Signal Transducers: *Terra Incognita* of Molecular Biology[**]

By Max Delbrück [*]

In this article four cases of signal transduction in biology are discussed, ranging from a case which we do understand in molecular detail (genetic induction) through two cases where the fog may be beginning to clear (vertebrate vision and bacterial chemotaxis) to a case where we are still struggling to define the participants of the play (the avoidance response of the fungus Phycomyces).—Although most of the facts presented are not brand new, the juxtaposition of them is perhaps unconventional and may be of interest at least by way of outlining an area of research of some promise. No doubt modern concepts and technologies of chemical and physical research will play a great role in this borderline area between a variety of fields, presenting great challenges to the ingenuity and versatility of the experimenter.

1. The Lactose Operon

E. coli cells respond to the presence of lactose in the medium within seconds with an increase in the rate of production of the enzyme β-galactosidase which can cleave this disaccharide to glucose and galactose.

The signal is lactose, the ultimate response is the production of the enzyme. In this case the control of the synthesis of the protein takes place at the DNA level: The signal causes increased transcription of the gene which codes for the enzyme. The synthesis of the appropriate m-RNA is *induced* by the substrate. How does the signal manage to give this effect? It acts by removing a physical obstacle to the transcription, the repressor (Fig. 1). An astounding trick and, surprisingly, one that can be quite clearly understood in physical and chemical terms. For once, in biology, the advance of our understanding of a problem has not led us to a confrontation with more baffling problems.

Let us have a closer look at this repressor, the transducer of a chemical signal from the environment into DNA transcription.

The lactose repressor[1] is a protein, a tetramer consisting of four identical subunits, MW 35000 each. It binds to the

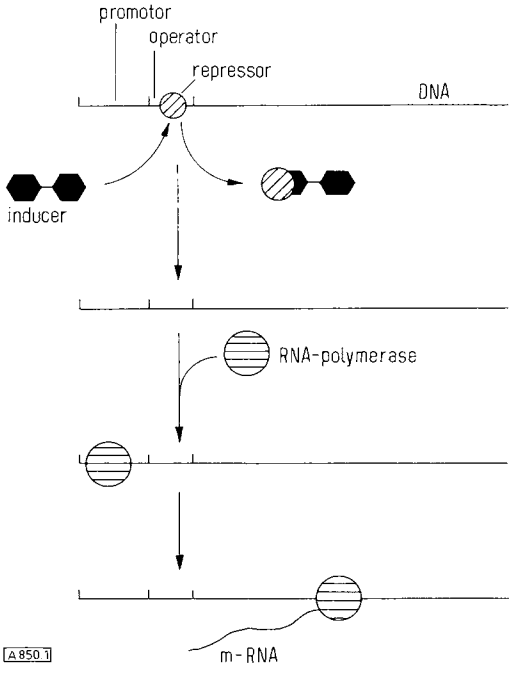

Fig. 1. Derepression of the lactose operon. The lactose operon, a piece of the DNA of the bacterium *E. coli*, codes for three proteins. Before the information coded in the DNA can be read, *i.e.* before it can be transcribed by the RNA polymerase into messenger RNA, an obstacle has to be removed, the repressor. The repressor sits on the operator region of the operon. The polymerase can initiate transcription only at the promoter, to the left of the operator, but cannot do so if its path is blocked by the repressor. The inducer, lactose, combines with the repressor and causes it to dissociate from the DNA. Transcription can then proceed.

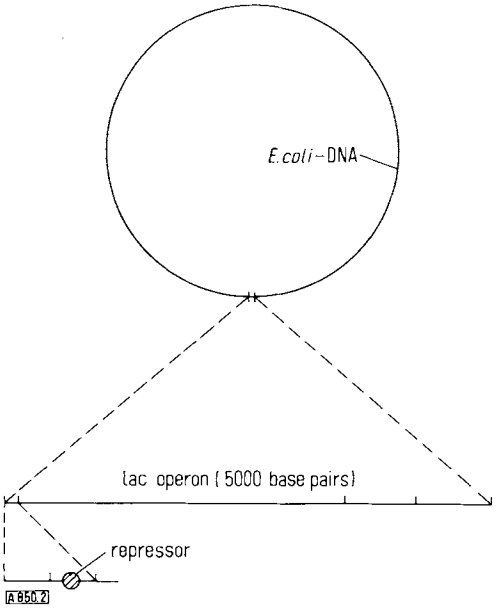
operator region of the lactose operon. The lac operon is a piece of DNA of the chromosome of *E. coli*, about 5000 base pairs. It codes for three proteins, of which the enzyme β-galactosidase is one. The operator region is a very short piece (12—15 base pairs) of DNA at one end of the operon, the end where transcription starts. The repressor recognizes this short piece of DNA with a very high degree of specificity (Fig. 2). The repressor is about 30 Å in diameter, the



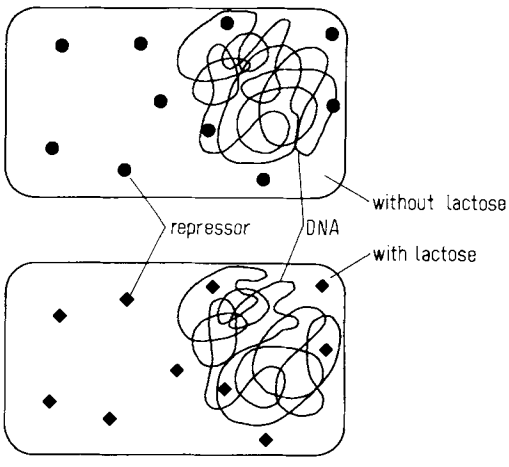


Fig. 2. Scale diagrams of genetic components. In the upper half the circle represents the bacterial chromosome, the tiny segment at the bottom of the circle the lactose operon. In the lower half the lactose operon has been enlarged across the width of the figure. The tiny section at the left end represents the promoter and operator region, respectively.

chromosome 500000 times longer. The binding of the repressor to the operator is very tight indeed, but distinctly finite. The dissociation constant *in vivo* can be estimated and it can be measured in the test tube. *In vivo* it is 10^{-11} M. There are only 10 repressor molecules per cell (a concentration of 10^{-8} M) yet this very small number suffices to keep the operator 99.9% blocked if there is no waste of repressor, *i.e.*, if none is sequestered by unspecific adsorption.

One knows, in fact, not only the dissociation constant, but also its components, the association and dissociation *rate* constants. It takes minutes for the operator-repressor complexes to dissociate. The association rate is *faster* than diffusion controlled. That seems at first paradoxical. How can operator and repressor get together faster than by diffusion? The answer is simple: The repressor finds its target by "reduction of dimensionality"; it adsorbs at first unspecifically on any portion of the DNA, sufficiently tightly not to come off for a while and sufficiently loosely to be able to diffuse along the DNA, by one-dimensional surface diffusion. This is a principle of zero-ing in on a specific target which the cell presumably employs in many situations[2].

The inducer, lactose, also interacts with the repressor (as do many of its analogs). The binding sites on the repressor for lactose and for the operator are distinct; the two ligands do not interfere with each other. The binding of lactose is tight (dissociation constant $\approx 10^{-6}$ M) but not nearly so

	dissociation constant repressor-operator (mol/liter)	blocking of operator (%)
without lactose	10^{-11}	99.9
with lactose	2×10^{-7}	5

A 850.3

Fig. 3. Chemical equilibria involving chromosome, repressor, and inducer. The bacterial cell contains *one* (or two) chromosomes, with *one* lactose operon, with *one* operator region, and about 10 repressor molecules. In the absence of lactose the operator is 99.9% blocked; in the presence of a low concentration of lactose it is blocked only 5% of the time.

tight as that of the operator to the repressor. The main trick of the transduction of the environmental signal consists in the structural modification of the repressor caused by the binding of lactose to the repressor (Fig. 3); the modification is of such nature as to increase the dissociation constant of the repressor to the operator by a factor 20000 from 10^{-11} M to 2×10^{-7} M, just sufficient to shift the equilibrium from nearly total blockage of the operator to nearly total release.

Organisms utilize a vast number of other biochemical control systems on the cellular and subcellular level. The most startling perhaps are the ones of which cyclic AMP forms a link. One of these involves a steroid hormone, the transmembrane enzyme adenyl cyclase, c-AMP as intracellular transducer, protein-kinase, and carbohydrate metabolism[3,4]. Many such control systems are being worked on but the lac-repressor still has the lead in telling us a chain of events without a gap from the environmental signal down to the gene and back to the effect on the environment, fermentation[*]

2. Vision

We turn now to our next example, vertebrate vision. Here the signal is light and the ultimate effect, by definition, is "seeing", *i.e.* a psychic effect, involving consciousness. It thus spans the vast gulf between the external world and consciousness that is as baffling to science now as it was to

[*] The lactose operon is controlled not only by the repressor, as discussed above, but also by a second protein, linking it to catabolism. This second protein binds to the operator DNA and its binding is regulated by c-AMP [5, 6].

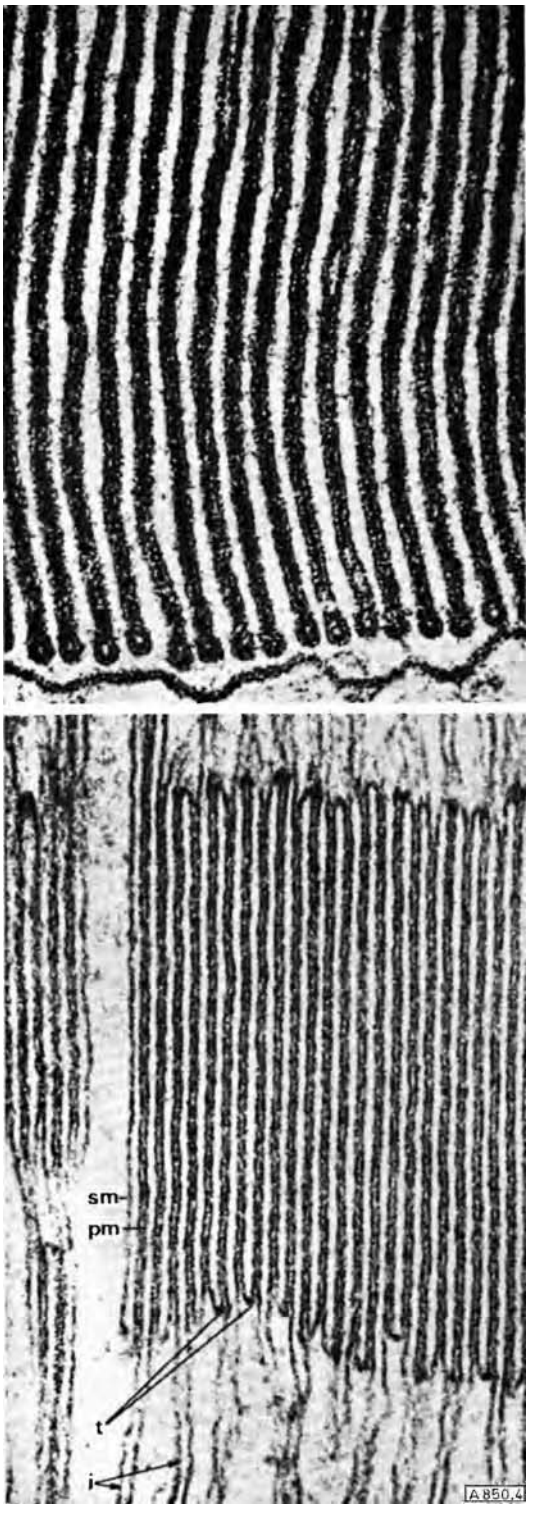

Fig. 4. Detail of retinal rod outer segment (above) and of chloroplast (below). These two specialized regions of specialized cells of vertebrates and higher plants, respectively, are both designed to deal with light: retinal rod for the purpose of vision, the chloroplast for the purpose of photosynthesis. Their ultrastructure, as revealed in electron micrographs of fixed and stained and sectioned preparations, is remarkably similar [24].

Descartes who first codified the language that still fetters us. The time may not be far off, however, when the exigencies of intensive experimental work in the area of psychobiology will lead us to develop a more fitting rational language.

In this discussion I will confine myself to a seemingly minute subproblem. Leaving aside the psyche, the brain, the eye and even most of the retina, let us focus our attention on the receptor cells, specifically those for dim-light vision, the rods. (For a general survey of the structure of receptor cells see *Thurm*, 1969[7].) These remarkable transducers act as quantum counters, converting the absorption of a single light quantum into a signal passed on to the synapse with the next cell, which is a bipolar one. At this synapse the effect produced by a single quantum is amplified sufficiently to cause a discernible signal[12].

The primary action takes place in the outer segment of the rod, a specialized structure containing, within the cytomembrane envelope, what appears to be a stack of several thousand flat membrane sacs, very similar in appearance (in the electron microscope, Fig. 4) to the stacks of sacs in the chloroplasts of higher plants. In both cases the stacks of membrane sacs are specialized for absorbing a large part of the impinging light and to do it with high efficiency. Accordingly, in both cases they are packed with pigments absorbing light of the desirable wavelengths. In the rod the pigment is rhodopsin with $\lambda_{max} = 500$ nm; in the chloroplast it is chlorophyll with two λ_{max} (420 and 680 nm).

The purpose of the absorption of light is radically different in the two cases. In the chloroplast maximal conservation of free energy is the purpose: Nature wants conversion of the free energy of light into free energy of carbohydrate; in the rod energy conservation is not the point; instead we want to "see" the light. The free energy is utilized merely to gate a much larger energy supply provided by general metabolism. In spite of this ultimate difference the constraints on the first step are quite similar: in neither case can we afford low absorbance or a low quantum yield of a primary photochemical reaction.

We used to believe that in the chloroplast there is the additional requirement of bringing together about eight primary photoproducts to reduce one CO_2 molecule and doing it in a reasonably short time even in dim light where the absorption acts are few and far between. We now know that this requirement is solved in part by intermediate chemical storage of energy in ATP and NADPH. However, the machinery for making and using these intermediates is massive, much more massive than a single chlorophyll molecule. It would be wasteful to have such a ponderous machine attached to each chlorophyll molecule. Nature has solved this problem by constructing photosynthetic units, assemblies of several hundred chlorophyll molecules that act as collecting antennas for reaction centers containing a few specialized chlorophyll molecules. To these centers energy is funneled by exciton travel (Fig. 5)[8]. Thus the vast majority of the chlorophyll molecules never undergo a photochemical reaction. Even the specialized ones in the reaction center get only momentarily oxidized. They get reduced so fast (within microseconds) that it has only very recently become possible, by elaborate ESR measurements, to identify this transient radical as a radical of chlorophyll[9].

Does a similar exciton travel towards specialized centers take place in the sacs of the rods? Apparently not, since there is *convincing* evidence that every absorbing rhodopsin molecule is a *potential* reaction center and can undergo a series of chemical changes ending with the detachment of

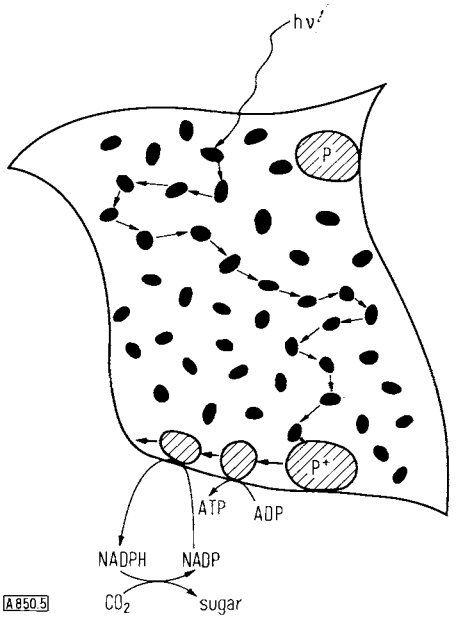

Fig. 5. The photosynthetic unit. The photosynthetic unit consists of several hundred chlorophyll molecules. These serve as "antenna" for a "reaction center" containing several specialized chlorophyll molecules. A light quantum absorbed by any one of the chlorophyll molecules of the antenna travels by exciton migration to the reaction center, where its energy is used for the synthesis of ATP or for the reduction of NADP. These compounds, in turn, bring about the reduction of CO_2 to sugar and the liberation of oxygen. Whether the 10^8 visual pigment molecules of a rod outer segment are organized into a very large number of analogous "antennas", feeding energy by exciton travel into reaction centers at the rim of the organelle is an open question.

the chromophore from its protein carrier. Actually, the experiments that have been performed do not preclude that *at low intensities* exciton migration to specialized reaction centers does occur and constitutes the decisive physiological transducer process. Too little attention has been paid to this possibility.

The chromophore is retinal, a C_{20} polyisoprenic type aldehyde, attached covalently as a Schiff base to the ε-amino group of a lysine in the carrier protein opsin[10, 11]. Absorption of a light quantum leads to a series of chemical changes that have been characterized very incompletely and inadequately by observing spectroscopic changes and lifetimes at various temperatures. The series of steps terminates, at least in the case of isolated rhodopsin, in the isomerization from 11-*cis* to all-*trans*-retinal and the hydrolysis of the Schiff base.

Thus we know at least where the light gets into the act but beyond this point we encounter two major unsolved problems:

1) How is the signal transduced from the photochemical step to the next known event?

2) How is rhodopsin regenerated?

Regarding the first transduction steps very important progress has recently been made[12]. By elaborate and ingenious extracellular potential recordings it has been shown that the rod cell maintains a rather large dark current of about 70 pA, directed outward at the inner segment and here presumably generated by energy coupled active transport of Na^+ ions, and inward through the cytomembrane of the outer segment, adjacent to the rhodopsin-containing sacs, by passive flux through Na^+ specific pores (Fig. 6). After a pulse of light this current decreases transiently, probably due to a reduction in the number of open Na^+ channels in the rod's cytomembrane. Perhaps only one Na^+ channel is closed when one quantum is absorbed. The amplification effected by this closure is enormous. The current transient amounts to a deficit of 10^6 charges passing the cytomembrane. It could be sufficient to effect a voltage change at the synapse lying above the thermal voltage noise. Therefore the voltage change could be adequate for further signal processing, provided the synapse constitutes an ideal detector.

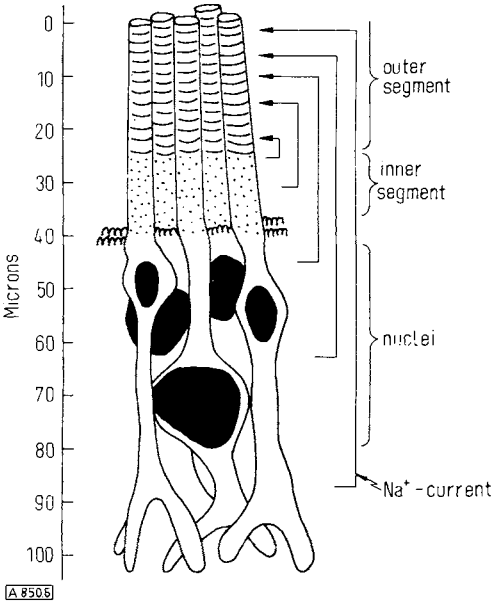

Fig. 6. Distribution of extracellular electrical current in the vicinity of retinal rods [12]. In the dark, current enters the cells along the outer segment and leaves it in other portions of the cell; presumably this current is driven by energy generated in the mitochondria. In light, there is superimposed a smaller current in the opposite direction which may cut down the net current from its value in the dark by 50%. This current is carried by Na^+ ions, through pores in the cell membrane of the outer segment which are specific for Na^+. A fraction of these pores are apparently closed when light is absorbed by the visual pigment in the outer segment, thus raising the impedance of the membrane of the outer segment. The mechanism of this transduction of the signal from the visual pigment to the cell membrane is unknown.

So far, so good. But there is still a big gap in our knowledge of this transduction chain. How does the signal get from the rhodopsin which absorbs the quantum to the cytomembrane where a Na^+ gate gets closed? Geometrically the gap is about 1 μ = 10000 Å, very large on the molecular scale. What transducing mechanism bridges this gap? The guesses that have been put forward proceed from the assumption that the absorbing rhodopsin molecule undergoes a photochemical reaction. However, none of these schemes seems even plausible to me; certainly none has been experimentally supported. Exciton travel towards reaction centers located in the cytomembrane would be the ideal transducer mechanism. Whether it really is a possible mechanism depends critically on the exact spacing of the rhodopsin molecules and their interactions. These are not known at present (cf. [13]). If such exciton travel is the physiological transducer mechanism then the photo-

chemistry of rhodopsin that has been studied at high intensities *in vivo* and *in vitro* might be quite unrelated to the primary function of the bulk rhodopsin.

About the regeneration we know practically nothing. Perhaps it is here that adenyl cyclase is involved. A strong cyclase activity in the dark and a strong repressing effect of light on this activity in rods has recently been reported[14]. One may suspect that this repression of cyclase activity has something to do with the regeneration of rhodopsin. It seems most unlikely to me that it is involved in the transduction of the signal.

3. Chemotaxis in Bacteria

We will leave this story here and move on to our third case history: taxis in bacteria. That motile bacteria "chase" light, oxygen, sugars, amino acids, *etc.*, has been known for 100 years. The bacteria somehow detect chemical or light gradients and respond to them, not indeed by pursuit of the good but by avoiding the bad. In recent years the armamentaria of genetics and biochemistry have been brought to bear on these stimulus-reaction chains, with remarkable but still very incomplete results, showing that bacteria have very clever sense organs.

On the response side we know that the response does *not* consist in a changed swimming rate, faster up-gradient than down-gradient, say. Rather, it seems that the mean free path, *i.e.*, the stretch of swimming straight between tumbles or reversals, is longer uphill than downhill. More precise statements must await the application of a new technique which permits tracking of individual bacteria in three dimensions over many free path lengths[15]. It is certain that bacteria do detect rather small chemical gradients, of the order of 10^{-4} over their body length (Fig. 7). Almost certainly they detect such gradients not by measuring a concentration difference between the two ends of their body, but, since they swim very fast, about 100 body lengths between turns, by detecting the concentration difference between two positions in space, say one free path length apart.

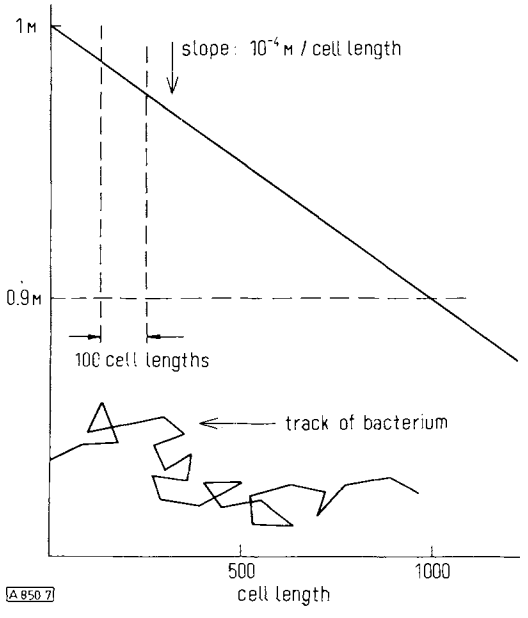

Fig. 7. Chemotaxis of bacteria. Bacteria can detect very small gradients in the concentration of some chemical compounds. The gradients may amount to a fractional change of concentration of only one part in 10000 between the two ends of the bacterial cell. Probably the cells sense the gradient not by detecting a difference in concentration between the ends of the cells but between points one hundred times further apart, since they swim fast and often nearly in a straight line for a distance of about this length. The cell would thus not sense an intracellular *space gradient* but a *time gradient* affecting the whole cell.

How do they detect? Recent work has shown that the detection is *not* done *via* a transient change in the energy metabolism, a transient increase, say, in ATP. This conclusion was reached by showing that analogs of the desirable chemicals which cannot be metabolized are nevertheless chased and that many substances that are readily metabolized are not chased[16, 17]. Detection must take place at an earlier step, prior even to the uptake of the attractant in the bacterial cell. Yet, a connection with uptake seems to exist: in the case of galactose a protein has been isolated, the gal-binder, which is necessary both for uptake and for chemotaxis[18, 19]. This protein is necessary for both these functions because when it is lost by mutation neither function persists. Yet, it is not sufficient for either: other mutations have been produced which leave the gal-binder intact but interfere *either* (some of them) with the uptake of gal *or* (others) with chemotaxis specifically for gal. The gal-binding protein is located in the periplasma of *E. coli*, *i.e.*, between the outer and inner membrane. The above findings suggest that this protein is the branch point between the route that leads to uptake and the route that leads to chemotaxis. We know a little about how the route to uptake goes on, but the one leading to the control of flagellar coordination is shrouded in a dense fog, as is, for that matter, all chemosensation, also in vertebrates and insects. Only in the case of chemosensing of acetylcholine in the neuromuscular joint, and some other chemical transmitter situations, can we point to a proximal effect, at least, the gating of ion channels in the subsynaptic membrane. How this gating is done, in molecular terms, is still quite as obscure here as it is in the case of the vertebrate rod outer segment.

4. A Chemical Self-guidance System

Let us turn, then, to the last example I propose to discuss, the avoidance response of *Phycomyces*. *Phycomyces* is a fungus, a lower fungus, lower on the scale of the taxonomists than the *Ascomycetes neurospora*, *aspergillus*, and yeast, which played such a tremendous role in the development of biochemical genetics. Almost 20 years ago I started work on this organism as a model system for sensory signal transduction since its huge unicellular fruiting structure, the sporangiophore and sporangium, reacts strikingly to light. Is it conceivable that we might learn something of general validity about signal transduction from a primitive creature? In biochemistry and genetics the study of microorganisms certainly did contribute handsomely to our understanding of molecular mechanisms and in fact revealed exceedingly broad principles of chemical organization ranging all the way from vitamins and co-enzymes to the DNA story. Our modern concepts

of the unity of the world of living organisms is based on these principles. It was therefore an obvious thought to turn to microorganisms once more for the study of general principles of signal transduction of sensory inputs.

I will not dwell here on the work concerning the responses to light of *Phycomyces*[20] since it has not yet paid off in the sense of giving us a molecular picture of the transduction chain from light input to growth rate control. In fact, the receptor pigment itself is not yet known as a chemical entity.

Instead, I would like to invite your attention to a new response, the avoidance of a solid or liquid barrier a short distance away[20–23]. This avoidance occurs by "growing away", just like the positive phototropic response is a "growing towards" the stimulating light (Fig. 8). But what

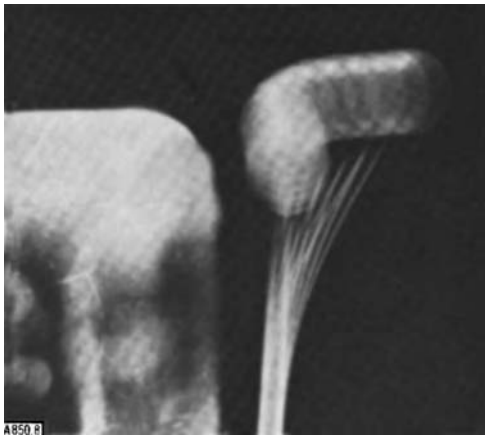

Fig. 8. Avoidance response of *Phycomyces*. The vegetative fruiting body of this fungus, the sporangiophore, possesses a chemical self-guidance system which enables it to "sense" solid objects in the vicinity and to avoid them by growing away from them. The figure is a multi-exposure, every two minutes. The pictures are taken in red light to which the fungus is totally insensitive. After the fifth exposure, a solid glass rod, diameter 5 mm, was moved up to the specimen, without touching it. Two minutes later the sporangiophore begins to grow away from the barrier. The diameter of the sporangium is 0.5 mm.

is the physical signal in this case? After considerable experimentation it turns out that we are dealing with chemical sensing of a volatile substance, the effector, emitted in minute amounts. The barrier affects the spatial distribution of the effector, such that a gradient of concentration is formed, higher on one side of the sensor (in the growing zone) than on the other. A barrier affects the distribution of the effector both by either reflecting or adsorbing the effector molecules, thus altering the boundary condition for diffusion, and by its effect on random winds, quieting them. A striking demonstration of the latter effect can be seen if a glass house of several centimeters in diameter is put over the specimen. In that case the effect is symmetric and no tropic response can be expected. But the quieting of random winds leads to a change of the average concentration of the effector near the sensor, resulting in a transient increase in growth rate within two minutes after enclosure.

We are thus dealing with a novel and clever device of nature, a kind of chemical self-guidance system remotely analogous to radar. In ordinary echo sounding, be it radar or sonar, a principal problem is to shield the sensor from exposure to the direct signal which is enormously stronger than the echo signal. Often this is done by separating emitter and sensor and by pulsing signal and sensor alternately. In our chemical radar system we may also find a separation of emitter and sensor, but the pulsing is replaced either by rapid decay or by strong adsorption of the effector.

5. Conclusions

Let us sum up, then, where we find ourselves today with respect to signal transducers. We find a vast array of phenomena, analyzed in patches, as it were, separated by large gaps which I designated in the title of this article as "*terra incognita*." This is an expression used by the map makers of the 15th century and earlier, before the age of exploration had filled in the globe's *terrae incognitae*. Columbus crossed the Atlantic four times to the new found lands which he, to the end of his life, believed to be part of the Asian continent. It took decades before the staggering truth dawned on humanity that the explorers had found a new continent and a totally unbargained for ocean.

What about our *terrae incognitae*? Will they all turn out to be part of known continents, or dare we hope for great surprises? I for one do so. And I hope that some of you will join us in these adventurous journeys of exploration.

The Mode of Action of Hormones

By Roland Schauer [*]

Higher organisms having anatomically and functionally differentiated organ systems must be able to coordinate biochemical processes within and between the various organs or cells, even under rapidly changing environmental conditions. Hormones play an important part in the regulation processes: they promote numerous metabolic reactions and differentiation processes, and show considerable differences in the speed with which they act. Some hormones act almost instantaneously by stimulating adenyl cyclase and thus initiating the production of adenosine 3',5'-monophosphate (cyclic AMP), which passes on the hormone message ("second messenger") to the intracellular metabolism by modifying enzyme activities. Delayed-action hormones, mainly morphogenetic hormones, act primarily on the cell nucleus where they induce the synthesis of certain enzymes by activation of genes.

1. Introduction

For a cell to function correctly, the numerous metabolic processes occurring within it must be coordinated. Only then can the available substrates be correctly utilized and contribute most effectively to the synthesis of vital substances and to growth. There are three fundamental possibilities for cell regulation by enzymes[1].

1. "Rate-limiting enzymes" determine the rate of reaction of the substrates in the metabolic reaction chains. As long as the quantity of a rate-limiting enzyme remains constant, the quantity of substance that reacts in the metabolic pathway in question is also constant, provided that sufficient substrate (*e. g.* glucose) is present. A change in the quantity of substance metabolized is possible only if the quantity of rate-limiting enzyme in the cell is increased or decreased (Fig. 1).

Fig. 1. Scheme of a metabolic pathway in which a substance A is converted into the product E by the successive action of several enzymes (E 1 to E 4). The enzyme that transforms its substrate most slowly (E 2 in this example) determines the rate of formation of the product E.

2. The second possibility for the regulation of the reaction rate is a stimulatory or inhibitory effect of an intermediate or final product of a reaction chain on the activity of rate-determining enzymes (Fig. 2). This mechanism is based on allosteric effects. Compounds (effectors) formed in metabolic processes interact with the enzyme protein at a site other than the active center in such a way that they change its conformation and influence the enzyme activity (end-product inhibition; feedback control; Fig. 3)[2–5].

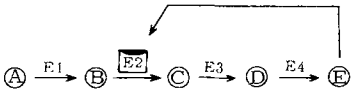

Fig. 2. Conversion of the substrate A into the product E by the action of several enzymes. The enzyme E 2 is inhibited by the end product E, which influences an allosteric action site on the enzyme (black).

An example of an allosteric effector is adenosine triphosphate (ATP) which is formed as an end product of energy metabolism, and which is needed for many energy-consuming processes. If ATP accumulates in the cell it can slow down the turnover of material *e. g.* by inhibiting the rate-limiting enzyme phosphofructokinase in the glycolytic breakdown of glucose[6]. If the ATP consumption increases, *e. g.* through muscular action, protein synthesis, or growth, the inhibitory action on the phosphofructokinase is abolished, and the glucose consumption and hence the formation of fresh ATP increase. Many examples of this type of control are known from intermediate metabolism[7, 8].

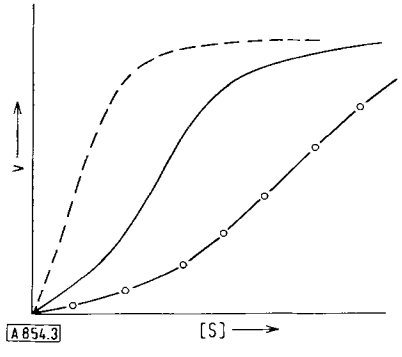

Fig. 3. Examples of the effect of allosteric modulators on the reaction rate (v) of an enzyme as a function of the substrate concentration [S]. The stimulatory effector (– – –) increases the affinity of the enzyme for the substrate, and the inhibitory effector (–o–o–) decreases it. The continuous curve shows the reaction rate without effectors.

3. The third possibility for the regulation of metabolism is a genetic control of the enzyme concentration in the cell. While some enzymes are always present in approximately constant quantities (*e. g.* many glycolysis enzymes), others are synthesized only when inducing substances act on the genetic material of the cell nucleus and make the information stored in the deoxyribonucleic acid (DNA) available for use[9, 10]. Clear examples of the initiation of enzyme synthesis by substrates were provided especially by the

[*] Doz. Dr. R. Schauer

4630 Bochum-Querenburg, Postfach 2148 (Germany)

investigation of the metabolism of bacteria. The best-known example is the induction of three lactose-utilizing enzymes in *Escherichia coli* simply by lactose added to the culture medium[10-12]. The opposite has also been found for bacteria; thus the enzyme synthesis can be repressed by "switching off" of a gene by the end product of a metabolic pathway. In *E. coli*, for example, histidine represses the formation of several enzymes that are necessary for the biosynthesis of this amino acid[13].

The regulation mechanisms outlined above are sufficient by themselves for a single cell, *e. g.* a bacterium. Higher organisms, on the other hand, require coordination of the metabolism not only within the cell ("intracellular regulation") but also between the cells and in particular between the various organs ("intercellular regulation"). This cooperation functions well even in the most highly organized life forms, the mammals, since the material turnover remains substantially constant, as is shown by the almost unvarying body temperature, the only slightly varying basal metabolic rate, *etc.* When the requirements of the body change, *e. g.* in illness, in cold conditions, and in times of danger, additional energy must often be made available very quickly by the intermediate metabolism. There are also periods in life, such as puberty, when pronounced changes of metabolism and new organ differentiations occur.

The possibilities available to the single cell are no longer sufficient for these changes. A central regulation in the body is therefore necessary. This is provided on the one hand by the nervous system and on the other by hormones[14]. (Of these two devices, the nervous system is a later evolutionary acquisition.) This can be illustrated by the following example. Healthy rats survive at an air temperature of 4 °C without ill effect. However, they quickly die at this low temperature if they have been artificially deprived of the ability to produce the hormone epinephrine. This hormone enables the animals to suit their metabolism to the new environmental conditions by increasing their basal metabolic rate[15-17].

2. The Nature of Hormones

The term "hormone" was first used by *Starling* and *Bayliss* in 1905 for secretin, a polypeptide formed in the upper regions of the small intestine, because it *stimulates* the secretory activity of the pancreas[18,19]. (In the classic experiment carried out by *Bayliss* and *Starling* on the dog, the production of digestive juice by the pancreas was stimulated when the mucous membrane of a section of the small intestine (jejunum) that is connected to the rest of the body only by blood vessels was wetted with dilute hydrochloric acid[18]. The same effect was achieved when a dog was injected with an extract from the mucous membrane of the acid-treated intestine.) Many substances produced in the body that exercise specifically stimulatory functions in the metabolism were subsequently classed as hormones. They belong to a very wide range of substance categories, and include *e. g.* peptides, steroids, and derivatives of aromatic amino acids and of fatty acids.

