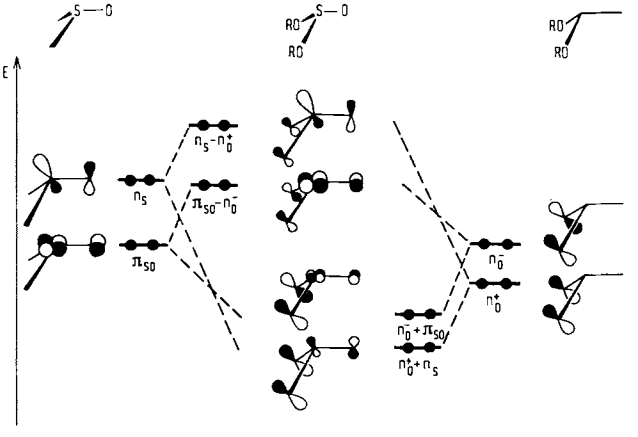
Table 1. Vertical ionization energies IE_n [eV] of sulfoxides.

R_2SO	IE_1	IE_2	ΔIE	$\Delta IE_{corr.}$
	9.66	9.78	0.12	0.12
	8.77	9.75	0.98	1.07
H_3C-	9.01	10.17	1.16 ≡	1.16
H_3CCH_2-	8.76	9.83	1.07	1.16
$(H_3C)_2CH-$	8.46	9.52	1.06	1.24
$(H_3C)_3C-$	8.18	9.20	1.02	1.29
X_2SO	IE_1	IE_2	IE_3	IE_4
$(H_3C)_2N-$	8.53	9.06	9.82	10.82
H_3CO-	10.25	10.95	11.60	11.90
	10.93	10.93	11.96	12.48
Br—	10.54	10.82	11.15	11.64
Cl—	11.13	11.78	12.08	12.48
F—	12.58	14.0	14.75	16.02

$n_S(-n_O)/\pi_{SO}(+\sigma)/n_O(+n_S)$— is best supported by the dynamic behavior of the system as a function of geometrical perturbation, as well as by band forms (n, unsymmetrical and sharp; π symmetrical and broad)[5].

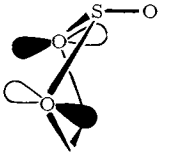
For open-chain dialkyl sulfoxides the ionization energy IE_2 decreases more than does IE_1 with increasing degree of methylation, and this can be understood as an effective hyperconjugative destabilization of the π_{SO} relative to the n_S orbital:



$(n_S - \sigma^+_{CC})$ $(\pi_{SO} - \sigma^-_{CC})$ (2)

If the donor effect of α-methyl groups (Table 1: ΔIE CH_3/CH_2CH_3)

$$\Delta n_S = \tfrac{1}{2}(8.76—9.01)\,eV = -0.12\,eV$$
$$\Delta \pi_{SO} = \tfrac{1}{2}(9.83—10.17)\,eV = -0.17\,eV \quad (3)$$



is subtracted, for example, from the ionization energies of the *tert*-butyl derivative ($IE_1 = 8.18 - 6(-0.12) = 8.9$ eV and $IE_2 = 9.20 - 6(-0.17) = 10.2$ eV), the resulting difference, $\Delta IE_{corr} = 1.3$ eV, is smaller than the separation of 0.16 eV in dimethyl sulfoxide. This increased energetic separation can be explained in terms of widening of the CSC-angle due to the bulk of the alkyl group in accordance with Figure 1.

For sulfoxides X_2SO in which the atom X next to sulfur carries an electron pair n_X, the energy level scheme (Fig. 1) is to be correspondingly expanded: for alkyl sulfites (X = OR) there result the following symmetry-correct combinations, with the assumptions that $E(n_O) \approx E(\pi_{SO})$ and $\Delta E(n_O^-/n_O^+) > 0.3$ eV[6]:

(4)

Again it is possible to test this by geometrical perturbation: In the *endo*-conformation of ethylene sulfite, which is the stable one according to CNDO/2 calculations, the electron pairs of the ring-oxygen atoms are oriented at an angle of about 45° to each other:

(5)

The steric rigidity, an unfavorable condition relative to that of dimethyl sulfite, decreases the antibonding interaction in the orbital $(n_S - n_O^+)$ and increases the antibonding interaction in the orbital $(n_O^- - \pi_{SO})$ [cf. (4)]; according to CNDO/2 calculations these two should have equal energy. As expected, the PE spectrum of ethylene sulfite shows the first band to have doubled intensity (Table 1).

The other derivatives X_2SO in Table 1 round out the picture: If $X = N(CH_3)_2$, then unlike (4), $E(n_N) \approx E(n_S)$, and if X = F[7], Cl or Br, then the "horizontal" electron pairs must also be taken into account. Collectively, the perturbations of the sulfoxides shown by PE spectroscopy indicate that

there are many possibilities for delocalization of the electrons. Therefore, as part of a more complex total system the "SO bond" cannot be treated as an isolated moiety.

Preparation of Pure Triacetylene, Tetraacetylene, and Pentaacetylene and Investigation of Their Electronic Spectra[**]

By *Else Kloster-Jensen*[*]

Unsubstituted polyacetylenes $(1)_n$ are among the simplest parent compounds in organic chemistry. Although their physical and chemical properties are of central importance, particularly for theoretical chemistry, only the first two members of the series ($n=1, 2$) have hitherto been studied in detail; the higher polyynes are extremely unstable.

$H-(C\equiv C)_n-H$ $(1)_n$

We report here the preparation of pure $(1)_3$, $(1)_4$, and $(1)_5$ which can be isolated at low temperatures *in vacuo* as colorless, crystalline (?) solids. $(1)_3$ and $(1)_4$ are sufficiently stable and volatile for their electron spectra to be measured in the gas phase in the far UV region (see Table 1).

Triacetylene (hexatriyne) $(1)_3$[2] was prepared from 1,6-dichloro-2,4-hexadiyne[2a, 3] by a slightly modified procedure given by *Bohlmann*[2b]. Working up at a low temperature and in a vacuum afforded a colorless, completely sublimable product. Photoelectron spectrum[4]: vertical ionization potentials $I_v(\pi_1)=9.50$ eV, $I_v(\pi_2)=11.55$ eV, $I_v(\pi_3)=12.89$ eV. IR spectrum (gas phase, 10 torr) (bands in cm^{-1}): ν(H—C), $\parallel$ band 3327, 3318 (s); ν(C≡C) 2115 (w); δ(H—C≡C; 1st overtone), $\parallel$ band 1243, 1234 (s); δ(H—C≡C), $\perp$ band 628, 623, 618 (s). The NMR spectrum ($CDCl_3$: $\delta=7.29$ ppm at -50°C) was measured for a mixture of $(1)_2$ and $(1)_3$: $(1)_3$, $\delta=2.14$ ppm; $(1)_2$, $\delta=2.06$ ppm[5]. Under the same conditions $(1)_1$ gives $\delta=2.01$ ppm[5].

Tetraacetylene (octatetrayne) $(1)_4$[6, 7] was prepared by oxidative coupling of (trimethylsilyl)diacetylene[8] and subsequent alkaline hydrolysis of the resulting bis-(trimethylsilyl)tetraacetylene $(2)_4$[9]:

$$2\,(CH_3)_3Si-C\equiv C-C\equiv C-H \xrightarrow[CH_3OH/H_2O/\text{pyridine}]{Cu(OAc)_2,\ Cu_2Cl_2} (CH_3)_3Si-C\equiv C-C\equiv C-C\equiv C-C\equiv C-Si(CH_3)_3 \quad (2)_4$$

$$(2)_4 \xrightarrow{NaOH/CH_3OH} H-C\equiv C-C\equiv C-C\equiv C-C\equiv C-H \quad (1)_4$$

Bis(trimethylsilyl)tetraacetylene could be isolated as colorless transparent crystals of m.p. 94.0—94.2 °C [IR spectrum (in KBr): characteristic bands (in cm^{-1}) at *ca.* 2957, 2895, 1402, 1245, 835, 754, 697 ($Si(CH_3)_3$); 2045 (s) ν(C≡C); further strong bands at 1028, 960, 625, 443, 352 cm^{-1}]. The hydrolyzate of tetraacetylene was acidified,

Table 1. Electronic spectra of the polyacetylenes (positions of maxima in nm) [***].

[***] For previous data see [2—7].

washed until neutral, and then chromatographed; the eluate was concentrated to dryness under vacuum in the cold. The NMR spectrum ($CDCl_3$, $\delta = 7.28$ ppm, $-50\,°C$) was measured for a mixture of $(1)_2$ and $(1)_4$: $(1)_4$, $\delta = 2.14$ ppm; $(1)_2$, $\delta = 2.03$ ppm. The minor discrepancy in the value for $(1)_2$ is probably due to a difference in concentration.

Pentaacetylene (decapentayne) $(1)_5$[6] was prepared as shown in the following scheme:

Trimethylsilylpropiolaldehyde[10] was coupled with butadiynylenebis(magnesium bromide) to give 1,10-bis(trimethylsilyl)-1,4,6,9-decatetrayne-3,8-diol, m.p. 118–119 °C [electronic spectrum: $\lambda_{max} = 259.5$, 246, 234, 222 (sh) nm]. Treatment with thionyl chloride and two-fold 1,6-elimination of hydrogen chloride gave bis(trimethylsilyl)pentaacetylene $(2)_5$. Subsequent alkaline hydrolysis and chromatographic separation yielded spectroscopically pure pentaacetylene $(1)_5$. After removal of the solvent under vacuum in the cold there remained a colorless, crystalline solid. The vapor pressure of $(1)_5$ was insufficient for an electronic spectrum to be recorded in the gas phase.

Cleavage of 1-Arylarsoles by Alkali Metals

By *Gottfried Märkl* and *Hagen Hauptmann*[*]

1-Phenyl-substituted aromatic arsoles, which are readily accessible by base-catalyzed cycloaddition of phenylarsane to 1,3-butadiyne[1], react with alkali metals in dimethoxyethane by stepwise addition of two electrons. 1,2,5-Triphenylarsole *(1a)* yields first the blue-green radical anion *(2a)* (λ_{max} 650 nm), whose ESR spectrum (Fig. 1) exhibits no fine structure and then the red-violet arsenide *(4)* (λ_{max} 610 nm); the resulting phenyl-Li(K) is decomposed by reaction with the solvent:

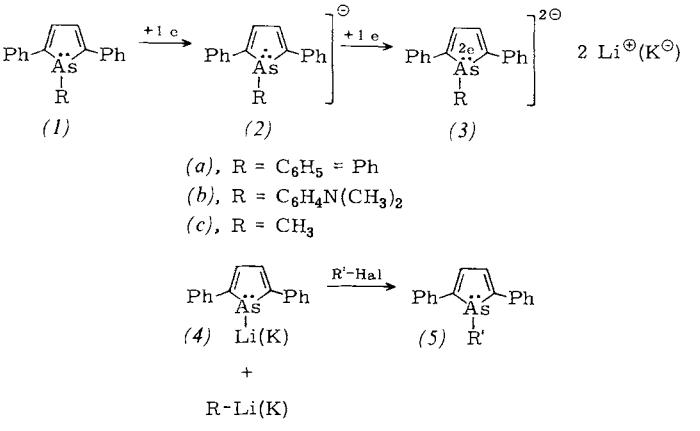

Table 1. Reaction of halides R'—Hal with *(2a)* or *(4)* to give arsole derivatives *(5)*.

(5), R'=	Yield (%) from *(2)*	Yield (%) from *(4)*	M.p. (°C)	UV λ_{max} (nm) (log ε) (in ethanol)	^{1}H-NMR (τ)	
(a), CH_3	63	52	101–102	367.5 (4.27) 218 (4.16)	$-CH_3$:	8.74 (s)

The dianion *(3a)*, isoelectronic with the stable 1,1-dimethyl-2,5-diphenylsilole dianion[2], could not be detected. Deuterolysis of the dianion *(3b)* formed by reaction of 1-(*p*-dimethylaminophenyl)-2,5-diphenylarsole *(1b)* with two equivalents of alkali metal should give only 4-D-*N*,*N*-dimethylaniline alongside 1-D-2,5-diphenylarsole; however, the dimethylaniline formed actually contains no deuterium.

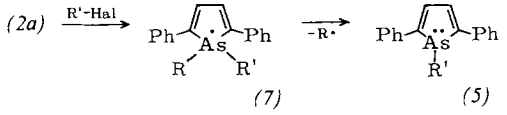
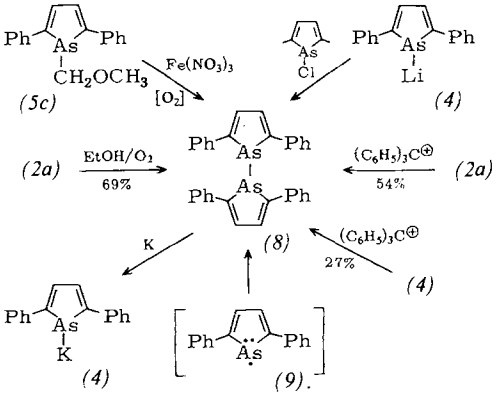
[7] *R. Eastmond* and *D. R. M. Walton,* Chem. Commun. *1968*, 204.



Reaction of *(2a)* with methylene chloride and benzal chloride yields not only the monochloroalkylarsoles *(5d)* and *(5f)*, respectively, but also the dinuclear arsoles *(6a)* and *(6b)* by double nucleophilic substitution:

(6)

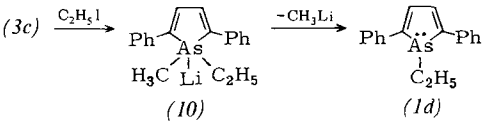
(6a), R = H: yield 10%; m. p. 225—227 °C; UV spectrum: λ_{max} 382 (log ε 4.42), 342 (4.28), 220 nm (4.52). *(6b)*, R = C_6H_5: yield 6%; m. p. 194—195 °C; UV spectrum: λ_{max} 376 (log ε 4.12), 346 (4.08), 230 nm (4.81).



The mechanism of alkylation of the radical anion *(2a)* has not yet been fully elucidated. The derivative *(7)* containing pentavalent arsenic is probably formed initially *via* reaction of the lone pair; loss of a phenyl radical then affords the arsole.

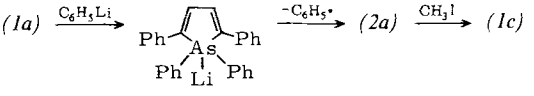
(7) *(5)*

Both the radical ion *(2a)* and the anion of *(4)* react in a surprising manner with trityl perchlorate: The deep red product consists of diarsolyl *(8)*, m. p. 209—212 °C, yield 54 and 27%, respectively. UV spectrum (in dimethoxyethane): λ_{max} 414 (log ε 3.96), 338 (4.38), 262.5 nm (4.23). ^{1}H-NMR spectrum: arsole ring H: 3.22 τ, 4H (s); aryl H: 2.92—2.34 τ, 20H (m). Mass spectrum (SM 1; 40 eV): M ($C_{32}H_{24}As_2$), *m/e* 558, rel. int. 100%; M/2 ($C_{16}H_{12}As$), *m/e* 279, 29%.



The tendency of formation and the stability of diarsolyl are unusual. Various routes to *(8)* are summarized in the following scheme.

(4) *(9)*



Oxidative formation of *(8)* probably proceeds by dimerization of the arsolyl radical *(9)*. On treatment with an alkali metal, *e. g.* potassium, *(8)* is smoothly cleaved to give the K arsenide *(4)* which gives the methylarsole *(1c)* on reaction with *e. g.* CH_3I.

Unlike triphenylarsole *(1a)*, 1-methyl-2,5-diphenylarsole *(1c)* produces a stable dianion *(3c)* on treatment with two equivalents of alkali metal; ethyl iodide reacts with *(3c)*, probably *via* the pentacoordinate species *(10)* to yield a mixture of 1-methyl- and 1-ethylarsole *(1c)* and *(1d)* (R = C_2H_5), respectively.

(10) *(1d)*

With respect to *(10)* the expected reactivity of the arsole system toward organolithium compounds has been confirmed experimentally. *(1a)* reacts with phenyl-Li at room temperature to give a radical species (Fig. 2), shown by chemical evidence to be the radical anion *(2a)* (*e. g.* reaction with methyl iodide affording *(1c)*).

According to the well-resolved, multiple-line ESR spectrum (Fig. 2), no polyaryl radicals appear to be present[3]; however, phenyl radical can be detected by ESR spectroscopy for a short while in a freshly prepared solution.

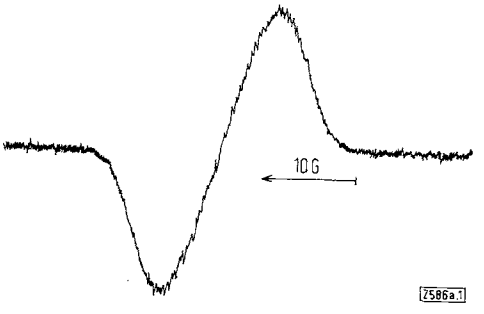


Fig. 1. ESR spectrum of the radical anion *(2a)*.

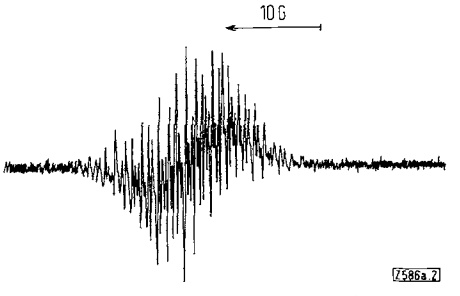

Fig. 2. ESR spectrum of the radical species formed on reaction of *(1a)* with C_6H_5Li.

Unusual Substitution in an Arsole Ring

By *Gottfried Märkl* and *Hagen Hauptmann*[*]

The less pronounced nucleophilic character of tertiary arsanes[1, 2] compared to phosphanes is further reduced in the aromatic arsole system *(1)*. The chemistry of the arsoles resembles that of pyrrole rather than the phospholes.

1,2,5-Triphenylarsole and 1-phenyl-2,5-dimethylarsole are unable to form quaternary salts and sulfides; arsole oxides are formed only in moderate yields alongside arsenic-free decomposition products on oxidation with H_2O_2.

However, these arsoles react smoothly with elemental chlorine (as phenyl iodide dichloride) to give the stable 1,1-dichloro derivatives *(2)* (Table 1), and with *tert*-butyl hypochlorite to give the 1-chloro-1-*tert*-butoxy derivatives *(3)*:

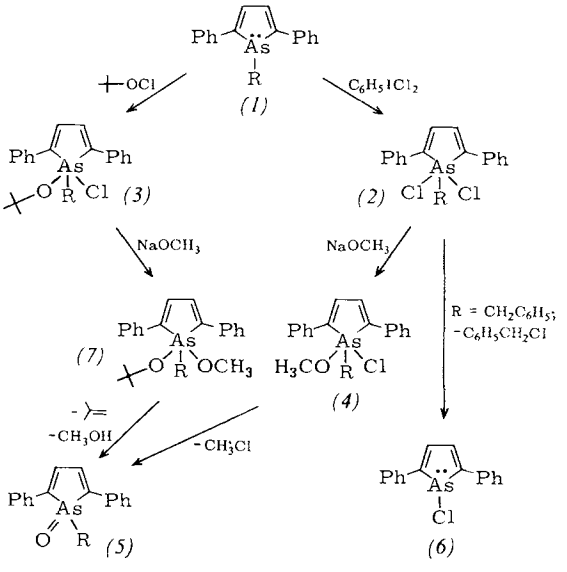

Table 1. 1,1-Dichloro derivatives *(2)* of 1,2,5-trisubstituted arsoles.

(2), R =	Yield (%)	M. p. (°C)	UV λ_{max} (nm) (log ε) (in ethanol)	^{1}H-NMR (τ) (in $CDCl_3$)
C_6H_5	96	168–169	395 (4.19) 239 (4.14) 220 (4.32)	
$CH_2C_6H_5$	88	85 (dec.)		
CH_3	83	170	400 (4.18) 237 (4.25)	—CH_3: 7.05 (s) aryl-H: 2.06–3.06 (m)

The dichlorides are thermolabile [1,1-dichloro-1-benzylarsole *(2)*, R = $C_6H_5CH_2$, decomposes at room temperature to 1-chloro-2,5-diphenylarsole *(6)*, fine red needles, m. p. 136—137 °C; yield 85%; UV spectrum (in CH_2Cl_2): λ_{max} (log ε): 402 (4.07), 246 nm (4.23)] but surprisingly stable toward water and alcohols (recrystallized from ethanol). Reaction with one equivalent of Na methoxide furnishes the unstable 1-chloro-1-methoxyarsoles *(4)* which spontaneously lose methyl chloride to give the arsole oxide *(5)* in good yield (R = C_6H_5, yield 80%; m. p. 226—227 °C. R = CH_3, yield 64%; m. p. 199 °C. R = $CH_2C_6H_5$, yield 35%; m. p. 115 °C (decomp.)).

[*] Prof. Dr. G. Märkl and Dr. H. Hauptmann
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

The yellow-orange voluminous *tert*-butyl hypochlorite adducts *(3)* (R = C_6H_5, $CH_2C_6H_5$) resemble *(4)* in structure but do not decompose to the arsole oxides; however, they disproportionate in solution at room temperature to give *(2)*. In the case of R = $CH_2C_6H_5$ the reaction proceeds further to give the 1-chloroarsole *(6)* directly in 41% yield.

Reaction of *(3)*, R = C_6H_5, with $NaOCH_3$ proceeds directly to the arsole oxide *(5)*, R = C_6H_5, *via* the 1-methoxy-1-*tert*-butoxy derivative *(7)*.

These results suggested that the reaction of the *tert*-butyl hypochlorite adducts *(3)* with organolithium compounds should give pentacoordinate arsoles *(8)* or their reaction products. Surprisingly, the pale yellow crystalline reaction products are actually 3-substituted arsoles *(9)* (Table 2):

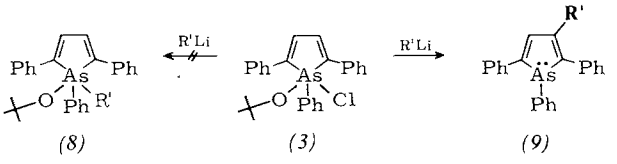

Table 2. 1,2,3,5-Tetrasubstituted arsoles *(9)*.

(9), R =	Yield (%)	M. p. (°C)	UV λ_{max} (nm) (log ε) (in ethanol)	^{1}H-NMR (τ) (in $CDCl_3$)
CH_3	36	122–124	353 (4.17) 234 (4.35)	—CH_3: 7.80 (s)
C_6H_5	40	151–152.5	370 (4.11) 265 (4.25) 240 (4.41)	aryl-H: 2.26–3.30
$C_6H_4N(CH_3)_2$	16	154–155	385 (4.00) sh 330 (4.30) 265 (4.32) 230 (4.39) sh	$N(CH_3)_2$: 7.08 (s) aryl-H: 2.24–3.46

Formation of *(9)* can be rationalized mechanistically as S_N2' substitution and subsequent aromatization by elimination of *tert*-butanol.

The bulky *tert*-butyl group induces the S_N2' mechanism by blocking nucleophilic attack at the heteroatom.

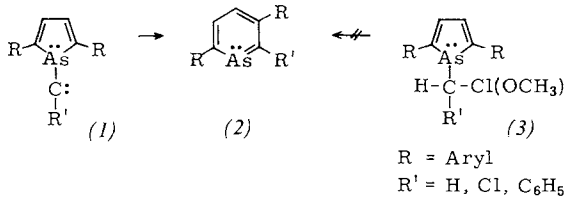
General Synthesis of Aryl-Substituted Arsabenzenes

By *Gottfried Märkl*, *Hagen Hauptmann*, and *Jürgen Advena*[*]



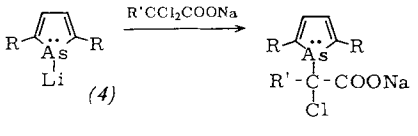
Both the "phenarsazine" described by *Wieland*[1] in 1921 and the "arsanthrene" of *Kalb*[2] have been shown by *Bickelhaupt et al.*[3, 4] to be dimers and therefore not arsa-aromatic compounds containing —As=C< (4pπ—2pπ) double bonds.

Evidence for the existence of this bond system was first provided by the preparation of arsamethinecyanines[5].

[*] Prof. Dr. G. Märkl, Dr. H. Hauptmann, and Dipl.-Chem. J. Advena
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

Following the spectroscopic detection of the unstable 9-arsaanthracene[6, 7], *Vermeer* and *Bickelhaupt*[8] successfully isolated a dibenzoarsabenzene, *viz.* 10-phenyl-9-arsaanthracene; *Ashe*[9] subsequently described unsubstituted arsabenzene itself.

In the present communication we report a general synthesis of arsabenzenes *(2)* bearing three or more aryl substituents by an intramolecular carbene insertion reaction of arsoles *(1)*.

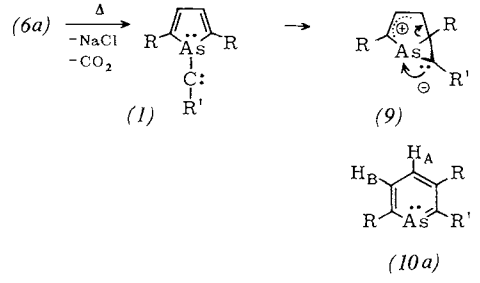


(1) *(2)* *(3)*

Previous attempts to prepare six-membered arsenic heterocycles from halo-(methoxy-)alkyl-substituted arsoles *(3)*[10] by ring expansion *via* carbonium, carbenoid, or carbene intermediates were unsuccessful. The organometallic bases required for deprotonation or α-elimination in these arsoles also attack the arsole ring; moreover, under such conditions —in analogy to the phosphabenzenes[11]—one must not forget that the expected arsabenzenes may react further.

In order to prepare arsolylcarbene species *(1)* while avoiding basic reactions we applied the method of generating dichlorocarbene by thermolysis of Na trichloroacetate to arsole chemistry.

The lithium arsenide *(4)*, which is readily accessible by lithium-induced cleavage of 1,2,5-triphenylarsole in dimethoxyethane[10], reacts with Na trichloroacetate and also with Na phenyldichloroacetate[12] to give the mono-substituted products *(5)* and *(6)*, respectively (Table 1), as potential carbene precursors:



(4) *(5)*, R' = Cl; *(6)*, R' = C_6H_5

Whereas Na arsolyldichloroacetate *(5a)* is degraded in an undefined manner at 170°C, its phenyl derivative *(6a)* decomposes a little above its melting point (140°C) to give a 77% yield of stable, non-autoxidable 2,3,6-triphenylarsabenzene *(10a)* as colorless crystals of m. p. 146°C.

This rearrangement results from an intramolecular carbene insertion, probably *via* the arsacyclopropane of the bicyclic betaine *(9)* (non-symmetrical arsoles should give two isomeric arsabenzenes—by insertion at position 2 or 5; see Table 2):

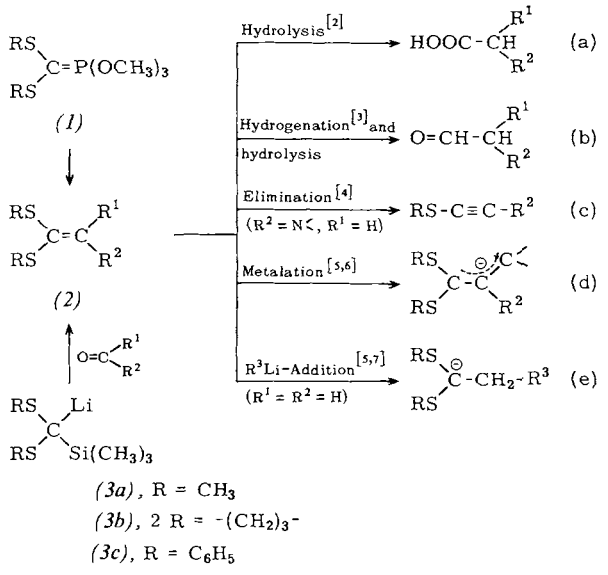
Ketene Thioacetals by "Peterson Carbonyl Olefination"[1] with Metalated Formyl Trimethylsilyl Thioacetals[**]

By *Dieter Seebach*, *B.-Th. Gröbel*, *A. K. Beck*, *Manfred Braun*, and *K.-H. Geiss*[*]

Dedicated to Professor R. Criegee on the occasion of his 70th birthday



As shown in the reactions (a)—(e) of the following scheme, ketene thioacetals *(2)* are useful synthetic intermediates.

A generally applicable method of preparation of these compounds is, however, not available[3, 5–8]. Thus Wittig-Horner olefination succeeds only with aldehydes (R^1 = H) as carbonyl components [*(1)* → *(2)*][3, 8b, 8d].

We report here a simple access to *(2)* by reaction of the metalated silyl thioacetals *(3a)*—*(3c)*[9] with carbonyl derivatives (Peterson olefination). The ketene thioacetals *(2)* are obtained in high yields when solutions of *(3a)* to *(3c)* in THF are combined at −80 °C with the aldehydes, ketones, and carboxamides[10] listed in the Table. The reaction mixture is left overnight at room temperature prior to product isolation. Even ketones such as cyclopentanone and cyclohexenone, which are readily enolized by other organometallic reagents, react smoothly.

[a] All new compounds give correct elemental analyses. C=C band in the IR spectrum between 1575 and 1600 cm^{-1}.
[b] Elimination reaction, see [4].

Procedure:

A solution of 2-lithio-1,3-dithiane [prepared from dithiane (24.0 g, 0.200 mol) in THF (200 ml) and 130 ml of a 1.58 M *n*-butyllithium solution in *n*-hexane] cooled to −30 °C is added to freshly distilled chlorotrimethylsilane (40 ml) stirred at −55 °C. The mixture is kept for 20 min at this temperature and for 5 h at +20 °C. Workup with pentane/water furnishes 35.1 g (91%) of 2-trimethylsilyl-1,3-dithiane, b. p. 96—97 °C/5 torr, $n_D^{22} = 1.5308$.—A solution of 2-lithio-2-trimethylsilyl-1,3-dithiane (20 mmol) prepared as usual[5] is combined at −50 °C with neat cyclohexanone (2.00 g, 20.4 mmol). The temperature is allowed to rise to +20 °C within 1 h. After 14 h the reaction mixture is poured

[8] a) *R. Gompper* and *H. Schaefer*, Chem. Ber. *100*, 591 (1967), and earlier work cited therein; b) *E. J. Corey* and *G. Märkl*, Tetrahedron Lett. *1967*, 3201; c) *E. J. Corey* and *D. Ber. *105*, 487 (1972).

[9] *(3a)* and *(3c)* were prepared similarly to the dithiane derivative *(3b)* (modification of the original procedure given by *E. J. Corey*, *D. Seebach*, and *R. Freedman*, J. Amer. Chem. Soc. *89*, 434 (1967), see procedure given there) from the corresponding silyl thioacetals *(3)* (H instead of Li, R = CH_3: b. p. 68 °C/10 torr, $n_D^{20} = 1.5071$; R = C_6H_5: b. p. 110 °C/0.005 torr).

[10] *(3b)* and tetramethylurea form an extremely sensitive substance whose NMR spectrum is in accord with the structure of an olefin $(RS)_2C{=}C[N(CH_3)_2]_2$ (N—CH_3 singlet at δ = 3.15 ppm). With water it decomposes quantitatively to give *N,N*-dimethyl-1,3-dithiane-2-carboxamide [5], m. p. 82 °C.

Isoelectric Focusing: Present and Future State of a New Method

By *B. J. Radola*[*]

Isoelectric focusing is a new method of separation in which amphoteric substances, in particular proteins, can be separated in a stable pH gradient owing to the differences in their isoelectric points. The method is extremely efficient and permits separation of proteins whose isoelectric points differ by only 0.02 pH unit. Further, the method enables the separated components to be characterized by a physicochemical constant, namely the isoelectric point. It is only recently that development of appropriate "carrier ampholytes" provided the prerequisites for practical use of the method. Several techniques of isoelectric focusing can be distinguished by the way in which the pH gradient is stabilized: 1. Focusing in a density gradient (*e. g.* saccharose); 2. focusing in polyacrylamide gel (either in flat gels or in an arrangement corresponding to disk electrophoresis); and 3. focusing in granulated gels (*e. g.* Sephadex or Bio-Gel).

Isoelectric focusing in layers of granulated gels can be used as a thin-layer method for analytical separations on plates of various lengths and widths. If the thickness of the layer is increased the work can be done preparatively in throughs. The separations are carried out in a double chamber developed for isoelectric focusing (Desaga, Heidelberg). After the focusing, the separated components are detected densitometrically directly in the gel layer or can be localized by dyeing in a paper print. Enzymes can be made visible by means of a buffered paper impregnated with substrate. Microgram to gram quantities of amphoteric substances can be separated by isoelectric focusing in gel-stabilized layers. For a number of proteins and enzymes it was possible, by thin-layer isoelectric focusing, to detect a heterogeneity that was not found previously by any other method. Preparative isoelectric focusing in gel-stabilized layers opens a completely new perspective for purification of proteins in respect of both the excellent resolution and of the capacity of the method; the latter exceeds greatly the capacity of preparative electrophoretic methods.

For protein chemistry isoelectric focusing is today one of the most efficient methods of separation. Analytical and preparative separation of proteins will in the future be supplemented to an increasing degree by introduction of this method for determination of isoelectric points as well as for studies of conformation and for modification of proteins by group-specific reagents.

Studies of Reaction Kinetics in the Solid State: First and Second Order Reaction Constants

By *Hermann Schmalzried*[*]

The kinetics of reactions involved in spinel and silicate formation have been studied by a thermogravimetric method. In all cases, initial results follow a linear rate law analogous to many oxidation processes. Interpretation of the rate determining mechanism of the phase boundary reactions is not yet certain, although dislocation movements are suspected at the solid-solid phase boundary, at least for spinels.

For spinel formation, the parabolic rate law followed as the reaction progresses allows quantitative interpretation based on counterdiffusion of cations. For formation of simple orthosilicates matters are more complicated. In independent diffusion measurements it was found that the mobilities of silicon and oxygen ions are of the same order of magnitude and astonishingly high [$D_{Si}(Zn_2SiO_4 \approx 10^{-13}$ cm^2/s (1300 °C); $D_O(Co_2SiO_4) \approx 10^{-13}$ cm^2/s (1300 °C)]. Diffusion measurements in glass, however, seem to confirm the behavior of these components of the SiO_4 tetrahedra.

If the starting oxides are mutually soluble, transport processes occur in them that must be taken into account when determining the overall reaction kinetics. First and second order reaction constants have therefore been defined and related mathematically to one another. First order reaction constants describe solid state reactions for pure starting oxides; second order reaction constants describe solid state reactions in which a single phase product is formed from its two saturated neighboring phases.

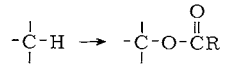
Polycations of Group VI, which have received considerable attention during recent years, are the subject of a review by *R. J. Gillespie* and *T. Passmore*. The unusual colors of solutions of S, Se, and Te in strong acid solutions, which have been known for more than 150 years, have recently been shown to be due to polyatomic cations. At least nine of these cations have now been characterized and isolated in the form of crystalline compounds. Discussed are, *inter alia*, the preparation and physical properties of compounds containing $O_2^{\oplus}$, $S_{16}^{2\oplus}$, $S_8^{2\oplus}$, $S_4^{2\oplus}$, $Se_4^{2\oplus}$, and $Se_8^{2\oplus}$ ions, and Te polycations; the structures of $Se_4^{2\oplus}$ and of $Se_8^{2\oplus}$ are also discussed. The high π-bond energy and low σ-bond energy of oxygen favor $O_2^{\oplus}$ formation rather than $O_4^{2\oplus}$. The reverse is the case for sulfur. The more metallic nature of tellurium is reflected in the formation of $Te_n^{n\oplus}$. [Polycations of Group VI. Accounts Chem. Res. *4*, 413–419 (1971); 69 references]

[Rd 479 –M IE]

The growth of large diamond crystals is reviewed by *H. M. Strong* and *R. H. Wentorf, jr.* Large crystals up to 6 mm in diameter are obtained at high pressures (55–60 kbar) and temperatures (1400–1500 °C) by causing diamantiferous material as carbon source to dissolve in a molten catalyst metal (such as Fe, Ni, or Co) in a hot region and to crystallize out in a cooler region on a seed crystal. The procedure requires several days and is influenced by several parameters. [The Growth of Large Diamond Crystals. Naturwissenschaften *59*, 1–7 (1972); 22 references]

[Rd 480 –M IE]

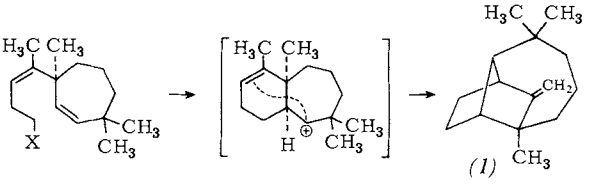


Molecular deficiencies of human blood coagulation are discussed in a review by *E. A. Beck*. Blood coagulation is a complex biochemical process; deficiencies in thrombin or fibrin formation lead to hemorrhages. Congenital hemophilia is due to a deficiency in the amount of or structural anomalies of the coagulation factor. Investigations on the functional breakdowns of anomalous fibrinogens indicate the existence of numerous structural variants which influence interaction with thrombin, fibrin polymerization, or fibrin stabilization differently. Analogous studies on the coagulation factors II, VII, VIII, IX, X, and XIII also suggest structural anomalies as the cause of most hemophilic disorders. [Molecular Deficiencies of Human Blood Coagulation. Experientia *28*, 1–7 (1972); 67 references]

[Rd 481 –M IE]

Organic geochemistry is reviewed by *J. R. Maxwell, C. T. Pillinger*, and *G. Eglinton*. Much more carbon is present in the earth's crust than in the biosphere. In spite of the great age of sedimentary rocks (up to 3.5×10^9 a) they are found to contain biogenic substances such as pristane, phytane, triterpenoids, and porphyrins. The authors go into the methods available for isolation and identification of organic compounds from geological sources and into the modifications of the initially deposited compound upon transformation of the sediments into solid rocks.—Extraterrestrial occurrence of organic compounds is also discussed. [Organic Geochemistry. Quart. Rev. Chem. Soc. *25*, 571–628 (1971); 296 references]

[Rd 488 –L IE]

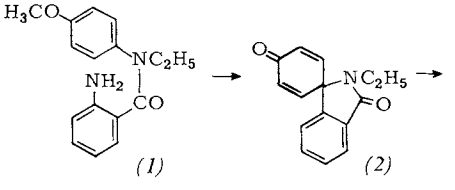


One-step substitutive acyloxylation at carbon involving reactions with organic peroxy compounds is reviewed by *D. J. Rawlinson* and *G. Sosnovsky*. The article covers acyloxylations—with and without catalysis by transition metal ions—of, *inter alia*, hydrocarbons, ethers, esters, aldehydes, ketones, amides, thioethers, phenols. Suitable peroxy com-

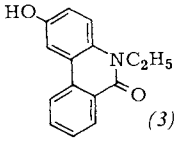
pounds are, *e.g.*, peroxy esters, hydroperoxides, dialkyl peroxides, peroxy acids, diacyl peroxides, and diaroyl peroxides. [One-step Substitutive Acyloxylation at Carbon. Synthesis *1972*, 1–28; 179 references]

[Rd 482 –M IE]

Computer-assisted analysis of complex synthetic problems, with particular regard to the derivation of synthetic routes to complex molecules, is described by *E. J. Corey*. The dialog is essentially between man and computer; *inter alia*, structural formulas serve as a means of communication. The capability of the method is illustrated using the hypo-



(1)



thetical synthesis of longifolene *(1)* as example. [Computer-assisted Analysis of Complex Synthetic Problems. Quart. Rev. Chem. Soc. *25*, 455–482 (1971); 23 references]

[Rd 483 –L IE]

Spirodiene rearrangements are summarized in a review by *D. H. Hey*. As an example of the formation of a spirodiene and its rearrangement into a phenanthridone derivative, the reaction sequence *(1)*→*(2)*→*(3)* is discussed. The reaction *(2)*→*(3)* only proceeds in 100% phosphoric acid at 170 °C.—The author also gives a comprehensive account of the photochemical rearrangement of spirodienes and of

(1) *(2)*

(3)

other reactions of compounds of type *(1)*, *e. g.* the formation of dimers, in dependence upon substituents and reaction conditions. [Spirodiene Rearrangements. Quart. Rev. Chem. Soc. *25*, 483–499 (1971); 18 references]

[Rd 484 –L IE]

Electrochemical measurements with amalgam electrodes are reviewed by *H. P. Bennetto* and *A. R. Willmot*. Numerous experimental difficulties that formerly limited the use of such electrodes have now been overcome. Apart from an historical introduction and experimental procedures, the article includes a discussion of the application of such measurements in two special cases, *viz.*, the association of ions in aqueous cadmium chloride solutions and the solvation of alkali metal ions. [Electrochemical Measurements with Amalgam Electrodes. Quart. Rev. Chem. Soc. *25*, 501–520 (1971); 77 references]

[Rd 485 –L IE]

The effect of polar substituents on the ionization of organic acids is the subject of a review by *P. D. Bolton* and *L. G. Hepler*. The authors attach importance not only to "internal" polar and steric effects of substituents but also to the reaction medium. An introduction to the thermodynamics of ionization is followed by a discussion of the effects of polar groups on the free energy of ionization, taking ω-amino acids, chloroacetic acid, and similar acids, as well as phenol and substituted phenols as examples. Further conclusions are drawn from entropy values. Such considerations and measurements could provide a theoretical basis for the (empirical) Hammett relation. [Polar Substituent Effects and the Ionization of Acids. Quart. Rev. Chem. Soc. *25*, 521–532 (1971); 22 references]

[Rd 486 –L IE]

Halogen and interhalogen cations are the topic of a review authored by *R. J. Gillespie* and *M. J. Morton*. The highly electrophilic cations can only be prepared and studied in very weakly basic solvents, *e. g.* fluorosulfuric acid, disulfuric acid, antimony pentafluoride, and sulfur dioxide. These cations form stable crystalline compounds only with extremely weakly basic anions such as $Sb_3F_{16}^{\ominus}$ [see eq. (1)–(4)].

$$2I_2 + S_2O_6F_2 \rightarrow 2I_2^{\oplus} + 2SO_3F^{\ominus} \quad (1)$$

$$Br_2 + BrSO_3F \rightleftharpoons Br_3^{\oplus} + SO_3F^{\ominus} \quad (2)$$

$$Cl_2 + ClF + AsF_5 \rightarrow Cl_3^{\oplus}AsF_6^{\ominus} \quad (3)$$

$$2ICl_3 \rightarrow ICl_2^{\oplus} + ICl_4^{\ominus} \quad (4)$$

Interhalogen cations are also present in the known adducts of ClF_3 and AsF_5 ($ClF_2^{\oplus}AsF_6^{\ominus}$) or BrF_3 and SbF_5 ($BrF_2^{\oplus}SbF_6^{\ominus}$).—The crystal structure of $Br_2^{\oplus}Sb_3F_{16}^{\ominus}$, $ClF_2^{\oplus}SbF_6^{\ominus}$, and $BrF_2^{\oplus}SbF_6^{\ominus}$ are also reported. [Halogen and Interhalogen Cations. Quart. Rev. Chem. Soc. *25*, 553–570 (1971); 50 references]

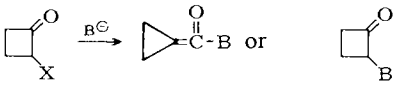
[Rd 487 –L IE]

Substitution reactions of platinum(IV) complexes catalyzed by platinum(II) or reducing agents are treated by *W. R. Mason*. The general rate law and the mechanism of these reactions are given, and kinetic data are tabulated for individual reactions. The kinetic data are analyzed for the influence of the ligands involved; medium effects (solvent, ionic strength) and some more common side-reactions are also discussed. [Platinum(II)-Catalyzed Substitutions of Platinum(IV) Complexes. Coord. Chem. Rev. *7*, 241–255 (1972); 41 references]

[Rd 489 –H IE]

The vibrational spectra of octahedral hexahalogen compounds are analyzed by *P. Labonville, J. R. Ferraro, M. C. Wall*, and *L. J. Basile*. Starting from the observed frequencies, different sets of force constants are calculated depending on the form of the intramolecular force field assumed. The best fit of frequencies calculated from the force constants with the observed frequencies is achieved by use of a Modified Orbital Valence Force Field (MOVFF). Finally, the effects of mass and oxidation number and the influence of nonbonding valence electrons (in transition metal compounds) are discussed. [Force Fields in Octahedral Hexahalogen Molecules. Coord. Chem. Rev. *7*, 257–287 (1972); 42 references]

[Rd 490 –H IE]



The literature on manganese-porphyrin complexes is surveyed by *L. J. Boucher*. The most stable compounds are formed by trivalent manganese; complexes with bi- and tetravalent manganese are accessible by redox reactions starting from the trivalent state. Minor sections on complexes derived from chlorophyll and phthalocyanine are included; finally, a comparison is made with the corresponding iron complexes and the relevance of these compounds for the investigation of biological problems is discussed. [Manganese Porphyrin Complexes. Coord. Chem. Rev. *7*, 289–329 (1972); 112 references]

[Rd 491 –H IE]

The circular dichroism (CD) of cobalt(III) chelates is the subject of a review by *L. I. Katzin* and *I. Eliezer*. The qualitative features (sign and order of magnitude) of the CD spectra of about 150 chelates in the spectral region of the first two ligand field transitions in the low spin d^6 system are tabulated and discussed throughly. An important topic is the determination of "absolute configurations" from CD spectra. In the authors' opinion the details of these spectra are not sufficiently understood to allow conclusions by analogy even to closely related compounds; also comparison with sufficient X-ray data is lacking. [Bonding Effects in Circularly Dichroic Co(III) Complexes. Coord. Chem. Rev. *7*, 331–343 (1972); 65 references]

[Rd 492 –H IE]

Cyclobutane ring contractions not involving carbonium ions have been reviewed by *J. M. Conia* and *J. R. Salaun*. The reaction of 2-bromo-(or 2-tosyloxy)-cyclobutanones *(1)* with nucleophilic reagents is not to be considered as a classical Favorskii rearrangement, but rather as a type of semibenzil rearrangement. Depending on the reagent used, one obtains compound *(2)* and/or *(3)*. This contraction, like the ring contraction of 2-halo(or 2-tosyloxy)-cyclobutanols with nucleophiles, which take place particularly readily (*e. g.* even in water), is apparently to be compared with the base-catalyzed rearrangement of cyclic glyco-

(1), X = Br, OTs *(2)* *(3)*

monotosylate or 1,2-halohydrin of the pinacol type. The ring contractions of 2-bromocyclobutanone hydrate, -hemiketal, and -ketals, as well as those of bromohydroxy- dihydroxy-, and epoxycyclobutanones on heating are obviously closely related to these rearrangements. [Cyclobutane Ring Contractions not Involving Carbonium Ions. Accounts Chem. Res. *5*, 33—40 (1972); 123 references]

The versatility of organocopper(I) compounds and organocuprates in organic syntheses is dealt with in a review by *J. F. Normant*. Both these reagents frequently prove to be more useful than the common organometal compounds. Condensations with organocopper(I) compounds R—Cu sometimes necessitate the use of an aprotic solvent (DMF, DMSO) and sometimes of a salt or a neutral complexing agent (phosphane, thioether, pyridine). The homocuprates, R_2CuLi, are often better reagents than organolithium compounds—especially for nucleophilic substitution of halogen derivatives. In the acetylene series mixed cuprates, RR CuLi, have to be employed. [Organocopper(I) Compounds and Organocuprates in Synthesis. Synthesis *1972*, 63—80; 142 references]

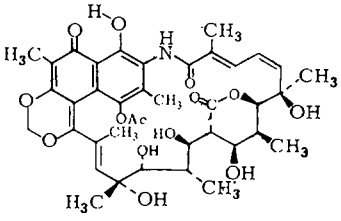
Structure, biosynthesis, and heterogeneity of chondroitin sulfate proteins, which are important structural units of the primary component of the connective tissue of vertebrates are reviewed in an article by *T. O. Kleine*. Many details concerning the biosynthesis, regulation, and structure of these compounds are still unknown. The considerable chemical and metabolic heterogeneity of chondroitin sulfate proteins can be understood in terms of the different sizes and turnover rates of acceptor protein pools and by the different activities and specificities of monosaccharide and sulfo-transferases. [Naturwissenschaften *59*, 64—71 (1972); 88 references]

[Rd 494 IF -M]



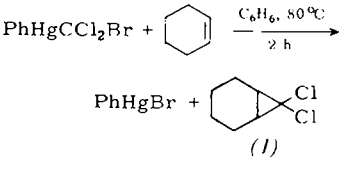
Investigations of the antibody-complement interaction with lipid model membranes are summarized, with special references to the author's own work, in a review by *S. C. Kinsky*. The immune damage of natural membranes can be imitated in very simple systems, thus opening up possibilities for further investigations of the molecular basis of the complement effect. Liposomes of the fractions IIa and IIb from the erythrocyte membranes of sheep serve as model systems. [Antibody-Complement Interaction with Lipid Model Membranes. Biochem. Biophys. Acta *265*, 1—23 (1972); 34 references]

[Rd 495 IE -M]

Investigation of the protein conformation in chemically unchanged, functionally and enzymatically active biomembranes by measurement of optical rotation and UV- and visual light-absorption is discussed in a review by *D. W. Urry*. At present, these methods afford the best information regarding conformation. The spectral data are complicated by artefacts and absorption by nonprotein material. The author deals in particular with special conformations for ion transport (valinomycin-cation complex gramicidin-A transmembrane canal). [Protein Conformation in Biomembranes: Optical Rotation and Absorption of Membrane Suspensions. Biochim. Biophys. Acta *265*, 115—168 (1972); 62 references]

[Rd 496 IE -M]

Ansamycins, a new class of antibiotics in which two nonadjacent sites of an aromatic nucleus are coupled by an aliphatic bridge, are reviewed by *K. L. Rinehart jr*. Up to now, four groups of the *Streptomyces*-type ansamycins have been recognized: Rifamycins *(S. mediterranei)*, Streptovaricins *(S. spectabilis)*, Tolypomycins *(S. tolyphorus)*, and Geldanamycins *(S. hygroscopicus* var. *geldanus)*. The structure of streptovaricin F *(1)* is given as example. The molec-



(1)

ular structures of the ansamycins can be varied considerably without lowering their antibiotic activity. Many derivatives are more active than the parent compound.—The author deals also with the biosynthesis. [Antibiotics with Ansa Rings. Accounts Chem. Res. *5*, 57 –64 (1972); 95 references]

[Rd 498 IE -M]

The chemistry of phenyl(trihalomethyl)mercury compounds, which are exceptionally versatile dihalocarbene precursors, is the subject of a review by *D. Seyferth*. $PhHgCX_3$ and other halomethylmercury compounds are suitable reagents for divalent carbon transfer:

(1)

In this reaction, 7,7-dichloronorcarane *(1)* is formed almost quantitatively with exclusive elimination of PhHgBr. A few of these compounds, such as $PhHgCCl_2I$, PhHgCClBrI, and $PhHgCBr_2F$ yield dihalocarbenes even at room temperature. Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry). Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. *Supplement to the 8th edition*, vol. 2/3: Organometallic Compounds of Vanadium and Chromium. Volume 2: Organovanadium Compounds, iii, 79 pp., 22 figures. Volume 3: Organochromium Compounds. x, 452 pp., 55 figures. Balacron, together DM 622.—.

The chemistry of organometallic compounds has developed explosively during the past two decades. This field is currently being dominated by the cyclopentadienyl, allyl, and olefin complexes and the π complexes with aromatic ligands. Their discovery and characterization have given fresh impetus in particular to theoretical chemistry. The carbonyl-metal compounds have also attracted renewed interest. New physical methods of investigation, including the latest type of spectroscopy, photoelectron spectroscopy, have led to extensive further information on structure and bonding in this class of compounds. Corresponding to this newness of much of the material discussed in both volumes, the literature has been evaluated up to the end of 1970, and in part even to early 1971.

The first chapter of Volume 2 deals with the mononuclear organovanadium compounds, divided into compounds with ligands bonded *via* one, two, three, five, six, and seven C atoms. Polynuclear compounds are discussed similarly in Chapter 2, again in sections on compounds with ligands bonded to the central atom *via* one, two, four, and five C atoms. The volume ends with a formula index of ligands. The main emphasis in the volume is placed on compounds of the classes mentioned earlier, such as bis(π-cyclopentadienyl)vanadium or dibenzenevanadium.

The organochromium compounds are arranged in the same manner in Volume 3. The chapter "Mononuclear Compounds" includes the sections dealing with compounds having ligands bonded to the central chromium atom *via* one, two, three, four, five, six, and twelve C atoms. Chapter 2 first describes dinuclear compounds with ligands bonded *via* one, two, three, four, five, six, and twelve C atoms. Trinuclear, tetranuclear, and polymeric compounds are then described in three chapters.

Both volumes contain shortcomings and inconsistencies in terminology, such as many terms taken too literally from English and different names for similar diagrams, methods, or quantities.

A table of reference substances at the beginning or at the end of a volume for physical measurements that occur very frequently would be useful, as would a list of abbreviations for common solvents. Finally, in the interests of the international readership, the reviewer would suggest that it is worth considering whether the symbol I should be used for the element iodine; this practice is now being followed in some German textbooks, though the official German version of the IUPAC rules for nomenclature in inorganic chemistry prescribes the symbol J.

The two supplementary volumes together are a valuable addition to Gmelin's Handbook. In conclusion, it should be emphasized that like some of the other recent volumes, they are very "readable" in two senses. Despite the concise presentation of the results of the investigations and of the many data, the text can be read continuously. Another contributory factor is the new types that have been used.

Ekkehard Fluck [NB 30 IE]

Handbook of Chemistry and Physics. By *R. C. Weast*. The Chemical Rubber Co., Cleveland, Ohio/USA 1972. 52nd Edit., xxvii, 2313 pp., bound DM 99.80.

A handbook, according to the preface of the 52nd edition of the present work, is an information system in miniature, and what one can retrieve from this system can only be as good as what has been stored in it. This imposes two duties on the publisher: he must strive after quality through expert advice (145 scientists are mentioned by name in the introductory part of the book), and he must try to keep up to date through annually improved, revised, and supplemented editions. The Handbook of Chemistry and Physics is in fact one of the few books (together with hotel guides and street plans) that are good for only one year, since they have already been improved by the time the next year comes.

The 52nd edition again contains a number of new tables, including the permissible intake of radionuclides by man, the equivalent conductivities of aqueous halohydric acids, the thermal properties of pure metals, and standard test sieves, to name but a few that are of interest to chemists. Chemistry is rightly named first in the title of the book, since out of a total of about 2300 pages (on India paper), nearly 70% carry exclusively, and the remainder predominantly, tables and data of a chemical nature. The publishers have made a start with the conversion of all the units used in the Handbook to the new SI system.

In this age of data banks and computers, anyone who would like to have his own compendium (because it rarely fails, and because its use requires only a sharp eye and a moist forefinger) will find the best solution in this work, which, as always, is supplied with 23 carat gold leaf for inscribing one's own name on the cover. What electronic data processor can offer *that*?

Helmut Grünewald [NB 41 IE]

Stabilisierung und Alterung von Plastwerkstoffen (Stabilization and Aging of Plastics). Vol. 2. Aging of Plastics. By *K. Thinius*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. 1st Edit., 498 pp., 95 figures, 58 tables, cloth DM 84.—.

As in the first volume[1], the author has again collected a large body of experimental material originating in his school or taken from the literature, which is relatively fully evaluated up to about 1968/1969. The excellently chosen and expertly described subject matter is divided into seven chapters and provided with subject and author indexes.

In Chapter 1, the aging processes are defined, and general principles and problems of aging investigations on plastics are described. The equipment and methods presented in Chapter 2, for the aging of plastics are discussed critically, with the inclusion of many details from the author's own experience. Detailed data on weather and radiation rela-

tions in outdoor weathering and artificial irradiation and weathering fit well into this discussion. The description of methods for checking biological damage provides a full insight into this special field.

Chapter 3 gives a number of methods for the recognition and determination of aging processes. These lead over to Chapter 4, in which the results of natural aging are described, and to the results of artificial aging in Chapter 5. These two comprehensive chapters contain many results of the author's own investigations and experience and numerous detailed findings. The literature has been critically scanned, and here again many single results have been reported. The separation of Chapters 4 and 5 on the basis of the type of aging is very appropriate in view of the different problems that arise in natural and in artificial weathering.

Chapter 6 deals with the increasingly important problem of the relation between the results of aging under natural and under experimental conditions. The author here exercises the necessary restraint not to overgeneralize. Chapter 7 gives only a loose survey of theoretical views on the mechanism of the aging process. There has been no critical sorting to present a picture of current ideas.

It is understandably not easy to deal in an easily comprehensible manner with the many aspects of this subject in about 450 pages. The numerous results collected from the literature and the notable investigations of the author and his students, who are outstanding experts on stability problems in plastics, is unfortunately presented too unsystematically and unclearly. Parts of the book are merely successions of individual results and conclusions. It is therefore difficult to use the book as a reference work, which would have been of great value in view of the volume of reading matter that is currently in existence. For those who are directly concerned with this many-faceted field, it is tedious to read through the book, but still worth the effort.

Chemical Synthesis of Polynucleotides[**]

By K. L. Agarwal, A. Yamazaki, P. J. Cashion, and H. G. Khorana[*]

Current methodology for the chemical synthesis of short chains (up to about twenty nucleotide units) of deoxyribopolynucleotides is reviewed.

1. Introduction

Methods have been developed in recent years for the chemical synthesis of short deoxyribopolynucleotide chains[1]. The availability of the synthetic deoxyribopolynucleotides with completely defined nucleotide sequences has permitted precise studies on the problems of protein biosynthesis, on the genetic code, and on DNA and RNA polymerases. Further studies of the biological functions of DNA at macromolecular level will also require the synthesis of bihelical products with defined nucleotide sequences. To this end, a general methodology has been developed which has been successfully used in the total synthesis of the gene corresponding to yeast alanine tRNA[2] (Fig. 1).

[*] Dr. K. L. Agarwal, Dr. A. Yamazaki, Dr. P. J. Cashion, and Prof. Dr. H. G. Khorana
Departments of Biology and Chemistry,
Massachusetts Institute of Technology
Cambridge, Massachusetts 02139 (USA)

Presented at the XXIII International Union of Pure and Applied Chemistry, Boston, July 1971.

[**] The following abbreviations have been used:
Ac = acetyl
An = anisoyl
iBu = isobutyryl
Bz = benzoyl
DCC = dicyclohexylcarbodiimide
Me = methyl
MMTr = monomethoxytriphenylmethyl (= monomethoxytrityl)
MS = mesitylenesulfonyl chloride
TEAB = triethylammonium hydrogen carbonate
TPS = 2,4,6-triisopropylbenzenesulfonyl chloride
Tr = triphenylmethyl (= trityl)

The methodology developed consists of the following three steps: 1. Chemical synthesis of deoxyribopolynucleotide segments containing eight to twelve nucleotide units. These should represent the entire two strands of the intended DNA and those belonging to the complementary strands should have an overlap of four to six nucleotides (see Fig. 1). 2. Enzymatic phosphorylation of the 5'-hydroxyl group with ATP carrying a suitable radioactive label in the γ-phosphoryl group in presence of T4 polynucleotide kinase. 3. The head-to-tail joining of the appropriate segments when they are aligned to form bihelical complexes using T4 polynucleotide ligase.

It is clear that the concept outlined in the above strategy will continue to form the basis of future syntheses of genes[2a] and manipulation of synthetic or natural DNA. Because of the relative rapidity with which steps 2 and 3 described above can be carried out, the progress-determining step in rapid and efficient syntheses of DNA will undoubtedly be the chemical synthesis of the deoxyribooligonucleotides. The aim of the present paper will principally be (1) to review the methodology which is currently available, (2) to describe some recent improvements and refinements which have been effected in our laboratory, and (3) to briefly mention the outstanding problems awaiting satisfactory solution.

2. Synthesis of the Internucleotide Bond and the Protecting Groups

The synthesis of the simplest dinucleoside phosphate, thymidylyl-thymidine (TpT), is shown in Figure 2.

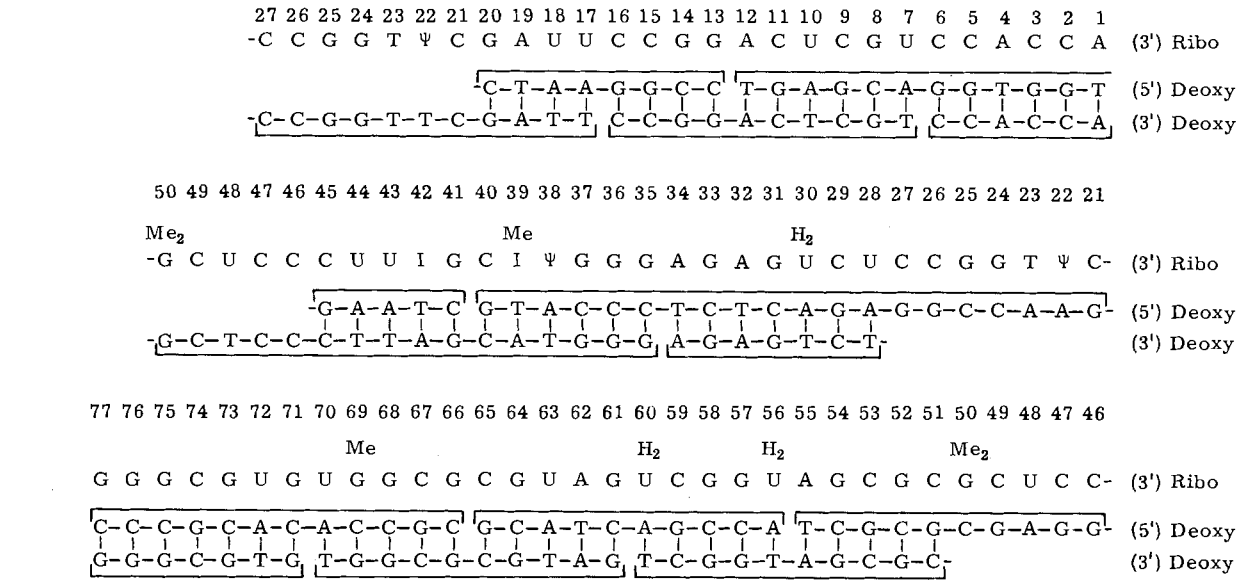

Fig. 1. Total plan for the synthesis of a $tRNA_{ala}$ gene. The chemically synthesized segments are shown in the brackets. 1st row, serial numbers; 2nd row, sequence of tRNA; 3rd and 4th row, sequence of the two strands of the $tRNA_{ala}$ gene.

In a synthesis of this kind one must note that: 1. The 5'-hydroxyl group of the nucleoside component is blocked by the classical bulky trityl group which can be removed by acid treatment when desired. 2. The 3'-hydroxyl of this component is free. 3. The second component involved in the reaction is a 5'-mononucleotide whose 3'-hydroxyl group is blocked by an acetyl group. This group is removed by very mild alkaline treatment when required. 4. The phosphate group has been used as the monoesterified component directly for the condensation step. An approach where diesterified nucleotide components were used has been suggested by *Eckstein, Letsinger*, and *Reese*, and their coworkers[3].

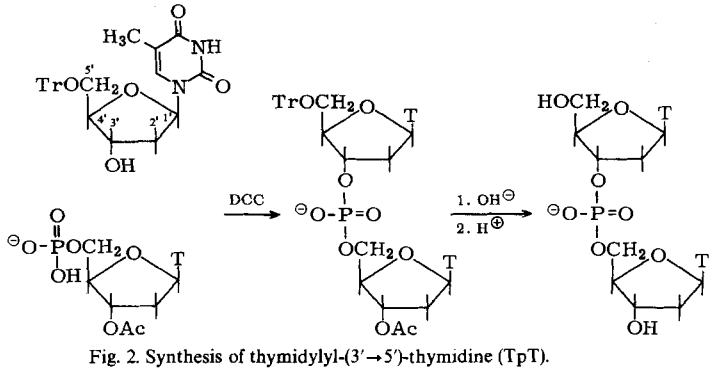

Fig. 2. Synthesis of thymidylyl-(3'→5')-thymidine (TpT).

These two components (Fig. 2) appropriately protected were condensed with dicyclohexylcarbodiimide (DCC). The condensing agents (Fig. 3), apart from DCC, currently used by us and others are aromatic sulfonyl chlorides, in particular mesitylenesulfonyl chloride (MS)[4] and 2,4,6-triisopropylbenzenesulfonyl chloride (TPS)[5]. The reason for using the trisubstituted aromatic sulfonyl chloride is to avoid sulfonation, especially of the 3'-hydroxyl end of the nucleoside or oligonucleotide component in deoxyribo-

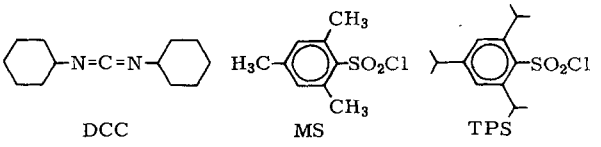

Fig. 3. Condensing agents dicyclohexylcarbodiimide (DCC), mesitylenesulfonyl chloride (MS), and 2,4,6-triisopropylbenzenesulfonyl chloride (TPS).

oligonucleotide synthesis. The activation of phosphate by DCC, MS, or TPS and the condensation of this activated intermediate with the 3'-hydroxyl of the nucleoside component is usually carried out in one step in anhydrous pyridine.

In a condensation reaction mixture, protected dinucleoside phosphate is the main product; the other minor products are the unreacted nucleoside derivative, and unreacted 3'-acetylated nucleotide component and its symmetrical pyrophosphate. The protected dinucleoside phosphate blocked at both the 3' and 5' ends is isolated by an organic solvent extraction procedure. Mild alkaline treatment hydrolyzes the acetyl group from the 3'-hydroxyl end. Under these conditions the trityl group blocking the 5' end is completely stable.

This product can now be used for further extension of the chain simply by reaction with another nucleotide component blocked at its 3'-hydroxyl end by an acetyl group. Repetition of the condensation and alkaline treatment followed by purification of products yields a polynucleotide of desired chain length. At the end of the synthesis the trityl group is removed by acidic treatment.

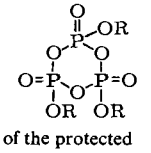

Fig. 4. Trimetaphosphate formed in the DCC reaction of the protected mononucleotide. R = amino protected nucleoside.

The mechanism of activation of phosphate by DCC, MS, or TPS is quite complex. In the case of DCC, it has been shown[6] that the initial phosphorylating species is a trimetaphosphate of the structure shown in Figure 4. The 3'-hydroxyl of the nucleoside component attacks the trimetaphosphate in a nucleophilic fashion to give an internucleotide bond. The trimetaphosphate of this type is a slow phosphorylating species. In the case of the arylsulfonyl chlorides, the activation and condensation steps are much faster, thereby suggesting that trimetaphosphates are probably not the phosphorylating species in this case[4].

We now return to the problem of the protecting groups which becomes important when nucleosides and nucleotides other than thymidine and thymidylic acid are included in the polynucleotide chains to be synthesized. Introduction of deoxyadenosine, deoxyguanosine, deoxycytidine, and their nucleotides in the synthesis of oligonucleotides requires the protection of their amino groups. If their amino groups are not protected, reaction with activated phosphate will be observed at least to some extent during the condensation reactions. The other reason for requiring the protecting groups is to increase the solubility of the nucleoside and nucleotide derivatives.

Selection of the protecting groups now requires the following considerations: 1. 3'-Hydroxyl protecting groups should be easily removed without disturbing the amino and 5'-hydroxyl protecting groups. 2. The selection of the amino protecting groups should be such that they can be removed in one step without affecting the phosphodiester bond, the 5'-hydroxyl protecting group, or the sensitive glycosyl bonds. 3. Conditions used for the removal of the 5'-hydroxyl protecting group should be such that no harm is caused to the intact oligonucleotide chain.

and specific for 5'-hydroxyl group is required. This is obtained by introduction of a *p*-methoxy substituent[8, 9] into the parent trityl group which has made removal possible under very mild acid or buffered conditions without causing any glycosyl bond cleavage. Such a modification of the trityl moiety did not lessen its 5'-hydroxyl group specificity. Introduction of each *p*-methoxy group into one or more phenyl rings increased the acid lability by a factor of 10. Both monomethoxy- and dimethoxy-trityl groups were used in our earlier studies for the protection of 5'-hydroxyl end; the group most favored and currently in use is the monomethoxytrityl group. The acetyl group is still satisfactory for 3'-hydroxyl protection and continues to be used in our current work. Other alternative groups such as β-benzoylpropionyl[10] and methoxyacetyl[11] have been suggested recently for protection of the 3'-hydroxyl group.

The amino protecting groups commonly used in syntheses are anisoyl for the cytosine, benzoyl for the adenine, and isobutyryl or 2-methylbutyryl[12] for the guanine rings. These protecting groups are removed in one step by concentrated ammonium hydroxide treatment without any side reactions. The reason for choosing different protecting groups for different nucleosides and nucleotides is due to their different stabilities. It should be noted that all of the protecting groups have to survive all the chemical manipulations during the very prolonged synthesis of an oligonucleotide.

The reaction shown in Figure 5 is an example of a general method now available for preparing deoxynucleosides containing blocked amino and 5'-hydroxyl groups. Acylation of the unprotected deoxycytidine is carried out with an excess of the acylating agent. The fully protected

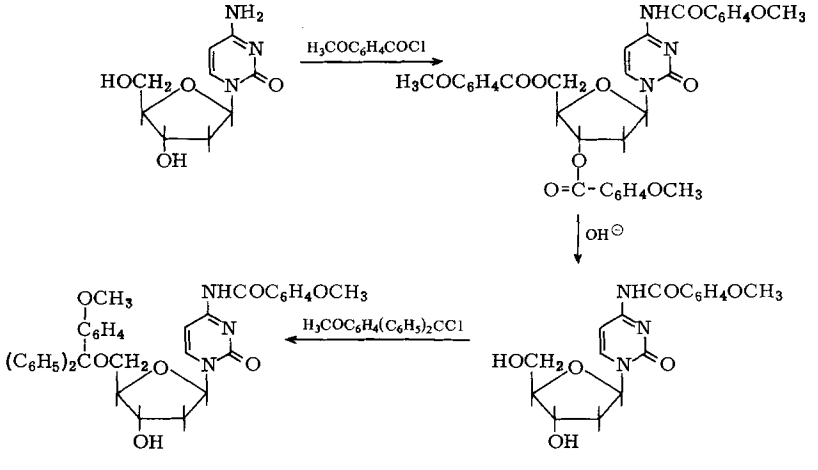

Fig. 5. Preparation of protected deoxycytidine derivatives.

The protecting groups which have already been introduced in the synthesis of thymidylyl-thymidine require reconsideration in the light of these new requirements. While the use of trityl group for the protection of the 5'-hydroxyl end is satisfactory for the synthesis of oligothymidylic acid, acidic conditions required for its removal at the end also cause appreciable cleavage of glycosidic bond in purines. Therefore, a group labile to very mild acidic[7] conditions

derivative thus obtained is treated with alkali under carefully controlled conditions to give the desired *N*-protected deoxycytidine. Selective hydrolysis is made possible by the ionization of the amide group in the aromatic system at alkaline pH which extends the resonating system and thus stabilizes the acyl group on the amino function. The rate of hydrolysis is simply proportional to the hydroxyl ion concentration.

In this way, all of the deoxynucleosides and nucleotides can be obtained in the *N*-protected form. Protection of the 5′-hydroxyl function with monomethoxytrityl group was carried out by the standard procedure used for tritylation. Protection of the amino function of the nucleotides followed the procedure described for the nucleosides. Protection for their 3′-hydroxyl group was carried out by treatment with acetic anhydride in pyridine. The three appropriately protected nucleosides and nucleotides (apart from thymidine and thymidylic acid) are shown in Figure 6.

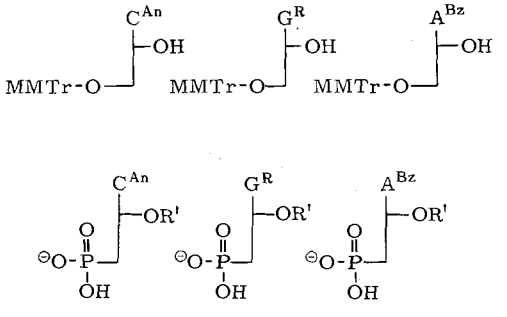

Fig. 6. Protected deoxyribonucleosides and deoxyribonucleotides (schematic). R = isobutyryl or 2-methylbutyryl, R′ = H or acetyl.

3. Synthesis of Higher Deoxyribopolynucleotides of Specific Sequences

The aim of chemical synthesis is to build deoxyribopolynucleotides of defined and specific sequences. Two approaches can be imagined: one in which mononucleotides are added one by one to a growing polynucleotide chain and a second approach involving the use of preformed oligonucleotide blocks to form successively longer chains. Both of these approaches have been investigated systematically and used in synthetic work in the last few years.

3.1. Stepwise Synthesis Using Protected Mononucleotides

The approach used first with greater success was that which involves the stepwise addition of protected mononucleotide units to the 3′-hydroxyl end of a growing oligonucleotide chain[13]. An example is given in Figure 7.

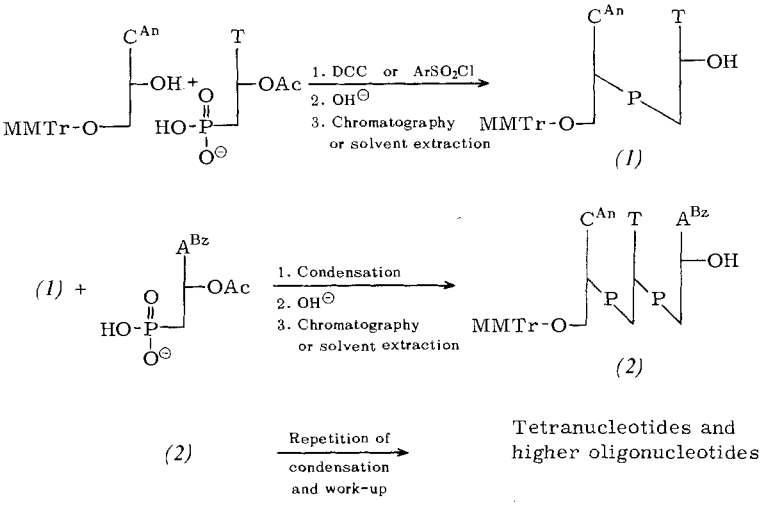

Fig. 7. Stepwise chemical synthesis of tetranucleoside triphosphate or higher oligonucleotides.

Although this approach requires a maximum number of synthetic steps in putting together a polynucleotide chain of desired size, it most often has the advantage of giving high yields in successive condensations. It has been used and continues to be used, either alone or in combination with the blockwise addition approach described below, in a great deal of synthetic work.

3.2. Stepwise Synthesis Using Preformed Protected Oligonucleotides Bearing 5′-Phosphate Groups

The second approach which utilizes preformed blocks[14,15] proceeds faster due to the fewer synthetic steps required for the oligonucleotide synthesis and provides a better system for chromatographic separation. However, the yields at the individual condensation steps are generally lower. On the whole, the blockwise approach is to be preferred in polynucleotide synthesis provided that the preformed protected oligonucleotides, especially the dinucleotides, can be readily prepared in quantity.

3.3. Synthesis of Protected Di- and Higher Oligonucleotides Carrying 5′-Phosphate Groups

Synthesis of the di- or trinucleotide blocks carrying 5′-phosphate end groups requires protection of the phosphomonoester group of the 5′-mononucleotide. Until recently this was done by condensation of the amino-protected nucleotides with cyanoethanol using DCC or $ArSO_2Cl$ as illustrated in Figure 8. The cyanoethylated derivative is

then brought into condensation with the second nucleotide component, appropriately blocked on the amino and the 3'-hydroxyl functions. The condensation is usually carried out with DCC or $ArSO_2Cl$ to give a fully protected dinucleotide. Cyanoethyl and acetyl groups are then removed from the dinucleotide by mild alkaline treatment. Purification of the reaction products is carried out by DEAE cellulose column chromatography, which is time consuming. By repeating the operations (cyanoethylation and condensation) higher blocks are prepared and used directly in the synthesis.

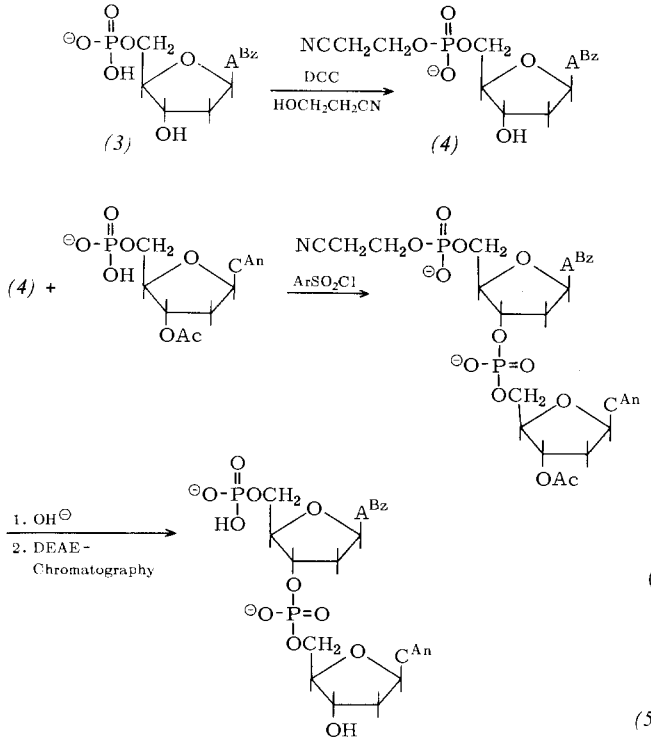

Fig. 8. Synthesis of an *N*-protected dinucleotide carrying a 5'-phosphate end group.

Alternative phosphate-protecting groups have been suggested from time to time and are shown in Figure 9. The trichloroethyl group originally introduced by *Woodward et al.*[16a] in the synthesis of cephalosporin has been suggested as a phosphate-protecting group by *Eckstein*[16b]. This group is removed by treatment with zinc in DMF. Use of substituted phosphorothioate has been suggested by *Nussbaum et al.*[17]. Conversion of phosphorothioate into phosphate was carried out by treatment with iodine in aqueous conditions. The third type, *N*-(*p*-methoxyphenyl)-carbamoylethyl, was introduced by *Narang et al.*[18] and is cleaved by alkaline treatment. The fourth type is a simple aromatic phosphoramidate. Compounds of this type were first prepared by *Moffatt* and *Khorana*[19] and used in the synthesis of nucleotide coenzymes. Recently, *Ohtsuka et al.*[20] have investigated the possible use of aromatic phosphoramidates for protection of the phosphate group and have shown that the amidate group can be cleaved by isoamyl-nitrite treatment under very mild conditions at pH 7.

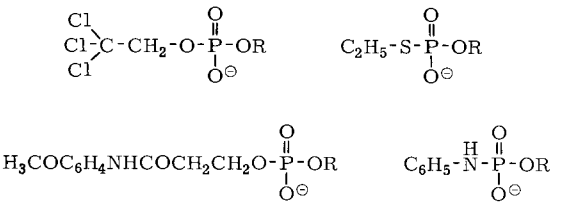

Fig. 9. Nucleosides with phosphate-protecting groups. R = thymidine or *N*-protected nucleosides.

As pointed out above, the greater part of the effort in the preparation of the protected dinucleotide blocks goes into the purification of the synthetic products by ion exchange chromatography, which requires several days. Clearly, a procedure which would eliminate the ion exchange chromatography would certainly reduce the time and effort required for the synthesis of the dinucleotide blocks. With this aim in view, an isolation procedure involving the principle of solvent extraction has been developed[21]. A highly lipophilic amine, *p*-(triphenylmethyl)aniline (see Fig. 10) was used for protecting the phosphate group of the nucleotide as the phosphoramidate. The reason for choosing the phosphoramidate type of linkage was because it could be cleaved by isoamyl nitrite under very mild conditions without any side reactions or loss of other protecting groups. All of the four phosphoramidates of the appropriately protected nucleotides were prepared by reaction of the nucleotide and the amine with DCC. These phosphoramidates were isolated in pure form by simple organic solvent extraction procedures and were shown to exist as the salts of the substituted guanidine. Formation of this guanidine inhibits the DCC reaction which is catalyzed by phosphate. Use of alternative activating agents gave lower yields of phosphoramidates. The phosphoramidate was then condensed with protected mononucleotide in the presence of TPS to give a protected dinucleotide as shown in Figure 11.

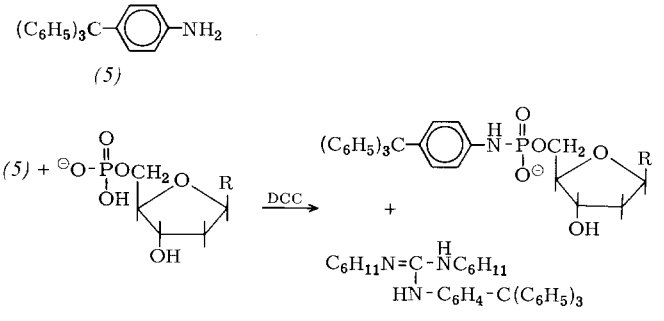

Fig. 10. Synthesis of *N*-protected phosphoramidates of nucleotides. R = thymine, *N*-anisoylcytosine, *N*-benzoyladenine, or *N*-isobutyryl-guanine.

The yields of the various dinucleotides prepared in this manner were in the range of 55 to 70%. The dinucleotide phosphoramidates were isolated free from the mononucleotide and its symmetrical pyrophosphate by solvent extraction. The yield of the dinucleotides protected on the amino functions were in the range of 50 to 65% determined after isoamyl-nitrite treatment. All the sixteen dinucleotides could be prepared in relatively short time and well characterized.

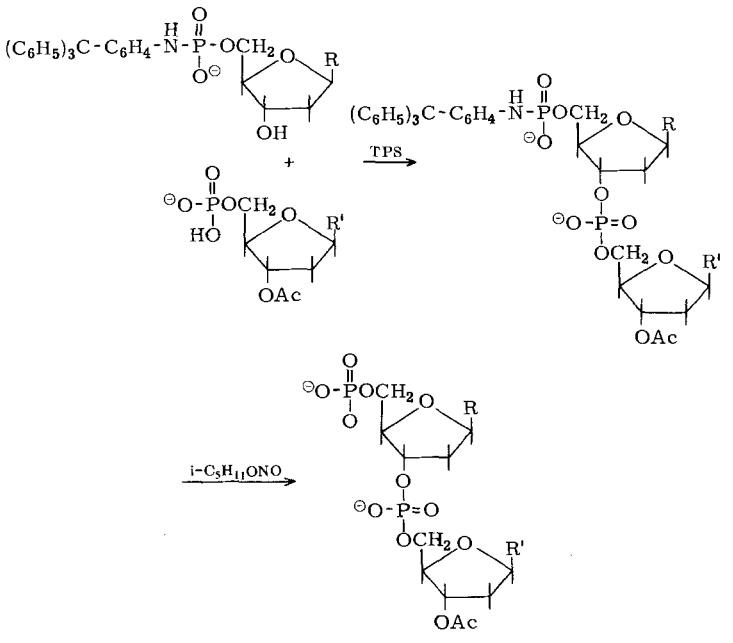

Fig. 11. Synthesis of *N*-protected dinucleotide using *p*-(triphenylmethyl)aniline as the 5′-phosphate protecting group [21]. R or R′ = thymine, *N*-benzoyladenine, *N*-anisoylcytosine, or *N*-isobutyrylguanine.

3.4. Synthesis of an Icosanucleotide

The approach using preformed oligonucleotide blocks, as mentioned above, is potentially more useful and continues to be used extensively in current work on polynucleotide synthesis. This is further illustrated by its use in the stepwise synthesis of the icosanucleotide complementary in sequence to nucleotide 21 through 40 of ala-tRNA (see Fig. 1). The synthetic steps used are shown in Figure 12. The bottom line shows the ultimate product.

The synthesis started from the 5′-end of the chain with guanosine whose 5′-hydroxyl function was protected with the monomethoxytrityl group and the amino function with isobutyryl. This was first condensed with the mononucleotide $pA^{Bz}OAc$ and the product dinucleoside phosphate was isolated by solvent extraction. Further steps involved the condensations between the 3′-hydroxyl end of the growing chain and the appropriately protected mononucleotide or di-, tri-, and tetranucleotide blocks.

At each step, the products were purified by prolonged ion exchange chromatography on DEAE cellulose. The purity of these compounds was further checked before use in the subsequent steps as follows:

1. Extensive paper chromatography of the products before and after removal of the protecting groups.

2. Determination of nucleoside and nucleotide ratios after enzymatic hydrolysis of the unprotected products.

3. DEAE cellulose chromatography in urea, a technique developed by *Tener et al.*[26] which offers very high resolution.

In syntheses of this kind, the yields tend to drop as the chain length increases and the use of large amounts of blocks becomes necessary—and even then the yields of the desired final products are only moderate in the final stages. It is, therefore, important that the choice of blocks is made after careful considerations, *e.g.*, condensations between two purines must be avoided if possible because of the low yields obtained. Pyrimidine to pyrimidine condensations are mostly favored because of the satisfactory yields obtained. The size of the blocks sometimes becomes very important because it determines the total negative charge difference between the starting chain and the product, which plays an important role in the separation of polynucleotides on ion exchange chromatography. A typical separation profile on DEAE cellulose chromatography of the reaction mixture obtained in condensation of hexadecanucleotide and tetranucleotide is shown in

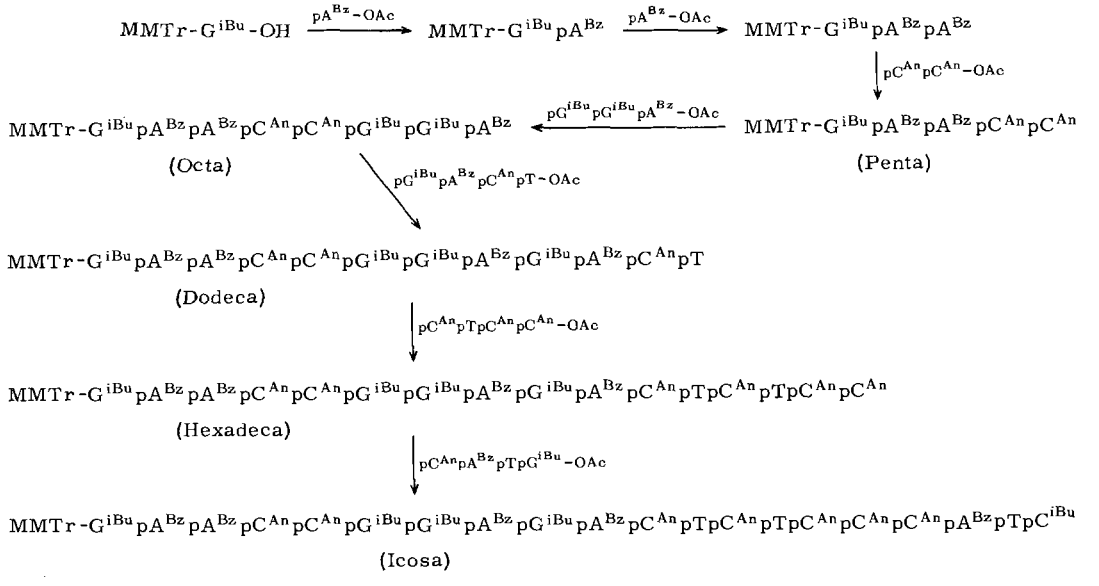

Fig. 12. Chemical synthesis of an icosanucleotide using preformed blocks.

Figure 13. The tetranucleotide block carried a tritium label so that the icosanucleotide could be distinguished from the hexadecanucleotide. Peak IV was identified as the icosanucleotide and had a constant ratio of radioactivity to ultraviolet absorbance.

formed in the synthesis of a hexanucleotide on trityl cellulose is shown in Figure 15.

The solid line shows the UV absorption and the dashed line shows the trityl estimation. Products eluted first

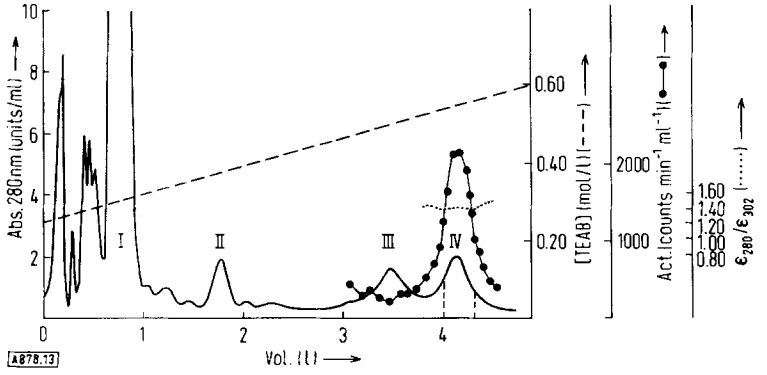

Fig. 13. Condensation of a protected hexadecanucleotide with a protected tetranucleotide (see Fig. 12). Separation of the reaction products on a DEAE cellulose (bicarbonate) column (1.8 × 60 cm) preequilibrated at 4 °C with 0.05 M triethylammonium bicarbonate (TEAB) (pH 7.5) in 40% ethanol. The bicarbonate concentration gradient used for elution was as shown by the dotted line, the solvent being 40% ethanol.

3.5. Use of Trityl Cellulose in Purification of Condensation Reaction Mixtures

The purpose of this new column adsorbent is best explained by examining the reaction products in a typical condensation reaction (Fig. 14).

1. The first type of product contains a monomethoxytrityl group at its 5'-hydroxyl function. These comprise the unreacted MMTr component and the required product.

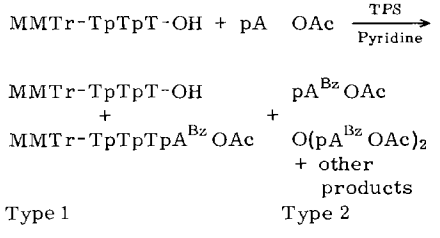

Fig. 14. Nature of products formed in a condensation reaction.

2. The second type of product includes the unreacted nucleotide and its pyrophosphate. Selective adsorption of the first type of products and consequent separation from the second type have recently been investigated using naphthoyl cellulose and trityl cellulose as the column adsorbents. The adsorbed products can then be eluted from the column simply by raising the alcohol concentration to 90%. Naphthoyl cellulose was found to be rather unstable due to the slow hydrolysis of the ester bond in presence of triethylammonium bicarbonate (TEAB) pH 7.5 to 8.0. Trityl cellulose is found to be quite stable under these conditions and is now being routinely used in our synthetic work. The elution profile of a reaction mixture (Type 2) with low alcohol concentration (45%; 0.05 mol/l TEAB) were free from trityl-containing components. When all the second type of products were washed off with low

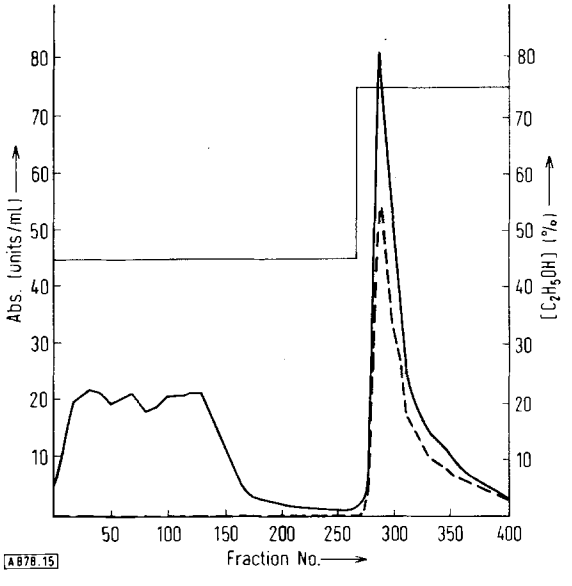

Fig. 15. Purification of condensation reaction mixture of MMTr—TpC^{An}pG^{iBu}pA^{Bz}OH and pC^{An}pC^{An}—OAc on trityl cellulose. ——, absorption at 280 nm; – – –, absorption at 472 (corresponds to content of monomethoxytrityl groups); ——, ethanol concentration.

alcohol concentration, the alcohol and TEAB concentrations were increased to 75% and 0.5 mol/l TEAB to elute the trityl-containing products. Examination of these products (Type 1) by extensive paper chromatography showed the absence of Type 2 products. Type 1 products were further purified by DEAE cellulose chromatography. A separation pattern is shown in Figure 16.

Only trityl-containing components were eluted from the column and the pattern thus obtained is relatively simple. This example clearly indicates that the introduction of trityl cellulose as a purification step prior to DEAE cellulose chromatography, not only increases the efficiency of the purification, but also reduces the overall time required.

3.6. Polynucleotide Synthesis on Polymer Supports

There has been a great deal of interest in carrying out synthesis of biopolymers on polymer supports. This concept has been used with striking success by *Merrifield* in the synthesis of peptides and enzymes[22], and by *Katchalsky*[23] in the synthesis of insoluble enzymes. Naturally the question arises whether similar concepts can be developed in the polynucleotide field. This would accelerate the synthesis of polynucleotides and would avoid separation of products at every condensation step. A number of groups have been investigating various approaches. We, ourselves, have investigated both insoluble and organic-solvent-soluble polymers[27] for this purpose, as suggested by *Shemyakin et al.*[24]. This concept is very attractive because the condensation reactions could be carried out in homogeneous medium. In our approach, commercially available polystyrene was converted into a polymer containing a few percent of methoxytrityl chloride groups by the reaction sequence shown in Figure 17.

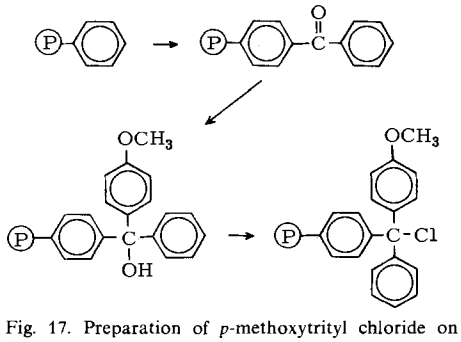

Fig. 17. Preparation of *p*-methoxytrityl chloride on a polystyrene backbone. Ⓟ = polystyrene backbone.

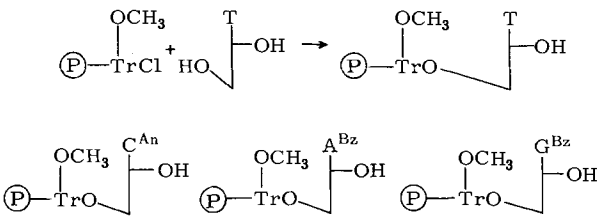

Fig. 18. Preparation of 5′-methoxytrityl-*N*-protected deoxyribonucleosides linked to a polystyrene backbone (= Ⓟ).

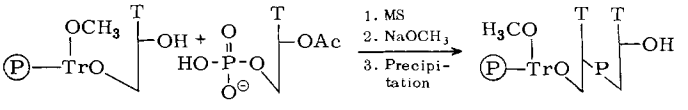
Deoxynucleosides appropriately protected on their amino functions were then allowed to react with this polystyrene derivative to give all four 5′-*O*-protected deoxynucleosides linked to a polystyrene backbone (Fig. 18). The subsequent chain elongation by stepwise addition of appropriately protected mononucleotides gave di- and trinucleoside phosphates as shown in Figure 19.



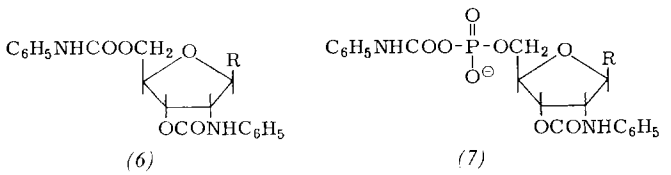


Fig. 19. Synthesis of a dinucleoside phosphate on a polystyrene backbone (= Ⓟ).

At the end of the synthesis the products were removed from the polymer by acid treatment. Although the yields were quite high in the condensation steps, they were not close to quantitative. A similar technique was investigated independently by *Cramer et al.*[25]. This approach seems quite promising but there are still some problems to be solved.

3.7. Selective Blocking of the 3′-Hydroxyl End Groups in Protected Deoxyribooligonucleotides

One main problem in the synthesis of deoxyribopolynucleotides is that the yields of the individual condensation steps are not quantitative. Synthesis cannot therefore be carried out on polymer supports because sequential isomers would result. Synthesis in solution requires time-consuming separation of starting material and elongated chain. An important advantage would accrue if the 3′-hydroxyl end groups in the unreacted components could be *specifically* and *quantitatively* blocked. A method of doing so has been found[28].

Aromatic isocyanates have been found to react with the appropriately *N*-protected nucleosides to give dicarbamoyl derivatives *(6)* (Fig. 20) in quantitative yields. Fully protected nucleosides (3′,5′-hydroxyl and amino functions appropriately blocked) did not react with the aromatic isocyanate. On the other hand, mononucleotides protected on the amino function reacted with aromatic isocyanate to give dicarbamoyl derivatives *(7)* (Fig. 20), the reaction occurring with the 3′-hydroxyl and the phosphomonoester groups. Phosphodiesters (internucleotide bonds) were resistant to aromatic isocyanate reaction, *e.g.*, the dinucleoside phosphate MMTr-TpG^{iBu}-OH reacted only on the 3′-hydroxyl group to give MMTr-TpG^{iBu}OCONHAr. Higher oligodeoxynucleotides of the size of a pentanu-

(6) (7)

cleotide appropriately protected on the 5'-hydroxyl end and the amino functions were also found to undergo quantitative reaction with the aromatic isocyanate on the 3'-hydroxyl group.

A practical application of the principle of blocking the 3'-hydroxyl end after every condensation step has been made in the synthesis of a pentanucleotide. The synthetic steps

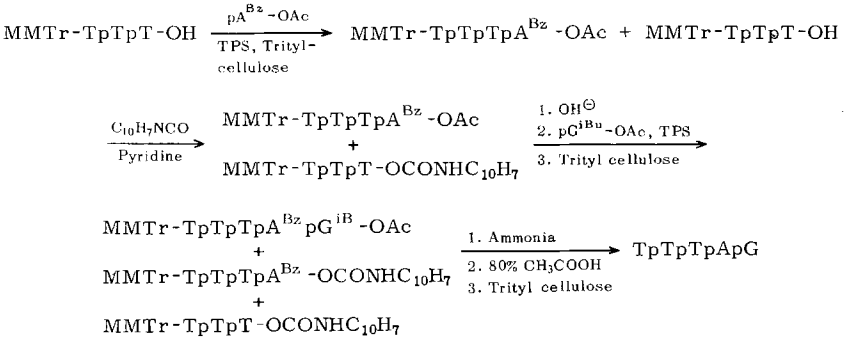

Fig. 21. Synthesis of a pentanucleotide.

are shown in Figure 21. After the condensation, the reaction mixture was first partially purified on trityl cellulose and then treated with naphthyl isocyanate to block the unreacted 3'-hydroxyl groups. Starting from a trinucleotide, the cycle: addition of appropriate mononucleotide, purification on trityl cellulose, and reaction with naphthyl isocyanate is repeated twice to give a pentanucleotide. At the end of the synthesis, the protecting groups were removed by standard procedures followed by filtration through trityl cellulose. The oligonucleotides bearing the 3'-naphthylcarbamoyl groups were selectively retained on the trityl cellulose whereas the product was present in the eluate. The product was about 90% pure. The application of this approach is now being studied in detail for the synthesis of oligonucleotides in both solution phase and solid phase synthesis.

Perspectives in Nonsteroidal Anti-inflammatory Agents

By T. Y. Shen[*]

Among numerous nonsteroidal anti-imflammatory agents synthesized in the past few years, various analogs of indomethacin, phenylacetic acid and heteroarylacetic acid have reached the stage of clinical evaluation. Their biochemical mechanisms of action are exemplified by the broad activity profile of indomethacin which includes inhibition of mediators and enzymes, effects on cell membranes, and, most recently, inhibition of prostaglandin biosynthesis. The importance of pharmacodynamic properties to clinical efficacy was clearly demonstrated in some cases. Several candidates were eliminated because of their side-effects. A group of α-methylarylacetic acids showed a high degree of stereospecificity in their potency and metabolisms *in vivo*, as well as inhibition of prostaglandin synthetase and albumin binding *in vitro*. Extrinsic Cotton effect provides a sensitive technique in the study of interactions of these drugs with biopolymers. Competitive binding and antagonistic interactions between nonsteroidal drugs, particularly salicylate, were observed *in vitro* and *in vivo*. Progress in salicylate research was marked by the synthesis of flufenisal as a new derivative with enhanced potency and longer duration of action. Several fenamate analogs and new chemical types have shown promise in preliminary clinical trials. Various immunological approaches are under investigation for the treatment of rheumatoid arthritis. Newer concepts are still needed to achieve more effective control of arthritic disorders.

1. Introduction[1]

Despite the intensive and ever-increasing efforts in anti-inflammatory studies during the past decade, the treatment of rheumatoid arthritis remains a major challenge for biologists and medicinal chemists alike. A better understanding of the disease, particularly its etiology and pathogenesis, the development of more significant animal models, new medicinal chemical concepts and novel chemical structures are still much needed to achieve a major breakthrough in this difficult field.

As was noted in the Annual Report in Medicinal Chemistry for 1966[2], a wide-spread interest in the search for new anti-inflammatory agents at that time was evidenced by the disclosure of more than one hundred groups of anti-inflammatory structures in the patent literature within one year. This feverish pace of screening and synthesis has apparently been maintained, if not accelerated. However, judging from the scientific literature, apparently only a small number of leads showed adequate potency and short-term tolerance to merit further consideration. An even smaller fraction of these eventually qualified as preclinical candidates after chronic toxicity studies. This process of elimination of anti-inflammatory compounds is certainly a costly and frustrating one.

Since the general background of arthritis research, *e.g.*, clinical aspects[3-6], pharmacological studies[7-10] and new active structures[11,12], is regularly reviewed by many excellent articles, the main emphasis of this review will be on the current status of a selected group which has advanced to the clinical stage or beyond. The selection is necessarily limited by the scarcity of clinical data on new drugs under development, but it may help to focus the attention of medicinal chemists on a few significant compounds among a maze of literature claims. It is also hoped that by examining the case history of these examples, the success of very few, the near-miss of many, the limitation of their clinical efficacy and, most of all, the tremendous amount of time and effort invested by so many will illustrate some critical problems in the field of arthritis research and underscore the need for realignment of our strategy and biological approaches.

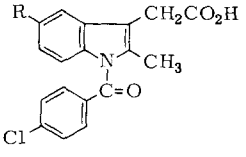
2. Arylacetic Acids

2.1. General

Interest in arylacetic acids as nonsteroidal anti-inflammatory agents was developed independently in several laboratories about 15 years ago. Although not explicitly considered by the investigators at that time, it is of interest to note that two plant growth regulators, indolylacetic acid and phenoxyacetic acid served as the basic structure for the earlier studies at Boots[13] and at Merck[14]. Hydrophobic substitutions, so effectively employed as activity-enhancing groups in many pharmacological agents, in the form of aryl, aralkyl or aroyl, readily converted these plant growth regulators into derivatives highly active in animal assays such as foot-edema, UV erythema, granuloma pellet, and adjuvant arthritis assays[15]. More recently, *in vitro* cytotoxicity and moderate *in vivo* anti-inflammatory activity have also been observed with analogs or derivatives of several other plant regulants[16].



The predominance of arylacetic acids in anti-inflammatory research is reminiscent of the association of antihistaminic activity with diarylalkylamines or central nervous activity

with phenothiazinylalkylamines. Not surprisingly, the optimal aryl moieties seem to be different in each case. Several attempts to interchange the dialkylamino side-chain with an acetic acid in each series resulted in mediocre analogs only[17].

2.2. Biochemical Modes of Action of Indomethacin

The primary modes of action of anti-inflammatory aryl acids are still being elucidated, but it seems likely that they exert a multitude of actions on the complex inflammatory process. Their broad activity-profiles are probably the basis for their rather nonspecific clinical efficacy and also for some potential side effects.

The introduction of indomethacin *(1)*[14,18] appeared to coincide with the recent interest in biochemical pharma-

(1), R = OCH_3 (Indomethacin)
(2), R = $N(CH_3)_2$

cology of nonsteroidal anti-inflammatory agents. As a new reference compound it has been evaluated in various biochemical systems. Although the significance of some observations remains to be substantiated, a selection of its biochemical properties reported in the literature is listed in Table 1. As noted before, most of these properties are commonly shared with other anti-inflammatory aryl acids.

Table 1. The biochemical profile of indomethacin

1.	Effect on Enzymes and Mediators ($10^{-4}-10^{-3}$ mol/l)
1.1.	Inhibition of proteolytic enzymes, *e.g.*, trypsin, α-chymotrypsin and "tissue proteases"
1.2.	Inhibition of histidine decarboxylase *in vitro*
1.3.	Inhibition of lymph node permeability factor (LNPF)
1.4.	Marginal effect on kinin systems, Hageman factor and fibrinolysis
1.5.	Antagonism of slow reacting substances (SRS)
1.6.	Uncoupling of oxidative phosphorylation
1.7.	Inhibition of mucopolysaccharide biosynthesis
1.8.	Stabilization of serum protein
1.9.	Inhibition of prostaglandin synthetase (10^{-6} mol/l)
2.	Effect on Membrane Structures ($10^{-5}-10^{-4}$ mol/l)
2.1.	Stabilization of erythrocytes
2.2.	Inhibition of platelet functions Aggregation and release of mediators
2.3.	Inhibition of neutrophil participation in Shwartzman Reaction
2.4.	Inhibition of fibroblast-leukocytes interaction *in vitro*
2.5.	Inhibition of leukocytes migration Chemotaxis and PMN motility
2.6.	Stabilization of human skin lysosomes *vs.* histamine

The biochemical profile of indomethacin may be broadly described in two parts: inhibition of enzymes and mediators, and effect on cellular membranes. The latter, in particular, seems to be the basis of many recent observations. As shown in Table 1, indomethacin, along with other anti-inflammatory aryl acids, inhibits several proteolytic enzymes *in vitro* at 10^{-4}—10^{-3} mol/l[19,20]. Some of those proteases may be involved in tissue degradation, immunoglobulin metabolism, and the activation of inflammatory mediators[21]. The possible roles of collagenase[22-24] and of a lysosomal enzyme, cathepsin D[25], in the degeneration of arthritic joints have received much attention recently[4]. The recognition of several mammalian collagenases with different pH optima and sensitivity to serum inhibitors suggests caution in interpreting the data obtained from model *in vitro* studies[26].

Interest in histamine as the prime mediator of inflammation has decreased with time. It was found earlier that indomethacin inhibits fetal histidine decarboxylase *in vitro* at a concentration of 0.4 mmol/l[27]. However, *in vivo*, the effect seems to vary with the tissue origin of the enzyme[28,29]. Conceptually, the inhibition of histidine decarboxylase was further complicated by the postulation of an "induced" enzyme[30]. Lymph node permeability factor (LNPF) is an inflammatory mediator derived from lymphocytes and associated with a variety of phenomena involved in delayed hypersensitivity[31]. The factor produces an increase in vascular permeability, leukocyte emigration, and fibrinoid deposition. The vasoactive effects of LNPF are antagonized by indomethacin. On the other hand, indomethacin has little or no effect on the formation and activity of bradykinin[32,33]. It has marginal effect on the activation of the Hageman factor in the dog knee joint[33] and it has very weak activity in fibrinolysis *in vitro*[34].

Indomethacin antagonizes the ability of "slow reacting substances" (SRS-A, SRS-C), arachidonic acid, and bradykinin, to increase the resistance of guinea-pig lungs to inflation[35]. This drug blocks directly the spasmogenic effect of SRS-C[36] and its possible release of an aorta-contracting substance[37].

Most nonsteroid anti-inflammatory agents uncouple oxidative phosphorylation and inhibit the biosynthesis of mucopolysaccharide[38]. The correlation of these properties with anti-inflammatory actions, however, was weakened by the lack of structure specificity and by the pharmacodynamic requirements for *in vivo* activities. The effect of these drugs on the ATP level do not seem to parallel the effect on ^{35}S incorporation[39]. There appears to be no direct correlation between these two actions.

The binding of serum protein by many anti-inflammatory aryl acids and their mutual interference have been well investigated. The ε-amino group of lysine, tryptophan, and tyrosine groups in serum albumin are possibly involved in the three strong binding sites[40]. As a result of the binding, the denaturation of protein is inhibited. Whether the free SH-disulfide exchange[41] is actually involved in pathological protein denaturation *in vivo* remains speculative. Some anti-inflammatory agents displace albumin-bound warfarin and interfere with its anticoagulant action[42], but the alleged effect of indomethacin was refuted[43]. In the clinic, indomethacin does not seem to have any effect on blood clotting in patients undergoing anticoagulant therapy.

The stabilization of protein denaturation was originally proposed by *Mitsushima* as a simple screening assay for compounds with potential anti-inflammatory properties[44]. At concentrations of 0.4 mmol/l indomethacin in-

hibits the heat denaturation of serum albumin[44]. It has been suggested that similar interaction of anti-inflammatory agents with membrane proteins may be the basis of their multiple effects on cells. Indomethacin at 0.05—0.3 mmol/l inhibits the lysis of human and animal erythrocytes induced by heat or hypotonicity[45,46]. It inhibits the *in vitro* aggregation of erythrocytes induced by gelatin or fibrinogen[47]. Indomethacin and salicylate inhibit the aggregation of platelets induced by collagen, epinephrine, ADP, *etc.*[48,49].

A transient but demonstrable effect was produced by a single oral dose of indomethacin in man[49]. At concentrations of 5 μmol/l indomethacin is one of the most potent compounds to inhibit the release of serotonin and other mediators by platelets in the presence of connective tissues, ADP, or other stimulants[50]. It also inhibits the function, though not the migration, of neutrophils in the Shwartzman reaction in rabbits[51] and the interaction of fibroblasts and leukocytes *in vitro*[52]. The membrane effect is further reflected in the chemotactic or migratory properties of cells. Indomethacin decreases the motility of polymorphonuclear leukocytes induced by crystalline urate[53], the migration of bone-marrow derived monocytes to the inflamed site *in vivo*[54], and the infiltration of neutrophils in inflamed rat paw[55]. The effect of anti-inflammatory drugs on the membrane of intracellular granules was demonstrated with the aid of an integrated microdensitometry technique[56]. At a concentration of 5×10^{-5} mol/l indomethacin inhibits the histamine-induced rupture of lysosomes in human skin culture[57]. Unlike steroids, it has no effect on the histamine-induced increasing permeability of the mitochondria.

The stabilization of lysosomal membrane has received a great deal of attention as a potential antirheumatic approach. Recent *in vivo* studies[58,59] with chloroquine showed that daily doses of 120 mg/kg stabilize lysosomes in rat liver *vs.* the damaging effect of hyperoxia and neutral red. It also produces myeloid body formation in liver and heart tissue, presumably by reducing the membrane permeability and thus interfering with the formation of primary lysosomes. Other nonsteroidal anti-inflammatory agents have no pronounced effect on isolated lysosomes at low concentrations[60]. Some confusion in *in vitro* results[61,62] was probably caused by the sensitivity of some experiments to varying pH, temperature, media, and drug concentrations. Progress has been made in the development of artificial lysosome models, but the validity of studying lysosome rupture in an artificial system outside its cytoplasmic environment may require careful consideration.

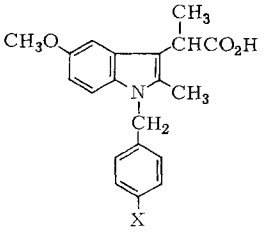
Complement fixation is a recognized process in arthritic joints[63,64]. In addition to its roles in antigen-antibody reaction and hemolysis, it releases in a sequential manner anaphylatoxin, chemotactic factor and prostaglandins. Available anti-inflammatory agents are generally ineffective in controlling this important pathological process.

The anti-inflammatory effect of indomethacin was originally evaluated in the carrageenin foot-edema assay in rats. In searching for the primary mode of action, it was hypothesized recently that the observed reduction of foot-swelling by indomethacin may be attributable to the suppression of migration of monocytes to the inflamed site, thus preventing the subsequent activation of complement or enzymes, formation of prostaglandins, permeability increase, *etc.*[54].

Recently, *Vane* and his colleagues reported that indomethacin and aspirin inhibit the biosynthesis of prostaglandins from arachidonic acid in several tissue homogenates[160], human platelets[161], as well as isolated, perfused, intact spleen of the dog[162]. Prostaglandins have been implicated as mediators of inflammation in several experimental systems including cutaneous inflammation in man[163] and carrageenin foot-edema in rats[164].

The inhibition of their biosynthesis by these two drugs *in vitro* and *in vivo* at levels below their physiological concentrations thus appears to be an attractive mechanism of action[165]. As an extension of these studies we have found that the 5-fluoro analog of indomethacin is a competitive inhibitor ($K_i = 8 \times 10^{-6}$ mol/l) of arachidonic acid ($K_m = 2 \times 10^{-4}$ mol/l) in our *in vitro* system[166]. A large number of nonsteroidal anti-inflammatory agents such as phenylbutazone, indomethacin analogs *(2)*—*(5)*, phenylacetic acids *(11)* and *(12)*, ibuprofen *(19)*, alclofenac *(22)*, naproxen *(24)*, metiazinic acid *(26)*, flufenisal *(33)*, fenamates[*], nifluril *(38)*, azapropazone *(41)*, and several nonacidic compounds (*e.g.*, indoxole and thiabendazole), strongly inhibit the conversion of labeled arachidonic acid into prostaglandin E_2 at 0.1 to 10 μg/ml. The magnitude of *in vitro* activities are approximately parallel with the potency of these compounds in the carrageenin foot-edema assay.

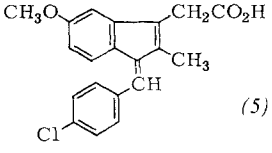
The specificity of the prostaglandin synthetase assay was further demonstrated by the findings that slow-acting antirheumatic drugs, D-penicillamine and chloroquine, and many other drugs such as benemid, disodium cromoglycate, glyvenol, colchicine, *etc.*, are inactive at 10 μg/ml or higher.



Of particular interest is the observation that the high degree of stereospecificity for the anti-inflammatory action of several pairs of α-methylarylacetic acids *in vivo* (see below) is also true for their inhibitory effect upon prostaglandin synthetase. In all cases examined, *e.g.*, *(3)*, *(4)*, and *(11)*, the dextrorotatory enantiomers are much more potent than the levorotatory ones. To our knowledge this is the first stereospecific correlation between an *in vitro* enzymatic effect and the *in vivo* activity of anti-inflammatory arylacetic acids.

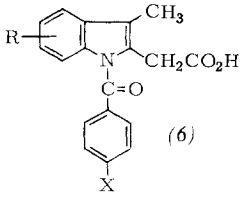
The ability of nonsteroidal anti-inflammatory agents to inhibit prostaglandin biosynthesis has many implications[167]. The central issue seems to be the selective effects of these agents upon different tissues. Drug localization, sensitivity of various prostaglandin synthetases and the changing ratio of prostaglandins E and F may explain the safety and the primary actions of these agents *in vivo*. A better understanding of the basis for tissue specificity is also essential for the broader application of compounds related to these types of structures to other prostaglandin-mediated problems such as asthma, cholera, fertility control[168], *etc.*

[*] Fenamates is the name given to compounds such as mefenamic acid and flufenamic acid.



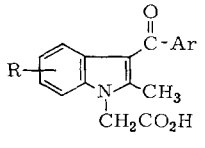
2.3. Indomethacin Analogs

In our study of indole derivatives, two dextrorotatory *N*-*p*-substituted α-(1-benzyl-5-methoxy-2-methyl-3-indolyl)propionic acids *(3)* and *(4)* were first investigated as clinical candidates. The demonstration of their clinical

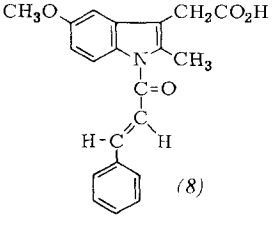


(3), X = Cl
(4), X = SCH_3
(4a), X = OCH_3

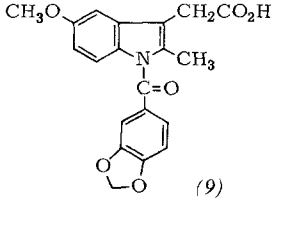
efficacy in man, albeit accompanied by gastrointestinal irritation at 1—2.5 g daily doses, established a reassuring correlation of their animal activity with clinical efficacy. Further study in this series led to the discovery of a more potent analog, indomethacin *(1)*[14]. Subsequently, the 5-dimethylamino analog *(2)*[65] and an indene isoster *(5)*[66] were found to be 1/3—1/2 as potent as indomethacin in animal assays, but with somewhat different metabolic and distribution characteristics[67,68]. Both analogs showed efficacy in clinical tests, but were less well tolerated. Other congeners of indomethacin are still under investigation.



(5)

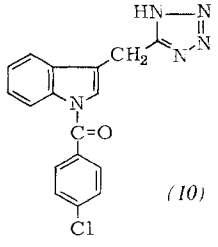


Meanwhile several analogs [*(6)*, *(7)*, *(8)*, and *(9)*] have been investigated by other laboratories. A position isomer *(6)* is described in a patent taken out by Geigy[69] and in some recent reviews, but no testing data are available. According to our previous studies some substituted indole-2-acetic acids appeared to be metastable and readily underwent thermal decarboxylation[70]. Another group of position isomers, the 3-aroyl-1-acetic acids *(7)*, was studied by us and independently at the firms Roussel[71], Geigy[72] and others. In general, they are less potent than analogs in the indomethacin series.



(6)

(7)



(8)

(9)

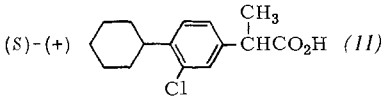
The Sumitomo laboratory in Japan has been very active in developing novel chemical processes for making indoles as well as in searching for newer analogs. The cinnamoyl analog *(8)* has a potency one-sixth that of indomethacin in the carrageenin edema assay and one third in some other assays[73]. The pharmacology of another Sumitomo compound, ID-955 *(9)*, the piperonylic acid analog, has also been described in detail[74]. It is about one-third as active as compound *(8)*.

The Bristol analog, Intrazole (BL-R 743) *(10)*, has a potency of 1/15—1/20th that of indomethacin[75]. Interestingly, the replacement of carboxyl by an acidic tetrazole moiety ($pK_a = 6$) circumvents the metabolic formation of

(10)

acyl glucuronide and thus prolongs its serum half-life[76]. Intrazole does not have the 2-methyl and 5-methoxy substituents which were found to be activity-enhancing in investigations of the indomethacin series. Intrazole appeared to be less irritating in the clinic but its overall assessment probably was less promising than expected.

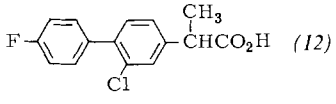
The continued interest in developing new indomethacin analogs is presumably based on the assumption that better-tolerated, even though less potent, derivatives should have clinical utility. This is an attractive approach but is complicated by the poor correlation of animal data with clinical efficacy and by the uncertainty of relating acute animal toxicity to long-term safety in man. The ED_{50}[*] of indomethacin is 2.5 mg/kg in the carrageenin foot-edema assay but only 0.5 mg/kg in the adjuvant arthritis assay. In man, the average daily dose is about 1—1.5 mg/kg. Although indomethacin is 20—80 times more potent than phenylbutazone in the above two assays, in the clinic its potency advantage is only 3—4-fold.



We have demonstrated previously that the toxicity and, to some extent, the metabolism of indomethacin are highly species specific[67]. In the selection of a new drug candidate any derivative which is less potent in animals but has higher plasma and tissue levels or other improved pharmacodynamic properties in man, may indeed be more effective in the clinic. However, the same metabolic differences may render its long-term tolerance in man even less predictable from toxic data of small animals. A remarkable instance of

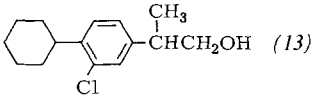
[*] ED_{50} = Dosage required to produce 50% response in the animal assay.

species difference in tissue accumulation and the resulting chronic toxicity was described recently with metazamide[7]. (See Section 5.1.)

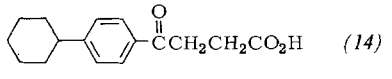


2.4. Phenyl Aliphatic Carboxylic Acids

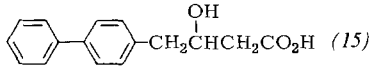
Among many active phenylacetic acids, the most potent compound is probably (*S*)-(+)-3-chloro-4-cyclohexyl-α-methylphenyl acetic acid *(11)* with a potency of 20 times that of indomethacin in the carrageenin foot-edema assay[77,78]. Unfortunately, further development of *(11)*



(11)

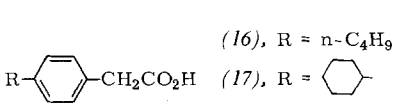


was discouraged by its narrow therapeutic ratio with respect to gastrointestinal irritation and renal papillary necrosis. No significant therapeutic advantage was obtained by replacing the cyclohexyl ring with 4'-fluorophenyl *(12)* or by reducing the acid *(11)* to its alcohol derivative

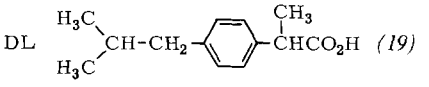


(12)

(13)[78]. Promising anti-inflammatory activities were also demonstrated by phenylbutyric acid derivatives such as *(14)*[78] and *(15)* (BDH 7538)[79,80] but no clinical data are available.



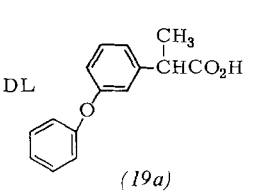
(14)



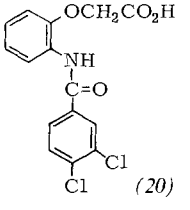
(15)

2.5. Development of Ibuprofen

The development of ibuprofen *(19)* (Brufen®) by Boots' laboratories dates back to their initial interest in *p*-alkylphenoxyacetic acids 15 years ago[13]. A total of 600 compounds have been examined. A notable feature in the Boots' study is their persistent attitude, undoubtedly for good reasons, in testing a series of candidates in the clinic. It was stated that[81] the first candidate, *p*-butylphenylacetic acid *(16)*, produced skin-rash in 50% of patients receiving doses of 2 g/day; the *p*-cyclohexyl analog *(17)* exhibited the same effect. Ibufenac *(18)* did not produce skin-rash and seemed less irritating to the G. I. tract than aspirin, but its clinical application was terminated by hepatotoxicity such as SGOT[*] elevation at high doses[82]. Finally, the α-methyl analog, ibuprofen *(19)*[83], was successfully developed as a mild and well tolerated antiarthritic agent at a daily dose of 0.8—1.6 g[84,85]. It is currently under evaluation by Upjohn laboratories in the U.S. (Further comments on ibuprofen's being a racemic mixture are included in Section 3.)



(16), R = n-C_4H_9
(17), R =
(18), R = i-C_4H_9



(19)

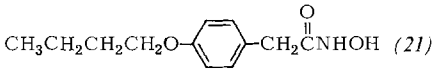
Fenoprofen[85a], DL-α-(3-phenoxyphenyl)propionic acid *(19a)*, is a *m*-substituted analog developed by the Lilly group. It is highly potent in the UV erythema assay in guinea pigs (ED_{50} = 0.5—1.0 mg/kg) but much less active in the rat foot-edema assay (ED_{50} ~ 50 mg/kg) and in febrile rats (at 25 mg/kg). The analgesic effect of (+)-propoxyphene was reported to be potentiated by fenoprofen and also by several other anti-inflammatory acids. The major metabolic conversion of *(19a)* is hydroxylation at the 4'-position. Its clinical trial is in progress.

An *o*-substituted phenoxyacetic acid with structure features resembling an open-chain analog of indomethacin is clamidoxic acid *(20)*[16].

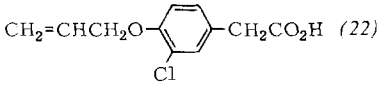
(19a)

(20)

It is equivalent to phenylbutazone in acute anti-inflammatory assays and is now undergoing clinical evaluation.



2.6. Bufexamac and Alclofenac



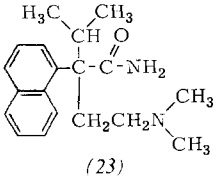
A generally assumed requirement for nonsteroid anti-inflammatory agents is that their mode of action should not be mediated by pituitary-adrenal stimulation and the release of endogenous cortico hormones. Whether a moderate degree of stimulation should always be avoided is controversial among some investigators. The hydroxamic derivative of *p*-butoxyphenylacetic acid, bufexamac *(21)* (Droxary®), represents such an example. Its anti-inflammatory effect in animals is, at least in part, attributable

[*] SGOT = Serum Glutamo-oxaloacetic Transaminase.

to adrenal stimulation[86]. In rheumatic patients it is used at a dose rate of 4 × 250 mg during the day and a 1 g suppository overnight[87]. Unlike most aryl acids it significantly decreases the abnormal sedimentation rate of erythrocyte in arthritic patients. It would be of interest to ascertain the long-term tolerance of this drug. The free acid of bufexamac is very weakly active in animal assays.

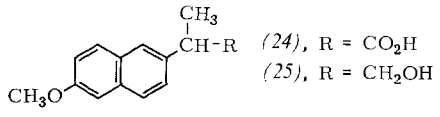
In our study of phenylacetic acids, a *m*-chloro substituent was found to be activity-enhancing[78]. In addition to the example of *(11)*, the 3-chloro derivatives of 4-isobutyl- and 4-cyclohexyl-phenylacetic acid are also more potent than their parent compounds. By combination of the 3-chloro- with the 4-allyloxy-substituents, *Buu-Hoi et al.* obtained alclofenac *(22)* (Mervan®)[88]. A marked species difference in the metabolism and toxicity was again demonstrated by

(21)



(22)

alclofenac[89]. Its LD_{50} is only 45 mg/kg in rats but 300 to 500 mg/kg in dogs and monkeys. The blood level, metabolism, and routes of excretion, *e. g.* urinary *vs.* biliary, also vary drastically with species. Compared with the metabolism of 4-alkylphenylacetic acids the presence of a *p*-allyloxy group apparently favors urinary excretion. Indications are that the allyloxy group is an active metabolic site leading to the formation of several metabolites.

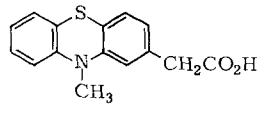


The activity of alclofenac is comparable to phenylbutazone in acute inflammatory assays[88]. However, in osteoarthritic patients it was used at 1.5 g to 3 g daily to match the efficacy of 300 mg phenylbutazone[90, 91]. The higher dosage required may be attributed to its low plasma level and short half-life in man.

2.7. Naphthylacetic Acid Derivatives

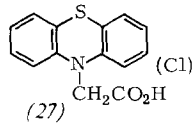
An α,α-disubstituted α-naphthylacetamide, naphthypramide *(23)* (DA-992), has been introduced as a mild analgesic anti-inflammatory agent with moderate muscle-relaxant activity as a useful adjunct[92, 93].

(23)

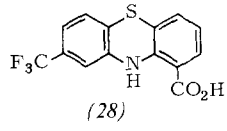


More recently (+)-α-(6-methoxy-2-naphthyl)propionic acid *(24)* (Naproxen) and its (−)-ethanol analog *(25)* (Naproxol) were found by the Syntex group to be potent

(24), R = CO_2H
(25), R = CH_2OH



anti-inflammatory agents[94, 95]. Naproxen possesses an anti-edema activity of *ca.* 1/3 that of indomethacin with similar G. I. irritation properties. Both *(24)* and *(25)* were reported to be in clinical trial.



2.8. Metiazinic Acid

Considering phenothiazine as a fused-ring aromatic moiety, its acetic acid derivative, metiazinic acid *(26)* (Soripal®) was found by the Rhône-Poulenc group to be a clinically

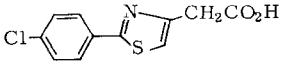
(26)

useful drug[96]. Several years ago, in order to compare the optimal aryl moieties in CNS and antihistamine drugs with those in anti-inflammatory agents, we investigated a number of phenothiazinyl-*N*-carboxylic acids *(27)* and were discouraged by their weak anti-inflammatory activities. In

(27)

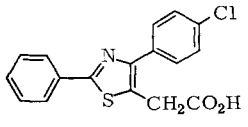
(28)

investigations by the Rhône-Poulenc's group, metiazinic acid was one of the first members of this series to be synthesized; the anti-inflammatory activity was not improved by the evaluation of some 300 analogs. It was tested in 6000 clinical cases over a period of 5 years. The daily doses were 3—6 capsules, each of 250 mg; several minor side-effects were observed[97, 98].



One may recall that the phenothiazine analog of flufenamic acid *(28)* was investigated by Smith, Kline and French a few years ago, but no clinical findings were reported[99].

2.9. Fenclozic Acid and Related Compounds



A less fortunate venture in the field of heteroarylacetic acids was I.C.I.'s fenclozic acid *(29)* (Myalex®)[100, 101]. Fenclozic acid showed early promise as a moderately active compound with a wide-range of tolerance. In short-term assays, such as the carrageenin foot-edema assay, fenclozic acid is comparable to phenylbutazone with an ED_{50} of *ca.* 90 mg/kg. It is four times more effective than phenylbutazone in the adjuvant arthritis assay, both against developing and established arthritis. In rats it was well tolerated at 70 mg/kg for 3 months. A species difference in serum half-life, in favor of man, was also noticed. In fact,

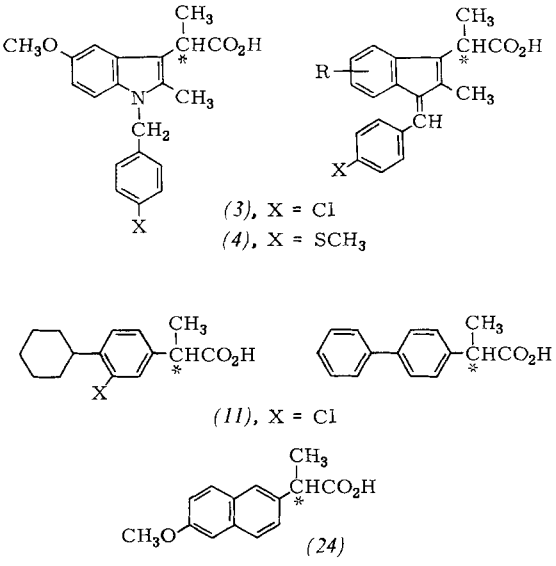
the half-life turned out to be longest in rheumatoid arthritis patients (46 hrs), almost twice that in normal volunteers[102,103]. It was excreted in the urine mainly as unchanged drug or ester conjugates. The clinical efficacy of 300—400 mg of fenclozic acid was comparable to 3.6 g aspirin[104]. However, further development of this drug was terminated by the occurrence of hepatotoxicity[105]. I.C.I.'s workers[106] found that the corresponding oxazole, isoxazole, pyridine, and pyrimidine analogs are less active.

It is of interest to note that the potency of fenclozic acid, on a weight basis, is higher in man than in animals. It is comparable to other arylacetic acids, *e.g.* ibuprofen, metiazinic acid and alclofenac, in animals, yet its effective clinical dose is only 1/4—1/5 times the others. Perhaps it is the pharmacodynamic advantage of fenclozic acid which enhances its potency and, unfortunately at the same time, toxicity in man.

(29)

(30)

A related compound [2-phenyl-4-(*p*-chlorophenyl)-5-thiazolyl]acetic acid *(30)* is undergoing clinical study by the Wyeth group in England[107].



3. Stereospecificity of Arylacetic Acids

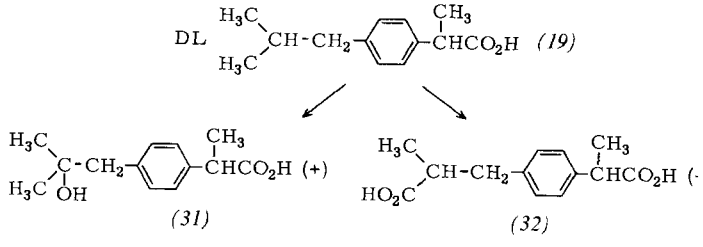
Generally speaking, arylacetic acids constitute a broad anti-inflammatory lead. As we have seen, moderate to good activities are readily found with many combinations of heteroaryl and substituted phenyl groups bearing an acetic acid side-chain. A partial dissociation of activity and toxicity, in terms of its tolerance in man, has been achieved by the fortuitous selection of some aryl moieties.

The object of the game is to find less toxic aryl moieties, but unfortunately not enough data are available to guide a rational approach. The preferred geometry of the aryl groups, their interaction with aromatic amino acids, such as tryptophan and tyrosine, in albumin or membrane proteins, their metabolic stability, their distribution and excretion characteristics *etc.*, have been examined as possible factors. During the past few years we have looked into some properties of the acetic acid side-chain, which is a constant feature of all arylacetic acids, particularly the stereochemistry of the α-methyl group.

3.1. Potency Correlation

In several series the activity of an arylacetic acid is enhanced several-fold by the introduction of an α-methyl group. In most cases, the dextrorotatory isomer, with (*S*) configuration, seems to possess higher, if not exclusive, activity *in vivo*[2]. A recent example is Naproxen *(24)* (see Scheme 1).

(3), X = Cl
(4), X = SCH_3



(11), X = Cl

(24)

Scheme 1. Examples of (*S*)-(+) isomers with higher activity than (*R*)-(−) isomers.

3.2. Preferential Metabolism

In the case of ibuprofen *(19)*, Boots' use the DL mixture; presumably similar activity was found with both optical isomers[83]. Interestingly, a partial analysis of the metabolic mixture showed that only dextrorotatory metabolites had been formed[108]. In metabolite *(31)* the only asymmetric center is present in the acetic acid side-chain. α-Alkylphenyl acetic acid generally gives a plain positive

(19)

(31) *(32)*

Scheme 2. Preferential metabolism of a racemic mixture of iboprufen.

ORD curve[109]. As the sign of rotation is not much affected by *p*-alkyl substitutions, one may assume that this metabolite has the same (*S*)-(+) configuration as the compounds in Scheme 1. With metabolite *(32)* assignment of absolute configuration is complicated by the presence of the second asymmetrical center in the molecule. The stereoselective metabolism of a racemic mixture has been observed in other cases[110]. Further characterization of metabolite *(32)* may shed some light on the specificity of side-chain oxidation of arylacetic acids.

3.3. Biochemical Comparisons

In order to see whether the observed difference in *in vivo* activity of optical enantiomers is really attributable to selective "receptor site" binding, their activities in several

in vitro biochemical systems were examined. With several pairs of substituted indolyl- and phenyl-α-methylacetic acids, no significant difference was observed in erythrocyte membrane stabilization[110], protein denaturation, and uncoupling of oxidative phosphorylation[112]. Both isomers showed inhibitor activity at 10^{-4}—10^{-5} mol/l, roughly parallel with the *in vivo* potency of the dextrorotatory enantiomer. So far, the only demonstration of stereospecificity is the inhibition of prostaglandin synthetase by dextrorotatory enantiomers (see Section 2.2).

3.4. Serum Albumin Binding

Most arylacetic acids have strong affinity for serum proteins, a property which has obvious pharmacodynamic, or even mechanistic, implications. We recently became interested in using the induced Cotton effect to study drug biopolymer interactions. Cotton effect denotes the anomalous change of optical rotation at the wavelength corresponding to the UV maximum of an asymmetrical molecule. A drug such as phenylbutazone is not asymmetric and shows no optical rotation. However,—as aptly described by *Chignall*[113,114]—when phenylbutazone is bound to serum albumin, the interaction between the ligand chromophore and an asymmetric locus at the binding site perturbs the chromophore in an asymmetric manner and induces optical activity. The rotatory dispersion curve of the mixture shows a Cotton effect near the UV maximum of phenylbutazone, this is referred to as an induced, or extrinsic, Cotton effect.

Chignall investigated the comparative binding of phenylbutazone analogs[114] and flufenamic acid analogs[40]. Each group shows three strong binding sites on human serum albumin. The molar ellipticities of drug-albumin complexes are enhanced by hydrophobic interactions and by rigidity of the complex. The change in ellipticity also provides a rapid method for estimating association constants[115]. The binding of drugs such as dicoumarol and warfarin to serum albumin quenches the native tryptophan fluorescence of the protein. The light energy absorbed by the tryptophan groups and nonradioactively transferred to bound warfarin is re-emitted by the drug as fluorescent light. The mean effective transfer distance between the two groups estimated in this way gives an indication of the receptor site structure[116].

Hypothetical "receptor sites" derived from structure activity relationships have often been postulated as working models by medicinal chemists. Until a real receptor site is actually isolated, as in the case of estradiol[117], or possibly, corticosteroids[118], the significance of postulated receptor contours can only be measured by their usefulness in suggesting new and active structure equivalents. For a drug like indomethacin, which possibly executes a multitude of primary actions, one would assume that the optimal structural features are the best fit for several similar but nonidentical binding sites. Since strong serum protein binding is a common characteristic for nonsteroid anti-inflammatory aryl acids, one might use serum albumin as a model to probe the "receptor site" interaction; thrombocyte and erythrocyte membrane preparations[119,120] may serve as other models.

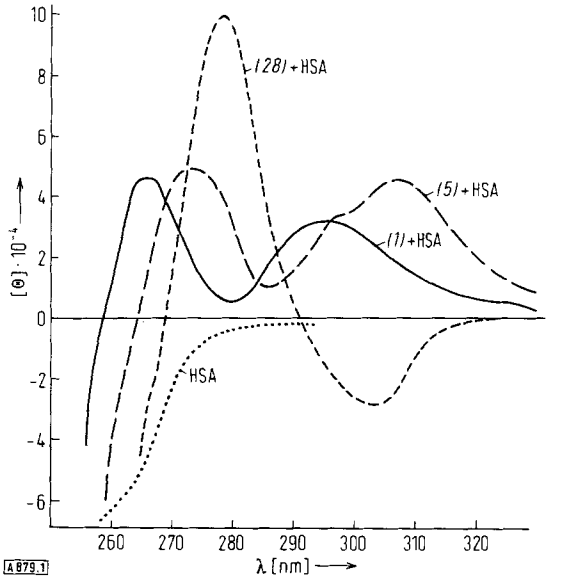


Fig. 1. CD spectra of indomethacin *(1)*, its indene isoster *(5)*, and flufenaminic acid *(28)* in the presence of human serum albumin; HSA = serum albumin alone (phosphate buffer pH 7.4).

Phenylacetic acid derivatives do not produce significant extrinsic Cotton effects in the presence of human serum albumin. The circular dichroic spectra of indomethacin and its indene analog are shown in Fig. 1[121]. The optical activities are in general less pronounced than that produced by flufenamic acid. We are particularly interested in the binding of their α-methyl analogs which have an asymmetric acid side-chain. As mentioned above the stereospecificity of the α-methyl side-chain in *in vivo* activity was not found in a number of *in vitro* assays. If albumin binding involves the acetic acid side-chain in a stereospecific manner one might detect the difference in binding in the circular dichroic spectra of those optical enantiomers. As shown in Fig. 2, the spectra of HSA plus an optical isomer do indeed vary according to the configuration of the α-carbon atom. The difference spectra in Fig. 3 seem to suggest two distinctive groups of binders. The influence of *p*-substituents

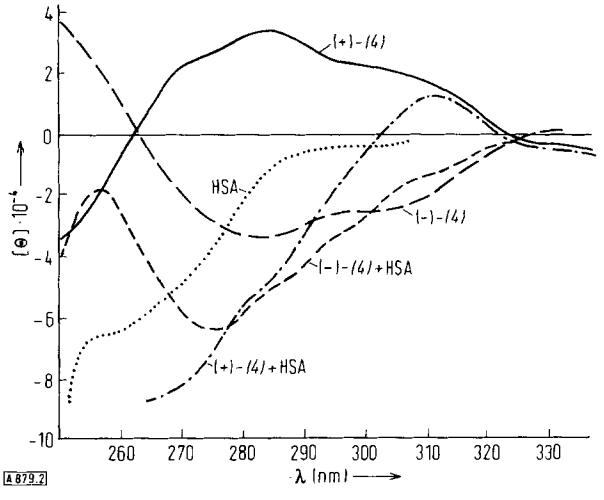

Fig. 2. CD spectra of the enantiomers of α-[1-(*p*-methylthiobenzyl)-5-methoxy-2-methyl-3-indolyl]propionic acid *(4)* with and without addition of human serum albumin (HSA).

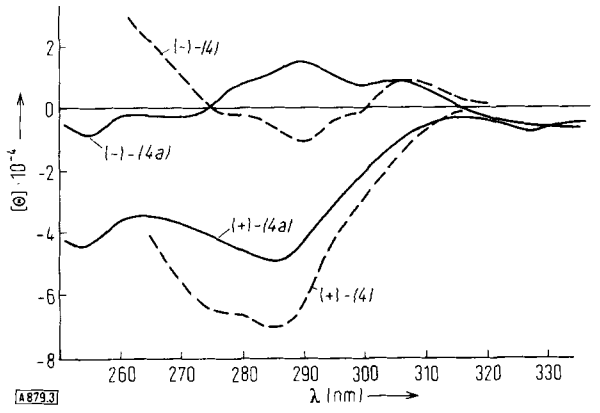

Fig. 3. Difference CD spectra of the enantiomers of α-[1-(*p*-methylthiobenzyl)-5-methoxy-2-methyl-3-indolyl]propionic acid *(4)* and the *p*-methoxy derivative *(4a)* with and without addition of human serum albumin (HSA): [Observed (compound + HSA)] — (spectrum of compound) — (spectrum of HSA).

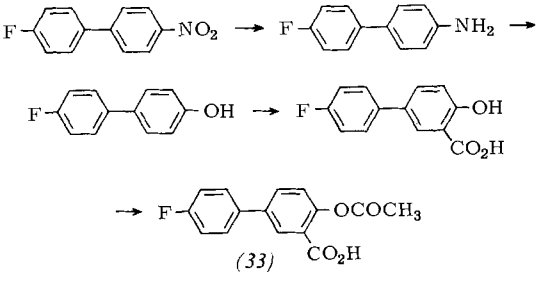
on binding is also observable. As the theoretical implications of an asymmetric side-chain on the extrinsic Cotton effect of a chromophore have not been analyzed, more detailed interpretation of these spectra was not attempted. Further investigations to elucidate the number of binding sites for each group of enantiomers and the competition of common binding sites between enantiomers and among different analogs are in progress. The sensitivity of this technique to steric and electronic environment and the small amount of sample required provide us with a valuable tool for studying drug-biopolymer interaction in solution.

4. New Salicylate Derivatives

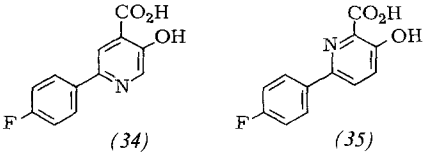
4.1. Objectives and Structure-Activity Relationship



The search for a novel salicylate analog as a superior anti-arthritic drug has been an attractive yet highly elusive goal for many years. In general, the objectives are three-fold: (i) to increase potency, (ii) to reduce gastric irritation, and (iii) to provide a longer duration of action. While various sustained-release and antiacid formulations of aspirin have been developed in recent years to improve the last two properties, no single chemical derivative of salicylate has been uncovered as a superior aspirin analog. In our broad-based research on nonsteroidal anti-inflammatory agents a determined effort was launched several years ago to evaluate a large number of substituted salicylic acid derivatives by the granuloma-pellet and carrageenin foot-edema assays, both of which seemed to be responsive to the anti-inflammatory activity of nonsteroidal drugs such as phenylbutazone, indomethacin, and other experimental agents.

The structure-activity relationships established by previous studies of salicylates[13] have shown that replacement of the *O*-acetyl group by other acyl or alkyl groups and derivatization of the carboxyl group, although beneficial in certain aspects, are generally detrimental to the overall anti-inflammatory-analgesic-antipyretic profile of aspirin. Ring-substitution of salicyclic acid with chloro, hydroxy, methoxy, amino, alkyl groups *etc.*, either diminished activity or increased both potency and toxicity in a nonspecific manner. Similar conclusions were readily verified in our assays with more than 300 salicylates including many newly synthesized analogs.

With salicylates, the establishment of a definitive structure-activity relationship was complicated by the low order of activity of many analogs which were very sensitive to biological variations, and by the apparent lack of additive effects of different activity-enhancing groups. Obviously, with a small molecule like salicylic acid the overall physicochemical and metabolic properties become easily influenced by multiple substitutions. Advantages sometimes occurred in the case of *O*-acetylation of less hydrophobic salicylic analogs, presumably due to an improvement of absorption or distribution. Perhaps more significant was the apparent trend of hydrophobic substitutions, *e.g.* phenyl, 4'-chlorophenyl, and benzyloxy, at the 5-position to enhance the activity of salicylic acid. Interestingly, similar preference of 5-alkyl[122] and 5-halo[123] substituents was recently observed in the inhibition of several enzyme systems by salicylic acid derivatives.



4.2. Synthesis of Flufenisal

The activity-enhancing effect of a *p*-fluorophenyl group in anti-inflammatory agents was well demonstrated by the potency of *p*-fluorophenylpyrazolo[3,2-*c*] steroids[124] and α-(4'-fluorobiphenyl)propionic acid *(12)* which were studied previously in our Laboratories. The 5-(4-fluorophenyl) derivative of aspirin, flufenisal *(33)*, was synthesized as shown in Scheme 3[125]:

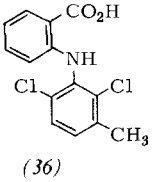
Scheme 3. Synthesis of flufenisal *(33)*.

Other aryl and heteroaryl analogs substituted in position 5[126] as well as two aza isosters of flufenisal *(34)* and *(35)*[127] were also investigated.

4.3. Biological Properties of Flufenisal

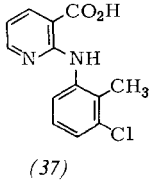
Compared to aspirin, flufenisal *(33)* is 4—5 times more potent in the carrageenin foot-edema and cotton pellet

granuloma assays. In acute gastric hemorrhage test in the rat the ED_{50} for flufenisal was *ca.* 200 mg/kg, almost 15 times the ED_{50} of 14 mg/kg for aspirin. Its analgesia in the yeast-induced hyperesthesia assay was estimated as twice that of aspirin during the first 2—3 hours; but more interestingly, the duration of effect was much longer. Flufenisal is present in the plasma as its deacetyl derivative which is 98—99.5% bound to the plasma protein in equilibrium dialysis experiments. It produces a higher and more prolonged plasma level than aspirin in rats and in dogs. The longer duration of analgesic action has been confirmed in the clinic[128]. Single doses of 300 or 600 mg of flufenisal appeared equal in effectiveness to 600—1200 mg of aspirin in relieving episiotomy pain; further, the duration of action was double that of aspirin.



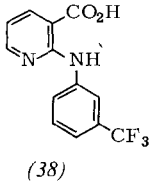
Aspirin has a spectrum of side-effects which are widely recognized but also accepted as reasonable risks by clinicians and patients alike[129]. An up-to-date pharmacological analysis of aspirin summarized its many actions in terms of depression of defensive reactions[130]. Some subtle biological properties, such as potential renal papillary necrosis[131] and *in vivo* acetylation of platelet membrane[132] and serum proteins, have attracted a certain amount of attention. The need to re-evaluate the safety of aspirin has also been suggested[129].

The difficulty in quantifying the anti-inflammatory effect of nonsteroids and aspirin-like compounds has been well documented in recent clinical literature. To improve the time-honored aspirin therapy by a new derivative may well require large-scale and long-term comparative studies. Nevertheless, with flufenisal we have both the encouragement and a new direction for further exploitation of this grand old lead in the arthritis field.



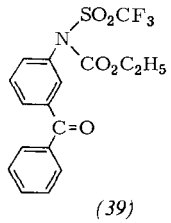
5. Other Chemical Compounds

5.1. Anti-inflammatory Agents

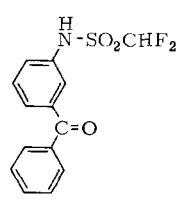


Several members of the fenamate family (mefenamic acid, flufenamic acid), such as meclofenamic acid *(36)* and Sch 10304 *(37)*, are still under clinical evaluation. The propensity of *N*-arylanthranilic acids to produce papillary necrosis in animals has been noted recently[133]. In clinical use, the aza analog of flufenaminic acid, Nifluril *(38)*, seems to be more irritating to the gastrointestinal tract than fenamates.

(36)

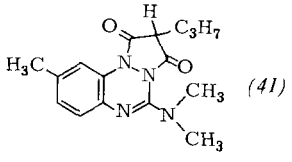


(37)

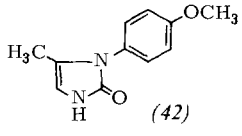


(38)

Two benzophenone derivatives[134], triflumidate *(39)* and diflumidone *(40)* bearing certain structural resemblance to fenamates, showed some promise as effective but less irritating anti-inflammatory agents. The fluorinated methanesulfonylamino groups constituted novel variations of the carboxy group in anti-inflammatory aryl acids.

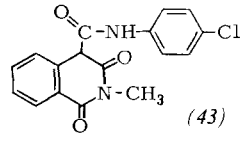


(39)

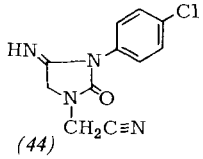


(40)

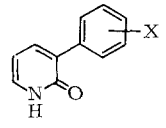
A new antiarthritic drug with a partial structure of phenylbutazone (or generally of 3,5-dioxopyrazolidines) is the azapropazon (MI 85, Apazone®) *(41)*[135]. This compound is generally comparable to phenylbutazone but is more active in the UV erythema assay. The daily dose for man is 0.6—1.2 g, *i.e.* about 2—4 times that for phenylbutazone[136].



(41)

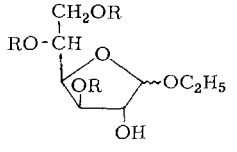


Several aryl lactam derivatives, *e.g.* metazamide *(42)*[6,137], tesikam *(43)*[138,139], nimazone *(44)*[140], and substituted pyridones *(45)*[141], showed activity in animals, apparently



(42)

(43)



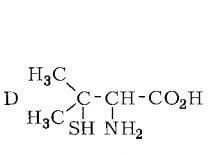
(44)

(45)

with activity-profiles different from aryl acids; however, their further development was curtailed by unexpected toxicities encountered in the clinic or in animals.

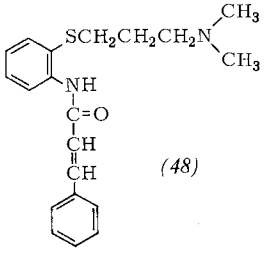
A novel carbohydrate derivative, tribenoside (Glyvenol®, Ciba 21401-Ba) *(46)*, was reported to be antiallergic, antiexudative, and capable of inhibiting antigen-antibody

(46), R = $CH_2C_6H_5$



reaction and capillary stabilization[142]. It was not very effective in the treatment of rheumatoid arthritis patients[143].

5.2. Antirheumatic Agents



Some renewed interest in D-penicillamine *(47)*[144-147] and gold therapy has been noted among rheumatologists

in Europe and in the USA. Both agents have a slow onset, but sustained objective improvements in rheumatic patients are often observed after 3—6 months' treatment. Their clinical application is still somewhat limited by various side effects. Unfortunately, no animal assay is available to aid the development of a superior agent with similar clinical efficacy. The mode of action of D-penicillamine remains speculative. There is not enough evidence to decide whether any of its biochemical properties considered previously, *e.g.* increase of tissue sulfhydryl groups[148], dissociation of macroglobulins[149], metal chelation, pyridoxine antagonism, and inhibition of collagen biosynthesis, play a major role in its antirheumatic action[144].

Immunosuppressants, such as cytoxan[150] and imuran, have been used effectively in severe cases of rheumatoid arthritis, but with anticipated toxicities. The possible application of the less cytotoxic cinanserin *(48)*[151] was precluded by its hepatotoxicity. Contrary to the general

(47)

(48)

assumption, no direct correlation could be made between the clinical efficacy of cyclophosphamide and its depression of several immunological parameters such as rheumatoid factor, serum immunoglobulins, and *in vitro* lymphocyte response *etc.*[152]. The activity of immunosuppressive agents may be enhanced if potential antibody-forming cells are first stimulated by antigen. When administered with antigen the drug suppresses both the primary response and immunological memory. Specific tolerance induced in this way may last for several months[153]. It would be of great interest if the autoimmune component in rheumatoid arthritis could be suppressed by a similar strategy.

Recent interests in the immunological aspects of rheumatoid arthritis have focused attention on abnormal immunoglobulins, complement fixation, degradative enzymes, mediators of delayed hypersensitivity, and deranged metabolic activities of synovial cells in arthritic joints[3]. The current fervor in immunological research may suggest additional approaches to curtail the pathogenesis process of arthritis. Undoubtedly, a new series of non-cytotoxic and narrow-spectrum inhibitors or immunoregulants should emerge from many laboratories in the years to come. Their clinical applications, either alone or in conjunction with conventional anti-inflammatory therapy, may bring forth a new era of antirheumatic treatment.

6. Drug Combinations and Interactions

As indicated above, a major concern in the current search for new antiarthritic drugs is to minimize their side effects. The clinical efficacy of some drugs may be limited not by their intrinsic activity but by their low ceiling of tolerable dosage. A logical approach to circumvent the side effects commonly associated with broad-spectrum nonspecific anti-inflammatory drugs would be the development of a group of narrow-spectrum agents, each acting specifically at one of the many facets of the complex inflammatory process, such as lysosomal enzymes, inflammation mediators, *etc.* A "cocktail" mixture comprising several such inhibitors has been suggested as an ultimate treatment[154]. This futuristic approach of combination therapy is worthy of consideration as we become more proficient in delineating the pathogenesis of various arthritic disorders and in prescribing the optimal combination for individual cases. On the other hand, many adverse problems associated with drug interactions must be very carefully investigated. Perhaps a case in point is the growing awareness of the possible interaction between aspirin and other nonsteroid anti-inflammatory agents. Salicylate is often used concurrently with other drugs in the therapy of arthritis, either by design or unintentionally. In two independent animal studies[155, 156] no cumulative anti-inflammatory effect was observed with combinations of salicylate and other agents. A dramatic antagonism was observed in certain adjuvant arthritis protocol[156], the inhibitor actions of indomethacin, phenylbutazone, and others were markedly diminished by low doses of aspirin given in combination. The mechanism of this antagonism is not clear, although it is reminiscent of the observation that the anticoagulant effect of warfarin is potentiated by aspirin or phenylbutazone through interference with serum protein binding of warfarin[157, 158]. A profound influence of salicylate, but not phenylbutazone, on the metabolism distribution and excretion of indomethacin by rats has recently been demonstrated[159]. Possible factors involved are inhibition of intestinal absorption, alteration of tissue deposition, competitive glucuronide conjugation, and serum protein binding. Whether these laboratory observations are also true in the clinic remains to be verified.

7. Conclusion

In conclusion, the extensive chemical efforts on arylacetic acids, fenamates, and salicylates in recent years have gradually produced a small group of "second generation" clinical candidates of the usual anti-inflammatory-analgesic-antipyretic category. Nevertheless, better tolerated and more effective agents of this type are still needed. Progress towards the elucidation of mechanisms of action of known drugs and the understanding of their potential side effects, such as gastrointestinal irritation, hepatotoxicity, and papillary necrosis, should help in the selection of a safer antiarthritic candidate. It would be interesting to see whether some newer types of active structures under study in many laboratories will lead to the discovery of superior drugs having distinct biological profiles. From the pathogenesis point of view, immunological control seems to offer a new direction with many promising possibilities, but further knowledge and more convincing clinical verification of some concepts are still needed to establish a rational approach with a high degree

of selectivity. To regulate the dynamic network of the chronic inflammatory process, advances in membrane chemistry, immunotolerance, and host resistance, may offer fresh perspectives.

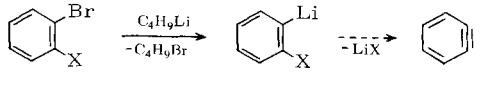
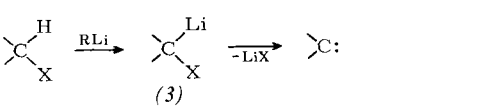
The Chemistry of Carbenoids and Other Thermolabile Organolithium Compounds[1]



By Gert Köbrich[*]

Dedicated to Professor G. Wittig on the occasion of his 75th birthday

Organolithium compounds are thermally quite stable, despite their extremely high reactivity. Thermolability, *i.e.* the property of undergoing irreversible changes at low temperatures without the participation of molecules of a different kind, is associated with additional functional groups, which may be readily eliminated together with the metal cation, may cause intramolecular rearrangements, or may lead to intermolecular additions and substitutions involving several molecules of the same type. Thermolabile organolithium compounds have frequently been postulated or detected as intermediates of important reactions, and are therefore of theoretical and practical interest. If certain precautions are taken, it is occasionally possible (mainly at low temperatures) to prepare them intact, and hence to release them from the constraint of the fate assigned to them as short-lived intermediates. Investigations with this aim have for some time occupied a place of considerable importance in the chemistry of organometallic compounds.



1. Introduction

A high tendency of an organometallic compound to decompose is not synonymous with a low formation tendency. On the contrary, because of their electron-attracting inductive and/or mesomeric effect, the functional groups that are responsible for the thermolability mostly increase the acidity of the neutral molecule from which the organometallic compound is derived. One consequence, to which too little attention was given in the past, is that the metal can often be introduced under very mild conditions. Early examples are *o*-fluorophenyllithium and *o*-chlorophenyllithium *(1)*, which are very unstable because of their tendency to form dehydrobenzene *(2)*, but which, according to *Gilman et al.*[2], can be prepared intact at -60 and $-90\,^{\circ}C$, respectively [eq. (1)].

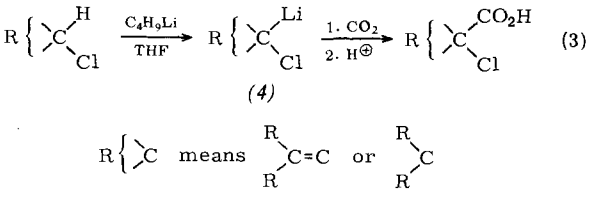
X = F, Cl (1) (2) (1)

A large class of thermally unstable substances consists of the α-haloorganolithium compounds *(3)*, which, together with a number of other thermolabile compounds investigated by our research group, form the subject of the present progress report. They are intermediates of the α-elimination whose general formulation is given in eq. (2), and since they function as latent carbenes, they are known as carbenoids[**]. Perhaps the best evidence of their instability is the fact that they were postulated as intermediates by *Wittig et al.*[4] as early as 1941, but despite subsequent intensive studies in the field of carbene chemistry, apart from a few perfluoro compounds having atypical behavior, they were not detected directly until 1963.

(3) (2)

Though the following sections are intended as a continuation of earlier reviews[5], the material presented in these earlier publications is repeated with a shift of accent wherever this seems essential to the overall picture. The reader is also referred to two reviews by other authors, in which lithiated organic halogen compounds are treated as a part of the field[6].

2. Preparation of Carbenoids by Metalation



In a method discovered by our research group in 1963, many carbenoids can be very easily prepared without decomposition by low-temperature metalation[***] of the corre-

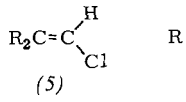
[**] Whereas the adjective "carbenoid" is used to describe any carbene-like reaction, and was first used in this sense by *L. Friedman* and *H. Shechter* (J. Amer. Chem. Soc. *81*, 5512 (1959)), the noun "carbenoid" is used in different senses. *M. E. Volpin, Yu. D. Koreshov, V. G. Dulova,* and *D. N. Kursanov* (Tetrahedron *18*, 107 (1962)) used the term to denote intermediates in which the role of the bivalent carbon is taken over by another element, and which are now known as "carbene analogs" (see *O. M. Nefedov* and *M. N. Manakov*, Angew. Chem. *78*, 1039 (1966); Angew. Chem. internat. Edit., *5*, 1021 (1966)). According to *G. L. Closs* and *R. A. Moss* (J. Amer. Chem. Soc. *86*, 4042 (1964)), a carbenoid is a species that is responsible for electrophilic reactions instead of a carbene; in particular, this may be an α-haloorganolithium compound, but the term is used primarily to characterize a type of mechanistic behavior, while the structural assignment remains a matter of interpretation. In this progress report, as in our earlier publications, the term carbenoid is used without mechanistic implications to denote α-haloorganolithium compounds, and compounds in general that have a metal atom and a leaving group on the same carbon atom.

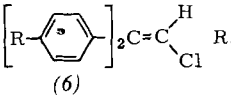
[***] The term "metalation" is used to denote the hydrogen-lithium exchange between an organic substrate and an organolithium compound (or a lithium amide).

sponding chlorinated hydrocarbons with *n*-butyllithium in tetrahydrofuran (THF) or THF-rich solvent mixtures (such as the Trapp mixture of THF, ether, and petroleum ether in a volume ratio of 4 : 1 : 1), and can then be characterized by suitable subsequent reactions, preferably by carboxylation [eq. (3)][7–10][*].



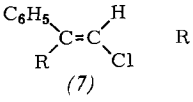
(3)

(4)



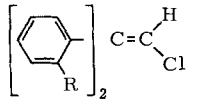
The optimum reaction temperature, which is normally between −70 and −120 °C, is limited at the lower end of the range by the rate of formation, and at the upper end by the tendency of the carbenoids *(4)* to decompose. Both of these factors are strongly and fairly predictably influenced by the hybridization of the carbon and by substituent effects.

The metalation proceeds on all sp^3-hybridized carbon atoms carrying at least two chlorine atoms[8, 10d, 10e, 11]; it fails with chloromethane[14]. In the case of olefins, where the hydrogen atoms are more acidic because of the sp^2-hybridized carbon atoms, activation by a single α-chlorine atom is sufficient[7, 9, 10]. However, chlorocyclopropanes (*e.g.* 7-chloronorcarane), whose C—H bonds are also assumed to be sp^2-hybridized[15], do not undergo metalation below −80 °C[16].

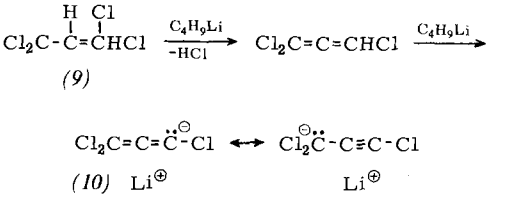


In addition to the hybridization, electronic and steric substituent effects are also active. They are particularly noticeable in the alkenes. Electron-attracting groups in the β position decrease the electron density at the α-carbon, and so increase its C—H acidity. Conversely, as the bulk of the β-substituent increases, the α-hydrogen is increasingly protected against attack by the metalating agent, and its removal is therefore slower. These patterns are evident from the relative rates of metalation of the chloroalkenes of the types *(5)* to *(7)* by *n*-butyllithium.

(5) R: $CH_3 < CH_2C_6H_5 < H < Cl$ [10c, 10f]

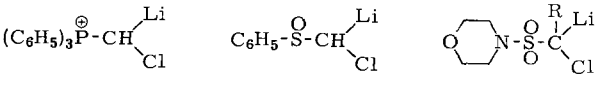


(6) R: $OCH_3 < CH_3 < H < C_6H_5 < Cl$ [10a, 10c, 10g]



(7) R: $t\text{-}C_4H_9 < C_2H_5 < CH_3$ [17, 18]

The *o*-substituted β,β-diaryl compounds *(8)* are metalated more slowly than their *p*-isomers *(6)*[10a].

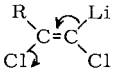


(8)

Trichloroallenyllithium *(10)* is obtained from the tetrachloropropene *(9)* with *n*-butyllithium (molar ratio 1 : 2)[19]. It presumably has an ion pair structure with resonance stabilization of the anion. The reaction therefore passes extremely rapidly through the stage of trichloroallene[19], which has been detected indirectly as an intermediate, and which can be intercepted under different conditions[20].

(9) *(10)*

Unlike the unstable chloromethyllithium[14], the carbenoids *(11)*[21], *(12)*[22], and *(13)*[23a] containing electron-attracting groups can be prepared at temperatures around −75 °C; the dimetalated compound *(14)* has recently been described[23b].

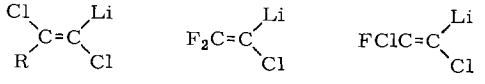


(11) *(12)* *(13)*, R = H, *(14)*, R = Li

Substituent effects that reduce the formation tendency of the carbenoids (electron pressure and steric crowding at the α-carbon atom) usually also increase their tendency to decompose. The range of temperatures that are suitable for their preparation is thus trimmed down both at the top and at the bottom end, and in unfavorable cases it shrinks to zero. (The halogen-metal exchange discussed in Section 3 is often helpful in such cases.) Conversely, sterically unhindered carbenoids with electron-attracting groups are obtainable over a wide range of temperatures, as can be shown for the compounds *(6)* to *(8)* and *(11)* to *(14)*.

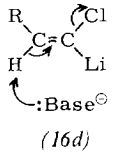
[*] Our priority is shown by the sequence of publications. It was repeatedly stated in the review literature [12] that the α-halo*alkyl*lithium compounds were discovered simultaneously by several groups of workers. This statement is correct, roughly speaking, but it is only half the truth. It should be pointed out that the method that is nowadays regarded as the best for the preparation of α-halo*alkyl*lithium compounds, which we published in 1964 after careful optimization for dichloromethyllithium and trichloromethyllithium [8], was a direct application of the method discovered earlier by our group for the preparation of α-halo*alkenyl*lithium compounds, which we had reported in three short communications [7] before any other publication on the subject appeared. *Miller* and *Whalen* [13] independently prepared trichloromethyllithium and 2,2,2-trifluoro-1,1-dichloroethyllithium by bromo-lithium exchange with methyllithium in diethyl ether at −115 °C, but this method is laborious, and cannot be used as a general method because of the destabilizing action of ether on carbenoids. Also at about the same time, apparently independently and in ignorance of our previous publications, *Hoeg* and *Lusk*, in an unpublished manuscript, described the preparation of trichloromethyllithium and α,α-dichlorobenzyllithium by metalation of chloroform and of benzylidene chloride respectively in THF at −100 °C. Their results, in an expanded form, were published only in 1965 [11a]. 1¾ years after our first report, when we had already published all the main experimental results in a series of ten short communications [7—9, 28a, 28b].

Exceptions to this rule are found in carbenoids with additional functional groups that offer a decomposition path which is energetically particularly favorable, as is shown by the following examples.



Trichloromethyllithium decomposes just above −90 °C, *i.e.* very much more readily than dichloromethyllithium[8, 24]. The reason for this is the ease of formation of the relatively "stable" dichlorocarbene (see Section 6.1).

$$\longrightarrow \text{R-C}\equiv\text{C-Cl} + \text{LiCl} \qquad (4)$$

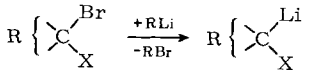


(15)

Compounds of the type *(15)* are readily formed, but decompose even below −100 °C. This is evidently due to a *trans*-β-elimination of lithium chloride in accordance with eq. (4)[10c]. The analogous *cis*-β-elimination takes place much less readily, as is shown by the comparatively high stability of *trans*-dichlorovinyllithium derivatives *(16a)*[10c, 19]. The *trans*-elimination in accordance with eq. (4) is slowed down by a second halogen in the β position (presumably as a result of electron attraction); trichlorovinyllithium *(16a)*, R = Cl, therefore decomposes only slowly at −120 °C, and can be isolated in good yields[10c]; the fluoro compounds *(16b)* and *(16c)* are even more stable[25].

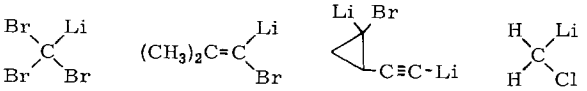
(16a) *(16b)* *(16c)*

Metalated chloroolefins *(16d)* having a β-hydrogen atom undergo dehydrohalogenation in accordance with eq. (5) [E2cb mechanism] in the presence of strong bases, and are therefore also very unstable[10c, 26].



$$\longrightarrow \text{R-C}\equiv\text{C-Li} + \text{HBase} + \text{Cl}^{\ominus} \qquad (5)$$

(16d)

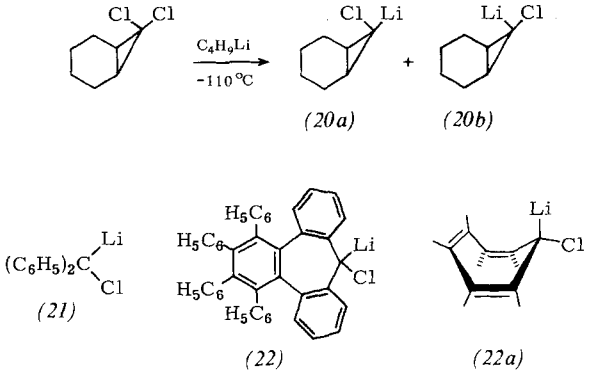


3. Thermolabile Organolithium Compounds by Halogen-Metal Exchange

Metalation has certain limitations as a path for the formation of carbenoids. Substrates such as chloromethane, 7-chloronorcarane, and 1-chloro-2-methyl-1-propene do not undergo lithiation at the low temperature required. While these reactions would be thermodynamically possible, since they would lead, in the sense of an acid-base formulation, from a stronger to a weaker acid-base pair, they are not ionic reactions in practice, but reactions of predominantly covalent species in a solvent of moderate polarity which contributes little to the stability of strongly polar transition states. The proton transfer therefore requires relatively high activation energies[*]. The limit to which the metalation is subject is therefore kinetic in origin, and not thermodynamic.

A solution is often provided by halogen-metal exchange, in which a halogen takes over the role of the hydrogen. With bromine and iodine, and less frequently with chlorine,

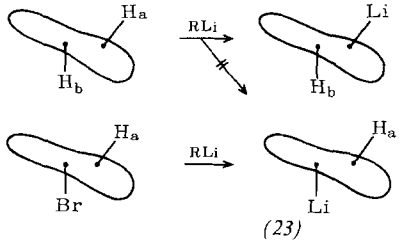
the exchange proceeds several orders of magnitude faster than the corresponding hydrogen-lithium exchange[4]. The reaction, which was discovered more than 30 years ago by *Wittig* and *Gilman*, and of which frequent use has been made[6], is therefore excellently suited for the preparation of thermolabile organolithium compounds. This can be illustrated by the preparation of tribromomethyllithium *(17a)* (from tetrabromomethane)[27] and of 1-bromo-2,2-dimethylvinyllithium *(17b)* (from the geminal dibromide)[28], which are obtained in 90% yield at −100 °C. The similarly prepared dilithiated cyclopropane *(18)* is stable even at −60 °C[29]. Chloromethyllithium *(19)*, which is very unstable even below −100 °C, was detected directly for the first time by Br—Li exchange on bromochloromethane[14].



(17a) *(17b)* *(18)* *(19)*

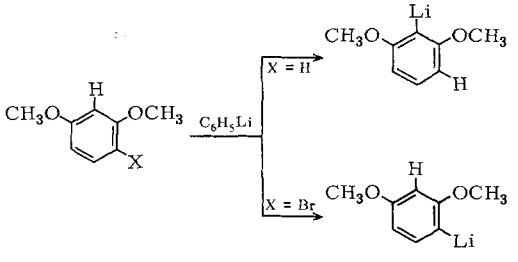
The chloro-lithium exchange can often be used as an alternative to metalation. Trichloromethyllithium is obtainable from tetrachloromethane[11a], and β,β-diaryl-α-chlorovinyllithium compounds can be prepared from the readily available geminal dichlorides[10g]. Even the chloro-lithium exchange occasionally leads to the desired result when metalation fails. Thus the reaction of 7,7-dichloronorcarane with *n*-butyllithium at −110 °C yields a mixture of the stereoisomeric carbenoids *(20a)* and *(20b)*[16]. Diphenylchloromethyllithium *(21)* can be prepared from the corresponding dichloride, but not by metalation of diphenylchloromethane[11a]. In the carbenoid *(22)*, the fixed conformer with quasi-axial metal [formula *(22a)*] is favored, presumably owing to the better overlap of the metal-bonding electron pair with the adjacent aromatic π systems. It is obtained from the corresponding dichloride *(22)*, Cl instead of Li, by chloro-lithium exchange or from the monochloride *(22a)*, H instead of Li, by metalation[30]. The monochloride with axial chlorine undergoes a chloro-lithium exchange under the same conditions to give the halogen-free lithium compound *(22a)*, H instead of Cl.

However, the halogen-metal exchange is not merely a faster variant of metalation. As a very fast reaction under



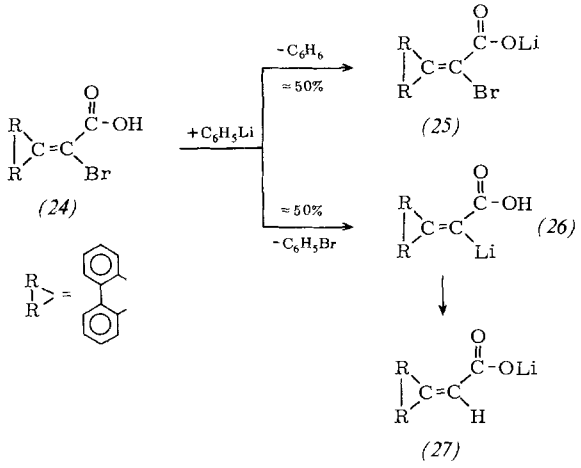
[*] The fact that the activation energies of many metalations are nevertheless very low is due to the extremely large basicity difference between the reacting and the resulting organolithium compound.

(20a) (20b)



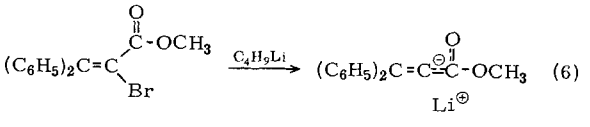
(21) (22) (22a)

conditions in which the product formation is kinetically controlled, it offers much more. Most organic molecules contain several differently bound hydrogen atoms, and are therefore polybasic acids from the standpoint of the acid-base theory. On metalation, only one of the hydrogen atoms (H_a), *i.e.* that having the highest kinetic acidity, is generally removed, while a less acidic C—H bond (H_b) remains intact. The halogen-metal exchange, because of its greater velocity, often allows the lithiation of a less acidic position, and so gives a new organolithium compound *(23)* that cannot be obtained by metalation.

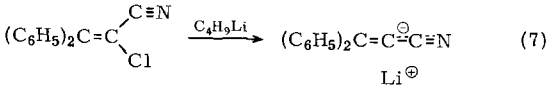


(23)

The first example was found on the discovery of the halogen-metal exchange[49a].

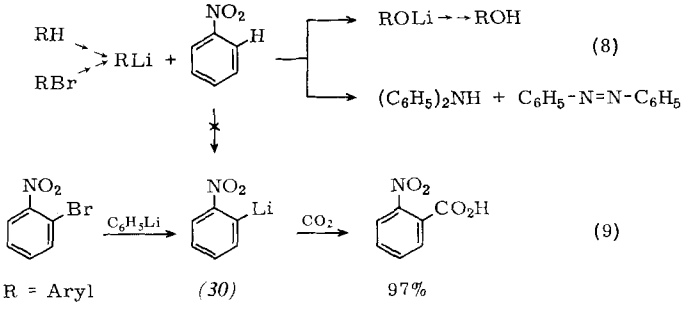


An extreme case is met in the reaction of fluorenylidene-bromoacetic acid *(24)* with phenyllithium in THF at −70 °C. On subsequent treatment with acid, 50% of the substrate is recovered, together with the bromine-free acid *(27)* and bromobenzene in a yield of about 50% each. The expected removal of the acidic proton by the strong base to form the α-bromocarboxylate *(25)* is thus accompanied in an almost equal measure by a bromo-lithium exchange to form the α-metalated carboxylic acid *(26)*, which then rearranges to give the thermodynamically stable halogen-free carboxylate *(27)*[31]. The bromo-lithium exchange thus competes successfully with the deprotonation of the carboxyl group in a position whose C—H acidity should be about 15—20 orders of magnitude lower than the acidity of the carboxyl group.



(24) (25) (26) (27)

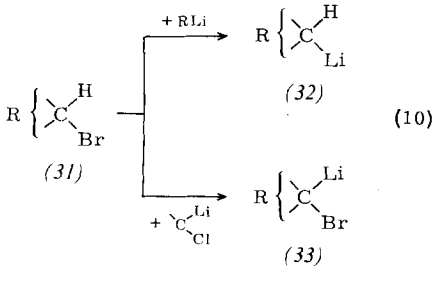
The halogen-metal exchange also allows the preparation of functional organolithium compounds in cases where metalation would have practically no chance because of other fast reactions. In the reactions indicated in eqs. (6) and (7), the halogen-metal exchange prevails against the addition of the organolithium compound to the double bond (Michael addition) or to the functional group. The resulting α-lithiated acrylic acid derivatives are stable at low temperatures, and can thus be subjected to further transformations as desired. Their deep yellow [*(28)*] and green colors [*(29)*] point to ion-pair structures with resonance-stabilized anions[31].



(28), 94%

(29), 75%

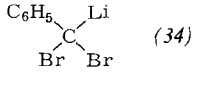
A similar situation is found for aromatic nitro compounds. The *o*-position in nitrobenzene is unquestionably much more acidic than that of most other benzene derivatives, and should therefore be very readily metalated with organolithium compounds. However, this is prevented by the redox reactions at the nitro group, which are very fast even at −100 °C in THF, and by which the aromatic nitro compound is converted *e.g.* into azobenzene and diphenyl-



R = Aryl (30) 97%

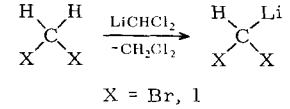
amine, while the aryllithium used is converted quantitatively into the corresponding lithium phenoxide[32, 33]. The reaction is thus suitable for the preparation of phenols from aromatic compounds, particularly from bromo compounds, in accordance with eq. (8), but not for the preparation of lithiated aromatic nitro compounds.