Hormones act as messengers carrying information to the organs. They are produced either in organs having this as their specific function, which are called endocrine glands (*e. g.* adrenals, thyroid, gonads, pituitary gland), or in tissues whose primary functions are entirely different; those produced in endocrine glands are called glandular hormones, while those formed in other tissues are called tissue hormones (*e. g.* secretin formed in the intestine, or histamine in the lungs, liver, and skin). Unlike the products of other glands (*e. g.* salivary, digestive, and sweat glands), hormones are released into the blood stream, a process that is known as "internal (endocrine) secretion". The hormones circulate at very low concentrations in the blood (*e. g.* about 10^{-7} to 10^{-8} mole/l for testosterone and thyroid hormones[20]), and usually act only on specific organs (target organs). (For example, the uterus and the mammary gland are the target organs of the female sex hormones.) How a hormone recognizes its target organ is still largely a mystery. It is assumed, however, (and evidence has been found to support the assumption, as will be shown later) that specific receptors in the cell membrane or in subcellular structures can selectively bind hormones circulating in small quantities in the blood to enable them to exert their effects.

This selective binding and the consequent selective action of the hormone allows the control of the metabolism of individual organs, often independently of the other organs in the body. This is an important condition for the division of work among the organs which becomes necessary, especially when unusual demands are made on the organism. To turn again to the example of secretin, this hormone is carried by the blood stream to all the organs in the body digestion, but it acts only in the pancreas[18,19].

3. The Control of Hormone Production

An essential feature of all regulatory systems is that the stimulating factors should not be free to act without any inhibition. If they were, there would be a danger of disequilibrium of the metabolic processes, particularly in the case of hormones, which generally have stimulatory functions. Metabolic dysfunction due to excessive hormone activity is prevented either by rapid breakdown of the hormone so that its duration of action is short or by control of the quantity of the hormone circulating in the blood. Epinephrine, for example, which can have a fatal effect in high concentrations by increasing the blood pressure and stimulating the heart, *etc.*[18] is rapidly broken down[21], as is acetylcholine, the transmitter substance for nervous impulses. Several other hormones, such as sex hormones, adrenocortical hormones, and thyroid hormones, inhibit their own synthesis by acting on controlling endocrine glands. The best-known organ in which this type of control occurs is the pituitary gland (appendix cerebri), which is located in man at the base of the brain approximately behind the root of the nose. This gland may be regarded as the command post for the hormonal regulation of the body[22]. It is the site of production of several peptide or glycopeptide hormones (glandotropic hormones) (Table 1), which act on the endocrine glands in the periphery of the

Table 1. Glandotropic hormones of the anterior lobe of the pituitary gland and their effects. ICSH, FSH, and LTH are also known as gonadotropic hormones because of their action on the gonads.

Hormone	Abbreviation	Effects
Adrenocorticotropic hormone (corticotropin)	ACTH	Stimulation of the synthesis of adrenocortical hormones
Thyroid-stimulating hormone (thyrotropin)	TSH	Stimulation of the synthesis of thyroid hormones
Interstitial cell-stimulating hormone (luteinizing hormone)	ICSH or LH	Stimulation of the synthesis of male and female sex hormones
Follicle-stimulating hormone	FSH	Stimulation of the maturation of the spermatozoon and of the ovum
Luteomammotropic hormone (prolactin, lactotropin)	LTH	Stimulation of the corpus luteum in the ovary and of the mammary gland

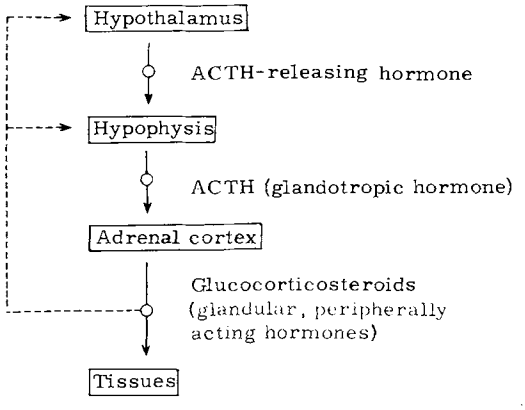

Fig. 4. Sequence of hormones that lead to the synthesis of peripheral hormones, illustrated by the case of the adrenocortical hormones; feedback inhibition of the pituitary gland and the hypothalamus by the peripheral hormones.
—○⟶ stimulatory, - - → inhibitory action.

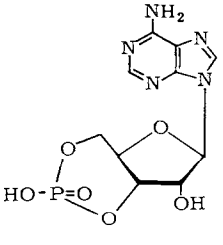
body and cause them to synthesize specific "peripheral" hormones (Fig. 4).

The function of the pituitary gland is not autonomous, but is controlled by a higher organ, the hypothalamus (part of the diencephalon), which is situated anatomically just above the pituitary gland. Thus there exists a definite hierarchy of endocrine glands in the organisms of higher animals. Neurohormones produced in ganglion cells pass directly from the hypothalamus through short veins to the pituitary gland, where they stimulate the formation of the glandotropic hormones (Fig. 4)[23].

Because of this stimulatory action on the secretory activity of the pituitary gland, the neurohormones are called "releasing hormones" (RH). Releasing hormones have been detected, and in some cases isolated, for ACTH (corticotropin-releasing hormone, CRH), FSH (follicle-stimulating hormone releasing hormone, FSH-RH), ICSH (luteinizing hormone releasing hormone, LH-RH), and for TSH (thyrotropin-releasing hormone, TSH-RH), as well as for the growth hormone, which is also formed in the pituitary gland (growth hormone releasing hormone, GR-RH). These are also peptide hormones[22, 24–26].

The hypothalamus also is not entirely autonomous but is subject to the influence of nervous impulses from higher coordinating centers of the cerebral cortex. In this way, *e. g.* cold stimuli and particularly psychic stimuli can affect hormone production. The stimulatory or inhibitory effects of the psyche on the thyroid gland and gonads, and hence *e. g.* on the menstrual cycle, are well-known examples.

The hormones of the thyroid, the ovary, the testes, and the adrenal cortex, which are produced in the periphery of the body under the influence of the glandotropic pituitary hormones, not only act on their target organs but also can exert an inhibitory effect both on the pituitary gland and on the hypothalamus (Fig. 4)[22]. If the concentration of these hormones in the blood increases, therefore, the production of the releasing hormones in the hypothalamus and of the glandotropic pituitary hormones is reduced. In this way the body keeps the hormone effects under control.



4. Modes of Action of the Hormones

Around ten years ago it was already possible to describe the many regulatory effects of various hormones on the general metabolism, the water and mineral balance, morphogenesis, growth, sexual development, the sexual functions, emotional and intellectual behavior, and defence and adaptation reactions of the organism. Apart from sexual differentiation in mammals and in man by sex hormones, the most remarkable effect is the transformation of a tadpole into a frog on administration of thyroid hormones[27]. On the molecular level, however, the mode of action of all hormones remained unknown for a long time. It was thought at first that hormones, like vitamins, could become prosthetic groups of enzymes[28]. However, no evidence supporting this assumption has ever been found. It was interesting, moreover, that the hormones usually cannot exert the same effect on isolated cell fractions, *e. g.* particle-free cell homogenates or microsomes, as they exhibit in the living organism or on the intact cell.

Some hormones, such as epinephrine, act immediately on the tissue, while others act only after hours or even days. Some, such as insulin, have both an immediate action (the permeability of the muscle cells of the diaphragm to glucose increases within a few minutes) and a delayed action (stimulation of protein synthesis after about 24 h[20]). This difference in the time taken for the hormones to act is based on different types of chemical reactions, which allow a tentative division of most hormones into two main groups.

4.1. Hormones Acting *via* Adenosine 3′,5′-Monophosphate

At least one of the effects of the hormones listed in Table 2 consists in the activation of the enzyme adenyl cyclase in the target cells of the hormones in question. This leads to the formation of adenosine 3′,5′-monophosphate ("cyclic AMP") *(1)* and pyrophosphate from ATP[29–31], a reac-

(1)

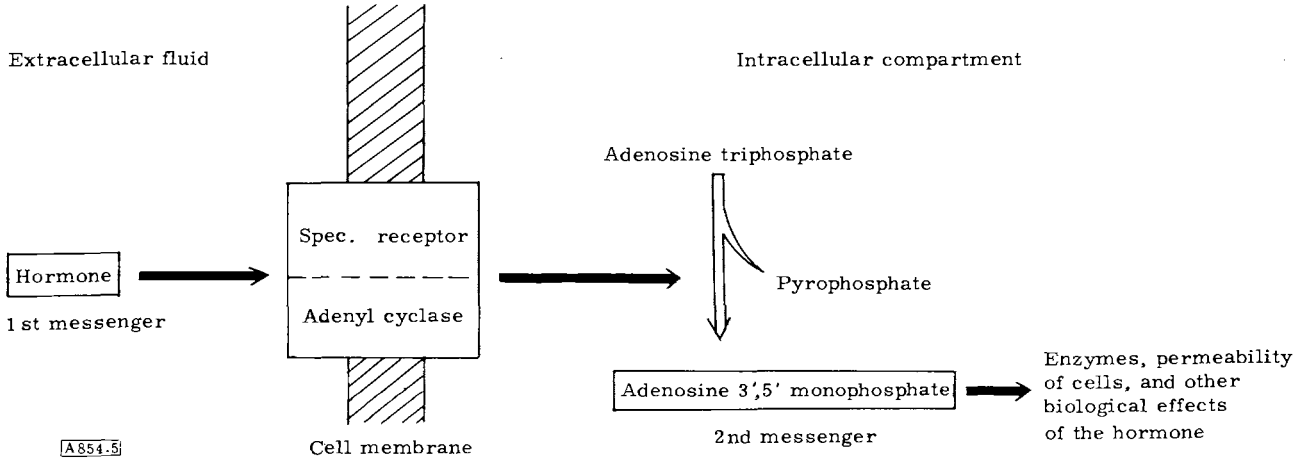
tion that was discovered by *Sutherland*'s research group during investigations on the mechanism of the liberation of glucose from the liver by epinephrine or glucagon[31].

Since the α-phosphate group of ATP rapidly undergoes ring closure to form cyclic AMP, only a short time elapses between administration or secretion of the hormone and the onset of action of those hormones that act *via* cyclic AMP. With parathyroid hormone, for example, cell cultures of bone tissue show an increase in the intracellular concentration of cyclic AMP after only 30–60 seconds[29].

Adenyl cyclase occurs in mammals, insects, and bacteria[35, 36]. In the dog, the enzyme is found in all the organs, but not in erythrocytes. The highest content is in the brain, and this is followed by the tissues that are subject to the action of the hormones that lead to the production of cyclic AMP (liver, muscle, adrenal cortex, ovary, *etc.*). The adenyl cyclase is firmly bound to cell membranes[37]. The tissues are assumed to contain hormone-specific or organ-specific adenyl cyclases, which are responsible for the selective binding of particular hormones. However, there may also exist one type of adenyl cyclase that is closely correlated sterically and functionally with specific hormone receptors in the different organs[38, 39]. This could allow the hormones that act *via* cyclic AMP to exert a selective influence on their target organs. Thus only thyrotropic hormone can

Table 2. Hormones whose effects are at least partly transmitted by cyclic AMP [31—34].

Hormone	Effects
Adrenocorticotropic hormone (ACTH)	Stimulation of the synthesis of glucocorticosteroids in the adrenal cortex
Luteinizing hormone (ICSH)	Stimulation of the synthesis of sex hormones in the ovary or testis
Thyroid-stimulating hormone (TSH)	Stimulation of the synthesis of thyroid hormones
Vasopressin (adiuretin)	Reabsorption of water in renal tubules; contraction of vascular muscle
Oxytocin	Contraction of smooth muscle, particularly of the uterus
Catecholamines (*e.g.* epinephrine)	Activation of phosphorylase in liver and muscle (increase in blood sugar level); stimulation of the tissue lipase; stimulation of cardiac and circulatory function; stimulatory action on the central nervous system
Insulin	Lowering of blood sugar level; stimulation of glucose transport through cell membranes; promotion of glucose consumption and of fat synthesis
Glucagon	Activation of phosphorylase in the liver (increase in the blood sugar level)
Melanocyte-stimulating hormone (MSH)	Regulation of the pigment distribution in the pigment cells of the skin, particularly of cold-blooded animals
Parathyroid hormone	Mobilization of calcium from the skeleton; increased phosphate excretion through the kidneys
Angiotensin	Increase in blood pressure; stimulation of the secretion of aldosterone by the adrenal cortex
Prostaglandins	Organ-specific contraction or slackening of smooth muscle; inhibition of fatty tissue lipase
Histamine	Organ-specific contraction or slackening of smooth muscle; stimulation of hydrochloric acid production in the stomach
Serotonin	Dose-dependent contraction or slackening of smooth muscle; several effects on the central nervous system



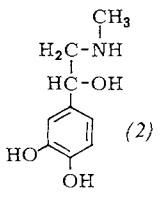


Fig. 5. Activation of the (specific?) adenyl cyclase in the cell membrane by hormones (after adsorption of the hormone on a specific receptor?). Modification of enzyme activities, cell permeability *etc.* by the second messenger. ⟶ stimulatory action, ⟹ enzyme catalysis (based on [39]).

stimulate the adenyl cyclase in the thyroid gland; this stimulation leads to the secretion of more thyroid hormone.

Cyclic AMP is also known as "second messenger", since it passes on the message of the hormone (first messenger) to the intracellular metabolism (Fig. 5)[39]. It influences the metabolic rate in the cell by acting allosterically on the rate-limiting enzymes and modifying their activity, or by activating enzymes that are present in an inactive form and so inducing a special synthesis[31,40]. Effects of cyclic AMP on many enzymes or biological systems of the animal kingdom and in bacteria are now known (for reviews see [31,34,40–43]).

(2)

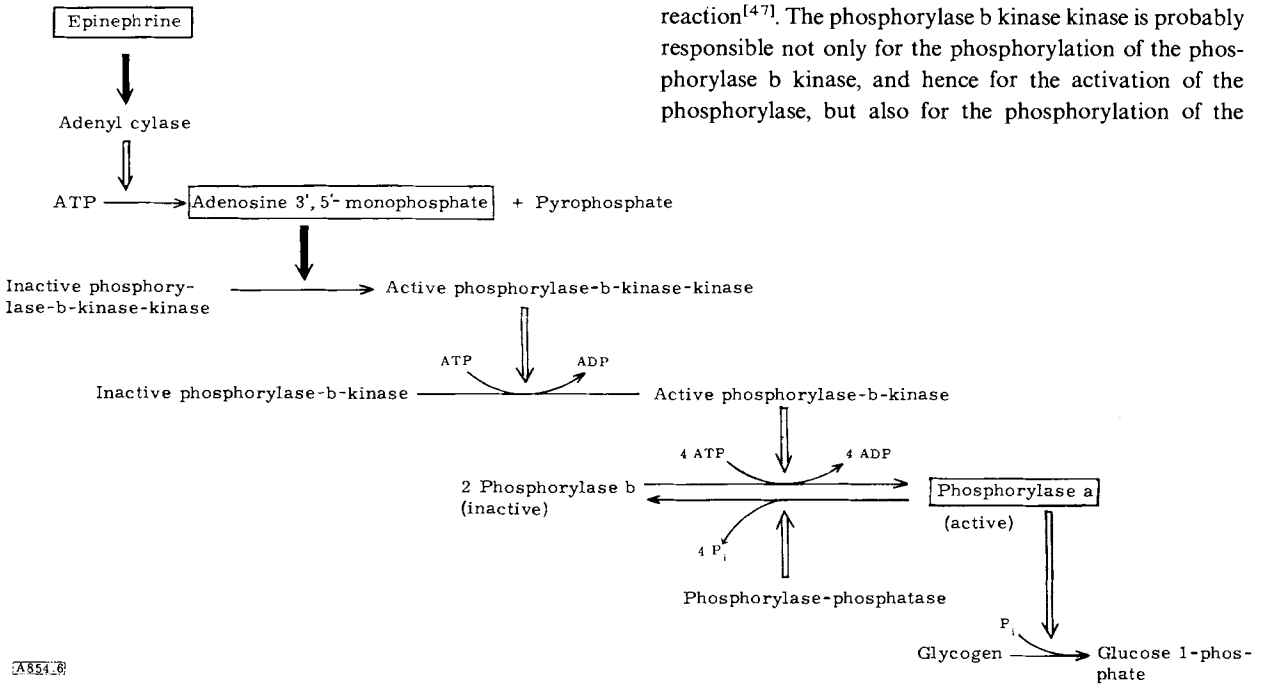

Fig. 6. Activation of glycogen phosphorylase (phosphorylase a) in muscle by epinephrine. For explanation see text. ⟶ stimulatory action, ⟹ enzyme catalysis.

By the action of cyclic AMP on isolated organs, cell cultures, cell fractions, or enzyme systems, it is possible to initiate biological effects that correspond to the known effects of hormones on the same tissue or enzymes in the intact organism. For example, both ACTH and cyclic AMP stimulate the release of corticosteroids from isolated adrenals or from cell cultures of the adrenal cortex in the same manner[33,44].

The most thoroughly investigated effects of cyclic AMP are those on enzymes concerned with the breakdown of glycogen in the liver or muscle and with the fat metabolism in fat cells of the epididymis. Under the action of epinephrine *(2)* (and also of glucagon in the liver), glycogen is degraded to glucose-1-phosphate in the liver and in muscle tissue by an enzyme called "phosphorylase". In the resting muscle phosphorylase is largely found in an inactive form (phosphorylase b) consisting of two subunits. Two phosphorylase b molecules are converted by epinephrine into the catalytically active phosphorylase a molecule, which consists of four subunits[45]. At the same time, four phosphate groups are transferred from ATP to the enzyme protein by the active phosphorylase b kinase, which must also be phosphorylated before it can act. This activation is effected by another kinase (active phosphorylase b kinase kinase), an enzyme that is itself activated by cyclic AMP, the second messenger of epinephrine[15,42,46]. As a result of an impulse of this complicated enzyme cascade, which is represented in Fig. 6, epinephrine makes more glucose available to the cell in moments when energy requirements are high. As soon as the energy demand and the epinephrine level fall, the phosphorylase phosphatase gains the upper hand, and the active phosphorylase a is dephosphorylated back to the inactive form.

According to recent investigations, these complicated regulation processes include yet another, very interesting reaction[47]. The phosphorylase b kinase kinase is probably responsible not only for the phosphorylation of the phosphorylase b kinase, and hence for the activation of the phosphorylase, but also for the phosphorylation of the glycogen synthetase. Unlike the phosphorylase, the glycogen synthetase loses most of its activity when it acquires the phosphate group. Glycogen synthesis is thus prevented at the time of the hormone-stimulated glycogen breakdown, so that large quantities of glucose-1-phosphate can be rapidly utilized for the production of energy in the glycolysis. Insulin, which opposes any increase in the blood sugar concentration, slows down the above epinephrine-stimulated process of the phosphorolytic degradation of glycogen by lowering the adenosine 3′,5′-monophosphate level in the cell (Fig. 7)[48,49].

Several hormones (ACTH, epinephrine, glucagon, TSH, LTH, and prolactin, in order of activity) activate the

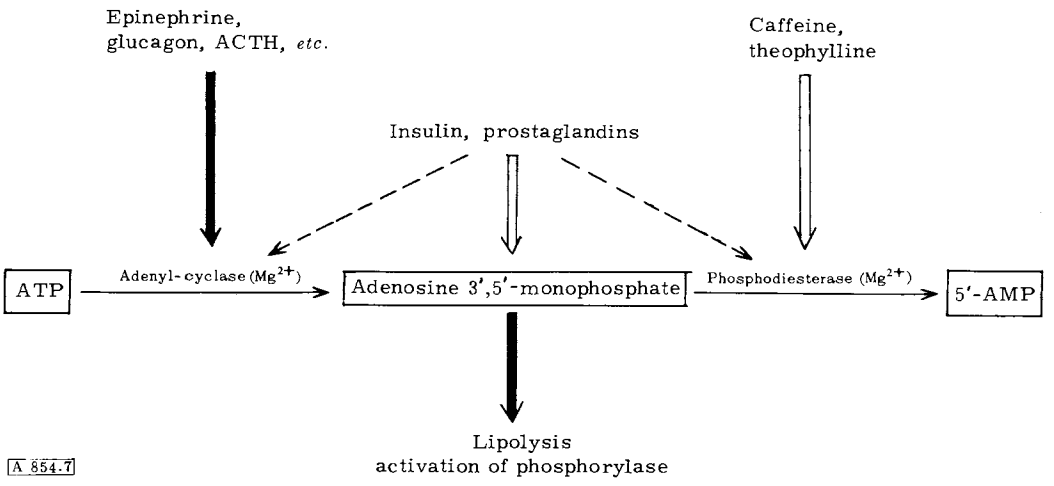

Fig. 7. Effects of hormones and of methylxanthines on the formation and degradation of cyclic AMP and hence on the lipase and phosphorylase activities in fat cells of the rat epididymis (based on [31]). ⟶ stimulation, ⟹ inhibition; - - → inhibition of adenyl cyclase or stimulation of phosphodiesterase? For further explanations see text.

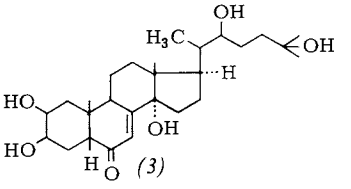
triglyceride lipase in fat cells, cyclic AMP presumably again acting as an allosteric effector for all these hormones[42,50]. The result is that more fat is hydrolyzed and made available to the oxidative degradation pathway. In the fatty cells also, insulin decreases the concentration of cyclic AMP and so opposes lipolysis[51]. The same effect has also been described for prostaglandin E_1 (Fig. 7)[31].

Rapid breakdown of cyclic AMP is essential for an adaptable regulation of metabolism. This is brought about by a specific phosphodiesterase in an Mg^{2+}-dependent reaction (Fig. 7), in which adenosine 5'-phosphate (AMP) is formed[31,52]. Methylxanthines, *e.g.* theophylline and caffeine, inhibit this hydrolytic breakdown[34,53], and this explains their epinephrine-like effects (acceleration of pulse rate *etc.*). It is not yet known whether insulin and prostaglandins decrease the concentration of cyclic AMP, particularly in fat cells of the epididymis of the rat, by activation of the phosphodiesterase or by inhibition of the adenyl cyclase (Fig. 7)[34,40].



Though cyclic AMP has been recognized as the intermediary for a large number of effects of the hormones of this first group, it has not yet been established whether it is the second messenger for all the effects of these hormones. Some of the hormones listed in Table 2, such as ACTH, have been found to have an additional mode of action that is characteristic of the group of hormones to be discussed in Section 4.2.

By discovering and naming cyclic AMP as a second messenger, *Sutherland* has made a great contribution to our understanding of the mode of action of hormones on the molecular level. It is quite possible that there are other substances as well as cyclic AMP that can transmit hormone messages to the intermediate metabolism. Further cyclic nucleotides whose concentrations show a striking variation with hormonal changes have been discovered in urine (*e.g.* guanosine 3',5'-monophosphate)[54].

4.2. Hormones Inducing Enzyme Synthesis

The hormones of this group (Table 3) act on the deoxyribonucleic acid (DNA) of the cell nucleus and induce the synthesis of fresh enzymes, unlike the hormones discussed earlier which cause cyclic AMP to modify the activity of enzymes that are already present. This group also includes hormones that were listed in Table 2 (ACTH, TSH, and insulin), which influence both the genetic material and the synthesis of cyclic AMP.

The understanding of the mode of action of this group of hormones owes a great deal to *Karlson*'s investigations on the pupation hormone ecdysone *(3)*[56]. This steroid

(3)

hormone was first isolated from pupating silkworms *(Bombyx mori)*[57].

By activating certain genes in the larva, ecdysone induces the synthesis of enzymes that produce from the amino acid tyrosine the sclerotization material required for the pupation process[58,59]. This type of mode of action was first postulated from the formation of "puffs" on the chromosomes after the administration of ecdysone or shortly before the natural pupation of insect larvas[59,60]. Puffs are (reversible) thickenings of the chromosomes, in which the DNA helices are despiralized. These "opened-up" chromosome regions are assumed to contain genes that are no longer resting, but that cause the synthesis of ribonucleic acid (RNA)[61]. In fly larvas or their isolated cell nuclei, it has been possible to detect the formation of new RNA in the nucleus and an increase in the activity of the DNA-dependent RNA polymerase under the action of ecdysone (*e.g.* [62,63]). The RNA that is synthesized under the action of the hormone is messenger RNA (m-RNA), which serves as a template for protein synthesis after attachment to ribosomes. In this process[28], the genetic information stored in the DNA molecules of the nucleus is translated into the amino acid sequence of a protein that is to be synthesized. The protein that is formed under

the influence of the hormone, *i.e.* whose synthesis is induced, is in this case an enzyme, which is now used for special metabolic processes leading *e.g.* to pupation.

Table 3. Hormones whose effects are based at least partly on the induction of the synthesis of enzymes.

Hormone	Effects
Adrenocorticotropic hormone (ACTH)	Stimulation of the synthesis of steroid hormones; growth of the adrenal cortex
Glucocorticosteroids	Stimulation of gluconeogenesis (increase in the blood sugar level, protein breakdown); inhibition of inflammation; immunosuppressive action
Thyroid-stimulating hormone (TSH)	Promotion of the synthesis of thyroid hormones
Thyroid hormones (thyroxine, triiodothyronine)	Induction of respiratory enzymes, *etc.*; growth; metamorphosis.
Growth hormone (somatotropic hormone, STH)	Growth; stimulation of protein synthesis; stimulation of gluconeogenesis
Insulin	Lowering of the blood sugar level; increase in cell permeability; promotion of glycogen, protein, and lipid synthesis
Estradiol and other estrogens	Female sexual differentiation; stimulation of lipid synthesis
Testosterone	Male sexual differentiation; promotion of protein synthesis
Erythropoietin	Promotion of the formation of red blood cells [55]
Ecdysone	Initiation of the metamorphosis (pupation) of insects

Though the formation of puffs cannot be observed under the microscope in the chromosomes of mammals, it can be shown by measurements of the rate of m-RNA synthesis or by measurement of the RNA polymerase activity, as well as by inhibition of m-RNA and protein biosynthesis with antibiotics such as actinomycin or puromycin[64], that here also the hormones of Table 3 (apart from ecdysone) increase the gene activity and lead to increased protein synthesis. Moreover, the effects of these hormones appear only after several hours or a few days, the period required for the complicated and time-consuming process of m-RNA and protein synthesis. (When thyroxine is administered therapeutically, several days elapse before the respiratory functions and the processes of the oxidative phosphorylation in the tissues return to normal[65].) These processes will be illustrated further by some examples.

Thyroid hormones intensify the respiration of the mitochondria by induction of a number of respiratory enzymes, *e.g.* succinate dehydrogenase and cytochrome oxidase. On administration of a single dose of triiodothyronine or thyroxine, thyroidectomized animals exhibit an increase in the radioactivity of the RNA in the cell nucleus after only 6 hours, and a distinct increase in the activity of the Mg^{2+}-dependent RNA polymerase after 10—12 hours (Fig. 8)[66]. The rate of protein synthesis, as detected by the increased incorporation of radioactive amino acids into proteins and by an increase in the cytochrome oxidase, rises significantly only after 30 hours. These processes explain why the action of thyroid hormones is totally suppressed by actinomycin D, which inhibits the synthesis of m-RNA[67].

Particularly vigorous RNA and enzyme syntheses occur during the metamorphosis of tadpoles, which is strictly dependent on thyroid hormones[27,66]. Enzymes of many biochemical systems are induced in this process, the induction of respiratory enzymes and enzymes for urea synthesis being particularly strong.

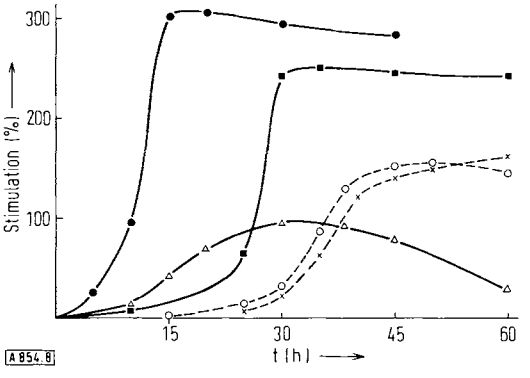


Fig. 8. Stimulation of RNA and protein synthesis in the liver of thyroidectomized rats as a function of time after a single administration of 15–22 μg of triiodothyronine.

(-●—●-) rate of synthesis of nuclear RNA *in vivo*. (-△—△-) Mg^{2+}-dependent RNA polymerase. (-■-—■-) accumulation of newly formed, radioactively labeled ribosomes and polysomes in the cytoplasm. (-○- - -○-) incorporation of ^{14}C-labeled amino acids into proteins/mg of RNA by ribosomes or microsomes *in vitro*. (-×- - -×-) cytochrome oxidase activity/mg of mitochondrial protein (after [66]). The stimulation is determined with respect to a control experiment on normal rats.

Effects on the nucleic acid and protein metabolism similar to those exerted by the thyroid hormones have also been detected for growth hormone, sex hormones, ACTH, adrenocortical hormones (listed in [65]), insulin[49], and erythropoietin[55]. The hormones insulin and glucocorticosteroids (*e.g.* cortisone), which are often used therapeutically, are particularly illuminating examples of a rational hormonal regulation of metabolic processes by induction of several enzymes (reviews in [49,68,69]).

Insulin and glucocorticosteroids have antagonistic effects on the glucose concentration in the blood. Whereas insulin decreases the blood sugar concentration by synthesis of glycogen from glucose, retardation of the breakdown of glycogen (cf. Section 4.1), and acceleration of the aerobic and anaerobic breakdown of glucose, glucocorticosteroids increase the blood sugar concentration by formation of new glucose from amino acids.

This process, which is known as gluconeogenesis, becomes very important in hunger, when too little carbohydrate is being supplied to the organism. Glucose is degraded in a complicated reaction sequence known as glycolysis, with formation of pyruvate, which can be consumed in the citric acid cycle (Fig. 9). At the beginning of the reverse process, *i.e.* gluconeogenesis, pyruvate is formed (together with other keto acids, *etc.*, which will not be considered here) from amino acids. Two molecules of pyruvate are converted into one molecule of glucose in an energy-consuming reaction chain (Fig. 9). This synthesis proceeds in part as a direct reversal of the glycolysis reactions, using the same enzymes. On thermodynamic grounds, however, some reaction steps require special enzymes, which are used only for the resynthesis of glucose from pyruvate, and which catalyze irreversible reactions[70]; these are pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-diphosphatase, and glucose-6-phosphatase. The key enzymes for the rate-determining steps in glycolysis are glucokinase, phosphofructokinase, and pyruvate kinase. Whereas the key enzymes of glycolysis (including glycogen synthetase) are induced by insulin, the quantities of the key enzymes for gluconeogenesis in the liver cells are increased under the influence of glucocorticosteroids (Fig. 9). Transaminases and tryptophan pyrrolase, for example, which are involved in the start of gluconeogenesis and in the supply of pyruvate, are also induced by glucocorticosteroids[69].

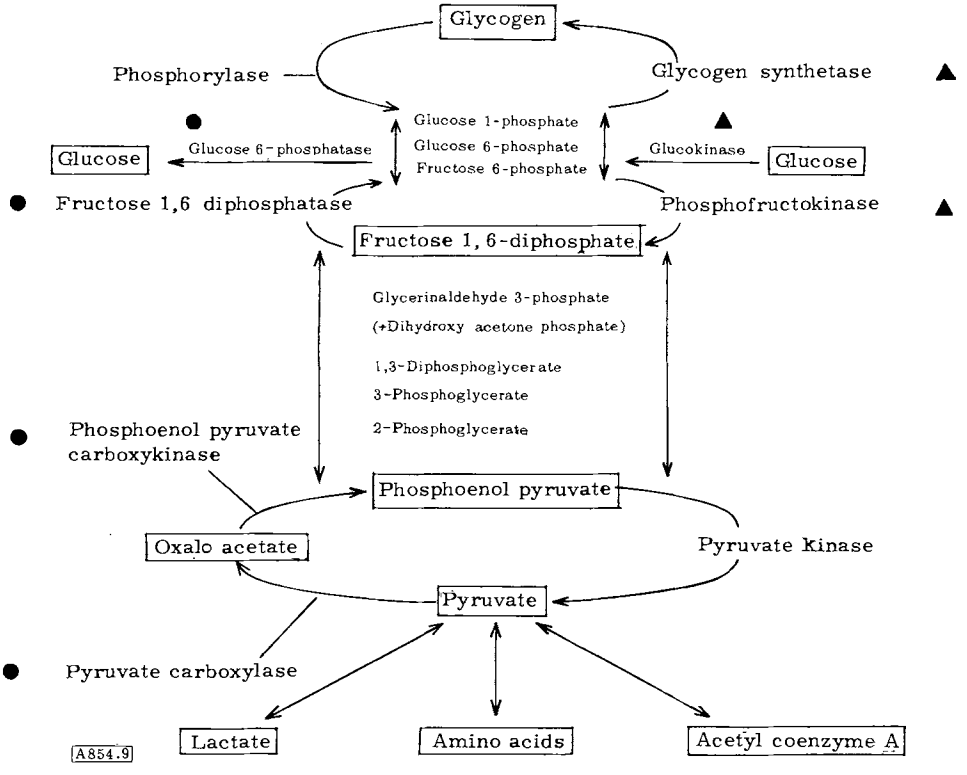

Fig. 9. Synthesis and degradation pathway of glucose (gluconeogenesis and glycolysis), schematic, with the key enzymes that catalyze the rate-determining irreversible reactions; regulation of these metabolic pathways by induction of the glycolytic key enzymes with insulin (▲) and of the gluconeogenetic key enzymes with glucocorticosteroids (●) (based on [49]).

The examples described have shown that a hormone (of group 2) can activate not just one gene but probably several. The associated induction of a group of enzymes by a single inducer (=hormone) recalls the processes, first described for bacteria by *Jacob* and *Monod*, in the induction of several enzymes by a single substrate, *e.g.* by lactose in the case of *Escherichia coli*[11,12]. The lactose here removes a specific repressor molecule from the "operator gene", and the "structure genes" can then bring about the synthesis of the m-RNA for the formation of the enzymes that transport and cleave lactose (Fig. 10).

Repressors are basic proteins, possibly histones[71], attached to the DNA; according to the current view, they shield and inactivate genes. After the repressor has been removed, the information stored in the relevant DNA section can be read by the RNA polymerase. Some repressors have already been isolated from bacteria and their binding to the genetic material detected. One example is the repressor of the lactose operon[72].

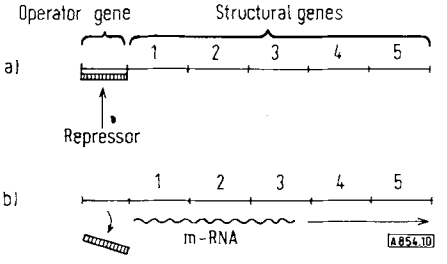

Fig. 10. a) Schematic representation of an operon [10] with repressed operator gene. b) An inductor removes the repressor (depression = induction of the operator gene). The synthesis of m-RNA on the structure genes then begins (after [65]).

It is quite conceivable that the hormonal induction of enzymes in the higher organism takes place in the same way as in bacteria. There is a steadily growing body of evidence in support of the assumption that hormones recognize specific repressors, combine with them, and remove them from the gene, possibly by changing their conformation (Fig. 11)[63].

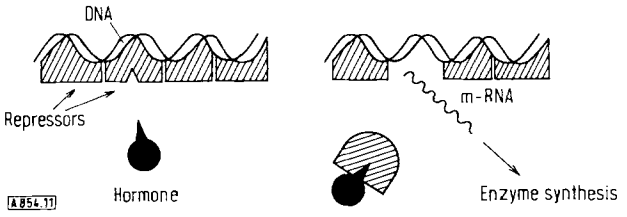

Fig. 11. Enzyme induction by hormones. Primary action of hormones on the transcription stage, presumably after removal of a specific repressor from the gene. A possible change in the conformation of the repressor molecule by the hormone is illustrated (based on [73]).

Selective binding of radioactive estradiol, hydrocortisone, testosterone, and ecdysone[74] to isolated cell nuclei of the target organs has been observed by several groups of workers (reviews in [63,75]). *Sekeris et al.*[63,76] were able to show that tritium-labeled hydrocortisone is bound to rat liver cell nuclei, and that within a few seconds it increases the RNA polymerase activity and the fraction of the nucleohistone (nuclear chromatin) that takes part in the transcription (cf. also [77]). A number of experimental findings also point to a structural change effected by hydrocortisone in the proteins bound to the nucleus (cf. Fig. 11)[63]. In cell nuclei from target organs of female sex hormones, estradiol is bound to a macromolecule fraction that can then be readily removed from the nucleus[78]. This is taken as evidence that this estrogen-binding protein could in fact be the repressor that masked the DNA and prevented it from exerting its biochemical action before the estrogen acted on it.

5. Closing Remarks

It was not the purpose of this progress report to consider all hormones and to describe their biological effects individually. The object was to present the known, presumably primary modes of action on the basis of which the hormones can be divided into two groups, *i.e.* action *via* cyclic AMP on the one hand and action *via* the induction of enzyme synthesis by specific attack on the genetic material on the other. Despite the great progress that has been made in the past ten years, our knowledge of the mode of action of these mysterious regulators of life is still far from complete. Least is known about the specific receptor in the cell membrane[79] or on the cell nucleus that enables a hormone circulating in the blood to be recognized only by cells of certain organs and to be bound by these cells in order that it may exert its specific action. Something else that has not yet been explained is the clock that one day causes the appearance of pupation or sex hormones, which mold the organism and then disappear again after a predetermined time. A great deal of experimental work is still necessary in order to find the answers to these questions.

Macrocyclic Polyethers and Their Complexes[***]

By C. J. Pedersen and H. K. Frensdorff[*]

The most important, and almost unique, property of the macrocyclic polyethers ("crown compounds") is their tendency to form complexes with alkali metal salts and salts with similar cations. Such complexes are held together by electrostatic attraction between the cation and the negative end of the C—O dipoles. The stability of the polyether complexes depends primarily upon how well the cation fits into the polyether ring; other factors are the charge density of the cation and—in solution—the solvating power of the medium. Cyclic polyethers have been successfully employed, inter alia, in experiments with ionic compounds in organic solvents and in studies of ion transport in biological systems.

1. Introduction

Complexing of sodium, potassium, and related cations by neutral molecules is an uncommon phenomenon. Strong stoichiometric complexes have been observed only in the last decade[1, 2], and then only with biological materials (see Section 1.3).

Hence some of the recently synthesized macrocyclic polyethers[3, 4] have aroused considerable interest in several divisions of chemistry because they form stable complexes, both in solution and in the crystalline form, with salts of alkali and other metals.

More than sixty macrocyclic polyethers have been synthesized. They are neutral compounds containing four to twenty oxygen atoms each separated from the next by two or more carbon atoms, but the most effective complexing agents are found among those containing five to ten oxygen atoms each separated from the next by two carbon atoms. These compounds form 1:1 salt-polyether complexes in which the cation is encircled by the oxygen atoms of the polyether ring, being held there by the elec-

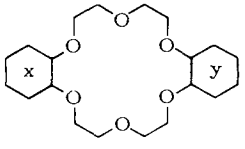
trostatic attraction between the negatively charged oxygens of the C—O dipoles and the cation. In some cases, 2:1 and even 3:2 polyether : salt complexes are found[5]. The following cations have so far been observed to form complexes with cyclic polyethers: Li^+, Na^+, K^+, Rb^+, Cs^+, NH_4^+, RNH_3^+, Ag^+, Au^+, Ca^{2+}, Sr^{2+}, Ba^{2+}, Ra^{2+}, Zn^{2+}, Cd^{2+}, Hg^+, Hg^{2+}, La^{3+}, Tl^+, Ce^{3+}, and Pb^{2+}[3]. Only a few complexes of transition metals have been reported[6].



This review will deal mainly with the preparation, the chemical and physical properties, the structures, and the stabilities of these macrocyclic polyethers and their salt complexes.

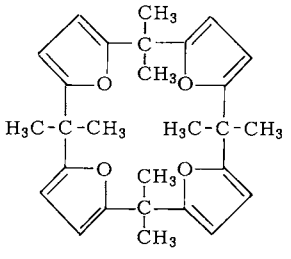
1.1. Nomenclature

The macrocyclic polyethers ("crown compounds") can be assigned unique but very cumbersome names by application of the IUPAC rules for bridged hydrocarbons (rules A-31 and A-32). Thus compound *(3f)* [*(3)*, $x=y=C_6H_{10}$] is called 2,5,8,15,18,21-hexaoxatricyclo[20.4.0.0^{9,14}]hexacosane, and compound *(5)* 2,5,12,15,22,25-hexaoxatetracyclo[24.4.0.0^{6,11}.0^{16,21}]triaconta-6(11),7,9,16(21),17,19,26(1),27,29-nonaene. The rules for fused polycyclic compounds (A-21 to A-23) likewise give unequivocal but most complicated names. A system of *ad hoc* names was therefore devised solely for the ready identification of these compounds[3]. The examples in Table 1 illustrate how these names are made up of the side-ring substituents, the total number of atoms in the polyether ring, the "crown", and the number of oxygen atoms in the main ring. The "crown names" are simple but should only be used in conjunction with formulas since they are not unambiguous. Cyclohexane rings fused to the polyether ring, as in compound *(3c)*, are termed "perhydrobenzene" in the present report; the more common, but ambiguous, term is cyclohexyl.

1.2. History



The pre-1967 literature on macrocyclic polyethers is meager and, above all, the possibility of their being complexing agents was not recognized. Among the previously reported compounds related to the crown polyethers are *(7)*[7], *(8)*[8], and *(9)*[8], as well as the cyclic tetramers of ethylene oxide[9] and propylene oxide[10].

The first crown compound, dibenzo[18]crown-6 *(3d)*, was formed as an unexpected by-product during a preparation of bis[2-(*o*-hydroxyphenoxy)ethyl] ether from bis(2-

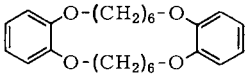


Table 1. Some representative macrocyclic polyethers with their "crown" names, methods of preparation, and melting points (see Section 2.1 for an account of synthetic methods).

Compound	Crown name	Synthesis eq.	Synthesis yield (%)	M.p. (°C)
(1)	dibenzo[14]crown-4	(3)	27	150–152
(2)	benzo[15]crown-5	(1)	62	79–79.5

chloroethyl) ether and the sodium salt of 2-(*o*-hydroxyphenoxy)tetrahydropyran which contained a small quantity of catechol[3,4]. It was recovered from the reaction products

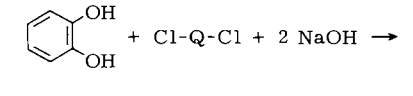
(7)

(8)

(9)

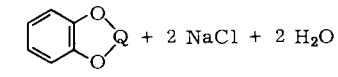
as a very minor component in the form of white fibrous crystals, which were quite insoluble in methanol itself but became readily soluble in it on addition of sodium salts. This observation led to the discovery of the complexing power of the crown compounds and to the synthesis of other macrocyclic polyethers.

1.3. Macrocyclic Antibiotics

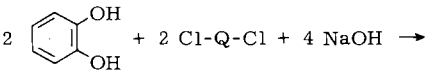


A number of antibiotics, such as valinomycin and nonactin, which contain ether, ester, and amide bonds in 32- to 36-membered rings exert interesting biological effects[11], which are related to the way in which these substances influence transport of Na^+ and K^+ across cell membranes[12]—one of the fundamental processes of living systems. Complexing of these cations by the macrocyclic antibiotics appears to be responsible for their effects on ionic transport across natural and synthetic membranes[1,2,13]. Reports on the solution properties of such complexes[1,2,14] and X-ray structural studies[15,16] have appeared recently. It will become evident in this review that the complexing properties of these biogenic macrocyclic compounds resemble those of the crown polyethers in many respects.

2. Preparation and Properties

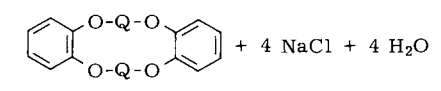


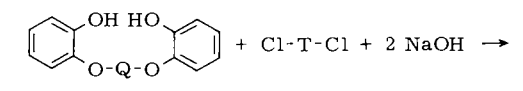
2.1. Synthetic Methods



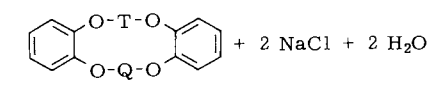
The aromatic crown polyethers are prepared by straightforward condensation methods[3,4] exemplified by the stoichiometric equations (1) to (3), in which Q and T represent divalent organic groups, generally of the type $-(CH_2CH_2O)_nCH_2CH_2-$.

The condensations are typically run in 2-butanol under reflux for 12 to 24 hours. Method (1) can be used to prepare, *e.g.*, benzo[12]crown-4 (yield 4%). Method (2) gives, for instance, dibenzo[18]crown-6 *(3d)* (see Table 1). The starting





(1)



(2)

(3)

material for method (3) is made by attaching a base-stable protecting group, *e.g.* benzyl or tetrahydropyranyl, to one of the hydroxyls of catechol; two moles of this compound are then condensed with Cl—Q—Cl, and the protecting group is subsequently removed. Eq. (3) is most convenient for synthesis of uneven-numbered polyether rings, *e.g.* dibenzo[21]crown-7 *(4b)* (see Table 1).

Aromatic macrocyclic polyethers containing neutral substituents, such as alkyl or chloro, may be prepared by using suitably substituted aromatic vicinal diols. Of course, the substituents must be inert toward sodium hydroxide and the open-chain dichloropolyether.

Saturated polyethers are prepared from the corresponding aromatic ones by catalytic hydrogenation, typically in 2-butanol at 100 °C and 7—10 atm over a ruthenium catalyst[3]. Recovery of the product is best done by column chromatography on alumina, and the yields are almost quantitative.

2.2. Properties

The macrocyclic polyethers with aromatic side rings are colorless crystalline compounds. For a given polyether ring the melting point rises with the number of benzo groups (see Table 1). These compounds, particularly those containing more than one benzo group, are nearly insoluble in water and sparsely soluble in alcohols and many other common solvents at room temperature. They are readily soluble, however, in methylene chloride and chloroform[3].

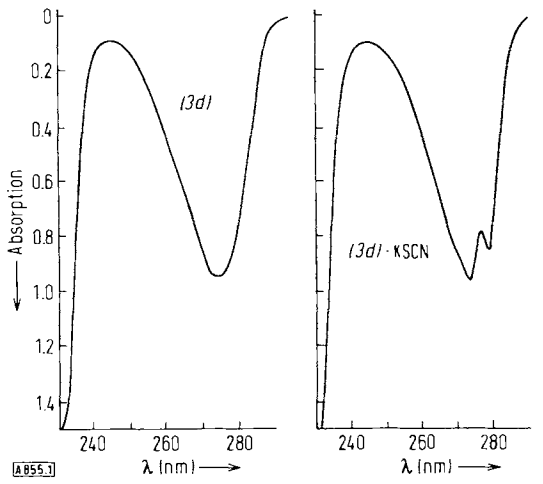


Fig. 1. Ultraviolet spectra of dibenzo[18]crown-6 *(3d)* and its KSCN complex (1.8×10^{-4} mol/l in methanol, 1 cm cell).

The saturated polyethers are colorless, viscous liquids or solids of low melting point. They are very much more soluble in all solvents than their aromatic precursors. Most of them dissolve even in petroleum ether and yet display appreciable water solubility.

While the saturated compounds do not show any absorption above 220 nm, the aromatic ones show absorption bands (in methanol) near 275 nm, which are characteristic for catechol and its ethers, with extinction coefficients of about 2200 per benzene ring (see Fig. 1). Saturated cyclic polyethers show an IR band near 1100 cm^{-1} (aliphatic ether), which is also shown by the aromatic ones in addition to another near 1230 cm^{-1} (aromatic-aliphatic ether).

Aliphatic crown compounds with two or more cyclohexane rings fused to the main ring show bridge-bond isomerism. For example, perhydrodibenzo[18]crown-6 *(3f)*, obtained by hydrogenation of dibenzo[18]crown-6 *(3d)*, can be separated into two isomers (A m.p. 61—62.5 °C; B m.p. 69—70 °C) by chromatography[17]. NMR studies[18] have shown that the bridge bonds of both isomers are *trans*, as are those of several other analogs[*].

The macrocyclic polyethers are thermally stable; for instance, dibenzo[18]crown-6 *(3d)* can be distilled at 380 °C. They must be protected from oxygen, however, at elevated temperatures. The aromatic crown compounds react like anisole or veratrole; for example, they can be halogenated, nitrated, or condensed with formaldehyde to give resins containing polyether rings.

3. Complexing of Salts and Other Compounds

Their ability to form complexes with salts and certain other compounds is the most remarkable property of the cyclic polyethers. In this section we shall discuss a number of different ways in which this complex formation manifests itself.

[*] Recent X-ray structural investigations of complexes of these isomers have led to apparently conflicting conclusions: *M. R. Truter* (personal communication) finds that isomer B in its $NaBr \cdot 2H_2O$ complex has a centrosymmetrical *trans* conformation, while *N. K. Dalley, D. E. Smith, R. M. Izatt*, and *J. J. Christensen* (Chem. Commun., in press) conclude that isomer A in its $Ba(SCN)_2$ complex is *cis-syn-cis*.

3.1. Complexing in Solution

3.1.1. Solubility Effects

The simplest, often spectacular, and potentially most useful way in which complexing by cyclic polyethers manifests itself is the solubilization of ionic compounds in organic solvents. In many cases addition of polyether causes dissolution of salts and related compounds in solvents in which they are otherwise substantially insoluble[3]. For instance, crystals of $KMnO_4$, *tert*-C_4H_9OK, or K_2PdCl_4 can be made to dissolve in aromatic hydrocarbons merely by the addition of perhydrodibenzo[18]-crown-6 *(3f)*.

In early experiments it was found that direct addition of salt and polyether to solvent was frequently not very effective, and that much more concentrated solutions could be prepared by solvent exchange: dissolving the ingredients in methanol, removing this solvent by evaporation *in vacuo*, and then redissolving in the final solvent. It later became apparent that the methanol is frequently not removed completely by this procedure, since it is often very tenaciously held by the complex and probably forms an integral part of it. The finding that addition of quite small concentrations of methanol greatly increases the quantities of salt which dissolve directly in solvents containing cyclic polyether (see Table 2) obviates the need for the solvent-exchange procedure and provides further evidence that methanol, or some analogous compound, may take part in the complex, possibly serving to complete the solvation sphere of the cation or to solvate the anion.

Table 2. Solubilization of alkali-metal halides in organic solvents by addition of 50 mmol/l of perhydrodibenzo[18]crown-6 *(3f)* [a].

Solvent	Methanol (mmol/l)	Solubility (mmol) [b] NaCl	NaBr	KCl	KBr	KI
C_6H_6	0	0.01	1.8	0.03	2.3	9.2
	250	0.48	24	8.7	30	46
CCl_4	0	0.03	2.7	0.6	4.1	0.8
	250	1.1	28	8.8	34	15
$CHCl_3$	0	1.8	37	21	41	43
	250	5.7	41	34	44	44
CH_2Cl_2	0	1.8	35	17	41	43
	250	5.8	42	33	42	44
Tetrahydro-	0	0.02	1.2	0.1	3.6	45
furan	250	0.04	5	0.4	13	50

[a] *H. K. Frensdorff*, unpublished data.
[b] Salt concentration after agitation of the polyether solution with enough salt to give 50 mmol/l solution.

While complexing of the cation is an obvious prerequisite for solubilization, the anion also plays an important role, as illustrated by the increase in solubility with anionic size (Table 2). The complexed cation is surrounded by organophilic groups and thus can be more or less easily accommodated in a nonpolar environment. However, interaction between the anion and a nonpolar solvent is much less favorable, especially for small anions of high charge density and low polarizability. Accordingly, salts of such "hard"[19] anions as fluoride or sulfate are often not solubilized appreciably by cyclic polyethers, while those of "soft" anions, *e.g.* iodide, thiocyanate, picrate, and fatty acid anions, are solubilized more easily.

Potassium and sodium hydroxide can be solubilized in benzene with perhydrodibenzo[18]crown-6 *(3f)* either by solvent exchange or by direct addition of 1% methanol to give solutions which are as much as 1 N in base. These solutions, which appear to contain methoxide as well as hydroxide anions, are capable, for instance, of readily saponifying esters of 2,4,6-trimethylbenzoic acid which are resistant to ordinary saponifying agents.

Solubilization by polyether is not a simple function of solvent polarity (cf. low solubility in tetrahydrofuran, Table 2). Specific interactions, such as solvation of the anion or competition between solvent and polyether, evidently overcome more general polarity effects in some cases.

3.1.2. Changes in Ultraviolet Spectra

All the cyclic polyethers containing benzo groups have a characteristic absorption maximum at 275 nm (in methanol). Complexing with a cation brings about distinctive changes in this band, generally by appearance of a second peak at about 280 nm (see Fig. 1), at other times by a hypsochromic shift and changed absorbance of the main band. Since the new peak is not clearly separated from the main one, it is not suitable for precise quantitative measurements. However, it has been used extensively for qualitative detection of complexing[3, 20].

3.1.3. Conductivity Changes

The existence and stoichiometry of the complexes are demonstrated simply and convincingly by conductance measurements[17]. The results in Fig. 2 clearly show the 1:1 stoichiometry of the complex formed from potassium chloride and perhydrodibenzo[18]crown-6 *(3f)*. This figure illustrates two contrasting cases: (a) in methanol the dissociation of KCl is essentially complete, and complexing, by increasing the size and thus decreasing the mobility of the cation, reduces the conductance; (b) in chloroform/methanol (90:10) KCl is largely undissociated, but complexing, by surrounding the cation with the polyether ring, shields its charge and thus greatly increases dissociation of the ion pairs, which results in an appreciable conductance increase.

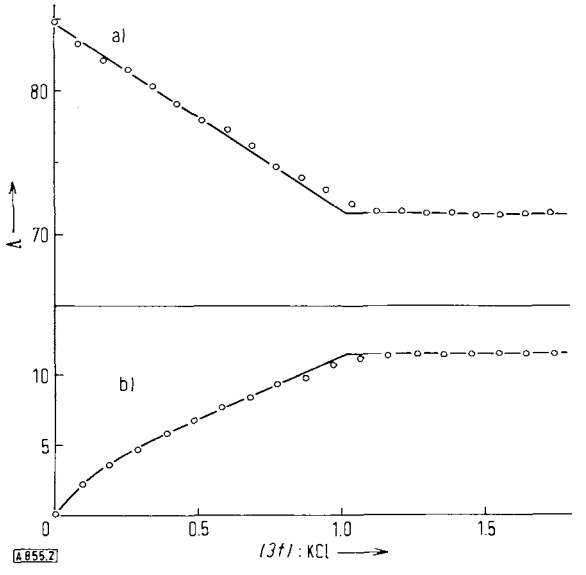

Fig. 2. Conductometric titration of KCl with perhydrodibenzo[18]-crown-6 *(3f)* a) in methanol and b) in chloroform/methanol (90:10). KCl concentration 10^{-3} mol/l [17].

3.2. Crystalline Complexes

3.2.1. Preparation

Numerous well-defined, sharp-melting, crystalline complexes of salts and cyclic polyethers have been prepared by straightforward methods, *i.e.* by bringing together the ingredients in a common solvent, in two immiscible solvents, in a medium which dissolves one of them, or in the dry state[3, 5]. Although salts with high lattice energy, such as fluorides, nitrates, and carbonates, form complexes with the cyclic polyethers in alcoholic solution, they cannot be isolated in the solid state because one or the other of the uncomplexed components precipitates when the solution is concentrated. Some typical crystalline complexes are shown in Table 3.

Table 3. Typical crystalline polyether-salt complexes [1, 5] (see Table 1 for formulas).

Polyether	m.p. (°C)	Salt	m.p. (°C)	Polyether: Salt (mol/mol)	Complex, m.p. (°C)
(1)	150–152	LiSCN	—	1:1	300
(2)	79–79.5	$AgNO_3$	210	1:1	134–135
(2)	79–79.5	NaSCN	323	1:1	162–165
(2)	79–79.5	KSCN	175	2:1	176
(2)	79–79.5	NH_4SCN	149	2:1	131–132
(3c)	<25	$Ba(SCN)_2$	—	1:1	282
(3d)	164	$NaNO_2$	271	1:1	154–157
(3d)	164	KI	685	1:1	232–234
(3d)	164	RbSCN	195	1:1	184–185
(3d)	164	RbSCN	195	2:1	175–176
(3d)	164	CsSCN	—	2:1	146–147
(3d)	164	CsSCN	—	3:2	145–146
(4d)	106–107.5	KSCN	175	1:1	176–178

As shown by several of the examples in Table 3, the complexes are not always of 1:1 stoichiometry, some polyether-cation combinations having a tendency to form 2:1, or even 3:2, complexes. As a rule, this occurs when the cation is too large to fit into the hole of the polyether ring (see Table 4), which suggests a "sandwich" structure[5].

Like most of the complexes, that formed by KSCN and dibenzo[18]crown-6 *(3d)* is stable in water containing an excess of the salt but decomposes in pure water. However, some of the complexes are stable in the presence of water, *e.g.* KI_3-perhydrodibenzo[18]crown-6.

Table 4. Polyether ring sizes and ionic diameters.

Polyether ring	Hole diameter (Å) [a]	Ion	Ionic diameter in crystal (Å)
[14]Crown-4	1.2–1.5	Li^+	1.36
[15]Crown-5	1.7–2.2	Na^+	1.94
[18]Crown-6	2.6–3.2	K^+	2.66
[21]Crown-7	3.4–4.3	Rb^+	2.94
		Cs^+	3.34
		NH_4^+	2.86
		Ag^+	2.52
		Ba^{2+}	2.68

[a] From ref. [5]; lower values estimated from Corey-Pauling-Koltun atomic models, higher values from Fisher-Hirschfelder-Taylor models.

3.2.2. Structure

The structures of four crystalline complexes have been determined by X-ray diffraction by *Truter et al.*[21,22]: NaBr-$(H_2O)_2$-dibenzo[18]crown-6; NaI-H_2O-benzo[15]-crown-5; $(RbSCN)_2$-(dibenzo[18]crown-6)$_3$; and KI-dibenzo[30]crown-10. The two sodium complexes contained water of crystallization though no water was deliberately added to the methanol in which they were prepared[22]. This observation confirms the strong propensity of Na^+ to complete its entire solvation shell (cf. Section 3.1.1).

In both of the sodium complexes the cation is located in the center of the very nearly coplanar ether oxygens. Water and bromide coordinate with the sodium in the direction perpendicular to the polyether ring, though the iodide anion does not interact directly with its sodium.

The 3:2 RbSCN complex has a very interesting structure, though not the postulated sandwich[21]. The unit cell contains four molecules of a 1:1 RbSCN-dibenzo[18]-crown-6 complex and two uncomplexed polyether molecules of crystallization. The Rb^+ is centrally located and approximately 1 Å below the plane of the ether oxygens (see Fig. 3), and the SCN group sticks out approximately perpendicular to the ether ring. In the uncomplexed molecules of polyether the O atoms are not quite coplanar.

No X-ray structure of any complex of the 2:1 polyether-cation type has been published so far. However, since these invariably involve a cation too large to fit into the hole of the polyether, they may be expected to have a structure with the cation "sandwiched" between two parallel polyether rings.

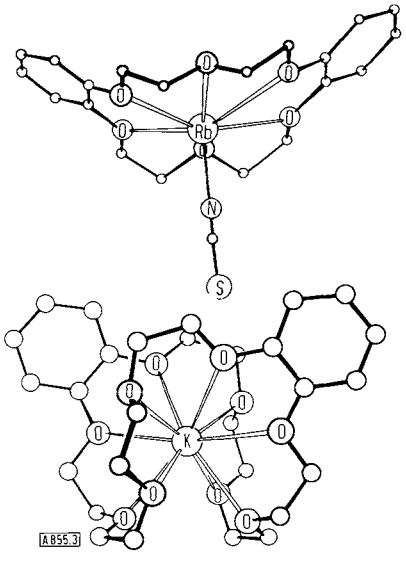

Fig. 3. Structures of typical complexes. Rubidium thiocyanate: dibenzo[18]crown-6 (above, free polyether molecule not shown), potassium iodide: dibenzo[30]crown-10 (below, anion not shown), according to *Truter et. al.* [21, 22].

Special interest resides in the complexes of much larger rings which, since they are more flexible and have enough oxygen atoms, may envelop the cations completely, as do the macrocyclic antibiotics in their complexes[14-16]. X-Ray analysis of one such complex, KI-dibenzo[30]-crown-10, has been accomplished recently[22]. It was found that this complex indeed possesses a wrap-around structure having all ten oxygen atoms coordinated with the central cation (see Fig. 3).

3.3. Complexes of Amino Compounds and Thioureas

Since ammonium ion resembles K^+ with respect to charge and size, it is not surprising that it forms similar complexes with the cyclic polyethers (see Table 3). Ammonia and unionized ammonium hydroxide, on the other hand, are not complexed because they do not carry a charge. In general, NH_3^+-substituted compounds form complexes, while those containing NH_2^+ and NH^+ groups, and quaternary ammonium ions do not[3]. Apparently the NH_3^+ group can intrude sufficiently into the polyether ring, but the others are too large to do so.

Thiourea and related compounds, such as thiosemicarbazide, as well as some of their derivatives have been found to form sharp-melting crystalline complexes with cyclic polyethers[23]. The stoichiometry of these complexes is unpredictable (from 1:1 to 6:1 thio compound: polyether), and their nature has not yet been elucidated. Inclusion complexes seem to be ruled out by the small ratios. One possibility is that at least one molecule of the sulfur compound is complexed in the zwitterion form, $^-S-C(=NH_2^+)-$, while the others merely fill up the crystal lattice.

4. Complexing Equilibria in Solution

4.1. Stability Constants

The stability constants for the polyether-cation complexes are the most straightforward measure of the strength of complexing in solution. They are defined as the equilibrium constants (in l/mol) for reactions (4) and (5) where M^+ and P represent uncomplexed cation and polyether; PM^+ and P_2M^+ 1:1 and 2:1 complex, respectively.

$$M^+ + P \underset{}{\overset{K_1}{\rightleftharpoons}} PM^+ \quad (4)$$

$$PM^+ + P \overset{K_2}{\rightleftharpoons} P_2M^+ \quad (5)$$

Such stability constants have been measured by a calorimetric titration technique[24], by potentiometric measurements with ion-selective electrodes[25], and by spectroscopic methods[26], besides being deduced indirectly from conductance and potential measurements on phospholipid bilayers[27].

4.1.1. Complexing in Aqueous Solutions

Stability constants for several cyclic polyethers with various cations are collected in Table 5. No data on benzo-substituted polyethers are available because of their generally low water solubility.

The stability constants for the [18]crown-6 polyethers with the alkali-metal cations go through a maximum at K^+ as the cationic size increases. This can be explained in terms of competition between hydration and complexing,

since at least some of the water of hydration must be stripped off the cation to accommodate it in the hole of the polyether ring. Though the smaller cations, with their high electric charge density, greatly attract both water and polyether, their tendency to undergo hydration is too strong for the polyether to compete successfully. On the other hand, the larger cations have comparatively low charge densities and, hence, low attraction for either polyether or water. Moreover, Rb^+ and Cs^+ are too large to fit into the hole of the [18]crown-6 ring, hence the complexing tendency is reduced by their inability to attain the position of maximum charge density in the plane of the ether oxygens. The comparatively high stability constants for the divalent cations Sr^{2+} and Ba^{2+} reflect their high charge densities, while those for Ag^+ are a consequence of its slight hydration tendency.

Table 5. Stability constants of polyether-cation complexes in water at 25°, based on K_1 in l/mol [a]; cf. eq. (4).

Polyether	$\log_{10} K_1$								
	Li^+	Na^+	K^+	Rb^+	Cs^+	NH_4^+	Ag^+	Sr^{2+}	Ba^{2+}
Perhydrobenzo[15]crown-5	<1.0	<0.3	0.6	—	—	—	—	—	—
Perhydrobenzo[18]crown-6 *(3c)*	<0.7	0.8	1.9	—	0.8	1.1	1.8	—	—
Perhydrodibenzo[18]crown-6 *(3f)* (isomer A)	0.6	1.7	2.2	1.5 [b]	1.2	1.4	2.3	3.2 [b]	3.6 [b]
Perhydrodibenzo[18]crown-6 *(3f)* (isomer B)	—	1.4	1.8	0.9 [b]	0.9	0.8	1.8	2.6 [b]	3.3 [b]
Perhydrodibenzo[21]crown-7	—	—	—	—	1.9	—	—	—	—

[a] Values from ref. [25], unless marked otherwise.
[b] Values from ref. [24].

Enthalpy changes on complexing in water, as measured calorimetrically by *Izatt et al.*[24], are small. They amount to −2 to −6 kcal/mol for reaction (4). They might be even closer to zero for some ions, *e.g.* Na^+, for which these authors found no measurable heat change[24], though potentiometry indicated measurable complexing[25].

4.1.2. Complexing in Methanol

Methanol is a particularly convenient solvent for complexing measurement and permits comprehensive study of the effect of polyether ring size and substituents on the strength of complexing[25] (see Table 6). Comparison between Tables 5 and 6 reveals that the stability constants are three to four decades higher in methanol than in water, evidently because methanol is a much weaker solvating medium and thus competes less with the polyether for the cations (cf. Section 4.1.1).

Table 6. Stability constants of polyether-cation complexes in methanol at 25°, based on K_1 in l/mol [25]; cf. eq. (4) and (5).

Polyether	$\log_{10} K_1$		
	Na^+	K^+	Cs^+
Tetramethyl[12]crown-4	1.4	—	—
Perhydrodibenzo[14]crown-4	2.2	1.3	—
Perhydrobenzo[15]crown-5	3.7	3.6 [a]	2.8 [a]
[18]Crown-6 *(3a)*	4.3	6.1	4.6
Perhydrobenzo[18]crown-6 *(3c)*	4.1	5.9	4.3
Perhydrodibenzo[18]crown-6 (isomer A) *(3f)*	4.1	6.0	4.6
Perhydrodibenzo[18]crown-6 (isomer B) *(3f)*	3.7	5.4	3.5
Dibenzo[18]crown-6 *(3d)*	4.4	5.0	3.6 [b]
Dibenzo[21]crown-7 *(4b)*	2.4	4.3	4.2
Dibenzo[24]crown-8 *(4c)*	—	3.5	3.8
Dibenzo[30]crown-10 *(4d)*	2.0	4.6	—
$CH_3(OCH_2CH_2)_5OCH_3$	1.5	2.2	—

[a] Polyether : cation = 2:1; $\log K_2 = 1.9$.
[b] Polyether : cation = 2:1; $\log K_2 = 2.9$.

The stability constant for each cation goes through a maximum with increasing polyether ring size: between-[15]crown-5 and [18]crown-6 for Na^+; at [18]crown-6 for K^+; and between[18]crown-6 and [21]crown-7 for Cs^+. These optimum ring sizes are exactly those which provide the closest fit between the cation and the "hole" (see Table 4). Table 6 also indicates the three systems in which clear evidence of 2:1 complexing in solution was found: perhydrobenzo[15]crown-5 with K^+ and Cs^+, as well as dibenzo[18]crown-6 with Cs^+. These are all cases of the cation's being too large to fit into the hole and represent combinations of cation and polyether ring of which crystalline 2:1 complexes have been found.

Comparison of the various [18]crown-6 derivatives in Table 6 shows that the effects of substitution on the polyether ring are relatively small and difficult to systematize. For instance, dibenzo[18]crown-6 complexes Na^+ more strongly than the unsubstituted parent ring or hydrogenated analogs, but the reverse is true for K^+ and Cs^+.

As illustrated by the last entry in Table 6, the stability constants of an open-chain polyether are three to four decades lower than those of its cyclic analog([18]crown-6). Evidently entropic forces work against complete envelopment of the cation by the non-cyclic polyether.

4.1.3. Complexing in Other Solvents

Very few data are available for solvents less polar than methanol. Since competition by solvation would become less significant, one expects stability constants to be higher, especially for the smallest cations. However, the results will be complicated by more or less extensive ion-pair formation, so that anion effects will become appreciable.

Wong, Konizer, and *Smid*[26] have reported some stability constants for alkali metal fluorenyl compounds in tetrahydrofuran as determined by spectroscopic methods. These authors found the stability constants for the fluorenylsodium ion pair to be above 10^6 l/mol with perhydrodibenzo[18]crown-6 *(3f)* and di(methylbenzo)[18]-crown-6 compared to 150 l/mol for dibenzo[14]crown-4 *(1)* and 450 l/mol for $CH_3(OCH_2CH_2)_5OCH_3$. They

found fluorenylsodium to be more strongly complexed in tetrahydrofuran than its potassium analog, while the reverse was true in oxetane.

4.2. Distribution between Phases

Since the polyether complexes display appreciable solubility in certain organic solvents, salts can often be extracted from aqueous solutions into organic solvents containing polyethers. Extraction is efficient only if the anion is large and highly polarizable, as for instance picrate, which has the additional advantage of an absorption near 360 nm for easy analysis. Accordingly, picrate extraction has been used extensively for quantitative determination of relative complexing power[4, 20]. The typical results in Table 7 show how extraction of any given cation is most efficient with polyethers of the ring size for which the stability constant indicates optimum strength of complexing.

Table 7. Extraction of picrates into methylene chloride containing polyether [20]. Initial concentrations: alkali hydroxide 0.1 mol/l; alkali picrate 7×10^{-5} mol/l; polyether 7×10^{-5} mol/l. Equal volumes of water and CH_2Cl_2. No measurable extraction of cation takes place in the absence of either picrate or polyether.

Polyether	Picrate extracted (%)			
	Li^+	Na^+	K^+	Cs^+
Di(*tert*-butylperhydrobenzo)[14]crown-4	1.1	0	0	0
tert-Butylperhydrobenzo[15]crown-5	1.6	19.7	8.7	4.0
Dibenzo[18]crown-6	0	1.6	25.2	5.8
Perhydrodibenzo[18]crown-6	3.3	25.6	77.8	44.2
Perhydrodibenzo[21]crown-7	3.1	22.6	51.3	49.7
Perhydrodibenzo[24]crown-8	2.9	8.9	20.1	18.1

When extraction results are available over wide concentration ranges, they can be analyzed in terms of the following equilibria[17]:

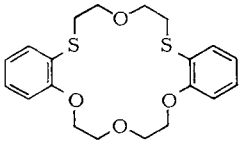
$$M^+_{aq} + A^-_{aq} + P_{org} \overset{K_E}{\rightleftharpoons} PMA_{org} \quad (6)$$

$$PMA_{org} \overset{K_D}{\rightleftharpoons} PM^+_{org} + A^-_{org} \quad (7)$$

where M^+ is the cation, A^- the extractable anion, P the polyether, PM^+ the complex cation, and PMA the complex ion pair, while the subscripts refer to the phases. Equilibrium constants for several systems are shown in Table 8. Under the conditions of Table 7 extraction of the cation is not very efficient, since the low concentrations of picrate and polyether are limiting. The equilibrium constants can be used to predict how much greater the extraction efficiency will be at higher concentrations. It is interesting to note that these extraction measurements permit evaluation of dissociation constants, K_D, and that the results indicate appreciable dissociation of the complex ion pairs in methylene chloride at submillimolar concentrations, in agreement with the conductance results (see Section 3.1.3) in similar solvents.