However, the fast redox reactions at the nitro group can be beaten by the even faster bromo-lithium exchange. Thus the reaction of *o*-nitrobromobenzene with phenyllithium in THF at $-100\,^{\circ}C$ leads almost quantitatively to *o*-nitrophenyllithium *(30)* [eq. (9)]. This interesting, black-red compound is stable only below $-100\,^{\circ}C$[34]. Many other lithiated aromatic mononitro, dinitro, and trinitro compounds are obtainable in the same way[32–34].



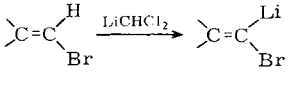
4. Carbenoids as Metalating Reagents

Because of the high reaction rates of bromo-lithium and iodo-lithium exchanges, the reaction of substrates *(31)* having hydrogen and bromine (or iodine) on the same carbon atom with common organolithium compounds proceeds predominantly by halogen-metal exchange to the product *(32)* containing less halogen, so that the metalated compounds *(33)* cannot be obtained in this way[35]. This gap can be filled by the use of sufficiently basic carbenoids as metalating reagents. The metalation of dibromomethane and of benzylidene bromide with dichloromethyllithium is the only method known at present for the preparation of dibromomethyllithium and α,α-dibromobenzyllithium



(31) *(32)* *(33)* (10)

(34) in good yields[35a]. Similarly, diiodomethyllithium can be obtained from diiodomethane in accordance with eq. (11) (an alternative method in this case is iodo-lithium exchange between triiodomethane and phenyllithium)[36]. Tribromomethane can be metalated with dichloromethyllithium[35a] (but also with nitrogen bases in THF/hexamethylphosphoramide mixtures[37]), though the bromo-lithium exchange gives better yields here as well as in the preparation of α-bromovinyllithium compounds, which can also be obtained by the above method [eq. (12)].



(34)

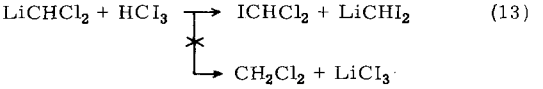
(11)

X = Br, I

(12)

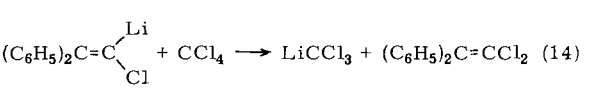
Dichloromethyllithium is very suitable for the preparation of the sulfonium ylide *(35)*, which reacts with carbonyl compounds to form oxiranes[38].

(35)



Why does dichloromethyllithium direct the reactions of eq. (10) toward the thermodynamically more stable base *(33)*?[*] The main reason is probably that no compound more strongly basic than the organolithium compound used can be formed. A bromo-lithium exchange on dibromomethane is possible with butyllithium, but not with dichloromethyllithium, since the resulting bromomethyllithium is a weaker base than butyllithium, but a stronger base than dichloromethyllithium. As is shown by these and other findings, the influence of the halogen on basicity as deduced by *Hine*[3a] from the investigation of the haloform anions in protonic media is also valid for the corresponding and other organolithium compounds in aprotic solvents.

The basicity increases



a) as the number of halogen atoms on the metalated carbon atom increases and

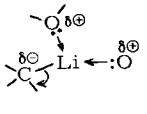
b) in the order Cl, Br, I for a given number of halogen atoms.

Of the alternatives indicated in eq. (10), the halogen-metal exchange can logically also become the principal reaction with carbenoids, provided that the product formed is a weaker base than the carbenoid used. For example, the reaction of iodoform with dichloromethyllithium proceeds exclusively by iodo-lithium exchange[36] [eq. (13)], and the carbenoid *(36)* reacts with tetrachloromethane to give trichloromethyllithium [eq. (14)][39].

(13)

(36) (14)

5. Solvent Effects



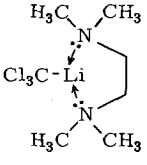
Reactions of organolithium compounds are strongly influenced by the solvent. They are usually faster in polar media, such as THF or 1,2-dimethoxyethane, than in less polar media. The deciding factor is evidently the donor-

[*] The terms "stable" and "unstable" used here in connection with base strengths should not be confused with thermal stability or instability. Thus trichloromethyllithium (or the trichloromethyl anion) is thermally less stable than dichloromethyllithium (or the dichloromethyl anion), but is the thermodynamically more stable base (owing to the additional halogen).

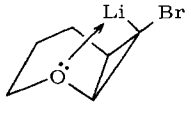
acceptor relationship between the metal and the oxygen of the solvent, which increases the polarity of the C—Li bond, and hence the carbanion character of the organometallic compound [formula *(37)*]. It should be remembered, however, that in a reaction yielding a new organolithium compound, the resulting compound is also subject to this solvent effect. Thus polar media accelerate not only the formation reactions but also the subsequent reactions if the nucleophilicity of the metalated carbon is decisive in the latter.

The fact that carbenoids, as described earlier, can often be prepared in high yields in THF is due to their relatively fast formation and above all to the remarkable retardation of their decomposition in this solvent[9b]. The stabilization effect differs in magnitude from one carbenoid to another. Thus trichloromethyllithium can also be obtained in diethyl ether[13], but it decomposes in this solvent at lower temperatures than in THF[9c]. Other compounds, such as dichloromethyllithium or the carbenoid *(36)*, which are stable in THF at −80 °C, decompose instantaneously in ether under otherwise identical conditions[9,10].

Carbenoids usually decompose by electrophilic reactions with replacement of the α-halogen. If the removal of the halogen is assumed to be facilitated in accordance with formula *(38)* by attraction of electrons from the halogen to the metal atom, the strength of the attraction, and hence the tendency to decompose, should decrease with increasing solvation of the metal by donor molecules, as observed[9b]. It is possible that other factors play a part, such as the degree of association of the carbenoids, which is unknown at present; however, the following recent findings support our assumption that the solvation of the lithium atom is of decisive importance. Trichloromethyllithium

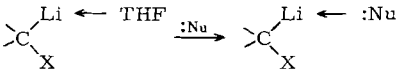


(37)



(38)

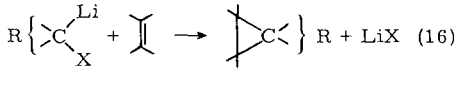
reacts with *N,N,N',N'*-tetramethylethylenediamine to form a complex *(39)* that is stable even in hexane at −90 °C[40]. The carbenoid *(40)* can be prepared in ether at (and above) −78 °C. It is much more stable than the carbocyclic analog *(20)*, presumably because of the intramolecular solvation by the ring oxygen. In addition to *(40)*, the *exo*-Li isomer can be detected in THF[41a].



(39)

(40)

The influence of the metal on the solvent-dependence of the stability of carbenoids is also instructive. It should be weaker for the higher alkali metals than for lithium, because of the less pronounced Lewis acid character of the former. A number of dihalomethyl and trihalomethyl derivatives of sodium and of potassium, which have recently been prepared by metalation of the corresponding halogenated hydrocarbons with alkali metal bis(trimethylsilyl)-amides[41b], are in fact no more stable in THF than in ether. The relative low tendency in particular of the sodium compounds to decompose (*e.g.* tribromomethylsodium decomposes only at −77 °C[41b], whereas tribromomethyllithium decomposes at −100 °C[27]) is probably also partly due to the low attraction acting on the neighboring halogen atom in accordance with *(38)*. Conversely, the solvent effect is very pronounced in the case of magnesium carbenoids; thus dibromomethylmagnesium chloride, which decomposes rapidly in THF at −45 °C, is protected against decomposition by hexamethylphosphoramide (HMPT)[41c].

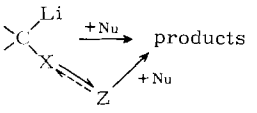


Other workers have argued that a nucleophilic compound that reacts with the carbenoid (*e.g.* an olefin) is first fixed to the lithium atom with displacement of a solvating molecule (as had been discussed earlier[5a]), and that the slower reaction in THF is simply due to the greater difficulty of displacement of the strongly attached THF molecule [eq. (15)]. This is refuted by the fact that the *intramolecular* Fritsch-Buttenberg-Wiechell rearrangement, in which this argument is inapplicable, exhibits the same solvent effect[9c,10a].

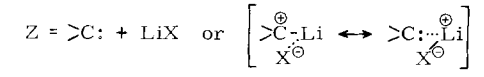
(15)

6. Electrophilic Reactions of Carbenoids

It is convenient to divide the reactions of carbenoids into nucleophilic reactions, which take place on the C—Li bond and are typical of conventional organolithium compounds, and electrophilic reactions, in which at least one α-halogen atom is eliminated, usually together with the metal atom. Electrophilic reactions, the best-known of which is carbene transfer to olefins [eq. (16)], can mostly be carried out without prior preparation of the carbenoid, though this is occasionally advantageous[42]. The *in-situ* production of the carbenoid in the presence of the nucleophilic reagent is generally sufficient. The following discussion will be concerned only with reactions in which the preparation of the carbenoid is either necessary or allows one to draw important mechanistic conclusions.



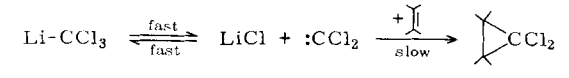
(16)



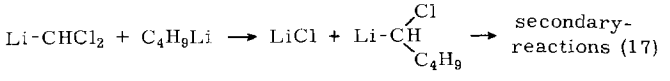
6.1. Mechanisms

The following mechanistic alternatives are fundamentally conceivable for the reaction of a carbenoid with a nucleophile Nu (*e.g.* an olefin) (cf. the scheme):

a) The nucleophile reacts with the carbenoid, without the intervention of an intermediate, to form the product.



b) The nucleophile reacts with an intermediate "Z", which is previously formed (reversibly or irreversibly) from the carbenoid.

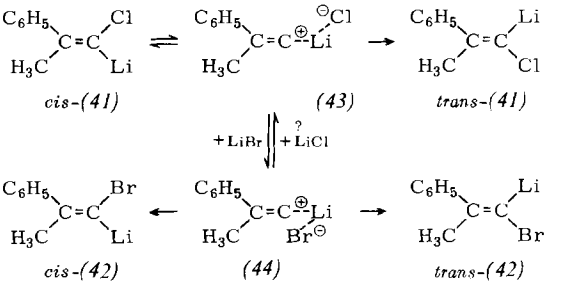


The intermediate "Z" may be either a free (but solvated) carbene or a species having an ionized C-halogen bond, in which the lithium halide remains bonded to the α-carbon atom *via* the metal atom (complexed carbene, carbene complex). The numerous types of behavior lead to the conclusion that a variety of mechanisms is operative. The direct reaction of carbenoids with olefins to form cyclopropanes (similar to that of Simmons-Smith reagents[43]) was first suggested by *Closs et al.*[44]. As another alternative, we[9c,10e] have considered the carbene complex with an ionized C-halogen bond, which was later also discussed by other authors[11a,45].

In view of numerous indications to the contrary, it seemed doubtful until recently whether carbene intermediates do in fact occur in reactions of lithiated organic chloro and bromo compounds. According to recent experiments by *Skell* and *Cholod*[40] and results from our research group[46], the competition constants found in the dichlorocarbene transfer from trichloromethyllithium to pairs of olefins at −70 °C are practically the same as those found when other dichlorocarbene sources are used. It may therefore be concluded that dichlorocarbene occurs as intermediate in all dichlorocyclopropanations, including those with trichloromethyllithium. Since olefins nevertheless accelerate the decomposition of trichloromethyllithium[46], a relatively rapid equilibrium is probably established between trichloromethyllithium and dichlorocarbene at −70 °C, from which the dichlorocarbene is slowly removed by the olefin.

Trichloromethyllithium thus behaves in the same way as the trichloromethyl anion in aqueous medium[3a]. Another carbenoid that establishes an equilibrium with its carbene in aprotic media is tris(phenylthio)methyllithium[47].

The other extreme case, *i. e.* an attack by the nucleophile on the carbenoid, is probable in particular with strong nucleophiles. The chloro-*n*-butyl exchange between dichloromethyllithium and *n*-butyllithium [eq. (17)] presumably follows this (S_N2-like) mechanism, since it takes place under conditions where dichloromethyllithium is thermally stable in the absence of butyllithium and does not react with weaker nucleophiles[10d].

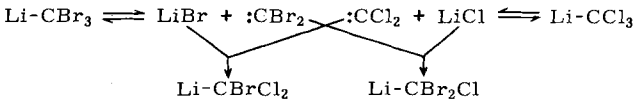


The types outlined above are probably the extreme cases of a continuous scale of reaction possibilities. However, it is not easy to determine the path that will be followed in a particular case, since there are no general criteria for differentiating between the reaction of a carbenoid and that of a carbene complex, and since the results of the competition method regarding the occurrence of intermediates are not beyond question.

There is so far only one discrete piece of stereochemical evidence for the existence of carbene complexes. The carbenoid *cis-(41)* rearranges irreversibly into the *trans*-isomer at −85 °C, and in the presence of lithium bromide it undergoes a Cl—Br exchange leading to the two bromocarbenoid isomers *(42)*[17]. Under the same conditions, the compound does not enter into reactions such as would be expected for a carbene intermediate (*e. g.* the dimerizing α-elimination or cyclopropanation with olefins); the only further reaction is the Fritsch-Buttenberg-Wiechell rearrangement to give phenylpropyne, which is known to involve no carbene intermediate.

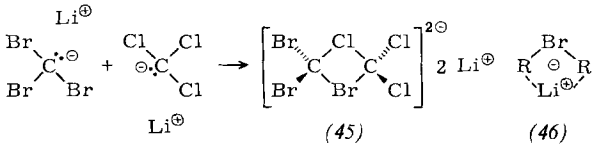
Substituent effects argue against a halogen exchange by the addition-elimination mechanism in the carbenoid, which is unlikely *a priori*. Finally, isomerization by carbanion inversion is unlikely, since halogen-free vinyllithium compounds are configurationally stable at low temperatures[48a] and an α-halogen atom, according to recent calculations, should raise the inversion barrier rather than lower it[48b].

The experimental facts are therefore best fitted by the assumption of a carbene complex intermediate *(43)*.



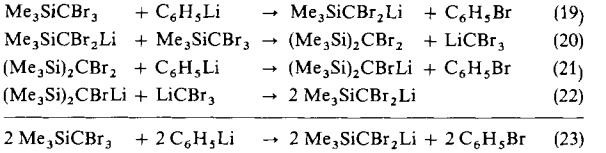
6.2. Ligand Exchange on Carbenoids

To conclude this mechanistic outline, we shall discuss a ligand exchange between tribromomethyllithium and other carbenoids, whose mechanism has not yet been conclusively established. When suspensions of tribromomethyllithium and trichloromethyllithium are mixed at −100 °C, bromodichloromethyllithium and dibromochloromethyllithium are formed [eq. (18)][27].

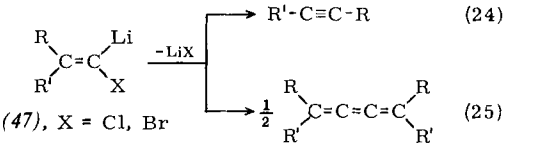


One would naturally expect such an exchange if the carbenoids used were in equilibrium with the corresponding carbenes and lithium halides.

However, the reaction[27] observed under the same conditions with dichloromethyllithium:



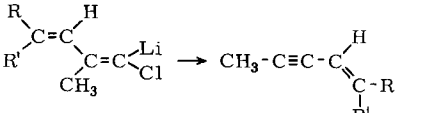
would be difficult to explain in this way, and certainly could not be explained without several intermediates. Moreover, none of the carbenoids exhibits any notable tendency to decompose in THF at −100 °C. Above all, tribromomethyllithium does not undergo halogen exchange with added lithium chloride under these conditions, nor does trichloromethyllithium in the presence of lithium bromide. A possible explanation is a direct reaction *via* a dinuclear complex *(45)* involving halogen bridges (the cations are to be regarded as lying above and below the plane of the paper). This complex is reminiscent of the complex *(46)* that was proposed for the halogen-metal exchange[49b], and the ligand exchange could in fact be regarded as a double halogen-metal exchange.



(45) *(46)*

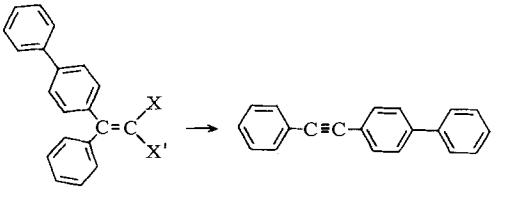
A similar ligand exchange occurs in the commutation reaction between tribromomethyllithium and bis(trimethylsilyl)bromomethyllithium [eq. (22)], and proves to be the key to the understanding of the following apparently simple but in reality rather complicated reaction[50]. Trimethylsilyltribromomethane reacts with an equimolar quantity of phenyllithium to give trimethylsilyldibromomethyllithium (which can be characterized *e.g.* with trimethylchlorosilane as bis(trimethylsilyl)dibromomethane) in high yield [eq. (19)]. With the normal reaction procedure (slow addition of phenyllithium to the substrate), however, the carbenoid formed in accordance with eq. (19) rapidly reacts with the remaining substrate to form bis(trimethylsilyl)dibromomethane and tribromomethyllithium [eq. (20)]. Further phenyllithium converts the disilyl compound in accordance with eq. (21) into bis(trimethylsilyl)bromomethyllithium, which undergoes the commutation mentioned above [eq. (22)] with the tribromomethyllithium formed in eq. (20)[50a]. Strangely, therefore, trimethylsilyldibromomethyllithium can be satisfactorily prepared in this way only because the secondary reactions (all of which have been confirmed by control experiments) finally lead back to the same carbenoid *via* the commutation [eq. (23)].

6.3. Dimerizing α-Elimination and the Fritsch-Buttenberg-Wiechell Rearrangement



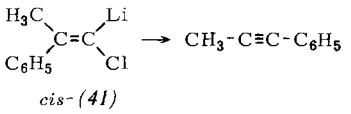
Olefinic carbenoids *(47)* have available two preparatively important decomposition paths, *i.e.* the Fritsch-Buttenberg-Wiechell (FBW) rearrangement to form disubstituted acetylenes [eq. (24)] and dimerizing α-elimination to form butatrienes [eq. (25)][51].

(47), X = Cl, Br (24) (25)



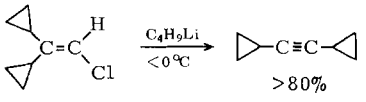
The dimerizing α-elimination (which, as a formal dimerization of a carbene, is the most general thermolysis reaction of carbenoids) is observed for compounds *(47)* having two β-alkyl residues (R,R′ = CH_3, $CH_2C_6H_5$)[10f,28c]; to obtain good yields, the carbenoid must be prepared before the thermolysis.

The FBW rearrangement, which also proceeds in high yields without prior preparation of the carbenoid, takes place under mild conditions whenever at least one of the β substituents has available a π system conjugated with the metalated olefin, *i.e.* with aryl[51] and alkenyl groups[18]. The migration of the alkenyl group proceeds stereospecifically with retention of configuration within the detection limits[18].



R = H, R′ = C_6H_5
R = C_6H_5, R′ = H

When two β substituents are capable of rearranging, the migration of the substituent *trans* to the α halogen[52] (*trans* migration) predominates; for example, 97% migration of the biphenylyl residue occurs in the case of the compound *(48)*, and 95% migration of the phenyl group (contrary to earlier reports[10g]) in the case of the isomer *(49)* (±2% in each case)[53].

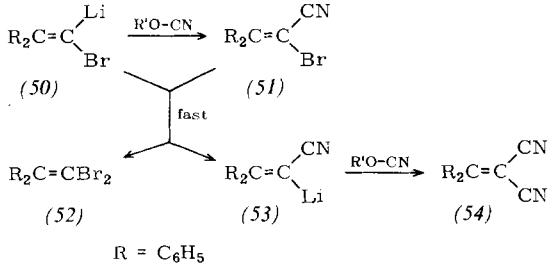


(48), X = Li, X′ = Cl
(49), X = Cl, X′ = Li

If the group *trans* to the halogen cannot rearrange while the *cis* substituent can, *cis* migration prevails. This was first observed for *cis-(41)*[17a], which decomposes at lower temperatures than the *trans* isomer, presumably on steric grounds.

cis-(41)

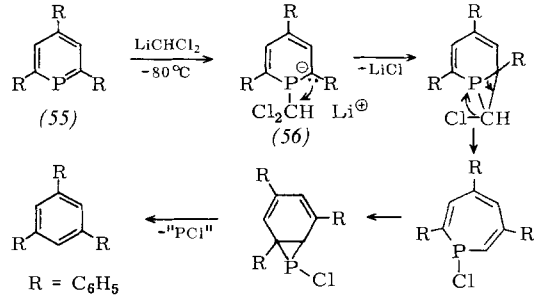
It was uncertain for a long time whether the nonstereospecific part of the FBW rearrangement in β,β-diarylated carbenoids is also due to a "true" *cis* migration, or whether the *cis* migration is simulated by partial isomerization of the carbenoid with subsequent *trans* migration. The results of recent investigations favor the *cis* migration[53]. On the one hand, the FBW rearrangement of β,β-diarylated carbenoids is suppressed in favor of dimerizing α-elimination when the aryl residues are linked by short bridges, since the rearrangement would then lead to a highly strained cycloalkyne. On the other hand, FBW rearrangement can be forced in β,β-dialkylated haloolefins under drastic conditions[51]. The rearrangement proceeds particularly smoothly with "vinyl-like"[115] cyclopropyl groups[54].



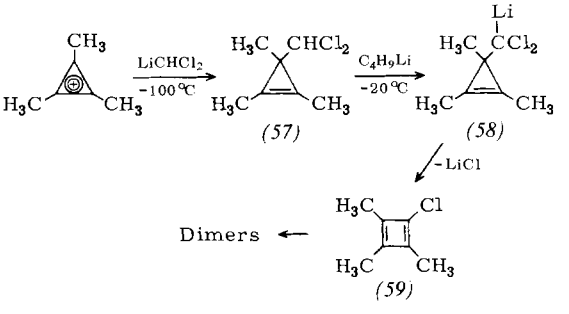
7. Nucleophilic Reactions of the Carbenoids

For nucleophilic reactions, the preparation of the carbenoids before their reaction with the electrophilic reagent is necessary or at least advantageous, since the organometallic compound used for the preparation of the carbenoid would otherwise compete with the latter for the electrophile. Examples of the addition to carbon dioxide and carbonyl compounds and of halogenation, cyanation, and alkylation were given earlier[5]. The nucleophilic reactions of the carbenoids also include the lithiation of halogenated hydrocarbons by metalation or halogen-metal exchange (Section 4). Some reactions that make use of special, preparatively useful properties of carbenoids are discussed below.

7.1. Multiple Functionalization



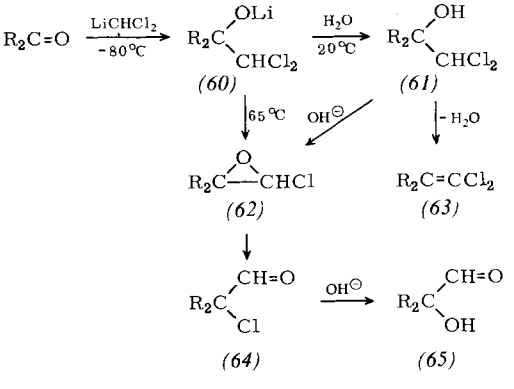
The replacement of the lithium by a functional group may activate the α-halogen (particularly Br or I) so strongly that the resulting compound undergoes a halogen-metal exchange with unreacted carbenoid. Thus the cyanation of the carbenoid *(50)* leads not to *(51)* but to an equimolar mixture of *(52)* and the dicyano compound *(54)* (the latter reacts further with *(50)* and *(53)* in Michael additions)[31].



Such transmetalations can occur in particular between a reaction product of a carbenoid and an excess of the organolithium compound used to prepare the carbenoid, and can thus simulate the occurrence of a dilithium intermediate[31].

7.2. Reaction with Electrophilic Aromatic Systems

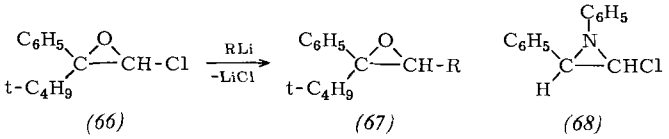
2,4,6-Triphenylphosphabenzene *(55)* reacts with dichloromethyllithium at −80 °C to form a deep red adduct *(56)*, whose thermal decomposition (presumably *via* the interesting intermediates indicated below) leads to *sym*-triphenylbenzene[55].



The alkylation of dichloromethyllithium with trimethylcyclopropenylium salt yields the cyclopropane *(57)*, whose metalation and subsequent carbenoid decomposition leads in 85% yield to four structurally isomeric dimers of chlorotrimethylcyclobutadiene *(59)*[56].

7.3. Reactions of Dichloromethylalkoxides

The alcohols *(61)* obtained from carbonyl compounds and dichloromethyllithium can, for R = aryl, be dehydrated in high yields to 1,1-dichloroolefins *(63)*[10g, 21b]. The overall



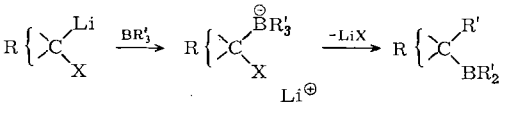
reaction provides a simple method for the dichloroolefination of diaryl ketones.

If the alkoxides *(60)* are heated for a short time at 65 °C before being hydrolyzed, they rearrange with elimination of lithium chloride into α-chloro aldehydes *(64)*, which can be readily converted into α-hydroxy aldehydes *(65)* by treatment with alkali[57]. The sequence leading from the carbonyl compound to *(65)* is a nucleophilic formylation; dichloromethyllithium is found to be a masked formyl anion[58].

According to *Kirrmann et al.*, the rearrangement of the alkoxides *(60)* into α-chloro aldehydes *(64)* proceeds *via* the unstable chlorooxiranes *(62)*, some of which can be obtained from the alcohols *(61)* by treatment with alkali under carefully chosen conditions[59].

The alkoxide from *tert*-butyl phenyl ketone and dichloromethyllithium, *i.e.* lithium 1,1-dichloro-3,3-dimethyl-2-phenyl-2-butoxide, is converted into the chlorooxirane *(66)* even below room temperature[57] (the chloroaziridine *(68)* is presumably formed in a similar manner from benzylideneaniline[60]). The chlorine atom of *(66)* is smoothly exchanged with organolithium compounds to give the trisubstituted oxiranes *(67)*[57]. The overall reaction is a carbene transfer (:CHR) to the carbonyl group by three nucleophilic addition and substitution steps. With bromomethyllithium produced *in situ*, carbonyl compounds are converted into oxiranes by methylene transfer[60b].

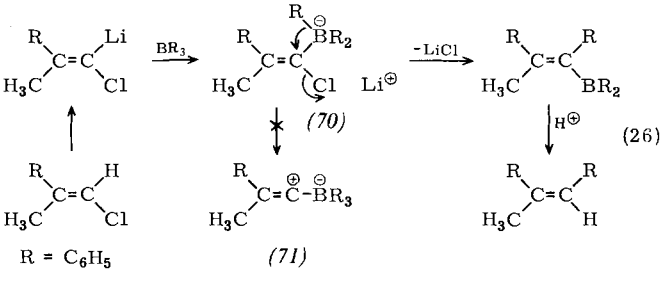
(66) *(67)* *(68)*



7.4. Reaction of Carbenoids with Metal Compounds

Like other organolithium compounds, carbenoids react smoothly with salts of less electropositive metals to give new organometallic compounds[5]. A simple example is the reaction of dichloromethyllithium with zinc chloride or mercury(II) chloride to form bis(dichloromethyl)zinc and bis(dichloromethyl)mercury, respectively[8,10d].

$$2\,Li{-}CHCl_2 + MCl_2 \xrightarrow[-2\,LiCl]{} M(CHCl_2)_2 \qquad M = Zn, Hg$$

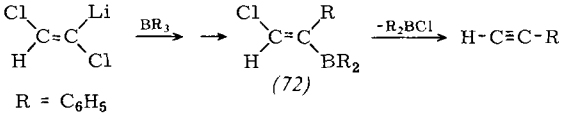


7.4.1. Rearrangement of α-Chloro Borates

Triphenylborane combines with carbenoids to form ate-complexes *(69)*. Because of the α-halogen, these complexes are thermolabile and decompose with elimination of lithium chloride and phenyl rearrangement to form boranes[61]:

R' = C_6H_5 *(69)*

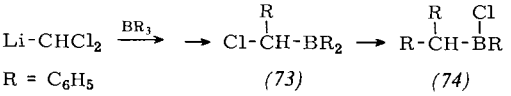
The stereochemistry has been elucidated from the reaction sequence shown in eq. (26). It proceeds with an overall yield of 65% and is a rare example of a nucleophilic substitution on olefinic carbon (replacement of chlorine by phenyl) with *inversion of configuration*; the stereoselectivity is 98% (the *cis*-isomeric substrate gives the *trans*-stilbene derivative with the same selectivity and in a yield of 73%)[61].



(26)

R = C_6H_5 *(70)* *(71)*

The inversion takes place in the rearrangement step [formula *(70)*], since all the other steps are electrophilic reactions at the olefinic carbon, for which *retention of configuration* is typical. The results conclusively rule out the conceivable "inverse ylide" *(71)* as an intermediate[*].



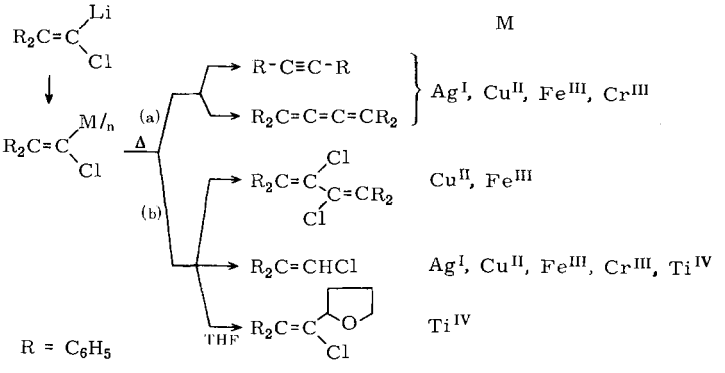
The ate-complex formed from α-lithiofuran and trialkylboranes is assumed to undergo a similar inversion to give 1,2-oxabora-4-cyclohexenes[63].

If the carbenoid contains several halogen atoms, the rearrangement may be followed by further reactions. Thus the reaction of *trans*-dichlorovinyllithium with triphenylborane leads, probably by a *trans*-β-elimination in the rearranged borane *(72)*, to phenylacetylene as the main product[61].

R = C_6H_5 *(72)*

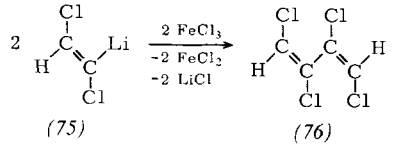
The primary rearrangement product *(73)* formed from dichloromethyllithium and triphenylborane undergoes a second phenyl rearrangement to form the borane *(74)*, as can be deduced from alkaline oxidation to 62% benzhydrol and 10% benzophenone[61].

R = C_6H_5 *(73)* *(74)*



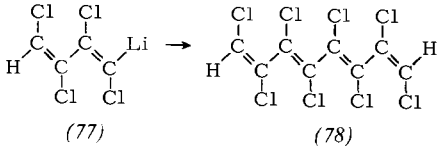
With trichloromethyllithium as the substrate, the third ligand from the boron can also be transferred to the α-carbon atom, so that alkaline oxidation leads to the tertiary alcohol (37% of tri-*n*-butylmethanol from tri-*n*-butylborane)[64].

[*] "Inverse" because of the reversed charge distribution on the α-carbon atom and the hetero atom in relation to that in conventional ylides, cf. Ref. [62].

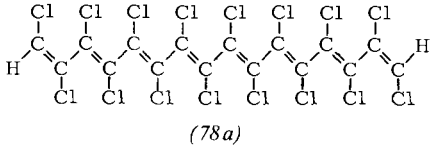


7.4.2. Reactions of Thermolabile Transition Metal Carbenoids

The organometallic compounds formed from Li carbenoids with transition metal salts by metal-metal exchange are mostly thermolabile. Their reactions depend on the nature and quantity of the metal salt and on the nature of the organic residue. Depending on the fate of the α-halogen, it is possible to distinguish two fundamental modes of reaction, which are illustrated for 1-chloro-2,2-diphenylvinyllithium[65, 66a].



The halogen is either removed together with the metal, with formation of carbenoid products [path (a)], or it remains in the molecule, and radicaloid secondary reactions are observed [path (b)].



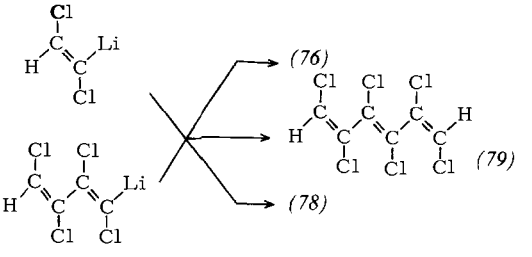
A system that has proved to be particularly interesting is that of *trans*-dichlorovinyllithium *(75)* with iron(III) chloride, which allows the stereospecific synthesis of polychloropolyenes and polychloropolyenynes[66, 67]. 1 mole of *(75)* couples with 1—2 moles of $FeCl_3$ to give tetrachlorobutadiene *(76)* in good yields. The metalation product *(77)* of *(76)* similarly gives octachlorooctatetraene *(78)*, from which a hexadecachlorohexadecaoctaene *(78a)* can be prepared in a similar manner[66].

(75) *(76)*

(77) *(78)*

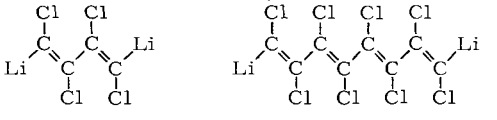
(78a)

The lithium carbenoids and their analogs with σ-bonded iron, which can be detected at low temperatures[67b], function as intermediates of an *oxidative* coupling, which can be represented by the following overall formulation:



$$2\ H{-}[CCl]_n{-}H \xrightarrow{-2H} H{-}[CCl]_{2n}{-}H \qquad n = 2, 4, 8$$

The only notable side reaction is the regeneration of the substrate by saturation of the intermediate organometallic compounds with H from the solvent. It is very probable that no free vinyl radicals occur here or in the coupling[67b].

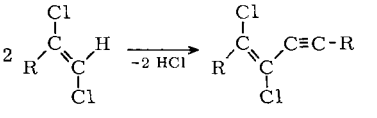


Two variants of the oxidative coupling allow the synthesis of intermediate members of the polyene series. In *mixed oxidative coupling* in accordance with:

$$H{-}[CCl]_m{-}H + H{-}[CCl]_n{-}H \xrightarrow{-2H} H{-}[CCl]_{m+n}{-}H$$

carbenoids with different chain lengths are allowed to react simultaneously with $FeCl_3$. In this way *(75)* and *(77)* give hexachlorohexatriene *(79)* besides *(76)* and *(78)*.

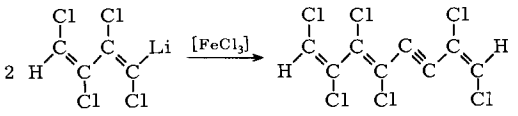
The *oxidative oligomerization* is based on the smooth formation of α,ω-dimetalated compounds such as *(80)* and *(81)*, which can be coupled at both ends. Mixtures of monometalated and dimetalated substrates *(77)* and *(80)* therefore



(80) *(81)*

give not only the dimers but also trimers, tetramers, and higher oligomers, whose relative yields depend on the ratio of the monometalated to the dimetalated species[66].

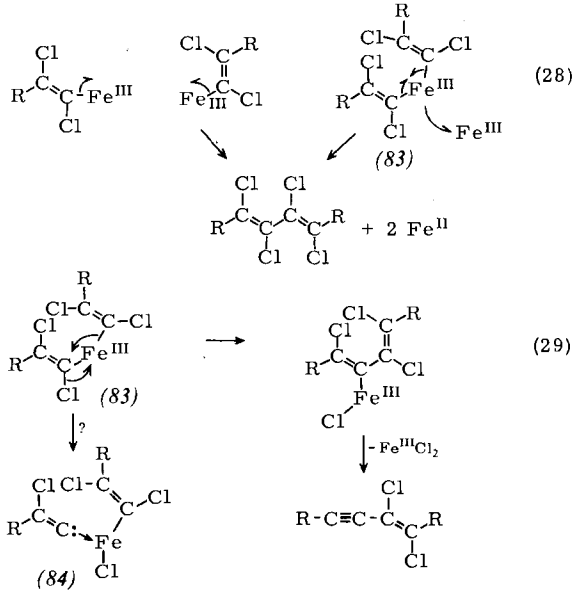
$$\underset{(77)}{H{-}[CCl]_4{-}Li} + (x-2)\,\underset{(80)}{Li{-}[CCl]_4{-}Li} + \underset{(77)}{Li{-}[CCl]_4{-}H} \rightarrow$$



$$\rightarrow H{-}[CCl]_{4x}{-}H \qquad x = 2, 3, 4 \ldots$$

If less than the equimolar quantity of iron(III) salt is used for the coupling (optimum 1/4—1/3 mole of $FeCl_3$ per mole of carbenoid), the reaction surprisingly leads to polychloropolyenynes[67a] in accordance with the overall equation (27).

(27)



This novel reaction, whose final result is a dehydrohalogenation, and which can therefore be described as an *eliminative coupling*[67b], also proceeds stereospecifically, and the main product obtained *e.g.* from *(77)* is 1,3,7-octatrien-5-yne *(82)*[67].

(77) *(82)*

According to the experiments carried out so far, the product always contains only *one* triple bond, which is located at one of the formerly metalated carbon atoms. It is formed during the coupling, and not by subsequent dechlorination of the polyene. In complete contrast with the oxidative coupling, the iron salt has a purely catalytic function in eliminative coupling, *i.e.* it is found in its original oxidation state at the end of the reaction[67a].

To explain the reactions, it is assumed that the intermediate organoiron compounds having the partial structure *(83)* preferentially undergo oxidative coupling in the presence of sufficient quantities of iron salt (or of some other oxidizing agent) [eq. (28)], but otherwise undergo a rearrangement (possibly *via* carbene-iron complexes *(84)*) with subsequent β-elimination [eq. (29)].

(28)

(29)

As can be seen especially from the last section, the chemistry of carbenoids, which is closely interwoven with the chemistry of other thermolabile organometallic compounds, is full of surprises and mechanistic problems, but also of preparative possibilities whose further investigation presents an attractive task.

My work in this field has been carried out at the Institute of Organic Chemistry at the University of Heidelberg. I am grateful to many persons at this Institute who have contributed in numerous ways to the success of this work, and above all to those named in the references as my co-workers. I am also grateful to the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the Bundesministerium für Wissenschaftliche Forschung, the Wirtschaftsministerium des Landes Baden-Württemberg, and numerous companies, particularly the Badische Anilin- und Soda-Fabrik, Ludwigshafen, for the promotion of the studies by material and financial support.

Intermolecular Interactions: van der Waals Molecules[**]

By George E. Ewing[*]

Recent experiments using electron diffraction techniques, optical and infrared spectroscopy and mass spectroscopy have provided convincing evidence for the existence of bound states of gaseous Ar_2, $(H_2)_2$, $(O_2)_2$, $(NO)_2$ and other simple dimers. The bond strength of these van der Waals molecules is hundreds of times weaker than ordinary chemical bonds. These experimental studies yield information on the structure and stability of van der Waals molecules and can provide new insight into weak intermolecular interactions.

1. Introduction

The study of intermolecular interactions has always been an active area of research and reviews of the general subject appear each year[1-4]. One of the main purposes of experimental and theoretical work in this area is to characterize the shape of the intermolecular potential function. This goal has been approached by using measurements of bulk properties of matter, *e. g.*, virial coefficient and transport data of gases and various physical properties of solids and liquids to evaluate parameters of intermolecular potential functions. Theoretical work and particularly molecular beam scattering experiments have been valuable in determining, on the molecular level, properties of the intermolecular interactions.

Recently a few experiments have been described in which molecules bound by these weak intermolecular interactions have been studied. The measured properties of such van der Waals molecules, which provide a particularly direct approach to the study of intermolecular interactions, is the subject of this review.

Since theoretical studies of intermolecular interactions have been discussed elsewhere only those investigations which emphasize van der Waals molecules will be outlined here in the section entitled, "Theoretical Background" (see Section 2). In the other sections, experimental results will be described. Rather than mentioning in a cursory fashion all the work done in these areas several examples will be presented in detail to give the reader an insight into the new approaches possible in the study of van der Waals molecules. The discussion will be primarily restricted to studies of small van der Waals molecules bound by weak intermolecular interactions between atoms (*e.g.*, Ar_2, RbKr), or diatomic molecules (*e.g.*, $(H_2)_2$, $(HCl)_2$, $(NO)_2$). These weak intermolecular interactions include dispersion forces, hydrogen bonding and electric multipole interactions and lead to van der Waals bond strengths hundreds of times less than those usually associated with ordinary chemical bonding.

2. Theoretical Background

It is particularly important to begin by defining what is meant by a van der Waals molecule. In the interaction of molecules in the gas phase it is possible to distinguish three types of binary encounters: collision pairs, metastable dimers, and bound dimers[5-7]. This is illustrated in Fig. 1 for atoms where the potential energy of interaction, $v(r)$, depends only on their separation, r. If the pair has angular momentum, indicated by the rotational quantum number L, then a centrifugal potential is added to give an effective potential

$$V_{eff} = V(r) + \frac{h^2}{8\pi^2\mu} \cdot \frac{L(L+1)}{r^2}$$

where μ is the reduced mass of the atoms and h is Planck's constant. The effect of the centrifugal potential is always positive and repulsive since when the pair is rotating centrifugal forces are in opposition to any attractive van

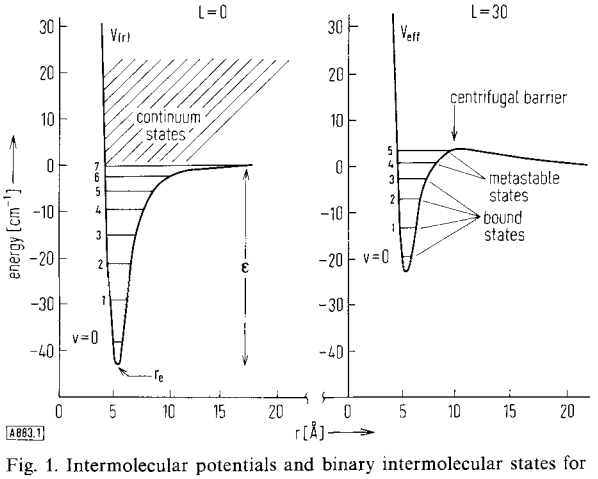

Fig. 1. Intermolecular potentials and binary intermolecular states for atoms.
The left side of the figure represents the binary pair interaction with no angular momentum (L = 0). The minimum of the potential curve occurs at a distance of r_e and the well depth is given by ε. The continuum states correspond to head-on collisions of the atoms. Below the dissociation limit bound states of the non-rotating van der Waals molecule exist.
On the right side of the figure the binary pair has angular momentum (*e. g.* L = 30). The atoms undergo glancing collisions above the centrifugal barrier. Below the barrier there are discrete levels for the rotating van der Waals molecules. (Data for RbAr are taken from Ref. [14]. The energy levels for L = 0 were estimated using a Morse potential, see Ref. [15].)

der Waals forces. Interacting atoms with no angular momentum ($L=0$; $V_{eff}=V(r)$) are described in Fig. 1.

Two atoms which reside in one of the vibration levels indicated by the quantum number v in the potential well below the dissociation limit are bound dimers. Atoms in the continuum of states above the dissociation limit are collision pairs.

If the interacting atoms are rotating then $L\neq 0$, and the effective potential exhibits a hump or barrier (centrifugal barrier). Dimers in the region below the dissociation limit are bound; dimers in the region above the dissociation limit but below the barrier of the effective potential curve are metastable. From the point of view of classical mechanics these dimers would be stable but quantum mechanically they can "leak" or "tunnel" through the potential barrier.

Formation of bound states without angular momentum, *i. e.* when $L=0$, can occur only when two approaching atoms in the continuum collide in the presence of another atom or molecule. This third body removes excess kinetic energy so the colliding pair can drop into one of the descrete levels in the intermolecular potential well. For $L\neq 0$ a third body is also needed if the pair has kinetic energy above the centrifugal barrier. However, if the colliding pair approach each other below the barrier, but above the dissociation limit, it is possible that tunneling can occur to form a dimer if the energy matches one of the metastable levels. Finally in the region immediately above the centrifugal barrier "resonances" can occur which physically correspond to multiple orbiting of the collision pair followed by dissociation.

Extension of the above definitions to intermolecular interactions of diatomic or polyatomic molecules in which the potential energy depends also on their relative orientations is analogous although exceedingly complicated.

For the purposes of this review van der Waals molecules will refer only to metastable and bound dimers. Molecules residing in the continuum above the potential barrier or —in the case of $L=0$—above the dissociation limit, will be called collision pairs.

There are a variety of potential functions which can be used to represent intermolecular interactions. In the experimental investigations of van der Waals molecules to be discussed here the analysis of data can often be made on the basis of angularly independent potential functions. If the system is complex and depends on the relative orientation of the constituents of the van der Waals molecule the analysis usually cannot be carried out far enough to specify angular dependence of the intermolecular potential.

A particularly useful angularly independent description of intermolecular interactions is the Lennard-Jones (6—12) potential,

$$V(r)=\varepsilon\left[\left(\frac{r_e}{r}\right)^{12}-2\left(\frac{r_e}{r}\right)^{6}\right] \tag{1}$$

where ε is the well depth and r_e is the value of the interparticle distance at the bottom of the well.

Table 1. Lennard-Jones (6—12)-parameters for some typical van der Waals interactions (after Ref. [8]).

System	ε/k [°K]	$R\varepsilon/k$ [cal/mole]	ε/hc [cm^{-1}]	r_e [Å]
He—He	10.22	20.31	7.10	2.869
H_2—H_2	37.00	73.53	25.72	3.287
Ar—Ar	119.8	238.1	83.27	3.822
Xe—Xe	221	439	154	4.602
N_2—N_2	95.05	188.9	66.07	4.151
O_2—O_2	117.5	233.5	81.67	4.02
NO—NO	131	260	91.05	3.56
Cl_2—Cl_2	357	709	248	4.619
I_2—I_2	550	1093	382	5.592
HCl—HCl	360	715	250	3.710
HI—HI	324	644	225	4.628

Values of the Lennard-Jones parameters for a number of molecules are given in Table 1. These values have not been determined from studies of van der Waals molecules but from an analysis of thermodynamic data. Non-spherical molecules are included even though they cannot be strictly treated by the angularly independent Lennard-Jones potential. However, as we shall see from the experiments to be discussed, angularly dependent interactions are very important for some of these molecules—particularly at low temperatures. A Lennard-Jones (6—10) potential is sometimes used, since it simplifies mathematical treatment. A variety of other intermolecular potentials have also been suggested[8].

A particularly useful function for analyzing spectroscopic data is the Morse potential[9],

$$V(r)=\varepsilon[(1-e^{-\beta(r-r_e)})^2-1] \tag{2}$$

which contains three parameters, r_e, β, and ε. The Hamiltonian containing this potential can be solved analytically by quantum mechanics. The resulting vibrational energy levels (in cm^{-1}) of the Morse potential (for $L=0$) are given by

$$G(v)=\omega_e(v+\tfrac{1}{2})-\omega_e x_e(v+\tfrac{1}{2})^2 \tag{3}$$

$$\omega_e=\frac{\beta}{\pi c}\sqrt{\frac{\varepsilon}{2\mu}};\qquad x_e=\frac{hc}{4\varepsilon}\omega_e$$

The vibration levels are measured from the bottom of the well. Thus if $G(v)$ is determined for several vibrational quantum levels the parameters ε and β can be evaluated. Using a value of r_e from other data enables the entire potential function to be evaluated from spectroscopic data.

There have been a number of theoretical determinations of the energy levels of van der Waals molecules. *Cashion*[10] has calculated numerical solutions of the radial Schrödinger equation for the vibrational and rotational energy levels using the Lennard-Jones (6—12) potential. The formula derived by this author is expressed by the coefficients Y_{ij}

$$T(v,L)=\sum_{i,j}Y_{ij}(v+\tfrac{1}{2})^i L^j(L+1)^j \tag{4}$$

where $T(v,L)$ is the energy of a level in the vibration and rotational quantum states v and L respectively. Each of the 18 Y_{ij} coefficients calculated is given in terms of the ε and r_e Lennard-Jones parameters. A desk calculator or

small computer can then be used to evaluate quantum levels with great precision. Despite the usefulness of these formulas and the ease with which precise energy values may be evaluated it must not be forgotten that a van der Waals molecule which obeys a Lennard-Jones (6—12) potential is a hypothetical molecule.

Cashion also gives the number of bound and metastable states for a few van der Waals molecules. For $(O_2)_2$ the (L=0)-state has seven bound vibrational levels. Since the centrifugal barrier effectively reduces the depth of the potential well (see Fig. 1) higher L states have fewer vibrational levels. The total number of bound v and L states for $(O_2)_2$ is 140. The total number of levels range from 1 for $(He)_2$, 2 for $(H_2)_2$, 171 for $(Ar)_2$ to over 10000 for $(I_2)_2$. The estimate for $(He)_2$ is particularly interesting since the existence of a bound state of this dimer depends critically on the values of ε and r_e selected for the calculation.

Estimates of bound state energy levels have been made by others. The Morse potential can be adjusted to describe gas phase intermolecular interactions, and the vibrational states follow from Eq. 3[10-12]. Perturbation, variational, and WBK calculations have also provided bound state energy levels[6, 13-15].

A knowledge of the van der Waals molecule energy level distributions enables the equilibrium constant, K, for the dimerization $A+A \rightleftarrows A_2$ to be calculated[15, 16]. It may be expressed in terms of the partition functions for monomer Q_A and dimer Q_A as follows:

$$K = \frac{[A_2]}{[A]^2} = \frac{(Q_{A_2}/V)}{(Q_A/V)^2} e^{+\varepsilon/kT} \quad (5)$$

where [ ] indicates concentration in moles/liter. If A represents a $^1S_0$ atom then only the translational energy contributes to the partition function:

$$Q_A = \frac{(2\pi m_A kT)^{3/2}}{h^3} V$$

with m_A the mass of A and V the volume of the system. The dimer partition function A_2 is

$$Q_{A_2} = \frac{(4\pi m_A kT)^{3/2}}{h^3} V \cdot \sum_{v,L} e^{-E(v,L)/kT}$$

where the sum over van der Waals bound levels must take account of nuclear spin symmetry. There are a number of simplications that can be used in evaluating K, particularly in summing terms of the dimer partition function. It is also important to notice whether a distinction between metastable and bound dimers is made in determining $[A_2]$.

Stogryn and *Hirschfelder*[6] who review earlier estimates use a classical partition function yet calculate metastable and bound dimer concentrations separately. These results are interesting to examine since they give an idea of the small concentrations of dimers present even under conditions which favor their formation. For example, consider argon at a temperature of 120°K which is equal to the well depth ε/k. At a concentration $[Ar]=1/22.4$ mole/liter (this would equal a pressure of 1 atm at STP) only 0.35% of the argon atoms are bound dimers while 0.16% are metastably dimerized. Concentration of van der Waals molecules have been calculated for alkali metal-rare gas pairs[14-15] and many other simple systems[11, 12, 17].

The lifetime of metastables has been estimated by the WKB method for a number of systems which are assumed to obey an angularly-independent intermolecular potential[6, 14]. For Ar_2 the mean lifetime of metastable states ranges from 10^{-11} s to well over 10^{10} s[6]. Since the mean time between collisions at one atmosphere and room temperature is of the order of 10^{-9} to 10^{-10} s most metastable molecules will probably be dissociated by collisions rather than by leaking through the centrifugal barrier. For the example in Figure 1 (L=30 for RbAr) *Baylis* has estimated a lifetime of 9×10^4 s for the v=4 level[14]; however, for v=5, which is near the top of the barrier, the lifetime is only 3×10^{-10} s.

Most of the discussion above applies to van der Waals molecules formed by the dimerization of atoms. In the case of dimers involving molecules (*e.g.*, HCl·Ar, $(N_2)_2$, $(O_2)_2$) it is often assumed that an angularly independent potential can be used to describe the interaction; this is probably a poor approximation in many cases. As we shall see, successful analysis of spectra of van der Waals data has been possible only in limiting cases: When both molecules of the dimer (*e.g.*, $(H_2)_2$) are freely rotating, angular dependent terms in the intermolecular potential are neglible. At the other extreme (*e.g.*, $(NO)_2$), molecules within the dimer have a locked geometry determined by very large angular-dependent potential terms. Between these two limiting cases the investigation of van der Waals molecules is exceedingly complicated.

One of the purposes of this Section has been to draw attention to some of the unique properties of van der Waals molecules. The extreme weakness of van der Waals bonds implies their exhibiting a number of properties which distinguish them from ordinary molecules.

The dissociation energy of a typical dimer is a few hundred cal/mol (see Table I) which is hundreds of times smaller than that of an ordinary chemical bond. Even at low temperatures where the kinetic energy becomes comparable to the well depth, less than 1% of the gas will be dimeric at pressures of 1 atm. Lowering the temperature further will of course increase the dimer concentration provided the monomer density does not change. However, below the gas condensation point the pressure decreases rapidly, so that the concentration of dimer, which depends quadratically on monomer density ($[A_2]=K[A]^2$), will also drop very significantly. These facts suggest that non-equilibrium techniques ought to be employed for the generation of van der Waals molecules. Since rotational kinetic energy is comparable to the intermolecular well depth, the concentration of metastable dimers is nearly the same as bound dimers.

Ordinary molecules are usually studied in their ground vibrational states because upper levels are not significantly populated. On the other hand, all the vibrational levels will be occupied in an investigation of van der Waals molecules because of their small spacings. As can be imagined, all these properties peculiar to van der Waals molecules make their experimental study particularly challenging. This explains, in part, why information on these interesting molecules has only recently become available.

3. Electron Diffraction

A direct and particularly exciting approach to the study of van der Waals molecules has been reported by *Audit, Rouault,* and *Farges*[18–21]. The authors describe the use of electron diffraction from molecular beams. Compressed gas is allowed to expand through a nozzle and the supersonic jet so produced is thereby adiabatically cooled (see Fig. 2). A skimmer and collimator placed in front of the nozzle reduces the jet to a molecular beam, and an electron beam directed perpendicularly produces an electron diffraction scattering pattern onto a photographic plate below. The condensation state of the final molecular beam depends on the initial pressure and temperature of the gas and on the geometry of the nozzle and collimator system. At room temperature and pressures of 50 atmospheres effective beam temperatures down to 35°K can be realized. Depending on the initial conditions, the molecular beam will contain monomers, dimers, polymers or particles of liquid or solid.

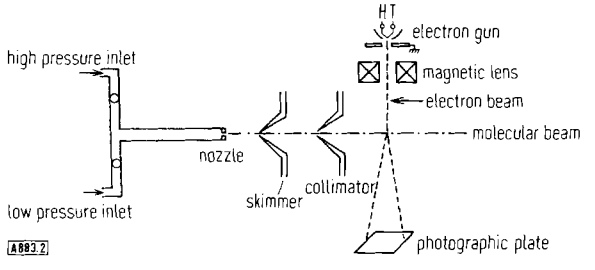

Fig. 2. Schematic diagram of a supersonic molecular beam electron diffractometer. Gases are expanded through a nozzle to produce an adiabatically cooled supersonic jet which is then collimated into a molecular beam which contains van der Waals molecules. An electron beam crossed into the molecular beam produces a diffraction pattern onto a photographic plate [18—21].

The diffraction pattern provides a means for determining the composition of the molecular beam: The smooth structureless pattern observed at low pressure is characteristic of scattering from atoms. At the highest pressures a complex scattering pattern corresponds to interference of the electron beam by an ordered array of atoms. From this pattern the crystal structure and lattice parameters for solid particles can be obtained. In regions of intermediate pressures a simpler diffraction pattern is observed which is produced by interference of atoms in van der Waals molecules. The scattering pattern on the photographic plate can be readily reduced to an interference function $G(s)$. The predicted form it takes for dimers is

$$G(s) = 2 + 2\frac{\sin sr}{sr} \tag{6}$$

where $s=(4\pi/\lambda)\sin\theta/2$ is called the scattering vector modulus; λ is the wavelength of the electron beam and θ the scattering angle[21]. The interference function is particularly simple for scattering from dimers because only a single characteristic distance, the bond length r, determines the interference of the electron beam. The dimer bond length may then be easily determined by fitting the experimental data to eq. (6).

Properly chosen initial gas conditions will produce a molecular beam containing about 50% van der Waals molecules. The interference function calculated for Ar_2 from Eqn. (6) is shown in Fig. 3[21]. The interatomic distance obtained is $r=3.93\pm.06$ Å. This is somewhat longer than the Lennard-Jones value of $r_e=3.82$ Å (cf. Table I); however, the distance measured in the electron diffraction experiment is averaged over the vibrational states of Ar_2 which are all significantly populated even at low temperatures. The expected values for the first vibrational levels, $<r>_v$, as given by *Cashion*[22] are $<r>_0=3.89$ Å, $<r>_1=4.08$ Å and $<r>_2=4.31$ Å. A comparison of these distances with the results of electron diffraction is therefore entirely consistent.

In addition to the positions of the maxima in the interference pattern the decay of the pattern also contains information on the properties of the van der Waals molecule. Since each vibrational state of the molecule produces a slightly different interference spacing the decay of the pattern becomes a measure of the distribution of bond lengths. Including this effect the interference function becomes

$$G(s) = 2 + 2e^{-l^2s^2/2}\frac{\sin sr}{sr}$$

where l is the mean vibrational displacement.

The intense scattering pattern observed for Xe_2 enabled the determination[21] of l. A value of $l=0.11$ Å was obtained for bond length $r=4.41\pm.03$ Å. The large value

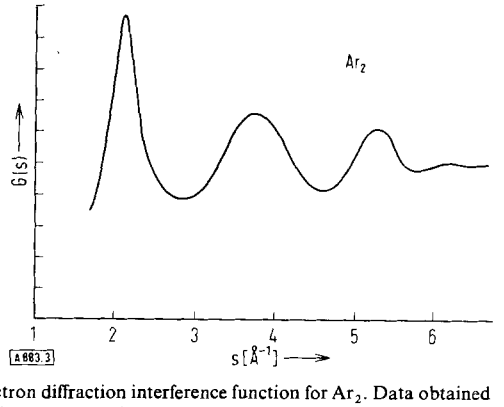

Fig. 3. Electron diffraction interference function for Ar_2. Data obtained from the electron scattering pattern of Ar_2 van der Waals molecules contained in a supersonic molecular beam [21].

of l is consistent with the anharmonicity of the intermolecular potential well and the population of many vibrational levels in the sample studied. Since the mean vibrational displacement depends on temperature and the shape of the potential function, a measurement of l at a known temperature would enable the van der Waals interaction to be characterized. Unfortunately, the effective vibrational temperature of these molecular beams is uncertain so l can only be used to test the feasibility of the Lennard-Jones parameters.

The application of supersonic jets and electron diffraction techniques to the study of polyatomic van der Waals molecules appears promising. Studies with CO_2 suggest that the molecular beams produced contain $(CO_2)_2$[23]. Since this system is more complex than dimers of the rare gases, analysis of the data is not yet complete. In the near future structural information on this and other polyatomic van der Waals molecules will undoubtably be available and, from the determined geometry, the angular dependence of intermolecular interactions can then be inferred. A recent review by *Bonham*[24] of electron diffraction studies of dimers and polymers of strongly hydrogen bonded molecules, which are somewhat outside the scope of the present review, is recommended. Future electron diffraction studies may provide some of the most valuable information on polyatomic van der Waals molecules.

4. Spectroscopy

One of the most dramatic examples of the usefulness of spectroscopy to the study of van der Waals molecules has been the recent investigation of Ar_2 by *Tanaka* and *Yoshino*[25]. The ground state of argon is $3p^6 — {}^1S_0$. On excitation a p electron is promoted to a higher unfilled atomic orbital. Absorption of low pressure gaseous argon at room temperature to these states occurs in the vacuum UV region and gives the usual atomic line absorption profiles. However, at liquid nitrogen temperatures the gaseous argon absorption reveals fine structure which has been convincingly assigned to vibration transitions of bound Ar_2 van der Waals molecules. In the longest wavelength region (System I, Fig. 4) the molecular absorption is described by a ${}^3\Sigma_u^+ \leftarrow {}^1\Sigma_g^+$ transition. The upper dimer state correlates to one atom being in its lowest excited state $3p^5 4s^1 — {}^3P_2^0$, while the other atom is in its ground state. The ground state dimer is bound by the dispersion forces of two ground state argon atoms. Absorption of a dimer with one ${}^1S_0$- and one ${}^3P_1^0$-atom is labeled as System II.

Fig. 4 shows the experimental data for these systems. On the long wavelength side of each of the atomic resonance lines, the vibrational bandheads of the dimer are plainly evident. For these systems transitions from $v''=0$ to $v''=4$ vibrational levels of the ground state dimer to several vibrational levels of the excited states are observed. The separation between the ground ($v''=0$) and first excited vibrational state ($v''=1$) of Ar_2 was determined as 25.5 cm^{-1}, and evidence from other observed band systems suggested six bound vibrational states for the potential with $L=0$. From the spectroscopically determined vibrational spacings, and an assumed equilibrium distance, the potential curve for Ar_2 is constructed using a Morse potential. The derived dissociation energy $\varepsilon = 91.6$ cm^{-1} (262 cal/mol) is within 10% of that determined from physical measurements (cf. Table I). *Bruch* and *McGee*[26] point out that the extrapolated value of ε obtained from the spectroscopic data depends significantly on the assumed functional form of the potential and can give results that vary by as much as 10%.

The band head positions determined from spectroscopic data do not correspond to a potential $L=0$. When an analysis of the rotational contour of the dimer bands is available, we can expect a more precise determination of

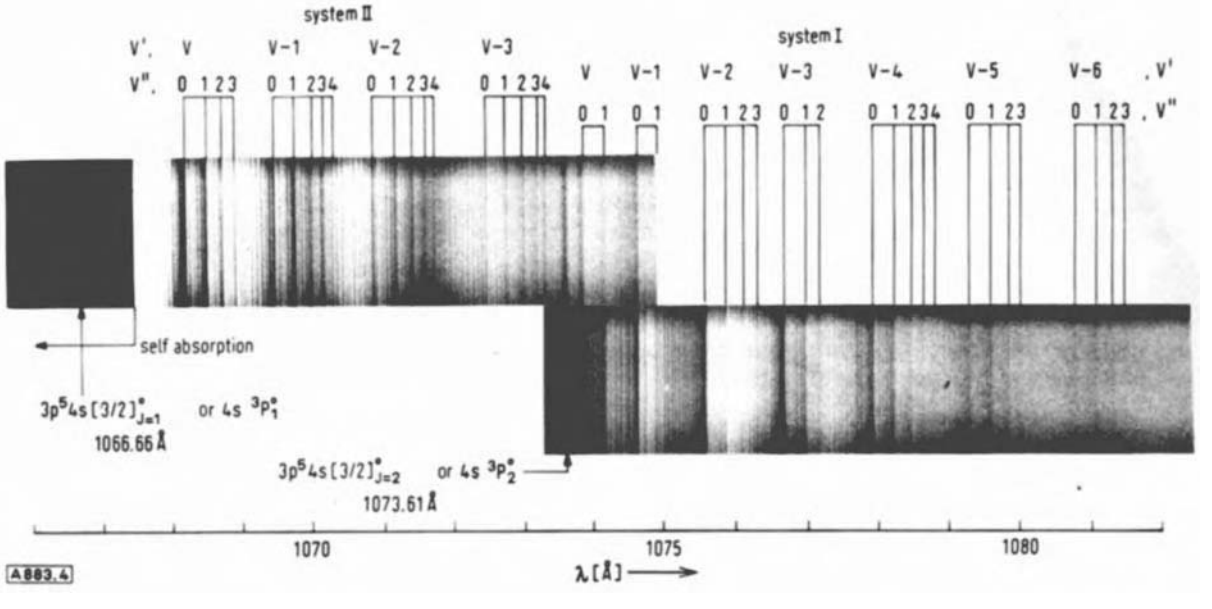

Fig. 4. The absorption spectrum of Ar_2. The absorption cell containing argon was cooled by liquid nitrogen. The argon pressures were 10 to 20 torr for the top and bottom exposures, respectively. The regions of strong absorption near 1066.66 Å and 1073.61 Å represent transitions of atomic argon. On the long-wavelength side of these atomic transitions are bandheads of the vibrational transitions of Ar_2 [25].

the intermolecular potential. Vacuum UV studies of Xe_2 and other rare gas dimers[27] will undoubtedly provide a rich source of information on these van der Waals molecules.

Optical absorption and emission studies of other diatomic van der Waals molecules have not yielded unambiguous information on intermolecular interactions. Diffuse band systems, which suggest collision pair transitions, have been reported for Hg_2, Cd_2, and Zn_2, and other homonuclear molecules[28]. Some fine structure has been observed in absorption studies of HgAr and a detailed analysis has provided evidence that the absorbing species are bound states based on energy level calculations on an assumed form of an intermolecular potential[29]. Structuring observed in other spectroscopic studies of Hg with foreign gases has been reported but has not been analyzed in detail[30]. Many studies of the emission and absorption spectra of alkali metal-foreign gas mixtures have been reported and are reviewed elsewhere[31-34]. Satallite bands both to the high and low frequency side of the alkali metal transitions depend on the foreign gas, pressure, and temperature in a complex way. Interpretation of this data is still controversial and while some of the features may involve transitions of van der Waals molecules[35-36], it is evident that much of the absorption arises from collision pairs[37].

Further experimental and theoretical work will be required before the spectroscopy of alkali metal—foreign gas mixtures is fully understood.

Optical pumping experiments have provided evidence for van der Waals molecules in alkali metal-rare gas pairs[38]. In these studies the hyperfine levels in the alkali metal are split by a magnetic field and are optically pumped to obtain a nonequilibrium population distribution; the relaxation of these states to equilibrium is then measured. Relaxation can occur during collisions with another atom, usually a rare gas.

In experiments with Rb—Kr two relaxation times were distinguished[39-40]. One, τ_2, of the order of 10^{-12} s, reasonably corresponds to the duration of a kinetic collision; the second, τ_1, of the order of 10^{-8} s, is identified with the lifetime of a metastable or bound state van der Waals molecule. Since, however, the Rb—Kr molecule is very likely destroyed on each collision with another atom, the time measured is actually the time between collisions. This is made apparent since τ_1 becomes shorter as a foreign gas such as He is added to the system.

It is difficult to predict what new information about the intermolecular potential will become available from optical pumping experiments. Nevertheless it does appear to be a useful technique for measuring lifetimes of van der Waals molecules containing an alkali metal.

A particularly valuable spectroscopic approach to the investigation of van der Waals molecules has been the use of collision induced absorption studies pioneered by *H. L. Welsh et al.*[41]. Homonuclear molecules such as H_2, N_2, O_2, *etc.*, possess no dipole moments and therefore have no allowed electric dipole infrared absorption. However, when one of these molecules comes into close contact with another molecule or atom its quadrupole moment can induce a dipole moment in the neighbor. In addition, overlapping electron clouds can become distorted and produce a dipole moment in the interacting pair of molecules. These induced dipoles are modulated as the molecule pair vibrates and rotates, and infrared absorption is then possible.

The theory of this absorption has been explored by *van Kranendonk*[42]. These effects are small and path lengths of 10—100 m are required for measurable absorption in gases at pressures of about 1 atmosphere.

The appearance of the absorption depends on the nature of the molecule pair interaction. For collision pairs, transitions originate from the continuum of states above the dissociation limit of the intermolecular potential (see Fig. 1) and a broad diffuse absorption results. Transitions from bound van der Waals molecules originate from descrete levels and sharp absorption profiles are expected (cf. Fig. 1).

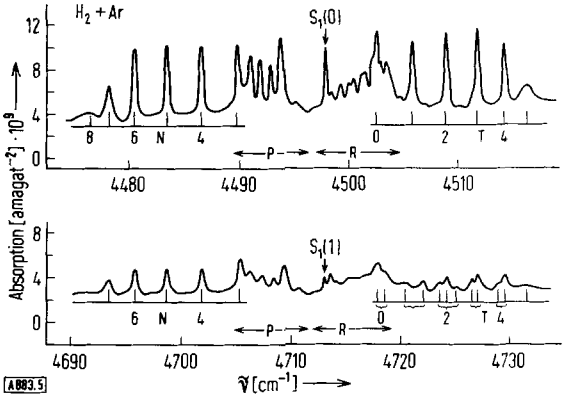

Fig. 5. Infrared spectrum of the H_2—Ar. The absorbing path length is 165 m. The total gas density is between 1—2 amagats (an amagat is the gas density at 1 atm pressure and 0 °C) [46].

Watanabe and *Welsh*[43] have obtained spectroscopic evidence for the $(H_2)_2$ van der Waals molecule which has a dissociation energy of only 10 cal/mol[44]. A somewhat stabler complex is formed between H_2 and foreign gases[45-47]. As example, a portion of the H_2—Ar spectrum[46] is shown in Fig. 5. The absorption is in the fundamental vibrational region of H_2 with the rotational transitions $J=0\rightarrow J'=2$ ($S_1(0)$) and $J=1\rightarrow J'=3$ ($S_1(1)$).

The transition originates from the ground vibrational state of H_2 and goes to the first excited vibrational state (indicated by the single prime). In the absence of Ar the only spectrum in the regions shown would be the two sharp features under the arrows of Fig. 5. These absorptions arise because of exceedingly weak electric quadrupole transitions which are possible in H_2. There is a broad underlying continuum which represents induced absorption by collisions of H_2 and Ar. The wealth of fine structure observed arises from absorption by bound states of H_2—Ar.

Since the binding energy of this complex is exceedingly small and H_2 is a light molecule and zero point vibration

is a significant fraction of the intermolecular potential well depth, only the v=0 bound state is involved in the absorption apparent in Fig. 5. The rotational quantum number J identifies the internal rotation of H_2 and L characterizes the end-over-end rotation of H_2—Ar. The selection rules permit transitions with $\Delta L = +1$ and $+3$, *i.e.* R and T branches respectively as well as $\Delta L = -1$ and -3, *i.e.* P and N branches respectively (Fig. 5). Having made these assignments the rotational constants can be used to find the intermolecular distance for H_2—Ar in its (v=0) state ($r = 3.94$ Å). The observed energy levels T(v,L) may also be used to evaluate Y_{lj} of eq. (4). Since *Cashion*[10] has given these Y_{lj} coefficients in terms of ε and r_e of the Lennard-Jones (6—12)-potential, spectroscopic data provide a direct evaluation of these parameters.

Most of the features shown represent bound→bound transitions of H_2—Ar, *i.e.* the absorptions are characteristically sharp. However, for transitions to high L states the absorptions become noticeably broad (*e.g.* compare T(5) with T(4) in the upper portion of Fig. 5). As the complex rotates faster, the well of the effective potential becomes shallower (see Fig. 1) and the (v=0) state comes closer to the top of the centrifugal barrier. "Tunneling" through the barrier can then occur rapidly with the result that the lifetime of the H_2—Ar van der Waals molecule is reduced and the level becomes broadened. These diffuse bands are the evidence of bound→metastable transitions.

The features discussed so far are consistent with the model that H_2 is freely rotating in the van der Waals molecule. This is to be expected if the intermolecular potential is isotropic. Evidence for anisotropic interactions in H_2—Ar appears in the lower portion of Figure 5. Splittings are apparent in the T branch features as a result of coupling between J and L. This coupling arises because of the weak anisotropic interaction between the rotation of H_2 in the complex and the end-over-end rotation of the complex.

This wealth of spectroscopic information is not only provided by the complex H_2—Ar but also by other H_2- and D_2—rare gas complexes[43,45-47]. Analysis of this data provides information on both ε and r_e for an assumed intermolecular potential function. A careful comparison of these spectra with the energy states calculated for various trial potentials can also provide a good test of acceptable functional forms of intermolecular interactions[48]. Although a quantitative explanation of the splitting of van der Waals rotational states is not yet available, further theoretical work will undoubtedly provide valuable information on anisotropic interactions. The spectroscopic findings of *Welsh et al.* probably provide the most detailed information available on intermolecular interactions for any polyatomic van der Waals molecule.

The coupling between internal rotation and end-over-end rotation of the complex is much more evident in H_2—CO or H_2—N_2 than in H_2—rare gas complexes[46,47]. In H_2—N_2 for example, spectroscopic features corresponding to ΔL changes are diffuse in comparison to the sharp features shown in Fig. 5 for H_2—Ar.

It is suggested[47] that the internal rotation of N_2 couples with the end-over-end rotation of the complex and a complicated splitting in energy levels results which cannot be completely resolved. Furthermore, transfer of rotational energy of N_2 to end-over-end rotation of the complex results in dissociation by centrifugal forces; this broadens the levels and shows up as the observed diffuse absorption. Evidence for this type of dissociation of van der Waals molecules through transfer of internal rotational energy is also supported by mass spectroscopic experiments (cf. Section 5).

Analysis of the infrared spectrum of $(NO)_2$[49] suggests that this dimer structure is nearly rigid. Figure 6 shows the spectrum of nitric oxide in the region of fundamental vibration of NO. Spectrum A is of the gas at room temperature and shows the usual vibration-rotation fine structure of NO. However, at low temperatures a new feature centered at 1790 cm^{-1} appears. This absorption depends quadratically on NO density, as would be expected if it is due to $(NO)_2$. The band shape of this feature resembles an unresolved vibration-rotation absorption of a near symmetric top. An analysis of this band shape and other observed absorption characteristics suggests that the dimer has a *cis* configuration with a van der Waals bond

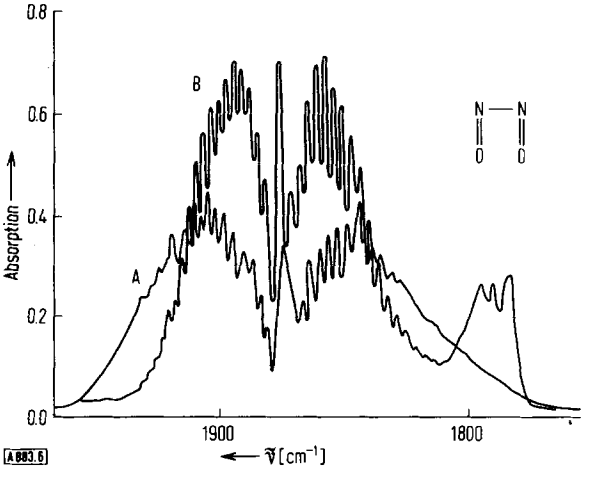

Fig. 6. IR spectrum of $(NO)_2$. Nitric oxide pressure 480 torr at 298 °K (A), and 270 torr at 123 °K (B). Path length is 6 cm. Curve (A) shows only the usual vibration-rotation absorption of NO near room temperature. However when the temperature is lowered, absorption due to $(NO)_2$ appears near 1780 cm^{-1} (curve B) [49].

length of 2.2±.2 Å and an NNO angle of *ca.* 90°. This molecule contains $3N-6=6$ vibrational modes. Two appear at high frequency (1860 and 1790 cm^{-1}) and belong to the in-phase and out-of-phase stretching of two coupled NO molecules. The other absorptions (~100 cm^{-1}) represent low frequency stretching, bending and torsional motions against the weak van der Waals bond. Since these low lying vibrational states will be populated even at low temperature, their occupation considerably complicates the observed spectrum and thus makes a more precise determination of $(NO)_2$ geometry impossible.

A study of the temperature dependence of the dimer absorption enables an estimation of the energy of dissociation of the dimer; it is found to be $\Delta E = 2450$ cal/mol. Unfortunately, ΔE is not directly related to ε as eq. 5 suggests.

The equilibrium constant K can only be calculated from ΔE and ε if estimates of the partition functions are available[50]. A comparison of the geometric data obtained from spectroscopic measurements and the relatively large energy of dissociation with the values listed in Table I shows considerable disagreement. This points to the inadequacy of forcing a fit of a Lennard-Jones intermolecular potential from thermodynamic data for some molecular systems. The descrepancy arises because the values presented in Table I were derived from gaseous measurements at room temperature. Molecules which collide at room temperature approach each other at random orientations, so in this case fitting the intermolecular interaction with the isotropic Lennard-Jones potential is acceptable. However at low temperatures angularly dependent interactions of bound states and colliding pairs become relatively more important and favor those orientations which increase the intermolecular attraction. The effective potential well depth becomes deeper and the intermolecular distance at the bottom of the well becomes shorter.

A careful examination of the low temperature properties of a gas reveals the existence of dimers and leads to energies of formation which are in good agreement with spectroscopic data[51-53].

The low temperature behavior of NO is significantly different from say O_2 or N_2 and suggests, as do theoretical studies, that the bonding in $(NO)_2$ is considerably stronger than that expected from dispersion forces[54].

In the search for the $(O_2)_2$ van der Waals molecule with induced IR absorption at low temperature we have found evidence for a somewhat rigid dimer but the data do not permit a structure determination[55]. The dissociation energy of $(O_2)_2$ is consistent with the value given in Table I. IR spectroscopic evidence for bound states of $(N_2)_2$ has been searched for but not found[56].

The formation energies of $(HCl)_2$, HCl—Ar, and other van der Waals molecules involving combinations of hydrogen halides and rare gases have been determined by IR spectroscopic investigations[57-60]. The interactions in $(HF)_2$ are particularly important to investigate since they represent the simplest examples of hydrogen bonding[61,62]. In such investigations sharp absorption features of the bound dimers can be detected between the intense vibration-rotation features of the uncomplexed hydrogen halides. The temperature dependence of these features provides a means of determining the heats of dissociation of these van der Waals molecules. A typical value is $\Delta H =$ 2140 cal/mol for $(HCl)_2$[58]. A difficulty met with in analyzing these data is that some dimer absorptions are obscured by intense monomer absorptions.

While a general theory for the coupling process in van der Waals molecules has already been developed, analysis of the observed spectroscopic features has not provided a complete picture of the geometry or nature of the angularly dependent forces in these interesting species[63].

Billingsley and *Callear*[64] have reported on the far ultraviolet absorption of gaseous $(NO)_2$ and obtained a dissociation energy in agreement with the IR results[49]. Attempts to study other van der Waals molecules by the examination of electronic transitions have usually not been too successful. One problem is that the allowed transitions of non-complexed molecules overwhelm the absorptions of the less plentiful van der Waals molecules. One way of circumventing this difficulty is to examine spectroscopic transitions which are forbidden in the monomer but are induced in the dimer by the presence of another component. Studies on $(O_2)_2$[65-68], $(Br_2)_2$[69] and $(I_2)_2$[70] have followed this procedure. An example is the examination of the forbidden oxygen-($^1\Delta_g \leftarrow {}^3\Sigma_g^-$) transition[67]. The absorption depends quadratically on the O_2 pressure. Since the selection rules are relaxed when one O_2 molecule is interacting with another, the observed band is due to $(O_2)_2$. If the temperature of the gaseous oxygen is lowered then the absorption increases, since more molecular aggregates are formed by the attractive intermolecular potential. However, it is still unclear whether the absorption by $(O_2)_2$ is due to collision pairs or van der Waals molecules. The absorption profile is broad and no fine structure which could positively identify van der Waals molecules have been detected. This of course does not mean that bound states of $(O_2)_2$ do not exist, for theory[6,10], as well as infrared[55] and mass spectroscopic evidence, to be discussed later, support their existence. As mentioned earlier, collision pairs yield broad absorptions. However, a complex overlapping spectral pattern originating from van der Waals molecules may also appear diffuse with insufficient spectroscopic resolution. Thus the low temperature electronic absorption of gaseous oxygen undoubtedly contains contributions from bound dimers although these spectroscopic data do not prove their presence.

Spectroscopic studies of $(Br_2)_2$ and $(I_2)_2$ have also revealed broad structureless absorption bands[69,70]. Moreover, the absorption by a given density of gaseous Br_2 or I_2, increases as the temperature is lowered, thus suggesting the formation of more dimers. However, the attractive intermolecular potential makes the collision of a pair of molecules more likely at lower temperatures as well as increasing the concentration of bound states. As in the case of $(O_2)_2$ the observed broad absorption profiles do not allow distinction between the concentration of collision pairs and van der Waals molecules.

Since equilibrium conditions do not favor high concentrations of van der Waals molecules, other experimental approaches have been considered for spectroscopic studies. For example, matrix isolation studies have been carried out on $(HCl)_2$[71] and $(NO)_2$[72]. The difficulty with this technique is that intermolecular forces of the surrounding matrix are comparable to the bonds of the van der Waals molecule and significant structural differences between the gas phase and matrix isolated molecule can be expected. Rotational motion is hindered by the matrix so band shapes do not yield structural information. Finally, since matrix isolation is under nonequilibrium conditions, heats of formation cannot be obtained from this type of experiment. Nevertheless, matrix isolation has provided valuable information for some of the stronger van der Waals molecules. The vibrational frequencies of $(H_2O)_2$ have been obtained only by this technique[73]. It

was also established that the van der Waals bonding of $(NO)_2$ was through N—N[72].

Supersonic molecular beams attain very low temperatures yet the total molecular concentrations are too low for the usual spectroscopic absorption experiments. The use of microwave absorption spectroscopy together with mass spectroscopic detection of the beam will probably prove a promising technique in the near future[74].

5. Mass Spectroscopy

Recent experiments using mass spectroscopy have proved particularly valuable in determining the properties of simple van der Waals molecules. As a source for the dimers, *Leckenby* and *Robbins*[75] used a gas reservoir with a small orifice. Since the mean free path of the escaping gas was comparable with the orifice diameter there was no adiabatic cooling of the gas as in the supersonic molecular beam experiments discussed previously. Provision was made for heating or cooling the sample gas, so that the monomer-dimer equilibrium properties in the reservoir could then be directly examined at various temperatures.

There are many experimental difficulties in making quantitative measurements on dimers with the aid of mass spectroscopy. Great care must be taken to dinstinguish between real dimers which originate from the equilibrium properties of the gas in the reservoir and dimers produced from ion-atom reactions in the mass spectrometer. Careful design of the sample source together with efficient pumping, which maintains the molecular beam, reduce the importance of ion-atom reactions. The low values of dimer concentration makes quantitiative detection difficult. Furthermore, uncertainties of ionization cross sections of dimers makes absolute measurements somewhat unreliable.

Leckenby and *Robbins*[75] have investigated dimers of CO_2, N_2O, N_2, O_2, Ar and Xe. They find, as expected, that the dimer concentration depends quadratically on the gas pressure. The temperature variation of $(Ar)_2$, for example, is shown in Figure 7. It compares favorably with the calculations of *Stogryn* and *Hirschfelder*[6]. Their calculated concentrations for bound states are indicated by the curve labeled "theor. (b.)" and bound and metastable states are shown by "theor. (b.m.)". Since the time of flight from reservoir to detector is of the order of 10^{-5} to 10^{-6} s, metastables contribute significantly to the dimers detected by mass spectroscopy. Although absolute measurements of dimers is uncertain by possibly a factor of 2 the relative concentrations at various temperatures provide a means of determining the energy of formation.

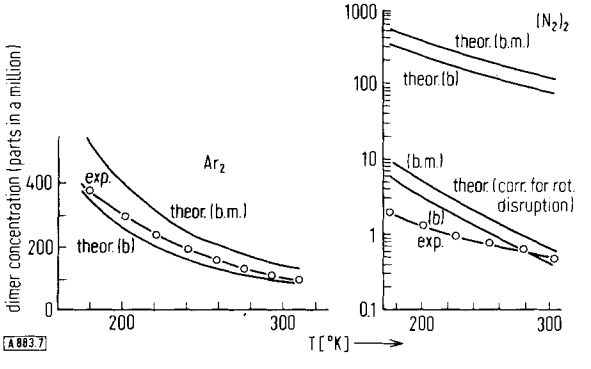

Fig. 7. Mass spectrometrically determined [75] and calculated [6] concentration of Ar_2 and $(N_2)_2$ as a function of temperature.

While the agreement between mass spectroscopic determination of rare gas dimer concentrations and the theory of *Stogryn* and *Hirschfelder* is satisfactory, there is a dramatic descrepancy when polyatomic van der Waals molecules are studied. For example, the measured concentrations of $(N_2)_2$ or $(O_2)_2$ are two orders of magnitude lower than the theoretical predictions. *Leckenby* and *Robbins* have proposed a simple and convincing model to account for this descrepancy. It is to be recalled that only a few collisions are required for the transfer of rotational-translational energy in gases[76]. Since a van der Waals molecule is in a state of perpetual collision this efficient transfer can be expected to occur between the rotation of the individual molecules in the dimer (*e.g.* N_2 in $(N_2)_2$) and the end-over-end rotation of the dimer. If the combined rotational energy of the two molecules in the dimer exceeds the van der Waals binding energy then after a short time there is the chance that all the rotational energy will be eventually transferred into the end-over-end rotation of the dimer and the resulting centrifugal forces will cause dissociation. Calculations based on this simple model give reasonable agreement with measured dimer concentrations for polyatomic van der Waals molecules. In Figure 7 the concentration of $(N_2)_2$ corrected for rotational disruption is compared to the measured concentration. Evidence for this type of metastable van der Waals molecule. which can occur only for polyatomic dimers, was observed in the infrared spectra of H_2—N_2 and H_2—CO (cf. Section 4).

Other groups[77-80] have studied van der Waals molecules with the aid of supersonic molecular beams produced from high pressure gas reservoirs. Since adiabatic cooling can produce very low temperatures, higher polymers as well as dimers are generated. For example, in a study by *Milne* and *Greene*[81] on argon clusters, species from $(Ar)_2^+$ to $(Ar)_{20}^+$ could be detected.

The advantage of high-pressure sources (up to 5 atm was used) is that cluster concentrations are higher. While this is interesting for the study of nucleation phenomena, quantitative conclusions on equilibrium properties are uncertain. If the size of the orifice is greater than the mean free path of the gas, no adiabatic cooling results. In this case information on the monomer-dimer equilibrium is utilizable. The results of *Milne* and *Greene* for dimers of Ar, N_2 and O_2 are in substantial agreement with those of *Leckenby* and *Robbins*.

6. Conclusions

It is apparent from the examples discussed above that electron diffraction, optical and infrared spectroscopic, and mass spectroscopic studies of van der Waals molecules provide a wealth of detailed information about intermolecular interactions. It is to be expected that such

experiments will, in the near future, not only afford quantitative details about the isotropic interactions between atoms but also about the anisotropic interactions between small molecules.

Structure and Function of Chromosomal Nucleohistones

By Eberhard Zimmermann[*]

The progress made in molecular biology has provided definite evidence that DNA is the genetic material of all cellular organisms. It is mainly localized within the cell nuclei and, in association with histones and acidic proteins, forms the fundamental structure of the chromosomes. The DNA-protein complex, called nucleohistone or chromatin, represents the sum of all existing genes of one cell type and can be considered as a functional genetic unit. All genetic structures contain this fundamental element and only their steric arrangement or multiplicity determine the species-specific differences in chromosomal morphology. The preservation of the three-dimensional structure seems to be the function of histones which, in general, are associated with densely packed and metabolically inactive DNA sequences. The lysine-rich histone I probably has a specific regulatory function since it inhibits the transcription of certain genes. Acidic proteins are mainly to be found in stretched chromosomal structures of high metabolic activity which accentuate the correlation between structure and function of nucleohistones. Approximately 50% of the DNA of the nucleohistone complex is not masked by proteins though only a small percentage of the free nucleotide sequences can be transcribed by RNA polymerase. The "open" structure of nucleohistones finds a plausible explanation in the fact that amino acid sequence analysis of several histones revealed an asymmetric distribution of charged groups and that therefore only these protein fractions can interact with DNA. In *Crick*'s recently published model of the chromosomal organization the unique structure of histones is taken into account and it is assumed that the histone-rich heterochromatin contains multiple but untranscribable control elements. Functional genes are represented by a single stranded DNA duplex within the interbands which utilize a special protein to preserve this unique conformation.

1. Introduction

Nucleohistones (chromatins) are naturally occurring biological macromolecules consisting of DNA and proteins (Section 3). They exist in all cell types of the animal and plant world and represent the main element of the chromosomal structure. Chromosomes of eucaryotic cells with true nuclei are 200 to 500 Å in diameter and are totally dispersed during the interphase of the cell division cycle (mitosis) and therefore cannot be detected by optical methods. In the prophase internal structural changes take place, aggregations of the nucleohistone filaments occur and the dense chromosomal structure is formed. In the continuation of this process chromosomes move in the equatorial plane of the metaphasic cell and are then divided into two identical chromatids, which are connected to each other by the centromer. This linkage disappears during the anaphase and after attachment of the filament to the centromeric region of the chromatids the two sets of daughter chromosomes are distributed in two new cells. The subsequent gradual fusion of these chromosomes into compact nuclei is the most dramatic effect of the telophase and the daughter cells pass into the interphase condition (Fig. 1). The doubling of the chromosomes and consequently the synthesis of new DNA is accomplished in the middle of the interphase. Another correlated reaction is the formation of new histones associated with nuclear DNA in all animal and plant cells. (Only in the mature sperms of some fish species are histones replaced by protamines, a specific class of basic proteins containing as much as 60% arginine.)

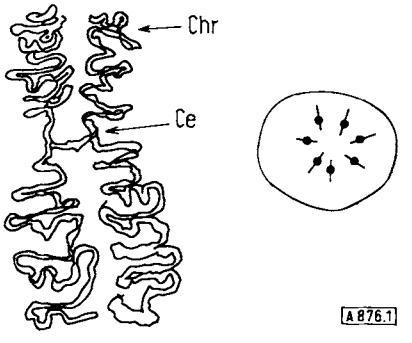

Fig. 1. Left: Metaphasic chromosome, consisting of two chromatids (Chr) held together by the centromer (Ce). Right: Arrangement of chromosomes in the equatorial plane of the metaphasic cell. Both diagrams highly schematized.

The detection of DNA in chromosomes was a result of *Feulgen*'s pioneering work in 1924; later estimations proved that a single nucleus may contain as much as 1.7×10^{-13} to 15.0×10^{-13} g DNA[1]. The most detailed information available about chromosomal structures originates from the study of giant chromosomes, which are especially well formed and easily detectable in the interphase nuclei of the salivary glands from Diptera larvae (flies and mosquitos). Their length is one hundred times that of normal chromosomes and they are 4 to 5×10^{-3} cm in diameter; con-

sequently, they contain essentially more DNA per cell nucleus than the corresponding diploid cell of mammalia.

The giant chromosomes, whose detailed structure is readily revealed by suitable staining, represent numerous genes with different biological functions, of which hundreds of identical copies can exist. Their transversal pattern of alternating bands of chromatic and achromatic material suggested the terms heterochromatin and euchromatin. Electron microscopic studies by *Ris* provided evidence that this pattern is mainly a result of different three-dimensional folding and packing of nucleohistone filaments. These staining patterns are so highly specific and colinear with phenotypic expressions that they are used by the cytologist as a basis for heriditary theories. Most of the heterochromatin regions do not appear to represent active genes and do not participate in the transference of genetic information. Their capability of reacting with specific stains is correlated with their high protein content[2, 3]. Localized structural modifications on giant chromosomes are characterized as "puffs" discernable as highly active metabolic regions associated with an enhanced RNA and protein synthesis (Fig. 2).

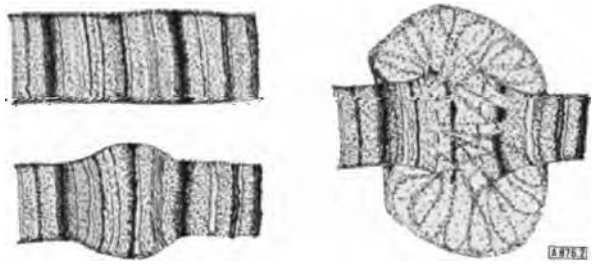

Fig. 2. Model of puff formation in giant chromosomes of the salivary glands of Diptera larvae.

2. Structure of Chromosomes

The fine filament structure of metaphasic chromosomes implies that nucleohistone elements of different diameter are contributing to their complex texture. Several theories were developed for a sophisticated explanation of the existence of different sized nucleohistone complexes. *Ris*[4] considers their characteristic appearance to result from the parallel aggregation of four DNA duplexes that are laden with histones and loosely twisted around one another. In accordance with the multistrand hypothesis, two nucleohistone filaments, each 40 Å in diameter, form the 100 Å subunit of the chromosomal structure. Two subunits randomly folded and packed represent one chromosome 200 to 500 Å in diameter. This concept found its strongest support in the highly specific arrangement of DNA in sperm nuclei. X-ray diffraction studies revealed a very compact alignment of parallel oriented nucleoprotamine subunits within the intact sperm head, forming a unique structure with a characteristic property in polarized light: it exhibits negative birefringence[5].

There is enough evidence to support the belief that same organization prevails in the case of giant chromosomes of Diptera larvae; about 1000 to 4000 single nucleohistone filaments with an average diameter of 200 to 400 Å, each of them representing one chromatid, are arranged in parallel. Stretched and densely folded regions alternate—whereby each nucleohistone molecule extends through the entire chromosome (Fig. 3). These subunits of the Diptera chromosomes are comparable with the fibrous nucleohistone structure of metaphasic eucariotic cells.

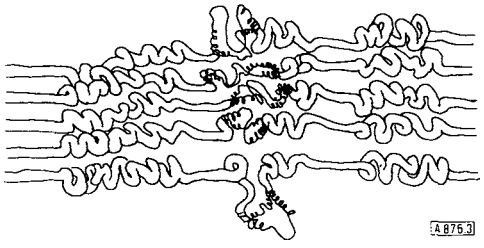

Fig. 3. Parallel arrangement of nucleohistone fibers with partial unwinding of the DNA double helix.

The single-strand hypothesis is based on the assumption that only one DNA molecule coated with basic and acidic proteins is randomly folded and packed to form the three-dimensional lattice of the 200 to 500 Å chromosomes. This theory has the appeal that it can most easily be brought into accord with *Watson* and *Crick*'s model[6] of semi-conservative replication of DNA[*]. During the mitotic cell division cycle each chain of the DNA duplex is transfered to one daughter cell and serves as template for the synthesis of a complementary chain.

On the basis of his investigations, *Taylor*[7] developed a quite different idea about the complexing of chromosomal elements: he suggested that transversally arranged short DNA helices are alternatively connected by proteinous linkers (Fig. 4). All attempts to isolate such structure-preserving proteins failed, as did also experiments designed to release the short DNA chains with proteolytic enzymes[8].

The behavior of the metaphasic chromosomes during cell division and the arrangement of nearly all chromosomes in the equatorial plane of the cell support the concept that

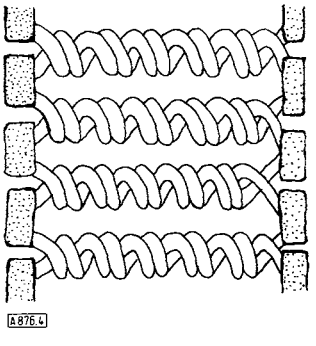

Fig. 4. *Taylor*'s model of the coupling of DNA helices by short proteinous linkers [7].

[*] In semi-conservative replication of DNA, both strands of the duplex are copied at the same time.

interchromosomal linkages do exist. In the case of some animal species all chromosomes are arranged in a circular pattern within the equatorial plane. It thus seems extremely likely that several chromosomes originate from one DNA helix and that the interchromosomal bridges represent only different and specific nucleotide sequences of the same DNA molecule[9].

The single-strand hypothesis is further confirmed by the more specialized structure of lampbrush chromosomes which exist in oocytes[*] of amphibians and other vertebrates. In this type of diploid cell the chromosomes are formed by two chromatids and develop a number of paired loops along the main axis of the DNA backbone. These loops proliferate from the two chromatids, exhibit very intensive RNA and protein synthesis, and seem to represent what we call a gene[10]. Taking into consideration the actual size of chromosomal loops *Gall* and *Callan*[11] elaborated their exciting hypothesis of "master" and "slave" genes. If we assume that these loops contain only one original gene and a number of more or less correct copies of the same nucleotide sequence, the discrepancy between the possible extension of one gene and the dimension of the existing loops is eliminated. Furthermore, the two authors believe that only the slave genes serve as a template for RNA synthesis.

The existence of one master gene coincides with the fundamental idea of classic genetics that one gene fulfills one biological function. According to *Beermann*'s concept of the "operative organization" of chromosomes the master gene serves as template for RNA polymerase transcription, while slave genes only bind and stabilize such RNA molecules[12].

The ingeniously predicted existence of reiterated sequences could be experimentally proved by *Spiegelman*'s hybridization technique, and such redundant genes were found in all higher developed organisms[13–17]. The copies of the original sequences are sometimes inaccurate, so that repeated genes exist which are incongruous with the master gene. It is still an open question whether these incompletely or incorrectly transcribed nucleotide sequences represent functional genes or are only parts of them with a specific regulatory activity.

3. Chemical Composition of Nucleohistones

Histones and a small percentage of acidic proteins can be extracted together from chromosomal nucleohistones by acidic solutions and precipitated in pure form with ethanol. The large scale extraction and fractionation procedure elaborated by *Johns*[18] is most commonly used for this purpose. However, it should be mentioned that heterogeneous histones prepared by this method contain a certain percentage of related material which increases the tendency for protein-protein interactions to take place in aqueous solutions. The application of more improved procedures made it possible to differentiate between several histone species and, furthermore, to classify them according to their characteristic amino acid content and their N-terminal residues (Table 1). Their elution sequence in column chromatographic fractionation was used for the enumeration of the histone fractions (I to IV); additional indices are used for the purpose of labeling their subfractions—*e.g.*, histone I is partially resolved into histone Ia and Ib, and histone II can be split into fractions IIa, IIb_1, and IIb_2[19].

Table 1. Amino acid composition of histone fractions in mol-%. F_1: very lysine rich; F_{2a}, F_{2b}: slightly lysine rich; F_3, F_4: arginine rich.

Aminoacid \ Fraction	F I	F IIa	F IIb	F III	F IV
Alanine	23.5	10.5	10.5	12.5	6.9
Arginine	2.5	11.5	7.5	13.0	13.7
Aspartic acid	2.8	6.0	5.5	5.0	4.9
Glutamic acid	6.0	8.5	9.0	11.0	5.9
Glycine	6.8	12.5	7.0	6.5	16.7
Histidine	0.5	2.0	2.5	2.1	2.0
Isoleucine	1.6	4.5	5.0	5.0	6.0
Leucine	4.4	10.5	6.0	8.5	7.0
Lysine	26.3	10.5	14.5	9.0	11.0
Methionine	—	—	0.7	0.7	2.0
Phenylalanine	0.8	1.6	2.0	2.5	2.0
Proline	7.9	3.0	4.5	4.5	0.9
Serine	6.2	3.1	9.0	7.0	2.0
Threonine	5.5	5.6	6.5	7.0	7.0
Tyrosine	0.5	3.0	3.1	2.0	3.9
Valine	5.0	7.0	6.8	6.0	8.8
	100.3	101.8	100.1	102.3	100.7
N-terminal residue	Acetyl	Acetyl	Proline or Alanine	Alanine	Acetyl

The lysine-rich histone I was carefully purified by *Peacocke*[20] and the molecular weight of this relatively monodisperse fraction was determined as 20000. Surprisingly, *Kinkade* and *Cole*[21] were able to resolve the same histone on Amberlite CG-50 columns into four subfractions and thus indicate the possible existence of modifications having slightly different amino acid compositions. Meanwhile, the arginine-rich histone IIb, containing acetylated alanine or proline as N-terminal groups, was fractionated by *Johns*[22] on carboxymethyl cellulose; three of the five subfractions thus obtained proved to have different amino acid compositions. Such observations justified the question whether these so-called subfractions were artificial complexes with impurities of obscure origin[23, 24]. It is notable in this context that *Stellwagen*[25] was able to demonstrate conclusively that even histones extracted from purified nuclei are contaminated by cytoplasmic proteins. More detailed information about this problem was provided by *Johns*[26], who investigated the binding conditions of cytoplasmic acidic proteins to the chromosomal nucleohistones.

In spite of all these difficulties *Bonner et al.*[27] were able to isolate histone IV in homogeneous form from calf thymus and from pea seeds and to analyze their amino acid sequences. In agreement with *Stellwagen*'s[28] and *Ogawa*'s results[29] they were able to establish that the lysine residues are accumulated in the N-terminal half of the molecule. On the other hand, acidic and aromatic amino acids, as well as the hydrophobic compounds, are clustered in the C-terminal half of the molecule[30] (Fig. 5). Surprisingly, both the histones investigated contain 102 amino acids with only two amino acid replacements; furthermore, certain

[*] Oocytes are cells which on undergoing meiosis form the ovum.

peptide sequences occur in which only one amino acid is replaced, thus implying that the histone IV gene may be formed from repeating sequences.

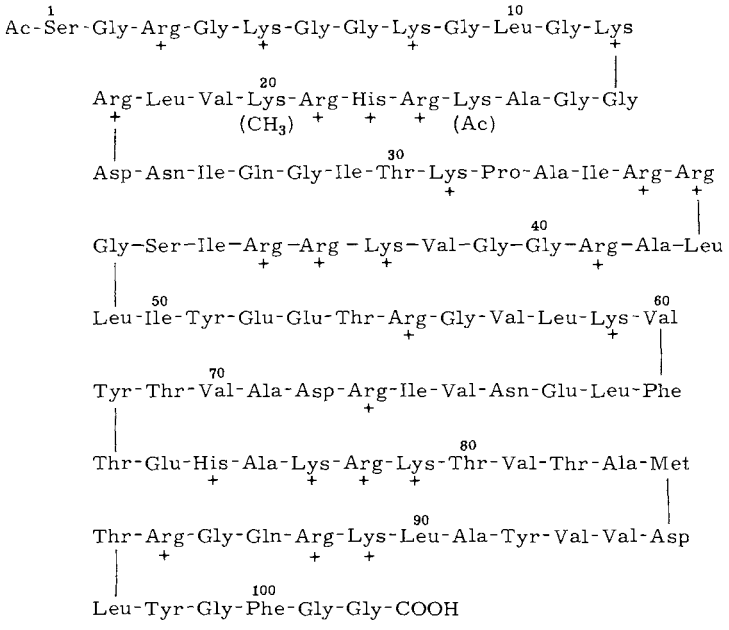

Fig. 5. Amino acid sequence of histone IV [23] (basic amino acid residues are marked).

The amino acid sequence analysis of histone IIb and a subfraction of F1 reveals a similar asymmetric distribution of amino acids within these histone molecules[31, 32]. The specific accumulation of positively charged groups on the ends of histone molecules opens up new aspects regarding the interaction between histones and DNA (Section 8).

Our fragmentary knowledge of the function of histones and their derivatives does not allow any conclusive statements to made regarding whether the steric conformation of these proteins contributes to their ability to associate with DNA[33]. All that we do know is that isolated lysine-rich histone I dissolved in ethylene chlorohydrin has a 46% helical conformation, whereas the fractions IIa and IIb have about 65 to 70%[34]. The values are drastically reduced

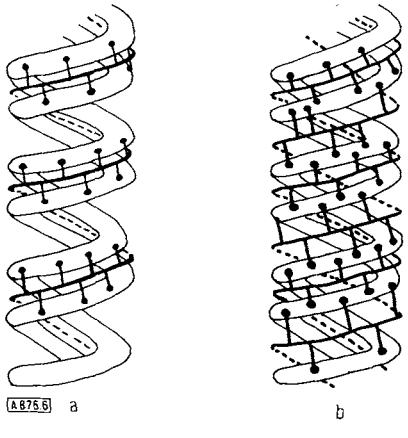

Fig. 6. a) Binding of protamine in the shallow groove of the DNA duplex. b) Binding of histones in the deep groove of the DNA duplex [37].

to about 20% in aqueous solutions but vary with the protein concentration and the age of the solution[35].

Zubay and *Doty*[36] conclude from their ORD measurements that half of the DNA bound histones exist in the α-helical configuration. This result gives strong support to *Wilkin*'s model of the tertiary structure of nucleohistones which is based on the assumption that only the α-helical conformation favors the binding of histones in the deeper groove of the DNA duplex (Fig. 6)[37]. A more questionable assumption that has been made regarding the DNA/histone interaction is that of a symmetric distribution of charged groups within the protein molecules. This requirement is not fulfilled in the case of histone IIb and IV; however, it seems likely that the DNA/protein interaction involves phosphorylating, acetylating, or methylating enzymatic mechanisms as essential metabolic procedures which differentiate both the structure and function of histones. Valuable information pertinent to this point has been provided by *Stocken*[38] who was able to prove that a significant correlation between the extent of phosphorylation and the biological activity of histone I really does exist. By contrast arginine-rich fractions IIb and III seem to be more susceptible to acetylating reactions[39, 40]. Since the biological activity of RNA and DNA synthesis reaches its maximum rate after one to two hours in the regenerating rat liver, it can be assumed that the rapid acetylation reaction is the first step in gene activation. Histone methylation occurs subsequently when DNA and histone synthesis have exceeded their highest values. Obviously such a reaction has nothing to do with regulatory processes, but it may be connected with the transport of newly synthesized histones from the cytoplasm to the cell nuclei.

4. Metabolism of Histones

Studies on the cellular mechanism of histone synthesis tend to confirm the conclusions reached above. *Robbins* and *Borun*[41], for example, proved experimentally that arginine-rich histone is synthesized in the cytoplasm in HeLa cells[*] and is subsequently transported to the cell nuclei. The synthesis of protamine in salmon testis also occurs outside the nuclei but within the cytoplasmic compartment[42]. Of particular interest in this connection is the investigation of a specific class of small polysomes which are detectable in the cytoplasm of histone synthesizing cells; they disappear shortly after cell division and thus emphasize their specific role in histone synthesis[43]. Furthermore, they contain a specific 7—9S RNA which is attached to the polysomes only during the time of histone synthesis and is therefore considered to represent the messenger RNA for histones IIa, IIb, and III.

A somewhat different result was reported by *Reid* and *Cole*[44] for isolated thymus nuclei which were found to be metabolically active and capable of synthesizing the arginine-rich histone III. *Birnstiel* and *Flamm* investigated the principal pathway of nuclear protein synthesis using

[*] HeLa cells are a strain of human cells originating from a carcinoma of the cervix and named after *Helen Lane* the patient from whom they were obtained.

pea seeds and cell cultures of tobacco leaves[45]. After pulse labeling and mechanical disruption of the cells the cellular particles were fractionated by centrifugation and their content of incorporated amino acids was determined. The nucleoli[*] of both cell types were found to have a significantly higher amino-acid incorporation rate, thus indicating that the histone synthesis is mainly located in these nuclear compartments. It was a crucial and decisive experiment to characterize some of the newly synthesized proteins as histones since it is a well known fact that the nucleoli are also responsible for the synthesis of ribosomal proteins.

The connection between nuclear and cytoplasmic histone synthesis becomes more understandable when one considers that the nuclear histone synthesis also involves a 9S RNA as messenger. The bulk of RNA isolated from cytoplasmic polysomes could be fractionated into three major species indicating their metabolic relation to the three main histone fractions described above[46]. Furthermore, there is sufficient evidence to prove that histone genes are reiterated and clustered within the chromosomes. This is an interesting but not surprising feature since we know that repeated nucleotide sequences can make up to 20 to 80% of the nuclear DNA of eucariocytes[47].

That a special mode and codon for chain initiation might exist is suggested by *Allfrey*'s finding that the initiation of histone IIa synthesis appears to involve *N*-acetyl-seryl-tRNA[48]. This possibility cannot be overlooked since the synthesis of ovalbumin[49] and of hemoglobin[50] is also initiated by acetylated seryl-tRNA. Our present knowledge is far too fragmentary to understand clearly the complicated functional correlation between DNA and histone synthesis. In general, however, it can be stated that the histone synthesis of dividing cells with chromosome replication coincides with the multiplication of DNA. In addition, the specific inhibition of the DNA synthesis supresses the synthesis of lysine-rich histones while the production of arginine-rich histones within the cytoplasmic compartment is unaffected[51].

5. Acidic Nuclear Proteins

The fundamental concept that acidic proteins may play a decisive role in the regulation of the biological activity of nucleohistones was originally put forth by *Stedman* and *Stedman*[52]. This idea has been frequently challenged during the past few years by the assumption that certain histones might play a more important role in regulation mechanisms. However, the high concentration of acidic proteins within the nuclei and their enormous metabolic activity compared to the nearly inert histones implies their possible involvement in gene regulation, but this cannot, as yet, be supported by conclusive experimental results. The isolation and quantitative determination of acid proteins is relatively difficult since they are partly dissolved during extraction of the histones. In addition, extraction of the acid proteins with dilute alkaline solutions according to the method of *Busch et al.*[53] has the disadvantage that part of these proteins are irreversibly denaturated. The deoxycholate procedure used by *Wang*[54], and later improved by *Bonner*[55], however, partially overcomes this difficulty and acidic proteins may even be fractionated on DEAE cellulose. Another equally promising method of isolation is the extraction of all proteins by sodium dodecyl sulfate or NaCl followed by fractionation on agarose columns, both operations being carried out in a single step[56, 57]. Unfortunately, a large percentage of the eluted material is still heterogeneous[58]. It has been argued that contamination with lipoproteins and phosphoproteins, concentrated within the nuclei[59, 60], may be the reason for this abnormal chromatographic behavior. An additional problem encountered in their fractionation and purification is the extreme tendency to interact with basic proteins. On consideration of the technical difficulties mentioned above in isolation and purification of acidic proteins it can be readily appreciated why insufficient experimental data are available for evaluation of the metabolic function and activity of these proteins.

Wang[61] has investigated the metabolic activity of some isolated nuclei in the cell-free system reported by *Allfrey*[62]. Purified nuclear fractions have been obtained that contain 40% to 50% protein together with about the same amount of DNA and 1 to 2% RNA; such nuclei may be considered as biologically functional elements[63]. *Wang*'s experiments indicate that especially the nuclear ribosomes and the "residual particles" (complexes between acidic proteins and RNA) have a significantly high metabolic activity.

Steele and *Busch*[64] have compared the metabolic activity of the nuclei of normal cells with that of Walker tumor cells. These authors used salt solutions of increasing concentration for the stepwise extraction of different histones from Walker tumor cells. The histone fractions isolated in this way from the nuclei of tumor cells take up a higher proportion of labeled amino acids than do the acidic proteins.

These studies would seem to confirm that acidic proteins fulfill a specific function in normal cells. More recent experimental results strongly support the assumption that acidic proteins may counteract the inhibition of RNA synthesis by histones and that they are likely to be involved in control mechanisms[65, 66]. The phosphorylation processes appear to control the interactions between acid proteins, DNA, and RNA polymerase. In addition, there exists a direct relation between enhanced RNA synthesis by hydrocortisone and estradiol and increased concentration of certain acidic proteins[67, 68].

6. Histone-Bound Nuclear RNA

Huang and *Bonner*[69] were the first to make the outstanding observation that a specific RNA/histone complex may exist within the chromatin. Quantitative nucleotide and phosphorus analyses led to the conclusion that this RNA has a molecular size of 40 nucleotides. The authors assume that this "c-RNA" is associated with as many as 15 to 20 histone molecules and may represent a nucleohistone sub-

[*] Nucleoli are spherical bodies associated with specific chromosomal segments, the nucleolus organizer, where the synthesis of ribosomal RNA takes place.

Table 2. Protein/DNA relation in nucleohistones from various tissues (after Ref. [108]).

Tissue	DNA	Histone	Other proteins	RNA
Rat liver	1.00	1.00	0.67	0.043
Rat ascites tumor	1.00	1.16	1.00	0.13
HeLa cells	1.00	1.02	0.71	0.09
Calf thymus	1.00	1.14	0.33	0.007
Sea urchin blastula	1.00	1.04	0.48	0.039
Pea embryonic axis	1.00	1.03	0.29	0.26

unit. Since 1 to 2 RNA molecules are related to one gene it seems likely that the c-RNA may participate in gene regulation (Table 2). Similar RNA-histone complexes could also be isolated from mammalian cells: rat liver cells[70], KB cells[71], Novikoff hepatoma cells[72], and calf thymus cells[73]. *Bonner*'s group succeeded somewhat later in isolating this RNA from rat ascites cells and embryonic chick tissue[74]. The true identity of a specific chromosomal RNA, distinguishable from cytoplasmic components by its high uracil content, is still a matter for discussion and becomes even more controversial since *Heyden* and *Zachau*[75] demonstrated that the existence of smaller RNA fragments is mainly caused by the nuclease degradation of pellicle-bound tRNA.

7. Dissociation and Reassociation of Nucleohistone

Numerous investigations have been carried out in an effort to gain a better understanding of the conformational changes of DNA under the influence of bound proteins and the mechanisms of complex formation in general. Evidently native nucleohistone presents such a complicated three-dimensional structure that simple recombination of its basic components rarely yields a reassociation product having comparatively similar biological activity: acidic proteins complex with histones; both of these proteins may interact with DNA as well as RNA; and, furthermore, sequence analog RNA may hybridize with DNA. The scope of complex formation is broad indeed. Step-by-step degradation of the chromosomal nucleohistone and monitoring the change in biological activity appears to be as equally promising a method as others for gaining an insight into the three-dimensional structure of genetic material.

In naturally occurring nucleohistones acidic and basic proteins are strongly but noncovalently bound to DNA. Although the positive charges of the basic amino acid residues are not uniformly distributed over the histone molecules, recent physicochemical experiments carried out by *Olins*[76] furnish evidence, in agreement with *Wilkin*'s model[33], that lysine-rich histones bind to the large groove along the DNA duplex and neutralize effectively the DNA phosphate groups. It is still an open question, however, whether attachment of basic proteins to DNA creates intermolecular crosslinking of parallel arranged DNA helices or contributes to formation of superhelices[77–79] (Fig. 7).

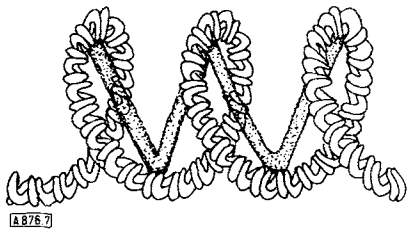

Fig. 7. Model of supercoiled DNA helices stabilized by protein linkers.

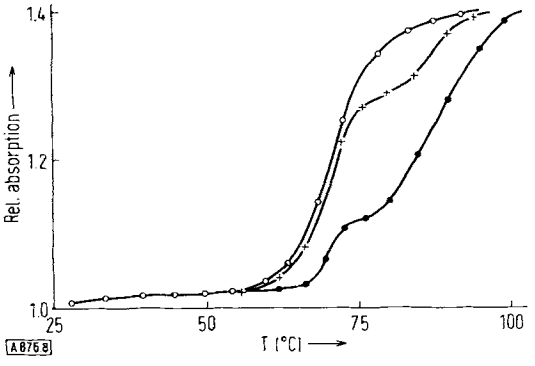

Fig. 8. Temperature dependent denaturation profiles for DNA (-○-○-), partially dehistonized nucleohistone (-+-+-), and intact nucleohistone (-●-●-).

Luzzati and *Nicolaieff*[80] elaborated the idea that the three-dimensional structure of nucleohistone is based on subunits formed by 4 DNA molecules complexed and surrounded with histones, whereas the nucleoprotamine structure tends more to a concentric arrangement of protamine molecules around a DNA backbone with water in the intermediate space. Reassociation experiments with nucleohistones show that the native conformation is restorable, even after almost complete dissociation in 3.5 M salt solution, by prolonged dialysis against water[81].

The outcome of this simple experiment implies that either the dissociation effect is totally reversible or cores of organizing structural elements are preserved under such experimental conditions.

Electron microscopic studies on preextracted nucleohistones show that the successive removal of histones at different ionic strengths leads to the formation of DNA loops which originate from structure-preserving cores of DNA and proteins[82,83]. It is possible that these morphological structures are identical with preexisting elements in the intact nuclei, as anticipated by *Bonner*, and are closely related to the DNA loops of lampbrush chromosomes[84]. Their degree of integration may explain the surprising observation that the dissociation of nucleohistones in high salt solutions is reversible. More detailed information about the histone-dependent conformational changes has been reported by *Allfrey* and *Mirsky*[85]. These authors showed that the removal of lysine-rich histone I causes a reversible formation of DNA loops while the subsequent extraction of arginine-rich fractions (III and IV) loosens irreversibly the entire chromosomal structure. The authors conclude that the two proteins fulfill different functions: arginine-rich histone forms intermolecular bridges between

different DNA molecules, whereas lysine-rich histone promotes condensation of chromatin.

The correlation between histone attachment and nucleohistone configuration has been intensively studied by *Murray*[86]. On decreasing the pH values of the solution the histones dissociate stepwise from the complex in a reversed manner, *i.e.* the lysine-rich fractions are the last to be released. The T_m-values for the temperature-dependent denaturation decrease as the amount of histone removed increases (Fig. 8). Since the histones, with an average molecular weight of 10000 to 50000, are much smaller than the native DNA, and the chromosomal nucleohistone contains approximately 50% to 60% protein, several histone molecules must be attached to one DNA duplex.

The distribution of the different histones along the main axis of the DNA may follow two extremly different patterns: either (i) histone molecules of one type are arranged consecutively or (ii) histone molecules of one type are never adjacent. The step-by-step extraction of histones should therefore result either in mixtures of free DNA and nucleohistone or in randomly deproteinized nucleohistone molecules. *Murray*'s results[86] demonstrate unequivocally that only DNA-protein complexes can be obtained which have T_m-values higher than protein-free DNA, and that their template activity for RNA polymerase is still significantly reduced.

In considering this evidence we have to assume that, in principle at least, histones are heterogeneously bound to DNA helices. This concept is supported by *Peacocke*'s studies on the influence of high salt concentrations on the conformation of nucleohistones[87]. The molecular weight decreases sharply to about 25% of the normal value of native material on increasing the salt concentration, while the radius of gyration of the DNA helix remains unchanged. Evidently the histones contribute far less to the conformation of the nucleohistone than assumed heretofore; consequently the stability of the three-dimensional structure, including superimposed foldings and twistings, is mainly dependent upon the existence of hydrogen bridges.

Nucleohistones dissolved in 4 M urea solutions show a distinct and reversible increase in viscosity[88]. Sedimentation experiments in the same solvent reveal that only 2% bound protein is dissociable and that the hyperchromatism of the temperature-dependent denaturation still amounts to 38%; this would suggest that the reversible conformation change may be caused by disruption of superhelical structures as was proposed by *Zubay* and *Doty*[32] on the basis of their hydrodynamic and light-scattering measurements. X-ray diffraction diagrams lead to the conclusion that the radius of gyration of such a superimposed helix could be in the range of 120 Å[89, 90].

8. Interactions between DNA and Histones

Our fragmentary knowledge about the tertiary structure and conformation of nucleohistones permits only a rough, overall assessment of the intricate binding conditions between the different components. An alternative way of elucidating the structural requirements for the formation of biologically active complexes is to examine reassociated DNA/polypeptide complexes. *Touvet* and *Champagne*[91] published some results of light-scattering and sedimentation studies on reassociated complexes and conclude that lysine-rich histone evidently reacts specifically but not covalently with definite binding sites of the DNA, whereby the helix becomes expanded longitudinally. The steric effect of bound arginine-rich histone is comparatively antagonistic and leads to contraction of the DNA duplex.

The preferential binding of histones or homogeneous polypeptides to definite nucleotide sequences was first investigated by *Chargaff*[92] and *Lucy*[93]. Further systematic studies on this very important phenomenon by *Felsenfeld et al.*[94] markedly clarified some important features of DNA-protein interactions; it was found that polylysine reacts cooperatively with adenine (A) and thymine (T) while polyarginine exhibits a certain preference for cytosine(C)- and guanine(G)-rich sequences of free DNA. *Felsenfeld* pointed out that these reactions are selective, reversible, cooperative, and stoichiometric; the end product of the complex-forming interaction consists of highly hydrated micelle-like particles of remarkably uniformity, with an average radius of 1700 Å[95]. Furthermore, the specificity of the polyarginine-DNA interaction is concentration-dependent and approaches optimal values of effectivity when the percentage of arginine is higher than 60%. There is only one protein known which fulfills this requirement and appears to be a natural binding partner of DNA: protamine. On the basis of results obtained from carefully conducted ORD studies it could be deduced that interactions between polylysine and DNA stabilize the DNA conformation, either by coil contraction or by superimposing a secondary helical structure[96, 97].

Unfortunately, all attempts to estimate the binding parameters and to reveal a sufficient degree of selectivity for the different reactants failed[98]. It should occasion no surprise therefore that pyrimidines do not exhibit any individual differences in their reactivity towards polypeptides, whereas a somewhat different situation is apparent in the case of purines. Polyarginine and polylysine show a slightly increased affinity for CG-rich polynucleotides[99]. This interaction can be inhibited quite strongly by sodium ions, which obviously compete with the ε-amino groups of the lysine residues for the binding sites of DNA[100]. Since sodium ions and bivalent metallic ions reveal a high affinity for AU- or AT-rich nucleotide sequences such competitive reactions could possibly limit specific translocation and thus interfere in gene regulatory mechanisms. On the other hand, aliphatic polyamines, like spermine or spermidine, are considerably more reactive than bivalent cations, though their specificity for AT-rich sequences is very much in doubt[101–104]. The temperature-dependent denaturation profiles are monophasic and thus indicate decisively that the interaction of these components with nucleotide sequences is non-cooperative; there is also evidence that a similar mode of interaction prevails in the case of short-chain polypeptides such as tetraarginine and tetralysine. Octalysine, however, preferentially reacts with certain nucleotide sequences. Interestingly, the DNA-protamine interaction, unlike the interaction of all other polypeptides so far discussed, is both a cooperative and an equilibrium

reaction. In accordance with a cooperative binding type, the denaturation profiles of nucleoprotamine are biphasic and the two T_m-values are correspondingly higher than in the case of free DNA. Related to this observation is the fact that the structure specificity as well as the affinity of protamine to DNA is illustrated by the first T_m-value of the complex being directly dependent on the amount of associated protein[105].

9. Biological Activity of the Chromosomal Nucleohistones

Further evidence suggesting a specific interaction between DNA and proteins in native as well as reassociated complexes derives from comparative studies of the template activity in RNA polymerase transcription. Native chromosomal nucleohistone generally contains RNA polymerase, DNA polymerase, and nucleoside-triphosphatase; the concentration and specific activity of these enzymes change with the development of the cells. Whereas it is not possible to decide whether RNA polymerase is specifically or unspecifically attached to this complex, sufficient experimental evidence is available to prove that DNA polymerase is bound to the complexed DNA duplex.

The susceptibility of nucleohistones for RNA polymerase transcription appeared to be one of the most appropriate methods for elucidating the efficacy of protein-DNA interactions in terms of gene regulation. RNA polymerase of *Escherichia coli* is commonly used in such experiments, the enzyme being incubated with increasing amounts of DNA or nucleohistone. Two important findings emerge from these studies:

i) The template activity of nucleohistones is significantly reduced in comparison to free DNA[106,107]. (A plausible explanation for this observation would be that the nucleotide sequences are partially masked by bound proteins.)

ii) RNA transcribed on nucleohistone templates hybridizes with DNA to a lesser extent than RNA synthesized on protein-free matrices[108].

These results lend support to the conclusion that restriction of RNA polymerase transcription must be due to the resultant steric alterations of the nucleohistone template by DNA-protein interactions. This effect can be specified by the fundamental observation that RNA chains synthesized on nucleohistone templates are 4 to 5 times shorter than in RNA synthesized on DNA templates[109,110].

Paul and *Gilmour*[111] were the first to recognize that some nucleotide sequences of chromatin are inaccessible for RNA polymerase transcription. Nucleohistones isolated from bone marrow cells and from calf thymus contain tissue-specific sequences which are transcribable by RNA polymerase but represent only 5 to 12% of the genetic information available in free DNA. In addition, these RNA do not contain any non-specific sequences, thus confirming the assumption that the chosen extraction procedure does not lead to conformational changes.

The hybridization capacity of RNA synthesized on nucleohistones partially deproteinized by 0.5 to 0.6 M salt solutions approaches values comparable with those observed for RNA synthesized with DNA templates[106]. Under these experimental conditions only histone I is selectively removed; this finding would appear to cast doubt on the validity of our working hypothesis that only the masking effect of bound histones suffices to explain this restricted

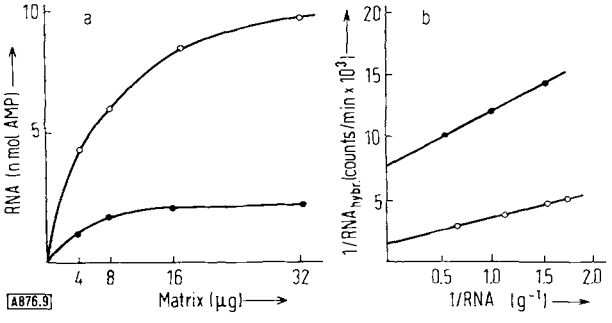

Fig. 9. a) RNA synthesis on DNA- (-○-○-) and nucleohistone matrices (-●-●-) with *E. coli* polymerase. b) Hybridization of *in vitro* synthesized RNA from DNA (-○-○-) and nucleohistone (-●-●-) matrices (after Ref. [130]).

template activity of nucleohistones. Recently, the view that extraction with 0.5 to 0.6 M salt solutions removes a repressor which directly influences either the steric conformation or the activity of the RNA polymerase has found more support. For example, it has been found that only 50% of the nucleotide sequences in nucleohistone are associated with proteins[112,113].

Spelsberg and *Hnilica*[114,115], however, have reported findings that are not in accord with this recent point of view: The selective extraction of histone I did not lead to an increase in the biological activity of the partially deproteinized nucleohistone. These authors are of the opinion that an activation of the RNA synthesis by the increased salt concentration is involved. Even after all the histones and part of the acidic proteins were removed, the biological activity of the extracted nucleohistone was still essentially restricted.

Insofar as experimental evaluation is concerned it should be noted that the available standard methods of transcription and hybridization are applicable only to those multiple genes which are repeatedly transcribed. However, the acceptance of technical limitations does not reduce the fundamental importance of these methods since repeated sequences represent highly specified operational genes with different activities corresponding to the stage of development of the cell. One example will suffice to illustrate this fact: RNA synthesis is detectable in the four-cell stage of sea urchin development whilst only those cistrons required for the synthesis of ribosomal RNA and tRNA are specifically activated during gastrulation[116].

The relative paucity of differences in the histone molecules of one cell, and the conservation of their amino acid sequences during phylogenesis, points to their being responsible for the general regulatory function in gene repression. As to whether arginine-rich histones take precedence over lysine-rich histones, or *vice versa*, for this function cannot

as yet be determined experimentally—available experimental evidence does not show any significant differences between the repressive action of arginine-rich and lysine-rich histones[117,118].

Johns and *Hoare* describe[119] an alternative solution to this problem. Investigations have shown that precipitating artificial DNA/histone complexes partly regain their solubility as well as template activity on reacting with an excess of histone. On the basis of this evidence it seems justified to assume that the repressive function of histones is more or less unspecific and related to the actual ratio of the reactants involved.

Acidic proteins probably play the most important role in gene regulation, since the concentration of these proteins is significantly increased in metabolically active regions of chromosomes while the histone concentration remains unaltered[120,122]. In this connection *Paul* and *Gilmour* have shown that the reassociation of nucleohistones with comparable biological activity depends on the actual concentration of acidic proteins involved[123]. The tissue-specific restrictions of nucleohistones as templates for RNA synthesis are due to the binding of acidic proteins[124]. The interactions between DNA and these proteins appear to be exceptionally complicated, since the addition of acid proteins leads, as *Wang* has reported[125], to enhanced RNA transcription on nucleohistone matrices. Somewhat contradictive to this observation, however, are the experimental results obtained by *Bonner*'s group[126], who support the view that the exceptionally crucial function of chromosomal RNA is to preserve and maintain the three-dimensional structure of nucleohistones as well as to regulate their biological activity. According to these authors it appears legitimate to equate the function of an operational factor with the existence of a specific RNA-histone complex.

This challenging conclusion does not seem too far fetched if we take into account the long known fact that the template activity of DNA for DNA polymerase is independent of the amount of associated histone[127] and that neither the amino acid composition nor amino acid sequence—and therefore charge distribution—of the histones seem to be related in any way to the activity of the RNA polymerase.

A very recent theory developed by *Crick*[128] partly circumvents these difficulties but retains the essential feature of protein-controlled genetic activity; it is based on the so-called "unpairing postulate".

Before considering the regulatory function of chromosomal proteins attention is again directed to the structure of nucleohistone. The alternating transversal bands of heterochromatin and euchromatin represent a densely packed and stretched tertiary structure, such as can be detected in the giant chromosomes of Diptera larvae. *Crick* bases his theory on these facts and assumes that the interbands or euchromatic regions contain single strand stretches of the DNA duplex. Only these nucleotide sequences represent recognition sites for RNA polymerase transcription and are large enough to code proteins having an average molecular weight of 30000 to 40000. The unwound conformation of DNA is due the action of chromosomal proteins, probably histones, which also preserve this unique structure. The much larger heterochromatin bands, on the other hand, are biologically inactive and are considered to contain multiple control elements which are essential for a graded and regulated biological activity of the euchromatin.

Further experimental information is now required in order to confirm this theory and to improve our understanding of chromosomal structures. It is obviously impossible to draw a correct and sophisticated picture of the correlation between structure and biological activity of chromosomal nucleohistones on the basis of our present fragmentary knowledge of DNA/protein interactions. *Mirsky*'s recent statement[129] sums up the situation by expressing that probably all the DNA in chromatin is linked to proteins and only the actual binding forces decide the accessibility of certain genes.

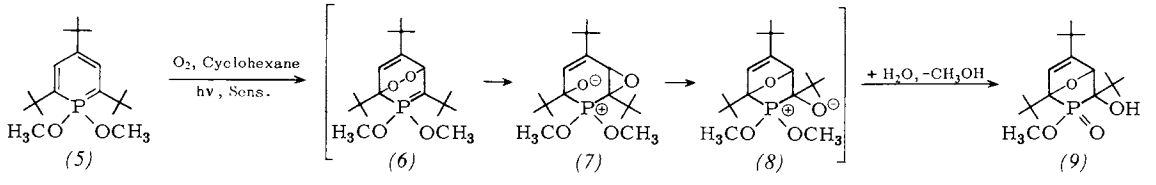
Photochemical Oxygenation of 2,4,6-Tri-*tert*-butyl-λ^3-phosphorin and 2,4,6-Tri-*tert*-butyl-1,1-dimethoxy-λ^5-phosphorin

By *Karl Dimroth*, *Anastasios Chatzidakis*, and *Ortwin Schaffer*[*]

Dedicated to Professor G. Wittig in grateful appreciation on his 75th birthday

Oxygenation of heterocycles by singlet oxygen produced by photosensitization[1] has recently excited great interest[2].



(1) (2) (4) (3)

Sensitized photooxygenation of 2,4,6-tri-*tert*-butyl-1,1-dimethoxy-λ^5-phosphorin *(5)* takes a different course. In this case the oxygen is added normally in the primary step at 1,4-positions, namely to *carbon atoms* 2 and 5. Again the primary product *(6)* could not be isolated. It probably rearranges with cleavage of the O—O bond, yielding the methyl 2-hydroxy phosphinate *(9)* by way of *(7)* and *(8)*. Its constitution follows from elemental analysis and spectroscopic data.

Experimental

Compound *(1)* (528 mg, 2 mmol) and eosin (15 mg) in anhydrous cyclohexane (60 ml) are irradiated for 45 min with a high-pressure mercury lamp (Hanau NK 6/20; emission maximum 366 nm) while anhydrous oxygen is passed into the solution. After removal of 2/3 of the solvent by distillation, addition of a little methanol precipitates the phosphinic acid *(3a)*, which melts at 167 °C when recrystallized from ethanol/water. With diazomethane it forms the *cis-trans*-isomeric methyl esters *(3b)*, m. p. 274 and 280 °C (dec.)[4] that are separable by thin-layer chromatography.

Preparative layer chromatography on silica gel with benzene/methanol as mobile phase affords *(4)* which after recrystallization from ligroin melts at 152 °C.

(5) (6) (7) (8) (9)

We have observed a new type of reaction in which in the primary step the oxygen is added at the 1,4-positions *with involvement of the heteroatom*: If 2,4,6-tri-*tert*-butylphosphor(III)-in *(1)*[3] in anhydrous cyclohexane containing eosin as sensitizer is irradiated by a high-pressure mercury lamp while oxygen is passed through the solution, then two crystalline compounds, m. p. 167 and 152 °C, can be isolated in 15% yield each. The higher-melting material is identical with the known 4-hydroxy phosphinic acid *(3a)* previously obtained by oxidation with HNO_3/H_2SO_4[4]. On the basis of elemental analysis and UV, NMR, and mass spectra, the compound of m. p. 152 °C has structure *(4)*. We assume the reaction course shown in formulas *(1)* to *(4)*. The primary product *(2)* was not isolated, as is generally also the case in other oxygenations[5].

On photooxygenation 2,4,6-triphenyl-λ^3-phosphorin[**] affords a larger number of products that are difficult to separate[6].

Irradiation and working up of *(5)* (yield 20%) are carried out analogously. The methyl hydroxy phosphinate *(9)* of m. p. 180 °C could not be separated into two diastereoisomers.

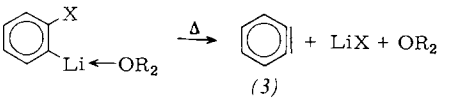
DTA Studies on Formation of Dehydrobenzene and Dichlorocarbene from Haloorganolithium Compounds

By *Oleg M. Nefedov* and *Andrej I. Dyachenko*[*]

Dedicated to Professor Georg Wittig on the occasion of his 75th birthday

In the present communication we report differential thermal analysis (DTA)[1] studies on the decomposition of *o*-halophenyllithiums, *o*-XC_6H_4Li *(1)*[1-3], and trichloromethyllithium *(2)*[3-5] in the present of ethers and amines. Compounds *(1)* and *(2)* were obtained by the addition of 1.0—10 ml of a 1.0 N solution of *o*-XC_6H_4Br



(1), X = F, Cl, Br

Cl_3CLi

(2)

(X = F, Cl, Br) or Cl_3CX' (X' = H, Br) in isopentane or *n*-pentane to an equal volume of 1.0 N *n*-C_4H_9Li in the same solvent at −150 °C. The mixture was then allowed to warm to room temperature (≈1 h) in a DTA instrument. The results are shown in Table 1. Independent experiments have shown that the observed exothermic effects are due to the decomposition of *(1)* or *(2)*[6].

Decomposition of the complex is evidently initiated by thermal dissociation of the Li←O coordinative bond. A free coordinative site becomes available at the lithium,

(3)

thus resulting in immediate elimination of lithium halide owing to intramolecular coordination X→Li. If this concept is correct complexes of *(1)* with cyclic ethers and other ligands of high basicity (*e.g.* dimethoxyethane or tetramethylethylenediamine) should be more stable that those with dialkyl ethers owing to a stronger Li←O bond.

Since the stability of complexes of *(1)* with cyclic ethers, dimethoxyethane, and tetramethylethylenediamine was indeed found to be independent of polarity, it seems reasonable to conclude that the Li←O bond strength is mainly determined by the steric requirements of the solvent in connection with its ability to undergo inversion.

As is also evident from the data in Table 1, the stability of complexes *(1)* increases in the sequence X = Br < Cl < F. This corresponds to the donor strengths of the halogens[7,8].

An analogous, albeit less pronounced, stabilization was also found for *(2)* in polar solvents (Table 1). This doubtless means that dichlorocarbene formation does not proceed

Table 1. Thermal stability of haloorganolithium compounds in polar solvents.

Solvent	Dipole moment (D)	Decomposition temperature (°C) [a] *o*-XC_6H_4Li *(1)* from *o*-XC_6H_4Br X = F	X = Cl	X = Br	Cl_3CLi *(2)* from Cl_3CX' X' = H	X' = Br
Diethyl ether	1.15	−48	−73	−85	−88	−89
Di-*n*-propyl ether	1.18	−50	−73	−83	−84	—
Di-*n*-butyl ether	1.22	—	−70	—	−87	−85
Triethylamine	0.82	—	—	—	−87	−85
Tetrahydropyran	1.55	−21	−50	−75	−65	−67
Tetrahydrofuran	1.75	−20	−51	−75	−66	−66
Oxetane	1.92	−19	−50	−76	−65	−65
Methyloxirane	1.95	−20	−52	−73	—	—
1,2-Dimethoxyethane	1.72	−19	−50	−80	−75	−75
Tetramethylethylenediamine	—	−16	−48	—	−76	—

[a] Average of 3—4 experiments.

As is seen from Table 1 the thermal stability of *(1)* increases substantially only on going from acyclic to cyclic ethers. Within the two series of ethers the stability remains practically unchanged in spite of the varying polarity.

(3)

(4)

These results are not in accord with formation of dehydrobenzene *(3)* *via* an *o*-halophenyl anion intermediate *(4)*[7], since such a mechanism would require a decrease in stability of *(1)* with increasing solvent polarity. Hence, we assume that *(3)* is formed by a concerted β-elimination of LiX from a complex of *(1)* with ether (or trialkylamine)[2,3].

via the intermediate anion (Cl_3C^-) but occurs as a concerted α-elimination of LiCl from the complex of *(2)* with ether or amine[9].

It is noteworthy that the temperatures of decomposition of *(2)* in triethylamine and acyclic ethers are the same. This fact may serve as further evidence for the above mechanism, because, according to *Lewis* and *Brown*[10], complexes of alkyllithium compounds with dialkyl ethers and corresponding trialkylamines are equally stable.

Formation of Macrocyclic Polyolefins on Autoxidation of Bifunctional Alkylenephosphoranes

By *Hans Jürgen Bestmann* and *Hans Pfüller*[*]

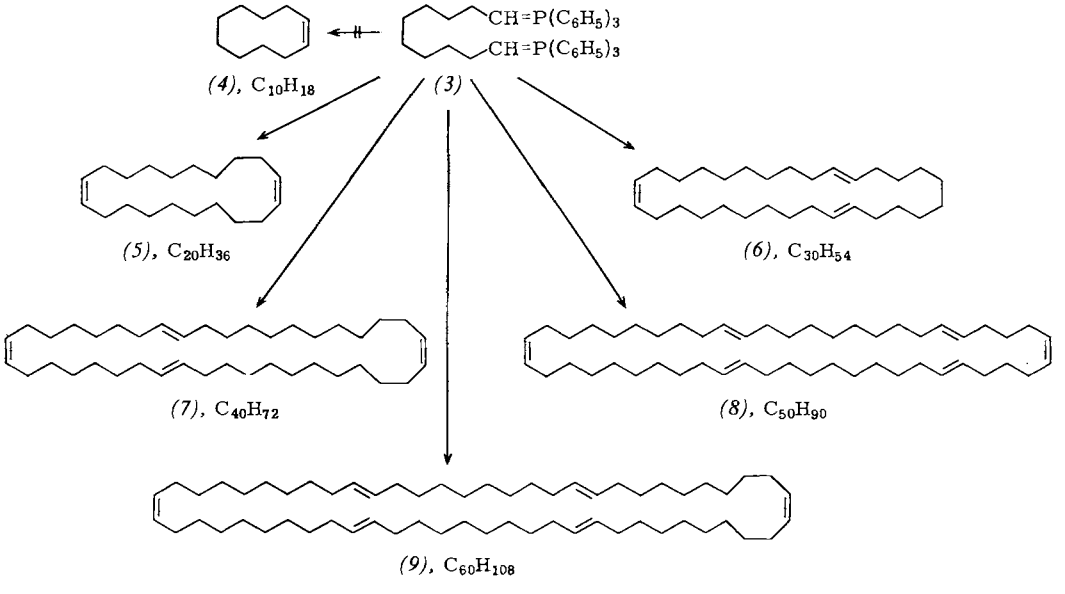
Dedicated to Professor Georg Wittig on his 75th birthday

Autoxidation of alkylenephosphoranes (ylides) of structure $R—CH=P(C_6H_5)_3$ affords olefins $R—CH=CH—R$[1] and triphenylphosphane oxide. If bifunctional alkylenephosphoranes (bisylides) *(1)* are used, cycloolefins *(2)*[2,3] are obtained. *(1)*, R = $—(CH_2)_2—$, reacts with cyclizing

(1) *(2)*

dimerization to yield 1,5-cyclooctadiene[2]. Our further investigations have given the following results:

If the structure of the starting bisylide of type *(1)* permits intramolecular ring closure on autoxidation, yielding a five-, six- or seven-membered ring, such a ring is formed either mainly or exclusively. A compound such as *(3)*, however, does not yield any medium-size ring compounds, *e.g. (4)*, but macrocyclic polyolefins such as *(5)—(9)* are obtained by dimerization, trimerization *etc.* Further examples are collected in Table 1.

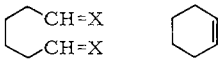


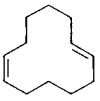
Correct analytical data and NMR and mass spectra are available for all the pure mono-, di-, and tri-mers listed in the Table. Formation of further cyclooligomers, of which in some cases only the trimer could be isolated, can be recognized by C, H analyses, NMR spectra, and clearly from the field ions in the mass spectrum; here the molecular ions gave the strongest mass lines, *e.g. (6)* $M^+ = 414$, *(7)* $M^+ = 552$, *(8)* $M^+ = 690$, *(9)* $M^+ = 828$. After hydrogenation, correspondingly heavier molecular ions appear.

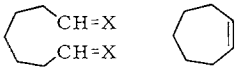
For examples 4, 6 and 7, the proportion of *cis,cis*-isomer in the dimer was determined (silver nitrate complex). It was then shown that this isomer was formed preferentially: *cis,cis*-1,9-cyclohexadecadiene·$2AgNO_3$, m.p. 142 to 143 °C, 78%; *cis,cis*-1,10-dioxa-5,14-cyclooctadecadiene·$2AgNO_3$, m.p. 153 °C, 62%; *cis,cis*-1,11-cycloeicosadiene·$2AgNO_3$, m.p. 135—136 °C (m.p. 136—137 °C[6]) 78%.

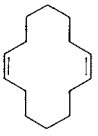
All the bifunctional alkylenephosphoranes, except that used for No. 5 of the Table (poor yield), are sparingly soluble in dimethyl sulfoxide. We therefore assume that formation of macrocyclic rings on autoxidation of the bisylides in an intermolecular Wittig reaction (according to Ref. [1]) begins with formation of a *cis*-double bond. Subsequently, either an intramolecular reaction may occur or the chain may grow by further intermolecular C=C junctions before ring closure to the cyclooligomer follows.

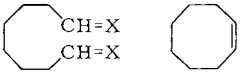
1,11-Cycloeicosadiene (5) and oligomers (6)—(9)

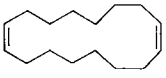


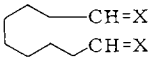


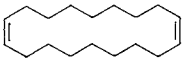


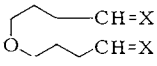


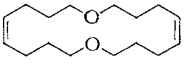


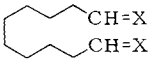


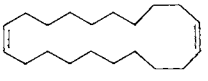


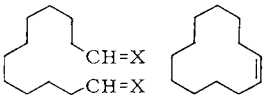


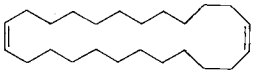


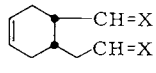


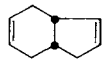


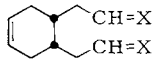


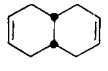


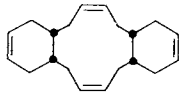


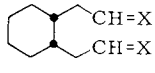


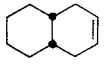


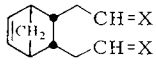


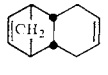












1,10-Decamethylenebis(triphenylphosphonium bromide) (49.5 g, 0.06 mol) is converted by the dimethyl sulfinate method[4] into a suspension of the corresponding bisylide in dimethyl sulfoxide, through which, in the apparatus

described previously[1], oxygen is passed with ice-cooling and magnetic stirring until the ylide precipitate has dissolved and a brown solution results (oxidation time 3 h;

oxygen uptake 1140 ml, 85%). The solution is then left overnight, after which it is extracted with light petroleum. The extracts are united, washed twice with water, dried over sodium sulfate, filtered and freed from solvent. The residue is boiled for a short time under reflux with methyl iodide (3—4 ml), then treated with light petroleum (200 ml), which precipitates the triphenylphosphane from the extract as methyltriphenylphosphonium iodide. The filtrate therefrom is concentrated and poured on an aluminum oxide column (length 20 cm, diameter 1.5 cm, neutral Al_2O_3 Woelm, activity II) for removal of triphenylphosphane oxide. Elution is with cyclohexane. On evaporation of the cyclohexane the hydrocarbon mixture separates as a mass of colorless crystals. *(5)* distils at 123—124 °C/0.15 torr (yield 1.1 g, 13.7%). The residue is distilled in a rotating tube at 180—240 °C/0.001 torr, affording 1.4 g (17%) of *(6)*, *(7)*, *(8)*, and *(9)*.

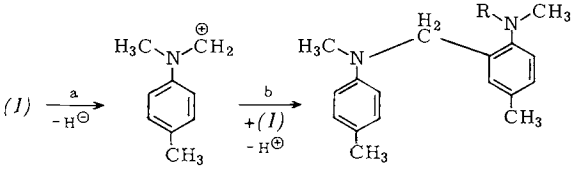
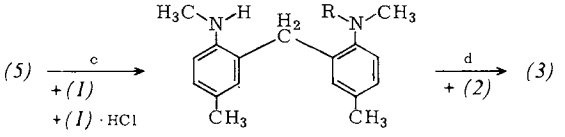
Structure and Mechanisms of Formation of a Novel Phosphorus-containing Heterocycle; P—Cl Bond Length and ^{35}Cl-NQR Frequency[**]

By *T. S. Cameron, C. Y. Cheng, T. Demir, K. D. Howlett, R. Keat, A. L. Porte, C. K. Prout*, and *R. A. Shaw*[*]

Dedicated to Professor G. Wittig on the occasion of his 75th birthday



We recently reported an unusual reaction between *N,N*-dimethyl-*p*-toluidine *(1)* and phosphorus oxide trichloride *(2a)* leading to a novel heterocycle *(3a)* m. p. 172 °C, yield 6%[1]. The X-ray structure analysis[1] has in the meantime been refined[2].



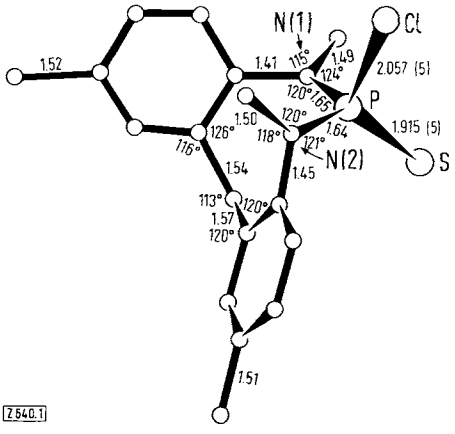
a, X = O
b, X = S

We have now found that a similar reaction occurs with phosphorus sulfide trichloride *(2b)* to give the sulfur analog of *(3a)*, 6-chloro-2,5,7,10-tetramethyl-6-thioxo-6,7-dihydro-5*H*,12*H*-dibenzo[*d*,*g*]-[1,3,2λ^5]diazaphosphocine *(3b)* (m. p. 209—210 °C, yield 6%).

We suggest a four-step mechanism for the formation of *(3)*. We have not yet established how Step a occurs, but the postulated electrophile *(4)* is well documented in the system *N*-methyl-*p*-toluidine/formaldehyde/H$^+$. It is probable that compounds *(3)* are formed *via* the intermediates *(5)* and *(6)* with R = CH_3. To date, we have shown that Steps c and d occur under the above reaction conditions for compounds *(5)* and *(6)*, when R = H. Indeed Step d

occurs under milder conditions (25—80 °C) with *(6)*, R = H, and gives better yields of *(3a)* and *(3b)* (*ca.* 70%).

(3b) crystallizes from CCl_4 in the monoclinic space group $P2_1/n$, with $a = 11.19 \pm 0.01$, $b = 10.95 \pm 0.01$, $c = 15.43 \pm 0.01$ Å, $\gamma = 109.5 \pm 0.1°$; $V = 1783$ Å^3, $d_{calc} = 1.30$ g/cm^3 for $Z = 4$, $d_{exp} = 1.29$, MW = 350; 1471 independent reflections using $Mo_{K\alpha}$ radiation; R = 0.10 (refinement continuing). Although the molecules *(3a)* and *(3b)* are isostructural, the crystals are not isomorphous.



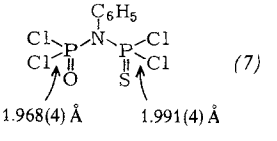


Fig. 1.

All bond lengths and angles are as expected (see Fig. 1). The two *N*-methyl groups can be seen to be non-equivalent (as suggested by NMR) owing to differences in the local environment of the ring. The length of the P—Cl bond in compound *(3b)* is 2.057(5) Å and that of the same bond in *(3a)* 2.069(3) Å (refined value)[2]. Different P—Cl bond lengths were also observed in the case of the acyclic-derivative *(7)*[3]. In comparison, the P—Cl bond length in gaseous $PSCl_3$ *(2b)* is longer than that in gaseous $POCl_3$ *(2a)*[4]. No other P—Cl bond lengths are available for strictly comparable *pairs* of compounds containing P(O)Cl and P(S)Cl.

(7)

Since we have recently demonstrated[5] an approximately linear relationship between P—Cl bond-length and ^{35}Cl nuclear quadrupole resonance (NQR) frequency in some chlorocyclophosphazenes containing the $\equiv PCl_2$ or $\equiv P(Cl)N(CH_3)_2$ structural units, it was of interest to extend this study to compounds *(3a)*, *(3b)*, and *(7)*. As has been reported, the ^{35}Cl-NQR frequencies of thiophosphoryl-derivatives always exceed those of analogous phosphoryl-derivatives (usually by about 0.5—2 MHz)[6, 7]. If the lowest frequencies are associated with the longest P—Cl bonds—as is the case in the chlorocyclophosphazenes—then longer P—Cl bonds would be expected for the phosphoryl-derivatives relative to the analogous thiophosphoryl-derivatives by consideration of the ^{35}Cl-NQR frequencies (see Table 1).

In the case of the cyclic compounds *(3a)* and *(3b)* the former appears to have the longer P—Cl bond length. Unfortunately, no reproducible ^{35}Cl-NQR signal was obtain-

Table 1. Relation between the length of P—Cl bond and ^{35}Cl-NQR frequency of a few compounds containing the XPCl grouping.

Cpd.	X	Bond Length (Å)	^{35}Cl-NQR frequency (MHz)	T (°K)
(3a)	O	2.069(3)	23.97_7	293 [e]
(3b)	S	2.057(5)	[a]	293, 77
(7)	O	1.968(4)	27.81_3 [b]	77
	S	1.991(4)	29.08_4 [c]	77
(8a)	O		27.93_8 [d]	77
(8b)	S		28.91_3 [d]	77
(8c)	O		27.57_1	77
	S		29.31_0	77

[a] No reproducible signal obtained.
[b] Mean value from 27.61_7 and 28.00_9.
[c] Mean value from 28.79_3 and 29.37_5.
[d] Mean of four values.
[e] To date, no signals have been obtained at 77°K; in general, a frequency increase of 0.5—0.8 MHz is obtained on decreasing the temperature from *ca.* 290 to 77°K.

ed from compound *(3b)*. The reverse relationship (as compared with the chlorocyclophosphazenes) is observed for compound *(7)*. The assignment of the frequencies was supported by comparison with the structurally related acyclic compounds *(8)*[8,9]. It is noteworthy that the difference in signals in the mixed compound *(8c)* is greater (*ca.* 1.7 MHz) than the difference (*ca.* 1 MHz) between the symmetric compounds *(8a)* and *(8b)*. This may be a reflection of the better π-acceptor properties of the phosphoryl compared to the thiophosphoryl group.

(8)

(8a), X = X' = O
(8b), X = X' = S
(8c), X = O, X' = S

In *(7)* both sets of P—Cl bonds are considerably shorter than in the cyclic compounds *(3a)* and *(3b)*, and this is reflected in their ^{35}Cl NQR frequencies; those of *(7)* are higher than the frequencies of *(3a)*.

Experimental:

24 ml (22.5 g, 0.166 mol) of *(1)* was placed in a 250 ml, two-necked flask, to which was attached a condenser and a dropping funnel containing 8.6 ml (14 g, 0.082 mol) of thiophosphoryl chloride. This was added dropwise to the tertiary amine while the flask was heated to 130°C in an oil-bath, and the mixture was maintained at this temperature for 9—36 hours. The mixture was then cooled, treated with sodium ethoxide (*ca.* 0.166 mol) in absolute ethanol, and the resulting suspension boiled on a water-bath for three hours, diluted with distilled water to 400 ml, extracted with ether, dried over Na_2SO_4, concentrated and eluted through a column packed with alumina, using a solvent mixture of toluene-ethyl acetate (9:1). *(3b)* was first eluted. It was recrystallized from ethyl acetate, m.p. 209—210°C (yield 0.9 g, 6%).

A New Principle for Preparation of Bicyclic Dithiazepine Systems

By *Walter Ried, Rüdiger Oxenius,* and *Wulf Merkel*[*]

Dedicated to Professor H. J. Bielig on his 60th birthday

Mercury bis(phenylacetylide)[2] can be used as a mild desulfurizing agent for preparation of carbodiimides or cyanamides from thioureas. Reaction of trisubstituted thioureas with mercury bis(phenylacetylide), however, gives the corresponding mercury dithiolates[3].

Cyclic *N,N'*-disubstituted thioureas such as *(1)*, which, because of their angular structure, cannot be converted into carbodiimides, yield thermally unstable mercury dithiolates still having two relatively basic NH groups available which it appeared possible to treat with reactive isothiocyanates.

(1), n = 2, 3 *(2)* *(3)* *(4)* *(5)* *(6)*

We therefore carried out a single-batch reaction with, as reactants, 1 molar proportion each of *(1)*, mercury bis(phenylacetylide) and isothiocyanate in pyridine.

[*] Prof. Dr. W. Ried, Dipl.-Chem. R. Oxenius [1] and Dipl.-Chem. W. Merkel
Institut für Organische Chemie der Universität
6 Frankfurt, Robert-Mayer-Strasse 7—9 (Germany)

The monothiolate first formed was converted by the trapping isothiocyanate into the intermediate *(3)* which cyclized immediately by attack of the nucleophilic sulfur on the triple bond[4], yielding *(4)* and thus preventing removal of the second phenylacetylene group. By careful working, the bicyclic thiolate *(4)* containing the eight-membered ring could be isolated. When even gently warmed it loses elemental mercury and passes by ring contraction into the dithiazepine *(5)*. The thiourea component may be *(1)* with a five- or a six-membered ring; the seven-membered ring analog, however, apparently yields the carbodiimide with loss of HgS. Only reactive isothiocyanates such as phenyl or *o*-tolyl isothiocyanate can be used as isothiocyanate component.

Satisfactory elemental analyses and IR, NMR, and mass spectra prove the assigned structures (see Table 1). The molecular ion does not appear in the mass spectra since it at once splits off the isothiocyanate which forms the reference mass line. By using deuterated thioureas *(1)* it can be shown that the original N—H proton appears in the product *(5)* as the olefinic C—H proton.

The phenylimino group in compound *(5a)* can be split off by several hours' heating with sulfur in carbon disulfide, being replaced by a thiooxo group *(6)*.

To the best of our knowledge the bicyclic dithiazepines prepared by this single-batch process belong to a new heterocyclic system, whose parent compound is unknown. This synthesis would not be possible without collaboration of the mercury atom as bonding agent.

7,8-Dihydro-3-phenyl-5-(phenylimino)-5H-imidazo-[2,1-b]-[1,5,3]dithiazepine (5a)

Equimolar amounts of 2-imidazolidinethione *(1)*, $n=2$, mercury bis(phenylacetylide) and phenyl isothiocyanate were heated in pyridine for about 30 min under reflux. Mercury separates. After the filtrate has been concentrated, the yellow-white *(5a)* crystallizes either directly or on addition of ether. *(5b)* and *(5c)* are prepared analogously.

7,8-Dihydro-3-phenyl-5-thio-5H-imidazo[2,1-b]-[1,5,3]-dithiazepine (6)

(5a) (1.7 g, 0.005 mol) is heated with sulfur (1 g) in CS_2 (100 ml) for some hours under reflux. After a short time the yellow compound *(6)* separates and can be recrystallized from pyridine [m.p. 168—171 °C (dec., loss of CS_2); yield 1.3 g, 93%].

Methylenenorbornadiene, a Bicycloheptafulvene[1][**]

By *Reinhard W. Hoffmann, Reinhard Schüttler, Werner Schäfer*, and *Armin Schweig*[*]

The reactivity of heptafulvene is to be ascribed to strong polarization with formation of an aromatic system[2].

This phenomenon is not restricted to classical aromatic compounds but can be demonstrated also for bicycloaromatic systems, as we wish to illustrate for methylenenorbornadiene *(1)*[3].

Crossed longicyclic interaction[4] of the exocyclic double bond of *(1)* with the norbornadiene π-system should destabilize the norbornadiene system[4]. This interaction can be demonstrated by photoelectron spectroscopy[5,6] in a comparison with norbornadiene *(2)*[6] and 7-methylenenorbornane *(3)*. It can be seen in Figures 1 and 2 that the HOMO (highest occupied MO) of *(1)* is raised by 0.2 eV relative to that of *(2)*. A direct consequence of this interaction is the tendency to formation of the bicycloaromatic state *(4)*, which causes polarization of the exocyclic double bond of *(1)*.

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The calculations were carried out by the Deutsches Rechenzentrum at Darmstadt.

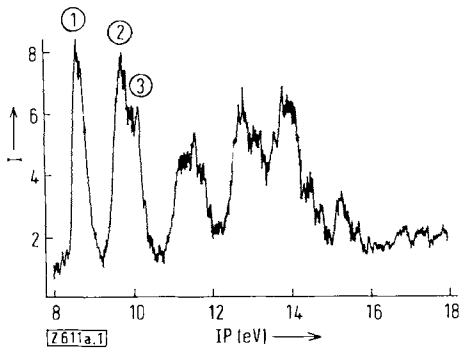

Fig. 1. Photoelectron spectrum of methylenenorbornadiene *(1)* [12].

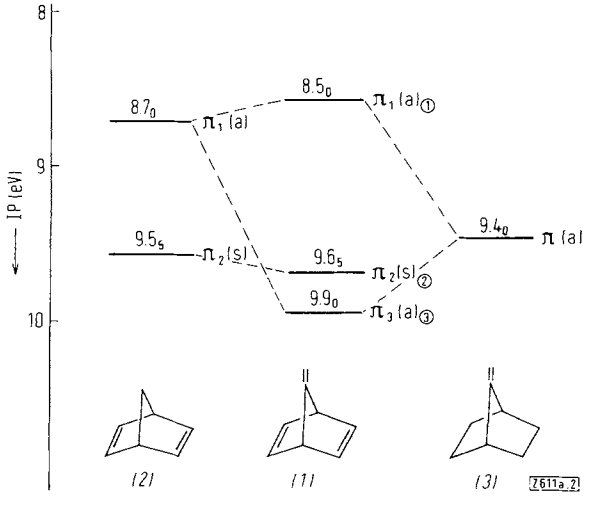

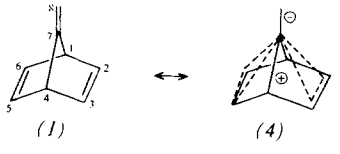

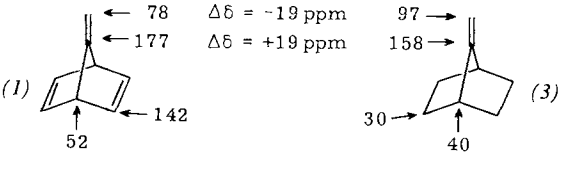

Fig. 2. Vertical ionization potentials of the relevant π-bands of norbornadiene *(2)* [6], 7-methylenenorbornane *(3)*, and methylenenorbornadiene *(1)*. The π-MO's are classified relative to the C^1—C^7—C^4 plane (s symmetrical, a antisymmetrical).—The assignments made for *(1)* are supported by the orbital sequence obtained by the MINDO/2 method [13].

This polarization[7] is evident even in the ^{1}H-NMR spectrum: Thus the signal of the methylene protons of *(1)* at $\tau = 6.48$ appears at unusually high field, about 0.9 ppm higher than in the comparison system *(3)*[8] ($\tau = 5.55$).

While this difference may or may not be solely the consequence of a charge effect, more sensitive and more certain information about the charge distribution may be obtained from ^{13}C-NMR spectra[9]. Thus comparison of the ^{13}C-NMR spectra of *(1)* and *(3)* (chemical shifts in ppm to lower field from TMS) shows clearly the strong polarization of the exocyclic double bond of *(1)*.

The chemical shift and thus the charge density at C-8 of *(1)* are comparable with those at the β-C atom of enol ethers ($\delta = 89$–83 ppm[9]), whilst the chemical shift for C-7 lies in the region typical of carbonyl-C atoms. The other ^{13}C-NMR signals of *(1)* and *(3)* are at positions similar to those of comparable parent compounds (±3 ppm)[10].

A dipole moment of 0.76 D for *(1)* can be estimated from the change in the chemical shift by 19 ppm. A CNDO/2 calculation[11] gave the same value; the experimental value was 0.71 D. Thus *(1)* is more than merely formally a bicycloheptafulvene.

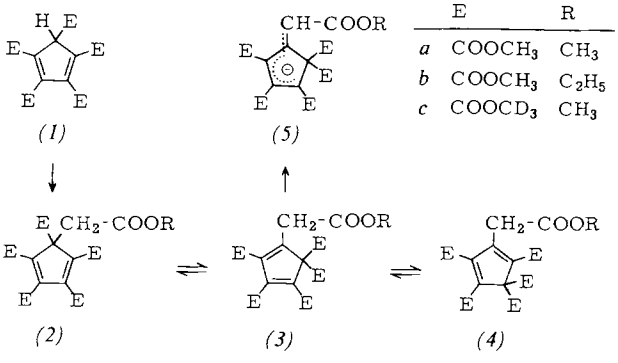
Sigmatropic [1,5]-Ester Migrations[**]

By *Peter Schmidt, Reinhard W. Hoffmann*, and *Jutta Backes*[*]

Dedicated to Professor B. Helferich on his 85th birthday



There has recently been increasing interest in migration of ester groups[1]: Thus, sigmatropic [1,5]-ester migrations on the 1,3-cyclohexadiene skeleton have been reported to

[*] Dr. P. Schmidt, Prof. Dr. R. W. Hoffmann, and Dipl.-Chem. J. Backes
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

[**] This work was supported by the Verband der Chemischen Industrie and the Max-Buchner-Forschungsstiftung.

occur [2], but only above 300 °C. We have now found an ester migration that proceeds even at 100 °C.

Pentamethyl 1,3-cyclopentadiene-1,2,3,4,5-pentacarboxylate *(1)* [3], on alkylation with silver oxide and methyl or ethyl iodoacetate in boiling benzene, gave 71% of *(2a)* [m.p. 87—88 °C; NMR ($CDCl_3$): singlets at $\tau = 6.15$, 6.20, 6.28, 6.38, and 6.64 ppm as 6:6:3:3:2; M^+ at $m/e = 428$, $M^+ - OCH_3$ at m/e 397] and 90% of *(2b)* [4] (m.p. 83 °C).

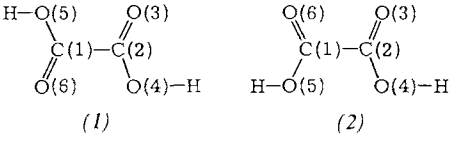
(1) *(5)* *(2)* *(3)* *(4)*

Heating in an inert solvent such as toluene at 100—130 °C sets up an equilibrium between *(2)* and *(3)* from which the vinylogous malonic ester *(3)* can be trapped in the form of the anion *(5)* by addition of sodium hydride. The esters *(3a)* [20%; m.p. 99—100 °C; NMR ($CDCl_3$): singlets at $\tau = 6.05$, 6.07, 6.17, 6.24, 6.27 ppm as 3:2:6:6:3] and *(3b)* (m.p. 103 °C) thus obtained show in their mass spectra the ($M^+ - CH_3OH$) signal characteristic of this type of structure.

Equilibration of *(2)* and *(3)* is more than 99% intramolecular; when a 0.23 M solution of *(2a)* and *(2c)* is heated for three half-lives of the rearrangement, no notable amount of cross-product could be detected by mass spectrometry. Thus the observed rearrangement probably involves a sigmatropic [1,5]-ester migration [5]. It was established by means of NMR spectroscopy that the reactions cleanly followed first order kinetics for more than three half-lives, setting up a 1:1 equilibrium between *(2)* and *(3)* in all cases (Table 1).

Table 1. The reaction *(2)* ⇌ *(3)*.

Reaction	Temp. (°C)	Solvent	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$ (cal mol deg^{-1})
(2a) → *(3a)*	113–150	Chlorobenzene	25.3 ± 2.5	− 9.7 ± 4.4
(2b) → *(3b)*	97–120	Toluene	25.3 ± 2.3	− 10.9 ± 3.5
(3a) → *(2a)*	113–134	Chlorobenzene	25.1 ± 3.7	− 10.4 ± 4.2
(3b) → *(2b)*	97–120	Toluene	26.9 ± 2.5	− 6.6 ± 3.5



A further ester migration, giving *(4)*, occurred above 150 °C; this process could be followed only in the case of *(2c)*, it having the simpler NMR spectrum, where rearrangement to *(4c)* in *o*-dichlorobenzene resulted in two further signals $\tau = 6.03$ and 6.45 ppm as 2:3. The position of the equilibria between the isomers *(2c)*:*(3c)*:*(4c)* in *o*-dichlorobenzene at 160 °C was estimated as 1:1:1.5. That the second ester migration *(3)* → *(4)* is slower than the first migration *(2)* → *(3)* corresponds to analogous hydrogen migrations [6] on the cyclopentadiene skeleton.

syn-Planar Conformation of Oxalic Acid: Crystal Structure of the Oxalic Acid-Acetamide Complex

By *Leslie Leiserowitz* and *Franz Nader* [*]

We have studied, *inter alia*, the 1:1 complex of acetamide with oxalic acid as part of our X-ray investigation of molecular packing and its dependence on functional groups. Although the molecular dimensions of the components in carboxylic acid—amide complexes [1, 2] compare well with those of the individual species, as far as the latter are known, we find striking deviations in this case. Here, oxalic acid does not exist, as is usually found, in the *anti*-planar conformation *(1)*, but rather in the energetically unfavorable *syn*-planar arrangement *(2)*.

(1) *(2)*

Colorless crystals of the (hygroscopic) complex [3] are obtained by slowly cooling a solution of equimolar parts of acetamide and anhydrous oxalic acid in ethyl acetate or nitromethane.

Crystallographic data: monoclinic, $a = 20.542$, $b = 9.709$, $c = 13.931$ Å; $\beta = 112° 5'$; space group A2/a; $Z = 8$ (the unit cell contains two molecules each of oxalic acid and acetamide); $d_{calc} = 1.537$ g/cm^3.

The structure was solved by the direct method [4]. Refinement with 2813 independent reflections gave an *R* factor of 7.6%. The positions of all the hydrogen atoms could be determined from the difference map (after anisotropic refinement of the heavy atoms). This is shown in Fig. 1 for the plane of one of the two independent oxalic acid molecules. Together with the experimental C—O bond lengths this proves the *syn*-planar conformation of the oxalic acid.

Table 1 permits a comparison of the geometrical parameters of *(2)* with those of the numerous published structural studies of *(1)* in the solid [1, 5] and gaseous [6] state. No significant difference in the bond lengths between the two conformers can be found, but there are such differences

[4] *(2b)* is accessible also from *(1)* and ethyl diazoacetate, albeit in poorer yield.

[5] A conceivable migration of the acetate side chain is degenerate in this system and is thus not directly recognizable.

[6] *W. R. Roth*, Chimia *20*, 229 (1966).

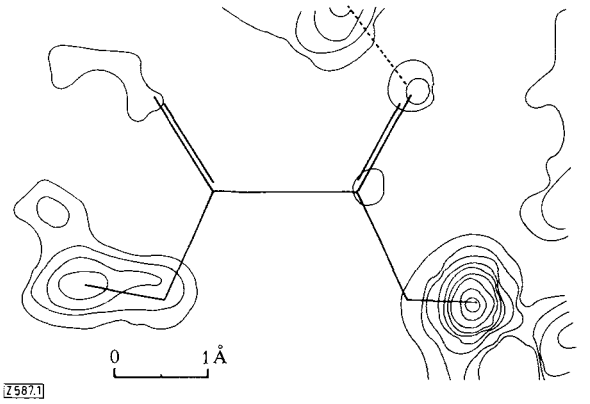

Fig. 1. Difference map for one of the two independent oxalic acid molecules in the 1:1 complex with acetamide; contour intervals 0.1/Å^3.

in bond angles. In *(2)* the angle C(1)—C(2)—O(4) is widened by about 2° in comparison with *(1)*, and the angle C(1)—C(2)=O(3) is decreased by a corresponding amount. In addition, *(2)* departs minimally from coplanarity, the torsion angle between the two COOH fragments being 2.1°.

Table 1. Structural parameters of oxalic acid *(1)* and *(2)*.

Bond lengths [Å]	in the complex [a] *(2)*	Ref. [b] [1, 5, 6] *(1)*
C(1)–C(2)	1.529 ± 0.007	1.536 ± 0.003
C(2)=O(3)	1.212 ± 0.006	1.202 ± 0.006
C(2)–O(4)	1.298 ± 0.006	1.291 ± 0.010
O(4)···O(5)	2.590	
O(3)···O(6)	2.728	
Bond angles [°]		
C(1)–C(2)=O(3)	119.6 ± 0.5	121.7 ± 0.4
C(1)–C(2)–O(4)	114.1 ± 0.4	112.0 ± 0.3
O(3)=C(2)–O(4)	126.2 ± 0.5	126.3 ± 0.4
O(3)=C(2)–C(1)=O(6)	2.1	180

[a] Mean values from two independent oxalic acid molecules.
[b] Mean values from six structure analyses.

Intramolecular interactions are clearly the cause of these deviations. If the intramolecular O···O distances are calculated for the *syn*-planar conformation *(2)* on the basis of the geometrical parameters of the *anti*-planar conformation *(1)*, the separation of the two carbonyl-oxygen atoms [O(3)···O(6)] comes out at 2.80 Å but that for the two hydroxyl-oxygen atoms [O(4)···O(5)] at 2.48 Å [compare the O···O separations of 2.70—2.74 Å in *(1)*]. At least partial balance can be achieved by altering the bond angles, so that a separation of 2.59 Å is found for O(4)···O(5). The deviation from coplanarity (2.1°) and its influence on the O···O separation in question are so small that *(2)* can well be designated as the *syn*-planar conformation.

[7] *E. G. Cox, H. W. Dougill*, and *G. A. Jeffrey*, J. Chem. Soc. *1952*, 4855.

This finding throws some doubt on the validity of the arguments used to explain the planarity of *(1)*. On the basis of the C—C bond length of 1.54 Å, which corresponds to a normal sp^3-sp^3 single bond, conjugation between the two carbonyl groups was ruled out[6, 7]. The coplanarity was therefore explained as due to attractive forces between the various hybridized O atoms[7]. This situation does not exist in *(2)*; but nevertheless here too a strong tendency to coplanarity is evident.

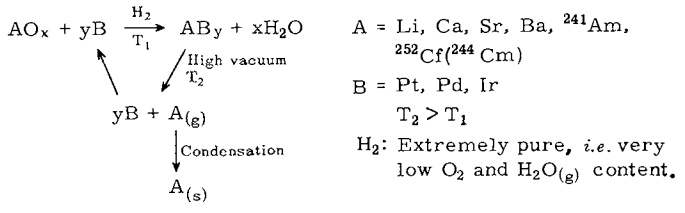
Preparation of Non-noble Metals (Li, Ca, Sr, Ba, Am, Cf) by Reduction of Their Oxides and Fluorides with Hydrogen[**]

By *Uwe Berndt, Bernhard Erdmann*, and *Cornelius Keller*[*]

It is known (*e.g.* see Ref. [1]) that intermetallic compounds are formed on reduction of mixtures of metal oxides and noble metals with extremely pure hydrogen ($p_{O_2} \leq 10^{-26}$, $p_{H_2O} \leq 10^{-7}$ torr), the process being termed "coupled reduction". With oxides of actinoids, lanthanoids, and other non-noble elements (*e.g.* Zr, Hf, Nb, Ta) on the one hand and Pt, Pd, Rh, or Ir on the other in the starting materials at the requisite reaction temperatures (1100—1550°C), the same ratio of metal to noble metal is found in the product as in the starting mixture, but with Am/Pt, particularly at higher temperatures, the product is poorer in Am[1a, 2-4].



A more detailed study of this and analogous systems has led to surprising results: On preparation of intermetallic phases of the elements Li, Ca, Sr, Ba, Am, and Cf (=A) from their oxides and/or fluorides with powdered noble metals (=B) in flowing hydrogen at the lowest possible temperature, the desired phase of composition AB_2, AB_3, AB_5, and/or AB_7 was obtained in high purity without change in the introduced proportions. At higher temperatures, however, part of the more volatile component A evaporated from these phases, so that a different A:B ratio was produced.

These observations make it possible to propose a method, simple in principle, for preparing non-noble metals from their oxides, fluorides, or other suitable compounds by reduction with hydrogen: If a very finely powdered mixture of metal oxide (Li_2O, CaO, SrO, BaO, $AmO_{1.5}$, or $CfO_{1.5}$) and noble metal is heated above 1100°C in a stream of pure H_2, one obtains the corresponding intermetallic phase in very pure form (typical analytical values: O_2 300—500 ppm, $N_2 < 100$ ppm, $H_2 < 100$ torr—on cooling under He). If these phases are further heated in a high vacuum (10^{-5} to 10^{-6} torr), the readily volatile components (Li, Ca, Sr, Ba, Am, Cf) evaporate and can be isolated by condensation. Because of its appreciably lower vapor pressure, the noble metal—so far Pt, Pd, and Ir have been investigated—remains as solid phase and is available for a further reaction, *i.e.* the noble metal functions wholly as catalyst for the reduction of the metal oxide to metal by hydrogen (direct reduction of the oxides in question is impossible because of their low partial pressure of oxygen or their high bond

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

enthalpy). Thus is obtained the following cyclic process for the catalyst in the preparation of the non-noble metal $A_{(s)}$:

Using the ^{241}Am/Pt and ^{244}Cm/Pt alloy phases prepared by us, *Spirlet* and *Müller*[5, 6] obtained ^{241}Am and ^{244}Cm metal in high yield and purity on a gram or milligram scale. In that work this volatilization process proved superior to all the methods described previously for preparation of americium.

Actinoids have very different vapor pressures, owing to the differing "valences" of the element in the metallic state[7], and this can be utilized for a relatively very simple separation of transplutonium elements: If an alloy mixed phase Pt_5(Am,Cm,Cf) produced by coupled reduction is heated in a high vacuum, californium evaporates out of it first at low temperatures ($\leq$1200 °C), followed by americium above 1300 °C, whilst curium, the least volatile actinoid component, remains behind or, in accordance with *Müller*'s results[6], can be evaporated above 1500 °C. These experiments have so far been carried out only with submicro quantities of ^{252}Cf (determination by neutron counting[8]), but on the basis of the results the process can doubtless be applied to larger amounts of material.

Also of interest was the finding that, *e.g.*, metallic Ca can be prepared from CaF_2 (mineral fluorite) by indirect reduction with hydrogen in almost a single step with "platinum as catalyst".

The metals isolated by evaporation were identified by X-ray diffraction and by chemical analysis. No attention has yet been paid to their quantitative recovery.

A detailed study of such reactions and of possible methods of separation (determination of enthalpies of formation and vapor pressures of the intermetallic phases) and the introduction of other metals (*e.g.* Eu, Es) is in progress. We wish to find in particular whether this process can be carried out with the "cheaper" elements of the eighth sub-group of the Periodic System—we are thinking of Co and Ni—and what special demands must be set on the hydrogen used for reduction in individual cases.

Coordination Compounds with Silicon-Molybdenum and Silicon-Tungsten Bonds

By *Wolfgang Malisch, Hubert Schmidbaur*, and *Max Kuhn*[*]

For some time much interest has been attached to transition metal-silicon compounds[1]. Although this type of complex has been relatively well studied for metals of Group VII (Mn[2]) and VIII (Fe[3], Co[4]), there is little information about the formation or reactivity of analogous species with metals of Group VI[5–7], mainly owing to lack of good methods for their preparation.

The "alkali salt method", usually the simplest way of forming IVb-element-metal bonds[8, 9], has, with one exception[7], so far failed to yield the expected products[9–11] for various reasons.

We have found, however, that this process can be used in modified form, namely by taking into account the thermal instability of the compounds produced and their pronounced tendency to decompose in *polar* solvents. Satisfactory yields (40—90%) can thus be achieved if a halosilane and an alkali-metal metalate are brought into reaction in cyclohexane or methylcyclohexane, *e.g.*:

$$[\pi\text{-}C_5H_5(CO)_3M]\,Na + HSiCl_3 \xrightarrow[15\ h]{C_6H_{12}/25\,^{\circ}C} \pi\text{-}C_5H_5(CO)_3M\text{-}SiHC + NaCl$$

M = Mo, W

The composition and structure of the compounds listed in Table 1 were proved by elemental analysis and NMR and IR spectroscopy (three strong carbonyl stretching vibrations). The molecular ion appeared in the mass spectrum (70 eV) in all cases[12].