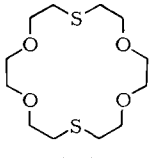
That extraction efficiency depends not only on strength of complexing but also on the solubilities of all the species in both phases is indicated by the lower extraction of sodium picrate by dibenzo[18]crown-6 *(3d)* compared to perhydrodibenzo[18]crown-6 *(3f)* (Table 7), even though the stability constant of the aromatic polyether is higher, at least in methanol (Table 6). In order to make these solubility effects more explicit, the extraction equilibrium constant K_E was analyzed in terms of the aqueous stability constant and the partition coefficients for polyether and for complex[17]. This analysis showed that the latter partition coefficient is a most important factor and varies through many orders of magnitude.

Table 8. Equilibrium constants for picrate extraction with polyether-containing organic solvents [17]; see eq. (6) and (7).



Polyether	Cation	Solvent	K_E (l/mol)^2	K_D (mol/l)
Perhydrodibenzo[18]crown-6 *(3f)*	K^+	CH_2Cl_2	2×10^6	4×10^{-5}
Perhydrodibenzo[18]crown-6 *(3f)*	K^+	n-C_6H_{14}	4×10^3	$< 1 \times 10^{-6}$
Dibenzo[18]crown-6 *(3d)*	K^+	CH_2Cl_2	7×10^5	4×10^{-6}
Perhydrodibenzo[18]crown-6 *(3f)*	Na^+	CH_2Cl_2	1.5×10^4	1×10^{-4}

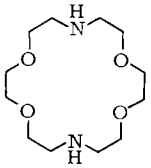
5. Polyethers Containing Other Heteroatoms



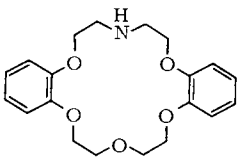
5.1. Monocyclic Polyethers Containing Nitrogen and Sulfur

5.1.1. Preparation

More than a dozen cyclic polyethers have been reported in which one or more sulfur atoms have been substituted for oxygen[28–30]. They are prepared by condensation methods similar to those used for the ordinary polyethers. The synthesis is, in many cases, facilitated by the greater reactivity of thiol groups compared to phenol.



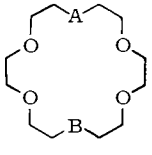
(10)



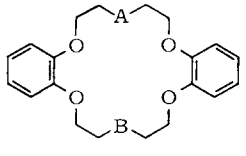
(11)

Mention has also been made of several cyclic polyethers in which one or two NH or NR groups replace oxygen[25, 31]. Synthesis of these compounds is accomplished typically by reaction of a diamine (*e.g.* $(CH_2OCH_2CH_2NH_2)_2$) with a diacid chloride (*e.g.* $(CH_2OCH_2COCl)_2$) and subsequent reduction of the resulting cyclic diamide[32].

(12)



(13)



5.1.2. Complexing Properties

As judged by the effect of salts on the UV spectra and by the picrate extraction method, complexing of alkali and alkaline earth cations is greatly decreased by substitution of S for O in the polyether ring, while complexing of Ag^+ is either increased or unaffected[30]. These conclusions were confirmed by the formation of crystalline silver nitrate complexes and the failure of attempts to prepare such complexes of KSCN with sulfur-containing polyethers.

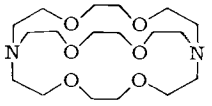
Similar effects are observed when one or two nitrogens are substituted for oxygen, as shown quantitatively by the K^+ stability constants (see Table 9), which decrease in the

I

II

Table 9. Effect of nitrogen and sulfur substitution in the polyether ring on the complexing properties, based on K_1 in l/mol [25].

Polyether				log K_1	
Type	A	B	Formula	K^+ in methanol	Ag^+ in water
I	0	0	*(3a)*	6.1	1.6
II	0	0	*(3d)*	5.0	—
II	NR [a]	0		4.1	—
I	NH	0		3.9	3.3
II	NH	0	*(13)*	3.2	—
I	NH	NH	*(12)*	2.0	7.8
II	NH	NH		1.6	—
I	S	S	*(11)*	1.2	4.3



[a] R = n-C_8H_{17}.

same order as the electronegativities, O > NR > NH > S[25]. In other words, the electrostatic attraction between the cation and the heteroatoms diminishes with the negative charge on the latter.

Nitrogen substitution greatly enhances Ag^+ complexing (see Table 9), just as sulfur was noted to do. Evidently the principal forces involved here are not simple electrostatic ones, but rather covalent bonding analogous to that present in the numerous well-known complexes of Ag^+ with amines and other nitrogen-containing compounds. Indeed some open-chain amine compounds have Ag^+ stability constants of the same order of magnitude as the corresponding cyclic amino polyethers[33].

5.2. Bicyclic Amine Polyethers

Preliminary reports have started to appear of bicyclic polyethers *(14)* containing amine bridge atoms[31]. They are made by an extension of the method used for the preparation of monocyclic amine polyethers[31] (see Section 5.1.1) in analogy to the preparation of bicyclic amines by *Simmons* and *Park*[34].

(14)

These bicyclic compounds have remarkable complexing properties, as demonstrated by their aqueous stability constants. Preliminary results[31, 35] obtained by a "pH-metric" method for compound *(14)* are Ba^{2+} (log K_1 9.5), Sr^{2+} (8.0), K^+ (5.4), Ca^{2+} (4.4), Rb^+ (4.4), Na^+ (3.9), *i.e.* two or more decades above the [18]crown-6 derivatives, in spite of the nitrogen atoms in the rings. Evidence of complexing was also obtained by NMR, solubilization in chloroform, and formation of crystalline complexes[31, 35, 36].

Bicyclic amine polyethers form complexes with the same cations as the cyclic polyethers. The complexes, which are termed "cryptates"[31], are formed by "encapsulation" of the cation within the cavity of the compound, as demonstrated by X-ray analysis of the crystalline KSCN complex[36]. Evidently the cation is held in the cavity under the influence of the negative charges of the six oxygen and two nitrogen atoms. Complexation in solution is pH sensitive, since protonation of the amino nitrogens prevents complex formation, apparently because of repulsion between the two positively charged nitrogen atoms and the cation. It is interesting to note that encapsulation of cations by the bicyclic polyether amines has a parallel in the encapsulation of anions by bicyclic amines which contain no oxygen atoms[37].

6. Applications

6.1. Organic Chemistry

Many salts or salt-like compounds of alkali and alkaline earth metals are used in organic synthesis, frequently under inefficient conditions, *i.e.* low concentrations or two-phase operation, because of their limited solubility in organic solvents. It is evident that the crown polyethers can help to overcome such difficulties in many cases, not only by solubilizing the salts but also by increasing the dissociation of ion pairs (cf. Section 3.1.3) to provide highly reactive, unsolvated anions. A related effect, more subtle than complete dissociation of ion pairs, is the conversion of contact ion pairs into solvent-separated ones. It has been demonstrated convincingly that this can be brought about by crown polyethers[26, 38].

Examples of such organic applications of crown polyethers based on solubilization and enhanced reactivity are sa-

ponifications by KOH in benzene (cf. Section 3.1.1) and oxidations by $KMnO_4$ in benzene[3, 39]. The cyclic polyethers have also been found to exert profound effects on the course of a number of different reactions involving alkali-metal cation-carbanion ion pairs[40–43].

A related development of great significance is the dissolution of potassium and cesium metal in tetrahydrofuran and diethyl ether by perhydrodibenzo[18]crown-6[44], which promises to extend greatly the range of solvents in which solvated electrons and related species can be obtained.

These examples, all published very recently, are just a hint of the impact which the crown polyethers will assuredly have on organic chemistry in studies of reaction mechanism and in syntheses involving such reagents as alkyllithium compounds, Grignard reagents, alkali salts of carbanions, and alkali metals.

6.2. Biophysics

The discovery of the complexing properties of the crown polyethers aroused much interest among the investigators of ionic transport phenomena because of the similar properties of the macrocyclic antibiotics (see Section 1.3). For the first time synthetic materials were available for systematic study of structural effects. Crown polyethers have indeed been found to affect cationic transport across bilayer membranes[13], though these effects are somewhat different from those of the antibiotics. Moreover, methods developed for studying the cyclic polyethers in solution, *i.e.* picrate extraction (see Section 4.2), have been profitably applied to the antibiotics[45].

The authors are indebted to Dr. R. N. Greene of this laboratory for many helpful suggestions and to several of the authors quoted for supplying pre-publication manuscripts.

Vibration-Spectroscopic Studies on Solid Compounds[**]

By Hermann J. Becher[*]

Considerably improved possibilities are now available for the investigation of the optical vibrations in lattice compounds by Raman and IR spectroscopy. These spectra can be interpreted on the basis of the models and findings of molecular vibration spectroscopy. For simple lattice types simple frequency equations are found for the optical lattice vibrations with in-phase vibration motions in all unit cells (wave vector $k=0$). As an approximation, the force constants that occur in these equations may be interpreted as stretching force constants. For typical ionic lattices, the influence of Coulomb forces due to the lattice polarization that occurs during the vibrational motion must be taken into account. As is shown by the example of some spinels, the assignment of lattice vibrations can be facilitated by model calculations.

1. Introduction

Corresponding to the line being followed by the author in his work, this article on vibrations in lattice compounds is based on the methods of molecular vibration spectroscopy. Raman and IR spectroscopic studies provide the experimental foundations. As far as possible, the bands observed should be assigned to vibrational motions of particular atoms in the structure as a whole, consideration being given to symmetry conditions and coupling of internal coordinates to normal coordinates. Such assignments may be based on model calculations with suitably estimated force constants, without which the coupling relationships in the normal coordinates usually cannot be clearly seen. In more complete calculations, efforts are made to obtain force constants for simple basic types of lattice compounds from the assigned vibrations with the aid of suitable potential functions, with the object of using these force constants for further model calculations and discussing them in connection with bonding questions.

Theoretical physics, on the other hand, has developed models that enable the lattice dynamics of solids and hence their complete optical, dielectric, and thermal behavior to be represented in a closed theory[1]. Only a few references can be made to these developments in the following discussions.

Whereas only $3n-6$ fundamental vibrations are possible in a molecule containing n atoms, a lattice has a practically infinite number of vibrational degrees of freedom. In order to be able to apply the approaches of molecular vibration spectroscopy to lattice vibrations, a limited number of degrees of freedom must be chosen from this infinite array for representation purposes. The theory of lattice vibrations shows that a single unit cell may be chosen as the basis of such a representation of the vibrational behavior[1-3]. For a unit cell containing n atoms, the possibilities of motion can be described by $3n$ coordinates. Three degrees of freedom of this motion lead to translations of the entire unit cell, while $3n-3$ belong to the optical vibrations of the lattice. The infinite multiplicity of the lattice vibrations arises from the fact that the vibrational motion of one unit cell may be out of phase with that of adjacent unit cells in the lattice. In the description of the optical vibrations that appear in the Raman and IR spectra, we can largely confine ourselves to the limiting case in which the vibrational motions of all the unit cells in the lattice are in phase. The number, symmetry behavior, and optical visibility of the vibrations in the Raman and IR spectra can be determined, according to group theory, from factor-group analysis, which replaces the point-group analysis of an isolated assembly of atoms[2-4].

2. Improvement of the Experimental Principles for the Investigation of Optical Lattice Vibrations

In earlier vibration-spectroscopic studies on solid compounds, the experimental principles were often insufficient to allow the correlation of the results with the predictions of a factor-group analysis. Fresh possibilities have been offered by recent improvements in the technique of Raman and IR spectroscopic studies. Raman spectroscopy has profited greatly from excitation with laser beams, since this allowed a huge increase in the excitation intensity in a very small volume, as well as a substantial decrease in the problems presented by stray light and the color of many compounds. In IR spectroscopy, the extension of the investigation range to ever lower wave numbers is of great importance, since the vibrations in many lattice compounds occur at very low wave numbers because of the small force constants.

Figures 1—3 should give some idea of these widened possibilities. Figure 1 shows the IR spectrum of solid barium trithiocarbonate embedded in Nujol between polyethylene windows in the frequency range 350—30 cm^{-1}. The vibrations that are essentially due to movements in the CS_3^{2-} ions in this compound have already been described in the literature[5]. The double band at 325 cm^{-1} also belongs to this group. In addition, there is a group of bands at 130 cm^{-1}, which must be assigned to translational and rotational movements of the ions in the lattice. An uncompensated band due to the window material is observed at 73 cm^{-1}.

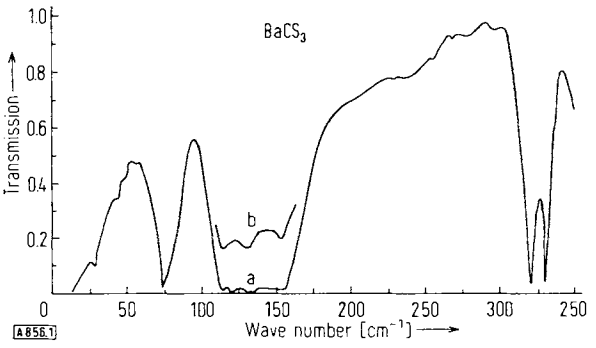

Fig. 1. IR spectrum of $BaCS_3$; ground in Nujol; measurement range 25—350 cm^{-1}. Layer thickness at b less than at a.

Figure 2 shows the Raman spectrum of polycrystalline, deep red chromium trioxide[6]. Together with the IR spectrum of this compound, the bands observed can be assigned to chain vibrations and CrO_2 group vibrations of the CrO_3 chains forming the lattice. This assignment is facilitated by consideration of the spectral changes observed on the transition from the dichromate ion *via* trichromate and tetrachromate to chromium trioxide[6].

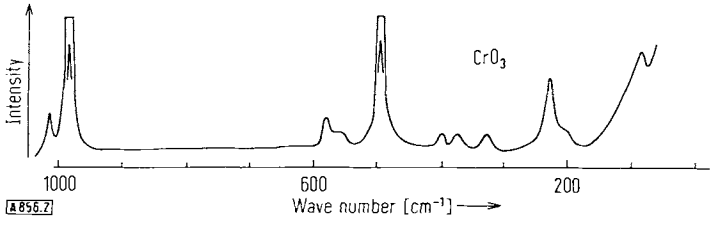

Fig. 2. Raman spectrum of CrO_3; 50—1000 cm^{-1}. Excitation with He—Ne gas laser [6].

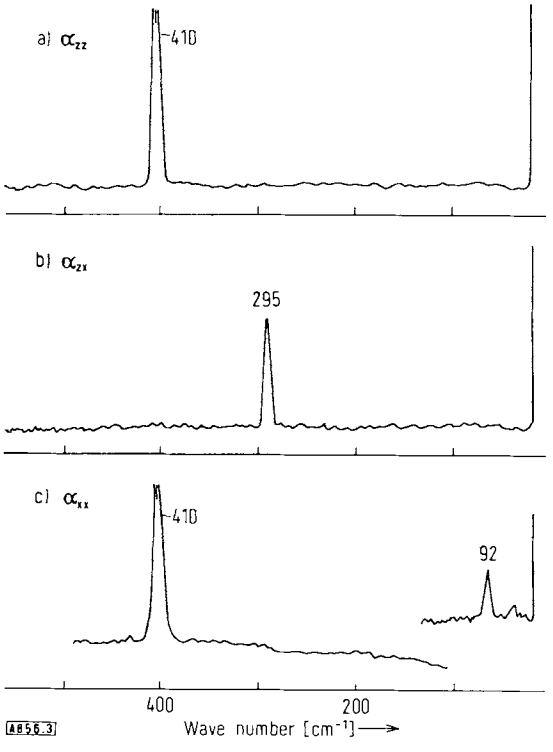

Fig. 3. Raman spectrum of an MgF_2 single crystal with various orientations of the crystal with respect to the laser beam [7]. Excitation with Ar ion laser. α_{zz}, α_{zx}, α_{xx} = components of the polarizability tensor. Assignment of the lattice vibrations: 410 = A_{1g}, 295 = E_g, 92 = B_{1g}.

Figure 3 shows the Raman spectrum of a single crystal of magnesium fluoride[7]. MgF_2 crystallizes in the rutile lattice. The three-dimensional lattice in this case is built up from bonds of a single type; there are no longer any isolated groups present. The assignment of the bands observed to the optical vibrations deduced from the factor-group analysis is conclusively established by their behavior with respect to the axes of symmetry of the crystal, which can be characterized by the investigation of the single crystal with polarized laser radiation.

3. Number and Symmetry Properties of the Vibrations of Lattice Compounds

3.1. Lattice Compounds with Characteristic Lattice Complexes

If the lattice compounds contain complex cations or anions, the observed vibration spectra can be approximately deduced from the expectations for the individual structural units. The expected normal vibrations for an isolated structural group are first enumerated from the point-group analysis. The second step is to determine the positional symmetry of the structural group in the lattice as a whole, which will generally be different from that of the isolated group[8]. The enumeration of the expected spectrum of the single structural unit according to its positional symmetry is known as site-group analysis. For structural groups of higher symmetry, site-group analysis generally leads to splitting of degenerate vibrations and to violation of the selection rules that apply to the group in isolation. In a third approximation step, the correlation between the various complex groups in the unit cell is considered. Factor-group analysis is used here, the possibilities of motion in a unit cell being classified according to its transformation by the operations of the factor group[2-4]. The factor group is given by the space group of the lattice when all operations that contain the translation group of the space group are regarded as unit operations. (The factor group is isomorphous with the point group that can be assigned to the space group.) Whereas the point-group analysis and the site-group analysis give only the internal vibrations of the complex structural unit in question, the factor-group analysis gives all the vibrational degrees of freedom of the unit cell. Those that are mainly due to movements of atoms within the individual complex structural units can be enumerated separately.

As an example, Table 1 shows the enumeration of the internal vibrations of the WO_4^{2-} ions in a scheelite lattice[9, 10]. Since the "spectroscopic" unit cell of scheelite contains two WO_4^{2-} units, the factor-group analysis leads to twice as many WO_4^{2-} vibrations as the site-group analysis.

The concept of "internal vibrations" has been found useful for numerous ionic compounds with oxo anions[10-12]. One frequently (but not always, owing to the band widths) observes the splitting predicted by the site-group analysis

Table 1. Internal vibrations of the WO_4^{2-} ions in scheelites: a) isolated anion, point group T_d; b) anion in the static lattice potential, site group S_4; c) two anions in the unit cell, factor group C_{4h}.

T_d	S_4	C_{4h}	Assignment
A_1(ia,p)	A(ia,p)	A_g(ia,p), B_u(ia,v)	$\nu_s WO_4$
E(ia,dp)	A(ia,p)	A_g(ia,p), B_u(ia,v)	$\delta_s WO_4$
	B(a,p)	B_g(ia,p), A_u(a,v)	
F_2(a,dp)	B(a,p)	B_g(ia,p), A_u(a,v)	$\nu_{as} WO_4$
	E(a,dp)	E_g(ia,dp), E_u(a,v)	
F_2(a,dp)	B(a,p)	B_g(ia,p), A_u(a,v)	$\delta_{as} WO_4$
	E(a,dp)	E_g(ia,dp), E_u(a,v)	

(i)a = (in)active; (d)p = (de)polarized; v = forbidden.

and the expected violations of selection rules for isolated anions. The translational and rotational vibrations of the complex anions within the lattice are generally situated far below the stretching vibrations, and usually even below the deformation vibrations of the anion itself. It follows that the force constants for the equilibrium changes in the anion are much greater than the force constants that describe the movements of the cations and anions in relation to one another.

3.2. Simple Lattices Having One Type of Bonding[13]

The total number of vibrational degrees of freedom can be characterized by the mode of motion of the atoms within a unit cell and by the phase difference between motions in this mode in successive cells. The phase difference is assumed to be propagated periodically through the lattice. Optical vibrations are possible only if at least two atoms are present in a unit cell. The spectroscopic unit cell is the smallest lattice unit that cannot be produced by a simple translation. A face-centered unit cell thus has no optical vibration. If a unit cell contains two atoms belonging to two different primitive sublattices, these must oscillate with respect to each other in an optical vibration.

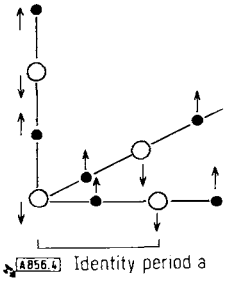

Fig. 4. Schematic representation of the optical lattice vibration of NaCl for $k=0$.

This mode of action is triply degenerate for all cubic lattices, corresponding to displacements parallel to the three equal axes. Figure 4 illustrates this for the case of the NaCl lattice.

The periodic phase difference of the vibrational motion of adjacent unit cells leads to a wave, which runs through the lattice and is characterized by a wave vector k. The value of the wave vector is zero when all the unit cells vibrate in phase, *i.e.* the corresponding wavelength is infinite. It has the value π/a when the phases of the vibrational motion in adjacent unit cells are opposed; a is the unit translation period. The wave vector is generally expressed in units of π/a for the characteristic lattice directions such as [001], [011], and [111]. The frequency of a lattice vibration depends on the mode of motion in a unit cell and on the wave vector k. From $k=0$ to $k=1$, a continuum is to be expected; this continuum is known as a branch. Each branch may be assigned to a particular vibrational motion of the atoms in a unit cell.

The factor-group analysis gives the number and the symmetry behavior of the vibrations for which $k=0$. A complication results from the fact that the vibrational motion in a cell and its propagation in the lattice as a wave may be parallel or perpendicular to each other. In the former case we speak of longitudinal branches, and in the latter case of transverse branches, of the lattice vibrations. Longitudinal and transverse branches differ in their frequency ranges when the vibrational motion leads to lattice polarization. They are also different when $k=0$. The longitudinal vibration can be observed in the IR spectrum of thin crystal films if the incident radiation has a field component normal to the surface of the crystal film[14]. The splitting into longitudinal and transverse branches can be represented in a continuum theory taking the refractive index and the dielectric constant of the lattice compound into account[13].

Figure 5 shows the dependence of the lattice vibrations of sodium iodide on the wave vector for three characteristic lattice directions. Two optical and two acoustic branches are recognized in each case; on the one hand the Na and I atoms in each unit cell oscillate in opposite directions, while on the other they oscillate in the same direction. The factor-group analysis for the NaCl lattice gives a triply degenerate vibration of the class F_{1u}. The frequency of the transverse optical branch in Figure 5 for $k=0$ corresponds to this expectation.

The assignment of the observed IR and Raman spectra of lattice compounds on the basis of the factor-group analysis is thus complicated on the one hand by the possible splitting into transverse and longitudinal optical branches. Further complications may arise through the occurrence of multiphonon transitions[13]. Combined transitions of this type are possible not only between different optical branches but also between optical and acoustic branches when $k \neq 0$, provided that the wave vector of the combined phonon is close to zero. Thus at low layer thicknesses, the IR spectrum of NaCl contains only a single band, corresponding to the expected transverse optical fundamental vibration; at greater layer thicknesses, this is joined by other bands in the form of shoulders at higher wave numbers[15]. This shows that for a reasonable assignment,

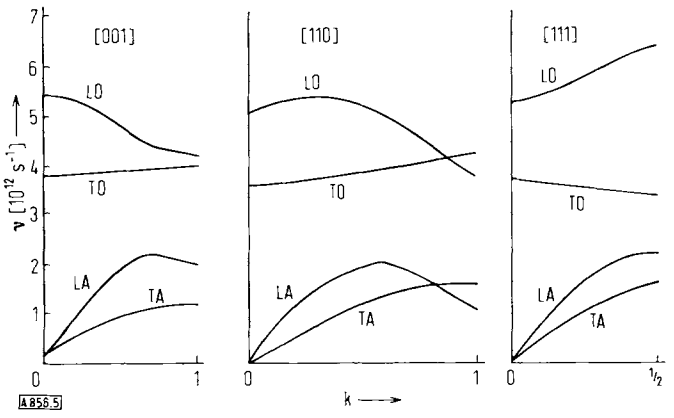

Fig. 5. Lattice dispersion curves for NaI after *Martin* [13]. Representation of the dependence of the frequency on the wave vector along three lattice lines. k in units of π/a. LO and TO = longitudinal and transverse optical; LA and TA = longitudinal and transverse acoustic.

it is necessary not only to establish the number of transverse optical vibrations expected and their symmetry properties but also to estimate their approximate frequencies.

4. Calculation of Force Constants from the Vibrations of Simple Lattices ($k \approx 0$)

4.1. Diamond and Sphalerite Lattices

The transverse optical vibration of a simple AB lattice leads to periodic motion of the two sublattices in relation to each other. The frequency of this lattice vibration, as in the case of a diatomic molecule, can be correlated with the reciprocal mass of the vibrating atoms and the force constant describing the displacement of the atoms from their equilibrium position[16]. This force constant is generally a combination of the force constants belonging to internal coordinates (distances and angles defining the relative positions of neighboring atoms), since the coordinate of the lattice vibration can be represented by a linear combination of the internal coordinates describing the equilibrium distances and equilibrium angles in the lattice. For atomic lattices such as diamond, silicon, or silicon carbide, it seems reasonable to make use of what has been found with the valence force fields of molecular compounds. The potential functions of many molecules can be satisfactorily described by stretching and deformation force constants of the bond lengths and angles if additional interaction constants belonging to neighboring bond lengths and angles are taken into account[17]. The application of the FG[*] method to the transverse optical lattice vibration with $k=0$ for the diamond lattice gives eq. (1) for the corresponding eigenvalue of the secular equation $F.G-\lambda=0$[16].

$$\lambda = \tfrac{4}{3} \cdot 2\mu_c \cdot F_v \qquad (1)$$

λ is found from the observed frequency by the formula $\lambda = \nu^2 \times 10^{-6} \times 0.5891$. The conversion factor is such that ν is to be given in cm^{-1}, F_v in mdyn/Å, and the masses of the vibrating atoms in atomic weight units. The following force constant should be taken into account in the potential function as force constants of internal coordinates and corresponding interaction constants:

f_r = stretching force constant of a bond;
f_{rr} = interaction constants of the neighboring bonds;
f_α = deformation force constant of a bond angle;
$f_{\alpha\alpha'}$ = interaction constant of two opposite bond angles on the same atom;
$f_{\alpha\alpha^*}$ = interaction constant of two bond angles adjacent to a bond;
$f_{r\alpha}$ = interaction constant of a bond with its adjacent bond angle;
$f_{r\alpha'}$ = interaction constant of a bond with a bond angle lying opposite.

The resultant force constant of the lattice vibration is thus found to be[18]:

$$F_v = f_r - f_{rr} + 4(f_\alpha - f_{\alpha\alpha'} + f_{\alpha\alpha^*}) - 4\sqrt{2}(f_{r\alpha} - f_{r\alpha'})$$

The value found for F_v from the lattice vibration of the diamond lattice is 4.7 mdyn/Å[18]. Roughly the same value is obtained when the above combination is formed from the results of valence force calculations for the CC bonds in saturated hydrocarbons[19]. It is remarkable that the F_v value almost coincides with that calculated for the stretching force constant of a CC single bond. In combinations between bond coordinates and the angle coordinates enclosed by these bonds, the contribution of the deformation force constants is evidently largely compensated by the contribution of the interaction constants between valence coordinates and angle coordinates. This relationship, which has been formulated elsewhere[20], makes it possible to obtain an approximate value for the stretching force constant in such combinations of stretching and deformation force constants even when the partial quantities are unknown. The force constants F_v were therefore calculated from the lattice vibrations of a series of tetrahedrally coordinated AB lattices. The results are summarized in Table 2. This table also contains some stretching force constants of molecular compounds that contain the same type of bond as one of the lattice compounds mentioned.

It can be seen that the force constant of the lattice vibration has approximately the value that may be expected for the stretching force constant of the bond between two neighboring atoms in the lattice. Comparison is made difficult by some uncertainty regarding the exact position of the lattice vibration. This is particularly true in the case of BeO, whose spectrum contains a broad band with three maxima. It is possible that the band at 950 cm^{-1} is due to a longitudinal vibration and the doublet at 720/850 cm^{-1} to the hexagonal symmetry of the wurtzite lattice. In this case it is convenient to take an average of the values 1.3 and 1.8 mdyn/Å calculated from the bands at 720 and 850 cm^{-1} as the force constant of the BeO lattice.

It is interesting to compare the force constants and the bond lengths in the isoelectronic lattices diamond, cubic

[*] FG method: Calculation of normal vibrations with the aid of F- and G-matrices for potential and kinetic energy; cf. [17].

Table 2. Transverse optical lattice vibration ($k=0$) and force constant of tetrahedrally coordinated AB lattices.

Lattice	ν (cm^{-1})	F_v [a] (mdyn/Å)	d_{AB} [b] (Å)	f_{AB} [c] (mdyn/Å)

[a] According to eq. (1) with $\mu_A+\mu_B$ for $2\mu_c$; [b] shortest distance in lattice; [c] stretching force constant of the AB bond in comparable molecular compound (C_2H_6 and homologs, $BH_3 \cdot NH_3$, $BH_3 \cdot PH_3$, Si_2H_6 and CH_3SiH_3).

boron nitride, and beryllium oxide. The force constant decreases very markedly in this order, while the bond length increases, though to a much smaller extent. A similar variation is found for the isoelectronic lattices GaP and ZnS and for InP and CdS. The marked decrease in the force constant in these isoelectronic series is evidently connected with the increasing polarity of the lattice bond. This situation is very evident in the typical ionic lattices described in the next section.

4.2. Ionic Lattices of the NaCl Type

For a lattice of the NaCl type, we find that the transverse optical lattice vibration ($k=0$), after conversion into λ, is given by the equation[16]:

$$\lambda = 2(\mu_A+\mu_B)F_v \qquad (2)$$

F_v is again a linear combination of force constants of internal coordinates. In the case of typical ionic lattices, it is reasonable to consider only the change in the force of repulsion between neighboring particles and the change in the Coulomb forces in the lattice instead of stretching and deformation force constants and the corresponding interaction constants. This model for the description of the lattice dynamics is known as the rigid ion sphere model[13]. Since the sublattices of the cations and of the anions vibrate as rigid units in relation to each other in the transverse optical lattice vibration ($k=0$), only the changes in the Coulomb forces between oppositely charged particles need be considered. F_v then contains, in addition to the force constant for a pair of immediately neighboring ions, the derivatives of the Coulomb forces between a particle and the more distant ions having the opposite charge. Instead of by stepwise summation of the derivatives of these Coulomb forces, their sum can be obtained by application of the continuum theory to the lattice vibration by introduction of the polarization of the lattice into the equations of motion[13]. In the case under discussion this leads to the equation

$$F_v \doteq f - \frac{4\pi}{3} \cdot \frac{q^2}{2d_0^3} \qquad (3)$$

f is the force constant for a pair of ions, q is the ionic charge, and d_0 is the distance between a pair of ions.

However, it is easy to show that this expression is not enough for a satisfactory reproduction of the complete lattice dynamics. In a first improvement, polarizable ions are introduced, and these are characterized by effective charges as well as by their polarizability. From the lattice frequency at $k=0$ and from the dielectric constants of the crystal at high and at low frequencies, one can determine the force constant f for two neighboring ions, the polarizability, and the effective charge of the ions. The measurements and their evaluation show that for alkali metal halides, the effective charge of the ions is approximately 80% of an elementary charge. However, the effect of this smaller effective charge on the lattice vibration is partly offset by the polarizability[13].

A shell model is used in more recent attempts to represent the lattice dynamics[30, 31]. In this model one considers forces between ion cores and rigid, spherically symmetrical shells of negative charge. The course of the individual branches in the lattice dynamics of alkali metal halides can be satisfactorily represented with the aid of such a model, as is shown in Figure 5. If one confines oneself to the transverse optical vibration with $k=0$, the resultant force constant F_v can be calculated first from the observed values with the aid of eq. (2), and can then be used to determine the force constant of a pair of ions from eq. (3). The results are shown in Table 3. When the Coulomb forces are taken into account, on application of eq. 3, a full unit charge is taken as the charge on the ion.

In the case of the alkali metal halide lattices, the influence of lattice polarization on the resultant force constant of the lattice vibration can also be taken into account by calculating the force constant from the frequency of the longitudinal lattice vibration at $k=0$[32]. This leads directly to a force constant in which the influence of the long-range forces is already eliminated by the lattice polarization. The values for the alkali metal halides are about 5—10% lower than the values calculated from eq. (3) for the force constant f (Table 3). The difference is due to the fact that the full ionic charge was used in the evaluation of eq. (3), whereas the effective charge is somewhat smaller.

As well as the force constants, Table 3 also contains the equilibrium distances and (for further comparison) the force constants and equilibrium distances in the gaseous molecules NaCl, NaBr, KCl, and KBr[33]. It can be seen that the force constants F_v obtained directly from the lattice vibrations are very small. They also show no variation for the various alkali metal halides, such as one might expect from the equilibrium distances and from the force constants in the molecular compounds NaCl and KCl. This variation is evidently masked by the influence of the Coulomb forces to the more distant oppositely charged ions, whose derivatives according to eq. (3) are opposite

in sign to the force constant of a pair of neighboring ions. The force constant f of a pair of neighboring ions in the lattice is also small when *e.g.* the result for NaCl in the lattice is compared with that for NaCl molecules. This is not unexpected, since the polarization of the sodium and

chloride ions will influence the electron density distribution differently in the lattice, where they are octahedrally surrounded by oppositely charged particles, and in an NaCl molecule.

The determination of the force constant of an ion pair in the lattice from the force constant of the lattice vibration according to eq. (3) depends on the assumption that the effective charge on the ion in the lattice can be estimated. As was mentioned earlier, the more complete lattice dynamics show that the effective charge must be taken as only about 80% of the full ionic charge even for alkali metal halides. With more highly charged ions in the lattice, even smaller fractions of the full ionic charge must be expected. Corresponding data can be evaluated for MgO and CaO, both of which have lattices of the NaCl type. Table 4 shows the observed transverse and longitudinal lattice vibrations at $k=0$[32] and the force constants calculated from them with the aid of eq. (2). For the ion sphere model with polarizable ions having an effective charge q, the value of q can be determined from eq. (3) if the force constant from the transverse lattice vibration is used for F_ν and the force constant from the longitudinal lattice vibration for f. The latter is justified, since the Coulomb forces of the lattice polarization do not affect the force constant for the longitudinal lattice vibration.

Table 4. Lattice vibrations ($k=0$) and force constants of MgO and CaO.

		ν (cm^{-1})	F_ν [a] (mdyn/Å)	q [b] (charge units)

	LO	717	1.46	
CaO	TO	286	0.28	1.56
	LO	577	1.12	

TO = transverse optical; LO = longitudinal optical.
[a] According to eq. (2); [b] according to eq. (3) for the condition $f=F_\nu$ (LO).

4.3. Calcium Fluoride

The force constants F_ν for CaF_2 can be calculated from the transverse and longitudinal components of the lattice vibration F_{1u}, and the effective charge can be determined in the same way as for CaO (Table 5). q in this case is the effective charge of the calcium ion and the sum of the charges of two fluoride ions, since the two fluoride sublattices vibrate in phase in the class F_{1u}. The effective charges found for the calcium ions are approximately equal to those in CaO. From the Raman-active lattice vibration of CaF_2 in F_{2g}, a force constant can also be calculated that is independent of the long-range forces of the lattice polarization, since no polarization of the lattice occurs in the corresponding vibration model. The transverse and longitudinal components of the lattice vibration therefore have the same frequency in F_{2g}. The calculated force constant is somewhat smaller than that from the longitudinal lattice vibration in F_{1u}. This shows that interaction forces of neighboring valence coordinates must also be taken into account in the assessment of the calculated force constants. Without these interaction forces, only approximate values can be found for the stretching force constants in the lattice, as is to be expected from findings with the simple valence force model in molecular compounds.

Table 5. Lattice vibrations ($k=0$) and force constants of CaF_2.

q according to eq. (3) for the condition $f=F$ (LO) in $F_{1u}=1.46$ charge units.

5. Spinel Lattice. Assignment of the IR-Active Vibration and Calculation of Force Constants

For the spinel lattice, the factor-group analysis gives four IR-active lattice vibrations in the class F_{1u}[34]. IR-spectroscopic studies have been carried out on a large number of spinels. We shall be concerned for the present only with Na_2MoO_4 and Na_2WO_4, which may be regarded as lattices with complex structural groups. The spectroscopic findings are summarized in Table 6. Of the four

expected IR-active vibrations, only two are observed. These can be approximately described as the stretching and deformation vibrations of the tetrahedral oxo anions. The "external vibrations", *i.e.* movements of the anions with respect to the cations, should occur at much lower wave numbers, since the stretching force constants to be expected for sodium-oxygen pairs are very small in comparison with those of the MoO and WO bonds.

Table 6. Observed IR bands (cm^{-1}) of the spinels Na_2MoO_4 and Na_2WO_4. Comparison with the solution spectra.

Na_2MoO_4	MoO_4^{2-} solution	Na_2WO_4	WO_4^{2-} solution
838	840 (νMoO_4)	835	833 (νWO_4)
≈325	318 (δMoO_4)	320	322 (δWO_4)

Force constants (mdyn/Å) from the vibrations of the "isolated" anions of class F_2:

	MoO_4^{2-}	WO_4^{2-}
$F(\nu)$	5.5	5.9
$F(\delta)$	0.35	0.4

A different situation is found for $MgAl_2O_4$. Figure 6 shows the vibration modes for the tetrahedral and the crosslinked octahedral structural units of the lattice that are possible in the class F_{1u} by symmetry combination of Cartesian coordinates[35]. The coordinates chosen for the tetrahedral structural units can be transformed in such a way that one of them becomes a valence coordinate and the other an angle coordinate. Such a transformation into pure stretching and deformation coordinates is not possible in the case of the octahedral units. The vibration modes represented in Figure 6 are coupled in the normal coordinates, since the oxygen ions belong to both coordination polyhedra. A simplification results if the angle-retaining forces are disregarded in the vibration modes of the octahedral unit. The frequency equations for the four IR-active lattice vibrations of the spinel lattice can then be divided into two blocks of two vibrations each, in which one vibration of the octahedron is coupled with the stretching vibration of the tetrahedron, and the other vibration of the octahedron with the deformation vibration of the tetrahedron. According to this model, for the spinel lattice in the case of $MgAlO_4$ we expect three vibrations in the stretching vibration region for the octahedron and the tetrahedron and one in the deformation vibration region.

The IR spectra of various compounds of the spinel type with bonding similar to that in $MgAl_2O_4$ have been found to contain two strong bands in the expected stretching vibration region, accompanied in some cases by a weaker band in the form of a shoulder at higher wave numbers[34]. The two strong bands can be plausibly assigned to the vibration modes that arise from the coupling of a stretching coordinate of the tetrahedral unit with a stretching coordinate of the octahedral unit. A weaker band in the form of a shoulder could be the expected third stretching vibration. Calculations for the assignment of the two strong bands have been carried out for various spinels (Table 7). It is found that plausible values for the stretching force constants are obtained for the first four compounds only if the stretching coordinate of the tetrahedral unit

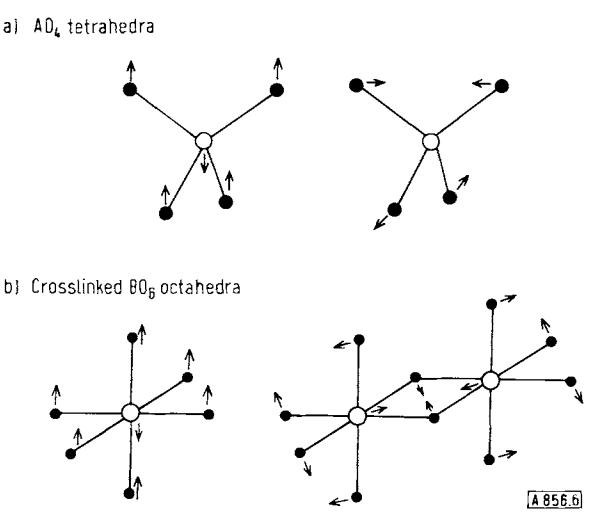

Fig. 6. Vibration modes for the F_{1u} vibrations of the spinel lattice; A in tetrahedral and B in octahedral sites of the oxygen packing.

predominates in the lower vibration in each case. The situation is reversed for the last two spinels, which have Cr in the B sites. However, the coupling between the two stretching vibrations is considerable. Real solutions for the force constants are obtainable from the observed frequencies only if the interaction force constant of the bonds from an oxygen atom to a metal atom in the tetrahedral group and to one in the octahedral group is positive. The calculated force constants depend on the value of this interaction constant. Within these solution ranges, only those values for the force constants in which the interaction term is as small as possible, so that one is at the limit of the real solution region, are plausible and bear comparison within the whole series. These values are given in the following table. They show that the force constants for the MgO and AlO bonds are both around 1.9 mdyn/Å. Because of the higher effective nuclear charge of aluminum, one would expect a greater force constant for the AlO bond than for the MgO bond. However, the influence of the higher nuclear charge of aluminum is evidently offset by the smaller coordination number of the magnesium. In agreement with the result of the calculation, the MgO and AlO distances in $MgAl_2O_4$ are almost identical. The force constant of the MgO bond is considerably greater in $MgAl_2O_4$ and $MgCr_2O_4$ than in MgO, and thus also shows the influence of the coordination number.

Table 7. Evaluation of two IR-active vibrations in spinels of the type AB_2O_4.

B	A	ν_B	ν_A	F_{AB}	F_B	F_A
Al	Mg	690	538	0.2	1.86	1.82

Al	Fe	671	562	0.5	1.81	2.85
Al	Co	680	562	0.5	1.88	2.85
Al	Zn	667	562	0.5	1.93	2.51
Cr	Mg	508	645	0.35	2.03	1.87
Cr	Co	526	627	0.75	2.17	2.80

ν_A and ν_B: coupled stretching vibrations of the AO_4 tetrahedron and of the BO_6 octahedron respectively; ν in cm^{-1}.
F_A = stretching force constant in the AO_4 tetrahedron in mdyn/Å.
F_B = stretching force constant in the BO_6 otahedron in mdyn/Å.
F_{AB} = interaction constant.

A similar influence of the coordination number of the force constant and hence the position of the lattice vibration can be seen in the spectra of FeO (NaCl lattice) and Fe_3O_4 (inverse spinel type). For the first of these compounds the lattice vibration is situated at $400\,cm^{-1}$, while the second, like the spinels discussed above, gives two strong bands at 375 and $570\,cm^{-1}$[36]. Of these bands, the first is more strongly determined by the stretching coordinates of the octahedrally coordinated iron, and the second by those of the tetrahedrally coordinated iron. It has been shown[36] that in the spectrum of FeO, in addition to the strong band at $400\,cm^{-1}$, a weak band at $590\,cm^{-1}$ appears at the composition $Fe_{0.95}O$, the intensity of this band increasing with increasing iron deficiency. It is concluded from its position that the Fe^{3+} ions present in the defect structure occupy tetrahedrally coordinated lattice sites. This conclusion is in agreement with the foregoing characterization of the stretching vibrations in spinel lattices by stretching coordinates of the tetrahedrally and octahedrally coordinated groups.

X-Ray Spectroscopic Investigation of Chemical Bonding in Solids[**]

By Alfred Faessler[*]

When an atom is incorporated into a molecule or a crystal, its X-ray spectrum undergoes characteristic changes, the study of which leads to important information on the nature of the chemical bonding and on the electronic structure in a substance. A number of examples are given to illustrate the possibilities of the X-ray spectroscopy of bonded atoms. Special attention is given to the displacement of the Kα lines, from which conclusions can be drawn regarding the charge on a bonded atom, as well as to the investigation of the emission bands resulting from valence electron transitions, which yields information on the energy band structure of the solid. X-ray spectroscopic studies on free molecules and theoretical work on the calculation of the molecular orbitals of simple molecules are finally reported.

1. Introduction

The influence of chemical bonding on the characteristic X-ray spectrum has attracted growing attention in recent years, since it has been shown that the spectrum of the bonded atom yields valuable information concerning the electronic structure and the nature of the chemical bonding in molecules and crystals.

How does the X-ray spectrum of an atom change when it is incorporated into a molecule or crystal? To answer this question, let us consider an element of the 3rd period, *e.g.* silicon, in a compound that exists in the solid state. In such a case, the valence electrons, *i.e.* the M electrons in the case of silicon, occupy an energy band as shown in the simplified level diagram (Fig. 1). The possible X-ray transitions are shown in the diagram.

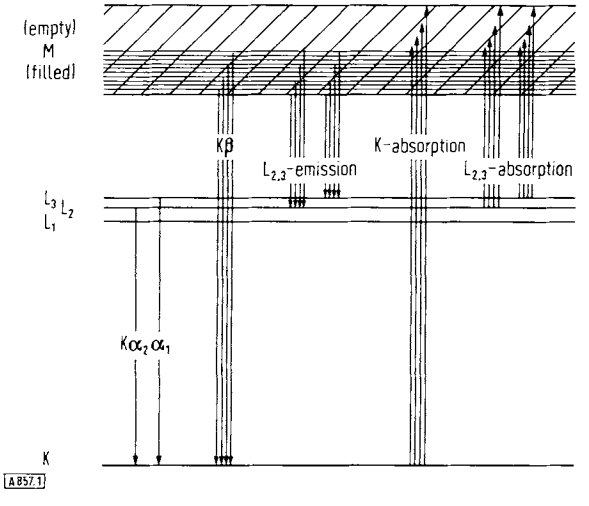

Fig. 1. Simplified level diagram with the possible X-ray transitions for elements of the 3rd period. The horizontal shading denotes the occupied part of the valence band.

[*] Prof. Dr. A. Faessler
Sektion Physik der Universität

[**] From a lecture delivered to the GDCh "Festkörperchemie" group on October 2, 1970 in Bonn (Germany).

The transitions of the valence electrons into the K or $L_{2,3}$ level give rise to emission bands whose position, width, and structure are characteristic of the solid in question and yield information on the occupied part of the energy band system. The absorption spectra, which correspond to electron transitions from the K and $L_{2,3}$ levels into the free valence electron levels, provide information about the unoccupied part of the energy band system.

The effect of bonding can be seen not only in transitions involving valence electron levels but also in the internal transition $L_{2,3} \rightarrow K$, which leads to the emission of the $K\alpha_{1,2}$ doublet. The main effect of chemical bonding on the doublet lines is a change in wavelength; this is accompanied by a small change in their width and symmetry. The wavelength changes in particular are subject to simple rules, which allow the deduction of the charge of the atom in the compound in question.

Finally, the influence of chemical bonding can also be seen, very clearly in some cases, in the non-diagram or satellite lines, which are due to multiply ionized atoms.

2. Displacements of Absorption Edges and Emission Lines

2.1. K Absorption Edge of Sulfur

The dependence of an X-ray spectrum on bonding was first observed in the K series of phosphorus, sulfur, and other elements of the 3rd period, since the effects in these cases can be detected even with simple spectroscopic aids and the radiation lies in an easily accessible wavelength range. It was found that the position of the K absorption edge of an element differs from compound to compound, and even among the various modifications of an element. Systematic studies on this phenomenon were carried out in particular by *Stelling*[1] between 1920 and 1930. They showed that the wavelength at which the edge occurs is generally greatest for the element, while for the compounds it is found that the higher the oxidation state in which the element is present, the shorter is the wavelength or the

higher the energy of the edge. The position of the edge is also influenced by neighbors bonded in the first sphere.

These simple empirical rules have been successfully used by *Stelling* for the investigation of chemical constitutions, and it is not surprising that the simple procedure aroused great interest among chemists. However, the method did not live up to expectations; it failed even in relatively simple problems. Thus *Stelling* found three absorption edges in the case of sodium thiosulfate, $Na_2S_2O_3$, instead of two as expected from the structural formula. This result, which was incomprehensible at that time, is now known to be due to a phenomenon known as the fine structure of the absorption edge, which also hinders the location of the principal absorption jump, and hence the determination of the oxidation state of the absorbing element, in other cases. Moreover, the relation between the position of the edge and the bonding state is not as simple as was originally thought. It was recognized only later that in addition to the position of the edge, its fine structure must generally also be taken into account in drawing conclusions regarding the bonding of the atom in question.

2.2. Kα Doublet of Sulfur

Effects of chemical bonding were also discovered at an early date in the *emission spectra* of light elements. Here an experimental difficulty was encountered in the systematic investigation of this phenomenon. It was found that on excitation with electrons on the anticathode of an X-ray tube, many substances undergo uncontrollable changes even at low intensities, so that it is frequently impossible to obtain the spectrum of an element in a given compound.

However, even the earliest measurements showed the nature and the magnitude of the influence of chemical bonding on the emission spectra. A surprisingly large effect was found for the Kα lines of the elements of the 3rd period. Close examination of the experimental findings revealed indications that the wavelength changes observed for the Kα lines depend in a clearer manner on the bonding state of the emitting atom than the changes in the wavelengths and structures of the Kβ lines and absorption edges. Particularly simple relationships were therefore to be expected for the dependence of the Kα doublet on bonding if the interfering effects during excitation could be avoided.

This type of reasoning led the author to the idea of investigating the influence of chemical bonding on the Kα doublet of sulfur with fluoresence excitation. The experimental means were available for the production of intense fluorescent radiation even from elements having low atomic numbers. They had been developed for chemical analysis with secondary X-ray beams (nowadays known as X-ray fluorescence analysis), and could also be used for the investigation of the relation between the X-ray spectrum and the bonding state.

The expectation that simple, clear rules would be found for the Kα lines by the fluorescence method was fully confirmed on investigation of a series of inorganic sulfur compounds[3]. Like the absorption edge, the Kα doublet moves to higher energies with increasing oxidation state of the element in the compound in question. In this case, however, the findings were fully consistent, unlike those for the absorption edges. All compounds with positively charged sulfur exhibit a shift to higher energies in relation to elementary sulfur, while compounds with negatively charged sulfur exhibit a shift to lower energies. Thus all sulfides, without exception, show a shift of the Kα doublet to lower energies, whereas the displacement of the K absorption edge is to lower energies for some sulfides and to higher energies for others, an indication that the situation is more complicated in the case of the absorption edges. The investigation of sodium thiosulfate, in agreement with the structural formula, gave two doublets, one corresponding to sulfur in the oxidation state +6 and the other to sulfur in a lower oxidation state. The relative positions of the two doublets are such that the $K\alpha_2$ line of the first sulfur atom overlaps with the $K\alpha_1$ line of the second. Figure 2 shows the Kα spectrum of the sulfur in thiosulfate, which consists of three lines, and the Kα doublet of sulfur in a sulfate and in a sulfide. Sulfide and sulfate give the extreme positions for the doublet; the energy difference in this case is not less than 1.33 eV, a surprisingly high value when one considers that the chemical bond energies are only a few electron volts. Accurate measurement of the wavelength showed that the $K\alpha_1$ line of the central sulfur atom does not coincide exactly with that of the sulfur in sulfate, just as the wavelength of $K\alpha_2$ of the second sulfur atom is not equal to that of $K\alpha_2$ of sulfide or elementary sulfur. Even within the "same oxidation state", therefore, we find small displacements that depend on the nature of the bonding partner.

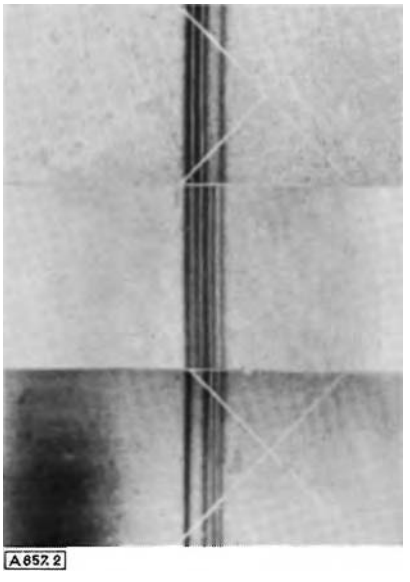

Fig. 2. Kα lines of sulfur in Na_2SO_4 (top), $Na_2S_2O_3$ (center), and ZnS (bottom). The two outer lines are reference lines (Co $K\alpha_1$ and $K\alpha_2$, 3rd order). The three lines of $Na_2S_2O_3$ result from the overlap of two doublets, whose positions are approximately as in Na_2SO_4 and ZnS.

Together with *M. Becke-Goehring*, the author later investigated a large number of chemically and crystallographically well-defined sulfur compounds[4]. The result of the earlier measurements were substantially confirmed by this

work, particularly the relation between the position of the doublet and the oxidation state of the sulfur. To supplement the earlier findings, a compound containing sulfur in the oxidation state +2 was also investigated; in this case we found a doublet whose position lay between those of S^0 and S^{IV}.

It was also found that within one and the same oxidation state, the doublet is increasingly displaced to higher energies with increasing electronegativity of the bonding partner. This relation has been confirmed for several series of compounds. In general, therefore, the doublet is displaced to higher energies as the positive charge on the atom is increased.

In addition to thiosulfate, a number of other compounds containing sulfur in different oxidation states were investigated. Polythionates gave results similar to those found for thiosulfate. There were again two overlapping doublets, indicating sulfur atoms in two different oxidation states. Dithionate, on the other hand, gives a single Kα doublet, corresponding to the fact that the two sulfur atoms in dithionate have the same formal oxidation number +5.

An interesting example in this connection is tetrasulfur tetranitride S_4N_4, whose molecule forms an eight-membered "ring". According to the formal view, the sulfur atoms should be in two different oxidation states, *i.e.* +2 and +4. The X-ray spectroscopic study gave a single, well-defined Kα doublet, whose position corresponds to the oxidation state +3. In this case, therefore, the sulfur atoms are not in different oxidation states, as one would expect from the classical valence theory, but the electron distribution in the system is evened out by delocalization. It also follows that sulfur may be regarded as the positive component of the compound, and S_4N_4 may be treated as a nitride. The derivative $S_4(NH)_4$ gave an S Kα doublet whose position corresponds to the oxidation state +2.

The measurement of the wavelengths of the S Kα doublet frequently allows a decision between two possible structural formulas. For example, it was found that "formaldehyde sodium sulfoxylate" (rongalite) contains sulfur in the oxidation state +4, and should therefore be regarded as a salt of hydroxymethanesulfinic acid.

2.3. Kα Doublet of Aluminum, Silicon, and Phosphorus

The rules found for the influence of the oxidation state and the electronegativity of the bonding partner in the case of sulfur were confirmed on extension of such studies to the Kα doublet of the elements phosphorus, silicon, and aluminum. As far as the influence of the electronegativity is concerned, it can now be said with greater precision, on the basis of measurements by *Fichter*[5] on the Kα doublet of phosphorus, that the displacement is approximately proportional to the difference between the electronegativities of the two bonding partners (Fig. 3).

Läuger established in the case of aluminum that not only the nearest but also the next-nearest neighbors can influence the Kα spectrum of an atom[6]. A distinct influence

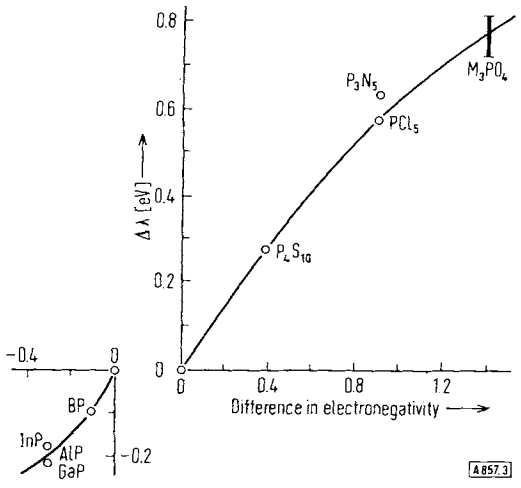

Fig. 3. Displacement of the P Kα doublet as a function of the difference in electronegativity of the bonding partners.

of coordination is also observed in the case of aluminum. On transition from tetrahedral to octahedral coordination, the doublet is considerably displaced to shorter wavelengths, so that it seems possible to obtain information on the coordination in aluminum compounds by accurate measurement of the wavelengths of the Kα lines.

A displacement of the P Kα doublet to higher wavelengths is found for the semiconducting III, V compounds BP, AlP, and InP; it follows from this, in agreement with other results, that the bonding in these semiconductors has a certain ionic component, and that phosphorus is the negative partner.

It is sometimes possible to investigate the spectra of both partners in a compound, as in the case of phosphorus sulfides. In agreement with the chemical properties, a shift to lower wavelengths is found for P Kα and a shift to higher wavelengths for S Kα, *i.e.* phosphorus is the positive partner and sulfur the negative. The displacement of P Kα increases with increasing number of sulfur atoms[5].

Many problems of chemical bonding in solids are encountered with silicon, whose K spectrum has been thoroughly investigated by *Krämer*[7]. In a series of compounds of silicon with the metals lithium, magnesium, and calcium, a displacement of the Si Kα doublet to longer waves, indicating a negative charge on the Si atom, was found only for Mg_2Si and Ca_2Si, which may also be regarded stoichiometrically as silicides. No shift or only a very small shift to lower wavelengths is found for the other metal compounds of silicon; this means that these are alloy-like compounds, as can also be deduced from their other physical and chemical properties.

The position of Si Kα for silicon carbide SiC indicates that this compound has an essentially homopolar structure; though a slight shift of the doublet to shorter waves points to a positive charge on the Si atom, the shift is much smaller than in the case of SiO_2, so that it is not permissible to regard SiC as an ionic crystal, as has occasionally been done on the basis of other physical measurements.

The two lower oxides of silicon, Si_2O and SiO_3, were also identified with the aid of the Kα doublet (Table 1).

Table 1. Wavelengths λ (in X units) of the Si-Kα doublet of elementary Si, "Si_2O", SiO_3, and SiO_2. δλ (in X units) and δE (in eV) denote the shifts of the doublet of silicon in the oxides [*] in relation to the doublet of elementary silicon.

Substance	λ		δλ	δE
	$K\alpha_1$	$K\alpha_2$	(mean)	
Si	7111.16	7113.77	—	—
"Si_2O"	09.32	12.00	1.81	0.44
Si_2O_3	08.89	11.55	2.25	0.55
SiO_2	08.69	11.36	2.44	0.60

[*] The oxide of the oxidation state +1 was in the form of a derivative $SiOR = Si_2O \cdot R_2O$, hence the designation "Si_2O".

If the electronegativities of oxygen and of silicon are taken into account, the positions of the Si Kα lines for the two compounds are in agreement with the assumption that each Si atom is surrounded by three Si atoms and one O atom in Si_2O, and by one Si atom and three O atoms in Si_2O_3.

The Si Kα spectrum of technical SiO shows an overlapping of several doublets, which cannot be resolved, but it can be said with certainty that this product is not a mixture of Si and SiO_2 alone; it is presumably a mixture of Si, SiO_2, and the lower oxides. It has not been possible to answer the question whether a definite silicon monoxide exists. (We once received a product for investigation that gave an Si Kα doublet at the wavelength expected for the oxidation state +2 of silicon, but the chemical analysis of this product did not correspond to the composition SiO; the investigations could not be continued at that time for reasons beyond our control.)

Among the oxygen compounds of silicon, a number of silicates have also been investigated. The position of the Si Kα doublet of various silicates varies over a wide range of wavelengths; this variation can be correlated with the various silicate structures. It may be assumed that investigations of this nature could contribute to the elucidation of silicate structures. It is interesting to note that the wavelength of P Kα is also different for different phosphates (cf. Fig. 3), though the scatter in this case is smaller; in the case of S Kα in sulfates, the scatter just exceeds the error limits.

To conclude the discussion of the dependence of the Kα lines on bonding, it should be mentioned that a systematic variation with bonding is found not only for the position of the lines but also for their width and shape; though these effects are not very pronounced, they have been used for the clarification of questions of chemical bonding[8].

The Kα satellites, *i.e.* lines due to doubly ionized atoms, show the influence of chemical bonding much more strongly than the principal lines $K\alpha_{1,2}$[9]. The displacements are roughly twice as large as for the latter, and are accompanied by pronounced changes in the widths and relative intensities of the lines. It is therefore perfectly reasonable to study the dependence of the satellite lines on bonding in greater detail, though their low intensity results in some difficulty in the measurements.

It should be added that the dependence of the wavelength of the Kα doublet on bonding has been detected even for elements with higher atomic numbers with the aid of special apparatus and measuring methods[10].

3. Valence Electron Transitions in Solids

3.1. Emission Bands

3.1.1. Elements and Compounds

In the discussion of the emission bands, which are due to valence electron transitions and are investigated in order to elucidate the electronic structure of a solid, we shall again confine ourselves to elements of the 3rd period. To obtain as much information as possible, it is essential to measure both the Kβ bands and the L bands, since only the part of the valence band with p symmetry is covered by the K bands and only those with s and d symmetry by the L bands.

The Kβ bands of these elements lie in a wavelength range for which crystal spectrographs are suitable; the K spectrum *e.g.* of silicon extends from 6.7 to 7.1 Å. The L bands lie in the region of ultrasoft X rays; the L band of silicon appears at 125—145 Å. Work in this wavelength range is nowadays carried out almost exclusively with concave grating spectrographs. The strong absorbability of the radiation imposes stringent requirements regarding the vacuum and the cleanness of the surfaces of the substances under investigation.

What results have been obtained so far in studies on valence electron transitions? One important result is the essentially direct confirmation of the fundamental concepts of the energy band model. In monographs on solid-state physics and in any detailed textbook, one can find diagrams showing that the emission bands due to the transitions of the valence electrons have a more or less symmetrical intensity distribution for nonconductors, corresponding to the fact that the valence band is fully occupied, whereas the emission band in the case of metals is unsymmetrical and shows a steep descent on the high-energy side, corresponding to the Fermi edge.

However, it is by no means easy to obtain X-ray spectroscopic data that provide information on the energy band structure of a given solid and can be compared with the results of theoretical work. The difficulties that arise are partly experimental, but they are also partly due to problems of a fundamental nature.

To obtain the true intensity distribution from the measured intensity distribution for a given emission band in the ultrasoft region, the reflecting power of the grating and the quantum yield of the photocathode of the multiplier, both of which depend on the wavelength, must first be taken into account; allowance must generally also be made for the window curve of the spectrograph.

Since the ultrasoft X rays come only from a very thin surface layer of the anode, contamination of the anode surface by oxidation, by carbon from the pump oil, *etc.* can lead to considerable falsification of the spectra. Finally, the absorption in the preparation itself must be considered, since this can lead to appreciable changes in the true intensity distribution if the high-energy part of the emission band and the low-energy side of the absorption band are situated close together or even overlap.

All these apparatus effects and interfering effects were taken into account in the measurement of the $L_{2,3}$ emission band of metallic aluminum (Fig. 4) by *Neddermeyer* and *Wiech*[11]. The band shows the steep descent on the high-energy side corresponding to the Fermi energy, which is characteristic of a metal, a fine structure in addition to the maximum between 67 and 72 eV, and finally the less steep descent on the low-energy side. At about 60 eV, this descent gives way to a shallow tail, which ends at about 42 eV after a small maximum at 45 eV. The small maximum is due to the transition $L_{2,3} \rightarrow L_1$. The long tail is a secondary effect, and is due to Auger transitions in the valence band. From the fourfold magnification of the low-energy part of the band, it can be seen that a satellite about 15 eV wide, known as the plasmon satellite, is also superimposed on the tail. After subtraction of the component that is not due to direct valence electron transitions, and on the assumption that the low-energy part of the spectrum follows an $E^{1/2}$ law, the actual width of the Al $L_{2,3}$ emission band is found to be 11.05 ± 0.2 eV, which agrees satisfactorily with the theoretical value of 11.64 eV.

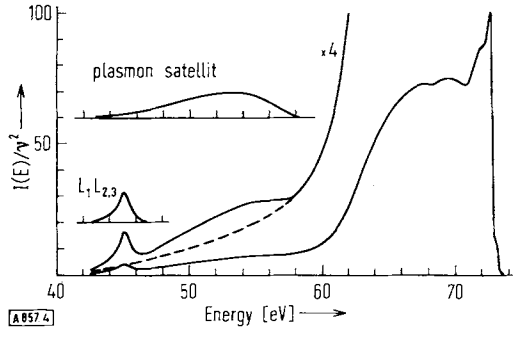

Fig. 4. $L_{2,3}$ emission band of aluminum metal. Low-energy part of the band (above) in fourfold magnification, with plasmon satellite and $L_1L_{2,3}$ line.

A comparison of the intensity distribution of an emission band with the results of theoretical calculations has only recently become possible. It has occasionally been asked whether it is in fact possible to obtain X-ray spectroscopic data that allow such a comparison. It has now been shown that the answer is yes, though possibly with certain reservations. One example, in which very satisfactory agreement was achieved between the emission bands measured in the experiment and the results of calculations, is that of elementary silicon. Figure 5a shows a plot of the state density N(E) for silicon, as determined by *Klima*[12] from energy band calculations. Because of the selection rules, the energy bands differ considerably from the N(E) curves. To allow substantially direct comparison with the bands found in the experiment, *Klima*[12] calculated the intensity distribution of the K and L emission bands using the matrix elements of the transition probability. The widths of the K and L levels and the influence of the Auger effect were also taken into account semi-empirically. Figure 5b shows the intensity distribution calculated in this way for the $L_{2,3}$ band of silicon, and Figure 5c shows the band measured by *Wiech* and *Zöpf*[13]. Figure 5d similarly shows the calculated Kβ band of silicon and the band measured by *Läuger*[6]. The measured and calculated intensity distributions agree well in both cases. The emission bands contain characteristics corresponding to the main characteristic points of the N(E) curve.

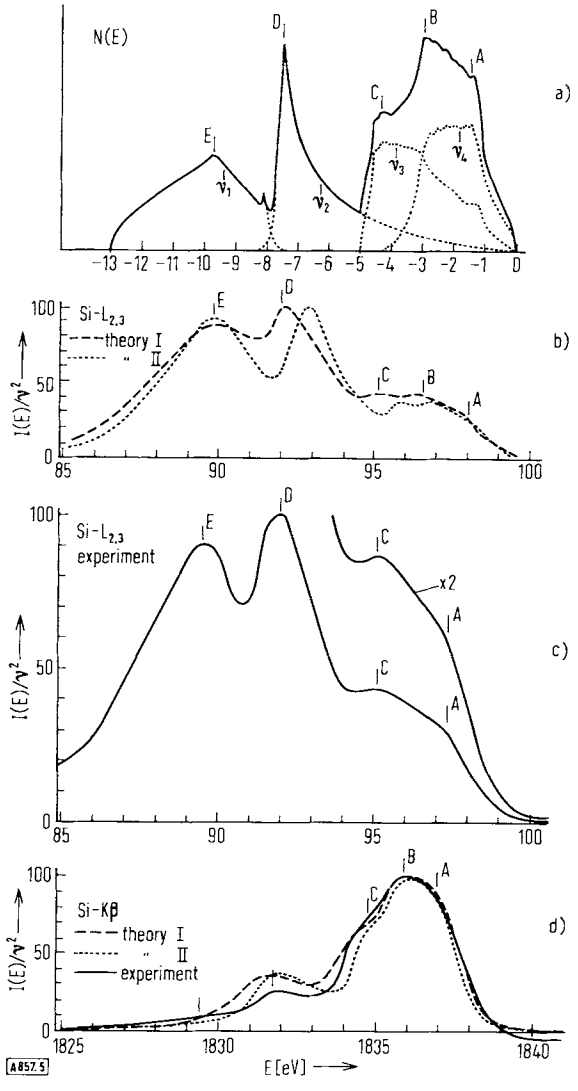

Fig. 5. a) N(E) curve for elementary silicon; b) L emission band calculated according to two different theories; c) measured L emission band; d) calculated and measured Kβ band.

The above example is probably the only one in which such good agreement is found between experiment and theory, even when the other experimental methods for the determination of band structures are included. Nevertheless, the consistency of a comprehensive body of experimental data within itself also suggests that the X-ray spectra contain the essentials of the electronic structure of a solid, at least in favorable cases.

Figure 6 shows the Kβ band of elementary silicon and the K band of carbon (diamond) together[13]. The two bands largely agree in their overall course, corresponding to the fact that silicon and diamond are crystals with homopolar bonding and with similar lattices. A different form is found for the Si Kβ band of quartz (Fig. 7), which is a crystal having a different structure, with 50% homopolar and 50% heteropolar bonding. As can be seen in Figure 7, the Si $L_{2,3}$

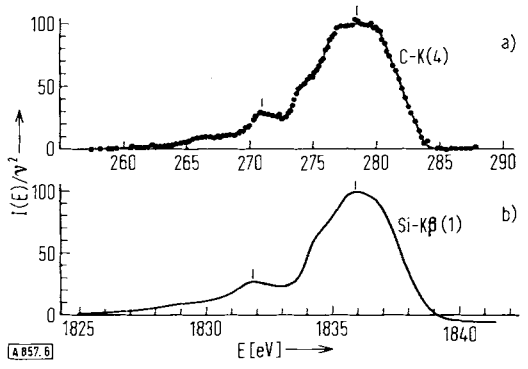

Fig. 6. a) K band of carbon (diamond) and b) Kβ band of elementary silicon.

band of SiO_2 is again similar to the P $L_{2,3}$ bands of $AlPO_4$ and Na_3PO_4[14]. The similarity is understandable, since the Si atom in SiO_2 and the P atom in $AlPO_4$ and Na_3PO_4 are tetrahedrally surrounded by four O atoms.

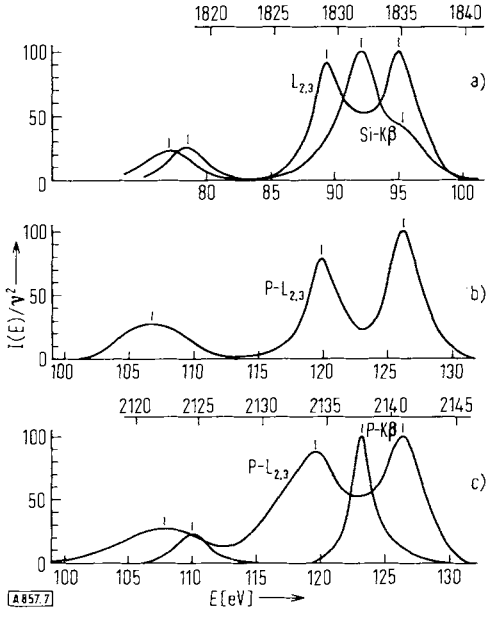

Fig. 7. a) Si Kβ and Si $L_{2,3}$ bands of quartz, b) P $L_{2,3}$ band of $AlPO_4$, and c) P Kβ and P $L_{2,3}$ bands of Na_3PO_4.

3.1.2. Alloys

X-ray studies have also been carried out on alloys. The results obtained so far are not yet entirely understandable, but they are sufficiently interesting to induce further studies. A typical example is a series of investigations by *Neddermeyer* on Mg/Al alloys[15]. Since the Mg $L_{2,3}$ and Al $L_{2,3}$ bands lie in the same wavelength region, they can be measured with the same apparatus. Both bands have characteristic structures.

According to the rigid band model, one would expect a similar valence band for both atoms, and hence the same width and shape of the emission bands of both components. However, the measurements do not yield the expected result. The widths are different, the value for the Mg band being 6—10 eV, while that for the Al band is more than 10 eV. The bands also differ in shape; the band of each component shows a characteristic change in the intensity distribution with increasing concentration of the other component in the alloy. With increasing aluminum concentration, the intensity of the low-energy part of the Mg $L_{2,3}$ band decreases (Fig. 8), while with increasing magnesium concentration, the intensity of the high-energy part of the Al $L_{2,3}$ band increases (Fig. 9). Moreover, the Fermi level, which should exhibit a large shift according to the rigid band model, is displaced measurably but only by a small amount.