Table 1. Properties of the complex compounds *(1)*—*(11)* of type π-$C_5H_5(CO)_3M$—R.

Reactant	Product M	Product R	No.	M. p. (°C)	Subl. (°C) [b]
$(CH_3)_3SiBr$	Mo	$Si(CH_3)_3$	*(1)*	80 [a]	[c]
	W	$Si(CH_3)_3$	*(2)*	90–92 [a]	[c]
$H(CH_3)SiCl_2$	Mo	$SiH(CH_3)Cl$	*(3)*	26–27	[c]
	W	$SiH(CH_3)Cl$	*(4)*	31–32	85–87
CH_3SiCl_3	W	$SiCH_3Cl_2$	*(5)*	86–87	65
$HSiCl_3$	Mo	$SiHCl_2$	*(6)*	80–81 [a]	65–67 [c]
	W	$SiHCl_2$	*(7)*	87–88	83–85
$SiCl_4$	Mo	$SiCl_3$	*(8)*	102–104 [a]	78–80 [c]
	W	$SiCl_3$	*(9)*	142–143	100–103
$SiBr_4$	Mo	$SiBr_3$	*(10)*	107–110	[c]
	W	$SiBr_3$	*(11)*	140 (dec.)	133–135

[a] Melting point difficultly reproducible because partial decomposition of the complex occurs on heating.
[b] Sublimation at 10^{-2} torr.
[c] Precipitated from pentane at −78 °C.

The complexes *(1)*—*(11)* are colorless to pale yellow crystals at room temperature but very sensitive to light. They have a strong tendency to decompose in solution,

Institut für Anorganische Chemie der Universität
87 Würzburg, Landwehr (Germany)
[**] Author to whom correspondence should be addressed.

except in cyclohexane, methylcyclohexane, or pentane; this property depends strongly on the nature of the metal atom M (Mo > W) and the substituents on the silicon:

$$(CH_3)_3Si > CH_3SiHCl \approx CH_3SiCl_2 > HSiCl_2 \approx SiBr_3 > SiCl_3$$

The fact that compounds of type $(\pi\text{-}C_5H_5)(CO)_3M—M(CO)_3(\pi\text{-}C_5H_5)$ are found after decomposition indicates that the metal-silicon bond is more labile in these cases than in the Co, Fe, and Mn analogs.

This is also shown in the smooth replacement of the trimethylsilyl group in reactions with heterosiloxanes[13]:

$$\pi\text{-}C_5H_5(CO)_3M\text{-}Si(CH_3)_3 + (CH_3)_3XOSi(CH_3)_3 \longrightarrow$$

$$\pi\text{-}C_5H_5(CO)_3M\text{-}X(CH_3)_3 + (CH_3)_3SiOSi(CH_3)_3$$

M = Mo, W

X = Ge[14], Sn[15]

The strong tendency to form the siloxane group provides additional driving force in this reaction[16].

General procedure:

A 3—5-fold excess of the halosilane (12—20 mmol) is added to a suspension of $Na[Mo(CO)_3(\pi\text{-}C_5H_5)]$ (1.1 g, 4.1 mmol). After 15—45 hours' stirring in a closed vessel at 25 °C the insoluble material is removed from the reaction mixture, and the filtrate is evaporated to dryness in an oil-pump vacuum. The crude product is extracted with pentane; from this solution the silyl complex can be obtained pure on cooling (−78 °C).

Kinetics of the Homotropilidene Valence Tautomerism[**]

By *Harald Günther, Josef Bernd Pawliczek, Joachim Ulmen*, and *Wolfram Grimme*[*]

The ability to detect fluxional systems by NMR spectroscopy was impressively demonstrated for the first time in the case of bicyclo[5.1.0]octa-2,5-diene (3,4-homotropilidene) *(1)*[1]. There has as yet, however, been no study of the kinetics of this rearrangement, which is preceded by a conformational equilibrium $[(A) \rightleftharpoons (B)]$[1,2], because the spin system of *(1)* (10 H) is too complicated for exact NMR line shape analysis.

We have therefore synthesized the mixture of octadeuteriobicyclo[5.1.0]octa-2,5-dienes *(2)*⇌*(2')*, each component having one dihydro-methylene group[3], and have, for the

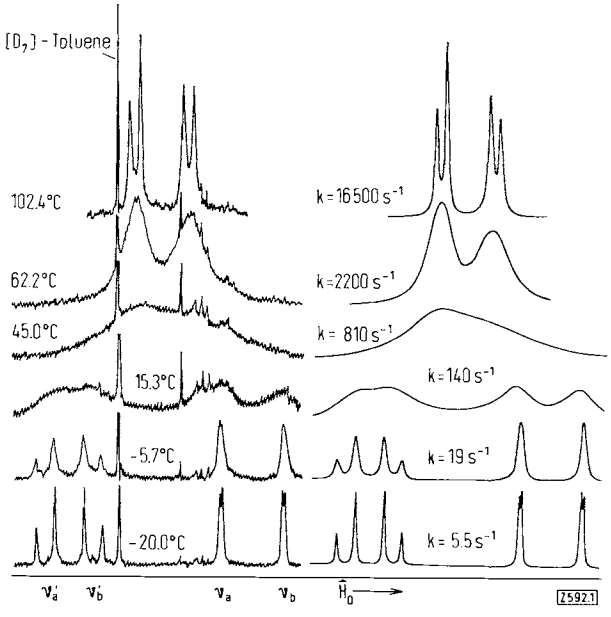

Fig. 1. Temperature-dependent experimental (left) and theoretical (right) ^{1}H-NMR spectra of the methylene protons of *(2)*⇌*(2')* on H{D}-decoupling; signals of incompletely deuteriated material appear below ν_A.

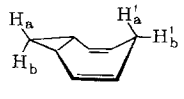
[*] Prof. Dr. H. Günther, Dr. J. B. Pawliczek, Dipl.-Chem. J. Ulmen, and Prof. Dr. W. Grimme
Institut für Organische Chemie der Universität
5 Köln, Zülpicher Str. 47 (Germany)

[**] Support of this work by the Landesamt für Forschung of Nordrhein-Westfalen and the Deutsche Forschungsgemeinschaft is gratefully acknowledged.

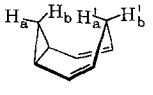
first time, derived data for the rearrangement *(2)*⇌*(2')* between −65 and 102 °C from the temperature-dependent line shape of the ^{1}H-NMR spectrum (solvent [D_8]toluene, frequency 100 MHz, internal reference benzene).

With H{D}-decoupling, two AB systems ($\nu_a = 620.6_4$, $\nu_b = 685.4_8$, and $J = 2.6_7$ Hz, and $\nu'_a = 424.0_5$, $\nu'_b = 474.9_6$, and $J = 20.6_5$ Hz) are observed for *(2)*⇌*(2')* in the slow exchange region (−65 °C) which must be assigned to the CH_2 groups in structure *(2)* and *(2')*, respectively (Fig. 1).



Temperature increase leads to line broadening, coalescence (*ca.* 35 °C) and finally in the region of fast exchange (40 °C) to an averaged spectrum: $\tilde{\nu} = 523.0_4$, $\tilde{\nu}_b = 582.2_2$, and $\tilde{J} = 11.4_9$ Hz. Integration of the low-temperature spectrum gave different concentrations for *(2)* and *(2')*: $K(-35\,°C) \approx 0.9$. A similar isotope effect, namely that hydrogen in competition with deuterium prefers the cyclopropyl to the allyl position, was recently observed for barbaralone[4] and for octadeuteriobicyclo[5.1.0]octa-2,4-diene[3].

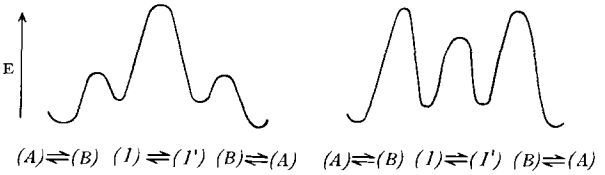
To determine the rate constants k, the temperature-dependent line shape of the spectrum was calculated quantum-mechanically[5] for the exchange process $AB \rightleftarrows A'B'$ (Fig. 1), taking into account changes in the spectral parameters[6] and the mole fractions. With 20 experimental points the best Arrhenius equation for the reaction *(2')*→*(2)* was:



$$k = 10^{11.5 \pm 0.1} \exp\left[-(12450 \pm 220)/RT\right] s^{-1}$$

and from a log $(k/T)/(1/T)$ diagram the activation parameters $\Delta H^{+} = 11.8 \pm 0.2$ kcal/mol and $\Delta S^{+} = -8.0 \pm 0.3$ clausius were obtained. For 1,3,4,6-tetramethyl-3,4-homotropilidene ΔG^{+} (0 °C) was previously[2] estimated as 13.6 kcal/mol. From the temperature-dependence of the K values a ΔH^0 of 240±25 cal/mol in favor of *(2)* was calculated by van't Hoff's equation.

Our results also make it possible to decide whether the rearrangement *(1)*⇌*(1')* proceeds through a transoid or a cisoid transition state[1]. From the $^3J_{H,D}$ values found the proton assignments *(3A)* or *(4B)* can be made according to whether the ground state of *(1)* has the conformation *(A)* or *(B)*:



(3A)
⇅
(3B)

(4B)
⇅
(4A)

On the other hand, double resonance experiments[7] yielded the exchange schemes $H_a \rightleftarrows H'_a$ and $H_b \rightleftarrows H'_b$, *i. e.* $AB \rightleftarrows A'B'$. These agree with the assignments only if the valence tautomerism is preceded and followed by a conformational change into the respective alternative conformations [*(3A)*→*(3B)* or *(4B)*→*(4A)*], because the transition state for the rearrangement *(1)*⇌*(1')* has either C_{2h} or C_{2v}

(A)⇌*(B)* *(1)*⇌*(1')* *(B)*⇌*(A)*
(C)

(A)⇌*(B)* *(1)*⇌*(1')* *(B)*⇌*(A)*
(D)

symmetry according to whether it is derived from *(A)* (transoid) or *(B)* (cisoid), and the proton exchange must follow this symmetry. Since the results of photoelectron spectroscopy indicate conformation *(A)* for the ground state of *(1)*[8], the rearrangement must occur through the cisoid transition state[1,9].

The energy profile *(C)* or *(D)* may be discussed for the reaction *(1)*⇌*(1')* that is accompanied by the conformational equilibrium *(A)*⇌*(B)*. If the energy barriers for the valence tautomerism in dihydrobullvalene *(5)* (12.6 kcal/mol)[10] and barbaralane *(6)* (8.6 kcal/mol)[11] and for the

(5)

(6)

ring inversion of 1,3,5-cycloheptatriene (6 kcal/mol)[12] are considered, preference must be given to *(C)*. The energy difference between conformations *(A)* and *(B)* thus amounts to 3 kcal/mol at most.

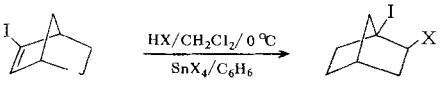
Does 1-Norbornene Exist?

By *Reinhart Keese* and *Ernst-Peter Krebs*[*]

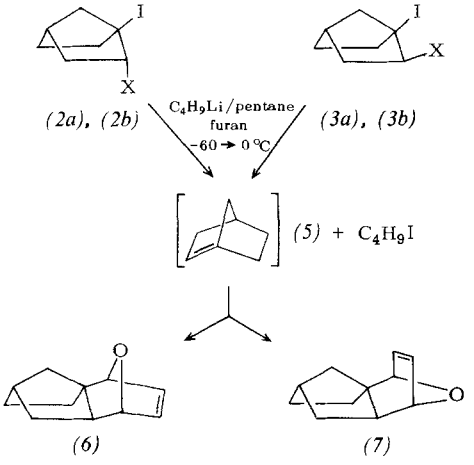


We have reported that 1,2-*exo*-dihalonorbornanes are bis-dehalogenated by butyllithium and that in the presence of furan the two diastereoisomers *(6)* and *(7)* result. The constant product ratio led us to assume that 1-norbornene was formed as an intermediate[1]. We now have strong evidence for the assumption that 1-norbornene is actually

[*] Dr. R. Keese and E.-P. Krebs, Dipl.-Natw. ETH
Organisch-chemisches Laboratorium der
Eidg. Techn. Hochschule
CH-8006 Zürich, Universitätsstrasse 6 (Switzerland)

formed in the bisdehalogenation of 1,2-dihalonorbornanes. The required diastereoisomeric dihalides *(2a)/(3a)* and *(2b)/(3b)* were prepared as shown in Scheme 1[2] or as described previously[1].

(1a), (1b) *(2a), (2b)*



(4) *(3a), (3b)*

Scheme 1. *a*, X = Br; *b*, X = Cl.

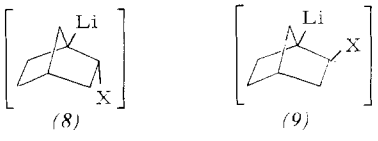
Methyl cyclopentadienecarboxylate reacts with vinyl bromide or vinyl chloride in an autoclave at 170 °C to give a mixture of cycloaddition products, from which pure 6-*endo*-bromo- or 6-*endo*-chloro-bicyclo[2.2.1]hept-2-ene-1-carboxylate *(1a)* or *(1b)*, respectively[3a, b], can be isolated. (The *endo*-configuration follows from the NMR spectrum.) 2-*endo*-Bromo-1-iodonorbornane *(2a)* and 2-*endo*-chloro-1-iodonorbornane *(2b)*[3b] are obtained from *(1a)* and *(1b)* resp. according to Scheme 1. 2-*exo*-Bromo-1-iodonorbornane[1] *(3a)* and 2-*exo*-chloro-1-iodonorbornane *(3b)* were obtained from 2-iodo-2-norbornene *(4)*[4] as shown in Scheme 1.

Bisdehalogenation of the diastereoisomeric pairs *(2a)/(3a)* and *(2b)/(3b)* induced by butyllithium in the presence of furan gave the trapping products *(6)* and *(7)* in a constant ratio. We found the same product ratio from the reaction of *(2a)* and *(3b)* with sodium amalgam in a mixture of furan and tetrahydrofuran (cf. Scheme 2 and Table 1).

Scheme 2. *a*, X = Br; *b*, X = Cl.

In general, proof of a metastable intermediate resting on a trapping reaction is valid only under the following conditions: First, the structural element of the metastable intermediate must be unambiguously detectable in the trapping products; secondly, the trapping reactions must give a constant product ratio under competitive conditions, and this ratio must also be independent of the nature of the starting materials[5].

A trapping reaction can also be considered competitive if the trapping reagent gives two *diastereoisomeric* products. In this case, however, a constant product ratio leads to valid conclusions only if the starting materials differ at least in their configurations.



As shown in the Table, this condition is fulfilled: the ratio of the diastereoisomeric furan adducts *(6)* and *(7)* is independent of the configuration of the 1,2-dihalonorbornanes *(2a)/(3a)* and *(2b)/(3b)*.

Table 1. Results of trapping reactions according to Scheme 2.

Cpd.	R in RLi	Furan adducts Reaction [%]	Yield *(6)+(7)* [%]	*(6)*:*(7)* [a]

(2a)	Na/Hg	100	5 [b]	25:75

[a] Ratio of peak areas in the gas-liquid chromatogram.
[b] At −65 °C.
[c] At +25 °C.

In the bisdehalogenation of *(2a)*, *(2b)* and *(3a)*, *(3b)* respectively it must be confirmed that lithium-halogen exchange yields only intermediates of type *(8)* and *(9)* because the consequent elimination of lithium halide is then dependent on the *exo*- and *endo*-configuration, thus reinforcing the evidence for the common intermediate.

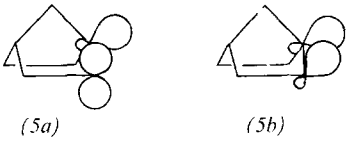
(8) *(9)*

The following experimental facts prove an exclusive lithium-iodine exchange:

1. Both 2-*exo*- and 2-*endo*-bromonorbornane were stable to *tert*-butyllithium in furan under the conditions of the bisdehalogenation.

2. 2-*exo*- and 2-*endo*-Chloronorbornane can be recovered unchanged after treatment with *sec*-butyllithium under analogous conditions.

3. On dehalogenation of *(2a)* with *tert*-butyllithium, 2-*endo*-bromonorbornane was isolated when the reaction was quenched after a short time by addition of methanol.



4. Butyl iodide was detected mass-spectrometrically in all the elimination reactions described. Further, in most cases,

n-, *sec*-, or *tert*-butyl iodide, corresponding to the isomeric butyllithium used, was isolated by gas chromatography and identified by its NMR or IR spectrum.

5. Under the conditions of the bisdehalogenation *tert*-butyl bromide reacts only to a limited extent with dehydrated lithium iodide in furan; *sec*-butyl bromide is inert to lithium iodide in furan even at room temperature.

The total experimental findings form the basis of our view that 1-norbornene occurs as a discrete intermediate in these reactions.

Our information regarding the nature of this double bond is still slight. We assume that the double bond can be described as a combination of a sp^x hybrid orbital ($x \approx 3$) on the bridgehead with a neighboring p- or sp^x-hybrid orbital—*(5a)* or *(5b)* (cf. Scheme 3).

(5a) *(5b)*

(10a) *(10b)*

Scheme 3.

Orienting extended Hückel calculations for ethylene which is taken to be sp^3-hybridized on one *(10a)* or both *(10b)* carbon centers show the following for a twisted structure with reasonable torsion angles[6]:

If one starts from a singlet ground state, *(10a)* with inclusion of all the σ-bonds is more stable than *(10b)*; the bond order decreases to half that of an unstrained double bond. Independently of the torsion angle, an excess of charge develops on the sp^3-hybridized carbon atom in the π-system of *(10a)*. If the energy difference between the highest occupied and lowest unoccupied molecular orbital in *(10a)* is compared with that for untwisted, planar ethylene, the electron excitation energy in *(10a)* is found to be only half that in ethylene; an absorption maximum above 300 nm would therefore be expected for *(10a)*. This energy difference is, however, of an order of magnitude that is assumed in the extended Hückel method to be an indication of a triplet ground state[7, 8]. We are presently investigating these questions.

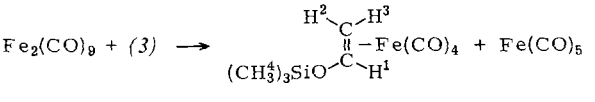
Tetracarbonyl(π-vinyl alcohol)iron[1]

By *Helmut Thyret*[*]

The existence of vinyl alcohol has not been demonstrated previously, a fact that is rationalized by theoretical calculations according to which acetaldehyde is more stable than vinyl alcohol by 12.9 or 14.6 kcal/mole respectively[2]. The existence of a π-bonded vinyl alcohol is, however, more probable; for instance, *(1)* has been postulated as an intermediate[4] in the palladium-catalyzed oxidation of ethylene to acetaldehyde[3]. However, no experimental proof has yet become available.

(1)



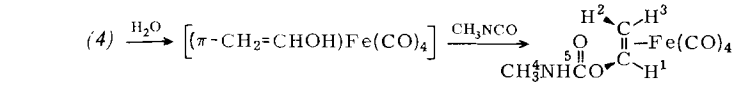
We have been unable to confirm the existence of a stable vinyl alcohol complex *(2)*[5] that is reported to be formed by a ligand exchange reaction of the ethylene complex with trimethylsilyl vinyl ether *(3)* and subsequent hydrolysis. Even at −10 °C the NMR spectrum indicates the immediate

$[(CH_2=CHOH)PtCl_2]_2$ *(2)* $CH_2=CHOSi(CH_3)_3$ *(3)*

formation of a mixture of products as results from the acid-catalyzed condensation of acetaldehyde—besides hexamethyldisiloxane; acetaldehyde and paraldehyde could be identified therein[6]. Furthermore, *(2)* could not be trapped by methyl isocyanate (see below). The formation of the vinyl alcohol complex *(2)* in this way can therefore be ruled out.

We report below the first π-complex of vinyl alcohol. In principle the route involving hydrolysis of a π-complex of *(3)* appeared promising. However, for this purpose it is clearly necessary to increase the energy of the d-orbitals of the metal atom in order to reduce the positive charge caused by the strong dative bonding—and the increased reactivity—at the oxygen atom; also, the metal atom should be coordinately saturated so that catalytic rearrangements cannot occur. From these points of view the tetracarbonyliron group seemed to be a suitable system for π-bonding to *(3)*.

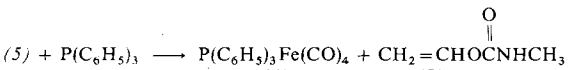
Tetracarbonyl(π-trimethylsilyl vinyl ether)iron *(4)* was synthesized by analogy to a known procedure[7, 8]. By



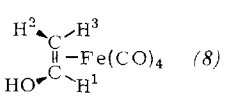
(4)

crystallization at −80 °C *(4)* can be isolated in pure form. It decomposes at as low a temperature as 0 °C. Its structure was proved by the NMR spectrum[9] [*(4)*: $\delta = 6.5$ (H^1), 2.75 (H^2), 2.35 (H^3), 0.12 ppm (H^4); $J_{12} = 9.7$, $J_{13} = 4.6$, $J_{23} = 3.0$ Hz. *(3)*: $\delta = 6.4$ (H^1), 4.3 (H^2), 4.0 (H^3), 0.1 ppm (H^4); $J_{12} = 14.0$, $J_{13} = 6.0$, $J_{23} \approx 0$ Hz].

[*] Dr. H. Thyret
Consortium für elektrochemische Industrie
8 München 25, Zielstattstrasse 20 (Germany)



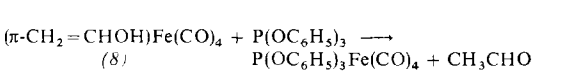
We first attempted an indirect proof of the formation of tetracarbonyl(π-vinyl alcohol)iron by a trapping reaction with methyl isocyanate. For this purpose *(4)* was hydrolyzed in acetone at −25 °C for several days in the presence of three equivalents of methyl isocyanate; the yellow crystals that precipitated in almost quantitative yield were identified as tetracarbonyl(π-*O*-vinyl *N*-methylcarbamate)-iron *(5)*, a compound that, like *(4)*, decomposes already



(5)

at about 0 °C. The NMR parameters of *(5)* are: $\delta = 6.6$ (H^1), 2.75 (H^2), 2.4 (H^3), 2.70 (H^4), 3.7 ppm (H^5); $J_{12} = 9.8$, $J_{13} = 5.2$, $J_{23} = 4.0$, $J_{45} = 5.0$ Hz.

An additional proof of the structure was provided by the reaction with triphenylphosphane:



(6) was identified by its m. p. (190 °C; lit.[10]: 199—200 °C) and IR spectrum ($\nu_{C=O} = 2051$ (A_1), 1978 (A_1), and 1945 cm^{-1} (E)[10]), and *(7)* was characterized by its NMR spectrum [$\delta = 7.15$ (H^1), 4.55 (H^2), 4.3 (H^3), 2.7 (H^4), 3.0 ppm (H^5); $J_{12} = 14.0$, $J_{13} = 6.5$, $J_{23} = 1.0$, $J_{45} = 5.0$ Hz]. After having proved indirectly for the first time the existence of a π-vinyl alcohol complex[11], tetracarbonyl(π-vinyl alcohol)iron itself could be isolated by hydrolysis of *(4)* for several days with small amounts of 5% aqueous trifluoroacetic acid in acetone at −90 °C. The NMR spectrum[13] of tetracarbonyl(π-vinyl alcohol)iron *(8)* was obtained at −75 °C. The complex decomposes above −70 °C.

(8)

The NMR parameters are very similar to those of the other complexes: $\delta = 6.9$ (H^1), 2.8 (H^2), 2.35 ppm (H^3), $J_{12} = 10.0$, $J_{13} = 4.9$, $J_{23} = 3.0$ Hz.

The reaction with triphenyl phosphite in which acetaldehyde is formed quantitatively, constitutes an additional proof of structure *(8)*:

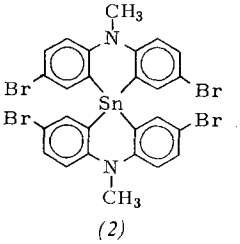
Electron-Impact Induced Rearrangements in Dibenzoazastannines

By *István Lengyel* and *Michael J. Aaronson*[*]



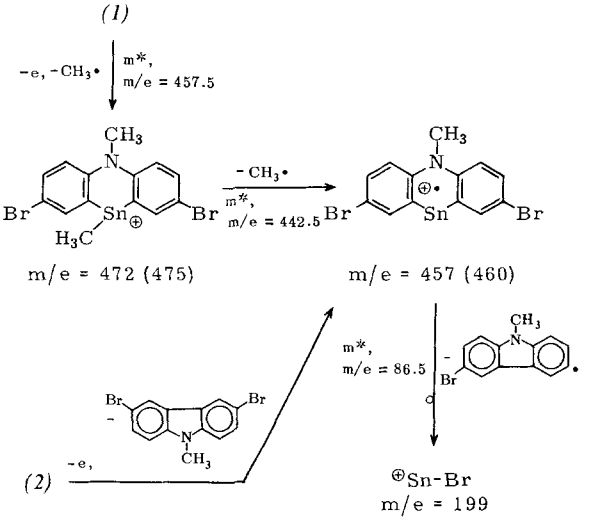
Many of the principal unimolecular ion-decompositions in the mass spectrometer have close thermal, photolytic, or chemical parallels. Indeed, information from mass spectra can occasionally[1] be used to predict the results of reactions initiated by other means in solution or in the gas phase.

On the other hand, some electron-impact induced transformations are typical high-energy reactions, difficult to reproduce in solution. The present communication deals with some unique, *a priori* not predictable, mass spectral fragmentation reactions involving complex molecular reorganizations and migrations in heterocyclic organotin compounds.

The 70-eV mass spectra[2] of 2,8-dibromo-5,10,10-trimethyl-5,10-dihydrodibenzoazastannine *(1)*[3] and 2,2',8,8'-tetrabromo-5,5'-dimethyl-10,10'-spirobi[5,10-dihydrodibenzoazastannine] *(2)* both exhibit an abundant metal-free odd-electron ion at *m/e* 179 (76 and 53% relative inten-

(1)
(1a), N-CD_3

(2)



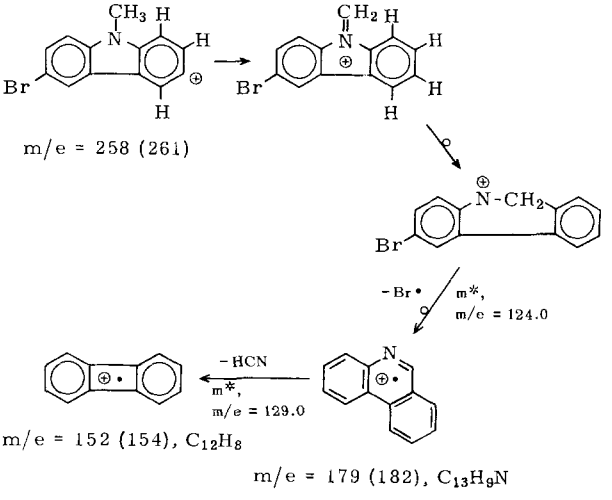
sity) and a tin-containing even-electron ion at *m/e* 199 (95 and 100% relative intensity). To learn more about the nature and genesis of these ions, a combination of specific isotope labeling, computer-coupled high resolution mass measurement[4], and metastable ion correlations[5] was employed.

High resolution elemental composition determination revealed both ions to consist of a single component,

[*] Prof. Dr. I. Lengyel and M. J. Aaronson, M. S.
Department of Chemistry, St. John's University
Jamaica, New York 11432 (USA)

$C_{13}H_9N$ and SnBr, respectively. Ion *m/e* 179 shifts to *m/e* 182 in the spectrum of the trideuterated compound *(1a)*, while no shift is observed for *m/e* 199. Both ions are absent in low energy (12 eV) scans.

Ion *m/e* 199 is formed from the molecular ion by ejection of the metal-ligands followed by expulsion of a resonance-stabilized radical (cf. Scheme 1), as supported by the appropriate metastable peaks. The last step of this sequence requires migration of a bromine atom from the aromatic ring to the electron-deficient tin.



Scheme 1. The mass numbers in parentheses refer to degradation of *(1a)*.

Study of the metastable ions also reveals that ion *m/e* 179 is formed by elimination of the second bromine atom from even-electron ion *m/e* 258, which in turn is generated by the sequence:

$$M^{+\bullet} \xrightarrow{-(CH_3)_2Sn} m/e\ 339 \xrightarrow{-Br\bullet} m/e\ 258$$

Generally, even- to odd-electron transitions such as *m/e* 258 → *m/e* 179 are not energetically favorable[6]. A prominent path of subsequent decomposition of *m/e* 179 is *via* loss of HCN [DCN in *(1a)*] to give biphenylene, *m/e* 152.

Scheme 2. The mass numbers in parentheses refer to degradation of *(1a)*.

The latter ion shifts by *two masses* to *m/e* 154 in the spectrum of *(1a)*, indicating that two of the three deuterium atoms migrate from the N—CD_3 group to the aromatic rings (Scheme 2).

These pieces of evidence, combined, suggest that the driving force for the unexpected 258 → 179 transition is the rearomatization of the product ion which is formulated as phenanthridine. It is suggested that skeletal rearrangement occurs already in ion *m/e* 258 (before further fragmentation) involving both enlargement of the center heterocyclic ring and hydrogen migration.

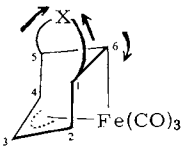
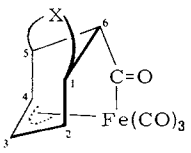
Reactions of Strained C—C Single Bonds with Transition Metals — Influence of Geometrical Factors on the Reactivity of Complex-bound Vinylcyclopropane Systems[1]

By *Rudolf Aumann*[*]

Vinylcyclopropane *(1)* can be converted into "homobutadiene"-transition metal complexes *(2)* or *(3)* in which four carbon atoms are bound to the metal M by π-allyl and σ-components[2–4, 13].



(1) *(2)* *(3)*



Competitive reactions of vinylcyclopropane systems of various conformations fixed in a polycyclic hydrocarbon showed that bonding in a complex occurs particularly rapidly if the four carbon atoms concerned therein are arranged optimally for a multicenter interaction with the metal[13].

The reactivity of *complex-bound* vinylcyclopropane systems is also strongly influenced by geometrical factors. For instance, distinctly different reactivities attach to the vinylcyclopropane complexes *(4a)*[5]—*(4d)* which are closely related structurally and in which there are only small differences in the C^6—Fe distance due to torsional forces [see arrows in *(4)*] from the bridges X.

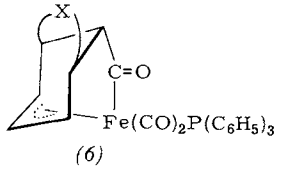
(4)

(5)

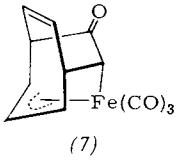
(a): X = 

(b): X = $-CH_2-CH=CH-$



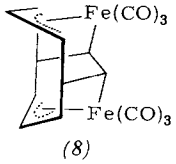
(c): X = 

(d): X = $-CH=CH-$



When carbon monoxide is led into a solution of *(4a)* or *(4b)* in hexane at 25 °C, yellow crystals of the adduct *(5a)* (m.p. 134—136 °C, from ether) or *(5b)* (m.p. 68—70 °C, from hexane), respectively, separate after a few minutes. However, *(4c)* takes up carbon monoxide only slowly at 25 °C and at *ca.* 100 atm, yielding *(4d)*. The adducts *(5c)* and *(5d)* are not formed.

Similar differences appear on treatment with triphenylphosphane. At 25 °C *(4a)* and *(4b)* give the thermally very stable adducts *(6)* within a few seconds. However, *(4c)* reacts with an excess of triphenylphosphane when warmed in benzene, yielding $P(C_6H_5)_3Fe(CO)_4$ and *(4d)*; at 70 °C more than 95% of compound *(4c)* is converted within two hours into *(4d)*, which is stable under these conditions for a further two hours.



Like *(4d)*, the structurally related complexes *(7)* and *(8)*[4] do not react with carbon monoxide or triphenylphosphane at 25 °C.

(6)

(7)

(8)

The IR spectra of *(5a)* and *(5b)* show intense absorption bands at 1662 and 1670 cm^{-1}, respectively, which are indicative of bridging carbonyl groups[12]. In addition, insertion of carbon monoxide into the C^6—Fe σ bond of *(4)* shifts the proton resonance signal of H^6 in the ^{1}H-NMR spectrum downfield by *ca.* 1 ppm and reduces the proton coupling constants $J_{1,6}$ ($J_{5,6}$) and $J_{1,2}$ ($J_{4,5}$) by about 1—2 Hz. The latter observation points to an increase in the dihedral angles $\chi_{1,6}$ ($\chi_{5,6}$) and $\chi_{1,2}$ ($\chi_{4,5}$) on converting *(4)* into *(5)*. The insertion of carbon monoxide into the C^6—Fe σ bond is reversible; in boiling hexane, *(5a)* and *(5b)* are reconverted into the complexes *(4a)* and *(4b)* respectively[6].

Consideration of models leads one to expect smaller C^6—Fe separations in *(4c)*, *(4d)*, *(7)*, and *(8)* than in *(4a)* and *(4b)* but it is not yet possible to decide whether the differing reactivities of these two sets of compounds is due mainly to stabilization of the ground state by homoconjugation in the vinylcyclopropane system [see *(3)*] or to increase in the energy of the transition state for the carbon monoxide addition reaction caused by, *e.g.* greater rigidity of the carbon skeletons.

The complexes *(4c)*, *(5b)* and *(7)* (m.p. 135—136 °C, from ether), here described for the first time, can be obtained in good yields by treatment of, respectively, tricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene ("semibullvalene") *(9)*[10], tricyclo[4.3.0.$0^{2,9}$]nona-3,7-diene ("homosemibullvalene") *(10)*[11], and tricyclo[3.3.1.$0^{2,8}$]nona-3,6-dien-9-one ("barbaralone") *(11)*[9] with $Fe_2(CO)_9$ in *n*-hexane at 55 °C[13].

(9)

(10)

(11)

The compounds were separated by column chromatography on silica gel with *n*-hexane or ether and were identified by means of their IR and mass spectra and elemental analyses[14]. *(4a)* is formed on thermolysis[3] of *(8)*[4], *(5a)* by the action of carbon monoxide on *(4a)*, and *(4b)* by warming *(5b)* in boiling hexane.

Photoelectron Spectra of Unsaturated Systems Containing Cyclopropane and Cyclobutane Rings[1]

By *Peter Bruckmann* and *Martin Klessinger*[*]

Interaction of double bonds with the Walsh orbitals of cyclopropane depends mainly on the conformation. Thus *Heilbronner et al.*[2] showed from photoelectron spectra (PES) that the value $\beta_{\mu\nu}=\langle 2p_\mu|\mathfrak{H}|2p_\nu\rangle$ characteristic of this interaction is almost zero for *endo*-cyclopropanonorbornene, whereas for the *exo*-isomer with $\beta_{\mu\nu}=-0.3$ eV it has almost the same value as for interaction between non-conjugated double bonds of similar steric arrangement. In the present work we compare the PE spectra of *(1)*, *(2)*, and *(3)* with those of *(4)*, *(5)*, and *(6)*[3] in which the cyclopropane ring is replaced by a cyclobutane ring.

According to *Walsh*[5], the highest occupied degenerate orbital of cyclopropane (e' in D_{3h}) is built from pure p-orbitals; for cyclobutane, however, construction of symmetry orbitals according to D_{4h} leads, in addition to the occupied a_{1g} and b_{1u} orbitals, to a degenerate e_u orbital from pure p-AO's and a further e_u pair from sp^2 hybrid AO's[6], which to a first approximation are non-bonding and thus mix with one another. According to the coordinate system chosen, form (a) or (b) shown in Fig. 1 is obtained for the occupied e_u orbital.

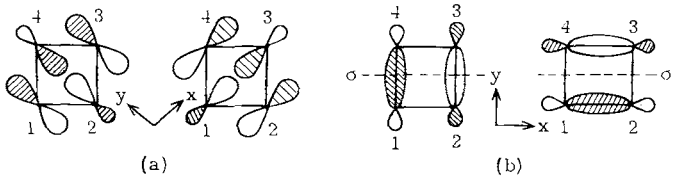

Fig. 1. The highest occupied orbitals of cyclobutane (e_u).

For symmetry reasons we use the orbitals (b), first given by *Salem*[7], which according to an INDO calculation[8] are given by the following linear combination of 2p- and 2s-AO's of the C-atoms μ and of 1s AO's h_μ and h'_μ of the H-atoms bonded to C_μ:

$$\phi(e_u)_S = 0.44\,(p_{y1}-p_{y2}+p_{y3}-p_{y4}) + 0.08\,(s_1-s_2-s_3+s_4) + 0.11\,(h_1+h'_1-h_2-h'_2-h_3-h'_3+h_4+h'_4)$$

(I)

$$\phi(e_u)_A = 0.44\,(p_{x1}-p_{x2}+p_{x3}-p_{x4}) + 0.08\,(s_1+s_2-s_3-s_4) + 0.11\,(h_1+h'_1+h_2+h'_2-h_3-h'_3-h_4-h'_4)$$

Experimental values and interpretation of the PE spectra[9] are listed in Table 1 and in Figs. 2 and 3. As in *exo*-cyclopropanonorbornene, so in *(2)* the π-MO (a') and the a' Walsh orbital repel each other mutually, whilst the a'' Walsh orbital has the same energy as in *(1)*. In *(3)* the a' Walsh orbital can interact only with that a' combination of the π-MO's, which corresponds to the b_1-π-MO in *(8)*, since in the other combination the interaction terms with the two double bonds have opposite signs and cancel each other. The second π-MO is thus hardly shifted relative to the a_1-π-MO in *(8)*. Quantitatively the behavior of *(2)* and *(3)* can be reproduced by a simple HMO calculation of the interaction, which affords the values given in parentheses in the Table. Here it is assumed that the cyclopropane orbitals are stabilized by 0.15 eV per double bond relative to *(1)*, and that $\beta_{\mu\nu}=-0.3$ eV for interaction between the a' Walsh orbital and the π-bond in *(2)* or the correspond-

Table 1. Vertical ionization potentials (in eV) of compounds *(1)*—*(6)* (calculated values in parentheses).

Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

ing π-bond in *(3)*, as for *exo*-cyclopropanonorbornene, whereas for interaction with the other π-bond in *(3)* $\beta_{\mu\nu}=0$, as for *endo*-cyclopropanonorbornene[10].

Assignment of the spectra of *(4)*, *(5)*, and *(6)* is simplified by a characteristic set of bands that corresponds to the two e_u orbitals and the a_1 orbital of cyclobutane[11]. As a result of substitution by two sp^3-centers, the center of the e_u orbitals is shifted by 1.7 eV from 11.35 in cyclobutane[11] to 9.65 eV in *(4)*. For the cyclopropane ring of *(1)* this effect is distinctly smaller, being 1.25 eV[2]. The correlation diagram for *(4)*, *(5)*, and *(6)* in Fig. 3 is very similar

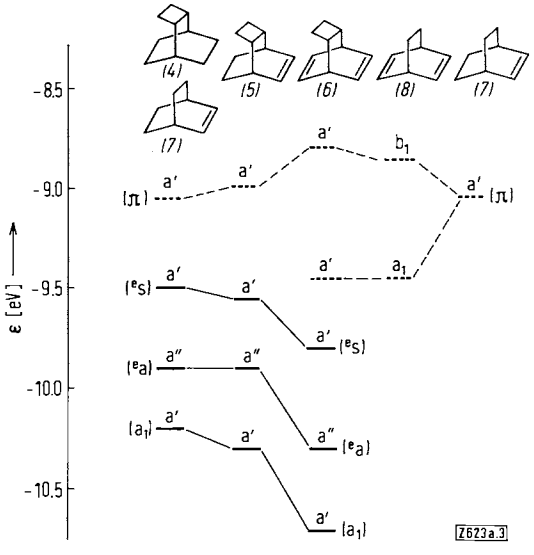

Fig. 3. Correlation diagram of compounds *(4)*—*(6)*.

to that in Fig. 2, but the interactions are smaller because of the reduced p-character of the cyclobutane orbitals; accordingly only the p-contribution of the cyclobutane orbitals given by eqn. (I) was considered in the HMO calculation of the interaction. Also, as for *(2)* and *(3)* it was taken that $\beta_{\mu\nu}=-0.3$ eV or $\beta_{\mu\nu}=0$ and it was assumed that the cyclobutane orbitals are stabilized by 0.15 eV per double bond with respect to *(4)*[10], which leads to good agreement with the experimental values.

The marked decrease in energy of the $a''(e_A)$ and the $a'(a_1)$ orbitals of the cyclobutane part on going from *(5)* to *(6)* is surprising. This may be due to the fact that the σ-contribution is greater than for cyclopropane, thus shifting these orbitals to lower energies on introduction of double bonds, similarly as for ordinary σ-orbitals.

Ionization Potentials of Substituted Benzenes[1]

By *Martin Klessinger*[*]

Within the HMO approximation simple perturbation calculations quite often lead to surprisingly good agreement between theory and experiment (cf. *Dewar*'s PMO method[2]). Another impressive example is provided by the removal of the degeneracy of the highest occupied benzene π-orbital (e_{1g}) under the inductive influence of substituents, which is directly measurable by photoelectron spectroscopy (PES).

Assuming that in the HMO approximation the effect of a substituent X on the π-electron system is given by a change $\delta\alpha_\mu(X)$ in the Coulomb integral α_μ of the substituted C atom μ, one obtains for the change of the orbital energy ε_i[2]

$$\delta\varepsilon_i = \sum_\mu c_{\mu i}^2 \delta\alpha_\mu(X) \qquad (1)$$

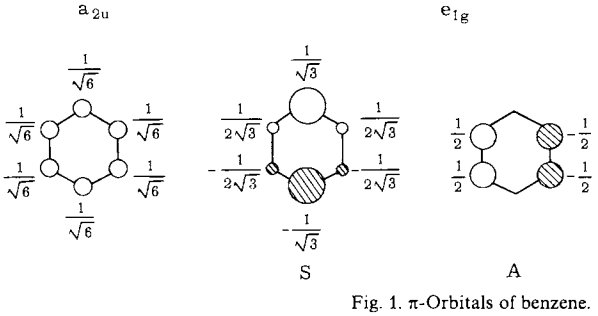

Fig. 1. π-Orbitals of benzene.

In Fig. 1 the occupied π-MO's $\Phi_i=\sum_\mu c_{\mu i}\varphi_\mu$ of benzene are shown diagrammatically; they belong to the irreducible representation A_{2u} and E_{1g} of the point group D_{6h} and have the orbital energies $\varepsilon(a_{2u})=\alpha+2\beta$ and $\varepsilon(e_{1g})\alpha+\beta$. According to *Koopmans*' theorem[3] the negative orbital energies are set equal to the vertical ionization potentials or the band maxima in the PE spectrum respectively:

$$-\varepsilon_i = I_v(i) \qquad (2)$$

In Fig. 2 the experimental PE spectra of some methyl- and fluoro-benzenes are compared with the negative orbital energies $-\varepsilon_i$ calculated according to eqn. (1) with the coefficients $c_{\mu i}$ shown in Fig. 1 and $\delta\alpha_\mu(CH_3)=+1.0$ eV and $\delta\alpha_\mu(F)=-1.2$ eV.

The almost quantitative agreement between HMO predictions and experiment, which is not limited to mono- and

[*] Prof. Dr. M. Klessinger
Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

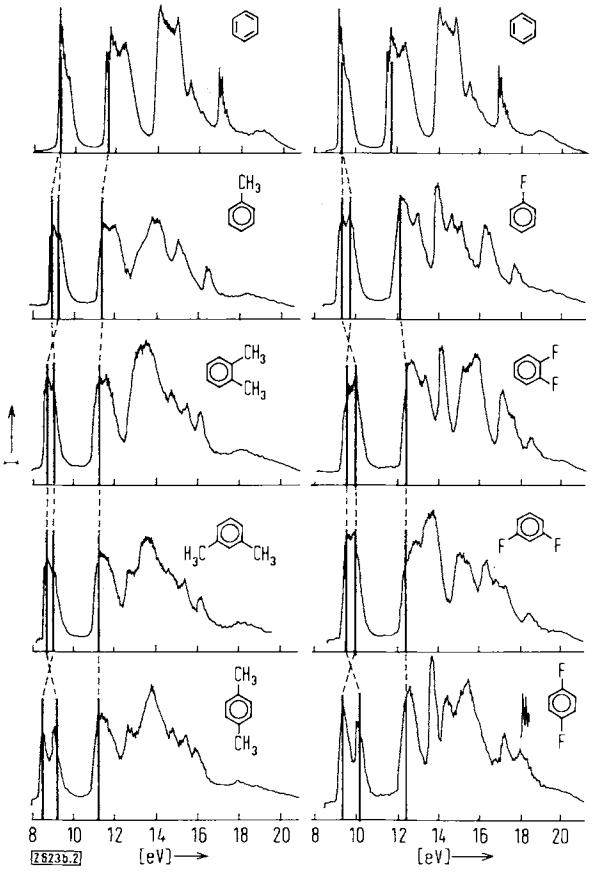

Fig. 2. PE spectra of methyl- and fluoro-benzenes, and correlation diagrams of the π-MO's derived from eqn. (1).

di-substituted benzene derivatives, can be further slightly improved by dividing the inductive effect of the substituents into the π-contribution given by eqn. (1) and a σ-contribution $\Delta I_\sigma(X)$ which is proportional to the number n of substituents[4].

This is made clear in Table 1 in which the experimental π-ionization potentials[5] are compared with the values calculated from the relation

$$I_v(i) = I_v(i)_{benzene} - \delta\varepsilon_i - n\Delta I_\sigma(X) \quad (3)$$

where $\delta\varepsilon_i$ is calculated from eqn. (1) with $\delta\alpha_\mu(CH_3) = 0.85$ eV and $\delta\alpha_\mu(F) = -1.10$ eV and the σ inductive effect is given by $\Delta I_\sigma(CH_3) = 0.05$ eV and $\Delta I_\sigma(F) = -0.10$ eV.

The fact that for $I_v(3)$ the same correlation exists in the HMO data as for $I_v(1)$ and $I_v(2)$ can be regarded as support for the assignment, proposed by *Turner et al.*[8], of these bands to an ionization from the lowest occupied π-MO (a_{2u})[9]. If eqn. (1) is valid for substituted polyenes in a way analogous to that for benzene derivatives, the two π-ionization potentials in fluorinated butadienes should be at higher energies than in unsubstituted butadienes. That, however, is not the case if, according to *Brundle* and *Robin*[10] $I_v(2) = 11.47$ eV is assigned to σ-ionization for butadiene, so that the bands $I_v(1) = 9.06$ eV and $I_v(3) = 12.23$ eV must correspond to π-ionizations, whereas in 1,1,4,4-tetrafluorobutadiene these π-ionizations are unambiguously correlated with $I_v(1) = 9.38$ eV and $I_v(2) = 12.04$ eV.

Further investigations of the influence of substituents on the PE spectra of aromatic and conjugated systems are in progress; the results reported here give hope that they will lead to more detailed information about the ordering of orbitals in benzene and similar systems.

Bis(π-cyclopentadienyl)(1,2,3-triphenyltriphosphanato-P^1,P^3)-titanium and -zirconium[1]

By *Kurt Issleib, Grete Wille,* and *Frieder Krech*[*]

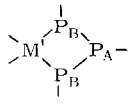
The treatment of 1,4-dialkali-1,2,3,4-tetraphenyltetraphosphanes with bis(π-cyclopentadienyl)-titanium or -zirconium dihalides leads, not as in the case of lithium dialkylphosphides[2] to compounds of the type $[(C_5H_5)_2MPR_2]_2$, but (contrary to statements by *H. Köpf*[3]) to bis(π-cyclopentadienyl)(1,2,3-triphenyltriphosphanato)-metal complexes *(1)* and *(2)*.

$$M_2P_4(C_6H_5)_4 + (C_5H_5)_2M'X_2 \rightarrow$$

M = Li, Na; X = Cl, Br

$$+ 2\,MX + \tfrac{1}{n}\,(PC_6H_5)_n$$

(1), M' = Ti



(2), M' = Zr

The four-membered metal-phosphorus ring structure of *(1)* and *(2)* is proved by determination of molecular masses and by ^{31}P-NMR data.

(1) forms dark violet and *(2)* orange crystals that are diamagnetic in the solid state and in solution [χ_g at 295 °K $= -0.60$ and $-0.62 \cdot 10^{-6}$ cm^3 g^{-1} for *(1)* and *(2)*, respectively]; in the solid state they are relatively stable to air, but in solution are readily oxidized, *(2)* more easily than *(1)*. The complexes dissolve as monomers in dioxane (cryoscopic by *Beckman*'s method), are readily soluble in THF, dioxane, benzene, or toluene but difficultly so in light petroleum or *n*-hexane, and decompose in water or alcohols.

The mass spectra (70 eV) of *(1)* show the molecular ion ($m/e = 502$) and, *inter alia*, fragments $(C_5H_5)_2M(PC_6H_5)_2^+$, $(PC_6H_5)_3^+$, $P(C_6H_5)_3^+$, $(PC_6H_5)_2^+$, $P(C_6H_5)_2^+$, $(C_5H_5)_2M^+$, $C_5H_5M^+$, and $C_6H_5^+$ ($m/e = 394$, 324, 262, 216, 185, 178, 113, 77), M = Ti.

The ^{31}P-NMR spectra of *(1)* and *(2)* (in THF, 85% H_3PO_4 as external standard) are of AX_2 type, as the Table shows.

	δ (ppm)	J_{PP} (Hz)
(1)	$P_A = +180.9 \pm 1$ $P_B = -184.9 \pm 1$	323.0 ± 10
(2)	$P_A = -181.4 \pm 1$ $P_B = -\ 90.7 \pm 1$	338.5 ± 10

The lower chemical shift δP_B of *(1)* than of *(2)* is to be ascribed to a larger electron delocalization $P_B \rightarrow Ti^{IV}$, which accords with the easier reducibility of $(C_5H_5)_2Ti^{2+}$.

(1) and *(2)* were characterized by degradative reactions in dioxane with ethereal HCl and iodine; the decomposition is instantaneous, with a color change from violet to red or from orange to colorless:

$$(1),\,(2) + 2\,HCl \rightarrow (C_5H_5)_2M'Cl_2 + C_6H_5PH_2 + \tfrac{2}{n}(PC_6H_5)_n$$

The metal:phosphorus ratio can be determined by treatment with iodine, hydrolysis of the oxidation product, $C_6H_5PI_4$, and back-titration of the iodine.

$$(1),\,(2) + 7I_2 \rightarrow (C_5H_5)_2M'I_2 + 3C_6H_5PI_4$$

Experimental

$(C_5H_5)_2TiCl_2$ or $(C_5H_5)_2ZrBr_2$ in dioxane is added dropwise during 30 min to a hot suspension of an equimolar amount of $Na_2P_4(C_6H_5)_4 \cdot 6$ Dioxane, $Li_2P_4(C_6H_5)_4 \cdot 4$ Dioxane, $Na_2P_3(C_6H_5)_3 \cdot 2$ Dioxane or $K_2(PC_6H_5)_3 \cdot 2$ THF in dioxane. There is an immediate color change to dark violet or orange, respectively. The reaction mixture is boiled under reflux for 30 min, then freed from solvent in a vacuum. The residue is treated with toluene. After separation of the alkali halide on a G4 frit, the solution is concentrated to about 10 ml, then kept in a refrigerator, whereupon *(1)* or *(2)* crystallizes. The crystals are filtered off, washed twice with ether and dried in a vacuum. M.p. under argon 243—245 °C for *(1)* and 233—235 °C for *(2)*; yield 43—60% according to the batch. All manipulation is done under argon. The amount of solvent is suited to the ratio and amounts of the components. Example: $Na_2P_4(C_6H_5)_4 \cdot 6$ Dioxane 12.1 g in 80 ml dioxane, $(C_5H_5)_2TiCl_2$ 3 g in 100 ml dioxane and 80 ml toluene. In this case $(C_6H_5P)_n$ is isolated from the filtrate after concentration.

Cationic γ-Oxo-isocyano Complexes of Iron, Ruthenium, and Osmium(II)[1]

By *Matthias Schaal* and *Wolfgang Beck*[*]

Alkylation of cyano complexes, leading to isocyanide compounds, has long been known[2]. In an attempt to prepare isocyano complexes by treating potassium hexacyanoferrate(II) with oxonium salts in acetone, we found new, hexacoordinated, cationic cyano complexes in which a keto group was in position 3 relative to the isocyanide group. Analogous ruthenium and osmium complexes are formed similarly in good yields (*ca.* 80%). These complexes are apparently formed by acid-catalyzed aldol addition of the acetone, in which it can be assumed that the carbonium ion of the dimeric acetone is trapped by nucleophilic attack of the coordinated cyano ligand. In fact, the iron(II) complex *(1)* is obtained in almost quantitative yield also from diacetone alcohol or mesityl oxide and

8 München 2, Meiserstrasse 1 (Germany)

$$[M(CN)_6]^{4-} + 12\ CH_3\text{-}CO\text{-}CH_3 + 6\ R_3O^+BF_4^- \xrightarrow[(CH_3)_2CO]{20\,^\circ C}$$

$$[M(C{\equiv}N\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3)_6]^{2+}(BF_4^-)_2 + 4\ BF_4^- + 6\ R_2O + 6\ ROH$$

(1)

M = Fe^{II}, Ru^{II}, Os^{II}; R = C_2H_5, n-C_3H_7)

$K_4[Fe(CN)_6]$ (or $K_3[Fe(CN)_6]$) with 35% aqueous HBF_4 solution.

The structure of the complexes follows from the IR and ^{1}H-NMR data (Tables 1 and 2). Only one νCN band of the isocyanide ligands appears in the IR spectrum; the keto absorption corresponds in its position to that of the saturated ketone. The ^{1}H-NMR spectrum of the complexes, like that of diacetone alcohol, shows three singlets with the intensity ratio 6[$C(CH_3)_2$]:2[CH_2]:3[—OC—CH_3].

Table 1. ^{1}H-NMR spectra of the γ-oxo-isocyano complexes (solutions in CH_2Cl_2 with TMS as internal standard).

M(II)	$\tau_{C(CH_3)_2}$	τ_{CH_2}	τ_{-OC-CH_3}
Fe	8.38	6.97	7.82
Ru	8.42	6.98	7.81
Os	8.40	6.97	7.82

Table 2. IR absorptions (cm^{-1}) of the γ-oxo-isocyano complexes (solid, in KBr).

M(II)	νC≡N	νC=O	νBF_4	M. p. (°C)
Fe	2215	1725	1058	149
Ru	2214	1720	1055	133
Os	2206	1718	1053	136–137

The keto group of the isocyanide ligand shows typical carbonyl reactions, *e.g.* with 2,4-dinitrophenylhydrazine it gives a hydrazone derivative.

Analogous reactions of cyano complexes can be effected with other organic carbonyl compounds. Thus iron(II) complexes were obtained by treating $K_4[Fe(CN)_6]$ with ethyl methyl ketone *(2a)*, cyclohexanone *(2b)* or acetophenone *(3)* in the presence of an oxonium salt. In the case of acetophenone only five cyano ligands were alkylated *(3)*.

$$[Fe(C{\equiv}N\text{-}C(R^1R^2)\text{-}CHR^3\text{-}CO\text{-}R^4)_6]^{2+}(BF_4^-)_2$$

(2a) $R^1 = CH_3$; $R^3 = H$; $R^2 = R^4 = C_2H_5$

(2b) R^1, $R^2 = -(CH_2)_5-$; R^3, $R^4 = -(CH_2)_4-$

$$[Fe(C{\equiv}N\text{-}C(CH_3)(C_6H_5)\text{-}CH_2\text{-}CO\text{-}C_6H_5)_5CN]^+(BF_4)^-$$

(3)

Experimental

Triethyloxonium tetrafluoroborate (5.7 g, 30 mmol) is added in small portions with stirring to a suspension of $K_4[Mn(CN)_6]$ (M = Fe, Ru or Os) (3 mol) in a ketone. Stirring is continued at room temperature until $[M(CN)_6]^{4-}$ ions are no longer detectable. The solution is then filtered and the residue is washed with much methylene chloride. The complex is carefully precipitated from the filtrate by light petroleum. Purification is by recrystallization from CH_2Cl_2 or $CHCl_3$, giving colorless crystals.

Synthesis of 2,2-Dichloro-1,5-dimethyl-4,6-dioxo-1,4,5,6-tetrahydro-1,5,2λ^5-diazaphosphorine

By *N. Singh* and *H. P. Latscha*[*]

In previous work we expanded the four-membered ring system of compound *(1)*[1] to a six-membered ring system by treatment with isocyanate derivatives[2]. We have now achieved an analogous ring expansion by means of ketene. A variety of products is obtained according to the reaction conditions[3]. At −20 to −25 °C a compound is formed to which we assign the structure 2,2-dichloro-1,5-dimethyl-4,6-dioxo-1,4,5,6-tetrahydro-1,5,2λ^5-diazaphosphorine *(2)* on the basis of its molar mass (228, mass spectrometry) and ^{1}H-NMR spectrum [in $CDCl_3$, δ = 5.77 (H^a, J_{HP} = 7.0 Hz), 3.55 (H^b), 3.25 ppm (H^c, J_{HP} = 7.5 Hz)]. *(2)* represents one of the limiting formulas whose various contributions cannot be estimated.

(1) *(2)*

The new compound throws some light on the ylene-ylide problem since the hydrogen of its methine group is firmly attached and therefore gives a split signal in the ^{1}H-NMR spectrum (cf. Ref. [4]).

(2) exists as a yellow powder or yellowish-brown crystals, is moderately sensitive to hydrolysis, and decomposes between 98 and 106 °C. It dissolves in, *e.g.* chloroform, methylene chloride, 1,2-dichloroethane, or tetrachloroethane; it is insoluble in, *e.g.* ether, light petroleum, or carbon tetrachloride. The results of elemental analysis and the IR spectrum accord with the assigned structure.

Experimental:

Ketene, completely freed from acetone, is passed into an ethereal solution of *(1)*[1] at −20 to −25 °C until the solution is yellow and viscous; the reaction can be followed by disappearance of the signal of *(1)* from the ^{31}P-NMR spectrum. The reaction time and the yield depend on the amount of ketene that can be made to react with *(1)*. The ketene generator that we used delivered *ca.* 40 g per hour (from acetone). The ketene was passed into the solution as gas through the stirrer plate of a vibro mixer. With this arrange-

[*] N. Singh, M. Sc. and Doz. Dr. H. P. Latscha
Institut für Anorganische Chemie der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

ment the average reaction time was 5 h and the yield of *(2)* was *ca.* 5 g from a 0.2 molar batch.

(2) can be freed from by-products by digestion of the viscous reaction mixture with warm benzene; about half of the mixture dissolves. If the filtrate is concentrated to one-third volume, analytically pure yellowish-brown crystals separate within a few days. If these are dissolved in, *e.g.* chloroform, and then precipitated by ether, the product, when dry, forms a yellow powder.

$CH_3AsS_2N_2$, a Five-membered Arsenic-Sulfur-Nitrogen Ring

By *Otto J. Scherer* and *Reinhard Wies*[*]

If sulfur bis[(trimethylsilyl)imide] *(1)* is treated with dichloro(methyl)arsane in the molar ratio 1:2, and not as before in the molar ratio 1:1[1], a poor yield is obtained of 3-methyl-1,4-dithia-2,5-diazaarsole *(3)*. The same compound is formed in minimal yield if *(2)* is treated with S_8 in absence of a solvent.

The product can be regarded as an arsenic analog of S_3N_2, the still missing member of the series of sulfur nitrides, S_4N_4[2a], S_4N_2[2a,b], and S_2N_2[2a]. It is a wine-red liquid that is readily hydrolyzed, extremely volatile, and readily soluble in ether or benzene, moderately so in carbon tetrachloride, but incompletely in pentane. It can be distilled without decomposition at 33—35 °C/0.05 torr and solidifies to a glass at low temperature. One hour's warming at 100 °C leads to irreversible darkening but not to decomposition.

Compound *(3)* was characterized by complete elemental analysis, cryoscopic determination of molecular weight (in benzene: found 187, calc. 182) as well as by ^{1}H-NMR, mass, IR, and UV spectra. ^{1}H-NMR (60 MHz; 10% CCl_4 solution; TMS ext.): $\delta(CH_3As) = -72.0$ Hz (s). Mass spectrum (70 eV)[3]: $m/e = 182$ (molecular ion, 43), 167 (AsN_2S_2, 100), 136 (22), 121 (21), 107 (16), 104 (2), 90 (10), 89 (8), 88 (5), 78 (5), 46 (8); none of the other fragments has a relative intensity of >1. IR (capillary film between KBr plates): we assign bands at 1050 and 930 cm^{-1} provisionally to the NSN system. UV (in CCl_4), $\lambda_{max} = 261$ ($\varepsilon = 2680$), 300 (860), 432 (1610).

Experimental

Dichloro(methyl)arsane (18.6 g, 116 mmol) is added to sulfur bis[(trimethylsilyl)imide] (12.0 g, 58 mmol) under nitrogen at room temperature. The original yellow color changes to wine-red within a short time without noticeable alteration in temperature. Chloro(trimethyl)silane, which separates as an upper layer, is distilled off in 2 h at atmospheric pressure (external temperature 80—85 °C). The residue is then fractionally distilled at oil-pump vacuum; b.p. 40—95 °C/2 torr (bath temperature up to *ca.* 130 °C). Redistillation gives a liquid of b.p. 33—35 °C/0.05 torr (2.2 g, 21% calculated on the imide used). As residue remains a voluminous foam of a still unidentified solid substance.

A Rapid Method for Determination of the Optical Purity of Amino Acids[**]

By *Wolfgang Parr* and *Patrick Y. Howard*[*]

Determination of small amounts of D-amino acids in the presence of a large excess of L-isomers (or *vice versa*) is still one of the most difficult exercises in analytical chemistry. However, since *Corrigan*[1] recently proved the widespread occurrence of D-amino acids in nature, a method for rapid and reliable determination of these "unnatural" amino acids is highly desirable.

We showed earlier that enantiomeric amino acids could be separated as TFA-amino acid isopropyl esters (TFA = trifluoroacetyl) by gas chromatography on optically active stationary phases[2, 3], but overlapping then occurred, *e.g.* of D-serine and L-leucine.

On the basis of our theoretical investigations of the diastereomeric association complex[4–6] responsible for the separation of chiral amino acids, we have synthesized a new, optically active, stationary dipeptide phase—cyclohexyl *N*-TFA-L-α-aminobutyryl-L-α-aminobutyrate.

First, the two necessary derivatives [*N*-Boc-L-α-aminobutyric acid (Boc = *tert*-butyloxycarbonyl) and cyclohexyl L-α-aminobutyrate hydrochloride] were prepared from L-α-aminobutyric acid. The peptide bond was formed by use of dicyclohexylcarbodiimide in presence of 1-hydroxybenzotriazole[7]. After removal of the Boc group with 5N HCl in dioxane the dipeptide was acylated with tri-

fluoroacetic anhydride. The new phase was then crystallized as white needles (yield 79%; m.p. 110—112°C; elemental analysis, calc.: C 52.45, H 6.88, N 7.59, F 15.56; found: C 52.44, H 6.90, N 7.62, F 15.66; homogeneous on thin-layer chromatography with various solvents and on gas chromatography-mass spectrometry on an SE-30 column).

The gas-chromatographic investigations with the new stationary phase were carried out on a Varian 1200-1 gas chromatograph equipped with an FID detector, modified for capillary columns. A stainless steel capillary column (122 m × 0.508 mm) was coated with a 10% solution of cyclohexyl *N*-TFA-L-α-aminobutyryl-L-α-aminobutyrate in methylene chloride and conditioned in the usual way[2, 3]. At 120°C with a carrier gas (He) pressure of 1.76 kp/cm², enantiomeric mixtures of the isopropyl esters of the TFA derivatives of D,L-alanine, D,L-valine, D,L-threonine, D,L-isoleucine, D,L-leucine, D,L-serine, D,L-proline, and D,L-aspartic acid could be completely separated, but glycine and L-threonine were not wholly separable. This resolution was achieved, however, at 110°C (Fig. 1). Separation of the higher-boiling isopropyl esters of *N*-TFA-amino acid esters on a 30 m capillary column has been previously described by us[2].

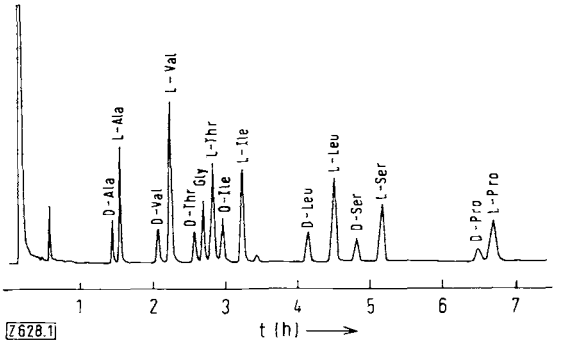

Fig. 1. Chromatogram of isopropyl esters of TFA-amino acids on cyclohexyl *N*-TFA-L-α-aminobutyryl-L-α-aminobutyrate as the stationary phase. Chromatographic conditions: 122 m × 0.508 mm capillary column 110°C isothermal; entry block 190°C, detector temperature 290°C; carrier gas helium at 1.76 kp/cm².

With this new, optically active, stationary phase the more volatile amino acid derivatives can now be separated unambiguously from one another. In this way, 16 of the naturally occurring amino acids can be investigated relatively rapidly (6 h) and with great precision (1%) to a limiting detection range of 0.1%. Since, unlike the separation of diastereomers on *optically inactive* stationary phases, nonasymmetric reagents were used for derivatization of the amino acids and correction of the results for antipodic impurities is unnecessary.

Phase Transfer Catalysis in the Hofmann Carbylamine Reaction[**]

By *William P. Weber, George W. Gokel*, and *Ivar K. Ugi*[*]

The Hofmann carbylamine synthesis[1] is one of the two classical methods for the preparation of isocyanides *(1)*[1-3] but has never enjoyed popularity because of low yields and experimental difficulties.

$$R{-}NH_2 \xrightarrow[\text{Base}]{CHX_3} R{-}N{\equiv}C \qquad (1)$$

The many procedural modifications proposed over the years have not improved the method substantially[3]. The one case where very high yields are reported[4] appears non-reproducible[5].

We wish to report a carbylamine synthesis utilizing the phase transfer catalysis method[6] of generating dihalocarbene from chloroform or bromoform and 50% aqueous sodium hydroxide which constitutes a very effective and convenient method for the direct one-step conversion of a primary amine into the corresponding isocyanide. In particular, we have applied this method to the synthesis of methyl and ethyl isocyanides utilizing commercially available aqueous amine solutions.

In comparable cases the overall yields of the present method are only slightly less than those of the phosgene method, which has been the method of choice for preparation of isocyanides[7]. Since the phase transfer carbylamine reaction is a one-step method *versus* the two-step phosgene method it may be preferable in many cases.

We have employed two basic procedures: one applies to low boiling amines, *e.g.*, methyl and ethyl (Procedure A), and the second to the higher boiling amines (Procedure B). Procedure A utilizes aqueous amine solutions and solid sodium hydroxide and because of the low boiling point of methyl and ethyl isocyanides, bromoform is used as the

Table 1. Preparation of isocyanides by the phase transfer carbylamine reaction.

[**] This research was partially supported by the Caltech President's Fund and NASA Contract NAS 7—100. A Biomedical Sciences Support Grant FR-07012-04 from the National Institutes of Health is also gratefully acknowledged.

[***] New address: Laboratorium für Organische Chemie der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

carbene source [residual chloroform can be separated from the product only by very careful fractionation (*e.g.*, spinning band)] instead of chloroform which is used in method B. The isocyanides prepared by the phase transfer carbylamine reaction are listed in Table 1.

Caution: All isocyanide preparations should be conducted in a fume hood.

Procedure A[8]:

A 500-ml flask equipped with a magnetic stirring bar and dry ice-acetone reflux condenser is charged with 33% aqueous ethylamine solution (40 ml), water (12 ml), benzyltriethylammonium chloride (0.6 g), sodium hydroxide (35 g), and finally bromoform (50.3 g, 0.2 mol). The mixture is stirred overnight at 20 °C and then distilled directly. The distillate contains ethylamine, water, and ethyl isocyanide. Drying over KOH pellets followed by distillation gives pure ethyl isocyanide, 5.2 g (47% based on bromoform), b. p. 65 °C.

Procedure B:

Aniline (18.6 g, 0.2 mol) is allowed to react with 50% aqueous sodium hydroxide (60 ml), chloroform (16 ml, 0.2 mol), and benzyltriethylammonium chloride (0.5 g) in dichloromethane (50 ml). After a short induction period (≈10 min), the flask warms and dichloromethane reflux maintains the reaction temperature close to 40 °C. After the exothermic reaction subsides, the reaction is stirred for an additional hour and then diluted with water (200 ml)[9]. The organic phase is separated off, washed with water and brine, and dried over K_2CO_3. Distillation affords 11.7 g (57% based on starting amine) of phenyl isocyanide b. p. 52—53 °C/12 torr.

ESR Measurements for the 2,2',6,6'-Tetrachloro Derivative of Chichibabin's Hydrocarbon[**]

By *Rolf Sartorius* and *Hans-Dieter Brauer*[*]

The tetrachloro derivative *(1)* of *Chichibabin*'s hydrocarbon[11] is considered to be a typical diradical[2]. This is based on the assumption that the two phenyl rings of the central biphenyl system are twisted under the influence of the four chlorine atoms in *ortho*-positions to make an angle of *ca.* 90°, and that the halves of the molecule thus present two independent radical centers of trityl type. If the two halves of the molecule are exactly perpendicular, theory requires their complete optical and magnetic independence; according to *Seel*'s quantum-theoretical calculations[3], the lowest singlet and triplet states are degenerate for such a conformation of *(1)*.

There has not yet been an unambiguous proof of this interpretation. Investigation of *(1)* is difficult because of its association which leads, *inter alia*, to the formation of open-chain dimeric or oligomeric diradicals[1,4]. Thus, for instance, *Gouy*'s method cannot be used to decide whether the monomers of *(1)* are really true diradicals. Examination of space-filling models, however, does not exclude the possibility that the two halves of the molecule *(1)* may make an angle of $<90°$ to one another; in that case the lowest singlet and triplet states would no longer have the same energy, so that a singlet state must also be considered for the ground state of monomeric *(1)*. To obtain more precise information we have carried out ESR measurements for *(1)* in both the solid state and in solution. For comparison, the monoradical *(2)* was also investigated by this method. Both compounds were prepared by the method described by *Müller* and *Neuhoff*[1].

(1) *(2)*

In the ESR spectrum of solid *(1)* a very intense doublet signal was observed at $H_0 = 3400$ G ($g = 2.0028$), probably due mainly to dimeric or oligomeric diradicals. In the half-field region, at $H_{min} = 1699$ G, a further signal of lower intensity was found that could be caused by either intra- or inter-molecular spin-spin coupling[5].

To clarify this, we studied dilute, glassy, solidified solutions of *(1)* in toluene. To suppress association as far as possible, the solutions (10^{-2} M, calc. on monomers) were first warmed to 60 °C and then rapidly cooled in liquid nitrogen. Fig. 1 shows an ESR spectrum of *(1)* measured at −120 °C. This contains, besides an intense doublet, several ($\Delta m = 1$) signals characteristic of molecules in the triplet state. The resonance field strength H_{min} of the outermost weak transition with $\Delta m = 2$ could not be measured under the conditions used. We ascribe the triplet spectrum found in the high-field region to monomeric *(1)*. This assignment is supported by the observation that the ESR spectrum of the monoradical *(2)*, measured under the same conditions, consists only of a doublet signal; intermolecular spin-spin coupling leading to formation of triplet systems can thus be excluded as the cause of the triplet spectrum observed for *(1)*. The zero-field splitting parameters calculated from the ($\Delta m = 1$) signals[6], have the values: $|D| = 0.0072$, $|E| \leq 0.0003\ cm^{-1}$.

In the region −150 to −110 °C the intensity of the ($\Delta m = 1$) signal increases with increasing temperature; the temperature-dependence of the signal amplitudes leads, by the known relation[7], to a triplet-singlet splitting of $\Delta E = 1.0 \pm 0.3$ kcal/mol.

[**] We are grateful to the Deutsche Forschungsgemeinschaft for financial support of this work.

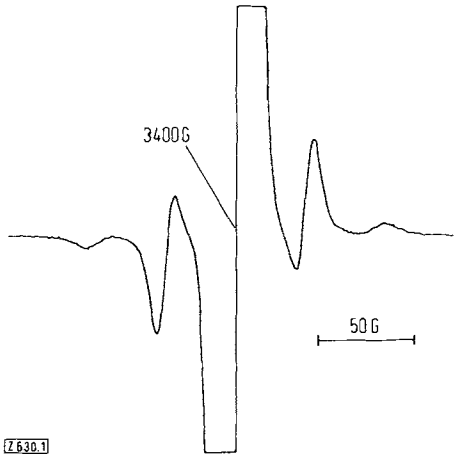

Fig. 1. ESR spectrum of 3,3',5,5'-tetrachloro-4,4'-bi(β,α'-diphenylbenzyl) *(1)* in glassy solidified toluene at −120°C.

The proved existence of monomeric triplet molecules indicates a clear magnetic interaction between the halves of the molecules *(1)*. This applies also to optical considerations, as can be derived from a comparison of the electron spectra of *(1)* and *(2)*: unlike *o,o'*-tetrasubstituted biphenyl derivatives, whose absorption spectra contain a maximum at almost the same wavelength as for the corresponding halved benzene derivatives[8, 9], the longest-wave absorption band ($\lambda_{max}=592$ nm) of *(1)* is found to be shifted by 65 nm to longer wavelengths in comparison with *(2)* ($\lambda_{max}=527$ nm). Whereas for biphenyl derivatives it is assumed that the two halves of the molecule are twisted to provide an angle of substantially 90°, there is for *(1)* evidently an increased tendency for the two halves of the molecule to become as nearly coplanar as possible, which may be derived from the concomitant, comparatively large increase in mesomerism energy.

The ESR spectra of compounds *(1)* and *(2)* in benzene at room temperature contain signals with clearly defined hyperfine structure. The HFS spectrum of *(1)* consists of *ca.* nineteen lines with individual line widths of about 550 mG. Appreciably more lines are found in the HFS spectrum of *(2)*, where the width of a single line is about 120 mG. From the line broadening that occurs on transition from the single-spin system *(2)* to the two-spin system *(1)* it can be concluded that there is considerable dipole-dipole coupling between the unpaired electrons in the two-spin system. It is not possible to make any unambiguous statement about the nature of the species causing the HFS spectrum of *(1)* because the spectrum could not be analyzed. The spectrum of *(2)* could, however, be analyzed: the coupling constants a^H have the following values: $a^H(p')=3.08$, $a^H(o')=2.78$ or 2.76, $a^H(p)=2.76$ or 2.78, $a^H(m)=1.15$ and $a^H(o)=2.54$ G.

From the results of our measurements it can be concluded that *(1)* is not a true diradical. Rather, there is considerable interaction between the two halves of the molecule in the equilibrium conformation of *(1)*, a fact evidently explicable by their twisting through an angle of $<90°$. The ground state of the equilibrium conformation is a singlet state lying about 1 kcal/mol below the lowest corresponding triplet state. However, the present results do not exclude the possibility that at medium temperatures there are diradicals (*i.e.* conformations with a torsion angle of $\approx 90°$) among the monomers in *(1)* which might be considered as the cause of the ESR hyperfine-structure spectrum.

Chemical Syntheses with Metal Atoms: Preparation of Bis(butadiene)iron Complexes and Butadienetetracarbonylchromium

By *Ernst Koerner von Gustorf, Ottmar Jaenicke*, and *Oskar E. Polansky*[*]

Wilke introduced the term "naked nickel atom" into organometallic chemistry. That means "nickel in complexes whose ligands can all be replaced by butadiene"[1].

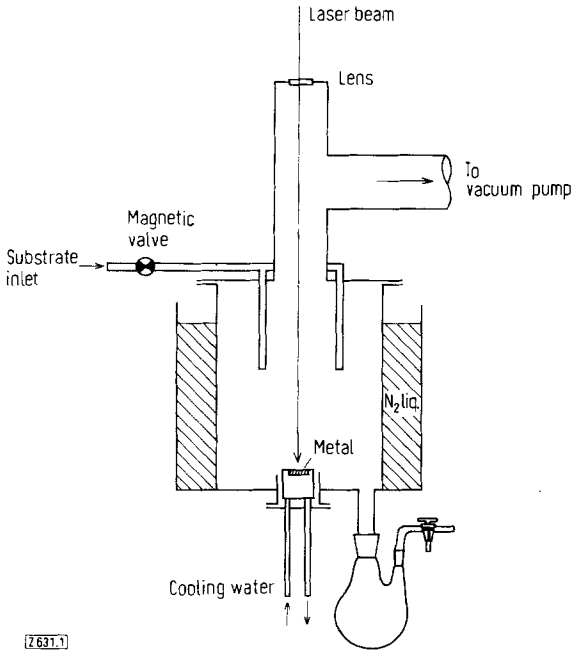
"Completely naked" metal atoms are obtained by evaporation of metals in a high vacuum[2]. It is well known that atomic and oligoatomic species are much more reactive than condensed phases—one can refer, *e.g.* to *Skell*'s work[3] with C_1 and C_3. This has led us to attempt to synthesize organometallic compounds by reacting metal atoms with organic substrates.

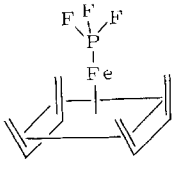
A first, largely unsuccessful, experiment in this direction was an attempt to obtain ferrocene by exploding iron wires in liquid, in gaseous or over solid cyclopentadiene[4]. The density of metal vapor in wire explosions is obviously too high to permit sufficiently rapid attack by cyclopentadiene in competition with formation of polyatomic iron species. Therefore, we have developed during the last two years an apparatus that makes it possible to evaporate metals in a high vacuum and to co-condense them with organic compounds, *e.g.* at the temperature of liquid nitrogen (see Fig. 1).

The metal to be evaporated is put into a water-cooled copper block[5] which is placed in a steel reaction vessel at 10^{-3} to 10^{-4} torr in the focus (diameter 1—3 mm) of a laser beam[6]. The evaporated metal is condensed on the cooled walls of the vessel simultaneously, or intermittently, with an excess of the organic substrate. At the end of the experiment the warming up of the products can, if necessary, be carried out in the presence of further components that convert the primary products and stabilize them.

In a first, exploratory experiment 42 mg of iron were evaporated by irradiation of pieces of iron wire[7] for 30 min at intervals of 1 min, butadiene being condensed in intermittently. Before thawing, the reaction mixture[8] was treat-

[*] Dr. E. Koerner von Gustorf, O. Jaenicke, and Prof. Dr. O. E. Polansky
Max-Planck-Institut für Kohlenforschung
Abteilung Strahlenchemie
433 Mülheim-Ruhr, Stiftstrasse 34—36 (Germany)





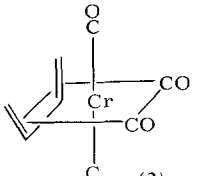


Fig. 1. Apparatus for evaporation and co-condensation of metals with organic substrates (scale 1:4).

ed with CO. Chromatography on silica gel/pentane afforded 45 mg (0.23 mmol) of bis(butadiene)monocarbonyliron (yield 31%, based on Fe evaporated), that proved identical in melting point and spectroscopic properties with a product already previously obtained by us photochemically[9, 10].

By this method other ligands also can be introduced in place of CO in the axial position of bis(butadiene)iron complexes. Intermittent evaporation of 385 mg of iron (6.9 mmol) in 55 min[5], co-condensation of butadiene, and subsequent treatment with PF_3 afforded a reaction mixture, from which 295 mg (1.2 mmol) of bis(butadiene)trifluorophosphaneiron *(1)* was obtained by crystallization from pentane as yellowish-brown needles (sublime at 73 °C; yield 17%, based on Fe evaporated). The structure of *(1)* follows from elemental analysis, the mass spectrum [*m/e*: 252 (M), 164 (M − PF_3), 110 (FeC_4H_6), 88 (PF_3), 56 (Fe)], and the ^{1}H-NMR spectrum (in C_6D_6) which shows three symmetrical multiplets, each for 2H, at 5.75, 9.1 and 10.5 τ. Since the chemical shifts are very similar for the protons in bis(butadiene)monocarbonyl iron and in *(1)*, it can be reasonably assumed that the butadiene units in *(1)* have the spatial arrangement that is proved for the monocarbonyl complex.

(1)

(2)

Chromium is more volatile than iron. On intermittent irradiation (each of 2 seconds duration), we were able to evaporate 530 mg (10 mmol) of chromium in 11.5 min[11]. Intermittent condensation of butadiene into the vessel and subsequent treatment with CO afforded a dark brown oil, from a solution of which in pentane at −70 °C 95 mg (0.44 mmol, yield 4.4%, based on Cr evaporated) yellow crystals separated; they decomposed above 0 °C. The composition $C_4H_6Cr(CO)_4$ follows from elemental analysis and the mass spectrum [*m/e*: 218 (M), 190 (M—CO), 162 (M—2CO), 134 (M—3CO), 106 (M—4CO), 52 (Cr)]. The formulation as butadienetetracarbonylchromium *(2)* is supported by the IR spectrum (in CCl_4), which shows four metal-carbonyl stretching vibrations at 2040, 1977, 1946, and 1932 cm^{-1}, and by the ^{1}H-NMR spectrum (in $C_6D_5CD_3$) at −10 °C, which shows three multiplets, each for 2 H, at 5.65, 8.3 and 9.45 τ. *(2)* is the first example of 1,3-dienetetracarbonylchromium complexes, which are apparently appreciably more labile than the relatively stable tetracarbonylchromium complexes of cyclic 1,5-dienes[12]. Complexes such as *(2)* have been postulated as intermediates in the photochemical hydrogenation of 1,3-dienes with $Cr(CO)_6/H_2$ but could then not be isolated, for reasons that can now be appreciated[13].

We are now investigating the general applicability of our method to the synthesis of labile transition-metal complexes.

Two other laboratories are at present carrying out studies on organometallic syntheses with metal atoms. *Timms*[14] succeeded in synthesizing ferrocene, dibenzenechromium and π-allylhalonickel complexes; he heats the metals electrically; but his apparatus is not suitable for investigation of relatively involatile, air-sensitive compounds[15]. *Skell* has carried out orienting experiments by similar methods with a variety of metals[16, 17].

Reversible N_2 Fixation by Dicarbonyl-π-cyclopentadienyl(tetrahydrofuran)manganese(I)[1]

By *Dieter Sellmann*[*]

Metal complexes that fix N_2 are of particular interest if, at the site of N_2 fixation, other ligands can also be introduced reversibly. Such a ligand exchange is required for the mechanism of N_2 reduction in nitrogenase systems, where replacement of complex-bound H_2O or NH_3 must occur:

$$M{-}OH_2 + N_2 \rightarrow M{-}N_2 + H_2O \quad (1)$$

$$M{-}NH_3 + N_2 \rightarrow M{-}N_2 + NH_3 \quad (2)$$

M = central metal atom

Eq. (1) describes the beginning of the reaction chain if a nitrogenase system interacts with N_2 for reduction, while eq. (2) describes the liberation of the end product. NH_3 is used for synthesis of amino acids, the N_2 complex re-entering the reduction chain.

A study of the reactions of $C_5H_5Mn(CO)_2N_2$ *(1)*[2] has made it possible to simulate such replacement reactions.

First it was shown that *(1)* is unstable in tetrahydrofuran (THF) at room temperature, being converted into the THF complex $C_5H_5Mn(CO)_2OC_4H_8$ *(2)* with evolution of N_2:

$$(1) + THF \rightarrow (2) + N_2\uparrow \quad (3)$$

The evolution of nitrogen stops after some time, although small amounts of *(1)* are still detectable by IR spectroscopy in the THF solution. The fact that the reaction leading to *(2)* does not procede to completion, in spite of the large excess of THF, led to the assumption of an equilibrium that is shifted largely to the side of *(2)* owing to the low N_2 concentration. If such an equilibrium exists it should be possible to synthesize *(1)* also by reaction of *(2)* with N_2 in a reaction that is the reverse of eq. (3):

$$(2) + N_2 \rightarrow (1) + THF \quad (4)$$

This could in fact be done, either by reducing the concentration of THF relative to that of N_2 or by raising the N_2 concentration by pressure. In the first case N_2 was bubbled through a freshly prepared solution of *(2)*[3] until the THF had volatilized completely in the gas stream. In the second case N_2 was pressed at 150 atm into a solution of the same kind for 24 h and the THF was then removed at room temperature *in vacuo*. At 20 °C and $\approx 10^{-3}$ torr a mixture of *(1)* and $C_5H_5Mn(CO)_3$ *(3)* sublimed from the residues of each reaction. *(1)* can be easily identified in the mixture by means of its characteristic IR bands. These findings prove the assumed equilibrium and thus the competition between N_2 and THF for the central metal in the complex fragment $\{C_5H_5Mn(CO)_2\}$ *(4)*:

$$(1) + THF \rightleftharpoons (2) + N_2 \quad (5)$$

When a CO/N_2 mixture is bubbled through a solution of *(2)*, the complex *(3)* is the only product. Thus, as in most N_2-fixing systems, *(2)* is inactivated for uptake of N_2 by absorption of CO.

It is, however, not possible from these facts to decide the important question whether the preferential formation of the CO complex is based on kinetic or thermodynamic grounds. Nevertheless, a kinetic cause is favored by the fact that spectroscopic data indicate N_2 to be a stronger electron donor than CO in *(1)*[2].

Comparing eq. (1) and (5) shows clearly the analogy to nitrogenase systems. Alongside $[Ru(NH_3)_5H_2O]^{+2}$[4] and $\{C_5H_5Fe[(CH_3)_2P(CH_2)_2P(CH_3)_2]OC(CH_3)_2\}BF_4$[5], *(2)* is the third system known in which N_2 is able to replace an oxygen-donor ligand at atmospheric pressure.

Methyl Hydrogen Carbonate[1]

By *Gerhard Gattow* and *Werner Behrendt*[*]

Continuing our studies of carbonic acid[2] we have now concerned ourselves with the half esters, which have not previously been prepared.

Methyl hydrogen carbonate *(1)* is formed on treatment of a suspension of $Na[CH_3OCO_2]$ (obtained by reaction of $NaOCH_3$ dissolved in methanol with CO_2) in dimethyl ether with a solution of HCl(g) in dimethyl ether at −50 °C. After filtration from the NaCl formed and removal of the dimethyl ether by distillation at −80 °C, the half ester remains as a solid.

$CH_3OCO(OH)$ is a colorless material that melts at −36 °C; decomposition ($\rightarrow CO_2 + CH_3OH$) at temperatures above the melting point. The half ester is only moderately soluble in dimethyl or diethyl ether; it decomposes immediately in water. The dissociation constant, determined by way of the hydrolysis constant of $Na[CH_3OCO_2]$, at 25 °C in H_2O is: $K_a = 2.44 \cdot 10^{-6}$. By measurement of the CO_2 pressure of the solid (−70 to −36 °C), the heat of formation of *(1)* was found to be: $\Delta H_f = -155.5 \pm 1$ kcal/mol.

The IR spectrum of a solution of *(1)* in $(C_2H_5)_2O$ at −70 °C contains, besides the ether bands, the following absorption bands that can be unambiguously assigned to the half ester: 3484 [s; ν(OH)], 1779 [m; ν_{as}(CO)], 1730 [s; ν_{as}(CO)], 1277 [s; $\delta_s(CH_3)$], 1255 [s, $\delta_s(CH_3)$], 823 [s, $\pi(OCO_2)$], 665 [m; ?], 652 [m; ?], 567 [w; $\delta_s(OCO_2)$] cm^{-1}.

2,3:3,4:4,2-Tri-μ-carbonyl-2,2,3,3,4,4-hexacarbonyl-1-aluminotricobalt: Preparation and Spectroscopic Findings[**]

By *Karl E. Schwarzhans* and *Hans Steiger*[*]

$AlCo_3(CO)_9$, a metal cluster containing aluminum-cobalt bonds, has been obtained by reaction of sublimed aluminum trichloride with an excess of sodium tetracarbonylcobaltate(-1) in dry benzene under an inert gas (N_2).

$$3\,Na[Co(CO)_4] + AlCl_3 \rightarrow AlCo_3(CO)_9 + 3\,NaCl + 3\,CO$$

$$[(18\ mmol) + (2\ mmol) \xrightarrow[30\,°C;\,3\,d]{250\ ml\ C_6H_6}]$$

This crystalline compound (yield 25—30% calc. on $AlCl_3$) is deep red, sensitive to moisture, and not very stable thermally, but can be sublimed at room temperature and 0.1 mm. Its composition is proved by elemental analysis and by IR and mass spectra.

In the mass spectrum (50 eV) the molecular ion ($I_{rel} = 5.4$) is accompanied by the following characteristic fragments:

$AlCo_3(CO)_8^+$ (16.3), $AlCo_3(CO)_7^+$ (5.2), $AlCo_3(CO)_6^+$ (3.6), $AlCo_3(CO)_5^+$ (18.2), $AlCo_3(CO)_4^+$ (34.6), $AlCo_3(CO)_3^+$ (18.3), $AlCo_3(CO)_2^+$ (18.2), $AlCo_3(CO)^+$ (14.5), $AlCo_3^+$ (31.1), $Co_2(CO)_3^+$ (20), $Co(CO)_3^+$ (14.4), $CoCO^+$ (3.7), Co^+ (100). The relatively high intensity of the $AlCo_3^+$ fragment is striking.

The ν_{CO} region of the IR spectrum is to a large extent comparable with that of dodecacarbonyltetracobalt[1] in respect of the positions, number, and intensities of the bands:

$AlCo_3(CO)_9$, ν_{CO} in benzene: 2100 (w), 2066 (m), 2053 (s), 2032 (m), 1893 (w), 1858 (m-s) cm^{-1};—$Co_4(CO)_{12}$, ν_{CO} in *n*-hexane: 2104 (w), 2063 (m-s), 2054 (s), 2037 (w), 2027 (w), 1898 (w), 1867 (m) cm^{-1}.

The IR spectra show that the structure of the metal skeleton is similar in the two clusters. A structure is therefore proposed for $AlCo_3(CO)_9$ that differs from that of $Co_4(CO)_{12}$ (for which several X-ray investigations are available[2–4]) in that the apical $Co(CO)_3$ group of $Co_4(CO)_{12}$ is replaced by the aluminum ion, as shown in Figure 1. The agreement of the IR spectra further indicates that $Co_4(CO)_{12}$ has this structure also in solution, contrary to a previous structural proposal[5] that was based on IR spectroscopic findings.

Cyclophanes Possessing Cavities[1][**]

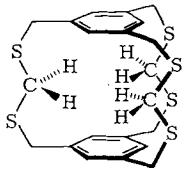
By *Fritz Vögtle* and *Rainer G. Lichtenthaler*[*]

We wish to report the planned synthesis of a new heterocyclic system in which approximately parallel benzene rings joined by three bridges enclose a cavity.

Using a method that had been optimized for the metacyclophane series[2] and applying the dilution principle we treated 1,3,5-tris(bromoacetyl)benzene with 1,3,5-tris(mercaptomethyl)benzene and with sodium sulfide ($\times 9\,H_2O$) in *tert*-butanol as solvent. We obtained the crystalline [4.4.4]-(1,3,5)cyclophane *(1)* [m.p. >360 °C, dec.; from $(CH_3)_2SO$] and the [5.5.5](1,3,5)cyclophane *(2)*[3] [m.p. >360 °C, dark coloration; from $(CH_3)_2SO$], respectively, in reproducible yields of 10 and 0.16%.

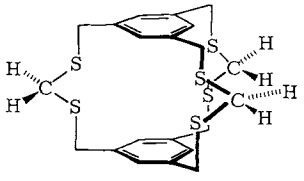
(1) *(2)*

The molecular weights of the two cyclophanes and the presence of three sulfur atoms were initially confirmed by mass spectrometry. Compound *(1)*, which was obtained



[*] Prof. Dr. F. Vögtle and Dipl.-Chem. R. G. Lichtenthaler
Institut für Organische Chemie der Universität
87 Würzburg, Landwehr (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



in larger quantities, gave a correct CHS elemental analysis. Determination of S in *(2)* was supplemented by a high-resolution mass spectrum.

The structures of *(1)* and *(2)* are proved by their ^{1}H-NMR spectra [$(CD_3)_2SO$]: *(1)* gives two singlets of equal intensity for the aromatic protons ($\tau = 2.0$ and 3.2 ppm) and, as expected, another two singlets of equal intensity for the methylene protons ($\tau = 6.0$ and 6.2 ppm). The proton resonance of *(2)* is made up of only two singlets at $\tau = 1.7$ (6 aromatic protons) and 6.0 ppm (12 CH_2 protons). Remarkably, the last-named peak is not shifted relative to the corresponding signal of an acyclic reference compound (diphenacyl sulfide).

These proton resonance findings are in agreement with model considerations which show that largely unhindered rotational movement is possible in the bridges of both compounds. However, only compound *(2)* can modify its cavity in a bellows-like manner by mutual approach of the two benzene rings without rotation about the threefold symmetry axis.

(3a)

(3b)

We attempted to shed some light on the question whether the conformation shown for *(2)* having three inwardly directed sulfur atoms is actually preferred in the [5.5.5]-(1,3,5)cyclophane system[4] by synthesis of 2,4,13,15,24,26-hexathia[5.5.5](1,3,5)cyclo-2-phane *(3)*. If the conformation *(3a)* were to predominate, as suggested by molecular models, an S—CH_2—S absorption would result at comparatively high field since the inwardly directed methylene protons would be exposed to the anisotropic effects of both benzene rings. In contrast, no significant shift of the signals relative to those of the open-chain reference compound bis(benzylthio)methane would be expected for the conformation *(3b)*.

We obtained compound *(3)* [almost colorless crystals, m.p. >380°C, dec.; from $(CH_3)_2SO$] in 10% yield on reaction of 1,3,5-tris(mercaptomethyl)benzene with methylene bromide in the molar ratio 2:3 according to the dilution principle in *tert*-butanol as solvent. The structure *(3)* given is based provisionally on the S analysis and the molecular weight as determined by mass spectrometry.

Here too the ^{1}H-NMR spectrum is highly informative: It contains [in $(CD_3)_2SO$] three singlets: $\tau = 3.2$ (6 aromatic protons), 6.5 (12 benzyl protons), 6.9 ppm (6 S—CH_2—S protons). A comparison with the analogous signals of bis-(benzylthio)methane [$\tau = 6.8$ (2 S—CH_2—S protons) and 6.4 ppm (4 benzyl protons), in $(CD_3)_2SO$] reveals no significant upfield shift. Synthesis of further representatives of this type of compound should establish whether the above finding is due to a low contribution of conformation *(3a)* to the time-averaged structure or whether the benzene rings are too far displaced from the inwardly directed protons owing to the large C—S bond length. The possibility of inserting metal atoms or ions into the cavities will also be studied.

Evidence for Conjugation through a Saturated Silicon Atom[1]

By *Ulrich Weidner* and *Armin Schweig*[*]

One of the focal points of organosilicon chemistry[2] is the question whether two π systems separated by a tetrahedrally coordinated Si atom are conjugatively coupled through this atom:

We have now succeeded in detecting this kind of conjugation ("through-conjugation"[2]) in the photoelectron (PE) spectrum of dimethyldivinylsilane *(1)*, $(CH_3)_2Si(CH{=}CH_2)_2$.

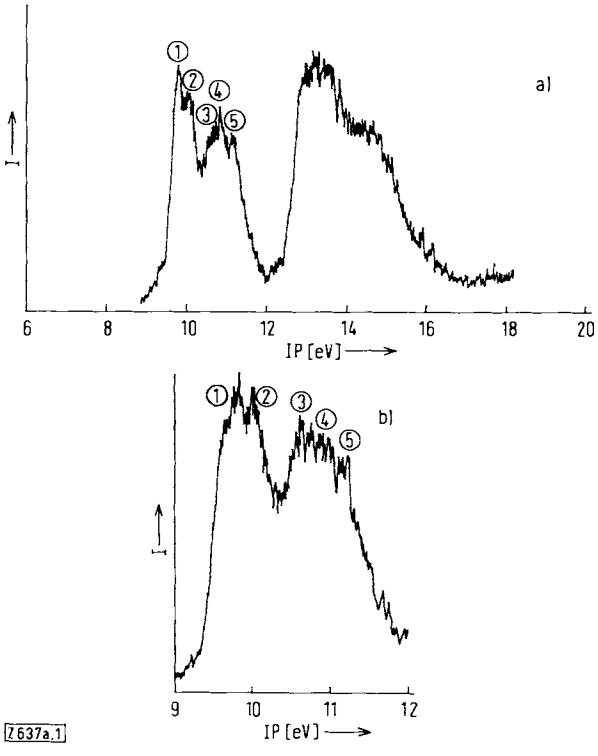

Fig. 1. Photoelectron spectrum (a) [7] of dimethyldivinylsilane *(1)*. The spectrum (b) shows the first two peaks on an expanded scale. The vertical ionization potentials (in eV), corrected relative [8] intensities, and the assignments (symmetries) of the bands ① to ⑤ are: ① 9.8/1.0/$\pi_1(b_1)$; ② 10.0/1.0/$\pi_2(a_2)$; ③ 10.6/1.0/$\sigma_1(b_2)$; ④ 11.0/0.9/$\sigma_2(a_1)$; ⑤ 11.2/1.0/$\pi_3(b_1)$.

[*] Dipl.-Chem. U. Weidner and Prof. Dr. A. Schweig
Physikalisch-chemisches Institut der Universität
355 Marburg, Biegenstrasse 12 (Germany)

Theoretically through-conjugation can arise by participation of a π-type Si bonding MO (Si—C hyperconjugation[3]) or the d_π AOs ($p_\pi d_\pi$ conjugation[2,4]) on the silicon atom in π conjugation. If *(1)* has C_{2v} symmetry then, provided that through-conjugation is a real phenomenon, three π MOs of different energy are to be expected: the $\pi_1(b_1)$ HOMO having a node in each Si—C bond, the next lower $\pi_2(a_2)$ MO having one node at Si, and finally the $\pi_3(b_1)$ MO without a node. π_1 corresponds to the antibonding π_1 MO and π_3 to the bonding π_2 MO in trimethylvinylsilane *(2)*[5]; the $\pi_2(a_2)$ MO in *(1)* is new and has no analog in *(2)*[5].

$\pi_2(a_2)$ is expected to lie a little lower than $\pi_1(b_1)$ since the above conjugation mechanisms of the saturated silicon atom should only exert a slight effect. Such arguments would predict that the first peak in the PE spectrum of *(1)* consist of two bands ① and ② in contrast to that of *(2)*[5]. The spectrum of *(1)* is reproduced in Figure 1. The intensity ratio of the first two peaks is 2:3[6] (the corresponding intensity ratio in the spectrum of *(2)* is 1:3[6]).

The expanded spectrum (Fig. 1 b) clearly shows the splitting of the first peak into two bands ① and ② separated by 0.2 eV. This finding demonstrates that a saturated Si atom between two π systems cannot be regarded as performing an isolating function.

Estimation of Spiro-Interaction (Spiroconjugation) in Tetravinylsilane[1]

By *Ulrich Weidner* and *Armin Schweig*[*]

The term "spiroconjugation"[2] denotes the interaction between two mutually perpendicular π systems separated by a tetrahedral atom. Such a system is present in tetravinylsilane *(1)*[3]. By comparison of the photoelectron (PE) spectra of *(1)* and dimethyldivinylsilane *(2)*[4] we have now been able to detect a spiro-interaction in *(1)* and to estimate its magnitude.

The PE spectrum[5] of *(1)* is reproduced in Figure 1 a, and the first two peaks of this spectrum are shown on an expanded scale in Fig. 1 b. The ratio of the corrected[6] intensities of the first two peaks is 4:3; the corresponding ratio for *(2)* is found to be 2:3[4]. These intensity ratios are readily understandable in the light of Figure 2 which demonstrates how the energy-level and MO diagrams of *(1)* can be derived from those of *(2)*[4]. The Si—C antibonding and bonding MOs $\pi_1(b_1)$ and $\pi_3(b_1)$ in *(2)* correspond to the degenerate MOs $\pi_1(e)$ and $\pi_4(e)$ in *(1)*. Instead of the antisymmetric and symmetric Si—C combination $\sigma_1(b_2)$ and $\sigma_2(a_1)$ in *(2)* the single Si—C MO $\sigma_1(b_2)$ is retained in *(1)*. The $\pi_2(a_2)$ MO unequivocally established in *(2)* splits into the spiroantibonding and spirobonding MOs $\pi_2(a_2)$

[*] Dipl.-Chem. U. Weidner and Prof. Dr. A. Schweig
Physikalisch-chemisches Institut der Universität
355 Marburg, Biegenstrasse 12 (Germany)

and $\pi_3(b_1)$ in *(1)*. Particular interest attaches to the magnitude of the splitting. We estimate a value of 0.2—0.3 eV for the spiro-splitting in *(1)* from the structure and width of the first peak in Figure 1b. To the best of our knowledge, this is the first spiro-splitting to be measured by PE spectroscopy and, in particular, the first detection of spiroconjugation both in a non-spiro compound and in an organosilicon compound.

The Photoelectron Spectra of Benzenoid Hydrocarbons $C_{18}H_{12}$ [1]

By *Franz Brogli* and *Edgar Heilbronner*[*]

While there has been an abundance of calculations of π-orbital energies, particularly those of fused benzenoid hydrocarbons, since the fundamental publications by *Erich Hückel* in the 1930's, experimental verification of the theoretical values obtained for large systems (more than 14 C atoms) has been lacking. The low vapor pressure of these compounds precludes measurement of their high-resolution photoelectron spectra with spectrometers of conventional construction. However, recent advances have now rendered even highly involatile compounds accessible to study by photoelectron spectroscopy.

[*] Dipl.-Chem. F. Brogli and Prof. Dr. E. Heilbronner
Physikalisch-Chemisches Institut der Universität
CH-4056 Basel, Klingelbergstrasse 80 (Switzerland)

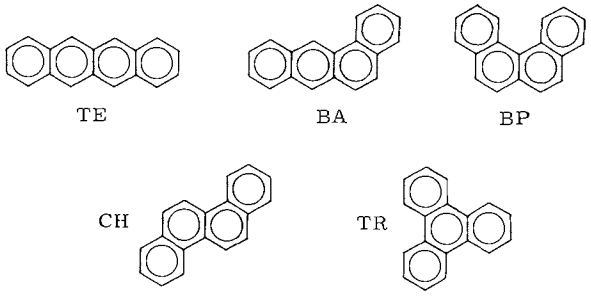
The preceding communication in this series[1] showed that for unsaturated benzenoid and nonbenzenoid hydrocarbons the π-orbital energies $\varepsilon_J(\pi) = -I_{v,J}$ calculated on the basis of Koopmans' theorem from the ionization potentials $I_{v,J}$ can be parametrized by a simple HMO model when first-order bond localization[2] is accounted for by a perturbation method[3]. The relevant regression function is

$$I'_{v,J} = -(\alpha + \beta x_J) + b \sum_{\mu\nu} (p^+_{\mu\nu,J} - p_{\mu\nu})(p_0 - p_{\mu\nu}) \qquad (1)$$

where

a) $\alpha + \beta x_J = \varepsilon_J^{HMO}$ is the orbital energy of the π orbital ψ_J in the usual Hückel approximation;

b) $p_{\mu\nu}$ is the bond order between the bonding centers μ,ν of the neutral hydrocarbon M;



c) $p^+_{\mu\nu,J} = p_{\mu\nu} - c_{J\mu}c_{J\nu}$ is the corresponding bond order in the radical cation $M^+(\psi_J^{-1})$, *i.e.* M^+ in the configuration in which ψ_J is only singly occupied;

d) $p_0 = 2/3$ is the standard bond order in benzene;

e) b is a factor dependent upon the force constants of the π and σ bonds and upon the derivative $d\beta/dR$ of the resonance integral β with respect to the length R of the π bond.

Summation is performed over all bonds.

An impressive test of the quality of the ionization potentials $I'_{v,J}$ calculated from equation (1) is provided by a photoelectron spectroscopic investigation of the five isomeric benzenoid hydrocarbons of molecular formula $C_{18}H_{12}$: tetracene (TE), 1,2-benzanthracene (BA), 3,4-benzophenanthrene (BP), chrysene (CH), and triphenylene (TR).

The PE spectra were recorded with a PS 16 spectrometer (Perkin-Elmer, Beaconsfield, England) whose specifications correspond to those given by *Turner*[4]. Table 1 lists the vertical π-ionization potentials $I_{v,J}$, their assignments to the corresponding π orbitals (cf. Ref. [5]) and the values

Table 1. Vertical ionization potentials of the five isomeric benzenoid hydrocarbons $C_{18}H_{12}$. $I_{v,J}(\pi)$ = measured vertical ionization potentials in eV; $I'_{v,J}$ = calculated according to (1) with $-\alpha = 5.782$ eV, $-\beta = 3.199$ eV, $b = 5.106$ eV. The designation of the orbitals ψ_J refers to the following symmetry groups: TE, D_{2h}; BA, C_s; BP, C_{2v}; CH, C_{2h}; TR, D_{3h} (cf. ref. [5]). Values in parentheses refer to shoulders and are therefore accurate to one decimal place only.

6	b_{1g}	10.25	10.31	a″	10.40	10.38	a_2	10.26	10.25	b_g	10.52	10.58			

$I'_{v,J}$ calculated from (1). The close correlation between $I_{v,J}$ and $I'_{v,J}$ may be seen from Figure 1.

The residual variance of the regression plotted in Figure 1 amounts to $V(I'_{v,J})=0.00483\ eV^2$ at $\phi = 22$ degrees of freedom. A corresponding value of $V(I^{HMO}_{v,J})=0.01128\ eV^2$ ($\phi=23$) is obtained for a simple HMO model which does not include bond localization (all $\beta_{\mu\nu}=\beta$). The variance

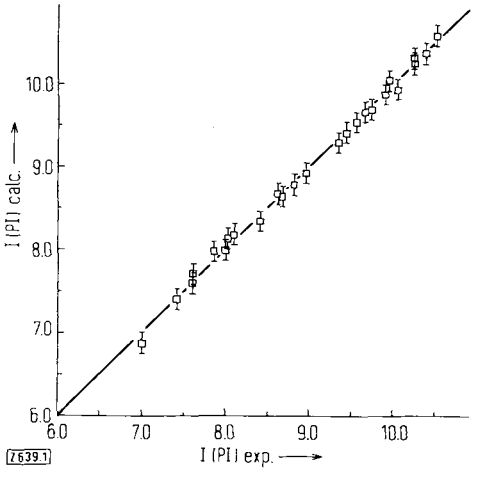

Fig. 1. Correlation between the vertical ionization potentials calculated from (1) ($I'_{v,J}\equiv I$(PI) calc.) and the experimental values ($I_{v,J}\equiv I$(PI) exp.). The confidence limits shown refer to 90% security.

ratio $F=0.01128/0.00483=2.36$ is greater than the critical value $F=2.03$ for 95% security, corresponding to degrees of freedom $\phi_1=23$ and $\phi_2=22$. This means that the regression (1) yields significantly better agreement with experiment than that based on orbital energies ε_j^{HMO} calculated from an unperturbed HMO model.

However, it should be borne in mind that the improvement of the correlation due to the perturbation term in (1), *i.e.* the significant reduction in residual variance, is smaller in the present case than for the smaller π systems studied in the preceding communication[1]. This was to be expected since the perturbation of the π-bond lengths due to removal of an electron will become smaller with increasing size of the π system.

The regression shown in Figure 1 supports the assumption that the first six bands (four bands for TR) in the PE spectra of the hydrocarbons $C_{18}H_{12}$ should be assigned to π orbitals. This assignment is also consistent with the band shapes and relative band intensities, as will be reported elsewhere.

Complex Shift Reagent for ^{13}C-NMR Studies on Carbohydrates

By *Wolfgang Voelter, Claus Bürvenich*, and *Eberhard Breitmaier*[*]

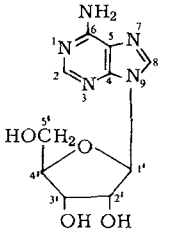
Application of the pulse Fourier transform technique has raised the sensitivity of NMR spectroscopy[1]. ^{13}C-NMR is consequently being employed increasingly for determination of configuration and conformation of carbohydrates[2] and nucleosides[3, 4].

The ^{13}C signals of carbohydrates are assigned by comparison of spectra of analogous compounds and on the basis of the following, experimentally well-substantiated rules[1–5]:

1. The resonances of deoxy carbon atoms appear at highest field.

2. The peaks of anomeric carbon atoms lie at lowest field.

3. A pyranose carbon atom having an axial hydroxyl group is generally more strongly shielded than a corresponding one with an equatorial hydroxyl group.



4. On changing a pyranose hydroxyl group from an equatorial to an axial position the signals of γ carbon atoms having an axial hydrogen atom on the same side of the ring are shifted upfield.

5. Replacement of a hydroxyl hydrogen by a methyl group shifts the signal of the ring carbon atom closest to the oxygen downfield by 6 to 12 ppm.

In the case of mutarotating sugars, recording the spectra before and after mutarotational equilibration has proved particularly valuable in signal assignment of anomeric pairs[4, 5].

A new means of investigating conformations and configurations of sugars or sugar residues has been found in comparison of the ^{13}C spectra of the sugar and its borate complex. (Circular dichroism of molybdenum and copper complexes can be employed for similar purposes[6, 7].)

The use of borate as a complex shift reagent will be demonstrated for adenosine and 2′-deoxyadenosine.

(1)

As with molybdate ion[6], complex formation with borate is pH dependent. In order to detect complex formation between borate and the sugar, the ^{13}C signals of adenosine *(1)* are recorded with and without borate at various pH values (cf. Figs. 1a and 1b).

The signals are assigned as in previous publications[3].

Figure 1a shows that the ^{13}C signals of C-1′ to C-5′ change by less than 0.5 ppm between pH 1 and pH 10. More pronounced shifts are observed for C-5 and for the signals of the remaining adenyl-C atoms at low pH. In

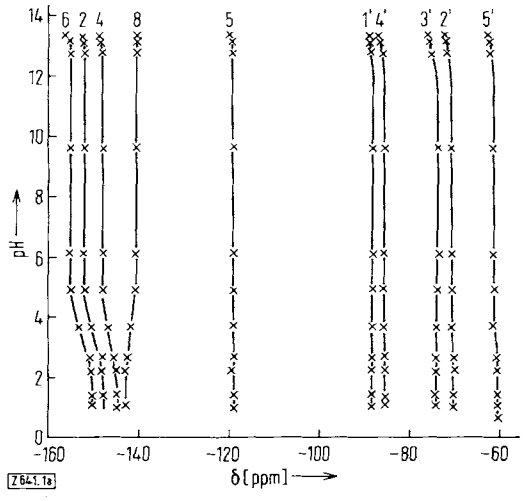

Fig. 1a. pH dependence of ^{13}C signals of adenosine solutions. The solution contained 30—270 mg of adenosine per 5 ml depending upon solubility.

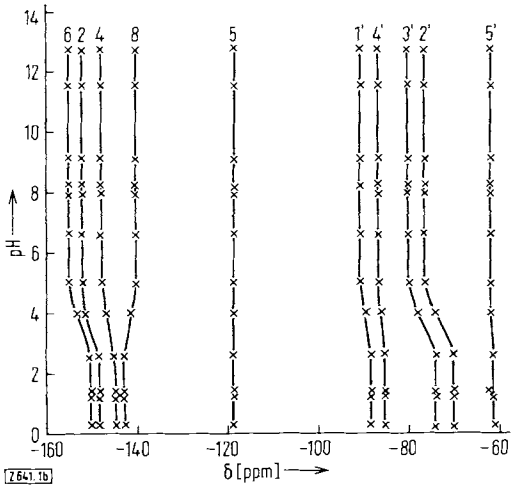

Fig. 1b. pH dependence of ^{13}C signals of adenosine-borate solutions. The solutions contained 30—270 mg of adenosine per 5 ml and 100 mg of boric acid.

6-substituted purines protonation occurs initially at N-1 (p*K* 2—4)[8]. Proton addition hardly affects the electron density on C-5; the resonances of C-2, C-4, and C-6 are shifted upfield and that of C-8 downfield (Figs. 1a and 1b). The upfield shift of the C-2 and C-6 signals on monoprotonation can be explained in terms of the rule found by *Pugmire* and *Grant*[9] for six-membered heterocyclics. The pH dependence of the ^{13}C resonances observed with pyrimidine does not apply to C-5 of the purine system.

Figure 1b represents the pH dependence of the ^{13}C signals of adenosine-borate solutions. The resonances of the adenyl-C atoms are almost identical with those in Figure 1a. The signals of C-2′ and C-3′, however, are shifted downfield by about 6 ppm in the presence of borate at pH > 6. Complex formation of neighboring *cis*-hydroxyl groups on C-2′ and C-3′ with borate can thus be unequivocally detected by ^{13}C-NMR spectroscopy. Whereas the signal of C-5′ is hardly affected by complex formation, the signals of C-1′ and C-4′ adjacent to C-2′ and C-3′ exhibit a slight but readily detectable downfield shift.

In the absence of a hydroxyl group on C-2′ the ribose residue can no longer form chelates with borate. The ^{13}C chemical shifts of 2′-deoxyadenosine solutions with and without borate are almost equal.

It may be seen from the above ^{13}C study that borate is particularly suitable as a complex shift reagent for the detection of neighboring *cis*-hydroxyl groups in carbohydrate chemistry. The requisite information is obtained without great experimental effort by measurement of sample solutions adjusted to pH 10, once with addition of borate and once without. Moreover, the method can be used for elucidation of hitherto debatable structures in this class of compounds[10].

The ^{1}H-broad band decoupled Fourier transform ^{13}C-NMR spectra were recorded with a Bruker HFX 90 multinuclear spectrometer. The (deoxy)-adenosine and (deoxy)-adenosine-borate solutions were adjusted to the desired pH values by addition of sodium hydroxide or hydrochloric acid of various molarities.

(1-Adamantyl)-α-peroxylactone: Synthesis, Kinetics, and Luminescence[**][1, 2]

By *Waldemar Adam* and *Hans-Christian Steinmetzer*[*]

Five years ago α-peroxylactones *(1)* were postulated for the first time as active precursors in the bioluminescence of the firefly[3] and of *Cypridina hilgendorfii*[3a]. This was confirmed in the latter case by ^{18}O labeling[4]. In the firefly[5] and in *Renilla*[6], however, an α-hydroperoxide *(2)* is responsible for bioluminescence. α-Peroxylactones are also suspected as luminescence-initiating species in the reaction of acridinium salts with H_2O_2[7] and of ketenes with singlet oxygen[8].

[**] Cyclic peroxides, Part 26.—Part 25: *W. Adam* and *L. Szendrey,* Tetrahedron Lett., in press. This work was supported by the National Science Foundation, the Petroleum Research Fund of the American Chemical Society, the Research Corporation, and the A. P. Sloan Foundation. *H.-Chr. St.* is indebted to the Deutsche Forschungsgemeinschaft for a traveling grant.

Our research team has recently succeeded in synthesizing the α-peroxylactone 4-*tert*-butyl-1,2-dioxetan-3-one *(1a)*, the chemiluminescence and decomposition kinetics of which were also recorded[1,2]. The instability of this first authentic α-peroxylactone at room temperature has hitherto prevented its isolation.

The present aim of our synthetic efforts is to substitute *(1)* in such a manner as to raise its stability or improve the possibilities for its isolation (increased volatility or ready crystallization).

We first attempted to obtain *(1b)* in a manner already described[1]. Unfortunately, compound *(5b)*, and even

a, R^1 = H, R^2 = *tert*-Butyl[1,2]
b, R^1 = R^2 = Phenyl
c, R^1 = H, R^2 = 1-Adamantyl
Me = CH_3

more so *(6b)*, decompose even at room temperature to give benzophenone *(7b)*, which would suggest a drastic reduction in stability on going from *(1a)* to *(1b)*.

In contrast, the synthesis of *(1c)* was completely devoid of problems. Compound *(4c)* (in analogy to those in ref. [9]) can be obtained in 92% yield as a colorless oil, b. p. 122 to 125 °C/0.01 torr. Its IR spectrum in CCl_4 exhibits characteristic bands at 1670 (C=C) and 1275, 1255 cm^{-1} (Si—O); the ^{1}H-NMR spectrum in CCl_4 is also in agreement with the structure: δ = 0.20 ($OSiMe_3$), 1.57—2.23 (aliph. H), and 3.27 ppm (olef. H).

The dye-sensitized photooxygenation of *(4c)* to *(5c)* proceeds with a not unexpected methylsilyl group migration similar to that found in the ene reaction[1,2]. An analogous shift in the photooxygenation of trimethylsilyl enol ethers[10] indicates a general reaction pattern. The reaction *(4c)* → *(5c)* can be followed by means of IR spectroscopy. The characteristic IR bands of *(5c)* lie at 1730, 1710 (C=O), and 1250 cm^{-1} (Si—O). The NMR spectrum of *(5c)* contains two signals for O—$SiMe_3$ at δ = 0.20 and 0.32, and a singlet at 3.87 ppm (C—H) alongside the almost unchanged multiplet of the adamantyl protons. Iodometric titration shows the oil to be 95 ± 1% pure.

Methanolysis of *(5c)* at *ca.* −20 °C gives a quantitative yield of the α-hydroperoxy acid *(6c)* [90% after recrystallization from cyclohexane, dec. point 114—115 °C, 97.8 ± 1% pure (iodometric titration). IR ($CHCl_3$): 3500—2400 (OOH and COOH) and 1715 cm^{-1} (C=O); NMR ([D_6]-acetone): δ = 1.50—2.40 (m/15H), 4.00 (s/1H), 9.25 ppm (s, broad/2H)]. *(6a)* and *(6c)* are the first authentic α-hydroxyperoxy acids[11]. Reduction of *(6c)* with H_2/Pd on active charcoal gives a quantitative yield of the α-hydroxy acid, m. p. 153—155 °C. The structure of the compound is confirmed by spectral data.

Ring closure of *(6c)* to *(1c)* proceeds best in CCl_4 at −20 °C with equimolar amounts of dicyclohexylcarbodiimide. The rapidly disappearing C=O absorption of the α-peroxylactone *(1c)* is seen at 1875 cm^{-1}. This instability of the highly water-sensitive compound has so far hindered its isolation in pure form. Apart from CO_2, adamantane-1-carbaldehyde *(7c)*[11] was identified as a decomposition product by its 2,4-dinitrophenylhydrazine adduct[11,12] (m. p. 224—225 °C, 218.1 °C[11], 225 °C[12]) and by a band at 1720 cm^{-1} (1720 cm^{-1}[11]).

The kinetics of decomposition of *(1c)* can readily be followed by observing the decay of the band at 1875 cm^{-1} when the sample is kept in a thermostated IR cell. Figure 1 shows the reaction to be of first order. The activation parameters resulting from the Eyring equation have the following values at 300 K [values for *(1a)* given in parentheses[2]]: $\Delta H^{\neq}$ = 13.7 ± 0.3 (18.8) kcal/mol, $\Delta S^{\neq}$ = −24.1 ± 1.0 (−8.9) e. u., and $\Delta G^{\neq}$ = 20.9 ± 0.5 (21.5) kcal/mol.

Since the decomposition kinetics of *(1c)* were followed in the reaction solution, the effect of external factors on the decomposition rate cannot be entirely ruled out in spite of strict first order behavior. It may, however, be regarded as probable that *(1c)* is less stable than *(1a)* owing to substituent effects that are still obscure. The large negative value of $\Delta S^{\neq}$ indicates not only a concerted, sterically very demanding rate-determining step but also that the adaman-

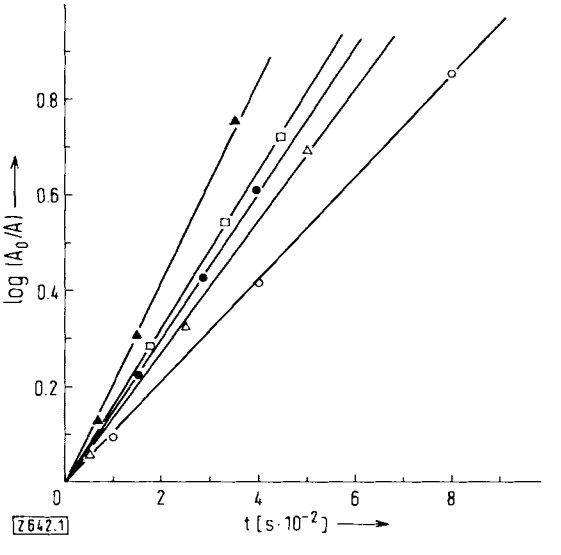

Fig. 1. First order kinetics of the thermal decomposition of α-peroxylactone *(1c)*. Decay of the 1875 cm^{-1} band at 295.1 K (-○-○-), at 301.7 K (-△-△-), and at 303.5 K (-□-□-). Decay of the emission band at 425 nm of *(1c)* (-●-●-) and decay of the emission band at 560 nm of *(1c)* and R (-▲-▲-).

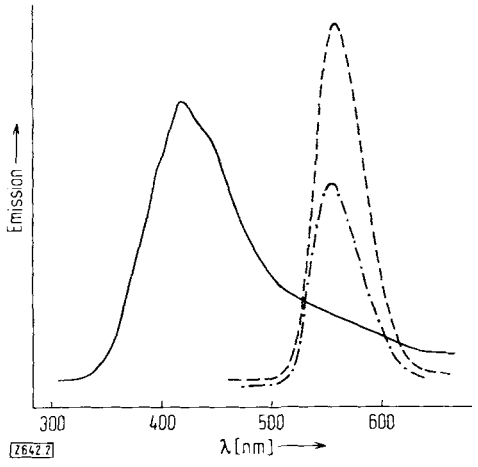

Fig. 2. Chemiluminescence of *(1c)* alone (——), chemiluminescence of *(1c)* and rubrene (– – –), fluorescence of rubrene alone (–·–·–).

tyl substituted molecule can only reach this stage in a state of increased order in comparison with its *tert*-butyl analog *(1a)*[2].

According to *McCapra*[13], α-peroxylactones should decarboxylate to the aldehyde or ketone with emission of light. Figure 2 reproduces the chemiluminescence spectrum of *(1c)* in CCl_4 with a maximum at 415 nm and a broad end emission up to about 650 nm. Excited di-*tert*-butyl ketone, which fluoresces at 405 nm[14], can serve as a model for *(1c)*.

The presence of a fluorescence acceptor like rubrene (R) enhances chemiluminescence by a factor of about 10^3, but only the fluorescence spectrum of R ($\lambda_{max} = 560$ nm) is seen, as is apparent from Figure 2. Since the chemiluminescence in the presence of R and the fluorescence spectrum of R are superimposable, energy transfer from electronically excited *(7c)* to R is established. The decrease in intensity of chemiluminescence also corresponds to a first order decomposition rate. Surprisingly, the presence of R causes a considerable increase in the K value for *(1c)* too [c.f. *(1a)*[2]] (Fig. 1). We cannot, as yet, offer an explanation for this observation.

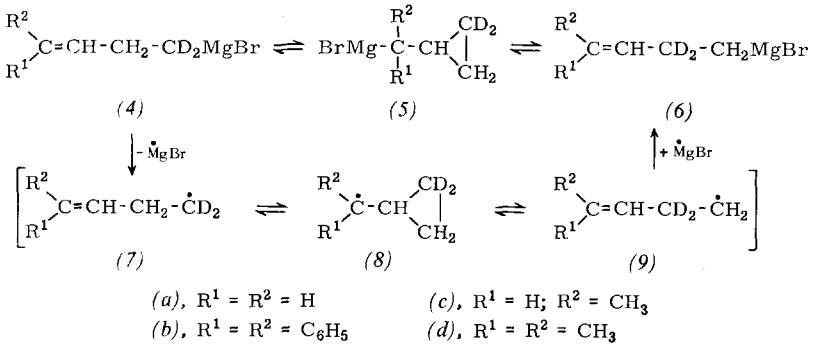
Rearrangement of 3-Butenyl Grignard Reagents: Anionic or Radical?[**]

By *Adalbert Maercker* and *Werner Streit*[*]

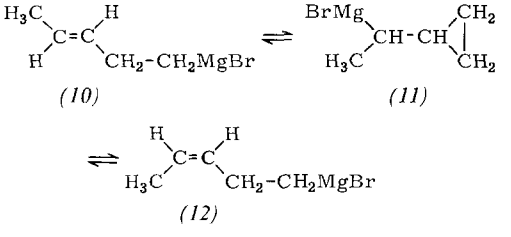
Dedicated to Professor G. Wittig on the occasion of his 75th birthday

The rearrangement of 3-butenide anions *(1)*, R = H, discovered by *Roberts* and his co-workers[1], during which the α- and β-carbon atoms exchange places *(1)* ⇌ *(3)*, has a special position among 1,2-shifts inasmuch as its mechanism may involve an intramolecular nucleophilic substitution according to an addition-elimination mechanism *(2a)*, whereas for the shift of saturated alkyl groups in accord with the *Woodward-Hoffmann* rules[2] only a cleavage-recombination mechanism can become operative. A decision between heterolysis according to an elimination-addition mechanism *(2c)* and homolysis to a radical pair *(2b)* with subsequent recombination within the solvent cage was achieved by the CIDNP method[3] in numerous cases in favor of the radical mechanism *(2b)*[4].



The starting point of our investigations was the question whether rearrangement of 3-butenide anions *(1)* occurs *via* an anionic cyclopropylmethanide intermediate[5] *(2a)* or whether homolytic processes are involved here too. An elimination-addition by way of *(2c)* was also conceivable. The strong retardation of isomerization[6] by methyl or phenyl groups in the γ-position to the carbanionic center *(1)*, R = CH_3 or C_6H_5, contraindicates a cleavage-recombination mechanism *via (2b)* or *(2c)*. On the other hand, acceleration of the rearrangement[7] by phenyl groups in the δ-position *(4b)* makes a cyclopropylmethanide intermediate *(5b)* probable. However, Grignard compounds contain mainly covalent carbon-metal bonds, so that homolysis by way of the radical intermediates *(7)* ⇌ *(8)* ⇌ *(9)* must also be taken into account inasmuch as the radical *(8b)* would also be stabilized.

After CIDNP experiments[3] with unsubstituted 3-butenylmagnesium bromide up to 120 °C had proved negative, we synthesized the compounds *(4c)* (*cis*:*trans* = 42:58) and *(4d)* in diethyl ether (1.1 and 1.3 mol/liter, respectively)



[*] Priv.-Doz. Dr. A. Maercker and Dipl.-Chem. W. Streit
Institut für Organische Chemie der Universität
852 Erlangen, Henkestrasse 42 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

(a), $R^1 = R^2 = H$ (c), $R^1 = H$; $R^2 = CH_3$
(b), $R^1 = R^2 = C_6H_5$ (d), $R^1 = R^2 = CH_3$

and studied the kinetics of the rearrangement *(4)*⇌*(6)* by NMR spectroscopy. While the unsubstituted compound *(4a)* had rearranged at room temperature with a half-reaction time of 30 h[1], the equilibrium *(4c)*⇌*(6c)* (*cis*:*trans* = 22:78) was established only after 775 hours at 100 °C. A still greater deceleration was brought about by introduction of a second methyl group in the δ-position: the Grignard compound *(4d)* was only 20% rearranged after 900 hours at 100 °C. This finding contraindicates a radical mechanism. Admittedly, according to recent views[8] the stability of *(8c)* and *(8d)* is not expected to be greater than that of *(8a)*, but the deceleration of the rearrangement cannot be brought into accord with formation of the radical intermediates *(7)*⇌*(8)*⇌*(9)*, but only with a carbanion mechanism[6] involving *(5)*.

(10) *(11)*

(12)

In order to determine whether the cyclopropylmethanide intermediate *(5)*, which cannot be detected in the equilibrium mixture, is a true intermediate or only a transition state, we studied the kinetics of the *cis-trans* isomerization

by gas-chromatographic determination of the carboxylation products as methyl esters. Independently of whether the starting material was *(10)* [98% + 2% of *(12)*] or *(12)* [60% + 40% of *(10)*], a reaction of the first order gave always the same *cis-trans*-mixture (21:79) ($K = k_1/k_2 = 0.266$) with $k_1 + k_2 = 14.5$ or $13.2 \times 10^{-3}\ h^{-1}$, respectively. Since this value is of the same order of magnitude as $k_1 + k_2$ for establishment of the equilibrium *(4c)*⇌*(6c)*, *(5)* and *(11)* are probably true intermediates in which the single bond between the carbanionic center and the cyclopropane ring has sufficient time for free rotation. The *cis-trans* isomerization *(10)*⇌*(12)* thus probably occurs by the same mechanism[6] as equilibration *(4)*⇌*(6)* of the α- and β-positions.

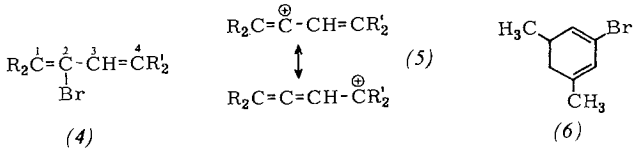
Formation and Detection of Vinyl Cations

By *C. A. Grob*[*]

Vinyl cations *(1)*, unknown and rejected a few years ago, are now the subject of an increasing number of investigations. In these cations the formal positive charge resides on the carbon atom of an olefinic double bond. With two—presumably linearly—attached ligands they belong to the group of disubstituted carbenium ions.



(1) *(2)* *(3)*

(a), R = Aryl
(b), R = Alkenyl
(c), R = Cyclopropyl

The objections which have frequently been raised against the existence of vinyl cations are justifiable inasmuch as simple vinyl halides *(2)* (X = halogen) resist hydrolysis and do not precipitate silver halide from aqueous silver nitrate as is observed with alkyl halides. However, an electron donating aryl substituent in the α-position, as in *(2a)*, can promote ionization under relatively mild conditions, as was first shown in 1964[1]. Thus α-halo styrenes *(2a)* react in aqueous alcohol to form ketones (*via* the enol), enol ethers, and acetylene derivatives by the S_N1—E1 mechanism. α-Alkenyl *(2b)*[2] and α-cyclopropyl substituents *(2c)*[3] likewise increase reactivity.

The reaction rates of α-aryl substituted vinyl bromides of the type *(2a)* depend on substituents in the benzene ring in a predictable manner. Since they are not influenced by the hydrogen ion concentration of the medium a mechanism involving acid-catalyzed hydration to the intermediate *(3)*[4] can be excluded.

(4) *(5)* *(6)*

It is noteworthy that the solvolysis rates of 2-bromodienes *(4)* are hardly influenced by the presence of one or two methyl groups on C-1 [*(4)*, R = CH_3]. However, two methyl groups on C-4 [*(4)*, R′ = CH_3] accelerate the reaction by more than five powers of ten, as expected on the basis of the electron distribution in the mesomeric vinyl cation *(5)*. However, charge delocalization can only occur if C-1, C-2, and C-3 have a linear arrangement, as required by the limiting allenic form. If this alignment is prevented, as in the cyclic bromodiene *(6)*, the negligible solvolytic reactivity characteristic of vinyl halides returns[5]. Vinyl cations have many features in common with ordinary carbenium ions, such as the tendency to isomerize[6] or to rearrange by way of ion pairs. Detailed mechanistic studies are in progress in several laboratories.

Energy Coupling and Electron Transport

By *Britton Chance*[*]

In recent years titrations of redox potentials of the redox components of respiration chains (flavoproteins, ubiquinones, cytochromes) have led to a new classification of the components of respiration chains. In this scheme four groups of redox systems are differentiated, within each of which the potential is approximately the same and fixed:

1. Flavoproteins and iron-sulfur proteins in the region −300 mV;

2. Flavoproteins, iron-sulfur proteins, ubiquinones and cytochrome b_K in the region 0 mV;

3. Cytochrome c_1, c and a, as well as copper- and iron-sulfur proteins in the region +240 mV; and

4. Oxygen in the region +840 mV.

Electrons are moved from one of these groups to another by means of electron transport components of alternating redox potential. They adjust their potentials to those of the acceptor or donor groups in the redox systems of fixed potential which function as redox buffers; the energy loss is minimal[1]. The transport systems are called energy transducer components. The nature of the transducer components of the first and second groups is unclear, but cytochrome b_T was recognized by redox potential titrations and kinetically as the transducer component between the second and the third group, and cytochrome a_{3T} spectrophotometrically as the linking compound between the third group and oxygen.

This classification has been supported by analysis of the kinetic models by computer simulation and by optimization of the kinetic constants for suitable mechanisms. In particular it was possible to differentiate cytochromes a and a_{3T} by measuring the kinetics of the reaction with oxygen at low temperatures (in presence of ethylene glycol down to −30 °C)[2]. In these experiments reaction of the respiratory system of intact mitochondria with oxygen was initiated by using a laser flash to decompose a preparation

saturated with carbon monoxide. It proved possible to measure directly the initial reaction of cytochrome a_3 with oxygen by the usual disappearance of absorption at 444 nm and, further, by hitherto unobserved disappearance of the absorption at 600 nm together with appearance of a small but significant absorption band at 428 nm[3]; in that work a new intermediate compound of oxygen and cytochrome a_3, formed extremely rapidly, was identified, whose spectral properties indicated the presence of an oxygenated cytochrome a_3-Fe^{2+} compound. Reaction kinetics at room temperature, redox titrations and computer analysis of the kinetics indicate that the reaction product of cytochrome a_3 and oxygen achieves a potential below that of cytochrome a prior to electron transfer between the two. By analogy with the behavior of hemoglobin it is probably to be expected that drastic changes in the conformation of hemin will occur on alteration of the redox potential of the components and of their spectral properties.

REVIEW ABSTRACTS

Formation of alkali metal complexes in solution is the subject of a review by *R. Winkler*. General characteristics of complex formation reactions are outlined in the introduction, and specific properties of alkali metal complexes are then described. Several techniques are mentioned for measuring rate and equilibrium constants for complexation reactions of alkali ions with the indicator and model ligand murexide in methanol. The article closes with a detailed discussion of the properties of biological substances with specific alkali ion carrier function, *e. g.* antibiotics with cyclopeptide, cyclodepsipeptide, or macrolide structure. [Kinetics and Mechanism of Alkali Ion Complex Formation in Solution. Structure and Bonding *10*, 1—24 (1972); 38 references]

[Rd 503 IE –H]

The bonding properties of inorganic pseudohalides with the triatomic groups azide, fulminate, cyanate, and thiocyanate are discussed by *Z. Iqbal*. Data about molecular and lattice geometries, vibrational and electronic spectra, lattice energies, and energies of formation are used for comparisons of these types of compounds. A special chapter is devoted to the exotic thermal behavior of azides and fulminates. [Intra- and Inter-Molecular Bonding and Structure of Inorganic Pseudohalides with Triatomic Groupings. Structure and Bonding *10*, 25—55 (1972); 86 references]

[Rd 504 IE –H]

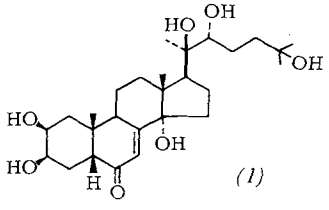
Current views of bonding in carbonylmetal compounds are treated by *P. S. Braterman*. The review provides a qualitative description of the metal-carbon bond in terms of molecular orbital theory and of bonding in polynuclear compounds without or with direct metal-metal interaction. In a second (smaller) section theoretical attempts at quantitative evaluation of energy states of carbonyls are discussed. [Spectra and Bonding in Metal Carbonyls, Part A: Bonding. Structure and Bonding *10*, 57—86 (1972); 110 references]

[Rd 505 IE –H]

The theory of the magnetic properties of polynuclear transition metal compounds is reviewed by *J. S. Griffith*. The treatment of anisotropic g tensor interaction leads to a closed expression for the susceptibility of binuclear compounds. For the treatment of three (or more) coupled magnetic moments the Racah and Wigner irreducible tensor method is used. Three-body interactions and the fine structure of degenerate ground states are also considered. As an example, the magnetic properties of proteins with two sulfur-bridged iron ions (spinach ferredoxin) are discussed. [On the General Theory of Magnetic Susceptibilities of Polynuclear Transition-metal Compounds. Systems with Two or Three Spins. Structure and Bonding *10*, 87 to 126 (1972); 93 references]

[Rd 506 IE –H]

The thermochemistry of the chemical bond is discussed by *V. Gutmann* and *U. Mayer*. Starting from a critical evaluation of *Pauling*'s concept of bond energy, electronegativity, and ionicity a new approach is suggested to describe the ionic character of a bond (valid only for that bond in a specified molecule) with the aid of thermochemical data. The new values of ionic character appear in some cases to be more reasonable than *Pauling*'s values, but they require a knowledge of the bond energies of the homoatomic molecules. A concept to circumvent this difficulty in the treatment of metal compounds is outlined. [Thermochemistry of the Chemical Bond. Structure and Bonding *10*, 127—151 (1972); 6 references]



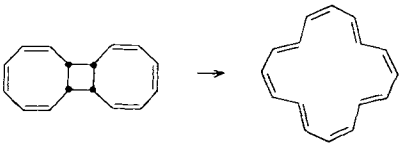
[Rd 507 IE –H]

Spectra and structural properties of complex tetracyanides of platinum, palladium, and nickel are reviewed in two papers by *S. Jerome-Lerutte* and *M. L. Moreau-Colin*. The former is concerned with the vibrational spectra of this group of compounds and with the force constants derived from them; the latter discusses their electronic spectra. A distinction is made between the spectra of "free" ions (in solutions) and the spectra of crystalline compounds. Finally, the luminescence of the tetracyanoplatinates is mentioned. [Vibrational Spectra and Structural Properties of Complex Tetracyanides of Platinum, Palladium, and Nickel. Structure and Bonding *10*, 153—166 (1972); 35 references.—Electronic Spectra and Structural Properties of Complex

Tetracyanides of Platinum, Palladium, and Nickel. *Ibid.* *10*, 167—190 (1972); 33 references]

[Rd 508 IE -H]

Arthropod molting hormones of plant origin are considered by *H. Hikino* and *T. Takemoto*. These phytoecdysones were isolated from *Achyranthes* and *Cyathula* species (Amaranthaceae, Centrospermae) where they are probably formed from cholesterol: β-ecdysone *(1)*; inokosterone; epiecdysterone; rubrosterone; amarasterone A and B; capitasterone; precyasterone; cyasterone; epicyasterone; isocyasterone; sengosterone; poststerone. 2β,3β-Dihydroxyl, 14α-hydroxy-7-en-6-one, and 20(*R*),22(*R*)-dihydroxyl partial structures are common to all these compounds. The article describes their isolation, chemistry, structure determination, synthesis and metabolism, physiological effects



(1)

of ecdysterols in higher animals, as well as physiological activity in arthropods (particularly insects). [Arthropod Moulting Hormones from Plants, Achyranthes, and Cyathula. Naturwissenschaften *59*, 91—98 (1972); 55 references]

[Rd 500 IE -M]

The annulenes form the subject of a review by *F. Sondheimer*. Particularly familiar members of this series are [6]annulene (benzene) and the nonaromatic [8]annulene (cyclooctatetraene). Recent years have seen the synthesis of additional, higher annulenes. Two general methods are available for their preparation: 1. oxidative coupling of a terminal diacetylene to a macrocyclic polyacetylene, conversion into a dehydroannulene, catalytic hydrogenation of

(1) *(2)*

the triple to double bonds; 2. photolytic ring opening of a polycyclic valence isomer, *e.g. (1)* → *(2)*. NMR spectroscopy proved indispensable in the study of the aromaticity (π-electron delocalization) of annulenes. Configurationally isomeric annulenes undergo ready interconversion. Several annulenes are susceptible to thermal and photochemical valence isomerization. Some substitution products are accessible from the parent system, others by independent synthesis. Annulene systems having an uneven number of C atoms are present in the completely conjugated monocyclic annulenones which may be aromatic [(4*n*+3)-membered ring] or nonaromatic [(4*n*+1)-membered ring]. Heteroannulenes are also accessible. Future progress of annulene chemistry will require simple and productive methods of synthesis, the extension of heteroannulene syntheses, and the synthesis of organometal-annulene complexes. [The Annulenes. Accounts Chem. Res. *5*, 81 to 91 (1972); 74 references]

[Rd 502 IE -M]

Transition states as acids and bases is the title of a review by *J. L. Kurz*. It can be shown that the pK_a value of an acidic activated complex ($pK_a(\ddagger)$) is derivable from observable reaction rates. The expressions are particularly simple for H^+ or OH^- catalysis. Far-reaching conclusions of a qualitative nature can be drawn from the $pK_a(\ddagger)$ values; a concept is also available for quantitative interpretation of the $pK_a(\ddagger)$ values. This is illustrated for a nucleophilic displacement reaction, *viz.* hydrolysis of methyl chloride, as example. [Transition States as Acids and Bases. Accounts Chem. Res. *5*, 1—9 (1972); 40 references]

[Rd 501 IE -M]

BOOK REVIEWS

The Chemistry of Nonaqueous Solvents. Vol. 3. Edited by *J. J. Lagowski*. Academic Press, New York–London 1970. 1 st edit., 408 pp., 28 tables, bound, 196 s.

In this third volume of the series[1] the authors *(D. F. Burow, M. Macclean Davis, F. Fehér, R. C. Paul, A. I. Popov,* and *S. S. Sandhu)* have provided considerable help in the development of preparative inorganic chemistry and have produced a handbook which shows the very latest state of the art.

The book deals with sulfur dioxide, hydrogen sulfide, some acyl halides, acetic acid, and other carboxylic acids in their capacity as solvents. One section, on the behavior of Brønstedt acids and bases in "inert" organic solvents *(Marion Macclean Davis)*, should provide valuable information to workers in a very wide range of fields, for example through the interesting survey of solvent mixtures and the good summary of hydrogen bonding.

In most cases the literature references are arranged in the text in such a way that one can rapidly gain access to the reference in question. It is up to the user to make his own evaluation of the numerous references given, and we should not hold it against the authors if occasionally they have paid more attention to complete coverage than to critical selection.

From the viewpoint of the pragmatic user, the contributions of *Feher* (H_2S) and the two chapters by *Popov* (acetic acid and other carboxylic acids) merit special attention. The methodological hints given in these chapters are in many cases also useful when working with other nonaqueous solvents.

H. D. Hardt [NB 21 IE]

[1] Cf. Angew. Chem. internat. Edit. 7, 557, 962 (1968).

Lehrbuch der analytischen und präparativen anorganischen Chemie (Textbook of Analytical and Preparative Inorganic Chemistry). By *G. Jander* and *E. Blasius*. S. Hirzel Verlag, Stuttgart 1970. 9th edit., xxv, 497 pp., 68 figs., 6 tables, bound, DM 28.—.

Recent editions of this book have shown a tendency toward the introduction of new theoretical chapters or the updating and extension of existing ones; this tendency is continued in the present edition. It is thus not surprising that the chapters on "The law of mass action and ionic theory" and on "The chemistry of complexes" have been reformulated and amplified.

However, the continual increase in the theoretical chapters is making it more and more difficult for the beginner to use the work as a textbook at the start of his studies, for too many topics are treated too briefly and with insufficient clarity. One might be forgiven for wondering whether students in their first year would, for example, gain much by working through the chapter on "Chemical bonding", especially since there is no obvious relationship to qualitative analysis. Again, it would require considerable effort to understand the concept of Lewis acids and bases (to which only a single sentence is devoted) or the completely isolated treatment of the Grimm hydride shift.

The analytical section is very good and comprehensive, and the separation procedures are well thought out and reproducible; however, it is so complicated that one cannot see the picture as a whole, and thus it is unsuitable as teaching material for chemistry students. It would only be required in this form in establishments where the topic of inorganic chemistry is represented solely by qualitative analysis. On the other hand, the preparative section is dealt with in far too brief and classical a manner; for example, not a single synthesis of a π-complex is given. This is regrettable, since preparative work is also a way in which information on compounds can be conveyed.

For these reasons, this imposing-looking work can only by recommended with reservations to chemistry students. The authors have written another book, "Einführung in das anorganisch-chemische Praktikum (Introduction to Practical Inorganic Chemistry)"; this book contains sufficient qualitative and quantitative analytical chemistry to provide the analytical training required for a chemist, and it is to be preferred to the book under review.

Alois Haas [NB 23 IE]

Physical Principles and Techniques of Protein Chemistry, Part B. From the series Molecular Biology. An International Series of Monographs and Textbooks. Edited by *S. J. Leach*. Academic Press, New York–London 1970. 1st edit., xiv, 491 pp., numerous figures, $ 11.20.

This volume[1] is a collection of further applications of physical methods in protein chemistry. It consists of the following chapters: 10. Ultracentrifugal analysis *(J. H. Coates)*; 11. Viscosity *(J. H. Bradbury)*; 12. Optical diffraction *(S. N. Timasheff* and *R. Townend)*; 14. Nuclear magnetic resonance spectroscopy *(J. C. Metcalfe)*; 15. Bonding of protons and other ions *(F. R. N. Gurd)*; 16. Differential thermal analysis *(H. Morita)*.

In most cases the authors place great weight on instructive hints. The reader is familiarized with the theoretical fundamentals of the method, and this is done both for methods which are not much used in protein chemistry (Chapters 14 and 16) and also for the well known methods (Chapter 10). Almost all the chapters are oriented toward practical applications. There are only a few errors to mar the high level of achievement; the most serious of these is the incorrect definition of the scale of chemical shifts. In some places an insufficiently clear distinction is made between "frequency" and "wave number". Selection of the methods and the arrangement of the chapters have already been discussed in the review of Part A[1].

It is to be hoped that the projected Part C will soon appear and complete this very useful survey. If it is still possible, I would recommend the inclusion of an informative chapter on electron spin resonance and spin labelling.

Karel Bláha [NB 24 IE]

[1] Cf. Angew. Chem. internat. Edit. *83*, 362 (1971).

The Chemistry of Synthetic Dyes. Volume III. Edited by *K. Venkataraman*. Academic Press, New York–London 1970. 1st Edit., xix, 485 pp., numerous illustrations and tables, bound, $ 27.50.

The first supplementary volume to the standard work on dye chemistry (Volumes I and II of *Venkataraman*'s "The Chemistry of Organic Dyes") has just been issued, recording the advances made in certain sectors over the past 20 years.

The decisive factor in the carefully balanced presentation of many of the chapters is certainly that the authors are all experts in their fields and work in large industrial research laboratories. Only in this way could the descriptive matter be so permeated with the knowledge and practical experience and the main lines of advance be traced out with the maximum of accuracy and clarity while working from a literature source often consisting of innumerable patents which are difficult to assess. As in the earlier volumes, the extremely high number of literature references ensures the practical usefulness of this book. In accordance with recent developments, the theoretical fundamentals receive a wider coverage than before, *e.g.* in the section on "Color and electronic state" by *Mason*, which will also be readily understood by the chemist. In almost all cases, care is taken to ensure a smooth transition (or occasionally an amplification) from the formerly used dyestuffs chemistry presented in the earlier volumes.

The volumes of this work correspond in content and price to a volume of *Houben-Weyl*, and wherever the latter work is found the former should also be present. The concept of the new volumes and the stimulus which the field of dyestuffs gives—or is capable of giving—to a large number of related fields raise this work to the same level. No dyestuffs chemist working in industry and research can manage without this book, and anyone who by his profession is predominantly concerned with the use of dyes will get useful information from relevant sections of the book.

Peter Dimroth [NB 35 IE]

Analytical Flame Spectroscopy—Selected Topics. Edited by *R. Mavrodineanu*. Macmillan and Co. Ltd., London–Basingstoke 1970, 1st Edit., xxii, 772 pp., numerous illustrations and tables, bound, £ 14.00.

According to the editor's foreword, this book, the result of a collaboration between 19 authors, is intended to present a consistent account of analytical flame spectroscopy, *i.e.* atomic emission, atomic absorption, and atomic fluorescence spectroscopy. Such a book, which covers the

whole complex field of flame spectroscopy and where possible enables comparisons to be made between the individual techniques, is indeed very welcome, because for years atomic absorption and atomic emission spectroscopy have been regarded as competitive rather than complementary techniques. A book of this kind should have been written a long time ago.

The monograph begins with an introduction to emission flame photometry, in which *C. Th. J. Alkemade* guides the reader in admirably clear form "from sample to signal".

In the following contribution on "Sensitivity, detection limit, precision, and accuracy in flame emission and atomic absorption spectrometry", the authors are unable to decide whether good limits of detection should be described as "high" or "low". In addition, the uncritical mention of such delicate matters as the multiple passes of the beam through the flame means that the statements on optimization of instrument components offer no genuine information to the analyst.

The next two sections are concerned with the optics and electronics of spectrophotometers. The first contribution certainly gives detailed descriptions of lenses, mirrors, prisms, and gratings, but does not go into the specific requirements of atomic absorption and fluorescence. In the second contribution the analyst who is interested in electronics will find a readily understandable explanation of various analog and digital circuits.

The fifth chapter is titled "Nonmetals" and provides a wealth of material. However, with its almost 200 pages and over 600 literature references, this "book within a book" almost bursts the boundaries of the present monograph, and the reader cannot escape the impression that a certain amount of tightening up would have increased the information content.

Next comes a brief, clear exposition of the relative advantages of atomic emission and absorption spectrometry for the determination of the rare earth elements in the fuel-rich oxyacetylene flame. This section is made particularly valuable for the analyst by the appendix giving emission spectra for this group of elements.

In contrast, "Spectroscopic investigations of low-pressure oxyacetylene flames" is a purely theoretical paper, and as such will arouse little interest in the analyst.

The eighth chapter is a report on the application of flame photometry to agricultural chemistry, with mention of rocks and soils, plants, water, and fertilizers. It is very regrettable that this section deals exclusively with emission analysis, since agricultural chemistry is one of the classical fields of application for atomic absorption spectroscopy.

The same is true of the next section, which is concerned with "Applications of flame photometry in biology and medicine". In this case, however, it is apparent that the author *(R. Herrmann)* is in no way to blame for this limitation, for he writes in his introduction "Since the application of atomic absorption and atomic fluorescence methods in biology and medicine will be described in a separate chapter . . .". The reader will look for this chapter in vain. This contribution begins with a pleasingly objective comparison between flame emission and atomic absorption spectroscopy, which I should have been only too happy to see continued in the practical section.

This series of contributions on the applications of the techniques is concluded by two introductions, to "Atomic absorption spectrometry" *(J. B. Willis)* and "Atomic fluorescence flame spectrometry" *(J. D. Winefordner* and *R. Smith)*. The qualifications of the authors are reflected in these two clear, brief, and readily understandable articles, which considerably raise the level of the entire work.

The topic of atomic absorption spectroscopy is rounded off with an article on the theory, manufacture, and applications of hollow cathode lamps, which gives many interesting details on these element-specific light sources.

The work ends with a "Bibliography on flame spectroscopy" prepared by the editor for the years 1966 and 1967 with over 2000 references, about two-thirds of which relate to flame emission spectroscopy, while atomic fluorescence spectroscopy is not mentioned.

The make-up of this bibliography is symbolic for the problems of the entire work, both in its over-emphasis of emission flame photometry in comparison with atomic absorption spectroscopy (this is not dictated by the subject matter) and its out of date nature. The book essentially deals with the position as it was in 1966: the only contribution that has any supplementary material is the one on atomic absorption spectrometry, and this supplement begins with the words "During the period of more than 18 months that has elapsed since writing this chapter...". The supplement includes the essential new work in this field up to and including 1968; this could have been repeated with advantage for some of the other contributions.

On the whole, however, this book (at least in certain chapters) provides a welcome supplement to other works and gives many useful details.

Bernhard Welz [NB 36 IE]

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry). Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. 8th fully revised edition.

System No. 47. Lead, Part C, 4. Conclusion of compounds. Coordination compounds. Ligand index. Subject index for Part C. Principal editor: *Hubert Bitterer*. 1971. vi, xix, 639 pp., 235 figures, Balacron DM 756.—.

Following remarkably quickly on the earlier volumes of Part C of System No. 47 "Lead"[1], the present 4th volume concludes the description of lead compounds. It begins with compounds of lead and zinc (System No. 32), and then, in accordance with the Gmelin arrangement, describes compounds with the elements up to System No. 46, *i.e.* tin. The coordination compounds of lead are then discussed. The organic ligands are arranged in a formula index based on Hill's system (according to the number of C atoms, then of H atoms, and finally of the other elements in alphabetic order).

The volume closes with a comprehensive subject index (91 pages) listing all the compounds, groups of compounds, alloys, and facts from Volumes C1 to C4. The literature is evaluated up to, and in some cases beyond, 1969.

The present volume is primarily of interest to metallographers, metallurgists, and metal physicists, since large parts are concerned with alloy systems. The superconducting lead-thallium and lead-indium alloys have been particularly intensively studied. Corresponding to the importance

(theoretical as well as industrial) of lead-tin alloys, 32 pages are devoted to this subject and a further 67 pages to lead-tin alloys that also contain other components and are used *e. g.* as bearing metals, solders, type metals, cable sheaths, metal baths, *etc.* Among the oxide systems containing lead, glasses are particularly important; the technical significance of these glasses has been known for a long time, but like glasses in general, they are gaining in scientific importance.

The last chapter deals with the coordination compounds of lead with neutral and inner complex forming ligands, with the exception of organo-lead compounds. Though the arrangement of this material naturally presents great difficulties, an arrangement that is simple from the chemical point of view has been found. The many structural formulas in this part of the volume are particularly commendable, as they provide the chemist with a general picture at a glance. Together with the alphabetically listed ligands or classes of ligands in the subject index and a formula index for organic ligands they enable the desired information to be found quickly.

Ekkehard Fluck [NB 31 IE]

[1] Cf. Angew. Chem. internat. Edit. 9, 913 (1970).

Physical Surfaces. Volume 20 in the "Physical Chemistry" series. By *J. J. Bikerman*. Academic Press, New York–London 1970. 1st Edit., ix, 476 pp., numerous illustrations, bound, $ 25.00.

J. J. Bikerman's "Surface Chemistry", published in 1958, will already have brought his name to the attention of many of those interested in surface physics and chemistry. As its title implies, this new book is intended primarily as a discussion of the basic physical aspects of surfaces rather than matters of chemistry and application. A restriction of this kind is essential to a book which, in a single volume, aims to cover such diverse topics as the mechanics and physical chemistry of liquid surfaces, liquid-liquid interfaces, foams and emulsions, solid surfaces, wetting, adsorption, electric surface phenomena, and adhesion.

The author familiarizes the reader with the many phenomena that can be observed on surfaces and interfaces, deals with the experimental results obtained, and describes approaches to their theoretical interpretation. The subject is dealt with in a comprehensive manner, old established facts appear side by side with information on the most recent discoveries, the references (about 800) cover a period ranging from the first half of the last century to the closing years of the 1960's. Thus, the work should be regarded more as a textbook than a report on recent progress.

The book should be of particular value to any teacher or student looking for a sound review of the physical chemistry of surfaces and interfaces.

Gerd Wedler [NB 37 IE]

Introduction to Molecular Biology. By *S. E. Bresler*. Academic Press, New York–London 1971. 1st Edit., xv, 556 pp., numerous illustrations, bound, $ 17.50.

The revolution in physics in the form of atomic physics was followed in the forties by a revolution in biology in the form of atomic biology. One need hardly be an expert to see that within the space of one short human lifetime biology has changed from a descriptive science to one based on a theoretical foundation. The development of molecular biology is due not only to the invasion of the biologists' Elysian fields by theoretical physicists but also to the application of new physico-chemical techniques to characterize megamolecular structures. Under the stimulus of such techniques and by means of the skill involved, molecular biology has gained a key position in modern thought and research, and thus a textbook-style introduction to this field is highly desirable. One therefore approaches this book with eager expectation, especially as the book is distinguished by two other facts. In the first place, the author is a physical chemist who has worked in the field of high polymers, and he cannot help but give a practical cast to his account of the application of mathematical and physical methods to the structure and function of biopolymers. Secondly, the book comes from the USSR, and although the Russians have a considerable need to catch up in molecular biology, their education gives them a thorough mathematical background. The work should therefore be elementary but not superficial. Both these expectations are indeed partly fulfilled, though we are left with the feeling that molecular biology is still a very heterogeneous field; wide areas of collected descriptive matter are followed by brief stretches of laws capable of physico-chemical interpretation. Only in rare cases can a biological process be derived theoretically and mathematically, or even predicted.

The book is fairly obviously derived from a lecture manuscript, which appeared in the USSR in 1963 and 1966 and to which some supplementary material was added for the purposes of the translation to bring it up to 1969. This may explain the extreme care with which the reader is artificially led from one topic to another, and the introduction, without derivation, of various complicated concepts. Thus, in order to explain the mechanisms of enzyme action, the theory of absolute reaction rates is abruptly introduced in *deus ex machina* fashion, and similarly statistical thermodynamics are used to clarify the concept of allostery. But these are just words, which will leave the biology student (for whom the book is primarily intended) unsatisfied and disappointed. Interesting concepts are, however, opened up for the chemist.

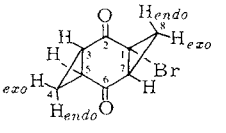
On closer inspection, the book has much to offer to advanced students of both biology and chemistry. The clear layout embraces the structure of proteins and nucleic acids, with particular emphasis on the methods of investigation and the problems of transition between states of ordering. The functions of proteins, deoxyribonucleic acids, and ribonucleic acids are made comprehensible, and fundamental research results are described in detail. It is true that in every chapter one may search in vain for many recent results and hypotheses, and it would have been helpful to have omitted the standard presentation of basic chemical facts in favor of a carefully thought out discussion of the innermost secrets of the molecular world. But if many sections of the book are disappointing, they are balanced by chapters that come closest to the author's experience and interests. These are the physico-chemical relationships in the behavior of biopolymers, which scarcely get a mention in other textbooks. These sections (and they are the better half of the book) may be strongly recommended to students capable of further advance, provided they have sufficient background in physics to understand them; they may also be recommended to biochemists and biophysicists who wish to be better informed on the modes of thinking and methods of operation of their colleagues.

L. Jaenicke [NB 38 IE]

Die biologische Zukunft des Menschen (The Biological Future of Mankind). Umschau-Verlag, Frankfurt 1971. 1st Edit., 131 pp., DM 13.80.

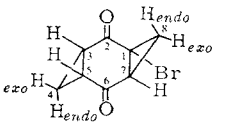
This book with its very imposing title is the German translation of eight articles which appeared a year ago in the UNESCO journal "Impact of Science on Society". The topics are as follows: Sex, drugs, ethics; Modifications to the reproductive process; Genetic engineering: can we change the hereditary material?; Problems and prospects of organ transplantations; Extension of active life; Knowledge by injection; Biotechnology: the body as machine; Robots, an extension of the human arm.

The contributions are of very variable quality. The only articles which are really worth reading in the light of the book's title are the ones on modifications to the reproductive process, genetic engineering, and organ transplants. They are clearly written and present the reader with problems that have a solid basis in the present. They may well be of importance for the biological future of mankind (although mankind has hardly learned how to master its biological present); indeed, some of them definitely will be of importance. The other contributions are, in comparison, on a considerably lower plane with regard to clarity or contents. This is a pity, since on all the topics collected here, and a few others besides, there are important things to be said, even when we realize (and this is yet another distinguishing mark of the good contributions in this book) that the word "future" in such compilations is just a synonym for "present". This present requires extremely careful and imaginative attention, and it requires it in good time. The true problems of the biological future of mankind lie in the fact that every new development seems to have the nature of a boomerang; to our eyes it appears as moving in a straight line, and we do not notice its return—we tend to recognize the wood for the trees only when a forest fire is well on its way.



Helmut Grünewald [NB 40 IE]

Errata



In the communication "Synthesis and X-Ray Structure Analysis of *anti*-1-Bromotricyclo[5.1.0.0^{3,5}]octane-2,6-dione (*anti*-1-Bromobishomoquinone)" by *Jürg Heller, André S. Dreiding, Rita Grieb*, and *Alfred Niggli*, Volume 11, March 1972, the following corrections should be made:

On page 236, right-hand column, lines 17 and 18 "*anti*-8,8-dibromo-1,4,4-trimethyltrichloro[5.1.0.0^{3,5}]octane" should read "*anti*-8,8-dibromo-1,4,4-trimethyltricyclo[5.1.0.0^{3,5}]-octane".

On page 236, right-hand column, the formula at the bottom of the column should not be

but

On page 238, left-hand column, line 15 "J. Chem. Soc." should read "J. Amer. Chem. Soc."

Structural Principles of Biomembranes[**]

By Werner Kreutz[*]

Dedicated to Professor O. Kratky on the occasion of his 70th birthday

The determination of the electron density distribution of the membrane cross sections of nerve myelin and the discs of the outer segments of retinal rods by a new X-ray evaluation method indicates, as in the case of the cross-sectional structure of the photosynthetic membrane, an "asymmetric" mass distribution. In connection with the detection of planar protein lattices in the membranes of photosynthetic bacteria, the chloroplasts of higher plants, erythrocytes, and retinal discs as well as the detection of a new category of lipid characteristics, comprising isothermal conformational and phase changes by specific ligand binding, a basis is established for the development of a general concept of biomembrane structure.

1. Introduction

The phenomenological capabilities of biomembranes comprise an impressive range of functions, such as nerve excitation, sensory transduction, gland functions, energy transformation (photosynthesis and respiration), osmotic regulation, *etc.* This quite apart from the fact that, as purely morphological elements, they are responsible for the compartmentation of "internal milieus" and thus create one of the essential prerequisites for life *per se*. For membranologists this fascinating complexity of biomembranes represents a great challenge, namely that of understanding this functional variety on the molecular level. It is this aspect as manifested in the dynamic molecular architecture, in the molecular characteristics, and in molecular interactions with which this progress report is concerned.

The following four questions outline the essential problems which confront us on the molecular level:

1. What is the steric state (conformation) of the proteins and what is their planar arrangement within the membrane? Are there variable protein states?

2. What is the conformation of the lipids and what is their planar distribution? Do variable lipid conformations exist?

3. What interactions occur between proteins and lipids? What is their steric relationship (coupling)?

4. What possibilities of structural variation and what physicochemical capabilities associated therewith are encountered in the molecular membrane architecture as a whole for the accomplishment of the various functions such as *e.g.*: ensuring a specific permeability, regulation of permeability changes, passive-, facilitated-, and active transport mechanisms and their control, generation of concentration gradients or potentials, regulation of potential changes (*e.g.* light-induced or

DGD = digalactosyl diglyceride
MGD = monogalactosyl diglyceride
PA = phosphatidic acid
PC = phosphatidylcholine
PE = phosphatidylethanolamine
PG = phosphatidylglycerol
PI = phosphatidylinositol
PS = phosphatidylserine

chemically induced changes), transmission of excitation, potential-linked chemical syntheses (phosphorylation), redox reactions, and probably also information storing capacities.

Our knowledge gained hitherto indicates that the extensive variability of membrane functions derives from a flexible "basis-membrane" whose versatile structural adaptability permits the association of various special functional proteins on both sides of the membrane and thus makes vectorial processes feasible in both directions. It therefore appears reasonable to distinguish between a "basis membrane" and a "function membrane". With this in mind, it will be our initial endeavor to develop a general concept of the basis-membrane structure. If we are to proceed in this manner, then the stereochemical and physicochemical characteristics of the basis-membrane proteins and of the lipids will have to be discussed as a first step. An exposition of the qualities of the two groups of substances will provide the pre-conditions essential for an examination of the possibilities of coupling, *i. e.* the joining of these substances to form a membrane. The second part of the paper pursues the conversion of the basis membrane into the function membrane and an attempt is made to explain some functional capabilities on the basis of this structural concept.

2. The "Basis Membrane"

2.1. The Intrinsic Dynamics of Lipids

Hitherto, in the assessment of membrane phenomenology functional predominance has been attributed to the proteins. The reason for this lies in the fact that the lipid characteristics so far established did not allow an appreciable functional variance. In this respect it will be necessary in future to make a fundamental adjustment.

The physico-chemical data available today are essentially the result of observations of *p,T*-phase transitions between laminar cubic and hexagonal lattices[1-3], of measurements of surface potentials, of surface pressure or surface tension[4, 5], as well as surface requirement of monomolecular lipid layers on an aqueous phase (summary: [6]). To these must be added the determination of permeability data and electrical qualities of bimolecular lipid layers[7-10] and also ESR-[11] and NMR measurements[12] with lipids. Furthermore, it has commonly been accepted that phospho- and galacto-lipid molecules occur in only one conformational state, *i. e.* the one shown in Figure 1 a. (There is only one exception: the lipid conformational state postulated by *Finean*[13] in his model of myelin-membrane structure.)

It is as the result of the following qualities that the lipids acquire actual functions:

1. In principle lipids are able to exist in two different conformational states[14] (Figs. 1 a and 1 b).

2. These conformational states can be transformed from one into the other by ligand binding. In other words, lipids can undergo chemically induced conformational changes[15].

3. Lipids can undergo phase transitions induced by ligand binding[15].

4. The miscibility of lipids with each other is highly selective[14, 15].

In view of these qualities one is led to speak of an intrinsic lipid dynamic behavior. In considering these intrinsic dynamics we must also allow for transverse and lateral lipid movements in lipid layers[16] as well as for cation-induced lipid-organization changes[17].

2.1.1. Conformational States and Micelle Types

The steric characteristics and the miscibility behavior of lipids can be examined by using low angle X-ray diffraction methods. Different conformational states and micelle types produce very distinct X-ray diffraction patterns. Further information can be obtained by quantitative titrations of the polar groups[18] in different conformational states, by ESR spin labeling[11], NMR measurements[12], enzymatic fragmentation, and measurements of calorimetric and kinetic data of conformational changes[2].

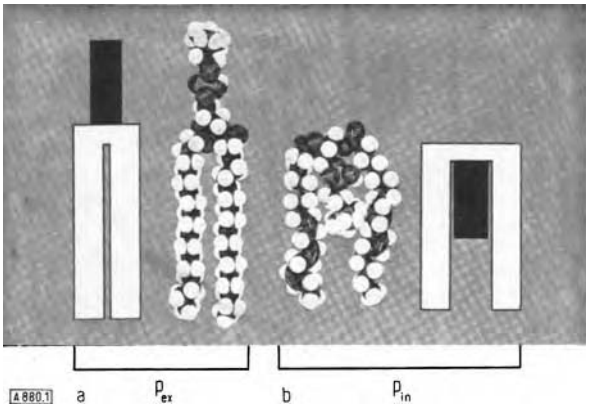

Fig. 1. a) p_{ex}-conformational state of lipids represented by a Stuart-Briegleb model and by the corresponding symbol used further on in this paper, b) representation of the p_{in}-conformational state.

The essential difference between the two conformational states of the lipids can most probably be ascribed to the fact that in the one case the polar group is located outside, and in the other it is incorporated in the fatty acid domains (Figs. 1 a and 1 b). In the following, the conformations shown in Fig. 1 will be referred to as the p_{ex}-conformation (polar group external conformation) and the p_{in}-conformation (polar group internal conformation). These two conformational states permit the formation of laminar and tubular-shaped lipid superstructures shown in Fig. 2. So far we have observed structures a, b, c, f of Fig. 2, but not e; d is questionable. It would appear that laminar micelles can be formed both by lipids in the p_{ex}-conformation and by lipids in the p_{in}-conformation, whereas the tubular structures, which are always arranged in hexagonal lattices, can only be formed by lipids in the p_{in}-conformation.

All saturated lipids, *i. e.* lipids comprising saturated fatty acids, occur at room temperature exclusively in the p_{ex}-conformation. This can be demonstrated very simply by

hydrogenating unsaturated natural lipids (n-lipids) thereby transforming them into saturated lipids (s-lipids). All lipids of this category so far studied[3] form laminar structures at room temperature, and accordingly reveal periods corresponding to twice the length of a fatty acid plus the polar groups in X-ray experiments (Fig. 2a)[14].

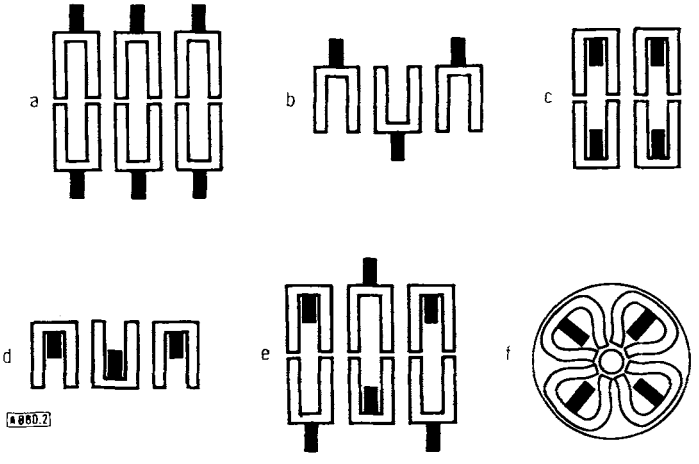

Fig. 2. a), b), c), d), e) conceivable laminar structures of lipids in the p_{in}- and p_{ex}-conformation, f) cross section of a tubular lipid superstructure formed by four lipid molecules in the p_{in}-conformation.

On the other hand the natural lipids which are partially or completely unsaturated exhibit a much more differentiated behavior. This category includes molecules of a static nature, *i.e.* which occur at room temperature invariantly in either the p_{ex}- or the p_{in}-conformation, and dynamic molecules which, depending upon physico-chemical parameters or ligand binding, acquire either the p_{ex}- or the p_{in}-conformation. Thus, for instance, PC (phosphatidylcholine) and DGD (digalactosyl diglyceride) represent typical static molecules, whereas PE (phosphatidylethanolamine), PA (phosphatidic acid), PS (phosphatidylserine), PG (phosphatidylglycerol), and PI (phosphatidylinositol) show a dynamic behavior.

2.1.2. Phase Transitions Caused by Ligand Binding

In this case the term "phase transition" signifies the cooperative transformation from one type of lipid lattice into another. Temperature-dependent phase transitions of lipids are well documented in the literature[1, 3] and since they take place at temperatures about 40 °C[11], they can scarcely play a significant role in physiological processes *in vivo*[*]. Of great physiological significance, however, could be the temperature-*in*dependent reversible phase transitions which can be performed by PE. The phospholipid PE possesses the unique quality of accomplishing temperature-independent phase transitions by bicarbonate and carbonic acid binding[15]. Since only bicarbonate and carbonic acid are bound in the ratio 1:1, this process also represents a pH-dependent phase transition. In other words, it constitutes a phase transition which is indirectly controlled *via* the auxiliary system:

$$H_2CO_3 \underset{+H^+}{\overset{+Na^+}{\rightleftharpoons}} NaHCO_3$$

According to the apparent p*K*-value of carbonic acid at pH = 6.3 the range of control extends from pH > 5.5 to pH < 7. In the pH range < 5.5 only tubular structures of PE in hexagonal arrangements are found (Fig. 3). In the range of regulation between pH = 5.5 and 7.0 the tubular structures are transformed into lamellae depending on the extent of bicarbonate and carbonic acid binding (max. at pH = 6.3). Our experiments also indicate that at pH > 8 the carbonic acid system no longer has any ligand function for PE, since in this pH-range PE again forms tubular micelles. It is an interesting fact that in the said pH-range PE mainly binds Ca^{2+}, its tubular micelles being transformed into laminar ones in the process (Fig. 3). Ca^{2+} and the carbonic acid system thus possess similar competing ligand functions; dominance of one over the other is in each case determined by a definite pH-range. Both in the case of bicarbonate (pH = 5.5—8) binding and in that of Ca^{2+} binding (pH > 7) PE occurs in the p_{in}-conformation and forms symmetrical bimolecular micelles of 44 Å or 45 Å thickness.

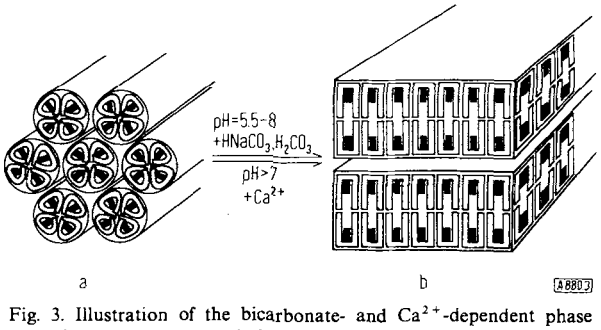

Fig. 3. Illustration of the bicarbonate- and Ca^{2+}-dependent phase transition of PE between tubular hexagonal lattices and laminar linear lattices.

A further significant characteristic is that Ca^{2+} is in part also bound in the acidic pH-range by PE, the PE undergoing transition from the p_{in}- to the p_{ex}-conformation and forming laminar bimolecular micelles that are 54 Å thick.

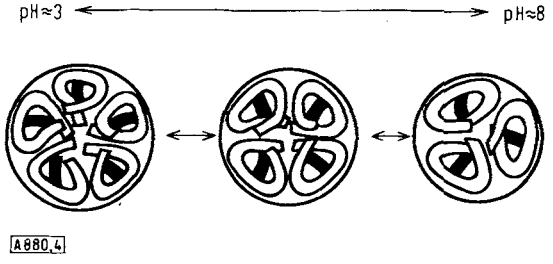

Fig. 4. pH-dependent cross-section construction of tubular PE-micelles consisting of five, four, and three PE molecules.

It is also noteworthy that in the absence of CO_2 and Ca^{2+} the diameter of the tubular structures decreases as the pH increases. It drops gradually from 48 ± 1 Å at pH ≈ 3, *via* 43 ± 1 Å, to 37 ± 1 Å at pH = 8. Since the tubular diameters are in a ratio of $\sqrt{5} : \sqrt{7} : \sqrt{3}$, the tubular cross sections apparently consist of 5, 4, or 3 PE molecules (Fig. 4)[15].

[*] The biological significance of the very well regulated body temperature of 36—37 °C in idiothermous animals could lie in the prevention of irregular thermal phase-transitions.

2.1.3. pH-Dependent and Ligand-Regulated Conformation Changes

In contrast to PE, which is outstanding for its ability to perform regulated phase transitions in which its conformational state essentially remains unchanged, PA is distinguished by the unique ability to undergo pH-, CO_2-, and Ca^{2+}-dependent conformational changes while maintaining the same laminar micelle type[15]. A decisive parameter in the conformational transition of PA is the p*K*-value of the second dissociation step of the phospho group at pH ≈ 7. In the acidic pH-range PA is found in the p_{in}-conformation, in the alkaline pH-range it exists in the p_{ex}-conformation (Fig. 5).

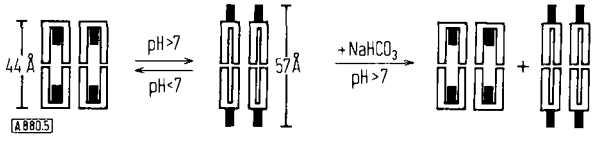

Fig. 5. pH-dependent conformational and micelle change of PA: The p_{in}-micelles are converted into p_{ex}-micelles. By the addition of bicarbonate at pH > 7 the p_{ex}-micelles are partly transformed into p_{in}-micelles.

In the presence of CO_2 both conformational states occur in about equal proportions in the alkaline range. On addition of Ca^{2+} throughout the entire pH scale, PA is quantitatively transformed from the p_{in}- into the p_{ex}-conformation (Fig. 6). In the acidic pH-range two different kinds of laminar micelle formation occur (Fig. 6a) (in varying proportions), whereas in the alkaline range only one laminar micelle type is formed (Fig. 6b). In conclusion it can be said that protonation of the secondary PO^- group of PA favors the p_{in}-conformation, whereas the binding of Na^+ and Ca^{2+} stabilizes the p_{ex}-conformation.

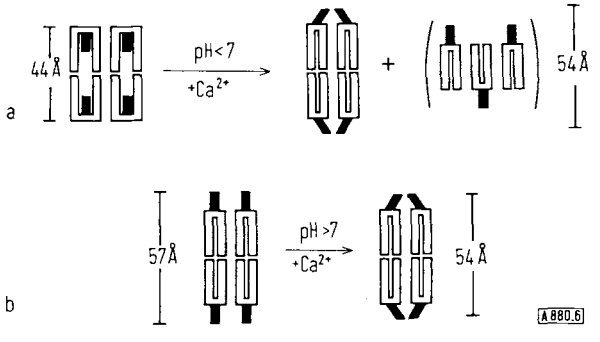

Fig. 6. Ca^{2+}-dependent conformational and micelle changes of PA: in the acidic range the p_{in}-micelles are converted into two types of p_{ex}-micelles, in the alkaline only one type of p_{ex}-micelle is formed.

PS shows neither the qualities of PE nor those of PA. Throughout the entire pH-scale, PS is found in the p_{ex}-conformation. Nor can this conformational state be modified by addition of Ca^{2+}-ions. However, PS is provided with another special property: The p_{ex}-conformation can be totally converted into the p_{in}-conformation by the addition of the amino acid alanine (Fig. 7a). This conversion cannot be achieved in such a perfect manner by other amino acids. Most amino acids are associated with the p_{ex}-conformation (Fig. 7b)[15].

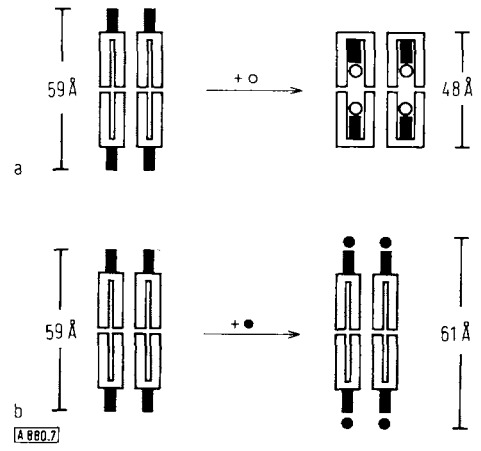

Fig. 7. Amino-acid induced conformational changes of PS. a) Alanine (○) transforms the p_{ex}-conformation quantitatively into the p_{in}-conformation, b) other amino-acids (●) are associated with the p_{ex}-conformation.