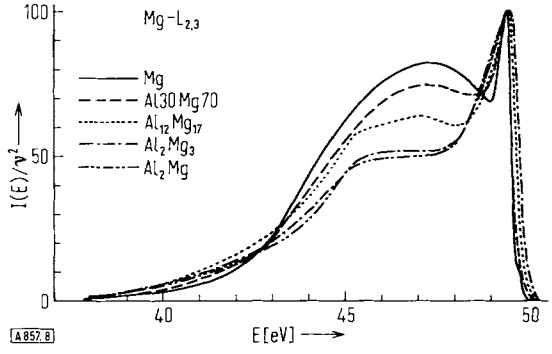

Fig. 8. Mg $L_{2,3}$ band of magnesium in various Mg/Al alloys.

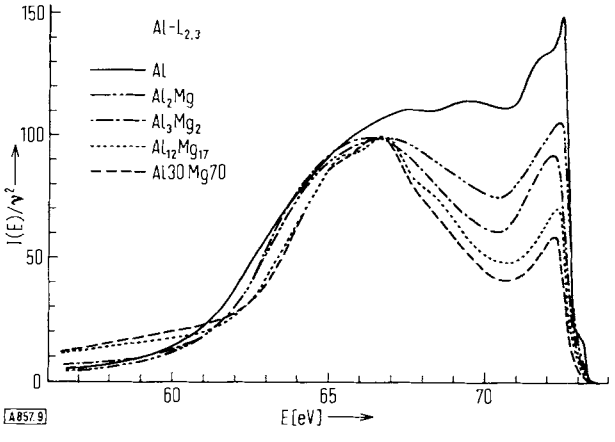

Fig. 9. Al $L_{2,3}$ band of aluminum in various Mg/Al alloys.

These findings, which will not be discussed in detail, can be qualitatively understood if the electron density is assumed to be higher in the vicinity of the trivalent aluminum atoms than in the neighborhood of the bivalent magnesium atoms, *i.e.* if one assumes that the electrons are not uniformly distributed in the crystal. However, we must await the results of further investigations; above all, it is again necessary in this case to measure the Kβ bands of the two elements as well as the L bands.

3.2. Absorption Spectra

On absorption of X rays, an electron is promoted from an inner shell into an unoccupied level; as was mentioned in Section 1, therefore the absorption spectra yield information on the unoccupied states of the energy band system. The absorption spectra are not easy to obtain in the region

of ultrasoft X rays, since very thin absorbing layers (a few hundred to a few thousand Å) are required and continuous radiation of sufficient intensity cannot be produced in this wavelength range by conventional means. Synchrotron radiation has therefore recently been used to record absorption spectra. In such spectra, one observes characteristic structures, which correspond to transitions into exciton states of the condensed phases[16]. However, investigations of this nature have so far contributed very little to the elucidation of chemical bonding in solids.

The same is true of the extended or Kronig fine structure of the absorption spectra; this is the name given to the fluctuations of the absorption coefficient that appear on the high-energy side of many K and L edges and extend over a range of a few hundred electron volts.

On the other hand, the fine structure close to the edge, which is also known as Kossel fine structure, is of interest to the chemist. The following example shows the type of question that can be answered by investigation of this edge fine structure. The K absorption edge of transition elements exhibits a step, which corresponds to the transition of the photoelectron produced by the absorbed X ray into the unfilled 3d states (Fig. 10). Nickel charged with hydrogen does not exhibit this step, and it follows that the 3d vacancies are filled by the electrons given up by the dissolved hydrogen[17]. This explanation is supported by the fact that nickel charged with hydrogen is no longer ferromagnetic, though the disappearance of the ferromagnetism could also be due to expansion of the lattice, since the exchange integral is very strongly dependent on the lattice constant. After desorption, the step reappears in the absorption edge in the same form, and the metal has also regained its ferromagnetism.

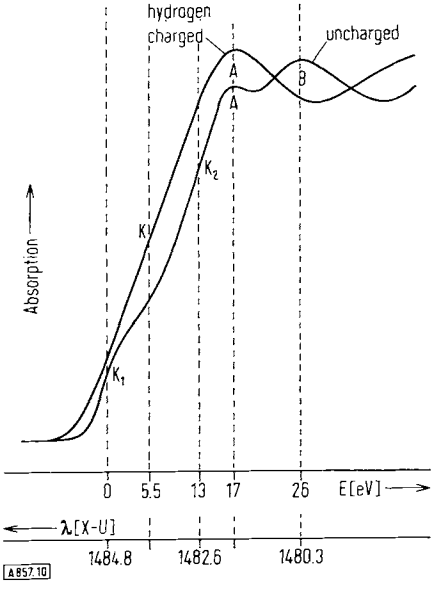

Fig. 10. Ni K absorption edge for pure and hydrogen-charged nickel.

However, the fine structure close to the edge is in general probably less important for problems of the solid state than for the study of chemical bonding in molecules and complexes. The investigation of edge fine structure for the transition elements is particularly promising for coordination chemistry, as has been shown by a series of investigations[18].

In this discussion of absorption spectra and their use, reference must also be made to an important method for the investigation of the structure of the unoccupied states of a solid, which does not fall strictly within the scope of X-ray spectroscopy, but is closely related to it. This is the isochromat method[19], in which an isochromat of the bremsstrahlung produced in the metal in question is recorded. The isochromat intensity is proportional to the state density in the unoccupied part of the conduction band. The method has the advantage that the resolution is not limited by the width of an inner level, and it can therefore also be applied to metals with high atomic numbers.

4. Investigations on Free Molecules

There have been few reports on investigations on the relation between the X-ray emission spectrum and chemical bonding in gaseous compounds, though such investigations may be expected to make valuable contributions to molecular physics. A brief account of X-ray spectroscopic studies on the electronic structure of free molecules may be justified at this point, since the results may also help with the interpretation of the spectra of solids.

4.1. K Spectrum of Chlorine in Gaseous Compounds

With a specially constructed tube, *Gilberg*[20] was able to obtain the Kα and Kβ spectra of chlorine in a number of organic chlorine compounds, molecular chlorine, hydrogen chloride, and phosgene.

It was found that the displacements of the Kα lines do not follow the rules found for the other elements of the 3rd period, and also for solid compounds of chlorine. The reason for this surprising behavior probably lies in the fact that the displacements caused by chemical bonding, which should not be very large, are masked by the influence of molecular vibrations. The differences in the line widths also indicate that the Kα lines are influenced by molecular vibrations.

The Kβ spectrum of chlorine consists of several strongly overlapping lines. The widths of the lines are given by the natural width of the K level. On the basis of optical and

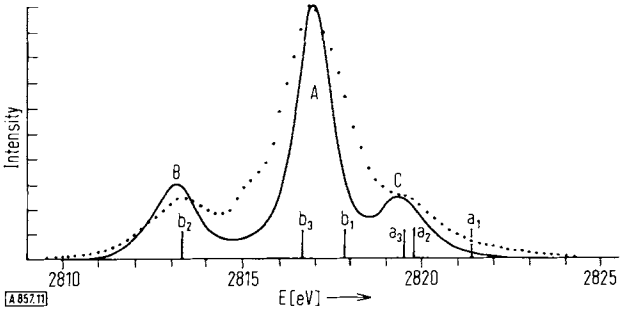

Fig. 11. Cl Kβ spectrum of HCl; the vertical lines a_1 to b_3 denote the positions of calculated satellites.

β-spectroscopic data, as well as of *ab initio* calculations by *Schrenk*[21], *Gilberg* was able to assign the lines to certain molecular orbitals. Figure 11 shows the Cl Kβ spectrum of HCl. The line A is assigned to the highest π orbital of the HCl molecule, which accepts the two lone pairs of electrons of the chlorine that are not involved in the bond. The line B corresponds to the highest σ orbital, which is very strongly involved in the bond. The line C is a satellite due to doubly ionized Cl atoms[21].

For methyl chloride, the spectrum consists of two lines (Fig. 12), of which the line A corresponds to the highest e orbital, which, as in HCl, again accepts the non-bonding electron pairs of chlorine, while the line B corresponds to the highest a_1 orbital, which is strongly involved in the C—Cl bond. The interpretation of this spectrum was possible through *ab initio* calculations by *Schmittinger*[22].

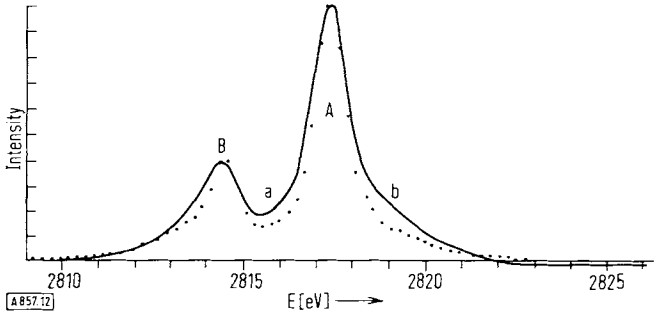

Fig. 12. Cl Kβ spectrum of CH_3Cl.

Figure 13 shows the spectra of the first four *n*-alkane derivatives. By analogy with the spectra of HCl and CH_3Cl, it is to be expected that the line A, which appears in the same position in all the spectra, is attributable to the orbitals of the lone pairs of electrons on the Cl atom, and the line B to the bonding orbitals.

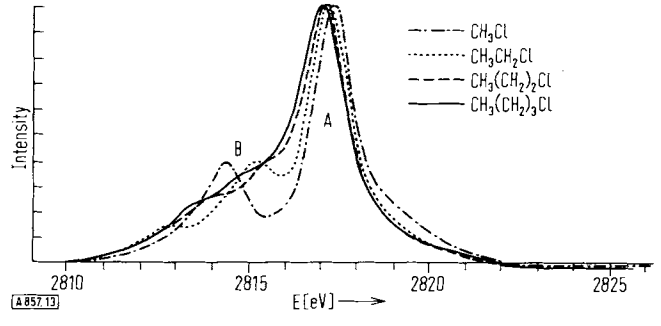

Fig. 13. Cl Kβ spectra of alkyl chlorides.

If the chlorine atoms are bonded to carbon atoms that participate in double bonds, the Cl Kβ spectrum contains five characteristic lines (Fig. 14). The interpretation of these lines is not yet complete, but it is probable that the line A again corresponds to the orbitals of the line pairs of electrons on the chlorine, and the line A′ to the orbital that effects the π bonding of the C=C double bond.

The Kβ spectrum of chlorine in chlorobenzene (Fig. 15) is very similar to the spectra of the ethylene derivatives. It again contains five lines, of which A is attributable to the

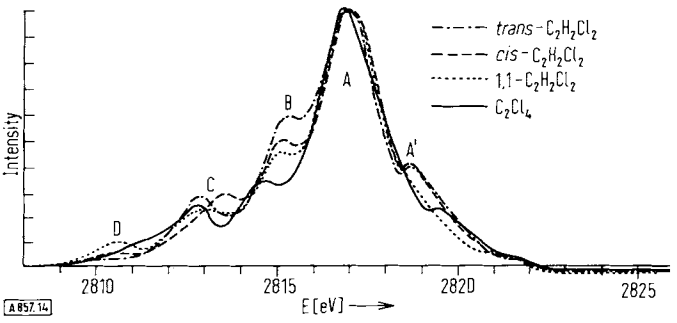

Fig. 14. Cl Kβ spectra of chlorine derivatives of ethylene.

lone pairs of electrons on the chlorine and A′ to the π electrons of the benzene ring. This similarity of the spectra suggests a similarity of the states of the valence electrons of the carbon atoms in the ethylene derivatives and in chlorobenzene.

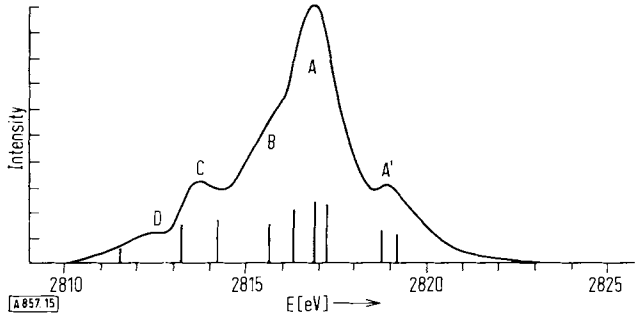

Fig. 15. Cl Kβ spectrum of C_6H_5Cl.

4.2. Ab Initio Calculations for Simple Molecules

The investigations on gaseous substances are particularly interesting, since free molecules are the simplest systems in which chemical bonding can be studied. Moreover, through the use of large computers, it is now possible to calculate the X-ray levels of small molecules and the corresponding wave functions in the SCF approximation.

Schrenk, whose calculations were mentioned in Section 4.1, has written an SCF program on the basis of the Roothaan-Hall method for molecules with closed shells or with one vacancy in a shell. The program is therefore suitable for the calculation of X-ray states in molecules in the adiabatic approximation; the same states can also be calculated by the Koopmans theorem.

The calculation of the ionization stages S, S^{2+}, S^{4+}, and S^{6+} for the sulfur atom, gave values that agree well with those of *Gianturco* and *Coulson*[23]. The X-ray levels of the molecules H_2, SO_2, HCl, and Cl_2 were also calculated for the first time by the adiabatic method, which gives better values for the bond energies than the Koopmans theorem. The calculated bond energies agree well with the values found in electronic spectroscopy.

The special value of the work is probably that it deepens our understanding of the change in the X-ray levels on chemical involvement of an atom. In agreement with the

experiment, it is found that the X-ray levels move to higher energies with increasing ionization of the atom. The inner orbitals are practically unchanged on ionization in the outermost shell. The displacement of the X-ray levels is mainly due to the changed interaction of the corresponding orbitals with the outermost shell.

The displacement of the X-ray levels on incorporation of an atom into a molecule is due to two effects. On the one hand, the ionization energy is increased by interaction of the orbital with the newly added atomic nuclei, while on the other it is decreased by interaction of the orbital with the modified valence electron shell and the newly added electrons. Depending on which of these effects predominates, the ionization energy will increase as in SO_2, or decrease, as in H_2S.

Since the satellites due to double ionization appear with considerable intensity in the X-ray spectra of molecules, it should be emphasized again that satellites can also be approximately calculated, as was indicated in Section 4.1.

Structure of $(CH_3OBC_5H_5)_2Co$, a Derivative of the Aromatic Hydridoborinate Anion[**]

By *Gottfried Huttner* and *Bernhard Krieg*[*]

Derivatives of the hydridoborinate ion $[HBC_5H_5]^-$, which is isoelectronic with benzene, were first stabilized as π-ligands in cobalt complexes by *Herberich et al.*[1]. Recently the synthesis of the free 1-phenyl-1-borabenzene anion has also been reported[2]. We have studied the structure of bis(methoxoborinato)cobalt in order to determine whether the ligand is bonded to the metal *via* all six ring atoms or whether the boron atom, like the methylene group in π-cyclohexadienyl-metal complexes, does not participate in the metal-ligand bond.

Bis(methoxoborinato)cobalt[3], $[(CH_3OBC_5H_5)_2Co]$ *(1)*, crystallizes in the monoclinic space group $P2_1/c$ with $a=6.76$, $b=8.14$, $c=11.61$ Å; $\beta=99.73°$; $Z=2$; $d_{exp}=1.444$[4], $d_{calc}=1.440$ g cm^{-3}. 3715 non-zero X-ray diffraction intensities were collected with a two-circle diffractometer for two different crystals. After Lorentz, polarization, and absorption corrections the data were reduced to a common scale ($R_1=3.0\%$). There remained 932 independent, non-zero structure factors. The structure was solved by Fourier methods and refined by the method of least squares to $R_1=0.044$. All hydrogen atoms were located and their parameters were refined. The result of the analysis is shown in the Figure and the most important inner-molecular distances and angles are given in the Table.

The crystallographic symmetry of the molecule is C_i ($\bar{1}$) since the Co atom occupies a center of inversion in space group $P2_1/c$. The six-membered ring has mirror symmetry (mirror plane through C3, B, and Co) within the limits of error; it is not strictly planar, the ring atoms lying alternately above and below the best plane defined by them. The individual deviations are significant but only small in magnitude (0.02 Å on average). The resulting chair conformation is characterized by a mean torsion angle of 5.3° (see Table). The C—C distances in the ring are all approximately equal and lie in a range (1.400 Å on average) that is typical of the delocalized system of complex-bonded cyclohexadienyl ligands (1.401 Å in tricarbonyl-π-cyclohexadienylmanganese[5]). In contrast to cyclohexadienyl complexes, in which the $BOCH_3$ group is replaced by a methylene group, the boron atom in *(1)* does not project out of the best plane of the ring by any more than the other ring atoms. The angle between the best plane defined by the atoms C1, C2,...C5 and the plane C1—B—C5 is only

2.3°; in cyclohexadienyl-metal complexes the corresponding angle is about 40°[6]. It therefore appears that the boron atom, in contrast to the methylene group in cyclohexadienyl complexes, participates in metal-ligand bonding.

The cobalt-ligand bond lengths vary systematically: The distance from the metal to the "central" carbon atom Co—C3 (2.057±0.006 Å) is the shortest, the bonds to the atoms C2 and C4 (mean value 2.153±0.011 Å) are considerably longer but still shorter than the distance to the "terminal" carbon atoms C1 and C5 (mean value 2.240 ±0.008 Å). This pattern of distances arises because the metal atom is displaced away from the boron atom toward the carbon atom C3. Added to this effect is the slight puckering of the ring. The cobalt-boron distance (2.348 ±0.008 Å) is the longest metal-ring distance in the complex. Although considerably longer than the Co—B distances in carborane complexes[7] it is certainly still within the range of a strong cobalt-boron interaction and thus indicates participation of the boron in complex bonding.

The distance between the boron and the ring carbon atoms C1 and C5 has a mean value of 1.523±0.008 Å and is therefore only slightly shorter than a B_{sp^2}—C_{sp^2} single bond[8]. The B—O distance of 1.395±0.007 Å corresponds to the bond length of 1.37±0.02 Å that is typical for trigonal borates[9], thus indicating considerable double bond character.

The bonding in complex *(1)* is not necessarily typical for the complexing behavior of a borinato ligand: The methoxo substituent on the boron atom could exert a significant influence on the structure; the electronic configuration of the central atom exceeds the inert gas configuration by one electron in the paramagnetic complex studied. This electron could have a weakening effect on the bonding. Further structural studies are in progress to clarify these questions.

$Ge_{38}P_8I_8$ and $Ge_{38}As_8I_8$, a New Class of Compounds with Clathrate Structure

By *Hans-Georg von Schnering* and *Heinz Menke*[*]

Preparations of germanium phosphides under the conditions of chemical transport reactions with I_2 as transport vehicle[1] yielded small amounts of cubic crystals whose X-ray structure analysis showed them to be $Ge_{38}P_8I_8$.

In order to prepare pure samples of the isotypic compounds $Ge_{38}P_8I_8$ *(1)* and $Ge_{38}As_8I_8$ *(2)*, stoichiometric amounts of the elements are heated in a quartz ampoule, the starting materials being kept at 900°C. After a few days the products *(1)* and *(2)* respectively deposit as well formed crystals in the colder part of the ampoule (800°C). The hard and brittle crystals, which have a silvery metallic sheen, are stable to attack by water and dilute acids and alkalis; they rapidly dissolve, however, in oxidizing alkaline melts. The synthesis is favored by a small excess of iodine because slight amounts of GeI_4 are invariably formed (readily removed with H_2O). Otherwise crystals are obtained which have a yellow, red, green, or blue tint.

In a vacuum, compound *(1)* is degraded to germanium between 550 and 650°C. No information could be obtained about possible intermediates such as germanium phosphides[2]. In the mass spectrum the fragments I^+, P_2^+, and P_4^+ are not recorded at temperatures below 440°C[3].

Compounds *(1)* and *(2)* form cubic crystals of space group $P\bar{4}3n - T_d^4$ with $a = 10.507$ and 10.611 Å, respectively. The atoms of $Ge_{38}P_8I_8$ occupy the following positions: 24 Ge(1) in 24(i) with $x = -0.0027$, $y = 0.1190$, $z = 0.3069$; 6 Ge(2) in 6(c); 8 Ge(3) in 8(e) with $x = 0.1841$; 8 P in 8(e) with $x = 0.8148$; 6 I(1) in 6(d) and 2 I(2) in 2(a) [225

[*] Prof. Dr. H.-G. v. Schnering and H. Menke
Anorganisch-chemisches Institut der Universität
44 Münster, Gievenbecker Weg 9 (Germany)

reflections *hkl*, diffractometer data, $Mo_{K\alpha}$ radiation, $R = 0.068$]. The 38 Ge atoms and the 8 P atoms together form a tetrahedral skeleton having (6+2) large cavities that are occupied by I atoms. The structure is thus completely analogous to those of the gas hydrates of type $Xe \cdot 5.75\,H_2O\,[Xe_8(H_2O)_{46}]$ or the correspondingly built phases K_8Ge_{46}, *etc.*[4] in which the cavities are occupied by Xe and K respectively. The Ge and P atoms are arranged regularly in the E_{46} skeleton: Every P and every Ge(2) is bound to four Ge neighbors, every Ge(1) and Ge(3) to three Ge and one P neighbors (Ge—Ge = 2.45 – 2.50 Å; Ge—P = 2.38 – 2.40 Å). The distances to the I atoms are 3.57 – 3.90 Å for I(1) and 3.35 – 3.46 Å for I(2). On the basis of their tetrahedral coordination and electron balance the P atoms can be regarded as phosphonium ions P^+ and the two compounds *(1)* and *(2)* characterized by the formulas $Ge_{38}P_8^+I_8^-$ and $Ge_{38}As_8^+I_8^-$ (compare also the large distances between the iodine atoms). If these views are correct then the compounds should be semiconductors. Conductivity measurements[5] and attempts to extend this novel class of compounds by variation of the main group elements are currently in progress.

1-Diazoindene and Spiro[indene-1,7′-norcaradiene]

By *Dieter Rewicki* and *Christian Tuchscherer*[*]

Unlike 5-diazocyclopentadiene[1] and 9-diazofluorene[2], 1-diazoindene *(1)* has not hitherto been isolated. We have now prepared *(1)* by reaction of tosyl azide with indene in diethylamine[3]. Diazoindene is stable indefinitely below 0 °C and can be chromatographed and distilled without decomposition.

(1)

(2a) *(2b)*

Photolysis of diazoindene *(1)* in benzene gives a 45% yield [based on reacted *(1)*] of spiro[indene-1,7′-norcaradiene] *(2a)* which is in rapid equilibrium with spiro[2,4,6-cycloheptatriene-1,1′-indene] *(2b)*. The valence tautomers *(2a)* ⇌ *(2b)* have comparable thermal stabilities with the analogous fluorene derivatives[4]: They are transformed into isomeric hydrocarbons only after several hours' heating at 100 °C.

The NMR spectrum in CS_2 at 38 °C exhibits peaks at $\tau = 2.90$ (4 H/m); 3.49 (1 H/d), $J = 5.4$ Hz; 3.72 (4 H/m); 3.90 (1 H/d), $J = 5.4$ Hz; 5.88 (2 H/m). The peaks at $\tau = 2.90$, 3.49, and 3.90 are due to the aromatic protons and the protons on C-3 and C-2 in the indene part of the molecule. The signals at $\tau = 3.72$ and 5.88 are the time-averaged signals of the β,γ-protons and the α-protons, respectively.

The position of the α-proton signal itself evidences a fluctuating norcaradiene-cycloheptatriene system[5]. The multiplet at $\tau = 5.88$ is shifted downfield by a rise in temperature and upfield by drop in temperature, as expected for a low-energy norcaradiene component. Marked broadening is observed, above all for the signals at $\tau = 5.88$ and 3.72, below −80 °C; at −105 °C the signal at highest field is only just recognizable. The individual isomer spectra, which could provide information about the stereochemistry of *(2a)*, could not be observed.

The position of the averaged α-proton peak ($\tau = 5.88$) at room temperature and the expected position of the α-proton signals in *(2a)* and *(2b)* ($\tau = 4.8$ and 7.0)[4] afford a ratio of *ca.* 1:1 for the valence tautomers. In contrast, the equilibrium lies predominantly on the norcaradiene side[6] in the corresponding cyclopentadiene system at room temperature, and preponderatingly on the cycloheptatriene side in the fluorene system[4]. The preference for the cycloheptatriene form with increasing degree of ring fusion can be explained in terms of likewise increasing steric hindrance in the norcaradiene form.

1-Diazoindene (1):

A mixture of indene (58 g) and diethylamine (100 ml) are treated at 0 °C with tosyl azide (98.5 g) and allowed to stand for *ca.* 70 h at 0 °C. To the deep red mixture is added water (250 ml) and the mixture is extracted with light petroleum (40—80 °C) until the extract is only yellow. The combined extracts are washed with water (5 ×), dried over Na_2SO_4, and concentrated in vacuum. The resulting deep red liquid is fractionally distilled under N_2 in 50-ml portions over a short Vigreux column: At a bath temperature of 50—70 °C unreacted indene distills over under oil-pump vacuum, and on evacuation with a Hg-diffusion pump diazoindene *(1)* (b.p. 80—95 °C) is collected in the receiver. (Caution! At a bath temperature in excess of 120 °C the contents of the distillation flask, predominately tosyl azide, decompose explosively.) Distillation over a 10-cm Vigreux column furnished 10.3 g of *(1)* as a dark-red oil of b.p. 67 °C/10^{-3} torr; yellow-red crystals of m.p. 23—25 °C (from petroleum ether), yield 15%. NMR (CCl_4): $\tau = 2.1$—3.1 (4 H/m); 3.23 (1 H/d), $J = 5.5$ Hz; 3.78 (1 H/d); $J = 5.5$ Hz. IR (in CCl_4 and CS_2): 3660, 3075 (w), 2068 (vs), 1469 (w), 1420 (s), 1380, 1307, 1212, 1207, 1088 (w), 761, 750, 702 cm^{-1} (m). UV/visible (in *n*-heptane): 490 (1.27), 328 (4.066), 265 (4.261) nm (log ε). MW: 142 (determined by mass spectrometry).

Spiro[indene-1,7′-norcaradiene] ⇌ spiro[2,4,6-cycloheptatriene-1,1′-indene] (2a) ⇌ (2b):

Diazoindene *(1)* (6.6 g) in anhydrous benzene (300 ml) is irradiated in a quartz recycling apparatus for 20 h with a 150-W high-pressure mercury arc lamp. During this period 60% of the calculated amount of N_2 is evolved. The benzene is evaporated off under vacuum and the residue chromato-

Reaction of Phenyl Radicals with Methanol

By *Eckehard König*, *Hans Musso*, and *Uwe-I. Záhorszky*[*]

It has hitherto been assumed that phenyl radicals abstract H atoms only from the α-C—H bonds of alcohols since the O—H bonds are more stable by at least 10 kcal[1,2], although *Bartlett* and *Nozaki*[3] have deduced a slight amount of alkoxyl radical formation from analysis of the decomposition products of dibenzoyl peroxide in ethanol, and the studies by *Melander*[1] are surrounded by a 10% error in this respect. In order to elucidate the mechanism of reduction of diazonium salts with complex hydrides[4–6] it was necessary for us to know the ratio in which phenyl radicals abstract hydrogen from the C—H and O—H bonds of methanol. We therefore decomposed nitrosoacetanilide, phenylazotriphenylmethane, and dibenzoyl peroxide in variously deuterated samples of methanol with almost complete exclusion of oxygen. The yields of benzene were determined by gas chromatography (±2%) and the degree of deuteration by mass spectrometry (±0.3%).

Table. (Yields) and degrees of deuteration of benzene (both given as percentages).

Source of radicals	Conc. (mol/l)	CH_3OH	CH_3OD	CD_3OH	CD_3OD
C_6H_5—N—$COCH_3$		(53)	(45)	(15)	(7)
NO	0.9	0.0	0.6	52	79
C_6H_6—N=N—$C(C_6H_5)_3$		(68)	(60)	(32)	(24)
	0.12	0.0	0.4	45	74
$(C_6H_5CO_2)_2$		(32)	(30)	(25)	(22)
	0.45	0.0	0.7	48	86

The data in the Table show that the degree of deuteration of the benzene formed in CH_3OD was about 1% while comparable figures for CD_3OH and CD_3OD were about 50% and about 80%, respectively, for phenyl radicals of different origin; the degree of deuteration was found to increase with increasing dilution[7].

Paying due attention to the yields and to isotope effects ($k_{C-H}/k_{C-D}=6-8$, $k_{O-H}/k_{O-D}=5-8$)[8] we have calculated the ratio in which phenyl radicals abstract H atoms from the CH_3 and OH groups as 9:1; thus a C—H bond reacts only three times as fast as the O—H bond. Consideration of the bond energies alone would suggest a much lower tendency for loss of hydrogen from the O—H group (C—H 95.5, O—H 103 kcal/mol[9]; 92 and 102 kcal/mol, resp.[10]). It therefore appears that only a small part of the difference in bond energies is effective in the transition states of the two competing reactions. Phenyl radicals therefore react more specifically with methanol in solution than do methyl radicals in the gas phase ($k_{C-H}/k_{O-H}=1.2$)[10].

[7] The somewhat differing degrees of deuteration are due, on the one hand, to differing concentrations in some cases, and to varying H and H_2O contents of the samples used (deuteration: CH_3OD 99%, CD_3OH 98%, CD_3OD 99%) on the other. And in addition the differences in the complicated decomposition mechanisms also account for the differences in yields.

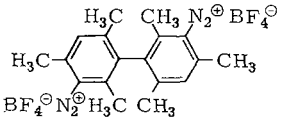
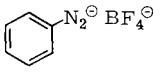
Phenyldiimine in the Reduction of Diazonium Salts by Sodium Tetrahydridoborate



By *Eckehard König*, *Hans Musso*, and *Uwe-I. Záhorszky*[*]

It has been shown that the hydrogen incorporated into the product of reduction of diazotized diaminobimesityl *(1)* to bimesityl by $NaBH_4$ in methanol does not originate from the hydride but from the OH group and to a slight extent from the CH_3 group of the solvent. This indicates that hydride ions attack the terminal nitrogen of the diazo group, as has also been established for many nucleophiles ($CN^{\ominus}$, $N_3^{\ominus}$, $OH^{\ominus}$, *etc.*), and that a phenyldiimine is formed as an unstable intermediate[1].



Since this mechanism has recently also been studied by other workers and discussed in some cases in different terms[2–4] we here wish to report experiments designed to demonstrate the presence of phenyldiimine for the simplest example of this reaction.

(2)

Reaction of phenyldiazonium tetrafluoroborate *(2)* in methanol with copper powder at 0°C affords benzene in 62% yield. In CH_3OD the benzene contains 1.6% deuterium, in CD_3OH 54%, and in CD_3OD 81% (see Table). These values are characteristic for free phenyl radicals[5]; it has been calculated that the radicals abstract hydrogen to the extent of 90% from the CH_3 group and 10% from the OH group[5]. In the absence of copper powder the diazonium salt is stable under these conditions; less than 0.3% of benzene is formed in 2 h.

If compound *(2)* is reduced by $NaBD_4$ in methanol at 0°C a 48% yield of benzene is obtained and the incorporation of deuterium amounts to only about 1%; in CH_3OD, however, 60% of deuterium is incorporated, in CD_3OH 26%, and in CD_3OD 88%. Reaction of the potassium salt of phenylazocarboxylic acid *(3)* under analogous conditions in CH_3OD, CD_3OH, and CD_3OD furnishes benzene containing 40, 14, and 94% of deuterium (see Table).

Table. (Yields) and degrees of deuteration of benzene (both given as percentages).

Source of radicals	Conc. (mol/l)	CH_3OH	CH_3OD	CD_3OH	CD_3OD
$C_6H_5-N=N^{\oplus}BF_4^{\ominus}$		(62)	(57)	(15)	(8)
+ Cu	0.6	0.0	1.6	54	81
	1.0		1.6	53	
$C_6H_5-N=N^{\oplus}BF_4^{\ominus}$		(48)	(33)	(45)	(28)
+ $NaBD_4$	0.6	0.7	60	26	88
	1.0	1.3	67	20	
$C_6H_5-N=N-CO_2K$		(28)	(23)	(32)	(25)
(3)	0.27	0.0	28	17	94
	0.82		40	14	

Studies by *Bunnett*[6], *Kosower*[7], *Hoffmann*[8], and *Heesing*[9] have established the formation of phenyldiimine on decomposition of the salt *(3)*, its esters, and other derivatives. Numerical data for the decomposition of *(3)* are in reasonable agreement with those for the reduction of *(2)* but differ widely from those obtained for reactions known to proceed by way of phenyl radicals. It is thus demonstrated that reduction of diazonium salts with $NaBH_4$ involves an intermediate that reacts with methanol in the same manner as phenyldiimine. In the meantime, UV maxima characteristic of phenyldiimine have also been found in the reaction solution[3].

The degrees of deuteration in lines 2 and 3 of the Table also provide some information about the further fate of the phenyldiimine. 20—30% decomposes into free phenyl radicals that abstract hydrogen from the CH_3 and OH group of the methanol (9:1). Some 65—80% of the phenyldiimine seems to decompose to give the phenyl anion which removes the acidic proton from the OH group. This ratio (20—30%/65—80%) is only valid, however, when approximately equal isotope effects are assumed for both pathways. The preceding communication[5] shows that this ratio will not be significantly falsified by the low proportion of OH abstraction by the free phenyl radicals.

As in the formation of phenyl radicals, the degree of deuteration of the benzene formed on decomposition of phenyldiimine by H abstraction from the CH_3 group of methanol also increases with increasing dilution. By way of contrast, the degree of deuteration of the benzene from phenyldiimine decomposition increases with increasing concentration when the OH proton is incorporated. There are two possible reasons for this behavior: Either the concentration of the diimine anion increases with the concentration of reactants, or a third decomposition pathway is available, *e.g. via* dimeric associates of phenyldiimine such as have been discussed by *Kosower* in acetonitrile[7] and by *Heesing* for acid solutions[9] in the formation of hydrazobenzene.

Reduction of the diazonium salt by $NaBD_4$ in methanol gives biphenyl (2—4%), hydrazobenzene, azobenzene, and phenyl azide as by-products. The deuterium content of the biphenyl (in CH_3OD, 56%; in CD_3OH, 14%; in CD_3OD, 88%) is similar to that of the benzene obtained from the same reaction solution (Table). The same applies to the decomposition of the salt *(3)* in deuterated methanol (biphenyl: 17, 12, and 40% D_1 resp.). The above constitutes a fairly rigorous proof that the major part of the biphenyl formed on decomposition of phenyldiimine arises by radical substitution of the incipient benzene and not by combination of two phenyl radicals.

The yields of benzene were determined by gas chromatography (±2%), and the degrees of deuteration by mass spectrometry (±0.3%). The methanol employed was at least 98% deuterated, the salts were dried at room temperature in high vacuum for about 1—2 h and certainly still contained traces of water that were not determined.

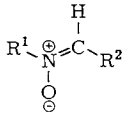
Conversion of Cyclic Nitrones to Thiolactams by Reaction with Carbon Disulfide

By *David St. Clair Black* and *Keith G. Watson*[*]

We report that the cyclic aldonitrones *(1a)*—*(1c)*[1] are converted into the related thiolactams *(3a)*—*(3c)*, simply by heating under reflux in carbon disulfide. The conversion is spectroscopically quantitative and the pure thiolactams can be isolated easily in high yields. The reaction presumably depends upon the loss of carbon oxysulfide from the intermediates *(2)*, which are the expected products of the cycloaddition of carbon disulfide to the nitrones *(1)*. A similar reaction[2] involves loss of sulfur dioxide from the cycloadduct of a nitrone and *N*-sulfinylaniline; related fragmentation reactions[3,4] often occur if aromatic products can be formed.



We have been unable to detect the presence of the cycloadducts *(2)*, even though reactions can be followed carefully by nuclear magnetic resonance spectroscopy. The previously unknown thiolactams 5,5-dimethylpyrrolidine-2-thione *(3a)*, 3,3,5,5-tetramethylpyrrolidine-2-thione *(3b)*, and 5,5-dimethyl-4-phenylpyrrolidine-2-thione *(3c)* have been characterized fully.