Comparable specific qualities are also to be anticipated in the case of PI and PG. However, in both instances no final results are yet available.

2.1.4. The Miscibility Behavior of Lipids

If phospholipids are mixed in organic solvents, dried by evaporation, and studied at room temperature by X-ray diffraction methods the following overall picture of lipid behavior is obtained: n-PC, n-PG, and sphingomyelin form laminar micelles, whereas n-PA, n-PE, and n-PS form tubular micelles. Tubular superstructures are also yielded by the combination PS/PA. A common characteristic of mixed micelle formation is that the mixing partners adapt their conformational state so that mixed micelles of homogeneous conformation are produced[14, 15].

In an aqueous environment, lipids show a far more complex behavior. This is already evident from the above description of the behavior of the pure lipids. The examination of aqueous lipid mixtures is rendered more difficult by the tendency of such aqueous suspensions to produce very diffuse X-ray diagrams, thus limiting evaluation possibilities. The data thus far obtained indicate that lipids are partly miscible and partly immiscible under such conditions. A decisive criterion for miscibility or immiscibility would appear to be an identical or divergent ligand-governed conformational state of the mixing partners. Immiscibility implies that the various lipid types are capable of forming separate domains within the lipid layer of biomembranes. Such a mosaic structure of the lipid layer may be regarded as an essential precondition for the possible performance of cooperative conformational and micellar transformations in lipid domains of identical population.

These viewpoints should be of particular interest with regard to the regulation of permeability in biomembranes. However, these problems cannot be considered exclusively from the lipid aspect. The lateral distribution of lipids must be decisively dependent upon the superstructure of the protein layer. A knowledge of the protein layer structure therefore seems to be indispensable for any further discussion of all these questions.

2.2. The Membrane Proteins

Each membrane is equipped with a special set of proteins according to its specific functional role. Some of these proteins are loosely associated with the membrane, whereas by far the larger part is firmly bound to the membrane or, in other words, actually constitutes part of the membrane itself. We do not propose to deal at this stage with the loosely attached proteins—they will be discussed in connection with the function membrane (Section 3)—but will limit ourselves to a consideration of the membrane-bound proteins. These have hitherto been referred to as "structural protein" in the literature. However, this general meaning of the term "structural protein" is too complex for the purpose of our discussion. At this point we only wish to deal with that part of the structural protein which can be defined by purely morphological physical criteria and which is distinguished by three main characteristics:

1. Its capability of forming two-dimensional lattices;
2. its particular solubility behavior;
3. its high volume occupancy.

The most notable quality is the first one. Therefore, we will henceforce designate this part of the structural protein "2d-lattice protein". The interrelationships between the "2d-lattice protein" and the structural protein will be established in Section 2.2.2.

2.2.1. The Tertiary Structure of the 2d-Lattice Protein

The best known 2d-lattice protein is that of the photosynthetic membrane. Moreover, this protein is the only one for which it has been possible to calculate a Gauss synthesis of the electron density distribution of the subunit (protomer) from X-ray data[14, 19]. For reasons which cannot be explained in detail here, this Gauss synthesis is still imperfect. Nevertheless, it is adequate to indicate certain basic structural features.

Fig. 8 illustrates the extent of our information so far gathered from the electron density maps[14, 19]. A possible interpretation is that two ring-like protein molecules, whose mass is unequally distributed between the upper and lower horizontal section, are arranged orthogonally to each other to form a subunit. Although the "ring" dimensions amount to 27 Å and 36 Å only, they cover the whole subunit plane of 42 × 93 Å; the only possible explanation is that linking side chains must be present between the two rings and between the subunits.

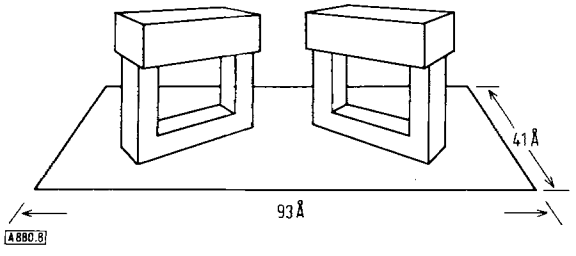

Fig. 8. Schematic representation of the mass distribution of the tertiary structure of the 2d-lattice protein subunit.

A clearer picture is obtained if the amino acid composition is taken into account. Based on the amino acid determinations of *Weber*[20], *Menke*[21], *Criddle*[22], and *Bailey*[23], the subunit should consist of 94 ± 2 amino acids (Table 1).

Table 1. Amino-acid composition of one lattice-protein subunit. The subunit consists of 94 ± 2 amino acids.

Amino acid	moles of amino acid per subunit
Asp-NH_2	7.45
Thr	4.07
Ser	4.80
Pro	5.08
Glu-NH_2	8.31
Gly	9.35
Ala	8.17
Val	7.0
Cys-SH	1.0
Met	1.46
Ile	3.76
Leu	9.25
Tyr	1.51
Phe	5.19
Lys	3.2
His	0.92
Arg	3.16
Trp	1.22
Amide	8.83

The sum of these amino acids represents a molecular weight of about 10000 for the subunit shown in Figure 8, *i.e.* 5000 per ring. The same result is obtained in estimating the molecular weight on the basis of the calculated mass distribution (Fig. 8).

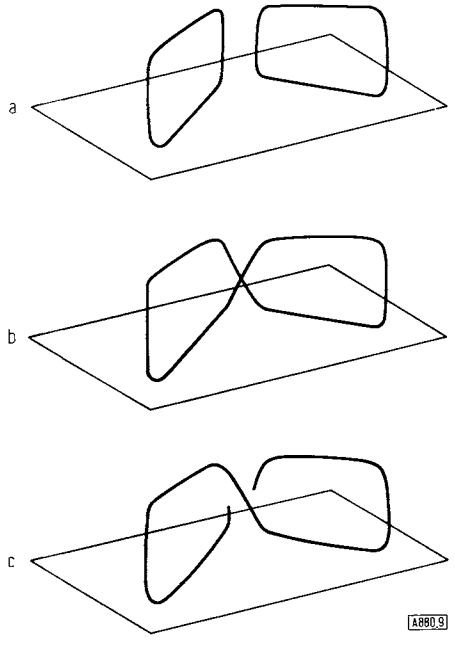

Fig. 9. Three possible conformations of a polypeptide chain consisting of 94 amino acids which are in agreement with the X-ray data.

In principle there are three conformational variations which might be in accordance with the X-ray data. A polypeptide chain consisting of 94 amino acids would suffice to form two separate rings (Fig. 9a), a closed figure-eight structure (Fig. 9b) or an open figure-eight structure (Fig. 9c).

The first two structures possess no amino acid end groups. The lowest identifiable molecular weight would be 5000 in the case of Figure 9a, and 10000 if the configuration of Figure 9b applies. The configuration of Figure 9c has two end groups and a molecular weight of 10000.

A combined end-group and molecular-weight determination could ascertain which of these three structures is the correct one. According to *Menke*[21] the number of C-terminal amino acids amounts to 13; however, other authors[22–24] have found no amino acid end groups, so that at present this problem remains unsolved. However, for the purpose of a discussion of the membrane structure as envisaged in this paper such details concerning the tertiary structure are of little importance.

2.2.2. The Aggregation Behavior of the "2d-Lattice Protein"

Of predominant significance is the aggregation behavior of the protein subunit shown in Fig. 8, *i.e.* the quaternary structure or the superstructure of the 2d-lattice protein. In principle the margin of variation in aggregation is restricted by the circumstance that only a limited number of symmetry operations is admissible in planar protein lattices. We would stress that here, as in other proteins, only L-amino acids occur.

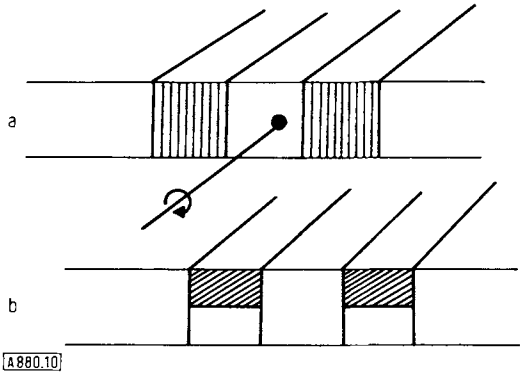

Fig. 10. a) Lamella with a twofold coplanar rotation axis, b) lamella without a coplanar rotation axis.

From the outset this very fact excludes symmetry centers and mirror planes. The only possible symmetry elements are limited to translations, transverse rotations (*i.e.* rotation axis vertical to the plane), and two-fold coplanar rotation- and screw axes (Fig. 10a). The combination of these symmetry elements permits the definition of 17 space groups[25].

In the case of biological membranes two essential restrictions in respect of possible symmetry operations are presupposed: it is alleged that biomembranes possess transverse and coplanar polarity. From our above discussion concerning the cross-sectional structure of the protein subunit it emerges that the 2d-lattice protein itself also possesses the property of transverse polarity. As regards the coplanar polarity of membranes it appears that this quality can only exist if it is provided by a two-dimensional lattice. On the other hand, two-dimensional lattices can only be imagined when formed by proteins. Therefore, we may also envisage tangential polarity in the protein layer. Transverse asymmetry (Fig. 10b) already reduces the potential number of planar space groups from 17 to 5, since all space groups with coplanar two-fold rotation- and screw axes are thereby excluded.

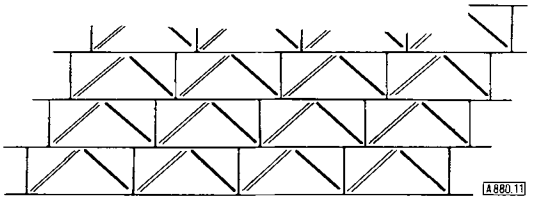

Fig. 11. Two-dimensional lattice of primitive polarity: One asymmetric protomer type forms an infinite 2d-lattice. The two thin lines and the bold one arranged at right angles within each protomer signify the position of the peptide rings.

Finally, allowing for tangential polarity, the transverse rotation axes are likewise eliminated so that out of the potential 17 space groups only one remains, namely that of the oblique planar lattice type as illustrated in Figure 11. This lattice type then would constitute the most complete but also the most primitive polarity possible: One single asymmetric protein subunit (protomer) would homogeneously cover the total membrane plane. However, this type of polarity does not seem to be desirable in biomembranes, since it would not allow any variability. The X-ray and electron-microscopic data of membranes so far available rather indicate that biomembranes are to be viewed as associations of linear superstructures which themselves may consist of a homogeneous distribution of subunits.

A second possibility is that two or more oligomeric superstructures may be arranged alternately in a linear pattern. Naturally, such a planar membrane design requires a higher number of different protomers (subunits). It is, however, quite admissible that such a variety is attributable to minute deviations in the primary structure of one and the same type of protomer. The photosynthetic membrane may serve to demonstrate this principle.

To permit a better understanding we must first of all explain that in the photosynthetic membrane of higher plants two types of light reactions or two photosynthetic systems (electron flow systems), known as system I and system II, cooperate. On the other hand, in the case of the photosynthetic bacteria (*e.g. rhodopseudomonas viridis*) only system I applies. A comparison of the structure of these two objects is most appropriate to demonstrate how on the molecular level a relatively simple structure, namely that of the bacteria, can develop into a complex structure designed to couple two systems. An electron-microscopic picture of the planar structure of a bacterial photosynthetic membrane recorded by *Giesbrecht*[26] reveals a homogeneous protein structure with two principal directions (Fig. 12). These two privileged directions enclose an angle of $\approx 56°$ and are accounted for by protein double strands 90 Å wide forming the membrane plane.

Further evidence is furnished by X-ray diagrams of the same object[27]. Two main interferences emerge which correspond to Bragg spacings of 77 and 51 Å. These interferences may be interpreted by means of the linear structure shown in Figure 13. The interferences corresponding to 77 and 51 Å and the angle of $\alpha = 56°$ (see Fig. 13a) indicate

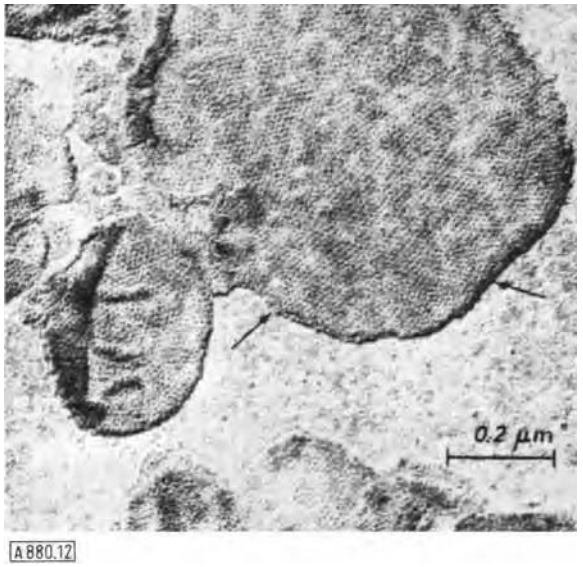

Fig. 12. Electron-microscopic plan view of thylakoids of *rhodopseudomonas viridis*. The surfaces are characterized by a regular planar arrangement of proteins in which two predominant directions exist (arrows). (After *P. Giesbrecht* [26].)

dimensions of the protein subunit of 41 and 93 Å. The existence of a planar structure, *i.e.* a structure possessing many net-planes in the x_1-direction as well as in the x_2-direction, can be ruled out because of the lack of a 41 Å-interference (Fig. 13a).

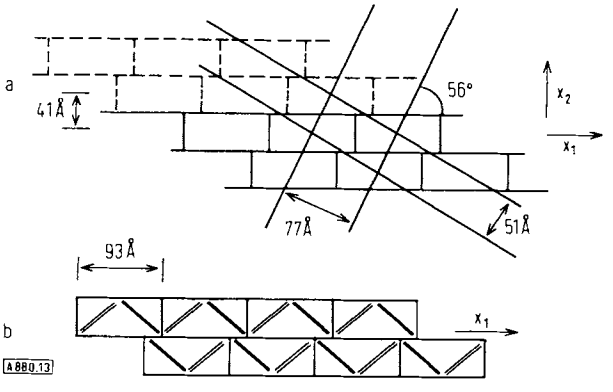

Fig. 13. Lattice arrangement which explains the occurrence of a 77 and a 51 Å reflection. Lattice b differs from a in the lack of the 41 Å periodicity. b corresponds to the real diffraction pattern.

A linear structure of the type shown in Figure 13b is, on the other hand, only plausible providing it is equipped with 2 twofold transverse rotation axes. In other words, this would presuppose preferential coupling between two rows of protein subunits. If we allow for the mass distribution of the structural protein subunit described earlier in the paper we come to a superstructure of the lattice protein of bacteria as depicted in Figure 13b.

We can now consider the construction principle of the lattice protein of the photosynthetic membrane of higher plants. Here also electron-microscopic pictures[28–30], *e.g.* that in Figure 14, reveal linear superstructures (chains), which, however, possess quite different dimensions from those in bacteria. The lateral distance between the chain axes amounts to about 190 Å, and the period along the chains to about 170 Å. The X-ray diagram of such objects consists of very strong interference corresponding to 41 Å, a strong interference corresponding to 31 Å, and a very weak interference corresponding to 62 Å which is, furthermore, considerably broader than the other two.

If for evaluation purposes one starts from the assumption that both in bacteria and in higher plants system I possesses a similar basic structure, then at least part of these reflections ought to be capable of interpretation by a modification of the lattice in Figure 13. The presence of a sharp 41 Å reflection and the absence of a 93 Å reflection indicates that in this case aggregation occurs in the x_2 direction but not in the x_1 direction. Moreover, the existence of a 62 Å reflection points to the fact that the aggregation in the x_2 direction forms an orthogonal lattice (Fig. 15). However, while the sharp 41 Å reflection provides evidence of a high

Fig. 14. Electron-microscopic picture providing the plane view of a thylakoid of higher plants showing linear superstructures. (After *R. B. Park* and *N. G. Pon* [28].)

aggregation state in the x_2 direction, the broad 62 Å reflection indicates that the aggregation breaks off after 4—5 periods. Although these findings may appear paradoxical we are able to furnish below a plausible explanation.

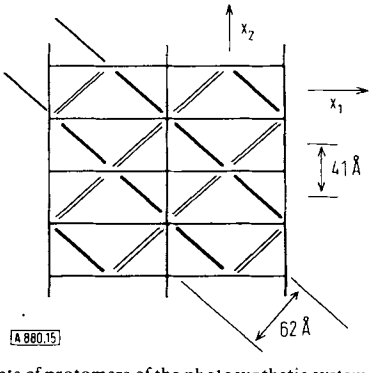

Fig. 15. Planar arrangements of protomers of the photosynthetic system I giving an explanation for the 62 Å reflection.

To this end we must first again touch upon the 31 Å reflection. Since it cannot be assumed that system I (Fig. 15) produces a 31 Å reflection, it seems justified to impute the said reflection to system II. There are two possible forms of aggregation of the protein subunit in the x_2 direction which could account for a 31 Å interference, the one being

polar and the other nonpolar (Figs. 16a and 16b). In the case of the polar structure in Fig. 16a there is no evidence as to why there should be a trend for a linear aggregation in the x_2 direction. One would far sooner expect there to be a two-dimensional association of any size, as shown in Figure 11. On the other hand, the association in Figure 16b satisfies the criteria for a linear structure and is therefore to be regarded as the most likely one. In addition to the 31 Å reflection, the lattice of Figure 16b should also produce a 41 Å reflection, the shape of which depends on the size of the linear aggregation in direction x_2.

We are now faced with the question of the coupling of systems I and II and the relative proportions of the two systems. As already pointed out, coupling can only take place under specific symmetry conditions, the ratios of the two systems being determined either by a definite number of different protomers, *i.e.* through the formation of finite associations (oligomers), or else through a definite ratio in the production rates of the subunits of system I and II. In the case under consideration it would appear that both possibilities apply. System I is turned into a finite structure

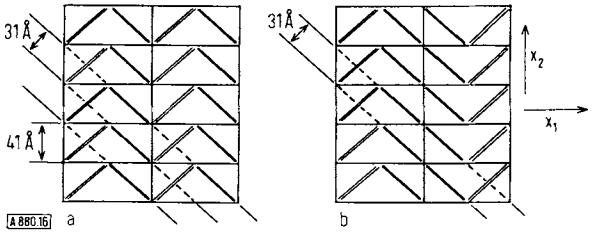

Fig. 16. Two possibilities for the planar distribution of system II protomers which can produce a 31 Å reflection. Configuration b is considered to be the true one.

by the input of several different protomers; however, the ratio between system II and I is determined by the production rate of each system.

Besides the X-ray criteria for the existence of a finite structure of system I (broad 62 Å reflection) and a fundamentally infinite structure of system II (sharp 31 Å reflection), there are also criteria provided by chemical experiments: It is possible to isolate system I oligomers from the membrane and to define their structural characteristics, whereas the remaining system II protomers join to give large superstructures, *i.e.* in the formal sense they constitute infinite structures[31-33]. X-ray investigations show that the dimensions of the system I oligomers in the x_1 and x_2 directions are 164 and 186 Å. Furthermore, we know from chemical experiments that the proportion of system I protein to system II protein is about 1:2[31]. Thus, in conjunction with the aforementioned symmetry conditions, the limits of the quaternary structure are traced.

From the dimension of the system I oligomers it can be deduced that they consist of eight protomers. For these oligomers to undergo coupling with the linear arrangements II, they would have to be equipped as a minimum with one twofold transverse rotation axis. On the other hand, the definite size of the system I oligomers can only be ensured if they consist of at least four different kinds of protomers, *i.e.* a definite set of binding sites. The symmetry and binding conditions are therefore in conformity.

The outcome of these considerations is the quaternary structure shown in Figure 17a, which as a whole will produce a broad reflection at 62 Å, a sharp one at 31 Å, and a very sharp one at 41 Å. The pseudo-contradiction concerning the sharpness of these reflections mentioned above is thus explained. This quaternary structure consists of five different protomers, four in system I and one in system II (Fig. 17b).

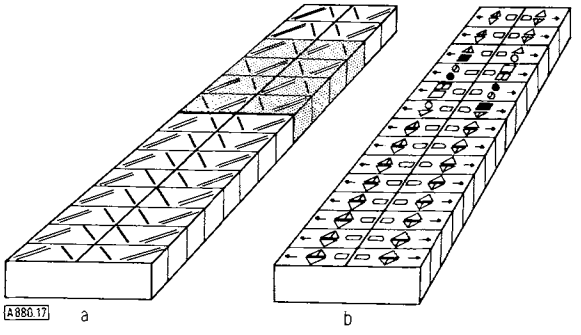

Fig. 17. a) Combined linear arrangement of system I and system II protomers which agrees with the X-ray diffraction data (41, 31, and a 62 Å reflection), b) the same arrangement demonstrating the necessary binding sites (number of different protomers) by different symbols.

In the case of an open tertiary structure as illustrated in Figure 9c one might expect a maximum of ten different terminal end groups in the 2d-lattice proteins. The ring structure and the closed figure-eight structure shown in Figure 9a and 9b would not allow for any end groups at all. A decision between these alternatives is not yet possible because of the aforementioned discrepancies in the amino acid end-group determinations.

Support for the general validity of these arguments is forthcoming from the X-ray investigations of the discs of rod outer segments (ROS) of the retina and the erythrocyte membranes. In ROS-discs the lattice protein provides the same interferences as were recorded in the case of photosynthetic bacteria, *i.e.* 77 and 51 Å reflections[34], and the erythrocyte planar lattice produce X-ray reflections corresponding to Bragg spacings of 41 and 33 Å.

The examples of the lattice protein configuration described above give an indication of the scope of variation of possible structural modifications. However, they also set limitations upon the principal realization possibilities: The given criteria allow for the existence of two-dimensional lattice types with primitive polarity (Fig. 11), linear lattice types with twofold rotation axes as shown in Figure 13b (ROS-discs, photosynthetic membranes of bacteria), in addition to more complex lattice types comprising several protomers and oligomer associations capable of performing most complicated functional tasks (Fig. 17) (photosynthetic membranes of higher plants). There is, however, one factor which appears to be of fundamental significance: For all these lattice types one single type of basic protomer, *i.e.* one type with identical or almost identical tertiary structure, suffices for every possible variation. In this context the chemical experiments on structural protein referred to earlier acquire particular significance since they have demonstrated that the structural protein of the membranes of various objects show only minute deviations in their

primary structure and that by the action of proteases or detergents they can be decomposed to basis peptides with a molecular weight of 5000, 10000, or 20000[20–24, 35–37].

This being so, what can be said about the required tangential polarity? The introduction of polarity into the anisotropic (linear) homogeneous structural elements obviously is brought about by the association of functional proteins. This creates periodically distributed linear bipolarity. That is to say, energy fluxes, impulses, or actions emanating from the polarity centers are propagated in a bipolar fashion. In this manner radial energy distribution, which would mean a waste of energy in this case, is prevented. A primitive polarity as shown in Figure 11 would permit an energy flux in only one direction, which would be less advantageous. In the more sophisticated linear structures consisting of several oligomers, strong polarity is also created in the phase boundaries between each pair of different oligomers.

A further feature of great importance for the construction of membranes is the distribution of hydrophobic and hydrophilic amino acids within the 2d-lattice protein subunit. We have learned from the Gauss synthesis of the cross-sectional structure of the protein unit that the ring centers represent hydrophobic areas[19]. In addition, that horizontal part of the ring with less mass would have to contain at least a predominance of hydrophobic amino acids. The latter statement derives from the sandwich behavior of the lattice protein in aqueous solution and the collapsing process in membranes dealt with in Section 3.2. This unusual distribution of amino acids will serve to clarify the fact that lipids are only associated with one side of the protein-layer (a feature considered in Section 2.3). And last, but not least, we must once again draw attention to the truly remarkable mass distribution inside the lattice protein subunit. The impression is gained that the aim is not to fill up the subunit with protein mass (and consequently also the protein layer), but rather as far as possible to keep the subunit free of protein mass. Such a structure opens up interesting possibilities with respect to the coupling of proteins with lipids and also of the lipid distribution and lipid superstructure.

2.3. Protein-Lipid Coupling

The answer to the question of protein-lipid coupling in biomembranes lies ultimately in their cross-sectional structure. It is only in the last decade that significant experimental progress has been made in this field. The first speculative concept advanced was that of a symmetrical membrane cross section[38]. However, it is evident that biophysically speaking such a membrane structure could give rise to no activity whatsoever, *i. e.* it would represent the biologically most unfavorable membrane. Indeed, our X-ray results on three different membranes point to an asymmetric membrane cross section. The most pronounced asymmetry seems to exist in the photosynthetic membrane of higher plants and the nerve myelin structure. On the other hand, the results so far obtained from rod outer segments of vertebrate retina indicate an alternate asymmetric membrane construction. It is to be expected that erythrocytes have the same type of membrane.

A fundamental asymmetry can be established in all membranes so far investigated by means of a fairly simple X-ray experiment, *i. e.* by a comparison of the X-ray data obtained in this experiment with electron-microscopic pictures of the same membrane system. The electron-microscopic pictures of membrane systems reveal that membranes always form closed vesicles. In flattened vesicles (*e. g.* ROS-discs, myelin membrane, photosynthetic membrane) two membranes are therefore arranged mirror-symmetrically and in this form give rise to the identity period observed in the membrane system (Fig. 18a).

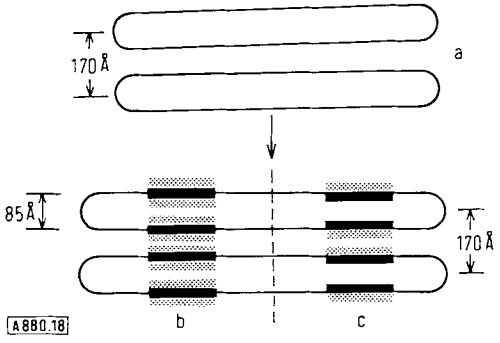

Fig. 18. Relationship between electron-microscopic and X-ray periods in lamellar systems. a) Electron-microscopic cross-section view of a flattened vesicle, b) X-ray period in the case of a symmetrical membrane, c) X-ray period in the case of an asymmetrical membrane.

The X-ray beam "senses" electron-density projections of these vesicles, such as for instance the electron-density projection onto the stacking axes which is under consideration here. This means that if the electron-microscopic periodicity is compared with that obtained by X-ray diffraction, the X-ray identity period would—in the case of a symmetric membrane (Fig. 18b)—amount to half of the periodicity visible on electron-microscopy. However, in the case of an asymmetric membrane cross section (Fig. 18a) the X-ray and electron-microscopic periods would be identical.

This comparison can best be made by using partly dehydrated membrane systems (up to 30% H_2O) of flattened vesicles, since the identity period then corresponds to the thickness of a single or of a double membrane. It is possible to make this comparison using chloroplasts of higher plants, nerve myelin, and ROS-discs. Each of these three membrane types yields an X-ray period which is comparable with that found by electron microscopy, that is to say, it is equal to or greater than twice a membrane thickness. (The situation is somewhat more complicated regarding membranes forming spherical vesicles. This aspect will be dealt with in Section 2.3.1.)

This result alone already justifies the statement that at least these three membranes have an asymmetric cross-sectional structure. Apart from this common characteristic, however, there are considerable deviations with regard to the magnitude of the period or the thickness of the vesicle. The period found in chloroplasts amounts in the dehydrated state to 150—170 Å, in ROS to 210—230 Å, and in myelin to

130—150 Å. The significance of these differences will be referred to in the detailed discussion on membrane cross sections. Let us first of all discuss the cross-sectional structure of the photosynthetic membrane, the most asymmetric one.

2.3.1. The Cross-Sectional Structure of the Photosynthetic Membrane

The structure of the photosynthetic membrane has been comprehensively dealt with in an earlier paper[14]. We may limit ourselves here to some essential aspects. The photosynthetic membrane of higher plants consists of three layers which are distinguished by three different sections in the electron-density diagram (Fig. 19a). The layer with the highest electron-density has proved to be a protein layer, that with the lowest density to be a porphyrin ring layer, and the layer with medium density to be a monomolecular

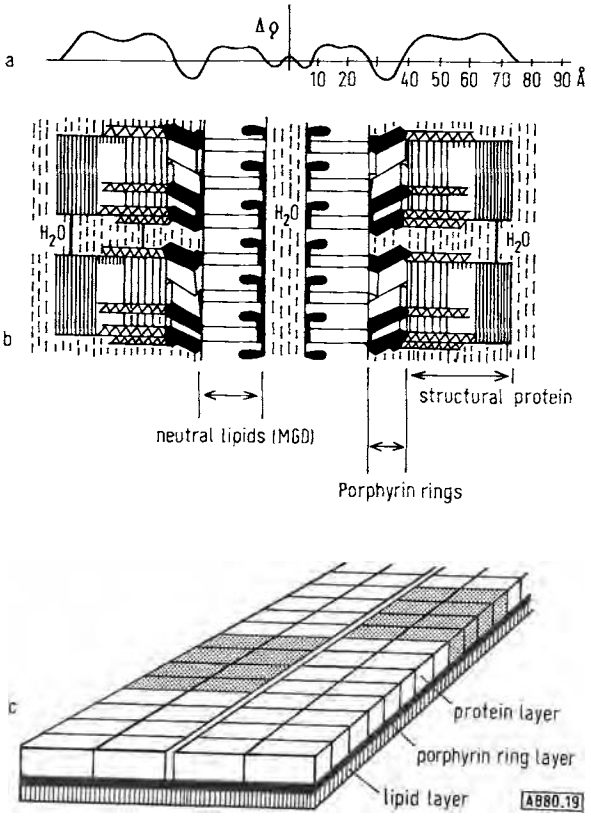

Fig. 19. Structure of the photosynthetic membrane of higher plants. a) Electron-density (ρ) distribution of the cross section of a vesicle (thylakoid) in the living state, b) its interpretation (see designations), c) plane view of one asymmetric membrane.

lipid layer (Fig. 19b). The mirror plane between the two membranes of the vesicle (thylakoid) is so arranged that the proteins form the outer layers.

The following points are essential for the discussion on the protein lipid coupling in Section 2.3.2:

1. Both chlorophyll a and b are not miscible with the principal lipid component MGD, with constitutes about two-thirds of the total lipids.

2. Phytol shows the same behavior.

3. Upon fragmentation of the membrane by detergents the major part of the chlorophyll adheres to the proteins[31].

4. In chlorophyll-protein complexes the lamellae are about 12 Å thicker than pure protein layers[31].

These results, which will not be further elucidated here, support the concept that chlorophylls are anchored in the 2d-lattice protein by means of the phytol chain and that the contact between protein and lipid is established by the porphyrin rings, which apparently partially penetrate into the unsaturated fatty acid zones of the lipid layer[14]. An overall view of the photosynthetic membrane of higher plants is given in Figure 19c.

2.3.2. General View of Protein-Lipid Coupling

Protein-lipid coupling by means of chlorophyll cannot apply to membranes containing no chlorophyll. However, the question arises as to whether we are confronted here with a special instance of a general coupling principle. Remarkably, most membranes studied hitherto have revealed a constant proportion of $30 \pm 5\%$ PC[6]. The only exception encountered is that of the photosynthetic membrane which has yielded only 1—2% of PC. The other phospholipids vary considerably from one membrane to another, depending upon their function. Once again the photosynthetic membrane provides an exception: The phospholipids are extensively replaced by galactolipids (MGD and DGD). Moreover, taking into account the fact that PC shows the least conformation and phase variability of all phospholipids, it emerges as the foremost candidate for a special structural role.

On the basis of these lipid qualities and experimental results obtained in respect of the photosynthetic membrane we postulated a general principle concerning protein-lipid coupling in biomembranes[14]: According to this postulation PC assumes the function of coupling between proteins and lipids in membranes containing no chlorophyll. The coupling is thought to be accomplished in such a manner that the fatty acids of PC interact hydrophobically with the peptide chains in the protein layer, while the choline groups penetrate the fatty-acid zone of the lipid layer (Fig. 20a). The stability of this type of coupling is assured on the one hand by the purely hydrophobic coupling between fatty acids and protein and on the other by the polar interaction of the choline group of PC with the polar groups of the coupled lipids (and the proteins). Maximum stability of the polar interaction is achieved by the fact that the interacting polar groups are embedded in hydrophobic fatty-acid phases (Fig. 20b). This coupling principle will be supplemented in this paper only to account for partial assumption of the role of PC by sterols in some membranes.

2.3.3. The Cross-Sectional Structure of the Nerve Myelin Membrane

In the past various phase combinations have been applied by different authors for calculation of the electron-density distribution of the myelin membrane cross section; consequently, different electron-density distributions were obtained (for summary, see [39]). In the last year we have

likewise made a calculation of the electron-density distribution of the myelin membrane cross section[40]. The evaluation method used by us (the Q_0-method), however, differs fundamentally from that employed by other authors. Our

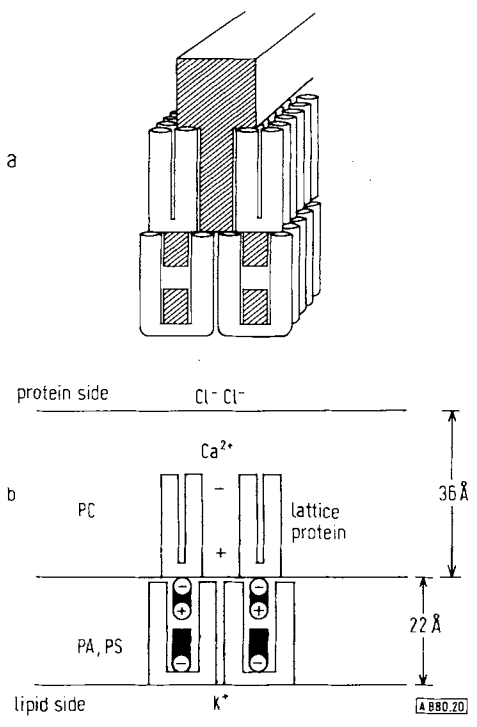

Fig. 20. General coupling concept of lattice proteins and lipids by PC. a) Spatial situation at one ring of the subunit (compare Fig. 8), b) charge distribution within such a coupling unit.

Q_0-method, which was developed for and applied in the structural investigation of the photosynthetic membrane[14], directly yields an unequivocal electron-density distribution from the intensity (and not as usual from the amplitude) distribution by straightforward calculation, leaving out the phase problem entirely. The electron-density distribution obtained for nerve myelin membrane *in vivo* is shown in Figure 21a.

We have interpreted these results as shown in Figure 21b. According to this concept the symmetry center of the electron-density projection is flanked by the cross-sectional profiles of mirror-symmetrically arranged lattice protein layers. These layers are first covered on the outside by a layer of the coupling choline groups and sterols, then by a pure fatty-acid layer, and lastly by a layer of polar groups of the lipids. In principle this structure corresponds to the cross-sectional structure of the chloroplast thylakoids if one replaces the chlorophylls by PC and sterols. There is, however, one important distinction: In the myelin structure the mirror plane is located between the two protein layers, whereas in the case of the photosynthetic membrane vesicles (thylakoids) it is positioned between the two lipid layers. We will refer to this again later in Section 3.1.

According to our membrane concept of nerve myelin each membrane possesses two C=C bond planes: one is formed by the C=C bonds of the unsaturated fatty acids of the PC located within the lattice protein, the other plane of the fatty acid C=C bonds being situated within the actual lipid layer. If it were possible to chemically label these double bond planes, for instance with OsO_4, our membrane concept could be tested experimentally. A difference-Fourier or difference-Q_0-evaluation would then directly yield the Os distribution in the membrane. Systematic incorporation experiments of this kind were first carried out by *Parsons* and *Akers*[39]. The Fourier-evaluation of these experiments by *Harker*[41] resulted in the same Os distribution as our evaluation *via* the Q_0-function (Fig. 21c)[40]. These evaluations reveal that each membrane possesses two planes with different Os concentrations and an Os enrichment between the membrane pairs. The best access for OsO_4 molecules is offered by the C=C bond layer within the protein layer,

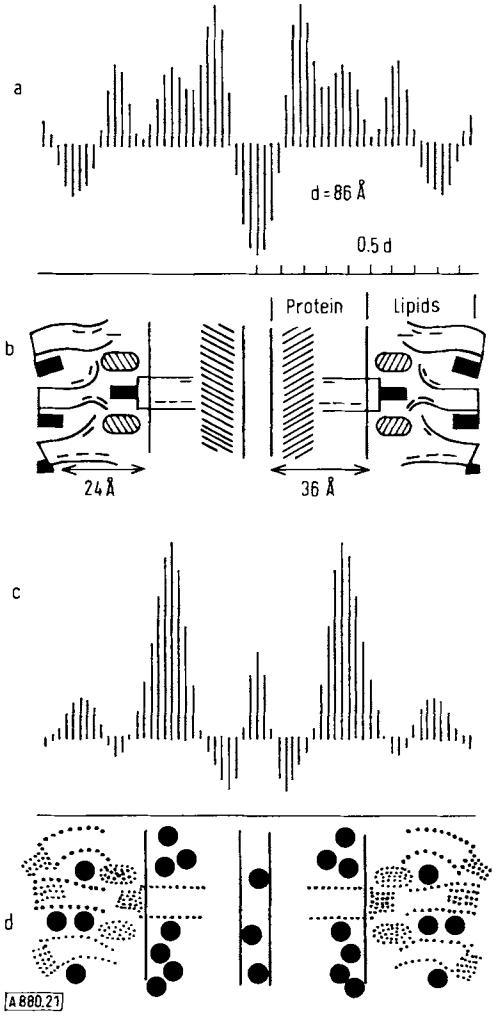

Fig. 21. Structure of the myelin membrane. a) Computer diagram of the electron-density (ρ) distribution of the cross section of a myelin membrane pair, b) its interpretation: Each membrane is composed of an inner protein layer and an outer lipid layer. The coupling is achieved by PC and sterols (hatched). A water interspace has to be envisaged between the two protein layers as well as between the two lipid layers, c) computer diagram of the pure Os distribution in the myelin membrane pair, d) Os distribution indicated by diagram c. Os atoms stain the two C=C bond planes within each membrane.

since the lattice protein is hydrated up to 70%. The action of the OsO_4 molecules on these double bonds can be carried out in an aqueous reaction medium. Therefore, the corresponding Os peak in Figure 21c is the most dominant one.

The situation is quite different with the second plane of C=C bonds. These double bonds are incorporated in a hydrophobic environment, which makes penetration and reaction of Os molecules more difficult. Accordingly, the corresponding Os peak in Figure 21c is considerably smaller. The Os distribution established within the membrane cross section agrees with our membrane concept of nerve myelin and consequently also with our concept of protein-lipid coupling in biomembranes.

A Fourier-transformation of the electron density distribution shown in Figure 21a and 21c provides the corresponding amplitude functions. They yield a phase set of $+ - - - -$ for the five reflection amplitudes of the nerve myelin *in vivo* and a phase set of $+ - - + +$ for the five reflection amplitudes of the pure Os distribution. The mirror-symmetrical phase set to the above phase set for nerve myelin *in vivo*, namely $- + + + +$, was already reported by *Moody* in 1963[42] as one of two possible phase sets ($- + + + +$ and $- + + - -$). In the case of the Os distribution *Harker*[41] found the same phase set as we did. *Harker* proposes the same phase set for the *in vivo* structure as for the Os distribution. Interestingly, these phase sets, which come nearest to, or are identical with, those determined unambiguously by us, were gained by systematic experimental phase determinations.

2.3.4. The Definition of the Basis Membrane

The calculation of the electron-density distribution of the cross section of the photosynthetic and myelin membranes has revealed totally asymmetric cross-sectional structures. Based on the particular cross-sectional structure of the photosynthetic membrane we were able to postulate a general coupling principle for lipids and proteins in biomembranes. And finally X-ray investigations on the myelin membrane have furnished support for this postulation. This structural knowledge combined with the intrinsic qualities of lipids and proteins and with the results of comparative chemical investigations of membranes permits the definition of a basis structure for biomembranes.

We may define the basis membrane as that part of the biomembrane which is exclusively constituted by 2d-lattice protein and the membrane lipids. Its cross-sectional structure is totally asymmetric and its planar structure is governed by the two-dimensional lattice formed by the proteins, while the coupling between the proteins and lipids is accomplished by PC. An area measuring 42×93 Å^2, covered by a single protein unit, accommodates 70—80 lipid molecules depending upon the conformational state. For the coupling of these molecules, 30 PC molecules are available, 15 per protein ring or 7—8 on each side of the rings. When arranged side by side these 7 or 8 lipid molecules can extend over a distance of *ca.* 35 Å or 70 Å, depending on whether the fatty acids are assembled in single or double file. In view of the fact that each structural protein ring has a diameter of *ca.* 30 Å, the double file assembly appears the more probable. This suggests a structural configuration as illustrated in Figure 20a. Each PC molecule couples one other lipid molecule. Over an area of 42×93 Å^2 there are thus left 40—50 uncoupled lipid molecules. These might be expected to form one of the micelle structures shown in Figure 2. Consequently the following possibilities for the cross-sectional structure of the basis membrane may be envisaged according to the type of uncoupled lipids present in the protein interspaces (Fig. 22):

a) Basis membrane with lipid regions of monomolecular symmetric construction and of homogeneous p_{ex}-conformation. This can apply to PG, PA, and PE (Fig. 22a).

b) Basis membrane with lipid regions of bimolecular symmetric construction and of homogeneous p_{ex}-conformation. This micelle structure can be formed by PA, PS, or PI (Fig. 22b).

c) Basis membrane with lipid regions of bimolecular symmetric construction and of homogeneous p_{in}-conformation. This micelle type could consist of PE or of PA (Fig. 22c).

d) Basis membrane with lipid regions of tubular construction. This configuration could be composed of PE alone or of mixtures of PE with PA and PS (Fig. 22d).

The specific type of micelles involved will depend upon the pH of the surrounding aqueous phase, whether CO_2 is present, and lastly upon the concentration of different cations (*e.g.* Na^+ or Ca^{2+}). This brings us to the question

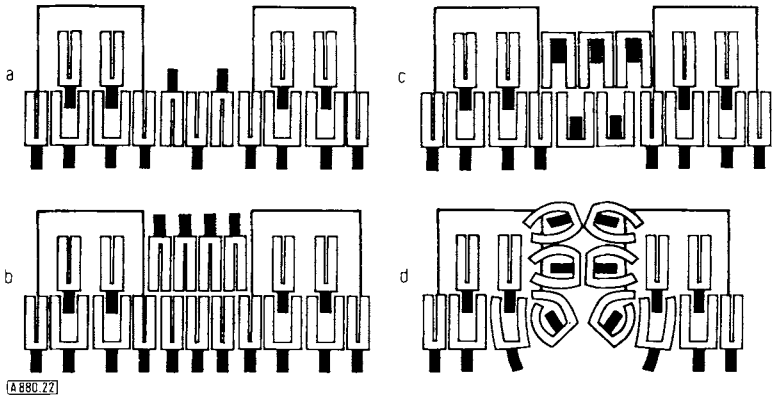

Fig. 22. Possible cross-sectional views of the basis membrane differing in their lipid interspaces (see text).

of the influence of the aqueous phases with their different constituents on the membrane structure. Section 3 deals with these functional aspects of biomembranes.

3. The Function Membrane

Before discussing actual functions of the membrane it is necessary to complete the structure of the basis membrane to give a function membrane. This completion may be achieved in three ways: By a loose association of functional proteins; by the incorporation of non-proteinaceous substances; and by the direct binding of prosthetic groups (*e.g.* heme groups) to the lattice protein, thus yielding modified or "converted lattice protein".

3.1. The Structure of the Function Membrane

The category of proteins which are loosely associated with the basis membrane comprises special functional proteins such as the ATPases which are indispensable for active transport of Na^+ and Ca^{2+} or the rhodopsin of the ROS membrane, *etc.* Some examples of non-proteinaceous substances of this category are NADP, ADP, acetylcholine, *etc.* We assume that the other category of membrane-bound functional proteins includes mainly converted lattice proteins (Fig. 23a). It is thought probable that they embrace a large proportion of the redox enzymes, *e.g.* the cytochromes f and b of the photosynthetic membrane.

At this point it may be noted that the mixture of pure lattice protein, converted lattice protein, and certain other coupled proteins has up to now been referred to as "structural protein". The converted lattice proteins should not differ essentially from the normal lattice protein; they should only vary slightly in their primary structure. Hence it is not surprising to find that the "structural proteins" of various membranes reveal only minute differences in their amino acid composition, that they can all be chemically fragmented in the same manner, and that they can be decomposed to the same peptide size. So far the structural proteins of the photosynthetic membrane[20–23], mitochondria[22,24], nerve myelin[36,37], the retina, and erythrocytes[24,35] have been analyzed by these procedures.

The coupling of the first category of proteins to the basis membrane may be achieved in two ways: on the protein side (Fig. 23b) or on the lipid side (Fig. 23c). The coupling to the protein side may occur specifically to the proteins or to the lipids, whereas on the lipid side the coupling can only occur specifically to the lipids. The lipid specificity is determined by the lipid composition of the membrane, and by the circumstance that coupling is only conceivable in those lipid regions which are not blocked by coupling PC molecules, *i.e.* in lipid regions of symmetrical micelle structure. These lipid regions are thereby converted from a symmetrical to an asymmetrical structure. Thus, the coupling of further addenda (*e.g.* proteins) to the basis membrane results either in a totally asymmetric function membrane (Figs. 23a and 23b), in an alternating asymmetric membrane (Fig. 23c), or in a mixture of both types.

It is to be expected that a coupling molecule is involved in the coupling of protein to the lipid side which is comparable in its action to PC in the case of the lattice-protein coupling. Presumably, however, these coupling molecules are bifunctional, *i.e.* apart from the coupling function they also have a role in the actual membrane process as characterized by the coupled protein. A typical example would appear to be the ATPase system. It is conceivable that ATP acts as the coupling molecule between the lipids and the ATPase, simultaneously serving as energy donor. An indication of this is certainly provided by experiments in which ADP and ATP were mixed with lipids[15].

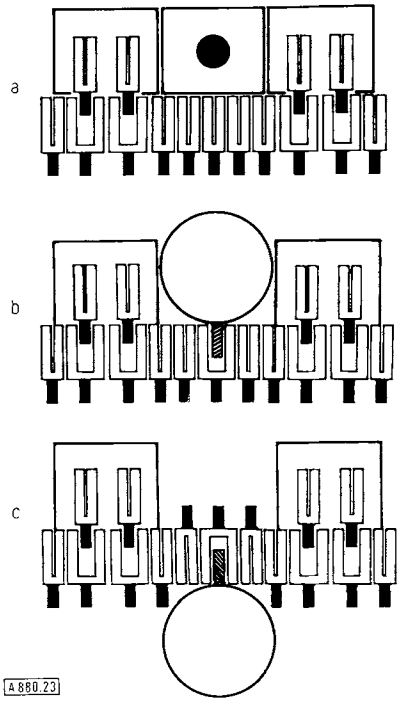

Fig. 23. Three possibilities for the association of functional proteins to the basis membrane. a) Conversion of a lattice protein subunit by the binding of a prosthetic group (●), b) coupling of an "other" protein molecule to the protein side by a coupling molecule (hatched) or by pure protein interaction, c) coupling of an "other" protein to the lipid side by a coupling molecule.

An example of the coupling of redox enzymes to the protein side is to be found in the electron transport chain in photosynthesis and respiration. The photosynthetic membrane therefore represents a typical asymmetric function membrane (Figs. 19, 23a, 23b). The same applies to the myelin membrane. Both these membranes have been dealt with earlier in this paper and only require completion in conformity with Figures 24a and 24b. Finally, it is necessary to discuss the second type of function membrane. Our experiments on ROS-discs have revealed that this membrane is representative of this category.

The straightforward calculation of the electron-density distribution of the ROS-disc membrane cross section *via* the Q_0-function[24] results in the distribution function shown in Figure 24a. [Recently, an electron-density distribution of the cross section of the ROS-discs was also calculated by *Blaurock* and *Wilkins*[43] by choosing a phase combination that most closely approached a symmetrical membrane cross section ("unit membrane"). For a further discussion, see [34].] The symmetry center of the electron-density diagram of Figure 24a is flanked by two peaks of high electron density followed by electron-density troughs

and then by two electron-density peaks of medium height. This electron-density distribution is, in our opinion, to be construed as illustrated in Figure 24b. Unlike the chloroplast thylakoids but in accordance with the myelin structure the lattice protein forms the two inner layers (the layers adjoining the symmetry center) of the discs, each layer being flanked on the outside by a monomolecular lipid layer. Furthermore, we assume that to the outside of the lipid layers the rhodopsin molecules are attached, which, together with the aqueous phase, account for the electron density in this region.

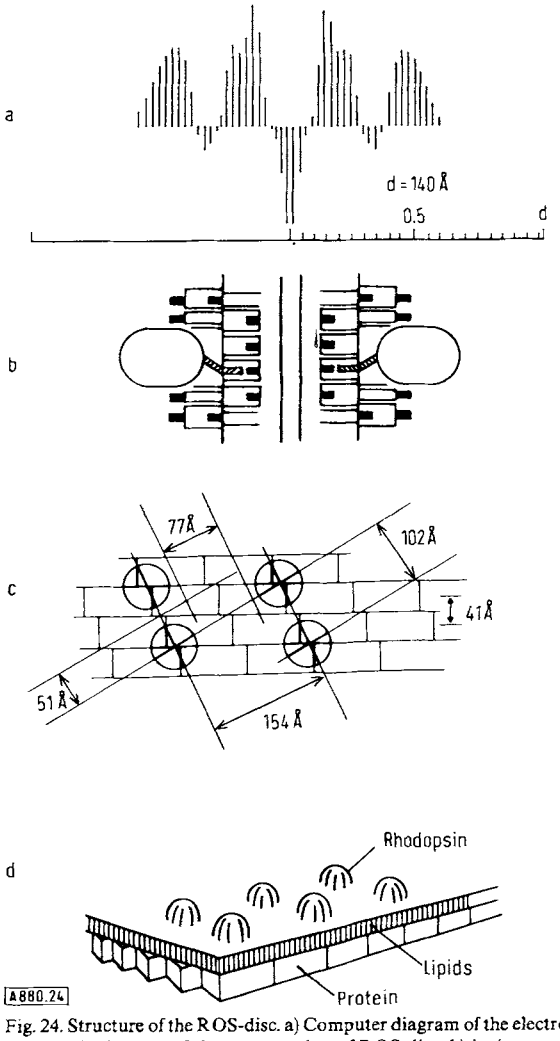

Fig. 24. Structure of the ROS-disc. a) Computer diagram of the electron-density distribution of the cross section of ROS-disc, b) its interpretation: two inner lattice protein layers flanked by lipid layers on the outer sides. Rhodopsin molecules are coupled to PE in the p_{in}-conformation by retinene, c) planar distribution of the lattice protein combined with a rhodopsin superlattice, d) overall view of the ROS-disc membrane.

Support for the concept of the rhodopsin molecules being attached to the outside of the lipid layer is provided by the following observations: Two different lattice types have been identified within the plane of the retina discs[34]. One lattice characterized by Bragg spacings of 51 and 77 Å, and the other by Bragg spacings of 154, 102, and 77 Å. The second lattice represents a superlattice of the first one (Fig. 24c). The first type of lattice has already been described in connection with photosynthetic bacteria in Section 2.2 and was attributed to the 2d-lattice protein. It is always found in those retina preparations in which the superlattice is disintegrated. The disintegration can be caused by operations resulting in the decomposition of the lipid layer or by light-induced uncoupling of the rhodopsin molecules[34]. Apparently the rhodopsin molecules are arranged in an oblique planar lattice with plane distances of 154 Å and 102 Å which is indirectly determined by the lattice protein on the opposite lipid side (Fig. 24d). These findings are in agreement with the results of *Blasie et al.* who could immunologically demonstrate that the rhodopsin molecules are arranged on the outside surface of the ROS-discs[44]. The ROS-disc membrane may, therefore, be classified as an alternating asymmetric type of membrane (Fig. 23c). For the sake of completeness it may be added that the electron-density distribution of Fig. 24a corresponds to a phase set of $+ - - - - - - -$ for the first seven reflection amplitudes.

Concluding these considerations on the structure of biomembranes it should be mentioned that the protein lattice structures and thus also the defined planar structure of the entire membranes discussed above are to be regarded as exceptional crystalline states which can exist only under special experimental conditions. *In vivo* these structures should exist in para-crystalline or still more fluidal crystalline states.

3.2. The Collapse of the Function Membrane

A feature providing significant information concerning the thermodynamic stability of function membranes and therefore also concerning the structure itself, is the phenomenon of function membrane collapse. In actual fact experiments carried out over the last ten years indicated the existence of this phenomenon, but it had not been recognized as such. The interrelationships became apparent when we recorded X-ray diffraction patterns of the ROS membranes. What happens is that in particular membranes of spherical vesicles, *e.g.* erythrocytes[45], photosynthetic bacteria[46], but also those of mitochondria[47] and the flattened vesicles of the ROS[34], in the partially dehydrated state (20—30% H_2O), produce a 58 ± 2 Å reflection in the X-ray experiment which is mostly accompanied by a 116 ± 4 Å reflection. Evidently these reflections must relate to a structural quality which is common to a wide variety of membranes.

The said reflections occur at the meridian when the three first mentioned membranes are orientated by drying on an object slide, *i.e.* they represent diffraction patterns analogous to those produced by membrane stackings. The quantitative analysis of the diffraction patterns of the photosynthetic membranes of *rhodopseudomonas spheroides* conducted by *Pape*[48] has revealed that the basic lamellar unit is a 115 Å thick double layer whose two asymmetric sublayers are arranged in mirror symmetry.

In our X-ray experiments on dehydrated orientated ROS-discs[34] we also encountered the 57 Å reflection but the amazing fact was that this reflection definitely came from the plane structure of the ROS-discs, *i.e.* the diffraction effects as compared with the corresponding effects in other membranes were swivelled through 90°.

For an interpretation of these findings it is necessary to divert briefly from the point. The original concept of the molecular membrane structure was that of a symmetrical membrane, *i.e.* a membrane construction of the highest thermodynamic stability was intuitively postulated[38]. This holds true, for instance, in the case of the photosynthetic membrane and the myelin membrane, *however not within one single membrane but in a mirror symmetrical arrangement of a membrane pair.* It should therefore not be surprising that these two membranes do not alter appreciably upon dehydration.

The situation is different with regard to membrane systems which form spherical vesicles or, in more general terms, in the case of those membranes, whose two lipid layers cannot adopt a mirror symmetrical arrangement, *i.e.* cannot stabilize upon dehydration. This formulation also applies to the ROS. In spherical vesicles contact between the lipid layers is inhibited by the "filling" of the vesicles, whereas in the case of the retina it is prevented by the rhodopsin molecules attached to the lipid side. The result is that when the water phase is eliminated upon drying, *i.e.* when the thermodynamic basis of the "hydrophobic bond"[49] is eliminated, and when the monomolecular lipid layers of the membranes are not stabilized by adjoining lipid layers, a protein-lipid dissociation takes place followed by a structural rearrangement of the proteins and the lipids (Fig. 25). However, it is to be expected that at this hydration stage of 20—30% water the PC molecules will still remain attached to the lattice protein and that only those lipids which form the proper monomolecular lipid layer of the membrane are disintegrated. The original thickness of the membrane is thereby reduced by about 25 Å, *i.e.* from 70 Å to 45 Å (45 Å = 36—38 Å lattice protein + 8 Å towering choline groups). A suspension of densely packed, flattened collapsed membrane vesicles which are 20—30% hydrated must contain 90 Å thick membrane pairs in mirror-symmetrical arrangement spaced by 20—30 Å water layers. When drying is complete the stacking period will shrink to about 90 Å (Fig. 25). Such a behavior was found by *Finean et al.* in X-ray experiments on mitochondria and erythrocytes[45,47].

Lipid extraction will result in a further state of collapse, or, more adequately expressed, state of denaturation: The elimination of the PC molecules from the lattice protein will be followed by a stabilization process of the pure lattice proteins. This stabilization is achieved by a tilting away of the protein subunits from the original lattice plane. In spite of the loss of the PC molecules this process leads to a thickening of the protein layer from 45 or 37 to about 55 Å. This membrane behavior is well established by electron-microscopic observations by *Fleischer* and *Stockenius*[50] as well as by X-ray investigations[51] (Fig. 25c_1 and 25c_2).

In electron-microscopic procedures, employing staining and alcohol dehydration, only collapsed membranes will be pictured, *i.e.* the pictures represent protein layers stained at their outer surfaces (Fig. 25d). There is no "*unit membrane*" but *a common appearance of denatured membranes. Sjoestrand* also comes to the same result in a comprehensive electron-microscopic study[52].

The ROS-discs represent an exception in so far as the orientating pressure is swivelled through 90° with respect to other membrane systems in such dehydration experiments. Whereas a transversal pressure is applied in the membrane systems discussed above, lateral forces have to be considered in the ROS-discs (Fig. 25b). In all X-ray experiments a strong 56 Å reflection appears when the 77 and 51 Å reflections of the initial 2d-lattice protein disappear on dehydration, indicating a breakdown of the 2d-lattice and the formation of a new linear lattice. We suppose that this 56 Å lattice is formed by the tilting away of the protein subunits from the lattice plane to arrange in a "pickaback" structure (Fig. 25b). (*Blasie* and *Worthington* attributed the 56 Å reflection to a liquid planar distribution of rhodopsin molecules[53].)

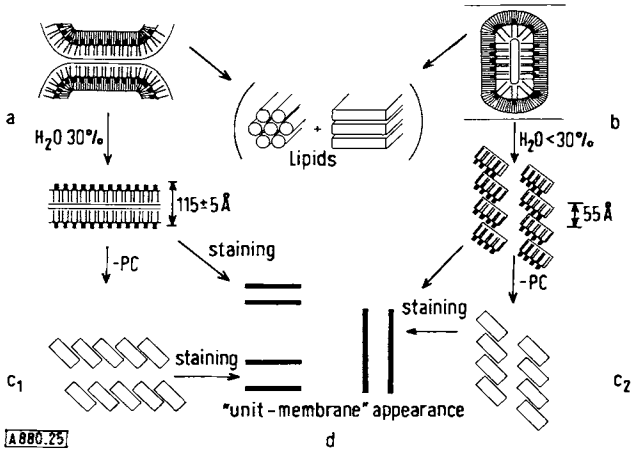

Fig. 25. Representation of the collapse process and the origin of the "unit-membrane" appearance in biomembranes. a) Collapse of membrane vesicles which are orientated by dehydration, b) collapse in ROS-discs on dehydration, c) thickening of the protein layers by rearrangement of the subunits after total lipid extraction, d) stained collapsed membranes: "unit-membranes".

3.3. Perspectives of Molecular Membrane Functions

On the basis of the membrane structure as projected in the preceding sections new possibilities are opened up concerning membrane functions on the molecular level. As an introduction to a consideration of this subject the following three directive postulations should be premissed:

1. The capability of the lipids to exist in two different conformational states and the control of conformational transitions by ligand binding may be regarded as the carrier basis of facilitated and active transport processes.

2. The maintenance of a definite permeability and its adjustability is founded on controllable phase transitions of phospholipids through binding or attachment of ligands as well as on the different binding capacities of individual lipids with respect to univalent and bivalent ions.

3. Proteins have the task of solving stereospecific structural problems, they are responsible for the enzymatic regulation of membrane processes, and in particular for governing the energy transmission between the outside aqueous phases and the membrane.

3.3.1. General Remarks on Carrier-Transport Mechanisms

The newly found intrinsic lipid characteristics point to the possibility of carrier-transport mechanisms based on conformational changes of phospholipids. (A "carrier" is considered to be a molecule which is able to effect a mechanical movement of substrate across the permeation barrier.) It is thought that the diversity in the mechanisms is due to the availability of different carrier molecules, and to the adaptability of various induction and energy-input systems to these individual carriers. In each instance, however, the initiation of the conformational change occurs by means of basically the same physico-chemical process, namely ligand binding or ligand exchange.

Despite the basic similarity of the carrier mechanisms, two categories are distinguishable from the energetic point of view. In the one case the ligands are only weakly associated, in the other they form a true chemical bond with the carrier. In conformity with the divergent energy requirements there are also two different types of energy supplies available. The energy is provided either by an efflux (source flux), *i.e.* by the maintenance of a concentration gradient, or in the form of chemically stored energy (*e.g.* in the form of energy-rich phosphate bonds).

The supply of chemically stored energy to the transport process, *i.e.* the conversion into a vectorial mechanical movement, is considered to be performed *via* the dissociation equilibria of the acid groups of the carriers. Thus, for instance, the energy supplied by the phosphoester bond of ATP enables exchange of protons from the carrier phospho acid groups for Na^+ or Ca^{2+}. The resulting alteration of intra- and intermolecular interaction energy results in a steric displacement of the polar carrier group which represents the actual mechanical transport process.

This type of mechanism naturally demands a considerably greater effort, as regards the substrate coupling and energy input directly at the membrane, than in the case of the efflux-driven transport mechanism. These two molecular mechanisms are probably identical with the so-called facilitated and active transport processes which are already well documented in the literature from the phenomenological point of view.

3.3.2. The Regulation of Permeability

The actual permeation barriers of biomembranes are formed by lipids. Consequently, the permeability parameters must ultimately depend on the lipid characteristics. Three fundamental aspects having an important bearing on permeability may be deduced from these lipid characteristics:

The first aspect concerns the thickness of the permeation barrier in biomembranes. It is certainly of decisive importance whether the permeation barrier is formed by a monomolecular lipid layer about 22 Å thick or by a bimolecular lipid layer at least 44 Å thick. The fact that the "outer" and "inner" aqueous phases surrounding biomembranes *in vivo* possess different pH-values as well as different ion concentrations makes it appear very improbable that bimolecular lipid layers exist in biomembranes. Structures as illustrated in Figure 22 will only be stable provided the two outer phases are identical, *i.e.* in membranes without a gradient. Such membranes are in a state of thermodynamic equilibrium, *i.e.* they are "dead". The "basis membrane" might therefore also be considered as the inactive basis form of biomembranes in thermodynamic equilibrium, the fictive ideal forms of which are shown in Figure 22. A membrane adapted to different "outer" and "inner" phases, *i.e.* a membrane in the biological steady state can, however, only exist if it forms monomolecular lipid layer domains which constitute, together with a one-sided protein association, a completely asymmetric structure. The asymmetric structures shown in Figures 23a, 23b, and 23c must therefore be regarded as the most stable membrane structures in the biologically steady state. In analogy to the definition of the basis membrane the "functional membrane" can be defined as the fully active biomembrane in the biological steady state.

These statements can be understood from the lipid characteristics. Let us assume that the pH of the cell interior is 6.5 and that of the cell exterior 7.5. In a bimolecular lipid micelle of PA for instance, the inner lipid layer would have to exist in the p_{in}-conformation, while the outer lipid layer would have to adopt the p_{ex}-conformation. According to our experience this is an unstable steric situation which results in a decomposition of the micelle. The reconstituted micelle of uniform conformation would, however, undergo the same process. This decomposition process would be repeated until a protein could become associated with one side of a monomolecular lipid layer. In other words, this process of reconstitution would again lead to a stable totally asymmetric structure of the kind shown in Figure 23. Conversely, it can also be envisaged that membranes which are removed from their *in vivo* milieu (*e.g.* by isolation *in vitro*) assume a tendency to undergo symmetrization and start symmetrization operations, *i.e.* they aim towards the basis membrane state.

We consider the jumplike permeability alterations, induced and regulated by pH-changes of the cell interior, to be a second essential aspect of permeability behavior. For the accomplishment of such unsteady permeability changes the CO_2- and pH-dependent phase transition of PE seems to be an appropriate system. It is considered that with this system the regulation of permeability is performed in the physiologically relevant pH-range of pH = 5.5 to 7.5, the steepest range of control lying at pH = 6.3 corresponding to the p*K*-value of the carbonic acid system. A further system which reacts even more sensitively to pH-changes than the PE/bicarbonate/carbonic acid system does is the complex formed by PS, Ca^{2+}, and inorganic phosphate. The normal binding capacity of PS for Ca^{2+} is enhanced many times in the small pH-range of pH = 6.3 to 6.4 if inorganic phosphate is available[54].

In conclusion a third aspect deserves brief consideration: just as important as the unsteady permeation—which most likely plays an essential role in the sensory signal conversion processes—is the establishment and control of a steady permeation flux (leak-flux). A constant permeation flux should be upheld by largely pH-independent Ca^{2+} binding to the phospholipids PA, PC, PE, and PS. The decisive parameter on which such a

leak-flux will largely depend is provided by the Ca^{2+}-concentration in the cell interior which for its part is determined by the active Ca^{2+} transport.

4. Conclusion

The general outline of membrane structure and functions given above is intended as an account of experimental results and of postulates based thereon. Taken as a whole it forms a comprehensive membrane hypothesis. This paper does not set out to furnish a complete membrane concept but rather to expound our standpoint regarding membrane problems and to advance new aspects which may lead to a widening of our understanding of molecular biology and molecular medicine.

I am especially indebted to Dr. H. Emrich for his valuable assistance in the preparation of this paper and for many discussions which have made a most helpful contribution to this study. Thanks are also due to Dipl.-Phys. S. Stange and to Dipl.-Ing. D. Walter who have provided many experimental data in connection with this work and to Dipl.-Phys. H. Pape for carrying out the computer calculations. I am also grateful to Miss G. Zippan for her technical assistance and for preparing the illustrations.

Kinetics of Cooperative Conformational Transitions of Linear Biopolymers

By Gerhard Schwarz and Jürgen Engel[*]

Cooperative conformational transitions of proteins and nucleic acids are of decisive importance to many processes of molecular biology, and particularly to their regulation. They proceed *via* numerous interdependent elementary processes, and their kinetics are therefore often complicated. They are frequently also very fast. However, kinetic analyses can be carried out by chemical relaxation methods. The theoretical interpretation is comparatively simple in the case of linear biopolymers. When the linear Ising model extended for kinetics was applied to model peptides and polynucleotides, it provided an insight into the fundamental principles of cooperative transformations.

1. Introduction

The biological function of nucleic acids and proteins is largely determined by their specific conformation. This function can be modified by a change in external conditions. Conformational transitions are in fact important steps in many reactions of molecular biology (examples: allosteric regulation of enzyme activity[1, 2], replication of nucleic acids[3]). An important requirement here is that small effects should induce large changes. This can be achieved only by a positively cooperative interaction between the elementary steps of the transformation, as a result of which an elementary change that has already occurred at one part of the molecule strongly promotes other elementary changes that have not yet taken place.

We have already[4] discussed the general characteristics of cooperative conformational transitions of biopolymers for the case of linear systems, since these present comparatively simple conditions both theoretically and experimentally, and so form a good basis for the interpretation of more complicated systems. Equilibrium data on the helix-coil transitions of some synthetic polypeptides or oligonucleotides built up from identical subunits and on the structural transition between two conformations of poly-L-proline were analyzed by means of the linear Ising model. The experimental and theoretical foundations discussed in this connection form the basis of the present progress report.

To obtain a complete understanding of cooperative conformational transitions, one must consider the kinetics of such processes. Even in the case of linear model systems consisting of chemically identical residues, however, one may expect from the outset a very complicated reaction course. As an example, let us consider the α-helix-coil transition of a polyamino acid with N possible hydrogen bonds between the CO and NH groups of complementary peptide linkages. The transition to the random coil in this case obviously requires N elementary steps, *i. e.* N breakages of hydrogen bonds. Owing to the cooperativity of the transition, these individual steps must proceed at different rates according to whether or not adjacent hydrogen bonds have already been broken.

Meaningful interpretations and evaluations of kinetic experiments on systems involving very many reaction steps cannot be based directly on the classical methods of kinetics. The first or second order plots that are often found in the literature are therefore of doubtful value unless backed by theory.

Advantages are offered by the relaxation method, which involves the kinetic study of the approach to a new equilibrium after a generally small disturbance of the old equilibrium (*e. g.* by a temperature change). Relaxation curves obtained in this way reflect in principle not only the kinetics of the slowest unit process but also those of the other intermediate reactions. Their theoretical calculation for a postulated mechanism is facilitated by the fact that the kinetic differential equations can be linearized for small disturbances. However, the evaluation methods that have been found suitable for simple reactions with one or two steps[5] frequently cannot be used. It is nevertheless possible, even in complicated cases, to establish the desired quantitative relation between a reasonable reaction mechanism and the experimental curves by measurement and calculation of mean relaxation times[6, 7].

Conformational changes may be so fast as to necessitate the use of relaxation methods with very high time resolution. Thus in the case of the α-helix-coil transition, the temperature jump method revealed only that the transition time is evidently shorter than the heating time of the measuring cell (approximately 1 microsecond)[8, 9]. Only by still "faster" methods was it possible to determine transition times in the region of 10^{-8} to 10^{-6} seconds (see Section 3.1).

Other transitions can be followed by more conventional methods. Thus the denaturing time of very long-chain deoxyribonucleic acids are in the region of seconds to minutes, and the helix-I⇌helix-II transition of poly-L-proline is even slower.

2. Theoretical Principles

2.1. Execution and Evaluation of Chemical Relaxation Experiments

A kinetic analysis by chemical relaxation experiments involves essentially three steps, *i.e.* the disturbance of a stationary state of the reaction system (usually of the chemical equilibrium), measurement of the time dependence of the subsequent change in a quantity P that depends on the concentration of the reactants (*e.g.* optical density, optical rotation), and finally the interpretation of the data in the context of an overall reaction. Whereas the first two steps present at most technical and experimental problems, complicated questions of mathematical theory may arise in the third for a reaction consisting of many unit steps.

As a concrete example, let us consider an experimentally fairly clear and versatile method, *i.e.* the temperature jump method. On the basis of the well-known van't Hoff equation for the temperature dependence of chemical equilibrium constants, a chemical equilibrium is displaced in a definite manner by a temperature change. This can be brought about experimentally in approximately a microsecond, *e.g.* by electric heating[5]. If the new equilibrium is established more slowly, the change in the quantity P as a function of time can be followed as a relaxation curve on the screen of an oscilloscope.

Similar curves are obtained with sudden changes in other parameters that influence the position of the equilibrium, such as pressure, electric field, solvent composition, and pH. As shown in Figure 1, a relaxation function $\Phi(t)$ that can be found directly by experiment is thus defined. This must now be correlated quantitatively and unambiguously with the underlying reaction mechanism.

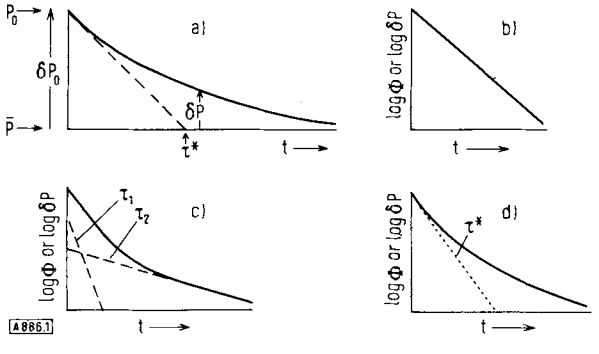

Fig. 1. Schematic representation of relaxation curves in jump experiments.
a) After a change in temperature, pressure, or other external parameter that is fast in relation to the reaction time, the initial equilibrium (measured quantity P_0) is replaced by a new equilibrium (measured quantity P). $\Phi(t) \equiv \delta P/\delta P_0$ defines a (normalized) relaxation function, which is directly obtainable by experiment. The tangent to $\Phi(t)$ at $t=0$ cuts the asymptote at $t=\tau^*$ [see eq. (4)]. b) When $\log \Phi(t)$ (or $\log \delta P$) is plotted against time, the resulting graph in the simplest case is a straight line with slope $= 0.434 \cdot 1/\tau$, when $\Phi(t)$ consists of a single exponential function. c) If there are two exponential functions with sufficiently different values of τ_1 and τ_2 (broken line), a curve with a linear tail is observed. This curve can still be satisfactorily broken down into its components. d) For several overlapping relaxation terms, an unambiguous breakdown is no longer possible, but the average relaxation time τ^* can be determined from the initial slope (dotted).

The situation is simple in a one-step process, *e.g.*

$$\mathrm{A} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \mathrm{B} \quad \text{where} \quad \frac{dc_B}{dt} = k_{12}c_A - k_{21}c_B \qquad (1a,b)$$

Because of the conservation of mass, $c_A + c_B$ is always constant, so that only one independent concentration variable is involved. This may be taken as *e.g.* c_B. The variation of any concentration-dependent parameter with time can then be calculated by solution of eq. (1b). We find here

$$\Phi(t) = e^{-t/\tau} \quad \text{where} \quad \frac{1}{\tau} = k_{12} + k_{21} \qquad (2a,b)$$

The relaxation time τ, as shown in Figure 1, can be easily determined graphically from the measured relaxation function $\Phi(t)$. If the equilibrium constant $K = k_{12}/k_{21}$ is known, the individual rate constants can be obtained directly from eq. (2b).

In more complicated reactions with more than one step, the variation of the concentration of each reactant can still be described by a differential equation. This includes the rate contributions of all elementary processes that lead to a change in the chemical state in question.

If the difference between the number of reactants and the number of mass conservation conditions is n (which corresponds to the number of "independent" reaction steps obtained when all the steps that lead to reaction cycles are struck out), the overall reaction is completely described by n kinetic differential equations. Naturally, these may be extremely complicated. However, they can be linearized (elimination of square and higher concentration terms) for small deviations from a time-independent reference state (small perturbations). A closed mathematical solution of the problem is now always possible in principle[6]. This is characterized by n time constants, the relaxation times $\tau_1, \tau_2, \tau_3 \ldots \tau_n$. These constants depend in a definite manner on the reaction mechanism, the kinetic constants, and the concentrations of the various reactants. It should be noted, however, that the individual relaxation times are not directly correlated with individual reaction steps. In particular, for the relaxation function $\Phi(t)$ of a sudden disturbance of the equilibrium, the theory gives

$$\Phi(t) = \sum_{i=1}^{n} \beta_i e^{-t/\tau_i} \quad \text{where} \quad \sum_i \beta_i = 1 \qquad (3a,b)$$

i.e. a sum of n exponential functions with the τ_i as time constants. The corresponding amplitude factors β_i do not contain any direct kinetic quantities. They are, however, dependent on the quantities measured and on the disturbing parameter. The β_i therefore generally change if *e.g.* the variation of the optical density with time is followed at a different wavelength or if a sudden change in pressure is used instead of a temperature change. However, such manipulations have no influence on the τ_i.

The complete set of relaxation times τ_i together with the corresponding amplitude factors β_i is known as the relaxation spectrum. A definite assignment of a relaxation spectrum to an experimental curve is practically impossible unless there are only a few τ_i with very different orders of

magnitude and comparable β_i (see Fig. 1b—1d). If this is not so, a kinetic analysis can be carried out with other parameters that are directly obtainable by experiment. A parameter that is particularly suitable for this purpose is the mean (reciprocal) relaxation time τ^*[6], which is defined by the following relation:

$$\frac{1}{\tau^*} \equiv \sum_i \frac{\beta_i}{\tau_i} = -\left(\frac{d\Phi}{dt}\right)_{t=0} = -\frac{1}{\delta P_0}\left(\frac{dP}{dt}\right)_{t=0} \tag{4}$$

(The relation with Φ is easily verified from eq. (3a).) As indicated in Figures 1a and 1d, τ^* is given by the tangent to the relaxation curve at time $t=0$ (instant of the disturbance). Because of this relation, τ^* is theoretically also relatively easy to obtain[6], provided that an equilibrium state of the system exists at $t=0$ (as is usually the case). Apart from a knowledge of the elementary processes and their kinetic constants, one then requires only equilibrium properties for the calculation of τ^*. There is thus no need to solve differential equations.

Very fast relaxation processes ($\tau \lesssim 1$ μsec) have so far been investigated only by methods that make use of a periodic disturbance in the form of a sine function, *e.g.* a sound wave or an alternating electric field. In this way, small fluctuations of the equilibrium state of the reaction system are produced. If the vibrations are fast enough in comparison with the reaction time, the actual change in concentration of the reactants with time will lag behind its equilibrium value. The theory then leads to an absorption of energy in the region around the relaxation frequency $\nu_R = 1/(2\pi\tau)$ (*e.g.* sound absorption when ultrasonic radiation is used, and ohmic or dielectric losses in an alternating electric field). The chemical relaxation times can be obtained by evaluation of corresponding measurements[6].

2.2. The Kinetics of the Linear Ising Model

As described earlier in some detail[4], the thermodynamic behavior of cooperative conformational transitions of linear biopolymers can be quantitatively understood with the aid of the linear Ising model. In this connection, the elementary states of the individual segments corresponding to the two extreme conformations are designated A and B. As kinetic elementary processes of the transition, therefore, we find reactions of the type

$$..XAY.. \rightleftharpoons ..XBY.. \tag{5}$$

at any point on the chain molecule; according to the basic assumption of the Ising model, the rate constants also depend on the two nearest neighboring states X and Y each of which may also be equal to A or B. We must therefore distinguish between two types of elementary reactions. The growth steps

$$\begin{matrix} ..AAB.. \\ ..BAA.. \end{matrix} \overset{k_F}{\underset{k_D}{\rightleftharpoons}} \begin{matrix} ..ABB.. \\ ..BBA.. \end{matrix} \quad \text{where } \frac{k_F}{k_D} = s \tag{6a,b,c}$$

describe the growth of existing A and B sequences, the equilibrium constant s being identical with the corresponding parameter of the Zimm-Bragg theory[4]. In the nucleation and decomposition steps

$$..AAA.. \overset{k_{FA}}{\underset{k_{DA}}{\rightleftharpoons}} ..ABA.. \quad \text{where } \frac{k_{FA}}{k_{DA}} = \sigma \cdot s \tag{7a,b}$$

and

$$..BAB.. \overset{k_{FB}}{\underset{k_{DB}}{\rightleftharpoons}} ..BBB.. \quad \text{where } \frac{k_{FB}}{k_{DB}} = \frac{s}{\sigma} \tag{8a,b}$$

the equilibrium constants σs and s/σ are fixed by the equilibrium theory, the cooperative parameter $\sigma \ll 1$ showing how much more difficult nucleation is than growth (a small σ indicates great difficulty of nucleation, *i.e.* high cooperativity). Since only the ratio of the equilibrium constants is fixed by thermodynamics, one kinetic parameter remains open for each of the processes. In the general case, special nucleation and decomposition steps for the ends of the molecule must also be taken into account, since only one nearest neighboring state exists in these positions[10].

In a chain with N segments, the sum of the molecules in the up to 2^N different conformational states must naturally remain constant. Since this at first sight is the only mass conservation condition, one should expect a practically continuous spectrum of 2^N-1 relaxation times. Fortunately, the problem can be further simplified to a greater or lesser extent according to the particular conditions. For example, the mean relaxation time can be calculated without special difficulties with the aid of the equilibrium theory and compared with experimental data.

In the common limiting case of very long chains with high cooperativity, *i.e.* for

$$N \gg \text{cooperative length } N_0 = \frac{1}{\sqrt{\sigma}} \gg 1$$

the effects at the ends of the molecule can be neglected[4]. Moreover, in the transition range (where A and B are present in roughly comparable quantities), the contributions of the processes (7) and (8) to the overall reaction become vanishingly small, since the "nuclei" ABA and BAB exist in very low concentrations in comparison with AAB, ABB, *etc.* The fraction of B segments, Θ, will therefore change almost exclusively by growth steps in accordance with eq. (6), *i.e.*

$$\frac{d\Theta}{dt} = 2k_F\gamma_{AAB} - 2k_D\gamma_{ABB} = 2k_D\{s\gamma_{AAB} - \gamma_{ABB}\} \tag{9}$$

where γ_{AAB} and γ_{ABB} are the fractions of A and B segments respectively with the neighbors A (left) and B (right) (the factor 2 arises because $\gamma_{AAB}=\gamma_{BAA}$ and $\gamma_{ABB}=\gamma_{BBA}$). If the equilibrium is suddenly disturbed at $t=0$, with the result that $s \rightarrow s+\delta s$ and the equilibrium value $\Theta_0 \rightarrow \bar{\Theta} = \Theta_0 + \delta\bar{\Theta}$, then according to eq. (4) (with $P=\Theta$, $\delta P_0 = -\delta\Theta$)[11,12]

$$\frac{1}{\tau^*} = \frac{1}{\delta\Theta}\left(\frac{d\Theta}{dt}\right)_{t=0} = 2k_D\frac{\bar{\gamma}_{AAB}}{(\delta\Theta/\delta s)} \tag{10}$$

(values with bars are equilibrium values). The thermodynamic theory enables us to express $\bar{\gamma}_{AAB}$ and $\delta\bar{\Theta}/\delta s$ by Θ and σ. Thus[10]

$$\tau^* = 4\Theta(1-\Theta)\tau^*_{max} \quad \text{where} \quad \tau^*_{max} = \frac{1}{4\sigma k_F} \tag{11a, b}$$

The maximum relaxation time τ^*_{max} thus occurs at the midpoint of the transition ($\Theta = 0.5$).

For $N \lesssim N_0$, end effects and nucleation can no longer be disregarded in the kinetics of the transition. With plausible assumptions for the nucleation rates, τ^* is obtained as a complicated function of the general form[10]

$$\tau^* = f(\Theta, \sigma, \beta', \beta'', N) \cdot \tau^*_{max} \tag{12}$$

(β', β'' describe the end effects[4, 10]). The function f always lies below the limiting function $4\Theta(1-\Theta)$ that is valid for $N \gg N_0$ according to eq. (11a), *i.e.* the transition becomes faster with decreasing chain length.

A calculation of the chemical relaxation behavior of cooperative transitions that goes beyond the average value τ^* can be carried out relatively easily in some cases if use is made of special properties of the system and special experimental conditions. Examples are the "all-or-nothing" behavior of short-chain poly-L-prolines (see Section 3.2) and oligonucleotides (see Section 3.3) and the "suppressed nucleation" in poly-L-proline (see Section 3.2). More complete calculations of kinetic curves have also been attempted for the case of long chains, with simplifying assumptions for the kinetics of the elementary processes[13-15] or by computer calculations[16, 17].

It has recently become possible to place the theory on a generally valid basis. It has been shown for any chain length that the complete kinetics of the linear Ising model are described by $4N-5$ independent, non-linear differential equations[18]. For $N \to \infty$ (*i.e.* $N \gg N_0$), the number of equations decreases to four. Three of the relaxation times defined in this way occur with vanishing amplitudes in the transition range with sufficiently high cooperativity ($N_0 \gg 1$), so that the fourth must be identical with τ^*. In this limiting case, which is of practical importance, the transition is therefore described by a single relaxation time [as eq. (2a)], despite the complicated reaction course[19].

3. Experiments on Simple Linear Model Systems

3.1. The α-Helix⇌Coil Transition

The experiments were carried out with sufficiently long polypeptide chains ($N \gg N_0$) to enable one to expect a relaxation time in accordance with eq. (11) in the transition range. The essential elementary process of the transition consists in the growth and degradation of helix fragments within a polypeptide chain by formation and rupture of hydrogen bonds at the junctions between coil and helix regions. The rate constant k_F describes the formation of such a hydrogen bond. This formation does not require any appreciable activation energy[20], but a favorable steric position of the correct CO and NH groups must be reached by suitable rotation about two intervening C—C or C—N bonds (see Fig. 2). With an activation energy of a few kcal/mole for the rotation, therefore, one may expect a k_F value of about 10^{10}—10^{11} s^{-1}. Since the σ values for polypeptides are in the region of 10^{-4}—10^{-2}, depending on the system, eq. (11b) gives maximum relaxation times of about 10^{-8} to 10^{-6} seconds for the helix-coil transition[11, 12].

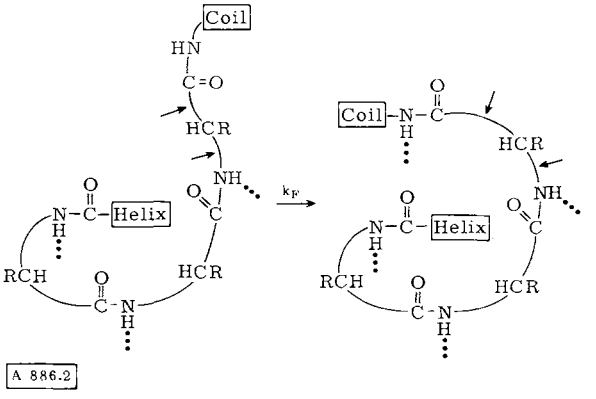

Fig. 2. Transition of a peptide linkage from the coil state to the helix state at a helix/coil junction with formation of a hydrogen bond characteristic of the α-helix between a NH and a CO group. The C—C and C—N single bonds of the amino acid residue (indicated by arrows), which allow free rotation in the coil state, are fixed by the formation of this bond.

This estimate agrees well with the experimental data obtained so far. Sound absorption measurements on polyglutamic acid (see Fig. 3) show the maximum effect at $\Theta = 0.5$ and 15 MHz[21]. According to the theory, the additional sound absorption coefficient α per wavelength λ (in aqueous solution) produced by the helix-coil transition should be

$$\alpha\lambda = \frac{\pi\rho v_\infty^2}{RT}(\Delta V)^2 \frac{2}{\sqrt{\sigma}} \{\Theta(1-\Theta)\}^{3/2} c_0 \frac{\omega\tau}{1+(\omega\tau)^2} \tag{13}$$

(ρ = density, v_∞ = velocity of sound in the solvent, ΔV = change in molar volume in the coil-helix transition, c_0 = concentration of the polypeptide in moles of monomer per unit volume[24]). From $\nu_R = 15$ MHz, τ_{max} is found to be 1×10^{-8} s. With $\sigma = 3 \times 10^{-3}$[4], therefore, eq. (11b) gives $k_F = 8 \times 10^9$ s^{-1}. Moreover, from the maximum value of $\alpha\lambda$, eq. (13) gives $\Delta V = 0.5$ cm³/mol, in agreement with direct measurements of ΔV[22].

Similar experiments with poly-L-ornithine[23] also gave $\tau^*_{max} \approx 10^{-8}$ s. The measured dependence on the degree of transition Θ confirms the formula (11a).

Measurements on poly-(γ-benzyl-L-glutamate) were carried out with the aid of a new chemical relaxation principle, which is based on the displacement of a chemical equilibrium in the direction of stronger dielectric polarization by an electric field[20]. If the associated chemical relaxation is much faster than the rotation of the dipoles involved in the reaction, in addition to the usual dielectric relaxation caused by rotation diffusion there is a further relaxation effect at higher frequencies which reflects the chemical

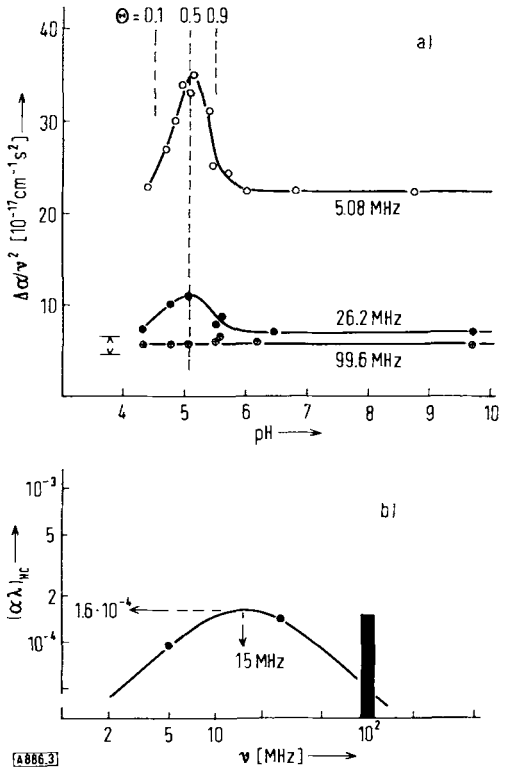

Fig. 3. Ultrasonic measurements of the helix-coil transition of polyglutamic acid in aqueous solution (after *Saksena et al.* [21]). The transition is brought about (reversibly) by pH changes in the region pH = 4 to 6. The midpoint ($\Theta = 0.5$) is situated at about pH = 5.1.
a) According to eq. (13), $\Delta\alpha/\nu^2$ ($\Delta\alpha$ = sound absorption coefficient of the solution minus that of the solvent, ν = sound frequency) should have a maximum at $\Theta = 0.5$. The experimental data plotted show this clearly for the frequencies 5.08 MHz and 26.2 MHz, whereas at 99.6 MHz, the accuracy of the measurements is evidently no longer sufficient to show the maximum. b) The sound absorption per wavelength $(\alpha\lambda)_{HC}$ resulting from the helix-coil transition (at $\Theta = 0.5$) is plotted on a double logarithmic diagram against the frequency. According to eq. (13) one should obtain a characteristic curve fixed by only two experimental points in accordance with the function $A\omega\tau/(1+\omega^2\tau^2)$ ($\omega = 2\pi\nu$, A = constant factor), which has a maximum at $\omega = 2\pi\nu_R = 1/\tau$. The values found here for ν_R and $A/2$ are indicated. They give τ and, with the aid of eq. (13), the reaction volume ΔV.

relaxation[24]. These conditions are satisfied for poly-(γ-benzyl-L-glutamate). In the transition range, the polypeptide chains consist of a sequence of coil regions and helix fragments, the latter having a considerable electric dipole moment. The applied electric field displaces the equilibrium between helix and coil regions in such a way that the helix dipoles increase in the field direction, while they decrease in the opposite direction. Since the rotation diffusion of the helices, because of their length, is much slower than the chemical relaxation of the helix growth, a relatively fast dielectric polarization occurs in addition to the rotational relaxation process. As expected, this effect is found to reach a maximum at the midpoint of the transition (see Fig. 4), as in the case of the sound absorption. The Θ-dependence, which was also measured, agrees well with eq. (11a)[25]. The effect was recently also found for the similar system poly-(β-benzyl-L-aspartate) in *m*-cresol[26].

From the τ^*_{max} of 5×10^{-7} s found for poly-(γ-benzyl-L-glutamate) and the value $\sigma = 0.4 \times 10^{-4}$ that is valid for this polypeptide at the high concentrations used[25], it is found that k_F is 1.3×10^{10} s^{-1}, which is still within the region of our earlier estimate. Another important result of these experiments is the observation that an electric field can directly influence a conformational transition. Calculation shows that a field strength of 200 kV/cm (such as occurs on biological membranes) can cause an almost complete structural transition in the system discussed here in times of about 1 μsec. It is therefore conceivable that *e.g.* nerve impulses may act directly on molecular processes by a cooperative conformational change.

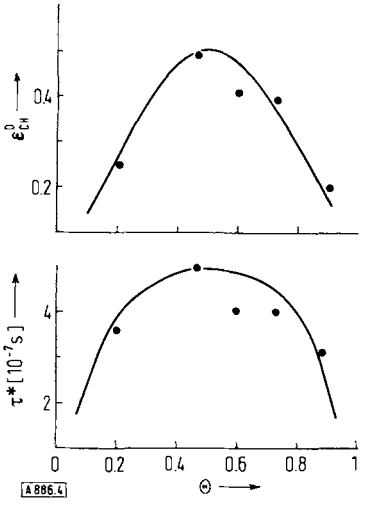

Fig. 4. Increment (maximum) of the dielectric constant (ε^0_{CH}) due to the helix-coil transition of a concentrated solution of poly-(γ-benzyl-L-glutamate) as a function of the degree of transition Θ (after [25]). The τ^* values are calculated from the dielectric data. The curves shown correspond to the calculated course.

An interpretation of double signals of the $C_\alpha H$ and NH protons in the nuclear magnetic resonance as resulting from a helix⇌coil exchange with a value of only 10^{-2} s for τ[27,28], which contradicts these results, has recently been refuted by a different interpretation of the signals[29,30].

3.2. The Helix I⇌Helix II Transition of Poly-L-proline

This transition between two ordered conformations is very cooperative[4]. A nucleus of the I form (*cis* state of the peptide linkage) inside a II helix (*trans* state of the peptide linkages) is about 10^5 times less probable at $\Theta = 0.5$ than an uninterrupted helix, and *vice versa* ($\sigma \approx 10^{-5}$, $N_0 \approx 300$). This is due to energetically unfavorable conditions at the I/II and II/I junctions. These therefore occur only relatively infrequently. For short chains, even the content of molecules containing only one junction is small in relation to the concentration of molecules in the pure forms (without such junctions).

Table 1 shows that this "all-or-nothing" case is still largely satisfied for $N = 20$. The probability that a junction occurs somewhere in the chain naturally increases with increasing chain length. It is found quantitatively (Table 1) that with $N = 100$ (*i.e.* about 1/3 of the cooperative length N_0), the content of molecules having one junction can no longer be disregarded, whereas the content of nuclei (two junctions)

is still very small ("suppressed nucleation"[17]). This simplification finally disappears above about $N=200$.

A relaxation process of the transition can be initiated by a sudden change in the solvent composition. Because of the fairly slow elementary steps of the *cis*⇌*trans* isomerization of the peptide linkage (with an activation energy of 20 kcal/mole), the course of the transition with time can be measured easily and very accurately (by polarimetry). The system thus becomes an ideal model for checking detailed predictions regarding the kinetics of cooperative transitions. Some interesting special cases will be discussed first.

Table 1. Fraction of polyproline molecules that contain I/II or II/I junctions in relation to the fraction of the pure forms I ... I and II ... II in benzyl alcohol/*n*-butanol at 70 °C and $\Theta \approx 0.5$ (calculated from the equilibrium data [4]).

Chain contains	Chain length N		
	20	100	200
only I	1	1	1
one junction	0.113	0.6	1.22
two junctions	0.003	0.09	0.37
only II	1	1	1

The kinetics of the "all-or-nothing" case are particularly simple. Since the system consists almost exclusively of chains with practically identical elementary states, we formally obtain a one-step process with first order reactions, *e.g.* for $N=4$:

$$\text{II II II II} \underset{\vec{k}}{\overset{\vec{k}}{\rightleftharpoons}} \text{I I I I} \qquad (14)$$

This process must naturally proceed *via* intermediate states. Only those with at most one junction need be considered (since all others are even less probable). If we also assume, for simplicity, that all growth steps (including those at the ends) are described by the same rate constant, the complete kinetic mechanism for (14) is found to be

$$\begin{array}{ccccc} \text{II II II II} & \underset{k_D}{\overset{k_F}{\rightleftharpoons}} & \text{I II II II} & \underset{k_D}{\overset{k_F}{\rightleftharpoons}} & \text{I I I I} \\ \sigma_I' k_F \downarrow\uparrow k_D & & & & \sigma_{II}'' k_D \downarrow\uparrow k_F \\ \text{II II II II} & & & & \text{I I I I} \\ k_D \downarrow\uparrow \sigma_I'' k_F & & & & k_F \downarrow\uparrow \sigma_{II}' k_D \\ \text{II II II I} & \underset{k_D}{\overset{k_F}{\rightleftharpoons}} & \text{II II II I} & \underset{k_D}{\overset{k_F}{\rightleftharpoons}} & \text{II I I I} \end{array} \qquad (15)$$

(σ_I', σ_I'', σ_{II}', σ_{II}'' = nucleation parameters at the chain ends[4]). Since all the intermediate states Z are present in very low concentrations, the well-known steady-state condition $dc_Z/dt=0$ may be assumed. We thus find from eq. (15) for the rate constants that occur in eq. (14)[31]:

$$\vec{k} = (\sigma_I' + \sigma_I'')\, s^{N-1} \frac{1-s}{1-s^N} k_F, \quad \bar{k} = (\sigma_{II}' + \sigma_{II}'') \frac{1-s}{1-s^N} k_D \qquad (16a,b)$$

($s = k_F/k_D$). According to eq. (2), the chemical relaxation of eq. (14) should be described by a single relaxation time $\tau = 1/(\vec{k}+\bar{k})$. Corresponding behavior was in fact found experimentally for $N<20$ (see Fig. 5a).

Relaxation curves for chains of medium length (*e.g.* $N \approx 100 \approx N_0/3$), for which the "suppressed nucleation" approximation is valid (see Table 1), proceed formally according to a zero-order rate law for a certain time if the initial equilibrium lies in the transition range (see Fig. 5b).

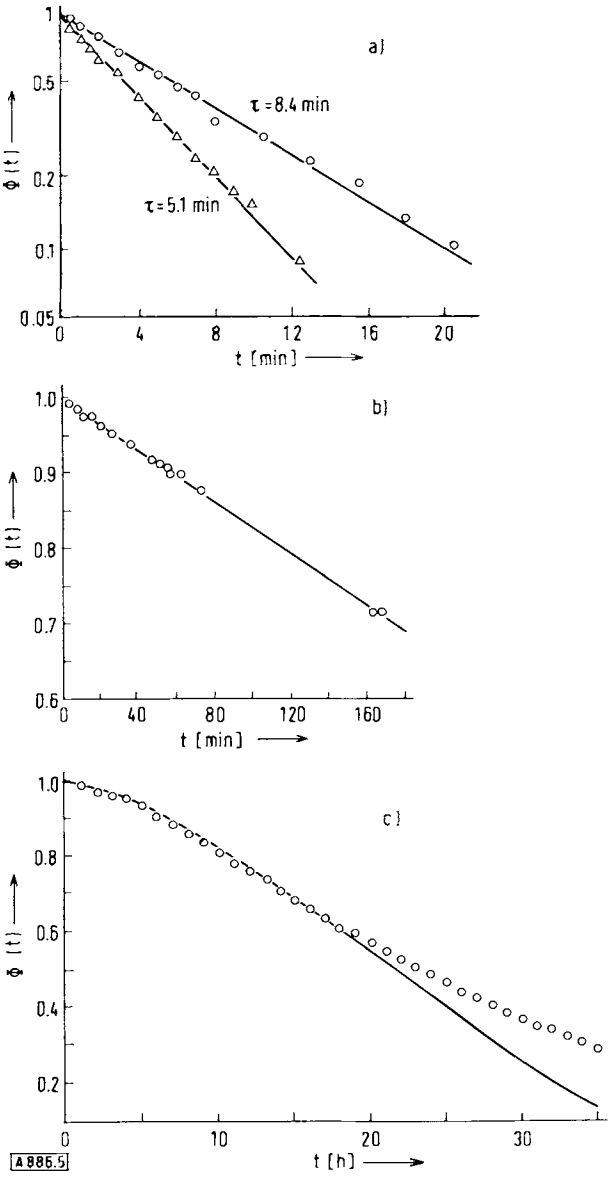

Fig. 5. Three limiting cases of the kinetics of the I⇌II transition of poly-L-proline (from [31]).
a) Semilogarithmic plot of two relaxation curves in the "all-or-nothing" range $N=18$. Change from 90 to 60 vol.-% of *n*-butanol in benzyl alcohol, whereupon $\Theta_I = 0.5 \rightarrow 0.1$ (—○—) and $0.1 \rightarrow 0.5$ —△—). The τ values differ because of the different starting conditions [corresponding to different *s* values in eq. (16)]. b) Course of the transition with time (linear plot) in the case of suppressed nucleation ($N=217$, change from $\Theta_I = 0.34$ to 0.71). The reaction rate remains constant for some time. c) Sigmoid build-up curve of the transition for $\Theta_I = 1 \rightarrow 0$ at $N=113$. Experimental values ○○○, calculated values ———.

The lack of dependence on the concentration of the I or II states still present is explained by the fact that under the above conditions, the number of actual reaction sites, *i.e.* of I/II and II/I junctions, remains constant for some time. The transition occurs essentially by a displacement of these sites in growth steps. New junctions are formed and disappear only very slowly and in comparatively small

numbers. This effect therefore becomes important only toward the end of the reaction. The initial rate in Figure 5b is thus proportional to the product of $k_F - k_D = (1 - {}^1/_s)k_F$ and the number of junctions. If the latter is known for the initial equilibrium (*e.g.* from Table 1) as well as s for the final state, k_F can be determined[31].

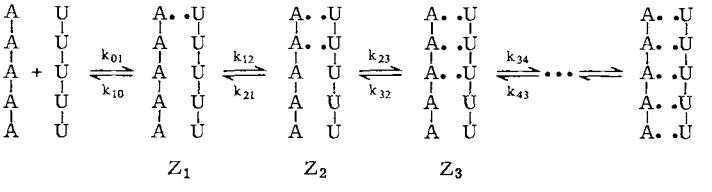
Another instructive special case is where the initial state chosen for long chains is outside the transition range, so that only one practically pure form exists at first ($\Theta = 0$ or 1). The fast growth steps can now occur only after the first junctions have been formed by nucleation, which is a very much slower process. The result is sigmoid build-up kinetics (see Fig. 5c). Experimental verification proves the validity of the special assumption in this case, namely that the rate constant of the nucleation is considerably smaller that that of the growth step. Note that the small equilibrium constant of the nucleation, $\sigma.s$, would also be explained by a correspondingly fast reverse reaction (destruction of a nucleus).

Whereas calculation of the total relaxation curve was at least approximately possible in the special cases described, the kinetic analysis was based in the general case on mean

equilibrium investigations[4,41], the "zipper model" (see Fig. 6, also Fig. 10 in[4]) proved useful for the interpretation of the kinetic data. For the short chains chosen by *Pörschke* and *Eigen* ($N \leq 18$), the all-or-nothing approximation is valid:

$$2A_N \underset{\vec{k}}{\overset{\vec{k}}{\rightleftharpoons}} (A_2)_N$$

$$A_N + U_N \underset{\vec{k}}{\overset{\vec{k}}{\rightleftharpoons}} (AU)_N \qquad (17a, b)$$



(Coil) (Double helix)

Only one relaxation time is in fact found, and this varies with the concentration of chains in the coil form as follows

$$1/\tau = 4\,\vec{k}c_{A_N} + \vec{k}$$

$$1/\tau = \vec{k}(c_{A_N} + c_{U_N}) + \vec{k} \qquad (18a, b)$$

according to the relations[5] for bimolecular single-step reactions. As in the "all-or-nothing" case of polyproline (see Section 3.2), $\vec{k}$ and $\overleftarrow{k}$ can be expressed by the elementary

$$A_5\text{-Coil} + U_5\text{-Coil} \underset{2.10^9 s^{-1}}{\overset{10^8 l\ mol^{-1} s^{-1}}{\rightleftharpoons}} Z_1 \underset{2.10^7 s^{-1}}{\overset{10^7 s^{-1}}{\rightleftharpoons}} Z_2 \underset{2.10^6 s^{-1}}{\overset{10^7 s^{-1}}{\rightleftharpoons}} Z_3 \underset{2.10^6 s^{-1}}{\overset{10^7 s^{-1}}{\rightleftharpoons}} Z_4 \underset{2.10^6 s^{-1}}{\overset{10^7 s^{-1}}{\rightleftharpoons}} (AU)_5\text{-Double helix}$$

Fig. 6. Top: Zipper model of the formation of a double helix from a poly-A and a poly-U strand for $N = 5$. Helices in which the base pairs (..) have not yet all been formed occur in small concentrations as intermediates (Z_1 to Z_4) ("all-or-nothing" case).
Bottom: Numerical values of the rate constants.

relaxation times[31-33]. As in the α-helix⇌coil transition, the theoretically[10] required maximum of τ^* in the region of $\Theta = 0.5$ was found. It was possible to determine τ^*_{max} from the dependence of τ^* on the chain length. From this and eq. (11b), the rate constant for the growth of *cis* (helix I) sequences was found to be $k_F = 1.5\ s^{-1}$ (at 70 °C in 60 vol.% *n*-butanol in benzyl alcohol), a value that agrees satisfactorily with that obtained by evaluation of the special cases described above. Similar values have in fact also been obtained completely independently for the *cis*⇌*trans* isomerization of the amide linkage in *N*,*N*-dimethylacetamide by measurement of the nuclear magnetic resonance[34-36] and from IR data[37,38].

3.3. The Double Helix⇌Coil Transition of Oligonucleotides

The formation and decomposition of short double helices of polyriboadenylic acid (poly-A) and of polyribouridylic acid (poly-U), respectively, with poly-A was investigated by *Pörschke* and *Eigen*[39,40] by the temperature jump method and by rapid mixing in a flow apparatus. As in the kinetic constants of the scheme in Figure 6 assuming steady-state conditions for all intermediate states. These are thus obtainable experimentally by measurement of the dependence of $\vec{k}$ and $\overleftarrow{k}$ on the chain length.

However, the discussion here is rather different from that in the case of polyproline. A satisfactory interpretation of the "all-or-nothing" kinetics of poly-L-proline was achieved by the assumption that in the interior of the chain, all elementary steps have equal rate constants [k_F and k_D in eq. (15)], and that only one elementary step, the nucleation step, has a different constant. On application of this simplest assumption to the formation of the double helix, $\vec{k}$ would be equal to the elementary rate constant of the nucleation step k_{01}, since by analogy with eq. (16a),

$$\vec{k} = k_{01}\frac{s^{N-1}(1-s)}{1-s^N} \approx k_{01} \qquad (19)$$

as $s \gg 1$ under the experimental conditions chosen by *Pörschke* and *Eigen*. It was found, however, that eq. (19), and hence the simplest reaction scheme on which it is

based, cannot be valid in this case, since measurement of the temperature dependence of the reaction gave a strong negative activation energy E_a for $\vec{k}$, whereas only positive activation energies are possible for rate constants of elementary reactions, *i.e.* for k_{01}. An increase in the rate with falling temperature points to one or more fast equilibria that precede the slower subsequent steps. The ΔH values of these equilibria (which are evidently negative here) contribute to the measured activation energy. It was concluded from the quantitative data (for ΔH and E_a) that Z_1, the first intermediate complex of two chains (with one base pair) though rapidly formed, also decomposes rapidly. The next intermediate state with two base pairs was also found to be labile. A stable nucleus results only for the next step (k_{23}).

The rate constants for the poly-A/poly-U system[42] at the midpoint of the transition, which agree best with the experimental data, are entered in the lower line of Figure 6. It can be seen that the formation and dissociation of a base pair takes place very rapidly (within 10^{-7} to 10^{-6} s). Nevertheless, the dissociation of a long section of helix can take considerable times (about 1 s for $N = 15$), since each opened pair in the interior of the chain closes again on average two to five times before the next pair is opened. This follows from the ratio of the rate constants of the propagation steps $s = 2$—5.

Eigen[43] has pointed out that the mutual recognition of the nucleic acid codon and anticodon of more that three nucleotides would be much too slow for biosynthesis, though increased specificity could be achieved in this way. The actual codon length of three units agrees with the length found for a stable pair; the time for the formation and redissociation is approximately 10^{-6} s.

4. Outlook for More Complicated Systems

The rate of coil formation of natural nucleic acids, because of their very great chain lengths, is determined by an effect that is negligible for short chain lengths. Since the chains in the helix are strongly twisted together, a considerable hydrodynamic resistance must be overcome in the coiling of long chains. *Crothers*[44] was the most successful in the theoretical treatment of this case, but because of various complications, no final conclusion has yet been reached[45].

The situation is even less clear for proteins, because of their more complicated three-dimensional structure. With very high cooperativity, one can expect an "all-or-nothing" mechanism with only two states that are appreciably occupied, and a correspondingly slow transition[46]. The reader is referred here to the progress report by *Pohl*[47].

To conclude, the following observation is valid for all cooperative systems. The greater the cooperativity of a system, the greater is the stability *e.g.* of a protein structure due to interactions that are very weak in some cases, and the more specific *e.g.* an enzyme can be. However, the rates of cooperative processes, *e.g.* of a conformational transition that is important to allosteric regulation, decreases. It must be assumed that in the evolution of biological macromolecules, a compromise has been reached in many cases between stability and dynamics.

Genetic Aspects of Hemoglobin Synthesis

By Berthold Schmidt[*]

Dedicated to Professor Fritz Strassmann on the occasion of his 70th birthday

The blood pigment hemoglobin (Hb) occurs in red blood cells in a higher concentration than the other proteins which are present. It is therefore particularly suitable for the investigation of genetically induced changes in protein molecules. Unlike the monomeric myoglobin (Mb) of muscle, the blood pigment is tetrameric. Several types of subunits are known that can tetramerize to hemoglobins having different properties. The information for all hemoproteins probably originated from the same primary gene. Doublets of this primary gene have developed differently, and now code different protein species. It is possible to establish from the Hb molecule the possible consequences of a mutation to the conformation and function of a protein molecule.

1. Introduction

Hemoglobin (molecular weight 64500) is a chromoprotein (containing heme as the prosthetic group), which, with a total content of barely 1 kg in the human organism, is responsible for the transport of O_2 from the lungs to O_2-consuming tissue, and also to a large extent for the transport of CO_2 in the reverse direction. The oxygen molecule reacts reversibly with the heme iron (Fe^{2+}-protoporphyrin) without oxidizing the iron, which is protected by the coordinate bond of Fe—N(histidine) (Fig. 1).

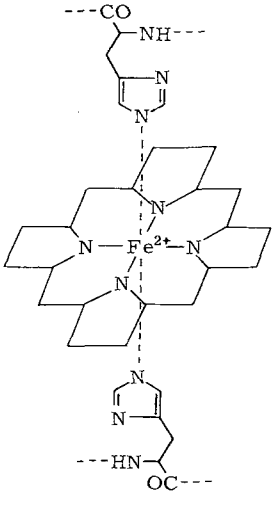

Fig. 1. Bonding of heme iron in hemoglobin. The coordination number 6 is reached by four pyrrole N and two imidazole N of histidine residues of the globin chain as ligands.

Hemoglobin (Hb) constitutes about 95% of the dry protein mass in red blood cells (erythrocytes), each of which contains 2.8×10^8 molecules of hemoglobin. Hemoglobin can therefore be investigated for genetically induced microheterogeneities or abnormalities, which cause distinct clinical symptoms, without previous purification steps, which are always accompanied by partial denaturation. Hemoglobins can be differentiated electrophoretically by differences in their migration rates. Sequence differences in individual peptide chains can be established by means of fingerprint mapping, which is based on two-dimensional chromatographic and electrophoretic development of the hydrolysis products obtained by standardized degradation with trypsin. The most accurate differentiation can be achieved by comparative overall analysis or sequence analysis of the amino acid composition of the peptide chains.

Evolutionary relationships can also be demonstrated by comparative biochemical paleogenetic studies. Thus it is practically never possible to isolate traces of proteins from fossil material, but proteins can be investigated in "living fossils", and by comparison of the amino acid sequences, they can be correlated with recent homologous proteins, *i.e.* proteins having the same function.

The genetic "experiments" set up by nature, which lead by inheritance to pathological symptoms (hemoglobinopathies) of various degrees of severity in man, produce changes[1] in the rate of synthesis and[2] in the amino acid sequence of the hemoglobin molecule. Therefore, it is possible to deduce the importance of individual amino acids to the conformation, quaternary structure, and functional modification of erythrocyte-bound Hb.

In addition to the major component hemoglobin A_1, the erythrocytes of adults also contain 1.5 to 4% of hemoglobin A_2 (A = adult). Each hemoglobin type has a pronounced quaternary structure, and is a tetramer. The three-dimensional structure was established by *Perutz*[3-8] for horse hemoglobin. The spherical molecule ($64 \times 55 \times 50$ Å^3) consists of two pairs of identical peptide chains. These globin subunits each contain a heme, and form the tetramer by noncovalent bonds (weak interactions)[3, 5, 7]. Hb A_1 consists of two α and two β chains: $\alpha_2\beta_2$. The minor component Hb A_2 can be written as $\alpha_2\delta_2$. During embryonal development, an Hb F: $\alpha_2\gamma_2$ (F = fetal) dominates, and this is preceded by an $\alpha_2\varepsilon_2$ hemoglobin type (during the first third). Starting with the last third of the embryogenesis up to the end of the first year of life, Hb F is gradually replaced by Hb A_1 (Fig. 2).

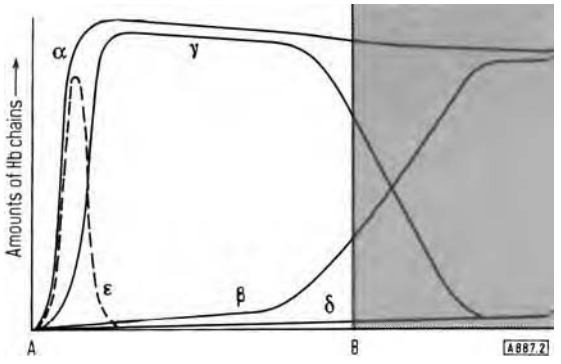

Fig. 2. Synthesis of the Hb subunits during the embryonal development (A-B) and after birth (B) [4].

Faults in the structure of the hemoglobin usually manifest themselves in functional losses and clinical symptoms, which may appear singly or together and in various degrees of severity (Table 1):

Instability of Hb to oxidation. Hemoglobin (Fe^{2+}) is converted into hemiglobin or methemoglobin (Fe^{3+}), which is no longer able to transport oxygen.

Increased or decreased O_2 binding capacity. An essential property of Hb is that O_2 transport is possible, *i.e.* O_2 uptake at the oxygen partial pressure in the lung and release of O_2 to other heme proteins (O_2 storage) in the tissue. A change in the Hb molecule may increase the strength with which O_2 is bound (Table 1, Nos. 11 and 12), so that the O_2 cannot be released where it is needed. Conversely, if O_2 binding is too weak (Table 1, No. 13), an insufficient O_2 number of oxygen molecules is bound and transported.

Instability of the Hb can considerably shorten the average life (120 days) of the erythrocyte as an Hb carrier: hemolytic anemia. Increased release of immature erythrocytes (reticulocytes) occurs from the red bone marrow, the site of formation of the Hb-carrying blood cells. The skin also assumes a yellow color (icterus), which is due to the increased quantities of bile pigments that result from the increased breakdown of Hb.

Table 1. Abnormalities in the Hb structure [2].

No.	Name [a]	Amino acid change [b]	Disturbance occurring	
1	Hb Sabine	β^{91} (F 7) Leu → Pro	fracture of F-helix	disturbance of conformation of globin subunit
2	Hb Santa Ana	β^{88} (F 4) Leu → Pro	fracture of F-helix	
3	Hb Genova	β^{28} (B 10) Leu → Pro	fracture of B-helix	
4	Hb Leiden	$\beta^{6\,or\,7}$ (A 3) Glu-deficiency	fracture of A-helix	
5	Hb Freiburg	β^{23} (B 5) Val-deficiency	fracture of B-helix	
6	Hb Borås	β^{88} (F 4) Leu → Arg	superficial loss of charge	
7	Hb Sydney	β^{67} (E 11) Val → Ala	"gap"	
8	Hb Köln	β^{98} (FG 5) Val → Met	"overfilling"	
9	Hb Toulouse	β^{66} (E 10) Lys → Glu	charge reversal, disturbance of the $\alpha^1\beta^1$ contact	
10	Hb Philly	β^{35} (C 1) Tyr → Phe	loss of H donor (hydrogen bridge)	disturbance of the $\alpha^1\beta^2$ contact
11	Hb Rainier	β^{145} (HC 2) Tyr → His	donor/acceptor reversal of a hydrogen bridge, stronger O_2 binding	
12	Hb Yakima	β^{99} (G 1) Asp → His	change of charge, stronger O_2 binding	
13	Hb Kansas	β^{102} (G 4) Asn → Thr	loss of charge, weaker O_2 binding	
14	HbS	β^{6} (A 3) Glu → Val	discharge on surface	polyagglomeration sickle cell anemia
15	HbC	β^{6} (A 3) Glu → Lys	discharge on surface	
16	Hb Bristol	β^{67} (E 11) Val → Asp	β^{63} His ..... HO_2C (Asp)	
17	HbM Milwaukee	β^{67} (E 11) Val → Glu	negative charge in heme pocket stabilizes Fe^{3+}	occurrence of methemoglobin (HbM) or hemiglobin
18	HbM Iwate	α^{87} (F 8) His (prox.) → Tyr	Fe^{3+} can readily be formed due to absence of the lone pair (imidazole-N)	
19	HbM Boston	α^{58} (E 7) His (dist.) → Tyr		
20	HbM Hyde Park	β^{92} (F 8) His (prox.) → Tyr		
21	HbM Saskatoon	β^{63} (E 7) His (dist.) → Tyr		
22	Hb Zürich	β^{63} (E 7) His → Arg	imidazole replaced by guanidyl-N: danger of methemoglobinemia occurring	
23	Hb Hiroshima	β^{143} (H 21) His → Asp	absence of basic point of attack for acid effectors: stronger O_2 binding	

[a] Abnormal hemoglobins are usually named after a place or person connected with their first detection.
[b] A symbol of the type β^{91} refers to the amino acid position 91 of the β chain, while F 7 denotes the seventh position of helix segment F.

2. Genetic Information

It is assumed[9, 10] that the information for the present-day variants of the heme proteins, *i.e.* of substances that can bind (myoglobin) or transport (α,β,γ,δ subunits of hemoglobin) O_2, is derived from a phylogenetically old gene. It is concluded from comparisons of amino acid sequences between heme proteins that are available at present that this primary gene could have coded a protein containing 154 (or more) amino acids.

Most genes are present in the chromosomes of a cell in several "redundant copies". In the case of protein synthesis the cell can thus rapidly synthesize a given type of protein with the aid of its ribosomal apparatus. This multiplicity is due to gene duplications that have occurred in the course of time.

From these identical gene doublets, mutations that affect individual gene loci separately can lead to modified genes, which contain modified information for the protein synthesis. Growing independence (migration of gene sections that have been split off, loss of base triplets) may lead to the formation of genes that contain the information for homologous proteins instead of for identical species.

The oldest heme protein from the homologous Mb/Hb group is myoglobin (Mb). This "muscle pigment" is a monomeric heme protein. Its peptide chain consists of 153 amino acids (molecular weight 17000). The sequence of sperm whale Mb has been elucidated[11]. The three-dimensional structure was determined by *Kendrew*[12, 13] for horse Mb.

Comparison of the amino acid sequence of the globin subunits of Hb with that of Mb reveals differences in 120 ± 5 positions[14]. The amino acids agree only in about 30 positions. The variation ± 5 arises when sperm whale Mb is compared with the subunits of all the vertebrate Hb types investigated so far. It means that differences between species may be regarded in the same way as an error range in connection with the statement that *the* Mb chain differs from *the* Hb subunit in 120 amino acid positions.

From these amino acid differences, *Pauling*[15] has tried to calculate the times required for such changes in the course of evolution. The basis of his arguments is as follows. Comparison of the amino acid sequence of the globin subunits of mammalian Hb (horse, pig, ox, rabbit) shows differences in 22 positions between the α and β chains. If each chain developed independently, this corresponds to 11 changes per chain. If one assumes that the development of the higher mammals began about 80 million years ago, one finds a period of 7 million years for each mutation (*i.e.* for each change). For events that happened very far back in time, it is advisable to reckon on the next higher order of magnitude, *i.e.* 10 million years per amino acid difference.

On application of the 10^7 year value to the myoglobin/globin difference, it is found that the Mb/Hb dichotomy occurred $(120/2) \times 10^7 = 600 \pm 50$ million years ago. "Snapshots" of this development are provided by species of animals that have developed only slightly since their first appearance. The earliest Hb forms can be studied in such "living fossils". Monomeric Hb types with 146 amino acids have been isolated from Cyclostomi[*] (hagfishes, lampreys)[16, 17].

From the pool of primary gene, the information for myoglobin (Mb) developed first, characterized by the loss of a base triplet that was retained in later gene doublets. The genetic information for the synthesis of early heme proteins of the Hb type shows the same deletion as for Mb, with the addition of a further loss, which may have resulted from a gene displacement. Thus the early monomeric Hb types show a deficit of 7 amino acids at the C-terminal end of the chain in relation to Mb. The primitive vertebrate Hb in the oxygenated state exhibits monomeric character, like Mb.

The gene pool for the primary form of monomeric Hb, which aggregated only weakly, was probably the basis of the development of the information for the α chain, which also exhibits no tendency to aggregate with its own kind. On comparison of the amino acid sequences, it is found that in the α-subunit of Hb, as in Mb and primary Hb, a deletion has occurred within the chain, as well as shortening by 6 amino acids at the C-terminus. The α subunit is characterized by two further "gaps" totaling 6 amino acids, and giving a typical number of 141 amino acids for the α chain.

The information for the synthesis of non-α chains developed from the gene pool much later than the information for the α subunit. The assumption of the later development is based on the fact that the non-α chains differ from the α chain only in 85 ± 10 positions[14]. *Pauling* believes that the α gene and the non-α gene separated 380 million years ago.

All the non-α chains exhibit the C-terminal shortening by 6 amino acids in relation to Mb that is characteristic of the globin subunits. They lack the "old" triplet deletion that occurs in Mb and primary Hb. It is replaced by a deletion of two triplets that is characteristic of the non-α chains. The characteristic length of the non-α chains is thus found to be 154 (primary gene) $-6-2=146$ amino acids.

The oldest non-α gene is the β gene, which contains the information for the synthesis of the β chain. Other non-α globins have probably developed from doublets of the β gene, since they exhibit a greater similarity to the β chain.

The information for the synthesis of the γ subunits evolved first from doublets of the β gene. According to *Pauling*'s ideas, 42 ± 6 amino acid differences between the β and γ chains indicates that the development of the γ gene from the β gene pool occurred about 150 million years ago. The γ gene remained immediately adjacent to the β gene. 35 million years ago, the δ gene separated from the β-γ gene assembly[9]. Here again, the time is deduced by the application of *Pauling*'s ideas to the difference of 10 amino acids between the δ and β chains.

The close neighborhood of the β-gene family in the genome[19] is deduced from experimental findings. A relation must exist between the transcription of β and γ genes, such that γ-globin suppresses the synthesis of β-globin. If the synthesis of the γ chains slowly dies out, the inhibition of the β-globin synthesis also vanishes, and this synthesis increases in proportion to the decrease in the γ-globin

[*] Cyclostomi are the oldest vertebrates (still without mandible). They developed 450 million years ago.

synthesis (cf. Fig. 2)[20]. The β and δ genes are even closer together. Investigation of the effect of hormone (erythropoietin[21]) on the Hb synthesis shows that the rates of synthesis of the β and δ chains increase in a constant ratio of 40:1[22]. There are various possible reasons for the greater rate of synthesis of the β chain: 1. The transport of the same amino acid may be effected by different tRNA's[23,24]. A deficit of one type of tRNA can lead to a deficit in the synthesis of a protein. 2. It is conceivable that complications arise in the folding for the younger δ chain. 3. The mRNA's or their ribosomal adducts may differ in their stability for the various globin subunits[1]. It is not yet known which of these is the true cause.

Closeness of the β and δ genes is also indicated by the occurrence of hybrid globin subunits, which have an N-terminal δ structure and a C-terminal β structure in the non-α chain. Three such hybrids are known at present[25,26].

Little is known about an ε subunit, which occurs in the first third of the embryonal Hb synthesis (Fig. 2). It disappears when the synthesis of the γ chains begins, just as the synthesis of the γ chains disappears later as soon as β chains are synthesized.

Though up to 120 positions in the sequence of the homologous hemoproteins may be differently occupied, depending on phylogenetic age, 11 positions are always identically occupied in all the peptide chains investigated so far[10]; these include the two histidine residues, which guarantee heme binding, and close to these a proline, which prevents any interfering helix formation in the vicinity of the heme binding site.

The globin subunits of the non-α type exhibit the property of aggregation even in the oxygenated state. Homotetramers and heterotetramers may be formed. Homotetramers of the type β_4 appear under pathological conditions, and are much less suitable for the transport of O_2 than the heterotetramer $\alpha_2\beta_2$, which first appears in the phylogeny of the vertebrates with the formation of the mandible. An early Hb of this type has been investigated in the carp, a teleost[18].

3. Changes in the Rate of Synthesis

After the embryonal development, the synthesis of Hb occurs under physiological conditions only in one type of cell of the red bone marrow, *i.e.* the (pro)erythroblasts. In these nucleated precursors of the (in mammals) later non-nucleated erythrocyte, the information required for the Hb synthesis can be totally recalled from the genome, *i.e.* only here can the requirements be satisfied for all the partial steps of the Hb synthesis. It is not clear how the cellular Hb synthesis is terminated. Hb probably represses certain genome sections after its synthesis, so that further transcription is suppressed. The globin synthesis continues until intact messenger-RNA is present for all peptide types[27] and a functioning *ribosomal* apparatus is available (cf. Fig. 3).

During the transcription, the copies of some genome sections required for the synthesis of the globin subunits are produced in the form of messenger-RNA. From each gene section there will be different mRNA's produced, *i.e.* the cistron codes an individual peptide chain. The unicistronal mRNA's for the synthesis of globin subunits have a remarkably long life of the order of days. They can be isolated from reticulocytes that have long been without nuclei, and Hb can be synthesized (starting at the N-terminal end) with the aid of the mRNA's from these reticulocytes in protein-synthesizing *in-vitro* systems[28].

In the translation of the mRNA information into α subunits, the polysomes (functional aggregates of the ribosomes for the translation of an mRNA) are found to be mostly pentamers, whereas hexamers can be detected in the synthesis of β subunits. It is possible that the β-mRNA, which is about 15 nucleotides longer, provides room for an additional ribosome.

The stoichiometric aggregation of α and β chains to form the complete tetramer takes place at the ribosomal level[29-31]. As in the myoglobin synthesis, the complete α chains separate from the ribosomes and are released into the cytosol. They do not form tetramers, but they may clump together in cases of pathological overfilling (β-thalassemia). Under physiological conditions, the free α chains enter into interaction with the longer, still growing globin subunits of the β family, whereupon αβ dimers detach themselves from the polysomes[29-33]. It is no longer believed that the β subunits detach themselves independently and influence the termination of the α subunits[34-36]. The αβ dimers then undergo interaction with the heme pool[37-39] of the cytosol[40]. Though monomeric α-globin does not bind heme[32], the affinity of heme for α-globin is greater than that for the β subunit[41,42], so that the α subunits of the dimers first become charged with the heme, and then the β subunits.

A deficit in preparation of special globin subunits is usually found if the rate of synthesis of one subunit is decreased. In α-thalassemia, the α chains are synthesized in insufficient quantity[1]. Since the α-gene occurs in isolation in the genome[43], the preparation of the non-α chains is not inhibited. The rate of synthesis of the β chains is then higher by a factor of 1.5 to 3. Under these conditions, the non-α chains form homotetramers[44], and an Hb H (β_4) can be detected in the erythrocytes[45,46]. This functionally inferior Hb form is unstable, and tends to form clumps, which can be detected as Heinz inclusion bodies (in the erythrocytes). Since the disturbance of the synthesis occurs during the embryonal development, self-aggregation of the γ chains occurs here, and Hb Bart (γ_4) appears[47].

In β-thalassemia, the rate of synthesis of the β chains is reduced. α chains are synthesized in sufficient quantity and released into the cytosol. Instead of the formation of α_4 tetramers, however, clumping occurs[48]. Because of the close neighborhood of the β family in the genome, it is possible that partial filling of the β pool can occur if *e.g.* the γ gene is not inactivated. The result is a persistence of Hb F, since the γ chains are available to the α chains for tetramer formation even after birth. The synthesis of δ chains is also increased under these conditions, so that where there is a deficit of Hb A_1 increased quantities of Hb F and Hb A_2 are found.

4. Replacement of Individual Amino Acids

Whereas changes in the rate of synthesis of the globin subunits probably occur at the ribosomal level, point mutations, which may lead to the replacement of individual amino acids, take place in the genome. Each amino acid is coded in the genome (Fig. 3) by a base triplet. By transcription the triplet information from DNA appears as the codon in the mRNA. Most amino acids are fixed only by the first two bases of their codons in the mRNA. For some, the third base position of the codon may be occupied by any base, but in most cases one of two bases may appear without making the coding uncertain.

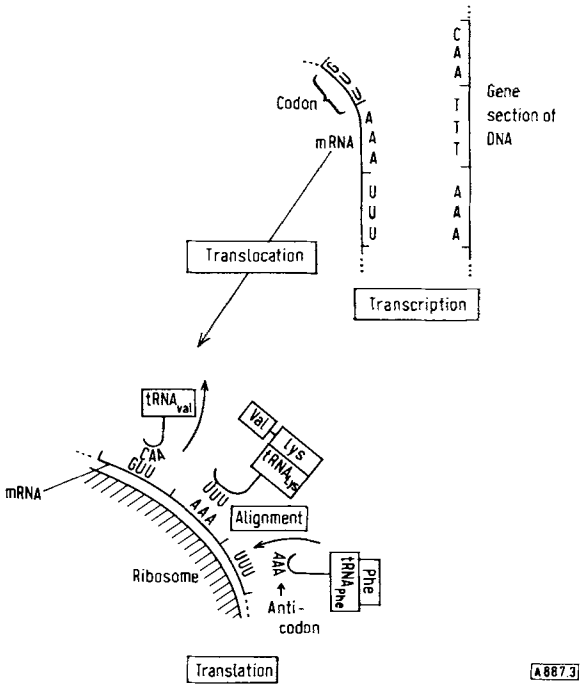

Fig. 3. Scheme of protein synthesis. At the top right, the mobile mRNA is synthesized enzymatically on an exposed gene segment of the DNA (transcription). The mRNA migrates to the ribosome, *i.e.* to the protein-synthesizing apparatus (translocation). In a checking process (according to the rule of base pairing), the anticodon of the transfer RNA (tRNA) charged with amino acid moves to the codon of the mRNA (translation). The newly supplied amino acid (in this case phenylalanine by $tRNA_{Phe}$) is attached to the already synthesized peptide residue (in this case valine-lysine).

For example, the amino acid glycine (Gly) is represented by the mRNA codon GGX, where X may be A, G, C, or U. Only one amino acid, *i.e.* methionine (Met), has an invariable code (the codon AUA).

Consequently, every point mutation, *i.e.* every base exchange, in the gene need not lead to a change in an amino acid in the protein chain. If a tolerated base exchange occurs in the third position of the codon (wobbling), there is no change in the amino acid. On the other hand, base faults in the first two positions of the codon nearly always lead to an amino acid change: $GA^A_G \rightarrow GU^A_G$ causes the replacement of glutamic acid by valine (Glu→Val), which leads to the formation of HbS (sickle cell anemia) if it occurs in position 6 of the β chain.

More than 100 amino acid changes have so far been found in globin subunits, more of these being in the β chains[15, 50] than in the α chains, probably because the oxygenation of Hb is promoted by a change in the conformation of the β subunit, and changes in the β chains are therefore more likely to be clinically noticeable. This means that the mutations that are *found* most often are not necessarily identical with those that *occur* most often, since one looks for molecular changes only if pathological symptoms appear. In tolerated mutations, other types of base exchange may occur more frequently[49].

The most common base exchange is the replacement of A by G in the codon. An example is AA^A_G (Lys)→GA^A_G (Glu). As far as the interactions between the side chains of the amino acids in the protein are concerned, this exchange means a charge reversal (Lys = $-NH_3^+$, Glu = $-CO_2^-$). The reverse exchange (A in place of G) is also common: GG^U_C (Gly)→GA^U_C (Asp). That means a neutral amino acid with a very low bulk (glycine) is thus replaced by a polar amino acid (aspartic acid), which can enter into ionic interactions or form hydrogen bonds, and which can cause disturbances by these properties.

If this exchange of two purine bases (A and G) of the codon is projected into the genome, it corresponds there to "confusion" between the pyrimidine bases cytosine and thymine, which may also result from a disturbance of the transfer of amino and methyl groups in the cell nucleus (Fig. 4).

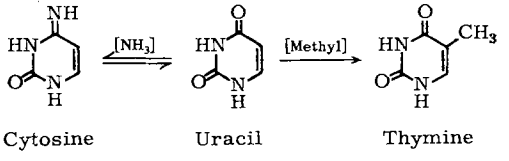

Fig. 4. The two most important pyrimidine bases of the nucleic acids. They are linked by enzymatic amination and methylation.

The replacement of a polar side chain, which enters into ionic interactions, will always lead to a change in conformation, particularly if a charge reversal occurs (Table 1, No. 9).

Hydrogen bonds between peptide structures or between the side chains of individual amino acids, *e.g.* between phenolic hydroxyl (Tyr) and a hetero atom (carboxyl O, heterocyclic N), will also collapse if one partner is absent.

5. The Globin Subunit

The globin subunits of Hb have a characteristic conformation, which is very similar to that of Mb[12]. 75% of the secondary structure consists of helix structures, which are grouped into eight sections A to H (see Fig. 5)[66]. Hydrophobic contacts predominate in the interior of the structure, particularly between the amino acids leucine, isoleucine, valine, and phenylalanine[5, 51, 52]. The replacement of such amino acids by others with polar side chains can lead to the breakdown of the conformation. If the same exchange takes place on the surface of the molecule, the conformation

is only slightly affected (Table 1, No. 6). On replacement of one amino acid by another, even the difference in bulk may be sufficient to labilize the conformation (Table 1, Nos. 7

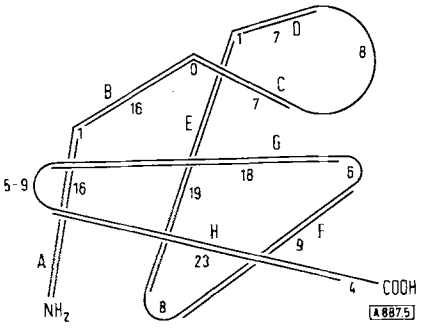

Fig. 5. Schematic representation of helical (double lines) and nonhelical (single lines) sections in myoglobin [67]. The numbers indicate how many amino acids are present in the various sections.

and 8), or the α-helix typical of a section of the conformation may be interrupted (also by the omission of an amino acid), and this again leads to unstable hemoglobins (Table 1, Nos. 1—3, 4 and 5).

5.1. Globin-Globin Contacts

In addition to the polar and nonpolar interactions within a globin subunit, side chains of amino acids in its external zone must allow the establishment of contacts between the subunits so that the quaternary structure can be formed from four subunits. The interactions between the four monomers differ in their nature. There is a stronger type of bond $\alpha^1\beta^1$ and $\alpha^2\beta^2$ and a weaker globin-globin contact $\alpha^1\beta^2$ and $\alpha^2\beta^1$. In the case $\alpha^1\beta^1$, 110 atoms from side chains of 34 amino acids approach to a distance of <4 Å. In the case $\alpha^1\beta^2$, contacts (with a distance of <4 Å) are formed between 80 atoms of the side chains of 19 amino acids[7]. The dissociation of the tetramer into dimeric subunits leads to the "stronger" $\alpha^1\beta^1$ dimer[53]: $\alpha_2\beta_2 \rightleftharpoons 2\,\alpha^1\beta^1$. The difference in the strength of the bonds between the subunits is a necessary condition for conformational changes in the Hb molecule, as it allows the two $\alpha^1\beta^1$ dimers to slip in relation to each other. This conformational change allows an allosteric activation of the oxygenation (charging with O_2) and indirectly of the deoxygenation (release of O_2) of the Hb in the erythrocyte. In the deoxygenated state, the conformation of the β chain has a loose structure, while in the oxygenated state it has a more compact structure. The conformation compression[8] occurs by widening of the heme pocket and reversible replacement of a coordinate Fe—N bond by an Fe—O_2 bond.

The optimum reversible charging with O_2 is possible only on the heterotetramer $\alpha_2\beta_2$. The homotetramers β_4 and γ_4 bind O_2 more strongly and exhibit no allosteric promotion of the binding of O_2[54]. Hb F ($\alpha_2\gamma_2$) binds O_2 more strongly than Hb A_1, since a lower O_2 partial pressure is available for supplying the fetal circulation. If the binding of O_2 is too strong, as in the homotetramers, the release of O_2 in the tissue, *e.g.* to Mb, is impossible, and O_2 transport is thus prevented.

If amino acids that are essential to the formation of the quaternary structure are replaced, the $\alpha^1\beta^1$ contacts (Table 1, No. 9) or the $\alpha^1\beta^2$ contacts (Table 1, Nos. 10—13) may be labilized.

Instead of leading to breakdown of the quaternary structure, the replacement of an amino acid may result in an increased tendency to aggregate. Since hydrophobic interactions predominate by far[7] among the secondary valence forces forming the tetramer, an excess of nonpolar side chains can lead to higher aggregates. The formation of Hb polymers results macroscopically in clumping of the Hb with a corresponding functional loss in the transport of O_2. The increased tendency to aggregate is particularly noticeable in deoxygenated Hb, since a looser conformation here facilitates interactions between the subunits. The best-known example of a pathological Hb type with an amino acid exchange on the surface of the molecule is sickle cell Hb (Table 1, Nos. 14 and 15). The replacement of the negatively charged side chain of Glu by the nonpolar Val leads to the formation of a hydrophobic contact in excess, which can induce polyaggregation. The clumping of Hb results in a decrease in the cell volume, and the characteristic sickle cell shape of the erythrocytes is produced.

5.2. Heme-Globin Contact

The function of Hb is extremely sensitive to disturbances in the amino acid sequence in the immediate neighborhood of the heme bonding site. The following are essential: 1. One proline, which suppresses the formation of a helical structure in this region. 2. Two histidines in this region, whose imidazole N serves for coordination of the Fe^{2+}. 3. The side chains of other amino acids, *e.g.* $\beta^{41\,Phe}$, $\beta^{42\,Phe}$, in the vicinity of the histidine residues. These side chains help to maintain a hydrophobic medium, in which the planar heme is embedded (Fig. 6). If this hydrophobic medium is disturb-

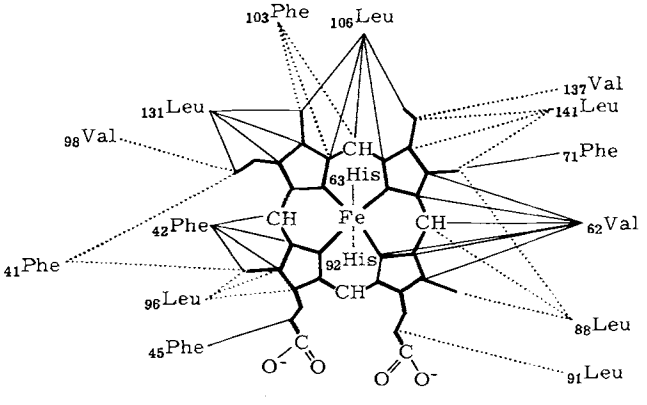

Fig. 6. Heme-globin contacts [7]. The diagram shows which amino acid side chains of the β chain interact with the porphin system of the heme in the β subunit. Continuous lines lead to amino acids lying above the plane of the heme, and dotted lines to those lying below this plane. The numbers indicate the positions of the amino acids in the β chain.

ed (even disturbances without charge effects are sufficient), the degradation of the Hb may be induced (Table 1, Nos. 7 and 8). A more striking effect is the labilization on incorporation of amino acids with polar groups. If a negative charge (Table 1, No. 17) appears in the heme pocket, the conditions for stabilization of a trivalent Fe are satisfied. Under physiological conditions, autocatalytic oxidation of Fe^{2+} (hemoglobin) to Fe^{3+} (hemiglobin, HbM) of the order of a few % occurs on oxygenation. The Fe^{3+} is reduced again by the hemiglobin reductase, which is NADP-dependent. The reduction equivalents are provided by the carbohydrate metabolism of the erythrocytes. If a negative charge is available to stabilize the Fe^{3+}, no enzymatic reduction can take place, and the hemiglobin is lost for the transport of O_2.

If the proton of a carboxyl group or the H donor of a hydrogen bond enters into competition with the electron gap of the heme Fe for the imidazole N (His), the Fe—N (His) bond is not formed, and Fe oxidation is possible (Table 1, No. 16). Loss of the Fe—N (His) bond by replacement of the histidine always leads to oxidation of the Fe and to the appearance of Hb M. All four conceivable possibilities of His replacement are found in nature; either the proximal or the distal His in α and β chains may be replaced (Table 1, Nos. 18—21). If the imidazole N is replaced by another ligand containing N, *e.g.* guanidyl N (Arg) (Table 1, No. 22), the Fe is more susceptible to oxidation than when bonded to His—N. Under the action of nitro derivatives (drugs), methemoglobinemia may occur.

6. Effectors

Allosteric changes in the conformation of enzyme proteins can greatly alter the activity of the enzyme. Substances that bring about such changes in the conformation of a protein are known as effectors.

The function of the Hb molecule can also be influenced by effectors. Oxygenation promotes further O_2 uptake after the manner of allosteric activation (Fig. 7). Deoxygenation can similarly be promoted. A cavity that remains free in the molecule of the $\alpha_2\beta_2$ heterotetramer contains basic side groups ($\beta^{143\,His}$), which allow the attack of CO_2 (Bohr effect) by formation of carbimino groupings[55-57]. If such a point of attack is lacking (Table 1, No. 23), deoxygenation is hindered[58-60].

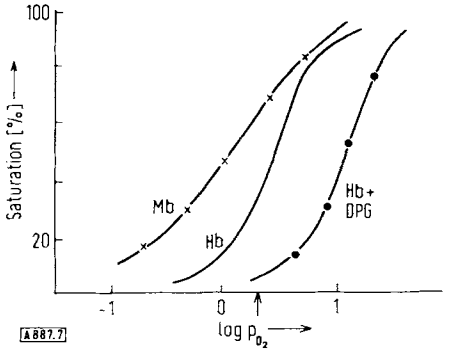

Fig. 7. O_2 binding curves. At the O_2 partial pressure prevailing in the tissue (↑), the tetrameric Hb is only slightly charged with O_2, while large quantities are bound to Mb, corresponding to the functions of Hb (O_2 transport) and Mb (O_2 storage). The dissociation of O_2 from Hb is particularly favored when it is bound in erythrocytes (–·–), *i.e.* in the presence of 2,3-diphosphoglycerate (DPG) [62].

Investigations on erythrocyte-bound and free Hb showed differences in the strength with which O_2 is bound (see Fig. 7). The mammalian erythrocyte contains a high concentration of a glycolysis metabolite that occurs only in catalytic quantities in other glycolyzing tissues; this substance is 2,3-diphosphoglycerate (DPG). When bonded molarly 1:1 to basic functions (His) of the heterotetramer $\alpha_2\beta_2$[62], DPG induces a change in conformation within the erythrocyte such that the bonding of O_2 is weakened and deoxygenation is promoted[63-65]. In bird erythrocytes, the function of DPG is taken over by an inositol hexaphosphate[62]. This allosteric control by acidic effectors is possible only in the phylogenetically youngest $\alpha_2\beta_2$ ($\alpha_2\delta_2$) heterotetramers[61] (Hb F contains an $\alpha^{138\,Ser}$ or $\gamma^{143\,Ser}$ instead of $\beta^{143\,His}$). The homotetramers β_4 and γ_4 exhibit no Bohr effect and no loosening of O_2 by DPG[54].

Fluorinated β-Sultones

By I. L. Knunyants and G. A. Sokolski[*]

Fluorinated β-sultones are formed on addition of sulfur trioxide to fluorinated olefins. Tetrafluoroethanesultone has been studied particularly thoroughly. The title compounds are characterized by the ease with which they undergo ring cleavage to give, *e.g.*, derivatives of α-sulfo carboxylic acids, of sulfonic acids, of carboxylic acids, and of sulfuric acid. Fluorinated compounds of this type containing an α-hydrogen atom are especially valuable in preparative work.

1. Introduction

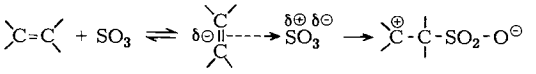
The name sultones refers to the inner esters of hydroxyalkanesulfonic acids, which may also be regarded as sulfur analogs of lactones. As with lactones, there exist α-, β-, γ-, δ-sultones and numerous other cyclic sulfonates of this kind. Among the unsubstituted compounds, the γ- and δ-sultones having five- and six-membered rings, respectively, are the most stable. Unsubstituted β-sultones decompose

$$X_2C{=}CF_2 + SO_3 \longrightarrow X_2\langle\begin{smallmatrix}SO_2\\ \diamond\\ O\\ F_2\end{smallmatrix} \quad (1)$$

extremely readily and have not yet been isolated. In contrast, fluorinated β-sultones of type *(1)*, formed by addition of sulfur trioxide to polyfluoroolefins, are relatively stable. Their formation by this reaction has been well studied for numerous examples. Moreover, a synthesis *via* sulfene intermediates has also been described[1a].

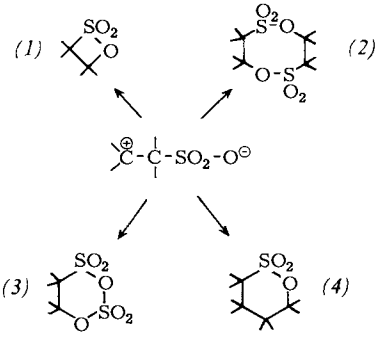
2. Synthesis of β-Sultones

That sulfur trioxide reacts with olefins was demonstrated as long ago as the beginning of the 19th Century for the case of ethylene[1b,2]. The reaction was subsequently extended to a large variety of substituted ethylenes[3–6], to a number of chloroolefins[7–11], and fairly recently to fluoroolefins[12–18].



The reactions of sulfur trioxide with polar reagents of type A-B can be described by a series of equilibria.

$$\overset{\delta\oplus\ \delta\ominus}{A\text{-}B} + SO_3 \rightleftharpoons \overset{\delta\oplus\delta\ominus}{A\text{-}B\text{-}SO_2\text{-}O^{\ominus}} \rightleftharpoons \overset{\oplus}{A}\text{-}B\text{-}SO_2\text{-}O^{\ominus} \rightleftharpoons B\text{-}SO_2\text{-}O\text{-}A$$



The initial step in the reaction of sulfur trioxide with olefins is an electrophilic attack by sulfur trioxide on the double

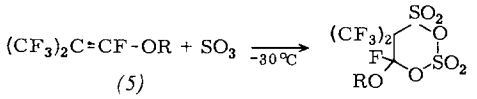
[*] Prof. Dr. I. L. Knunyants and Prof. Dr. G. A. Sokolski
Institute for Organoelement Compounds of the
Academy of Sciences of the USSR
Moscow V 312, Ul. Vavilova 28 (USSR)

bond[6, 19, 20]. The intermediate π-complex isomerizes to give a zwitterion in which the sulfur atom is bonded covalently to the carbon atom having an enhanced electron density.

Further reaction of the zwitterion is determined by the properties of the starting olefin and the reaction conditions. Apart from the β-sultones *(1)*, the eight- and six-membered heterocycles *(2)* and *(3)*, each containing two —SO_2—O— groups, and the δ-sultones *(4)* may be formed in individual cases.

Addition of sulfur trioxide to unsubstituted olefins proceeds extremely readily and is so exothermic that the primary adduct is very difficult to trap. It is therefore necessary to subdue the electron-accepting properties of sulfur trioxide, which is readily accomplished by using sulfur trioxide in the form of its quasi-complexes, *e.g.* with dioxane (Suter-Bordwell method) or with pyridine (Terent'ev method).

The presence of electron-withdrawing substituents in the olefin reduces its proclivity to add sulfur trioxide. Whereas ethylene[21] and vinyl chloride[10] even react with pyridine-sulfur trioxide, addition to dichloro-, trichloro-, and tetrachloroethylene occurs only with free sulfur trioxide. 1,2-Dichloroethylene reacts exothermally at room temperature[9] but trichloroethylene[8, 11] and especially tetrachloroethylene react only on heating[7, 22]. Reaction products of β-sultones are formed in all these cases.

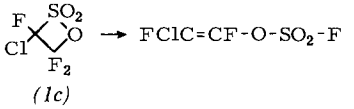


The opposite is observed on going from chloro- to fluoro-compounds within the series of perhalogenoolefins: fluoroolefins react more readily with sulfur trioxide than do their chlorine analogs. Thus tetrachloroethylene and fluorotrichloroethylene react with sulfur trioxide at 180—200 and 160—180 °C[22] respectively, symmetrical and unsymmetrical difluorodichloroethylene at 80 °C[12, 15, 18], and tetrafluoroethylene at 40—50 °C[17].

The optimum temperatures for the reaction of various fluoroethylenes with sulfur trioxide are given below:

$F_2C{=}CF_2$	$FHC{=}CF_2$	$H_2C{=}CF_2$	$H_2C{=}CHF$
40—50 °C	20—30 °C	0 °C	−30 °C

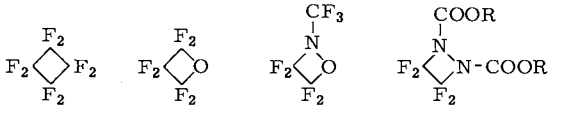
Finally, an alkoxy group in a fluoroolefin activates the molecule so strongly that some of these compounds of type *(5)* still even react with sulfur trioxide at −30 °C[23].



Reaction of polyfluoroolefins correspondingly gave β-sultones or compounds of type *(3)* (Table 1). Attempts to isolate the highly unstable primary adducts formed by vinyl fluoride[18] and fluorotrichloroethylene[22] were unsuccessful. Tetrafluoroethylene gives not only the β-sultone *(1f)* and the six-membered heterocycle *(3b)*, but also the eight-membered cyclic compound *(2a)*[24]; we were unable to

(5)

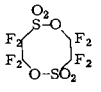
confirm whether tetrafluoroethanesultone *(1f)* is accompanied by tetrafluoro-1,3,2-dioxathiolane 2-oxide[15, 18]. This cyclic glycol sulfite was not isolated but merely postulated to explain the results of alkaline hydrolysis of *(1f)* and the ^{19}F-NMR spectra of its hydrolysis products.

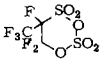


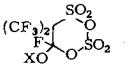
It was later established[29] that the observed deviations are due to isomerization of the β-sultone *(1f)* to the alkenyl fluorosulfate (see Section 3). A similar explanation probably applies to the unconfirmed report[15, 18] that a mixture of two β-sultones results on reaction of chlorotrifluoroethylene with sulfur trioxide. It is reasonable to assume that, in this case too, only the α-chloro β-sultone *(1c)* is formed which then isomerizes to the alkenyl fluorosulfate.

(1c)

The data listed in Table 1 show that strict orientation always prevails in the addition of sulfur trioxide to unsymmetrical polyfluoroolefins. This definite orientation confirms the ionic character of the reaction and the intermediacy of a zwitterion (see above). Further evidence is provided by the additional, and sometime predominating, formation of six-membered cyclic compounds of type *(3)*. This is also the only possible explanation of the formation of the eight-membered cyclic by-product *(2a)* on reaction of tetrafluoroethylene with sulfur trioxide. Styrene and sulfur trioxide are known to form a similar compound[30].







The stability of fluorinated β-sultones came as no surprise. Many different types of polyfluorinated four-membered ring compounds are already known, *e.g.* perfluorocyclobutane *(6)* and the extremely stable perfluorooxetane *(7)*, as well as the relatively stable polyfluorooxazetidines *(8)* and polyfluorodiazetidines *(9)*.

(6) *(7)* *(8)* *(9)*

The comparatively high stability of fluorinated β-sultones permits their large-scale production by heating a mixture of sulfur trioxide and polyfluoroolefin in a pressure reactor or passing the gaseous components through a heated tube. The accessibility of fluorinated β-sultones was the main reason for the detailed study of their chemical properties and for their suggested use as intermediates in the laboratory and in industry.

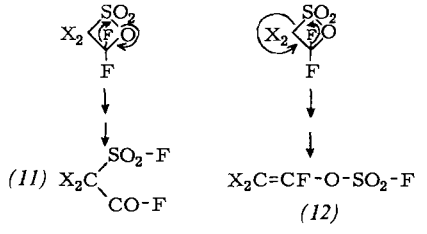
3. Possible Reactions of β-Sultones

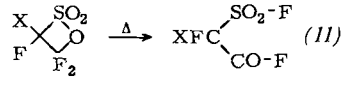
Fluorinated β-sultones dissolve readily in saturated hydrocarbons, in their fluoro and chloro derivatives, and in polyhalogenoolefins. With water and most inorganic and organic compounds β-sultones undergo vigorous decomposition to give derivatives of sulfonic acids or sulfuric acid, depending upon the nature of the reagent.

The hydrolysis of fluorinated β-sultones is very informative. Thus alkaline hydrolysis of tetrafluoroethanesultone or of 1-chlorotrifluoroethanesultone gives dihalogenosulfoacetic acid *(10)*, whereas fluorosulfuric acid and glyoxylic acid are obtained on hydrolysis with sulfuric acid.



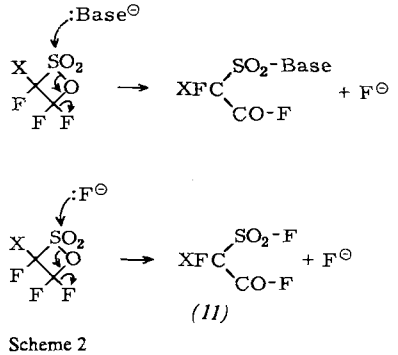
Various differences in dependence upon the pH value of the solution are also observed in the hydrolysis of other fluorinated β-sultones, *e.g.* 1,2,2-trifluoroethanesultone *(1i)* and perfluoro-1,2-propanesultone *(1g)*.

(1i)



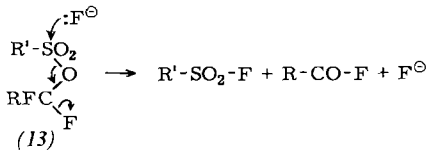
(1g)

The reactivity and in particular the chemical properties of fluorinated β-sultones on hydrolysis can be explained in terms of Scheme 1[31,32].

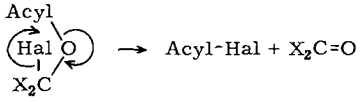


Scheme 1

On prolonged heating, β-fluorinated β-sultones isomerize to α-fluorosulfonyl polyfluoro carbonyl fluorides *(11)*[26,31,33]. Isomerization is initiated by nucleophilic reagents including triethylamine[15,18], ammonia[34], and dioxane[33,35]. Even on brief exposure to moist air some isomerization is observed. The best catalysts for this reaction are hydrogen fluoride and alkali metal fluorides.

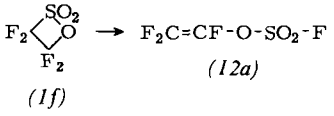


The course of this isomerization and its initiation by nucleophilic compounds can be represented as a chain process (Scheme 2) in which the fluoride ion—liberated from fluorinated β-sultone—plays the main role[35].



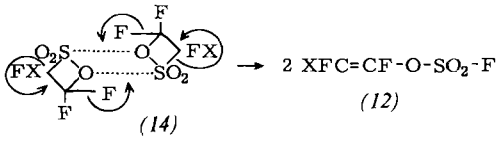
Scheme 2

Decomposition of α-fluoroalkyl sulfonates of type *(13)* is also initiated by nucleophilic compounds[36-38].

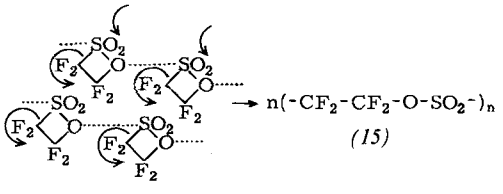


(13)

The well-known decomposition of α-halogeno alkyl esters and thio esters of phosphoric acid, nitrous acid, and even of carboxylic acids can be explained similarly. These reactions confirm the lability of esters bearing an α-halogen, which class includes the fluorinated β-sultones.



The second kind of isomerization of fluorinated β-sultones has so far been observed in one case only, *viz.* conversion of tetrafluoroethanesultone *(1f)* into trifluorovinyl fluorosulfate *(12a)* which occurs on prolonged storage at room temperature in the absence of water[29].

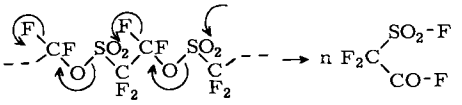


(1f)

The process is accelerated by phase transitions, *i.e.* by repeated crystallization and melting (between −40 and 0 °C). It was assumed[20] that isomerization is facilitated by the orientation of the β-sultone molecules [cf. *(14)*].

(14)

Such an orientation occurs randomly in the liquid phase but regularly on crystallization: isomerization is therefore incomparably slower in the former case than in the latter. If crystalline tetrafluoroethanesultone is kept for a long time at −78 °C it yields a polymer *(15)* whose formation is also attributable to the regular arrangement of molecules[39].

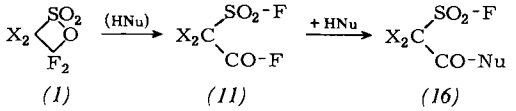


(15)

On heating or in the presence of nucleophiles depolymerization sets in to give fluorosulfonyldifluoroacetyl fluoride *(11a)*[39].

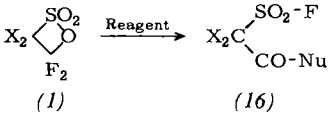
The combination of the sulfonyl group and a fluorine atom in a strained four-membered ring is a particular feature of

fluorinated β-sultones. These characteristics and the thermodynamic stability of the fluorosulfonyl group[40,41] would suggest ready ring cleavage to form that group.



(15) *(11a)*

If the process is initiated by nucleophilic attack by an electron donor on the sulfonyl group, derivatives of α-sulfo polyfluoro carboxylic acids of type *(11)* are formed by heterolysis of the ester linkage. Under phase transition conditions, on the other hand, heterolysis of the S—C bond ensues giving sulfates of type *(12)* or polysulfates of type *(15)*. Transformations of this kind in stable compounds under phase transition conditions represent a truly remarkable phenomenon.

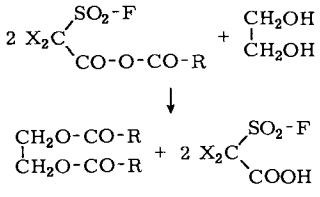


3.1. Conversion of β-Sultones into Derivatives of α-Sulfo Carboxylic Acids

Treatment of β-fluorinated β-sultones with nucleophilic compounds containing mobile hydrogen atoms furnishes derivatives of α-sulfo carboxylic acids. The β-sultone initially isomerizes to a linear α-fluorosulfonyl polyfluoroacyl fluoride of type *(11)* that subsequently acylates the nucleophile to give *(16)*[20,31,35]. The reactions summarized in Table 2 are in accord with this view.

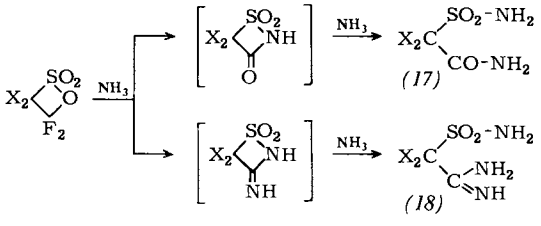
(1) *(11)* *(16)*

Table 2. Formation of α-fluorosulfonyl polyfluoro carboxylic acid derivatives *(16)* from β-sultones *(1)*.



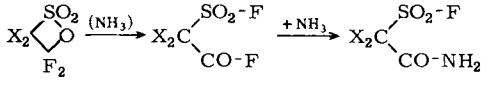
(1) *(16)*

Reagent	Nu	Ref.
H_2O	OH	[14–16, 18, 42, 43]
ROH	OR	[14–16, 18, 33, 44–46]
H_2S	SH	[15, 18]
RSH	SR	[14–16, 18, 47]
KSCN	SCN	[15]
R_2NH	NR_2	[14–16, 18, 46]
$(NH_2)_2CO$	NH—CO—NH_2	[15]
RCOOH	O—CO—R	[48, 49]



Fluorosulfonylfluoroacetic acid and fluorosulfonyldifluoroacetic acid are isolable; they are stable and behave as strong carboxylic acids. The fluorosulfonyl carboxylic acids can be converted into anhydrides, acyl halides, esters, thio esters, amides, hydrazides, *etc.* by the usual methods. Synthesis and investigation of numerous derivatives of α-fluorosulfonyl carboxylic acids have permitted derivation of the molar refraction of the fluorosulfonyl group bound to carbon: $R_{F-SO_2} = 10.54$ cm^3[50].

Mono- and polybasic aliphatic and aromatic acids have been used to form mixed anhydrides with β-sultones. The resulting mixed anhydrides of carboxylic and α-fluorosulfonyl polyfluoro carboxylic acids are effective acylating agents for alcohols, phenols, and thiols[51]. Reaction yields derivatives of the carboxylic acid[48,49].

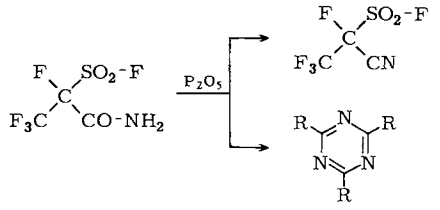


Only in those cases in which a strong carboxylic acid is made to react with the β-sultone does the acylation reaction lead to a derivative of the α-fluorosulfonyl carboxylic acid alongside the major product. The ratio of the strengths of the two acids apparently determines which product is formed in this process (S_N1 or S_N2)[49]. Thus the mixed anhydride of fluorosulfonyldifluoroacetic acid and trifluoroacetic acid reacts with alcohols to give both expected products in the approximate ratio 1:1.

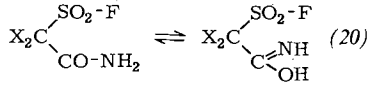
Exhaustive ammonolysis of fluorinated β-sultones yields the diamides *(17)* and the amidoamidines *(18)* whose formation can be explained by repeated conversions involving β-sulfam derivatives[34].

(17) *(18)*

Ammonolysis undoubtedly starts with isomerization of the β-sultone followed by formation of the α-fluorosulfonyl carboxamide.



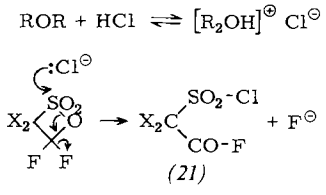
α-Fluorosulfonylperfluoropropionamide has been isolated and converted into the nitrile and the triazine derivative *(19)*[52,53]. The nitrile is stable; it can yield the triazine derivative only by way of the imidoyl chloride or the imidic ester[52]. It was concluded from this observation that the simultaneous formation of nitrile and triazine on dehydration of the amide must be due to presence of the isomeric imidic acid *(20)*.



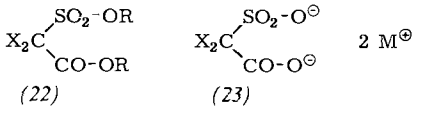
This peculiarity of the amide would also explain the result of exhaustive ammonolysis reported above.

Fluorinated β-sultones can be made to react with nucleophilic compounds under conditions unfavorable for isomerization by liberated fluoride ions. An appropriate method

is to work with a large excess of the nucleophile[35]; initial attack by an anion affords a derivative of the α-sulfo carboxylic acid whose sulfonyl group bears a substituent

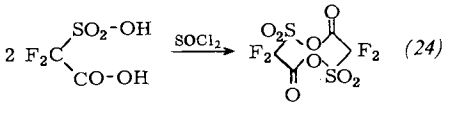


(19), R = $F_3C-CF-SO_2-F$



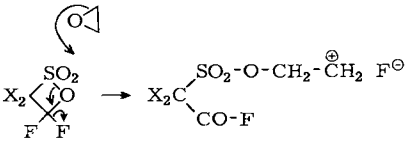
(20)

other than fluorine. The reaction of a β-sultone with an excess of hydrogen chloride in ethereal solution to give the α-chlorosulfonyl polyfluoro acyl fluoride *(21)* may be cited as an example[35].



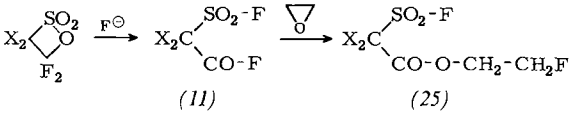
(21)

Analogously, diesters of α-sulfo polyfluoro carboxylic acids *(22)* are formed with an excess of alkali metal alkoxide in an alcohol[35]. On treatment with aqueous alkali, fluorinated β-sultones are converted into salts of α-sulfo carboxylic acids *(23)*[15, 18, 54].



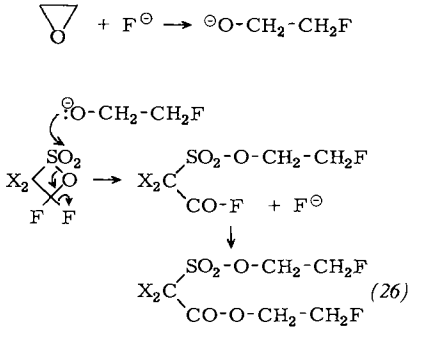
(22) *(23)*

It proved possible to isolate free sulfodifluoroacetic acid as a crystalline hydrate after hydrolysis of tetrafluoroethanesultone *(1f)*. The acid yields derivatives including a cyclic dianhydride *(24)*[54].



(24)

Competition between the nucleophilic reagents is illustrated particularly well by the reaction of fluorinated β-sultones with ethylene oxide[55]. Addition of ethylene oxide to the β-sultone furnishes the 2-fluoroalkyl ester of the α-fluoro-

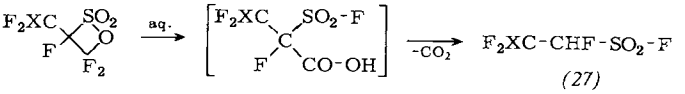


sulfonyl carboxylic *(25)* as major product. If addition is carried out in the reverse order the bis(2-fluoroethyl ester) of the α-sulfo carboxylic acid *(26)* is formed. In both cases reaction begins with a nucleophilic attack by ethylene oxide with elimination of a fluoride ion.

Excess β-sultone is isomerized by fluoride ion; the resulting α-fluorosulfonyl acyl fluoride *(11)* cleaves the ethylene oxide, as could also be confirmed in an independent experiment. The diester *(26)* is not formed[55].

(11) *(25)*

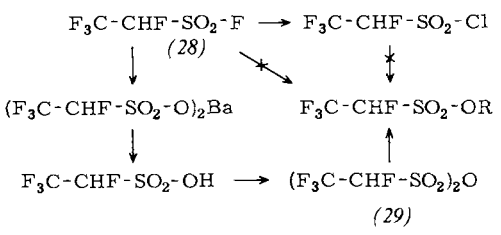
If an excess of ethylene oxide is present it is cleaved by fluoride ion[56, 57]; the α-fluoroethoxy anion then converts the β-sultone into α-(2-fluoroethoxysulfonyl) acyl fluoride which reacts with ethylene oxide to give the diester *(26)*. By-products are naturally also formed by telomerization of the ethylene oxide[57].



(26)

To summarize, it may be said that when reaction begins with nucleophilic attack by the reagent the β-sultone ring is always opened with elimination of fluoride ion and formation of an α-sulfo carboxylic acid derivative.

3.2. Conversion of β-Sultones into Derivatives of Polyfluoroalkanesulfonic Acids



Hydrolysis of β-sultones based on hexafluoropropylene and other higher fluoroolefins yields unstable α-fluorosulfonyl polyfluoro carboxylic acids which readily undergo decarboxylation[58, 59]. Whereas fluorosulfonylfluoroacetic acid and fluorosulfonyldifluoroacetic give off carbon dioxide only on heating[59, 60], higher homologs decarboxylate at room temperature to give α-monosubstituted polyfluoroalkanesulfonyl fluorides *(27)*[33, 58, 59].

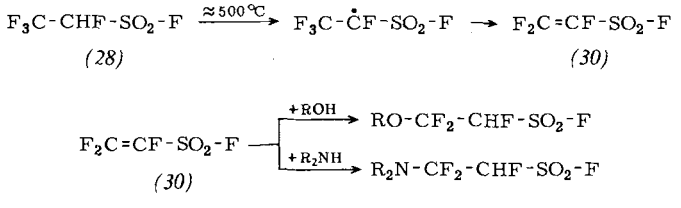
(27)

Classical methods cannot always be used with these acids for conversion of one derivative into another[61–64].

Thus attempts to synthesize esters from acyl halides were unsuccessful. In neutral and acidic solution the acyl halides are inactive towards alcohols; even in the presence of alkali metal hydroxides or alkoxides as well as tertiary amines they do not yield esters but salts of the sulfonic acid.

The methyl and ethyl esters can only be prepared by the action of the sulfonic anhydride *(29)* on the corresponding ether[63].

$$(F_3C{-}CHF{-}SO_2)_2O + R{-}O{-}R \rightarrow 2\,F_3C{-}CHF{-}SO_2{-}OR$$
(29)



Aminolysis of the sulfonyl fluoride *(28)* also took a surprising course: The expected sulfonamides are accompanied by β-aminoalkanesulfonamides, in some cases as major product[61].

$$F_3C{-}CHF{-}SO_2{-}F \xrightarrow{R_2NH}$$
(28)

$$F_3C{-}CHF{-}SO_2{-}NR_2 + R_2N{-}CF_2{-}CHF{-}SO_2{-}NR_2$$

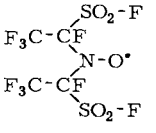
The peculiarities shown by some of the reactions of these 1,2,2,2-tetrafluoroethanesulfonic acid derivatives were interpreted as being due to the mobility of the hydrogen atom[61] resulting from the inductive effect of the sulfonyl and the trifluoromethyl group.

Pyrolysis of 1,2,2,2-tetrafluoroethanesulfonyl fluoride *(28)* yields trifluoroethylenesulfonyl fluoride *(30)*[58] which readily adds nucleophiles.

The lability of the C—H bond in the derivatives of 1,2,2,2-tetrafluoroethanesulfonic acid is particularly obvious on solvolysis with bases. The sulfonyl fluoride *(28)*, like alkali metal sulfonates, forms stable adducts with tertiary amines[65].

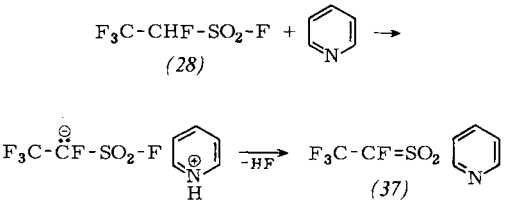
$$F_3C{-}\overset{\ominus}{C}F{-}SO_2{-}F \quad \overset{\oplus}{H}NR_3$$

A method for the synthesis of α-substituted polyfluoroalkanesulfonyl compounds has been worked out on the basis of similar compounds having carbanion character. The method consists in the electrophilic substitution of the hydrogen in α-monosubstituted polyfluoroalkanesulfonyl halides under base-solvolysis conditions. Thus α-chlorosulfonyl halides of type *(31)* could be prepared in the presence of tertiary amines and chlorine or sulfuryl chloride; the halides could be converted into the sulfonic acids, their anhydrides, esters, amides, and a few other derivatives[61,66,67]. Derivatives of tetrafluoroethanesulfonic acid containing bromine, nitroso, acyl groups, or cyano in the α position were prepared similarly[61,66].



$$F_3C{-}CFCl{-}SO_2{-}F \quad (31)$$

Of the compounds listed, particular attention attaches to α-nitrosotetrafluoroethanesulfonyl fluoride *(32)* which is characterized by the instability of the sulfonyl fluoride and nitroso moieties. It was transformed into numerous novel compounds, *e.g. (33)—(35)*[61].



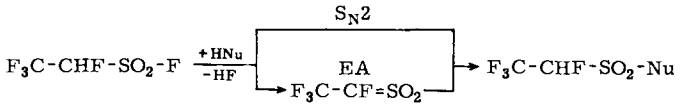
$F_3C{-}CF(NO){-}SO_2{-}F$ *(32)* $\qquad$ $F_3C{-}CF(NO_2){-}SO_2{-}X$ *(33)*

$F_3C{-}CF(N{=}NR){-}SO_2{-}X$ *(34)* $\qquad$ $F_3C{-}CF(NR_2){-}SO_2{-}X$ *(35)*

In addition, transition of the α-nitroso sulfonyl fluoride *(32)* into relatively stable radicals, *e.g.* bis(α-fluorosulfonyltetrafluoroethyl)aminyl oxide *(36)*, was shown by the ESR spectrum[61].

(36)

Finally, under conditions of base solvolysis 1,2,2,2-tetrafluoroethanesulfonyl fluoride *(28)* gives trimethylfluorosulfene[*] as a complex *(37)* with pyridine[65,68].



Sulfenes have so far defied all attempts at isolation; they have only been demonstrated as intermediates in the reactions of sulfonyl compounds[69,70]. A similar complex *(38)*, which likewise is extremely unstable, could be isolated on dehydrochlorination of methanesulfonyl chloride[71,72].

$$H_3C{-}SO_2{-}Cl \xrightarrow{(C_2H_5)_3N} H_3C{-}SO_2{-}CH{=}SO_2N(C_2H_5)_3$$
(38)

The detection of complexed trifluoromethylfluorosulfene permits a new interpretation to be given for the reaction

[*] We suggest the name "sulfonenes" instead of "sulfenes" for such compounds in order to emphasize the presence of both a sulfonyl group and a double bond.

of 1,2,2,2-tetrafluoroethanesulfonyl fluoride *(28)* with nucleophilic reagents. The mechanistic alternatives for this reaction are an S_N2 substitution or elimination with subsequent addition (EA).

The thermodynamic stability of the sulfonyl fluoride group[40,41] makes the S_N2 process appear highly unlikely. The results of potentiometric titration of some sulfonyl fluorides can be explained by invoking the EA reaction mode[67]. The rate constants of their alkaline hydrolysis in the presence of potassium chloride are listed in Table 3,

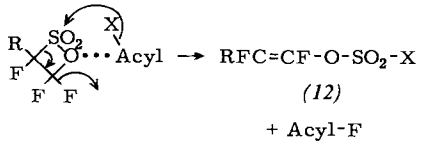


Table 3. Rate constants of alkaline hydrolysis K_c of sulfonyl fluorides in the presence of potassium chloride at 25 °C and pH 10.0.

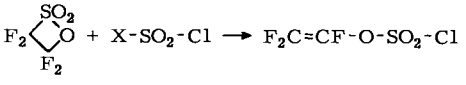
R—SO_2—F R	K_c (l mol^{-1} s^{-1})
F_3C—CFCl	3.3
C_6H_5	8.2
H_2C=CH	18.3
H_3C	46.1
C_6H_5—CH_2	912
F_3C—CHF	923

from which it may be seen that sulfonyl fluorides having no α-hydrogen atom react least readily with nucleophilic reagents and which sulfonyl fluorides can only undergo S_N2 substitution. Methane and particularly ω-toluene- and 1,2,2,2-tetrafluoroethanesulfonyl fluorides are distinguished by their high rate constants. The reactivity of these compounds is apparently due to the intermediacy of a sulfene.

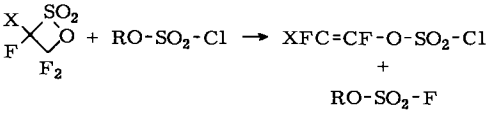
3.3. Conversion of β-Sultones into Derivatives of Alkenylsulfuric Acids

Treatment of fluorinated β-sultones with some acyl chlorides or esters furnishes derivatives of fluoroalkenylsulfuric acids *(12)* and acyl fluorides. The reaction must pass through a transition state having both the sultone and the reagent in favorable orientations. The transition state is stabilized by cleavage of the sultone S—C bond.



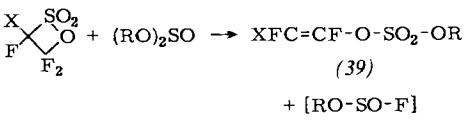
When carried out with an acyl chloride (acyl-X) the reaction yields fluoroalkenyl chlorosulfate. In this way trifluorovinyl chlorosulfate was obtained from tetrafluoroethanesultone and pentafluoropropenyl chlorosulfate from hexafluoro-1,2-propanesultone. Derivatives of sulfuric acid and sulfonic acids, nitrous acid, phosphoric and phosphonic acids, and silicon- and titanium tetrachloride were used as acid chlorides.

The success of the reaction is determined by two factors: Firstly by the coordinative accessibility of the central atom in the acid chloride and secondly by the acylating power of this reagent. Thus silicon tetrachloride and titanium tetrachloride do not react with fluorinated β-sultones (up to 100 °C). This observation was explained by the coordinative saturation of silicon and titanium which hinders formation of a transition state with the β-sultones[73]. In contrast, reaction with nitrosyl chloride occurs at −35 °C. Similarly vigorous reactions are observed between β-sultones and methylphosphonyl dichloride (at −10 °C) and phosphorus oxide trichloride (at −20 °C); the resulting fluorochlorophosphoric acids can also react with β-sultones[73].



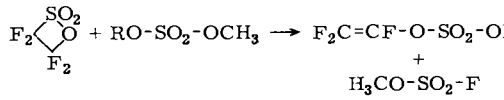
The reactions with chlorosulfuric acid derivatives[73–77] such as alkanesulfonyl chlorides[76,77], alkyl chlorosulfates[76,77], chlorosulfuric acid[75,77], and sulfuryl chloride[76] proceed analogously. The reaction temperatures required and the yields of alkenyl chlorosulfate are consonant with the acylating power of the chlorosulfonyl compounds (Table 4).

Table 4. Temperature and yield in the reaction



X	T(°C)	Yield (%)
R	20–60	90–95
RO	30–80	65–80
HO	80–100	70–80
Cl	100	20

The reaction of fluorinated β-sultones with alkyl chlorosulfates is the sole general method available for the preparation of aliphatic esters of fluorosulfuric acid (RO—SO_2—F)[76,78].



This route was used to prepare methyl and *n*-hexyl fluorosulfate[76] and thereby permitted estimation of the refraction of the fluorosulfate group: $R_{F-SO_2-O} = 11.50$ cm^3. Alkyl fluorosulfates are powerful alkylating agents.

Reaction of fluorinated β-sultones with sulfurous esters gives esters of fluoroalkenylsulfuric acids *(39)*[77,79,80]. Esters of trifluorovinylsulfuric acid were obtained from tetrafluoroethanesultone[77,79] and esters of pentafluoropropenylsulfuric acid from hexafluoro-1,2-propanesultone[79,80]; the refractions of the polyfluoroalkenyl groups are $R_{F_2C=CF} = 9.82$ cm^3 and $R_{F_3C-CF=CF} = 15.71$ cm^3.