(1) *(2)* *(3)*

(a), $R^1 = R^2 = H$
(b), $R^1 = H$, $R^2 = CH_3$
(c), $R^1 = C_6H_5$, $R^2 = H$

Reports of cycloaddition reactions between carbon disulfide and nitrones or *N*-oxides are rare. In one special case[5], a stable adduct is reported. On the other hand, isoquinoline *N*-oxide[4] and the diphenyl nitrone *(4a)*[6] are deoxygenated, supposedly *via* their respective cycloadducts. This competing deoxygenation reaction is apparently successful when it can afford a highly conjugated product.

(4a), $R^1 = R^2 = C_6H_5$
(4b), $R^1 = C(CH_3)_3$; $R^2 = C_6H_5$

We have also observed that the *C*-phenyl nitrone *(4b)* undergoes thermal rearrangement and decomposition in preference to any reaction with carbon disulfide.

Thus the conversion of aldonitrones to thioamides does not hold for all nitrones and appears to require a nitrone configuration which allows a reasonable rate[7] of cycloaddition.

The Willgerodt-Kindler reaction[8] already provides a method for the conversion of simple aldehydes into thioamides, but is not readily applicable to the preparation of thiolactams. The method described in this communication compares very favorably with the main existing alternative, which is the reaction[9] of a lactam with phosphorus pentasulfide.

Cycloaddition of Isocyanides to 4,5-Dihydro-1,3,5-oxazaphosph(v)oles[**][1]

By *Klaus Burger* and *Josef Fehn*[*]

We recently reported [3+2]cycloadditions of 4,5-dihydro-1,3,5-oxazaphosph(v)oles *(1)*[2] to alkynes and alkenes[3]. We have now found an example of the very rare [3+1]-cycloaddition type[4]: Compounds *(1)* react with isocyanides in boiling benzene with elimination of phosphoric acid esters to give 1:1 adducts to which we ascribe the structures of substituted azetines *(2)* on the basis of spectroscopic data. The reaction could involve a nitrile ylide intermediate.

(1) *(2)*

Cpd.	Groups R $R^2 = CH_3$	M.p. (°C) B.p. (°C/torr)	Yield (%)	IR (cm^{-1})
(2a)	$R^1 = C(CH_3)_3$ $R^3 = C_6H_{11}$	58/0.2	80	1705, 1645 [a]
(2b)	$R^1 = C(CH_3)_3$ $R^3 = CH(CH_3)C_6H_5$	58/0.2	75	1705, 1645 [a]
(2c)	$R^1 = C_6H_5$ $R^3 = C_6H_{11}$	61	82	1705 [b]
(2d)	$R^1 = C_6H_5$ $R^3 = CH(CH_3)C_6H_5$	110/0.3	45	1700, 1630 [a]

Recorded [a] as films, [b] in KBr with a Perkin-Elmer Infracord.

Supporting evidence for structure *(2)* comes from the acid hydrolysis of *(2c)* to phenylglyoxylic acid as well as from the hydrogenation of the endocyclic double bond of *(2c)* with $LiAlH_4$ and acid hydrolysis of the resulting azetidine to *N*-(2,2,2-trifluoro-1-trifluoromethylethyl)phenylglycine cyclohexylamide.

2-Alkyl- and 2-aryl-1-azetines have become accessible only very recently by pyrolysis of cyclopropylazides[5]; hitherto only a few 2-alkoxy-, 2-alkylthio-, and 2-chloro-1-azetines derived from β-lactams were known[6].

A Facile Synthesis of 2-Alkynoic Esters[1]

By *Edward C. Taylor, Roger L. Robey,* and *Alexander McKillop*[*]

We report a facile one-step synthesis of 2-alkynoic esters *(5)* from the readily available 5-pyrazolones *(1)* by treatment with two equivalents of thallium(III) nitrate[2] in methanol. Yields are high and reaction conditions are extremely mild. Since 5-pyrazolones may be prepared in quantitative yield by the reaction of hydrazine with β-keto esters[3], this conversion represents in a formal sense the dehydration of β-keto esters to 2-alkynoic esters[4]. In fact, the direct conversion of β-keto esters into 2-alkynoic esters *(5)* without isolation of the intermediate 5-pyrazolones *(1)* can be achieved by treatment in methanol solution first with hydrazine and then with thallium(III) nitrate; comparable overall yields are obtained. Representative conversions are summarized in the Table.

We suggest that this transformation involves initial electrophilic thallation of the 3-pyrazolin-5-one tautomer *(2)*[5] to give *(3)*, which undergoes a subsequent oxidation by the second equivalent of thallium(III) nitrate to give the oxopyrazole *(4)*. Solvolysis by methanol, with concomitant elimination of nitrogen and thallium(I), yields the 2-alkynoic ester *(5)* directly. Previous observations that 5-pyrazolones mercurate at position 4[6] and undergo oxidation to oxopyrazoles[7] support this interpretation.

Table. Synthesis of 2-alkynoic esters *(5)* from 5-pyrazolones *(1)* with thallium(III) nitrate in methanol. Products were identified by comparison with authentic material and/or spectral data and yields determined by GLPC.

R	Yield (%)
CH_3	78
CH_2CH_3	95
n-C_3H_7	85
$CH_2CH(CH_3)_2$	85
n-C_5H_{11}	90
C_6H_5	67

Experimental

A solution of thallium(III) nitrate (0.021 mol) in methanol (25 ml) is added to a suspension or solution of the 5-pyrazolone (0.010 mol) in methanol (25 ml), and the reaction mixture is stirred for 15 min at room temperature and then for an additional 15 min at reflux (water bath). The cooled reaction mixture is filtered to remove precipitated thallium(I) nitrate and the filtrate diluted with water and extracted with chloroform. The extracts are washed with water, dried over anhydrous Na_2SO_4, filtered through a short column of Florisil and evaporated to give the pure (GLPC) 2-alkynoic esters.

Anodic Oxidation of Trihexylmethoxyborate in Presence of Butadiene[1][**]

By *Hans Schäfer* and *Dietrich Koch*[*]

Alkyl groups in borates can be dimerized with Ag(I)[2] or made to give alkyl-metal compounds by reaction with active anodes[4]; aryl groups in borates can be dimerized electrochemically[3]. In the course of our work on the anodic bifunctionalization of olefins[5] we have now been

[*] Doz. Dr. H. Schäfer and Dipl.-Chem. D. Koch
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

able to transfer anodically the hexyl group from trihexylborane to butadiene.

Voltammetric measurements on a 10^{-2} M solution of trihexylborane prepared *in situ* in the electrolyte 0.3 mol/l $NaClO_4$/0.5 mol/l $NaOCH_3$/methanol at a graphite disk anode[6] revealed the peak potentials: $E_p(1) = -0.04$ V and $E_p(2) = +0.3$ V (*vs.* Ag/AgCl). Comparison of the corresponding peak currents $i_p(1)$ and $i_p(2)$ with that of an aqueous solution of $K_4Fe(CN)_6$ shows that both oxidation steps involve transfer of a single electron.

The preparative electrolysis of hydroborated 1-hexene (50 mmol) and $NaOCH_3$ (80 mmol) in methanol employing a diaphragmless electrolysis cell with a graphite anode at an anode potential of $\leq +0.5$ V (*vs.* Ag/AgCl), a current density of 25 mA/cm^2, and a temperature of -5 °C affords dodecane *(3)* (25% current yield; 48% based on reacted borane). Under otherwise identical reaction conditions but at -20°C and in the presence of 0.63 mol/l of butadiene a 41% yield (based on reacted borane) of the following products is obtained: 9%[7] of dodecane *(3)*; 18% of 8-hexadecene *(6)*; 23% of 1-methoxy-2-decene *(8)*; 20% of 3-methoxy-1-decene *(9)*; 16% of 8,12-eicosadiene *(10)*; and 13% of 8-vinyl-10-octadecene *(11)*. Three isomeric dimethoxyoctadienes *(7)*, methoxy-substituted dimers of butadiene[8], are formed simultaneously in a current yield of 17%.

As a working hypothesis we assume that trihexylmethoxyborate *(1)*—and presumably also dihexylborate—and butadiene are oxidized simultaneously to the hexyl radical *(2)* and the butadiene radical cation *(4)*, respectively, which give *(3)* and *(7)* on dimerization and *(8)* and *(9)* on mixed coupling. The products *(6)*, *(10)*, and *(11)* could be formed by addition of *(2)* to butadiene and subsequent coupling of the primary adduct *(5)*; oxidation of *(5)* would give *(8)* and *(9)*. Formation of *(6)* and *(8)*—*(11)* by electrophilic attack of *(4)* on *(1)* is also conceivable.

The electrolysis of alkyl borates in the presence of olefins is of interest as a method for the alkylation of olefins. It complements the anodic addition of Grignard compounds[9] since it starts from alternative precursors and can be carried out in protic solvents. Owing to the lower anionic reactivity of the borates it should be possible to use boranes or olefins carrying substituents such as halogen, NO_2, COOR, or SO_2R.

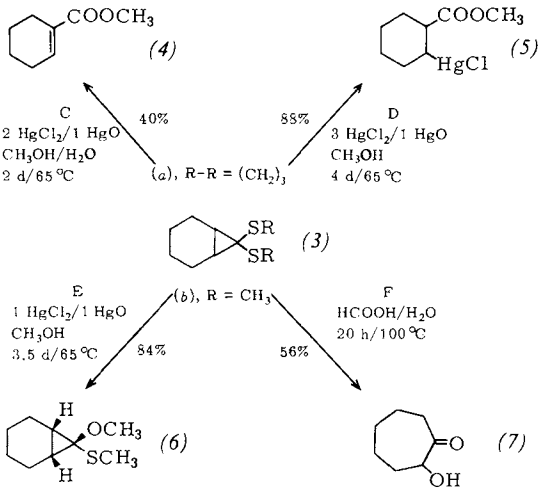
Solvolysis of 7,7-Bis(alkylthio)norcaranes. A New Method of Homologation

By *Dieter Seebach* and *Manfred Braun*[*]



Bis(alkylthio)cyclopropanes (cyclopropanone dithioacetals) *(1)* are readily available either from epoxides[1,2] (with extension by one carbon atom) or from α,β-unsaturated aldehydes[1,3] (with conservation of the carbon skeleton). Their solvolysis should produce derivatives *(2)* of acyloins[4]. Effectively, this would provide a means of "intermolecular"—route A—or "intramolecular"—route B—insertion of a carbonyl group between the carbons of a double bond.

Because of the potential synthetic value of such transformations we investigated the solvolytic behavior of the norcaranes *(3a)* and *(3b)* obtained from cyclohexene oxide

[*] Prof. Dr. D. Seebach and Dipl.-Chem. M. Braun
Institut für Organische Chemie der Universität Karlsruhe
Present address:
Institut für Organische Chemie der Universität

by a simplified procedure (see below). It turns out that the three-membered ring of these compounds, when subjected to the usual conditions[1] of neutral thioacetal hydrolysis or methanolysis, opens up (very slowly) either on the "wrong side" (reactions C and D) or not at all (reaction E), while the expected process takes place when the methylthio derivative is heated with aqueous formic acid (reaction F).

The structures of *(4)*—*(7)* were established as follows: *(4)* by comparison with an authentic sample; *(5)* (m.p. 88.5—89.0 °C) by $NaBH_4$ reduction to methyl cyclohexanecarboxylate; *(6)* (m.p. of sulfone 68.8—69.4 °C) by elemental analysis and spectroscopic data; and *(7)* by removal of the hydroxyl group (Zn/acetic acid) to give cycloheptanone, identical in every respect (IR, NMR, VPC, DNPH) with authentic material.

The cleavages C and D are caused by attack of $ClHg^{\oplus}$ at a cyclopropane C—C bond[5,6] of *(3)* rather than at sulfur, suggesting that compounds of type *(1)* might also, under certain conditions, serve as protective groups for "future" ester groups. The reaction leading to the formation of *(6)* is a rare[7] example of nucleophilic displacements at a cyclopropyl carbon atom.

The conditions of reaction F have not yet been optimized. Preliminary experiments show that the conversions of *(3)* described here are typical of other mono- and bicyclic cyclopropanes *(1)*.

α-Hydroxycycloheptanone (7) from cyclohexene oxide:

To a solution of bis(methylthio)methane (10.8 g, 100 mmol) in THF (120 ml) are added successively (inert atmosphere, stirring) *n*-butyllithium (110 mmol, 2 M in *n*-hexane; addition at −50 °C, reaction time 2.5 h at −25 °C), cyclohexene oxide (11.0 ml, 108 mmol; −78 °C, 15 h, 0 °C), toluenesulfonyl chloride (19.0 g, 100 mmol in 100 ml of THF; −78 °C, 6 h, 0 °C), and again *n*-butyllithium (110 mmol; −78 °C to −30 °C in 2 h, 20 h, 0 °C). Workup with pentane furnishes 15.2 g (81%) of *(3b)*, b.p. 65 °C/1 torr, m.p. of disulfone 87.8—88.4 °C.

A stirred mixture of *(3b)* (5.64 g, 30 mmol), formic acid (25 ml), and water (5 ml) is heated at reflux in a hood for 20—30 h. Pouring into water, extracting with dichloromethane, neutralizing with bicarbonate solution, and distilling gives 3.52 g of crude product, b.p. 91—94 °C/13 torr. 2.10 g [56% based on *(3b)*] of *(7)* are separated from the distillate by VPC (2 m, silicone on chromosorb, WAW-DMCS 60/70, 150 °C, 200 ml H_2/min, retention time 16 min), IR spectrum (neat): 3460, 2930, 2850, 1695, 1450, 1400, 1340, 1265, 1190, 1150, 1100, 1075, 1040, 1015, 1000, 930, 800 cm^{-1}.

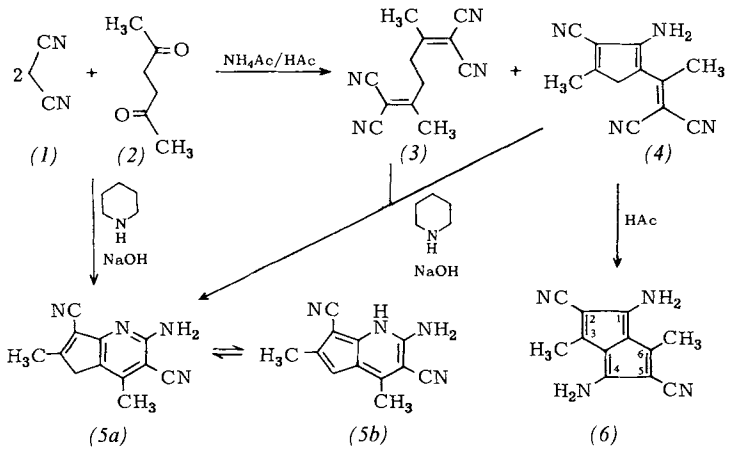
Aminopentalenecarbonitriles, a Group of Stable Pentalenes[**]

By *Klaus Hartke* and *Rudolf Matusch*[*]

Knoevenagel condensation of 2 mol. equiv. of malononitrile *(1)* with 1 mol. equiv. of 2,5-hexanedione *(2)* in the presence of NH_4Ac/HAc as catalyst in boiling benzene with constant removal of water yields the cyclopentadiene derivative *(4)* as a precipitate of yellow needles in 62% yield [*(4)*, m.p. 285 °C (decomp.); IR (KBr): 3425, 3344, 3257 (NH_2); 2222, 2208, 2188 (C≡N); 1661 (NH_2); 1613, 1534 cm^{-1} (C=C); NMR [D_6-acetone, δ (ppm)]: 2.43 (CH_3/s); 2.53 (CH_3/s); 3.87 (CH_2/s); 6.5—7.5 (NH_2/s)]. Shaking of the benzene phase several times with NaCl solution followed by removal of the organic solvent under mild conditions yields 8% of tetracyanohexadiene *(3)* [*(3)*, m.p. 127 °C; IR(KBr): 2232 (C≡N); 1577 cm^{-1} (C=C); NMR [D_6-acetone, δ(ppm)]: 2.43 (CH_3/s); 3.00 (CH_2/s)].



Brief boiling of *(3)* or *(4)* in ethanol in the presence of a few drops of alkali hydroxide solution or another base (*e.g.* piperidine, morpholine) converts it into the 1-pyrindine *(5a)*[1] for which we have been able to detect a solvent-dependent equilibrium with the tautomeric azalene *(5b)* by NMR spectroscopy.

Six hours' boiling of *(4)* in glacial acetic acid followed by removal of the solvent and sublimation of the residue (215 °C/0.1 torr) or chromatography on acidic alumina [first acetone/methylene chloride (1:1), then methanol] furnishes 1,4-diamino-3,6-dimethylpentalene-2,5-dicarbonitrile *(6)* in 40% yield. We deduce the pentalene structure

from the following information: Correct elemental analysis; M. W. 210 (mass spectrum); IR (KBr) 3436, 3413, 3356, 3311, 3257, 3236 (NH_2); 2193 (shoulder), 2179 (C≡N); 1667, 1647 (NH_2); 1587, 1550 cm^{-1} (C=C); [D_6-DMSO, δ(ppm)]: 2.07 (CH_3/s); 7.67 (NH_2/s, broad); UV [CH_3OH, $\lambda_{max}(\log\varepsilon)$][2]: 656 (3.55); 434 (4.18); 319 (4.39); 278 nm (4.86).

(1) (2) (3) (4) (5a) (5b) (6)

Compound *(6)* is the third example in the series of non-annelated pentalenes[5] that are stable at room temperature, *viz.* hexaphenylpentalene[3] and 1,3-bis(dimethylamino)-pentalene[4]. The unusual chemical and thermal stability of the pentalene *(6)*[6] probably arises from the push-pull effect of a strong electron acceptor and a strong electron donor attached to the ends of the two diene structures. In this respect compound *(6)* resembles the similarly stable 2,4-bis(dialkylamino)cyclobutadiene-1,3-dicarboxylic esters[7].

The condensation of other aliphatic 1,4-diketones (*e.g.* 2,5-heptanedione) with malononitrile also proceeds in accord with the reaction scheme shown. Cyclization of the cyclopentadiene precursor corresponding to *(4)* in glacial acetic acid gives 1,4-diamino-3-ethyl-6-methylpentalene-2,5-dicarbonitrile *(7a)* [blue-black needles, decomp. >330 °C]. Knoevenagel condensation of a typical aromatically substituted 1,4-diketone, dibenzoylethane, with malononitrile directly gives the 1-pyrindine derivative corresponding to *(5)*; we were not able to isolate a cyclopentadiene intermediate. However, if dibenzoylethane is refluxed for 24 h with malononitrile and piperidinium

(7a), $R^1 = CH_3$, $R^2 = C_2H_5$
(7b), $R^1 = R^2 = C_6H_5$

acetate in ethanol, chromatography of the residue left on evaporation of solvent on basic alumina with acetone under nitrogen yields about 2—3% of *(7b)* [blue-black crystals, decomp. >300 °C].

Simple Synthesis and NMR Spectroscopic Behavior of 1,2-Dihalo[18]annulene[1]

By *Gerhard Schröder*, *Rainer Neuberg*, and *Jean F. M. Oth*[*]

[18]Annulene, which was first prepared by *Sondheimer et al.*[2], exhibits temperature-dependent NMR spectra. At 60 MHz and −60 °C the spectrum corresponds to the structure (12 outer H at τ = 0.75, 6 inner H at τ = 12.9). At 120 °C (18 H as singlet at τ = 4.55) it reflects the prevailing dynamic situation[2]. The 17 protons of monosubstituted [18]annulenes exhibit less mobility[3]; in this case the 6 outer and the 6 inner protons are undergoing exchange while 5 outer protons retain their positions[3].

This dynamic situation, which may appear surprising at first glance, can be explained in the following way: In the case of [18]annulene three conformers of equal energy are in equilibrium with one another[2c, 3]. This number of conformers is reduced to two for monosubstituted[3] and 1,4-, 1,7-, and 1,10-disubstituted [18]annulenes[4]. For 1,2-, 1,3-, 1,5-, 1,8-, and 1,9-disubstituted annulenes the equilibrium is dominated by only one conformer, *i. e.* that having two outwardly directed substituents. Such disubstituted [18]-annulenes should exhibit NMR spectra *independent* of temperature[5].

We wish to report the synthesis of two 1,2-disubstituted [18]annulenes and their *temperature-independent* NMR spectra.

Dimeric cyclooctatetraene[6] *(1)* *(5g)* is heated with 1,1-difluoro-2,2-dichloroethylene (100 g) to 115 °C in an ampoule for *ca.* 70 h. Colorless crystalline *(3)*, m. p. 136 °C (from ethanol)[7], is formed in 21% yield (1.7 g) by way of a [2+2]cycloaddition of difluorodichloroethylene to a double bond of the cyclohexadiene system of *(2)*. *(2)* is a valence isomer of *(1)* and cannot be detected by spectroscopy in the presence of *(1)*. The double bonds of the six-membered ring system in *(2)* are thus considerably more reactive towards difluorodichloroethylene than those of the eight-membered ring in *(1)*. Compound *(3)* is dehalogenated to colorless crystalline *(4)* [yield 80%, m. p. 95 °C (from ethanol)[7]] on treatment with zinc powder in boiling ethanol. Irradiation of *(4)* (1.5 g) in ether (1.5 l) with a low-pressure UV lamp (2537 nm, quartz glass, 200 mA/500 V *ex* Gräntzel, Karlsruhe) at −70 °C ruptures the four "*endo*" σ bonds, probably successively, and a greenish-yellow ethereal solution results. After removal of the ether in a rotary evaporator the residue is taken up in a little chloroform. On standing in a refrigerator 1-chloro-

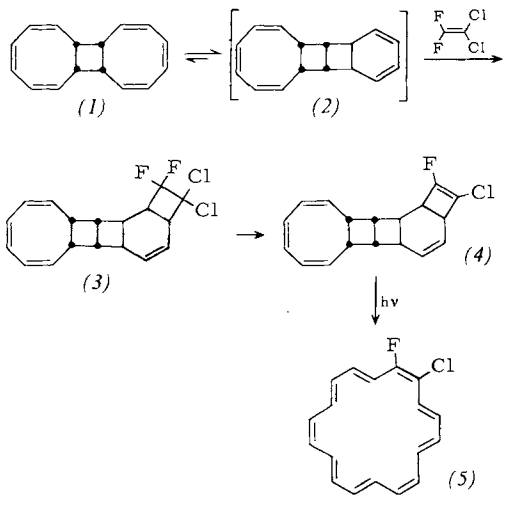
[1] Compound *(5)*, which was unknown at the outset of our investigations, has since been prepared by condensation of malononitrile and 2,5-hexanedione with piperidine or NaOH without isolation of intermediates: *H. Junek* and *R. J. Schaur*, Monatsh. Chem. *99*, 89 (1968).

[2] All the maxima found except that at 434 nm are in good agreement with recently published NNDO MO calculations for unsubstituted pentalene: 659, 335, 273, and 232 nm; cf. *N. C. Baird* and *R. M. West*, J. Amer. Chem. Soc. *93*, 3072 (1971).

[3] *E. Le Goff*, J. Amer. Chem. Soc. *84*, 3975 (1962).

[4] *K. Hafner*, *K. F. Bangert*, and *V. Orfanos*, Angew. Chem. *79*, 414 (1967); Angew. Chem. internat. Edit. *6*, 451 (1967).

[5] *R. Bloch*, *R. A. Marty*, and *P. de Mayo*, J. Amer. Chem. Soc. *93*, 3071 (1971), have recently been able to establish the existence of methylpentalene at −196 °C by spectroscopy; it dimerizes at as low a temperature as −140 °C.



[6] Pure samples of *(6)* remained unchanged after two years' storage at room temperature.

[7] *R. Gompper* and *G. Seybold*, Angew. Chem. *80*, 804 (1968); Angew. Chem. internat. Edit. *7*, 824 (1968); *M. Neuenschwander* and *A. Niederhauser*, Chimia *22*, 491 (1968); Helv. Chim. Acta *53*, 519 (1970).

[*] Prof. Dr. G. Schröder und Dipl.-Chem. R. Neuberg

75 Karlsruhe, Richard-Willstätter-Allee (Germany)

Prof. Dr. J. F. M. Oth,
Eidgenössische Technische Hochschule, CH-8006 Zürich (Switzerland)

2-fluoro[18]annulene *(5)*[7] crystallizes as reddish violet needles [330 mg, 22%; m. p. 210 °C (from $CHCl_3$; decomp.)]. The three-step synthesis of *(5)* from *(1)* is not only simple but also makes *(5)* accessible in gram quantities (overall yield 3.7%).

UV spectrum (in methanol) of *(5)*: $\lambda_{max} = 279$ (8600), 373 (210000), 453 nm (15000); $\lambda_{sh} = 410$ nm (8000).

The NMR spectrum of *(5)* at 35 °C exhibits a narrow multiplet centered at $\tau = 1.40$ (10 outer H) and several multiplets between $\tau = 11.66$ and 13.03 (6 inner H). At 100 °C the multiplets have neither lost their fine structure nor have they undergone broadening. The signal at low field is shifted slightly upfield ($\tau = 1.87$), those at high field are shifted slightly downfield (between $\tau = 10.0$ and 11.7). This temperature effect of the chemical shift was also observed for [18]annulene in the temperature range in which no exchange of resonance signals is visible (below −20 °C)[8].

If 1,1-difluoro-2,2-dichloroethylene is replaced by trifluorochloroethylene then the reaction yields 1,2-difluoro-[18]annulene, m. p. 200 °C (from $CHCl_3$; decomp.)[7], albeit in much poorer overall yield (≈0.8%); the compound also exhibits NMR spectra that are independent of temperature.

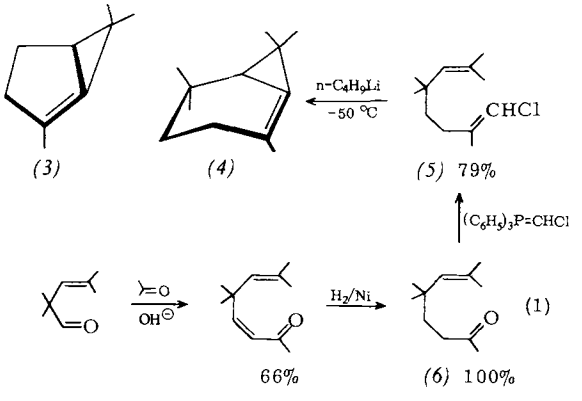
Bridged Methylenecyclopropanes as Test Cases for Bredt's Rule: 2,5,5,7,7-Pentamethylbicyclo[4.1.0]-hept-1-ene[**]



By *Gert Köbrich* and *Manfred Baumann*[*]

According to studies on molecular models, methylenecyclopropanes of type *(1)* ($n < 5$) having short-chain bridges are subject not only to the ring strain inherent in methylenecyclopropanes (41 kcal/mol[11]) but also to strong additional strain forces arising a) from planar and non-planar bond angle deformations of the σ skeleton and b) from the twisting of the π bond about the longitudinal axis of the double bond at the bridgehead. The same strain forces also operate in bicycloolefins such as *(2)*, whose behavior is described by Bredt's rule[2], and which were formerly not considered to include compounds *(1)* owing to the latters' "zero bridge"[3].

According to model considerations, the bicyclic compounds *(1)* and *(2)* having the same value of *n* should exhibit comparable overall strain [with different individual contributions from a) and b)]. The results obtained for the bicyclic compounds *(1)* should therefore provide information about the range of validity of Bredt's rule.

The hydrocarbon *(3)* [a trimethyl derivative of *(1)* with $n = 2$] has recently been detected as a short-lived intermediate[4]. We have now prepared the homolog *(4)* [a pentamethyl derivative of *(1)* with $n = 3$]. It is formed in 20 to 30% yield on carbenoid cyclization of the chloro

olefin *(5)* [prepared according to eq. (1)] with *n*-butyllithium in THF at −50 °C. The compound, which has not yet been isolated, decomposes in solution at room temperature with a half-life of about 70 h (gas chromatography) and is thus considerably more stable than *(3)*.

To establish the structure of *(4)* we converted it into the saturated bicyclic compound *(7)* ($n_D^{20} = 1.4585$) by treatment with diimine[5]; *(7)* was isolated by gas chromatog-

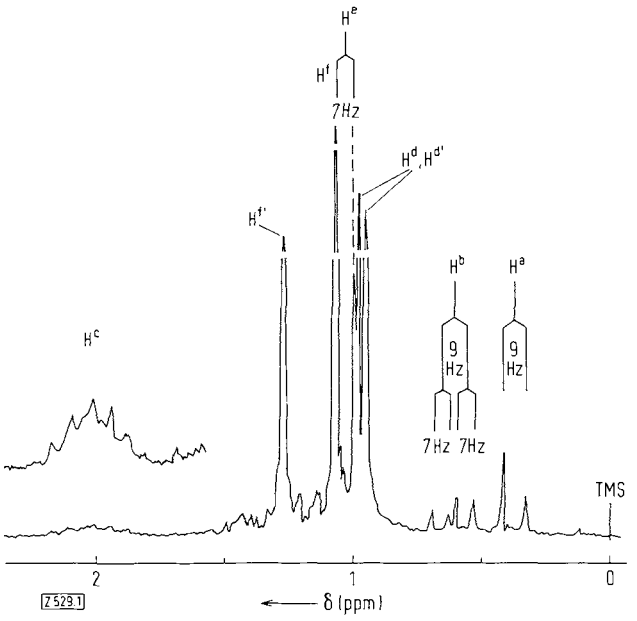

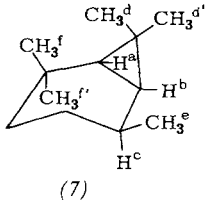

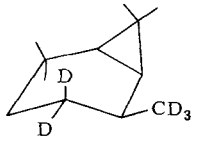

Fig. 100-MHz ^{1}H-NMR spectrum of 2,5,5,7,7-pentamethylbicyclo-[4.1.0]heptane *(7)* (in $CDCl_3$, chemical shifts referred to TMS).

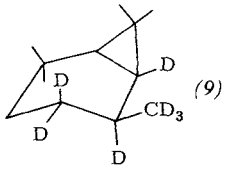
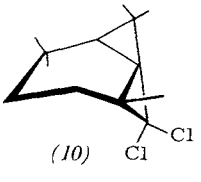


raphy and its empirical formula determined by analysis and mass spectrometry. In the NMR spectrum the protons H^a and H^b combined with H^c give a characteristic line system (Figure) with $J_{ab}=9.0$ Hz and $J_{bc}=7.0$ Hz which, as expected, simplifies to an unresolved triplet (D coupling) for H^a at 0.35 ppm in the case of the 1,2-dideuterio derivative [from *(4)* with $[D_2]$diimine]; moreover, the H^c multiplet at 2.0 ppm disappears. The position of the double bond at the bridgehead is thus clearly established.

(7)



(8)

(9)

Starting from the ketone $[D_5]$-*(6)* bearing deuterium labels at the α and α′ positions we prepared $[D_5]$-*(4)*, which gave *(8)* and *(9)* on treatment with diimine and with dideuteriodiimine respectively. The CH_3^e doublet of *(7)* at 1.03 ppm ($J=7$ Hz; the peak at lower field is masked by the CH_3^f singlet at 1.07 ppm; these signals are resolved in the 60 MHz spectrum) is absent in the NMR spectrum of *(8)*; the H^c multiplet of *(7)* appears as a broad doublet for *(8)*. *(9)* shows the same H^a signal as *(8)*; the four different

(10)

methyl groups are seen as four singlets at 0.96 and 0.98 (CH_3^d, $CH_3^{d'}$)[6], 1.07 (CH_3^f), and 1.28 ppm ($CH_3^{f'}$).

In spite of its strained double bond, compound *(4)* exhibits only a slight tendency to undergo cycloadditions; it either fails to react or gives undefined products with phenyl azide, furan, and diazomethane—presumably owing to the strong repulsion between the methyl groups CH_3^d and CH_3^f in the hypothetical cycloadducts. Dichlorocarbene (from $LiCCl_3$), however, reacts readily to give the bridged spirane *(10)* whose structure is supported by spectroscopy.

Our findings suggest that the hitherto unknown bicyclic compounds *(2)*, $n=2$ and 3, have finite though limited lifetimes.

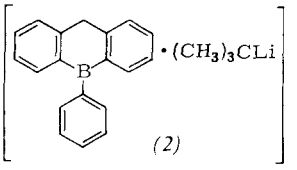
Preparation of the 9-Phenyl-9-boraanthracene Anion[**]

By *Peter Jutzi*[*]

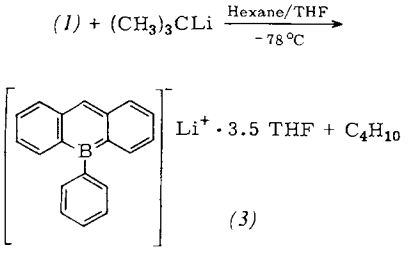


π-Bonds between boron and carbon, which command considerable theoretical interest, are hardly known: The preparation of a highly unstable 9-boraanthracene-dimethylsulfane adduct[1] and of the free[2] and complexed[3] 1-phenyl-1-borabenzene anion have only been accomplished very recently[11].

Depending on the reaction conditions the reaction of 9-phenyl-9,10-dihydro-9-boraanthracene *(1)*[4] with *tert*-butyllithium can yield different products:

In hexane as solvent the reactants form the Lewis acid-base pair *(2)* almost quantitatively; *(2)* can be isolated as a very reactive crystalline substance[5].

(1)



(2)

In hexane/tetrahydrofuran (1:1) compound *(1)* is metalated in position 10; the orange-red ion pair *(3)* containing the 9-phenyl-9-boraanthracene anion crystallizes from the initial oily product.

[*] Dr. P. Jutzi
Institut für Anorganische Chemie der Universität
87 Würzburg, Landwehr (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

(3) is stable when stored in an inert gas but decomposes when exposed to air and moisture. The coordinated THF molecules cannot be removed by reduction of pressure (1 torr) for several hours: the ratio THF/Li remains constant at 3.5:1. The structure of *(3)* follows from spectro-

scopic data. Thus the ^{1}H-NMR spectrum gives the required ratios for the various protons (Table). An expected upfield shift for C_{10}-H in *(3)* is largely compensated by anisotropic or weak ring-current effects. The diamagnetic shift of the THF protons in *(3)* can also be interpreted in terms of anisotropic and ring-current effects. The enhanced electron density on the sp^2-hybridized boron atom in *(3)* due to the π-bond—and the resulting partial negative charge—become clearly apparent on comparison of the ^{11}B-NMR spectra[6] of *(1)* and *(3)* (Table): In the anion the resonance signal is shifted upfield by 68 ppm.

Table. ^{1}H- and ^{11}B-NMR spectra of tetrahydrofuran, *(1)*, and *(3)*.

Cpd.	Phenyl-H	C_{10}-H	THF protons α	THF protons β	^{11}B
THF	—	—	−3.52	−1.43	—
(1)	−(8.10–6.91)	−4.14	— [7]	—	−58
(3)	−(7.83–6.89)	−4.05	−3.10	−1.28	+10

Ca. 30% solution in C_6D_6; chemical shifts in ppm relative to TMS as internal standard and $BF_3 \cdot OEt_2$; a negative sign indicates a downfield shift.

The electronic spectra of the 9-boraanthracene-dimethylsulfane complex[11] and of *(3)* are reproduced in Fig. 1. The characteristic form of the curve is almost identical in both cases, though it is shifted to longer wavelengths in the case of *(3)*.