Fluorinated β-sultones react with dialkyl sultates to give esters of fluorosulfuric acid and of fluoroalkenylsulfuric acid; however, this reaction is recommended only for the preparation of fluoroalkenylsulfates of higher alcohols because lower dialkyl sulfates are more typically alkylating rather than acylating agents[81]. This is particularly obvious from the reaction of fluorinated β-sultones with unsymmetrical alkyl sulfates[73]: The products are the fluoroalkenylsulfate of the higher and the fluorosulfate of the lower alcohol.

The derivatives of trifluorovinylsulfuric acid are characterized by their ability to react with nucleophiles; thus their alkaline hydrolysis leads in a vigorous fashion to complete decomposition of the reactants[29, 75, 80].

$$F_2C{=}CF{-}O{-}SO_2{-}F + 4KOH \rightarrow HOOC{-}CHO + 3KF + KOSO_2F + H_2O$$

$$F_2C{=}CF{-}O{-}SO_2{-}Cl + 6KOH \rightarrow HOOC{-}CHO + 3KF + KCl + K_2SO_4 + 2H_2O$$

$$F_2C{=}CF{-}O{-}SO_2{-}OR + 4KOH \rightarrow HOOC{-}CHO + 3KF + KOSO_2OR + H_2O$$

The initial step in their alcoholysis is substitution in the vinyl group[29, 82].

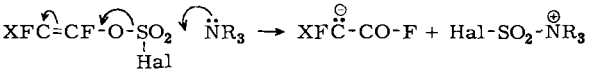
$$F_2C{=}CF{-}O{-}SO_2{-}X + ROH \rightarrow RO{-}CF{=}CF{-}O{-}SO_2{-}X + HF$$

Excess alcohol then adds to the product. Thus a bis(alkoxy) compound *(40)* could be isolated on reaction of trifluorovinyl chlorosulfate[82]. Only addition occurs to give compounds like *(41)* and *(42)* on reaction with acids[75, 82].

$(RO)_2FC{-}CHF{-}O{-}SO_2{-}Cl$ *(40)*

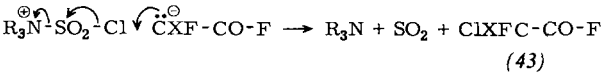
$H_3C{-}COO{-}CF_2{-}CHF{-}O{-}SO_2{-}Cl$ *(41)*

$Cl{-}SO_2{-}O{-}CF_2{-}CHF{-}O{-}SO_2{-}Cl$ *(42)*



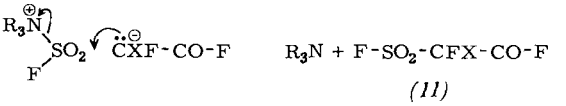
Derivatives of pentafluoropropenylsulfuric acid can also react with nucleophiles[77, 83]. The results of alkaline hydrolysis and alcoholysis show the double bond in these compounds to be polarized, unlike that in the trifluorovinyl compounds. The trifluoromethyl group therefore appears to exert a more pronounced effect than the sulfonyl group.

$$F_3C{-}CF{=}CF{-}O{-}SO_2{-}Cl + 5KOH \rightarrow F_3C{-}CFH{-}COOK + KF + K_2SO_4 + KCl + 2H_2O$$



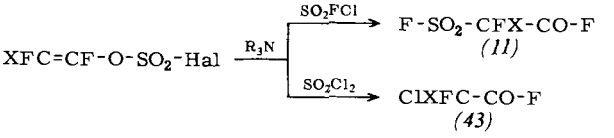
$$F_3C{-}CF{=}CF{-}O{-}SO_2{-}OR + 3KOH \rightarrow F_3C{-}CHF{-}COOK + KF + KOSO_2OR + H_2O$$

$$F_3C{-}CF{=}CF{-}O{-}SO_2{-}X \xrightarrow{ROH} F_3C{-}CHF{-}COOR$$



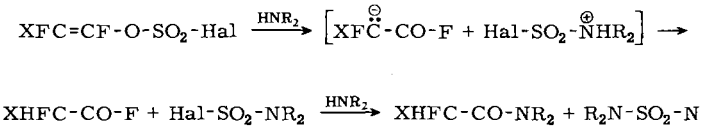
The behavior of fluoroalkenyl halogenosulfates towards tertiary amines, which initiate decomposition of the chlorosulfates and isomerization of the fluorosulfates of these acids, occupies a special place[84]. In both cases the reaction starts with a nucleophilic attack on the sulfonyl group with cleavage of the ester.

What then ensues is determined by the reaction of the carbanion with the sulfonylammonium ion. In the case of a chlorosulfonylammonium ion attack is centered on the chlorine atom and an α-chloro acyl fluoride *(43)* is formed; with a fluorosulfonylammonium ion the sulfonyl group is attacked and an α-fluorosulfonyl acyl fluoride *(11)* results.



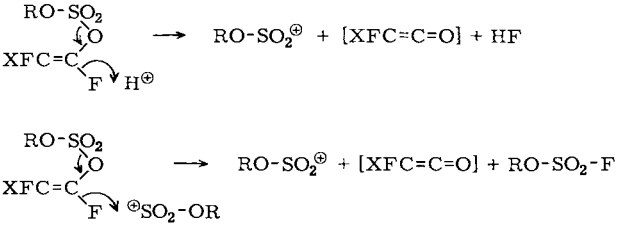
(43)

(11)



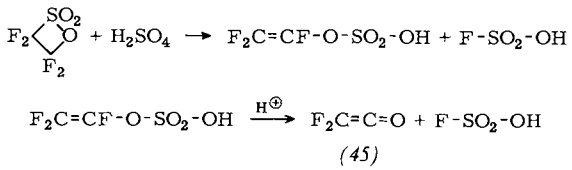
If a similar reaction is carried out in sulfuryl fluoride chloride solution—a source of fluorosulfonyl cations[85]—then α-fluorosulfonyl fluorides are formed exclusively, irrespective of which halide of fluoroalkenylsulfuric acid is used. Reaction in sulfuryl chloride (source of chlorine cations) likewise affords solely α-chloro acyl fluorides[84].

(11)



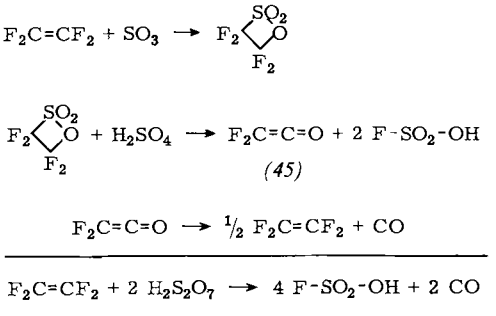
(43)

However, if a secondary amine is used to initiate decomposition of fluoroalkenyl halogenosulfates one obtains tetrasubstituted sulfamide and the amide of the corresponding carboxylic acid *(44)* having an α-hydrogen atom[77, 82].



(44)

Derivatives of fluoroalkenylsulfuric acid are also very unstable in the presence of acids. Thus their esters decompose on heating with strong mineral acids (sulfuric, chlorosulfuric, and fluorosulfuric acid) to give fluorosulfates[86] in a chain reaction (Scheme 3).

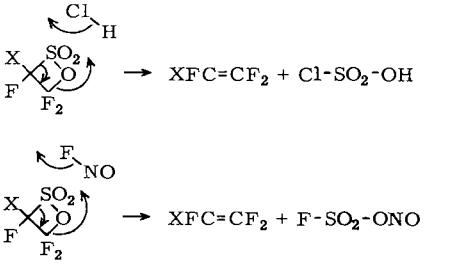


Scheme 3

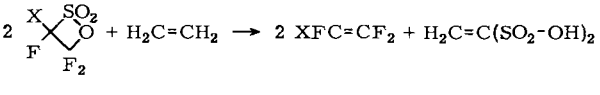
The instability of trifluorovinylsulfuric acid becomes readily understandable in the light of these results. These acids, which are formed from tetrafluoroethanesultone and sulfuric acid at room temperatures, are converted into difluoroketene *(45)* and fluorosulfuric acid on heating to temperatures above 40 °C in what is probably an autocatalytic reaction.

(45)

At higher temperatures difluoroketene *(45)* decomposes to tetrafluoroethylene and carbon monoxide[86,87]. In view of these and the foregoing reactions and the conditions of β-sultone synthesis it was deduced that the processes shown in Scheme 4 take place when tetrafluoroethylene is passed through heated disulfuric acid.



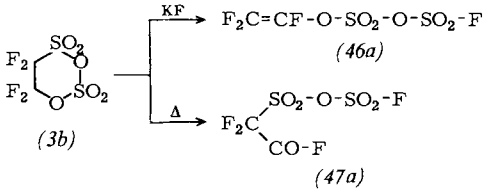
Scheme 4



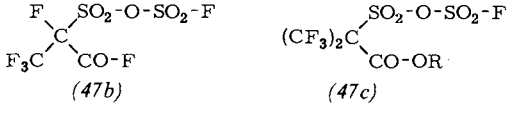
The failure of previous attempts to isolate organofluorine compounds after passage of polyfluoroolefins through oleum can presumably be explained similarly[88].

The above reactions of fluorinated β-sultones with mineral acids and their derivatives reveal the relatively labile character of the S—C bond in the sultone ring, which also determines the course of the following reactions.

Passage of dry hydrogen chloride through a cooled fluorinated β-sultone or hexafluoro-1,2-propanesultone affords chlorosulfuric acid and the corresponding olefin[89]. An analogous reaction takes place with nitrosyl fluorides[89].



Fluoroolefins are also eliminated on passage of ethylene through β-sultones[89].

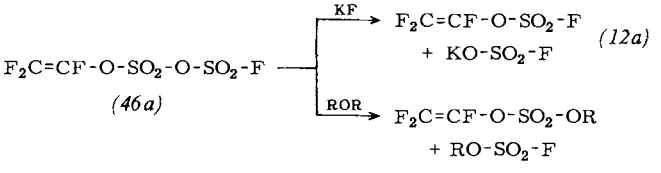


4. Fluorinated β-Disultones

Like the β-sultones, fluorinated β-disultones (1,3,2,4-dioxadithiane 2,2,4,4-tetroxides) are extremely reactive compounds. They can isomerize to sulfate- or sulfonate-type derivatives.

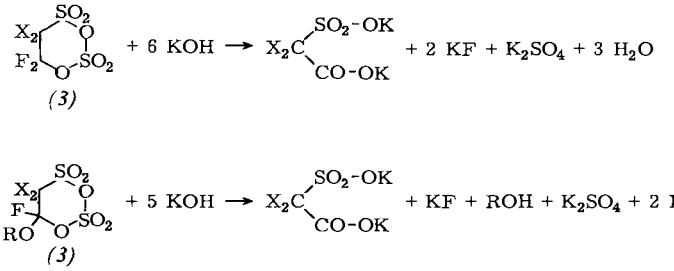
(3b) *(46a)* *(47a)*

In the case of the tetrafluoro compound *(3b)* both possible linear isomers were isolated[28]. Treatment of *(3b)* with potassium fluoride in catalytic amounts below 0 °C furnishes trifluorovinyl fluorodisulfate *(46)*; heating of *(3b)* to over 130 °C yields fluorosulfonyloxysulfonyldifluoroacetyl fluoride *(47a)*. Other fluorinated β-disultones have so far only been isomerized to derivatives of type *(47)*[23,28].

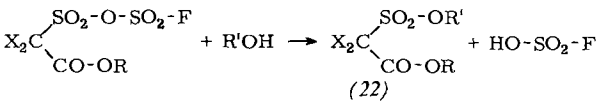


(47b) *(47c)*

Hitherto only the reactions of fluorinated β-disultones with nucleophilic compounds A-B have been studied. After ring cleavage the linear isomer sulfonylates the reagent[90].

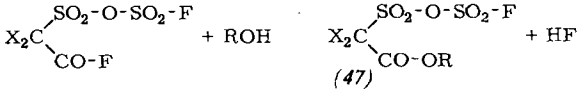


Reaction of the tetrafluoro compound *(3b)* with an excess of potassium fluoride gives potassium fluorosulfate and trifluorovinyl fluorosulfate; with ethers, alkyl fluorosulfates and alkyl trifluorovinyl sulfates are formed[28].



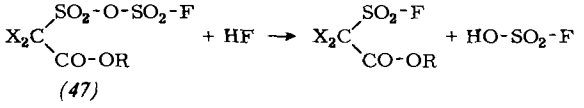
(46a) *(12a)*

Alkaline hydrolysis of compounds *(3)* also results in ring cleavage[23,24,28]. Isomerization here follows the second course. Similarly, alcoholysis initially gives a derivative of α-sulfonyloxysulfonyl carboxylic acid; the further course of the reaction depends upon the structure of the compound *(3)* and the reaction conditions.



(3)

On alcoholysis of β-alkoxy derivatives ring opening is followed by sulfonylation of the alcohol and formation of the diester of the α-sulfo carboxylic acid of type *(22)*[23].

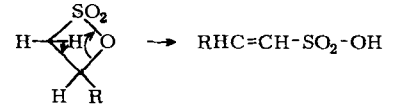


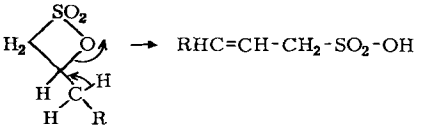
(22)

In the case of the β-fluoro derivative the alcohol is acylated to compounds of type *(47)* by the acyl fluoride formed.

(47)

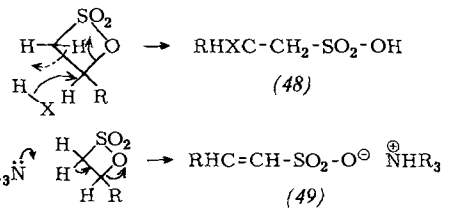
The final reaction step is sulfonylation of either the alcohol (if present in excess) or the hydrogen fluoride (if insufficient alcohol is present) by compound *(47)*; depending on the conditions one obtains either the diester *(22)* or the α-fluorosulfonyl carboxylic ester[28, 91, 92].





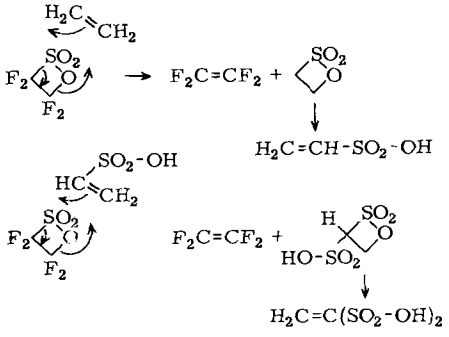
(47)

5. Transformations of β-Sultones Containing No Fluorine

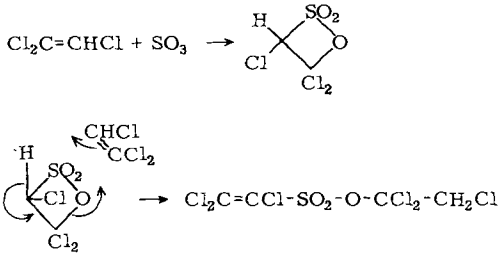


It was shown in Section 3 that the transformations of fluorinated β-sultones lead to derivatives of α-sulfo carboxylic acids or sulfuric acid. Anions play an important role in these reactions[20, 35, 73].

In contrast, β-sultones containing hydrogen atoms are characterized by their ability to undergo reactions involving proton shifts[20]. The primary products of reaction between olefins and sulfur trioxide—β-sultones, β-disultones, and δ-sultones—are known to be extremely unstable. Their transformations result from the mobility of the α-hydrogen atom in the sultone ring or of a hydrogen atom in the β-alkyl group[20]. The failure of attempts to isolate β-sultones can be explained by the ease of ring cleavage with concomitant shift of the proton to the oxygen.



Treatment of olefin-sulfur trioxide adducts with water, hydrogen halides, alcohols, thiols, and primary or secondary amines affords β-substituted sulfonic acids *(48)*; with tertiary amines one obtains salts of α,β-unsaturated sulfonic acids *(49)*.



(48)

(49)

The formation of ethylenebis(sulfonic acid) on reaction of tetrafluoroethanesultone with ethylene can be interpreted in terms of the intermediacy of unsubstituted β-sultone (see Section 3.3)[89].

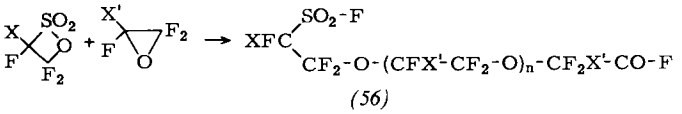
The reactions of bromine- and chlorine-containing olefins with sulfur trioxide can be rationalized in a similar way[11].

If a β-sultone molecule has a proton in the α-position and halogen in the β-position the reaction can, in principle, take two courses. In chlorinated or brominated β-sultones reactions involving proton shifts predominate while fluorinated β-sultones preferentially undergo reactions with participation of anions.

6. Applications

Although their study only began as late as 1957, fluorinated β-sultones have already been thoroughly investigated and numerous preparative methods have been worked out for their synthesis. Their ready accessibility prompted a search for possible applications.

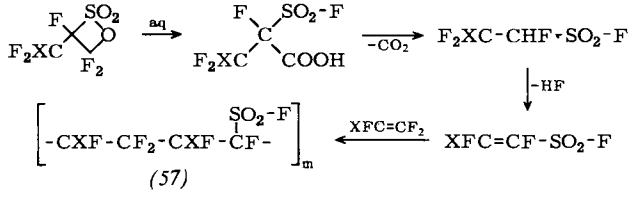
Thus it has been reported that derivatives of α-sulfo polyfluoro carboxylic acids prepared from β-sultones inhibit the growth of microorganisms[15]. The derivatives *(50)* to *(53)* exhibit the greatest bactericidal effect.



(50), R = $NH-CO-NH_2$
(51), R = $N(CH_3)C_6H_5$
(52), R = $O-CH_2-CH_2-O-CO-CF_2-SO_2-F$
(53), R = $S-C_6H_5$

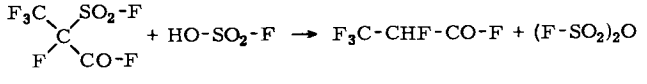
Polyester and polyamides of α-sulfo polyfluoro carboxylic acids such as *(54)* and *(55)* are noninflammable polymeric materials[91].

$$[-O-SO_2-CFX-CO-O-(CH_2)_n-]_m$$
(54)



$$[-NH-SO_2-CF_2-CO-NH-(CH_2)_n-]_m$$
(55)

Telomerization products of β-sultones and fluorinated epoxides are also characterized by high thermal stability[93,94].



(56)

These polymers can be converted into highly stable ion-exchange resins[93]. Copolymerization of alkenesulfonyl fluorides with fluoroolefins has also been utilized to produce ion-exchange resins *(57)*[58].

(57)

A method based on desulfurization of sultones and the derivatives of α-sulfo polyfluoro carboxylic acids by the action of sulfuric, fluorosulfuric, or chlorosulfuric acid has been suggested for production of polyfluoro carboxylic acids having an α-hydrogen atom and their derivatives[86,95,96].

Finally, fluorinated β-sultones are so hygroscopic that they, and the fluoroolefins from which they are formed, can be used as stabilizers for liquid sulfur trioxide[97,98].

Further research on fluorinated β-sultones will doubtless suggest new preparative and industrial applications.

Metal-Olefin and -Acetylene Bonding in Complexes

By Frank R. Hartley[*]

The molecular orbital (MO) and valence bond (VB) descriptions of the bonding in metal-olefin and -acetylene complexes are examined in relation to their ability to explain the known properties of these complexes. It is concluded that whereas there are difficulties with the valence bond description, the molecular orbital description can satisfactorily explain all the known properties of these complexes and has the necessary versatility to enable it to be readily applied to any series of metal-olefin or -acetylene complexes. It is further shown that olefin and acetylene complexes can be usefully divided into two main classes: those that resemble the platinum(II)-complexes (class S), and are either square-planar or octahedral with essentially free rotation about the metal-olefin bond; and those that resemble platinum(0)-complexes (class T) and are either trigonal planar or trigonal bipyramidal and in which there is no rotation about the metal-olefin or -acetylene bond.

1. Introduction

The metal-olefin bond is usually described in molecular orbital terms using the theory which *Dewar*[1] put forward for silver(I)-olefin complexes and which *Chatt* and *Duncanson*[2] subsequently extended to include platinum(II)-olefin complexes. The bonding, according to the Dewar-Chatt-Duncanson model essentially involves a σ-bond, from the filled $p\pi$-orbital of the olefin to an empty hybrid orbital on the metal, complemented by a π-back bond, from a filled hybrid orbital on the metal to the empty $p\pi^*$-(antibonding)-orbital of the olefin. In this bonding scheme the olefin is formally neutral and the platinum in the +2 oxidation state.

Gel'man[3] has put forward an alternative description of the bonding within the framework of the VB theory. This involves two platinum-carbon σ-bonds giving a three membered  ring. In this bonding scheme the olefin carries a formal 2− charge and the platinum is in the +4 oxidation state. Although this description of the bonding went out of favor after the Dewar-Chatt-Duncanson description was put forward, it has recently been revived to explain some of the properties of metal-olefin complexes that were apparently hard to explain on the Dewar-Chatt-Duncanson theory.

The present paper effectively falls into three parts. In the first part (Section 2) the more important properties of platinum(II)-olefin and -acetylene complexes, together, where appropriate, with their palladium(II) and nickel(II) analogs, are put forward. The molecular orbital and valence bond descriptions are then examined to see how they can explain these properties. It will then be shown that a molecular orbital description, modified slightly from the rather rigid scheme put forward initially, can explain all the presently observed phenomena and further that this description has greater flexibility than the valence bond description.

In the second part (Section 3) the same treatment is accorded to platinum(0)-olefin and -acetylene complexes, together, where appropriate, with their palladium(0) and nickel(0) analogs. Again it will be shown that all the current experimental data can be understood in terms of the molecular orbital approach, which because of this and its greater flexibility is considered to be the more useful description of the bonding.

In the third part (Section 4) the more important properties of the olefin and acetylene complexes of the other transition metals are examined and it is shown that the complexes fall into one of two classes. One class, class S, resemble the platinum(II) complexes and the other, class T, the platinum(0) complexes[*].

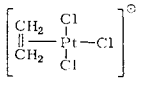
Throughout this paper only monoolefins and occasionally non-conjugated diolefins are considered because the bonding in conjugated polyolefin-metal complexes is considerably more complex and less well understood owing to the greater number of olefin orbitals that must be considered.

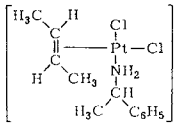
2. Platinum(II)-Olefin and -Acetylene Complexes

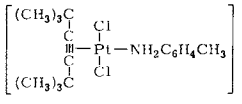
2.1. Experimental Observations

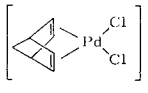
In this section are listed the more important experimental observations on platinum(II)-olefin and -acetylene complexes that any successful description of the bonding must be able to account for. Where appropriate the properties of the palladium(II) and nickel(II) analogs are also considered.

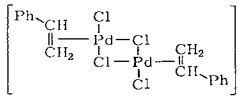
1. The structure of the olefin or acetylene is modified only slightly on coordination. Although platinum(II)-olefin and -acetylene complexes have been widely investigated by X-ray diffraction there are many difficulties, which have been summarized by the present author[4]. These have led











[*] Dr. F. R. Hartley

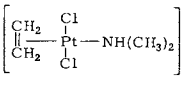
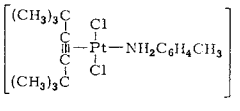
The University
Southampton SO 9 5NH (England)

[*] These two classes and the significance of S and T are discussed in Section 4.4.

to a number of inaccurate results being published. However, a survey of the more accurate results (Table 1) suggests that on coordination there is a very slight lengthening of the multiple-bond and that the substituents are bent out of the plane of the multiple-bond away from the metal.

surprising, since it would be anticipated that with such a low energy barrier to free rotation crystal forces would lead to a distortion from 90°. The more accurate results obtained recently indicate angles slightly different from 90° (see Table 1).





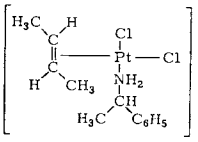


Table 1. Bond lengths and angles in olefins and acetylenes coordinated to platinum(II) and palladium(II).

Complex	Multiple bond length (Å)		Angle that alkyl substituent is bent out of the plane of the multiple bond (°)	Angle between C≡C axis and square plane (°)	Ref.
	Coord.	Free			
	1.37	1.335	—	84	[5]
	1.36	1.339	13	77	[6]
	1.24	1.20	16.5	85	[7]
	1.37		—	90	[8]
	1.32		—	89	[9]

2. The energy barrier to free rotation of the olefin about the platinum(II)-olefin bond is low[10-12], generally lying between 10 and 15 kcal/mol. This observation makes the early reports that the plane of the multiple bond is perpendicular to the square-plane surrounding the platinum atom

3. The olefin can twist slightly about the carbon-carbon double-bond axis. This is indicated by the lower ^{195}Pt-^{1}H coupling constant in the NMR spectrum of the proton *cis* to the methyl group in $[Pt(CH_3CH{=}CH_2)Cl_3]^-$ than of the *trans*-protons[13].

Table 2. Platinum-ligand bond lengths *trans* to olefins.

Metal-ligand bond	Bond length (Å)	Ref.	Comparison metal-ligand bond	Bond length (Å)	Ref.
Pt—N in 	2.02	[20]	Pt—N in *cis*-$[Pt(NH_3)_2Cl_2]$	2.01	[21]
Pt—N in 	2.10	[7]	Pt—N in *trans*-$[Pt(NH_3)_2Cl_2]$	2.05	[21]
Pt—Cl in $[Pt(dipentene)Cl_2]$	2.33	[22]	Pt—Cl in *cis*-$[Pt(NH_3)_2Cl_2]$	2.33	[21]
Pt—Cl *trans* to C_2H_4 in $[Pt(C_2H_4)Cl_3]^-$	2.33	[5]	Pt—Cl in *trans*-$[Pt(NH_3)_2Cl_2]$	2.32	[21]
Pt—Cl in 	2.35	[6]			

4. The NMR spectra show that both the *cis* and the *trans* proton-proton coupling constants of olefins decrease on coordination to platinum suggesting that the sp^2 hybridization of the carbon atoms of the free olefin has altered slightly towards sp^3 hybridization[12,14].

5. The infrared spectra indicate that the C=C stretching frequency[15,16] of olefins decreases by about 300 cm^{-1} and the C≡C stretching frequency[17] of acetylenes decreases by about 250 cm^{-1} on coordination to platinum(II). The value quoted here for olefins is that originally suggested by *Babushkin et al.*[18], but rejected by subsequent workers in favor of a decrease of about 140 cm^{-1} on coordination to platinum(II) until the recent reinvestigation of the IR and Raman spectra of Zeise's salt and its deuterated ethylene analog by *Hiraishi*[15].

6. Olefins exert a strong *trans*-effect as deduced from their influence on the substitution of ligands in the *trans*-position[19]. As mentioned above, much of the data on platinum(II)-olefin complexes obtained by X-ray diffraction is of doubtful accuracy, but the more accurate results (see Table 2) do suggest that olefins have little or no *trans*-influence as deduced from the lengths of the platinum-ligand bonds *trans* to olefins.

2.2. Description of Bonding

If the *x*, *y*, and *z* axes are those shown in Figure 1, then the original molecular orbital treatment[1,2] envisaged a σ-(olefin to platinum) bond being formed by donation of charge from the full pπ-orbital on the olefin to the empty $5d_{z^2}$ $5d_{x^2-y^2}$ 6s $6p_z$ hybrid orbital on platinum and a π-(platinum to olefin) bond being formed by back-donation of charge from the $5d_{yz}$ $6p_y$ hybrid orbital on platinum to the empty pπ*-(antibonding) orbital on the olefin. This bonding scheme required the olefin to be bound perpendicularly to the square-plane surrounding the platinum and the early X-ray structures seemed to support this[23]. However, subsequent NMR evidence suggested that the energy barrier to free rotation of the olefin about the platinum-olefin bond was low[10-12]. This can be accounted for by allowing the π-back donation to occur from either the $5d_{yz}$ $6p_y$ hybrid orbital or the $5d_{xz}$ orbital on platinum (the $6p_x$ orbital is not available for hybridization as it is involved in bonding to the *cis*-chloride ligands). Since calculations have shown[24] that d_π—p_π hybridization involving an unoccupied p-orbital can lead to a strengthened metal-ligand π-bond by increasing the overlap power of the metal

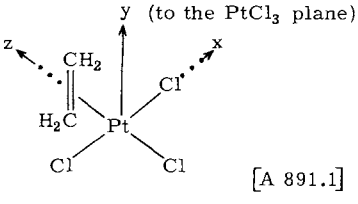

Fig. 1. Axes used in discussing platinum(II)-olefin complexes.

d_π-orbital, and that only a small amount of p character need be added to the d-orbital for this effect to be noticed, it is anticipated that the $5d_{xz}$ orbital will give less overlap with the olefin pπ*-(antibonding) orbital than the $5d_{yz}$ $6p_y$ hybrid orbital. Consequently use of the $5d_{xz}$ orbital not only accounts for the observation of rotation about the metal-olefin bond but also explains why the perpendicular arrangement of the C=C double-bond (with respect to the square-plane through the Pt atom and the Cl atom) is the most stable. This argument has recently[25,26] been put on a semiquantitative basis by calculating the total energy of the complex *trans*-$[Pt(NH_3)Cl_2(C_2H_4)]$ as a function of the angle between the C=C double-bond axis and the $PtNCl_2$ plane. The results show a deep energy minimum when this angle is 90°, which corresponds to the position necessary for maximum π-back donation from the $5d_{yz}$ $6p_y$ orbital of the platinum and a shallow minimum when the angle is 0°, which corresponds to the position necessary for maximum π-back donation from the $5d_{xz}$ orbital of the platinum.

Recent molecular orbital calculations[27,28] have indicated that the platinum 6s orbital is not significantly involved in the bonding. This has necessitated modification of the empty acceptor orbital on the metal from d^2sp to d^2p^2.

The molecular orbital treatment, as outlined above, accounts for the slight weakening of the olefinic double-bond on coordination, as required by the X-ray and IR studies, since both loss of electron density from the olefin pπ-(bonding) orbital and gain of electron density in the olefin pπ*-(antibonding) orbital will result in a weakening of the C=C double-bond.

The bonding in platinum(II)-acetylene complexes is formally similar to that in platinum(II)-olefin complexes. The two perpendicular pπ-orbitals of the acetylene interact to give a cylindrically symmetric bond[29] which forms a σ-bond in a similar way to the olefin to platinum σ-bond. The platinum to acetylene π-bond is similarly analogous to the corresponding bond in the olefin complexes.

The high *trans* effect of olefins is readily explained, as described previously by the present author[4], by the above bonding scheme in terms of the π-bonding mechanism for the *trans* effect[30]. The negligible *trans* influence of olefins, where the *trans* influence is defined as the tendency of a ligand to weaken the bond *trans* to itself[31,32], arises naturally from the bonding scheme described above, since ligands which exert their *trans* effect by a π-acceptor mechanism will only cause weakening of the *trans* bond if this bond has a π-component. If there is no π-component (*e.g.* in Pt—N) or only weak π-bonding (*e.g.* in Pt—Cl) in the *trans* bond then that bond may either not be weakened or even be strengthened[33].

The experimental material discussed so far has been that traditionally used to support the molecular orbital description of the bonding. It is important, however, to consider how the molecular orbital description accounts for (i) the bending back of substituents out of the plane of the multiple bond away from the metal, (ii) the lowering of the double-bond stretching frequency from that of an olefin to a value half-way between that of an olefin and an alkane and (iii) the reduction that occurs on coordination of the *cis* and

trans proton-proton coupling constants in the NMR spectra. All these experimental results have been used to advocate a greater or lesser modification of the sp^2 hybridization of the carbon atoms of free olefins towards sp^3 hybridization on coordination. To include these results within the molecular orbital description it is necessary to consider what the bonding scheme would look like if the olefinic carbon atoms were to be completely rehybridized to sp^3. In such a case the olefin is considered to be a dicarbanion and the platinum atom to be formally in the +4 oxidation state. Although superficially this appears to be very different from the σ-donation/π-back donation scheme discussed above, in reality the two approaches merge. This can be seen from Figure 2, which shows the effect on the distribu-

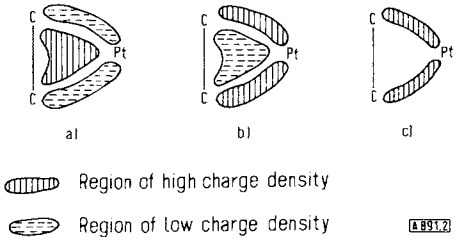

Fig. 2. Effect of varying the relative importance of the σ- and π-components of the platinum(II)-olefin bond on the density of the charge between the olefin and platinum.
(a) sp^2 hybridized carbon atoms with a strong σ-(olefin to platinum)-component and a weak π-(platinum to olefin)-component in the platinum-olefin bond. (b) sp^2 hybridized carbon atoms with a weak σ-component and a strong π-component in the platinum-olefin bond. (c) sp^3 hybridized carbon atoms.

tion of electron density in the region between the metal and the olefin when the relative importance of the σ- and π-components of the metal-olefin bond are altered. The two extremes, (a) and (c), involve a migration of electron density from inside the Pt  triangle, where it is located for sp^2 hybridized carbon atoms which give strong σ-donation and weak π-acceptance of electron density, to the edges of the Pt  triangle, where it is located for sp^3 hybridized carbon atoms. A carbon hybridization scheme mid-way between sp^2 and sp^3 would give an electron density distribution mid-way between these two extremes. This mid-way point coincides with that for an sp^2 hybridization scheme in which the π-back donation of charge (from platinum to olefin) is as important as or more important than the σ-donation of charge (from olefin to platinum). There is some evidence, such as that from stability constant studies for platinum(II)-olefin complexes[34], that the π-back donation of charge is more important than the σ-donation for the formation of a stable platinum(II)-olefin bond (*i.e.* the situation shown in Figure 2b).

The electron density distribution around the olefin shown in Figure 2b accounts for the reduced proton-proton coupling constants observed in the NMR spectra of coordinated olefins, which have been quoted as evidence for some sp^3 hybridization on the olefinic carbon atoms[12, 14]. The bonding scheme in Figure 2b can also account for the substituents R (where R = H or a more bulky group) on the multiple bond being bent out of the plane of the multiple bond away from the metal, since on going from the situation in Figure 2a to that in Figure 2b the electron density is shifted towards the C—R bonds. This will repel the C—R bond by bond-pair/bond-pair repulsion so forcing R away from the metal[35]. When this purely qualitative argument was examined semi-quantitatively using the CNDO-MO theory (Complete Neglect of Differential Overlap Molecular Orbital Theory) it was shown that for acetylenes addition of electron density to the pπ*-(antibonding) orbital of the multiple bond must cause either *cis*- or *trans*-bending of the substituents. *Cis*-bending is favored by both non-bonded interactions between the substituents and the central metal group, and by the fact that it enables the s-orbitals of the acetylene to assume the correct symmetry to contribute to the bonding[36]. Other explanations for the *cis*-bending of the substituents, that are in effect equivalent to the present one, consider the coordinated olefin or acetylene to be in an excited state[37, 38]. However, there is some disagreement as to the description of the excited state[37–39].

2.3. Summary

In conclusion, the σ-donation/π-back donation molecular orbital description of the bonding in platinum(II)-olefin and -acetylene complexes can explain all the known properties of these complexes. There is no necessity to invoke changes of hybridization of the olefinic carbon atoms from sp^2 to sp^3, since the same effect can be obtained by altering the relative importance of the σ- and π-components of the metal-olefin bond.

3. Platinum(0)-Olefin and -Acetylene Complexes

3.1. Experimental Observations

The more important experimental observations that any satisfactory description of the bonding in the zerovalent olefin and acetylene complexes of platinum, palladium and nickel must be able to explain are as follows:

1. The multiple bond is weakened and lengthened on coordination. This is indicated by the bond lengths of coordinated olefins and acetylenes as determined by X-ray diffraction (Table 3) and also by the lowering of the C≡C stretching frequency of acetylenes by about 500 cm^{-1} on coordination[47].

2. X-ray diffraction studies have shown that the axis of the multiple bond lies close to the plane containing the platinum and the other ligands. Values of between 8 and 14° have been reported for the dihedral angle α (Figure 3 and Table 3). The angle β (Figure 3) which the multiple bond subtends at the platinum atom is about 40° (Table 3).

3. X-ray diffraction studies have indicated that the substituents bound to the multiple bond are bent out of the plane of this bond away from the platinum atom (Table 3).

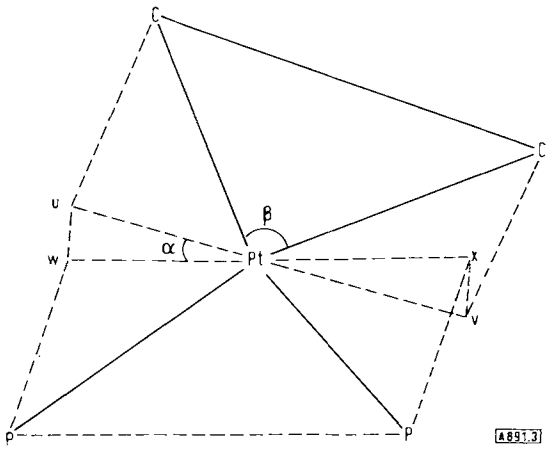

Fig. 3. The structure of olefin and acetylene complexes of platinum(0). The plane containing the points u, v, w and x together with the Pt atom is perpendicular to both the PtCC and PtPP planes.

Table 3. Results of X-ray diffraction studies of platinum(0) complexes.

Complex	C=C or C≡C Bond length (Å)		α [a]	Angle [°] β [a]	γ [b]	Ref.
	Complex	Free				
$[(PPh_3)_2Pt(TCNE)]$ [c]	1.49	1.34	8.3	41.5	32.5	[40, 41]
$[(PPh_3)_2Ni(C_2H_4)]$ [d]	1.46	1.33	12	42		[42]
$[(PPh_3)_2Pt(NC—C=C—CN)]$	1.40	1.19	8			[43]
$[(PPh_3)_2Pt(PhC\equiv CPh)]$	1.32	1.19	14	39	40	[44]
$[(^tBuNC)_2Ni(TCNE)]$ [c]	1.48	1.34	23.9	44.4	28.4	[45]

[a] See Figure 1 for definition of α and β.
[b] γ = angle by which substituents are bent out of the plane of the multiple bond away from the platinum atom.
[c] TCNE = tetracyanoethylene.
[d] Isomorphous with platinum(0) analog [46].

4. Olefins and acetylenes in which strongly electron-withdrawing substituents are bound direct to the multiple bond give more stable complexes than olefins with less electron-withdrawing substituents. This is indicated firstly by the decrease in the thermal stability of $[(PPh_3)_2Pt(R_2C=CR_2)]$ in the order R = CN (decomp. point 268—270 °C[48]) > R = F (decomp. point 218—220 °C[49]) > R = H (decomp. point 122—125 °C[50]), and secondly by studies of equilibrium (1), which showed that the position of the equilibrium favors the formation of the platinum(0) complex with the acetylene containing the most electron-withdrawing substituents (ac and ac' are substituted acetylenes)[51, 52].

$$[(PPh_3)_2Pt(ac)] + ac' \rightleftharpoons [(PPh_3)_2Pt(ac')] + ac \quad (1)$$

5. The melting-points of the complexes $[(PPh_3)_2Pt(olefin)]$, which vary from 122—125 °C for the ethylene complex to 268—270 °C for the tetracyanoethylene (TCNE) complex[53], are relatively high indicating the considerable thermal stability of the complexes.

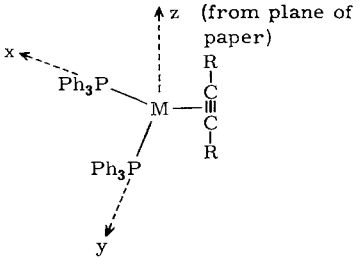
6. The observation of two separate coupling constants between the methyl group and the phosphorus atoms in the NMR spectrum[54] of $[(PPh_3)_2Pt(PhC\equiv CCH_3)]$ and the inequivalence of the two phosphorus atoms[55] in $[(PPh_3)_2Pt(CF_2{=}CFX)]$ (where X = Cl or CF_3) both indicate that rotation of the olefin or acetylene about the platinum(0)-olefin or -acetylene bond is slow relative to the NMR time scale (*i.e.* less than 1.2 s^{-1}). Further similar NMR evidence on related complexes supports these observations[56, 57].

7. The geminal fluorine-fluorine coupling constant in the NMR spectrum of $[(PPh_3)_2Pt(CF_3—CF=CF_2)]$ is of the same order as in a saturated fluorocarbon, which suggests sp^3 hybridization of the "olefinic" carbon atoms[49].

3.2. Molecular Orbital Treatment of the Bonding

The observations firstly that olefins and acetylenes in which strongly electron-withdrawing substituents are bound direct to the multiple bond give more stable complexes than ligands with less electron-withdrawing substituents and secondly that percyano-olefins and -acetylenes, which are known to be very good π-acceptor ligands but poor σ-donors, form stable complexes with platinum(0) suggest that if the bonding in platinum(0)-olefin complexes is described in terms of the Dewar-Chatt-Duncanson model[1, 2] it would be expected that the π-bond (from platinum(0) to the unsaturated ligand) would be fairly strong whereas the σ-bond (from the unsaturated ligand to platinum(0)) would be almost non-existent. This would lead to a substantial increase in the electron density in the pπ*-(antibonding) orbitals of the olefin or acetylene which would weaken and lengthen the multiple-bond as is observed (cf. Section 3.1). Furthermore, molecular orbital calculations have shown that addition of electron density to the pπ*-(antibonding) orbital of TCNE will increase the bond-order of the C—CN bond[58]. The decrease of the C—CN bond length from 1.449 Å in free TCNE[59] to 1.41 ± 0.04 Å on coordination to platinum(0)[40, 41] is thus consistent with the Dewar-Chatt-Duncanson model. The observation that the substituents attached to the multiple bond are bent out of the plane of this bond away from the platinum atom is also consistent with a substantial electron density in the pπ*-(antibonding) orbitals of the ligand, as discussed above in connection with platinum(II) complexes.

The near planarity of platinum(0)- and nickel(0)-olefin and -acetylene complexes (see Table 3 and Figure 3) as opposed to the almost perpendicular arrangement of the multiple-bond in relation to the square-plane around the platinum atom in the divalent complexes is readily explained by the



molecular orbital treatment. Zerovalent platinum complexes are tetrahedral (*e.g.* $[(PPh_3)_3Pt(CO)]$[60,61] and $[Pt(PF_3)_4]$[62]) because for a d^{10} atom there is no difference in the ligand field stabilization energies between a square-planar and a tetrahedral arrangement so that the ligands arrange themselves as far apart as possible (*i.e.* tetrahedral) to minimize bond-pair/bond-pair repulsion energies[35]. However, in an olefin or acetylene complex, where the π-back donation of charge from metal to olefin is large and the σ-donation from olefin to metal is small, there will be rather less than ten d-electrons around the platinum atom. This will lead to a Jahn-Teller distortion in which the tetrahedron is flattened, thus increasing the energy of one of the t_{2g} orbitals, which is left partly empty, and decreasing the energy of two of the t_{2g} orbitals, which are left full, relative to the energies in an undistorted tetrahedral environment[63].

The molecular orbital explanation for the observation that the geminal fluorine-fluorine coupling constant in the NMR spectrum of $[(PPh_3)_2Pt(CF_3—CF=CF_2)]$ is of the same order as in a saturated fluorocarbon is the same as advanced above for a similar observation with platinum(II) complexes (cf. Figure 2 and the related discussion).

The absence of free rotation of the olefin or acetylene about the platinum(0)-olefin or -acetylene bond arises because the platinum $6p_z$ and $5d_{z^2}$ orbitals are not readily available for back-donation to the unsaturated ligands because they are involved in back-donation to the triphenylphosphane ligands. Thus the flattened tetrahedral structure, in which the back-donation occurs from the $d_{x^2-y^2}$ orbital[27,28], is considerably more stable than any other arrangement, so preventing the occurrence of free rotation about the platinum(0)-olefin or -acetylene bond. This argument has recently[25,26] been put on a semi-quantitative basis by calculating the total energy of the complexes $[(PH_3)_2Pt(CH_3C{\equiv}CCH_3)]$ and $[(PH_3)_2Pt(C_2H_4)]$ as a function of the angle between the multiple bond axis and the PtP_2 plane. The results show a single minimum when the multiple bond lies in the PtP_2 plane. The fact that these calculations predict a minimum energy when the dihedral angle α (see Figure 3) is zero is probably an indication of the approximate nature of the calculations rather than an indication of the importance of crystal packing effects in the solid state, since crystal packing effects would be expected to vary markedly over the range of complexes shown in Table 3, whereas, with the exception of $[(t\text{-BuNC})_2Ni(TCNE)]$ the complexes show a remarkably constant value of α.

Recent molecular orbital calculations[27,28] have reinforced the conclusion mentioned above that the strength of the metal(0)-olefin or -acetylene interaction is strongly dependent on the amount of π-back donation from the metal. These calculations also indicated that the metal s-orbital was not involved to any significant extent in bonding. When group theory was used to develop a new bonding model that was consistent with this the bonding scheme in Table 4 was obtained.

Table 4. Orbitals involved in the bonding in metal(0)-olefin and -acetylene complexes.

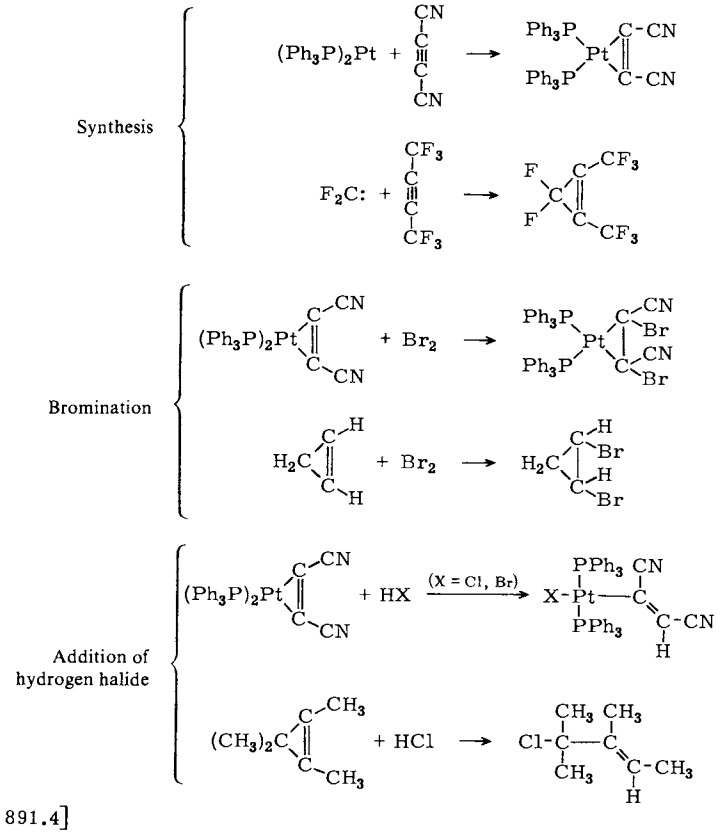
Type of bonding	Orbitals involved in olefin complexes	Orbitals involved in acetylene complexes
σ-donation to the metal	From π-orbital of olefin to dp^2 ($d_{xy}+p_x+p_y$) hybrid on metal	(1) From π_{xy}-orbital of acetylene to dp^2 ($d_{xy}+p_x+p_y$) hybrid on metal. (2) From π_z-orbital of acetylene to d^2 ($d_{xz}+d_{yz}$) hybrid on metal.
π-back donation from the metal	From $d_{x^2-y^2}$ orbital on metal to π^*-(antibonding) orbital on olefin	(1) From $d_{x^2-y^2}$ orbital on metal to π^*_{xy}-(antibonding) orbital on acetylene. (2) From d^2 ($d_{xz}+d_{yz}$) hybrid on metal to π^*_z-(antibonding) on acetylene.

3.3. Valence Bond Treatment of the Bonding

In the valence bond description the olefin or acetylene is considered to be a dicarbanion which forms two σ-bonds to platinum, which is itself in the +2 oxidation state. This description can readily account for the following experimental observations:

1. The substituents at the multiple bond are bent away from the platinum atom on coordination. This would be an immediate consequence of the rehybridization of the carbon atoms from the sp^n to the sp^{n+1} arrangement necessary for the formation of two platinum-carbon σ-bonds ($n=1$ for acetylenes and $n=2$ for olefins). However, if the carbon atoms of the olefin are rehybridized from sp^2 to sp^3 on coordination, then the angle γ in Table 3 should be 54°44′. Since the observed values of γ (Table 3) are substantially less than 54°44′, the argument in favor of sp^3 hybridization does not appear to be warranted, particularly

in view of the ease with which the MO theory can interpret the experimentally observed values of γ.



2. The geminal fluorine-fluorine coupling constant in the NMR spectrum of $[(PPh_3)_2Pt(CF_3{-}CF{=}CF_2)]$ is of the same order as in a saturated fluorocarbon, which suggests sp^3 hybridization of the "olefinic" carbon atoms and hence platinum-carbon σ-bonds[49].

3. There is no free rotation of the olefin or acetylene about the metal-olefin or -acetylene bond.

4. The VB treatment is useful in accounting for the analogies between the acetylene complexes and cyclopropenes as shown in the preparation, bromination, and addition of hydrogen halide reactions given below[64].

and rehybridization of the carbon atoms of the multiple bond[66], has recently been criticized on the grounds that the actual twisting is very small, even in $[(t\text{-BuNC})_2Ni(TCNE)]$ where the largest value of α yet observed was found[45].

2. The small values observed for the C—Pt—C angle (β in Figure 3) together with the values of about 70° observed for the C—C—Pt angle, which are in contrast to the optimum C—C—Pt angle of 109°28′ for the formation of a strong σ-bond, suggest that the three-membered  ring would be very strained. However, since the melting points of the $[(PPh_3)_2Pt(olefin)]$ complexes vary from

[A 891.4]

However, whilst the valence bond conception provides a useful way of looking at these reactions, the mechanisms of the bromination and hydrohalogenation reactions are not yet sufficiently well understood to know if the structural and mechanistic implications of the valence bond formulation are valid.

In spite of the apparent successes just listed, the valence bond description is hard pressed to account for the following experimental observations:

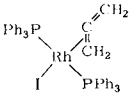
1. The angle α in Figure 3 generally lies between 8° and 14°. To account for this it is necessary to assume that the eclipsed position of the substituents on the multiple-bond is sufficiently unstable to cause the sp^3 hybrid orbitals to rotate towards the staggered position[65]. However, these substituents are sufficiently remote from each other for this to be rather unlikely. A suggestion, similar to the present one, that the values of α arise from a combination of twisting

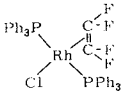
122—125°C for the ethylene complex to 268—270°C for the TCNE complex[53], there would not appear to be as much strain as is suggested by these small angles.

3.4. Summary

The MO and VB descriptions of the bonding in the zerovalent complexes are equivalent in that both predict that the platinum atom has less than ten 5d-electrons (*i.e.* is formally in a positive oxidation state) and that the coordinated unsaturated ligand has a higher electron density around it than when it is free. In addition, both theories suggest that the bulk of the electron density in the platinum-olefin or -acetylene bond lies along the edges of the  triangle rather than in the center of this triangle (cf. Fig. 2c).

The MO description has two important advantages over the VB description. Firstly it can readily explain all the experimental observations reported to date for these complexes whereas the valence bond description cannot, and secondly its flexibility in terms of variations of the relative strengths of the σ- and π-components of the metal-olefin bond allows essentially the same bonding description to be used for the complexes of a whole series of metals.

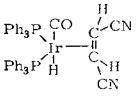


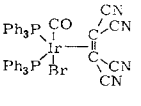


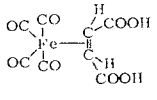
4. Olefin and Acetylene Complexes of Other Metals

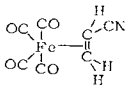
In the present section the physical properties of olefin and acetylene complexes of the transition metals other than nickel, palladium, and platinum are considered. It is immediately apparent that the depth of study that has so far been accorded to these complexes is slight relative to that given to the complexes of nickel, palladium, and platinum.

4.1. X-Ray Diffraction Studies









The structural data obtained from X-ray diffraction, summarized in Tables 5 and 6, is similar in its consequences for the bonding scheme to that in Tables 1 and 3. Thus in all the complexes the multiple-bond increases in length on coordination and where they have been observed the substituents attached to the multiple bond have been found to be bent out of the plane of that bond away from the metal atom. In the square-planar rhodium(I) complexes (Table 5) the olefin axis is approximately perpendicular to the ligand plane as found in the square-planar platinum(II) complexes reported in Table 1, whereas in the trigonal-bipyramidal

Table 5. Structural data on square-planar [a] rhodium(I)-olefin complexes.

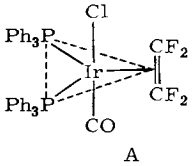
[c] TCNE = tetracyanoethylene.
[d] Reference [75].



complexes (Table 6) the olefins lie in or nearly in the trigonal plane, which is similar to the arrangement in the zerovalent complexes reported in Table 3.

The X-ray diffraction studies that have been reported so far thus provide no information which cannot be accounted for in the molecular orbital description of the bonding as outlined above for divalent and zerovalent complexes of platinum.

4.2. NMR Studies

The temperature dependence of the ^{1}H-NMR spectrum of $[(\pi\text{-}C_5H_5)Rh(C_2H_4)_2]$ can best be understood in terms of free rotation about the rhodium-ethylene σ-bond axis with a rotational energy barrier of about 6 kcal/mol[76]. This can be understood in an essentially similar way to the rotation of olefins about the metal-olefin bond in platinum(II) complexes discussed above, and therefore once again does not introduce any new experimental data that the MO bonding scheme cannot accommodate.

A study of the ^{19}F-NMR spectra of the fluoro-olefin complexes of rhodium(I), iridium(I) and nickel(0) has shown that these fall into two main series[77]. In the first series, typified by $[Rh(acac)(C_2F_4)]$ and $[Ni(PPh_3)_3(C_2F_4)]$, all the fluorine atoms absorb in the same region suggesting a square-planar structure with free rotation about the metal-tetrafluoroethylene bond. This structure is of course analogous to that found for platinum(II) complexes. In the second series, typified by $[Rh(acac)(n\text{-}C_5H_{11}NC)(C_2F_4)]_2$ and $[IrCl(CO)(PPh_3)_2(C_2F_4)]$, two fluorine resonances were observed indicating the presence of two sets of fluorine atoms in chemically non-equivalent environments. By analogy with $[IrCl(CO)(PPh_3)_2(TCNE)]$ the structure of the iridium(I) complex is probably trigonal bipyramidal:

A

If the tetrafluoroethylene molecule lies in the trigonal plane and if there is no rotation about the iridium(I)-tetrafluoroethylene bond two ^{19}F-NMR signals would be expected. This structure, as already pointed out in Section 4.1, is analogous to the structure found in zerovalent platinum complexes. Thus these ^{19}F-NMR results substantiate the conclusion reached above from the X-ray diffraction results that olefin complexes fall into two main classes, those formally analogous in structure and bonding to the square planar platinum(II) complexes and those formally analogous to the platinum(0) complexes.

4.3. Infrared Studies

The IR spectra of olefin complexes indicate that the double-bond stretching frequency decreases on coordination, although, as mentioned above, the absolute magnitudes of the values which are quoted in Table 7 may be open to some doubt due to the problem of coupling of the $>CH_2$ deformation mode with the C=C stretching mode. What is certain is that there is a decrease in the C=C stretching frequency on coordination in agreement with the predictions of the MO bonding scheme.

Table 7. Stretching frequencies for the double bond of ethylene.

Metal	Complex	$\nu_{C=C}$ (cm^{-1})	Ref.

[a] acac = acetylacetonate = 2,4-pentanedione.

When an olefin coordinates to $[IrCl(CO)(PPh_3)_2]$ there is an increase in the CO stretching frequency of the coordinated carbon monoxide ligand[86]. Furthermore, this increase is greatest for olefins with weak σ-donor but strong π-acceptor capacities (see Table 8). An increase in the CO stretching frequency of a metal-carbonyl complex indicates a reduction in the π-back donation of charge from the metal to carbon monoxide. Such a reduction in π-back donation accompanies the oxidation of a metal; for example $[IrCl(CO)(PPh_3)_2]$ containing iridium(I) has ν_{CO} equal to 1966 cm^{-1}, whereas $[IrCl_3(CO)(PPh_3)_2]$ containing iridium(III) has ν_{CO} equal to 2080 cm^{-1}. A series of complexes such as that shown in Table 8 demonstrates the advantages of the MO approach to metal-olefin bonding because of its built-in flexibility. It is apparent that as Table 8 is descended there is an increase in the relative importance of the π-component of the metal-olefin bond and a decrease in the rela-

tive importance of the σ-component of that bond which leads to an effective transition from iridium(I) to iridium(III) as the Table is descended. The strength of the MO approach lies in its relative disinterest in the oxidation state of the metal, whereas by contrast the VB approach can only draw the two extreme formulations shown in Figure 4, and then consider resonance between unequal amounts of these two canonical forms.

Fig. 4. Extreme valence bond formulations for iridium-olefin complexes.

4.4. Summary

The physical properties of metal-olefin and -acetylene complexes just discussed suggest that they fall into two classes, class S and class T[*].

Class S Complexes are formally analogous in their properties and bonding to the square-planar complexes of platinum(II), discussed in Section 2 of this paper. It is also possible to have ligands above and below the square-plane and still have essentially the same properties. For example the room temperature proton NMR spectrum of the octahedral complex *cis*-$[Re(CO)_4(C_2H_4)_2]^+PF_6^-$ exhibits only the single proton signal[80] that would be consistent with the free rotation of ethylene about the metal-olefin bond found for other class S complexes.

Class T Complexes are formally analogous in their properties and bonding to the trigonal complexes of platinum(0) discussed in Section 3 of this paper. Again it is possible to have ligands coordinated above and below the trigonal plane giving trigonal bipyramidal complexes.

Thus class S complexes, as the name implies, involve three other ligands coordinated to the metal in the same plane as the unsaturated ligand, whereas class T complexes only have two other ligands in addition to the unsaturated ligand. One of the principal differences between the two classes of complexes is that whereas class S complexes exhibit free rotation of the olefin or acetylene about the metal-olefin or -acetylene bond, there is no such free rotation in the class T complexes.

5. Conclusions

It has been shown that the transition metal complexes of monoolefins and monoacetylenes fall into two main structural classes which are labeled S and T. An examination of of the description of the bonding in each of these two classes has indicated that the MO scheme is able to interpret all the experimental observations reported to date for these two classes whereas the VB description cannot. The MO scheme is simple to visualize and, since it is anticipated that the relative importance of the σ- and π-components will vary according to (i) the metal atom, (ii) the oxidation state of the metal atom, (iii) the nature of the olefin, and (iv) the nature of the other ligands present, this description of the bonding can readily be applied to all metal-olefin complexes. It should be pointed out that this scheme precludes any involvement of the carbon 2s orbital in the metal-olefin bond. As yet no evidence that unequivocally supports carbon 2s participation has been put forward.

I should like to thank Imperial Chemical Industries Limited for the award of a Research Fellowship during the tenure of which part of this work was carried out.

Nuclear Magnetic Resonance in Solid-State Chemistry[**]

By Alarich Weiss[*]

Various problems of solid-state chemistry can be solved by spectroscopic investigation of the nuclear magnetic resonance (NMR and NQR methods). This progress report presents a survey of the nature of the interactions in the crystal that underlie such measurements, of the observations in the spectrum, and of the information obtainable from it. The field of application of the methods covers both static and dynamic properties of solids.

1. Introduction

During the past twenty years, nuclear magnetic resonance has acquired a dominant place in molecular chemistry as a physical method of investigation in the liquid phase. In solid-state chemistry NMR is comparable with other methods of solid-state spectroscopy, such as IR and Mössbauer spectroscopy, as a source of information.

A well-developed theory of nuclear magnetic resonance, which is substantially complete in its fundamental principles, is provided by physics[1-6]. It is only in recent years, however, that experimental advances have opened up new areas for the use of the method in the investigation of solids.

One usually distinguishes two experimental branches of nuclear resonance spectroscopy, *i.e.* nuclear magnetic resonance (NMR) and pure nuclear quadrupole resonance (NQR or PQR).

For our purposes, however, it seems more appropriate to choose a classification based on the aim of application rather than on the procedure, *i.e.* the determination of (a) static properties and (b) dynamic properties of the solid by nuclear magnetic resonance.

The possibilities offered by the application both of the NMR and of the NQR method to problems of solid-state chemistry will be discussed below with the aid of examples.

2. Physical Principles

2.1. Nuclear Magnetic Resonance (NMR)

We start with the observation that atomic nuclei in many cases have a nuclear angular momentum $\hbar\vec{I}$, which is associated with a magnetic dipole moment $\vec{\mu}$ because of the rotating charge of the nucleus. The vector of the magnetic dipole moment is parallel and proportional to the angular momentum vector:

$$\vec{\mu} = \gamma\hbar\vec{I} \tag{1}$$

γ is the magnetomechanical (gyromagnetic) ratio and $\hbar\vec{I}$ is the nuclear angular momentum vector. To determine the quantities in eq. (1), it is necessary to bring about an interaction between $\vec{\mu}$ and a second quantity in order to obtain an observable value.

If a macroscopic magnetic dipole $\vec{M}$ interacts with a magnetic field $\vec{H}_0$, the interaction energy according to classical theory is

$$E = -\vec{M}\cdot\vec{H}_0 \tag{2}$$

In the case of the magnetic moment of an atomic nucleus (or of an electron), however, certain restrictions must be imposed on the relation (2). The possible orientations of the vector $\vec{I}\hbar$ with respect to the field $\vec{H}_0$ are limited, since only certain angles are possible between $\vec{I}\hbar$ (and hence $\vec{\mu}$) and $\vec{H}_0$. The angular momentum is subject to quantum conditions. For stable nuclei, the angular momentum quantum numbers $I = 1/2, 1, 3/2, \ldots, 6$ are found in the periodic system of elements. For a nucleus with the angular momentum quantum number I there are only $2I+1$ allowed orientations of the angular momentum vector $\vec{I}\hbar$ in relation to the preferred direction $\vec{H}_0$. The energy of these states is given by

$$E_m = -m\gamma\hbar H_0 \tag{3}$$

m is the magnetic quantum number, with the values $I, I-1, \ldots, -I$, and $\hbar = h/2\pi$ represents the Dirac constant. The nuclear spin axis precesses with the Larmor frequency $\nu_0 = \omega_0/2\pi$ about the direction of $\vec{H}_0$. A transition of the nucleus from an energy state characterized by the magnetic quantum number m_a to another energy state with $m = m_b$ is allowed only if $\Delta m = m_a - m_b = \pm 1$. Thus if the energy corresponding to the energy difference between two successive levels is supplied to the system from outside, this energy can be taken up by the nuclear spin system. This "resonance energy" is given by

$$E_R = |E_{m+1} - E_m| = \hbar\omega_0 = \gamma\hbar H_0 \tag{4}$$

and one obtains the general resonance equation

$$\omega_0 = \gamma H_0 \tag{4a}$$

New address (since March 5, 1972):
Eduard-Zintl-Institut für Anorganische und Physikalische Chemie der Technischen Hochschule
61 Darmstadt, Hochschulstrasse 4 (Germany)

[**] Based on a lecture to the "Solid-State Chemistry" Group of the GDCh on October 1, 1970, in Bonn.

If the external magnetic field is denoted by H_0, this equation is strictly valid only if the experiment is carried out on the bare nucleus, since only then is the effective field H_0 at the position of the nucleus identical with the applied field. In all cases that can be realized in practice, however, it is necessary to modify eq. (4a):

$$\omega_0 = \gamma\left(H_0 + \sum_i H_i\right) = \gamma H_{\text{eff}} \tag{4b}$$

where the H_i may be internal magnetic fields arising from various sources. To give one example, the nuclei are surrounded by electrons, and in a magnetic field H_0, according to *Lenz*'s law, these produce a magnetic field H_i that opposes the external field. The external field is thus weakened at the position of the nucleus (diamagnetic shielding), and the effective field is $H_{\text{eff}} = H_0 - H_{\text{diamagnetic}}$.

2.2. Nuclear Quadrupole Resonance (NQR)

In addition to their electric charge some nuclei also possess electric moments of higher order, a fact which was already deduced many years ago from the study of the hyperfine structure of atomic spectra[7]. An interaction is therefore to be expected between the electric moment of the nucleus and the electric field, or more precisely its derivatives at the position of the nucleus. To calculate the electrostatic interaction of a nucleus with its environment, let us consider a nucleus having an atomic number Z, whose electric charge Ze is distributed over the entire volume of the nucleus. Let the charge density at the point $\vec{x}$ of the nucleus be $\rho_K(\vec{x})$. Let $V(\vec{x})$ be the electrostatic potential produced at the point $\vec{x}$ by all charges situated outside the nucleus in question. Taking the finite volume of the nucleus into account, one thus obtains the electric interaction energy between the nucleus and its environment:

$$\begin{aligned} W_{\text{el}} &= Ze \cdot V(0) + \vec{d} \cdot \vec{E} + \tfrac{1}{2} e\, \mathbf{Q} \cdot \nabla \vec{E} + \cdots = \\ &\text{(nuclear charge} \times \text{potential)} \\ &+ \text{(electric nuclear dipole moment} \times \text{electric field)} \\ &+ \text{(electric nuclear quadrupole moment} \times \text{electric field gradient)} \\ &+ \text{higher terms} \end{aligned} \tag{5}$$

The first term in eq. (5) is of no importance to our discussion, since it is a constant that is independent of direction, and which merely corresponds to a shift of the zero point on the energy scale. The second term (for symmetry reasons) is zero. The third term, however, is of great interest for the study of solids by NMR. The higher order terms that are also possible will be disregarded. One of the conditions for the occurrence of an interaction energy between the electric nuclear quadrupole moment and an electric field gradient at the position of the nucleus is of course the presence of an electric nuclear quadrupole moment, $e\mathbf{Q}$, where e is the elementary charge and $\mathbf{Q}$ is a 2nd rank tensor, which characterizes the symmetry of the charge distribution in the nucleus. The condition for an $e\mathbf{Q}$ different from zero is a nuclear angular momentum quantum number $I > 1/2$. The nuclear quadrupole moment tensor $e\mathbf{Q}$ can be described by the scalar moment eQ, since it may be assumed that the tensor is symmetrical and has a vanishing trace. We have: $Q \gtreqless 0$, as illustrated in Figure 1. Q is expressed in units of 10^{-24} cm^2. The second term in the product describing the interaction energy is the electric field gradient $\nabla\vec{E}$ at the position of the nucleus. It is determined by the charge distribution, *e.g.* by the electric charges, electric dipole moments, electric quadrupole moments in ionic crystals and molecular lattices, by deviations from spherical symmetry of the electron core surrounding the nucleus, by bonding electrons, *etc.*

In solid-state chemistry, knowledge of the nuclear quadrupole moment eQ will generally be assumed (this is not trivial), and conclusions concerning the bonding in the solid will be drawn from the study of the nuclear quadrupole interaction energy.

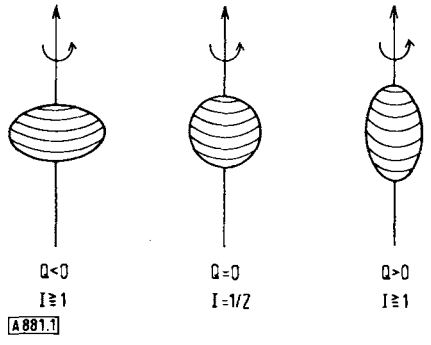

Fig. 1. Nuclear quadrupole moment and rotationally symmetrical charge distribution of nuclei.

The electric nuclear quadrupole moment is also connected with the nuclear angular momentum axis. Corresponding to the interaction energy between $\vec{\mu}$ and $\vec{H}_0$, an interaction energy arises here between $e\mathbf{Q}$ and the electric field gradient at the position of the nucleus [eq. (5)]. $\nabla\vec{E}$ is the second derivative of the potential with respect to the space coordinates at the position of the nucleus, a symmetrical tensor $\boldsymbol{\phi}$ with three principal axial components $\phi_{xx}, \phi_{yy}, \phi_{zz} : |\phi_{xx}| \leqq |\phi_{yy}| \leqq |\phi_{zz}|$. The maximum component of $\boldsymbol{\phi}$, *i.e.* ϕ_{zz}, is often expressed by eq, where e is again the elementary charge.

The interaction energy can be calculated without difficulty, and we find for the simplest case ($\phi_{xx} = \phi_{yy}$)

$$E_m = \frac{eQ}{4I(2I-1)}\left[3m^2 - I(I+1)\right]\phi_{zz} \tag{6}$$

The supply of energy quanta $h\nu$, *i.e.* the resonance experiment, is carried out in practice in the same manner as in the nuclear magnetic resonance experiment by irradiation of the sample with electromagnetic waves of frequency ν. The transition from the energy state with $m = m_a$ to a state with $m = m_b$ is again brought about by the interaction of the magnetic nuclear dipoles with the alternating magnetic field H_1 of the incident radiation.

Finally, let us consider briefly the energy level diagram for magnetic dipoles and electric quadrupoles in the magnetic field, H_0, and in the gradient of the electric field, ϕ_{zz}, respectively.

Equation (3) shows that the energy level diagram of the nuclear spin system in the magnetic field H_0 is split proportionally to the field (Fig. 2; Breit-Rabi diagram for $I = 3/2$).

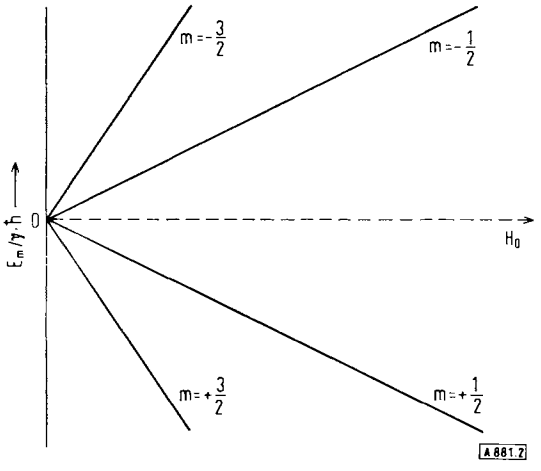

Fig. 2. Breit-Rabi diagram for the nuclear spin $I = 3/2$. The energy unit $E_m/\gamma\hbar$ is arbitrarily chosen.

In the experiment we consider only the transitions $\Delta m = \pm 1$ between two adjacent energy levels. For the case $I = 1/2$, we have $\Delta E = E_{-\frac{1}{2}} - E_{\frac{1}{2}} = \gamma\hbar H_0$. For $I = 3/2$, the transitions $\Delta E_{(-1/2 \rightleftarrows -3/2)}$, $\Delta E_{(-1/2 \rightleftarrows +1/2)}$, and $\Delta E_{(1/2 \rightleftarrows 3/2)}$ are possible; for each transition, $\Delta E = \gamma\hbar H_0$. Figure 3 shows the energy levels and the spectrum expected according to eq. (4) for $I = 1/2$ and $I = 3/2$.

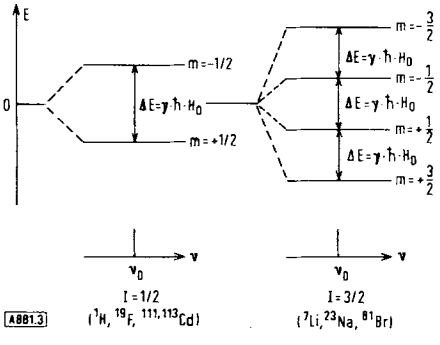

Fig. 3. Energy levels of nuclear spin systems with $I = 1/2$ and $I = 3/2$ in the magnetic field. The transitions with $I = 3/2$ are triply degenerate (energy scale arbitrary).

For the case of the interaction between the electric field gradient and the nuclear quadrupole moment, eq. (6) gives the energy level diagram illustrated *e.g.* for $I = 1$, $I = 3/2$, and $I = 5/2$ in Figure 4.

So far we have considered only resonance frequencies, *i.e.* energy states. As in all branches of spectroscopy, however, intensities and line shapes are also important in NMR spectroscopy. The effective intensities and line shapes are essentially determined by the interactions of the nuclear spins with their environment. Two parameters are important for their description, *i.e.* the spin-lattice relaxation time (longitudinal relaxation time) T_1 and the spin-spin relaxation time (transversal relaxation time) T_2. As will be shown later, the determination of

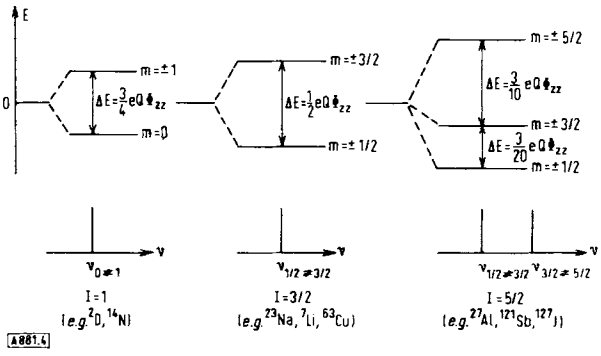

Fig. 4. Energy splitting due to nuclear quadrupole interaction ("pure nuclear quadrupole resonance", PQR) for $I = 1, 3/2$, and $5/2$. Since $E \sim m^2$, the levels are degenerate. The energy scale is arbitrary. As a limiting condition $|\Phi_{xx}| = |\Phi_{yy}| = \frac{1}{2}|\Phi_{zz}|$. The quantity $eQ\Phi_{zz}/h \equiv e^2qQ/h$ is known as the quadrupole coupling constant, and is usually expressed in hertz [Hz].

these parameters leads to results that are of interest in solid-state chemistry. However, the theory of relaxation times will not be discussed here (see *e.g.*[1],[2] or[4]).

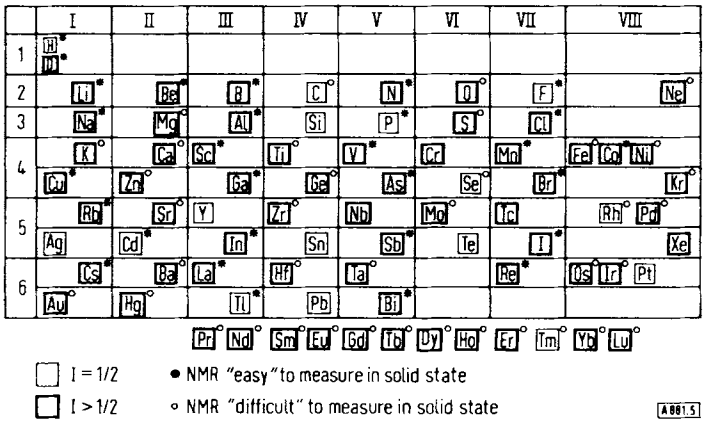

Fig. 5. Stable nuclei with $I \neq 0$ in the periodic system of the elements.

Unlike high-resolution NMR spectroscopy, NMR spectroscopy on solids is subject to only a few restrictions regarding the periodic system of the elements. Figure 5 summarizes schematically the nuclei on which NMR and (for $I > 1/2$) NQR experiments can be carried out. (Unstable nuclei with short half-lives, which escape the normal experimental methods, are not included; the statement that the NMR is "easy" or "difficult" to measure is a personal opinion, and is also strongly dependent on the relaxation times T_1 and T_2.)

3. Application of Nuclear Magnetic Resonance to the Study of Properties of Solids

3.1. Magnetic Nucleus-Nucleus Interactions in the Ideal Rigid Lattice

The simplest case, and also the first one investigated[8], of an interaction in solids that can be studied by the NMR method is the interaction between nuclear moments in a rigid lattice. The interaction energy E_{ij} of two nuclear

dipoles $\vec{\mu}_i$ and $\vec{\mu}_j$ separated by the distance vector $\vec{r}_{ij}$ is given by:

$$E_{ij} = \frac{\vec{\mu}_i\vec{\mu}_j}{r_{ij}^3} - 3\frac{(\vec{\mu}_i\vec{r}_{ij})(\vec{\mu}_j\vec{r}_{ij})}{r_{ij}^5} \qquad (7)$$

The most important case in solid-state chemistry is the interaction between two like nuclei, *e.g.* the two protons of the water molecule in crystalline hydrates. A qualitative interpretation of this interaction is that in addition to the field H_0, a field due to the magnetic moment of the proton j acts at the position of the proton i [see eq. (4b)], this second field being given by $\pm\mu r_{ij}^{-3}(3\cos^2\theta - 1)$.

Thus according to *Pake*[8], the "splitting" of the ^{1}H-NMR in the lattice is given by

$$\Delta H = 2\alpha[3\cos^2\delta\cos^2(\varphi - \varphi_0) - 1] \qquad (7a)$$

where $\alpha = \pm\frac{3}{2}\mu_p \cdot r_{ij}^{-3}$. The angles δ, φ, and φ_0 give the orientation of the vector $\vec{r}_{ij}$ joining the protons and of the magnetic field $\vec{H}_0$ with respect to each other and to a system of coordinates (Fig. 6).

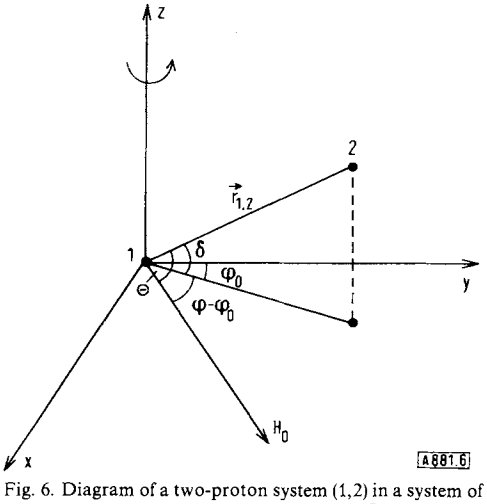

Fig. 6. Diagram of a two-proton system (1,2) in a system of coordinates x, y, z to illustrate the Pake formula [eq. (7a)].
$\vec{r}_{1,2}$ is the vector joining the pair of protons, $\varphi = \sphericalangle\,[\vec{H}_0$, reference axis $(y)]$, δ = angle between $\vec{r}_{1,2}$ and the plane containing $\vec{H}_0$ and the reference axis: $\theta = \sphericalangle\,(\vec{r}_{1,2}, \vec{H}_0)$.

The resulting NMR splitting spectrum of protons according to eq. (7a) for a two-spin system is shown in Figure 7 for $Li_2S_2O_6 \cdot 2H_2O$[12].

What information is obtainable from the spectra?

a) The splitting ΔH is very strongly dependent on the distance r_{ij}, and the H-H distance can therefore be determined very accurately.

b) The spectrum is strongly dependent on angle, and the direction cosine of the H-H vector can therefore be determined.

From the spectrum of a single crystal of a crystalline hydrate, therefore, it is possible to find the length and direction of the H-H vectors in a molecule. Further information is necessary in order to relate these vectors to the origin of the unit cell. For example if the point

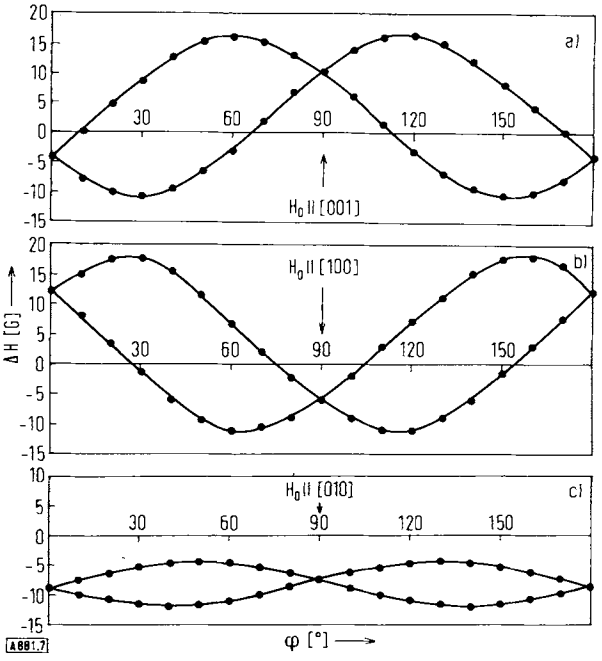

Fig. 7. Pake splitting in the ^{1}H-NMR spectrum of single crystals of $Li_2S_2O_6 \cdot 2H_2O$; after [12]. a) Axis of rotation ∥ [100]; b) axis of rotation ∥ [010]; c) axis of rotation ∥ [001].

positions of the oxygens of the water molecules in a crystalline hydrate are known, the H-H vector is fixed by the NMR experiment on the lateral surface of a cylinder. To obtain information on hydrogen bonds or on the point positions of the protons in general, therefore, it is necessary to know the angle between the two vectors O-H in the molecule, or to know the O-H distance, and to assume the direction of the hydrogen bond. Numerous NMR studies have already been carried out on the geometry of H_2O molecules in crystals (cf.[9-11]). For a complete determination of the positions of the protons, it should be sufficient in principle to know the point positions of the oxygens and to take into account the nuclear magnetic ^{1}H-^{1}H interactions of nearest and next-nearest neighbors. Owing to the strong dependence of the interaction on r_{ij}, however, the resolving power of the method is probably too low to allow a complete crystal structure determination of the proton partial lattice in this way (see *e.g.*[12, 13]).

It is often impossible to obtain suitable single crystals (which should have a size of about 1 cm^3 for classical nuclear magnetic resonance experiments) for the NMR studies. The measurements are then carried out on polycrystalline samples. For very simple cases (two-spin and three-spin systems), such a spectrum can be evaluated in accordance with eq. (7a) if an average has been taken over the angles. However, only r_{ij} can be determined from the result, while the information on the angles is lost. CH_3 groups or $(H_3O)^+$ ions in solids have been studied in this way in several investigations. A typical example is the proton resonance in crystalline $HNO_3 \cdot H_2O$, which may be regarded as $[H_3O]^+[NO_3]^-$ [14] (Fig. 8).

For a four-spin system, *e.g.* NH_4^+ or CH_4, evaluation by *Pake*'s method can no longer be used for crystalline

powders or even for single crystals. It is then necessary to use *Van Vleck*'s method, *i.e.* the "method of higher moments"[15]. Numerous examples can be found in the literature. In any case, the ^{1}H-NMR measurement is very useful as a complement to the diffraction method.

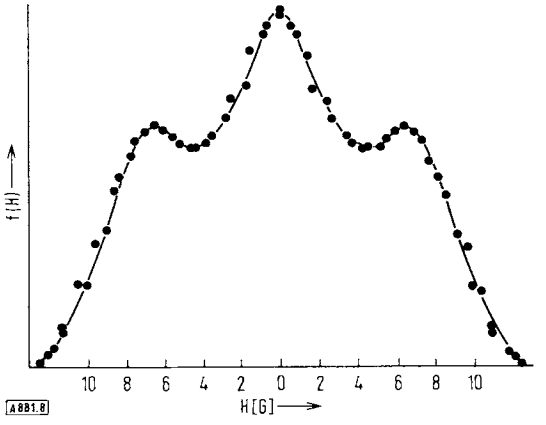

Fig. 8. ^{1}H-NMR spectrum of crystalline $HNO_3 \cdot H_2O$. The experimental data (points) were obtained at 90°K. The continuous curve was calculated from *Van Vleck*'s theory for an H_3O^+ ion (the protons are situated on a triangle having a side length of 1.72 Å). The ordinate scale is arbitrary [14].

Apart from the interaction between protons in the lattice, the only others that can be considered are those between ^{19}F and possibly between ^{31}P nuclei and $^1H \leftrightarrow {}^{19}F$, $^1H \leftrightarrow {}^{31}P$, and $^{31}P \leftrightarrow {}^{19}F$ interactions. For all other nuclei, the determination of distances (and of point positions) by means of nuclear magnetic resonance is too inaccurate to compete with the diffraction methods.

3.2. Interaction between Nucleus and Electron Cloud in the Rigid Lattice

3.2.1. The Chemical Shift

It is known that when the NMR method is used in molecular spectroscopy, two effects characterize the resonance spectrum, *i.e.* the chemical shift and the electron-coupled spin-spin interaction. The second of these effects is of practically no importance in the case of solids; the hyperfine structure produced thereby in the spectrum is masked in most cases by the line widths due to dipole-dipole interaction. However, it is possible to study the chemical shift.

As a result of an investigation of the chemical shift, we expect information about the chemical bonding. In solids, however, the chemical shifts are often superimposed by very much stronger effects, *e.g.* the dipole-dipole interactions; such shifts can therefore be easily measured only under certain conditions. For this reason we shall group these interactions on an experimental basis. It should be noted that the "overall range" of the chemical shift of the NMR is strongly dependent on the atomic number (or rather on the number of electrons in the atomic shell), the effect increasing with the number of electrons *(Lamb)*. Thus it is known from high-resolution NMR spectroscopy that the shifts, which are defined by

$$\delta = \frac{H_{sample} - H_{standard}}{H_{standard}} \times 10^6 \qquad (8)$$

cover a range of about 30 ppm for ^{1}H-NMR. This range is 150 ppm for ^{11}B, about 300 ppm for ^{19}F, about 600 ppm for ^{14}N, about 800 ppm for ^{18}O, about 2000 ppm for ^{119}Sn, and about 15000 ppm for ^{207}Pb.

3.2.2. Chemical Shift of the NMR of Nuclei with $I = 1/2$

1. *Heavy nuclei* (mass number >100): The chemical shifts here are in the region of a few 10^3 ppm, *i.e.* with a field H_0 of 10000 Oe they have values of up to 100 Oe. On the other hand, the heavy atoms and ions have fairly large radii (>1 Å), so that because of nucleus-nucleus interaction in accordance with eq. (7a), the line widths reach values of around 1 Oe (an exception is Tl metal).

The chemical shifts of the NMR in solids can thus be readily observed for the nuclei ^{207}Pb, ^{205}Tl, ^{203}Tl, ^{199}Hg, ^{195}Pt, ^{119}Sn, ^{113}Cd, ^{109}Ag, and ^{107}Ag if the spectrum is recorded against a standard in the usual manner (see *e.g.*[25, 26, 32]).

2. *Light nuclei:* The most important of these are ^{1}H, ^{19}F, and ^{31}P. Their magnetic moments are very high, and the magnetic nucleus-nucleus dipole interaction therefore leads to considerable line widths. The chemical shift, on the other hand, is small. There are two methods of suppressing the nucleus-nucleus interaction corresponding to eq. (7a) and revealing the chemical shift:

a) Rotating solid sample after *Andrew*[16] and *Love*[17]: A series of interactions in solids depend on the angle between H_0 and the direction that determines the interaction of the nuclei with their environment according to a law that contains the term $(3\cos^2\theta - 1)$ (cf. *e.g.* eq. (7a) and Fig. 6). These interactions can be partly averaged out by rapid rotation of the sample about an axis that forms the angle $\theta = 54°44'$ with the field H_0, since the value of $(3\cos^2\theta - 1)$ is then 0. However, the experimental arrangement is not simple. *Andrew et al.*[16], for example, have investigated the chemical shift of ^{31}P resonances in a number of crystalline phosphorus compounds; they obtained the results indicated in Table 1.

Table 1. Chemical shift of the ^{31}P-NMR of phosphorus compounds (δ in ppm, with respect to 85% H_3PO_4); after [16].

Substance	δ		
P_4S_3	−72,	+103	
P_4S_5	−200,	−20,	+120
P_4S_{10}	−45		
$H_4P_2O_7$	+12		
PCl_5 ($[PCl_4]^+$ $[PCl_6]^-$)	−91,	+282	
Zn_3P_2	+217,	+250	

b) Multiple pulse nuclear spin spectroscopy after *Waugh et al.*[18]: In nuclear spin pulse spectroscopy, suitable sequences of high-frequency pulses can be used to rotate the resultant magnetization vector $\vec{M} = \Sigma \vec{\mu}_i$ into certain

directions with respect to the external field $\vec{H}_0$, and undesirable interactions can thus be eliminated in the study of the chemical shift. This method is developing rapidly at present, and it remains to be seen to what extent it will prove to be of general applicability in the chemistry of solids.

3.2.3. Chemical Shift of the NMR of Nuclei with $I > 1/2$

We have to distinguish here between nuclei whose point symmetry in the lattice is cubic, *i.e.* characterized by the point groups 23, m3, 432, $4\bar{3}$m, or m3m, and those with lower point symmetry.

In the latter case the interactions between the nucleus and the environment are considerably influenced by the nuclear quadrupole interactions, and the chemical shift of the NMR can be studied only on the single crystal. (Complete information on the chemical shift for all nuclei with noncubic point symmetry is obtainable only from the single crystal, since the chemical shift is a tensor quantity.) Few complete measurements of the chemical shift of the NMR of nuclei with $I > 1/2$ and with noncubic point symmetry have been reported for diamagnetic crystals. Recent investigations have been carried out by *Spiess, Haas,* and *Hartmann*[31]. The authors investigated single crystals of cobalt(III) complexes and determined in each case the tensor of the chemical shift and the nuclear quadrupole coupling tensor. A linear relation was found between the anisotropy of the shift and the nuclear quadrupole coupling constant, and this relation was discussed in terms of the MO theory.

A series of investigations was carried out on nuclei with $I > 1/2$ in crystals with cubic point symmetry. Attention was centered mainly on the alkali metal halides and ammonium halides. Both the chemical shifts and the spin-lattice relaxation time T_1, which is related to the chemical shift by $\log T_1 = A - a \cdot \log \sigma$ (σ = shielding constant), were investigated[19–24]. The interpretation of the results is following two directions: a) assumption of a covalent bonding component, and b) consideration of the influence of the crystal potential and of the overlap effect.

The second model (b) shows satisfactory agreement between experiment and theory, and should be important to the discussion of the chemical shifts and of the bonding in ionic crystals with complicated structures.

3.2.4. Knight Shift (Chemical Shift in Metals and Alloys)

A focal point at present in the NMR spectroscopy of solids is the measurement of the chemical shift in metals and alloys. *Knight* discovered in 1949 that a shift of the nuclear magnetic resonance occurs in metals as a result of the paramagnetism of the conduction electrons. This shift, which is known as the Knight shift, has a magnitude of up to 30000 ppm (with respect to a diamagnetic salt in aqueous solution)[27]. The Knight shift K is given by

$$\frac{H_{metal} - H_{standard}}{H_{standard}} = K = \frac{8\pi}{3} \chi_p V_0 \langle |\psi(0)|^2 \rangle_F \qquad (9)$$

where χ_p is the paramagnetic spin susceptibility of the conduction electrons, V_0 is the atomic volume, and $\psi(0)$ is the wave function, normalized over the volume V_0, of an electron having the Fermi energy E_F. $\langle |\psi(0)|^2 \rangle_F$ is thus the average electron density on the nucleus for all electronic states on the Fermi surface. It is clear that quite far-reaching conclusions can be drawn from the measurement of the Knight shift K if χ_p is known (*e.g.* for the metals Li, Na, Rb, Be)[28]. The anisotropy of K in noncubic metals is also of interest, and can be studied.

Changes in the valence electron concentration, VEC, can be readily determined by measurement of K. An example is the metallic system V-Cr-H, where it has been shown that K varies in proportion to the VEC[29]. Figure 9 shows the results both for K and for $1/T_1 T$ as functions of the VEC.

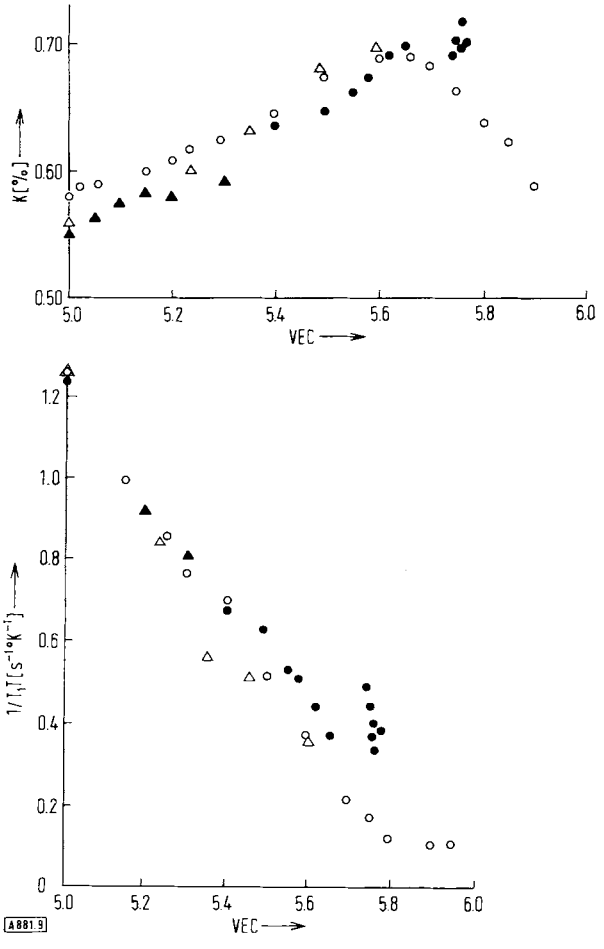

Fig. 9. ○, ▲ = $V_{(1-x)}Cr_x$; ● = $V_{(1-x)}Cr_xH_y$; △ = VH_y. Knight shift of the ^{51}V-NMR as a function of the valence electron concentration VEC in the systems V-Cr, V-Cr-H, and V-H [29].

The problems that can be tackled by nuclear magnetic resonance experiments include *e.g.* the oscillations of the conductivity electron density in metals about an impurity atom. Reviews on the Knight shift have been published by *Rowland*[27] and by *Lütgemeier*[30].

A difficulty that arises in the investigation of solids is that the chemical shift and the Knight shift often cannot be separated, since only the total effect of the internal fields

$\sum_i H_i$ is measured (cf. *e.g.*[59]). If the g factor is known for the conduction electrons, it is possible to split up δ_{total} into $\delta_{total} = \delta_{chem} + \delta_{Knight}$ ($\delta_{Knight} \equiv K$).

3.3. Nucleus-Electron Interaction in Substances with Permanent Magnetic Moments of the Individual Particles

3.3.1. Nucleus-Electron Interaction in Paramagnetic Substances

For crystals with paramagnetic ions (unpaired electrons) the internal magnetic field H_i can be studied very successfully by NMR measurements. The simplest case is that of pure dipole interaction between the electron spin at the position of the paramagnetic ion and a nuclear spin in the lattice, *e.g.* between the magnetic moment of Cu^{2+} ions and the protons in copper salts such as $CuSO_4 \cdot 5H_2O$[33], $K_2CuCl_4 \cdot 2H_2O$[34], or $CuF_2 \cdot 2H_2O$[35]. One can expect the shift of the ^{1}H-NMR frequency (after correction for the ^{1}H-^{1}H interactions) with respect to the Zeeman frequency $\omega_0 = \gamma H_0$ to be proportional to the susceptibility χ. It should be noted that this shift should be dependent upon direction. The relative shift of two groups of ^{1}H resonance lines of $K_2CuCl_4 \cdot 2H_2O$ as a function of temperature (Curie's law) is shown in Figure 10.

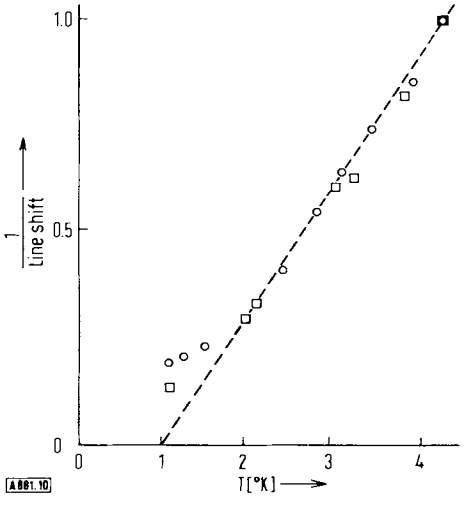

Fig. 10. Temperature dependence of the relative splitting between two groups of ^{1}H-NMR lines of $K_2CuCl_4 \cdot 2H_2O$. $H_0 \parallel [110]$. $\circ \triangleq \omega_0 = 30$ MHz; $\square \triangleq \omega_0 = 15$ MHz [34].

In many cases, however, the effect of the exchange correlation dominates the electron spin-nuclear spin coupling. This becomes clear if one examines the NMR spectra of nuclei of atoms having a covalent bonding component with the paramagnetic ion. Very strong coupling then appears. Figure 11 shows the ^{1}H-NMR spectrum and the ^{19}F-NMR spectrum of single crystals of $CuF_2 \cdot 2H_2O$ ($CuF_2 \cdot 2H_2O$ is monoclinic; the Cu^{2+} ion and two F^- ions at a distance of 1.89 Å all lie in the plane normal to the twofold axis [010]; the two oxygen atoms of the water molecules are situated on the b axis at a distance of ± 1.93 Å from the Cu^{2+} ion). Whereas the Cu^{2+}-^{1}H interaction is weak between 77 and 300°K and contains only an anisotropic component, the ^{19}F-NMR is strongly influenced, both isotropically and anisotropically, by the electron spin.

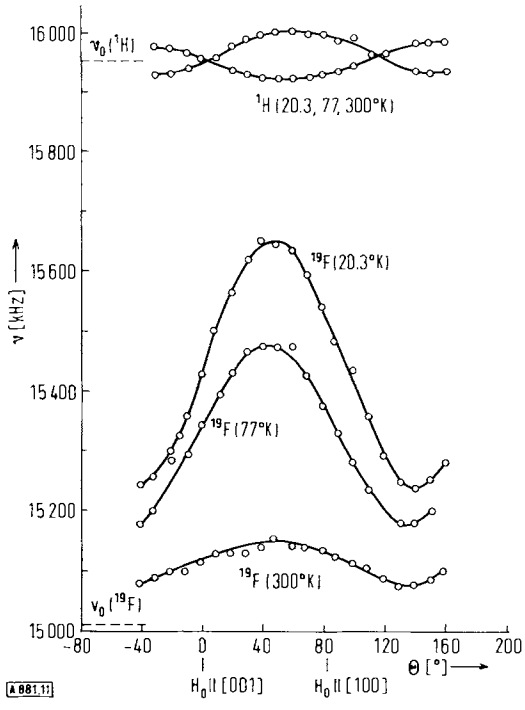

Fig. 11. Angular dependence of the ^{1}H-NMR and ^{19}F-NMR in $CuF_2 \cdot 2H_2O$ single crystals. $\vec{H}_0$ lies in the a,c plane. $\nu_0(^1H) = \gamma_H \cdot H_0/2\pi = 15.954$ MHz and $\nu_0(^{19}F) = \gamma_F \cdot H_0/2\pi = 15.001$ MHz correspond to the Larmor frequencies at field H_0 [35].

The "distribution" of the unpaired electrons over the lattice can be calculated from such measurements. *Itoh* and *Kamiya*[34] found for $K_2CuCl_4 \cdot 2H_2O$ and $(NH_4)_2CuCl_4 \cdot 2H_2O$ at $T = 4.2$°K: about 80% of the density on Cu^{2+}, 2% on each oxygen, 0.1% on each H of H_2O, less than 0.5% on the cation (K^+ or NH_4^+), and about 16% on the four Cl^-. Other examples are investigations on the nucleus-electron interaction and the susceptibility tensor by NMR measurements on ^{17}O in MnO and CoO[36] and the study of the magnetic shift tensor at the position of the Cl^- ions in $CsNiCl_3$ and $CsCuCl_3$[37].

Many investigations are concerned with the mechanism of the nuclear spin-lattice relaxation in paramagnetic substances.

3.3.2. NMR in Crystals with Collective Magnetic Behavior (Ferromagnetism and Antiferromagnetism)

Numerous investigations have shown during the past few years that NMR spectroscopy is excellently suited to the study of the magnetic structure and internal fields in crystals with collective magnetic behavior.

1. *Antiferromagnetic crystals:* Below the Néel point, ordered magnetic structures are formed, such that microscopic compensation of the spin occurs. The investigation of the NMR spectra of various nuclei in single crystals below the Néel temperature allows the determination of the magnetic field (strength and direction) at the positions of these nuclei. The magnetic structure (magnetic space group) can be obtained in this way.

Thus by a detailed study of the NMR spectra of ^{35}Cl, ^{133}Cs, and ^{1}H in $CsMnCl_3 \cdot 2H_2O$, *Spence et al.*[38] were able to determine the magnetic space group. As a typical example of the internal field at the position of the ^{1}H nuclei, Figure 12 shows $\nu(^{1}H)$ in the zero field $H_0 = 0$ as a function of the temperature.

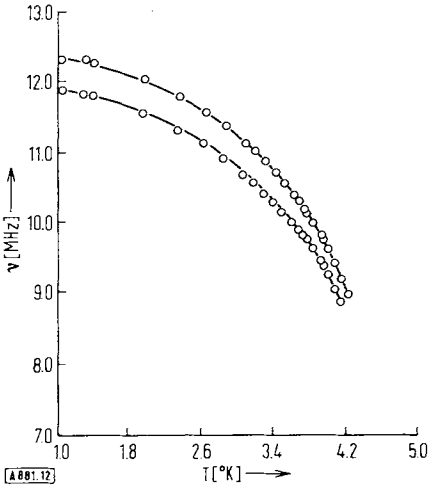

Fig. 12. ^{1}H-NMR frequencies of the protons in single crystals of $CsMnCl_3 \cdot 2H_2O$ as a function of temperature. The external field H_0 is 0 (zero-field resonance) [38].

Figure 13 shows $\nu(^{133}Cs)$ as a function of the angle θ with the field $H_0 = 5320$ Oe. The weak quadrupole interaction can be seen (example of the superposition of magnetic and

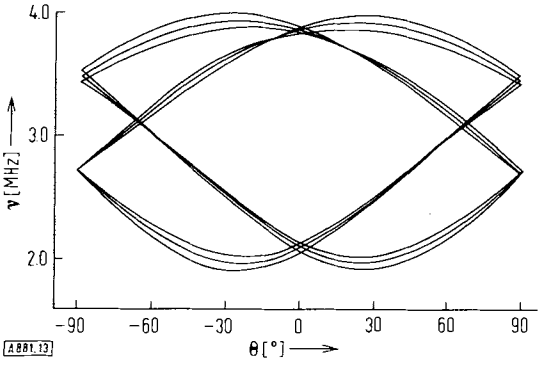

Fig. 13. Angular dependence of the ^{133}Cs resonance in single crystals of $CsMnCl_3 \cdot 2H_2O$ in an external field of 5320 Oe. At angle $\theta = 0$, $H_0 \parallel [010]$. The splitting of each curve into three lines shows the quadrupole interaction. The transitions $-\frac{1}{2} \leftrightarrow \frac{1}{2}$, $-\frac{7}{2} \leftrightarrow -\frac{5}{2}$, and $\frac{5}{2} \leftrightarrow \frac{7}{2}$ are shown. $T = 4.2$ °K; $H_i = 1.88$ kOe [38].

electric crystal fields). In any case, nuclear magnetic resonance in magnetically ordered materials is a valuable supplement to neutron diffraction.

2. *Ferromagnetic crystals:* Particularly strong magnetic fields may be expected in ferromagnetic substances. Both the NMR spectra of the nuclei with a paramagnetic electron shell and the spectra of other nuclei are observed here. The internal field is very high in many ferromagnetic materials; it is sufficient to enable the experiment to be carried out without the aid of an external field.

The most important result is probably the determination of internal fields. The pioneering work of *Gossard* and *Portis*[39] was followed by numerous other studies. As an example, Figure 14 shows the hyperfine field at the position of the ^{59}Co nucleus in iron-cobalt alloys as found by NMR experiments[40].

A review on nuclear magnetic resonance in magnetic substances has been published by *Bose*[41].

4. Use of Nuclear Resonance for the Study of Electric Fields (Crystal Fields) in Solids

The use of the NMR method for the investigation of internal magnetic fields H_i arising from various sources in crystals was discussed in the last section. Another wide field of application of the method is the study of the

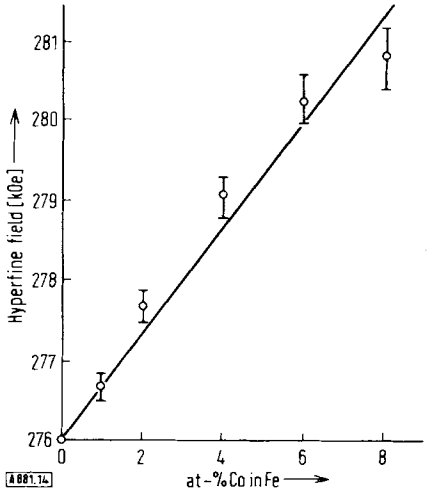

Fig. 14. Hyperfine field at the position of the ^{59}Co nucleus in Fe-Co alloys, as found by NMR measurements, as a function of the Co concentration [40].

electric field gradients in crystals by measurement of the interaction energy $eQ \cdot \phi_{zz}$ [see eq. (6)]. A condition that must be satisfied for this measurement is the presence of a nucleus with $I > 1/2$. This condition is met by a number of stable isotopes with high abundances (see Fig. 5). The use of the method for the systematic investigation of relationships in solid-state chemistry is unfortunately restricted by a quadrupole moment gap in group II (Mg, Ca, ...; exception: Be) and in group IV (C, Si, ...). Many of the NMR experiments on nuclei with $I > 1/2$ in crystals are directed toward the study of chemical bonding in molecules. The measurements are carried out on solids in this case because of the method rather than because of the problem. The main area of interest here is the investigation of ^{2}D, ^{11}B, ^{14}N, ^{35}Cl, ^{81}Br, and ^{127}I in organic molecules. The energy equation for the nuclear quadrupole interaction [eq. (6)] contains the nuclear moment eQ and the field gradient ϕ_{zz}. This gradient is due to the electric charges surrounding the nucleus:

a) the point charges, dipoles, and quadrupoles in the lattice, which produce a gradient ϕ_{zz} at the position of the atom;

b) the electron core around the nucleus in question, which may be distorted by the external fields;

c) the bonding electrons in the molecule, whose distribution around the nucleus in question deviates strongly from spherical symmetry, and which thus produce a high field gradient at the position of the nucleus.

Let us first consider case c). The electric field gradient at the position of the nucleus, and hence the coupling constant, can be used as a basis for conclusions regarding the chemical bonding. A comparison of the coupling constants with those of a standard exhibiting "pure covalent" bonding

(*e.g.* $\frac{eQ\phi_{zz}}{h}$ (XCl) compared with $\frac{eQ\phi_{zz}}{h}$ (Cl_2))

yields information on the bonding[42,43]. However, the main interest here is in the molecular properties; the solid is an "experimentally necessary evil", whose only contribution to the effects are perturbation terms, which are usually undesirable[48]. From investigations of this type it is possible to draw conclusions regarding:

1. the chemical bonding in molecules (bond strength),

2. bond angle (by measurements on single crystals—Zeeman splitting),

3. the symmetry of the bonding electrons (double bond character), by study of the components $\phi_{\nu\nu}(\nu=x,y,z)$ of the electric field gradient tensor and hence of the asymmetry parameter $\eta=(\phi_{xx}-\phi_{yy})/\phi_{zz}$; $0\leqq\eta\leqq1$,

4. symmetry elements and point position symmetry in the crystal lattice.

Detailed information on this line of investigation will be found in Refs. [42,43,46,47]

In ionic lattices or in lattices with a strong ionic bonding component between the atoms (cases a and b), the interaction between the nuclei and their environment is strongly influenced by the lattice. On the other hand, the interaction energy between the electric nuclear quadrupole and the electric field gradient is often weak here; this interaction is then investigated as a superposition over the pure Zeeman splitting. The situation in the energy level diagram for $I=3/2$ is shown in Figure 15.

A simple example of a weak quadrupole interaction with direct observation on the oscilloscope is shown in Figure 16

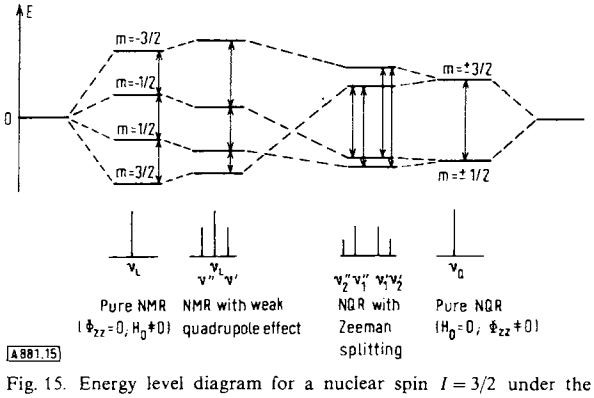

Fig. 15. Energy level diagram for a nuclear spin $I=3/2$ under the influence of an external magnetic field H_0 and a field gradient ϕ_{zz}.

for the case of the ^{23}Na-NMR in $Na_2ZnCl_4\cdot3H_2O$; Figure 17 then shows the complete "rotation diagram" of the quadrupole splitting of the NMR spectrum of ^{23}Na in this compound. In the evaluation of the experiments,

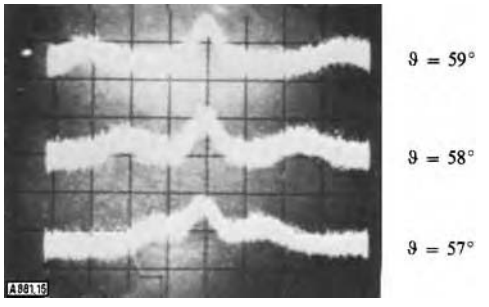

Fig. 16. ^{23}Na resonance in $Na_2ZnCl_4\cdot3H_2O$. Rotation about [100]. ϑ = angle between [001] and H_0. 1 cm (screen) ≅ 4 kHz [66].

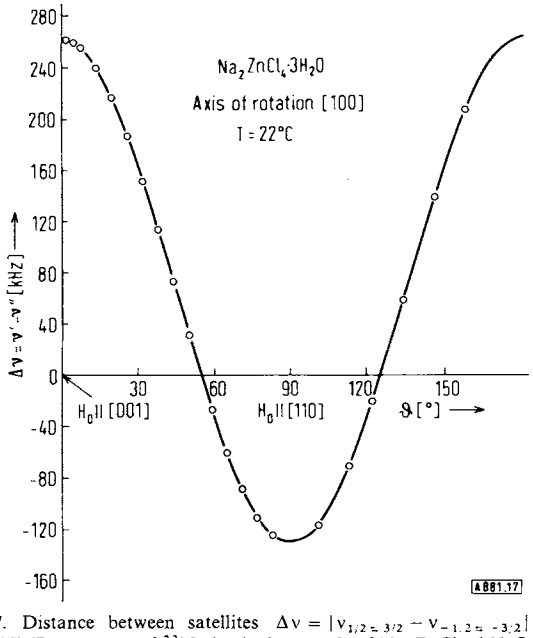

Fig. 17. Distance between satellites $\Delta\nu=|\nu_{1/2\leftrightarrow3/2}-\nu_{-1/2\leftrightarrow-3/2}|$ in the NMR spectrum of ^{23}Na in single crystals of $Na_2ZnCl_4\cdot3H_2O$ as a function of the angle between H_0 and the crystal axis [001] of the trigonal crystal [66].

however, it is often necessary to use the intermediate region of the Zeeman splitting perturbed by weak quadrupole interactions on the one hand and the pure quadrupole resonance on the other (Fig. 15). In this way one obtains the greatest possible amount of information about the solid under investigation. The arrangement of the energy levels of all possible relationships of Zeeman energy, $\nu_L=\gamma H_0/2\pi$, and nuclear quadrupole interaction energy e^2qQ/h of a nucleus with $I=5/2$ is shown in Figures 18 and 19 for the angles $\vartheta=0°$ and 60° between H_0 and ϕ_{zz}[67].

The practical evaluation of such transition states is necessary in NMR measurements on chloro complexes[37], periodates, perrhenates, *etc.*

These experiments yield information in particular on:

1. the crystal structure: the NMR experiment enables one to draw conclusions regarding the point symmetry

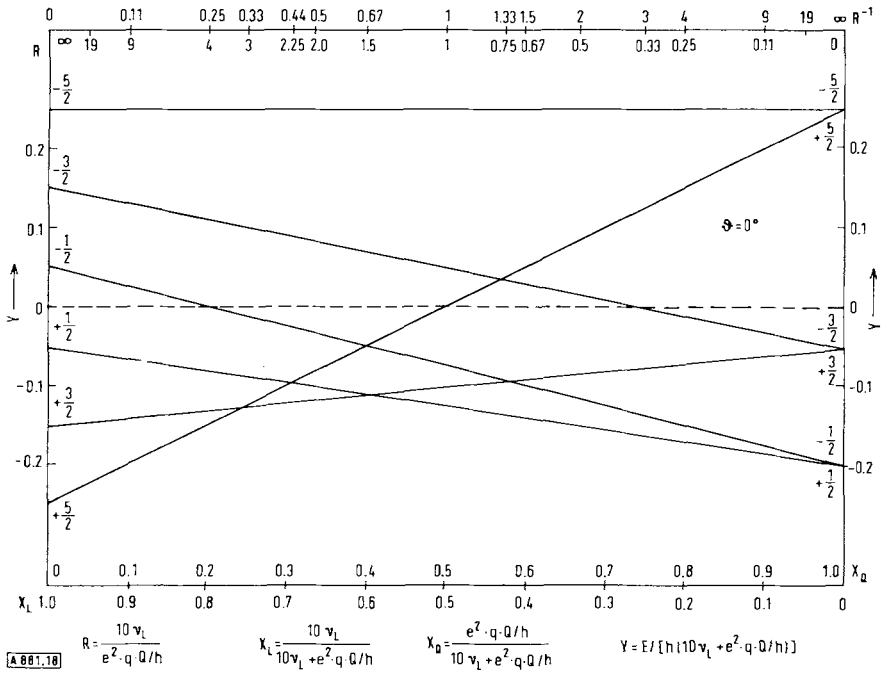

Fig. 18. Energy level diagram for a nuclear spin $I = 5/2$ under the influence of an electric field gradient and an external field H_0 for various ratios of the interaction energies $E_{Larmor}/h : e^2qQ/h$. The angle ϑ between ϕ_{zz} and H_0 is 0°.

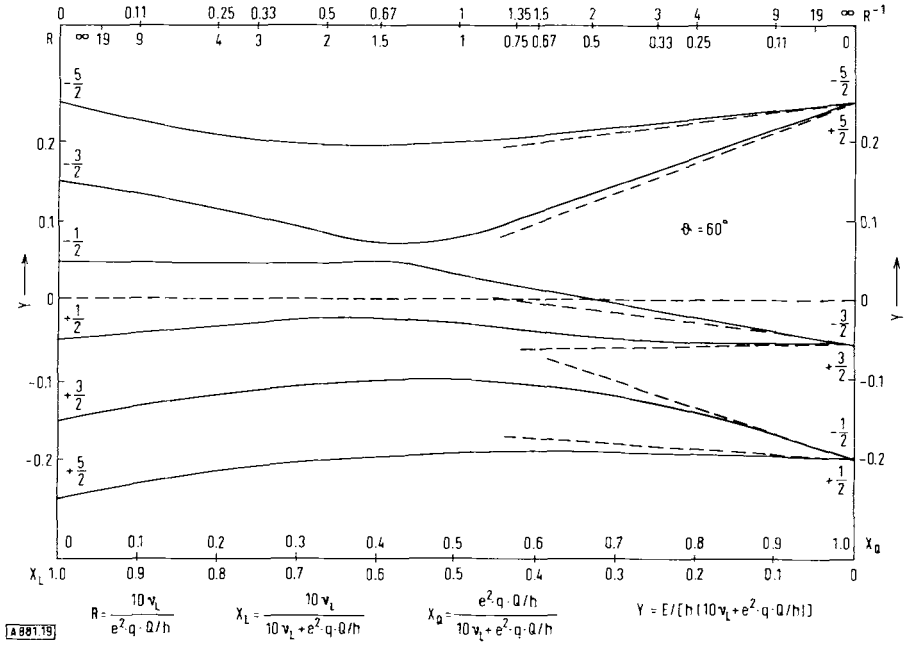

Fig. 19. Energy level diagram for a nuclear spin $I = 5/2$ under the influence of an electric field gradient and an external field H_0 for various ratios of the interaction energies $E_{Larmor}/h : e^2qQ/h$. The angle ϑ between ϕ_{zz} and H_0 is 60°.

of the nucleus in question and the symmetry elements of the unit cell (only the Laue groups influence the spectrum),

2. the charge distribution in the crystals, the arrangement of the point charges, the direction and strength of the induced dipole and quadrupole moments, *etc.*; these data are obtained indirectly from a model calculation, which can respond very sensitively to the point positions of the ions (atoms) in the lattice[45, 61],

3. the bond character (ionic component), as was mentioned earlier in connection with molecular crystals,

4. the ease of deformation of the electron core in the solid: the electric field gradient ϕ_{zz} acting at the position

of the nucleus is made up from the "external" gradient ϕ^a_{zz} and the gradient ϕ^i_{zz} induced in the core belonging to the nucleus under examination. The following relation is valid

$$\phi_{zz} = \phi^a_{zz} + \phi^i_{zz} = \phi^a_{zz}(1 - \gamma_\infty) \quad (10)$$

where γ_∞ is the Sternheimer factor. This factor, which can be found only by calculation, is very strongly dependent on the electron density distribution in the core. The NMR experiment allows a check on the quantum-mechanical calculations. For most of the ions γ_∞ is negative with values even down to -200.

The theory of quadrupole interactions in ionic crystals has been discussed at length by *Cohen* and *Reif*[44], and the literature between 1960 and 1966 is reviewed in[45]. The measurements should generally be carried out on single crystals if possible. However, the spectroscopic investigation of crystalline powders also leads to valuable though less extensive information.

One disadvantage of the interpretation of NMR studies on crystal fields is that one can usually obtain only quantitative information (after laborious calculations). Qualitative information is very difficult to obtain. This is because practically no systematic measurements on single crystals (which are fairly time-consuming) have been carried out for isotypic solids. As an example of a qualitative relationship, Figure 20 shows the linear dependence of the electric field gradient at the position of the Al^{3+} ion in alums on the radius of the monovalent cation (after[60] and literature values). Another example was provided by Mössbauer and NMR experiments on various garnets[62-65].

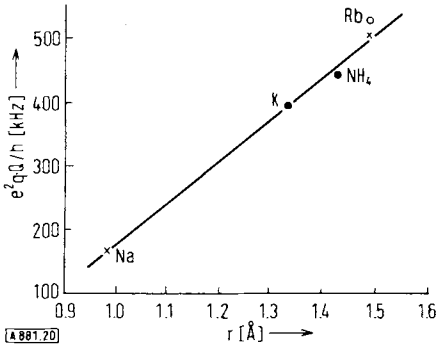

Fig. 20. Quadrupole coupling constants e^2qQ/h of ^{27}Al in sulfate alums as a function of the ionic radius $r(M^{1+})$ [60].

4.1. Crystal Defects

NMR spectroscopy is a valuable method for the investigation of lattice defects. It is mainly the electric field gradients due to defects that influence the nuclear magnetic resonance and can therefore be studied. Thus stresses due to cold working of metals affect the line widths of NMR spectra[27]. Dislocations in nonmetallic solids can also be studied in a similar manner. Very detailed information on dislocations can be obtained from measurements on single crystals[49].

Defects in solids have been intensively studied in alkali metal halides[6], and interesting and detailed results on the distortions around a foreign atom have recently been obtained by *Andersson*[50]. The development of sensitive nucleus-nucleus double resonance methods now makes it possible to study crystals with low contents of foreign atoms and thus to obtain information on crystal fields and field symmetry at the position of the nearest and next-nearest neighbors of foreign atoms (ions) (cf. *e.g.*[51]). Paramagnetic centers and their interactions with the environment can be determined from the spin-lattice relaxation time T_1 and from electron-nucleus double resonance experiments (ENDOR).

4.2. Glasses and High Polymers

It should be mentioned briefly here that the range of the interaction between nuclei and their environment is small (the electric field gradients fall off with $1/r^3$ from the point of origin). To a first approximation, therefore, the short-range order is decisive for the NMR experiment, and a glass behaves in the same manner as a crystalline powder. It has been reported that the point symmetries at the positions of alkali metal ions, Al^{3+}, B^{3+}, *etc.* in glasses can be determined in this way[52].

5. Dynamic Behavior of Solids and Nuclear Magnetic Resonance

So far we have considered only static lattices or we have assumed that the lattices are rigid. However, NMR spectroscopy is also very useful for the study of dynamic properties of solids. Both the line positions (resonance frequencies) and line shapes (line widths) as well as the relaxation behavior, particularly the spin-lattice relaxation time T_1, provide information about the dynamic behavior of solids.

5.1. Motions of Molecules and of Individual Groups on Molecules in Molecular Crystals

In molecular crystals, which are held together only by van der Waals forces, the potential barriers that hinder translation and rotation in the crystal are particularly low. The internal motions partly average out the nucleus-nucleus interactions [see eq. (7)]; as a result of motions of atoms and molecules, the NMR spectrum of a solid approaches that of a liquid. Numerous investigations have been carried out in this field. *Andrew*[54] has published a general report on motions in molecular crystals. As an example, we shall first discuss a recent investigation[53] on an organic crystal, hexamethylbenzene.

Figure 21 shows the second moment after *Van Vleck* and the spin-lattice relaxation time T_1 of the protons in hexamethylbenzene as functions of the temperature.

In the low-temperature phase I, the second moment slowly decreases with rising temperature. Its calculated value for the rigid lattice is 32.7 G^2. The difference from the values found by experiment is explained by a slow reorientation of the methyl groups, which occurs even at 2°K.

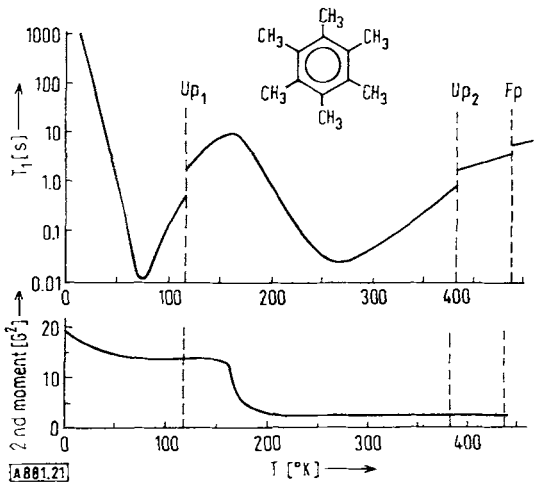

Fig. 21. Spin-lattice relaxation time T_1 and second moment of the ^{1}H-NMR of hexamethylbenzene. The substance has two transition points Up_1 and Up_2 below the melting point Fp [53].

At 50°K this reorientation becomes fast (compared with the Larmor frequency). The knowlege of the relaxation time T_1 in the region of the low-temperature phase allows the determination of the activation energy for the rotation of CH_3. T_1 is a function of the correlation time τ_c

$$T_1^{-1} \sim \left[\frac{\omega_0 \tau_c}{1+(\omega_0 \tau_c)^2} + \frac{4\,\omega_0 \tau_c}{1+(2\,\omega_0 \tau_c)^2}\right] \quad (11)$$

(ω_0 = Larmor frequency), and from the law for the activation energy of rotation (or translation):

$$\tau_c = \tau_0 \exp\{E_a/RT\} \quad (12)$$

it is possible to determine the activation energy E_a of the motion from measurements of T_1 as a function of temperature. The value found in this way for the rotation of CH_3 in $C_6(CH_3)_6$ is $E_a = 1.9 \pm 0.1$ kcal/mol. In phase II ($116\,°K \leqq T \leqq 383\,°K$), the entire molecule begins to rotate about the sixfold axis (above 150°K); the activation energy is 6.7 ± 0.1 kcal/mol. The high-temperature phase III cannot be interpreted by an additional motion.

In addition to various methylbenzene derivatives, molecules and ions having a tetrahedral structure, such as CF_4 [55], ammonium salts, and salts with BF_4^- as the anion, have been investigated.

Diffusion in solids can often be followed by NMR methods. Of the many published reports, we shall mention only the measurement of the diffusion of H and D in β-UH_3 and β-UD_3, respectively[56]. In addition to the Knight shift of the ^{1}H-NMR and the quadrupole coupling constants of ^{2}D, activation energies of 8.4 kcal/mol and 8.9 kcal/mol were found for the self-diffusion of protons and of deuterons, respectively, above 370°K.

Nuclear quadrupole resonance spectroscopy reacts very sensitively to internal motion of molecules and atoms (the ^{35}Cl resonance in $KClO_3$ has been proposed as a "thermometer"). From the temperature dependence of the resonance frequencies, it is possible to obtain information about the vibrations in the lattice, which usefully complements the findings of IR and Raman spectroscopy, as has been shown for the ^{35}Cl-NMR spectrum of K_2PtCl_6 [57]. Many studies are concerned with the elucidation of the "flipping" of the water molecules in crystal hydrates about their twofold axis by investigation of the temperature dependence of the ^{2}D-NMR spectrum.

5.2. Phase Transitions

NMR spectroscopy has frequently been used for the study of phase transitions, particularly for the investigation of ferroelectric crystals. The electric field gradients in ferroelectrics are of great interest. In the ferroelectrics characterized by hydrogen bonds, ^{2}D-NMR is an important aid in the investigation of the mechanism that leads to spontaneous polarization (see *e.g.*[58]).

6. Conclusion

The field of application of nuclear magnetic resonance in solid-state chemistry is thus large. With the aid of this

Table 2. NMR and NQR in solid-state chemistry.

Nature of the interaction	Observation in the spectrum	Information
Magnetic nuclear dipole interaction (NMR)	(a) Broadening or splitting of the resonance line as a function of the angle between the crystal axis and the external field H_0 and as a function of temperature (b) Spin-lattice relaxation time T_1	Determination of interatomic (internuclear) distances in the crystal (static); motions of atoms, groups and molecules in solids, such as translation (diffusion) and rotation
Interaction: nuclear dipole-electron (NMR)	(a) Shift of the resonance line due to internal fields H_i (b) T_1	Chemical bonding; valency state; magnetic properties such as susceptibility, fields in ferromagnetic materials, magnetic structures; metallic state (electron gas in metals)
Interaction: nuclear quadrupole-electric field gradient (NQR)	(a) Broadening and splitting in the spectrum (b) T_1	Chemical bonding; charge distribution in ionic crystals; point symmetries in the crystal (crystal structure); defects and dislocations (real structure); dynamic properties (internal degrees of freedom)

method, many partial questions can be answered, models can be confirmed, and theories supported. The simultaneous use of other methods, particularly diffraction methods, can increase the value of NMR information. A synopsis of the points discussed in this article is presented in Table 2.

I am grateful to Dr. Wolf Weyrich for critical comments on the manuscript.

The Study of Prehistoric Metallurgy

By Axel Hartmann and Edward Sangmeister[*]

The puzzle we have to solve is: How did prehistoric man live? Archeologists and scientists, chemists and prehistorians have now joined forces in applying much imagination and painstaking effort to the search for a solution. Some of the fruits of their cooperation are presented in this progress report.

1. Scientific Methods

Archeology is now able to provide us with an—admittedly still rather sketchy—picture of prehistoric man, his way of life, customs, and environment. The more we see and learn of his utensils, jewellery, and tools, the more pressing becomes the question of how all these objects were made, *i. e.* the question of the technical knowledge, aptitude, and scope of prehistoric man. This field is to some extent the precinct of the archeologist himself. However, as far as the study of prehistoric metallurgy goes, *i. e.* the working of metals and their extraction from ores in prehistoric times, it is clear that close cooperation between archeologists and scientists is very necessary. The aim of such studies should be, on the one hand, a metallographic investigation of the structure of prehistoric metal finds, and, on the other, a chemical investigation of such finds to ascertain their quantitative composition. It is primarily the second aim that has been pursued during the last twenty years by the "Study Group for Ancient Metallurgy of the Central Roman-Germanic Museum" with whose work the present article is largely concerned. With the support of the Deutsche Forschungsgemeinschaft such studies have been carried out at the Württemberg State Museum in Stuttgart, this work now having become the main research activity of the physical chemistry laboratory.

At Stuttgart attention was first directed to the analytical study of a large number of prehistoric copper and gold specimens rather than metallographic texture investigations, since:

1. Analytical studies require only a small sample of material; the object itself can remain in the museum. This aspect becomes particularly important when considering specimens in the possession of foreign museums. Textural studies, on the other hand, require that the object of investigation be transported to the laboratory.

2. Analytical studies also promised to reveal trading routes and connections between prehistoric cultures whenever it is possible to detect differing degrees of skill in alloying metals or to distinguish between metallic materials of different origin according to the various constituents present and to recognize historical and geographical boundaries. The eventual goal is to elucidate the direction and rate of spreading of ancient methods of metal extraction and working.

In contrast, textural studies mainly yield information about the technical details of the way in which the metal was worked to give the finished product, *e. g.* whether is was beaten, cast, annealed, or quenched. It would certainly be most interesting to be able to follow the dissemination of this technical knowledge too; however, chemical analysis appeared more promising and more practicable.

For the reasons mentioned in point 1 above, it was not so much a matter of finding a completely non-destructive method of analysis—as might initially be thought—but of choosing a method capable of providing a complete quantitative analysis with a small sample of material, in which the possible concentrations of minor components may range over several powers of ten. Bearing in mind that an examination of several thousand objects, and not just random samples, was intended (over 20000 prehistoric copper finds and about 3300 gold ones have so far been analyzed), it becomes clear that time-consuming micro or semimicro wet analyses had to be ruled out immediately. Emission spectroscopy offered a working compromise between the time and effort invested, size of sample, and costs incurred on the one hand and accuracy and sensitivity of analysis on the other.

An additional factor influencing our choice was the existence of earlier spectral analyses of prehistoric copper objects by *Winkler*[1], *Otto* and *Witter*[2], and *van Doorselaer*[3]. *Scheufele*[4] utilized the available experience to develop a method requiring 40 mg of substance that was suitable for routine analyses. However, the technique requires calibration alloys containing all likely minor components Sn, As, Sb, Ni, Bi, Ag, Pb, *etc.*, which are not always easy to prepare.

It was only after several years' experience in the analysis of about 10000 Early Bronze Age copper objects producing some encouraging results that the question arose of extending such studies to prehistoric gold finds.

The particular value of the objects involved makes it all the more important to work with samples that are as small as possible. A method was successfully developed[5] that permits spectral determination of minor components down to 0.01% or less in a 2-mg sample of gold. Above all it proved possible to avoid use of calibration alloys of gold/silver/copper containing possible minor components by

applying drops of the dissolved sample to graphite electrodes. Calibration then only requires gold solutions containing the same minor components in known concentrations.

In this way it was possible to include even highly valuable collections from German and foreign museums in our studies and to dispel any original misgivings.

2. Interpretation of Copper Analyses[6]

As mentioned above, spectral analyses of prehistoric copper objects can be interpreted in two ways. Firstly, the kinds of alloys can be determined and technical advances traced; secondly, it appears possible, on the basis of characteristic impurities, to establish the ore used and thereby the deposits from which prehistoric man obtained the raw materials for certain utensils. The distribution of the utensils and their distance from the source of raw materials should then permit further conclusions to be drawn regarding trading in the period concerned and thus also regarding the direction and rate of propagation of techniques for extraction and working of metals.

However, whereas the determination of the kinds of alloys gave rise to no significant difficulties, ascertainment of the ore deposits proved less simple than originally envisaged since the deviations between the deposits are hardly sufficient to provide more than rough indications. Moreover, comparison of presently accessible ore samples with analyses of prehistoric finished articles is beset with problems. The ore samples come largely from modern underground mines and their composition may differ widely from those surface outcrops accessible to prehistoric man. In addition, we have no knowledge of the smelting processes used at the dawn of history to extract metals from their ores; the technical details—*e.g.* temperature control alone—of the process would certainly affect the composition of the final product.

The direct question of ore deposits was therefore dropped by the Stuttgart group and some indication of origin sought instead by comparison of analyses of prehistoric objects. Such comparisons require a method capable of sifting through large amounts of analytical data for material whose uniform composition can be attributed to the same raw material and corresponding technical processes. The method of choice was a statistical model previously described by *Klein*[4]. Its use permitted classification of materials having the same combinations of elements to a first approximation as so-called "material groups". The material groups can be localized geographically and chronologically, as will be seen from the maps in Figures 1—4.

The distribution of a material group A indicates the area in which this material has been most frequently used and those in which it remained unknown, it can also be seen in which prehistoric periods it first featured in trading, when it dominated the market, and when it disappeared again. Although the exact origin of the raw material is not established, a definite contribution is made to the history of commerce. And if it also proves possible to demonstrate that the material in question is endowed with characteristic qualities that render it suitable or unsuitable for one purpose or another, then reasons can also be given for its popularity or decline.

Copper and its alloys and gold were chosen for our studies. A factor in their choice was that these two materials are the first metals to have been used by man. This is not altogether surprising since they both occur as the native metal. Prehistoric man will have been more readily confronted with them than with, *e.g.* iron, which occurs native only in meteorites.

It is important to realize the full meaning of the sentence: "Man was confronted with these materials." In the course of prehistory we see man constantly searching for materials—this searching is therefore by no means limited to the industrial age—and subjecting all new substances to familiar technical procedures. For instance, we know that during the Neolithic age, in which the first copper and gold was found, man had mastered the following techniques: hewing, chipping, grinding, perforation of soft stones and bones; hewing and grinding of flint; all kinds of woodworking with stone tools; firing of clay (ceramics). On application of these techniques to native gold or copper he will have seen how to shape these materials by beating and thus discover "cold forging". After overcoming his initial disappointment about the lack of any hardening effect akin to that clay when the metals were heated in an open fire or in a simple potters kiln, he will have found that they are more readily shaped while hot ("hot forging"). He must also have seen the melting of these metals although unable to utilize it because of the inadequate temperatures reached in his simple pottery kiln. Such temperatures only became accessible in the kilns available in the Mesopotamian cultures of the 4th millenium BC. Although there was no copper in Mesopotamia itself such a state of culture had been reached in the 4th millenium that raw materials could be transported from deposits in the surrounding mountainous country. The demand arose when the Mesopotamian cultures began to fashion precious materials into amulets, statuettes, jewellery, *etc.* Polished malachite was one such material used for adornment. It is conceivable that fire testing in a pottery kiln gave the first smelted copper, although we shall never be able to prove it. We can be sure, however, that the first copper artifacts come from the 4th millenium in Mesopotamia, as do the oldest gold objects known. The exploitation of the malleability as a characteristic metal property marks the beginning of metallurgy.

Our reasons for not studying objects from hither Asia are of a purely practical nature. It would simply have been too costly to obtain sufficient analytical samples from relevant finds, for we were fully aware that only extensive series of samples could provide conclusive results in view of the statistical method of evaluation necessary. We therefore began our investigations on prehistoric finds from Europe although we knew that we were dealing with a kind of "developing area" where the first techniques of metalworking were introduced as established procedures. However, we may assume that then, as now, nobody would freely

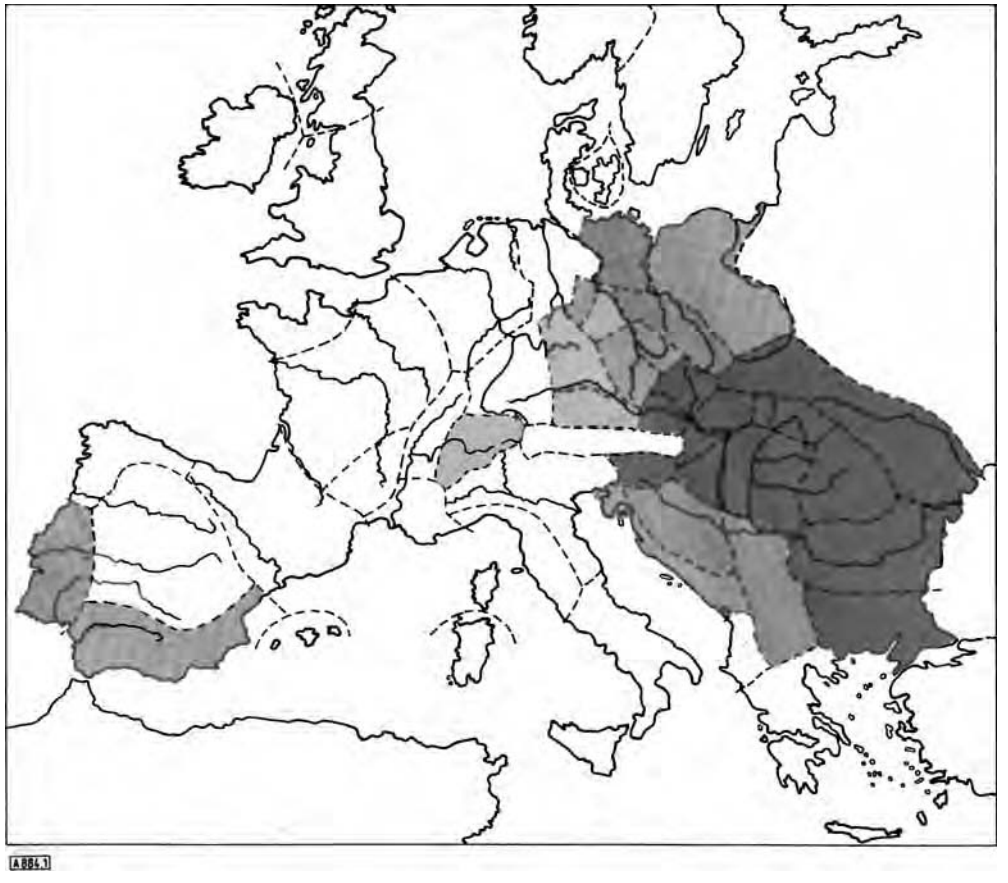

Fig. 1. Distribution of material group copper E 00 during the Copper Age at the end of the 3rd and beginning of the 2nd millenium BC. The material is free from impurities except for small quantities of silver. The map shows the first regions of copper-working in Europe and the directions in which it spread. It is assumed that the requisite knowledge was transmitted from the Near East. The areas of densest distribution are most heavily shaded and those of less dense distribution correspondingly lightly.

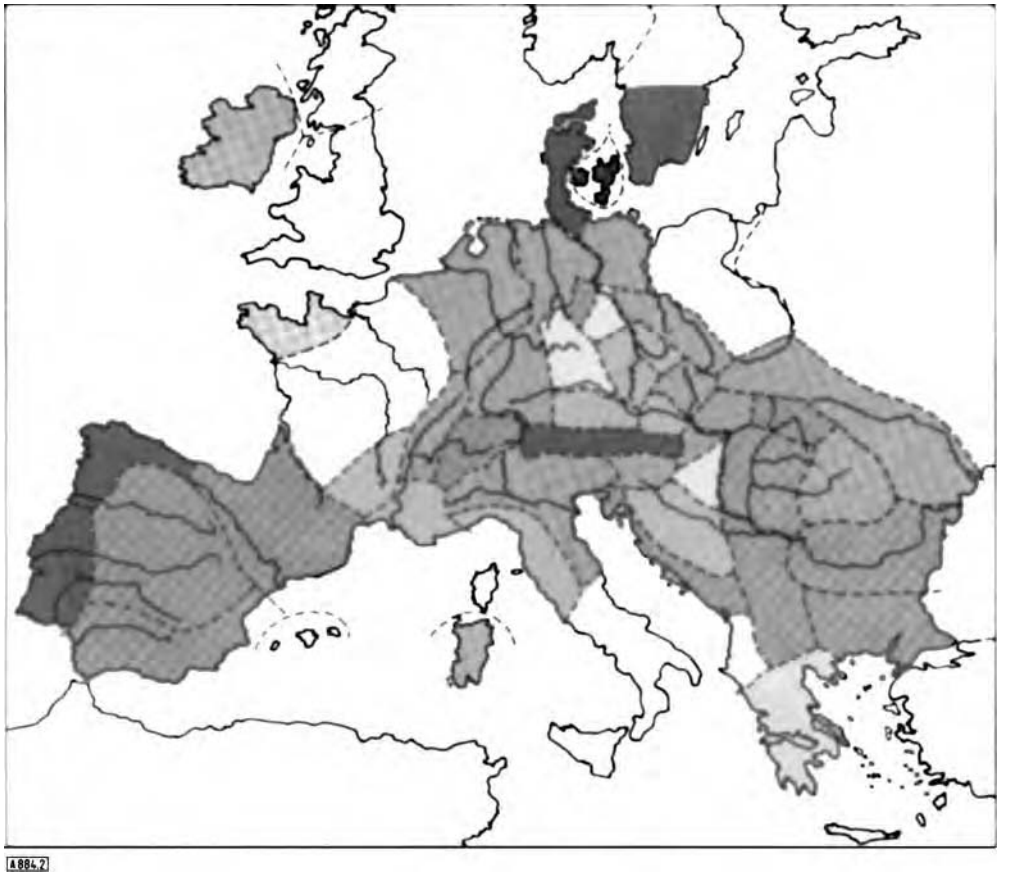

Fig. 2. Centers and distribution of the first arsenic bronze (material group copper E 01 A). Arsenic bronze seems to have been discovered in the Aegean and then produced in areas possessing the raw material. From these areas it was traded over large distances during the later Copper Age at the beginning of the 2nd millenium BC. The material shown contained no impurities other than arsenic (up to about 7%) and small amounts of silver. For meaning of shading see Fig. 1.

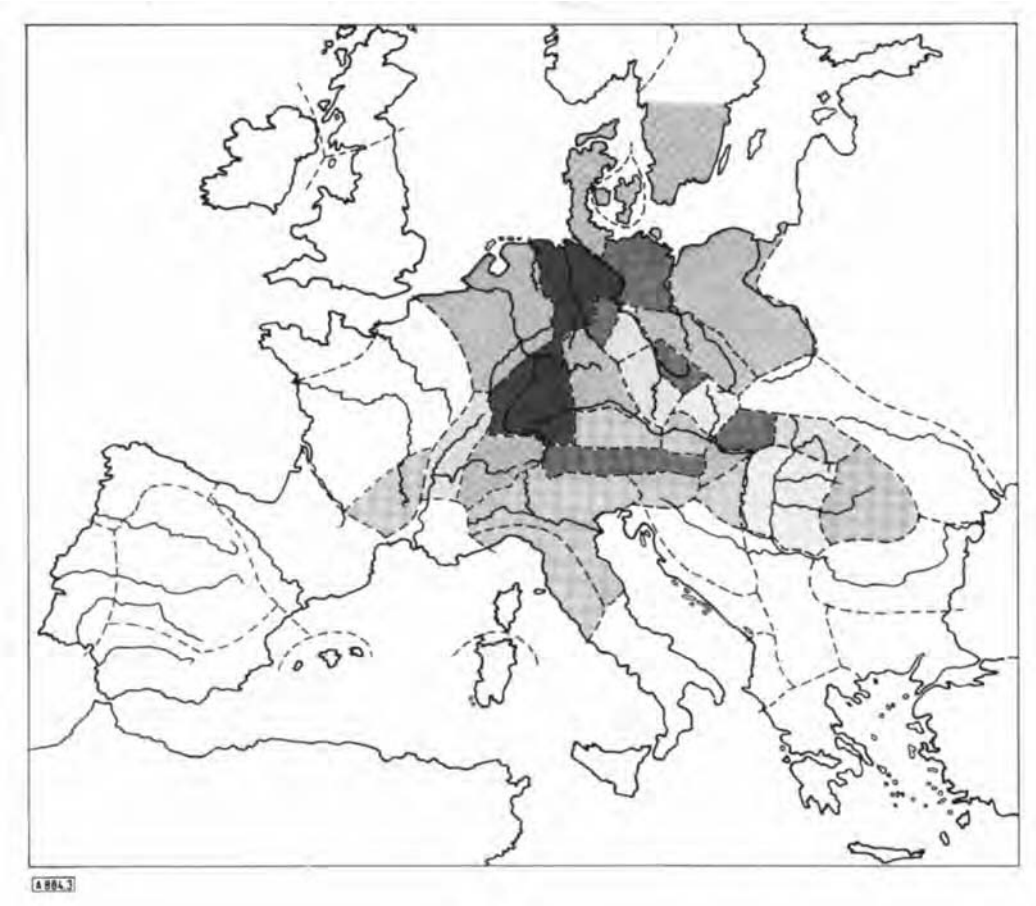

Fig. 3. Distribution of material group copper A during the Early Bronze Age, 18/17th century BC. The material is characterized by high contents of arsenic, antimony, silver, and nickel and by the complete absence of bismuth. Antimony and nickel often reach several per cent. For meaning of shading see Fig. 1.

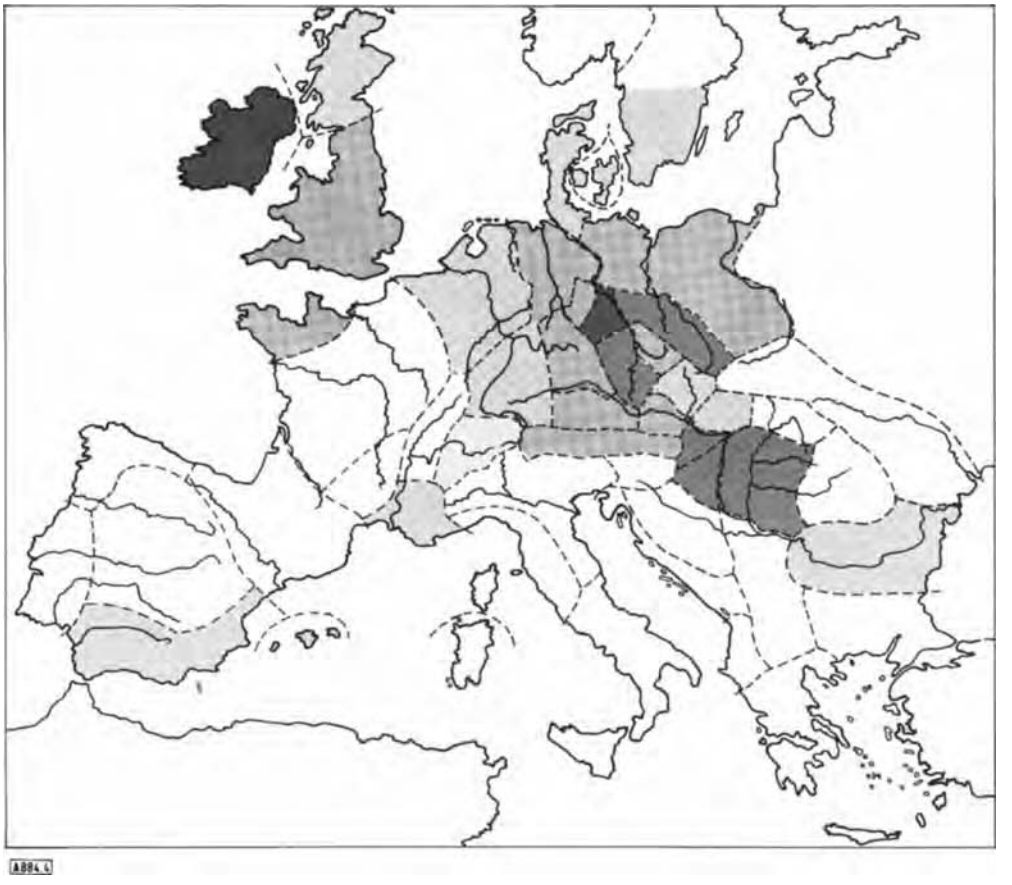

Fig. 4. Distribution of material group copper E 11 B, characterized by contamination with arsenic, antimony, and silver, by the absence of nickel, and by the presence of less than 0.02% of bismuth. The material was used exclusively during the Early Bronze Age, 18/17 century BC, although apparently discovered later than A. For meaning of shading see Fig. 1.

broadcast the secrets of working a new material. Rather, attempts will have been made to satisfy home demand from foreign deposits without revealing too much secret knowledge.

3. Results of Copper Studies[6]

After preliminary evaluation of about 20000 analyses of prehistoric copper and bronze objects we can now provide the following picture regarding Europe.

In the middle of the 3rd millenium BC certain communities having a farming economy and living in permanent settlements in present-day Bulgaria, Romania, and southern Yugoslavia came to know copper. They used it to produce simple utensils and jewellery such as awls, needles, and wire and sheet rings. The copper is almost completely free from impurities and probably partly native copper and partly won from surface outcrops of ore. Possible sources are deposits in the neighborhood of Niš in Yugoslavia and in the Carpathians. This copper is very different from that used during the same period in the eastern Mediterranean and Anatolia, in so far as suitable analytical samples were at our disposal. This seems to confirm the assumption that copper-seekers from the Near East traveling to the Carpathians and the region of Niš passed on a knowledge of rudimentary metallurgical processes to the local inhabitants.

The picture changes about 100 years before the beginning of the 2nd millenium. It appears that large scale exploitation then began of the copper deposits throughout the whole Carpathian basin, the material being worked for local requirements and for export. The utensils, axes, axe-adzes, hammer axes, *etc.*, are characterized by their large size, thickness, and corresponding weight. They were possibly also used as a source of raw material in the same way as the later ring ingots. They are frequently found, like the latter, in large numbers where they had apparently been hoarded. This would also suggest that a special closed guild of metalworkers provided the farming settlers with an established supply of utensils. Utensils produced in these parts traveled as far as the Baltic in the north and Bavaria in the west. The copper of this period is practically free from impurities and was therefore probably still obtained largely from oxide ores. The large amounts worked preclude any large contribution by native copper.

An analogous process probably took place in west Europe during the same period. Originating from the Cyclades or from Syria, the copper seekers seem to have established a series of fortified factories along the coast of Spain and Portugal. They probably again initially used oxide ores from surface outcrops, as is apparent from the complete lack of impurities in the oldest artifacts. A little later, evidence is found for all stages of copper extraction and working; crude ore was in places transported more than 40 km from the deposits to the factories where it was smelted on a small scale and made into ingots, utensils, and jewellery, and prepared for transport and stored. Some of the objects resemble those from the eastern Mediterranean, as does the composition of the material in a number of cases, thus suggesting a certain degree of mutual trading. The metal concerned is characterized by the, presumably natural, presence of antimony, arsenic, and bismuth.

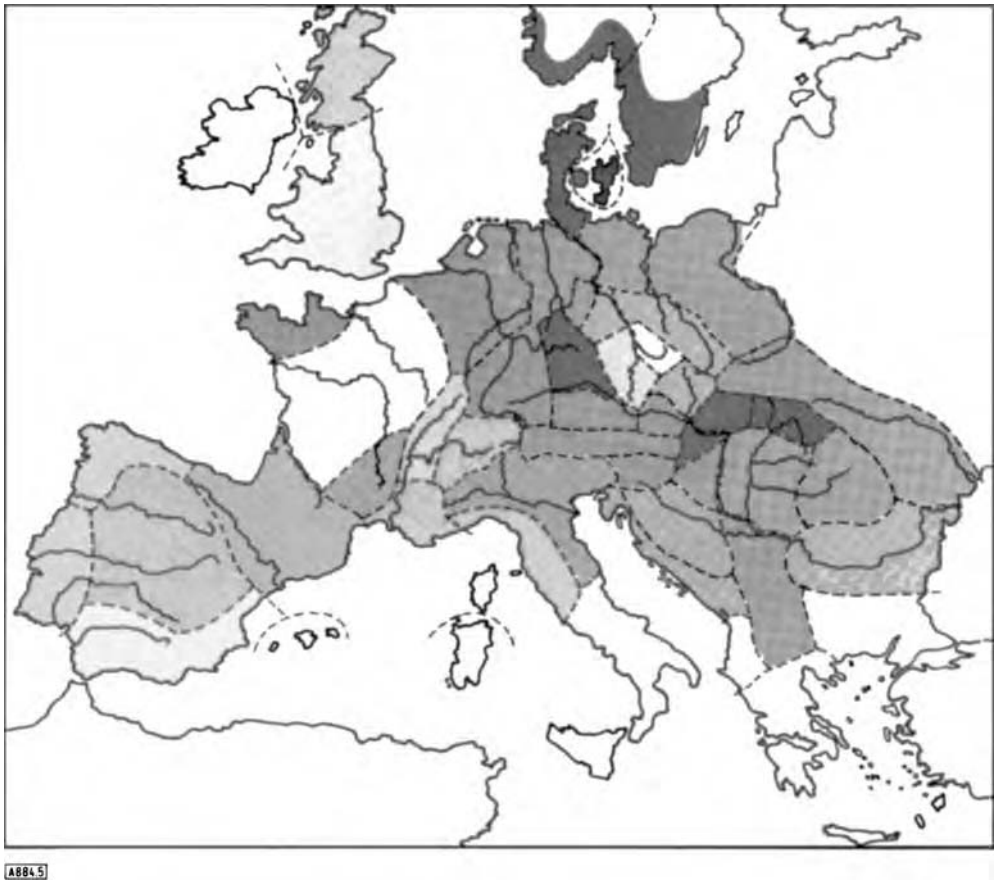
Thanks to its arsenic content the eastern Mediterranean copper produced during this period—at the dawn of the 2nd millenium BC—could readily be cast in one- or two-piece molds, as have also been found. It would also seem probable from the suggested trading that searches were instigated for copper ore having a similar arsenic content and the same good casting properties on the Iberian peninsula. Such deposits were found in abundance and formed the basis for the production of "arsenic bronze" in which copper-arsenic alloys having 5—8 % As were manufactured by raising the proportion of arsenic, possibly even by addition of the native element.

Arsenic bronze, equally familiar in the western and the eastern Mediterranean, then spread throughout the whole of Europe. Interestingly, the first metal-saving utensils, *e.g.* small sharp-edged axes, appear simultaneously with arsenic bronze. The material clearly competed with other kinds of copper produced at the same time in southeast Europe. However, the latter were technically inferior to arsenic bronze because the impurities they contain—antimony, silver, in some cases bismuth too—do not enhance its properties, at least in the proportions present.

A further metallurgical improvement occurred in the 18th century BC when new ores were worked and production began using central European ores from the eastern Carpathians to the Harz Mountains, and possibly even those from the Hardt region in southwest Germany. These ores are characterized by a varying high content of arsenic, antimony, nickel, silver, and bismuth. They yield at least five readily distinguishable kinds of copper and explain the abundance of metal objects in particular groups of societies, an abundance that led archeologists to speak of "Bronze-Age" cultures. It is only since the advent of chemical analysis that we know the frequently light-colored products to be neither arsenic- nor tin bronzes but that their light color is often attributable to their content of silver and nickel, the impurities amounting to 5 to 10% in many cases.

The production of these kinds of copper is associated with a whole new range of utensils and jewellery. It appears that the ring ingots were then first used as currency. They are open neck rings with recoiled ends which, after surface finish, were worn as adornment, and also represented the trading form of the metal. Hoards of several hundred such ring ingots have been discovered. They usually still carry direct evidence of the casting process.

Each variety of copper in this period has its own area of distribution from which the production and marketing regions can be deduced as exemplified by the distribution maps in Figures 3 and 4. Thus Figure 3 depicts the rather narrow distribution of the variety of copper denoted as material group A, while Figure 4 shows the much larger export distribution of another variety of copper (E 11 B) from central Europe. Such exports traveled to areas that had hardly been reached before, for instance Ireland and England, and areas, such as northern Germany, where they were in direct competition with the established



southern European suppliers (cf. Fig. 1). This trade also extended to the south, namely to Italy, where it counteracted local trade not discussed here. It even penetrated the old exporting regions of southeast Europe, without going much farther to the east or south, however, than the Carpathians. Southwest Europe was hardly affected by these exports, for production of the extremely useful arsenic bronze was continued there (Fig 2).

One of the export routes mentioned above assumed particular importance because it initiated the next step in metallurgy, for this period of central European copper manufacture witnessed the crucial step of alloying with tin, to produce the genuine tin bronze which played a dominating role for many centuries until finally ousted by iron.

Even today we still cannot say where and when alloying with tin was discovered. It appears that tin bronze was known in the orient during the 3rd millenium BC although it is still mysterious from which deposits the tin came. We do know that the tin bronze that suddenly appeared in central Europe in the 17th century BC was manufactured from typically central European varieties of copper. It therefore appears reasonable to think of a rediscovery of bronze in these regions, particularly since one of the few accessible tin deposits was located in the frontier mountains between Saxony and Czechoslovakia. Copper seekers and -workers could have come across a mixture of copper and tin ores and thus become acquainted with the tin alloy which was even superior in its casting and hardening properties to arsenic bronze. Possessing such experience, concentrated searches for tin ores could now be made.

Alloying with tin opened up further technical possibilities. Reuse of older material, which could be rendered suitable for producing all kinds of castings by admixture of tin, became more important. As a result new varieties of copper dating from about 1600 BC and thereafter can be legitimately suspected to have been manufactured from previously worked material. Hoarded older material—belonging to scrap collectors— features far more often in archeological finds from this time than deposits of bars (Fig. 5).

Understandably, it becomes difficult in these circumstances to find really informative material groups on analysis of prehistoric objects. We have to content ourselves with distinguishing between groups obtained from raw materials and those produced from salvaged material or from a mixture of scrap and ore. It already appears possible to make a preliminary statement on this topic: In the Mediterranean regions, from the Greek Archipelago *via* Italy to southern France, and also in Switzerland, recourse was apparently again made to ore deposits affording uncontaminated copper; or perhaps the first success at refining can be placed in this period. In southeast, central, and north Europe, however, it must remain an open question to what

A884.5

Fig. 5. Distribution of material group copper FB 1. The material appears to have dominated the central and north European market from the 16th century BC onwards. Arsenic and antimony are present in small to average quantities ($\approx 0.05\%$), and the nickel concentration is invariably $> 0.1\%$. It is possible that different kinds of older material were melted down together. For meaning of shading see Fig. 1.

extent local ore was worked together with scrap material from the whole region. We do know, though, that underground mining of copper had already begun by this time (as found in the Austrian Alps). The metal produced probably contained nickel as the sole impurity.

It may be of interest in conclusion to dwell for a moment on the effect of the smelting and working of copper on the social structure of European regions. Whereas copper-working played a subordinate role in the cultures of the Near East and Crete at the end of the 3rd and beginning of the 2nd millenium BC, it seems at least to have contributed to a change in social structure in Europe before the middle of the 2nd millenium. At this time, a socially superior class can be detected in many parts of Europe whose graves were richly provided with noble metal objects and other valuables. It is certainly significant that they are found in the Aegean commercial and cultural center, in the shaft graves of Mycenae, and in the copper production region of, *e.g.* Transylvania, the western Carpathians, the Harz Mountains, and in west Switzerland. They likewise occur in the tin producing areas of Brittany and the south of England. Applying all caution it is probably valid to assume a mutual connection between the appearance of this socially privileged class and a prosperity due to production of and trading in metal.

4. Interpretation of Gold Analyses

Many parts of Europe have no natural gold deposits at all. As examples we can consider the whole north German plain, the Netherlands, Belgium, and Denmark. Nevertheless, these regions abound in archeological gold specimens dating from prehistoric times; indeed, Denmark can be regarded as particularly rich in such finds. The material used to produce the gold bracelets, dishes, beakers, *etc.* must therefore have originated from other parts, it remaining an open question whether the gold was transported and traded as the raw material or as finished jewellery. Analysis of the material can clearly provide no answer; each case must be treated individually on the basis of archeological considerations of style and similar characteristics.

Location of natural gold deposits, which were worked in prehistoric times and which produced such high yields as to supply regions devoid of gold, should prove easier than the search for corresponding copper deposits, since the number of gold deposits is far smaller. Only sources of elemental gold—primary or secondary deposits—need be considered. No prehistoric smelting process involving modification of impurities and accompanying elements took place; moreover, the deposits themselves—at least as regards those of a secondary nature—are much more uniform in their composition.

An attempt to characterize significant natural gold deposits on the basis of accompanying elements, and thus to retrace the routes by which the gold was transmitted to regions far and near in prehistoric times, could therefore be undertaken with considerable hope of success. It has so far proved possible to distinguish, with a fair degree of certainty, two of the European gold sources according to their minor components and to recognize this gold in prehistoric finds.

Even if it proves impossible to ascribe the gold in prehistoric objects to particular natural deposits according to analyses of accompanying elements, *i.e.* the question of the origin of the gold must remain unanswered, it will still be possible to correlate gold finds on the basis of characteristic contaminants and to class them as so-called material groups, as in the case of copper. A material group comprises all those objects made of material whose content of accompanying elements is the same with regard to quality and quantity (within certain limits of variation). It is assumed that the gold occurring in all finds belonging to the same material group come from the same natural deposit, even if it has yet to be located.

Nevertheless, it will have to be borne in mind when considering such material groups that two distant natural deposits may well yield gold whose composition varies so little that the resulting objects are assigned to the same material group. The greatest caution must be exercised when a material group embraces widely differing periods and cultures and particularly when the nature and amounts of accompanying elements are not very characteristic.

5. Results of Gold Studies

We shall first consider a number of observations made with natural gold. Copper and silver are regularly found in natural gold, although in very different concentrations. The silver content is at least about 2% and can reach values of 40%. In contrast, only 0.01% of copper is often present and is reported never to exceed 1.5%[7]. Apart from these two elements we found that more than 30 samples of native gold from the Rhine and its tributaries, Transylvania, Bohemia, Ireland, Wales, and Scotland all contain mercury, sometimes only in traces of less than 0.01% but usually in the order of 0.1%, irrespective of whether the samples come from primary or secondary deposits.

Platinum and tin, however, two elements frequently encountered in prehistoric gold finds, are completely absent in gold from primary deposits. Our studies on alluvial gold concentrates revealed them to regularly contain tin and in some cases platinum too. However, these two elements are not incorporated in the grains of gold present in the concentrate but are enriched owing to their density—tin in the form of cassiterite[8,9] and platinum as the native metal[9]. Both elements will readily have gone into the gold regulus during prehistoric recovery operations and now witness to the production of the gold from placer deposits. Results of studies on about 3300 European gold finds dating from the Bronze Age to the beginning of our era indicate that placer gold was the only gold available, for, with very few exceptions, all these finds contain some tin[*].

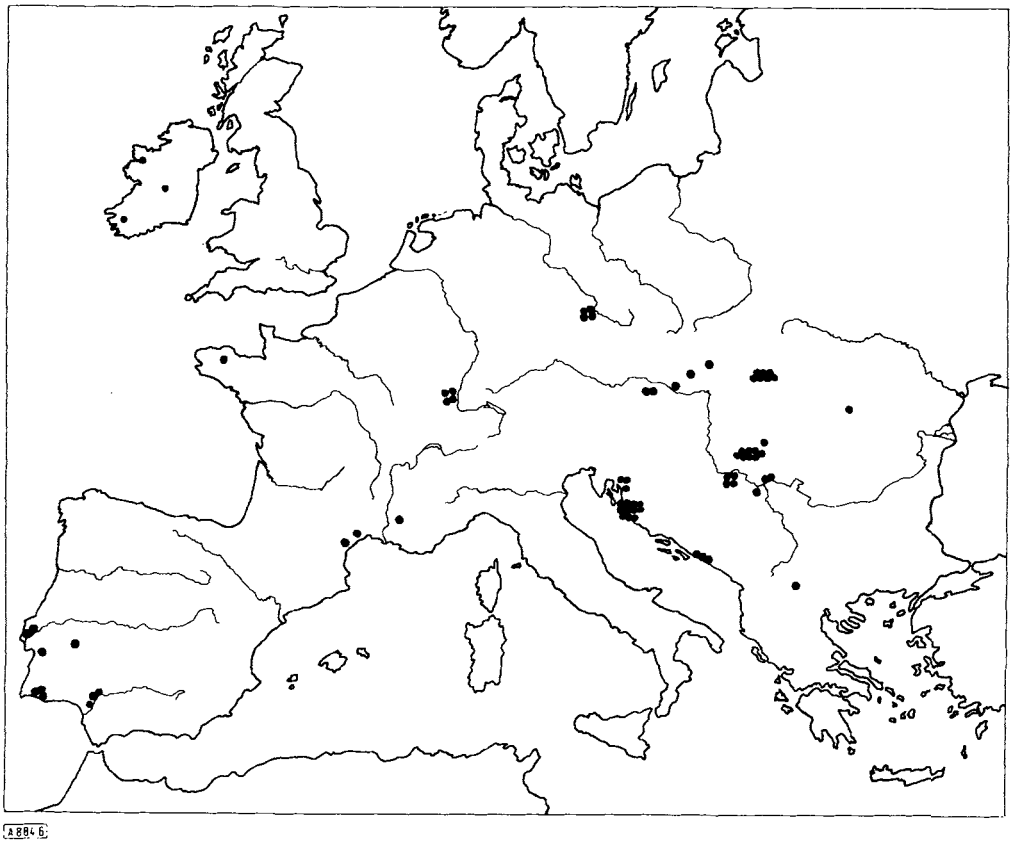
[*] Exceptions can arise owing to the presence of large nuggets in alluvial gold; such nuggets will readily be separable from accompanying minerals and are thus no longer associated with tinstone. Nevertheless, with regard to the other compounds, this gold exhibits the same composition as the stanniferous, finely divided material from alluvial deposits and is treated as such in our studies.

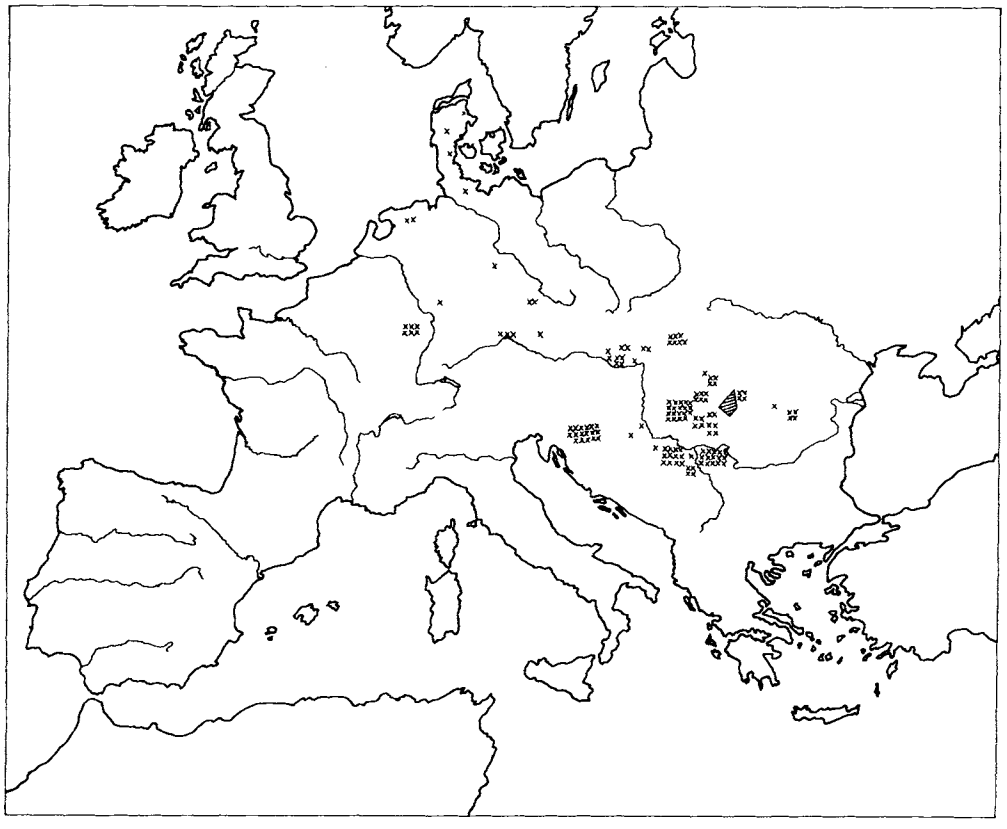
Mining for gold was apparently unknown in prehistoric Europe and seems to have been gradually introduced in Roman times.

Strikingly, it is precisely the earliest prehistoric European gold finds that are made from tin-free material which may well have been mined, although this naturally cannot be proved since alluvial deposits free from tinstone are perfectly conceivable. However, when it is remembered that this tin-free gold (which, moreover, generally has a silver content of less than 10% and rarely as much as 15%) is limited specifically to the earliest Metal Age—and disappears in the Middle Bronze Age—some justification may be seen for assuming that this material was imported from the eastern Mediterranean region where the cultures of Asia Minor are known to have engaged in the mining of ores as long ago as the 3rd millenium BC. When local extraction from alluvial deposits got under way in Europe there was no longer any need for these imports. This would provide a ready explanation for the disappearance of the tin-free material in the Middle Bronze Age.

Further support for this conception comes from the distribution of the tin-free gold we have designated "B", as shown in Figure 6. Each prehistoric gold object having this composition is indicated by a point at its place of discovery. It is clearly seen that such finds have been registered particularly frequently in coastal regions, again suggesting that they were imported, especially since the south coast of Spain and Portugal is known beyond doubt from the fortified factories established by copper seekers (Section 3) to have been exposed to the influence of the eastern Mediterranean. Non-coastal locations of such finds lie almost exclusively in the region of the lower Danube and possibly mark an inland import route. Of course, a distribution map of this kind should not be consulted without remembering the respective gaps in research, applying in this case to the regions covered by present-day Greece, Italy, Bulgaria, and Romania. Closing of these gaps by future investigations will undoubtedly do much to clarify the situation.

Utilization of the tin-free material B coincides in the Early Bronze Age with that of the slightly later material "A_3" having a considerably higher silver content (on average 26% Ag) whose distribution is shown in Figure 7. The map clearly shows the high frequency of finds in the middle reaches of the Danube. This would possibly suggest some connection with the well-known gold deposits near Brád in Transylvania. Unfortunately, we had no comparison samples of alluvial gold from this region at our disposal, but samples of gold from recent mining operations in the neighborhood of Brád also exhibit an average silver content of about 25% Ag[10]. It may therefore be assumed that during the Early Bronze Age material A_3 was obtained from alluvial deposits in a wide area surrounding the primary deposits of Transylvania (shown as hatched trapezium). This local gold displaced the imports of material B and was doubtless also exported since it is encountered in individual Bronze Age gold finds in Scandinavia, the Netherlands, and Germany, and even a flat gold ring found in Brittany appears to have been made of Transylvanian material. So far we are completely ignorant of the extent to which Transylvanian gold found its way to Mycenaean Greece, to the Hittite Kingdom in Asia Minor, and to





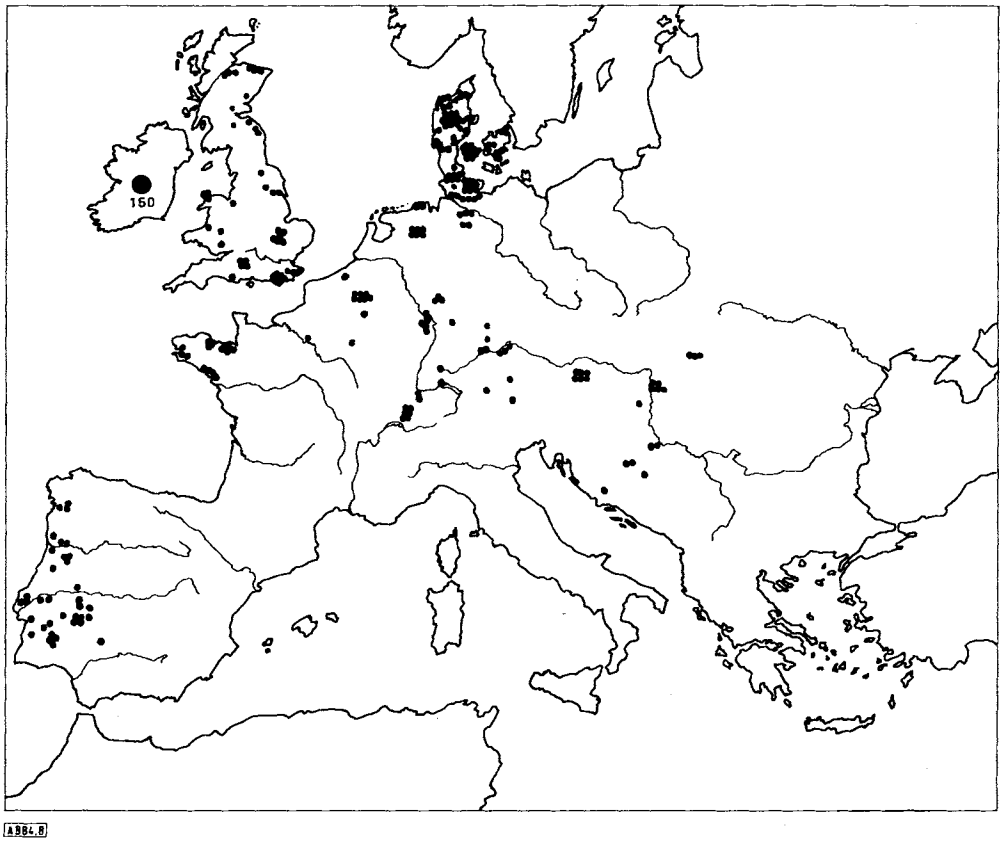


Fig. 6. Distribution of material group gold B.

A884.7

Fig. 7. Distribution of material group gold A_3. Natural gold deposits in Transylvania shown as hatched area.

A884.8

Fig. 8. Distribution of material group gold N. More than about 150 objects found in Ireland belong to this group. Little work has so far been done on specimens from England (British Museum, London) and Denmark.

Troy. However, it is our hope that future research will shed some light upon these questions.

Towards the close of the Bronze Age in Central Europe—around the turn of the 2nd to the 1st millenium BC—a particularly widely distributed variety of gold appears whose tin content clearly points to its alluvial origin. Figure 8 shows how this material, hitherto unencountered in the geographical area studied, was in use from the Balkans to Spain and Ireland. The centroid of the distribution of this gold, which we have designated "N" and which is characterized by its relatively high tin content (>0.1%) and high copper content (≈2%)[*], appears to lie in present-day Schleswig-Holstein/Denmark, the British Isles and the areas of Brittany accessible therefrom, and the western part of the Iberian peninsula. There is a temptation to regard the finds in the extreme west of Europe as comprising local gold of fortuitously identical composition; however, archeological excavations provide unequivocal evidence for extensive trading and cultural ties, particularly between Portugal/west Spain, Brittany, and the British Isles, going back far earlier than the period discussed in this report. It is therefore justifiable to relate this unexpectedly widely distributed variety of gold with a single source whose location we cannot yet define. However, the extent of this source seems so considerable that we can hardly expect to find it in west or central Europe. Furthermore, the appearance of N-type gold in central Europe coincides with that of the Urnfield culture in a period marked by significant folk migrations, and the time graduation of these folk movements from east to west is also reflected in the occurrence of N-type gold. Further conclusions will hardly be possible until the research gaps in the GDR, Poland, and Romania have been remedied. We would therefore like to do no more than cautiously express the tentative conjecture that this gold stems from somewhere in east Europe and was traded—as adequately shown by Figure 8—by a maritime route *via* the Baltic, the North Sea, and the Atlantic. Maritime trading routes must therefore have played a very important role at this time, as in the Mediterranean 1000 years previously (Fig. 6), a fact that is still not sufficiently appreciated. However, there remains some uncertainty as to what goods and valuables can have figured as objects of exchange in such a widely distributed gold trade.

This period, *i.e.* the dawn of the last millenium BC, also witnessed the first large-scale adulteration of gold with copper, particularly in the case of N-type gold. The amounts of copper found generally fluctuate in the order of up to 10% and only occasionally exceed this value. The gold assumes a particularly warm, golden-yellow color and its hardness also increases. Indeed, it is really rather surprising that this device was discovered so late: it soon became common practice in the British Isles but found somewhat less following on the European mainland. Considering that the art of alloying copper with tin had been known for half a millenium, one is forced to the conclusion that certain mythical-religious concepts had hitherto prevented abasement of the pure native gold with copper.

Finally, this is a fitting place to take a stand on a question that has long occupied archeologists. The alluvial gold deposits along the Upper Rhine were actively worked until modern times, and the assumption that gold was obtained from this source in prehistoric times, and at least those prehistoric finds excavated in the neighborhood of the Upper Rhine Valley were made from Rhine gold, appeared not entirely without foundation. Since concentrates from gold-bearing Rhine sands are still accessible today we had no difficulty in following up this proposition and were able to confirm the composition of Rhine gold—low Ag content below 10% and, in the lower reaches of the Upper Rhine, mainly accompanying platinum—as found in early analyses. However, comparison with prehistoric gold finds, primarily from southwest Germany, showed that Rhine gold was not worked until the La Tène period, *i.e.* in the last centuries BC, and that gold extraction from the deposits of the Rhine was not practiced at all, or only to an insignificant extent, before this time. The low number of La Tène objects that are made of Rhine gold also emphasizes that the production of Rhine gold can never be compared with that from the Transylvanian deposits or possibly with that of material N discussed above.

The final problem dealt with stresses once again how indispensable the application of scientific methods is for investigations of prehistoric metallurgy when any serious attempt is made to engage in successful studies of this topic, which is so important for the history of technology as a whole. That the methods employed in the natural sciences are merely aids open to continuous improvement hardly needs demonstrating to the readership of this journal.

Pentafluoroorthoselenic Acid

By *Konrad Seppelt*[*]

Compounds of fourth-row non-metals (As, Se, Br) generally resemble their homologs from the third row, whereas an increase in coordination number is often observed on going to the fifth row, *e.g.* SO_4^{2-}, SeO_4^{2-}, $H_4TeO_6^{2-}$. Thus selenium oxide tetrafluoride, analogous to sulfur oxide tetrafluoride, should be capable of existence; tellurium, on the other hand, is found to give pentafluoroorthotelluric acid[1].

However, all attempts to prepare $SeOF_4$ have been unsuccessful. Fluorination of seleninyl fluoride $SeOF_2$ with halogen fluorides (ClF_5, IF_7) gives only selenium tetrafluoride; treatment with elemental fluorine under pressure affords selenium hexafluoride.

Surprisingly, the latter reaction yields the hitherto unknown pentafluoroorthoselenic acid *(1)*, alongside a large amount of selenium hexafluoride, when carried out in the presence of hydrogen fluoride.

$$SeOF_2 + F_2 + HF \rightarrow \underset{(1)}{HOSeF_5}$$

Occasional explosions in the autoclave, which is slightly above room temperature, introduce a certain element of risk. Synthesis from selenyl fluoride[2] proved less dangerous:

$$SeO_2F_2 + 2HSO_3F + KHF_2 \rightarrow \underset{(1)}{HOSeF_5} + H_2SO_4 + KSO_3F$$

This reaction is carried out in a large excess of fluorosulfuric acid. Compound *(1)*, contaminated with SeO_2F_2 and HF, distills over in a yield of about 30% on heating the reaction mixture. The product can be purified by distillation and fractional crystallization. Yields of less than 10% are obtained in the following reactions:

$$BaSeO_4 + 5HSO_3F + 2HF \rightarrow (1) + 3H_2SO_4 + Ba(SO_3F)_2$$
$$H_2SeO_4 + 3HSO_3F + 2HF \rightarrow (1) + 3H_2SO_4$$
$$SeO_2F_2 + SeF_6 + 2HF \rightarrow 2\,(1)$$
$$SeO_2F_2 + SOF_4 + HF \rightarrow (1) + SO_2F_2$$

Compound *(1)* is a colorless crystalline solid having a high vapor pressure (0°C: 76 torr; 15°C: 186 torr); m.p. 38°C, b.p. 44°C. The empirical formula was established by molecular weight determination according to *Dumas*, from the mass spectrum [*m/e* 188—194 (F_5SeOH 0.5%), 171—177 (F_5Se 3.8%), 168—174 (F_4SeO 3.8%), 149—155 (F_3SeO 6.5%), 133—139 (F_3Se 9%), 130—136 (F_2SeO 100%), 114—120 (F_2Se 5.3%), 111—117 (FSeO 74%), 95—101 (FSe 3.8%), 92—98 (SeO 13%); 75 eV] and elemental analysis. Compound *(1)* sublimes extremely readily and exhibits a strongly depressed melting point in the impure state—typical properties of spherically shaped molecules.

[*] Dr. K. Seppelt [**]
Anorganisch-chemisches Institut der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

[**] I wish to thank Dr. *R. Geist* for recording the mass spectrum and Farbenfabriken Bayer AG, Leverkusen, for the fluorosulfuric acid.

The IR spectrum [gas phase: 3609 (s, νOH), 1171 (s, δOH), 750 (vs, νSeF), and 436 cm^{-1} (s, δSeF)] is surprisingly simple; its interpretation, which is based on a slightly perturbed octahedral model, is only tentative. The ^{19}F-NMR spectrum, a complex multiplet between −65 and −85 ppm (in $CFCl_3$ as internal standard, 56.4 MHz) which can be unequivocally interpreted as an AB_4 spectrum[3], is particularly informative: $\delta_{F_A} = -77.9$, $\delta_{F_B} = -68.3$ ppm; $J_{F_A-F_B} = 224$ Hz; $R = J/\Delta\delta = 0.395$. In addition, sidebands arising from the isotope ^{77}Se can also be observed: $J_{^{77}Se-F} = 1300 \pm 5$ Hz. The ^1H-NMR spectrum exhibits a sharp singlet ($\delta = 7.65$ ppm in $CFCl_3$, TMS as external standard).

Compound *(1)* is a strong, oxidizing acid that immediately liberates chlorine in an exothermic reaction with sodium chloride. It attacks glass and metals; this corrosivity is possibly promoted by the presence of traces of hydrogen fluoride. Teflon and, to a lesser extent, quartz are resistant. The existence of pentafluoroorthoselenic acid and its detailed resemblance to pentafluoroorthotelluric acid represents an interesting exception to the much more frequently encountered analogy between the chemistries of sulfur and selenium.

X-Ray Structure Analysis of 2,3,6-Triphenylarsenin

By *F. Sanz* and *J. J. Daly*[*]

A recent report[1] describes a general synthetic route to substituted arsenins *(1)* by a carbene insertion into an arsolene. The spectral data (MS, NMR, UV, and IR) of the compounds obtained from this reaction were consistent with the presence of an aromatic C_5As heterocyclic ring system. The synthesis of arsenin *(2)*, the arsenic analog of pyridine, has recently been accomplished[2]. We have used single crystal X-ray methods to determine the structure of 2,3,6-triphenylarsenin, *(3)*, and thus to ascertain the geometrical characteristics of the arsenin ring.

(1)

(2), $R^1 = R^2 = H$
(3), $R^1 = R^2 = C_6H_5$(=Ph)

The small, colorless, air-stable crystals[3] of *(3)* are monoclinic, space group C2/c with $a = 31.768$, $b = 10.456$, $c = 10.543$ Å, $\beta = 94.6°$, there are eight molecules of $C_{23}H_{17}As$ in the unit cell, The arsenic and carbon atom positions were found from the three dimensional Patterson function and, after some refinement, the hydrogen atoms were found from a difference synthesis. Further least squares refinement of

Monsanto Research S. A.
CH-8050 Zürich, Eggbühlstrasse 36 (Switzerland)

1623 diffractometer data gave a final R ($=\sum|\Delta|/\sum|F_o|$) value of 0.085.

The bond lengths and angles in the arsenin ring are shown in Figure 1. This six-membered ring is, within the limits of experimental error, planar and has mm2 (C_{2v}) symmetry. The arsenic-carbon bond length of 1.872 Å (average) is less than the sum of the covalent bond radii[4] (1.98 Å) and the standard[5] As—C single bond length (1.96 Å). The carbon-carbon bond lengths in the heterocyclic ring have an average length of 1.405(20) Å and this may be compared with the corresponding lengths in pyridine[6] (1.394 Å) and in 2,6-dimethyl-4-phenylphosphorin[7] (1.388 Å). The arsenin ring angles show large deviations from 120° but they are subject to geometrical constraints[7]; only five parameters are required to define this ring if it has mm2 (C_{2v}) symmetry. These parameters may be chosen as As—C1 = 1.872 Å, C1—C2 = C2—C3 = 1.405 Å, ring angles at C1 = 122.1° and at C2 = 121.5°, and may be used to calculate the ring angles at As, 101.6°, and at C3, 131.1°. Thus deviations of ring angles from 120° are a consequence of non-equality of the As—C and C—C bond lengths in the ring. The observed geometry of the arsenin ring is consistent with a delocalized 6π electron system.

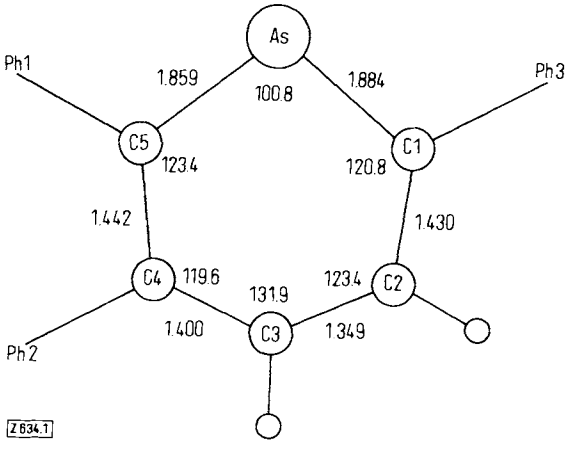

Fig. 1. Bond lengths (Å) and angles in the arsenin ring of 2,3,6-triphenylarsenin. Standard deviations: As—C, 0.014; C—C, 0.02 Å; C—As—C, 0.6; As—C—C, 1.0; C—C—C, 1.3°.

The phenyl groups are attached to the arsenin ring by essentially equal carbon-carbon bonds of average length 1.482(20) Å. These groups are individually planar with an average carbon-carbon bond length of 1.388 Å and the angles between these planes and that of the heterocyclic ring are 63, 47, and 36° for Ph(1), Ph(2), and Ph(3) respectively.

Unusual Sequence of the Two Highest Occupied π-Molecular Orbitals in the Phosphorin System[1]

By *Armin Schweig, Werner Schäfer,* and *Karl Dimroth*[*]

In a previous paper[2] we postulated that the highest occupied molecular orbital (HOMO) in the λ^3-phosphorus system[**] is the π-MO with non-zero coefficient, $\pi_1(s)$[3], and not the π-MO with its node, $\pi_2(a)$[3], on the phosphorus atom. Meanwhile we have proved this hitherto unique MO sequence by means of the photoelectron spectrum of a λ^5-phosphorin, namely 2,4,6-tri-*tert*-butyl-1,1-dimethoxyphosphorin[4] *(1)*.

(1)

(2)

Each methoxyl-oxygen atom in *(1)* has two lone pairs, one of them oriented along the C_{2v} axis and the other perpendicular thereto. The former is described by an n(s)-MO, the latter by an n(a)-MO. The interaction of the dimethoxy system with the π-MO's of the phosphorin system can arise only by linear combinations, antisymmetric with respect to the molecular plane, of the n(s)-MO's on the one hand and the n(a)-MO's on the other. In this process $\pi_1(s)$ couples with the n(s)-linear combination and $\pi_2(a)$ with the n(a)-linear combination in an antibonding manner. Coupling can be effective only in the first case, since $\pi_1(s)$ has a non-zero coefficient on the P atom. Thus it is to be expected that the HOMO $\pi_1(s)$ will be raised by a large amount. In the second case, because of the node on the phosphorus atom in $\pi_2(a)$, there remains only the possibility of a spiro-conjugative interaction, which, however, can only be slight[5]. Thus it is to be expected that $\pi_2(a)$ is only slightly raised by the action of the dimethoxy system.

These predictions were fully confirmed by experiment, as comparison of the PE spectra of *(1)* and 2,4,6-tri-*tert*-butylphosphorin *(2)* shows (Fig. 1)[6]. Band 1, which in *(2)* we had assigned to $\pi_1(s)$[2], is shifted in *(1)* by 1.3 eV to

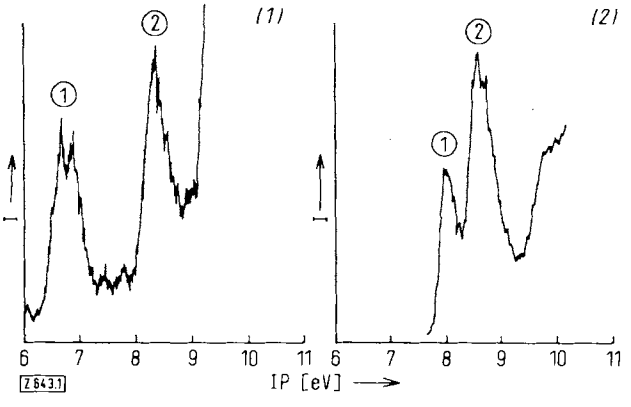

Fig. 1. Photoelectron spectra of 2,4,6-tri-*tert*-butylphosphorin *(2)* and 2,4,6-tri-*tert*-butyl-1,1-dimethoxyphosphorin *(1)*. The vertical ionization potentials of the two first bands of *(1)* are 6.7 and 8.4 eV.

smaller IP values, while band 2 remains almost unchanged. In *(2)*, because of the measured intensity ratio band 1: band 2 = 1:2, we had assigned band 2 to π_2(a) and the n-MO that describes the lone electron pair on the P atom[2]. Since this n-MO is not present in *(1)*, the intensity ratio must there be approximately 1:1, as was confirmed by experiment. These findings prove that the assignment made for *(2)* is correct. They also prove that the unusual and hitherto unique MO sequence (π-MO with non-zero coefficient on the hetero atom higher in energy than the π-MO with node on the hetero atom) actually occurs in the phosphorin system.

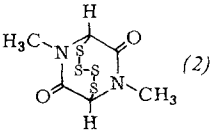
X-Ray Structural Analysis of *N,N'*-Dimethyl-3,6-epitetrathio-2,5-piperazinedione [**]



By *Betty R. Davis, Ivan Bernal*, and *Ulrich Schmidt*[*]

The structural fragment common to gliotoxin[1,2a], virus inhibiting antibiotics of the aranotin type[3], sporidesmins[2b,4] and the cancerostatic antibiotic chaetocin[5] is a 2,5-piperazinedione ring with an epidithio bridge *(1)*. A study of methods for the direct insertion of sulfur functions (such as S_n, with $n=2,3,4$, *etc.* ...) has been reported previously[6]. *Benedetti et al.*[7] have previously reported that the supposedly "rigid" diketopiperazines are surprisingly flexible. We are interested in establishing the systematics of the stereochemistry of the piperazinedione fragment and the S_n bridge as a function of the length of the polysulfide chain.

The title compound crystallizes in the orthorhombic space group Fdd2 with $a=15.352(5)$, $b=20.432(7)$, and $c=6.635(2)$ Å; $V=2081.2(8)$ Å^3; $d_{obs.}=1.72(2)$ gm cm^{-3}, $d_{calc.}$ ($Z=8$) $=1.71$ gm cm^{-3}. The data were collected with a computer controlled diffractometer using monochromatic $Mo_{K\alpha}$ ($\lambda=0.71069$ Å) radiation. Data of the form hkl and $\bar{h}kl$ were collected to $2\theta \leq 69.8°$, resulting in 2856 reflections of which 1326 were unique. The 1135 independent reflections for which $F_0^2 > 3\sigma(F_0^2)$ were used to refine the structure. No absorption correction ($\mu=8.71$ cm^{-1}) has been applied to the observed structure amplitudes. A least-squares refinement in which the hydrogen atoms were added as a fixed contribution to the structure factors ($B=3.06$ Å^2) and all the other atoms were assigned anisotropic thermal parameters, converged at values of $R_1=0.033$ and $R_2=0.052$, with an error in an observation of unit weight of 1.72 electrons.

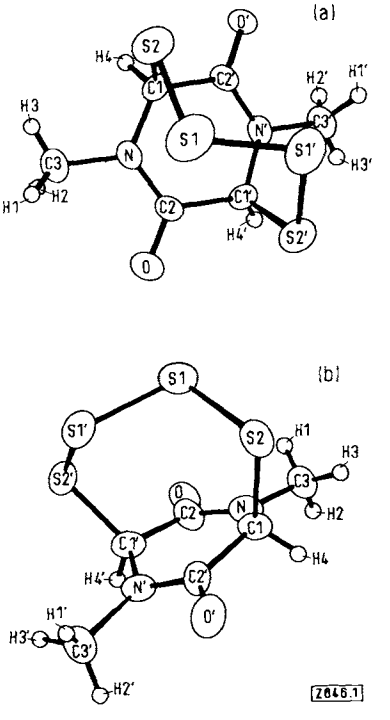

Fig. 1. Crystal structure of *N,N'*-dimethyl-3,6-epitetrathio-2,5-piperazinedione. (a) View approximately down the two-fold axis of symmetry which bisects the S1—S1' bond. (b) View along an arbitrary line of sight chosen to emphasize the three-dimensionality of the tetrasulfide chain and the non-planarity of the piperazinedione ring.

Two views of the molecule[9] are shown in Figure 1. View (a), down the crystallographic two-fold axis of symmetry, shows the geometry of the S_4 fragment projected onto the piperazinedione ring. The primed and unprimed labels on the atoms are chosen to emphasize the two-fold axis relationship between the two molecular halves. View (b) shows more clearly the three-dimensional character of the epitetrathio link and also the non-planarity of the piperazinedione ring at positions 3 and 6 (=Cl and Cl'). The dihedral angle between planes defined by C2—N—C2'—N' and C2'—Cl—N is 18.07°. In 2,5-piperazinedione[10] and in *trans*-3,6-dimethyl-2,5-piperazinedione[9], the rings are planar, while in *cis*-3,6-dimethyl-2,5-piperazinedione, the

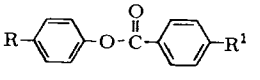
Nematic Liquids with Positive Dielectric Anisotropy[1]



By *Ralf Steinsträsser*[*]

According to the *Gruler-Meier* model[2], nematic liquid crystals show the dynamic scattering effect described by *Heilmeier*[3] only if their dielectric anisotropy has a negative sign, *i.e.* if the dielectric constant ε_1 measured in the direction of the long molecular axis of a nematic single crystal is smaller than the constant ε_2 measured perpendicular thereto[4]. Nematic phases of this type are known at room temperature; they have the general formula *(1)*, in which the —X=Y— bridge is —CH=N—[5,6],

(1)

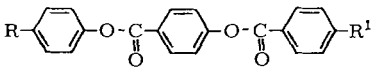
—N=NO—[7] or —CH=CCl—[8]. Low-melting nematic liquids having a negative dielectric anisotropy and thus capable of dynamic scattering were recently described[9] also among esters of type *(2)*[12].

(2)

Nematic liquid crystals with positive dielectric anisotropy ($\varepsilon_1 > \varepsilon_2$) cannot be excited to dynamic light scattering simply by electric fields, but they can find use as electro-optical detection systems[10] or for electrically-controllable color filters[11] that can be used in polarized light.

By lengthening the central part of the molecule of esters *(2)* by a further benzoyloxy group one obtains the diesters *(3)*[12], some of which are listed in Table 1.

Unlike the esters *(2)*, the compounds *(3)* show very broad enantiotropic mesophases extending over *ca.* 100 °C. It is interesting that even the phenol *(3)*, $R = C_4H_9$, $R^1 = OH$ (m.p. 177 °C, cl.p. 218 °C) can still form a stable nematic phase.



The influence of the substituents R and R^1 on the mesomorphic properties is less marked with the diesters *(3)* than with the monoesters *(2)* in which the nature and chain length of the substituents is decisive for appearance or absence of nematic phases.

The melting points of the compounds *(3)* are too high for their practical applications as nematic dielectrics to be of interest. However, the melting points fall when the com-

[**] Application of an electric field can disorientate the molecules of a nematic liquid that contains ionic impurities. Molecular 'turbulences' arise that become scattering centers. This effect is described as dynamic scattering.

pounds are mixed. Thus the eutectic from *(3)*, $R=R^1=C_4H_9$ (60%) and *(3)*, $R=C_4H_9$, $R^1=OCH_3$ (40%), melts at 54 °C (clear pt. 204 °C). Nematic phases are obtained at room temperature if two substances of type *(3)* and one or several low-melting esters *(2)* are melted together. With some of these mixtures crystallization does not occur even on storage for many hours at temperatures well below 0 °C.

(3)

As an example of such a system, a mixture of 25% of *(3)*, $R=R^1=C_4H_9$, 25% of *(3)*, $R=C_4H_9$, $R^1=OCH_3$, 15% of *(2)*, $R=OCH_3$, $R^1=C_4H_9$, and 35% of *(2)*, $R=C_4H_9$, $R^1=OCH_3$, may be cited. This mixture has a clearing point of 110 °C and is liquid even at −80 °C. Differential thermal analysis did not show a melting point; it was also impossible to determine whether this was a eutectic mixture and thus a thermodynamically stable liquid, because mixtures of the same components in other proportions also showed no melting point.

Measurement[13] of the dielectric anisotropy gave a positive $\Delta\varepsilon$ ($\varepsilon_1 > \varepsilon_2$), so that the non-occurrence of dynamic scattering can be understood. However, the detection principle described by *Schadt* and *Helfrich*[10] could be readily demonstrated for this mixture.

The Catalytic Deoxygenation of Aromatic Nitro Compounds by Carbon Monoxide in the Presence of Diphenylacetylene[1]

By *Abul F. M. Iqbal*[*]

Reactive species occurring in the deoxygenation of nitro compounds by carbon monoxide have been trapped by aldehydes[2, 3] and protic solvents[4, 5] to give a variety of products. We now report the interaction of diphenylacetylene with carbon monoxide and aromatic nitro derivatives in the presence of catalytic quantities of hexadecacarbonylhexarhodium $[Rh_6(CO)_{16}]$ to afford high yields of the corresponding *N*-aryl-2,3-diphenylmaleimides *(1)*.

(1)

Apparently, carbon monoxide performs here the dual function of a reducing and carbonylating agent. No maleimide is formed in the absence of catalyst. The reaction is fairly selective and conveniently carried out in a steel autoclave. Tertiary amines (such as pyridine, *N*-methylpyrrolidine *etc.*) are used as solvents. In benzene, a small amount of a brick-red polymer is formed which was not further examined.

Some results are presented in Table 1. All products have been characterized by mixed melting point, elemental analysis, and IR and NMR spectroscopy. Compounds *(1a)* and *(1b)* have previously been prepared by an independent route[6].

Since formation of amines and isocyanates cannot be excluded under the given conditions[2, 3], the question arises whether they play a role in the formation of the diphenylmaleimide derivatives *(1)*. This has been checked by performing under analogous conditions the reaction of di-

[*] Dr. A. F. M. Iqbal
Monsanto Research S. A.
Eggbühlstrasse 36
CH-8050 Zürich (Switzerland)

phenylacetylene with aniline and phenylisocyanate, respectively. In the former case, *N*-phenyl-2,3-diphenylsuccinimide (20—30%) is obtained as major product apart from a trace amount of *(1a)*, while from the latter conversion the only product thus far isolated consists of a high melting (> 300 °C) crystalline compound, which has not yet been identified.

Table 1. Compounds prepared by the reaction of diphenylacetylene with aromatic nitro compounds and carbon monoxide in the presence of carbonyl rhodium.

	R	Yield (%) [a]	M.p. (°C) [b]	IR (ν_{CO}) (μ) [c]	^{1}H-NMR Chemical Shift δ(ppm) [d] aromatic	methyl
(1a)	H	75	175 [e]	5.67 5.85	6.85–7.7	–
(1b)	*p*-CH_3	77	192–194 [f]	5.68 5.85	7.0 –7.7	2.38
(1c)	*m*-CH_3	77	160–161	5.70 5.88	6.9 7.7	2.37
(1d)	*m*-Cl	75	145–146	5.68 5.83	7.0 –7.7	
(1e)	*p*-OCH_3	50	188–189	5.68 5.85	6.85–7.7	3.78
(1f)	*p*-C_6H_5	80–85	244–246	5.70 5.87	7.2 –7.9	–

[a] Crude yield, based on diphenylacetylene.
[b] Melting points are uncorrected.
[c] KBr disc.
[d] Measured in $CDCl_3$.
[e] 174—175 °C after Ref. [8].
[f] 192 °C after Ref. [6].

In view of these findings we tend to rule out intermediacy of amine or isocyanate in the direct formation of *(1)* from diphenylacetylene and nitro compounds. In analogy to related cases[2, 3, 5] we believe in intervention of some sort of a nitrenoid species originating from the nitro component.

N-(p-Biphenylyl)-2,3-diphenylmaleimide (1f):

A solution of diphenylacetylene (0.005 mol), *p*-nitrobiphenyl (0.0055 mol) and hexadecacarbonylhexarhodium[7] (10^{-5} mol) in anhydrous pyridine (6 ml) was allowed to react with carbon monoxide (150 atm) in a stainless steel autoclave (30 ml capacity) at 165—170 °C (external temperature) for 3 hours. After cooling to room temperature, the autoclave was discharged and pyridine removed *in vacuo* at 50 °C. The residue was swirled with 10—15 ml of *(1f)* in 80—85% yield, m.p. 244—246 °C.

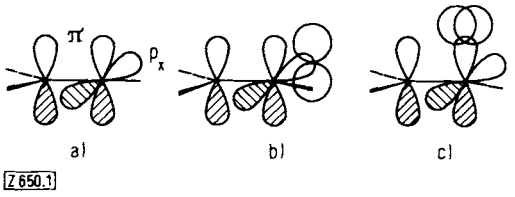
MO Calculations on the Insertion Reactions of Vinyl Cations[**]

By *Herbert Kollmar* and *Harry O. Smith*[*]

The chemistry of vinyl cations and related species[1] is characterized by rearrangements and additions to unsaturated systems[2, 3]. MO calculations, however, predict that such ions should also be able to participate in insertion reactions, in analogy to the well-known insertions of carbenes. The simplest example of such a reaction is the addition of the vinyl cation to the hydrogen molecule to form the ethyl cation:

$$C_2H_3^+ + H_2 \longrightarrow C_2H_5^+ \qquad (1)$$

The reverse of (1) is observed in mass spectrometry as a fragmentation reaction[4]. We have studied this example in some detail.



A modified[5] CNDO[6] method was used which allows the complete minimization of the energy of a molecule with respect to its geometry and thus is particularly well suited to the calculation of reaction coordinates[7].

The vinyl cation has an almost empty p orbital (p_x in Fig. 1a) perpendicular to the π bond orbital. The π orbital is strongly polarized; hence the vinyl cation can be described as a methylene with CH_2^+ as a substituent. Various modes of H_2 addition are conceivable in reaction (1). For instance, the H_2 molecule could approach the occupied π orbital of the $C_2H_3^+$ ion from the side (Fig. 1c). This is a very

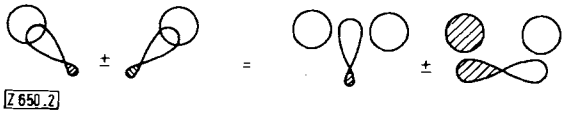
[**] First communication of MO calculations on electrophilic reactions.



unfavorable reaction path because two occupied orbitals are forced to interact with each other. (Assuming C_s symmetry, this path is forbidden according to the Woodward Hoffmann rules[14]). On the other hand, the approach of H_2 along the empty p_x orbital (Fig. 1 b), leading initially to a three-center bond, should be energetically more favorable[8, 9].

Z 650.1

Fig. 1. Addition of H_2 to the vinyl cation.

The ethyl cation formed, of course, normal C—H bonds and not three-center bonds. As demonstrated in Fig. 2, however, two *vicinal* C—H bonds can be described by a linear combination of two three-center bonds. The calculations show that these three-center bonds are formed consecutively during the course of the reaction.

Z 650.2

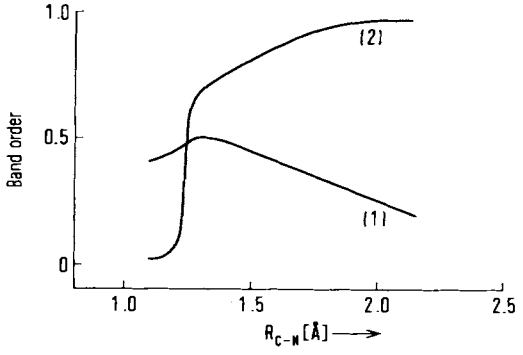


Fig. 2. Representation of C—H bond orbitals as a linear combination of three-center bonds.

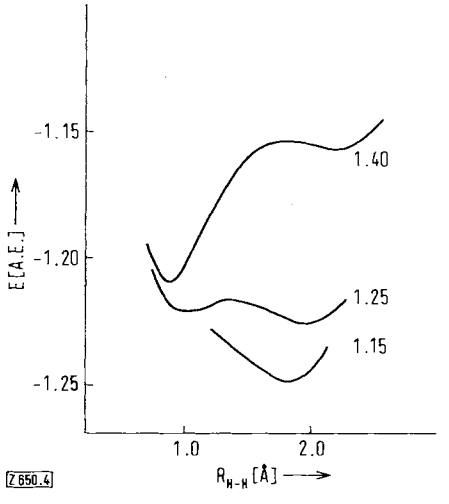
The detailed results of the calculations of the reaction path for reaction (1) are as follows: The reaction proceeds with relatively little activation energy (9 kcal/mol at a C—H distance of 2.3 Å). ΔH_0 for the addition is calculated to be 46 kcal/mol (experimental value 60 kcal/mol[10]). An interesting result is that the reaction proceeds in two easily discernable steps:

1. In the first step a three-center bond is formed between the H atoms and the empty p_x orbital ("electrophilic phase of the reaction"). This step is analogous to the electrophilic addition of carbenium ions to saturated C—H and C—C bonds, which can be observed in highly acidic solutions[9]. The prototype reaction is the addition of H_2 to CH_3^+ to form the CH_5^+ cation, which, according to MO calculations, should proceed without activation energy[11].

2. In the second step, beginning at a C—H distance of about 1.3 Å, the antibonding orbital of H_2 combines with the occupied π orbital of the vinyl cation to form the second three-center bond. The H—H distance becomes larger and the geometric structure of the product is obtained. This phase of the reaction corresponds to the characteristic breaking of the bond of the substrate during an insertion process (the "nucleophilic phase", involving the occupied π orbital of the vinyl cation).

The two-phase mechanism is reflected in the changes of the parameters describing the electronic structure along the reaction coordinate. Figure 2 shows the change in the bond order between the originally empty p_x orbital of the vinyl cation and the 1s orbital of an approaching H atom as a function of the C—H distance. During the formation of the first three-center bond, this bond order increases from 0 at infinite distance to about 0.5 at a C—H distance of 1.3 Å. The decrease at smaller distances is due to rehybridization. Similarly, the bond order between the two H atoms of the approaching H_2 molecule sinks continuously from 1 at infinite distance to 0.6 at 1.3 Å. At this point it then drops sharply to almost 0 due to the admixture of the antibonding H_2 orbital to an occupied orbital in the second phase of the addition.



(1) p_x-H
(2) H-H

Z 650.3

Fig. 3. Changes in the electronic structure during reaction (1).

The reaction coordinate is also affected by the two-phase mechanism (Fig. 4). The H—H distance remains relatively small (0.9 Å) down to a C—H distance of 1.3 Å and then increases rapidly with further shortening of the new C—H bond to the final value of 1.85 Å. At intermediate C—H distances (1.25—1.4 Å) there exist two local energy minima at different H—H distances. Above 1.3 Å the minimum with a short H—H bond is energetically more favorable. This order is reversed at shorter C—H distances ($\leq$1.25 Å).

Z 650.4

Fig. 4. The energy as a function of the H—H distance at constant C—H distances.

The two-phase mechanism does not entail any steric consequences (and thus chemical repercussions) in this case. Such effects become important in the analogous insertion reactions of carbenes[12, 13].

Dimethylene(2-propenylidene)methanetricarbonyliron[1]

By *W. Edward Billups, Lee-Phone Lin*, and *Otto A. Gansow*[*]

Reactions of carbonyliron complexes with compounds whose structural features incorporate the vinylcyclopropane *or* methylenecyclopropane grouping are of current interest.

Thus the reaction of $Fe_2(CO)_9$ with cyclopropylstyrene[2a,b] or spiro[2.4]hepta-4,6-diene[2c] gives substituted 1,3-diene-$Fe(CO)_3$ complexes, whereas bullvalene[2e] and semibullvalene[2f] give complexes resulting from cleavage of the cyclopropane ring with formation of both a π-allyl and a σ component bound to the $Fe(CO)_3$ unit. Methylenecyclopropane[2d] also gives a low yield of butadienetricarbonyliron upon reaction with $Fe_2(CO)_9$; however, methylenecyclopropanes bearing a phenyl or methyl substituent on C-2 give trimethylenemethane-coordinated products[2d].

Methylene(vinyl)cyclopropane *(1)*[3] is a molecule that incorporates *both* these functionalities and the present communication reports on a stable iron complex dimethylene(2-propenylidene)methanetricarbonyliron *(2)* derived from *(1)* and $Fe_2(CO)_9$.

(1) *(2)*

Complex *(2)* is prepared (43% yield) by stirring a 1:1 mixture of *(1)* and $Fe_2(CO)_9$ in benzene at 35—40 °C for 2 h. After removal of benzene, bulb to bulb distillation at 92 °C/2.5 torr gives *(2)* as a deep green oil whose composition was shown to be $C_6H_8Fe(CO)_3$ by its mass spectrum (parent molecular ion *m/e* 220). The infrared spectrum shows C≡O absorptions at 2048 and 1984 cm^{-1}. The ^{1}H-NMR spectrum (Table 1) of *(2)* provides convincing evidence for the proposed structure. In addition, the decoupled ^{13}C-NMR spectrum of *(2)* at ambient probe temperature shows seven distinct signals (Fig. 1). Two ^{13}C resonances may be immediately identified as due to the carbonyl carbon and the central carbon of the trimethylene-methane ligand by simple chemical shift[4] and signal intensity considerations. The two methylene resonances at −51.9 and −52.5 ppm are quite near those observed for trimethylenemethanetricarbonyliron[4], while those at −137.6 and −118.7 ppm are near the resonances of the vinyl group of compound *(1)*.

Table 1. ^{1}H-NMR parameters of *(2)* determined at 60 MHz and relative to TMS.

	δ(ppm)	J(Hz)
H-1	3.67 (d, d)	$J_{1,6} = 9.7$; $J_{1,4} = 2.1$
H-2	1.80 (d)	$J_{2,5} = 4.3$
H-3	1.79 (s)	
H-4	2.18 (m)	
H-5	2.66 (d)	$J_{2,5} = 4.3$
H-6 to H-8	4.83—6.03 (m)

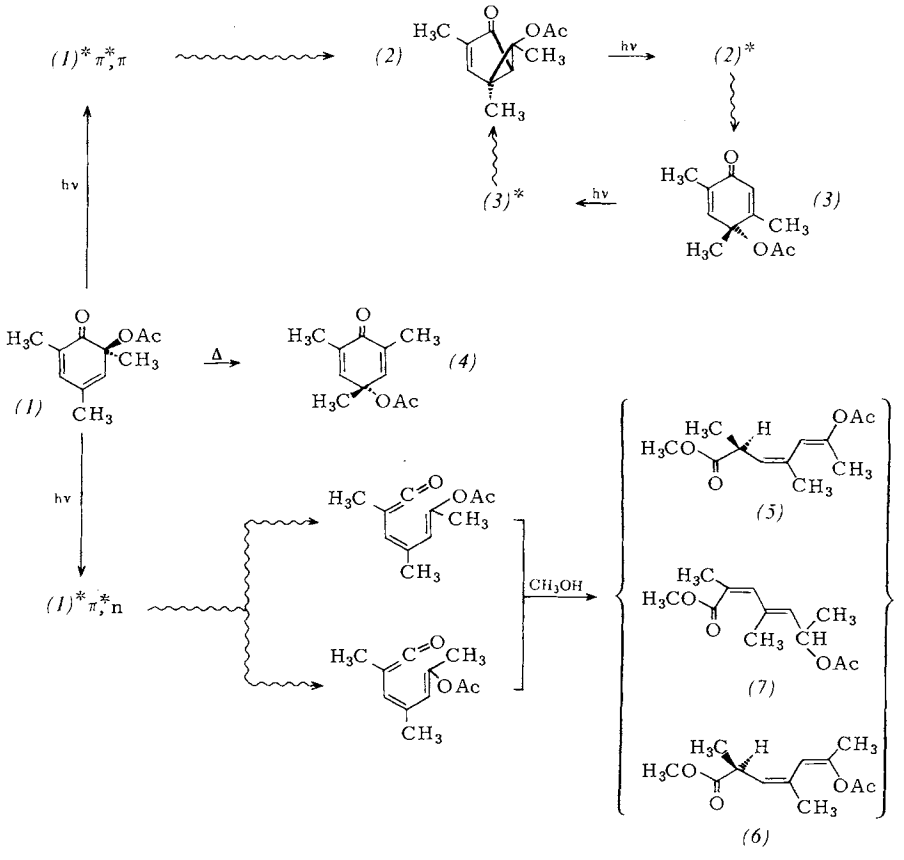
Three Isomerization Routes Originating from Different Electronic States of a Linearly-Conjugated Cyclohexadienone[1][***]

By *Gerhard Quinkert, Bernd Bronstert*, and *Klaus R. Schmieder*[*]



Comparative chemistry is directed towards the elucidation of the reaction paths starting from different electronic states of a compound[2]. The chiral but racemic 6-acetoxy-

2,4,6-trimethylcyclohexa-2,4-dien-1-one *(1)*[3] provides an example in which the routes originating from the electronic ground state, from the π^*,n or from the π^*,π excited states, respectively, lead to different products (see reaction scheme).

If solutions of *(1)* in polar solvents are heated they yield mainly the cross-conjugated cyclohexadienone *(4)* together with minor amounts of phenols (see Table 1). The constitution of the symmetrical isomerization product follows from its spectroscopic properties (see Table 2) and from the observation that, on treatment with zinc in boiling acetic acid, mesitol is produced.

Table 1. Composition of the products isolated after heating of *(1)*. 5.15×10^{-2} M solutions were kept at the temperature stated for 24 h with exclusion of light.

Solvent	Temp. (°C)	Compounds isolated (%) *(1)*	*(4)*	Phenols [a]
Methanol	65	60	30	10
Trifluoroethanol	70	40	50	10
+ cyclohexylamine [b]	70	40	50	10
Xylene	140	60	35	5
Cyclohexane	80	100	—	—
Carbon tetrachloride	77	100	—	—

[a] Mainly mesitol.
[b] 0.769 M.

Irradiation of *(1)* in 2,2,2-trifluoroethanol at room temperature with 365 or 313 nm light furnishes, besides a small amount of phenols[4], the isomeric ketones *(2)* and *(3)* in a *spectroscopically complex photoreaction* (non-linear ED diagram[5]); the relative yields of the ketones depend on the wavelength and on the irradiation time used. According to spectroscopic monitoring, the complex process is composed of two partial photoreactions (linear EDQ diagram[5] for the irradiation of *(1)* and linear ED diagram[5] for the separate photoisomerization of *(2)* to *(3)*; see reaction scheme).

Photoisomerization of *(3)* to *(2)* can be effected by 254 nm light, considerable amounts of phenols[7] being formed during this process. The constitution of the unsymmetrical cross-conjugated cyclohexadienone *(3)* is supported by spectroscopic data (see Table 2) and by the formation of 2,4,5-trimethylphenol on reaction with zinc in boiling acetic acid; for the constitution and stereochemistry[8] of the bicyclo[3.1.0]hexenone *(2)*, see the spectroscopic data in Table 2.

Irradiation of *(1)* in methanol[9] at room temperature with 365 or 313 nm light affords the stereoisomeric methyl esters *(5)* (93%) and *(6)* (2%) in a *spectroscopically simple photoreaction* (linear ED diagram[5]); in addition to traces of phenols (<1%), the constitutionally isomeric methyl ester *(7)* (5%) is also produced. The constitution and stereochemistry of all three esters are confirmed by their spectroscopic data (see Table 2). The carboxylic acid derivatives arise from respective 1,2- or 1,6-addition of the nucleophilic solvent to the corresponding dienylketenes (see reaction scheme); low temperature UV- and IR-spectroscopic evidence for the existence of the transient[10], *seco*-isomeric with *(1)*, has already been presented earlier[11]

The thermal isomerization of *(1)* to *(4)* can be interpreted as a sigmatropic rearrangement of the order [3,3][12] occurring on the lowest energy surface. Since the light-induced isomerization of *(1)* either to *(2)* or to the dienylketene precursors of *(5)* and *(6)* does not give *(4)*[13], one can safely argue that the photoisomerizations do not originate from the electronic ground state of the reactant. Which of the two photoisomerizations actually takes place is

Table 2. Physical data for the isomers obtained from *(1)* and their transformation products [a].

[a] Satisfactory analytical data have been secured for all compounds.
The UV spectra were measured in methanol; S = shoulder.
The IR spectra of the crystalline ketones were determined in KBr, those of the liquid methyl esters as films; s = strong, m = medium.
The NMR spectra of the ketones and methyl esters were measured in $CDCl_3$ and C_6D_6, respectively; s = singlet, ψs = pseudosinglet, d = doublet, ψd = pseudodoublet, m = multiplet.

controlled by solvent effects that also influence the relative positions of the π*, π and π*, n transitions in the absorption spectrum (see Fig.) not, however, by the wavelength of the absorbed light (365 or 313 nm). This indicates that the initially excited states are not necessarily the reactive ones. In the present example the rule is obviously obeyed that in the condensed phase the reaction starts on the lowest rung of a given multiplicity ladder. We attribute π*, n and π*, π character to the reactive excited states of the *cyclo/seco* isomerization[12] and the intramolecular $[_\sigma 2 + _\pi 2]$ cycloaddition[14] respectively.

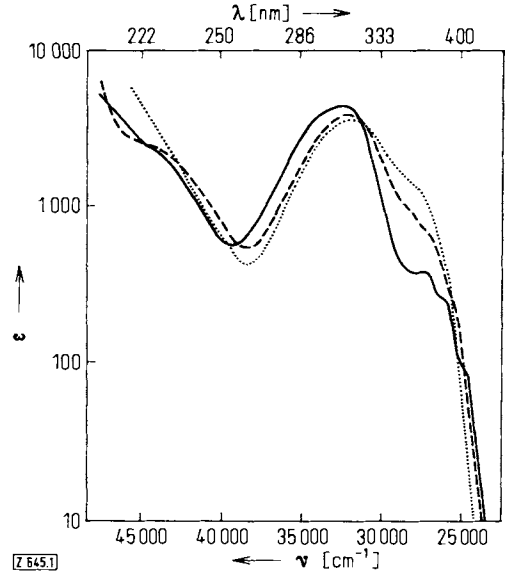

Fig. 1. Electronic absorption spectra of *(1)* in methylcyclohexane (——), ethanol (– – – –), and trifluoroethanol (·····) at room temperature.

1-Cyclopentadienyldifluorophosphane: A New Fluxional Molecule

By *John E. Bentham, Evelyn A. V. Ebsworth, Hans Moretto,* and *David W. H. Rankin*[*]

Cyclopentadienyl derivatives of silicon[1], germanium[1], and tin[1] have been shown by NMR spectroscopy to behave as fluxional molecules. We have prepared cyclopentadienyldifluorophosphane, whose ^{19}F-NMR spectrum demonstrates this behavior simply and clearly.

When potassium cyclopentadienide is allowed to react for 1 h with an excess of bromodifluorophosphane at −78 °C in the absence of solvent, a mixture of products is obtained, from which pure cyclopentadienyldifluorophosphane can be isolated in 25% yield by fractional distillation (−12 °C/8 torr). The compound has been characterized by its molecular weight, by its mass and infrared spectra, and by vapor pressure measurements: the m.p. is −71 °C, the extrapolated b.p. is 88 °C, and the infrared spectrum is typical of a σ-bound C_5H_5 derivative.

(1)

At low temperatures in a mixture of $CFCl_3$ and $(CH_3)_4Si$ (1:1) as solvent the ^{19}F-NMR spectrum shows the pattern expected for 1-cyclopentadienyldifluorophosphane; there is a wide doublet due to PF coupling [^1J(PF) = 1170 Hz], at $\delta_F = 76.8$ ppm, and each component of the doublet shows a further doublet splitting due to coupling with the single proton bound to the saturated carbon atom [^2J(HF) = 11.5 Hz]. Further splittings were not resolved at temperatures down to −85 °C. At temperatures above −30 °C the wide doublet splitting remains, but the narrower splitting collapses, and at temperatures above 25 °C a sextet pattern develops in its place; at 50 °C the resonance consists of a wide doublet of well-resolved sextets. This shows that at temperatures above 25 °C the fluorine nuclei are coupled equally to all 5 ring protons [^2J(HF) = 2.5 Hz], and therefore that the molecule is fluxional. There is no change in ^1J(PF) over this temperature range, which emphasizes that the fluxional process is intramolecular.

The ^{1}H resonance spectrum also reflects this behavior. At 50 °C the spectrum consists of a single very broad line near 3.2 ppm. At −10 °C this splits into a strong and complex resonance with two peaks near 3.1 and 3.6 ppm and a weaker triplet resonance (J = 11 Hz) near 6.1 ppm, due to the proton bound to the saturated carbon atom. At −85 °C the complex resonance consists of two strong and complex lines at 3.07 and 3.57 ppm, and the triplet at 6.06 ppm shows further splittings. It appears that ^2J(HP) is small, at least at low temperatures.

Synthesis of 7,7-Dimethylbicyclo[4.1.1]octan-3-one by Pinacolic Rearrangement[**]

By *William Tubiana* and *Bernard Waegell*[*]

Access to ketones of the bicyclo[4.1.1]octane series is difficult[1]. We have found that the pinacolic rearrangement of the monotosylate *(5)* provides an entry into this series by way of a ring expansion reaction.

A Wittig reaction of isonopinone *(1)*[3] gave the methylene derivative *(2)* which could be converted, *via* the diol *(3)*[4], into the monotosylate *(5)*[4]. Compound *(5)* was then transformed into 7,7-dimethylbicyclo[4.1.1]octan-3-one *(7)* by *Corey*'s procedure for pinacolic rearrangement[5] [*(2)* → *(3)* → *(5)* → *(7)*, see experimental procedure].

Epoxide *(4)* is not an intermediate in this reaction because the mixture of isomers obtained from *(2)* was found to give *(1)* and the corresponding aldehyde under the conditions of pinacolic rearrangement. The monotosylate *(6)* isomeric with *(5)*[6] does not rearrange to the ketone under the above conditions[5].

[**] We thank Dr. *Teisseire* for providing us with α-pinene, and the Roure Bertrand et J. Dupont for a research scholarship *(W. T.)*.

Experimental:

Alkene *(2)* (1 g, 7.3 mmol) is added to a solution of osmium tetroxide (2 g, 7.7 mmol) in dry ether (50 ml). After four hours' stirring (magnetic stirrer) at room temperature the reaction solution is mixed with a solution of sodium chlorate (3 g) in dioxane (20 ml), water (10 ml), and a few drops of acetic acid, and heated gently until decoloration. The pH is adjusted to 10 by addition of sodium hydroxide. The organic products are extracted with ether, and the extract is washed with water, dried over magnesium sulfate, and the solvent evaporated. Purification of the residue (620 mg) by GLC (S.E.30 3%, 3.0 m, 160 °C) yields a white crystalline product (400 mg, 50%). IR (CCl_4): 3400, 1050 cm^{-1}. NMR (CCl_4): $\tau = 7.25$ (2H/complex), 6.60 ppm (2H/s). $m/e = 152$ $(M-18)^+$.

Diol *(3)* (500 mg, 2.9 mmol) is dissolved in dry pyridine (20 ml). A stoichiometric amount of *p*-toluenesulfonyl chloride is added portionwise and the mixture then stirred overnight at room temperature. Water (20 ml) is added and the tosylate extracted in the usual manner with ether. Yield 70%. IR (CCl_4): 1600, 1180—1170, 3600, and 3400 cm^{-1}. NMR (CCl_4): $\tau = 2.5$ (4H/m); 6.10 (2H/s), 6.7 (1H/broad), and 7.6 (3H/s).

(5) (1.32 g, 4.0 mmol) is stirred in dry tetrahydrofuran in presence of calcium carbonate (400 mg, 4.0 mmol) and a catalytic amount of lithium perchlorate for 72 hours at 60 °C. The solution is washed with water, dried over magnesium sulfate, and evaporated. The residue (300 mg) is transferred to an alumina column (Merck, activity grade II-III) and eluted with pentane. The procedure yields 200 mg (50%) of *(7)*, m.p. (semicarbazone = 142 to 143 °C, IR (CCl_4): 1715 cm^{-1}; NMR (CCl_4): $\tau = 2.2$ (5 H/broad) and 3.5 ppm (4 H/m); $m/e = 152$ (M^+).

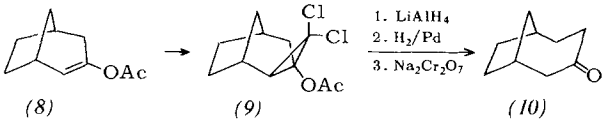
Reductive Fragmentation of 3,3-Dihalotricyclo[4.2.1.0^{2,4}]non-2-yl Acetates: a New Route to the Bicyclo[4.2.1]nonane Series[1]

By *Wolfgang Kraus, Walter Rothenwöhrer, Horst Sadlo,* and *Gerhard Klein*[*]



Bicyclo[3.2.1]oct-2-en-2-yl acetate *(1)*, b.p. 86 °C/10 torr, which can be obtained in 87% yield from bicyclo[3.2.1]octan-2-one by means of isopropenyl acetate, does not react with dihalocarbenes if these are produced by potassium *tert*-butoxide from trihalomethanes or from sodium trihaloacetates[2]. However, treatment of *(1)* by *Mąkosza*'s procedure[3], namely, with chloroform and 50% aqueous sodium hydroxide, and catalytic amounts of benzyltriethylammonium chloride, affords 3,3-dichloro-*exo*-tricyclo[4.2.1.0^{2,4}]non-2-yl acetate *(2)*, b.p. 96 °C/0.5 torr, in 67% yield.

(1) *(2)* *(3)* *(4)* *(5)* *(6)* *(7)*

With $LiAlH_4$ in ether[4], *(2)* yields a mixture (91% yield) of the *exo-endo*-isomeric allylic alcohols *(5)* *via* the alkoxy anion *(3)* and the ketone *(4)*, by reductive fragmentation. Hydrogenation of *(5)* over palladized charcoal in tetrahydrofuran and aqueous sodium hydroxide gives the saturated alcohols *(6)* (93% yield), which can be oxidized to pure bicyclo[4.2.1]nonan-2-one *(7)*, m.p. 92—93 °C (92% yield). This ketone thus becomes accessible by a simple route, whereas previously it could be prepared in a pure state only relatively tediously by cyclization of *cis*-4-(3-cyanocyclopentyl)butyronitrile[5-7] or 5-(tosyloxymethyl)cyclooctanone[10].

Bicyclo[3.2.1]oct-2-en-3-yl acetate *(8)*, b.p. 84 °C/10 torr, accessible in 93% yield from bicyclo[3.2.1]octan-3-one and isopropenyl acetate, affords bicyclo[4.2.1]nonan-3-one *(10)* (62% yield; m.p. 117—118 °C) analogously by reductive fragmentation by way of 3,3-dichloro-*exo*-tricyclo[4.2.1.0^{2,4}]non-3-yl acetate *(9)* (58% yield) with subsequent hydrogenation and oxidation.

(8) *(9)* *(10)*

The IR spectra of *(7)* and *(10)* are identical with those of authentic samples[2, 5, 11].

4-(Difluorooxophosphoranyl)-1λ⁴,3,5,2,4,6-trithiatriazine

By *Herbert W. Roesky* and *Ludwig F. Grimm*[*]

Reaction of *N,N'*-bis(trimethylsilyl)sulfur diimide[1] with the anhydride of difluorophosphoric acid occurs exothermally with cleavage of trimethylsilyl difluorophosphate. Sublimation of the residue under vacuum (oil pump) affords a yellow compound, m.p. 68 °C, which according to elemental analysis and IR, ^{31}P-NMR, ^{19}F-NMR and mass spectra, probably has the cyclic structure *(1)*. Investigation of the reaction mechanism is in progress.

(1)

The mass spectrum shows, alongside the molecular ion at *m/e* 223, fragment ions at *m/e* 177 ($OPF_2N_2S_2$), 131 (OPF_2NS), 92(N_2S_2), 85 (OPF_2), 78 (NS_2), 69 (PF_2), 66 (OPF), 64 (S_2), 50 (PF), 47 (OP), 46 (NS), and 32 (S). The mass spectrum of tetrasulfur tetranitride, S_4N_4, shows similar fragments; thus, *e.g.*, the fragmentation of S_4N_4 also involves initial cleavage of an SN unit from the ring.

IR spectrum (NaCl and KBr region): 1325 (s), 1303-1265 (s), 1153 (vs), 1015 (w), 985 (w), 960 (w), 917 (vs), 890 (vs), 735 (vs), 718 (s), 700 (m), 645 (m), 580 (m), 536 (vs), 450 (s), 447 (m), 425 (vs) cm^{-1}. The absorptions between 1325 and 960 cm^{-1} are tentatively assigned to the (P=O), (S=N), and (S—N) vibrations and those at 917 and 890 cm^{-1} to the asymmetric and symmetric (P—F) stretching vibrations.

The ^{19}F- and ^{31}P-NMR spectra show that the fluorine atoms are magnetically non-equivalent. A characteristic ABX spectrum, $J_{AB}/J_{BX} \approx 1$, is obtained. The ^{31}P-NMR spectrum contains two doublets of equal intensity, $\delta_P = 9.8$ ppm (against 85% H_3PO_4, external), $J_{P-F} = 1010$, $J_{P-F'} = 1016$ Hz; the most accurate value that has been measured is $J_{AB} + J_{BX} = 2026.3$ Hz. ^{19}F-NMR: $\delta_F = 8.85$, $\delta_{F'} = 13.9$ ppm (against CF_3COOH, external), $J_{F-F'} = 102$ Hz; measured in CH_2Cl_2.

Experimental:

$[F_2(O)P]_2O$ (0.25 mol) is added dropwise with stirring to $[(CH_3)_3SiN]_2S$ (0.125 mol), the temperature of the reaction mixture not being allowed to increase beyond 40 °C. After addition of $[F_2(O)P]_2O$ is complete, components of the reaction mixture which are volatile under oil-pump vacuum are sucked from a sublimation apparatus into a condensation trap. Sublimation of the residue remaining in the apparatus at 30—40 °C/0.01 torr affords 7g of crude product (74%), from which pure *(1)* can be obtained in 57% yield (6 g) on resublimation.

1,3,3,5,5-Pentachloro-1λ⁴,2,4,6,3λ⁵,5λ⁵-thiatriazadiphosphorine

By *Herbert W. Roesky*[*]

Although "trichlorocyclotrithiazene" (1,3,5-trichloro-1λ⁴,3λ⁴,5λ⁴,2,4,6-trithiatriazine, $S_3N_3Cl_3$)[1] and hexachlorocyclotriphosphazene" (2,2,4,4,6,6-hexachloro-1,3,5,2λ⁵,-4λ⁵,6λ⁵-triazatriphosphorine, $P_3N_3Cl_6$)[2] were known before the turn of the century, no reports have appeared in the literature regarding a "mixed derivative" of these two compounds. It has now been shown that $S(N{=}S{=}O)_2$, prepared from thionyl chloride and ammonia[3], reacts with PCl_5 to give "cyclothiaphosphazene" (1,3,3,5,5-pentachloro-1λ⁴,2,4,6,3λ⁵,5λ⁵-thiatriazadiphosphorine) *(1)*.

(1)

Small amounts of $P_3N_3Cl_6$ and $O{=}PCl_2{-}N{=}PCl_3$ are also formed in the reaction. *(1)* can be isolated from the reaction mixture by distillation at reduced pressure.

The phosphorus atoms in *(1)* are magnetically equivalent; the ^{31}P-NMR spectrum shows a singlet at −24.5 ppm (in 40% CH_2Cl_2, external standard 85% H_3PO_4). By way of comparison, chemical shifts of about −20 ppm were found for $P_3N_3Cl_6$[4].

The structure of *(1)* follows from its mass spectrum, which, alongside the molecular ion at *m/e* 311, shows the following, in part characteristic fragments: 276 (M − Cl), 241 (M − Cl_2), 216 (PCl_2NPCl_2), 206 (M − Cl_3), 181 (Cl_2PNPCl), 160 ($P_2N_2Cl_2$), 146 (ClPNPCl), 111 (ClP_2N), 101 (PCl_2), 91 (PN_2S), 90 (P_2N_2), 80 (NPCl), 77 (PNS), 76 (P_2N), 66 (PCl), 46 (NS), 45 (PN). The isotopic ratio is not given here; the peaks with the highest relative intensity correspond to (M − Cl), (NS), and (PCl_2).

At room temperature *(1)* is a colorless, readily hydrolyzable liquid, b.p. 68—70 °C/0.01 torr (decomp.) whose composition could be confirmed by complete elemental analysis.

The IR spectrum (capillary film between KBr plates) contains broad absorption bands in the region of the N=P- and S=N-ring vibrations. Strong bands also appear in the

[*] Prof. Dr. H. W. Roesky
Anorganisch-Chemisches Institut I der Universität
6 Frankfurt 1, Robert-Meyer-Strasse 7–9 (Germany)

region of the S—Cl and P—Cl stretching vibrations. Because of coupling and the small mass differences, an assignment of the vibrations is, as yet, impossible: 1330 (m), 1255 (w), 1205 (vs), 1110 (vs), 1065 (w), 1015 (s), 980 (vs), 855 (s), 785 (w), 730 (s), 660 (s), 600 (vs), 525 (vs), 460 (s), 432 (s) cm^{-1}.

Experimental:

A mixture of $S(NSO)_2$ (19 g) and PCl_5 (46.7 g) in carbon tetrachloride (100 ml) is heated at 35—38 °C for 2—3 h, stirred for 12 h at room temperature, and filtered. Finally, the solvent and the volatile products are removed by evaporation under vacuum (oil pump) and the residue is purified by distillation at a bath temperature of 45—47 °C. Yield of *(1)*: 4.1 g. About four days are required for the distillation; the reaction product soon becomes viscous if a higher temperature is used for the separation.

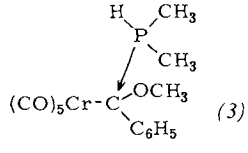
Dimethylphosphane(phenylmethoxy)methylene-pentacarbonylchromium(0) – A Route from Carbene- to Ylide Complexes[1]

By *Fritz R. Kreissl, Cornelius G. Kreiter*, and *Ernst Otto Fischer*[*]

Alkoxycarbenepentacarbonylchromium(0) complexes react with ammonia, primary and secondary amines, and with thiols or selenols with cleavage of alcohol to give the corresponding amino-[2], thio-[3], and seleno-carbene complexes[4]. Tertiary phosphanes, on the other hand, readily substitute a carbonyl or the carbene ligand of the above mentioned complexes at elevated temperatures[5].

By way of contrast, dimethylphosphane *(1)* merely adds to phenylmethoxycarbenepentacarbonylchromium(0) *(2)* in pentane at −50 °C without cleavage of either methanol or a ligand.



$$\underset{(1)}{HP(CH_3)_2} + \underset{(2)}{(CO)_5Cr{-}C(OCH_3)C_6H_5} \xrightarrow[-50\,^\circ C]{\text{pentane}} \underset{(3)}{CrC_{15}H_{15}O_6P}$$

The addition product *(3)* precipitates as a pale yellow, diamagnetic complex. Analytical data and the mass spectrum prove that *(3)* has the empirical formula $CrC_{15}H_{15}O_6P$. The mass spectrum contains, in addition to the molecular ion at $m/e = 374$, the expected fragmentation pattern for the $(CO)_5Cr$ residue, $[Cr(CO)_nC_{10}H_{15}OP]^+$ with $n = 4.3$, ..., and the peaks of the starting components *(1)* and *(2)* at $m/e = 62$ and 312.

The structure of *(3)* follows from the ^{1}H-NMR spectrum in [D$_6$]-acetone at −10 °C; a total of four signals occur at $\tau = 2.68$ (M, 5), 6.57 (S, 3), 7.55 (M, 3), and 8.12 (M, 3)[6]. The first two signals are assigned to a phenyl group and a methoxy group, the latter two to *P*-methyl groups. A *P*-H signal was not observed[7]; the presence of the *P*-H atom, however, is revealed by the splitting of the *P*-methyl signals.

The fact that two separate signals occur for the two *P*-methyl groups characterizes them as being magnetically non-equivalent. Their signals are split by coupling both with the P atom and as well as with the *P*-H atom. Hence, four peaks are to be expected for each *P*-methyl group. In the spectrum, there now appear double triplets and not the expected double doublets. The additional peaks are attributed to a slow H/D exchange of the *P*-H atom with the solvent; their intensity increases rapidly on addition of only a small amount of [D$_4$]-methanol to the sample. Compared to the original signal peaks they are noticeably broadened by coupling with the *P*-D atom.

The absolute values of the coupling constants of the two *P*-methyl signals at $\tau = 7.55$ and 8.12, $^3J_{HPCH}$ and $^2J_{PCH}$ differ very little from each other, being 5.0 and 13.7 and 5.5 and 12.2. Hz. The values are indicative of a quadrivalent phosphorus atom[8]. The signs of the coupling constants were not determined.

(3)

The ^{1}H-NMR spectrum of *(3)* is consistent with a bonding of *(1)* to *(2)*, provided one assumes that the lone pair on the phosphorus interacts with the "vacant" p orbital of the strongly positive carbene carbon[9]. The nonequivalence of the *P*-methyl groups is caused by the asymmetric carbon atom[10]. Highly informative is the position of the OCH_3 signal, which, compared to that of *(2)* (*cis*: $\tau = 5.76$, *trans*: $\tau = 4.93$)[11] is shifted to very much higher field strength and thus lies in the region of normal OCH_3 signals.

Addition of *(1)* to *(2)* obviously leads to formation of a phosphorus ylide complex from a carbene complex, namely to formation of dimethylphosphane(phenylmethoxy)methylenepentacarbonylchromium(0) *(3)*. Directly synthesized

transition metal complexes of other phosphorus ylides have already been reported[12]; however, *(3)* is of additional significance as a model compound for the primary step of the aminolysis of alkoxycarbene complexes[13].

Experimental:

All reactions must be carried out in an inert atmosphere (N_2) and in N_2-saturated, anhydrous solvents. A solution of dimethylphosphane (1.0 g, 16 mmol) in pentane (10 ml) is slowly added dropwise at −60 °C to a solution of phenylmethoxycarbenepentacarbonylchromium(0) (0.73 g, 2.4 mmol) in a 100 ml flask fitted with dropping funnel, magnetic stirrer, and tube for nitrogen supply. The mixture rapidly changes color from red to yellow and a precipitate is formed. The contents of the flask are stirred for 2 h at −50 °C and then filtered at this temperature through a G3 frit. The yellow residue is washed five times with 10 ml portions of pentane (−50 °C) and finally dried for 10 h at −30 °C under vacuum. Yield *ca.* 0.75 g [84% based on *(2)*].

Demonstration of Isomers and Intramolecular Isomerization of Carbene Complexes of Chromium[1]

By *Ernst Otto Fischer, Helmut Fischer,* and *Helmut Werner*[*]

Reaction of pentacarbonyl(methoxyorganylcarbene)chromium(0) complexes $Cr(CO)_5C(OCH_3)R'$ *(1)* with $P(C_6H_5)_3$ occurs with replacement of one CO group and formation of *cis*-$Cr(CO)_4P(C_6H_5)_3C(OCH_3)R'$[2].

We have now found[3] that by interaction of trialkylphosphanes with *(1)*, $R' = CH_3$, in solvents such as hexane, benzene and tetrahydrofuran at *ca.* 60 °C one obtains mixtures of *cis*- and *trans*-$Cr(CO)_4PR_3C(OCH_3)CH_3$ [*(2)* and *(3)*, respectively].

(1) *(2)* *(3)*

(a), R = C_2H_5 *(d)*, R = C_6H_{11}
(b), R = i-C_3H_7 *(e)*, R = n-C_8H_{17}
(c), R = n-C_4H_9

The pairs of isomers *(2)* and *(3)* can be separated by column chromatography on silica gel. They form orange-red, diamagnetic crystals that are insoluble in water but very readily soluble in organic solvents and are only slightly sensitive to oxidizing agents.

Two isomers are also obtained if trialkylarsanes or trialkylstibanes are used instead of trialkylphosphanes[4].

When *(2)* or *(3)* are heated in hexane, benzene, toluene or methylcyclohexane at *ca.* 60 °C isomerization occurs and proceeds to establishment of an equilibrium:

$$(2) \underset{k_2}{\overset{k_1}{\rightleftharpoons}} (3)$$

Methylcyclohexane	*(2a)*→*(3a)*	21.2 ± 0.5	−6.5 ± 1.5
Methylcyclohexane	*(3a)*→*(2a)*	22.5 ± 0.5	−3.5 ± 1.5
Toluene	*(2a)*→*(3a)*	24.3 ± 0.5	+2.8 ± 1.5
Toluene	*(3a)*→*(2a)*	22.2 ± 0.5	−2.5 ± 1.5

According to these findings the following mechanisms must be considered for the isomerization:

(a) Dissociation of a Cr—CO bond and readdition of the CO ligand.

(b) Dissociation of the Cr—PR_3 bond and readdition of the PR_3 ligand.

(c) Dissociation of the Cr—$C(OCH_3)CH_3$ bond and readdition of the carbene ligand.

(d) Intramolecular rearrangement without bond fission.

Isomerization by (a) or (b) should be slowed down by addition of free CO or free PR_3, respectively. As Table 1 shows, this is apparently not the case. If the isomerization of *(2a)* is followed by ^{1}H-NMR spectroscopy in $[D_8]$-toluene in presence of a five-fold molar excess of $P(C_6H_{11})_3$, it is found that the intensity of the CH_3 and OCH_3 signals of *(2a)* decrease and those of *(3a)* increase to almost identical extents. Signals that would indicate formation of *(2d)* or *(3d)* are not detectable[5]. The small difference between the sums of the corresponding peaks of *(2a)* and *(3a)* increases slowly during the reaction, but this is to be ascribed to decomposition with formation of $Cr(CO)_4P(C_6H_{11})_3P(C_2H_5)_3$[6]. The rate of decomposition is, however, distinctly smaller than that of the isomerization. Thus not only mechanism (a) and (b) but very likely also mechanism (c) are excluded as possible routes for the isomerization, so that only the *intramolecular rearrangement* (hitherto observed only for octahedral *chelate* complexes) should occur. Whether the mechanisms previously discussed in the literature[7] prove right for this rearrangement cannot be decided on the basis of the present results; clarification is being sought in current investigations.

CONFERENCE REPORTS

Enzymic Synthesis of Homogeneous Stereoregular Polymers

By *Beate Pfannemüller*[*]

The lecture concerned the use of enzymes for specific synthesis of models of carbohydrate polymers.

Enzymic synthesis affords strictly stereoregular polymers. The molecular weight and the molecular weight distribution of native biopolymers are, however, determined by *in vivo* conditions; it is thus not possible to change these two parameters which are significant for the physical properties of the products.

As an example, it was shown for the *in vitro* synthesis of amylose by phosphorylase, that, provided certain conditions are maintained, enzymic synthesis may be directed towards production of monodisperse polymers with any desired degree of polymerization. When maltotetraose or higher maltooligomers are used as a primer the kinetics of phosphorolytic synthesis of amylose are comparable to those of anionic polymerization: in both cases the mechanism of initiation and propagation is the same; chain termination does not occur; the degree of polymerization is determined by the number of initiator molecules and the degree of conversion of monomer. Since the enzymic products exhibit a Poisson distribution it follows that the enzyme dissociates from the growing chain after each step (multi-chain reaction). When maltotriose is used as a primer a characteristically unsymmetrical molecular weight distribution is obtained since in this case the initiation step is rate-determining.

Since the enzyme is specific only for the sugar residues immediately adjacent to the initiation point phosphorolytic synthesis can also be used for preparation of branched polymers with a "comb" or "star" structure. The degree of branching can be controlled at will.

Some of the various applications of the substances were illustrated:

1. Study of the mode of action of exo-, endo-, and debranching enzymes.

2. Study of the influence of chain length on the conformation and solubility of amylose in water and on the properties of the amylose-iodine complexes (ORD and CD investigations).

3. Electron-microscopic study of the supermolecular structure of substances when complexed with iodine.

High-Pressure Properties and Their Dependence on Molecular Structure

By *Eduard Kuss*[*]

Density is the most important factor in the evaluation of measurements and the interpretation of other physical properties at high pressure, since the relative distance between the molecules and the intermolecular forces that depend thereon determine the properties of the material.

[*] Prof. Dr. E. Kuss
Institut für Erdölforschung
3 Hannover, Am kleinen Felde 30 (Germany)

In the equation of state for compressed *gases* the second virial coefficient B is found from the potential energy U as a function of r, the distance between the molecules. The higher virial coefficients C, D, E ... are given by the simultaneous interaction of 3,4,5 ... molecules. In considering more than two molecules the mathematical difficulties become so great that the sixth virial coefficient, for instance, cannot be calculated for $U(r)$ but only for hard spheres without attractive forces.

For compressed *liquids* an exact theoretical treatment meets with further difficulties and, as yet, is not possible since:

a) such high densities require a knowledge of the seventh and eighth virial coefficients;

b) the spatial partition of molecules is not random and the partition function must also be taken into account;

c) even in simple cases and for the lower virial coefficients only a potential with spherical symmetry can be used. At high densities, however, the geometrical form of the molecule plays an important role and it is therefore necessary to take into account a very complicated non-spherical potential.

To investigate this influence of molecular structure the pVT-data of homologous series and isomers were measured with a special high-pressure piezometer. The compressibility and also the constant B of *Tait's* equation of state depend markedly on the chain length of the molecule, but are relatively little influenced by the side-chain groups in the molecule[1].

In contrast to this the viscosity-pressure coefficient, as measured by high-pressure capillary and falling ball viscometers, depends largely on the number and the positions of side-chain groups in the molecule and only rarely on chain length[2]. To characterize the behavior a "degree of molecular branching" was defined, whose numerical value is a direct measure of the positions of side-chain groups. Substances could be synthesized whose viscosity was 6 powers of ten greater at 2000 at than at atmospheric pressure[3].

Finally the electric double refraction, which is very sensitive to small changes of molecular structure, was discussed. In a strong electric field not only polar but also apolar molecules are turned in the direction of field because of their anisotropy of polarizability. The double refraction caused thereby leads to a difference in the ninth decimal of the refractive indices for the two light components, polarized parallel and perpendicular to the direction of the field. The pressure dependence of the Kerr constant, together with the *Langevin-Born* orientation theory, permits conclusions concerning the hindrance to rotation of the apolar molecule and the anisotropy of the internal field due to the structure of liquids. Here benzene behaves highly anomalously[4].

REVIEW ABSTRACTS

The deformation of polyethylene is dealt with by *R. S. Stein*. Polyethylene is a typical semicrystalline polymer whose idealized form consists of perfect crystallites embedded in a rubbery phase. The mechanical properties of the polymer depend not only upon the crystallite content but also upon details of chain topology and morphology and defects of the crystallites. No complete theory of the deformation processes is yet available. The processes are dependent upon the rate of extension because realignment of the crystallites requires finite time. Changes during extension can be followed, *e.g.* by microscopy and by light-scattering and X-ray diffraction experiments. [Deformation Mechanisms of Polyethylene. Accounts Chem. Res. *5*, 121—127 (1972); 37 references]

[Rd 513 IE –L]

Metathetic reactions of olefins are reviewed by *N. Calderon*. Such reactions comprise catalytically-induced bond rearrangements as shown in the following scheme:

Experiments with 2-pentene and 6-dodecene led to the expected statistical distribution and prove that the rearrangements occur by transalkylidenation. The catalytic formation of macrocycles from olefins and catalytic *cis-trans* isomerizations are also metathetic reactions. [Olefin Metathesis. Accounts Chem. Res. *5*, 127—132 (1972); 41 references]

[Rd 514 IE –L]

Synthetic Peptides. Vol. 1. By *G. R. Pettit.* Van Nostrand Reinhold Co., New York–London 1971. 1st Edit., xii, 467 pp., numerous tables, £ 10.00.

One of the chief problems for workers in the field of synthetic chemistry is to find out as quickly as possible whether the substance in question has already been prepared, and if not, the way in which substances of similar structure can be obtained. This is particularly troublesome in the case of bio-oligomers, and therefore peptides. Specialized handbooks in which substances that have already been characterized are brought together are thus extremely useful.

The present book, which covers the period 1960—1969, links up with earlier reviews of similar nature (*e. g. Goodman* and *Kenner* 1957, *Greenstein* and *Winitz* 1961). The great upsurge in peptide synthesis has resulted in the fact that practically the entire volume consists of tables on amino-acid derivatives and di- to polypeptides. Physical constants (m. p., [α]) and synthetic routes are included. In some cases the tabulated data have been critically selected. For the derivatives this evaluation agrees with the experience of other peptide chemists, except that the *o*-nitrobenzenesulfenyl protective group may not have been ranked highly enough. Not all compounds of a given type are included in the tables, but random sampling in the reviewer's laboratory showed that only a few compounds have been overlooked.

The number of printing errors *etc.* is not outside the limits expected for a work as ambitious as these tables. The only thing that may bother the reader is the inconsistent use of abbreviations; in many cases these differ from the ones given in the introduction. Some compounds are not in the proper order (*e. g.* pp. 366, 425).

This book will be a useful aid to all chemists concerned with peptide synthesis.

Karel Bláha [NB 39 IE]

Regeln und Steuern. Eine Einführung für Chemiker und Ingenieure (Regulation and Control. An Introduction for Chemists and Engineers). By *A. Schöne.* Verlag Chemie GmbH, Weinheim/Bergstrasse. 1971, 1st Edit. viii, 207 pp., 136 figures, 8 tables, bound DM 33.—.

The high degree of automation of chemical production plants inevitably confronts chemists and engineers involved in process development and operation with problems of control engineering. The purpose of the present book is to provide this group of persons with an account of the fundamentals of control engineering and to explain the regulatory function of control circuits frequently encountered in practice. The author therefore places the main emphasis on the process, and in particular the dynamic behavior of processes, and has consciously renounced any attempt to present a complete account of the theory of control or measuring techniques which usually occupy a large part of monographs on control engineering. The many standard terms of control engineering are not presented *en bloc* in an introductory section, as is usually the case, but introduced almost in passing in the individual chapters, a feature which will certainly facilitate their assimilation. Fundamentals are explained with the aid of simple and illustrative examples presented as block circuit diagrams; the occasional analytical treatment of these examples contributes to an improved understanding without making too severe demands on the mathematical knowledge of the reader.

A brief introduction to the typical dynamic behavior of processes and the basic dynamic models derived therefrom is followed by four chapters on the mode of action of a regulator and the regulatory processes employed in practice, ranging from the simple control loop to the control of multi-loop systems with many variables. A short chapter is devoted to the functioning of analog computing modules and their practical use in switching operations.

The most important chapter, and also a particularly valuable aspect of the book, is doubtless the following one on dynamic behavior and control systems of process plant. Current knowledge of the dynamics of the most important groups of equipment in chemical production plant—heat exchangers, distillation columns, and reactors—is surveyed, and proven circuitry is demonstrated, and, insofar as is possible, critically discussed. The experienced control engineer will also find this chapter stimulating, due in part to the numerous literature references which will be a great help to further study.

In view of the present-day significance of fully automated control of batch processes in chemical process engineering, the next chapter on control could have been more detailed. The book closes with a chapter on process computers, in which a terse review of the mode of action and process periphery of computers precedes accounts of direct digital control (DDC) and process optimization.

The book is a highly successful, practically oriented introduction to control engineering that can be warmly recommended to production chemists and engineers, as well as to control experts.

Theo Ankel [NB 42 IE]

Essential Fiber Chemistry. By *M. E. Carter.* Marcel Dekker Inc., New York 1971. 1st Edit., vii, 216 pp., numerous figures, bound $ 19.50.

No such book has hitherto been available. Its appearance is most welcome, particularly in view of its numerous virtues, and will certainly satisfy a need of all those having an interest in fiber chemistry. The book presents a didactically exemplary introduction to the chemistry and physics of natural and synthetic fibrous materials. The description of fundamental principles of chemical and physical structure and their relation to the most important properties of fibers is completely devoid of such ballast as the various techniques available for working the fibers. Interesting indications of new developments and fiber modification, particularly with regard to dyeability, flame resistance, and temperature resistance, round off the survey of an interesting area of modern organic and macromolecular chemistry.

In spite of a certain degree of criticism with regard to unnecessarily extensive tables of patents, the preference for American literature, and the absence of any assessment of the technical and economical viability of certain processes, the book can be warmly recommended to textile chemists and all those who were unable to devote sufficient attention to this field as students.

Giselher Valk [NB 43 IE]

Mass Spectrometry of Heterocyclic Compounds. By *Q. N. Porter* and *J. Baldas*. John Wiley and Sons, London–New York 1971. 1st Edit., xvii, 564 pp., numerous figures, bound £ 11.75.

The importance that mass spectrometry has acquired in organic chemistry in recent years has led to such a spate of primary literature, distributed through a wide range of journals under a variety of titles, that an overall view of the field is becoming increasingly elusive. The related difficulty of becoming acquainted with even a restricted range of material or of merely keeping abreast of recent developments often has the result that the possibilities of mass spectrometric analysis are not fully exploited. Good secondary literature has therefore become a *conditio sine qua non*.

With this in mind the authors of the present work have turned their attention to an area of study that was in desperate need of a critical assessment and survey, *i.e.* mass spectrometry of heterocyclic compounds. The effect of the ring system on the general fragmentation behavior in various environments is discussed on the basis of ring size and the nature and the number of hetero atoms and illustrated by numerous examples of spectra. Although the subject matter is extremely heterogeneous, in spite of being limited to saturated and unsaturated N, O, and S heterocycles, the description of the individual structural types is both detailed and, particularly, not uncritical, thus obviating the need to refer back to the original literature in many cases. It would have been better, however, if the relative intensities of the fragments had been listed more consistently.

Generally speaking, the relevant literature has been covered in considerable detail (apart from papers in the Russian language) although examples from the field of natural products (particularly alkaloids) are included only when they are characteristic of the behavior of a particular fundamental skeleton in a specific environment. Unfortunately, and this remark concerns more the publisher than the authors, more than three years seem to have passed between completion of the manuscript (the literature is evaluated up to 1967) and appearance of the book, and research has by no means stood still during this time; the brief addenda at the end of each chapter, which provide a survey of the most important publications up to 1970, are rather inadequate.

Nevertheless, the present book is not only a great help to the mass spectroscopist as far as information content and a solid basis for further literature searches are concerned, but it also provides the organic chemist with an overall picture of where he can profitably apply mass spectrometry in the wide field of heterocyclic chemistry. It is to be hoped that supplementary volumes surveying the latest developments will appear at regular intervals.

Herbert Budzikiewicz [NB 44 IE]

Quantitative Management in R & D. By *C. J. Beattie* and *R. D. Reader*. Chapman and Hall Ltd., London 1971. 1st Edit., x, 347 pp., numerous figures, bound £ 5.00.

The use of quantitative methods to increase the profitability of research and development has been attracting increasing interest in recent years even though the objective value of such methods is still disputed. Although the knowledge hitherto collected has long been the subject of numerous seminars organized by consultant companies the publication of the present book is to be welcomed. The authors have presented the current situation in an extremely understandable and purposely simplified manner in order to assist the reader in familiarizing himself with the subject matter. Anybody who wishes to delve deeper into the methods described can refer to the highly informative appendix and to the exceptionally detailed bibliography at the end of each chapter.

The book opens with a brief introduction (5 pages) to the essential phases of a research project followed by a chapter on the generation of useful ideas (12 pages) which describes special methods such as "brainstorming" and also more conventional practices such as the cooperation between colleagues from different disciplines.

There follows a chapter on the planning of research projects (30 pages) which is concerned with the preparation required for the evaluation of a project. The most important diagrammatic planning techniques are briefly considered. The chapter on project evaluation itself (38 pages) discusses in how far the intuitive assessment of suggestions can be supported by analyses of the expected costs on the one hand and the expected economic advantage on the other.

This kind of numerical assessment is a prerequisite for choice of research projects as considered in the next chapter (48 pages). The methods described range from simple classification on the basis of a more or less suitable parameter to relatively complicated processes requiring access to a computer.

Further chapters essentially provide practical instructions for the application of such systems of choice (together 40 pages) and for the execution and control of research projects (13 pages). Particular emphasis is placed on the writing of suitable reports on the results of studies (34 pages).

The appendix contains detailed information about methods of technological forecasting (20 pages), diagrammed planning techniques (55 pages), discounted cash flow calculations (9 pages), and uncertainty analyses (21 pages). An index makes for easy reference to the book.

Peter Haug [NB 45 IE]

The Avenue of Years—A Memoir of Sir James Irvine. By *Mabel V. Irvine*. William Blackwood, Edinburgh and London 1970. 1st Edit., iv, 268 pp., 9 figures, bound £ 1.80.

Sir James Colquhoun Irvine (1877—1952) was Professor of Chemistry at St. Andrews, Scotland, from 1909 to 1920, and was then Principal and Vice Chancellor of this university from 1921 to 1952. He is one of the leading figures of Scottish university history and was well known far beyond the boundaries of his country. As a chemist he was active in the field of carbohydrate chemistry and among other achievements he introduced the methylation of hydroxyl groups as an aid in the structural elucidation of carbohydrates.

Irvine's wife, who survived her husband by 15 years, authored the present biography which remained uncompleted and does not extend beyond 1944. The book is not an historical work, and makes no pretence to be one, but rather a very personal series of recollections. The authoress describes family life, social obligations, the atmosphere of the small Scottish university town steeped in tradition, *Irvine*'s administrative activities, and his numerous journeys abroad in his capacity as Principal.

Unfortunately the reader learns next to nothing about *Irvine*'s research as a carbohydrate chemist, which was

held in such high esteem by *Emil Fischer* that he suggested an agreement regarding research programs. The missing information can be obtained from an obituary by *John Read* in J. Chem. Soc. *1954*, 476. However, it is even difficult to gain a true picture of *Irvine*'s personality since the authoress tends to idealize her husband in a rather uncritical manner, which disqualifies the book as source material for future historical studies.

The book cannot therefore really be recommended to the chemist who is interested in the history of his subject unless he would enjoy reading a biographical report described by the authoress as "an old-fashioned chronicle of an era that is past."

Jost Weyer [NB 46 IE]

Solid Acids and Bases. By *K. Tanabe*. Academic Press, New York–London 1970. 1st Edit., viii, 175 pp., numerous tables and figures, bound $ 11.50.

The author of the present work is not content to "put new wine in old vessels" since the topicality of his subject can readily be assessed even from a glance at the bibliography which contains mainly references from the last ten years (up to 1970). Why is it that acid-base catalysis, well known for a long time in the homogeneous phase, should again arouse such great interest?

The main reason lies in the discovery of numerous refined methods (color indicators, spectroscopic measurements, adsorption from the gas phase or from solution, titrations with substances showing acidic or basic reactions, *etc.*) for determination of acidity and basicity (Hammett function) and the concentration of functional groups on solid surfaces. Two chapters are concerned with these methods and the important question of distinguishing between Brønsted and Lewis acids is also discussed.

In two other chapters the author undertakes a characterization and systematic treatment of solids. At the beginning of his book he divides a large number of solids into solid acids and bases and uses the largest chapter (chapter 4) for a treatment of the structure and the acid and basic properties of the sites present on the surfaces of solids (metal oxides and sulfides, mixtures of metal oxides, zeolites, metal sulfates and phosphates). The connection between catalytic activity and selectivity and the nature of the surface is shown for reactions of widely differing kinds (decomposition reactions, cracking, isomerization, polymerization, *etc.*) on catalysts having acidic, basic, or bifunctional character.

Both the scarcity of literature on this scientifically and industrially important subject and the presentation of the book with its clear tables and illustrations make the work a valuable aid for all who are concerned with heterogeneous catalysis or wish to enter the field.

Willi Herzog [NB 47 IE]

Allgemeine Organische Chemie (General Organic Chemistry). By *K. Heyns*. Akademische Verlagsgesellschaft, Frankfurt 1970. 1st Edit., x, 348 pp., bound DM 19.60.

The series of study texts including the present work presents lecture manuscripts of proven value in somewhat modified form. An experimental presentation which relies heavily on the illustrative power of the experiments themselves can only be incompletely replaced by a manuscript, however good it is. The above text by *Heyns* has been thoroughly prepared and betrays many years of lecturing experience. Its information content and size approach those of a textbook. The many references to experiments in the text are no doubt intended as suggestions for experiments during a practical course rather than as a replacement for experimental demonstration.

The present study text is intended for students of chemistry, medicine, pharmacy, and biology from the second semester onwards. The amount of material included is probably rather overpowering for biologists and medical students. For such an audience it would certainly have been better to emphasize the more important points by use of different types. For students of pharmacy and chemistry, on the other hand, this text is highly recommended as supplementary material to lectures and as an aid in preparation for examinations.

Harald Suhr [NB 48 IE]

Chemical Analysis in Extractive Metallurgy. By *R. Young*. Charles Griffin and Co., London 1971. 1st Edit., vii, 427 pp., bound £ 7.—.

The book deals primarily with the analysis of 42 technically significant elements, primarily metals, and is intended mainly as a list of procedures for analysts working in the field of nonferrous metals. According to the concept of the author it should be "less comprehensive and more selective than the excellent multi-volume treatises on analytical chemistry, be more attuned to the routine industrial tempo than is desirable in a university textbook, and to contain more discussion of theory and interferences than is found in the valuable analytical manuals of companies and trade associations."

The individual chapters usually open with rather general statements about separation procedures, which are followed by more or less detailed instructions for gravimetric, titrimetric, and, in some cases, also photometric methods. Instrumental methods dominating the present industrial scene are dismissed with brief comments that frequently are devoid of real information content.

Overall the book fails to fulfil the stated aim of the author. Only a few analytical procedures are described so precisely that successful repitition is assured; essential details are frequently missing. Trivial and elementary analytical information also occupy considerable space. A general preference for time-consuming gravimetric methods grossly contradicts the author's intention to consider mainly fast methods.

The book which contains 1200 references, exclusively to English-language literature, can therefore only be regarded as a relatively comprehensive survey but not as a really useful tool for the analyst working in this field.

Günther Kraft [NB 50 IE]

Practical Catalytic Hydrogenation. Techniques and Applications. By *M. Freifelder*. John Wiley and Sons Ltd., New York 1971. 1st Edit., xxii, 663 pp., numerous figures, bound £ 11.75.

Catalytic hydrogenation can certainly be regarded as a particularly effective and reliable method throughout the whole field of organic chemistry whose successful application to particular problems nevertheless requires adherence

to specific conditions and catalysts recorded in a large body of rather widely distributed empirical data.

The present book has been born out of the personal participation of the author in over 7500 catalytic reduction reactions and provides a wealth of suggestions for use in practice when a suitable method has to be sought and executed for a particular case.

The index covers barely three pages and provides but little information about individually treated compounds. More ready access to the subject matter is afforded by a detailed list of contents (14 pages) where the various sections and classes of compounds are easily found along with the representative examples treated in the text. The initial sections are concerned with the catalysts and the general reaction conditions and are followed by broadly subdivided sections on functional groups and finally by reductive amination, alkylations, debenzylation, dehalogenation, hydrogenolysis of compounds containing O and N, *etc.* A section on gas phase hydrogenation would have been welcome.

Directly applicable working prescriptions are not given so recourse to the original publications is necessary. More than 2000 literature references are given (unfortunately not in alphabetical order) at the end of each of the 35 chapters. It is therefore almost impossible to follow the work of a particular author, especially since there is no author index at the end of the book.

The work draws on a rich mine of experience and offers much well-founded and valuable information to all concerned with catalytic hydrogenation and the reduction of organic compounds.

Kurt Heyns [NB 49 IE]

Flavor Research Principles and Techniques. By *R. Teranishi, I. Hornstein, P. Issenberg*, and *E. Wick*. Marcel Dekker Inc., New York 1971. 1st Edit., ix, 315 pp., numerous figures, bound $ 19.50.

Flavor research with physical and chemical methods is a young branch of science caught up in rapid development about which there is little in the way of comprehensive surveys. The authors' attempt to provide such a survey in the present book can be described as very successful.

Complete descriptions of all principles and techniques are not given. Instead the authors have been able to present all the essentials in a terse, precise manner and to illustrate them with the aid of individual well-chosen examples. They restrict themselves largely to volatile flavors. The greatest space is devoted to analytical techniques (221 pages): isolation of flavor concentrates, separation by gas chromatography, identification by NMR, IR, and Raman spectroscopy, and above all by mass spectrometry which, as the method of choice, is deservedly treated particularly thoroughly, especially in combination with gas chromatography. These methodological chapters are set off against general considerations of odor and taste perception, the connections between odor and chemical constitution, and those between sensory and instrumental analysis. Perhaps the purely sensory method could have been described in a little more detail.

The book is of a relatively high standard. The problems and the pros and cons of the various methods are discussed very critically. The literature coverage is by no means complete but all important publications, especially the more recent ones up to 1969, seem to be included. The monograph is warmly recommended to all interested persons, particularly to those wishing to gain an overall picture.

H. G. Maier [NB 52 IE]

Einführung in die Immunchemie und Immunologie (Introduction to Immunochemistry and Immunology). By *E. A. Kabat*. Translated by *K. Jann* and *E. Rüde*. Heidelberger Taschenbücher Vol. 79. Springer-Verlag, Berlin–Heidelberg–New York 1971. 1st Edit., 322 pp., paperback, DM 18.80.

The present book is more than just an introduction to immunochemistry and immunology. In accord with the English title "Structural Concepts in Immunology and Immunochemistry" it attempts not only to describe immunological phenomena but also to interpret them on a molecular level. Since fundamentals are also described the work can be regarded as a successful synthesis of classical and modern immunology.

An introduction to serological specificity is followed by a detailed chapter on antigens which places particular emphasis on the characterization of antigenic determinants. The resulting possibility of elucidating the structure of antigens with the aid of antibodies is illustrated by practical examples. Quantitative and qualitative serological methods of detection are also considered in this context. On the other hand, a complete chapter is devoted to the characterization of the site of antibody binding by antigens. Considerable attention is also paid to the heterogeneity of antibodies and the resulting purification problems. The account of studies on the primary structure of antibodies is afforded much space with regard to both the binding site and the mechanism of antibody formation. There follow concluding chapters on complements, allergy, and immunotolerance.

Summing up, this book is written in a very understandable and clear manner and can be heartily recommended to anyone interested in immunology.

Norbert Hilschmann [NB 53 IE]

Spektroskopische Methoden in der organischen Chemie (Spectroscopic Methods in Organic Chemistry). By *D. Williams* and *J. Flemming*. Translated by *B. Zeeh*. Georg Thieme Verlag, Stuttgart 1971. 2nd Edit., ix, 346 pp.,145 figures, 42 tables, bound DM 12.80.

The book is divided into six chapters: A short summary of the physical methods currently in use for structural elucidation of chemical compounds is followed by accounts of the four established spectroscopic methods ultraviolet, infrared, nuclear magnetic resonance, and mass spectroscopy, in that order. A final chapter is devoted to examples designed to give practice in the combination of the methods discussed.

The present 2nd German edition differs from the 1st edition in the following points only: The section on NMR now contains a survey of recently developed special techniques; the chapter on mass spectrometry has been rearranged or slightly expanded in a number of places; and the number of exercises has been increased from 15 to 71.

Without delving too deeply into the physical fundamentals the book provides a simple and lucid description of those

physical phenomena which can be utilized in analytical chemistry. The relationship between measured physical values and structural units is demonstrated with the aid of selected examples and in tabular form. This limitation to the purely analytical aspects makes the book an ideal introduction to these techniques for chemistry students. Owing to the good selection of examples and tables the work will also prove useful to the preparative chemist who wishes to use the methods described for product characterization.

J. B. Pawliczek [NB 55 IE]

Struktur und Funktion der Proteine (Structure and Function of Proteins). By *R. Dickerson* and *I. Geis*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. 1st ed., vii, 120 pp., 134 figures, 10 tables, bound DM 32.—.

The text of this book by *R. Dickerson* presents the quintessence of the enormous growth that has become possible in science over the past 14 years through the X-ray analysis of the structures of proteins. The book begins with a description of simple bonding, and the approach of the crystallographer who can "see" many of these things in his X-ray structure analysis, is immediately evident in the interpretaion here. *Via* the description of fibrous structural proteins, in which even weighty subject matter is incorporated with playful ease into a readable and fascinating account, the book passes to the crowning achievements of X-ray structure analysis, *i. e.* the description of the enzymes whose tertiary and quaternary structures are now known, and of their mode of action. It ends with a chapter on more complicated interactions of proteins, on antibodies and the complement system.

Electron micrographs of current interest in this field are reproduced in this part in a very striking and understandable manner.

The book can be recommended for students, but there is no doubt that specialists in the field of protein chemistry will also be able to learn from it. The description of the interaction of many proteins in the serum complement system is itself a masterpiece of a feuilletonistically interesting and at the same time extremely accurate account of a very complicated situation.

The second author is *I. Geis*, and it is clearly only through the cooperation of these two specialists that the excellent presentation by which this book is characterized has been possible. The hand of this master artist of molecular biology, whose unmistakable brilliance must now be known to every biologist and biochemist, can be discerned on every page of the book, in cleverly selected drawings, in structural formulas that give a clear picture of spatial relationships, in skillfully shaded diagrams, and in careful but extremely striking arrangements of drawings and photographs.

Hugo Fasold [NB 58 IE]

Physikalische Chemie in Experimenten – Ein Praktikum (Physical Chemistry in Experiments—A Practical Handbook). By *H.-D. Försterling* and *H. Kuhn*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. 1st ed., ix, 505 pp., 348 figures, 23 tables, bound DM 38.80.

Owing to the rapid development of instrument techniques, which is having a particularly pronounced effect on physico-chemical investigation methods, the older German-language standard works on physico-chemical practical work are now quite out of date. The appearance of a book that takes into account the use of modern instruments is therefore very welcome.

The book is divided into the following sections: the working principles (with a short description of the most important instruments and an introduction to the evaluation of experiments), the main part, which contains about 80 experiments, and an appendix on physical quantities and units as well as some special experimental techniques. A list of references and an index complete the book.

In reading the book, one finds a number of well-known experiments, but these are largely carried out with modern instruments. However, there are also many extremely instructive new experiments, particularly from the fields of spectroscopy, photochemistry, and quantum chemistry. The related fields of macromolecular chemistry and biochemistry are also represented by a number of very fascinating experiments. In this connection, as one of many, mention should be made of a model experiment on the evolution of self-organizing systems, which is to be carried out with a digital computer, and which is very impressive in its didactic conception. Provision is also made in some experiments for the use of analog computers, which the student can construct for himself with the aid of detailed instructions.

Many passages in the theoretical explanations that accompany the experiments show that the authors place particular value on an intuitive presentation. As can be seen from the preface, this effort has led to the avoidance of the use of the chemical potential in thermodynamic calculations. However, the reviewer is doubtful whether the use of cyclic processes promotes intuitiveness.

The layout and printing are good. However, it is to be feared that the binding will be unable to withstand for long the treatment received by practical handbooks. The inevitable printing errors of a first edition are not excessive in number.

The reviewer, whose long experience has made him well aware of the special problems of a practical handbook of physical chemistry, can wholeheartedly recommend this book to students, assistants, and laboratory supervisors. The book should be particularly valuable in re-equipping a physico-chemical laboratory.

W. Eichenauer [NB 59 IE]

Dictionary of Science and Technology—German–English. By *A. F. Dorian*. Elsevier, Amsterdam 1971. 1st Edit., viii, 879 pp., bound Dfl. 95.00.

Since the beginning of the 1950's there has been a succession of specialist dictionaries for various subjects and languages. This situation reflects not only the demand that exists but also the frequent inadequacy of the existing dictionaries. The specialist generally has no need of a dictionary in his own narrow field since he will be keeping abreast of latest developments in foreign journals and can assimilate new terms as they occur without any special effort. Difficulties arise in neighboring fields. In place of a collection of small dictionaries for each individual subject, *Dorian* now offers the whole vocabulary of science and technology in one volume extending into the boundary fields of economics and law insofar as they are of interest to the scientist and technologist.

As the author states in the preface it is no simple task to cover all these topics with the same degree of thoroughness.

He has nevertheless succeeded well in doing so. Although it would be illusory to expect absolute completeness, cases in which one has to approach an expert are rare.

The German–English volume is now available. It will clearly be of most use to English-speaking scientists in evaluating German specialist literature. Anyone whose mother tongue is German will need this volume less, except when he requires an English term to refer to an English-language encyclopedia or when attempting to write an English summary. A difficulty encountered in such cases should be mentioned. For instance, the word "Kristallebene" is rendered as "crystal face, crystal plane" and the word "Kristallfläche" likewise as "crystal face, crystal plane". A crystallographer naturally knows which expression to use: but he does not have to look it up anyway. It would be more helpful to the nonspecialist for whom the dictionary is intended if the less common terms were to be given in parentheses.

However, we can well be grateful for what is probably one of the best dictionaries of its kind available. It is hoped that the present volume will prove as useful as the previously published English–German volume[*].

The Organic Compounds of Germanium. By *M. Lesbre, P. Mazerolles* and *J. Satge*. From the series "The Chemistry of Organometallic Compounds". John Wiley and Sons, London–New York 1971. 1st Edit., xii, 701 pp., bound £ 16.00.

The present book continues the series of monographs on organometallic compounds which has so far dealt with the metallocenes of the iron group and the organometallic compounds of lead and tin. It is not the first comprehensive work on this branch of organometallic chemistry, which only attracted sporadic interest for many a year; a similar book by *Mironov* and *Gar* was published in Russian in 1967 and a monograph by *Glockling* appeared in 1969. Nevertheless, its publication just a few years after the above two books is most welcome since it represents the first monograph to give a really complete account of all the work so far performed in the field of organogermanium chemistry. A total of 2127 literature references, including patents, covers all the relevant literature up to 1968.

The book is clearly arranged and deals with the synthesis, properties, and reactions of all organogermanium compounds. A chapter on general aspects of organogermanium chemistry is followed by accounts of compounds with germanium-carbon bonds, cyclic organogermanium compounds, derivatives with bonds between germanium and hydrogen, halogen, oxygen, sulfur, selenium, tellurium, nitrogen, and phosphorus, as well as polygermanes and compounds having germanium-metal bonds.

Each one of these chapters contains tables of the compounds so far found in these classes with structural formulas, molecular formulas, and the most important physical constants. These tables appear absolutely complete to the reviewer. Modern physical and spectroscopic aspects, as well as mechanistic ones, have been included and are critically discussed by the authors who have all been active in this field for some time. Particular mention should be made of the fact that the authors have repeatedly compared the properties and the reactions of the organogermanium compounds with those of analogous silicon and tin derivatives and have thus been able to demonstrate with the aid of numerous examples the often astonishing independence of germanium chemistry. A bibliography is appended to each subsection, thus enhancing the overall clarity of the work and facilitating rapid reference to the original literature.

The book is a valuable reference work which surpasses and effectively replaces existing surveys and monographs on organogermanium chemistry. It provides the reader with a comprehensive overview of this branch of organometallic chemistry which has become more and more important in recent years. It only remains to hope that a work of this kind is frequently revised and brought up to date so that it does not lose its value as a reference book all too quickly.

Decomposition of Organometallic Complexes in the Mass Spectrometer

By Jörn Müller[*]

The reliable interpretation of mass spectra for the determination of molecular constitutions requires systematic studies on the fragmentation behavior of classes of compounds, since the large number of kinetic and energy parameters that determine the decomposition of excited polyatomic ions makes *ab-initio* predictions of spectra almost impossible. In this progress report, a number of general rules for the decomposition of organometallic complexes upon electron impact are discussed; a classification into decomposition types is also presented, and is illustrated by selected examples.

1. Introduction

Mass spectroscopy, together with NMR and IR spectroscopy, is nowadays one of the most important standard methods of investigation in the field of molecular chemistry[1]. Its application to problems of structure and bonding in the organometallic complexes of transition elements started with systematic investigations around 1964, and has so far embraced the following aspects[2]:

1. analysis, *i.e.* the accurate determination of relative masses of molecules (molecular weights) and chemical molecular formulas, determination of constitutions;

2. measurement of ionization energies and metal-ligand bond energies;

3. study of ion-molecule reactions.

In the most common analytical application of the mass spectrometer, the ionization of the vaporized substance is brought about by bombardment with 50—100 V electrons. The energies thus transferred to the molecules, which vary within wide limits, lead to numerous differently populated excited states of the resulting molecular ions, from which various decomposition processes can take place. The molecular weight of the compound in the gaseous state is found directly from the group of parent ion peaks recorded in the spectrum after mass separation. The precise molecular formula of the substance can also be found by accurate determination of the mass of the molecular ion by means of a double-focusing instrument. The transition metals mostly have characteristic isotope distribution patterns; from the appearance of a group of molecular ion or fragment ion peaks in the mass spectrum, it is then possible to deduce whether one or more of the atoms in question are present in a complex. The fragment ions resulting from the decomposition of the parent ion and the decomposition scheme constructed on the basis of the "metastable bands"[1] observed provide fundamental information about the constitution of a compound.

Numerous attempts have been made to devise a general theory of mass spectra that would allow the prediction of the nature and abundance of fragment ions of a molecule. The "statistical" or "quasiequilibrium the-

[*] Doz. Dr. J. Müller
Anorganisch-chemisches Laboratorium der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

ory"[3-6], which has been developed furthest, allows the calculation of the relative intensities of fragments of small molecules, but it is necessary to know the appearance potentials of these ions and to have relatively reliable estimates of the energies transferred in the ionization process and of the frequency factors of decomposition processes. The quantitative description of the decomposition of larger molecules fails because of the complexity of the problem. The mass spectroscopist therefore still has to derive empirical rules for the degradation of ionized and energetically excited molecules in the mass spectrometer. The mechanistic interpretation of decomposition reactions is complicated by the fact that ions in the spectrometer are primarily identifiable only by their masses; the elucidation of ionic structures, on the other hand, requires very complicated processes such as comparisons of the decomposition characteristics of ions, labeling with isotopes, measurement of appearance potentials, investigations of the shapes and intensity ratios of "metastable bands", and the study of ion-molecule reactions. The reader of mass spectroscopic literature should always bear in mind that most of the suggested ion structures are fictitious, and are merely based on plausibility considerations regarding the most stable form of an ion or the most suitable form for a decomposition process. Nevertheless, the heuristic value of such representations is undeniable, so long as speculation remains within acceptable limits.

On the basis of the now fairly extensive body of mass-spectroscopic data, an attempt is made in the following discussion to develop a general picture of the laws determining the fragmentation of organic complexes of transition metals and to present a series of characteristic decomposition reactions.

2. Experimental Problems

If the mass spectrum of a substance is to be recorded, the substance must be volatilizable, *i.e.* when heated in a high vacuum it must be capable of reaching a vapor pressure of about 10^{-6} to 10^{-4} torr without decomposing completely. Salt-like complexes or complexes that are thermally unstable and at the same time difficult to volatilize are at best identifiable from their pyrolysis products.

Thermal decomposition phenomena frequently complicate the mass-spectroscopic investigation of organometallic complexes[7] and not uncommonly lead to incorrect interpretations regarding the constitution or the purity of a compound. For example, ferrocene appears as a thermolysis product in the mass spectra of cyclopentadienylcarbonyliron derivatives[8,9], $(CO)_5MnCl$ similarly gives $Mn_2(CO)_{10}$[10], and many pentacarbonylchromium or tetracarbonyliron compounds decompose with formation of $Cr(CO)_6$ or $Fe(CO)_5$, to give only a few examples. The decomposition of the complexes is accelerated by the metal walls of the inlet systems and of the ion source; the fine metal deposits left behind by the compounds degraded in the instrument prove to have a particularly strong catalytic action[7,10]. These handicaps can be greatly mitigated by evaporation of the sample in the immediate vicinity of the ionization chamber of the ion source, which should be kept at the lowest possible temperature, and in the investigation of very volatile complexes by the use of glass inlet systems; however, they cannot be completely eliminated. The deposition of metal, which occurs in particular in the region of the hot cathode, may necessitate more frequent cleaning of the source.

The molecular weight determined from the mass spectrum, particularly in the case of polynuclear complexes, may differ from the molecular weight in the solid or dissolved state if the evaporation is accompanied by dissociation. This type of behavior is exhibited *e.g.* by dimeric cyclopentadienyltricarbonylchromium, which, as is shown *inter alia* by the mass spectrum, exists exclusively as the monomer in the gaseous state because of a weak Cr—Cr bond[11].

Cases that must be distinguished from the irreversible thermolyses or reversible dissociations that precede the ionization are those in which only fragment ions appear in the mass spectrum, while the molecular ion is absent. The decomposition here is initiated entirely by the vertical ionization, and requires no additional excitation. For example, the heaviest ion in the mass spectra of the following compounds is the fragment containing one CO group less than the molecular ion: $RSn[Co(CO)_4]_3$ ($R = CH{=}CH_2$, Cl, Br, I)[12], $(CO)_4FeL$ (L = maleic anhydride, dimethyl maleate)[13], $C_5H_5(CO)_2Fe{-}COC_6H_5$, and $C_5H_5(CO)_3Mo{-}CH_2CO_2C_2H_5$[9].

3. Ionization and Charge Localization

A qualitative approach that is very useful for the interpretation of the mass-spectroscopic decomposition of organic compounds is the primary excitation theory[14]. This is based on the idea that during the interaction of the bombarding electron and the molecule, certain centers of the latter, particularly π bonds, p electrons on hetero atoms, and bonds that are easily broken, are readily excited and hence preferentially emit an electron. The excitation processes start at the center of excitation and charge, and lead preferentially to the formation of the stablest possible ionic and neutral cleavage products.

This concept can be applied directly to the fragmentation of organometallic complex ions. The central metal can generally be regarded as the site of the highest positive charge density. Energy-level diagrams show that the highest occupied MOs (*e.g.* t_{2g} for $Cr(CO)_6$, e'' for $Fe(CO)_5$, a'_{1g} for $Cr(C_6H_6)_2$, or e_{2g} for $Fe(C_5H_5)_2$), from which an electron is primarily removed on ionization, are nonbonding or only weakly bonding or antibonding, and largely possess the character of metal d electrons, if such exist in the compound. This is confirmed experimentally by photoelectron spectra[15-18] and by the ionization energies found by mass spectroscopy for organometallic complexes. It can be seen from Table 1 that the ionization potentials (IP) of representative complexes are much

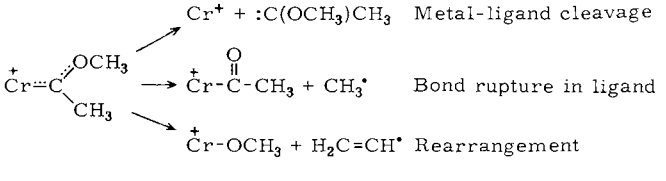
closer to the IP value of the free metal atom than to that of the free ligand.

Table 1. Ionization potentials [eV] of some organometallic complexes as found by electron bombardment.

Complex	IP	IP of the free metal atom	IP of the free ligand
$Cr(CO)_6$	8.20 [18]	6.76	14.01
$Cr(C_6H_6)_2$	5.91 [19]	6.76	9.25
$Cr(C_5H_5)_2$	6.26 [20]	6.76	8.69 [21]
$Fe(CO)_5$	8.14 [22]	7.87	14.01
$Fe(C_5H_5)_2$	7.15 [20]	7.87	8.69 [21]
$Ni(CO)_4$	8.64 [24]	7.63	14.01
$Ni(C_5H_5)_2$	7.16 [20]	7.63	8.69 [21]

Two important consequences arise from these considerations:

1. The decomposition of organometallic complexes is largely controlled by the central metal; the decomposition of complexed ligands follows mechanisms different from those of the fragmentation of the free organic molecules.



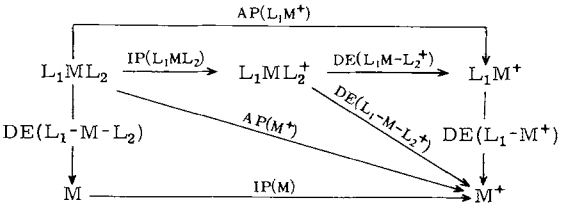
2. On decomposition of a complex ion, the positive charge usually remains on the fragment containing the metal.

Ions with multiple positive charges occur relatively often in the mass spectra of organometallic complexes. The tendency for this to happen increases considerably from complexes of the first transition period to those of the third, and thus corresponds to the general trend of metals in the stabilization of higher oxidation states. Moreover, ions carrying a double positive charge are found in a higher intensity for polynuclear than for mononuclear compounds. The fragmentation of ions with multiple positive charges has not been very extensively investigated, and will not be discussed here. It will merely be pointed out that differences in the decomposition characteristics have been found in some cases between singly and doubly charged ions.

4. Decomposition Reactions of Organometallic Ions

The decomposition processes of complex ions can be divided into three groups: the cleavage of metal-ligand bonds, simple cleavage of bonds within the complex ligands, and fragmentation reactions with rearrangement. Owing to the difficulties in the elucidation of the structures of ions, it is not generally possible to determine whether decomposition reactions of the first two types are accompanied by rearrangements.

In many cases, competition between all three principal degradation types is possible, starting from one and the same ion, as is shown by the following example[23]:



4.1. Cleavage of Metal-Ligand Bonds

This degradation type, which is both the simplest and the most common, is found both for parent ions and for fragment ions. There is a high probability of elimination of the ligand if the ligand molecules or radicals are themselves sufficiently stable to allow their removal as neutral particles, if they contain no easily degradable functional substituents, and if the metal-ligand bond is not too strong in relation to the bonds between the atoms of the ligand. Eliminations of ligands are characterized by their successive course, though exceptional cases of the simultaneous removal of two ligands have also been observed. The order of the degradation processes is determined by the relative metal-ligand bond strengths in the ions, which may well differ from those in the neutral compounds. The end product of fragmentations by this scheme, which are accompanied in most cases by the corresponding "metastable bands", is the free metal ion.

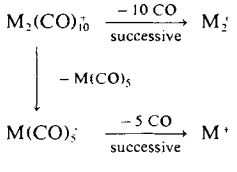
The simple decomposition route presented here allows a rapid identification purely on the basis of the mass spectrum in the case of complexes with simple ligands such as CO, NO, ethylene, acetylene, cyclopentadienyl, and benzene, and is therefore of great practical significance. Another consequence of the cleavage of the metal-ligand bonds is the possibility of obtaining information about metal-ligand bond strengths by measurement of the appearance potentials (AP)[1] of fragment ions. Consider the decomposition of a complex L_1ML_2 (M = metal atom, L = ligand) in the mass spectrometer:

$$L_1ML_2 \xrightarrow{+e;\,-2e} L_1ML_2^+ \xrightarrow{-L_2} L_1M^+ \xrightarrow{-L_1} M^+$$

If the appearance potentials of the ions $L_1ML_2^+$ [$= IP(L_1ML_2)$], L_1M^+, and M^+ are known, it is possible to construct an energy cycle:

Four different bond dissociation energies (DE) are found:

$$DE(L_1M{-}L_2^+) = AP(L_1M^+) - IP(L_1ML_2)$$
$$DE(L_1{-}M^+) = AP(M^+) - AP(L_1M^+)$$
$$DE(L_1{-}M{-}L_2^+) = AP(M^+) - IP(L_1ML_2)$$
$$DE(L_1{-}M{-}L_2) = AP(M^+) - IP(M)$$

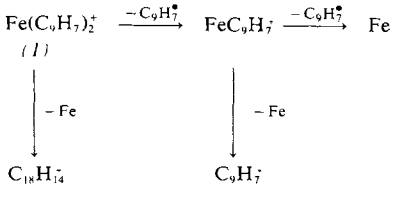


Since the fragment ions may be formed with excess kinetic or electronic excitation energy, the calculated DE values are upper limits for the true values. It is recommended that such calculations be carried out only if the fragmentation path is known as definitely as in the example given.

4.1.1. Complexes with Like Ligands

The principle of the metal-ligand cleavage can be best demonstrated for the simplest compounds of this type, the carbonylmetal and bis(π-aromatic) metal complexes.

In accordance with the rules discussed earlier, the mass spectra of the binary mononuclear carbonyl complexes $M(CO)_n$, *e.g.* $V(CO)_6$, $Cr(CO)_6$, $Fe(CO)_5$, and $Ni(CO)_4$, always contain the complete series of ions $M(CO)^+_{n-x}$ ($x = 0 - n$) formed by successive removal of the CO groups[22,24-30]. It follows from the appearance potentials of the fragment ions that the dissociation energies required for the removal of the CO ligands increase with increasing x; during the stepwise decomposition of a carbonylmetal ion, therefore, the M—CO bond becomes stronger. An increase in stability is also found on transition from the carbonyl complexes of the first to those of the third transition period, this increase being manifested *e.g.* in the series $Cr(CO)_6$—$Mo(CO)_6$—$W(CO)_6$ in an increase both in the appearance potentials of analogous fragment ions and in the relative intensities of the CO-richer fragments[22,25].



In polynuclear binary carbonyl complexes $M_m(CO)_n$, the cleavage of the metal-metal bonds competes with the elimination of CO[31-35]. The tendency toward the breakdown of the metal cluster decreases markedly from metals of the first to those of the third transition series. The decacarbonyl compounds of manganese and rhenium, for example, exhibit the following somewhat simplified fragmentation scheme:

At 55 eV the intensity ratio $\Sigma M(CO)_x^+ / \Sigma M_2(CO)_x^+$ is 0.2 for M = Mn, but only 0.05 for M = Re[33]. The increase in the stability of the metal-metal bonds with increasing number of metal atoms in the cluster is also reflected in the fragmentation behavior. Thus the mass spectrum of $Co_2(CO)_8$ contains the series of ions $Co_2(CO)^+_{0-8}$ and $Co(CO)^+_{0-4}$ in comparable intensities[31], whereas in the decomposition of $Co_4(CO)_{12}$, all twelve CO ligands are preferentially eliminated before the stepwise breakdown of the Co_4^+ cluster begins[34]. Even trinuclear ions $Co_3(CO)^+_{1-6}$ appear with only a low intensity, while these ions are completely lacking in the spectrum of the analogous iridium compound. Finally, an extreme example is the decomposition of $Ru_6C(CO)_{17}$[36]; the stepwise loss of all seventeen CO molecules leads to the ion Ru_6C^+, which does not undergo any further fragmentation.

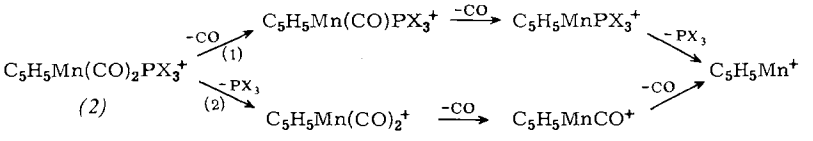
Binary cyclopentadienylmetal[20,37,38] and dibenzenemetal complexes[19,39-41] also decompose in the same way as the binary carbonylmetal complexes, with stepwise loss of the ligands, but partial fragmentation of the π-bonded aromatic groups may also occur to a considerable extent here (cf. Section 4.3.1.). Characteristic differences exist between carbonyl and pure bis(aromatic) complexes in the variation of the energy requirements during the fragmentation; the latter, unlike the carbonyl complexes, require much more energy for the removal of the first ligand than for that of the second. The molecular ions of bis(aromatic) complexes therefore appear in a much higher intensity than those of the carbonyl compounds. On the other hand, the parent ions are less abundant in the spectra of the tris- and tetrakis(cyclopentadienyl) complexes; the intensity ratios in this case reflect the relative stabilities of the various oxidation states of the metals (the removal of a C_5H_5 radical is associated with a decrease in the formal oxidation number). Corresponding to the preference for the oxidation numbers +3 in the lanthanoids and +4 in uranium and thorium, the ions $(C_5H_5)_2$Lanthanoid$^+$, $(C_5H_5)_3U^+$ and $(C_5H_5)_3Th^+$ appear with the greatest intensity at 50 eV. The relatively high intensity of $C_5H_5Yb^+$ in the spectrum of $(C_5H_5)_3Yb$ is explained by the fact that the oxidation number +2 is easily attainable by ytterbium[38].

The ionization potentials of highly condensed aromatic hydrocarbons are often lower than those of transition metals. In such cases the positive charge may remain on the aromatic group on cleavage of the metal-ligand bond, as is illustrated by the fragmentation of bis(indenyl)iron *(1)*[42].

4.1.2. Complexes with Unlike Ligands

In the majority of known organometallic compounds, several different ligands are bonded to the central atom. The sequence of the metal-ligand cleavages is important in the decomposition of these complexes upon electron impact. The ligands can be roughly divided into two groups, according to their ease of removal:

Group 1 (easily removed ligands): CO, NO, N_2, H, PF_3, CH_3, CF_3, PH_3, AsH_3, ethylene, acetylene.



Group 2 (ligands that are difficult to remove): F, phenyl, allyl, phosphanes, phosphites, amines, isocyanides, carbenes, thioethers, sulfoxides, cyclic oligoolefins, aromatic hydrocarbons.

Gradations occur within these groups, but no rigorously valid elimination series can be constructed, since the central metal affects the ease of elimination of ligands, and ligand interactions may also affect the sequence.

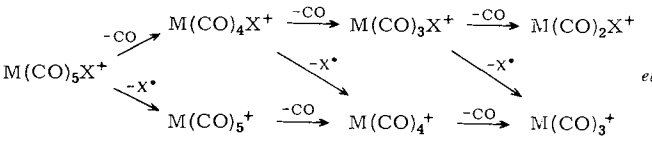
The donor strength/acceptor strength ratio of the ligand is of considerable importance to the ease of cleavage of metal-ligand bonds. Thus the ease of removal of some of the ligands of the first group (CO, NO, N_2, PF_3) is due to their pronounced acceptor character. In

the complex ions, the back-bonding, *i.e.* the transfer of d-electron density into empty acceptor orbitals of the ligand, is greatly weakened by the positive charge located predominantly on the central metal atom. This is in agreement with the small number of cationic carbonylmetal complexes known and with the fact that carbonyl complexes have been found to be most suitable for the study of negative ions in the mass spectrometer[31,43-45]. The second group, on the other hand, contains mainly donor ligands; donor bonds are stabilized by the positive charge on the central metal atom.

The donor/acceptor ratio of ligands and hence also their ease of removal can be varied within wide limits by the choice of the substituents on the complexed ligand center. This can be illustrated by the decomposition of cyclopentadienyldicarbonyl-manganesephosphane complexes *(2)* containing various groups X[18,46,47]; among others, two decomposition paths starting with the molecular ion are observed.

(2)

In path (1), the removal of the two CO molecules may also be coupled. The competition of paths (1) and (2) can be expressed in a simplified form by a ratio Q of the ion intensities I:



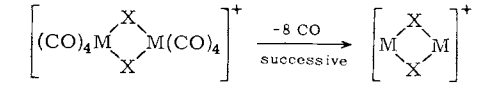
$$Q = \frac{I[C_5H_5Mn(CO)_2^+] + I[C_5H_5MnCO^+]}{I[C_5H_5Mn(CO)PX_3^+] + I[C_5H_5MnPX_3^+]}$$

A measure of the donor/acceptor ratio of the PX_3 ligands is provided by the ionization potentials of the complexes, which generally increase as the ratio of donor strength to acceptor strength decreases, and hence as the d-electron density produced on the central metal atom by the metal-ligand interaction decreases[18,23,39,46-51]. A comparison of the ionization potentials and of the Q values in Table 2 confirms the close relationship between the donor/acceptor ratio and the ease of removal of ligands. If the donor properties of PX_3 predominate (corresponding to lower IP values), the alternative decomposition path (2) is no longer followed and Q disappears. Similar relations have been found for other types of complexes[13,51].

Table 2. Ionization potentials [eV] and Q values of $C_5H_5Mn(CO)_2PX_3$ complexes (IP of $C_5H_5Mn(CO)_3 = 8.12$ eV).

(2), X =	IP	Q
F	8.24	5.57
Cl	8.12	0.69
Br	8.01	0.63
C_6H_5O	7.40	0.02
H	7.28	0.05
i-C_3H_7O	7.17	0
C_6H_5	6.93	0
i-C_3H_7	6.90	0

In addition to the donor/acceptor strength, the number of bonds to be broken also determines the ease of removal of a ligand. Let us consider the decomposition



etc. (3)

M = Mn, Re; X = Cl, Br, I[32, 34, 52, 53], H[54, 55]

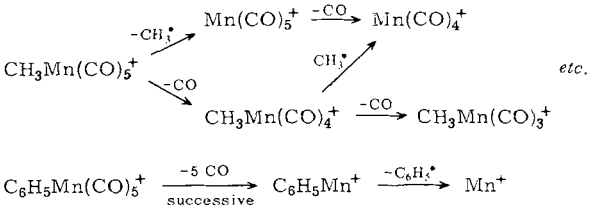
of carbonyl halides and carbonyl hydrides. If halogen or hydrido ligands are bonded terminally to the central metal, they are eliminated as easily as CO [eq. (3)].

In halogen-bridged carbonyl complexes, on the other hand, the cleavage of the metal-halogen bond occurs only after the complete loss of all the CO groups [eq. (4)][32,34,52]. The complex $(CO)_5Re{-}Re(CO)_4{-}H{-}Re(CO)_5$, with a linear Re—H—Re grouping, loses up to fourteen CO molecules, while a competing elimination of hydrogen begins at the earliest from the fragment $HRe_3(CO)_2^+$[56].

(4)

M = Mn, Re; X = Cl, Br, I

The following elimination sequence for π ligands also shows the influence of the number of bonds to be broken:



ethylene, acetylene, cyclic monoolefins > diolefins > aromatic hydrocarbons.

Among the aromatic systems, the cyclopentadienyl ring is the most difficult to eliminate.

The number of electrons transferred in the cleavage of a metal-ligand bond may also determine the ease of removal. The fragmentation of nitrosyl-carbonyl complexes shows clearly that CO is more easily eliminated than NO, whose removal involves a three-electron step, whereas the loss of CO is only a two-electron process.

Some examples of decomposition schemes in which the above-mentioned relationships regarding elimination sequences are evident are given below (partial fragmentations of the complexed ligands are not taken into account).

Methyl- and phenylpentacarbonylmanganese[57]:

Bis(cyclopentadienyl)hydridotechnetium[20]:

$$(C_5H_5)_2TcH^{\cdot} \xrightarrow{-H^{\bullet}} (C_5H_5)_2Tc^{\cdot} \xrightarrow{-C_5H_5^{\bullet}}$$

$$C_5H_5Tc^{\cdot} \xrightarrow{-C_5H_5^{\bullet}} Tc^{\cdot}$$

Cyclopentadienylnitrosylcarbonylchromium-L complexes with L = monoolefin, acetylene[58], methylmethoxycarbene[59]:

$$C_5H_5Cr(NO)(CO)L \xrightarrow{-CO} C_5H_5Cr(NO)L^{\cdot} \xrightarrow{-NO}$$

$$C_5H_5CrL^{\cdot} \xrightarrow{-L} C_5H_5Cr^{\cdot} \xrightarrow{-C_5H_5^{\bullet}} Cr^{\cdot}$$

Cycloheptatrienylcycloheptadienechromium[60]:

$$C_5H_5CrC_7H_{10} \xrightarrow{-C_7H_{10}} C_7H_7Cr^{\cdot} \xrightarrow{-C_7H_7^{\bullet}} Cr^{\cdot}$$

Cyclopentadienylbenzenemetal complexes[19]:

$$C_5H_5MC_6H_6^{\cdot} \xrightarrow{-C_6H_6} C_5H_5M^{\cdot} \xrightarrow{-C_5H_5^{\bullet}} M^{\cdot}$$

M = Cr, Mn

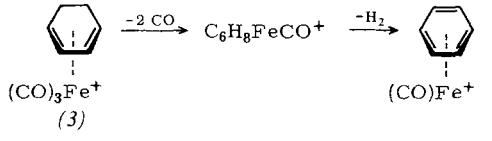
Cyclopentadienylcycloheptatrienylmetal complexes[19,61,62]:

$$C_5H_5MC_7H_7 \xrightarrow{-C_7H_7^{\bullet}} C_5H_5M^{+} \xrightarrow{-C_5H_5^{\bullet}} M^{+} \qquad (5)$$

M = Ti, V, Cr

The effects governing the elimination of the terminally bonded halogens chlorine, bromine, and iodine are difficult to incorporate into a scheme, since these can compete in their ease of removal both with ligands such as CO and NO and with allyl and even cyclopentadienyl ligands, as is shown by the decomposition of cyclopentadienylcarbonylmetal halides[63] [eq. (6)].

$$\begin{array}{ccccc} C_5H_5Fe(CO)_2Br^{+} & \xrightarrow{-2\,CO} & C_5H_5FeBr^{+} & \xrightarrow{-C_5H_5^{\bullet}} & FeBr^{+} \\ \downarrow{\scriptstyle -Br^{\bullet}} & & \downarrow{\scriptstyle -Br^{\bullet}} & & \downarrow{\scriptstyle -Br^{\bullet}} \\ C_5H_5Fe(CO)_2^{+} & \xrightarrow{-2\,CO} & C_5H_5Fe^{+} & \xrightarrow{-C_5H_5^{\bullet}} & Fe^{+} \end{array} \qquad (6)$$

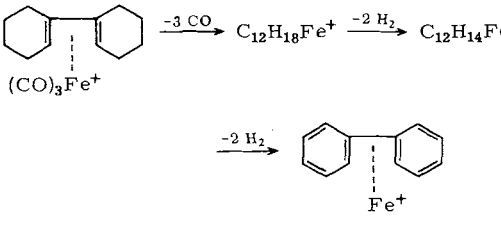


However, the marked increase in the strength of the metal-halogen bond from iodine to fluorine can be detected mass-spectroscopically; in the decomposition of the cyclopentadienylmetal fluorides investigated so far, only the loss of the C_5H_5 ligands is observed[38].

4.2. Simple Bond Cleavages in Complexed Ligands

4.2.1. Removal of Hydrogen

The removal of H atoms and H_2 molecules occurs mainly in the decomposition of π-bonded cyclic olefins. The driving force of such processes is the formation of new double bonds and their coordination to the central metal if this no longer has the inert gas configuration in a complex ion after the occurrence of a few decomposition steps. The elimination of hydrogen is facilitated in particular if it involves the formation of 6π-electron systems.



Whereas no appreciable elimination of hydrogen is observed in the decomposition of 1,3-dienetricarbonyliron complexes with open-chain dienes, the loss of H_2 occurs in the case of 1,3-cyclohexadienetricarbonyliron *(3)* before all three CO ligands have been removed[64-66] [eq. (7)]. The base peak in the spectrum of free 1,3-cyclohexadiene, on the other hand, is due to the $C_6H_7^{+}$ ion.

(7)

(3)

Cyclopentadienyl-1,3-cyclohexadienecobalt, $C_5H_5CoC_6H_8$, similarly forms the fragment $C_5H_5CoC_6H_6^{+}$, from which all further decomposition processes proceed, whereas cyclopentadienyl-1,3-butadienecobalt exhibits no elimination of H_2[67]. Cyclohexene ligands can also be aromatized[65] [eq. (8)].

(8)

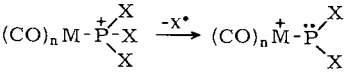
The relatively high stability of cationic cyclopentadienyl complexes greatly favors the elimination of H from cyclopentadiene compounds. The base peak in the mass spectrum of cyclopentadienylcyclopentadienerhodium, $C_5H_5RhC_5H_6$, is due to the fragment $(C_5H_5)_2Rh^{+}$ [68].

Free cycloheptatriene loses an H atom on electron impact to form the very stable tropylium ion, whereas this tendency is not necessarily shown by π-bonded

cycloheptatriene. Cyclopentadienylcycloheptatrienechromium, $C_5H_5CrC_7H_8$, gives the ion $C_5H_5CrC_7H_7^+$ in a very high intensity; the fragments $C_7H_7VC_7H_8^+$ and $(C_7H_7)_2V^+$ similarly appear in the spectrum of bis(cycloheptatriene)vanadium, $(C_7H_8)_2V$[68]. On the other hand, the intensity ratio of the ions rC_7H_7 and $CrC_7H_8^+$ in the spectrum of $(CO)_3CrC_7H_8$ is only 1:58[69].

In this connection, let us consider briefly the question of the benzylium-tropylium analogy. The ion $C_7H_7^+$, which is formed usually as a fairly intense fragment from toluene, cycloheptatriene, and benzyl and cycloheptatrienyl compounds, always exhibits the same fragmentation characteristics, irrespective of the starting compound; a rapid interconversion between the benzylium and the tropylium structure is postulated. This type of mutual rearrangement is suppressed by π-complex formation, *i.e.* in ions having the composition $MC_7H_7^+$ the benzyl or cycloheptatrienyl structure of the starting compound is retained, and different modes of decomposition are accordingly found[69].

4.2.2. Cleavage of the C—O Bond in Carbonylmetal Complexes

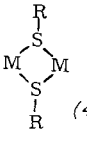


The mass spectra of carbonylmetal compounds also show ions of the type $M(CO)_xC^+$, which are formed by cleavage of the C—O bond of complexed carbon monoxide. The intensities of these fragments are determined by the ratio of the strengths of the M—C and of the C—O bonds in the ions that act as the precursors of the $M(CO)_xC^+$ fragments. Since the strength of the M—C bond increases with the number of CO ligands removed (cf. Section 4.1.1.), the C—O cleavage normally begins only after the loss of some CO molecules. Moreover, the intensities of $M(CO)_xC^+$ ions increase with increasing atomic numbers of the metal atom, since the stability of the metal-carbon bond also increases in this order.

4.2.3. Removal of Halogen Atoms and of R, OR, and NR_2 Radicals

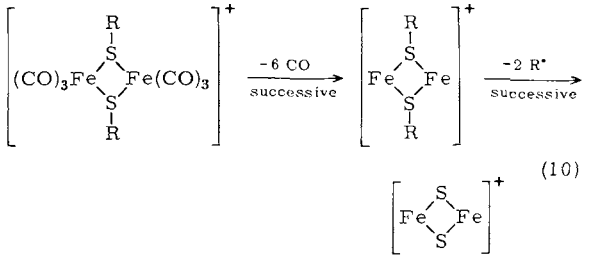
In the partial fragmentation of complexed ligands, the elimination of stable neutral particles generally predominates; however, free radicals may also be eliminated under certain conditions. Free-radical eliminations, like all simple bond cleavages, are fast reactions (high frequency factor) even on the mass-spectroscopic time scale; there are therefore often no accompanying "metastable bands", or else these are only of low intensity. Of the organometallic complexes whose decomposition involves the loss of free radicals, four different types will be dealt with here.

1. Groups X (X = halogen, alkyl, aryl, alkoxyl, phenoxyl, dialkylaminyl) that are bonded to the central metal *via* a hetero atom such as N, P, As, O, or S may be eliminated as free radicals. Numerous processes of this type have been observed for PX_3 complexes[46,47,51,70–74] and their arsenic analogs[68,75,76]. The trifluorophosphanemetal compounds, which are similar in many respects to the carbonylmetal compounds, exhibit the cleavage of P—F bonds together with the successive elimination of PF_3. The mass spectrum of $Ni(PF_3)_4$ thus shows, *inter alia*, the series of ions $Ni(PF_3)_n^+$ ($n = 0–4$) and $Ni(PF_3)_mPF_2^+$ ($m = 0–3$), as well as the fragment $NiPF^+$[70].



An unusual mode of decomposition is found for mixed carbonylmetal-PX_3 complexes with X = halogen, OR, and $N(CH_3)_2$; the elimination of an X radical from the molecular ion occurs here in competition with the elimination of CO. The reason for this may be assumed to be that the tetracoordinate phosphorus takes over positive charge density in the molecular ion, and this leads to weakening of the P—X bond and simultaneous stabilization of the M—CO bond (cf. Section 4.1.2) [eq. (9)].

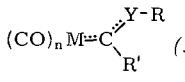
(9)



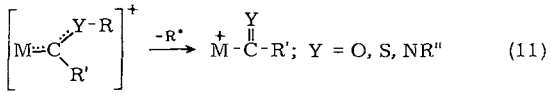
These processes evidently have a very low energy requirement, so that even thermal excitation of the molecules affects the relative intensities of $(CO)_nMP_2^+$ ions[46]. The spectrum of $(CO)_5WAs[N(CH_3)_2]_3$ even shows fragments having the composition $(CO)_nWAsN(CH_3)_2^+$ ($n = 0–2$) as well as ions formed by the stepwise elimination of CO and the series $(CO)_nWAs[N(CH_3)_2]_2^+$ ($n = 0–5$)[75].

A group of μ-mercapto compounds contain the structure *(4)*.

(4)



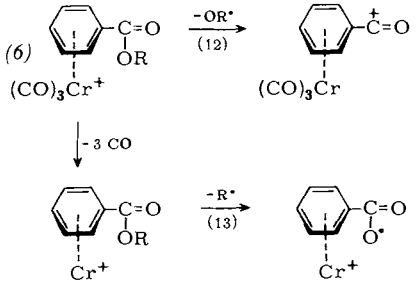
The four-membered M_2S_2 ring is found to be very stable, as can be deduced *e.g.* from the decomposition scheme of $(CO)_6Fe_2(SR)_2$ complexes[52,77] [eq. (10)].



(10)

Similar decomposition modes are found for μ-alkoxo and μ-dialkylamino compounds[78,79]. If R is an alkyl residue, elimination of olefin with migration of hydrogen becomes increasingly prominent with increasing chain length of R (cf. Section 4.3.2).

2. In carbene complexes of the type *(5)*, the removal of an R radical from the CO-free fragment leads to an acylmetal fragment, the oxidation number of the central metal being increased by one unit[23] [eq. (11)].



(5)

(11)

3. The decomposition of ester functions in π complexes with aromatic or olefinic ligands is also characterized by free-radical eliminations, and differs markedly in this respect from the fragmentation of the free esters. If the complex also contains CO ligands, the elimination of an OR radical from the molecular ion is also observed, while the CO-free fragment in some cases loses an R radical instead[68,69,80]. This is illustrated by part of the decomposition scheme of benzoic acid ester tricarbonylchromium complexes *(6)*[80].

The decomposition processes (12) and (13) are independent of the chain length of R. The reaction (12) leads to an ion in which the π-bonded ligand can take over the positive charge, with relative stabilization of the metal-CO bond.

4. As was mentioned in Section 4.2.1, π-bonded cyclic olefins lose hydrogen to form π-bonded aromatic groups. It can be seen from the mode of decomposition of cycloheptatrienetricarbonylchromium complexes and cyclopentadienemetal complexes substituted on the methylene group of the ring ligand in the *exo* or *endo* position with respect to the metal that the *exo* substituent is preferentially eliminated as a free radical[68,69,81]. This provides one of the rare possibilities of distinguishing conclusively between stereoisomers by mass spectroscopy. The comparison of the mass spectra of such an *exo-endo* isomer pair in Figure 1 shows that the substituent on the π-bonded ring is removed from the molecular ion M^+ only in the *exo* case (the elimination of *exo*-H atoms is of minor importance in this class of compounds).

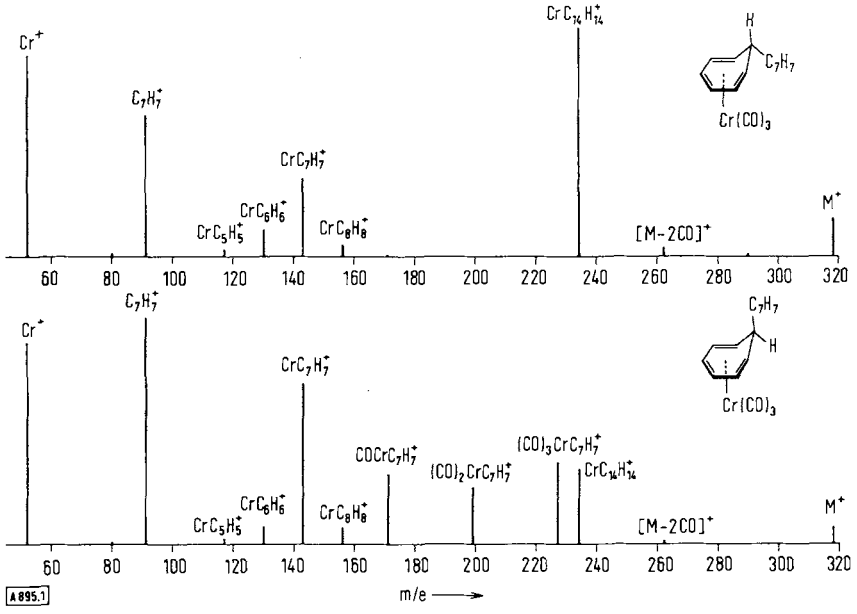


Fig. 1. Mass spectra of *exo*- and *endo*-7,7′-bi(1,3,5-cycloheptatrienyl)tricarbonylchromium (50 eV; the spectra are normalized with respect to the isotope distribution of the ions).

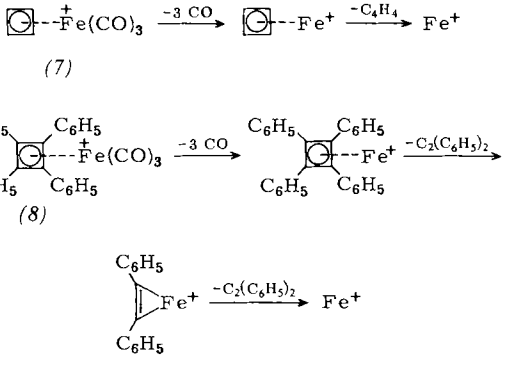
4.3. Rearrangements

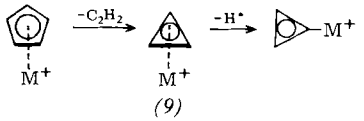


The decomposition of molecules upon electron impact is frequently accompanied by rearrangements. Whereas rearrangements involving the migration of hydrogen predominate in the mass spectroscopy of organic compounds, the range of atoms and groups that can migrate in the decomposition of organometallic complexes is much wider. The important role of the central metal in such processes is attributable to its character as a preferential carrier of the positive charge and to its tendency to enter into coordinate bonding with newly formed ligand centers that are capable of complex formation. Rearrangements generally proceed *via* sterically demanding transition states; they therefore have low kinetic frequency factors, and as slow reactions they are consequently accompanied in most cases by "metastable bands". In this review, only a few characteristic

types will be selected from the many known rearrangements of organometallic complexes upon electron impact.

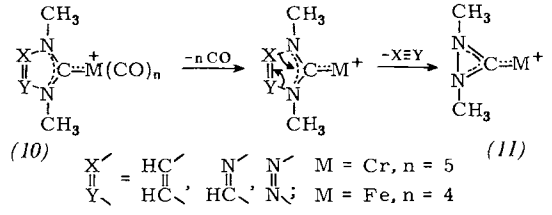
4.3.1. Ring Cleavage Processes

Decomposition reactions with ring cleavage of cyclic ligands cannot always be definitely described as rearrangements, since there is often doubt regarding the constitution of the product ions. For the sake of simplicity, however, they will be treated together under this heading.



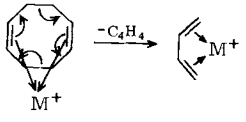
A typical ring cleavage reaction of π-bonded aromatic groups or cyclic olefins proceeds with loss of C_2 units, which are preferentially removed as acetylene in the case of aromatic complexes, but may also be removed as ethylene in the case of complexes with cycloolefins containing methylene groups in the ring (a further mode of ring decomposition with loss of C_3H_3 radicals is of limited importance). This type of partial ligand decomposition becomes increasingly important with increasing covalent character and increasing stability of the metal-ligand bond. Ferrocene and dibenzenechromium mainly undergo metal-ligand cleavage, whereas by far the predominant process in the decomposition of osmocene and dibenzenetungsten is the partial fragmentation of the ligands with stepwise elimination of acetylene, so that the mass spectra of these thermodynamically more stable homologous complexes provide practically no information about the structure. Owing to the predominance of the elimination of C_2H_2, for example, the isomeric compounds $C_5H_5WC_7H_7$ and $W(C_6H_6)_2$, unlike the corresponding chromium complexes, are practically indistinguishable by mass spectrometry[68,82]. Another example of the relationship between stability and partial fragmentation is provided by a comparison of the decomposition of the cyclobutadiene complexes *(7)* and *(8)*; the ring-metal bond is much stronger in *(8)* than in *(7)*[83].

(7)



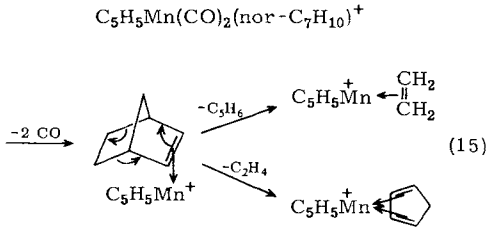
(8)

Cyclopentadienylmetal ions are converted by elimination of C_2H_2 into fragments that probably contain a cyclopropenylium structure *(9)*; loss of hydrogen may also occur, as is generally observed in the partial decomposition of hydrocarbon ligands.



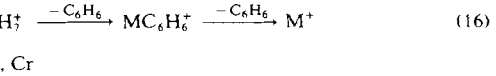
(9)

The partial ligand decomposition of π-pyrrolyl complexes proceeds similarly to the fragmentation of the corresponding π-cyclopentadienyl complexes, with loss of HCN, C_2H_2, and $C_2H_2N^{\bullet}$[61,84]. A related mode of decomposition is found for complexes with heterocyclic carbene ligands *(10)*; the fragment having the probable structure *(11)* undergoes a further ring cleavage reaction with loss of CH_3NC[85].



(10) *(11)*

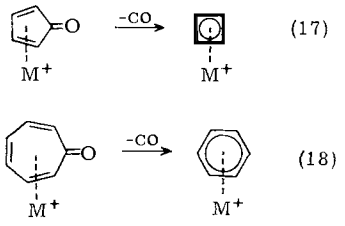
The number of possible decomposition modes increases with the ring size of cyclic ligands. Even complexes with π-bonded eight-membered ring systems give highly branched fragmentation schemes[61,67,86–89]; the allylic cleavage of 1,5-cyclooctadiene complexes [eq. (14)] should also be mentioned here.



(14)

An interesting case is the decomposition of norbornene and norbornadiene complexes. Either of the fragments formed from the bicyclic ligands by retro-Diels-Alder degradation can remain on the central metal [eq. (15)]; the analogous norbornadiene complex similarly gives the fragments $C_5H_5MnC_5H_6^+$ and $C_5H_5MnC_2H_2^+$[47].

(15)



Mutual ring contraction-ring expansion processes of two π-bonded cyclic ligands have been observed in various cases. Cyclopentadienylcycloheptatrienylmetal complexes, in addition to the usual decomposition with ring-metal cleavage [eq. (5)], also exhibit the successive loss of two C_6H_6 units[19,61,90–92] [eq. (16)]. An already rearranged dibenzenemetal ion may be involved as an intermediate. The formation of the ion $CrC_8H_8^+$ that appears in the spectra of Figure 1 is due to a related process (elimination of benzene from $CrC_{14}H_{14}^+$).

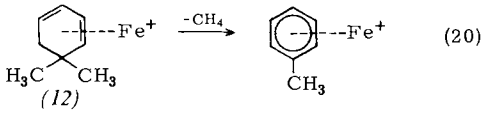
(16)

M = Ti, V, Cr

Among the ring cleavage processes involving exocyclic groups, special mention should be made of the decomposition reactions of π-bonded cyclopentadienones[93,94] and cycloheptatrienones[92]. The CO elimination with ring contraction shown in equations (17) and (18) is explained by the stability of the neutral particle re-

(17)

(18)



moved with simultaneous retention of the coordination number of the central metal ion.

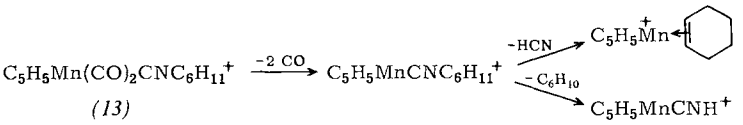
4.3.2. Decomposition with Migration of Hydrogen

Rearrangements of organic or organometallic compounds that proceed with migration of hydrogen usually include the elimination of molecules, *e.g.* alkanes, alkenes, H_2O, H_2S, hydrogen halide, HCN, alcohols, thiols, aldehydes, azomethines, CO, or ketenes. The driving force for such processes lies in the stability of these neutral particles. On elimination of unsaturated systems, the hydrogen is transferred to the remaining ion containing the metal. Such partial fragmentations of complexed ligands frequently follow an entirely different course from the decomposition of the free organic molecules. This often led to the assumption that the central metal should be regarded as the actual hydrogen acceptor (formation of metal hydride ions)[52,71,95,96], though no conclusive proof for this could be given, except in cases where there was no ambiguity, as in equation (19).

$$MOC_nH_{2n-1}^+ \xrightarrow{-OC_nH_{2n}} MH^+ \qquad (19)$$

An example of the elimination of an alkane is given in equation (20). The aromatization of the π-bonded six-membered ring in *(12)*, unlike in *(3)*, cannot be achieved by H_2 elimination, but only by loss of methane[65].

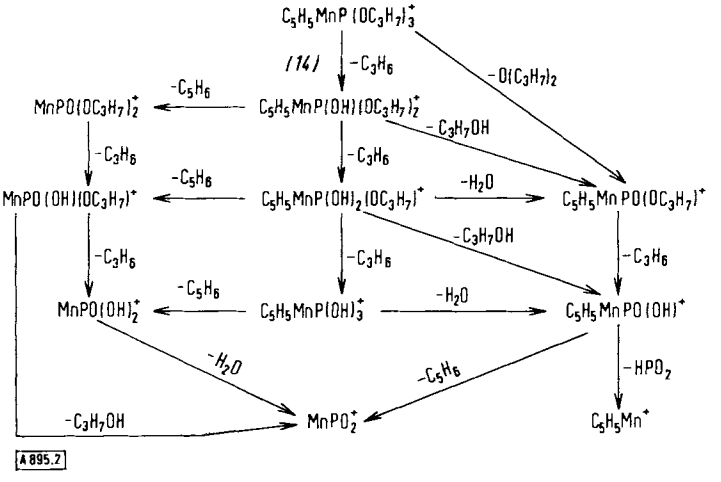
(20)



(12)

Alkylmetal ions, $MC_nH_{2n+1}^+$ with $n > 1$, decompose preferentially with elimination of olefin and formation of metal hydride fragments. In the decomposition of allyl complexes, the elimination of allene [eq. (21)][61] or propylene [eq. (22)][97] may occur in competition with the metal-ligand cleavage.

$$C_5H_5PdC_3H_5 \xrightarrow{-C_3H_4} C_5H_6Pd^+ \qquad (21)$$



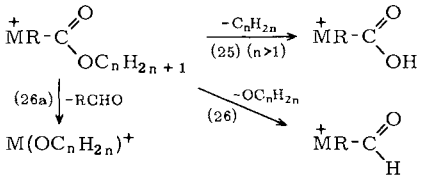
$$Pd(C_3H_5)_2^+ \xrightarrow{-C_3H_6} PdC_3H_4^+ \qquad (22)$$

The elimination of HCN (or CNH) with hydrogen transfer occurs preferentially in the case of isocyanide complexes[47,51]. The example of the decomposition of the cyclohexyl isocyanide compound *(13)* shows that the CNH fragment may also remain on the central metal[47].

(13)

Rearrangements with H migration are definitely to be expected in the decomposition of complex ions containing alkyl groups with chain lengths greater than C_2 bonded *via* O, S or N. It is of no importance, in principle, whether these hetero atoms are coordinated directly to the central metal [cf. eq. (19)] or occur in uncoordinated groups of ligands. The complete fragmentation scheme of the ion *(14)* (formed from cyclopentadienyldicarbonyl(triisopropyl phosphite)manga-

A 895.2



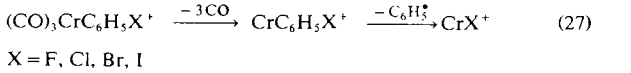
nese) gives an impression of the large number of possibilities that exist for H transfers[46]. Complexed phosphites can also decompose by elimination of aldehyde. This is true in particular of trimethyl phosphite ligands [eq. (23)], for which no elimination of olefin is possible[71,74]. Tris(dimethylamino)phosphane and tris(dimethylamino)arsane ligands decompose similarly with loss of *N*-methylazomethine [eq. (24)][71,73,75].

$$MP(OCH_3)_3^- \xrightarrow{-H_2C=O} MPH(OCH_3)_2^+ \qquad (23)$$

$$MP[N(CH_3)_2]_3^+ \xrightarrow{-H_3CN=CH_2} MPH[N(CH_3)_2]_2^+ \qquad (24)$$

Finally, mention will be made of a number of decompositions of π-bonded ligands with ester functions that are accompanied by hydrogen transfer, which have been very extensively studied[13,69,80,92,96,98,99]. Which of the processes (25) or (26) predominates depends on the central metal and on the π-bonded group R. Reaction (25) proceeds for the free esters with transfer of the H atom from the β position of the alkyl chain to the carbonyl oxygen (McLafferty rearrangement). How-

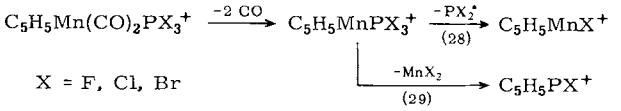
ever, investigations on deuterated π-benzoic acid ester tricarbonylchromium complexes showed that the H atom can be transferred from any position of the alkyl chain, an example of a change in the mechanism of the decomposition of an organic molecule by complexing, while the overall reaction remains similar[100]. Process (26) is not normally observed for the free ligand.



R = H_2C=CH, C_6H_5, C_5H_4, C_7H_6, C_7H_7

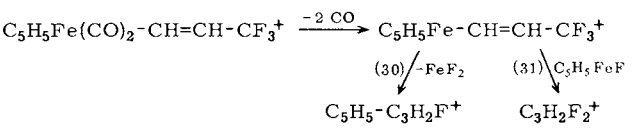
It is usually associated with a preceding, coupled, or subsequent removal of the carbonyl group with formation of the ion MRH^+. Processes corresponding to reactions (25) and (26) are also found in the partial fragmentation of π-bonded ligands with alkyl substituents.

4.3.3. Decomposition with Transfer of Nucleophilic Groups

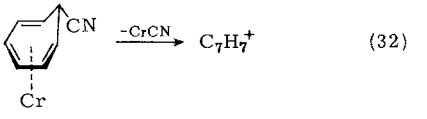


The electropositive character of the transition metals and the resulting substantial localization of the charge on the central atom in complex ions make this a preferred point of attack for nucleophilic atoms or groups if these are present in the complex as components of ligands and are not directly bonded to the central metal. Nucleophiles that may be capable of being transferred include electronegative substituents such as halogens, oxygen, and hydroxyl, alkoxy, cyano, or amino groups; the probability of migration increases with the electronegativity. Alkyl and aryl residues are transferred if certain structural features are also present in the ligand, particularly if these groups are bonded *via* a carbonyl function. The processes described here are frequently accompanied by drastic rearrangements of the remaining ligand fragments.

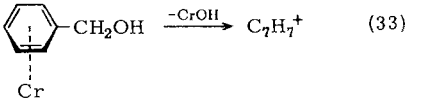
Among the atoms most easily transferred to the metal are the halogens. The spectra of halobenzenetricarbonylchromium compounds show chromium halide ions [eq. (27)], whose intensities increase markedly from the iodide to the fluoride, corresponding to the variation of the electronegativities[80].



X = F, Cl, Br, I (27)

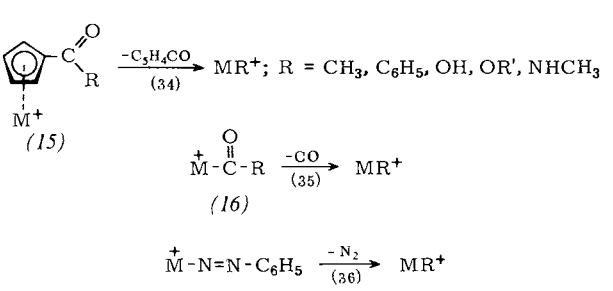


If the ligand contains several halogen atoms, metal dihalides are also formed during the decomposition of the complex; because of their high ionization energies, these are generally eliminated as neutral particles. Thus in the decomposition of trihalophosphane compounds, one [eq. (28)] or two [eq. (29)] halogen atoms can migrate[46].



Such rearrangements are characteristic of the frequently described decomposition of complexes with halogenated organic ligands having a wide variety of structures[23,57,77,101–107]; two examples are given in equations (30) and (31).

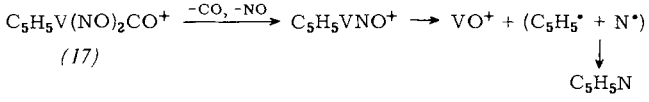
The process (27) proceeds in the same manner when X = OH, NH_2, or OCH_3. Similarly, halogen can be replaced by OC_6H_5 in equations (28) and (29). Migrations of electronegative groups are particularly favored if very stable ions such as the tropylium ion can be formed at the same time [eq. (32)[69] and (33)[108]].



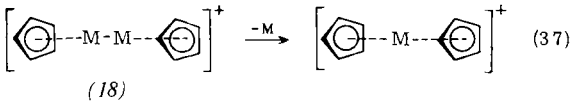
(32)

(33)

Complexes containing the structure *(15)* decompose *inter alia* in accordance with equation (34), as has been found above all for compounds with M = Fe and Mn[96,98,109]; alkyl and phenyl groups can also be transferred in decompositions of this type. Acylmetal ions *(16)* undergo fragmentation corresponding to the reversal of the formation of the neutral complexes (insertion of CO in metal-carbon σ bonds), again with formation of alkylmetal or arylmetal fragments [eq. (35)][9,23,57]; the latter are formed in a similar manner in the decomposition of arylazo complexes[110] [eq. (36)].



(15)



(16)

Very unusual fragmentation behavior is exhibited by complex ions that contain both nitrosyl and organic ligands and also have an even number of electrons. With migration of the O atom of an NO group to the central metal, the nitrogen is transferred to a free-radical ligand fragment[59]. The decomposition of *(17)* involves the formal elimination of a cyclopentadienyl radical and an N atom; an energetically plausible explanation is the combination of the two radicals to form the cyclopentadienylnitrene and the rearrangement of the latter to give the stable pyridine.

Finally, let us consider decompositions of polynuclear complexes, which can be provisionally assigned to the present rearrangement type with migration of nucleo-

philic groups to the central metal. The decomposition of polynuclear cyclopentadienylmetal carbonyl, nitrosyl, or halogeno complexes yields fragments *(18)*, which are stabilized by elimination of a metal atom and migration of a C_5H_5 ligand[32,63,111,112] [eq. (37)]. The decomposition of cyclopentadienylmetal thiolates yields the fragment *(19)*, which decomposes in a disproportionation reaction, again with formation of $M(C_5H_5)_2^+$ [78,79] [eq. (38)].

(18)

(19)

The number of examples of rearrangements in the decomposition of organometallic complexes in the mass spectrometer could be extended almost indefinitely; however, many of the rearrangement processes observed so far can be classified under the three main types proposed in this review.

Metal Isotope Effect on Metal-Ligand Vibrations

By Kazuo Nakamoto[*]

Exploitation of the isotope effect using heavy metal isotopes now makes it possible to give clear-cut assignments of the metal-ligand vibrations in the IR and Raman spectra of complex compounds. The results previously obtained with this new method and their current limitations form the subject of this progress report.

1. Introduction

The metal-ligand vibrations of coordination compounds are most important since they provide direct information about the structure of the complex and the nature of the metal-ligand bond. These vibrations appear in the low-frequency region because of the relatively heavy mass of the metal atom and the weak nature of the metal-ligand bond. It is not an easy task to assign the metal-ligand vibrations unequivocally since the interpretation of low-frequency spectra is complicated by the appearance of ligand vibrations (some of which are activated by complex formation) and by the crystal field effect (lowering of symmetry, appearance of lattice modes, coupling of lattice with internal modes, *etc.*) in the solid state.

Thus far, the metal-ligand vibrations have been assigned by the use of one or more of the following methods:

1. A comparison of the spectra between a free ligand and its metal complex; the metal-ligand vibration should be absent in the spectrum of the free ligand. This method often fails to give a clear-cut assignment, since some ligand vibrations activated by complex formation may appear in the same region as the metal-ligand vibrations.

2. The metal-ligand vibration should be metal-sensitive and be shifted by changing the metal or its oxidation state. This method is applicable only when a series of metal complexes have exactly the same structure with different metals.

3. The metal-ligand stretching band should appear in the same frequency region if the metal is the same and the ligands are similar. For example, the Zn—N stretching frequencies of Zn^{II}-α-picoline complexes are similar to those of Zn^{II}-pyridine complexes. This method is applicable only when the metal-ligand vibration is known for one parent compound.

4. The metal-ligand vibration shows an isotopic shift if the ligand is isotopically substituted. For example, the Ni—N stretching band of $[Ni(NH_3)_6]Cl_2$ at 334 cm^{-1} is shifted to 318 cm^{-1} upon deuteration of the ammonia ligands[1]. The observed shift of 16 cm^{-1} is in good agreement with that predicted theoretically for the Ni—N stretching mode. Similar shifts are observed if the α-atom of the ligand (atom directly bonded to the metal) is isotopically substituted. For example, this method has been used to assign the metal-ligand vibrations of oxamido(^{14}N and ^{15}N)[2] and acetylacetonato-(^{16}O and ^{18}O) complexes[3]. It should be noted, however, that metal-ligand vibrations as well as ligand vibrations involving the motion of the α-atom are shifted by this method. Thus it may not provide a clear-cut assignment for the metal-ligand vibration.

5. The frequency of a metal-ligand vibration may be predictable if the metal-ligand stretching and other force constants are known *a priori*. At present, this method is not practical since not many force constants are known for coordination compounds.

It is obvious that none of these methods is perfect; furthermore, they encounter more and more difficulties as the structure of the complex (and hence the spectrum) becomes more complicated.

In order to solve this difficulty, we have recently developed a new method which utilizes the heavy metal isotopes[4]. The use of isotopes in vibrational spectroscopy is not new. The pairs of isotopes such as (H, D), (^6Li, ^7Li), (^{10}B, ^{11}B), (^{14}N, ^{15}N) and (^{16}O and ^{18}O) have long been used to assign the vibrations involving the motion of these atoms. However, the use of heavy metal isotopes had not been reported until our first communication appeared in 1969[4][*]. This is probably due to two reasons: (i) Pure metal isotopes were not commercially available, and (ii) the magnitude of such an isotopic shift was thought to be too small to be observed. The former obstacle has been eliminated since a number of metal isotopes can be purchased from Oak Ridge National Laboratory[**]. Table 1 lists some stable metal isotopes, their purity and current prices. Using these isotopes, it is possible to prepare a pair of metal complexes in which only the metals are isotopically substituted. Although metal isotopes are relatively expensive, this factor does not cause serious financial burden since most of the preparations can be carried out on a milligram scale and normally less than twenty milligrams of samples are sufficient to measure the entire spectrum. Furthermore, some of these metal isotopes can be easily recovered after the measurement. Table 1 also indicates that several natural abundant elements may be used as substitutes for pure metal isotopes such as ^{52}Cr, ^{56}Fe and ^{58}Ni since the concentrations of

[*] After our first communication appeared in 1969, *P. Tarte* and *J. Preudhomme* independently reported the application of the metal isotope technique to inorganic salts such as Ni_2GeO_4 and $CaMoO_4$ (C. R. Acad. Sci. Paris, *270*, 474 (1970); Spectrochim. Acta, *26A*, 2207 (1970)).

[**] Isotopes Development Center, Oak Ridge National Laboratory, P. O. Box X, Oak Ridge, Tennessee 37830 (USA).

these isotopes are exceptionally high in natural abundance.

As stated above, the magnitude of a metal isotope shift is expected to be small since relative mass difference between isotopes ($\Delta m/m$) is small and the metal-ligand bond is generally weak. However, it is beyond possible experimental errors in most compounds containing the metal isotopes listed in Table 1. For mass differences of 2 units or more, we have so far observed shifts ranging 10 to 1.5 cm^{-1} for the metal-ligand stretching modes. The instrumental resolution and reproducibility of typical far-infrared and Raman spectrophotometers is 0.5 cm^{-1} if proper conditions are used[*]. Therefore, a shift of more than 1 cm^{-1} can be observed without difficulty if a band is relatively sharp and not overlapped by other bands. Thus far, the heaviest isotopes we have studied are ^{116}Sn and ^{124}Sn. As will be shown later, the Sn—Cl and Sn—N stretching modes of $SnCl_4(py)_2$ are shifted by 5—4 cm^{-1} by such isotopic substitution. This method may be applicable to elements heavier than tin if a proper combination of metal isotopes and a ligand is found.

The ligand-metal-ligand bending modes are much less sensitive to the metal isotope substitution than the metal-ligand stretching modes. In fact, the observed shifts of the bending modes are less than 2.0 cm^{-1} in most cases. Thus, the metal isotope method is not so effective in assigning the metal-ligand bending modes.

It is well known that the Teller-Redlich product rule holds for the ratio of products of all the frequencies between two isotopic molecules. Consider an octahedral XY_6-type molecule where X is ^{58}Ni or ^{62}Ni and Y is an NH_3 ligand (point mass approximation). If the product rule is applied to the infrared active F_{1u} species which contains one stretching (ν_1) and one bending mode (ν_2), the result is

$$\frac{\nu_1'}{\nu_1}\frac{\nu_2'}{\nu_2} = \left\{\left(\frac{m_x'+6m_y}{m_x+6m_y}\right)\left(\frac{m_y}{m_y'}\right)\right\}^{1/2} = \left\{\left(\frac{164}{160}\right)\left(\frac{58}{62}\right)\right\}^{1/2} = 0.9793$$

This gives a general idea about the magnitude of the metal isotope shift. However, the product rule does not give information about the individual isotope shift. In order to predict individual isotope shifts for ν_1 and ν_2, normal coordinate analysis must be carried out on an XY_6-type molecule. Conversely, metal isotope data are highly useful in refining a set of force constants to be used for normal coordinate analysis. In some cases, vibrational coupling occurs between metal-ligand and ligand vibrations. If so, even ligand vibrations become slightly metal isotope sensitive. The degree of vibrational coupling can be estimated from the calculation of the L-matrix or the potential energy distribution. Thus, the metal isotope data are useful in confirming the presence of vibrational coupling predicted by normal coordinate analysis.

Table 1. Some stable isotopes available at Oak Ridge National Laboratory.

Element	Atomic Weight	Inventory Form	Isotope	Natural Abundance (%)	Purity (%)	Price ($/mg)
Chromium	51.996	Cr_2O_3	^{50}Cr	4.31	90—95	2.20

			^{124}Sn	5.94	80—96	0.50
Chlorine	34.453	NaCl	^{35}Cl	75.529	> 98	0.50
			^{37}Cl	24.471	> 95	1.75

[*] It is not necessary to measure the spectrum under high resolution unless two or more bands are closely located. In most cases, the spectra are run under normal resolution with a slow scanning speed and on an expanded scale to measure the peak position as accurately as possible. The peak frequency is calculated by taking an average value of multiple scans over the desired frequency range.

2. Phosphane Complexes[5,13,16]

Triethylphosphane complexes of the type, $M(PEt_3)_2X_2$, where M is Ni^{II} and Pd^{II} and X is a halogen, are known to be *trans*-planar. Thus, one M—X stretching and one M—P stretching vibration should be active in the infrared. Furthermore, both bands should be sensitive to metal isotope substitution. Figure 1 gives the actual tracing of the spectra of $^{58}Ni(PEt_3)_2X_2$ (X = Cl and Br) and their ^{62}Ni analogs[5]. Table 2 lists the observed frequencies, isotopic shifts and band assignments. The bands above 420 cm^{-1} are not listed since they are not sensitive to metal isotope substitution. It is seen that each complex exhibits two bands which give large isotopic shifts relative to others. The band at 403.3 cm^{-1} of $^{58}Ni(PEt_3)_2Cl_2$ is clearly due to the Ni—Cl stretching mode since this band is strong and not present in its bromo analog[6,7]. Then, the remaining band at 273.4 cm^{-1} must be assigned to the Ni—P stretching mode. This band persists in $^{58}Ni(PEt_3)_2Br_2$ at 265.0 cm^{-1}. Previously, the Ni—P stretching modes of the $Ni(PEt_3)_2X_2$ type complexes were assigned at 426—410 cm^{-1} [6,7]. These assignments must be revised in view of our new results.

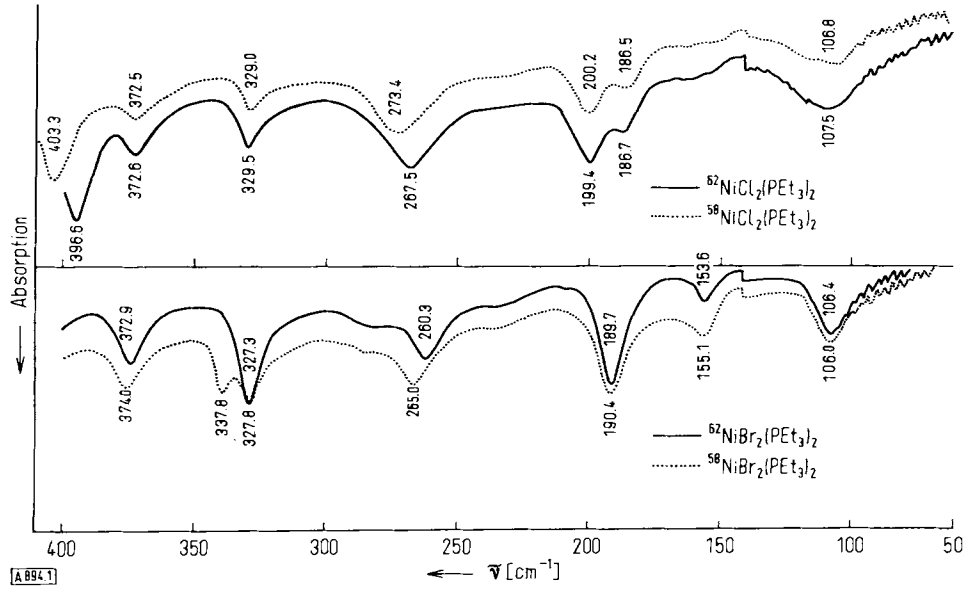

Fig. 1. Far infrared spectra of *trans*-$Ni(PEt_3)_2X_2$ (X = Cl and Br).

Table 2 also shows that two bands at 358.3 and 234.5 cm^{-1} of $^{104}Pd(PEt_3)_2Cl_2$ are sensitive to the ^{104}Pd-^{110}Pd substitution. The former can be assigned to the Pd—Cl stretching mode since it is in a frequency range expected for the Pd—Cl stretching mode (370—345 cm^{-1})[8]. Then, the band at 234.5 cm^{-1} must be assigned to the Pd—P stretching mode. Previous investigators[6,7,9] have assigned the Pd—P stretching bands of $Pd(PEt_3)_2X_2$ and $Pd_2(PEt_3)_2Cl_4$ type complexes at 450—380 cm^{-1}. The Pd—P stretching bands of analogous trimethylphosphane complexes have also been assigned at 380—340 cm^{-1} by many other investigators[7,10,11]. Our results show that these frequencies are too high for the Pd^{II}—P stretching modes of square-planar complexes.

The skeletal bending bands which appear below 200 cm^{-1} are much less sensitive to metal isotope substitution and more difficult to assign than the metal-ligand stretching modes. In Table 2, we have proposed band assignments which were predicted from an approximate normal coordinate analysis described later. The band at 183.8 cm^{-1} of $^{104}Pd(PEt_3)_2Cl_2$ gives an isotopic shift of 1.8 cm^{-1} which is rather large for a pure ligand vibra-

Table 2. Infrared frequencies of triethylphosphane complexes containing metal isotopes (cm^{-1}).

PEt_3	$^{58}Ni(PEt_3)_2Cl_2$		$^{58}Ni(PEt_3)_2Br_2$		$^{104}Pd(PEt_3)_2Cl_2$		Assignment[b]

[a] $\Delta\tilde{\nu}$ indicates metal isotope shift, $\tilde{\nu}(^{58}Ni) - \tilde{\nu}(^{62}Ni)$ or $\tilde{\nu}(^{104}Pd) - \tilde{\nu}(^{110}Pd)$.
[b] ν_a, asymmetric stretch, δ, bending. Ligand vibrations were assigned according to Ref. [12].
[c] In $^{62}Ni(PEt_3)_2Br_2$, these two bands are overlapped (see Figure 1). Therefore, $\Delta\tilde{\nu}$ values are only approximate.

tion. This may suggest the presence of vibrational coupling between this ligand vibration and the Pd—P stretching mode at 234.5 cm^{-1}.

$Ni(PPh_3)_2Cl_2$ is tetrahedral whereas $Pd(PPh_3)_2Cl_2$ is *trans*-planar. Thus, the former exhibits two Ni—Cl and two Ni—P stretching bands whereas the latter exhibits one Pd—Cl and one Pd—P stretching band. In fact, $^{58}Ni(PPh_3)_2Cl_2$ exhibits four bands at 341.2, 305.0, 189.6 and 164.0 cm^{-1} which are sensitive to the ^{58}Ni-^{62}Ni substitution. The former two bands are assigned to the Ni—Cl stretching modes since they are relatively strong and absent in the bromo analog. Then, the latter two bands must be assigned to the Ni—P stretching modes. In $^{104}Pd(PPh_3)_2Cl_2$, two bands at 360.3 and 191.2 cm^{-1} show large isotopic shifts (4.3 and 4.2 cm^{-1}, respectively) relative to others. The former band is in the region of terminal Pd—Cl stretching frequencies[8] and assigned safely to this mode. Then, the latter must be assigned to the Pd—P stretching mode. Again, previous workers[9] assigned the Pd—P stretching modes of $Pd_2(PPh_3)_2Cl_4$ at 450 and 428 cm^{-1}. These bands may be assignable to the vibrations of the triphenylphosphane ligand.

In order to calculate theoretical isotope shifts, we have carried out a normal coordinate analysis on a *trans*-planar MY_2X_2 model by assuming that the PEt_3 ligand is a single atom having the mass of PEt_3. Evidently, such an approximation provides only a rough measure of theoretical isotope shifts. Even so, the results of Table 3 are sufficient to show that the magnitudes of the observed shifts are at least reasonable.

Table 3. Comparison of theoretical and observed isotopic shifts for *trans*-$Ni(PEt_3)_2X_2$ (cm^{-1}).

$Ni(PEt_3)_2Cl_2$	Theoretical [a] ^{58}Ni	$\Delta\tilde{\nu}$	Observed ^{58}Ni	$\Delta\tilde{\nu}$
Ni—Cl Stretch	402.4	7.2	403.3	6.7
Ni—P Stretch	270.8	7.3	273.4	5.9
Ni—Cl Bend	189.5	0.0	186.5	−0.2
Ni—P Bend	168.2	1.7	161.5	−0.5
$Ni(PEt_3)_2Br_2$				
Ni—Br Stretch	340.9	8.6	337.8	10.5 [b]
Ni—P Stretch	265.9	7.5	265.0	4.7
Ni—Br Bend	141.0	0.1	155.1	1.5
Ni—P Bend	147.1	0.5	— [c]	

[a] The molecular parameters used for calculations were: Ni—Cl, 2.30 Å; Ni—Br, 2.40 Å; Ni—P, 2.25 Å. The four angles around the Ni atoms were assumed to be 90°. The Urey-Bradley force constants used were: K(stretching), 1.35 for Ni—Cl, 1.25 for Ni—Br and 0.75 for Ni—P; H(bending), 0.11 and F(repulsive), 0.13, all in units of mdyn/Å.
[b] See footnote [c] of Table 2.
[c] Hidden by the neighboring band.

Similar isotope studies have also been made on the $Ni(diphos)_2X_2$ type complexes where diphos is ethylene-bis(diphenylphosphane) and X is a halogen[13]. In this case, two Ni—X and two Ni—P stretching modes are infrared active since these compounds have a *cis*-planar NiP_2X_2 skeleton. Table 4 lists the four stretching frequencies determined by the Ni isotope method. It also compares the Ni—X and Ni—P stretching frequencies of *trans*-planar, *cis*-planar and tetrahedral $Ni(phosphane)_2X_2$ type complexes. It is seen that there are marked differences in Ni—X stretching frequencies between *cis* and *trans* complexes. The Ni—X stretching frequencies of the *cis*-complex are always lower than those of the corresponding *trans*-complex, since the Ni—X bond of the *cis* complex is *trans* to the phosphane ligand which exerts a strong *trans*-effect. Conversely, the Ni—P stretching frequencies of the *cis*-complex are always higher than that of the corresponding *trans*-complex since the Ni—P bond is *trans* to the halogen.

It is well known that complexes of the type, $Ni(PPh_2R)_2Br_2$ (R = alkyl) exist in two isomeric forms: tetrahedral (green) and *trans*-planar (brown) forms[15]. According to Table 4, the Ni—Br and Ni—P stretching frequencies of these two forms should be markedly different. This has also been confirmed by our Ni isotope experiments on both forms of $Ni(PPh_2Et)_2Br_2$[16]. In general, the tetrahedral form exhibits two Ni—Br stretching bands near 250 cm^{-1} whereas the *trans*-planar form exhibits one Ni—Br stretching near 330 cm^{-1} and one Ni—P stretching band near 260 cm^{-1}.

3. 8-Quinolinolato (Oxinato) Complexes[17]

Figure 2 shows the far-infrared spectra of potassium oxinate (abbreviated as KQ) and several anhydrous bis-(oxinato) complexes (MQ_2). These spectra are too complicated to allow empirical band assignments. It is possible, however, to assign the metal-ligand vibrations by using the metal isotope method and to elucidate the structure of these complexes based on observed numbers of metal-ligand vibrations. There are three probable structures for bis(oxinato) complexes: *trans*-planar (C_{2h}), *cis*-planar (C_{2v}) and tetrahedral (C_{2v})

structures. The number of infrared active metal-ligand stretching bands should be two for C_{2h} symmetry ($2B_u$) and four for C_{2v} symmetry ($2A_1 + 2B_1$ for *cis*-planar, and $2A_1 + B_1 + B_2$ for tetrahedral).

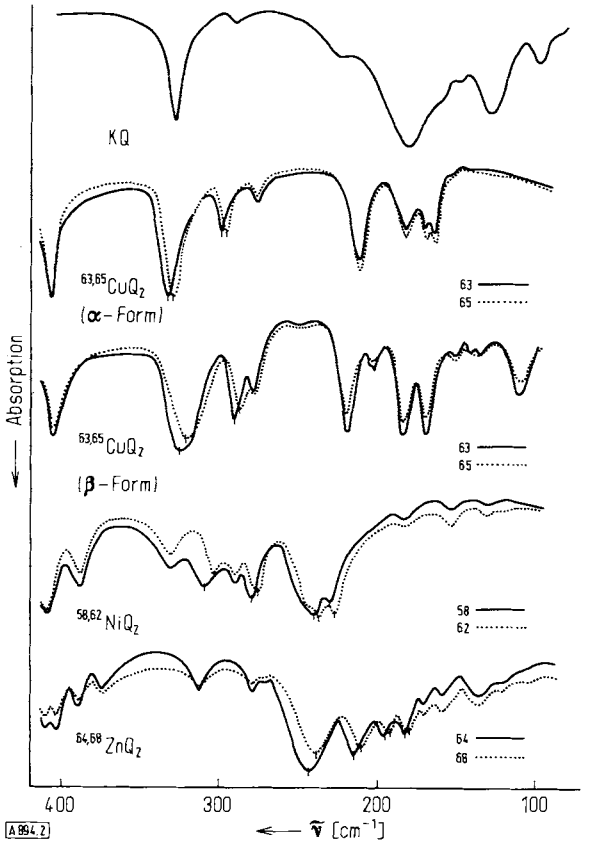

Fig. 2. Far-infrared spectra of KQ, CuQ_2, NiQ_2, and ZnQ_2 (Q = anion of 8-quinolinol).

Anhydrous copper oxinate (CuQ_2) has been isolated as two crystal forms, *i.e.*, α-form and β-form. As is seen in Fig. 2 and Table 5, both forms exhibit two bands (332.1 and 297.3 cm^{-1} for the α-form and 324.0 and 289.7 cm^{-1} for the β-form) which give relatively large isotopic shifts by the ^{63}Cu-^{65}Cu substitution. Thus the structures of both forms must be *trans*-planar (C_{2h}). The present results are in good agreement with those of previous X-ray studies[18–20].

In general, the metal-oxygen stretching band is stronger than the metal-nitrogen stretching band in the infrared. Therefore, the stronger bands (332.1 cm^{-1} (α) and 324.0 cm^{-1} (β)) with higher frequencies may be assigned to the Cu—O stretching modes, whereas the weaker ones (297.3 cm^{-1} (α) and 289.7 cm^{-1} (β)) with lower frequencies may be assigned to the Cu—N stretching modes.

Figure 2 and Table 5 show that four bands at 309.6, 280.8, 242.0 and 231.0 cm^{-1} of NiQ_2 show large isotopic shifts relative to other bands by the ^{58}Ni-^{62}Ni substitution. NiQ_2 is also known to have a magnetic moment of 3.24 μ_B[21]. Combining these results, it may be concluded that NiQ_2 is tetrahedral (C_{2v}). Generally, the asymmetric stretching mode appears at a higher frequency and is expected to give a larger isotopic shift by the ^{58}Ni-^{62}Ni substitution than the symmetric one. Considering this trend with their relative intensities and frequencies, we have assigned two bands at 309.6 and 280.8 cm^{-1} to the asymmetric (B_1) and symmetric (A_1) Ni—O stretching modes, respectively, and two bands at 242.0 and 231.0 cm^{-1} to the asymmetric (B_2) and symmetric (A_1) Ni—N stretching modes, respectively. It should be noted in Fig. 2 that the Ni—N stretching bands (242.0 and 231.0 cm^{-1}) are relatively strong since they are overlapped on the strong ligand band at around 230 cm^{-1}.

Table 5. Observed frequencies, isotopic shifts, and band assignments for MQ_2-type metal oxinates and potassium oxinate (cm^{-1}).

[b] Overlapped with ν(M—O).

In accordance with the expected tetrahedral structure, ZnQ_2 exhibits four bands which are sensitive to the ^{64}Zn-^{68}Zn substitution. Figure 2 also shows that the general pattern of the far-infrared spectrum of ZnQ_2 is similar to that of NiQ_2 but is rather different from that of CuQ_2 (*trans*-planar). From the intensity and frequency considerations, these four bands at 243.0, 214.4, 195.5 and 182.4 cm^{-1} may be assigned to the asymmetric Zn—O (B_1), symmetric Zn—O (A_1), asymmetric Zn—N (B_2) and symmetric Zn—N (A_1) stretching modes, respectively.

4. 2,4-Pentanedionato (Acetylacetonato) Complexes[22]

The band assignments of the Cr—O stretching modes of *tris*(acetylacetonato)chromium(III) have been a subject of controversy. Originally, *Nakamoto et al.*[23] assigned the bands at 459 and 307 cm^{-1} (calculated) to these modes based on normal coordinate analysis of the 1:1 (metal/ligand) model. *Gillard et al.*[24] extended the measurement down to 55 cm^{-1} and assigned two bands at 459 and 355 cm^{-1} to the Cr—O stretching modes. On the other hand, *Pinchas et al.*[3] assigned the 592 cm^{-1} band to the pure Cr—O stretching and the 456 cm^{-1} band to the C—CH_3 bending coupled with the Cr—O stretching mode since the former gave the largest isotopic shift (19 cm^{-1}) by ^{16}O-^{18}O substitution of the ligand. In order to solve this controversy, we have compared the infrared spectra of $^{50}Cr(acac)_3$ and its ^{53}Cr analog. As is seen in Fig. 3 and Table 6, the observed isotopic shift of the 592 cm^{-1} band (0.7 cm^{-1}) is much smaller than those of the 459 and 335 cm^{-1} bands (3.0 to 3.9 cm^{-1}). Thus, it is most reasonable to assign the latter two bands to the Cr—O stretching modes, and the former band at 592 cm^{-1} to a ring deformation in which the oxygen atom is displaced appreciably.

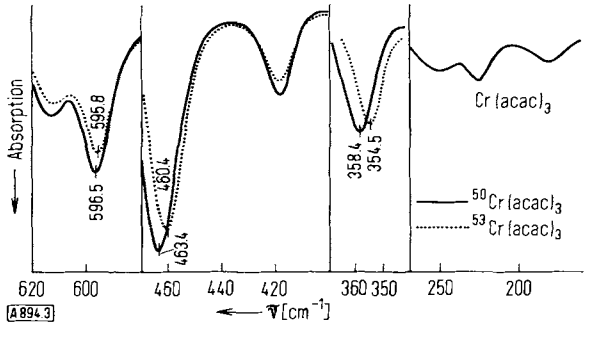

Fig. 3. Far-infrared spectra of $^{50}Cr(acac)_3$ and its ^{53}Cr analog.

Recently, *Mikami et al.*[25] carried out a rigorous normal coordinate analysis on $Fe(acac)_3$. In agreement with our metal isotope study, their results show that the 592 cm^{-1} band is due to an out-of-plane ring deformation and the bands at 459 and 355 cm^{-1} are due to the Cr—O stretching modes. As stated before, the band shifts due to isotopic substitution of the α-atom of the ligand must be interpreted with caution since the metal-ligand stretching as well as ligand vibrations involving the motion of the α-atom are shifted by such substitution.

5. Complexes of 2,2′-Bipyridyl and 1,10-Phenanthroline[26,27]

The assignments of the metal-ligand vibrations of *tris*-complexes of 2,2′-bipyridyl (bipy) and 1,10-phenanthroline (phen) have been controversial. Originally, *Inskeep*[28] assigned the M—N stretching bands of tris-(bipy) complexes of Co^{II}, Ni^{II}, Cu^{II} and Zn^{II} in the 300—260 cm^{-1} region by assuming that the highest frequency band which is absent in the free ligand is the M—N stretching vibration. On the other hand, *Clark* and *Williams*[29] assigned these bands to ligand vibrations and concluded that no bands above 200 cm^{-1} can be assigned to the M—N stretching modes. In order to solve this controversy, we have carried out an extensive study on the far-infrared spectra of these and many other bipyridyl complexes by using the metal

[a] Values obtained for $[Co(phen)_3](ClO_4)_3$.

As is seen in Table 7, each complex exhibits two M—N stretching bands and their frequencies are governed by the electronic structure of the central metal. All the complexes which have filled or partially filled t_{2g} (bonding) orbitals and empty e_g (anti-bonding) orbitals exhibit the M—N stretching bands in the 390—300 cm^{-1} region, whereas other complexes which have filled or partly filled e_g orbitals exhibit the M—N stretching bands in the 290—180 cm^{-1} region. Thus, a dramatic decrease in the M—N stretching frequency is seen in going from Co^{III} to Co^{II}. However, the M—N stretching frequencies do not change appreciably in the series Cr^{III}, Cr^{II}, Cr^{I} and Cr^{0} although the oxidation state of the metal changes in a wide range. This result may suggest that, as the formal oxidation state is lowered, σ-bonding becomes weaker and π-bonding becomes stronger so that the overall M—N bond strength is approximately constant. If this is the case, there will be considerable interaction between metal dπ orbitals and the anti-bonding ligand π* orbitals so that increasing amounts of electrons of the metal will reside essentially in ligand orbitals as the oxidation state is lowered. Thus, Cr(bipy)$_3$ may be represented as $Cr^{3\delta+}$ $(bipy^{\delta-})_3$ as suggested by *Koenig* and *Herzog*[30] who studied the electronic spectra of these complexes.

6. Complexes of Pyridine[31,32]

Thus far, the application of the metal isotope technique has been limited to infrared spectroscopy. This technique is also useful in assigning the metal-ligand vibrations in Raman spectra. If a molecule contains one metal atom at the center of symmetry, no metal isotope shifts are expected for all Raman-active fundamentals. Therefore, the lack of metal isotope shifts in the Raman spectrum proves the presence of a center of symmetry. As an example, Table 8 lists the Raman frequencies of $SnCl_4(py)_2$ (py = pyridine). The structure of this complex must be *trans*-octahedral since no isotopic shifts have been observed in the Raman spectrum. This is also supported by the fact that the mutual exclusion rule holds between infrared and Raman spectra of this compound (Table 8 and Fig. 4). For the *trans*-octahedral structure, one Sn—Cl and one Sn—N(py) stretching mode should be infrared-active and both bands are expected to show relatively large shifts by ^{116}Sn-^{124}Sn substitution. In agreement with this, two bands at 323.0 and 227.5 cm^{-1} of the ^{116}Sn complex are shifted by *ca.* 4 to 5 cm^{-1} while other bands show almost no shifts by the metal isotope substitution in the infrared spectra. Since the former band is strong and insensitive to the py-[D_5]py substitution, it can be assigned to the Sn—Cl stretching mode. The latter band is relatively weak and sensitive to the ligand deuteration. Hence, this band is assigned to the Sn—N stretching mode. These and other band assignments listed in Table 8 have been confirmed by an approximate normal coordinate analysis on a *trans*-SnX_4Y_2 model where Y (single atom) represents a pyridine ligand[31].

[a] $\Delta\tilde{\nu} = \tilde{\nu}(^{116}Sn) - \tilde{\nu}(^{124}Sn)$.
[b] $\Delta\tilde{\nu} = \tilde{\nu}$(Sn, py) − $\tilde{\nu}$(Sn, [D_5]py).

In a tetrahedral $ZnX_2(py)_2$ type complex, two Zn—X and two Zn—N(py) stretching modes are infrared as well as Raman active. Furthermore, all these four modes should be sensitive to ^{64}Zn-^{68}Zn substitution. As is seen in Table 9 and Fig. 5, four infrared bands at 329.2, 296.5, 222.4 and 203.9 cm^{-1} of $^{64}ZnCl_2(py)_2$ show relatively large shifts when ^{64}Zn is substituted by ^{68}Zn. The former two bands are strong and show little

shifts by the py-[D_5]py substitution. Therefore, these bands can be assigned to the Zn—Cl stretching modes. The latter two bands are relatively weak and sensitive to the ligand deuteration. Thus, these two bands can be assigned to the Zn—N stretching modes.

Similar results are seen in the Raman spectra of these compounds. In general, the antisymmetric mode is stronger in the infrared and weaker in the Raman spectrum than the symmetric mode. Therefore, the bands at *ca.* 329 and 222 cm^{-1} are assigned to the antisymmetric whereas the bands at *ca.* 297 and 204 cm^{-1} are assigned to the symmetric types[32].

7. Ammine Complexes[33]

Theoretically, two metal-nitrogen stretching vibrations (A_1 and F_2) should be Raman-active for tetrahedral (T_d) ammine complexes. The totally symmetric A_1 mode involves no motion of the central metal atom and should thus be independent of the ^{64}Zn-^{68}Zn isotopic substitution. On the other hand, the F_2 mode involves the motion of the central metal atom and should be sensitive to the isotopic substitution. Fig. 6 shows the Raman spectra of crystalline $[^{64}Zn(NH_3)_4]I_2$ and its ^{68}Zn analog in the Zn—N stretching region. It is seen that the 432.0 cm^{-1} band of the ^{64}Zn complex gives a shift of 0.5 cm^{-1} which is within the experimental error, whereas the 412.0 cm^{-1} band gives a large shift of 2.0 cm^{-1}. Thus, it is possible to assign the former to the A_1 and the latter to the F_2 species on the basis of observed isotopic shifts alone. This assignment has also been confirmed by the observation that the 427 cm^{-1} band of an approximately 4.0 M ammonia solution of $[Zn(NH_3)_4]I_2$ is strongly polarized.

Other vibrations such as N—H stretching, NH_3 degenerate and symmetric deformation, and NH_3 rocking modes do not involve the motion of the metal atom and show little shifts by the ^{64}Zn-^{68}Zn substitution. In order to calculate theoretical isotopic shifts, we have carried out a normal coordinate analysis on the whole $[Zn(NH_3)_4]^{2+}$ ion (T_d symmetry). As is seen in Table 10, the results are in good agreement with those observed.

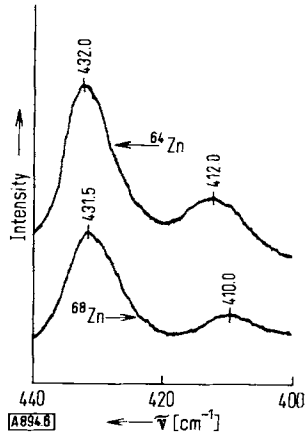

Fig. 6. Low-frequency Raman spectra of $[^{64}Zn(NH_3)_4]I_2$ and its ^{68}Zn analog.

8. Other Complexes

In addition to those complexes listed above, the metal isotope method has been applied to mercaptoalkylamine complexes (Ni^{II} and Pd^{II})[34], allyl-Pd complexes[35] and ferrocene[36]. Recently, this method has also been applied to metal complexes of octaethylporphin (Ni^{II} and Zn^{II}) by *Buerger et al.*[37].

In principle, the metal isotope method is applicable to any inorganic and coordination compounds. Practically, however, its application may be limited by several factors:

1. Pure and stable metal isotopes are available only for certain elements.

2. Some metal isotopes are too expensive even for a small scale synthesis.

3. Some compounds are difficult to prepare on a small scale. This is particularly true if a compound is gaseous or liquid.

Shift Reagents in NMR Spectroscopy

By Reinhard von Ammon and R. Dieter Fischer[*]

The number of possible applications of NMR spectroscopy has rapidly increased during the past few years. New fields of applications have been opened by the development of supraconducting solenoids and various spin-decoupling techniques and by the method of "pulsed Fourier transform NMR-spectroscopy". These methods originate mainly from progress in instrumentation. Recently, another "technique" has been introduced into NMR spectroscopy, which—principally on the basis of chemical and spectroscopic experience—is much less expensive but nevertheless useful. The basic principles, background, and most important applications of this method, known as the "NMR-shift-reagent technique", form the subject of this paper.

1. Introduction

An NMR-spectrum can be analyzed the more easily the more pronounced the chemical shifts of the nuclei of a sample are in comparison to the spin-spin coupling effects. The ideal case is a first order spectrum where the shift difference of the multiplet centers are large compared to the components of the multiplets. Possible means of simplifying spectra are spin decoupling[1] or—in certain cases—the introduction of suitable isotopes into the molecule under investigation. Another way is the variation of the magnetic field acting on the various nuclear magnets. If we discern between increasing the homogeneous, external magnetic field of the spectrometer and superimposing the "primary field" by additional internal "secondary fields", two alternative possibilities are evident.

A consequence of choosing the first possibility is the aim of commercial suppliers to produce NMR spectrometers with higher field strengths and improved resolution. The present status has—by means of supraconducting solenoids—reached field strengths corresponding to proton resonance frequencies of approximately 300 MHz.

The development of the other alternative is based upon experience of the chemist with materials whose magnetic properties are strongly anisotropic[*]. An example is the ring current effect causing chemically not very different

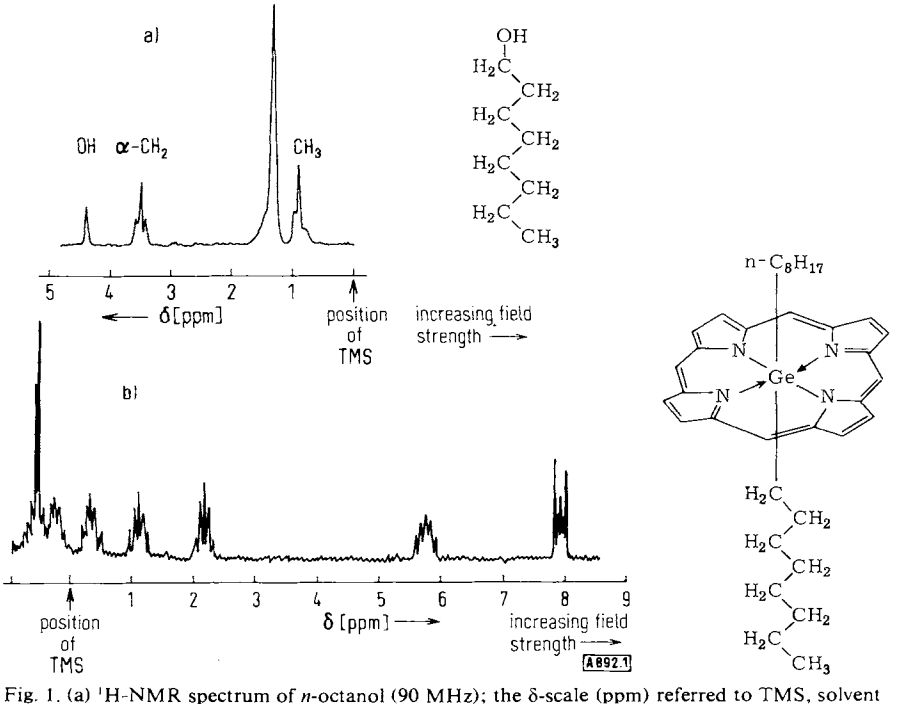

Fig. 1. (a) ^{1}H-NMR spectrum of *n*-octanol (90 MHz); the δ-scale (ppm) referred to TMS, solvent CCl_4; (b) ^{1}H-NMR spectrum (100 MHz) of the *n*-octyl part of dioctylgermanium-porphin [2]; δ-scale referred to TMS, solvent $CDCl_3$.

protons to exhibit a large separation of their resonance lines. Thus, in the diamagnetic porphin ring of the compound shown in Fig. 1, the primary field induces

[*] A secondary field is anisotropic if its magnitude and direction change with the direction of the primary field.

an additional anisotropic field which acts very differently upon the methylene proton pairs of the two axially coordinated *n*-octyl chains[2]. Similar signal spreadings are caused by the magnetic anisotropy of the phthalocyanine (= Pc) system in adducts of the type Fe(II)Pc·2S (S = amines *etc.*)[126] or by the weakly paramagnetic uranyl ion[3].

Any perceptible change of the structure of the substrate during the adduct formation is, however, to be avoided.

The molar ratio [S]:[R] does not necessarily have to be 1:1; it is important, however, that the mean lifetime of the adduct S—R is sufficiently small on the NMR time scale that only *one* averaged spectrum is observed for S and S—R.

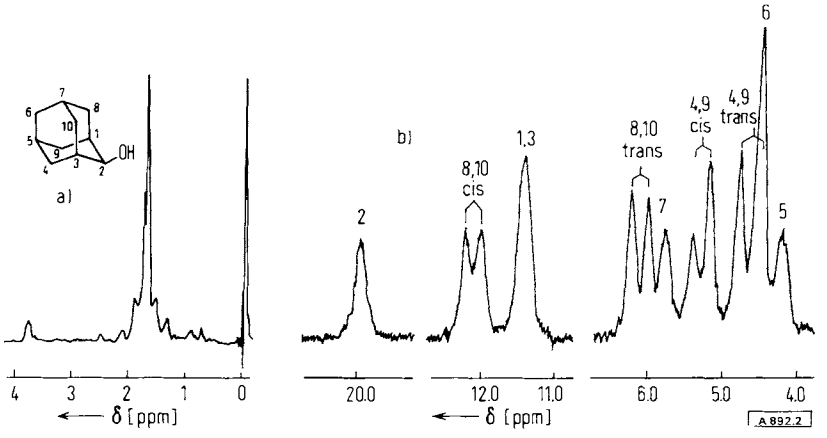

Fig. 2. ^{1}H-NMR spectra (60 MHz) of 2-adamantanol (a) before and (b) after addition of $Eu(dpm)_3$ as shift reagent; molar ratio shift reagent: substrate = 0.67, solvent $CDCl_3$ [4].

Much stronger secondary fields and therefore a still more pronounced expansion of the spectra can be induced, however, in paramagnetic systems with at least one unpaired electron. Fig. 2 illustrates the changes in the ^{1}H-NMR spectrum of adamantanol caused by the interaction of this substrate with the paramagnetic "shift reagent" tris(dipivalomethanato)europium(III), $Eu(dpm)_3$ (cf. Fig. 7), a system with six unpaired 4f electrons[4].

A further illustration is the ^{1}H-NMR spectrum of (−)-nicotine recorded at 60[5] and 220 MHz[6] in the absence (Fig. 3a and 3b) and at 90 MHz (Fig. 3c) in the presence of the organometallic shift reagent tricyclopentadienylpraseodymium(III)[7].

Whereas the enhancement of the external primary field causes a linear expansion of the spectra leaving the relative chemical shifts (in ppm) unchanged, the internal secondary field may also change the sequence of the signals. Since the strength of this field decreases with increasing distance from the origin of the magnetic field lines, "geometric shifts" (see below) become the ordering principle of the spectrum instead of the familiar chemical shifts in all cases where the influence of the secondary field is strong.

One may speak of an NMR shift reagent (R) if the NMR spectrum of a substance S is simplified (with respect to spectral analysis) through interaction with the reagent. The interaction between S and R should be prompted by addition of the reagent to the sample in the sense of at least one of the three equilibria (1a)—(1c).

$$S^{(1)} + R^{(1)} \rightleftharpoons S^{(1)}R^{(1)} \qquad (1a)^{[*]}$$

$$S^{(1)}R^{(1)} + S^{(2)} \rightleftharpoons S^{(2)}R^{(1)} + S^{(1)} \qquad (1b)^{[*]}$$

$$S^{(1)}R^{(1)} + R^{(2)} \rightleftharpoons S^{(1)}R^{(2)} + R^{(1)} \qquad (1c)^{[*]}$$

[*] For simplicity only 1:1 adducts are considered at the monent (cf. Section 3.2.1.2).

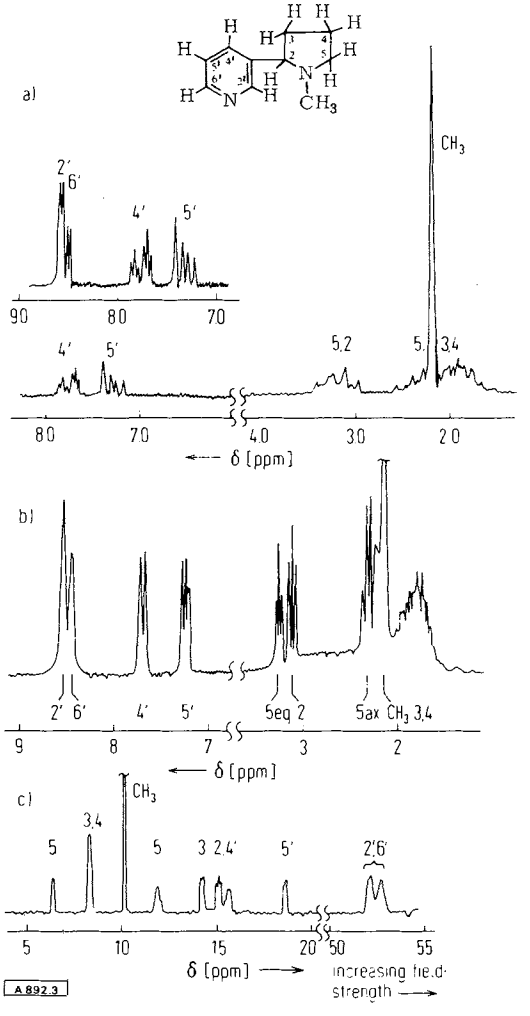

Fig. 3. ^{1}H-NMR spectra of (−)-nicotine, recorded under various conditions: (a) 60 MHz in CCl_4 [5]; (b) 220 MHz in $CDCl_3$ referred to TMS [6]; (c) 90 MHz in D_8-toluene after adduct formation with an equimolar amount of $Pr(C_5H_5)_3$; δ-scale referred to C_6H_6 [7].

2. Theory

Although the principle of the shift reagent technique has been known for some time and, in several cases, has been applied before[8-11,155], it was not until 1969 that *Hinckley*[12] initiated the systematic development of this branch of NMR spectroscopy[13,14,127,128,158,160]. The following survey of the theoretical background, which has been treated elsewhere in several detailed articles[15-21], concentrates on the most important aspects necessary for an understanding of the quantitative correlations between the properties of a shift reagent, the substrate, and the observed spectra.

2.1. The "Isotropic" Shift

The contribution Δ_i^{iso} of an internal secondary field to the resonance frequencies δ_i of a substance S within the adduct S—R in solution is experimentally obtained as the difference of the resonance frequencies under the influence of and without the secondary field:

$$\Delta_i^{iso} = \delta_i(S—R) - \delta_i(S) \tag{2}$$

Although the internal secondary field is practically always anisotropic, Δ_i^{iso} is generally called the "isotropic" shift, because it is the averaged result over all orientations of a molecule moving freely in solution. In the case of a paramagnetic shift reagent the term "paramagnetic shift" is also used.

If the shift reagent does not contain unpaired electrons, Δ_i^{iso} is identical with the dipolar or "pseudocontact" term Δ_i^{dip}, which takes into account all magnetic dipolar interactions of the magnetic moment of the i^{th} nucleus with the anisotropic magnetic field of the valence electron shell of the shift reagent. If unpaired electrons are present, Δ_i^{iso} is composed of the dipolar contribution and a (Fermi-)contact term Δ_i^{con} taking into account the influence of a possible spin delocalization within the adduct S—R:

$$\Delta_i^{iso} \equiv \Delta_i^{para} = \Delta_i^{dip} + \Delta_i^{con} \tag{3}$$

2.1.1. Magnetic Dipolar Interactions

It often seems justified to relate the internal secondary field of a molecule in solution for any orientation relative to the direction of the external primary field to a magnetic "point dipole" of well defined position within the molecule. (The center of this point dipole is generally at the nucleus of a paramagnetic transition metal ion, but not necessarily at the center of a cyclic π-electron system.) Δ_i^{dip} can then be expressed as a function of the internal molecular coordinates r_i, ϑ_i and ω_i (see Fig. 4) and the three principal components χ_x, χ_y and χ_z of the measurable magnetic susceptibility[23,24] (N_L = Loschmidt's constant).

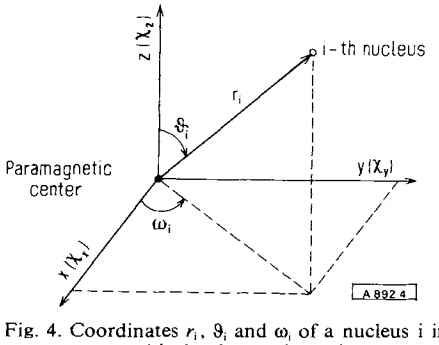

Fig. 4. Coordinates r_i, ϑ_i and ω_i of a nucleus i in the coordinate system x, y, z with the three principal components χ_x, χ_y, and χ_z of the magnetic susceptibility.

$$\Delta_i^{dip} = -D'G_i - D''G_i' \tag{4}$$

$$D' = \frac{1}{3N_L}(\chi_z - 1/2\chi_x - 1/2\chi_y) \quad (5a); \qquad D'' = \frac{1}{2N_L}(\chi_x - \chi_y) \tag{5b}$$

$$G_i = \frac{3\cos^2\vartheta_i - 1}{r_i^3} \quad (6a); \qquad G_i' = \frac{\sin^2\vartheta_i \cos 2\omega_i}{r_i^3} \tag{6b}$$

The equations (5a)—(6b) are valid for certain types of relaxation conditions which are particularly frequently encountered[22].

Particularly important for the shift reagent technique is the special case of an *axially* symmetric secondary field, defined by: $\chi_z \equiv \chi_\parallel$; $\chi_x = \chi_y \equiv \chi_\perp$.

This case applies, for instance, to metal complexes with axially symmetric ligand fields, but also to the example in Fig. 1b. Since $D'' = 0$, equation (4) reduces to

$$\Delta_i^{dip}(ax) = -D'G_i \tag{7}$$

Contrary to the non-axially symmetric case the $\Delta_i^{dip}(ax)$-values of a system are directly proportional to the corresponding "geometric factors" G_i:

$$\Delta_1^{dip} : \Delta_2^{dip} : \Delta_3^{dip} \; etc. = G_1 : G_2 : G_3 \; etc. \tag{8}$$

Unfortunately, the rigorously axially symmetric case is rarely met in practice[161,162]. However, in a number of S—R systems with lower symmetry the second term in equation (4) should average to zero because of the rotations of S relative to R which are often very fast on the NMR time scale. It is, nevertheless, most essential that—in accordance with equations (4) and (7)—Δ_i^{dip} is proportional to r_i^{-3} in all cases (cf. Section 4.1).

For the case of a non-axially symmetric complex where the substrate rotates freely around an axis running through the metal ion, the following equation has been proposed[162]:

$$\Delta^{dip} = \frac{1}{2r^3}[-D'(3\cos^2\alpha - 1) - D''\sin^2\alpha\cos 2\beta](3\cos^2\gamma - 1) \tag{9}$$

The angle γ is included by the radius vector r_i (Fig. 4) and the rotation axis of the substrate; α and β refer to the position of the rotation axis in analogy to ϑ and ω.

The spectral shifting potential of a shift reagent is determined by its anisotropy parameters D' and D'', which are usually temperature dependent[163]. In the series of axially symmetric, organometallic shift reagents of the type $(C_5H_5)_3Ln(III)$[27,144] with Ln = La through Lu, the parameter $D'(ax)$ is proportional to the para-

magnetic shift Δ_j^{para} of a specified proton of the substrate S. If S = cyclohexylisonitrile, the variation of $D'(ax) = -\Delta_\delta^{para}/G_\delta$ is quite pronounced (Fig. 5).

A similar periodicity has been found for a series of homologous chelate adducts $Ln(dpm)_3S_2$[14]. The same very characteristic dependence of Δ^{dip} on the number of f electrons of Ln was confirmed with the magnetic anisotropy parameters very recently determined for the crystalline adducts[162]. It is remarkable that, according to available data for homologous series of lanthanoid complexes, the ions of each of the three "triads" [Ce, Pr, Nd], [Tb, Dy, Ho], and [Er, Tm, Yb] induce dipolar shifts of the same sign[28]. *Bleaney et al.*[163] have just recently given a theoretical explanation for this periodicity.

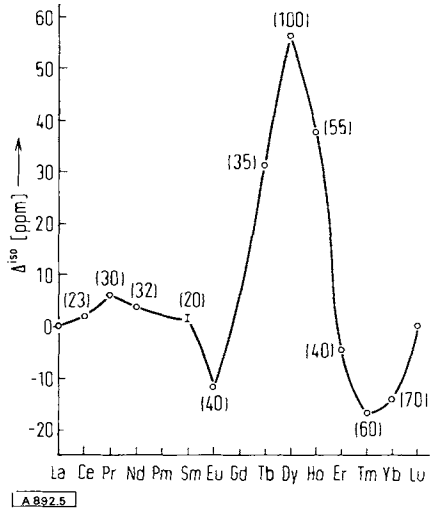

Fig. 5. Isotropic shifts (in ppm) of the C_6H_{11}-protons in δ-position of the adducts between cyclohexylisonitrile and the lanthanoid(III)-tricyclopentadienides, $Ln(C_5H_5)_3$ [7]. Solvent D_8-toluene; $T = 302$ °K, 90 MHz. The linewidths at half-height (Hz) are given in parentheses.

The sign of Δ_i^{dip} can often be predicted more easily than its absolute magnitude: thus, in the example of Fig. 1b we have $\chi_{||}, \chi_\perp < 0$ (diamagnetism) and in the case of the UO_2^{2+} ion $\chi_\perp > 0$ (temperature-independent paramagnetism). Further, $G_i > 0$ and $G_i < 0$, respectively, for the two examples. If $\chi_{ii} < \chi_\perp$, then, according to equations (5a), (6a) and (7), Δ_i^{dip} has a positive sign in the first case (shift to high field) and a negative sign in the second case. Fairly reliable dipolar shifts of protons with known steric positions can be read from modified contour diagrams of the magnetic field of the type shown in Fig. 6 for these two examples.

2.1.2. Contact Interactions

The contact term Δ_i^{con} in equation (3) is proportional to the temperature dependent mean value of the spin polarization $\langle S \rangle$ at the paramagnetic central ion and to a hyperfine coupling parameter A_i (equation (10)).

$$\Delta_i^{con} = K \cdot A_i \cdot \langle S \rangle \qquad (10)$$

A_i is proportional to the transferred unpaired spin density at the nucleus $(r_i, \vartheta_i, \omega_i)$. Equation (10) becomes the more familiar equation (11) in the case of an isotropic "spin-only" system:

$$\Delta_i^{con} = -\frac{\gamma_e}{\gamma_N} A_i \cdot \frac{g_e \beta S(S+1)}{3kT} \qquad (11)$$

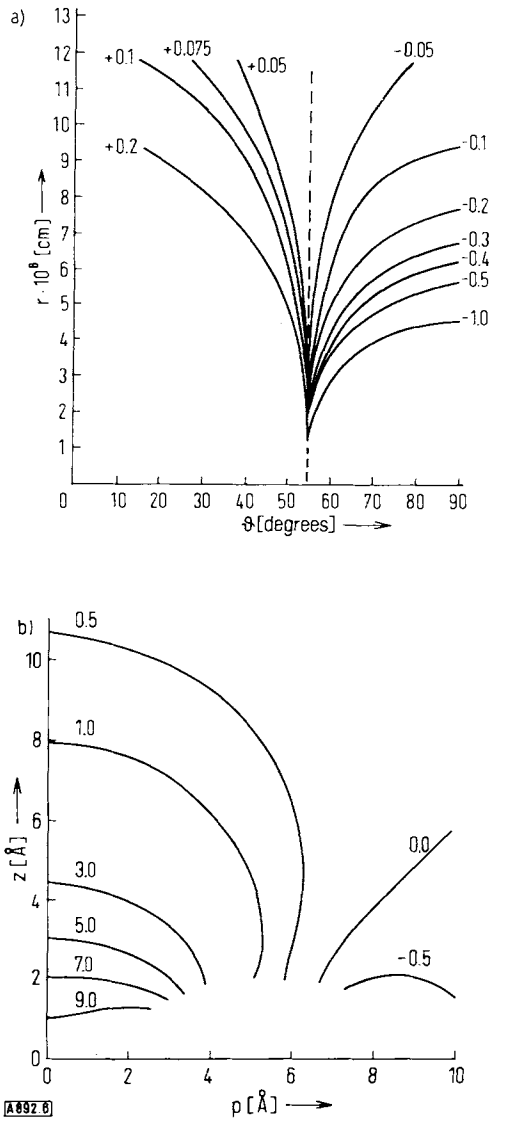

Fig. 6. (a) The anisotropic magnetic field in the vicinity of the UO_2^{2+} ion, expressed by lines of equal isotropic shift (in ppm) ("isoshielding lines") induced on protons in the coordination sphere of the UO_2^{2+} ion [3]. r = distance vector U—H; ϑ = angle formed by r and the principal axis of symmetry O—U—O; the number next to the curves indicate the isotropic shifts Δ^{iso} (ppm). The dashed vertical line corresponds to $\Delta^{iso} = 0$. (b) "Isoshielding lines" (in ppm) of protons under the influence of the anisotropic field of the ring current induced by the π-system of phthalocyanine [126]. Ordinate: distance from the ring center along the fourfold axis; abscissa: distance from the ring center in the ring plane.

In this equation γ_e and γ_N are the magnetogyric ratios of electron and nucleus, respectively; S is the spin quantum number, β the Bohr magneton, and k Boltzmann's constant. In anisotropic systems A_i includes all possible orientations of the molecule tumbling freely in solution, in complete analogy to the parameters D' and D''.

The calculation of A_i is even more difficult than the calculation of D' and D'' [26]. Since there is no means of correlating the contact shift with geometric coordinates, as was shown for the pseudocontact shift, and since a reliable factorization of the experimental shift into the dipolar and contact contributions is not possible in many cases, noticeable contact contributions in the shift reagent technique usually prevent quantitative structural evaluations.

Paramagnetic lanthanoid complexes fulfil the requirement of negligible contact interactions particularly well [60], because the radial extension of the 4f orbitals is exceedingly small. According to experience, however, it is safe to neglect contact contributions even in 4f-systems only if at least three atoms (*i. e.* four bonds) are situated between the nucleus under investigation and the paramagnetic center. From extensive ^{17}O- and ^{1}H-NMR studies of lanthanoid aquo-complexes [29] it was concluded that $\Delta_O^{con} \gg \Delta_O^{dip}$ holds for the O-atoms in the first coordination sphere, whereas the overall shift Δ_H^{iso} of the neighboring H-atoms still contains a contact contribution of at most 60%.

2.2. Dynamic Effects

The equations given in Section 2.1 allow quantitative predictions as to magnitude and sign of the isotropic shifts; they do not, however, contain a term including the linewidth allowing predictions referring to the chances of a signal to be observed. Unfortunately, drastic signal broadenings have to be expected frequently in paramagnetic samples containing unpaired electrons. These may be caused not only by intramolecular spin delocalization, but also by time-dependent intermolecular interactions [19].

These undesirable line broadenings may be partially compensated for if the mean lifetime of the electronic spin states (electron spin-lattice relaxation time T_{1e}) is drastically reduced with respect to the correlation time for the thermal motion of the molecules. Besides extremely low T_{1e} values, rapid changes of the ligand field at the paramagnetic metal ion can also give rise to narrow linewidths.

The term T_{1e}^{-1} clearly corresponds to the rate of transforming the excitation energy of a discrete spin level into thermal energy of the surrounding "lattice" (*i.e.* coordination + solvation sphere). T_{1e}^{-1} increases with increasing temperature and with the strength of the external magnetic field, and, at the same time, with increasing magnitude of the spin-orbit coupling constant, but with decreasing energetic difference between the electronic ground state and the next excited (= ligand field) states. The last two requirements are again fulfilled particularly well by systems containing unpaired 4f or 5f electrons.

Apart from the spin-only system Gd^{3+} (f^7), lanthanoid and actinoid complexes actually exhibit NMR linewidths between a few Hz and several hundred Hz [14, 30, 165]. According to systematic study of the linewidths in the spectra of the adducts $Ln(dpm)_3S_x$ by *Horrocks* [14] and according to general experience complexes of Eu and Pr exhibit the sharpest signals. On the other hand, the signals of most d^n-transition metal complexes are sufficiently narrow only in exceptional cases (Co^{2+} and Ni^{2+}). The detection of the NMR signals of paramagnetic organic radicals is usually prevented by their excessive linewidths.

Chemically, the lifetime of the relevant electronic states can also be reduced by rapid reactions of type (1a)—(1c). Signal narrowing is also to be expected if the adduct S—R is able to alternate between several conformations $(S—R)^I$, $(S—R)^{II}$... *etc.*

3. Systematic Approach to Shift Reagents

3.1. General Requirements

An effective and versatile shift reagent should fulfil at least four requirements:

1. Optimal shifting potential combined with minimal signal broadening effect;

2. ability to interact with a great number of substrates, *i.e.* marked acidic or basic properties;

3. sufficient solubility;

4. absence of interfering absorptions in the usual range of substrate spectra.

Ideal, universally applicable shift reagents cannot be realized: Lewis-acid shift reagents are effective only with basic substrates (and *vice versa*). High reactivity (for instance towards extremely weak bases) is not compatible with the chemical stability required at the same time. A high reactivity even excludes the use of polar solvents, since their functional groups would compete with the substrate.

Requirements 1 to 4 do not yet take into consideration that quantitative information about the molecular structure or the conformational behavior of a substrate is sometimes desirable. With regard to such studies the following requirements should also be fulfilled:

5. Pseudocontact should dominate over Fermi-contact interactions;

6. the secondary fields should have axial symmetry, and the point-dipole approximation should be valid;

7. the adduct S—R should be conformationally uniform (whereas the substrate itself may have several conformations);

8. a straightforward temperature dependence of the isotropic shifts (*e. g.* temperature-independence or linear variation of Δ^{iso} with $1/T$).

Whereas postulates 5 to 7 are the prerequisites for the applicability of equations (4) to (8), postulate 8 is particularly advantageous for conformational studies within wide temperature ranges [27]. This last point, however, has rarely been found to be true [97, 123, 124, 152].

3.2. Types of Shift Reagents Applied

3.2.1. Coordination Compounds Containing Unpaired d of f Electrons

Although numerous examples of the application of d^n-complexes as shift reagents have become known[8-11,34-38,129-131,155], coordination compounds of the rare earth elements have more favorable properties.

The special features of the 4f radial functions[39] of these elements result in an optimal fulfilment of requirements 1 and 5. In addition, the characteristic flexibility of the rare earth ions with regard to their preferential coordination number[146] ensures the spontaneous formation of sufficiently stable adducts.

With respect to their various applications and their chemical nature we classify shift reagents containing unpaired d or f electrons as typical salts, chelates, and organometallics.

3.2.1.1. Salts

Most representatives of this class are simple salts of transition element or lanthanoid ions forming solvated ions—mainly in aqueous solution—which are capable of additionally coordinating a polar substrate (cf. Table 1). Shift reagents of this type are suited only in rare cases to quantitative spectral analyses because of inadequate fulfilment of postulations 1, 6, and 7[115,156]. Such reagents had already been employed for more than a decade[8] before *Hinckley*'s first paper[12].

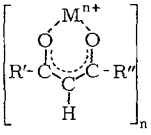

Table 1. Some examples for the application of shift reagents of the salt type to studies on substrates in aqueous solution.

Shift reagent	Substrate	Ref.
$CoCl_2$	*n*-propanol	[8]
$CuCl_2$	carnosine	[40]
$(FeNH_4)_2(SO_4)_3$	amino acids	[41]
$Eu(NO_3)_3 \cdot 6D_2O$	organophosphorus compounds	[42]
$Ln(ClO_4)_3 \cdot 6H_2O$ (Ln = Pr, Eu)	amino acids, carboxylic acids	[43]
$EuCl_3 \cdot 6H_2O$	carboxylic acids	[44]
$EuCl_3$	ribose 5-phosphate	[115]
$EuCl_3$	mononucleotides	[156]

3.2.1.2. Chelates

This category comprises the systems best known and most widely used, including also *Hinckley*'s original reagent $Eu(dpm)_3 \cdot 2pyr$[12]. All representatives of this class (Fig. 7) constitute β-diketonato complexes of the general formula $L_m MX_n$ (L = chelate ligand). In the case of transition metal complexes L_2M at best two coordination sites are available for the substrate. Lanthanoid complexes L_3MX_n with $n = 0$ provide several free, acidic coordination sites. Because of the variability of the coordination number of rare earth elements[146,147], complexes with $n = 1$ or 2 may still exhibit at least one free coordination site, even in the case of *Hinckley*'s reagent (M = Eu, X = pyridine, $n = 2$, formal coordination number: 8).

Voluminous substituents of simple structure are preferably chosen as substituents R (Fig. 7), *e.g.* CH_3, C_6H_5, n-C_3F_7 or $C(CH_3)_3$. Thus postulations 3, 4, and 7 are accounted for.

A 892 7

dpm or tmhd: R' = R'' = $-C(CH_3)_3$

fod: R' = $-C(CH_3)_3$, R'' = $-CF_2-CF_2-CF_3$

Fig. 7. General structure of shift reagents of the chelate type.

The accumulation of voluminous substituents R should limit the number of possible conformations of the shift reagent, especially if $m = 3$[45]. It also diminishes the affinity of the reagent toward water, which, if absorbed, decreases its shifting ability[46-48]. Fluorinated substituents[49,157] enhance the solubility and—presumably through inductive effects—the acceptor strength of the reagent.

For the chelate ligand with $R' = R'' = C(CH_3)_3$[50] the notation "dpm" (from: "*dip*ivalo-*m*ethanato-") or "tmhd" (from: "*t*etra*m*ethyl*h*eptane*d*ionato-") has come into current use in the literature. The ligand with $R' = C(CH_3)_3$ and $R'' = n$-C_3F_7[49,154] is written "fod" (from: "hepta*f*luoro-dimethyl*o*ctane*d*ionato-"). "Fod" complexes are also in use in their perdeuterated forms (postulate 4). A good account of the practical problems connected with the application of lanthanoid shift reagents is given in Ref.[127].

The composition of the adducts formed in solution between a shift reagent and a monofunctional substrate is by no means uniform. Obviously it also depends on the nature of the substrate. Thus, the existence of 1:1 adducts[31b,141] and 2:1 adducts[133] has definitely been proven. So far little is known about the conformations of the adduct in solution. According to recent observations it cannot be excluded that the preferential conformation of an adduct is influenced by the nature of the coordinated substrate[51].

In the crystalline state evidence exists for well-defined adducts between tris(β-diketonato)lanthanoid complexes and 1 to 4 additional ligands, especially water[146,147]. X-ray structure analyses of the 1:2 adducts $Ho(dpm)_3 \cdot 2$(4-picoline)[45] and $Eu(dpm)_3 \cdot 2pyr$[87] provided evidence that the two substrate molecules do not have coaxial positions in the adduct. The symmetry of the complexes is only C_2[162]. Analogous results are provided by the known structures of several crystalline 1:1 adducts[146]. If these results would hold also in solution, axially symmetric ligand fields at the central ion could be expected only in rare cases.

Most chelate reagents are more or less hygroscopic and chemically unstable towards weak acids such as carbonic acids and phenols, and sometimes even alcohols[164]. They are, nevertheless, the shift reagents most widely used today and are certainly the ones best suited for standard applications.

3.2.1.3. Organometallics

The tricyclopentadienyl complexes of several lanthanoids $(C_5H_5)_3Ln(III)$[52] belong to this category. These compounds can coordinate only a single unidentate ligand S:

$$(C_5H_5)_3Ln + S \rightleftharpoons (C_5H_5)_3LnS$$

The acceptor strength of these compounds generally exceeds the acidity of the chelate complexes[125,148]. Thus it is often possible to isolate well-defined 1:1-adducts free of the components. On the other hand, the sensitivity of the organometallic shift reagents towards acids, water, and oxygen exceeds the sensitivity of the chelate complexes considerably. Therefore they have to be manipulated in an inert gas atmosphere and in carefully purified solvents.

Apart from the fact that the shifting potential of the tricyclopentadienyl complexes sometimes exceeds the corresponding chelate complexes, a particular advantage of many adducts $(C_5H_5)_3LnS$ is the C_{3v} point symmetry of the effective ligand field at the central ion[*]. Such systems fulfil postulates 6 and 7 and thus often allow quantitative evaluations of the observed spectra with respect to refined structural and conformational analyses[7,27,144].

Although the solubility of the free complexes $(C_5H_5)_3Ln$ in inert media like benzene or toluene is often rather limited, the solubilities of the adducts often turn out to be quite high, depending on the substrate [*e.g.* $(C_5H_5)_3Nd$: *ca.* 1 mg/ml; $(C_5H_5)_3Nd$·nicotine: *ca.* 100 mg/ml].

3.2.2. Shift Reagents without Unpaired d or f Electrons

3.2.2.1. Metal-free Radical Systems

Organic nitroxide radicals often exhibit electron spin-lattice relaxation times which—in contrast to other stable organic radicals—allow relatively sharp NMR signals to be observed. Therefore utilization of systems like $(CH_3)_2NO$ or $[(CH_3)_3C]_2NO$ as shift reagents was attempted[53,54]. In contrast to the acidic metal complexes these compounds tend to interact with acidic substrates. This fact has been made use of in the investigation of hydrogen bonds.

Moreover, nitroxide radicals can weakly interact with other organic radicals thus reducing drastically the originally very large T_{1e} values of these compounds. By this means the NMR spectra of several organic radicals could be observed[55,56].

3.2.2.2. Non-radical Shift Reagents

This category comprises those systems which develop a noticeable anisotropy either through a strong induced diamagnetism (*e.g.* in cyclic π-electron systems, Fig. 1b) or through temperature-independent paramagnetism (*e.g.* UO_2^{2+}). Another shift reagent of this class is iron(II)phthalocyanine, FePc, which is paramagnetic. On axial coordination of two bases like amines, however, the resulting quasi-octahedral, low-spin complex $FePcS_2$ is diamagnetic[126].

The advantages of shift reagents of this category are sharp signals and temperature-independent isotropic shifts. Their resolving power, however, is only exceptionally equivalent to shift reagents with unpaired electrons.

Recently, the use of some anionic π-electron systems as shift reagents (*e.g.* $[B(C_6H_5)_4]^-$ or $[P(C_{12}H_8)_3]^-$) has been reported[57]. These compounds are especially suited to reaction with cationic substrates in strongly polar solvents. The results published so far deal mainly with short-lived ion pairs of these anions with various—in some cases chiral—quaternary phosphonium ions.

4. Analysis of Shifted Spectra

4.1. Concentration Dependence of the Isotropic Shifts

The concentration dependence of the isotropic shift of a substrate signal averaged over all possible species present in solution can be expressed most clearly by the equilibrium concentrations of the free and complexed substrate:

$$\delta_{exp} = n_{R-S} \cdot \delta_{R-S} + n_S \cdot \delta_S = n_{R-S}(\delta_{R-S} - \delta_S) \quad (12)$$

In this equation, n_{R-S} and n_S are the molar fractions of the adduct and the substrate, respectively.

Practically, however, only the initial concentrations $[R]_0$ and $[S]_0$ of the shift reagent and substrate are usually known. One is forced, therefore, to express δ_{exp} as a function of $L = [R]_0/[S]_0$ instead of the molar fractions. In diagrams of both $\delta_{exp} = f(n_{R-S})$ and $\delta_{exp} = f(L)$ curves of the type shown in Fig. 8a are obtained.

In the first case, the extrapolated ordinate intercept and the slope of the linear part are always equal to δ_S (= chemical shift of the free substrate) and $\delta_{R-S} - \delta_S$, the "molar isotropic shift" of the 1:1-adduct. The analogous correlation in the second case can be approximated only with the restriction that $[R]_0 \ll [S]_0$ and the formation constant K[31] of the adduct is sufficiently large. The main reason is that, as was observed experimentally[47,141], the slope of the linear sections in diagrams $\delta_{exp} = f(L)$ depend noticeably on the absolute substrate concentration.

Several authors have derived equations allowing the evaluation of δ_{R-S} and K with satisfactory accuracy[141-143,169]. According to *Armitage et al.*[141,159], a diagram $[S]_0 = f(\delta_{exp}^{-1})$ in the concentration range $[S]_0 \gg [R]_0$ at constant $[R]_0$ yields straight lines:

$$[S]_0 = [R]_0 \cdot \delta_{R-S} \cdot \delta_{exp}^{-1} - ([R]_0 + K^{-1}) \quad (13)$$

[*] The assumption of this relatively high symmetry is justified for the NMR experiment in view of the proven free rotation of the C_5H_5-rings.

From the slope and the y-intercept of such a straight line the chemical shift δ_{R-S} and the formation constant K of the adduct can easily be obtained. These two parameters are occasionally termed "intrinsic LIS parameters" (*l*anthanoid *i*nduced *s*hift)[143]. Fig. 8b is a diagram of $[S]_0 = f(\delta_{exp}^{-1})$ showing the straight lines obtained for the three different protons of *n*-propylamine in the presence of $Eu(dpm)_3$[159]. It is remarkable that for the three protons the intercepts are identical (thus resulting in an identical K value), although the slopes (and thus the values δ_{R-S}) vary markedly.

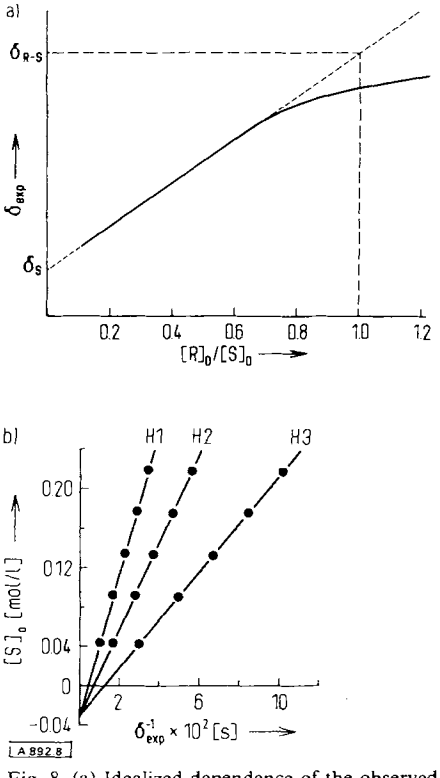

Fig. 8. (a) Idealized dependence of the observed shift δ_{exp} on the molar ratio of the initial concentrations of shift reagent $[R]_0$ and substrate $[S]_0$. δ_S = Chemical shift of the free substrate, $\delta_{R\ S}$ = shift of the 1:1-adduct. (b) Plot of $\delta_{exp}^{-1} = f([S]_0)$ for the three different protons of *n*-propylamine at constant $Eu(dpm)_3$ concentration (*ca.* 0.006 M in $CDCl_3$) [159].

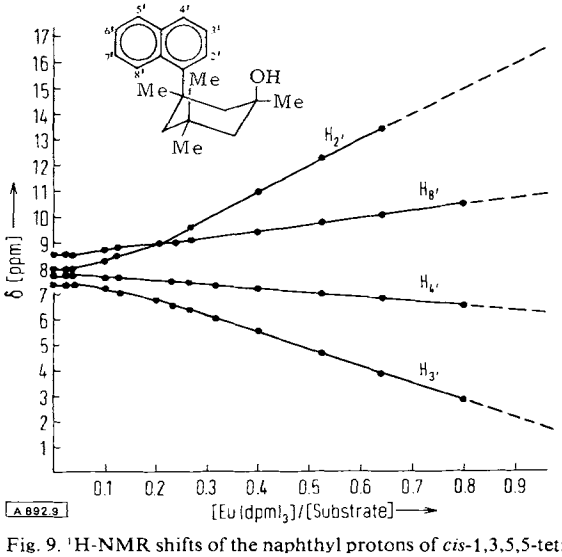

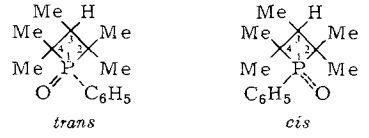

Fig. 9. ^{1}H-NMR shifts of the naphthyl protons of *cis*-1,3,5,5-tetramethyl-5-(1-naphthyl)cyclohexan-1-ol as a function of the $Eu(dpm)_3$ concentration [33].

Equation (13) is valid only for 1:1 adducts. Suitable modifications can be obtained, however, taking into account different stoichiometries. Unknown adduct compositions may thus be determined[151,159].

Deviations of the idealized curve shown in Fig. 8a at higher values of L may be caused by the finite magnitude of K or by the self-association of $Pr(dpm)_3$ and $Eu(dpm)_3$ which has been proved independently also in solution[32]. Occasionally curvatures at low L values are also observed (Fig. 9)[33]. However, a determination of the chemical shifts δ_S by extrapolation appears to be justified in most cases[10,34]. If either substrate or shift reagent are polyfunctional, the plots $\delta_{exp} = f(L)$ may be completely curved or may exhibit several linear parts (cf. Section 5.2).

4.2. Graphical Signal Assignment

Frequently the problem of signal assignment can rapidly be solved by making use of the fact that the isotropic shifts decrease with increasing distance of the respective nuclei from the bonding site between shift reagent and substrate. An example is the distinction between the *cis*- and the *trans* form[58,59,78,145,153] of geometric isomers, as in the case of a phosphetane (Fig. 10)[61].

Δ^{iso}(H-3) = 160 Hz Δ^{iso}(H-3) = 224 Hz

Fig. 10. Isotropic shift of the 3-proton in *cis*- and *trans*-2,2,3,4,4-pentamethyl-1-phenylphosphetan-1-one after addition of 0.48 equivalents of $Eu(dpm)_3$ in $CDCl_3$ [61].

Because of the direct proportionality between Δ_i^{dip} and r_i^{-3} [cf. equations (4) and (7)] it is usually practical to plot these quantities on a logarithmic scale[62,63]. In the case of axial symmetry one gets on taking the logarithms of equation (7):

$$\log|\Delta_i| = -3\log r_i + [\log|(3\cos^2\vartheta_i - 1)| + \log|D|] \qquad (14)$$

As long as the term in the brackets is constant, equation (14) is the function of a straight line with slope -3. The essential requirement for this term to be constant is:

$$\log|D| \gg \log|(3\cos^2\vartheta_i - 1)|$$

If this condition holds, ϑ may take all values between 0 and *ca.* 50°, and between 60 and *ca.* 90°. Since with $\vartheta = 54.7°$

$$\log(3\cos^2\vartheta_i - 1) = -\infty$$

large deviations from linearity are to be expected in the critical angular range $50° < \vartheta < 60°$.

Fig. 11 shows the diagram $\log\Delta_i = f(\log r_i)$ for the two conformers present at $-70\,^{\circ}C$ of the compound $(C_5H_5)_3PrCNC_6H_{11}$ with the cyclohexane ring equatorially or axially substituted[27]. The deviation from the best straight line with slope -3 of the points with ϑ-values close to the critical range is obvious.

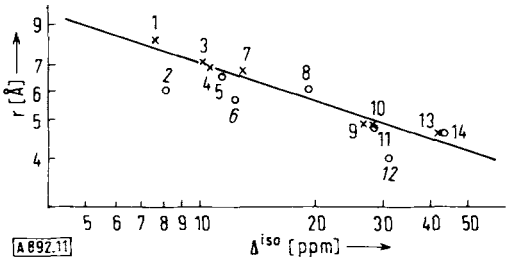

Fig. 11. The isotropic shifts Δ^{iso} of the C_6H_{11}-signals in the ^{1}H-NMR spectrum of $(C_5H_5)_3PrCNC_6H_{11}$ at $-70\,^{\circ}C$ as a function of the geometric parameters r(Å) and ϑ; slope of the best straight line: -3.2 [27].

1 = δ-H (Ee), $\vartheta = 9^{\circ}$	8 = β-H (Aa), $\vartheta = 14^{\circ}$
2 = δ-H (Ae), $\vartheta = 39^{\circ}$	9 = β-H (Ea), $\vartheta = 24^{\circ}$
3 = γ-H (Ee), $\vartheta = 20^{\circ}$	10 = β-H (Ee), $\vartheta = 24^{\circ}$
4 = δ-H (Ea), $\vartheta = 20^{\circ}$	11 = β-H (Ae), $\vartheta = 26^{\circ}$
5 = δ-H (Aa), $\vartheta = 24^{\circ}$	12 = γ-H (Aa), $\vartheta = 37^{\circ}$
6 = γ-H (Ae), $\vartheta = 35^{\circ}$	13 = α-H (E), $\vartheta = 13^{\circ}$
7 = γ-H (Ea), $\vartheta = 12^{\circ}$	14 = α-H (A), $\vartheta = 13^{\circ}$

A = axially substituted conformation
E = equatorially substituted conformation
a = axial proton
e = equatorial proton
Underlined numbers = points with greatest deviation from the best straight line.

In the case of protons separated from the metal ion by only three bonds (*e.g.* the α-protons in alcohols or epoxides[63–65]), the large deviations frequently encountered from the best straight line have been tentatively interpreted with the assumption of Fermi-contact interactions (see Section 2.1.2). *Farid et al.*[66], however, could prove for two such cases[62,67] that these deviations were due to the neglect of the angular dependence.

From equation (14) it can be deduced that a better fit of all points to the straight line should be achieved by appreciably increasing the anisotropy factor D (*i.e.* by replacing the Pr ion by Tb(III) or Dy(III), cf. Fig. 5).

Occasionally, in the diagram $\log\Delta_i = f(\log r_i)$ straight lines with slopes smaller than -3 have been found[67–75,137]. In spite of the approximations used which are responsible for this effect[76], reliable assignments were achieved in these cases also.

4.3. Position of the Metal Atom

The distances r_i can be determined from molecular models (*e.g.* Dreiding). The metal-ligand distances should be known for this procedure; if they are not, they must be approximated. In some cases sufficiently linear plots of $\log\Delta_i = f(\log r_i)$ were obtained even when r_i was put equal to the distance between the atom i of the substrate and the periphery of the lone pair at the donor atom[67–69]. Using this method, *Ernst*[75] found, *e.g.*, that the preferential conformation of 2,6-dimethylcyclohexylamine is that shown in Fig. 12. It appears to be somewhat more realistic to express the distance metal-donor atom as the sum of the two covalent radii[64].

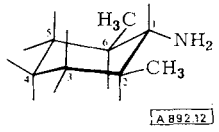

Fig. 12. Preferential conformation of 2,6-dimethylcyclohexylamine [75].

Sanders and *Williams*[77] found the distance between Eu ion and O atom in the adduct of 4-*tert*-butylcyclohexanone and $Eu(dpm)_3$ shown in Fig. 13a by iterative adjustment of the distances r with the isotropic

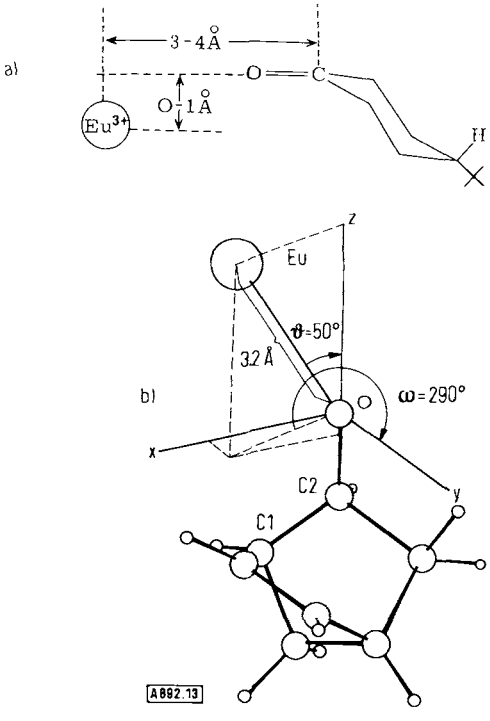

Fig. 13. (a) Probable position of the Eu(III) ion in the adduct between $Eu(dpm)_3$ and 4-*tert*-butylcyclohexanone [77]; (b) Most probable position of the Eu(III) ion in the adduct between $Eu(dpm)_3$ and *endo*-norbornenol [139]. The O atom is at the origin of the internal coordinate system, the O—C-2 bond is placed along the negative z axis, atom C-1 is placed in the x—z plane with the positive x coordinate.

shifts. Such iterations can conveniently be carried out by computer[66,139,140,156], especially if the angular term and internal rotations are also taken into consideration. The adduct of $Eu(dpm)_3$ with *endo*-norbornenol[139,140] is an example (Fig. 13b). The distances Eu—O or Yb—O thus obtained in adducts with shift reagents of the chelate type are generally between 3.0 and 3.5 Å[78–80]. In the case of fluorenone and 1-indanone, however, a satisfactory correlation was obtained with a distance Yb—O of 1.5 ± 0.2 Å[81] (Fig. 14). The results of two structure determinations by X-ray methods in the solid state are, for comparison: Ho—N in $Ho(dpm)_3(4\text{-picoline})_2$ 2.53 Å[45] and Eu—N in $Eu(dpm)_3(pyr)_2$ 2.65 Å[87].

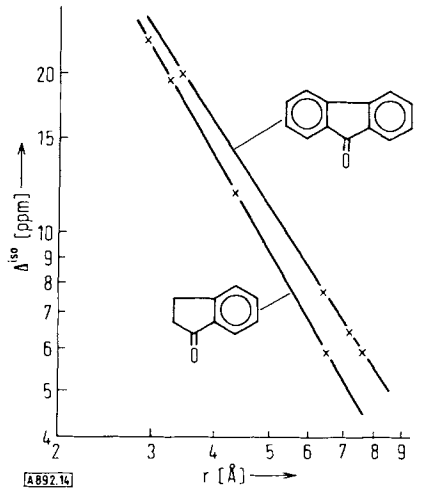

Fig. 14. The isotropic shifts as a function of the distance r in the adducts between Yb(dpm)$_3$ and fluorenone and 1-indanone, respectively [81].

4.4. Influence of the Angular Term

If the angular dependence of G_i [equation (6)] is taken into account, the correlation between the Δ_i-values and the geometric factors is generally improved[27,48,66,82,83,138].

Thus, in the case of the axially symmetric adduct $(C_5H_5)_3PrCNC_6H_{11}$[27] the standard deviation of the best straight line $\log\Delta_i = f(\log r_i)$ is 25.6% (Fig. 11), whereas it decreases to 2.8% in the plot $\Delta_i = f(G_i)$ (Fig. 15). A similar improvement by nearly an order of magnitude could be achieved with an adduct of a shift reagent of the chelate type[84]. This example shows that it is obviously advantageous not to neglect the term $3\cos^2\vartheta - 1$ also in cases of lower than axial symmetry.

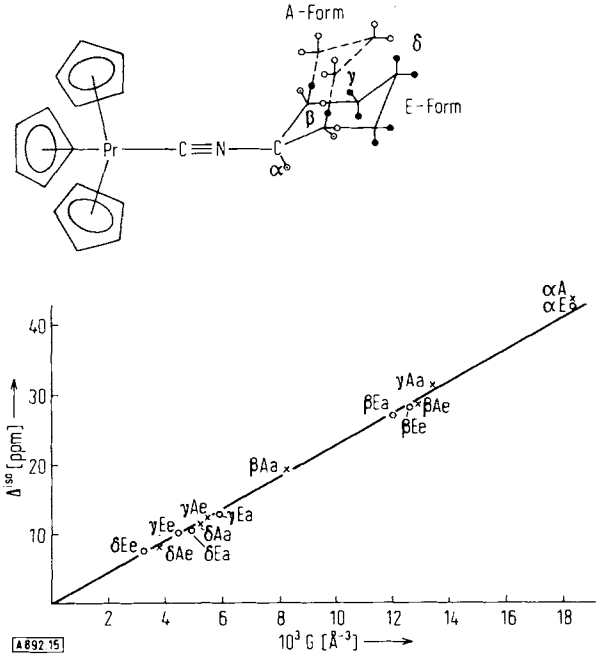

Fig. 15. Correlation between the isotropic shifts measured at -70 °C of the C_6H_{11}-protons and their G-values in the two chair conformers of the adduct $(C_5H_5)_3PrCNC_6H_{11}$ (solvent: D_8-toluene) [27]. The nomenclature used to label the protons belonging to the points of the plot is given in the caption to Fig. 11.

The change of sign of this term at $\vartheta = 54.7°$ is responsible for the occasional observation of shifts to high field using Eu complexes, which generally cause shifts to lower field[33,44,85,86,88,89]. For instance, in the alcohol shown in Fig. 9 the signals of the naphthyl protons 3′ and 4′ are shifted, contrary to the signals of all other protons, to high field[33]. These results are explained in a straightforward manner by the coordination of the Eu ion at the axial OH-group.

4.5. Internal Rotations

In substrate molecules with internal rotational degrees of freedom which cannot be frozen-in in the temperature range used for the measurements, the Δ_i-values have to be correlated with mean G_i values taking into account all possible rotamers. The mean G_i value is influenced most strongly by internal rotations whose rotational axes do not coincide with the principal axis of symmetry of the complex. Equation (9) has been proposed for the case that the metal ion lies within the rotation axis[162].

From the good correlation in the diagram $\Delta_i = f(G_i)$ of $(C_5H_5)_3PrCNC_6H_{11}$[27] (Fig. 15) a linear Pr—CN≡N arrangement along the threefold principal rotation axis of the complex can be deduced. For the analogous alkoxy-complex $(C_5H_5)_3UC_6H_{11}$[82], however, a quantitative correlation between Δ_i and G_i was not achieved, since the rotation axis O—C in the bent U—O—C group does not coincide with the principal molecular axis U—O. In most cases of this kind an exact determination of the mean G_i values is quite tedious and requires the use of a computer. In unfavorable cases, therefore, only qualitative signal assignments are possible, even if a powerful shift reagent is used.

5. Special Applications

5.1. Determination of Spin Coupling Constants

Shift reagents lowering the order of the spectrum of a substrate without broadening the signals excessively, simplify the determination of coupling constants[90–93].

Table 2. Coupling constants of *trans*-5-*tert*-butyl-2-methyl-1,3,2-dioxaphosphoran-2-one (Fig. 16).
Upper line: Numbers obtained with computer program LAOCN3.
Lower line: Numbers directly taken from the expanded spectrum.

[Eu(dpm$_3$)] / [substrate]	J_{AB}	J_{AX}	J_{BX}	J_{AP}	J_{BP}
0	−11.1	10.5	4.47	4.14	20.2
0.5	11	11	4	3	20

Table 2 shows the coupling constants of a heterocyclic AA′BB′XY-system (Fig. 16)[94]. The data obtained from an iterative computer analysis of the spectrum of

the free substrate are listed in the upper line, and in the lower line the constants directly read off from the spectrum recorded in the presence of a shift reagent.

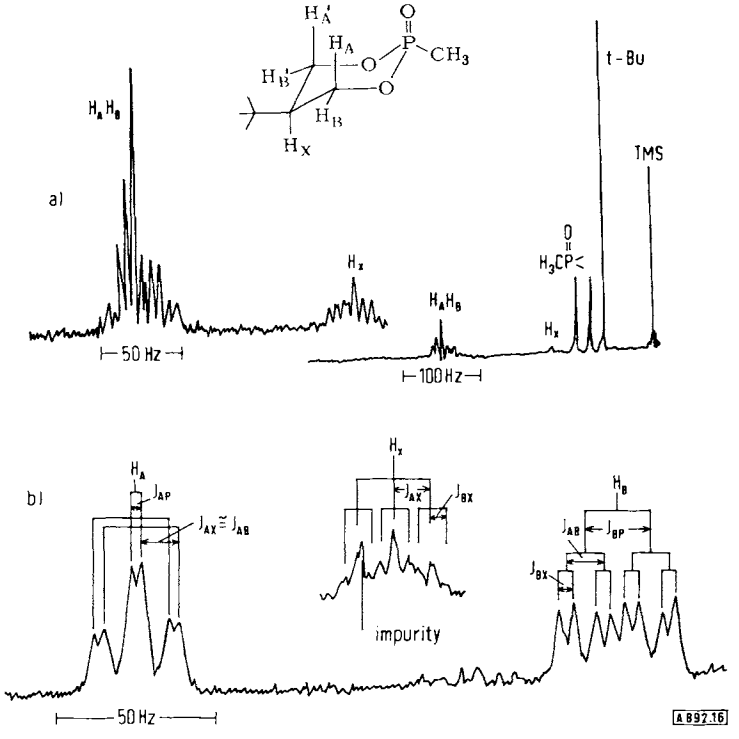

Fig. 16. ^{1}H-NMR spectrum of *trans*-5-*tert*-butyl-2-methyl-1,3,2-dioxophosphoran-2-one [94]. (a) 0.2 M in CCl_4; (b) With 0.5 equivalents of Eu(dpm)$_3$. The coupling constants directly taken from the spectrum are indicated.

The influence of adduct formation on the magnitude of the coupling constants of a substrate is comparable to a substituent effect in all cases where a change of the substrate conformation is negligible[157]. A linear increase of up to 10% in several geminal coupling constants in camphor and 3,5,5-trimethyl-3-(*p*-chlorophenyl)cyclohexane has been noted upon increasing the concentration of the reagents Eu(dpm)$_3$ or Eu(fod)$_3$ up to a molar ratio $L \approx 0.7$[157]. In the case of noticeable contact interactions additional changes of the coupling constants may possibly occur[95,96]. A closer examination of this effect is generally prevented by line broadening.

5.2. Influence of the Basicity of the Substrate; Polyfunctional Substrates

The formation constant of an adduct between a substrate and a shift reagent (cf. Section 4.1) and thus the isotropic shifts of the substrate depend markedly on the basicity of the substrate. Thus, the "molar shift" induced in substrate RX by Eu(dpm)$_3$ decreases in the order $X = NH_2 > OH > C{=}O > -O- > CO_2R > CN$[77]. This series could be extended by some very weakly basic molecules, such as $M{-}SO_2CH_3$, or the organometallics $(C_5H_5)_2Sn$ or $[(C_5H_5)Fe(CO)_2]_2$[98].

Ernst and *Mannschreck*[99] found a linear correlation between the pK_a-values of a series of *p*-substituted anilines and the shift of the phenyl protons in the *o*- and *m*-position obtained at constant Eu(dpm)$_3$ concentration (Fig. 17a).

As important as the basic strength of the substrate are the steric conditions in the vicinity of the basic center[79]. Thus, in the series aniline, *N*-methylaniline, and *N*,*N*-dimethylaniline the shifts decrease in spite of increasing pK_a-values (Fig. 17b)[99].

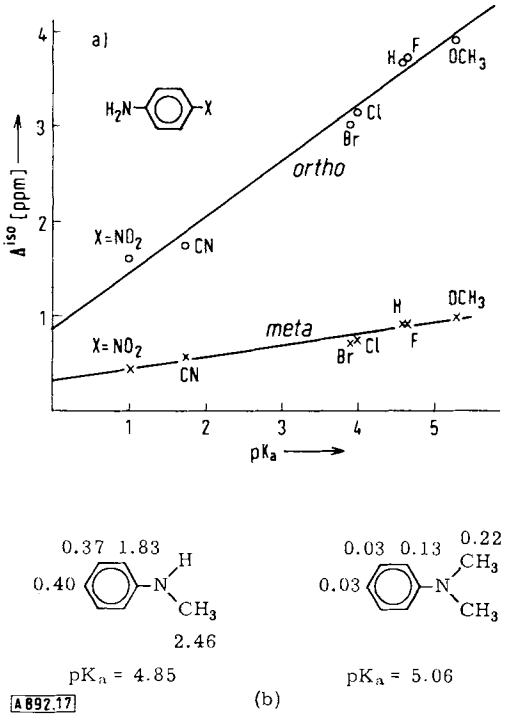

Fig. 17. (a) Correlation between the pK_a-values of *p*-substituted anilines and the isotropic shifts (in ppm) of the *o*- and *m*-protons (molar ratio Eu(dpm)$_3$/substrate = 0.2; solvent $CDCl_3$). (b) Influence of the substitution at the nitrogen of aniline on the isotropic shifts (in ppm) of the phenyl protons [99].

If a substrate molecule contains two donor functions whose equilibrium constants of complex formation with the shift reagent differ greatly (like —OH and $-CO_2R$[100] or P=O and C=O[101]), in the diagram $\delta = f(L)$, where δ is the additive isotropic shift[137], pronounced changes of the slope at the equimolar ratio ($L = 1.0$) for nuclei close to one of the two basic centers are observed. Evidently the weaker basic group does not coordinate before most or all of the stronger function has reacted. Figure 18 shows the results obtained with a substrate carrying an alcohol and an ester function[100].

According to *Hinckley*[63] the contributions of the two donor centers of a bifunctional substrate to the overall shift can be separated graphically in the following manner (Fig. 19): in the diagram $\log\Delta_A = f(\log r_A)$ of testosterone the Δ_A value of proton i very likely originates from Eu(dpm)$_3$ coordinated at the OH-group. It seems justified to draw a straight line of slope -3 through point i, since such a line was experimentally found for the protons of the structurally very similar, but monofunctional cholesterol[12]. The vertical differences of the experimental shifts of protons j and l from this line are equal to the contribution Δ_B resulting from

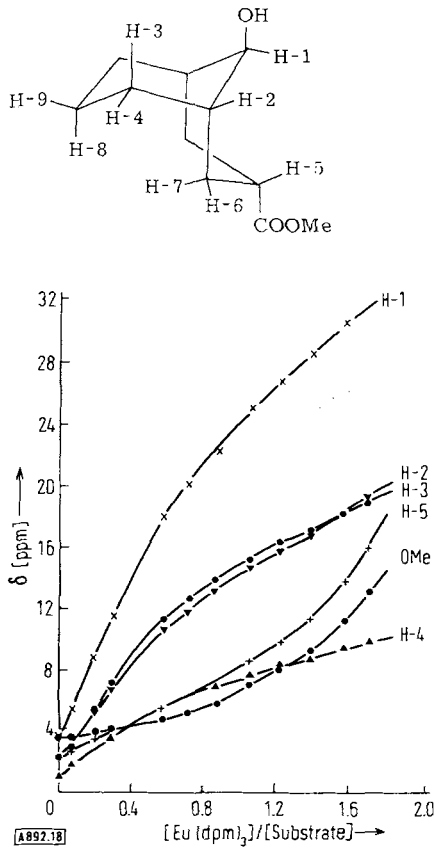

Fig. 18. The chemical shifts (ppm relative to TMS) of the protons of methyl-*trans*-9-hydroxybicyclo(3.3.1)nonane-*endo*-3-carboxylate as a function of the molar ratio $Eu(dpm)_3$/substrate [100].

$Eu(dpm)_3$ coordinated at the carbonyl group. These shifts again fall approximately on a straight line $\log \Delta_B = f(\log r_B)$ of slope -3. The shifts $-\Delta_A$ and Δ_B corresponding to the same distance r are proportional to the complex formation constants K_{CO} and K_{OH}. In this case the ratio $\Delta_A/\Delta_B = K_{CO}/K_{OH} = 0.47$.

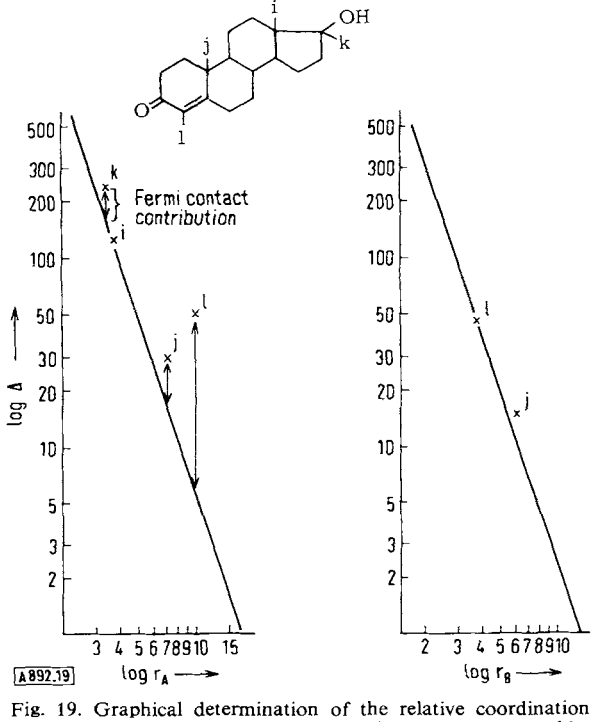

Fig. 19. Graphical determination of the relative coordination strength of the OH and C=O functions in testosterone: double-logarithmic plot of the isotropic shifts Δ (in Hz) of protons i, j, k, and l as a function of the distances r_A and r_B (in Å) (cf. text) [63].

Hart and *Love*[102] determined the relative basic strength of functional groups by inter- or intramolecular competition: under the influence of $Eu(dpm)_3$ an equimolar mixture of acetone-tetrahydrofuran exhibits the molar shifts indicated in Fig. 20a and b. From the changes of the shifts one can deduce that $Eu(dpm)_3$ coordinates tetrahydrofuran about 8 times better than acetone.

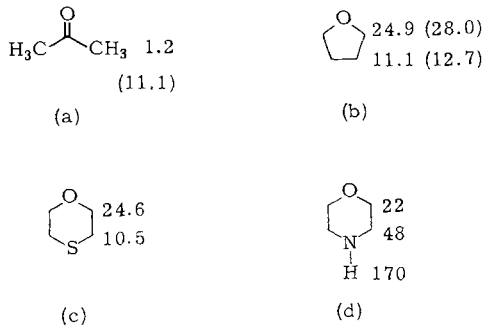

Fig. 20. Extrapolated molar isotropic shifts (in ppm) of the protons of two monofunctional substrates in an equimolar mixture and of two bifunctional substrates on addition of $Eu(dpm)_3$ [102]. In parentheses: values of the pure substances. (a) acetone, (b) tetrahydrofuran, (c) thioxane, (d) morpholine.

Similar competition experiments were carried out with bifunctional molecules (Fig. 20c and d). From a large number of data a series of basicity was deduced which was practically identical to the one cited above.

5.3. Polymers

Solutions of polymers such as polyethylene oxide[103] and poly(methyl methacrylate)[103,104] also display induced shifts upon the addition of lanthanoid chelates leading to a substantial improvement of the resolution of their rather complex NMR spectra. In the case of polypropylene glycol[105] it was possible to separate the ^{1}H-NMR bands of the end methyl groups from the bands of the methyl groups in the polymeric chain, thus allowing determination of the molecular weight by direct comparison of signal intensities.

5.4. Dynamic Processes

Dynamic processes whose reaction rates are in a favorable range on the NMR time scale (rate constant k: 3 to 300 s^{-1}) cause line broadening, and finally line splitting, if the temperature is lowered. At the splitting or coalescence temperature T_c the following approximate correlation holds between the rate constant k_c and the maximum peak separation $\Delta\nu$[106]:

$$k_c = \Delta\nu/\sqrt{2} \qquad (15)$$

Apart from the fact that the rate of such a process can be changed by complex formation with a shift reagent,

the temperature T_c rises if $\Delta\nu$ is increased by the paramagnetic effect. Some processes can therefore be observed better in the presence of a shift reagent, because the broadening and splitting of the signals occurs in a more suitable temperature range.

One has to distinguish between intra- and intermolecular dynamic processes. Intramolecular processes within the substrate are sometimes obscured in the NMR spectrum by intermolecular ligand exchange phenomena[107,108].

Ligand exchange in a system lanthanoid chelate-substrate was observed for the first time by *Evans* and *Wyatt*[133]: in a mixture of $Eu(fod)_3$ with an excess of dimethyl sulfoxide in CD_2Cl_2 the CH_3 signal broadens considerably on cooling the solution to -45 °C (Fig. 21).

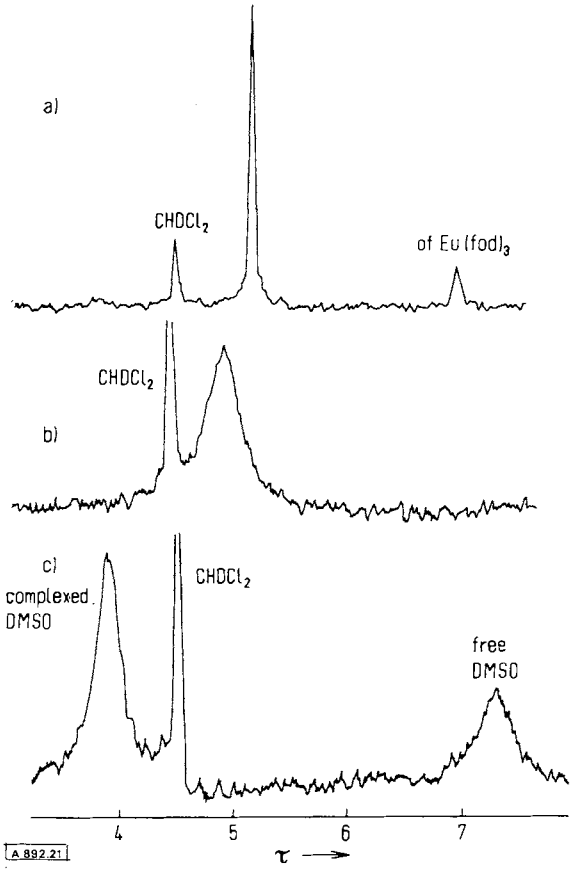

Fig. 21. ^{1}H-NMR spectra of a 0.131 M solution in $CHDCl_2$ of dimethyl sulfoxide (DMSO) after addition of 0.044 M $Eu(fod)_3$ at (a), 38 °C; (b) -45 °C; and (c) -80 °C [133].

At -80 °C this signal splits into signals corresponding to the free and complexed substrate. A stoichiometric ratio S:R = 2:1 can be deduced from the relative intensities of these lines.

The determination of solvation numbers of metal ions (*e.g.* UO_2^{2+}) in solution by the separate observation of the NMR signal of the free and the shifted signal of the complexed solvent at low temperature is a well established technique[111,112].

An intramolecular process observable without the interference of ligand exchange is the rotational isomerism of amides whose coalescence temperature is rather high (50 to 127 °C[20,109]). On addition of $Yb(dpm)_3$ *Beaute et al.*[109] noticed an appreciable increase in the coalescence temperature, but no significant change in the

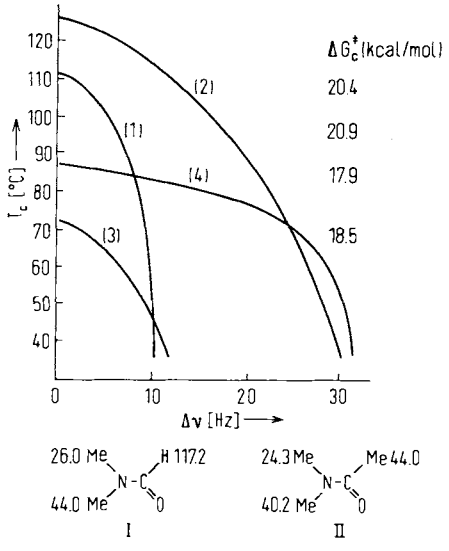

Fig. 22. Coalescence temperatures (T_c) and free enthalpies of activation ($\Delta G_c^{\ddagger}$) for *N,N*-dimethylformamide (I) and *N,N*-dimethylacetamide (II) without and with addition of $Yb(dpm)_3$. The curves represent the temperature dependence of the frequency difference $\Delta\nu$ of the methyl signals [109]. Molar ratio [$Yb(dpm)_3$]/[I]: (1) = 0, (2) = 0.06; [$Yb(dpm)_3$]/[II]: (3) = 0, (4) = 0.05. The numbers at the formulas represent the extrapolated molar shifts (in ppm) of the respective protons.

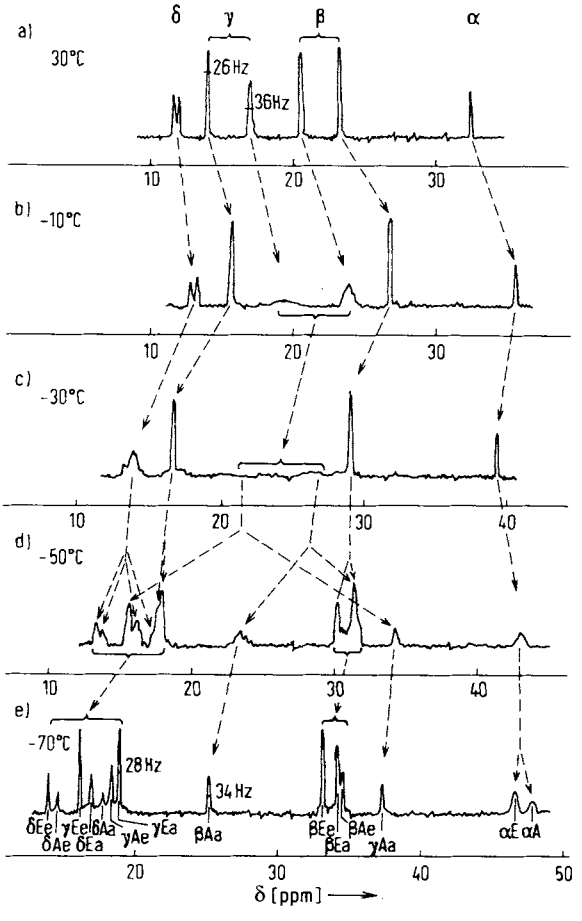

Fig. 23. Temperature dependence of the ^{1}H-NMR spectrum (C_6H_{11}-part) of the adduct between $(C_5H_5)_3Pr$ and CNC_6H_{11} [27]; δ-scale (abscissa) relative to C_6H_6; solvent: D_8-toluene. Nomenclature of the protons the same as in Fig. 11.

free enthalpy of activation of this rotation (Fig. 22). *Schwarzhans*[20], however, found the coalescence temperature in the spectrum of *N,N*-dimethylacetamide unchanged upon complex formation with UBr_4[110]. Thence he deduced that the CO group and not the nitrogen atom is the center of coordination.

The chair-chair interconversion of a monosubstituted cyclohexane (cyclohexylisonitrile) upon adduct formation with $(C_5H_5)_3Pr$[27] was studied by observing the temperature dependence of seven signals of the C_6H_{11} protons. The coalescence temperatures of several signal pairs with particularly large $\Delta\nu$ are raised so much that large signal broadenings occur already at a little below room temperature (Fig. 23).

5.5. Reaction Mechanisms

The mechanism of a reaction which is catalyzed by lanthanoid ions can be studied with the shift reagent technique if these ions can act at the same time as paramagnetic shift reagents on the NMR spectrum of the substrate. Thus, during the decarboxylation of oxaloacetic acid either of the complexes I and II

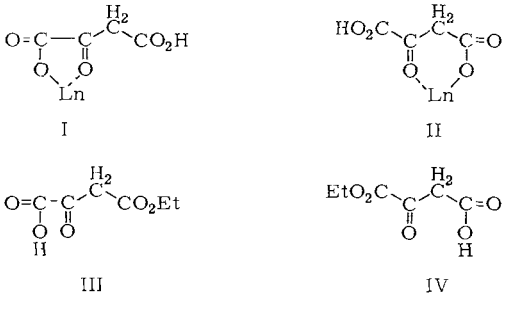

Fig. 24. Possible intermediates (I and II) during the decomposition of oxaloacetic acid catalyzed by Ln(III) ions [44]. III and IV: Substances of comparable structure.

(Fig. 24) can be formed as an intermediate. For the elucidation of the mechanism, *Reyes-Zamora* and *Zsai*[44] prepared the half esters III and IV (Fig. 24). Upon addition of $EuCl_3$ the CH_2 protons of III exhibited the usual low field shift in the ^{1}H-NMR spectrum, in contrast to the signals of IV which were shifted to high field. As oxaloacetic acid shows a low field shift on addition of $EuCl_3$, the authors concluded that the intermediate must have structure I which is the only possible one that the half ester III can form with the metal.

The kinetics of the catalytic deuteration of 4-*tert*-butylhexanone were studied by measuring the intensity decrease of the various ^{1}H-NMR signals of that substrate after spectral simplification with $Eu(dpm)_3$[134].

5.6. Pulsed Fourier-Transform ^{13}C-NMR Spectroscopy

Shift reagents have hitherto been employed almost exclusively in ^{1}H-NMR spectroscopy, not only because the proton is still the nucleus most widely used, but also because the spectral resolution efficiency of the shift reagents is greatest here. However, there are interesting applications in the NMR-spectroscopy of other nuclei, *e.g.* in pulsed Fourier-transform (=P.F.T) ^{13}C-NMR-spectroscopy[113]. The investigation of cholesterol in the presence of $Eu(dpm)_3$[166] is an example.

Gansow et al.[114] assigned the P.F.T. ^{13}C-NMR spectrum of isoborneol, recorded by the common ^{1}H-broadband decoupling technique (Fig. 25). British

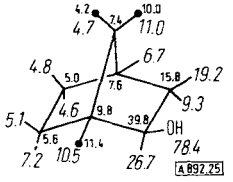

Fig. 25. Isotropic ^{13}C-NMR [114] and ^{1}H-NMR [64, 114] shifts (in ppm) of isoborneol (0.34 M) in an equimolar mixture with $Eu(dpm)_3$ in CCl_4. CH_3 groups = •; all shifts are to low field; the ^{1}H data are written in italics.

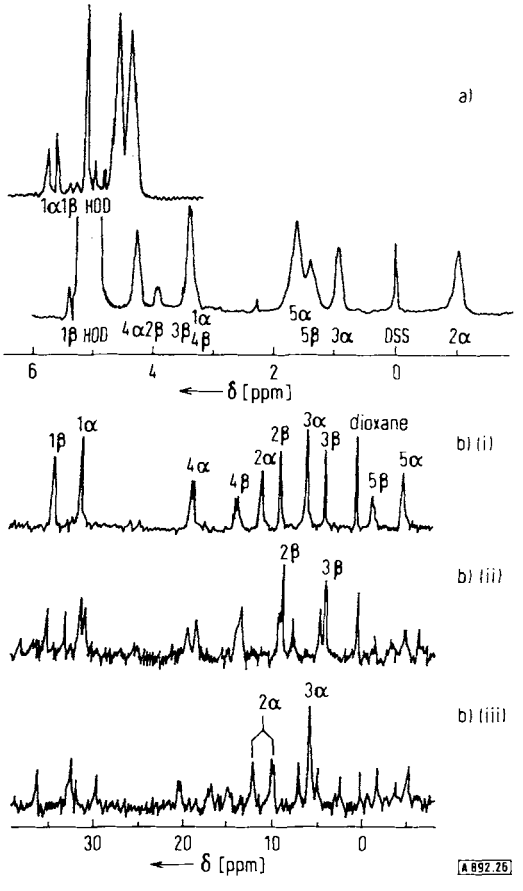
authors[115] expanded the relatively complex ^{13}C-NMR spectrum of ribose-5-phosphate by adding Eu^{3+} ions in aqueous solution. The assignment of the signals was achieved by means of hetero-spin-decoupling: the selective irradiation of definite ^{1}H-decoupling frequencies was feasible only in the spectrum simplified by the Eu ions (Fig. 26).



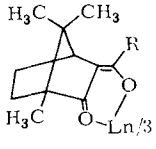


Fig. 26 (a) ^{1}H-NMR spectrum (100 MHz) of ribose-5-phosphate (0.7 M in D_2O) in the absence (above) and in the presence of 0.97 M Eu^{3+} ions at pH = 1.1. DSS = sodium salt of 2,2-*dimethyl*-2-*silapentane*-5-*sulfonic* acid; 1 α to 5 β = nuclei in position 1 to 5 with respect to the phosphate group of the α- and β-anomer, respectively. (b) ^{13}C-NMR spectra (25.2 MHz, P.F.T. technique) of ribose-5-phosphate (0.6 M) with an addition of 0.72 M Eu^{3+} ions [115]; (i) ^{1}H-broad band decoupling; (ii) selective irradiation of the 2β-^{1}H frequency; (iii) selective irradiation at the 3α-^{1}H frequency.

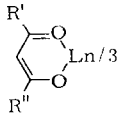
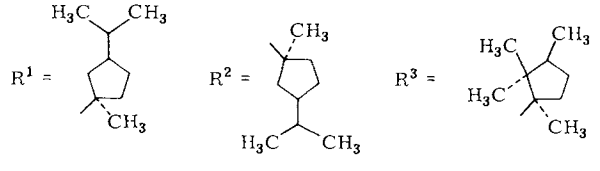


5.7. Chiral Shift Reagents

Pirkle et al.[116,132] noticed that the NMR spectra of the enantiomers of asymmetric compounds (particularly alcohols, α-hydroxy-acids, amines, amino acids and sulfoxides) differ appreciably in optically active solvents, *e.g.* (*R*)-(−)-2,2,2-trifluorophenylethanol. These differences are presumably caused by the formation of diastereomeric adducts between the substrate and the optically active solvent. The latter is to be considered as a chiral shift reagent. The splitting of the spectra results from a different position of the substrate nuclei in the diastereomers with respect to the magnetic field produced by the ring current of the π-system of the solvent.



Prior to the introduction of more efficient chiral shift reagents of the chelate type numerous NMR studies were conducted on paramagnetic complexes of the d-transition elements with asymmetric chelate ligands[117,118]. Primary concern in investigations of this type is directed, however, at the spectra of the chelate ligands. The first chiral shift reagent of the chelate type with a lanthanoid central ion was prepared by *Whiteside* and *Lewis*[119]. Other, similar reagents with praseodymium and europium as central ions were described later[120,121]. Fig. 27 illustrates the effect of the chiral shift reagent *(1)* (Table 3) on the ^{1}H-NMR spectrum of pure (*S*)-α-phenylethylamine and on a mixture of both enantiomers of this substrate. All signals in the spectrum of the pure (*S*)-enantiomer appear doubled in the spectrum of the mixture with the splitting Δ_{chir} being largest for nuclei in the vicinity of the asymmetric center of the substrate. Whereas the utilizability of *(1)* is limited to relatively strong donors like amines, chiral splitting is also induced in the spectra of alcohols, ketones, esters, and sulfoxides by the more acidic chiral shift reagents *(2)* to *(8)* (Table 3). Table 4 gives a survey of the chiral shifting potential of such reagents. A particularly straightforward synthesis of the ligand of chiral shift reagent *(2)* (Table 3) is given in Ref.[149].

Table 3. Chiral shift reagents of the β-diketonato type.

(1) R = $-C(CH_3)_3$
(2) R = $-CF_3$
(3) R = R^1
(4) R = 77% R^2 + 23% R^1
(5) R′ = R″ = R^1
(6) R′ = R^1, R″ = R^3
(7) R′ = 77% R^2 + 23% R^1; R″ = R^3
(8) R′ = R^1; R″ = 77% R^2 + 23% R^1.

The absence of chiral splitting in the case of enantiotopic[150] pairs of nuclei in otherwise nonchiral substrates (*e.g.* the methyl groups in 2-propanol or dimethyl sulfoxide)[120] as well as the dependence of Δ_{chir} on the concentration ratio reagent: substrate[119] is consistent with the assumption that the formation of conformationally stable diastereomers is an essential requirement for the spectral splitting. In particular, if the formation constants of the diastereomers differ measurably, the assumption seems justified that different geometric factors correspond to analogous nuclei of the substrate in the diastereomeric pair. A comparison of the Δ_{chir} values given in Table 4 with comparable data of diastereomeric systems without unpaired electrons[122]

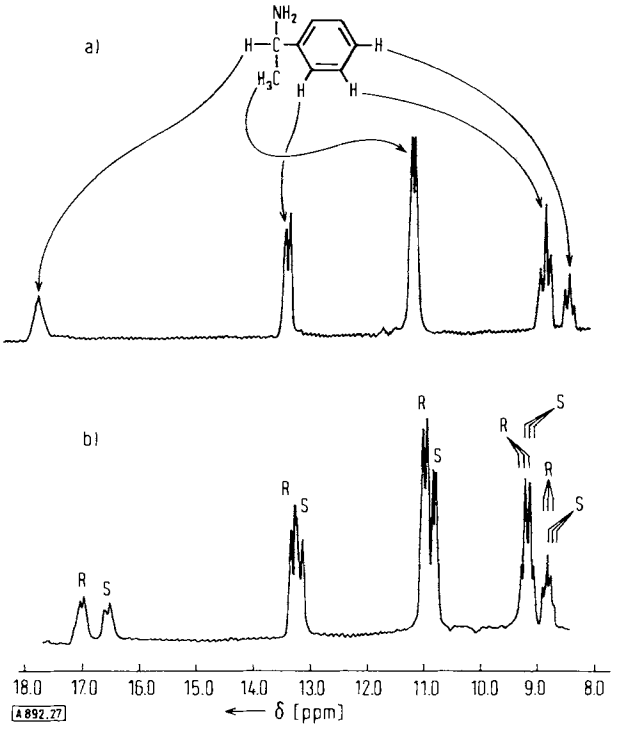


Fig. 27. ^{1}H-NMR spectra of α-phenylethylamine in CCl_4 after addition of tris[(3-*tert*-butylhydroxymethylene)-D-camphorato]-europium(III) [119]. Molar ratio [Eu-complex]/[substrate]: 0.5 to 0.6. (a) Pure (*S*)-form of the amine; (b) mixture of (*S*)- and (*R*)-form.

Table 4. Signal shifts Δ_{chir} induced by chiral shift reagents (R).

Substrate	Proton	R [a]	Δ_{chir} (ppm)	[R] / [substrate]
2-octanol	α-CH_2	*(2)*	0.11	>0.6
1-phenylethyl acetate	—CO_2—C(H)—CH_3	*(2)*	0.18	>0.6
1-methyl-2-norbornanone	1-CH_3	*(2)*	0.17	>0.6

benzyl methyl sulfoxide	—CH_2S—	*(3)*	0.32	*ca.* 1.3
		(8)	0.40	*ca.* 0.8
2-butyl formate	O—C(H)—CH_3	*(3)*	0.00	*ca.* 1.3
		(8)	0.10	*ca.* 0.8

[a] The numbers refer to the compounds in Table 3.

shows that the anisotropic field of the lanthanoid ion improves the splitting of the spectrum by approximately an order of magnitude.

5.8. Isotope Effects

A further interesting application of shift reagents of the chelate type was found by *Hinckley et al.*[135,136] and other authors[151,167,168]: the ^{1}H-NMR spectra of alcohols partially deuterated at the position geminal to the OH-group are doubled under the influence of Eu complexes. The isotropic shifts of the doubled signals differ by 1 to 3.5%. The authors discuss as possible reasons for this splitting a change in the basicity of the hydroxyl oxygen by the deuterium substitution or differences in the strength of a secondary hydrogen bonding between the geminal H (or D) and the ring oxygens of the metal chelate ligands.

Organic Syntheses *via* Free-Radical Displacement Reactions of Organoboranes[**]

By Herbert C. Brown and M. Mark Midland[*]

In the few short years since the discovery that organoboranes undergo facile free-radical substitution, application of these reactions has become a major new area of synthetic utility. Organoboranes undergo a wide variety of free-radical reactions such as autoxidation to the alcohol or hydroperoxide, 1,4 addition to α,β-unsaturated derivatives, addition to disulfides, and oxygen-induced radical coupling. It is evident that organoboranes constitute a versatile new source of free radicals and that these reactions can be readily controlled to give very clean syntheses. The application of these reactions will be discussed.

1. Organoboranes as Excellent Sources of Free Radicals

Recognition that the organoboranes are excellent sources of free radicals and can participate in free-radical chain reactions came about through detailed mechanistic studies of the reaction of organoboranes with oxygen[1-3] and with α,β-unsaturated carbonyl compounds[4].

Originally, it was suggested that the autoxidation of a trialkylborane proceeds *via* an intermediate "borineperoxide" (*1*)[5]. More recently, it was recognized that

$$R_3\overset{\ominus}{B}-\overset{\oplus}{O}=O \qquad (1)$$

these peroxides are true alkyl peroxide derivatives, containing the structure ROOB≤. Thus, the reaction of oxygen with tri-*sec*-butylborane in dilute solution yields the diperoxide (*2*)[6]. However, the formation of these

$$sec\text{-}Bu_3B + 2O_2 \longrightarrow sec\text{-}BuB(O_2\text{-}sec\text{-}Bu)_2 \qquad (2)$$

peroxides was long considered to involve non-radical processes because many of the usual radical inhibitors, such as hydroquinone, had no apparent effect upon the reaction[7].

The oxidation of optically active 1-phenylethylboronic acid gave a racemic product and this was considered to be suggestive of a process involving radicals[1]. Indeed, it was observed that a remarkable induction period occurs in the autoxidation of this compound in the presence of added inhibitors such as copper(II) *N,N*-dibutyldithiocarbamate and galvinoxyl [2,6-di-*tert*-butyl-α-(3,5-di-*tert*-butyl-4-oxo-2,5-cyclohexadien-1-ylidene)-*p*-tolyloxyl][1]. It was then discovered that galvinoxyl also effectively inhibits the autoxidation of triisobutylborane[3], the epimeric trinorbornylboranes[2] and other organoboranes[3]. These findings led to the suggestion that the autoxidation of trialkylboranes proceeds *via* a free-radical chain process[1-3].

$$\begin{aligned} R_3B + O_2 &\longrightarrow R\cdot + R_2BO_2\cdot \\ R\cdot + O_2 &\longrightarrow RO_2\cdot \\ RO_2\cdot + BR_3 &\longrightarrow RO_2BR_2 + R\cdot \end{aligned}$$

Perhaps the most unusual feature about this proposed process is the assumption that a free alkylperoxy radical is capable of rapidly attacking boron with displacement of an alkyl radical, the latter then continuing the chain. Evidence for this reaction course has accumulated rapidly. For example, when di-*tert*-butylperoxide is

[*] Prof. H. C. Brown and M. Mark Midland

Lafayette, Indiana 47907 (USA)

[**] Based in part on Chapter XIX of a forthcoming book (Baker Lectures) by *H. C. Brown:* Boranes in Organic Chemistry. Cornell University Press, Ithaca, N.Y. (USA)

photolyzed in the presence of trimethylborane in the cavity of an ESR spectrometer the ESR spectrum of the methyl radical can be recorded[8].

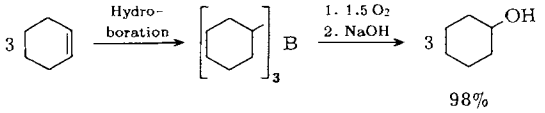
$$(tert\text{-}BuO)_2 \xrightarrow{h\nu} 2\,tert\text{-}BuO\cdot$$

$$tert\text{-}BuO\cdot + B(CH_3)_3 \longrightarrow tert\text{-}BuOB(CH_3)_2 + CH_3\cdot$$

Similar results have been obtained with triethylborane[8] and tri-*n*-butylborane[9]. This reaction, in which an alkyl group is readily displaced by reaction of a free radical containing the odd electron on oxygen ($RO\cdot$)[8,9], nitrogen ($R_2N\cdot$)[12], and sulfur ($RS\cdot$)[13], appears to be of wide generality for the trialkylboranes[10,11].

The ease with which these reactions proceed may be due to the high strengths of the bonds of boron with oxygen, nitrogen, and sulfur, providing a potent driving force for the facile displacement of alkyl radicals from organoboranes. However, irrespective of the precise reason for this new facile reaction, the reaction itself opens up a major new area of application for the organoboranes in free-radical chemistry.

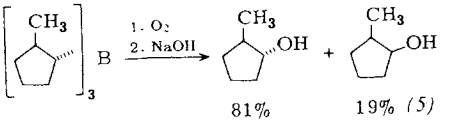
2. The Autoxidation of Organoboranes



2.1. Alcohol Formation

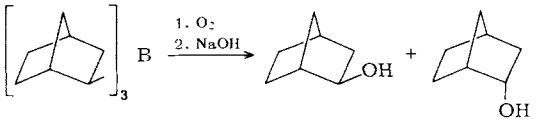
It has long been known that organoboranes, both aliphatic and aromatic, are highly reactive toward oxygen[14]. Considerable attention has been paid to the mechanism of the autoxidation reaction[15]; but the reaction was considered not to hold promise for synthetic purposes[16,17]. Sufficient oxygen is readily absorbed to oxidize all three carbon-boron bonds, but the reaction is reported to be complex. In an unsuccessful attempt to achieve high conversion to the alcohol, long reaction times and elevated temperatures were used in the oxidation.

It is quite clear that the initial product of such oxidations is the peroxide *(3)*[6].



$$R_3B + O_2 \longrightarrow \underset{(3)}{R_2BO_2R}$$

It appeared possible that the low yields were due to the thermal instability of the peroxide. Consequently, gentle conditions (0 °C) were used for the introduction of the stoichiometric amount of oxygen (1.5 mol O_2 per mol R_3B) into a solution of the organoborane (0.5 M) in tetrahydrofuran (THF)[18,19]. The reaction product, possibly $RB(O_2R)OR$, was treated with aqueous alkali. Essentially quantitative yields of alcohol were obtained.



98%

A disadvantage of this procedure is that it does not possess the stereospecificity of the oxidation with alkaline hydrogen peroxide, which, for example, gives *exo*-norborneol in an isomeric purity of 99.5%. Similarly, the alcohol from 1-methylcyclopentene is essentially pure *trans*-2-methylcyclopentanol. The oxidation with oxygen produces a much larger amount of the alternate isomers *(4)* and *(5)*.

81% 19% *(5)*

86% 14% *(4)*

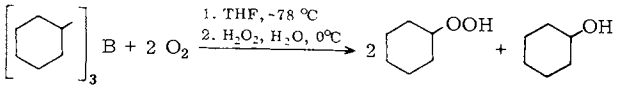
The formation of the alternate isomers is presumably a result of the free-radical chain reaction involved in the uptake of oxygen by the organoborane[2]. In cases where such stereochemical properties are not involved, simple oxidation with oxygen can be utilized to achieve essentially quantitative conversion of the organoborane to the corresponding alcohol. The alternative oxidation with alkaline hydrogen peroxide[20] does not involve free-radical intermediates and is very widely applicable.

2.2. Hydroperoxides

The initial product of the autoxidation of organoboranes is a peroxide *(3)*, which may either react with a second mol of oxygen to give *(6)* or undergo an intermolecular redox reaction to give *(7)*[17]. In concentrated solution (0.5 M) the redox reaction predominates at 0 °C and the peroxide content is substantially decreased.

$$\underset{(3)}{RO_2BR_2} + O_2 \longrightarrow \underset{(6)}{(RO_2)_2BR}$$

$$\underset{(3)}{RO_2BR_2} + R_3B \longrightarrow \underset{(7)}{2ROBR_2}$$



Control over formation of *(6)* and *(7)* would provide a useful route to alkyl hydroperoxides. Indeed, the intermolecular reaction has been minimized by using highly dilute (0.01 – 0.05 M) solutions. Two mols of oxygen are absorbed to form a diperoxide *(6)*. The remaining boron-carbon bond was then oxidized by the addition of an oxidizing agent such as perbenzoic acid[7]. Consequently, the autoxidation of dilute solutions of organoboranes provides a possible synthesis for alkyl hydroperoxides[21]. However, the procedure suffers from several disadvantages. It would be much more convenient if the synthesis could be realized using relatively concentrated solutions of the organoborane in THF, the preferred solvent for hydroborations.

Examination of the autoxidation of 0.5 M solutions of organoborane in THF at −78 °C using the automatic

gas generator[19] (adapted for oxygen production[18]) revealed that the reaction is initially very fast, even at this low temperature[22]. The first mol of oxygen is absorbed within 2 – 3 minutes. Organoboranes produced from disubstituted olefins having internal double bonds, such as cyclohexene, absorb the second mol of oxygen within a period of 1 hour. On the other hand, organoboranes produced from olefins with terminal double bonds, such as 1-butene, fail to absorb the second mol of oxygen at this temperature. In both cases, however, warming to 0 °C results in the rapid absorption of a second mol of oxygen. Addition of a 30% aqueous solution of hydrogen peroxide to the reaction mixture at 0 °C liberates the alkyl hydroperoxide with concurrent oxidation of the remaining boron-carbon bond. The reaction is applicable to a wide variety of structures and gives excellent results.

$$n\text{-}Bu_3B + 2\ O_2 \xrightarrow[-78\,^\circ C \rightarrow 0\,^\circ C]{THF} n\text{-}BuB(O_2Bu)_2 \xrightarrow[H_2O]{H_2O_2} 2\ n\text{-}BuOOH + n\text{-}BuOH$$

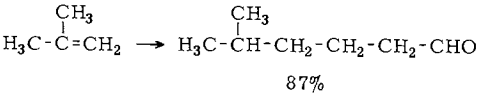
91%

95%

The above procedure provides the alkyl hydroperoxide in THF solution in a molar ratio of $2RO_2H:1ROH$. For many purposes, such mixtures of hydroperoxide may be used directly. If, however, it is desirable to separate and to isolate the pure hydroperoxide, this is readily done by treating the above solution with an excess of aqueous potassium hydroxide. The potassium salt of the hydroperoxide dissolves in the aqueous phase while the alcohol remains in the organic phase. Acidification of the aqueous phase provides the pure hydroperoxides. The low temperature autoxidation of organoboranes provides a rapid, convenient synthesis of alkyl hydroperoxides. The reaction is applicable to a wide variety of derivatives. Unlike the reaction of alkyl methanesulfonates with hydrogen peroxide[23], which produces hydroperoxides in 10—15% yield, the present procedure accommodates substrates which do not readily undergo nucleophilic substitution, such as cyclohexyl and norbornyl. The organoborane route also accommodates a wide variety of functional groups which cannot be used in the Grignard reaction[24].

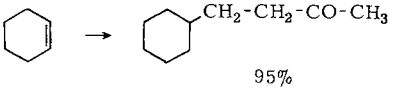
3. The 1,4 Addition of Trialkylboranes

3.1. Methyl Vinyl Ketone and Acrolein



Organoboranes are much less reactive organometallic compounds than the organolithium and organomagnesium derivatives and they do not add to the carbonyl groups of aldehydes and ketones in the same manner as the latter more reactive organometallics. However, certain α,β-unsaturated carbonyl derivatives, such as methyl vinyl ketone[25] and acrolein[26], undergo an exceptionally fast 1,4-addition reaction with representative organoboranes produced *via* hydroboration.

$$R_3B + H_2C{=}CH{-}CHO \xrightarrow[25\,^\circ C]{THF} RCH_2CH{=}CH{-}OBR_2 \quad (8)$$

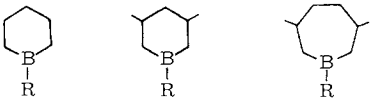


Addition of water to the reaction mixture results in the rapid hydrolysis of the intermediates *(8)* and subsequent liberation of the corresponding aldehyde or methyl ketone.

$$RCH_2{-}CH{=}CH{-}OBR_2 + H_2O \longrightarrow RCH_2{-}CH_2{-}CHO + R_2BOH$$

The reaction provides an exceedingly simple means of homologation, in which the chain is lengthened by three or more carbon atoms. Moreover, it appears to be generally applicable to a wide range of olefins structures.

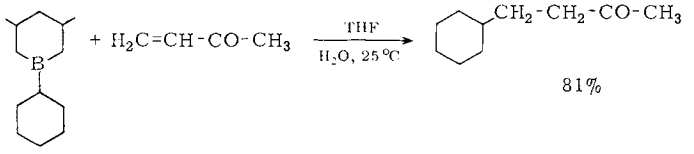
87%



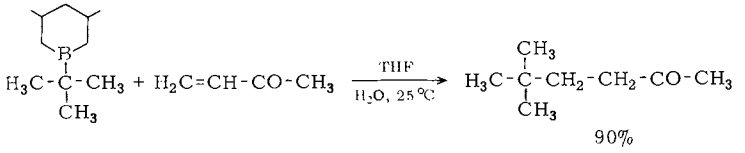
95%

Recycling of the intermediate R_2BOH on an industrial scale should offer no difficulty. However, it is inconvenient to attempt such a recycle in laboratory syntheses.

Tri-*n*-butylborane, prepared by hydroboration of 1-butene, contains 94% *n*-butyl and 6% *sec*-butyl groups; however, the product from this tri-*n*-butylborane and acrolein contains 85% of *n*-heptanal and 15% of 4-methylhexanal[26]. Clearly the *sec*-butyl groups in the trialkylborane are transferred preferentially.



This observation suggested that *B*-alkylborinanes *(9)* or the more readily available methyl derivatives *(10)* and *(11)*, containing secondary or tertiary groups on the boron atom, might solve the difficulty.

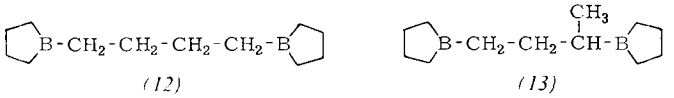


(9) *(10)* *(11)*

Convenient methods have been developed for the synthesis of the parent reagents[27].

These *B*-alkylboracycloalkanes react easily with methyl vinyl ketone and similar α,β-unsaturated carbonyl derivatives to give the desired products in excellent yields[28].

81%



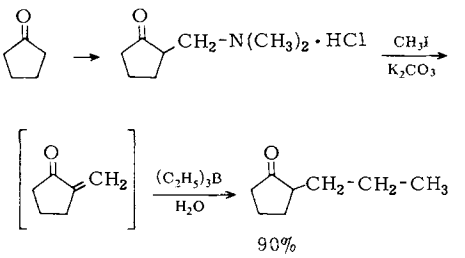
90%

3.2. Scope of the 1,4-Addition Reaction

The 1,4-addition reaction of organoboranes to methyl vinyl ketone and acrolein is capable of accommodating a wide range of structures in the alkyl group—from acyclic, to cyclic, to bicyclic. Indeed, cyclic organoboranes, which can be obtained by hydroboration of dienes, readily participate in the reaction, thus providing a simple route to the synthesis of ω-hydroxyaldehydes and -ketones[29].

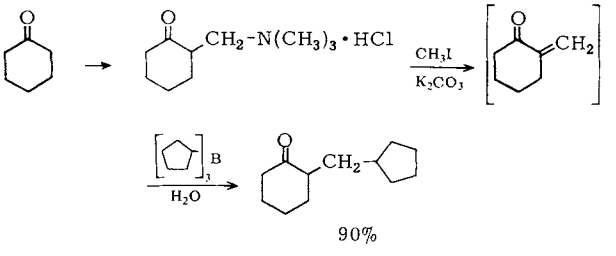
For example, the product obtained by hydroboration of 1,3-butadiene contains 1,4- and 1,3-diborabutane moieties *(12)* and *(13)*[30]. Reaction with methyl vinyl

(12) *(13)*



ketone in the presence of water or alcohol, followed by oxidation with alkaline hydrogen peroxide gave an 85% yield of ω-hydroxyketones containing 8-hydroxyoctan-2-one and its isomer, presumably 7-hydroxy-5-methyl-2-heptanone in a ratio of 70:30. If *(13)* is removed by thermal treatment[30], the 8-hydroxy-2-octanone is formed in a purity of 95%.

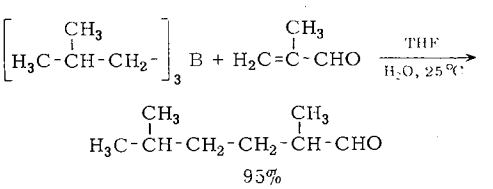
We also investigated the scope of this new synthesis with respect to the α,β-unsaturated carbonyl component. Derivatives such as acrolein and methyl vinyl ketone are often highly reactive and difficult to isolate in pure form. Organic chemists have frequently simplified the problems of working with these species by utilizing them in the form of the corresponding Mannich bases[31,32]. Accordingly, we examined the question of whether Mannich bases could be used in this synthesis.



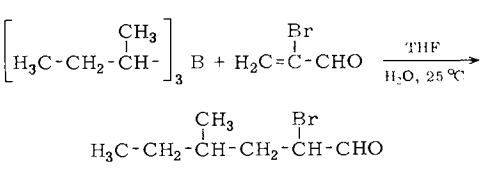
We found that Mannich bases, derived from ketones such as cyclopentanone, cyclohexanone, and norbornanone, quaternized *in situ*, react smoothly in alkaline solution with organoboranes to give the corresponding alkylated ketones[33]. A wide range of trialkylboranes can evidently be accommodated in this reaction. These reactions presumably proceed *via* the *in situ* formation of the labile α,β-unsaturated carbonyl derivatives.

Substituents in the 2-position of acrolein do not affect the reaction adversely. Thus, both 2-methylacrolein and 2-bromoacrolein react smoothly[34] (figures quoted are yields of isolated products). This appears to be the most suitable possible route to the α-bromoaldehydes.

Unexpectedly, neither crotonaldehyde nor 3-penten-2-one reacted with the organoborane under these condi-



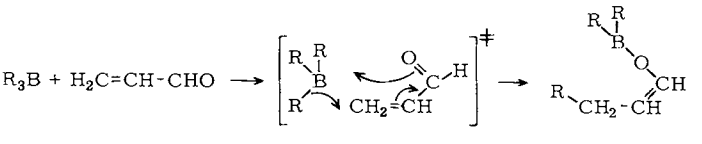
90%



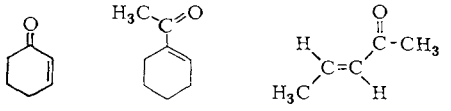
90%

tions. This was surprising. Evidently, the introduction of a methyl group in the acrolein molecule in the 1-position or the 2-position had no adverse effect on

95%



81%

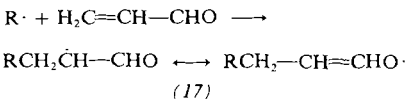


the ease of reaction. However, a methyl group in the 3-position completely blocked the reaction even under drastic conditions (24 hours at 125 °C). This was puzzling and induced us to investigate the reaction mechanism.

3.3. The 1,4 Addition as a Free-Radical Chain Reaction

The 1,4 addition of the Grignard reagent to α,β-unsaturated ketones is believed to proceed through a cyclic transition state[35]. As a working hypothesis, we originally assumed that the 1,4 addition of the organoborane likewise proceeded *via* a cyclic transitition state.

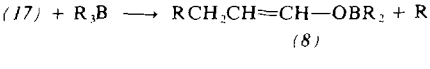
The failure of 2-cyclohexen-1-one *(14)* to react was not surprising and seemed to be consistent with the cyclic mechanism[4]. That the 1-cyclohexenyl methyl ketone *(15)* also failed to react appeared to be difficult to rationalize in terms of the proposed cyclic



(14) *(15)* *(16)*

mechanism. However, the failure of *trans*-crotonaldehyde and the related *trans*-3-penten-2-one *(16)* to react was much more difficult to explain in terms of this mechanism.

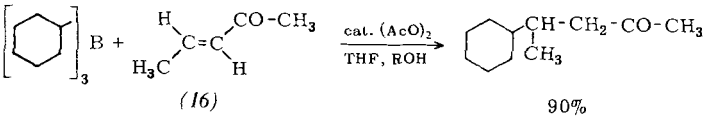
Such enormous effects of terminal methyl groups on reactivity are often observed in free-radical polymerizations[36]. We were therefore led to consider the possibility that free-radical intermediates are involved in this reaction.



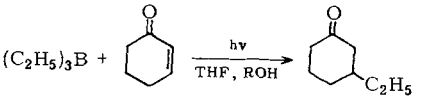
Galvinoxyl is known to be an efficient scavenger for free radicals[37] and has been successfully employed to inhibit the autoxidation of certain organoboranes[1-3]. We therefore explored its effect on the 1,4-addition and found that the presence of 5 mol % of galvinoxyl does, in fact, effectively stop the otherwise very fast reaction of trialkylboranes with acrolein and methyl vinyl ketone. It can be concluded, therefore, that the reactions must be free-radical chain reactions.

The mechanism evidently involves the addition of a radical to the carbon-carbon double bond of the carbonyl compound, whereby a radical intermediate *(17)* is formed. In the absence of a reactive organoborane, this intermediate would add to the monomer through

(17)



carbon to initiate a typical vinyl polymerization[38]. However, in the presence of free trialkylborane this intermediate evidently reacts through the oxygen atom to form the borinate *(8)* with its very strong boron-oxygen bond. This step thus resembles the reaction of

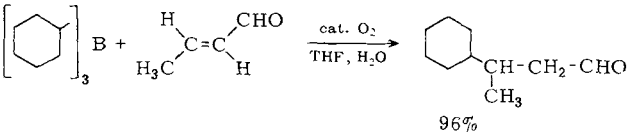


(8)

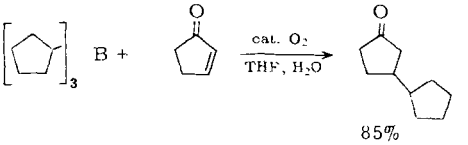
alkoxy radicals with organoboranes[8,9] as was discussed earlier.

If the inability of these terminally substituted α,β-unsaturated carbonyl compounds to undergo 1,4-addition is the result of a relatively short chain-length, it should be possible to effect the reaction by introducing an efficient free-radical initiator. We observed that the 1,4-addition reactions could be extended to these terminally substituted derivatives by both photochemical activation and the addition of diacetyl peroxide[39].

(16) 90%



(14) 95%



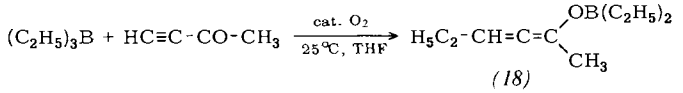
As was pointed out earlier, the addition of oxygen to organoboranes produces free radicals. It was suggested, therefore, that the addition of air to a mixture of the organoborane and the "inert" α,β-unsaturated carbonyl derivative might induce the desired 1,4-addition. This was tested. Indeed, 4-methyl-2-hexanone was formed in 70% yield when a slow stream of air was passed over a solution of triethylborane and *trans*-3-penten-2-one in aqueous THF[40].

It is essential that the air be added slowly and in controlled amounts. In experiments in which oxygen was added rapidly, oxidation of the organoborane became the dominant reaction, and only a minor amount of the 1,4-addition product was obtained. Even when oxygen is added slowly, some of the organoborane is lost through oxidation. However, this is usually so small that the loss can be considered insignificant; a small excess of the organoborane can be added to compensate for that lost through oxidation.

The reaction appears to be one of general applicability, accommodating a wide variety of organoboranes and α,β-unsaturated carbonyl compounds; the corresponding β-substituted aldehydes and ketones are formed in excellent yields.

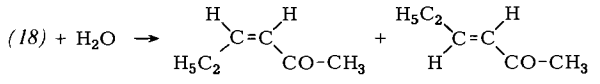
96%

85%



This finding suggested that the slow introduction of oxygen or air into an organoborane generates free radicals, which in turn initiate free-radical chain reactions. In suitable systems the organoborane is also active for chain propagation. Consequently, the organoboranes appeared to be very promising reagents for free-radical chain reactions, so we undertook to explore such systems.

3.4. Extension of the 1,4-Addition Reaction to New Systems

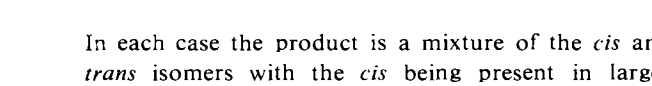


3.4.1. Acetylacetylene

No reaction takes place between triethylborane and acetylacetylene when air and light are carefully excluded

from the reaction mixture, even with an extended reaction time of 24 hours. However, 3-hexen-2-one is obtained in 79% yield in 2 hours under identical reaction conditions provided the reaction mixture is exposed to a slow stream of air[41].

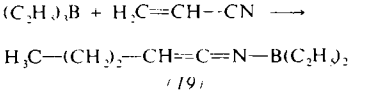
(18)



In contrast to the behavior of methyl vinyl ketone, the presence of water in the reaction mixture is required in order to achieve a good yield of the desired product. Presumably, the allene intermediate *(18)* is highly susceptible to further attack by the free-radical intermediates and this side reaction is minimized by the *in situ* hydrolysis of the borinate. Solvolysis of the intermediate may also be achieved through the use of alcohols, such as methanol and ethylene glycol. This is especially recommended in cases where anhydrous conditions should be maintained.

The conclusion that the reaction proceeds *via* a free-radical chain reaction is supported by the fact that other typical free-radical initiators may be used to induce the 1,4-addition. As an example, the reaction of triethylborane can be induced photolytically or by the thermal decomposition of azobis(isobutyronitrile) at 40 °C. The yields are comparable to those obtained when air is used for the initiation.

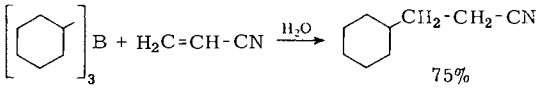
The reaction appears to be one of wide generality; unsaturated methyl ketones can be prepared in this way from various types of alkenes.



In each case the product is a mixture of the *cis* and *trans* isomers with the *cis* being present in larger amounts than the *trans*. The ratio of the isomers appears to vary with the conditions of the protonolysis stage. However, further investigations are necessary for a complete understanding of the reaction in this connection.

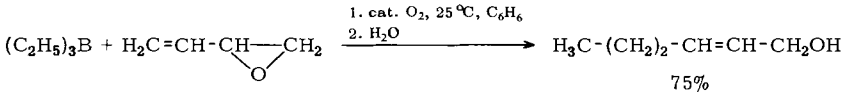
This oxygen-induced reaction of organoboranes with acetylacetylene produces α,β-unsaturated ketones. These have previously been shown to undergo the 1,4-addition reaction with organoboranes. Accordingly, the reaction appears capable of being controlled introduce two different groups from two different organoboranes, thus making available a wide variety of ketones.

3.4.2. Acrylonitrile



Similarly, acrylonitrile fails to react with trialkylboranes in the absence of oxygen or other free-radical initiators. In the presence of oxygen the reaction of triethylborane with acrylonitrile proceeds readily, the reagents being consumed in a 1:1 ratio[42]. However, the intermediate *(19)* evidently undergoes some other reaction

(19)



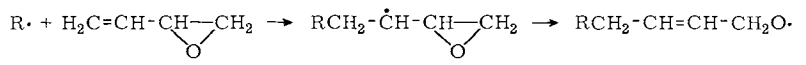
prior to hydrolysis, since valeronitrile is not present in the reaction mixture.

With secondary alkyl derivatives, such as tricyclohexylborane, the reaction proceeds in the normal manner. In this case oxygen or other initiators initiate a reaction resulting in the formation of 3-cyclohexylpropionitrile.

3.4.3. 1,3-Butadiene Monoxide

No reaction takes place between 1,3-butadiene monoxide and triethylborane in the absence of oxygen.

However, the reaction proceeds smoothly on introduction of small quantities of air[43]. With equimolar amounts of the two reactants, the yield was only 44%.

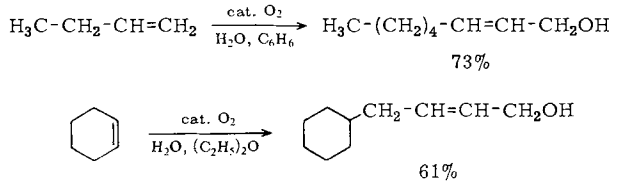


However, use of an excess of 1,3-butadiene monoxide led to improved yields. The 2-hexen-1-ol product was predominantly the *trans* isomer (89% *trans*, 11% *cis*).

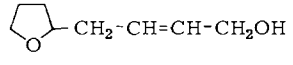
Typical free-radical initiators, such as di-*tert*-butyl peroxide, azobis(isobutyronitrile), and oxygen, are also effective in promoting the reaction. Moreover, a typical free-radical scavenger, galvinoxyl, inhibits the reaction. Thus the reaction must involve a free-radical chain mechanism.

As was discussed earlier, trialkylboranes react with oxygen to generate alkyl radicals.

In the presence of 1,3-butadiene monoxide, these alkyl radicals must add to the double bond of the epoxide



to yield an intermediate radical which rearranges to give an alkoxy free radical.



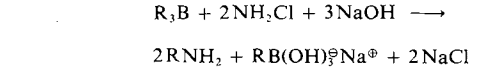
The alkoxy radical reacts with the trialkylborane to form a borinate, displacing an alkyl radical which continues the chain.

Hydrolysis of the intermediate borinate affords the 4-alkyl-2-buten-1-ol. The reaction proceeds satisfactorily with a variety of alkyl groups and reasonable yields of product are obtained.

Since trialkylboranes are generally prepared in THF solution, this has usually been the solvent of choice for reactions of organoboranes. However, in the present case, we observed the formation of considerable quantities of 4-(2′-tetrahydrofurfuryl)-2-buten-1-ol *(20)*.

(20)

Apparently the free-radical intermediates can attack the THF molecule, producing a new free-radical intermediate which can add to the 1,3-butadiene monoxide. This side reaction can be avoided in benzene; accordingly, this was the preferred solvent for the reaction of organoboranes with primary alkyl groups. For some reason, organoboranes with secondary alkyl groups give slightly higher yields in ethyl ether as the solvent, in spite of a competitive reaction with solvent analogous to that observed in THF.



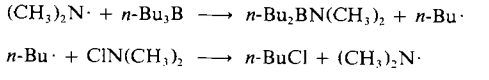
These initial results indicate that the free-radical addition of organoboranes must be quite general, far more general than was indicated by our initial explorations. Thus, our studies directed at understanding why crotonaldehyde and 3-penten-2-one failed to undergo a reaction that is readily participated in by the very similar structures acrolein and methyl vinyl ketone led to a wide extension of the original reaction.

4. Other Types of Free-Radical Reactions

An essential feature of the chemistry discussed up to this point has been the newly discovered facile reaction of alkoxy free radicals, $RO\cdot$, with organoboranes with displacement of alkyl radicals. As was pointed out earlier, this reaction also occurs readily with the related free radicals, $R_2N\cdot$ and $RS\cdot$. This suggests that a large number of chain reactions of organoboranes involving $R_2N\cdot$ and $RS\cdot$ intermediates should exist; these would be analogous to the many chain reactions we have been reviewing involving $RO\cdot$. In fact, recognition of this possibility resulted in the resolution of a long-standing problem.

4.1. Reaction of Boranes with *N*-Chlorodimethylamine

It had previously been observed that chloramine reacts with organoboranes in the presence of base to produce the corresponding amine[44].



Although this reaction utilizes only two of the three groups of the organoboranes, it provides a very convenient stereospecific route to certain amines.

Sharefkin and *Banks* tried to extend the reaction to the synthesis of alkyldiethylamines, especially *n*-butyldiethylamine[45]. However, the reaction took another course: *n*-butyl chloride was formed.

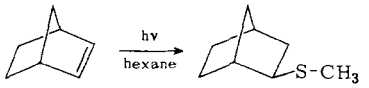
It has now been shown that this last reaction is a free-radical chain reaction, proceeding *via* the $(CH_3)_2N\cdot$ radical[46]. Addition of galvinoxyl inhibits the free-

radical reaction and the reaction then follows the polar pathway, leading to formation of the tertiary amine.

Unfortunately the reaction, in its present state of development, does not yet appear to be of any use for synthetic purposes. Nevertheless, it looks highly promising and is being further explored.

4.2. Reaction of Boranes with Organic Disulfides

Trialkylboranes either do not react, or react very slowly, with disulfides such as phenyl disulfide or methyl disulfide. However, under the influence of light or with passage of a slow stream of air into a mixture of the



organoborane and disulfide, a facile reaction is induced that appears to be broady applicable, and provides the

$$R_3B + H_5C_6{-}S{-}S{-}C_6H_5 \xrightarrow[\text{or air}]{h\nu} R{-}S{-}C_6H_5 + R_2B{-}S{-}C_6H_5$$

$$R_3B + 2\,H_3C{-}S{-}S{-}CH_3 \xrightarrow[\text{or air}]{h\nu} 2\,R{-}S{-}CH_3 + RB(S{-}CH_3)_2$$

corresponding sulfide in excellent yield[47].

$$H_3C{-}(CH_2)_5{-}CH{=}CH_2 \xrightarrow[\text{hexane}]{h\nu} H_3C{-}(CH_2)_7{-}S{-}CH_3 \quad 95\%$$

95%

The reaction is strongly inhibited by iodine and consequently must involve a free-radical chain reaction proceeding *via* methylthio radicals. An interesting feature is the conclusion that free radicals must attack

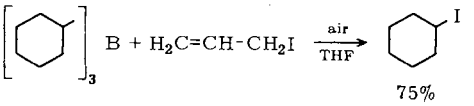
$$R_3B + O_2 \longrightarrow R_2BO_2\cdot + R\cdot$$
$$R\cdot + R'SSR' \longrightarrow RSR' + R'S\cdot$$
$$R'S\cdot + R_3B \longrightarrow R'SBR_2 + R\cdot$$
$$R'S\cdot + R'SBR_2 \longrightarrow (R'S)_2BR + R\cdot$$

one of the sulfur atoms in the disulfide linkage to form the corresponding sulfide with liberation of an organothio radical. Such reactions of sulfides have been long accepted[48].

4.3. The Oxygen-Induced Reaction of Alkyl Iodides with Organoboranes

4.3.1. Alkyl Iodide Formation

As was pointed out earlier, the rate of oxygen absorption by solutions of organoboranes can be conveniently followed with the aid of the automatic gas generator. We used this technique to establish the rate of oxygen uptake by representative organoboranes and then began to investigate the effect of various added materials. Added iodine caused a complete inhibition of oxygen absorption; this phenomenon was subjected to a detailed study[49,50].



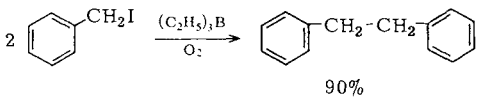
An examination of the effect of typical organic iodides on the rate of reaction of trialkylboranes with oxygen revealed that the rate is not significantly altered (unless significant amounts of iodine are liberated), but the products are very different. With tri-*n*-butylborane, *n*-butyliodide was formed[51].

The products suggest that the *n*-Bu· formed in the initiation step of autoxidation can react either with the organic iodide present or with oxygen in the usual way.

$$n\text{-Bu}\cdot + RI \longrightarrow n\text{-BuI} + R\cdot$$
$$n\text{-Bu}\cdot + O_2 \longrightarrow n\text{-BuO}_2\cdot$$

These considerations suggested that it might be possible, by controlling the rate and quantity of oxygen introduced, to control the course of the reaction to produce alkyl iodide preferentially. Indeed, we discovered that by introducing air into a reaction mixture containing equimolar amounts of R_3B and allyl iodide it was possible to obtain essentially quantitative yields of the alkyl

$$(C_2H_5)_3B + H_2C{=}CH{-}CH_2I \xrightarrow[THF]{air} C_2H_5I \quad 100\%$$



iodide. Consequently, the reaction may be used as an alternative to the base-induced iodination of trialkylboranes for the preparation of alkyl iodides[52]. It should be especially valuable for alkyl groups which are sensitive to alkaline solutions.

4.3.2. Coupling

In the reactions which have been discussed earlier (other than oxidation), only a catalytic amount of oxygen has been required to induce the desired reaction. However, in the present reaction involving organic halides, approximately one mol of oxygen is required per mol of alkyl iodide formed. Hence the reaction is not a chain reaction.

The stable radicals produced after halogen abstraction, such as allyl and benzyl, do not continue the chain, but undergo coupling. Initially, the molar quantity of biallyl formed is one-half that of the alkyl iodide produced in the reaction. However, in the final stages of the reaction the amount of biallyl formed fails to increase significantly, even though additional alkyl iodide is formed. A possible explanation for this is that in the final stages of the reaction the autoxidation of the residual organoborane (proceeding *via* ethyl radicals) fails to compete effectively with the allyl radicals for the oxygen dissolved in the solution.

To obtain high yields of the coupled product, the reaction of the allyl radical (and related radicals) with oxygen must be minimized. This is readily achieved by using an excess of organoborane. The readily available triethylborane was adopted as the reagent and was used in 100% excess to obtained the desired coupled product.

$$2\ H_2C{=}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{-}CH_2I \xrightarrow[O_2]{(C_2H_5)_3B} H_2C{=}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{-}CH_2{-}CH_2{-}\underset{\displaystyle CH_3}{\overset{\displaystyle |}{C}}{=}CH_2 \quad 90\%$$

The reaction was very clean; no detectable amount of coupling with ethyl radicals was observed. Evidently the ethyl radicals abstract iodine or react with oxygen

rapidly and do not couple. On the other hand, mixed coupling products could be obtained from mixed allylic and benzylic iodides. The coupling gave a nearly statistical distribution of products. If one desired to couple an expensive or rare iodide with a more available iodide, an excess of the latter can be used to increase the conversion of the more valuable material. Thus 4-phenyl-1-butene was obtained in 72% yield when a 4-fold excess of allyl iodide was used along with benzyl iodide.

The free-radical coupling of olefins may be readily achieved by hydroboration followed by treatment of the organoborane with alkaline silver nitrate[53, 54]. The air-induced coupling of allylic and benzylic iodides now provides a method of coupling alkyl groups under mild conditions—a feature which hydroboration cannot offer. Both methods may accommodate a wide variety of functional groups.

5. Conclusion

The reaction of oxygen with organoboranes was first studied in 1862[55], yet it was not until 1967 that it was finally recognized that the reaction must involve a facile free-radical chain process[1]. The 1,4-addition reaction of organoboranes with methyl vinyl ketone[25] and acrolein[26] was first reported in 1967. Recognition that these reactions also proceeded *via* free-radical chain reactions was reported in 1970[4]. We are presently only in the initial stages of our studies of such free-radical reactions; however, the present state of our knowledge of these systems indicates that we can anticipate a large increase in the number and kinds of free-radical reactions involving organoboranes.

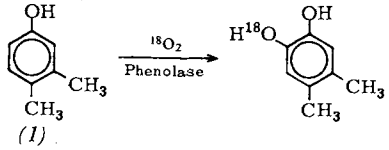
Enzymatic Hydroxylations with Molecular Oxygen

By Volker Ullrich[*]

For thermodynamic reasons, biological hydroxylations cannot usually proceed according to the β-oxidation scheme, but are possible only with the aid of molecular oxygen by a route requiring a large amount of energy. The corresponding enzymes, known as "mixed function oxygenases" or more appropriately "monooxygenases", require two reduction equivalents for the activation of oxygen. The cytochrome P-450-dependent monooxygenases are taken as examples for the discussion of the chemistry of the enzymatic catalysis. The central problem of the activation of oxygen has not yet been solved, but an "oxenoid" mechanism can be deduced from model investigations.

1. The Problem of the Activation of Oxygen

Molecular oxygen owes its existence to photosynthesis, and may therefore be regarded as a bioelement. Its formation in biological systems in this manner and its universal occurrence often lead us to forget that only a metastable equilibrium exists between organic material and oxygen. Once the necessary activation energy has been supplied, organic compounds undergo very rapid oxidation, with simultaneous reduction of oxygen. The free energy change of these "combustion reactions" is considerable, and is exceeded only by that of reactions with molecular fluorine[1].



These two characteristics of oxygen, *i.e.* inertia on the one hand and high oxidation potential on the other, are responsible for its unique importance to the energetics of vital processes. It is therefore not surprising that many investigations aimed at the elucidation of the complex chemistry of the oxygen molecule arose from interest in its biological reactions.

To explain the readiness with which oxygen reacts under physiological conditions, it was essential to postulate some "activation of oxygen". This was proposed at an early stage in the publications of *Traube*[2], *Engler*[3], and *Bach*[4], and its experimental foundation was laid by the investigations of *Otto Warburg*. *Warburg*'s model experiments in conjunction with the investigations on the photochemical action spectrum of cytochrome oxidase proved the importance of the bivalent iron ion to the binding of oxygen[5]. If one bears in mind the more recent discovery that the paramagnetic structure of oxygen has a very stable electron configuration, which can be partly disrupted by bonding to iron[6,7], the oxygen "activation" concept introduced by *Warburg* can be justified for all biological oxidations involving molecular oxygen.

It was only in 1955 that proof was found that *Warburg*'s ideas on the activation of oxygen could be applied much more directly to a special group of enzymatic reactions of oxygen. With the aid of the heavy oxygen isotope $^{18}O_2$, *Mason et al.*[8] were able to demonstrate the direct incorporation of molecular oxygen into 3,4-dimethylphenol (*1*), a substrate of phenolase.

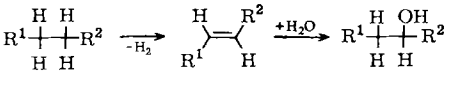
[*] Prof. Dr. V. Ullrich
Physiologisch-Chemisches Institut
der Universität des Saarlandes
665 Homburg/Saar (Germany)

In contrast with the principle of biological oxidation, according to which oxygen merely functions as an electron acceptor, the substrate in these reactions undergoes

(*1*)

oxygenation *via* direct attack by oxygen. The cleavage of a CH bond with hydroxylation of the carbon undoubtedly requires enzymatic activation of the oxygen molecule, so that a fresh discussion of this problem was necessary.

2. General Properties of Monooxygenases



2.1. Definition and Nomenclature

In enzymatic hydroxylations with molecular oxygen, one oxygen atom is introduced into the substrate, while the other is reduced to water. The overall equation for the reaction was first formulated by *Mason*[9]:

$$RH + DoH_2 + {}^{18}O_2 \rightarrow R^{18}OH + Do + H_2{}^{16}O$$

RH = substrate
DoH_2 = hydrogen donor

The hydrogen donor in many reactions is reduced nicotinamide adenine dinucleotide phosphate ($NADPH_2$) or reduced nicotinamide adenine dinucleotide ($NADH_2$). However, tetrahydropteridines, reduced flavins, or ascorbic acid can also provide the two electrons (cf. Table 1). It seems paradoxical at first that oxidation proceeds only in the presence of and with consumption of reduction equivalents, which are thus lost to the cell for the production of energy. One could therefore ask why hydroxylation does not take place by the much more economical dehydrogenation of the substrate with subsequent addition of water.

In this way, *e.g.* malic acid is formed from succinic acid *via* fumaric acid in the citric acid cycle, and the

hydrogen formed in this hydroxylation can yield 2 ATP *via* the respiratory chain.

Hydroxylations with xanthine oxidase[10] and with a nicotine hydroxylase[11] proceed similarly. Thermodynamic considerations show that for aliphatic or aromatic compounds without polarizing groups, energy factors rule out this path, leaving hydroxylation with oxygen as the only alternative.

The fact that hydroxylations can occur in principle by the two routes described makes a more specific nomenclature necessary. Owing to the "mixed" function of the oxygen as an oxidizing and oxygenating agent, *Mason* proposed the term "mixed function oxidase", whereas *Hayaishi*[12] later suggested the designation "monooxygenase". This suggestion by *Hayaishi* places more emphasis on the oxygenating function of these enzymes and allows a more systematic distinction from the "dioxygenases", which introduce both atoms of molecular oxygen into the substrate[13].

The official nomenclature of the Enzyme Commission treats the enzymes as "hydroxylases" under the number 1.14. The systematic name is based on the designation "oxygen oxidoreductase"; in addition to the substrate, it specifies the electron donor, and the word "hydroxylating" is added; *e. g.* 1.14.1.2. L-kynurenine, reduced-NADP: oxygen oxidoreductase (hydroxylating). The nomenclature used in the present article will be based on the term monooxygenase, so that the enzyme mentioned above will receive the simpler name "L-kynurenine 3-monooxygenase". There is no need to name the electron donor, since this is generally not very specific.

2.2. Significance in Metabolism

To provide aliphatic or aromatic CH bonds with functional groups, the chemist has available a series of reactions, such as halogenations, sulfonation, or nitration followed by reduction with amination. In metabolism, the synthesis and degradation of substrates always requires the presence of functional groups, on which the enzymatic reactions take place. If these are lacking, as in many lipophilic compounds, the introduction of hydroxyl groups *via* the monooxygenases is the only route available for the formation of derivatives. This need arises *e. g.* in steroid biosyntheses, in which the highly active hormones are formed from cholesterol by introduction of hydroxyl groups. Monooxygenations are also common in amino acid metabolism, *e. g.* in the synthesis of tyrosine, hydroxyproline, hydroxykynurenine, or dopamine. Monooxygenations are of the greatest importance in the degradation and excretion of lipophilic compounds. Substances of this type can leave the body only after they have been made water-soluble by hydroxylation. The monooxygenases for foreign substances in the liver have been claiming the attention of pharmacologists and physicians for about ten years. Hormonal regulation by steroids requires the continuous inactivation of these compounds, which is also performed in the liver by monooxygenases.

The importance of monooxygenases to the adaptive microorganisms has only recently been recognized. Bacteria and yeasts can grow even on nonphysiological carbon sources, such as aromatic or aliphatic hydrocarbons. This process requires the specific induction of monooxygenases, which prepare the way for the degradation of these inert substrates by one or more hydroxylations to enable the metabolites to enter the normal metabolic pathways. Since the activities of the monooxygenases are usually very low, the hydroxylations are nearly always the rate-determining step of the degradation reactions. To ensure fast breakdown of the organic compounds and hence rapid cell growth, such adapted microorganisms contain very high concentrations of monooxygenase proteins. The conversion of petroleum into animal feeds is possible in this way, and has already been achieved[14].

Bacterial strains that contain highly specific steroid monooxygenases, and can therefore be used for the synthesis of hydroxylated steroid hormones, which are difficult to obtain by chemical routes, are of commercial interest[15].

2.3. Survey of the Principal Monooxygenases

The above-mentioned adaptive properties of microorganisms allow the induction of monooxygenases for practically any organic compound. Only monooxygenases that are important in the mammalian metabolism and that have been investigated sufficiently will therefore be mentioned in the review (Table 1).

2.4. Problems of the Mode of Action of Monooxygenases

To exercise its catalytic function, any monooxygenase requires not only the substrate but also molecular oxygen and an electron donor as cosubstrates. The simultaneous presence of these three components in the monooxygenation offers many possibilities of combination, all of which have been discussed in detail[9].

A feature common to all monooxygenases is the activation of the oxygen molecule, which occurs with the uptake of two electrons. The principle underlying this activation of oxygen can be discerned only in broad outline from the existing results on the enzymatic reactions and their models. In their other properties, however, the monooxygenases exhibit far-reaching differences. The following three points are largely decisive for the characterization of these enzymes.

2.4.1. The Substrate Specificity

The specificity of an enzymatic reaction is determined by the bonding of the substrate to the "active site" of the protein. The affinity of the substrate for the enzyme is determined by the nature and number of the interaction forces. At least three bonding sites must be present for stereospecific binding of the substrate molecule in the protein[48]. This condition must be satisfied *e. g.* for the stereospecific hydroxylations of steroids or amino acids.

With some monooxygenases, the formation of the enzyme-substrate complex can be followed by direct optical measurements. In this case, the affinity of the

Table 1. Survey of the principal mammalian monooxygenases.

Enzyme	Electron donor	Occurrence [a]	Remarks	Ref.
Steroid monooxygenases				
Squalene 2,3-monooxygenase (epoxidizing) (EC 1.14.1.3)	$NADPH_2$	ER of the liver	Epoxide is the precursor of lanosterol	[16, 17]
11β-Monooxygenase (EC 1.14.1.6)	$NADPH_2$	Mitochondria of the adrenal cortex	Consists of reductase containing FAD, non-heme iron protein, and cytochrome P-450, reconstitutable	[18—20]
C-21 monooxygenase (EC 1.14.1.8)	$NADPH_2$	ER of the adrenal cortex	Contains cytochrome P-450	[21, 22]
Cholesterol 20-monooxygenase (EC 1.14.1.9)	$NADPH_2$	Mitochondria of the adrenal cortex, testes, ovary, placenta	Contains cytochrome P-450, precursor for side-chain removal	[23, 24]
2β-, 6α,6β-, 7α,7β,1α,1β-, 15α,16α-, 18α-monooxygenases	$NADPH_2$	ER of the liver	Participates in the breakdown of steroids	[25—28]
Amino acid monooxygenases				
L-Kynurenine 3-monooxygenase (EC 1.14.1.2)	$NADPH_2$, NADH	Liver mitochondria (outer membrane)	Contains FAD	[29, 30]
Dopamine β-monooxygenase (EC 1.14.2.1)	Ascorbate	Adrenal medulla	Contains 2Cu	[31, 32]
4-Hydroxyphenylpyruvate 1-monooxygenase (EC 1.14.2.2)	Aldehyde formed as intermediate	Liver cytoplasm	Sensitive to oxidation. Side chain migrates into *ortho* position	[33, 34]
Phenylalanine 4-monooxygenase (EC 1.14.3.1)	Tetrahydrobiopterin	Liver cytoplasm		[35, 36]
Proline 4-monooxygenase	Ascorbate	Collagen-synthesizing tissue	Contains Fe^{2+}, hydroxylates proline only in the peptide	[37, 38]
Various				
Heme α-monooxygenase	$NADPH_2$	ER of the liver and spleen	Contains cytochrome P-450, products are biliverdin and CO. Inducible by hemin	[39]
Fatty acid ω-monooxygenase	$NADPH_2$	ER of the liver and kidney	Contains cytochrome P-450. Inducible by laurate	[40 - 42]
Xenobiotic monooxygenases				
Aryl 4-monooxygenase	$NADPH_2$		Probably contains cytochrome P-450 and flavoprotein. Inducible by polycyclic hydrocarbons; nonspecific	[43, 44]
Alkane monooxygenase	$NADPH_2$ ($NADH_2$)	ER of the liver	Contains cytochrome P-450 and flavoprotein. Inducible by barbiturates. Nonspecific, prefers ω-1-position and tertiary CH bonds	[41, 45—47]

[a] ER = endoplasmic reticulum.

enzyme for the substrate can be described by the substrate concentration required to convert half of the enzyme into the enzyme-substrate complex (spectral dissociation constant, "K_s").

2.4.2. The "Terminal Oxidase"

This is the name given to the component of the monooxygenase system that binds the oxygen and activates it with the aid of the two electrons. The binding of oxygen is possible on the basis of its character as an excellent electron acceptor. The terminal oxidases are therefore always electron donors. Particularly stable bonding of the oxygen to the active site of the terminal oxidase arises if back-bonding also occurs between the p_π orbital of the oxygen and the d orbitals of heavy metal ions[49]. Iron(II) and copper(I) complexes are therefore the most common terminal oxidases. However, organic compounds such as reduced flavin systems can also activate oxygen. Monooxygenases of this type are found mainly among the bacterial enzymes[50 - 52].

2.4.3. The Electron Transport

The terminal oxidase is a redox system, which converts the oxygen into an active form by transfer of two electrons.

After the hydroxylation of the substrate, the terminal oxidase remains in its oxidized form, and must be converted back into the reduced, oxygen-binding form

for the next cycle. This reduction is possible in principle with any electron donor that has a sufficiently negative potential. It can be seen from Table 1 that ascorbic acid and tetrahydropteridines play the part of the electron donor for some monooxygenases, but reduced pyridine nucleotides are necessary for the majority.

In this case, the transport of electrons to the oxygen is a complicating factor, since the pyridine nucleotide can give up its reaction equivalents only by hydride ion transfer in a two-electron step[53], whereas oxygen can be reduced only in one-electron steps. $NADPH_2$- or $NADH_2$-dependent monooxygenases therefore also contain redox components such as flavin and iron-sulfur proteins, which allow the two-electron transfer to be split up into one-electron steps. These pyridine nucleotide-dependent monooxygenases form multienzyme complexes similar to those that occur in the respiratory chain and are often bound to biological membranes. It should be mentioned that these reduction systems are not always very specific for the acceptor, and can frequently even be interchanged in related systems.

A monooxygenase is therefore characterized, not by the electron transport system, but primarily by the nature of its terminal oxidase. The monooxygenases should therefore be classified as iron-containing, copper-containing, or flavin-containing enzymes. The monooxygenases containing iron in the form of cytochrome P-450 as the oxygen-activating component have been the most intensively studied so far. The mode of action of these enzymes will be discussed in the following sections as an example of the action of monooxygenases in general.

3. Cytochrome P-450-Dependent Monooxygenases

As was shown by *Warburg*'s experiments, iron ions are the most important cofactors in the metabolism of oxygen. A particularly important place is occupied by the porphyrin complexes of iron, in which the nitrogen atoms of the four pyrrole rings fix one plane of the octahedral coordination sphere of the iron ion. The fifth and sixth coordination sites are thus separated by this plane, so that ligand exchange is impossible. This allows the stereospecific fixation of the oxygen molecule by all enzymes with iron-porphyrin complexes as prosthetic groups. The bonding of oxygen occurs on the sixth coordination site, while the fifth coordination site is used for the bonding to the protein.

In 1958 *Klingenberg*[54] and *Garfinkel*[55] discovered, in the microsome fraction of rat livers, a cytochrome whose reduced state formed a carbon monoxide compound having an absorption maximum at 450 nm. The position of this band was unusual, since all known carbon monoxide compounds of iron-porphyrin complexes absorb at much shorter wavelengths (at about 420 nm). This new cytochrome was also found in the microsome fraction of the adrenal cortex. It was known from experiments by *Ryan* and *Engel*[21] that the same fraction was able to hydroxylate steroids on C-21, and that the hydroxylation was inhibited by carbon monoxide. On the basis of the observation of the photodissociation of the iron(II)-carbon monoxide complexes, and using *Warburg*'s classic experimental arrangement for the photochemical action spectrum, *Estabrook et al.*[56] showed that this cytochrome participates in the C-21 hydroxylation as the terminal oxidase (Fig. 1).

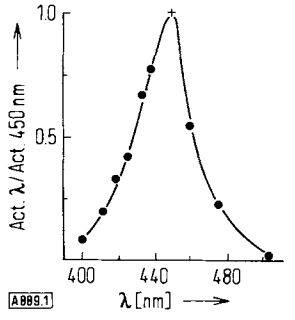


Fig. 1. Photochemical action spectrum of the steroid C-21 monooxygenase in the presence of carbon monoxide [56].

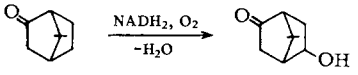
Because of the unusual absorption band of its CO compound, the heme protein was given the temporary name "cytochrome P-450"; however, this has not yet been replaced by any more systematic name.

The cytochrome was found in subsequent years not only in mammals but also in insects[57], yeast[58,59], and bacteria[60-62].

This detection was made possible through the methods developed by *Chance*[63] for absorption measurements in turbid solutions. Every attempt at protein-chemical purification of the particulate cell fraction had led to rapid destruction of the cytochrome. The active cytochrome was converted into an inactive form, whose CO compound absorbed at 420 instead of 450 nm, and which was therefore named "cytochrome P-420"[64,65].

In nearly every case it was possible to assign a function in a hydroxylation to the cytochrome P-450 found in the various tissues and cells, so that it may justifiably be regarded as the preferred prosthetic group of monooxygenases.



In the investigation of the C-21 hydroxylation in the microsome fraction of the adrenal cortex, *Cooper et al.*[22] observed a change in the spectrum of the cytochrome P-450 when substrates of the C-21 monooxygenase were added. The same observation in rat-liver microsomes on addition of hexobarbital was interpreted by *Schenkman et al.*[66] as resulting from the formation of an enzyme-substrate complex. Further elucidation of the mode of action of the enzyme in these microsome fractions was hindered by the strong attachment of the monooxygenase system to the membrane.

The first successful enrichment and purification of a structure-bound monooxygenase system was achieved by *Omura et al.*[19] in the case of the steroid 11β-monooxygenase from mitochondria of the adrenal cortex (see Table 1). Three protein components, which together restore the full activity of the enzyme, were isolated from detergent-treated suspensions. These were an NADPH-oxidizing flavoprotein[67], an iron-sulfur protein[68], and cytochrome P-450[69]. Reconstitution experiments showed that the iron-sulfur protein was reduced

by the flavoprotein, which in turn transferred the electrons to the cytochrome P-450. Further protein-chemical purification of the cytochrome was again found to be difficult in this system, since only "pseudo-solubilization" could be achieved in the presence of the detergent. Important clues to the course of the cytochrome P-450 catalysis were nevertheless obtainable from spectroscopic studies on the membrane-bound cytochrome of the various tissues. However, clarification of many unanswered questions became possible only after the discovery of a soluble cytochrome P-450-dependent monooxygenase system from bacteria.

3.1. The Camphor 5-Monooxygenase from *Pseudomonas putida*

In 1968, *Katagiri et al.*[61,70] reported the occurrence of cytochrome P-450 in the (+)-camphor monooxygenase from *Pseudomonas putida*, which had been studied by *Gunsalus*'s research group[71,72]. This enzyme is present in high concentrations in the cells of a strain of *Pseudomonas putida* grown on camphor, and is responsible for the first hydroxylating step in the degradation of camphor *(2)*.

(2)

The stoichiometry of the hydroxylation requires 1 mol of $NADH_2$ and 1 mol of oxygen per mol of 5-hydroxycamphor[72,73]. The entire monooxygenase system, like the 11β-monooxygenase system, consisted of a flavoprotein, a non-heme iron protein, and cytochrome P-450. However, the cytochrome was completely soluble, and was therefore obtainable in the pure state[74]. It was thus possible to carry out detailed studies on the unusual spectral properties of the cytochrome in the absolute spectra (Fig. 2).

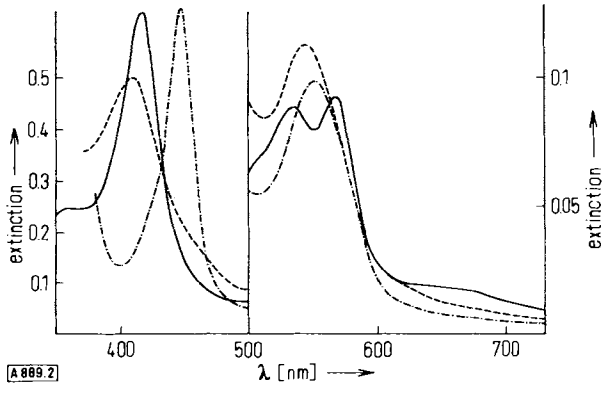


Fig. 2. Absolute spectrum of the cytochrome P-450 from *Ps. putida* [73]. (——) oxidized cytochrome, (– – –) reduced cytochrome, (–·–·–) reduced cytochrome + carbon monoxide.

In the presence of oxygen, the cytochrome occurs only in its oxidized form with trivalent iron, in which it has a Soret band at 417 nm with a pronounced α band at 578 nm and the β band at 535 nm. Under anaerobic conditions, it can be reduced by sodium dithionite or, after addition of the flavoprotein and of the iron-sulfur protein, by $NADH_2$. This leads to unusual broadening of the Soret band, with displacement to shorter wavelengths (maximum at 410 nm). In the visible region only one band at 540 nm appears. This iron(II) form can add on carbon monoxide, and it then has the typical maximum at 448 nm. This reaction competes with the addition of oxygen, and so inhibits the hydroxylation of camphor[75].

In the presence of D-(+)-camphor one finds the change observed previously for other cytochrome P-450 preparations in the spectrum of the oxidized cytochrome on addition of the corresponding substrates (Fig. 3).

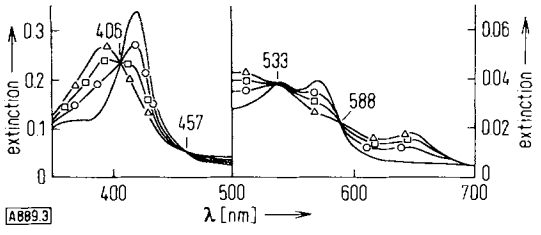

Fig. 3. Titration of cytochrome P-450 from *Ps. putida* with camphor [73]. Concentrations: cytochrome P-450 3.3 μmol/l, camphor (——) 0, (– ○ – ○ –) 2 μmol/l, (– □ – □ –) 6 μmol/l, (– △ △ –) 20.5 μmol/l.

Increasing concentrations of (+)-camphor lead to the development of a new absorption band at 388 nm. At the same time, the α and β bands disappear, and a new long-wave absorption appears at 646 nm. The camphor concentrations required for complete conversion correspond to the saturation concentrations for the hydroxylation reaction[73]. Only a few derivatives of camphor have a similar effect, and these act only in much higher concentrations. All the results point to the formation of an enzyme-substrate complex. Considerable stabilization of the cytochrome is achieved by the binding of the substrate, so that it was even possible to crystallize the enzyme-substrate complex[74].

The development of the long-wave absorption is characteristic of "high-spin" iron-porphyrin complexes[76], so that the probable reason for this spectral change is the transition from a "low-spin" form to a "high-spin" complex of the trivalent cytochrome. This assumption has been confirmed with the aid of electron spin resonance (EPR)[73,77] and by measurement of the magnetic susceptibility[73]. The anisotropic EPR spectrum of oxidized cytochrome P-450 is typical of "low-spin" hemin compounds, but with the characteristic that the g values lie close together. In the presence of (+)-camphor, the signal largely disappears, and a new absorption appears at $g = 7.9$; however, this new signal can be observed only at about 7 °K (Fig. 4).

The measurement of the magnetic susceptibility shows that this transition is accompanied by an increase in the number of unpaired electrons, which corresponds to the conversion of a heme with one unpaired electron into a state with five unpaired electrons[73].

According to preliminary results, the spin transition is also linked with a change in potential. The free cytochrome has a strongly negative normal potential at pH = 7.0 (E'_0) of about −380 mV, whereas after the

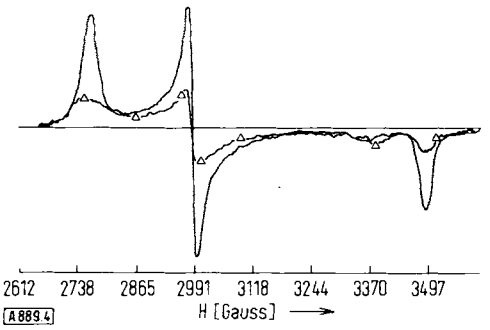

Fig. 4. EPR spectrum of cytochrome P-450 from *Ps. putida* with (–△–△–) 5 μmol/l and (——) without camphor [73]. Cytochrome P-450: 68 μmol/l, temperature: −170 °C.

binding of camphor, the "high-spin" complex has a corresponding potential of about −170 mV[78]. This change in redox potential presumably plays a significant part in the hydroxylation mechanism (Section 3.3).

The activation of oxygen begins with the addition of the oxygen molecule to the reduced form of cytochrome P-450. Since the cytochrome is a one-electron acceptor and donor[73,79], the first step should be the transfer of an electron to the oxygen and the formation of an "oxy form" of the cytochrome:

$$Fe^{2\oplus} + O_2 \rightleftharpoons Fe^{2\oplus}O_2 \rightleftharpoons Fe^{3\oplus}O_2^{\ominus}$$

An oxygen adduct of this type can be observed if the reduced form of the cytochrome is rapidly mixed with oxygen and the spectrum recorded immediately (Fig. 5)[80,81].

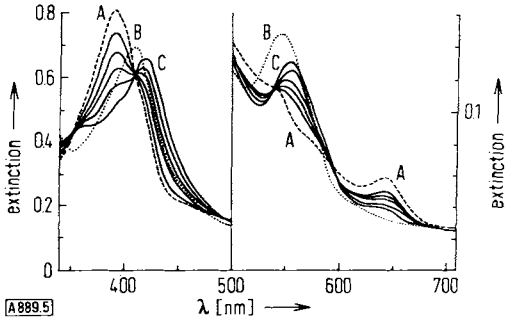

Fig. 5. Autocatalytic decomposition of "oxy"-cytochrome P-450 from *Ps. putida* at 5 °C [81]. A (– – –) cytochrome P-450-camphor complex, B (·····) reduced cytochrome P-450, C (——) reduced cytochrome P-450 aerated with oxygen. The spectra were recorded in the course of 45 min.

The "oxy"-cytochrome P-450 becomes a very stable compound with a half-life of 10—20 minutes if the subsequent further reduction is prevented. The only possible decomposition reaction is a disproportionation with formation of hydrogen peroxide and the "high-spin" form[80]:

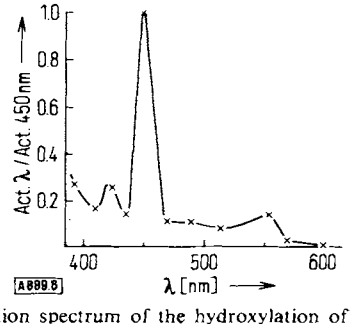
$$2Fe^{3\oplus}O_2^{\ominus} \xrightarrow{+2H^{\oplus}} 2Fe^{3\oplus} + O_2 + H_2O_2$$

The absorption maxima of the oxygenated compound are situated at 418, 555, and 580 nm. At the temperature of liquid nitrogen, it gives no ESR spectrum, so that this form, like oxyhemoglobin, is probably diamagnetic. The actual "active oxygen" should be formed only on reduction of the oxy complex with a second electron. This process has not yet been investigated, but is the most interesting step in the course of the enzyme reaction. Possible structures for the expected "active oxygen" are discussed in Section 4 on the basis of model investigations.

3.2. The Microsomal Monooxygenases of the Liver

The "microsome" fraction of the liver consists predominantly of the fragments of the endoplasmic reticulum. It has been known since about 1950[83] that these cell organelles are responsible for the breakdown of steroids, drugs, and foreign substances ("xenobiotics")[82]. The monooxygenase system contained in this microsome fraction hydroxylates numerous organic lipophilic compounds, which become water-soluble as a result of the introduction of the hydroxyl group, and can thus be eliminated from the organism *via* the kidneys. The characteristic feature of the microsomal hydroxylations is the extensive nonspecificity of the enzyme system responsible. This enables the organism to metabolize and excrete even entirely new synthesized compounds, and hence to avoid intoxication.

It was shown by the above-mentioned method of the photochemical action spectrum that the monooxygenation of codeine, 4-methylaminoantipyrine, acetanilide, and testosterone is catalyzed by the microsomal cytochrome P-450[84]. However, the preferred substrates are the aliphatic hydrocarbons[46,47,85–87], for which the action spectrum of a typical representative, *i.e.* cyclohexane, is shown in Figure 6[45].



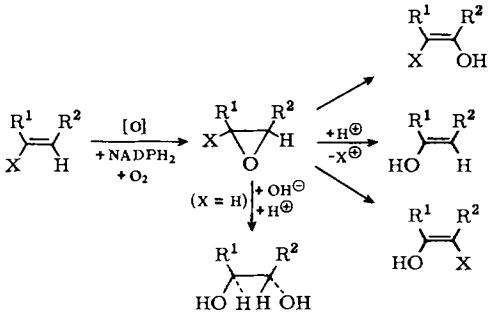


Fig. 6. Photochemical action spectrum of the hydroxylation of cyclohexane with rat-liver microsomes in the presence of carbon monoxide [45].

The influence of the substrate on the spectral properties of the oxidized cytochrome cannot be investigated with the aid of absolute spectra, but only by recording the difference spectra, owing to the turbidity of the microsome solutions. As in the case of the camphor monooxygenase, the half-maximum saturation concentration ("K_s") for the bonding of the substrate to the cytochrome corresponds to the Michaelis-Menten constant (K_M) for the hydroxylation of cyclohexane to cyclohexanol[86]; this again points to the formation of an enzyme-substrate complex. As in the case of bacterial cytochrome P-450, the spectral change is associated with the

transition from the "low-spin" to the "high-spin" form of cytochrome P-450[88]. The fact that a molecule like cyclohexane, with no functional groups, can be bonded to the cytochrome shows that strong lipophilic interactions must occur between the substrate and the active center. Owing to the nonspecificity of these bonding forces, it was reasonable to assume that hydrocarbons related to cyclohexane would also be bound and transformed by the same cytochrome. It has been shown that this is probably so for the C_4 to C_7 alkanes[46, 87].

Another consequence of the nonspecific hydrophobic bonding is the large number of hydroxylation products, among which nearly all the possible isomeric alcohols have been detected[87] (Table 2). The attack by the active oxygen takes place preferentially on the tertiary CH bonds, followed by the secondary and primary CH bonds. For the hydrocarbons mentioned, the proportions in which these bonds are attacked are roughly 150:25:1, and thus correspond to the ratios for a very selective substitution reaction.

indicated in the following scheme are available for the monooxygenation of the sp^2-hybridized carbon atom.

An important question that now arises is whether the same cytochrome P-450 is involved in all monooxygenations catalyzed by the microsome fraction. A number of observations indicate that there are in fact several species of cytochrome P-450, each having a certain

Table 2. Product distribution in monooxygenations in rat-liver microsomes.

Substrate	Products (% relative yield)	Remarks	Ref.
Cyclohexane	Cyclohexanol (100)	Inducible by barbiturates	[86]
n-Butane	2-Butanol (< 100)	Inducible by barbiturates	[87]
Isobutane	2-methyl-2-propanol (< 100)	Inducible by barbiturates	[87]
2-Methylbutane	(2-Methyl-1-butanol + 3-methyl-1-butanol), 3-methyl-2-butanol, 2-methyl-2-butanol (6:20:74)	Inducible by barbiturates	[87]
Methylcyclohexane	1-, 2-, 3-, 4-Methylcyclohexanols, hexahydrobenzyl alcohol (25:8:43:23:1)	Inducible by barbiturates	[87]
Toluene	Benzyl alcohol ≫ cresols (*o*-:*m*-:*p*-cresol = 59:13:28)	ω-Hydroxylation inducible by barbiturates	[88–90]
Anisole	Phenol, 2-, 4-hydroxyanisoles (60:7:33)	*O*-Dealkylation *via* hypothetical α-hydroxylated intermediate	[90]

A very similar result is obtained in the hydroxylation of monosubstituted and disubstituted aromatic hydrocarbons (Table 2). In this case, the hydroxylation clearly follows the rules of electrophilic aromatic substitution, and must therefore proceed *via* an addition of the active oxygen to the π-electron system. This assumption is confirmed by the fact that isolated double bonds are converted into epoxides. In polycyclic hydrocarbons whose π bonds exhibit partial double-bond character, the addition leads to epoxides as intermediates[91, 92]. However, these are very rapidly hydrolyzed both enzymatically and spontaneously to *trans*-dihydrodiols.

The possibility that the hydroxylation of simple aromatic hydrocarbons might also proceed *via* arene oxides was suggested by the observed migration of substituents to the neighboring ring carbon atom, which is referred to in the literature as the "NIH shift"[93]. The hydroxylation of the aromatic carbon atom is accompanied by the displacement not only of chlorine and bromine, but also of tritium, deuterium, and hydrogen into the *ortho* position, often to a large extent[94, 95]. This effect is observed even for isolated double bonds[96], and it must therefore be assumed that the reaction possibilities

group specificity. Important evidence on this point is provided by pharmacological studies on the induction of the monooxygenase system of the liver[97, 98]. Pretreatment of experimental animals with drugs or other foreign substances leads to an increase in the concentrations of cytochrome P-450 and of its reductase in the microsome fraction, which causes an increase in the specific monooxygenase activity, often by a factor of four to eight, and which is the cause of acquired tolerance to drugs.

It was found in these induction experiments, however, that depending on the nature of the compound administered, different increases occur for the various substrates. Barbiturates, for example, increase the monooxygenase activity toward the predominantly aliphatic substrates, whereas pretreatment with polycyclic hydrocarbons greatly increases the activity for the hydroxylation of aromatic compounds. Differences in the spectral properties of the cytochromes[99, 100] and in their inhibition behavior[47, 101, 102] have also been reported.

Small differences in substrate and product specificity exist even within these two groups[103], so that instead

of the total nonspecificity formerly assumed for microsomal monooxygenases, it is now necessary to postulate a group specificity.

3.3. The Course of the Cytochrome P-450-Catalyzed Monooxygenation

Insofar as a general picture of the reactions on cytochrome P-450 is now available, the course of these reactions is independent of the source of the cytochrome. The sequence of the individual reaction steps follows logically from the results obtained so far; it is summarized in Figure 7.

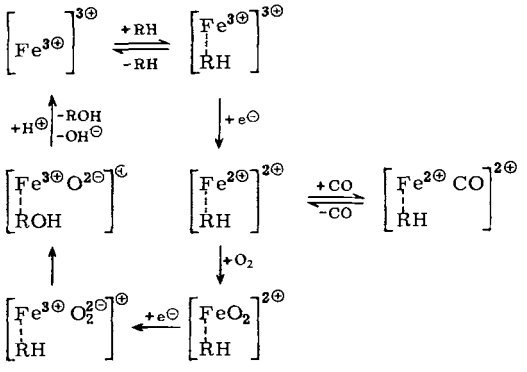

Fig. 7. Reaction scheme for the mode of action of cytochrome P-450-dependent monooxygenases.

As in any enzymatic catalysis, the first step is the formation of an enzyme-substrate complex. The associated change in the conformation of the enzyme allows the spin change, and so leads to the spectral shift observed. This process proceeds at a high rate. For example, the second order rate constant for the formation of the camphor-cytochrome P-450 complex at 8 °C is $3.7 \times 10^6 \,\mathrm{l\,mol^{-1}\,s^{-1}}$[104]. The equilibrium constant in the presence of potassium ions has the following value[73]:

$$K = \frac{[\mathrm{E \cdot Camphor}]}{[\mathrm{E}]\,[\mathrm{Camphor}]} = 0.47 \times 10^6 \,\mathrm{l\,mol^{-1}}$$

In addition to the dipole interactions between the substrate and the protein, the main bonding forces are the apolar bonds, which are largely responsible for the increase in entropy on transfer of the lipophilic substrate from the aqueous phase into the hydrophobic environment of the active center. The substrate can often be completely displaced from the active center by addition of organic solvents[105].

The precise location of the substrate will be obtainable only from the X-ray structure analysis of the crystallized cytochrome P-450-camphor complex[74]. Inhibition experiments with metyrapone [2-methyl-1,2-bis-(3-pyridyl)-1-propanone][106] have shown that the bonding site of the substrate must lie in the immediate vicinity of the oxygen bonding site, *i.e.* of the iron ion. The metyrapone molecule is bonded stoichiometrically *via* a pyridine nitrogen to the iron, and at the same time competitively inhibits the bonding of camphor. In the reduced state, this compound also inhibits the addition of carbon monoxide, so that the sixth coordination site, as the oxygen bonding site, must be occupied[106]. The particular properties of cytochrome P-450 can be satisfactorily explained by the ligand on the fifth coordination site, which is probably the $S^{\ominus}$ group of a cysteine[107]. The main evidence, apart from the reactivation of cytochrome P-420 to cytochrome P-450 by cysteine[108], is the unusual EPR spectrum, which has been very closely simulated in a model from myoglobin and alkylthiols (Fig. 8)[109].

Fig. 8. EPR spectrum of rat-liver microsomes (bottom) and of the metmyoglobin-butanethiol complex (top) at −170 °C [109a].

As a "soft" ligand[110], the sulfur could be responsible for the strongly negative potential of the cytochrome.

The details of the spin reversal on bonding of the substrate are not yet clear. It is assumed[73,77,111] that the substrate displaces a histidine residue from the sixth coordination site, with the result that the formation of the "high-spin" complex becomes possible. In this case, the entire process of the bonding of the substrate could proceed as indicated in the hypothetical Figure 9.

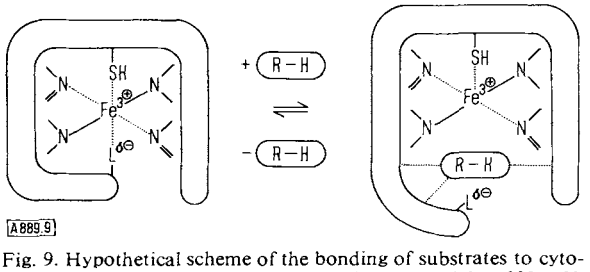

Fig. 9. Hypothetical scheme of the bonding of substrates to cytochrome P-450. Left: "low-spin" complex, potential −380 mV, Soret band at 418 nm; right: "high-spin" complex, potential approx. −170 mV, Soret band at 390 nm.

The next step in the reaction must be transfer of an electron to the cytochrome. It can be shown for the microsomal cytochrome P-450 that the cytochrome-

substrate complex is reduced one order of magnitude more rapidly than the free cytochrome[112]. The electron transport is thus coupled with the presence of the substrate in the active center, and mere oxidation of the hydrogen donor is avoided. This reduction step proceeds relatively slowly; it is usually the rate-determining step in the monooxygenase-catalyzed reactions[112,113]. The oxygen molecule then adds to the reduced enzyme-substrate complex to give the oxy form, from which it can be displaced again by carbon monoxide.

The actual active form of the oxygen is produced from the oxy complex by the transfer of a further electron. This follows first from the stoichiometry of the monooxygenases and from the model reactions that will be discussed in Section 4. Experimental evidence may be seen in *Cooper*'s observations[114], which show that the cytochrome P-450 of the 11β-hydroxylase is unable to hydroxylate deoxycorticosterone after stoichiometric reduction followed by addition of oxygen. The 11β-hydroxylation of the substrate occurs only upon addition of reduced iron-sulfur protein (adrenodoxine).

No measurements have yet been reported for the rate of this second reduction step. The observation that the oxy form of the cytochrome can be detected in microsomes in the steady state of the hydroxylation[115,116] suggests a relatively slow reduction, which cannot, however, be slower than the first electron transfer.

The structure of the active oxygen on the cytochrome P-450 is still completely unknown; a peroxide complex is indicated only formally in Figure 7. The actual monooxygenation of the substrate on transfer of an oxygen atom probably occurs rapidly. It is usually not rate-determining, as is shown by the absence of an isotope effect in the hydroxylation of cyclohexane in microsomes[86].

After the uptake of a proton, the second oxygen atom, which has been reduced to the oxidation stage of water, can dissociate from the cytochrome P-450, so releasing the latter for bonding of the next substrate molecule.

A special situation arises when a compound can be bonded like a substrate, but has no position that can be hydroxylated. This case arises in particular for the microsomal cytochrome P-450, whose substrates are bound to cytochrome P-450 merely because of their lipid-solubility. For example, perfluorinated hydrocarbons can form the enzyme-substrate complex just as easily as the corresponding alkanes, but cannot be hydroxylated because of the stability of the CF bond[117]. In this case, the active oxygen is further reduced to water; the system is thus "uncoupled". This phenomenon is frequently found in the less specific monooxygenase systems.

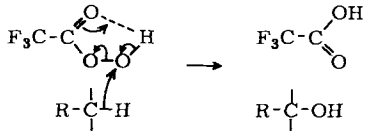
4. Model Investigations on the Activation of Oxygen by Monooxygenases

As in many enzymatic reactions, the direct investigation of the transition state of monooxygenases is not yet possible. In such cases, one may turn to the study of model reactions, but it is then necessary to face the problems that arise in the application of results obtained from models to enzymatic reactions. In the monooxygenase models, because of the numerous reactions of oxygen, the agreement of the enzyme reactions with the model reactions must be checked repeatedly.

Any proposed model must satisfy the stoichiometry of the monooxygenation of two electrons per mole of oxygen and hydroxylated product. It is always difficult to check this stoichiometry in model hydroxylations, since coupling of the reduction and activation of oxygen with the hydroxylation of the substrate can be brought about only by the enzyme through conformational changes in the protein. In all the models known at present, the further reduction of the active oxygen to water accompanies and may even predominate over the hydroxylation.

Because of the high specificity of the reactions, the distribution of the products in the enzymatic catalysis generally provides little information about the transition state. In the microsomal monooxygenases of the liver, we are dealing with a largely unspecific enzyme system, by which, as shown in Table 2, aliphatic compounds undergo selective hydroxylation and aromatic compounds electrophilic hydroxylation. A further characteristic is the epoxide formation and the migration of the aromatic substituent into the *ortho* position, which thus largely characterize the chemical properties of the "active oxygen". Similar attacks on CH bonds and additions to π-electron systems have also been reported for carbenes or carbenoids[118]. It therefore seems reasonable to postulate an "oxenoid" structure for the active oxygen[119,120], the attacking oxygen thus being defined as an electrophilic particle with six valence electrons[121].

4.1. Oxenoid Reactions



The stoichiometry of the monooxygenase reactions suggests that the active oxygen is in the oxidation state of peroxide or of the oxygen atom. Hydrogen peroxide itself is too weak an oxidizing agent to be responsible for the observed hydroxylations. With increasing polarization of the O—O bond by substitution, however, its oxidation potential also increases. Perbenzoic and peracetic acids are still relatively weak oxidizing agents,

Table 3. Hydroxylations with trifluoroperacetic acid.

Compound	Products (% relative yield)	Ref.
2-Methylbutane	(2-methyl-1-butanol + 3-methyl-1-butanol), 3-methyl-butanol, 2-methyl-2-butanol (1.7:5.8:92.5)	[124]
Methylcyclohexane	1-, 2-, 3-, 4-methylcyclohexanol, hexahydrobenzyl alcohol (88.7:3.4:3.6:4.2:0.2)	[124]
[4-D]-Toluene	4-methylphenol, [2-D]-4-methylphenol (32:68)	[125]
Acetanilide	2-, 3-, 4-hydroxyacetanilide (43:1:56)	[44]
4-Bromoacetanilide	2-, 3-hydroxy-4-bromoacetanilide, 4-hydroxy-3-bromoacetanilide, 4-hydroxyacetanilide (41:5:45:9)	[44]

though they already allow epoxide formation[122]. Trichloroperacetic acid is much stronger, and the strongest polarizing action is achieved with the trifluoromethyl group[123]. Table 3 shows the products obtained on oxidation of some compounds with trifluoroperacetic acid.

The essential characteristics of the enzymatic reactions, *i.e.* selectivity, electrophilicity, and substituent migration, are also found in the oxidations with trifluoroperacetic acid, which are best interpreted by the assumption of a concerted substitution mechanism[23,125,126].

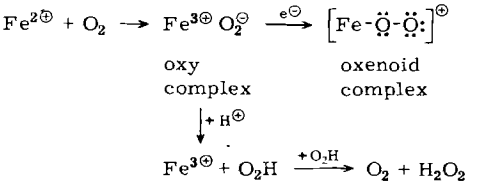
This is in agreement with the observed isotope effect of 2.9 in the hydroxylation of cyclohexane and perdeuteriocyclohexane[86]. Aromatic compounds exhibit no isotope effect in their hydroxylation, since the rate-determining step is the rearomatization of the intermediate product[86]. No evidence of the occurrence of a hydroxyl cation (OH^+) has been found from isotope experiments[125,127].

4.2. Model Hydroxylations with Molecular Oxygen

Though an oxenoid reaction course is very probable for the monooxygenases, it is not known at present how such a peroxide could be formed from molecular oxygen and whether the reaction of an acid in an almost anhydrous medium can be compared with an enzyme reaction in aqueous media.

The first hydroxylase model with molecular oxygen was proposed by *Udenfriend et al.*[128,129]. It consisted of the iron(II)-ethylenediaminetetraacetic acid complex and ascorbic acid, and it catalyzed the electrophilic hydroxylation of aromatic compounds with incorporation of molecular oxygen at pH 7. *Breslow* and *Lukens*[130] found, however, that this system is only a modified Fenton reagent, which yields OH radicals *via* hydrogen peroxide formed as an intermediate. These radicals do not form epoxides and alcohols, and exhibit no substituent migration; they must therefore be ruled out as a model for the active oxygen[120].

The "Udenfriend system" was greatly simplified in subsequent investigations by the replacement of ascorbic acid by other reducing agents and of the iron complex by other autoxidizable metal complexes of iron(II), copper(I), titanium(III), vanadium(III), and tin(II). In addition to the OH radicals, however, these hydroxylation systems also clearly contain a further form of active oxygen, which is much more reactive and also attacks aliphatic compounds with hydroxylation. This new hydroxylation reaction was most easily observed in the reduction of oxygen with tin(II) phosphate complexes, since hydrogen peroxide formed as an intermediate here was immediately reduced to water before OH radicals could be formed[131]. The oxygen of the hydroxyl group introduced was derived exclusively from the gas phase, and the stoichiometry also satisfied the condition of the enzymatic reactions[131]:



$$Sn^{2\oplus} + {}^{18}O_2 + RH \xrightarrow{H^{\oplus}} Sn^{4\oplus} + R^{18}OH + OH^{\ominus}$$

However, the attack by the unknown active form of oxygen took place nonselectively and almost randomly on all the CH bonds present[131,132].

This increased reactivity in comparison with that of the postulated "oxenoid" complex of the monooxygenases could be due to weaker stabilization of the active oxygen on the tin(IV) ion. To assimilate the model further to the enzymatic reactions, iron(II) chelates containing the thiol ligands characteristic of cytochrome P-450 were investigated. Because of the poor water-solubility of the organic chelating agents, it was necessary to work in an organic phase.

A hydroxylating system with new properties was found in the iron(II)-2-mercaptobenzoic acid complex, with acetone as the solvent. With reduction of molecular oxygen, this system not only hydroxylates aromatic compounds in good yields by an electrophilic mechanism, but also selectively hydroxylates aliphatic compounds[124]. However, epoxides are not formed, and the characteristic substituent migration cannot be detected. It is therefore not yet certain how far this system can serve as a model for hydroxylation.

However, the use of organic solvents may be essential to the further development of the model reactions, since they undoubtedly correspond more closely than aqueous solutions to the conditions in the active center of the monooxygenase. Further investigation of the chemistry and thermodynamics of the reduction of oxygen by metal complexes in nonaqueous solutions is still necessary. It is conceivable, however, that the protonation of the O_2^- intermediate, which decreases the yields in the model reactions at present, can be suppressed by avoidance of the aqueous phase.

5. Outlook

For the sake of clarity, it has been necessary to confine this review to the illustrative discussion of the cytochrome P-450-dependent monooxygenases. However, some of the enzymes containing copper[31,32] or flavin[50-52] have also been intensively studied and described in reviews[8,13,15,52,95,121,133,134]. The oxenoid mechanism appears to be common to all monooxygenases. The necessary coupling of the reduction of oxygen and the monooxygenation is evidently always achieved by the substrate-induced change in the conformation of the terminal oxidase.

Since the spin reversal on substrate bonding can be readily followed for cytochrome P-450 by optical

methods and by the electron spin resonance, this cytochrome should be a suitable model for the study of enzyme-substrate complexes. Cytochrome P-450 also offers good prospects for the direct investigation of the activation of oxygen in the transition state, though no suitable measuring methods are available at present. All the model reactions used so far for this purpose have the disadvantage that the reduction of oxygen with homogeneous catalysis does not stop at the stage of the active peroxide, but proceeds further, mainly with formation of water.

It is even possible that the enzymatic monoxygenations may be able to serve in future as models for chemical hydroxylation processes. Further study of the monooxygenases would also seem worthwhile from this point of view, since the specific introduction of hydroxyl groups into organic compounds is undoubtedly an important aspect of preparative chemistry, and is even of technical interest because of the cheap reactants, oxygen and electrical power.

I am deeply grateful to the colleagues mentioned in connection with my own results for their collaboration, as well as to the Deutsche Forschungsgemeinschaft (SFB 38) and the Stiftung Volkswagenwerk for their financial support. A great deal of valuable advice and assistance has resulted from collaboration with Prof. Dr. R. W. Estabrook, Prof. Dr. D. Y. Cooper, and Dr. J. A. Peterson. I am particularly grateful to Prof. Dr. Hj. Staudinger for many joint investigations and for his support of my work over the years.

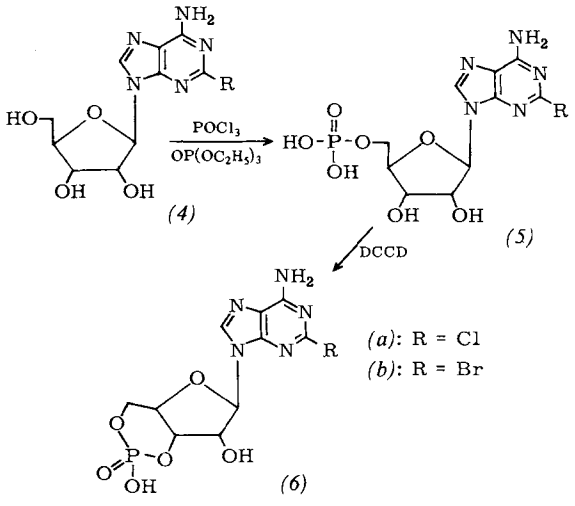
New Analogs of Adenosine-3′,5′-cyclophosphate

By *Bernd Jastorff* and *Wolfgang Freist*[*]

During the past few years adenosine-3′,5′-cyclophosphate (c-AMP) has become recognized as being one of the most important low-molecular weight regulation molecules in all stages of evolution[1]. Numerous derivatives of c-AMP have recently been synthesized[2] in order to obtain substances having specific biological activity and to elucidate the molecular interaction with the receptor. Here we report the synthesis of derivatives modified in the N-1, C-2, and C-2′ positions.

For modification of the N-1 and C-2′ positions, we used adenosine-3′,5′-cyclophosphoric acid *(1)* as starting material.



Oxidation (48 h, room temperature) of adenosine-3′,5′-cyclophosphoric acid *(1)* with monoperphthalic acid[3] in phosphate buffer (pH = 7)[4] affords the 1-*N*-oxide *(2)* in 78% yield (paper chromatographic isolation).

The dinitrophenyl ether *(3)* was prepared by reaction (72 h, room temperature) of the tri-*n*-butylammonium salt of *(1)* with four equivalents of 2,4-dinitrofluorobenzene in DMF/diisopropylethylamine (Hünig base) (40:1) and isolated by preparative layer chromatography (yield 66%).

The C-2 substituted derivatives *(6)* cannot be obtained directly from c-AMP; they were prepared by phosphorylation of the 2-halonucleosides *(4)*[5] with $POCl_3$ in triethyl phosphate[6] [yields: *(5a)*, 68%; *(5b)*, 61%] and subsequent cyclization of the 5′-phosphate *(5)* with dicyclohexylcarbodiimide in anhydrous pyridine: DMSO[7] [yields: *(6a)*, 72%; *(6b)*, 55%].

Preliminary biological investigations of the c-AMP analogs synthesized showed that all compounds are cleaved by bovine-heart cyclophosphodiesterase (E. C. 3.1.4.1). In the case of *(2)* the rate of cleavage is only slightly, in *(3)* about 50%, and in *(6a)* and *(6b)* considerably reduced. Reaction of c-AMP with the enzyme was inhibited 12% *(2)*, 50% *(3)*, 55% *(6a)*, and 77% *(6b)* by equimolar amounts of the analogs. At a concentration of 10^{-5} M all analogs activate the protein-kinase of bovine muscle to about the same degree as c-AMP itself. The combination of reduced rate of cleavage

by the phosphodiesterase and undiminished power of activation of the kinase could lead to enhanced physiological action in intact cells.

A Novel Carrier for the Solid Phase Synthesis of Oligomers[1][**]

By *Hubert Köster* and *Stephan Geussenhainer*[*]

The principal drawbacks exhibited by most of the carriers previously used for solid phase synthesis by the Merrifield method[2] are porosity and swelling[3]. In the synthesis of oligonucleotides further difficulties are presented by the polarity of the phosphodiester bond during reactions in the cavities of the apolar carrier substance[4]. These disadvantages ought to be overcome if non-swellable and non-porous carriers are used. The

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

reactions can take place only on the outer surfaces. The requirement of a sufficiently large surface area necessitates the preparation of very small beads of carrier substance. We were able to prepare a polymer having the desired properties from styrene and 20% divinylbenzene. It consisted of beads having diameters between one and two μm and smaller, and a specific surface area of 8.1 m^2/g. No swelling or porosity was discernable under the conditions used in our studies.

The material can be benzoylated by a Friedel-Crafts reaction. The benzophenone groupings react with *p*-bromoanisole in a Grignard reaction to give *p*-methoxytriphenylmethanol, which is converted into the chloride on reaction with HCl gas in acetic anhydride. Bonding of the nucleotide material takes place *via* the 5'-OH group. As is to be expected on the grounds of specific area, the order of magnitude of the loading is: 6.6 μmol of 3'-*O*-acetyldeoxythymidine and 6.1 μmol of 3'-*O*-acetyldeoxythymidylyl-3',5'-deoxythymidine per gram of carrier substance. These loadings are almost equivalent, whereas in the case of the macroporous bead polymers and emulsion-polymers-used previously a ratio of about 10:1 was observed[5,6]. Cleavage of the nucleotide material from the carrier takes place within 10 minutes in acetic acid at 70°C. Cleavage of the 3'-*O*-acetyl group takes place quantitatively within 2 h in dimethylformamide/pyridine/1 M sodium methoxide (5:4:1, v/v) at room temperature.

Preparation of the polymer:

A two-necked 2 l flask was used for the polymerization (diameter of flask: 12 cm; neck sizes: NS-29 and NS-14.5; distance of top edge of the NS-29 neck from bottom of flask: 26 cm). The NS-29 neck was used for incorporation of a "Tornado-Emulsion" stirrer (manufactured by Emmendinger Maschinenbau) and the NS-14.5 neck for a delivery tube whose drawn-out tip lay directly beneath the stirrer vanes.—A 0.5% aqueous solution of polyvinyl alcohol (1 liter; Schuchardt) was fed into the polymerization flask and the apparatus purged with nitrogen. The stirrer was set at 20000 rpm and the mixture of monomers [divinylbenzene (78 mmol), styrene/ethylstyrene (312 mmol), and azoisobutyronitrile (4.68 mmol) introduced slowly into the flask. The temperature of the reaction mixture increased to 50°C within an hour due to the frictional heat of the stirrer, and commencement of polymerization was readily noticed by the cloud point. The temperature rapidly increased to 65—68°C because of the heat of reaction. This temperature was maintained for a further 3 h, and polymerization was terminated after an additional 3 h at 75°C. The mixture was then passed through a fine sieve (6400 meshes/cm^2) and centrifuged at 2000 rpm. The centrifugate was discarded and the sediment was slurried and centrifuged several times in hot water and then twice in methanol. After drying, the sediment was subjected to several hours' Soxhlet extraction with benzene and finally dried under high vacuum: Yield of polymer 36.5 g (78.3%).

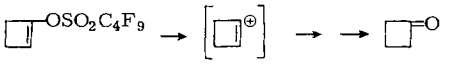
Solvolysis of 1-Cyclobutenyl Nonafluorobutanesulfonate[1][**]

By *L. R. Subramanian* and *Michael Hanack*[*]



Cyclic vinyl trifluoromethanesulfonates (triflates) and cyclic vinyl nonafluorobutanesulfonates (nonaflates) of structure *(1)*, $n = 5$ to 8, undergo solvolysis in solvents of varying ionizing strength to give the corresponding

(1a), X = $-OSO_2CF_3$
(1b), X = $-OSO_2C_4F_9$

ketones[2]. From the very slowly reacting 1-cyclopentenyl triflate (or nonaflate) onwards, increasing rates of solvolysis were measured as the ring size was increased[2,3]. The maximum rate of solvolysis was found in the case of cyclononenyl- *(1a)*, $n = 9$, and of cis-cyclodecenyltriflate *(1a)*, $n = 10$[1]. The dependence of the reaction rate on the ring size is further experimental proof of the intermediary formation of vinyl cations as well as of their preference to assume linear geometry[2,3].

A still lower rate of solvolysis was to be expected for 1-cyclobutenyl nonaflate *(2)*, the lowest homolog of the cyclic vinyl fluoroalkylsulfonates known so far, than for 1-cyclopentenyl nonaflate *(1b)*, $n = 5$, if a highly strained 1-cyclobutenyl cation *(3)* occurs as intermediate.

(2) *(3)* *(4)*

All attempts to prepare 1-cyclobutenyl triflate *(1a)*, $n = 4$, were without success, presumably because of its high volatility. However, we were able to synthesize 1-cyclobutenyl nonaflate *(2)* by reaction of cyclobutanone with nonafluorobutanesulfonic acid anhydride[3] in the presence of tributylamine at 0°C (yield (15%)). *(2)* was purified by column chromatography (silica gel; petroleum ether, b.p. 40—60°C). IR spectrum (capillary): 1643 ($\nu_{C=C}$); 1445, 1225, 1150 cm^{-1} (ν_{-SO-O-}); NMR spectrum (CCl_4): $\tau = 4.58$ (broad s, 1 H, vinyl proton), 7.02 (m, 2H, next to Nf), 7.7 (m, 2H).

1-Cyclobutenyl nonaflate *(2)* (1 mmol) was solvolyzed for two days at 100°C in 50% aqueous ethanol buffered with triethylamine (2 mmol). Cyclobutanone *(4)* was the only reaction product formed.

Table 1. Rates of solvolysis of cyclobutenyl nonaflate *(2)* [a].

Compound	Temp. (°C)	k_1 (sec^{-1})	$\Delta H^{\neq}$ (kcal/mol)	$\Delta S^{\neq}$

[**] This work was supported by the Fonds der Chemischen Industrie. L. R. S. thanks the Alexander-von-Humboldt Foundation for a grant.

Table 1 shows the rates of solvolysis of cyclobutenyl nonaflate *(2)* in ethanol/water mixtures of various ionizing strengths; Table 2 shows the rates of solvolysis of *(2)* in comparison with those of other vinyl nonaflates. Although the highly strained vinyl cation *(3)*

Table 2. Rates of solvolysis of cyclic Vinyl nonaflates in 50% Ethanol at 100 °C [a].

Nonaflate	k (sec^{-1})	k_{rel}
Cyclobutenyl-	3.5×10^{-3}	73400
Cyclopentenyl-	4.7×10^{-8}	1
Cyclohexenyl-	9.4×10^{-7}	20
Cyclooctenyl-	10.5×10^{-3}	222500

[a] Extrapolated from measurements at other Temperatures [3].

ought to be formed from *(2)*, the latter has a comparatively very high rate of solvolysis. It reacts much more rapidly than cyclopentyl nonaflate and at about the same rate as cyclooctenyl nonaflate, for which the linear geometry of the vinyl cation is readily attainable.

In order to exclude a possible addition-elimination mechanism[5] in the solvolysis of 1-cyclobutenyl nonaflate, the reaction rate constant of *(2)* was measured within a pH range of 3.2 to 9.2. As shown in Table 3, the rate of solvolysis is almost independent of pH[6].

Table 3. Rates of solvolysis of *(2)* as a function of pH in 50% Ethanol at 52.2 °C [a].

pH	$k_1 \times 10^5$ (sec^{-1}) [b]
3.2	2.66
4.2	2.55
5.2	2.69
6.2	2.57
7.2	2.74
8.2	2.86
9.2	2.83

[a] Determined by the continuous method [4].
[b] Mean error: 1.7%.

Further evidence for the formation of a vinyl cation in the solvolysis of *(2)* is provided by the fact that the rate of solvolysis increases with increasing ionizing strength of the solvent (Table 1). The calculated *m*-value (Winstein-Grunwald) of 0.61 is in good agreement with values expected for S_N1 reactions of vinyl derivative [5, 7].

The high rate of solvolysis of cyclobutenyl nonaflate *(2)* is indicative of a stabilization of the intermediary vinyl cation. We have already suggested the formation of a stabilized 1-cyclobutenyl cation in the rearrangement of homopropargyl compounds to cyclobutanones and cyclopropyl ketones[5, 8]. CNDO calculations for the cyclobutenyl cation *(3)* have shown[9] that a bridged form *(5)* ought to be more stable than *(3)*. The high reactivity of *(2)* thus points to the formation of a non-classical vinyl cation *(5)* in which the conditions are particularly suitable for orbital overlapping[9].

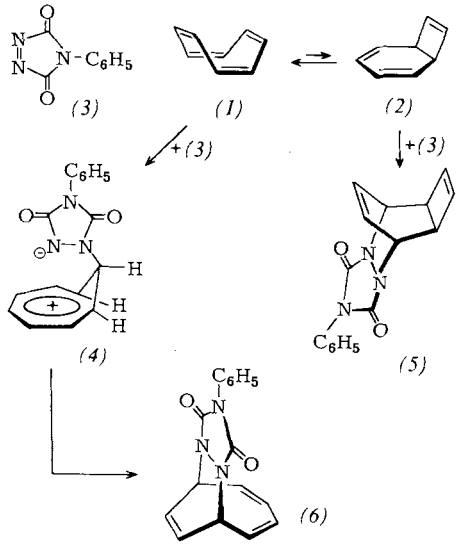
1,4-Cycloaddition of Azodicarboxylic Phenylimide [4-Phenyl-1,2,4-triazoline-3,5-dione] to Cyclooctatetraene and Its Halogen Derivatives



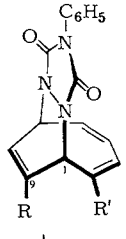
By *Rolf Huisgen, Will Elmar Konz*, and *Ulrich Schnegg*[*]

The boat conformation *(1)* of cyclooctatetraene results in maximal hindrance to conjugation of the localized double bonds and thus does not provide a planar 1,3-diene system suitable for the Diels-Alder reaction. It is not only formally that the Diels-Alder adducts with dienophiles[1] are derived from bicyclo[4.2.0]octatriene *(2)*, for kinetic study of the reactions with tetracyanoethylene and other highly active dienophiles has shown that the cycloaddition is preceded by the valence tautomerization *(1)* → *(2)*, which affords the necessary quasiplanar diene system[2, 3].

(1) *(2)*

Azodicarboxylic phenylimide [4-phenyl-1,2,4-triazoline-3,5-dione] *(3)* combines with *(1)* to give not only the "normal" adduct *(5)*[4], but also the direct 1,4-

(3) *(1)* *(2)* *(4)* *(5)* *(6)*



[*] Prof. Dr. Rolf Huisgen, Dr. W. E. Konz, and Dipl.-Chem. U. Schnegg
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

adduct *(6)* of cyclooctatetraene[5, 6]. The activation energy of the valence isomerization *(1)* → *(2)* amounting to 27.4 kcal/mol[3] must be provided for the formation of *(5)*. However, a smaller temperature coefficient is to be expected for the 1,4-cycloaddition; both the multicenter Diels-Alder reaction and the two-step reaction by way of a zwitterion should show large negative activation entropies. If the reaction of *(3)* with itself[7] is suppressed in dilute solution, the temperature dependence of the composition of the mixed adducts (determined by NMR spectroscopy) accords with expectation (Table 1). The formation of *(5)* is suppressed at 20 °C; that the yield of *(5)* + *(6)* decreases from 100 to 20 °C is explained by the fact that an increasing percentage of the sensitive *(3)* suffers decomposition during the long reaction times required at low temperatures.

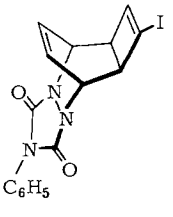


Table 1. Yields of the cycloadducts *(5)* and *(6)* on reaction of cyclooctatetraene (0.04 M) with azodicarboxylic phenylimide (0.01 M) in dioxane.

Temp. (°C)	Reaction time	Yield (%) *(5)*	*(6)*	*(5)*/*(6)*
100	15 min	32	31	1.0
60	3 h	13	41	0.32
40	2 days	6	37	0.16
20	14 days	0	37	0.00

The activity of *(3)* exceeds that of tetracyanoethylene not only as dienophile[4] but also as electrophile. We presume therefore that the cycloaddition of *(3)* to *(1)* proceeds *via* the homotropylium zwitterion *(4)*. Halogenation of *(1)*[8, 9], 1,4-addition of *N*-chlorosulfonyl isocyanate[10], and formation of the cyclic sulfone by $SO_2 \cdot SbF_5$[11] also occur by way of the homotropylium zwitterion.

	R	R'
(7)	H	I
(8)	I	H

(9)

Whereas fluoro-[12] and chlorocyclooctatetraene[13], on reaction with *(3)*, afford only adducts of type *(5)*, both types of adduct are obtained from bromocyclooctatetraene[13]. The latter situation is also the case for iodocyclooctatetraene[14], which with 1.2 M *(3)* in ethyl acetate at 20 °C gives 7.4% of *(7)* and 4.2% of *(8)* in 4 weeks, but at 80 °C gives 5.0% of *(7)*, 3.5% of *(8)*, and 13% of *(9)* in 2 hours; the main product is 1,2-hydrazinebis(dicarboxylic phenylimide), which arises from 2 molecules of *(3)*[7]. The adducts *(7)* to *(9)* were separated by thin-layer chromatography and their structures were determined by double resonance NMR spectroscopy.

1,4-Cycloaddition of Tetracyanoethylene to Methoxy- and Phenoxy-cyclooctatetraene

By *Johann Gasteiger* and *Rolf Huisgen*[*]

An increase in dienophile activity by 6 powers of ten is observed for Diels-Alder reactions in the series maleic anhydride, tetracyanoethylene *(1)*, and azodicarboxylic phenylimide[1], this order also being that of increasing electrophilicity.

With maleic anhydride or *(1)*, cyclooctatetraene reacts exclusively through the quasiplanar diene system of the valence tautomer bicyclo[4.2.0]octatriene[2]. With the azodicarboxylic imide, however, this is accompanied by direct 1,4-addition, presumably through the homotropylium intermediate[3]. If the electron density of the cyclooctatetraene is increased by a methoxyl or phenoxyl substituent, then tetracyanoethylene, but not maleic anhydride, also undergoes 1,4-addition to the four-fold unsaturated, eight-membered ring. The homotropylium intermediate *(3)* is additionally stabilized by the ether group.

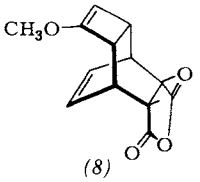
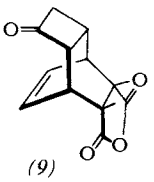
Reaction of methoxycyclooctatetraene *(2a)*[4] with *(1)* in benzene for 15 hours at 20 °C yields a cycloadduct



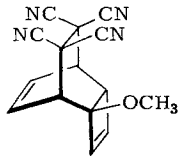
[*] Dr. J. Gasteiger and Prof. R. Huisgen
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

mixture that according to NMR analysis contains *(4a)* and *(5a)* in the ratio 1:4; fractional crystallization leads to the yields shown in the formula scheme. Treatment of phenoxycyclooctatetraene *(2b)*[4] with *(1)* for 40 hours gives an analogous result, but in this case the main product is *(6b)* containing a four-membered ring.

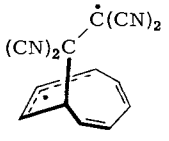


All the adducts were analyzed by NMR spectroscopy; double resonance measurements at 100 MHz and spin tickling provided all the τ- and *J*-values and made it possible to assign them unambiguously. Iteration of the spectra calculated by the LAME computer program[5] led to simulation of the experimental spectra and precise values for the parameters.

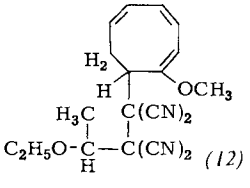
(7)



(8)



(9)



Maleic anhydride reacts with *(2a)* only by way of the valence tautomer *(7)*: after 40 hours in benzene at 70°C 99% of *(8)* can be isolated, this being hydrolyzed even in moist ethyl acetate to *(9)*, which was previously obtained from cyclooctatrienone and maleic anhydride[6].

(10)

(11)

(12)

Irradiation of the adduct *(5a)* in ether by a mercury high-pressure lamp in a glass vessel furnishes 37% of methoxycyclooctatetraene *(2a)*, 44% of the tricyclic adduct isomer *(10)*, and 6.5% of the compound *(12)* in which the adduct has formally taken up a molecule of diethyl ether. The structures *(10)* and *(12)* were likewise elucidated by 100 MHz NMR spectra with decoupling experiments.

The photolysis of *(5a)* to *(2a)* is symmetry-allowed as cycloreversion [6 + 2] from S_1; fission of *(11)* could also lead to *(2a)*. The disrotatory cyclization of the 1,3-diene systems in *(5a)* to the cyclobutene ring in *(10)* is allowed from the S_1 state. The ether adduct *(12)* could be formed through the biradical *(11)*.

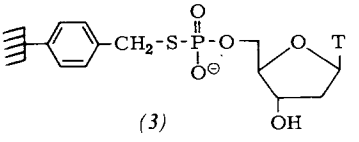
Synthesis of Oligodeoxynucleotides with 5′-Terminal Phosphate Groups



By *Hans Sommer* and *Friedrich Cramer*[*]

In most oligonucleotide syntheses[1] on polymeric carriers a nucleoside is first attached to the carrier by its 5′-OH group. Removal of the synthesized oligonucleotide regenerates a free 5′-OH group, which must be phosphorylated for further block condensation of the product[2]. This additional step can be avoided if a nucleotide is attached to the carrier by the 5′-phosphate group. Two methods of this type have already been described[3].

We have found a new and simple method of synthesizing oligonucleotides containing 5′-phosphate groups. The carrier used is a 5% crosslinked macroporous chloromethylpolystyrene *(1)*[**] (chloromethylation of the polystyrene effected by *Merrifield*'s method[4]), containing 0.75 mmol of chloromethyl groups per gram of polymer. It is treated in dimethylformamide for 24 h at 60°C with a 1.3-fold excess of sodium thymidine 5′-phosphorothioate *(2)*[5], affording *(3)* by *S*-alkylation[6]. The amount of loading with *(2)* depends on

(1) (T = Thymine) *(2)*

(3)

the reaction time, the temperature, and the relative amounts of the reactants; it ranges from 0.083 to 0.41 mmol per gram of polymer, the optimum for oligonucleotide syntheses being 0.175 to 0.27. Unchanged chloromethyl groups are etherified by 2 N Na methoxide in anhydrous pyridine (1:6) in 1 h at room temperature.

Stepwise formation of the oligonucleotide chain is achieved by linking the free 3′-OH group with a 3- to 5-fold excess of protected 3′-*O*-acetyldeoxynucleoside 5′-phosphate in anhydrous pyridine during 6 to 8 h at room temperature in presence of 2,4,6-triisopropylbenzenesulfonyl chloride (TPSCl) as condensing agent (2.5-fold excess with respect to the phosphate component). After removal of the 3′-*O*-acetyl group by 2 N Na methoxide in anhydrous pyridine (1:9) during 25 min at room temperature the next condensation step can be undertaken.

Removal of the oligonucleotide from the polymer is effected by iodine (10 mg/ml) in pyridine/water (3:1) during 20 h at room temperature, the protecting groups being retained during this process. The following oligodeoxynucleotides were prepared by this method and were characterized by paper chromatography and enzy-

[2 + 4]- and [4 + 4]-Photoaddition of Cyclopentadiene to Anthracene[**]

By *Gerd Kaupp*[*]

The question whether photochemical four-center additions occur by concerted or multistep processes is important for the quantum balance and in particular is of preparative interest[1-3]. We report here about competing [2 + 4]- and [4 + 4]-photoadditions of cyclopentadiene to electronically excited anthracene[2].

On selective irradiation of anthracene (5 successive portions of 1.0 g each) in cyclopentadiene (500 ml) [0 ± 5 °C; N_2; $\lambda > 330$ nm; Hanovia 450 watt Hg high-pressure lamp, $Cu(NO_3)_2$ filter solution] to complete reaction (*ca.* 5 × 1 h), subsequent recovery of cyclopentadiene and evaporation in a high vacuum (5×10^{-4} torr, 40 °C), 1.24 g (25%) of the known anthracene dimer[4] was isolated by filtration. The ether-soluble portion of the residue consists, according to NMR analysis, of 42% of *(2)* and 58% of *(4)*. The two isomers can be separated by repeated fractional crystallization from acetonitrile or by preparative layer chromatography (SiO_2, CCl_4) and can be identified by their spectral properties[5].

The asymmetry of *(2)* (m.p. 153—154 °C) accounts for its complicated NMR spectrum [60 MHz, $CDCl_3$: $\tau = 2.6$ to 3.1 (8 H/m), 4.7 (2 H/degenerate AB with central s, $\Delta\nu_{1/2} = 1.8$), 5.75 (1 H/AB, $J = 3.0$, $\Delta\nu_{1/2} = 1.1$), 5.9 (1 H/BA, $\Delta\nu_{1/2} = 1.4$), 6.6 to 6.95 (1 H/m), 7.0 to 8.4 ppm (3 H/overlapping m)].

On the other hand, the symmetry plane present in *(4)* (m.p. 117 °C) can be recognized in its NMR spectrum [$CDCl_3$: $\tau = 2.7$ to 3.05 (4 H/AA'BB'), 2.8 to 3.15 (4 H/AA'BB'), 4.3 to 4.45 (2 H/AA'XX'), 6.05 (2 H/AB, $J = 9.0$, $\Delta\nu_{1/2} = 1.5$), 7.2 (2 H/BA, $J = 9.0$, numerous couplings), 8.3 (1 H/tAB, $J = 11.4$, 4.4), 8.75 ppm (1 H/BA, $\Delta\nu_{1/2} = 3.2$)].

Further differences between the isomers which may be hydrogenated catalytically to *(3)* (m.p. 131—132 °C) and *(5)* (m.p. 159 °C)[5], respectively, occur in the positions of the UV maxima [CH_3CN; *(2)*: $\lambda_{max}(\varepsilon) = 252$ sh (720), 259sh (920), 265.5 (1440), 272.5 (1860); *(4)*: 267sh (1050), 273.5 (1740), 281nm (2550)], the fluorescence behavior [cyclohexane; *(2)*: $\lambda_{max}^{corr.} = 286$ nm, $\Phi_{Fl} = 0.38$; *(4)*: 293, $\Phi_{Fl} = 0.03$], and the efficiency of the photocycloreversion.

On irradiation (272 nm, CH_3CN; $c_0 = 5 \times 10^{-4}$ mol/liter), the intensely fluorescing hydrocarbon *(2)* affords less than 1.5% of anthracene along with unidentified other products. However, *(4)* is photolyzed largely uniformly to anthracene and cyclopentadiene (yield of anthracene 79—80%; quantum yield of anthracene formation, $\Phi = 0.26$; $c_0 = 5 \times 0^{-4}$ mol/liter; CH_3CN; 20 °C) and *(2)* (see formula scheme).

This behavior can be utilized to simplify the isolation of *(2)*, namely by (almost) selective irradiation (CH_3CN, mercury high-pressure lamp, Pyrex filter) of the longer-wave absorbing component *(4)* of *(2)*/*(4)* mixtures, whereafter 80% of dimeric anthracene [based on *(4)*] can be filtered off and an increase in the yield of *(2)* achieved [from 150 mg of pure *(4)*, 28 mg of *(2)* (the result of a photochemical 1 → 3 shift) can be isolated by chromatography].

The ratio 5:7 of [2 + 4]- to [4 + 4]-photoaddition on selective irradiation of anthracene in cyclopentadiene (quantum yield of anthracene consumption amounts to 0.065: $c < 3 \times 10^{-4}$ mol/liter, 365 nm, 18.5 °C, N_2)[6] is understandable in terms of the experimentally proved two-step mechanism of photochemical four-center reactions[1] assuming that the intermediate product *(1)* has a long enough life-time for (partial) rotation around

Chemisches Laboratorium der Universität
78 Freiburg, Albertstrasse 21 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

the first σ-bond formed before stabilization to give the end products or starting materials. Experiments to date provide no indication whether the σ-complex *(1)* is formed from a single definite π-complex (exciplex). Molecular models and the quantum yield—the latter relatively small in comparison with dimerization of anthracene ($\Phi_{max} = 0.3$[4])—indicate, on the contrary, steric hindrance to a sandwich-like approach. The reduced fluorescence yield of anthracene in cyclopentadiene ($\Phi_{cyclohexane}/\Phi_{cyclopentadiene} = 1.8$) should then be largely the result of σ-interaction. This is indicated also by the relatively large quantum yield for the photochemical formation of anthracene from *(4)* (see formula scheme and [1]).

Unlike the observations reported above, the addition of 1,3-cyclohexadiene to anthracene appears to lead exclusively to the [4+4]-adduct (homolog of *(4)*)[7]. The results reported in the present communication, as well as previous measurements on cyclovinylogous model systems[1], strongly suggest that 1,3-cyclohexadiene is added nonconcertedly in two discrete steps. This is indicated also by the considerable geometrical change occurring in the four-center reaction, even if *chemical deactivation* begins with the postulated exciplex intermediate[7,8]. This suggests that chemical quenching of fluorescence[1] can be ruled out on the evidence of photochemical quantum yields only in cases where it is possible to make quantitative predictions about all the deactivation processes of exciplexes and intermediates of type *(1)* (see, however, p. 288 in [8]).

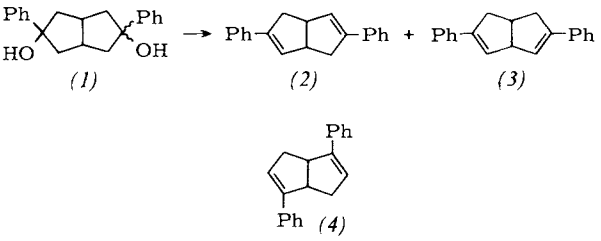
Photoprocesses of Phenyl-Substituted Tetrahydropentalenes[**]



By *Gerd Kaupp* and *Klaus Krieger*[*]

The experimental evidence for the two-step course of photochemical four-center reactions[1] made it desirable to seek intramolecular [$_\pi 2 + _\pi 2$]-photocycloadditions to substrates that contain *non-parallel, fixed double bonds*[2]. We report here on the irradiation of the phenyl-substituted tetrahydropentalenes *(2)*, *(3)*, and *(4)*[3].

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

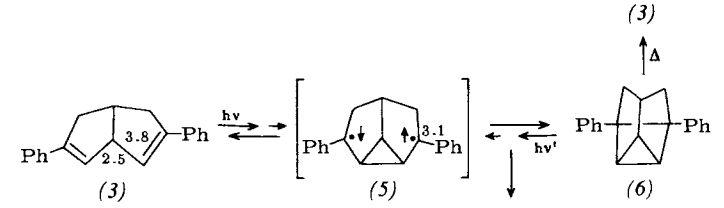
Contrary to previous assumptions[4], dehydration of the diol *(1)*[4] by oxalic acid at 115°C affords the two dienes *(2)* and *(3)* approximately in the ratio

(1) *(2)* *(3)*

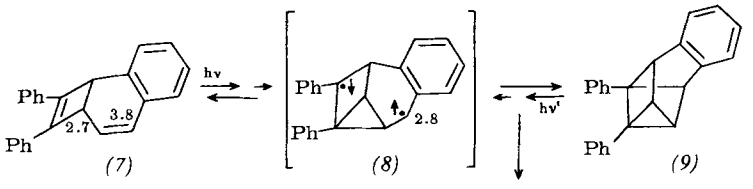
(4)

1:1 (NMR analysis). On recrystallization from CH_3OH they are isolated as 1:1 mixed crystals (long needles, m.p. 109 to 115°C [4]: 104°C) and can be separated by chromatography (Al_2O_3, activity 1; cyclohexane), which involves large losses of *(3)*[5].

A decided improvement in the isolation of *(3)* is achieved by irradiation (CH_3CN, N_2, 0 ± 5°C, Hg high-pressure lamp, Pyrex filter) of the 1:1 mixture of *(2)* and *(3)* to nearly complete reaction of *(3)* [formation of *(6)*, see formula scheme], addition of benzoyl peroxide (molar ratio = 1:1) and further irradiation [radical polymerization of *(2)*], heating for 30 min in CCl_4 to regenerate *(3)*, and chromatography (SiO_2/CH_2Cl_2) for 0.5 h, whereupon 40 to 50% of the *(3)* originally present is obtained.



The structures of the isomers *(2)* (m.p. 118—119°C) and *(3)* (m.p. 121—122°C)[6] can be assigned from the NMR spectra because of the magnetic equivalence of the bridge protons in *(2)* [$CDCl_3$, $\tau = 2.45$ to 2.9 (10 H/m), 3.9 to 4.1 (2 H/m), 6.15 to 6.5 (2 H/m), 6.7 to 7.6 ppm (4 H/m)], the difference for *(3)* [$CDCl_3$, $\tau = 2.35$ to 2.9 (10 H/m), 3.75 to 3.9 (2 H/m), 5.75 to 6.1 (1 H/m), 6.55 to 7.65 ppm (5 H/m)], and comparison with *(4)*[7] [$CDCl_3$, $\tau = 2.4$ to 2.85 (10 H/m), 3.9 to 4.1 (2 H/m), 5.75 to 6.15 (2 H/m), 6.75 to 7.85 ppm (4 H/m)]. The UV spectra of *(2)* [$\lambda_{max}(\varepsilon) = 253$ (30000), 258 (32000)] and *(4)* [252 (29500), 257 nm (30000)] in CH_3CN are almost superposable and have long-wave fine structure; but for *(3)* [$\lambda_{max}(\varepsilon) = 269$ (28500)] also short-wave shoulders can be resolved (spectral band width 0.5 nm), and the onset of absorption (at *ca.* 310 nm) is red-shifted by about 10 nm in comparison with *(2)* and *(4)*.



On irradiation (250 to 292 nm, CH_3CN, N_2, 20 and −190°C in ether/alcohol glasses), *(2)* and *(4)*, whose double bonds are separated by about 3.5 Å (measurement on molecular models), do not undergo intramolecular formation of tetracycles. They give intense fluorescence spectra with fine structure [cyclohexane, N_2, 20°C; *(2)*: $\lambda_{max}^{corr.}$ (Φ_{Fl}) = 300 sh, 310, 317 sh, 332 sh (0.088); *(4)*: 297, 310, 318 sh, 335 sh nm (0.090)].

However, no fluorescence ($\Phi < 10^{-4}$) can be detected for *(3)* although photochemical formation of *(6)* occurs rather slowly [NMR ($CDCl_3$, 20°C): $\tau = 2.5$ to 3.35 (10 H/m with central s, $\Delta\nu_{1/2} = 2.0$), 7.15 to 8.4 ppm (8 H/m)]. The quantum yield, measured photokinetically[1] [CH_3CN, N_2 or O_2, 20°C, 289 nm, bandpass 4.8 nm, $c_0 = (1 \text{ to } 2) \times 10^{-4}$ mol/liter] amounts to 0.025 and the isosbestic points are at 233 and 221 nm.

The failure of *(3)* to fluoresce [in contrast to *(2)* and *(4)*] is interpreted by almost quantitative transformation of electronically excited diene *(3)* into the short-lived intermediate *(5)* (chemical quenching of fluores-

cence) considering the relatively minor geometrical change (molecular models; cf.[1]). Primarily because of the rather large separation of the radical centers in *(5)*, there is a greater likelihood of cleavage of the three-membered ring to give *(3)* than of formation

of the tetracycle *(6)*. It is, therefore, not surprising that *crystalline (3)* (pure or in KBr, $\lambda > 270$ nm) does not form any *(6)* but instead polymerizes and is photostable (no phosphorescence) at -190 °C (methylcyclohexane/*n*-pentane glass, 250—292 nm), whereas the light-induced reverse reaction [*(6)* → *(3)*, 250 nm] occurs very rapidly and largely uniformly at -190 °C.

The interconversion *(7)* ⇄ *(9)*[8] substantiates this interpretation, according to which formation of the tetracycle from *(5)* is hindered by an activation barrier of geometrical origin. For geometrical reasons (molecular models) the formation of *(8)* should be more difficult than of *(5)*. Conversely, the final four-membered ring closure to give *(9)* should be more favored than that leading to *(6)*. In fact, during irradiation of *(7)* there is concurrent intense fluorescence of the stilbene chromophore (313 nm, cyclohexane, $\lambda_{max}^{corr.} = 390$ nm, $\Phi_{Fl} = 0.012$). Nevertheless, *(9)* is formed in appreciably higher quantum yield than *(6)*: $\Phi_{(7)\rightarrow(9)} = 0.16$ to 0.17 (CH_3CN or C_2H_5Br, N_2 or O_2, 20 °C, 313 or 334 nm; isosbestic points in CH_3CN at 243 and 248 nm). Again the intramolecular cycloaddition can be frozen out at -190 °C (ether/alcohol glass) and in this case can be effected also from the crystalline state at room temperature.

The photoreversion *(9)* → *(7)* (250 nm) occurs with an initial quantum yield $\Phi \leq 0.2$ (CH_3CN, N_2, 20 °C). As with *(6)*, luminescence was observed only after formation of appreciable amounts of by-products and the photoreaction becomes more uniform at -190 °C. It is conceivable that excitation of *(6)* and *(9)* affords other intermediate photoproducts besides *(5)* and *(8)*, respectively.

The experimental results do not require postulation of either a triplet mechanism or of a photochemical transition state with unequally advanced bond formation at four reaction centers.

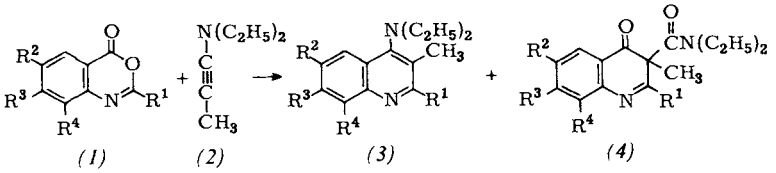
4-(Dialkylamino)quinolines and 3,3-Disubstituted 4(3*H*)-Quinolones from 4*H*-3,1-Benzoxazinones and Ynamines

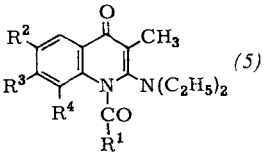
By *Gerhard Höfle*, *Oswald Hollitzer*, and *Wolfgang Steglich*[*]

The 2-(trifluoromethyl)-4*H*-3,1-benzoxazinones *(1a)* to *(1d)* react with *N*,*N*-diethyl-1-propynylamine *(2)* in ether even at -20 °C with vigorous evolution of CO_2 and formation of 4-(diethylamino)quinolines *(3)* within a few minutes. In acetonitrile or 2-propanol appreciable amounts of 3,3-disubstituted 4(3*H*)-quinolones *(4)* are also formed.



Replacing the CF_3 groups by H, CH_3, or C_6H_5 reduces the reactivity. Whereas *(1e)*[2] still reacts exothermally, for *(1f)* and *(1g)* heating or standing for a considerable time is necessary[4]. Unlike the reactions of the CF_3 compounds *(1a)* to *(1d)*, these always lead, even in apolar solvents such as ether and benzene, to mixtures of *(3)* and *(4)*. From *(1g)*, 1-benzoyl-4(1*H*)quinolone *(5)* is isolated as third product. The separation of

[*] Dr. G. Höfle, Dipl.-Chem. O. Hollitzer, and Prof. Dr. W. Steglich
Organisch-Chemisches Institut der Technischen Universität
1 Berlin 12, Strasse des 17. Juni 135 (Germany)



(3), (4), and (5) was achieved by different methods. Thus (4c) and (4d) are easily separated from (3c) and (3d) respectively by their lower solubility in ether/light petroleum. In case of (3f)/(4f) the stronger base (3f) was extracted with aqueous citric acid from ether. (3g), (4g), (5g) were separated by chromatography on alumina.

positions of the substituents on the pyridine nucleus were proved by synthesis of (3f) from 4-chloro-2,3-dimethylquinoline and diethylamine.

The amides (4) are of interest as the first representatives of the 4(3*H*)-quinolone series. On acid hydrolysis they afford 4(1*H*)-quinolones and when heated at 150 to

[a] All the compounds gave correct elemental analyses.
[b] Singlet; for (3a) to (3d) a multiplet, J = 1.8 Hz.
[c] Perchlorate.

The structure of *(5g)* follows from the spectroscopic data [IR, see Table 2; UV (ethanol), $\lambda_{max}(\varepsilon) = 334$ nm (12500), 325 (13800), 240 (27400)] and from acid hydrolysis to 2-(diethylamino)-3-methyl-4(1*H*)quinolone[6].

The dipolar species *(7)*, arising by nucleophilic attack of the ynamine on the C=N double bond of *(1)*[8], can be considered as intermediate leading to *(3)*. However, it is not possible to decide without ^{18}O labeling experiments, whether *(4)* and *(5)* are formed *via* attack on the C=N or the C=O group[9] of the azaanhydride system.

(6)

(7)

Our methods of preparing *(3)* extend the synthesis of 4-(dialkylamino)-2-(*sec*-alkyl)quinolines by reaction of ynamines with ketene imines as recently reported by *Ghosez* and *de Perez*[7].

4-(Diethylamino)-3-methyl-2-(trifluoromethyl)-quinoline (3a):

(2) (1.7 ml) in CCl_4 (5 ml) is added dropwise to a stirred, ice-cold solution of *(1a)* (2.15 g) in CCl_4 (10 ml). Vigorous evolution of CO_2 occurs during this addition. After 10 min the solvent and excess of *(2)* are removed in a vacuum and the residue is distilled in oil-pump vacuum. Yield: 2.65 g (94%).

6,8-Dichloro-3-[(diethylamino)carbonyl]-3-methyl-2-(trifluoromethyl)-4(3H)-quinolone (4c):

(2) (1.7 ml) in acetonitrile (2 ml) is added dropwise to *(1c)* (2.85 g) in acetonitrile (5 ml) with ice-cooling and vigorous stirring. After 10 min the solvent is removed at oil-pump vacuum and the remaining oil (3.7 g) crystallizes on addition of ether (5 ml) and light petroleum (40 ml). Filtration and two washings with ether/light petroleum (3:10) affords 1.35 g, and the mother liquor affords a further 40 mg. Total yield: 1.39 g (35%). A sample was recrystallized from CCl_4/light petroleum for analysis.

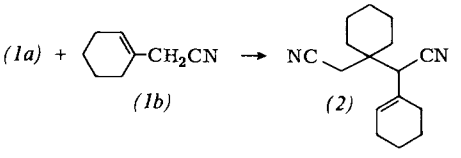
Reaction of Acetonitrile with Cyclohexanone

By *H. J. Arpe* and *I. Leupold*[*]



Acetonitrile reacts with ketones in liquid ammonia in the presence of stoichiometric amounts of alkali metal amide to give β-hydroxynitriles[1–3]. We have investigated the catalysis of this reaction for the case of acetonitrile and cyclohexanone.

Cyclohexylideneacetonitrile *(1a)* can be prepared in 70% yield by azeotropic distillation from H_2O at about 80 °C if the alkali metal alcoholate of a high-boiling alcohol, *e.g. n*-octanol, is used as catalyst.

(1a)

With alkali ethoxide the reaction comes to a standstill after 5—10% conversion since the ethanol formed in the hydrolysis of the alcoholate distills off. The basicity of the remaining alkali hydroxide is insufficient for abstraction of H^+ from the acetonitrile. 1-Cyclohexenylacetonitrile *(1b)* is in equilibrium with *(1a)*[4]. Under the reaction conditions it reacts with *(1a)* to give 2-(1-cyclohexenyl)-3,3-pentamethyleneglutaronitrile *(2)* in 20% yield. The structure given for *(2)* is in good agreement with the C—H—N analysis and with the ^1H-NMR, IR, and MS data.

(1b) *(2)*

Procedure for the synthesis of (1a):

A mixture of acetonitrile (1.0 mol), cyclohexanone (0.5 mol), and sodium *n*-octyl oxide (10 mmol) in benzene (100 ml) is boiled in a round bottomed flask fitted with water separator. After about 20 h the separation of water is so slow that the reaction may be terminated, 80—85% of the theoretical amount of water of reaction having been removed. The reaction mixture is washed with dilute H_2SO_4 and finally with H_2O. Distillation of the washed mixture affords 42.2 g (70%) of compound *(1a)*, b.p. 90 °C/10 torr. Recrystallization of the residue from the distillation with methanol yields 12.1 g (20%) of *(2)*, m.p. 107 °C.

Aromatization of Cyclohexylideneacetonitrile

By *H. J. Arpe* and *I. Leupold*[*]

Cyclohexylideneacetonitrile *(1)*, which is obtained in good yields from cyclohexanone and acetonitrile[1], can be catalytically converted into benzyl cyanide *(2)*, which, in turn, can be converted into β-phenylethylamine *(3)*.

Formation of benzyl cyanide is favored on ZnO catalysts, and that of β-phenylethylamine on Co catalysts.

Gaseous *(1)*, diluted with a threefold molar amount of nitrogen, is fed over a fixed bed catalyst, of which the first stage (450°C; residence time: 10 s) consists of SiO_2 with 1.3 wt-% ZnO and the second (150°C; residence time: 5 s) of SiO_2 with 39 wt-% of cobalt. If both stages are heated compound *(3)* is formed (50% yield), whereas *(2)* is formed in 80% yield if only the first stage is heated. The reaction products are condensed at −70°C and finally distilled. An hydrogenolytic cleavage of *(1)* to give toluene occurs as secondary reaction.

Simple Synthesis of Substituted Glutaronitriles

By *I. Leupold* and *H. J. Arp* [*]

The dimerization and formation of a substituted glutaronitrile containing a quaternary C-atom which we observed during the preparation of cyclohexylideneacetonitrile[1] induced us to investigate the reaction of cyclohexylideneacetonitrile *(1)* with nuclear-substituted benzyl cyanides *(2)*. It was found that the 2-aryl-3,3-pentamethyleneglutarodinitriles *(3)* are formed in high yields.

(3)	R	Yield (%)	M.p. (°C)
(a)	H	92	106
(b)	4-H_3	64	87
(c)	4-CH_3O	76	99
(d)	4-Cl	88	157
(e)	3-Br	82	88
(f)	4-Br	90	156

The IR, ^{1}H-NMR, and MS data are in complete agreement with the given structures.

General procedure:

A mixture of cyclohexylideneacetonitrile (0.1 mol), a nuclear substituted benzyl cyanide (0.1 mol), and potassium *tert*-butoxide (0.001 mol) is stored under an atmosphere of nitrogen at 50—80°C for 12 h. The solid melt is recrystallized from methanol, which can contain 10% acetonitrile; the product is dried under high vacuum.

Xenon Bis(pentafluoroorthoselenate) and Xenon Fluoride Pentafluoroorthoselenate

By *Konrad Seppelt*[*]

Disregarding the thermal stability of xenon difluoride, all the other xenon(II) compounds except the pentafluoroorthotellurate[1] are unstable. No explanation of this behavior has hitherto become available. Because of its high acid strength the recently discovered pentafluoroorthoselenic acid[2] should prove more suitable for preparation of stable compounds having high valences.

Reaction of xenon difluoride[3] with a small excess of $HOSeF_5$ in an all-Teflon distillation apparatus leads immediately to xenon bis(pentafluoroorthoselenate) *(1)*.

$$XeF_2 + 2HOSeF_5 \longrightarrow \underset{(1)}{Xe(OSeF_5)_2} + 2HF$$

(1) is a stable crystalline solid which can readily be purified by vacuum sublimation owing to its high melting point (m.p. 69°C) and vapor pressure (0°C, 0.05 torr; 25°C, 0.35 torr). The compound is thereby obtained as large yellow crystals. It was characterized by its mass spectrum [m/e = 316—329 ($XeOSeF_5$ 100%), 171—177 (SeF_5 8%), 168—174 ($OSeF_4$ 3%), 149—155 ($OSeF_3$ 17%), 141—148 (XeF 22%), 133—139 (SeF_3 37%), 130—136 ($OSeF_2$ 27%), 129—136 (Xe 59%), as well as SeF_2, OSeF, SeF, SeO, Se; 75 eV], its IR spectrum [mull in Kel-F oil (cm^{-1}): 787 m, 725 vs, 700 s, 612 s, 550 m, 430 s, 402 w, 307 m, 270 w, 249 m], its Raman spectrum [solution in $CFCl_3$ (cm^{-1}): 750 w dp, 725 m p, 692 m p, 639 s p, 613 w dp (νSeF and νSeO), 510 w p, 493 m dp (νSeO), 429 w p, 412 w p, 375 w dp, 299 s p (δSeF and δSeO), 197 w dp, 157 vs p, 130 s p, 77 m dp (δSeO and τ)], its ^{19}F-NMR spectrum [solution in $CFCl_3$, internal; 56.4 MHz: multiplet having AB_4 character, $\delta_A = -80.5$, $\delta_B = -69.4$ ppm; $J_{F_A-F_B} = 234$ Hz, $R = J/\Delta\delta = 0.346$, $J^{77}_{Se-F_A} = 1323$, $J^{77}_{Se-F_B} = 1318$ Hz], and its elemental analysis (F, Se, Xe).

[*] Dr. K. Seppelt [**]
Anorganisch-chemisches Institut der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

[**] I am grateful to Dr. *R. Geist* for recording the mass spectra.

(1) is sensitive to hydrolysis and reacts explosively with oxidizable substances. Solutions in freons are stable; CCl_4 and CH_3CN solutions are also temporarily stable. Its high solubility in nonpolar solvents indicates that *(1)* is largely covalent. Molten *(1)* is stable in a dry glass tube up to 100 °C; above 130 °C rapid decomposition occurs with evolution of xenon and vigorous attack of the glass surface. The striking yellow color of *(1)*, especially in concentrated solution, is shown by the UV spectrum to be attributable to an absorption at 3630 Å observed as the weakest member of a series of absorptions (2320, 2420, 2530, 2770, 3130, 3630 Å; solution in CH_3CN). The longer-wave absorptions must be due to bonded xenon since none of the compounds containing the F_5SeO investigated so far shows such absorptions.

An equimolar mixture of xenon difluoride and *(1)* liquifies completely within a few hours in a Teflon tube. The reaction course could be followed by means of the ^{19}F-NMR spectrum. Xenon fluoride pentafluoroorthoselenate *(2)* is formed in about 80% yield.

$$\underset{(1)}{XeF_2} + \underset{}{Xe(OSeF_5)_2} \rightleftharpoons \underset{(2)}{2\,FXeOSeF_5}$$

A purer product is obtained with an excess of XeF_2; *(1)* is almost completely consumed while XeF_2 crystallizes on cooling to 0 °C. Compound *(2)* prepared in this way is about 90% pure but undergoes dismutation corresponding to the equilibrium reaction.

(2) is a pale yellow liquid, m.p. ≈ -13 °C, that is very sensitive to hydrolysis. In spite of its low purity the following spectroscopic data could be recorded. Mass spectrum: *m/e* 335—348 ($FXeOSeF_5$ 5%), 316 to 329 ($XeOSeF_5$ 55%), 278—291 ($XeOSeF_3$ 2%), 171 to 177 (SeF_5 36%), 149—155 ($OSeF_3$ 40%), 141—148 (XeF 100%), and SeF_3, $OSeF_2$, Xe. IR spectrum (capillary film between CsI windows covered with FEP film; cm^{-1}): 772 s, 717 vs, 699 s, 610 m, 543 s, 422 s, 400 w, 250 w. Raman spectrum (cm^{-1}): 785 s dp, 764 w dp, 710 w p, 692 m p, 614 m p (νSeF and νSeO), 541 w dp, 501 vs p (νXeF and νXeO), 421 w dp, 416 mp, 399 w dp, 375 w dp, 416 m p, 399 w dp, 375 w dp (δSeF and δSeO), 173 s p (δOXeF) and 92 m dp (γOXeF).

The ^{19}F-NMR spectrum is particularly informative ($CFCl_3$, external): AB_4 multiplet, $\delta_A = -85.5$, $\delta_B = -68.5$ ppm; $J_{F_A-F_B} = 226$ Hz, $R = 0.246$, $J^{77}_{Se-F_A} = 1280$, $J^{77}_{Se-F_B} = 1300$ Hz; and a singlet, $\delta_{Xe-F} = +155.8$ ppm. The xenon isotope 129 (26% abundance, nuclear spin $\pm 1/2$) gives rise to a doublet that is symmetrically disposed about the main Xe—F peak: $J^{129}_{Xe-F} = 5790$ Hz. No coupling was observed between the fluorine atoms bound to xenon and to selenium.

The noble gas compounds discussed above appear to be of comparable stability to the analogous fluorotellurates; stability studies in inert vessels should provide even more information.

Ring Opening of a Cyclopropyl Anion and Cycloaddition of the Allyl Anion[**]

By *Gernot Boche* and *Diether Martens*[*]

Since the advent of the rules for the conservation of orbital symmetry[1] particular interest has been shown towards the ring opening of the cyclopropyl anion, predicted to proceed in a conrotatory fashion[2]. Several examples are known of treatment of substituted cyclopropanes with bases leading directly to allyl anions[6, 7]. H/D exchange and isomerization experiments at the anionic center of the three-membered ring strongly suggest the intermediacy of cyclopropyl anions[6d, 6e, 7]. Nevertheless, many cyclopropyl anions are also known which do not exhibit ring opening to give allyl anion[8].

We have been able to prepare a cyclopropyl anion which undergoes electrocyclic isomerization to the allyl

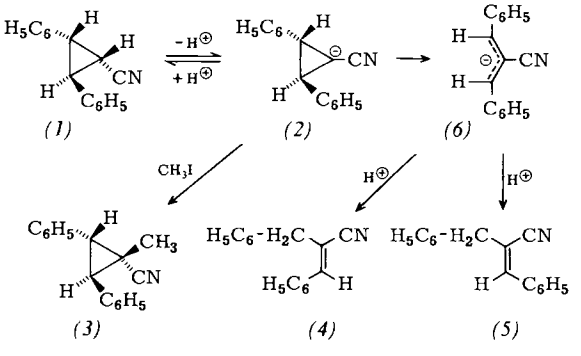

Table 1. Reaction of 1,3-diphenylallyl-2-carbonitrile anion *(6)* with alkenes [15].

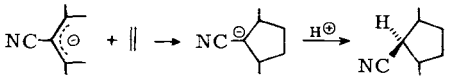
Alkene	Reaction conditions	Product	M.p. (°C)	Yield (%)
Styrene	2 h, 25 °C	2,3,5-Triphenyl-cyclopentane-1-carbonitrile	134—135	65
trans-Stilbene	15 h, 25 °C	2,3,4,5-Tetraphenyl-cyclopentane-1-carbonitrile	120—120.5	59
1,1-Diphenylethylene	2 h, 25 °C	2,3,3,5-Tetraphenyl-cyclopentane-1-carbonitrile	186—186.5	69
Acenaphthylene	2 h, 25 °C	7,9-Diphenyl-6b,9a-dihydrocyclopent[*a*]-acenaphthylene-8-carbonitrile [a]	213—215 309—311	18 37

[a] Two cycloadducts are formed.

[*] Dr. G. Boche and Dipl.-Chem. D. Martens
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We are grateful to Frl. *G. Schneider* for preparative assistance.

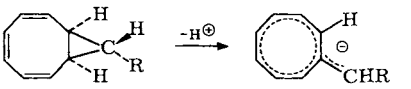


anion. The cyclopropyl anion *(2)* is formed instantaneously when *trans*-2,3-diphenylcyclopropane-1-carbonitrile *(1)* is united with two mol. equiv. of lithium diisopropylamide in tetrahydrofuran at $-30°C$.

Immediate reaction of *(2)* with methyl iodide at $-30°C$ gives *(3)* in 95% yield. Protonation of *(2)* with glacial acetic acid under the same conditions regenerates *(1)* in 93% yield.

However, if the reaction mixture is first allowed to warm to room temperature and then protonated a mixture (about 1:1) of the isomeric olefins *(4)* and *(5)*[9] is formed in 95% yield. Since *(1)* is no longer regenerated in this experiment[10], complete isomerization of cyclopropyl anion *(2)* to the red-violet allyl anion *(6)* must have occurred on warming.

Kinetic studies of the ring opening of the cyclopropyl anion *(2)* prepared with two and four mol. equiv. of lithium diisopropylamide indicated a valence isomerization *(2)* → *(6)* [half-life 27 min at 24.5 °C] which was independent of the base concentration; the activation parameters determined between -32.5 and -20.3 °C have the following values: $\Delta H^{\neq} = 19.0 \pm 1.5$ kcal/mol, $\Delta S^{\neq} = 2.5$ e.u.



The reaction of an allyl anion with an olefin to give a cyclopentyl anion is the prototype of the symmetry-allowed 1,3-dipolar $[_{\pi}2_s + _{\pi}4_s]$ cy loaddition[11]. This reaction has not previously been described. The nearest approaches known hitherto are reactions of cyclic allyl anions with benzyne[12] and cycloadditions of 2-azaallyl anion to multiple bonds[13]. In addition, *Kauffmann*[14] has recently reported the formation of a five-membered ring adduct during the reaction of α-methylstyrene and lithium diisopropylamide with stilbene which was interpreted as involving an intermediate allyl anion.

(6) *(7)*

We found that the allyl anion reacts with the alkenes listed in Table 1 to give adducts isolable as cyclopentane derivatives *(7)* after protonation (or methylation).

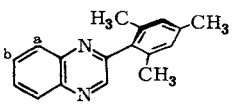
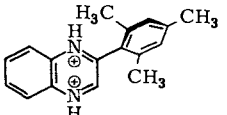
The Mesityl Group as a Ring Current Probe in Transition Metal 1,2-Diimine Chelates



By *Günter Häfelinger, Rudolf G. Weissenhorn, Fritz Hack*, and *Gerlinde Westermayer*[*]

Overlapping of metal d_{t2g} orbitals with the π-electron system of the ligands to give a cyclically conjugated system, purportedly having aromatic[3] or quasiaromatic[4,5] properties, has been postulated in transition metal chelates of the type tris(*N,N'*-dimethylethanediimine)iron(II)[1,2]. Aromaticity or cyclic π-electron delocalization is detectable by the occurrence of a ring current effect[6]. Since the NMR chemical shifts of the ring protons[7] are too sensitive to the charge density distribution in the hetero π-electron system, chelates bearing mesityl substituents were synthesized in which deviations between the chemical shifts of the two equivalent *o*-methyl groups below and above the plane of the chelate ring and the *p*-methyl acting as an internal standard afford a means of detecting a ring current[8,9].



The 2-mesitylquinoxaline *(1)* serving as aromatic reference system exhibits a 0.25-ppm splitting of the methyl signals, a value that is comparable with 0.30 ppm in phenylmesitylene[8] and 0.45 ppm in bimesityl[8]. The splitting of 0.33 ppm in tetracarbonyl(mesityl-*N,N'*-dimethylethanediimine)molybdenum *(3a)* is also of the same order. Surprisingly, tris(mesityl-*N,N'*-dimethylethanediimine)iron(II) perchlorate *(3b)* gives a negative splitting of -0.15 ppm. Negative splitting was also observed in simple mesityl derivatives in which functional group and mesityl group are substantially coplanar (*e.g.* mesitaldehyde, -0.25 ppm; dimesitylacetylene[10], -0.20 ppm; bromomesitylene, -0.14 ppm; mesitylic acid, -0.05 ppm) while derivatives whose mesityl group is largely perpendicular to the functional

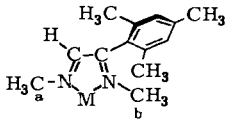
Lehrstuhl für Organische Chemie der Universität
74 Tübingen, Wilhelmstrasse 33 (Germany)



group as a result of steric constraints show small positive splittings (*e.g.* dimesityl ketone, 0.19 ppm; mesitylglyoxal, 0.15 ppm, dimesitylethanedione, 0.13 ppm).

(3a) M = $Mo^0(CO)_4$

(3b) M = $\frac{1}{3}Fe(ClO_4)_2$

the yellow oil solidifies to a mass of pale yellow crystals, m. p. 59 °C. Yield: 6.7 g (47.5%).

Tetracarbonyl(mesityl-N,N'-dimethylethanediimine)-molybdenum (3a):

A solution of mesitylglyoxal (3.52 g, 20 mmol) in methanol (30 ml) is united with 6 ml of a 7.3 M methanolic solution of methylamine (ice cooling) and the mixture then stirred for two hours at room temperature. After addition of a slurry of hexacarbonylmolybdenum (Schuchardt) (4.74 g, 18 mmol) in methanol (200 ml) stirring is continued for two days at room temperature and the mixture subsequently refluxed for 8 hours. Filtration of the boiling hot blackish violet solution is followed by removal of solvent. Crude yield: 6.5 g (88%) of black crystals that can be resolved into two components (red-violet, R_z 0.57; brown-yellow, R_z 0.8) by thin-layer chromatography (silica gel/methanol).

Cpd.	N=C<H	H_a	H_b	$\Delta(NCH_3)$	*m*-C—H	*p*-CH_3	*o*-CH_3	$\Delta(CH_3)$	Solvent
(1)	0.53	1.90 (m)	2.40 (m)	—	3.06	7.68	7.93	0.25	CCl_4
(2)	0.66	1.67	1.67	—	3.14	8.00	8.00	0.00	H_2SO_4
(3a)	2.05	5.85	6.26	0.41	3.08	7.67	8.00	0.33	CCl_4
(3b)	1.87 (t)	6.21	6.75 (t)	0.54	2.87	7.82	7.67	−0.15	$(CD_3)_2C{=}O$

The metal chelates of 1,3-diketones were found to give small splittings of around 0.15 ppm[8] that proved to be independent of the nature of the metal and of the same order of magnitude as in enolized ligands; no ring current was therefore detected in the metal chelates of 1,3-diketones. The Mo^0 and Fe^{2+} chelates under study on the other hand exhibit large splittings between the *o*- and *p*-methyl signals, albeit in differing directions. The value of 0.33 ppm for the Mo^0 chelate *(3a)* is larger than in phenylmesitylene and in 2-mesitylquinoxaline *(1)* and therefore evidences a ring current effect. However, the splitting could be influenced by the field effect of the two axial carbonyl groups. Consideration of models, however, indicates that the *o,o'*-methyl groups lie in the region of downfield shift due to the anisotropic cone of the carbonyl group.

The negative splitting of −0.15 ppm in the Fe^{2+} chelate could arise from the positive charge of the central ion reducing the overall electron density compared with that in the Mo^0 chelate. It therefore provides no indication of a diamagnetic ring current. The NMR spectrum of the reference compound *(1)* in concentrated sulfuric acid, in which the formation of the dication *(2)* can be assumed, shows coincidence of the *o*- and *p*-methyl signals, *i.e.* a negative shift of the splitting by 0.25 ppm as a result of protonation of the nitrogen atom.

It would therefore appear that the mesityl group represents a probe not only for ring current effects but also for varying electron densities in ring systems. Further studies designed to shed more light on this behavior are currently in progress.

2-Mesitylquinoxaline (1):

A solution of *o*-phenylenediamine (6.2 g, 57 mmol) in methanol (100 ml) is added dropwise under nitrogen to a solution of mesitylglyoxal[11] (10 g, 57 mmol) in methanol (100 ml) at room temperature. The red solution is refluxed for 5 hours, dried with sodium sulfate after cooling, and the solvent then stripped off. The residual reddish brown oil is distilled twice *in vacuo*, b. p. 162—164 °C/0.55 torr. After the second distillation Column chromatography (200 g silica gel 0.2—0.5 mm, column diameter 4.5 cm) of 800 mg of crude product in chloroform afforded 100 mg of *(3a)* as black crystals having a metallic luster.

Tris(mesityl-N,N'-dimethylethanediimine)iron(II) perchlorate (3b):

A solution of mesitylglyoxal (5.28 g, 30 mmol) in methanol (60 ml) is treated with 10 ml of a 7.3 M methanolic solution of methylamine as described for *(3a)*. After addition of solid iron(II) perchlorate hexahydrate (3.27 g, 9 mmol) stirring is continued for four hours and the solvent is then stripped off and the residue dried overnight over phosphorus pentoxide *in vacuo*. A portion (2 g) of the lustrous black crystals was dissolved in methanol (20 ml), filtered and, after dilution with more methanol (60 ml), reprecipitated by a 5:2 mixture of ether and light petroleum (400 ml). Yield: 1.25 g (62%) of brownish red crystals.

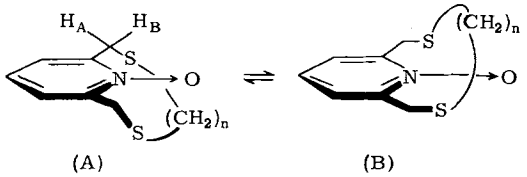
Spatial Requirements of Pyridine *N*-Oxide Oxygen[1][**]

By *Fritz Vögtle* and *Helga Risler*[*]

The spatial requirements of the oxygen in pyridine *N*-oxides have apparently not yet been studied. The polar O← N group, having *ca.* 40% double bond character according to recent calculations[2], is particularly interesting because it can exert polarizing effects in different directions[3].

The method we adopted in our approach to this problem was based on proton magnetic resonance studies on compounds of type *(1)*. For a series of substituents (X = H, F, Cl, Br, CH_3, C≡N, OCH_3) we first determined the smallest number of ring members for which the bridge could still pass by the intraannular group X despite incipient steric hindrance[1,4]. Substituents giving the same number of ring members were distinguished by the ring inversion barrier ($\Delta G_C^{\ddagger}$ values). The numbers of ring members and the $\Delta G_C^{\ddagger}$ values determined in this way give a kind of calibration curve for the determination of the spheres of influence of further internal substituents[5].



In the case of pyridine *N*-oxide oxygen, determination of the energy barriers to the intramolecular inversion process A⇌B in pyridinophane *N*-oxides *(2)* revealed detectable steric interactions between the oxygen atom of the *N*-oxide group and the hydrogen atoms of the bridge at $n = 6$, on going from large to small numbers of ring members. Those compounds having many ring members *(2f)* to *(2i)* exhibited no significant steric

(1) *(2)* *(3)*

(f), 7
(g), 8
(h), 9
(i), 10

interaction in the NMR; ring inversion A⇌B is therefore essentially unhindered here. In contrast, the cyclic compounds *(2a)* and *(2b)* containing fewer bridging members are conformationally rigid; the benzyl protons give an AB system in the accessible temperature range ($\Delta G_C^{\ddagger} > 23$ kcal/mol).

(A) (B)

The intermediate representatives *(2c)* to *(2e)* exhibit temperature-dependent ^{1}H-NMR spectra. The ring inversion barriers ($\Delta G_C^{\ddagger}$) decrease in the expected order: *(2c)* > 21.3 kcal/mol; *(2d)* = 15.8 kcal/mol; and *(2e)* = 12.7 kcal/mol.

The AB system of the benzyl protons of *(2d)*, which broadened at room temperature, is compared with the ^{1}H-NMR spectrum of *(1d)*, X = F, in Figure 1. The latter compound shows temperature-dependent benzyl signals in almost the same temperature range ($T_c = 37$ °C; $\Delta G_C^{\ddagger} = 15.2$ kcal/mol), which is attributed to steric hindrance of the "rocking process" analogous to A⇌B. The lower ring inversion barrier ($T_c = -55$ °C; $\Delta G_C^{\ddagger} = 10.5$ kcal/mol)[4] determined for the fluorine compound *(1e)*, $n = 6$, than for the pyridinophane *N*-oxide *(2e)* having the same number of ring members is also in agreement with this finding.

The inversion barrier of *(1c)* ($T_c = 185$ °C, $\Delta G_C^{\ddagger} = 22.6$ kcal/mol), in contrast to that of *(2c)*, could still just be determined by the coalescence point method.

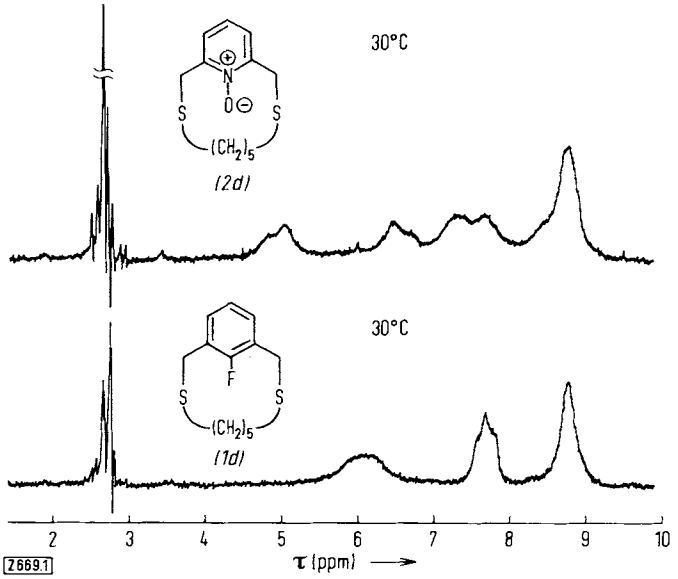

Fig. 1. ^{1}H-NMR signals of compounds *(1d)*, X = F, and *(2d)* [in $CDCl_3$; 60 MHz].

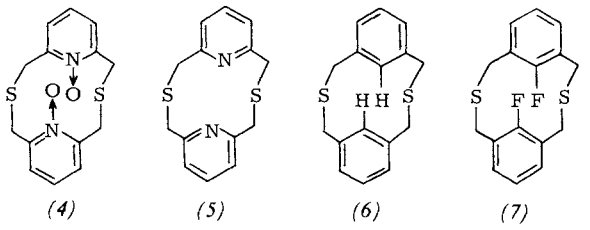

The considerable increase in spatial requirements on going from pyridine to pyridine *N*-oxide is clear from the fact that even in pyridinophane *(3)* having a shorter bridge ($n = 3$) no steric interaction can be observed[4].

Studies on the series *(4)* to *(7)* substantiate our finding that the spatial requirements of the aromatically bonded fluorine atom and the aromatic *N*-oxide oxygen are of the same order of magnitude. Whereas *(5)* and *(6)* are conformationally flexible[6], *(4)* and *(7)* exhibit temperature-dependent CH_2 resonances. The methylene absorption of *(4)* at room temperature consists solely of an extensively broadened AB system (Table 1). Although the coalescence temperature of *(7)* (157 °C) is higher than that of *(4)*, the $\Delta G_C^{\ddagger}$ values cannot be directly deduced from this system since the inversion processes are between non-isolable, energetically non-equivalent *syn* and *anti* conformers[5,6].

The results quoted induced us to construct a spatial model of the pyridine *N*-oxide group according to *Brieglieb*'s method[7] in a transformation ratio $1:(1.5 \times 10^8)$, which is compared in plan and side view with the F—$C_{arom.}$ "calotte"[8] in Figure 2. It can be seen that the "calotte" of the quaternary nitrogen atom in aromatic six-membered rings resembles very closely that of the $C_{arom.}$ atom[7,9]. If commercially available Stuart-Briegleb models are used in conjunction with the O← N "calotte" for constructing the described pyridinophane *N*-oxides then steric interactions are obtained which are compatible with the measurements laid down for such models.

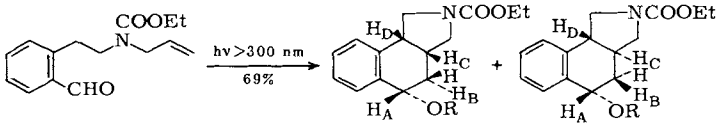
Photoisomerization of 2-[2-(*N*-Ethoxycarbonyl-*N*-allylamino)ethyl]benzaldehyde

By *Wolfgang Oppolzer* and *Kathrin Keller*[*]

In connection with our investigations of the synthetic application of intramolecular *o*-quinodimethane cycloadditions[1] we have found that irradiation (high-pressure mercury-vapor lamp) of a toluene solution of the aldehyde *(1)*[3], prepared from 2-(2-bromoethyl)-benzaldehyde[2], leads to formation of a 3:1 mixture of the stereoisomeric benz[*e*]indoles *(2)* and *(3)* in 69% yield. The major product *(2)* (m.p. 126—128 °C) crystallized out, and the oily secondary product *(3)* could be isolated by crystallization and subsequent alkaline hydrolysis of its dinitrobenzoate *(5)* (m.p. 105 to 110 °C). The constitutions and configurations given in the formulas *(2)* and *(3)* for the photoproducts are supported, *inter alia*, by the following arguments:



Firstly: NMR double resonance experiments show a diaxial coupling of the proton H_B of the dinitrobenzoate derivative *(4)* (m.p. 89—91 °C) of the major product *(2)*, thus revealing the *cis* relationship of the protons H_A and H_C. In the ester *(5)*, on the other hand, the axial proton H_B couples with an equatorial H_A and an axial H_C, thus indicating the *trans* relationship of H_A and H_C in this compound.

SANDOZ AG
CH-4002 Basel (Switzerland)

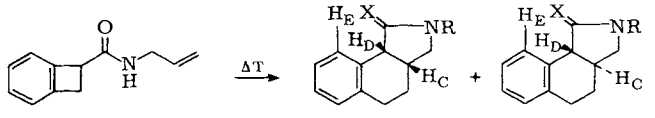

Table 1. Characteristic NMR data of benz[*e*]isoindoles ($CDCl_3$, coupling constants J in Hz, chemical shift δ in ppm).

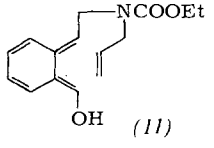
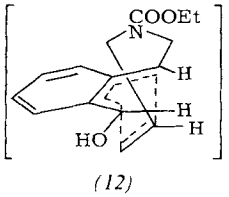
Compound	$^3J_{AB}$	^3J_B	$^3J_{CD}$	δH_D	δH_E
(4)	12	12	?	?	—
(5)	4	12	?	?	—
(7)	—	—	7—8	3.55	7.55
(8)	—	—	10	3.18	8.22

Secondly: Thermal isomerization of the benzocyclobutene *(6)* at 155 °C leads to a mixture of the lactams *(7)* (m.p. 171—172 °C and *(8)* (m.p. 203—205 °C)[4], which can be separated by chromatography and whose

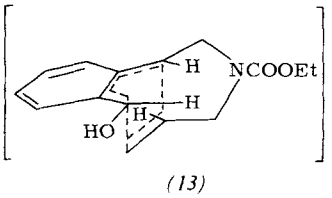


(1) *(2)*: R = H *(3)*: R = H
(4): R = 3,5-Dinitrobenzoyl *(5)*: R = 3,5-Dinitrobenzoyl



(6) *(7)*, X = O, R = H *(8)*, X = O, R = H
(9), X = H_2, R = COOEt *(10)*, X = H_2, R = COOEt

configurations are evident from the NMR data given in Table 1. Reaction of the *cis*-lactam *(7)* with aluminum hydride[5] and ethyl chloroformate yields the same urethane *(9)*[6] as is formed on hydrogenolysis (Pd—C/H_2) of the major photoproduct *(2)* whose H_C and H_D protons must therefore be *cis* to each other. Analogous correlation of the *trans*-lactam *(8)* with the secondary photoproduct *(3)* reveals the *trans* relationship of the protons H_C and H_D in the latter.



From the above it is evident that the benzylic hydrogens H_A and H_D are *cis* to each other in both photoproducts *(2)* and *(3)*. This observation provides supporting evidence for the mechanistic conclusions drawn from studies of the photochemistry of *o*-toluylcarbonyl compounds[7]. Hence the reaction *(1)* → *(2)* + *(3)* may be explained by a mechanism involving a 1,5 H shift of

(11)

(12)

(13)

the excited aldehyde *(1)* to give a triplet dienol, which is converted into the ground state of the *trans,trans*-quinodimethane *(11)*. The non-isolable intermediate *(11)*[8] is obviously capable of undergoing a rapid thermal [4s + 2s] cycloaddition[9] to the neighboring olefinic double bond leading to the major product *(2)* *via* the *endo* transition state *(12)* and to the secondary product *(3)* *via* the *exo* transition state *(13)*.

Experimental:

A solution of the aldehyde *(1)* (4.5 g) in toluene (200 ml) was irradiated under a slow stream of nitrogen with a high-pressure mercury-vapor lamp (Hanau TQ 81); the solution was water-cooled during the irradiation.

After four hours no starting material could be detected in the thin-layer chromatogram (SiO_2, benzene/ethyl acetate 3:1)—only one new spot was recognizable. After removal of the solvent the oily residue was chromatographed with benzene/ethyl acetate 1:1 on a 25-fold amount of silica gel. The eluate, after removal of solvent, was shown by NMR spectroscopy to consist solely of a 3:1 mixture of products *(2)* and *(3)* (3.1 g, 69%), from which 1.4 g of the major product *(2)* could be isolated by crystallization from ether/pentane. Reaction of the remaining mother liquor with 3,5-dinitrobenzoyl chloride/pyridine and sixfold recrystallization of the resulting ester mixture afforded 0.41 g of the dinitrobenzoate *(5)* (m.p. 105 to 110 C), which on hydrolysis with 2 N ethanolic KOH at 25 C for 20 min yielded 0.23 g of the oily photoproduct *(3)*.

Received: June 9, 1972 [Z 658 IE]

[1] *W. Oppolzer*, J. Amer. Chem. Soc. *93*, 3833, 3834 (1971); *W. Oppolzer* and *K. Keller*, *ibid.* 3836.

[2] *A. Rieche* and E. Schmitz, Chem. Ber. *89*, 1254 (1956).

[3] Conversion of 2-(2-bromoethyl)benzaldehyde into the oily aldehyde *(1)* was achieved in 70% yield by the following series of operations: a) acetalization with triethyl orthoformate/ethanol/toluenesulfonic acid, 18 h, 25 °C; b) heating under reflux with 20 equivalents of allylamine, 7 h; c) acylation with 1.1 equivalents of ethyl chloroformate + 2 equivalents of pyridine in methylene chloride; and d) acetal cleavage with 2 N HCl in dioxane/water (1:1), 30 min, 25 °C.—We thank Dr. *G. Wersin* for preparation of the 2-(2-bromoethyl)benzaldehyde diethyl acetal.

[4] In boiling dichlorobenzene the *trans*-lactam *(8)* epimerizes into the thermodynamically more stable *cis*-lactam *(7)*. This process is catalyzed by traces of acid and is obviously responsible for the fact that only the *cis*-lactam *(7)* was isolated after thermolysis of the benzocyclobutene *(6)* in a steel autoclave at 190 C; cf. Ref. [1], p. 3833.

[5] *N. M. Yoon* and *H. C. Brown*, J. Amer. Chem. Soc. *90*, 2927 (1968).

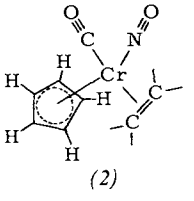
[6] The identity of the oily urethane *(9)* prepared by the two independent routes was confirmed by NMR and IR spectroscopy.

M. Mellows* and *P. G. Sammes*, *ibid. 1971*, 21; *B. J. Arnold* and *P. G. Sammes*, *ibid. 1972*, 30.

[8] A stereoisomeric *trans*-alkyl-*cis*-hydroxyquinodimethane can hardly be considered to compete with the *trans-trans*-quinodimethane *(11)* as a cycloaddition partner because of its short lifetime and for steric reasons; cf. Ref. [7].

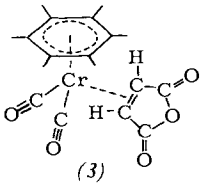
[9] According to *F. Nerdel* and *W. Brodowski* [7] the photoaddition of *o*-methylbenzophenone to maleic and fumaric acids proceeds stereospecifically with preservation of the olefinic configuration.

CONFERENCE REPORTS



Transition-metal π-Complexes with Activated Olefins

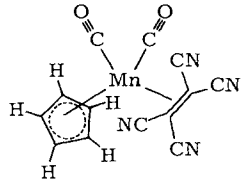
By *Max Herberhold*[*]



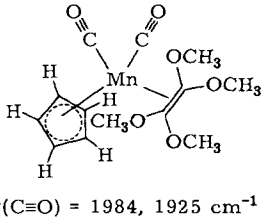
The great importance of monoolefin π-complexes formed as intermediates in homogeneous catalysis (*e. g.* during oxidation of ethylene to acetaldehyde, hydroformylation, dimerization of olefins, Ziegler-Natta polymerization, and hydrogenation of olefins) calls particularly for model study of stable olefin π-complexes. Both the factors that influence the formation of π-complexes by an olefin, and the extent of interaction between the olefin and its neighboring ligands have been investigated for the case of complex formation by olefins with photochemically produced carbonylmetal fragments ($[Cr(CO)_5]$, $[C\,H_5Mn(CO)_2]$,$[C_5H_5Cr(CO)(NO)]$ or $[C_6H_6Cr(CO)_2]$).

In addition to olefinic hydrocarbons, "electron-poor" olefins such as tetracyanoethylene (TCNE) and maleic anhydride (MA) can also be introduced as monodentate π-olefin ligands in carbonylmetal complexes; with cyanoolefins (acrylonitrile, fumarodinitrile) a competing complex formation by way of the lone pair of electrons on the nitrogen atom of the cyano group must be taken into account[1]. In all π-complexes the acceptor properties of the olefin play a decisive role; this is true also for the coordination compounds of the "electron-rich" olefin tetramethoxyethylene (TME)[2]. Different olefin ligands can be best compared in the system olefin-dicarbonylcyclopentadienylmanganese *(1)*, where not only the complex with ethylene[3] but also complexes of the persubstituted derivatives TCNE and TME[2] have been obtained.

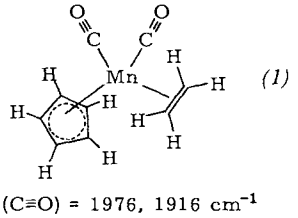
There are considerable electronic interactions to be observed between the π-bonded olefin and its neighbor ligands, and these are transmitted through the central metal; clearly the donor-acceptor properties of the individual ligands compete with one another. In the system *(1)* there is an approximately linear relation between the Cotton-Kraihanzel valence force constants $k(C{\equiv}O)$[4] of the two CO ligands and the chemical shift $\tau(C_5H_5)$ in the ^{1}H-NMR spectrum (in D_6-acetone)[5]; an analogous relationship has been found to exist in the system *(2)* between the IR stretching frequencies $\nu(C{\equiv}O)$ and $\nu(N{\equiv}O)$, respectively, and the chemical shift $\tau(C_5H_5)$[6]. In complexes of type *(3)* both



(2)



(3)



the C≡O stretching frequencies of the carbonyl ligands and the C=O stretching frequencies of the anhydride group of maleic anhydride (MA) are determined by the substituents on the π-bonded aromatic six-membered ring, whose influence can be characterized by the sum $\Sigma\sigma_p$ of the Hammett substituent parameters. Maleic anhydride is a stronger electron-withdrawing ligand than carbon monoxide[7].

$\nu(C{\equiv}O)$ = 1992, 1966 cm^{-1}

$\nu(C{\equiv}O)$ = 1984, 1925 cm^{-1} (in cyclohexane)

(1)

$\nu(C{\equiv}O)$ = 1976, 1916 cm^{-1}

Optical Properties of Cholesteric Liquid Crystals

By *Horst Stegemeyer*[*]

Nematic and cholesteric liquids have largely similar structures: they show the parallelism of the molecular axes that characterizes all liquid crystals; the molecular centers of gravity are distributed statistically. Cholesteric phases, which are formed only by optically active, formanisotropic molecules, have additionally a helical arrangement of the molecular axes in relation to the preferred axis, which causes striking optical properties: namely an optical rotatory dispersion (ORD) of extremely high amplitude, selective reflection of light within a narrow spectral region, and a circular dichroism (CD) of almost 100%.

Since chiral centers in the individual molecules are responsible for formation of the helical structure, it is to be expected that chiral molecules which do not themselves form liquid crystals will induce a helical structure in nematic phases. Such a phase transformation nematic → cholesteric has been demonstrated for various systems, where the chirality of the added non-mesomorphic molecules may be caused by asymmetric carbon atoms or by dissymmetry of the whole molecular skeleton[1]. The extent of the induced optical activity depends on the strength of the interactions between the dissolved molecules and the solvent molecules. The position of the induced CD bands is strongly temperature-dependent, as is the case in "normal" cholesteric phases. The concentration-dependence of the ORD amplitude reaches a maximum at *ca.* 2 mol-%. The decrease in this effect at increasing concentrations can be explained qualitatively as follows: Since the optically active molecules do not show strong anisotropy, they disturb the parallel arrangement of the rod-like solvent molecules, so that eventually the long axes are distributed statistically in space, whereby the fundamental cause of the appearance of helical structure is abolished.—The induced optical rotation is larger by a factor of 10^3 than the molecular rotation of the dissolved non-mesomorphic molecules in isotropic solution. Provided that the interaction between the dissolved molecules and the nematic solvent suffices, the effect can be used to detect small amounts of optically active substance.

If achiral molecules are dissolved in cholesteric liquid crystals, a Cotton effect is induced within their absorption bands, this overlying the anomalous rotatory dispersion of the cholesteric phase and having the same sign as the latter. The CD is smaller than that of the cholesteric phase ($< 10\%$). The effect disappears above the clearing point. Further, since the molar amplitude of the ORD curves is extremely high, a chiral distortion of the chromophores by solvation can be excluded. The helical structure of the solvent molecules is in fact transferred to the spatial distribution of the preferred axes of the dissolved molecules, so that the incident light "sees" a chiral system of coupled chromophores[2].

Kinetics and Mechanism of the Formation of Transition-Metal Complexes

By *Hartmut Diebler*[*]

Complex formation with simple ligands in aqueous solution occurs in general by a dissociative (or S_N1) mechanism in which replacement of the first H_2O molecule in the innermost coordination sphere of the hydrated metal ion represents the rate-determining step. The rate constant k_i assigned to this reaction step is characteristic of a given metal ion and can be determined from the bimolecular rate constant k_f for complex formation if the formation of the outer-sphere complex (stability constant K_o) is taken into account[1]:

$$k_f = K_o \cdot k_i$$

For metal ions with closed outer electron shells the values of k_i depend mainly on the radius and charge of the metal ion as well as on the coordination number. With transition-metal ions, however, effects due to specific configurations of the only partly filled 3d electron shell are also observed. Thus a contribution of crystal field stabilization energy to the activation energy of the substitution process leads to a decrease in the reaction rate of ions with d^3 (V^{2+}, Cr^{3+}) and d^8 (Ni^{2+}) configurations, whereas the Jahn-Teller distortion occurring with d^4 and d^9 configurations gives rise to extremely high k_i values (*ca.* $10^9\ s^{-1}$ for Cr^{2+} and Cu^{2+}). The dissociative nature of the substitution mechanism apparently still holds for ions with a Jahn-Teller distortion[2].

However, numerous reactions are known which do not fit into this simple scheme. In the case of trivalent metal ions, hydrolysis often prevents an unambiguous interpretation of the kinetics of complex formation with basic ligands (indistinguishability of the reaction pathways $M^{3+} + L^{n-} \rightarrow ML^{(3-n)+}$ and $MOH^{2+} + HL^{(n-1)-} \rightarrow ML^{(3-n)+}$, where M = metal and L = ligand)[3]. Nevertheless, there is evidence that for some trivalent metal ions the substitution mechanism has associative (or S_N2) character. This is indicated, for instance, by some of the experimentally determined activation parameters for ligand exchange and by the ligand-dependence of the substitution rate observed with V^{3+} [4]. It might be that the availability of an empty t_{2g}-orbital in the case of V^{3+} (and also of Ti^{3+}) facilitates the formation of a transition state with an increased coordination number.

Reactions with more complicated ligands frequently lead to deviations from "normal" behavior. Complex formation of β-amino acids with metal ions is usually distinctly slower than that with the corresponding α-compounds. Obviously it is not the replacement of the first water molecule but rather the ring closure step that is rate-determining in the reactions with the β-amino acids[5]. Particularly drastic decreases in the reaction rate are found with some multidentate macrocyclic ligands, which owing to a lack of flexibility do not allow a rapid stepwise replacement of solvate groups from the metal atom. Very rigid ligands (porphyrins) probably require *simultaneous* removal of several solvate groups[6].—Monoprotonated bidentate ligands also often react slower by orders of magnitude than the corresponding unprotonated ligands; here the rate-

[*] Dr. H. Diebler
Max-Planck-Institut für Biophysikalische Chemie
34 Göttingen-Nikolausberg, Postfach 968 (Germany)

determining step is the dissociation of the proton from the monodentate-bound intermediate[7].

Surprisingly, some very strongly basic bidentate ligands react appreciably *faster* than predicted by the simple mechanism of complex formation. As an explanation a mechanism involving internal conjugate-base formation has been proposed[8].

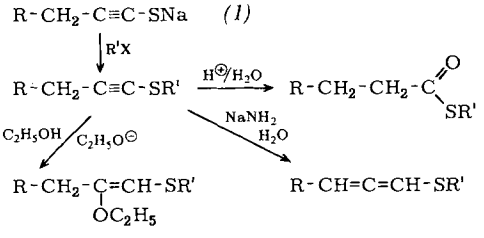
ABSTRACTS



Reviews

Abstracts of selected progress reports and review articles

Recent developments in the synthetic organic chemistry of sulfur are considered by *L. Field* in an article dealing with more than 50 classes of sulfur compounds and including experimental procedures. Primary alkanethiols are accessible by the following reaction:

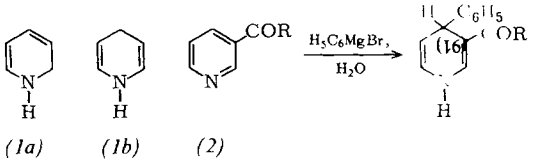
$$R{-}Cl + Na_2CS_3 \rightarrow R{-}S{-}CS_2Na \xrightarrow{H^{\oplus}} R{-}SH + CS_2$$

The unknown alkynethiols are available as thiolates *(1)* for reaction with electrophiles and nucleophiles:

Thiobenzoates and thiobenzamides can be prepared according to:

$$Ar{-}H + ClC(S){-}X \xrightarrow{AlCl_3} Ar{-}C(S){-}X$$

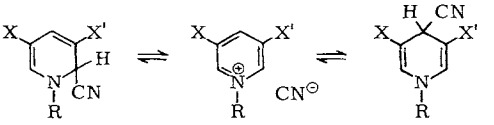
Syntheses of thiocarbonic acid derivatives, mercaptals and mercaptols, disulfides and polysulfides, sulfenic acid derivatives, sulfides, thials and thiols are accompanied by detailed discussions of dimethyl sulfoxide as solvent and oxidizing agent, and of the dimsyl anion *(2)*



$$R{-}COOCH_3 + [H_3C{-}S(O){-}CH_2]^{\ominus} \xrightarrow{DMSO}$$

$$R{-}C(O){-}CH_2{-}S(O){-}CH_3 \xrightarrow{Al(Hg)} R{-}C(O){-}CH_3$$

Further sections are devoted to sulfonium compounds, sulfinic acids, sulfones, sulfenes, sulfonic acids, and derivatives of sulfurous and sulfuric acid. [Some Recent Developments in Synthetic Organic Sulfur Chemistry. Synthesis *1972*, 101—133; 213 references]

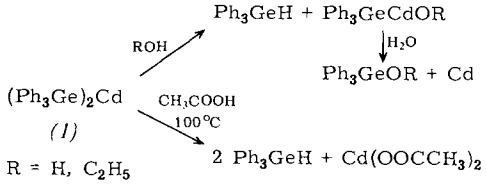


[Rd 509 IE–M]

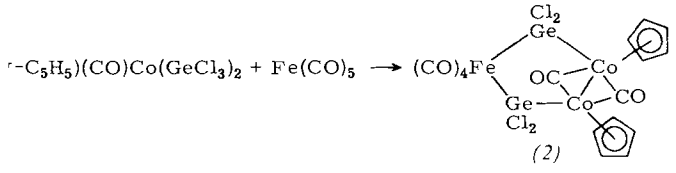
The chemistry of dihydropyridines (excluding pyridinemethenes, ketodihydropyridines, pyridonimines, benzodihydropyridines, quinolizidines) *(1)*, which are important intermediates in syntheses and reactions of pyridine and of great biological import, are summarized in a detailed review by *U. Eisner* and *J. Kuthan*. By far the most representatives of *(1)* have the 1,2- *(1a)* or 1,4-dihydro structure *(1b)*. Possible syntheses from pyridines or pyridinium salts include reduction with $NaBH_4$, addition of organometallic compounds *e.g.* to *(2)*, dithionite reduction, or

(1a) *(1b)* *(2)*

addition of cyanide ion. Treatment of pyridines or pyridinium salts with metals effects transfer of an electron into the LUMO to give a radical that dimerizes or undergoes further reduction. Silylation of pyridines in the presence of Pd affords mixtures of type *(1a)* and *(1b)*. Hantsch synthesis and related condensations provide numerous representatives of *(1)*. Their most striking property is their oxidation to pyridines. Reduction leads to tetrahydro- and hexahydro derivatives. Whereas nucleophilic addition to *(1)* and protonated *(1)* and cycloadditions and ring



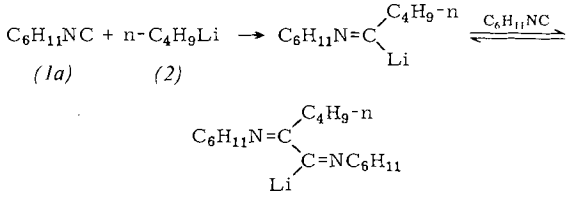
X = X' = CN, R = CH_3



opening have been extensively studied, only few isomerizations are known. Our knowledge of the photochemistry of *(1)* is also fragmentary. [The Chemistry of Dihydropyridines. Chem. Rev. *72*, 1—42 (1972); 611 references]

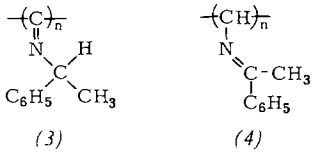
[Rd 510 IE –M]

Publications on organogermanium compounds from 1970 have been reviewed by *B. C. Pant*. Compounds having Ge-metal bonds, *e.g. (1)*, appear to be valuable for further syntheses. The metal heterocycle *(2)* has been shown to



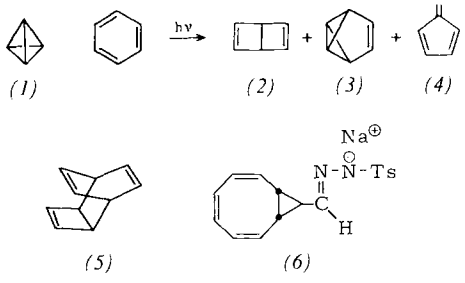
have a remarkable structure by X-ray methods. Heterocycles containing C, Si, N, and/or O in addition to Ge were also considered. 1,3-Digermacyclobutane derivatives polymerize readily.—Further sections deal with, *e.g.* organo-

germanium compounds with Ge—N, Ge—P, Ge—O, Ge—S, Ge—Se, and Ge—Te bonds as well as physicochemical studies. [Germanium. Organometal. Chem. Rev. B9, 205—247 (1972); 260 references]



[Rd 512 IE –L]

The polymerization of isocyanides *(1)*, which has only been studied systematically during the past few years, is summarized by *F. Millic. (1)*, the only stable carbenes known apart from CO, have become readily accessible by a variety of recent methods. Self-condensation of *(1)* is of synthetic interest since not only high polymers but also heterocycles and oligomers can be obtained. Thus anionic initiators *(2)* produce dimers from *(1a)* in toluene at 0°C:



The synthesis of polyisocyanides can be divided into four types: Catalysis by protonic acids, with and without promotors (O_2, peroxides); catalysis by certain Lewis acids, especially BF_3; decomposition of metal-*(1)* complexes of suitable instability; spontaneous polymerizations and polymerization in the presence of powdered glass. Most polyisocyanides are insoluble. Optical data for poly-α-phenylethyl isocyanide suggest structure *(3)*, while *(4)* is less likely. [Polymerization of Isocyanides. Chem. Rev. *72*, 101—113 (1972); 138 references]

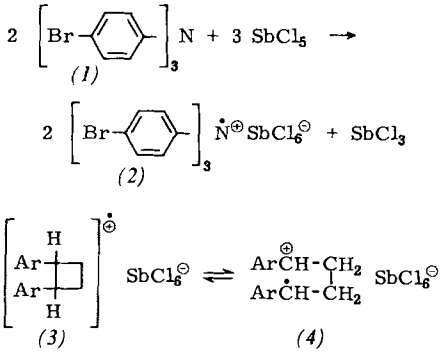
[Rd 515 IE –M]

Rearrangements of $(CH)_n$ compounds are the topic of a review by *L. T. Scott* and *M. Jones jr.* $(CH)_4$: Numerous studies have been undertaken with regard to the energetics of the highly strained molecules cyclobutadiene and tetrahedrane *(1)*. $(CH)_6$: Photolysis of benzene leads to Dewarbenzene *(2)*, benzvalene *(3)*, and fulvene *(4)*. Derivatives of further structural isomers are known. $(CH)_8$: Cyclooctatetraene has been most extensively investigated. Tricyclo-[3.3.0.$0^{2,6}$]octa-3,8-diene, barrelene, and tricyclo-

[4.2.0.$0^{2,5}$]octa-3,7-diene undergo interesting thermal or photochemical rearrangements. $(CH)_{10}$: The first representation of this series was *Nenitzescu*'s hydrocarbon *(5)*, which was followed by bullvalene. $(CH)_{10}$ compounds are obtained, *e.g.*, from cyclopropylcarbene presursors such as *(6)*. $(CH)_{12}$ isomers are also discussed. [Rearrangements and Interconversions of Compounds of the Formula $(CH)_n$. Chem. Rev. *72*, 181—202 (1972): 254 references]

[Rd 517 IE –M]

The chemistry of the higher oxidation states of manganese is reviewed by *W. Levason* and *C. A. McAuliffe*. Brief descriptions of the preparation and chemical properties are given along with redox potentials, crystal structures, magnetic moments, and vibrational frequencies. Special chapters are devoted to the electronic spectra of the tetraoxo anions of manganese(V)—(VII), the interpretation of which is not yet settled, and to the spectra of manganese(III) compounds which are interesting because of the strong Jahn-Teller distortion of their ground states. [Higher Oxidation State Chemistry of Manganese. Coord. Chem. Rev. *7*, 353—384 (1972); 294 references]

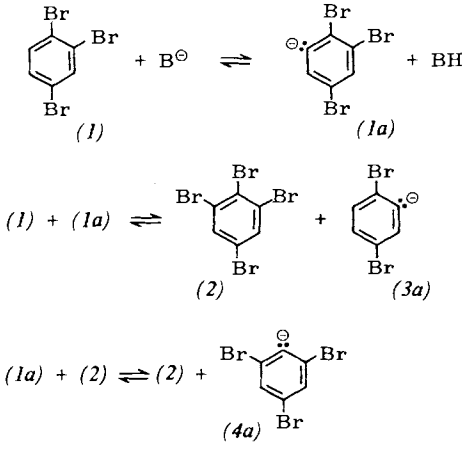


[Rd 518 IE –H]

The structure of metal complexes of some quadridentate Schiff bases is treated in a review by *M. Calligaris, G. Nardin*, and *L. Randaccio*. Atomic distances stemming from X-ray structural analyses are given, and the different possible conformations are discussed. This class of compounds is interesting a) because of their capability of reversibly binding molecular oxygen, and b) because they can be regarded as vitamin B_{12} models.

[Structural Aspects of Metal Complexes with Some Tetradentate Schiff Bases. Coord. Chem. Rev. 7, 385—403 (1972); 56 references]

[Rd 519 IE –H]



Cation radicals in electron transfer reactions are the subject of a report by *A. Ledwith*. The appearance of the species $M^{\cdot+}$ in mass spectrometry is well known; oxidation of the amine *(1)* to the cation radical *(2)* serves as example for the chemical synthesis. Compounds such as *(2)* can oxidize neutral molecules rapidly, *e.g.* cycloheptatriene derivatives to tropylium salts. Noteworthy is the quantitative oxidation of *N*-vinylcarbazole in CH_2Cl_2/CH_3OH to 1,4-dimethoxy-1,4-diphenylbutane. Interestingly, this methanolysis product is also formed from diphenylcyclobutane and

thus provides evidence for the formation of the intermediates *(3)* and *(4)*. Further examples of reactions which proceed *via* cation radicals are oxidations by bipyridylium salts and cyclodimerizations. [Cation Radicals in Electron Transfer Reactions. Accounts Chem. Res. 5, 133—139 (1972); 52 references]

[Rd 520 IE –L]

The base-catalyzed halogen dance and other reactions of aryl halides are described by *J. F. Bunnett*. In the halogen dance 1,2,4-tribromobenzene *(1)*, for example, is mainly converted into 1,3,5-tribromobenzene *(4)* on reaction with potassium amide/ammonia; also produced are 1,3- and 1,4-dibromobenzene *(3)*, 1,2,4,5- and 1,2,3,5-tetrabromobenzene and significant amounts of 3,4- and 3,5-dibromoaniline. This finding demonstrates that several reactions are involved, the most important of which are the following: From *(1)* arises

the anion *(1a)*, which reacts further with *(1)* to give *(2)* [and *(3a)*], which in turn acts as cocatalyst in the transfer of positive bromine ions to *(4a)*. The ions *(3a)* and *(4a)* are then protonated to *(3)* and *(4)*. [The Base-Catalyzed Halogen Dance, and Other Reactions of Aryl Halides. Accounts Chem. Res. 5, 139—147 (1972); 57 references]

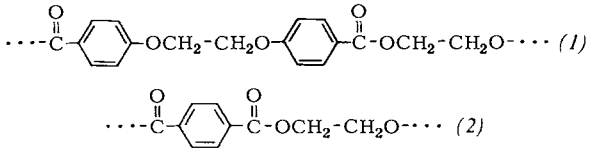
[Rd 521 IE –L]

The exploration of biochemical mechanisms by tritium labeling is reviewed by *A. R. Battersby*. The substrate can be labeled in the following ways: (i) proton exchange at activated sites; (ii) tritiation of carbanions; (iii) reductions; (iv) syntheses from commercially available T-labeled intermediates. The possible applications of the methods are illustrated by examples such as the enzymatic deamination of phenylalanine, the biosynthesis of colchicine, haemanthamine, morphine, and terpenoids and indole alkaloids. [Some Applications of Tritium Labeling for the Exploration of Biochemical Mechanisms. Accounts Chem. Res. 5, 148—154 (1972); 40 references]

[Rd 522 IE –L]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office



Polymer-based synthetic fibers with antibacterial properties contain 5-nitrofurfural, β-(5-nitro-2-furyl)acrolein, 1-[β-(5-nitro-2-furyl)acrylidenamino]hydantoin, 3-(5-nitro-2-furfurylidenamino)-2-oxazolidone, diphenylamine, 8-hydroxyquinoline, or combinations of these compounds as antibacterial agents. It is reported that synthetic fibers modified with the compounds mentioned, unlike previously known bacteriostatic synthetic fibers, do not lose their antibacterial properties during use, *e.g.* on wet treatment or sterilization or under mechanical stresses. [DOS 1769993; Leningradskij Institut Textilnoj i Legkoj Promyschlennosti, Leningrad]

[PR 1 –A IE]

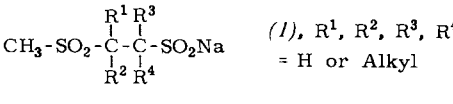
Crystalline polycarbonate fibers having a reduced tendency to shrink are obtained by two-stage fixing of drawn polycarbonate fibers. The drawn polycarbonate fibers are further stretched above the glass transition point in the first fixing zone, and are then relaxed below the crystallite melting range in the second fixing zone. The temperature ranges and fixing conditions are given. As a result of this two-stage fixation, which has been tested for drawn crystalline polycarbonates, particularly for those based on bis(monohydroxyaryl)alkanones and bis(monohydroxyaryl) sulfones, sulfoxides, sulfides, or ethers, the tendency to shrink is reduced in the fixed product, and contrary to expectations, the initially good mechanical and textile properties of the fibers are retained or even improved. [DOS 1785137; Farbenfabriken Bayer AG, Leverkusen]

[PR 2 –A IE]

A new composite fiber contains a polymer A having at least 75 wt.% of repeating units with the formula *(1)* and a polymer B having at least 75% of repeating units with the formula *(2)*. The polymers mentioned may contain an admixture of up to 25% of glycols other than ethylene glycol and aromatic or aliphatic carboxylic acids or polymers such as polystyrene, polyethylene, nylon 6, or nylon 6,6. The polymer A must exhibit a shrinkage of less than

(1)

(2)



8% on boiling, and must exhibit stronger shrinkage than the polymer B under goffering conditions. The polymer B lies on the inside of the spiral in the goffered fiber. The new composite fibers are characterized *inter alia* by high elastic recovery and a high Young's modulus. [DOS 2009413; Asahi Kasei Kogyo K.K., Osaka]

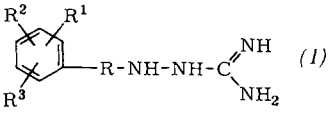
[PR 4 –A IE]

Solid, non-tacky polyimide polymers based on linear, heat-curable polyimides of benzophenonetetracarboxylic dianhydride and a saturated C_{3-12} diamine containing not more than a 2% excess of the dianhydride or diamine can be used as the binding layer between a polyimide film and a copper foil as sheathing for insulated wires and as an adhesive. The polyimides, which can be stored in the form of solid, dry powders and exhibit good adhesion after heat-curing, have an intrinsic viscosity of about 0.1 to about 2.0, measured in a 0.5% solution in *m*-cresol. The softening point is around 150 to 300°C. 10 wt.% of polymer is almost completely soluble in 90 wt.% of solvent at 25°C. [DOS 2103500; Minnesota Mining, St. Paul]

[PR 5 –A IE]

Compositions containing block polymers of vinyl chloride can be prepared at −50 to 0°C if the block polymerization is carried out in the presence of systems that consist of a peroxy compound that yields active oxygen and a reducing compound having the general formula *(1)*. Small quantities of water lead to a uniform reaction, particularly at the

(1), R^1, R^2, R^3, R^4 = H or Alkyl



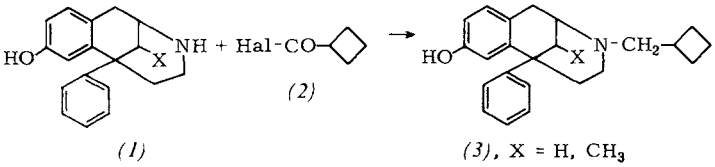
beginning of the polymerization. The polymers produced by this process are suitable for the production of textile fibers, pipes that can withstand high temperatures, and calendered sheets for vacuum forming. [DOS 1770971; Produits Chimiques, Pechiney-Saint-Gobain, Paris]

[PR 7 –E IE]

Aqueous graft and/or block copolymer emulsions having high solids contents and film-forming ability are obtained by polymerization of vinyl monomers in an aqueous reaction mixture in the presence of polyvinyl alcohol and at least one salt of cerium(IV) as the polymerization initiator. The mixture consists of 1) 82—65 parts by weight of vinyl monomer(s) and 2) 18—35 parts by weight of polyvinyl alcohol having an average degree of polymerization of 450 to 1200 and a degree of hydrolysis of 96 to 99%; the polymerization is carried out until the solids content of the final emulsion is 22—32 wt.%. The concentration of the cerium(IV) salt is not critical. Examples of suitable vinyl monomers are acrylates, methacrylates, styrene, α-methylstyrene, *p*-chlorostyrene, acrylonitrile, methacrylonitrile, vinyl chloride, vinylidene chloride, and vinyl esters of fatty acids. It is possible to copolymerize these monomers with small quantities of other monomers, such as acrylic, methacrylic, crotonic, maleic, fumaric, and itaconic acids or their esters, as well as acrylamide and methacrylamide. The reaction is preferably carried out at pH < 6.0, particularly < 3.0. The emulsions are suitable for the production of paints, adhesives, and coating and impregnating compositions, as well as for cellophane or plastic films. [DOS 2138202; Daicel Ltd., Osaka]

[PR 8 –E IE]

Alkylaminoguanidine derivatives *(1)* are suggested as antidiabetics and as drugs for the treatment of obesity. The compounds *(1)* are known, and can be prepared by methods described in the literature.

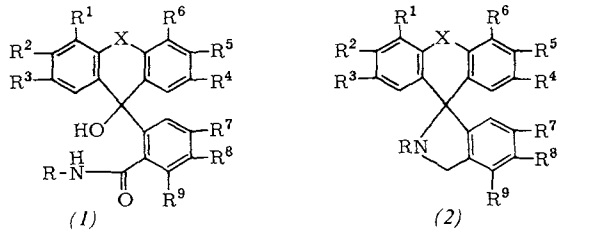


(1)

R^1, R^2, and R^3 are H, F, Cl, alkyl (C_{1-4}), or alkoxy (C_{1-4}), with the condition that two CF_3 groups may not be attached to neighboring carbon atoms; R = —$(CH_2)_n$— (n = 2,3,4,5) or —O—$(CH_2)_m$— (m = 2,3,4). [DOS 2139801; Sandoz AG, Basel]

[PR 21 –K IE]

New racemic and optically active 2-cyclobutylmethyl-5-phenyl-6,7-benzomorphans *(3)* are obtained by reaction of the benzomorphans *(1)* with the acyl halides *(2)*, followed by reduction. The benzomorphans *(3)* and their



(1) *(2)* *(3)*, X = H, CH_3

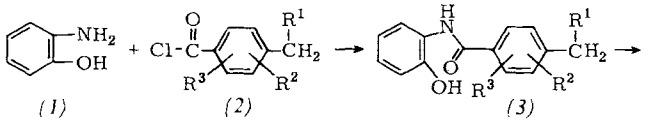
salts are characterized by analgesic and antitussive effects. They are practically free from habit-forming characteristics, and act as morphine antagonists. [DOS 2041658; CIBA-Geigy AG, Basel]

[PR 22 –N IE]

Spiroisoindolines *(2)* are obtained as follows: ring closure of the benzamides *(1)* in the presence of acids or acid anhydrides leads to the spiroisoindolinones, which are reduced with hydrides to form the spiroisoindolines *(2)*. These compounds *(2)* with X = —O—, —S—, —CH_2—S— have

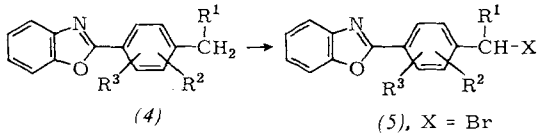
(1) (2)

X = direct linkage, —O—, —S—, —CH_2—S—, >N—R^{10}; R^{10} = CH_3, C_2H_5;



R = alkyl (C_1—C_3);

R^1—R^9 = H, Cl, *O*-alkyl (C_1—C_3) (not more than two substituents being different from H)



analgesic effects. If X is a direct linkage or >NR^{10}, they can be used as hypoglycemic agents. The same is true of adducts of *(2)* with acids. [DOS 2146340; Sandoz AG, Basel]

BOOK REVIEWS

Die Verarbeitung des Erdöls (The Processing of Petroleum). By *B. Riediger*. Springer-Verlag, Berlin–Heidelberg–New York 1971. 1st Edit., xvii, 1088 pp., 319 figures, 131 tables, bound DM 220.—.

This excellently produced work, provided with numerous tables and, in some cases, full-page figures, gives a critical account of the processing of petroleum. A description of the crude oils available for processing and the properties of the intermediates and finished products is followed by a consideration of the constructional units of petroleum processing plants. Distillation of crude oil and its primary products, thermal cracking on residual oil or coke, thermal reformation, and corresponding catalytic steps represent the main processes and consequently occupy about one half of the book.

There follows a description of the so-called auxiliary operations, which are actually highly interesting and important processes, and the plant involved, *e.g.* polymerization, alkylation, and isomerization. The author also goes into refinery processes for the removal of undesirable contaminants such as sulfur, nitrogen, and oxygen. Then come solvent methods for separation of asphalt and high-boiling oils, solvent-extraction and dewaxing of lubricants, and the production of bitumen.

High-pressure catalytic hydrogenation for maximum production of gasoline or middle distillates from heavy oil or residues and for refinement is devoted the space it deserves as a modern process. The latest processes for the production of town gas, synthetic gas, and hydrogen from petroleum products round off the descriptions of processes. The final chapter, which also covers 100 pages, is concerned with the planning of complete refineries. A comprehensive author, geographical, and subject index concludes the work.

The book provides both the constructer and designer as well as the operator of refineries with even more than the information collected on over 1000 pages since the detailed references to the original literature facilitate serious study of individual problems. The clear arrangement and the wealth of subject matter make the book a valuable supple-

ment to the available literature on petroleum technology and science because of the exemplary way in which it goes into the chemical structure and uses of the products and the chemistry of the individual processes. Particular mention should be made of the references to the historical development of important processes and equipment which make the book very interesting reading for the older expert too.

Theoretical fundamentals, chemistry, economic necessity, and statistics of the demand for petroleum products precede the descriptions of the processes, thereby contributing significantly to an understanding of the subject.

In the preface the author stresses that he has no intention to deal with the rapidly expanding field of petrochemistry in the present work. Perhaps he will change his mind for his experience in this field too would be sure to enrich the current literature.

Hans Weller [NB 51 IE]

The Chemistry of Synthetic Dyes. Vol. IV. Edited by *K. Venkataraman*. Academic Press, New York–London 1971. 1st Edit., xix, 548 pp., numerous figures, bound $ 28.50.

The present book in the second of four volumes[*] reporting on the progress made in the last twenty years in the field of dyestuff chemistry. They are intended as supplementary volumes to *Venkataraman*'s classis two-volume standard work covering this discipline up to about 1950.

An idea of the contents and the main emphasis of the book can best be gained from a glance at the titles and the sizes of the seven chapters by nine different authors, some of whom are well known experts: 1. Application of Dyes by Dyeing (*O. Glenz*, 74 pages); 2. Application of Dyes in Textile Printing (*K. Neufang*, 27 pages); 3. Basic Dyes (*N. R. Ayyangar* and *B. D. Tiak*, 58 pages); 4. Cationic Dyes for Synthetic Fibers (*D. R. Baer*, 50 pages); 5. Cyanine Dyes (*G. E. Ficken*, 130 pages); 6. The Photographic Color Development Process (*J. Bailey* and *L. A. Williams*, 46 pages); 7. Photochemistry of Dyes (*H. Meier*, 126 pages). These chapters are preceded by a preface by the editor, a list of contents of the already published volumes, and a provisional list of contents of those that have yet to appear. The book closes with a good author and subject index. The clear formulas, reaction equations, and tables deserve special praise, and a certain amount of nonuniformity in the charge symbols (+ or ⊕) in the formulas does little to mar the overall impression.

The editor has succeeded well in matching the undoubtedly very different manuscripts submitted by the various authors to one another to give a well balanced blend of theoretical and practical articles, as is reflected in some 2000 literature references including more than 600 patents. It can hardly be expected that multiple authorship on this scale will not produce some slight degree of inconsistency. Thus some repetition and overlapping occurs between chapters 3 and 4. As examples, it will suffice to mention the designations "basic" and "cationic" dyestuffs, mμ and nm, and the various symbols used for indicating concentrations such as [ ], *c*, or *C*. These and a number of printing errors, which are all trivial in nature, are by no means able to detract from the tremendous value of the book.

Like the preceding volumes, the present book depicts the field of dyestuff science within the context of the principles of modern inorganic, organic, and physical chemistry. It can therefore be recommended without reservation to every modern and receptive dyestuff chemist.

Chemie 1, Anorganisch (Chemistry 1, Inorganic). By *H.-H. Vogt*. Südwest Verlag, München 1972. 1st Edit., 167 pp., bound, DM 12.80.

"The present volume purposely refrains from any kind of specialization. It provides a foundation of chemical theory as a stepping stone to the specialist literature." Thus a part of the foreword—so far so good. However, what should one make of the statement on page 21 (after a conventional introduction to what chemistry is all about) that: "The smallest particles of an element still exhibiting the properties of the element in question are called atoms"?—That is the chemistry of a bygone age and was no more true then than now. With regard to uniformity of properties the author would probably be surprised if he could compare an atom of mercury with a drop of that element.—Atomic weight and molecular weight (instead of relative masses) are introduced, and concerning the molecule one is told: "Because the atoms in a molecule are held together by special binding forces the properties of the molecules differ from those of their constituent atoms". *Schrödinger*'s classical warning against believing what comes out must also be inside seems not to apply here.—And finally a sample of the "logical presentation" proclaimed in the foreword: on page 36 reduction is removal of oxygen (nothing else), on page 73 it becomes take-up of electrons. That is how chemistry was taught while the novelty of these discoveries still stood in the way of intellectual detachedness. We have advanced several decades since then and this kind of logic has begun to acquire rather a musty air.—The reviewer must admit that he did not enjoy reading the book.

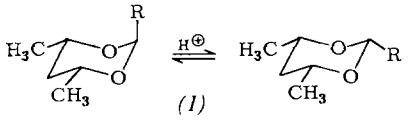
Conformational Analysis in Heterocyclic Systems: Recent Results and Applications[1]

By Ernest L. Eliel[*]

This review deals with the following aspects of conformational analysis in saturated heterocyclic systems: 1. Conformational equilibria in 2-aryl and 2-ethynyl-1,3-dioxanes in various solvents. 2. The generalized anomeric effect in perhydro-1,3-diazines and its origin. 3. Unexpected conformational equilibria in 5-heterosubstituted 1,3-dioxanes. 4. Normal and anomalous solvent effects in conformational equilibria of 1,3-dioxanes with heteroatoms at C-5. Calculation of solvent effects. Correlation of ΔG^0 as a function of solvent with solvatochromic transition energy $E_T(30)$; a new scale of "solvent polarity". 5. Interplay of hydrogen bonding with dipolar, non-bonded and eclipsing interactions in 5-hydroxymethyl-1,3-dioxanes. 6. Highly stereoselective H-D exchanges in anancomeric 1,3-dithianes. 7. Potential distortion of a cyclohexane or 1,3-dioxane ring by a *tert*-butyl substituent. Evidence from ^{1}H-NMR and ^{13}C-NMR investigations and from X-ray structure analysis.

1. Introduction

The universal importance, in chemistry and molecular physics, of the subject of conformational analysis has been recognized by the award of the 1969 Nobel prize to two of the principal exponents of the field: *D. H. R. Barton* and *O. Hassel*[2,3]. Several comprehensive summaries of the field[4–6] as well as accounts of recent symposia[7–9] are available.



In recent years, interest in the conformational analysis of small molecules has shifted away from six-membered carbocyclic rings to rings of other sizes and to saturated heterocyclic rings; particular interest has been directed toward conformational interpretation of physical properties, notably NMR spectra (including ^{19}F and ^{13}C as magnetic nuclei), barrier measurements and *a priori* calculations of molecular conformation by either molecular mechanical or quantum mechanical methods. There has also been much activity in the application of conformational analysis to macromolecules, both natural and synthetic.

The present review deals mainly with recent advances in the conformational analysis of saturated heterocycles[10] and with some more general applications of conformational methodology. Because of limitations of space, the topics to be discussed are confined to work presently in progress or recently completed in the author's own laboratory: conformational equilibria in 2-substituted 1,3-dioxanes, the generalized anomeric effect, equilibria in 1,3-dioxanes with heterosubstituents at C-5, the effect of solvent on conformation of dipolar molecules, hydrogen bonding and conformation, stereoselective H-D exchanges in sulfur-containing heterocycles, and ring distortion by substituents, especially as revealed by ^{13}C-NMR spectroscopy. Attention should, however, be drawn to some novel contributions to the field from other laboratories: conformational enthalpies by heats of combustion[11], by microcalorimetric determination of reaction heats[12] and by mass spectrometry[13], quantitative correlation of conformation with boiling point[14], correlation of NMR spectra with the shapes of six-membered rings[15] and molecular mechanical calculation of conformational energy in heterocycles[16].

2. Conformational Energies in 2-Substituted 1,3-Dioxanes

Previous study[17] of a number of 2-substituted 1,3-dioxanes of type *(1)* has shown that the preference of the substituent for the equatorial position is generally much greater than in cyclohexane, *i.e.* $-\Delta G^0(1) > -\Delta G^0$(cyclohexyl-X). An exception occurs for alkoxy substituents, which, because of the anomeric effect[18], prefer the axial position at C-2 in a 1,3-dioxane.

(1)

This finding is easily explained on the basis of the geometry of the 1,3-dioxane ring[19]: because of the shorter C—O (as compared to C—C) bond length, an axial substituent at C-2 in a 1,3-dioxane is closer to the *syn*-axial hydrogens than a similar substituent in cyclohexane, and this effect is enhanced by the puckering which has been observed in this region of the ring (torsional angle C O C O = 63°)[19].

In view of this finding, it seemed at first sight surprising that the $-\Delta G^0$-value for phenyl (Table 1, entries 1—3) is nearly the same as the corresponding value in cyclohexane (3.1 kcal/mol)[20]. This apparent mystery has been resolved as the result of a recent publication[21] in which it was pointed out that the preference for the equatorial conformation of phenyl in cyclohexane is only partly due to the repulsion of the ring and the *syn*-axial hydrogens in the axial conformation. A substantial part of the energy difference derives from the fact that equatorial phenyl prefers a conformation in which the phenyl ring bisects the cyclohexane chair ("parallel conformation") whereas in axial phenyl, the *syn*-axial hydrogens make this conformation prohibitive and force the ring into a flatside-on ("perpendicular") conformation. In this conformation the major source of the steric interaction is the compression of the *ortho*-hydrogens of the phenyl ring with the equatorial hydrogens at C-2 and C-6 in the cyclohexane chair. Clearly, this compression disappears in a 2-phenyl substituted 1,3-dioxane where the CH_2-groups of the cyclohexane chair are replaced by bare oxygen atoms. Under these circumstances, even equatorial phenyl prefers the perpendicular conformation, as shown by X-ray evidence[19], and the only significant difference between equatorial and axial phenyl is the interaction of the axial ring with the *syn*-axial hydrogens. Although this interaction is greater than in cyclohexane because of the shorter interatomic distances[10d] (cf. the case of the ethynyl group discussed below), the absence of the "*ortho*-interaction" (see above) fortuitously compensates almost exactly for the greater *syn*-axial compression, with the result that $-\Delta G^0$(phenyl) is the same in cyclohexane as at C-2 in 1,3-dioxane. It is also of interest that $-\Delta G^0$(phenyl) is solvent dependent (Table 1, entries 1—3) suggesting the contribution of a polar (anomeric) effect which favors axial phenyl; calculation actually confirms the contribution of this effect[16a]. It is not yet, however, clear why introduction of the strongly electron-withdrawing *p*-CF_3 group does not affect $-\Delta G^0$ and, if anything, diminishes the influence of solvent (Table 1, entries 4—6). Perhaps the fact that the phenyl ring is the positive end of the F_3C—C_6H_4 dipole introduces a reverse anomeric effect[22] into 4,6-dimethyl-2-*p*-trifluoromethylphenyl-1,3-dioxane which compensates for the overall effect of the enhanced dipole.

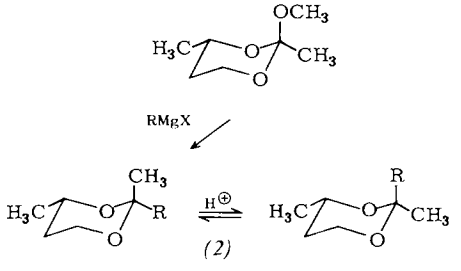

Table 1. Conformational energies $-\Delta G^0$ for 2-substituted 4,6-dimethyl-1,3-dioxanes of type *(1)* at 25 °C [17, 23].

No.	R	Solvent	$-\Delta G^0$ [kcal/mol]
1	C_6H_5	hexane	2.85 ± 0.02
2	C_6H_5	ether	3.12 ± 0.01
3	C_6H_5	CH_3CN	3.40 ± 0.03
4	*p*-F_3C—C_6H_4	hexane	3.08 ± 0.01
5	*p*-F_3C—C_6H_4	ether	3.16 ± 0.01
6	*p*-F_3C—C_6H_4	CH_3CN	3.30 ± 0.01
7	C_6H_5—C≡C	CCl_4	−0.32 ± 0.03
8	C_6H_5—C≡C	ether	0.00 ± 0.02
9	C_6H_5—C≡C	CH_3CN	0.59 ± 0.01
10	HC≡C	CCl_4	−0.21 ± 0.02
11	HC≡C	ether	−0.06 ± 0.02
12	HC≡C	CH_3CN	0.94 ± 0.01

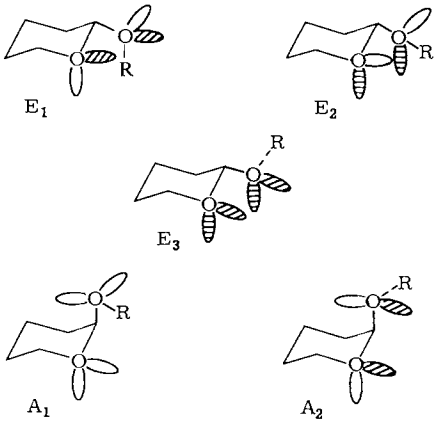
Entries 7—9 (Table 1) show the operation of a substantial anomeric effect for the phenylethynyl group, and entries 10—12 imply the same for the ethynyl group itself; in a non-polar solvent (CCl_4) both groups prefer the axial conformation. In a polar solvent (acetonitrile) the equatorial preference of the phenylethynyl group is about 0.6 kcal/mol and that of ethynyl group 0.9 kcal/mol which, in view of the more crowded C-2 axial situation in the dioxane, would seem to be in agreement with the reported values of 0.2—0.41 kcal/mol[20,24] for axial ethynyl in cyclohexane. The concordance is satisfying, especially in view of the fact that the cyclohexyl value[24] was found indirectly assuming additivity of ΔG^0-values of geminal substituents—an assumption which has not always proved to be correct in 5,5-geminally di-

substituted 1,3-dioxanes[10f,25]. A preliminary determination[23] of the $-\Delta G^0$ value for the vinyl group has given a value of between 2 and 3 kcal/mol indicating that the group is somewhat "smaller" than methyl ($-\Delta G^0$ = 4 kcal/mol[17]) but substantially larger than ethynyl, as is to be anticipated from consideration of Dreiding models. Once again the value for the 2-substituted dioxane is substantially larger than that (1.35 kcal/mol) found for cyclohexane, again by an indirect method involving geminal disubstitution[26].

Table 2 shows $-\Delta G^0$-values for the 2,2-geminally disubstituted 1,3-dioxanes of type *(2)*[23,27]. Values calculated assuming additivity are indicated also. The agreement for methyl-ethyl and methyl-isopropyl is reasonable, especially if one considers that the ethyl and isopropyl groups engender additional methyl/methyl,

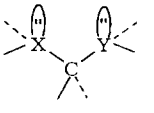
(2)

Table 2. Conformational energies $-\Delta G^0$ for 2,2-geminally disubstituted 2,4-dimethyl-1,3-dioxanes of type *(2)* at 25 C.



R	$-\Delta G^0$ [kcal/mol] found	calculated
C_2H_5	0.32 [27a], 0.28 [27b]	0.41 [27b]
$(CH_3)_2CH$	0.63 [27a], 0.54 [27b]	0.96 [27b]
C_6H_5	−2.42	−0.86 [a]

[a] Assuming additivity of ΔG^0 of CH_3 and R.

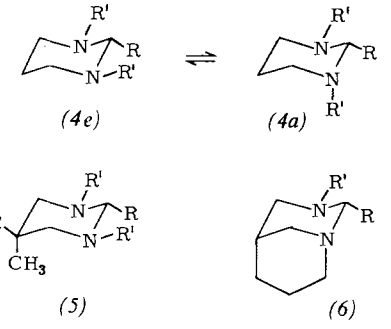


gauche interactions with the geminal methyl group when they are axially place. The vastly greater-than-calculated preference of phenyl for the axial position, in competition with methyl, has its parallel in 1-phenyl-1-methylcyclohexane[21]. In that compound it is due to the fact that the geminal methyl group forces the normally parallel equatorial phenyl group to be perpendicular, with resulting increased steric compression. In 1,3-dioxane this cannot, *per se*, be the reason for the non-additivity, since equatorial phenyl is already perpendicular (see above). However, it turns out[16a] that in cyclohexane, axial perpendicular phenyl causes a much more serious bending of the 2- and 6-equatorial hydrogens of the cyclohexane ring toward their axial partners (which is energetically quite unfavorable) than does equatorial perpendicular phenyl; it is the absence of this effect that makes the axial phenyl so highly favored in 2,4-dimethyl-2-phenyl-1,3-dioxane. The calculated value is 2.7 kcal/mol[16a]. The configurations of the compounds shown in Table 2 follow not only from the chemical shifts of the 2-alkyl substituents but also from the method of synthesis[28].

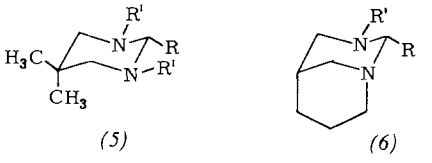
3. The Generalized Anomeric Effect

The preference of axial over equatorial C-1 alkoxy groups (aglycones) in pyranose sugars has been known for some years and has been called the "anomeric effect"[18,22,29,30]. A related effect has been seen in acyclic molecules such as dimethoxymethane, which has *gauche* conformations around the O—CH_2 bonds[31,32]. The solvent dependence of the effect has been studied in simple 2-alkoxytetrahydropyrans[33]; the axial preference of the alkoxy group is diminished in highly polar solvents, such as acetonitrile. It was concluded that dipole-dipole repulsion played a substantial part in the effect, and since component dipoles of C—N and C—O bonds are directed along the axis of the unshared electron pairs, the effect was rationalized[33] in terms of such "pair-pair repulsions". It was subsequently shown[34] that, of the five sterically reasonable conformations of a 2-alkoxytetrahydropyran, only one axial one (A_1) and one or two equatorial ones (E_1 and/or E_2) are appreciably populated, with A_1 (zero pair-pair repulsion) having preference over E_1 and E_2 (one pair-pair repulsion).

The idea was generalized to propose that the arrangement *(3)* was an unfavorable one, and, for obvious reasons, the effect was called[10c,35] the "rabbit ear effect".



(3)



Since, however, this phenomenon is merely a more general manifestation of what has long been known as the "anomeric effect" (see above), *R. U. Lemieux*[22,36] and the author[10d] have agreed to call it "generalized anomeric effect".

A controversy has developed over the source of the effect. We had originally thought that it was responsible for the axial preference of one of the *N*-methyl groups in *N,N'*,2-trimethylperhydro-1,3-diazine[35] *[(4a)* ($R = R' = CH_3$); see also Ref.[36]]. More recent studies[37], using model compounds *(5)* and *(6)* ($R = R' = CH_3$) have indicated the magnitude of this axial preference to amount to about 0.55 kcal/mol (Table 3, entry 1).

On this basis, the generalized anomeric effect in *(4)* ($R = R' = CH_3$) would amount to about 1.2 kcal/mol, taking into account that 0.42 kcal/mol of the preference for *(4a)* is due to its entropy-of-mixing advantage

(4e) *(4a)*

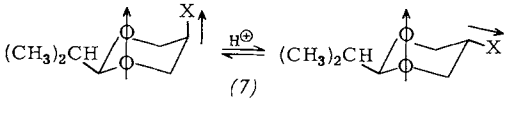
(5) *(6)*

(DL-pair, RT ln 2) and that in the absence of the generalized anomeric effect, *(4e)* should be preferred by about 1 kcal/mol. However, dipole moment measurements of *(4)* ($R = H$)[38] did not confirm the preference for the *N*-axial conformation (Table 3, entries 2—5).

Table 3. Nitrogen inversion equilibria in 2-substituted *N,N*-dialkylperhydro-1,3-diazines of type *(4)*. The conformation energies ΔG^0 quoted are corrected by RT ln 2.

No.	R′	R	ΔG^0 [kcal/mol]	T[°K]
1	CH_3	CH_3	−0.13 [35, 37]	303
2	CH_3	H	0.54 [38]	
			0.65 [37]	196 ± 5
			0.4 [39]	
3	C_2H_5	H	0.62 [38]	
			0.63 [37]	192 ± 4
4	$(CH_3)_2CH$	H	> 1.8 [38]	
			0.83 [37]	200
5	$(CH_3)_3C$	H	large [38]	
6	$C_2H_5(CH_3)_2C$	H	1.03 [37]	200

NMR measurements[37,39] of *(4a)* ($R = H$; Table 3, entries 2—4, 6) at low temperatures (to stop ring inversion) support the dipole moment results at least for $R' =$ methyl or ethyl. (For secondary and tertiary R′ the agreement between dipole and NMR measurements is not good; but since both methods may be subject to systematic errors, it is not clear which one gives more accurate results.) Thus for *(4)* ($R = H$, $R' = CH_3$; Table 3, entry 2) the diequatorial conformer *(4e)* is preferred by 0.4—0.65 kcal/mol, which allows only about 0.5 kcal/mol for the generalized anomeric effect. Moreover, contrary to expectation, the equilibria *(4e)* ⇌ *(4a)* for $R = H$ and varying R′ seem to be independent of the polarity of the solvent[40]. The conclusion seems inescapable that the preference for *(4a)* ($R = R' = CH_3$) is caused in the main by something other than the generalized anomeric effect. Our best hypothesis, at present, is that perhydro-1,3-diazine, like 1,3-dioxane[19] is a "hyperchair", *i.e.* puckered up in the N-1/C-2/N-3 region (torsional angle 1-2-3-4 or 3-2-1-6 > 60°). The effect of this puckering is to make interaction of an equatorial group at C-2 with an equatorial substituent on nitrogen larger than the corresponding interaction with the group on nitrogen axial.



Wolfe et al.[41] have recently performed an *ab initio* calculation on the hypothetical fluoromethanol molecule, F—CH_2—O—H, and find the *gauche* conformation preferred over the *anti*. While this result might have been formally predicted on the basis of repulsion of unshared pairs, the calculation indicates no such repulsion but suggests that the preference for the *gauche* conformation rests on a dominant nuclear-electron attraction involving the C—F and C—O *bond* electrons which is greater when these electrons are *gauche* than when they are *anti*. *Wolfe et al.* have therefore rejected the "rabbit-ear" picture of the generalized anomeric effect as being misleading; specifically they say that their calculation indicates that the "effect cannot be ascribed in any straightforward way to coulombic interaction." Nevertheless, it seems to be an experimental fact—based on the observed solvent effects mentioned earlier—that a classical dipole-dipole repulsion must, in many instances, form part of the anomeric and generalized anomeric effect.

Our present hypothesis is that the nuclear-electron attraction postulated by *Wolfe et al.*[41] as well as "classical" electrostatic repulsion both contribute to the generalized anomeric effect to a greater or lesser extent. There may be cases, such as the *N,N*′-dialkylperhydro-1,3-diazines, where, as judged from the absence of solvent effects, classical dipole-dipole repulsion contributes little to the total effect; whereas in other cases, for example in 2-alkoxytetrahydropyrans, dipole-dipole repulsions must be substantial, as evidenced by a strong solvent response. It should be mentioned here that yet another interpretation of the anomeric effect in terms of double bond—no bond resonance (or its molecular orbital equivalent) has been given in the literature[42].

4. 1,3-Dioxanes with Hetero-substituents at C-5

4.1. Solvent Effects

Equilibria in 5-alkyl substituted 1,3-dioxanes of type *(7)* had been studied previously[43]; because of the absence

(7)

of the *syn*-axial hydrogens at O-1 and O-3, the $-\Delta G^0$ values for 5-substituents are substantially less than corresponding values in cyclohexane. For example, $-\Delta G^0$ for *(7)* (X = *tert*-butyl) is only 1.4 kcal/mol as compared to over 5 kcal/mol in cyclohexane, indicating that there is no appreciable compression of the alkyl group by the unshared electrons of the ring oxygens. These studies have been extended to hetero-substituted dioxanes[44]. Because of the existence of a ring dipole [in *(7)*] one might have expected that an electron-withdrawing substituent X in the axial position at C-5 would suffer destabilization by dipole-dipole repulsion, unless there is a compensating attraction, *e.g.* by intramolecular hydrogen bonding. The summary of findings in Table 4 indicates that this prediction is not uniformly borne out.

Table 4. Conformation energies $-\Delta G^0$ of 5-substituted 2-isopropyl-1,3-dioxanes of type *(7)* and cyclohexane derivatives RX [20] in ether at 25 °C; R = cyclohexyl.

X	CH_3	OH	OCH_3	$OCOCH_3$	F	Cl	Br	NO_2

[a] In 1,2-dimethoxyethane.
[b] In carbon tetrachloride.
[c] In cyclohexane.

The $-\Delta G^0$ values for hydroxyl are summarized in Table 5[25,44]; it is clear from infrared spectral studies[45] that axial hydroxyl in solvent cyclohexane is intramolecularly hydrogen bonded, which accounts for its stabilization. Association in more concentrated solution favors the equatorial isomer somewhat and displaces the equilibrium toward it. In strong hydrogen-donating or hydrogen-accepting solvents the intramolecular hydrogen bond of axial hydroxyl is destroyed or at least its advantage offset; ΔG^0-values for such solvents are similar to those for cyclohexanol, perhaps by an accidental compensation of various factors.

Table 5. ΔG^0 values for 5-hydroxy-2-isopropyl-1,3-dioxane *(7)* (X = OH) in various solvents at 25 °C; for comparison: values for 4-*tert*-butylcyclohexanol [45a].

A more unexpected situation is encountered for the halogen, methoxy and ethoxy substituents as summarized, for various solvents, in Table 6[46].

Considering only the data in CCl_4, where dipole repulsion should be at a maximum, it is striking that axial fluorine is preferred over equatorial fluorine. The situation has some parallel in 1,2-difluoroethane, FCH_2CH_2F, in which the *gauche* isomers in the vapor have the same enthalpy as the *anti* conformation[47]. The reason for this apparent attractive interaction between fluorine atoms, or a fluorine and an oxygen atom, located *gauche* with respect to each other, is not known at this time; it may lie in a dominant nuclear-electron attraction similar to that in fluoromethanol[41].

It is of interest that whereas the oxygen-fluorine interaction is attractive, the oxygen-chlorine interaction is repulsive. A qualitatively similar situation is seen in the comparison of oxygen-oxygen (CH_3O group) with oxygen-sulfur (CH_3S group[48]. The data in Table 4 show that the ΔG^0 difference between CH_3S and CH_3O is greater at C-5 in dioxane (0.9 kcal/mol) than is is in cyclohexane (0.5 kcal/mol); the discrepancy is somewhat greater in solvent acetonitrile where, for the 5-substituted dioxane, $\Delta G^0_{OMe} = 0.0$ kcal/mol (Table 7) whereas $\Delta G^0_{SMe} = 1.1$ kcal/mol[48]. The enhanced repulsion of the second-row (and higher-row) atoms by the ring oxygens has also been reported by *Zefirov*[49] and is reasonably ascribed by him to an electron-electron repulsion involving the unshared electrons of the outer shell of the larger elements.

Comparing data in solvents carbon tetrachloride, ether, acetonitrile (Table 6) one sees the expected increase in proportion of the more polar equatorial isomers as the dielectric constant of the solvent increases. In the highest-dielectric solvent, acetonitrile, fluorine prefers the axial position by a factor of about 9; the ΔG^0-value for methoxy is nearly zero (suggesting absence of pair-pair repulsion between the ring oxygens and the methoxy oxygen) and the $-\Delta G^0$-value for chlorine (but not for bromine) is less than the value in the corresponding cyclohexyl halide (Table 4).

The effect of solvent on the equilibrium of the 5-halo- and 5-methoxy-1,3-dioxanes can be fairly well predicted

by a calculation employing classical electrostatic theory[46,50] taking into account the dipole and quadrupole moments of the substrates. Table 7 gives a comparison of the calculated and experimental ΔG^0-values; it should be stressed that the calculation only provides the differenece in ΔG^0 between solvents, and the way in which the calculated and experimental scales are made to coincide (the location of the origin of the scale, so to speak) is somewhat arbitrary. It is of interest that good agreement between calculated and experimental values is obtained at least in the case of the halogens (the

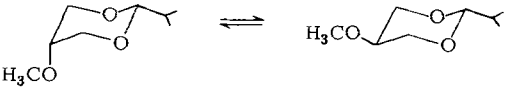
case of methoxy is complicated by its potential conformational inhomogeneity) and that it is predicted that in the vapor phase, 5-fluoro-2-isopropyl-1,3-dioxane will be more stable when the fluorine is equatorial—a prediction which we hope to test.

It is clear from Table 6 that benzene does not fit into the treatment: although its dielectric constant is i ilar to that of carbon tetrachloride, the ΔG^0-values in the two solvents are quite different, benzene behaving as a more polar solvent than it actually is, as has been found elsewhere[51]. Chloroform also behaves anomalously toward solute 5-methoxy-2-isopropyl-1,3-dioxane, whose axial configuration is preferred in that solvent more than one would expect on consideration of dielectric constant (compare solvents ether and chloroform in Table 6); however, chloroform does not seem to show anomaly toward the halodioxanes (Tables 6 and 7). Solvent anomalies will form the topic of the next section.

4.2. Abnormal Solvent Effects

A more extensive study of solvent effects in the equilibria of the 5-methoxy- and 5-ethoxy-2-isopropyl-1,3-dioxanes *(7)* ($X = OCH_3$ or OC_2H_5) is shown in Table 8[52]. Since correlation of the data in terms of the dielectric constant ε or the usual function $(\varepsilon - 1)/(2\varepsilon + 1)$ proved unsuccessful, we decided to plot the ΔG^0-values against the solvatochromic energies E_T (30) of *Dimroth* and *Reichardt*[53,54]. The plot for the methoxy derivative is shown in Fig. 1 (a very similar plot was obtained for the ethoxy derivative) and corresponding plots for the halogen compounds are shown in Fig. 2.



There is a good linear correlation if one excepts the data for methanol (not actually shown on the plots because they would have required reducing the scale) and with some provisos involving benzene, toluene, chloroform, deuteriochloroform and methylene chloride. The lack of correlation for methanol is not surprising considering

Table 8. Conformation energies $-\Delta G^0$ in 5-methoxy- and 5-ethoxy-2-isopropyl-1,3-dioxanes of type *(7)* in various solvents at 25 °C; correlation with the solvatochromic energies E_T (30).

the strong specific hydrogen bonding interactions with this solvent which do not necessarily parallel E_T (which is a measure of solvent "polarity"). Chloroform deviates seriously only for the alkoxydioxanes, not for the halogen derivatives.

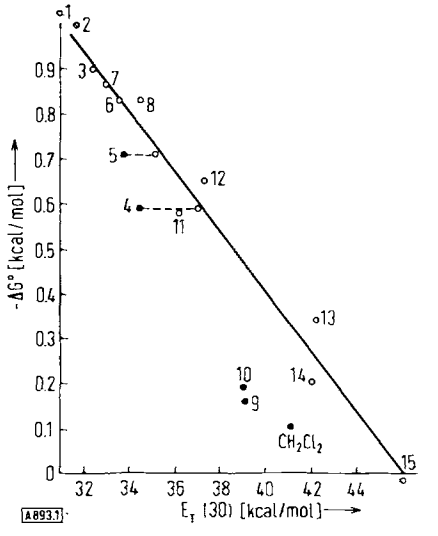

Fig. 1. Correlation between $-\Delta G^0$-values and solvatochromic energies E_T (30) for 2-isopropyl-5-methoxy-1,3-dioxanes *(7)* ($X = CH_3O$) in various solvents. The numbers refer to those in Table 8. Correlation coefficient $r = 0.988$.

It is usually believed that deviations from expected solvent behavior in the case of chloroform are due to hydrogen bonding, but we reject this hypothesis for several reasons: 1. Deuteriochloroform, though forming a less strong hydrogen bond than chloroform, deviates to about the same extent (Fig. 1). 2. Methylene chloride, which is a much less powerful hydrogen bonding solvent than chloroform is also anomalous (Fig. 1). 3. If hydrogen bonding were a major cause of the chloroform anomaly, one would expect the equatorial (less polar but more easily hydrogen bonded) alkoxy group

to be preferred, *i.e.* the chloroform point should lie above the correlation line in Fig. 1 (the methanol point does, indeed, lie above it). In fact, it lies below. We rather think that the anomaly has to do with the detailed (and as yet unknown) solvent structure of chloroform

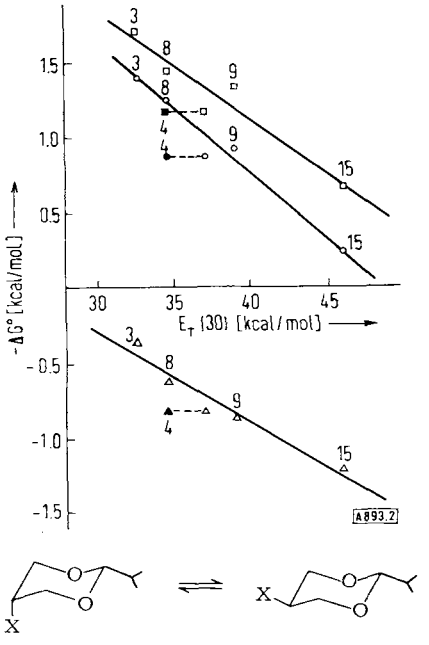

Fig. 2. Correlation between $-\Delta G^0$-values and solvatochromic energies E_T (30) for 2-isopropyl-5-halo-1,3-dioxanes of type *(7)* in various solvents. The numbers refer to those given in Table 8. (—△—△—) X=F, $r=0.972$ (—○—○—) X=Cl, $r=0.984$; (—□—□—) X=Br, $r=0.950$.

which may also account for its relatively high E_T value and the well-known fact that it is such a good solvent for polar solutes.

As far as aromatic solvents go, it is interesting (Fig. 1) that benzene, and, to a lesser extent, toluene, behave anomalously whereas mesitylene and *tert*-butylbenzene display near-normal behavior. In fact, the line fit for benzene and toluene can be much improved by changing their true E_T values of 34.5 and 33.9 to "adjusted" values of 37.1 and 35.3 respectively. It should be stated at this point that the correlation lines of Fig. 1 and Fig. 2 were drawn with these "adjusted" E_T values; both the "true" E_T points (black circles) and the adjusted points (open circles) are shown on the diagram. In Fig. 1, $CHCl_3$, $CDCl_3$ and CH_2Cl_2 have also been omitted from the correlation. It is clear that the correlation would be less good if the black points had been included; for example, for methoxy the correlation coefficient including *all* points is 0.917, and that including the "true" values for benzene and toluene, but not the halocarbons, is 0.963, as compared to a value of 0.988 when the adjusted values are used.

The $-\Delta G^0$ (OCH_3) values may provide a solvent scale which is more appropriate than existing scales.

Fig. 3 shows a plot of log k *vs.* E_T (30) for the rate of reaction

$$(n\text{-}C_3H_7)_3N + CH_3I \xrightarrow{k} (n\text{-}C_3H_7)_3\overset{\oplus}{N}CH_3 + I^{\ominus}$$

in eleven different solvents[55]. (Only those solvents for which $-\Delta G^0$ (OCH_3) values were also available have been included for reasons indicated below.) The correlation coefficient of 0.924 is quite good; if a wider array of solvents is included[56], the correlation coefficient drops somewhat, to 0.879. It had previously been noted[57] that the rates of Menshutkin reactions do not always parallel the dielectric constant of the solvent although, *grosso modo*, the reaction, involving a highly polar transition state, is faster in more polar solvents. In particular, benzene and chloroform had previously been seen to be "faster" solvents than their dielectric constants warrant. Fig. 9 suggests that correlation with E_T (30), in contrast, is quite reasonable. Again it may be

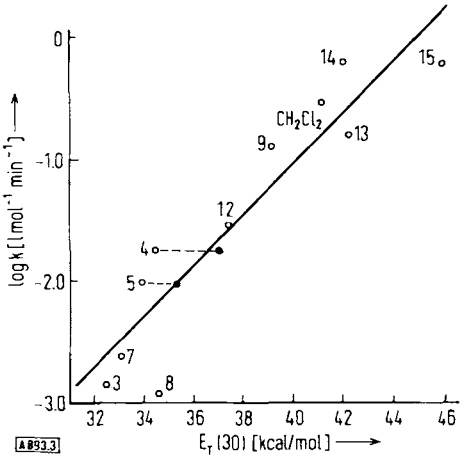

Fig. 3. Correlation between log k (Menshutkin reaction) and solvatochromic energies E_T (30) [55]. The numbers refer to those in Table 8. $r=0.924$.

noted that using "adjusted" (see above) values for benzene and toluene (solid circles) gives better correlations than "true" values (open circles; the open circle values were used in the construction of the correlation line). That the "adjusted" values give better correlations in both Fig. 3 and Fig. 1 suggests that a direct plot of log k (Menshutkin) *vs.* $-\Delta G^0$ (OCH_3) might give a better correlation than log k *vs.* E_T *without* the artifical device of adjusting the scale parameters for the aromatics. Fig. 4 bears out this contention and suggests that $-\Delta G^0$ (OCH_3) may indeed provide a good solvent scale for rates, in different solvents, of a reaction which involves a very polar transition state, such as the Menshutkin reaction.

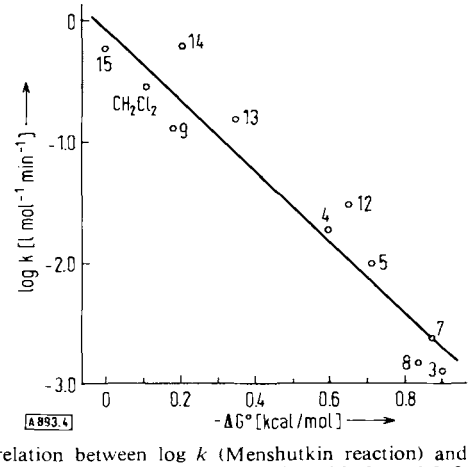

Fig. 4. Correlation between log k (Menshutkin reaction) and $-\Delta G^0$ (OCH_3). The numbers refer to those in Table 8. $r=0.958$.

One can only speculate as to the cause of the solvent anomaly for benzene and toluene which is not paralleled by *tert*-butylbenzene and mesitylene. We believe that the phenomenon is related to the extent of penetration of the aromatic molecule into the cavity formed by the solute. With a planar dye molecule (basis of E_T scale) or a sterically hindered solvent (*tert*-butylbenzene, mesitylene), this penetration may be low. For a sickle-shaped molecule, such as a 5-alkoxy- or 5-halo-1,3-dioxane and a solvent with flat molecules, such as benzene, a few solvent molecules may penetrate the solute cavity and may orient themselves in such a fashion as to assume dielectric properties different from those of the bulk solvent with its randomly oriented molecules. (For example, benzene may have a high microscopic dielectric constant along the direction of its π-electrons, *i.e.* at right angles to the plane of the ring.) These speculations remain to be supported by independent corroboration; the high polarizability of the aromatic solvents in their respective molecular planes may also be of significance.

4.3. 1,3-Dioxanes Containing 5-Nitro, 5-Acetyl, 5-Methylsulfinyl, and 5-Methylsulfonyl Groups

The ΔG^0-values for compounds of type *(7)* containing nitro, cyano and carbomethoxy groups in solvent acetonitrile are 1.0, 0.55 and −0.22 kcal/mol, respectively, compared to 0.38, −0.21 and −0.82 kcal/mol in less polar solvents (Table 4). The solvent effect is typical and the value for carbomethoxy seems unexceptional when compared to that of methyl (Table 4). The axial preference for CN in solvent acetonitrile suggests a net attraction between the cyano group and the ring oxygens. In this context it might be recalled that succinonitrile prefers the *gauche* conformation in the liquid phase[58].

In the case of the 5-nitro-2-isopropyl-1,3-dioxanes, a study[59] of the ultraviolet absorption of the two isomers disclosed a small but reproducible difference in λ_{max}, the equatorial isomer absorbing at 282 nm, the axial at 278 nm. A similar difference was found with the 5-methyl-5-nitro-2-isopropyl-1,3-dioxane isomers. The shift is reminiscent of that observed with simple nitro compounds when the solvent is changed from a non-polar one, such as hexane, to a polar one, such as ether[60]. The 282-nm absorption is due to an $n\rightarrow\pi^*$ transition and its shift to lower wavelengths is explained by a stabilization of the ground state by solvation of the (unshared) n-electrons. The transition state is not stabilized by this solvation (though, by the operation of the Franck-Condon principle, it must still have solvent associated with it). As a result, the energy gap for the $n\rightarrow\pi^*$ transition widens in polar solvents.

Applying these ideas to the present case, we may hypothesize that, in the case of the axial nitro compound, the polar O—C—O region of the dioxane ring provides "internal solvation" for the n-electrons of the oxygens of the NO_2-group; no corresponding solvation can occur with the equatorial isomer for steric reasons.

The energetic situation is depicted in Fig. 5; the difference between 278 and 282 nm translates itself into 1.5 kcal/mol of ground-state stabilization. It is assumed (Fig. 5) that the excited state is of the same energy for the two isomers; indeed, the absorption due to the $\pi\rightarrow\pi^*$ transition at 213.5 nm is exactly the same for the two. Since ΔG^0 for nitrocyclohexane is −1.11 kcal/mol[20] (cf. Table 4) the change in passing from the

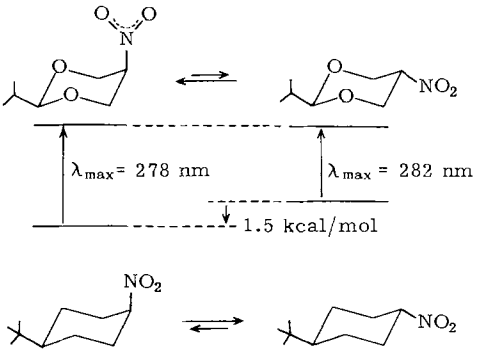

Fig. 5. Energetic situation in 5-nitro-2-isopropyl-1,3-dioxane (in acetonitrile) and 1-*tert*-butyl-4-nitrocyclohexane.

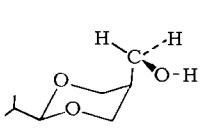
cyclohexane to the 1,3-dioxane system is 2.1 kcal/mol favoring the axial isomer. If 1.5 kcal/mol of this difference is due to "internal solvation" of the axial nitro group as indicated in Fig. 5, only 0.6 kcal/mol remain to be explained, and this can be easily accounted for by absence of the *syn*-axial hydrogen interactions which occur in axial nitrocyclohexane.

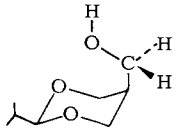
A similar, though perhaps somewhat less clear-cut situation is found in the 5-acetyl compound. Its ΔG^0-value, 0.53 kcal/mol in ether, 0.28 kcal/mol in acetonitrile is substantially smaller than the cyclohexane value of 1.5 kcal/mol and there is a shift in the absorption maximum from 281 nm in the equatorial isomer (solvent: cyclohexane) to 273 nm in the axial[61].

However, the most dramatic change is found in the methylsulfinyl and methylsulfonyl groups which show an equatorial preference of about 1.5 kcal/mol (RSO) and 2.5 kcal/mol (RSO_2) in cyclohexane, which is changed to an axial preference of 0.6 kcal/mol (CH_3SO) and 1.1 kcal/mol (CH_3SO_2), respectively, at C-5 in the dioxane[48]. Here, also, the large stabilization of the axial isomer reflects itself in the ultraviolet spectrum of the sulfoxide, which shows a change from the normal maximum (probably due to an $n\rightarrow d$ transition) at 208 nm, $\varepsilon = 3390$, to 202.5 nm, $\varepsilon = 1490$. (No corresponding change is seen in the *cis*- and *trans*-4-*tert*-butyl-1-methylsulfinylcyclohexanes, both of which absorb at 208 nm with the same intensity.) In the axial methyl sulfone, the long-range [H—CH_2SO_2C—H] coupling constant suggests that the methyl group is turned toward the *inside* of the ring. These findings suggest a strong electrostatic interaction (C—$O^-\cdots S$—O^-) between the axial sulfoxide and sulfone functions and the ring oxygens.



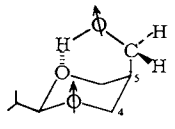
5. Hydrogen Bonding and Energy Minimization

Returning to Table 4 we have not yet discussed the axial preference of the hydroxymethyl group. It was at

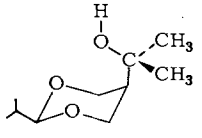


first believed[62] that this, like the corresponding preference of the OH-group, was due to intramolecular hydrogen bonding. The similarity of the ΔG^0 values for hydroxymethyl and methoxymethyl makes such an explanation unlikely; in any case, infrared studies disclosed the complete absence of any intramolecular hydrogen bond in *cis*-2-isopropyl-5-hydroxymethyl-1,3-dioxane *(8)*[63-65].

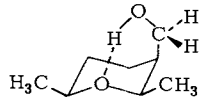
This finding is surprising, since the acyclic model, 3-methoxy-1-propanol, shows strong intramolecular hydrogen bonding[66]. Three hypotheses suggested themselves to explain the absence of bonding in *(8)*: 1) The CH_2OH group is turned outward (A_1) because the oxygen atom is too crowded inside the ring. 2) The OH is either turned upward (A_2) or outward (A_1) because of overriding dipole-dipole repulsion involving the unbonded ring oxygen dipole and the C—O—H dipole in the (disfavored) hydrogen bonded form A_3. 3) Eclipsing of the H—O—CH_2—C-5 and O—CH_2—C-5—C-4 segments in A_3 is too severe in the bonded form to allow bonding.



To test these hypotheses in turn, we synthesized the tertiary alcohol *(9)* in which now the oxygen should be



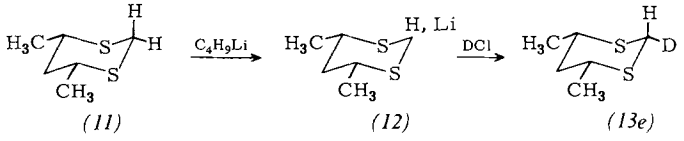
(8) A_1



(8) A_2

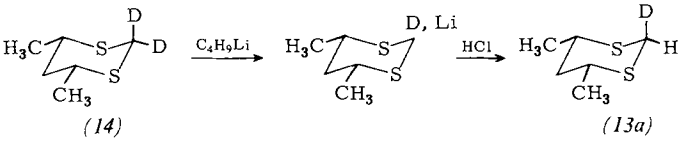
(8) A_3

(9)



(10)

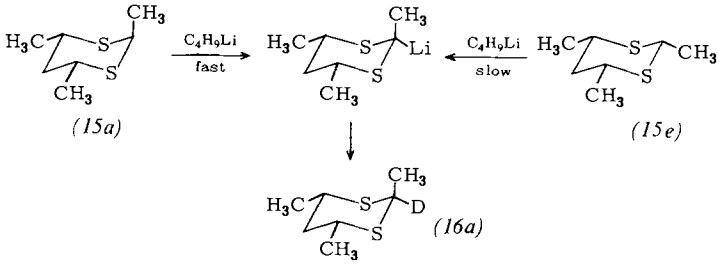
favored inside the ring, since the alternative conformations with methyl inside the ring are known not to be favorable[43]. *(9)* did show intramolecular hydrogen bonding, but the bonded conformation was of very low population, as indicated by the low intensity of the IR-band due to the "hydrogen bonded" hydroxy group. We conclude that crowding of the oxygen over the ring is not the major factor preventing hydrogen bonding in *(8)*.



We next synthesized[67] the tetrahydropyran derivative *(10)*. This compound did show a strong intramolecularly bonded hydroxyl in the OH-stretching region of the infrared. The main difference between *(10)* and *(8)* is the absence of the second oxygen in the ring. It would therefore appear that dipole-dipole repulsion in the hydrogen bonded conformation of *(8)* is mainly responsible for the absence of an intramolecular hydrogen bond, with non-bonded repulsion in the "O-inside" conformation and bond eclipsing perhaps contributing in a minor way to the depopulation of that conformation.

6. Highly Stereoselective H-D Exchanges

We will now turn to a rather different topic. In the course of our work on alkyl-substituted[68] and hetero-substituted[69] 1,3-dithianes, we had occasion to apply the Corey-Seebach reaction[70] to an anancomeric[71] dithiane, namely the *cis*-4,6-dimethyl derivative *(11)*. Upon treatment of the resulting lithium derivative with

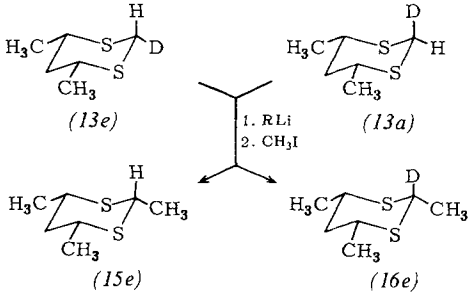


(11) *(12)* *(13e)*

(14) *(13a)*

DCl, we were surprised to find formation of the equatorial deuterium compound *(13e)* *to the exclusion* of the axial isomer *(13a)*. The latter was the exclusive product of lithiation of the 2,2-dideuterio compound *(14)* followed by treatment with HCl; comparison of the NMR spectra of *(13e)* and *(13a)* with those of synthetic mixtures of the two isomers indicated cross-contamination of less than 1%, probably less than 0.5%[72].

Lithiation of the isomeric trimethyl-1,3-dithianes *(15a)* and *(15e)* followed by treatment with DCl yielded exclusively the deuterated *trans,trans* isomers *(16a)*[72]. Since the result is the same in ether and in 1,2-dimethoxyethane[73] it would appear that we are dealing with a carbanion pair which prefers the equatorial conformation to the near exclusion of the axial and whose subsequent protonation occurs with retention of conformation[74]. Alkylation of the lithium derivative *(12)* with methyl iodide also proceeds exclusively from the equatorial side and yields *(15e)* free of *(15a)*[72].

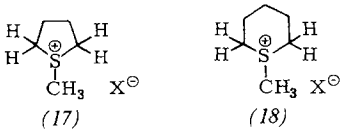


(15a) *(15e)* *(16a)*

Even qualitative observations show clearly that the lithium derivative of *(15a)* (involving removal of equatorial H-2) is formed much more rapidly than that from *(15e)* (removal of axial H-2). This observation suggests that not only is the equatorial lithium derivative preferred thermodynamically (see above)[*]—

[*] We assume that axial and equatorial RLi are readily interconverted by anion inversion.

more so than in 4-*tert*-butylcyclohexyllithium[75] but also that abstraction of equatorial hydrogen is more facile kinetically. In the case of 2-*tert*-butyl-*cis*-4,6-dimethyl-1,3-dithiane, in fact, only the stereoisomer with axial *tert*-butyl would form the lithium derivative readily, but the latter, on treatment with HCl, would return exclusively the axial *tert*-butyl isomer, despite the considerable tendency for the 2-*tert*-butyl group to be equatorial ($-\Delta G^0 = 2.7$ kcal/mol[68]).



The thermodynamic tendency for the metal to be equatorial is obviously quite large, perhaps as high as 4—5 kcal/mol. Possibly of greater interest, however, is the kinetic tendency for a highly stereoselective hydrogen abstraction, since such highly stereoselective abstractions are common in enzyme chemistry[76]. To gauge the extent of the kinetic preference, we performed[77] the following experiment: The lithium derivatives obtained from *(13e)* and *(13a)* were methylated, so that there could be no confusion with starting material which had accidentally escaped lithiation. The methylated product *(15e, 16e)* was analyzed for deuterium mass spectrometrically. It should be noted that whereas there should be a kinetic preference for abstraction of

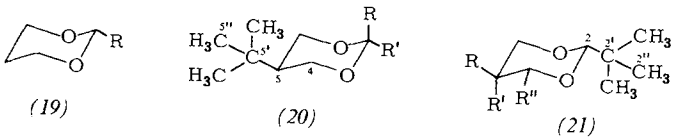
(13e) *(13a)* *(15e)* *(16e)*

equatorial H or D in both *(13a)* and *(13e)*, the isotope effect should counteract this preference in the case of *(13e)* but reinforce it in the case of *(13a)*. In fact, the product from *(13e)* retained 21 ± 5% deuterium (axial attack, 79 ± 5% equatorial attack) whereas that from *(13a)* contained 95 ± 2% deuterium (equatorial attack). From these figures one may calculate[77] a selectivity factor of *ca.* 9 favoring equatorial hydrogen abstraction and an isotope effect of *ca.* 2.5 (which appears reasonable).

For a "simulation" of enzyme systems, it would be desirable to have a reaction of higher stereoselectivity in the abstraction step. A highly stereoselective exchange reaction has recently been reported by *Fava et al.*[78]: The five-membered sulfonium salt *(17)* was reported to exchange only *two* of its four α-hydrogens (along with the three methyl hydrogens) with D_2O and base at 80°C. In an attempt to investigate this reaction in more detail, we studied the sulfonium salt *(18)* hoping to locate the hydrogens exchanged by proton NMR.

(17) *(18)*

This hope was not fulfilled, but we did succeed[79] in analyzing the exchange mass spectrometrically as a very clean succession of four pseudo-first-order reactions of relative rate constants 4.40:3.00:1.83:0.84. Interpretation of these constants requires assumptions as to the secondary isotope effect, if any, and as to the stereochemistry of the exchange itself. Assuming an isotope effect of unity and exchange with retention of configuration leads to the conclusion that the two rate constants for exchange of the α-hydrogens stand in a ratio of 3:1. This ratio may be as low as 1:1 or as high as 5:1 if one allows for a possible secondary isotope effect of ±30%.



Since the exchange in the six-membered ring *(18)* was not very selective, we reinvestigated[79] the five-membered ring *(17)* also and found $k_1:k_2:k_3:k_4 = 5.66:3.00:0.48:0.22$. With the same assumption as above this yields relative rate constants of 30:1 for exchange of the α-hydrogens by D_2O in NaOH at 40°C, a ratio which is substantial if not quite as large as reported[78] by the previous investigators.

The reason why the exchange is more selective in the five-membered ring *(17)* than in the six-membered ring *(18)* is not obvious at the present time; it must be stressed that the assumption of exchange with retention may be wrong and that any exchange with inversion will serve to lower the observed ratios since it puts the second hydrogen in the place of the first where it will then exchange rapidly. Thus our rate ratios represent lower limits and it is possible that the lesser selectivity in the six-membered ring is only apparent and reflects a higher degree of exchange with inversion rather than retention in that ring compared to the five-membered one.

7. The Effect of a *tert*-Butyl Substituent on Ring Conformation

In 1955, *Winstein*[80] imparted considerable impetus to the study of conformational analysis in mobile systems when he proposed the use of a 4-*tert*-butyl substituent as a "holding group" in cyclohexane systems[80]. This trick has been used extensively since (for a review, see Ref.[81]), but recently the use of the *tert*-butyl group has been criticized (see Ref.[82] for references), since the *tert*-butyl group may (and, in some cases does) affect properties by distortional as well as through-space and through-bond effects.

This point has now been explored in several ways. In one investigation[82], 220-MHz NMR spectra of several 2-substituted 1,3-dioxanes of type *(19)* were analyzed; it was found that for substituents methyl, isopropyl, *tert*-butyl, and phenyl the vicinal coupling constants

(19) *(20)* *(21)*

were invariant at 12.4—12.5 Hz (4a/5a), 1.3 Hz (4e/5e), 5.0 Hz (4e/5a) and 2.6 Hz (4a/5e). The ^{1}H-NMR spectrum of the unsubstituted 1,3-dioxane at −135°C, *i.e.* well below its coalescence temperature, can be simulated very closely using the same coupling constants[83]. Thus, within the limits of error of this experi-

ment, the 2-alkyl groups have no palpable distortional effect; whatever effect might have gone undetected by the limits of accuracy of the simulation of the low-temperature spectrum must at least be the same for all alkyl groups.

Further evidence for the substantial absence of distortion comes from a study of ^{13}C-NMR spectra of a variety of 2-substituted 5-*tert*-butyl-1,3-dioxanes *(20)*[84]. The chemical shifts of C-4, C-5, C-5′ and C-5″ are tabulated in Table 9. Again there is no clear evidence for distortion, although the shift at C-5 for the 2-*tert*-butyl compound is somewhat different from that of the others, perhaps significantly so.

Table 9. Chemical shifts in the ^{13}C-NMR spectrum of various 2-substituted 5-*tert*-butyl-1,3-dioxanes *(20)*.

R	R′	−δ(TMS) [ppm] C-5	C-5′	C-5″	C-4
H	H	44.4 (44.5)	30.7 (31.3)	27.6 (27.0) [a]	68.5
CH_3	H	44.6	30.5	27.7	68.6
$(CH_3)_3C$	H	43.7	30.0	27.5	68.6
C_6H_5	H	44.0	30.6	27.9	69.3
CH_3	CH_3	44.2 (44.3)	31.0 (31.7)	27.5 (26.9) [a]	[60.1] [b]

[a] Values in parentheses are corrected for conformational inhomogeneity of the compounds in question.
[b] Not comparable.

In Table 10 are summarized effects of various 4- and 5-substituents on chemical shifts of a 2-*tert*-butyl group and its adjacent ring carbon in compounds of type *(21)*. Since the equatorial substituents at C-5 are in somewhat more crowded environment than those at C-2, one might have expected more palpable effects in this series which is more representative of substituted cyclohexanes. However, the data in Table 10 evidence no significant distortions at C-2 except in those cases where there is an axial substituent at C-5.

Table 10. Chemical shifts in the ^{13}C-NMR spectrum of 4- or 5-substituted 2-*tert*-butyl-1,3-dioxanes *(21)*.

R	R′	R″	−δ(TMS) [ppm] C-2	C-2′	C-2″
H	H	H	107.8	35.3	25.0
CH_3	H	H	107.7	35.3	24.9
$(CH_3)_3C$	H	H	107.2	35.0	25.0
H	H	CH_3	107.3	35.1	25.0
H	CH_3	H	108.1	35.3	24.7
CH_3	CH_3	H	108.4	35.0	25.2
H	$(CH_3)_3C$	H	108.6	35.2	25.1

Most recently, the structures of *trans*-4-*tert*-butylcyclohexyl *p*-bromobenzoate[85], the *cis*- and *trans*-4-*tert*-butylcyclohexyl *p*-toluenesulfonates[86] and *cis*-1-*p*-bromophenyl-4-*tert*-butylcyclohexane[87] have been studied by X-ray diffraction and, in some instances, compared with the structure of cyclohexane derivatives without *tert*-butyl substituents. While the *tert*-butyl group does undergo some bending and exerts slight compression on the ring hydrogens at C-3 and C-5, the studies suggest but very small deformations (not clearly outside experimental error limits) at C-1. It thus appears unlikely that the 4-*tert*-butyl group exercises a palpable distortional effect except in situations which are extremely sensitive to small geometric changes, *e.g.* in ^{19}F-NMR studies[88] and in chemical reactions involving highly compressed transition states or transition states with major changes, from the corresponding ground states, at C-1.

8. Conclusion

While conformational analysis in model systems for its own sake offers less of a challenge now than it did, say, twelve years ago, it continues to be an extremely useful tool in the investigation of more general chemical phenomena, such as non-bonded interactions between atoms, physical and chemical effects of unshared electron pairs, solvent effects and hydrogen bonding effects. Some hetero systems, notably those containing sulfur, provide a framework for potentially highly stereoselective reactions of possible biochemical import. Finally, the increasing importance of ^{13}C-NMR spectroscopy makes desirable a detailed investigation of all pertinent conformational factors affecting ^{13}C chemical shifts. We are continuing research in these various areas.

Collaboration with Professor David M. Grant, University of Utah, Professor Alan J. Jones, University of Alberta, and Professor Raymond J. Abraham, University of Liverpool is gratefully acknowledged. The work here described was carried out by a number of able coworkers: Mr. William F. Bailey, Dr. Harold Banks, Mrs. Janet E. Dennis, Dr. Nicholas Dennis, Dr. Slayton A. Evans, Dr. Armando A. Hartmann, Dr. Otmar Hofer, Dr. Moses Kaloustian, Mr. Laurence D. Kopp, Dr. Sorin Mager, and Dr. Jean M. McKenna. Financial support was provided by the National Science Foundation, the Petroleum Research Fund of the American Chemical Society, the Air Force Office of Scientific Research, the U.S. Army Research Office and the Warner-Lambert Pharmaceutical Corporation.