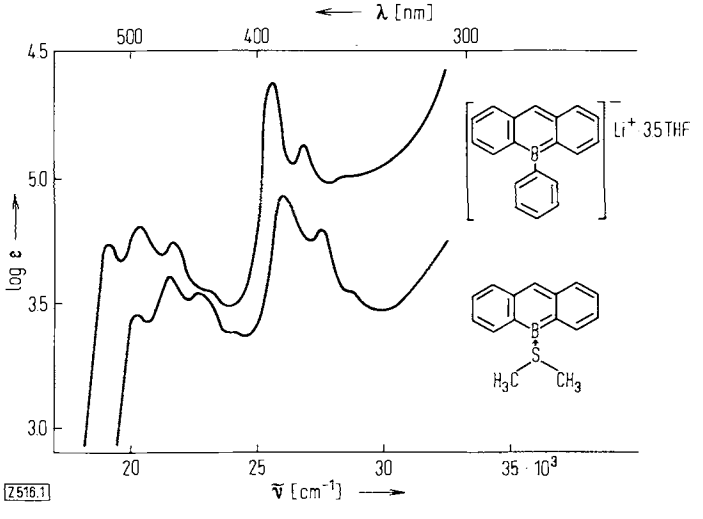


Fig. 1. Electronic spectra of the 9-boraanthracene-dimethylsulfane complex and of compound *(3)* recorded in tetrahydrofuran [8].

The structures of the long-wave absorption maxima in the spectra of anthracene (^{1}La band), 9-phosphaanthracene[9], 9-arsaanthracene[10], and 9-boraanthracene are very similar and provide a clear indication of comparable 14 π-electron systems. The bathochromic shifts of the curves, which increase in the above order, are presumably due to the decreasing electronegativity of the hetero atoms in position 9.

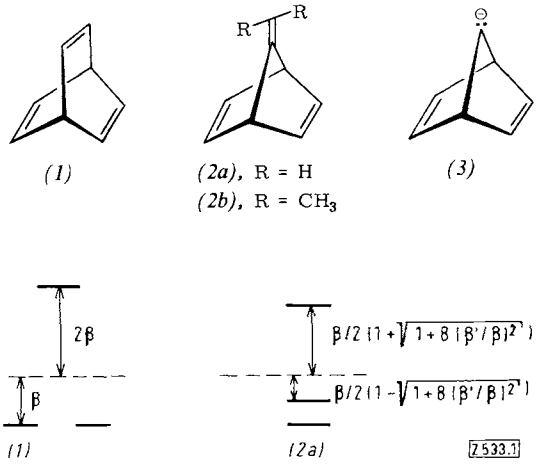
7-Isopropylidenenorbornadiene

By *Hans-Dieter Martin* and *Dieter Forster*[*]

In the present communication we report a bicyclic triene having formally isolated double bonds whose spectroscopic properties indicate a considerable measure of homoconjugation[1].



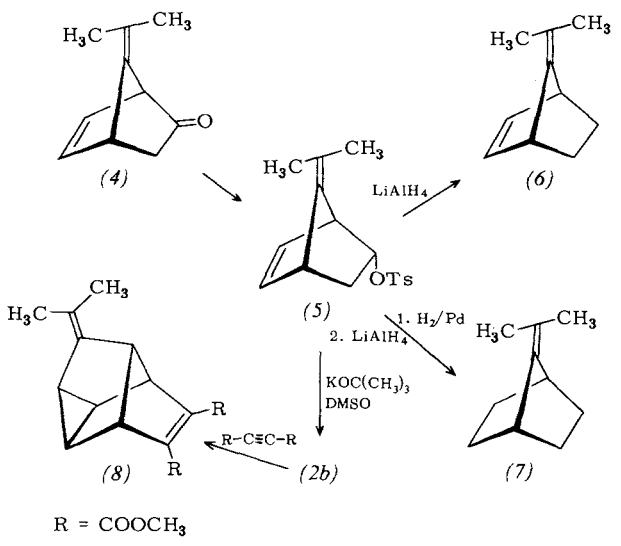


Fig. 1. Hückel eigenvalue schemes of *(1)* and *(2a)*. β is the resonance integral for homoconjugation in barrelene *(1)* and in the norbornadiene part of *(2a)*; β' refers to the interaction of the 7-methylene double bond with the two endocyclic π bonds in *(2a)*. Equal energies have been assumed for all three basis orbitals.

[*] Dr. H.-D. Martin and D. Forster
Institut für Organische Chemie der Universität
78 Freiburg, Albertstrasse 21 (Germany)

The tosylate *(5)* was prepared by way of the ketone *(4)*[6]; dehydrotosylation of *(5)* to *(2b)* (15–20% yield) with potassium *tert*-butoxide was carried out in dimethyl sulfoxide at 70 °C. *(5)* could also be reduced directly to *(6)* (74% yield) by $LiAlH_4$ in ether; if reduction is performed after prior hydrogenation[6] of *(5)* then *(7)* is obtained in 82% yield.

The most important data for these compounds are collected in the Table. *(2b)* is a weakly yellow liquid[8] which has a peculiar odor and survives 24 hours' heating at 100 °C. Together with dimethyl acetylenedicarboxylate at 100 °C it gives the adduct *(8)* in a kind of homo-Diels-Alder reaction [NMR data of *(8)* (see also footnote [b] to the Table): $\tau = 6.15$ (s), 7.05 (m), 7.35 (m), 7.75 (t), 8.15 (m), 8.27 (s), 8.35 (s)].

Photoelectron spectroscopic studies[9] on *(2b)* revealed a high degree of cyclic homoconjugation. If the *exo*-isopropylidene bond in *(2b)* is assumed to have a basis

[c] Column, temperature, retention time (helium, 170 ml/min).
[d] In ether.

If a further double bond approaches a 1,4-cyclohexadiene system then the possible arrangements include two particularly significant ones: Barrelene *(1)* and 7-methylenenorbornadiene *(2a)*, which is iso-π-electronic with the hitherto unknown longicyclic[2] anion *(3)*. The Hückel eigenvalue schemes of *(1)* and *(2a)* are depicted in Figure 1.

Whereas adequate information is available regarding the electronic system of *(1)*[3], there is a dearth of comparable data for system *(2)*. Hitherto reference has been made only to the interesting electron-spectroscopic properties of various substituted methylenenorbornadienes that are readily available by diene synthesis[4]. The vapor pressure of these compounds was too low, however, for gas phase spectroscopic studies.

Attempted syntheses of the more symmetrical and relatively volatile 7-isopropylidenenorbornadiene *(2b)* by oxidative decarboxylation of the maleic acid/dimethylfulvene adduct (electrochemically and with lead(IV) acetate) have so far been unsuccessful[5]. We chose a synthetic pathway leading *via* the tosylate *(5)*, from which the partially hydrogenated derivatives *(6)* and *(7)* (essential for detailed spectroscopic analysis) could also be obtained.

energy ($E = -3\beta/2$) differing from that of the two other double bonds ($E = 0$), more in line with the actual conditions prevailing, then the expression for the energy of the highest

Bridgehead Reactivities of Trishomobarrelene and Trishomobullvalene[**]

By *Armin de Meijere, Otto Schallner*, and *Christian Weitemeyer*[*]

The extent to which a carbonium ion is stabilized by α-cyclopropyl substituents depends upon the orientation of the cyclopropane rings relative to the axis of the adjacent vacant p orbital of the carbonium ion[1]. Whereas the tricyclopropylmethyl cation is about as stable as the triphenylmethyl cation[2], destabilization is observed in a

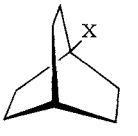
(1) *(4)*, 30%

(2)

(3a), X = O-OH
(3b), X = OH 10%
(3c), X = CCl_2H 60%
(3d), X = Cl 30%

case in which the plane of the cyclopropane ring and the axis of the vacant p orbital are held perpendicular to each other[3]. In "trishomobarrelene" *(1)* and "trishomobullvalene" *(2)*[4] the "propeller"-cyclopropane rings are arranged in such a way that a partial stabilization of the corresponding bridgehead carbonium ions should result.

Bridgehead substituted derivatives of *(1)* and *(2)* are accessible by radical substitution reactions. *(2)* is readily autoxidized; upon standing in the presence of air the hydroperoxide *(3a)* is formed. *(3a)* decomposes upon heating to 100 °C to give the alcohol *(3b)*, m.p. 183 to 186 °C, which could be isolated in 10—15% yield by gas chromatography. The reaction of *(2)* with dichlorocarbene, generated by the method of *Makosza* and *Wawrzyniewicz*[5, 6], gave a 60% yield of the dichloromethyl derivative *(3c)*, m.p. 91 °C. Photochlorination of *(2)* in carbon tetrachloride with *tert*-butyl hypochlorite at −20 °C yielded 30% of pure 1-chlorotrishomobullvalene *(3d)*, m.p. 128—129 °C. 1-Chlorotrishomobarrelene *(4)*, m.p. 114 to 116 °C, could be obtained analogously in the same yield.



The NMR- and mass spectra as well as elemental analyses of compounds *(3b)*—*(3d)* and *(4)* are in accord with the proposed structures.

The exclusive substitution at the bridgehead positions in *(1)* and *(2)* observed in the reported reactions suggests a special reactivity of these positions. In order to obtain some information about the stabilization of the bridgehead carbonium ions of *(1)* and *(2)*, we measured the half-reaction times of the solvolysis of *(3d)* and *(4)* in 90% aqueous ethanol[7]. The rate constants which were estimated from these data (see Table 1) indicate that at 25 °C *(4)* reacts about 300 times faster than *tert*-butyl chloride *(5a)* and more than 10^9 times faster than 1-chlorobicyclo[2.2.2]octane *(6a)*[8].

(3d) is so reactive that it is readily hydrolyzed to the alcohol *(3b)* upon exposure to moist air; in 90% aqueous ethanol even at 0 °C it is solvolyzed so rapidly that the half-reaction time could not be measured very accurately. At 0 °C *(3d)* reacts more than 10^{11} times faster than *(6a)* at 25 °C.

The geometry of *(1)* and *(2)* which is pertinent to this reactivity may be estimated from NMR-spectroscopic data (see Table 2). The $^{13}C,H$ coupling constants indicate that the bridgehead carbon in *(2)* is sp^3 hybridized whereas the bridgehead C—H bond in *(1)* exhibits a slightly higher

[a] Estimated from the measured half-reaction time.

s character, *i.e.* the C—C—C angles at the bridgehead in *(1)* are smaller than in *(2)*. The dihedral angles (φ_{HH}) between the bridgehead protons (H^a) and the adjacent tertiary cyclopropyl protons (H^b) can be estimated from the vicinal coupling constants ($^3J_{HH}$) between the two[11] (see Table 2). The angle between the plane of a cyclopropane ring and a vacant bridgehead p orbital ($\varphi_{p-\pi}$) is approximately $90°-\varphi_{HH}$. Since the energy of interaction between two π-electron systems is proportional to $\cos^2\varphi$ of the torsional angle φ between the two[12], one may derive the crude approximation that the stabilization of the bridgehead carbonium ion per α-cyclopropyl group in *(1)* should be about 67% and in *(2)* about 45% of the greatest possible stabilization.

The experimentally determined reactivities of *(3d)* and *(4)* are in satisfactory agreement with these estimates.

(2)	127	25 [a]	5.44	42	48 [14]	0.45

[a] Calculated from the equation $\% s = J_{^{13}C,H}/500$ [13].

Although the effect of stabilization in *(4)* is predicted to be larger than in *(3d)*, the latter reacts about 10^2 to 10^3 times faster than *(4)* because the bridgehead in *(3d)* is less strained and therefore the corresponding carbonium ion should more readily attain planarity.

[14] *Note added in proof* (Dec. 5, 1971): An electron diffraction structure analysis of *(2)* has indicated that the angle $\varphi_{p-\pi}$ is actually about 65°, *i.e.* larger than the crude estimate obtained from the H,H-coupling constant. This will probably also apply to *(1)* (*B. Andersen*, *A. de Meijere*, and *O. Schallner*, unpublished results).

Mössbauer Measurements on Neptunium(VII) Compounds[**]

By *Klaus Fröhlich*, *Philipp Gütlich*, and *Cornelius Keller*[*]

Until a few years ago neptunium(VII) compounds were unknown. Recently, a number of neptunium compounds were prepared, which, on the basis of the preparation method and stoichiometric composition, are supposed to contain heptavalent neptunium (nominal valency with electronic configuration $[Rn]5f^0 6d^0 7s^0$)[1-6]. We have carried out Mössbauer measurements on a few of these compounds, namely Li_5NpO_6 *(1)*, $[Co(en)_3]NpO_5 \cdot xH_2O$[7] *(2)*, $Ba_3(NpO_5)_2 \cdot xH_2O$ *(3)*, and $Ca_3(NpO_5)_2 \cdot xH_2O$ *(4)*, to prove the oxidation state of the neptunium and to learn more about the structural and bond properties[8].

All measurements were made with source and absorber at 4.2 K. The compounds were used as absorber and the source was an alloy of ^{241}Am (5%) in thorium metal.

A more negative isomer shift (δ) than that for NpF_6 was obtained for all the materials studied (see Table). [According to previous Mössbauer spectroscopic investigations of neptunium(VI) compounds, NpF_6 is the most ionic in character and consequently exhibits the most negative isomer shift: its value, $\delta = -58$ mm/s (relative to NpO_2)[9], is the lower limit of the assumed characteristic isomer-shift range for Np^{VI} compounds.] Since $\Delta\langle r^2\rangle/\langle r^2\rangle$ for ^{237}Np is negative[10], it follows from the δ values that the electron density at the neptunium nucleus of the compounds under investigation is greater than in the case of NpF_6. In the oxygen-bonded compounds the valence electrons of the oxygen, which tends to be more covalent than fluorine, mainly occupy orbitals of the neptunium atom which shield s electrons from the nucleus. The covalent contribution to the Np—O bonding must introduce additional shielding to the s electrons of the central neptunium atom and thus lead to a lower electron density at the Np nucleus in Np—O compounds compared to Np—F compounds. The higher electron densities following from the measured δ values can be adequately explained only by the presence of heptavalent neptunium. The absence of the last 5f electron in Np(VII)—compared to Np(VI)—results in a weaker shielding of the s electrons (mainly on the 6s shell) and thus leads to the observed increase in electron density at the Np nucleus.

Table. Isomer shift (δ), quadrupole splitting (ΔE_Q), and asymmetry parameter (η) of neptunium compounds *(1)*—*(4)*. Source ($^{241}Am/Th$) and absorber at 4.2 K.

Absorber	δ [a] [mm s^{-1}]	ΔE_Q [mm s^{-1}]	η
(1)	-68.7 ± 2.9	15.3 ± 0.5	0.33 ± 0.01
(2)	-61.1 ± 2.6	44.6 ± 1.0	0.23 ± 0.02
(3)	-60.2 ± 2.8	43.2 ± 1.0	0.40 ± 0.03
(4)	-60.7 ± 3.0	33.7 ± 1.0	0.38 ± 0.03

[a] Isomer shift relative to NpO_2.

The occurrence of quadrupole splitting ΔE_Q (see Table) in the case of Li_5NpO_6 *(1)* disproves the previously presumed O_h symmetry of the NpO_6^{5-} ion[5,6]. Present findings are more consistent with a compressed octahedron (neptunyl group in the *z* direction). The deviation of the asymmetry parameter η from zero (see Table) indicates that the central Np atom is not situated at the symmetry center (*e.g.* due to presence of a non-linear neptunyl group) or that the *xy* plane formed by oxygen atoms is rhombically distorted.

The ΔE_Q values for compounds *(2)*, *(3)*, and *(4)* are two to three times greater than the value for *(1)*. This is explained as being due to the Np—O bond lengths of the neptunyl group in these compounds being shorter than in Li_5NpO_6. The more positive δ values measured for these three compounds support this explanation. The deviations of the η values from zero suggest that the common anion formed by all three compounds is $[NpO_4(OH)_2]^{3-}$ and not NpO_5^{3-}. The presence of both *trans*-O atoms and *trans*-OH groups in this anion in addition to the neptunyl group readily explains the observed values of the quadrupole splitting and asymmetry parameters (the two Np—O bond lengths in the *xy* plane are smaller than the Np—OH dis-

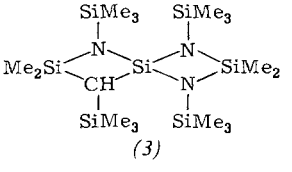
Two Crystal Structures of Cyclic Silicon-Nitrogen Compounds with Different Disorder[**]

By *Dietrich Mootz, José Fayos*, and *Annette Zinnius*[*]



Dropwise addition of silicon tetrachloride to sodium bis(trimethylsilyl)amide at 200 °C gives the compound $C_{17}H_{49}N_3Si_7$, whose structure could not for a long time be determined unequivocally by chemical and spectroscopic methods[1]. We have carried out an X-ray crystal structure analysis of this substance in an attempt to decide between the formulas *(1)* and *(2)*, proposed to be equally probable. The results indicate that both these formulations can be ruled out in favor of a four-ring spirane structure *(3)*.

[**] These investigations were supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. They were carried out at the Institut für Anorganische Chemie der Technischen Universität Braunschweig. We are indebted to Prof. Dr. *U. Wannagat* for posing the problems and supplying the crystals.

The substance crystallizes in the orthorhombic system with $a = 19.552$, $b = 33.518$, and $c = 10.196$ Å; $d = 0.97$ g cm^{-3}. Hence, by calculation, the unit cell contains $Z = 8$ (7.93) $C_{17}H_{49}N_3Si_7$ molecules. This number and the observed space group Fddd-D_{2h}^{24} as lowest symmetry of the molecule in the crystal necessitate the point group 222-D_2, which, in principle, is not realized by formulas *(1)* and *(2)*, but very closely approached by formulation *(3)*. Consequently, the further structural analysis had to be carried out on the basis of a four-fold superposition of structure *(3)*, which leads to statistical equivalence of the three N atoms and the CH group of the spiro system. However, because of the different stereochemistry of N and CH, such a superposition does not give *exact* coincidence of these and all other, especially the outer, atoms. As a consequence of this, and of a further disorder in the orientation of the trimethylsilyl group, the accuracy of the analysis is limited.

Reflection intensities were measured on an automatic single crystal diffractometer fitted with punched-tape control (AED, *W. Hoppe*, *ex* Siemens) using $Cu_{K\alpha}$ radiation and the θ:2θ scan technique ($\theta_{max} = 50°$). Conventional methods were used for solving the structure. Refinement with anisotropic thermal parameters led to R factors of 0.071 for 591 observed reflections alone, and 0.088 on inclusion of 236 "unobserved" data. The bond lengths and angles thus obtained [bond lengths: Si—N(C) = 1.74 Å (in and at the spirosystem; three independent measurements) and Si—C = 1.82 Å; bond angles: N(C)—Si—N(C) = 88° (two independent measurements in the four-membered ring), Si—N(C)—Si = 92° in the ring and 130 and 138° at the ring, and C—Si—C = 104° at the ring] support this structure and disorder model (standard deviations *ca.* 0.01 Å and 1°).

(4)

Hexachlorocyclotrisilazane *(4)* can be prepared by controlled ammonolysis of silicon tetrachloride[2]. Its IR spectrum indicated a planar six-membered ring structure with point group $\bar{6}m2$-D_{3h}[3]. A crystal structure analysis carried out by us in an attempt to gain further information about the architecture of this purely inorganic Si—N compound once again led to a disordered structure adversely affecting accuracy of analysis.

The X-ray photographs show diffuse ($h - k \neq 3n$) reflections as well as sharp ($h - k = 3n$) reflections, indicating an order-disorder (OD) structure. The symmetry is hexagonal (Laue group 6/mmm). Only the sharp reflections were used for determination of structure (102 data, $Cu_{K\alpha}$, $\theta_{max} = 70°$, diffractometer). The superimposed structure defined by this data has the lattice constants $A = 4.554$ and $C = 11.766$ Å and contains 2/3 molecules in the unit cell. Of the three space groups $P6_3mc$, $P\bar{6}2c$, and $P6_3/mmc$ that are possible on the grounds of the single extinction $0KL$ with $L = 2n$, the last, centrosymmetric one was assumed in order to provide the relatively best resolution for the superimposed structure. Thus, from the outset, the molecular symmetry was restricted to $\bar{6}m2$-D_{3h}. The determination and refinement of the atomic positions—which could be carried out by conventional methods—led to the following plausible bond lengths and angles: Si—N = 1.68, Si—Cl = 2.03 Å; Si—N—Si = 131°, N—Si—N = 109°, and Cl—Si—Cl = 103° (standard deviations *ca.* 0.01 Å and 1°; R-factor 0.093).

The molecules form layers perpendicular to the *c*-axis and rotated through 60° to one another. Thus, a layer B′ *or* a layer C′ can follow a layer A without influencing the interatomic distances and angles between adjacent layers (see Figure; the dash signifies rotation with respect to the start-

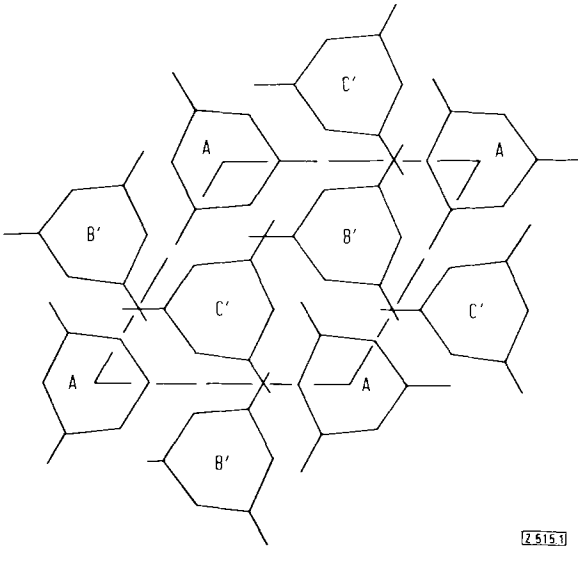

Fig. Disorder of hexachlorocyclotrisilazane.

ing layer; the outlined rhombus is the basal plane of the unit cell defined by *all* reflections). Stacking faults of this type give the structure its OD character.

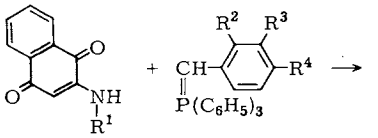
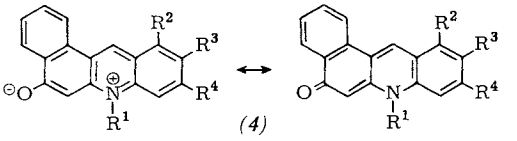
A Novel Method for the Synthesis of Acridinium Betaines



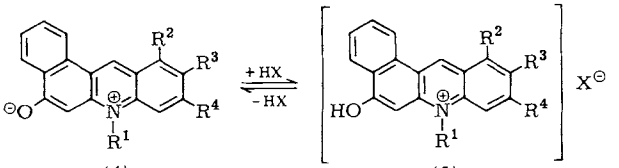
By *Hans-Jürgen Bestmann, Hans-Jochen Lang,* and *Werner Distler*[*]

During the course of our investigations on reactions of quinones with ylides we were able to isolate the red quinone methide *(3)* from the reaction of 2-anilino-1,4-naphthoquinone *(1a)* with benzylidenetriphenylphosphorane *(2a)*[1].



(1a) *(2a)* *(3)*

We have now found that reaction of naphthoquinones *(1a)*—*(1c)* with phosphoranes *(2a)*—*(2c)* leads, under more drastic conditions, to the new class of compounds of the benzo- or dibenzoacridinium betaines *(4)*. *(4)* can be described by two mesomeric limiting formulas.



(1a), $R^1 = C_6H_5$ *(2a)*, $R^2 = R^3 = R^4 = H$
(1b), $R^1 = CH_3$ *(2b)*, $R^2 = R^3 = H$, $R^4 = OCH_3$
(1c), $R^1 = C_2H_5$ *(2c)*, $R^2, R^3 =$  , $R^4 = H$

(4)

On treatment with hydrochloric acid or trifluoroacetic acid, compounds *(4)* are converted into the acridinium salts *(5)*; the conversion is reversible.

All compounds of type *(4)* are orange to dark-red and fluoresce exceptionally strongly in polar solvents. Proof of structure for *(4)* followed from elemental analysis, IR

(4) *(5)*

and mass spectra, and from the fact that distillation of 10-phenylbenzo[*a*]acridinium-3-olate *(4aa)* in the presence of zinc dust gives benz[*a*]acridine, which is identical with authentic material[2].

Table. Acridinium betaines *(4)* from 2-amino-1,4-naphthoquinone *(1)* and benzylidenetriphenylphosphoranes *(2)*.

Cpd.	R^1	R^2	R^3	R^4	Yield (%)	M.p. (°C)	Color
(4aa)	C_6H_5	H	H	H	20	270	orange-red
(4ab)	C_6H_5	H	H	—O—CH_3	11	280	orange
(4ac)	C_6H_5	—$(CH)_4$—		H	42	293	red-brown, metallic luster
(4bc)	$-CH_3$	—$(CH)_4$—		H	46	285	red
(4cc)	$-C_2H_5$	—$(CH)_4$—		H	11	253	dark-red, metallic luster

Experimental:

(1a) (50 mmol; 12.5 g) is added portionwise with stirring under nitrogen to a salt-free solution of the ylide *(2a)* (50 mmol) in anhydrous xylene[3]. The reaction mixture is heated under reflux for five days. The solvent is then distilled off and the residue boiled in benzene (100 ml). On rubbing the benzene solution and allowing it to cool in the refrigerator, a crude crop of *(4aa)* is precipitated which is then purified by reprecipitation from chloroform/petroleum ether and recrystallization from ethyl acetate. All the compounds *(4)* mentioned above were prepared analogously.

The acridinium chlorides of type *(5)* are obtained in almost quantitative yields by treatment of compounds *(4)* with

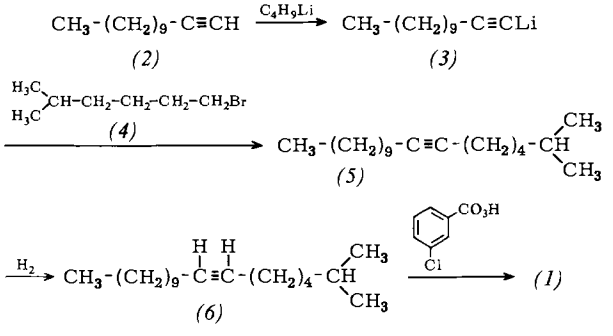
Novel Total Synthesis of the Sex Attractant of *Porthetria dispar* (7,8-*cis*-Epoxy-2-methyloctadecane)

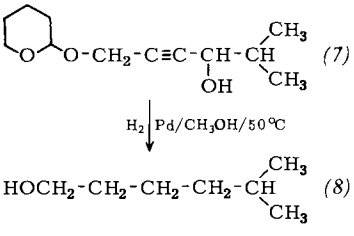


By *Karl Eiter*[*]

Bierl, Beroza, and *Collier*[1] isolated the sex attractant of the gypsy moth *(Porthetria dispar, Lymantria dispar)*, determined its structure and composition as 7,8-*cis*-epoxy-2-methyloctadecane *(1)*, and successfully carried out its total synthesis.

(1)

We have now tried to synthesize large amounts of this substance in a sterically homogeneous form in order to test its suitability as an attractant or decoy in combating this destructive insect. In view of the demands of modern environmental pollution control, this approach to the problem of pest control can be considered of utmost importance.



(2) *(3)* *(4)* *(5)* *(6)* *(1)*

For the synthesis of *(1)* we chose the following route:

$$C_{10} + C_2 = C_{12}, \qquad C_{12} + C_7 = C_{19}$$

A mixture containing small amounts of 1-dodecyne *(2)* has already been described[2]. We obtained pure, halogen-free 1-dodecyne in more than 70% yield by the following route: A molar amount of Na-acetylide, freshly prepared from a suspension of Na in anhydrous THF, was treated with an equal amount of 1-bromodecane dissolved in dimethyl formamide that had been distilled over CaH_2. THF was distilled off under pure N_2 until reaction at an internal temperature of 110°C proceeded exothermally. According to gas chromatography the distilled 1-dodecyne *(2)* was 96% pure. Under Zerewitinoff conditions, *(2)* gave only about 0.28% active hydrogen (calc. 0.605%). For the alkylation, *(2)* was treated in diethylene glycol dimethyl ether with an equimolar solution of *n*-butyllithium in *n*-hexane; the *n*-hexane was subsequently removed by distillation under pure N_2, and metalation to *(3)* brought to completion by eight hours' heating at 120—130°C. Introduction of isoheptyl bromide *(4)* and further reaction at 130°C (8 h) gave, after working-up, 96%[3] 2-methyl-7-octadecyne *(5)* in 50% yield. The molecular ion appears in the mass spectrum in only low intensity; the fragments occurring in the spectrum prove that degradation takes place from the unbranched end of the chain to the triple bond. The NMR spectrum shows a characteristic multiplet for $-C\equiv C-CH_2$ protons at $\delta = 2.1$ ppm (4H/m); the CH_3 protons appear at 0.80 (3 H/s) and 0.89 ppm (6 H/s), and the remaining 23 protons between 1.02 and 1.75 ppm. As is to be expected the IR spectrum [1460 (s), 1360, 1380, 1330, 760, and 725 cm^{-1}] shows no acetylene bonds in the region around 2100 cm^{-1}.

(7) *(8)*

The isoheptyl bromide *(4)* was prepared from 5-methyl-1-hexanol *(8)*, which we obtained directly in 50% yield by a novel reaction—hydrogenation of 6-(tetrahydropyran-2-yloxy)-2-methyl-4-hexyn-3-ol *(7)*. *(7)* is accessible in satisfactory yield from 3-(tetrahydropyran-2-yloxy)-1-propyne and isobutyraldehyde by organometallic reaction.

Specific *cis*-hydrogenation of the triple bond of 2-methyl-7-octadecyne *(5)* with a modified Lindlar catalyst (5 g 1%-$Pd/CaCO_3$ catalyst poisoned with 0.02 g lead acetate) proceeds exceptionally smoothly. In low-boiling petroleum ether as solvent, the calculated amount of hydrogen was taken up at about 25°C and hydrogenation terminated automatically; the 96%-pure 2-methyl-7-*cis*-octadecene *(6)*, which was obtained in quantitative yield, is an oil that is distillable under high vacuum and does not show any bands in the region of 960 cm^{-1} of its IR spectrum—proof that no symmetrically substituted *trans* ethylene bond is present. Since the olefinic protons are magnetically equivalent, no conclusions can be drawn from either the 60-MHz or the 220-MHz spectrum regarding symmetry. In the NMR spectrum three methyl groups are observable at $\delta = 0.91$ (s) and 0.81 ppm (s), and signals for 11 CH_2 groups and a C—H group occur as a multiplet in the region 1.06 to 1.07 ppm; signals for the two methylene groups adjacent to the *cis*-ethylene group appear as a doublet at 2.93 ppm and the triplet for the olefinic protons with $J = 5$ Hz occurs at 5.37 ppm. The IR spectra of *(5)* and *(6)* differ very little from each other; the mass spectrum of *(6)* contains the molecular ion.

[3] Determined gas-chromatographically.

[4] Unpublished work.

No problems were encountered in the epoxidation of 2-methyl-7-*cis*-octadecene *(6)* with *m*-chloroperbenzoic acid, which gave 97%[3] 7,8-*cis*-epoxy-2-methyloctadecane *(1)* in almost quantitative yield. The IR spectrum shows a band for the epoxide group at about 1270 cm^{-1}; the NMR spectrum contains a multiplet at 2.88 ppm due to the *cis*-protons of the three-membered ring. This data together with the results of an elemental analysis provided confirmatory evidence for the structure. The mass spectrum showed fragmentation under the conditions used.

7,8-*cis*-Epoxy-2-methyloctadecane *(1)* exhibits a remarkable degree of biological activity, both in the laboratory and in the field[4].

CONFERENCE REPORTS

Radiochemical Investigations on Noble Gas Compounds

By *J. P. Adloff*[*]

The noble gases occupy an important place in radiochemistry. Noble gas nuclides are formed in various nuclear reactions, and, in particular, in nuclear fission; xenon and krypton nuclides are being produced in ever-increasing amounts in nuclear fuel reprocessing plants.

Although the chemical reactivity of the noble gases increases with increasing atomic number of the element, most of the data published so far for the elements of Group 0 concern xenon and its compounds. Investigations on radon compounds can be carried out only with tracer amounts of the element since the longest-lived isotope, ^{222}Rn, decays with a half-life of 3.8 d. Radon difluoride, formed by reaction of radon with fluorine, is soluble in halogen fluorides and liquid hydrogen fluoride. Radon difluoride solutions are also obtained by spontaneous reaction of radon with FCl, F_3Cl, F_5Br *etc.*, the radon functioning either as anion or as cation depending on the nature of the solvent. Radon compounds are much more ionic in character than the corresponding xenon compounds.

Noble gas compounds are also formed in nuclear transformations. Thus, several xenon compounds are obtainable *via* β-decay of iodine isotopes in iodine compounds, *e.g.* periodate and iodobenzene. Such compounds have also been detected by Mössbauer spectroscopy. It is possible that noble gas compounds are also formed in naturally occurring nuclear reactions; thus, xenon oxides could be formed by spontaneous fission in uranium ores.

Model Reactions for Electrophilic Substitution of Aromatic Compounds

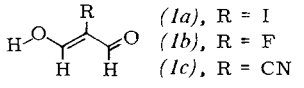
By *Franz Effenberger*[*]

Symmetrical triaminobenzenes are particularly suitable as model compounds for studying electrophilic aromatic reactions; due to the additive electron releasing influence of three mutually *meta* dialkylamino groups in *(1)*, cationic intermediates are stabilized to such a degree that individual steps of electrophilic substitution can be separately studied. The stabilizing effect increases in the order morpholino < piperidino < dimethylamino < pyrrolidino. By HMO calculations, the mesomeric interaction of the individual amino groups with the aromatic π system may be assessed quantitatively from the position of the ^1H-NMR ring proton signals if anisotropic effects are carefully eliminated.

The σ complexes *(2)* formed on protonation, alkylation, and bromination of tripyrrolidinobenzene prove to be isolable; in some cases, primary reaction at a dialkylamino nitrogen of *(1)* and subsequent rearrangement to *(2)* can be established. In contrast to the intermediates described by *Olah*, compounds *(2)* are true "Wheland intermediates", *i.e.* cationic analogs of the Meisenheimer complexes formed in the course of nucleophilic aromatic substitution.

Tris(dialkylamino)benzenes *(1)* may be oxidized readily; the isolable intermediates *(4)* are presumably formed by dimerization of *(3)*. Spectra and model calculations offer unequivocal evidence for the "*endo*" conformation of *(4)*; the preorientation thus indicated for dimerization of *(3)* is significant also with regard to the benzidine rearrangement.

[*] Prof. Dr. F. Effenberger
Institut für Organische Chemie der Universität
7 Stuttgart, Azenbergstrasse 14 (Germany)



In many cases the information gained from reactions of *(1)* can be successfully applied to the reactions of *N,N*-dialkylanilines. Although isolation of cationic intermediates is not feasible here under normal conditions, the product-determining steps may be influenced in a clearly defined way, based on the model concepts developed for *(1)*. This principle is exemplified by the action of bromine on *N,N*-dialkylanilines and the reversibility of bromination of dialkylanilines.

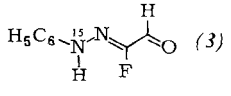
(1b), R = F
(1c), R = CN

Fluoromalonaldehyde is formed on alkaline hydrolysis of 2-fluoro-3-dimethylaminoacrolein *(2b)*, which can be obtained by Vilsmeier formylation of sodium fluoroacetate in the presence of triethylamine in 40 to 50% yield according to a method described in principle by *Arnold*[2].



(2b), R = F
(2c), R = CN

Vilsmeier formylation of cyanoacetyl chloride in the presence of triethylamine gives initially 3-dimethylaminoacrylonitrile which affords 2-cyano-3-dimethylaminoacrolein *(2c)* on renewed formylation, and cyanomalonaldehyde *(1c)* on hydrolysis. Acetonitrile can be converted directly into *(2c)* in 32% yield by reaction with DMF/$POCl_3$.

IR and NMR spectroscopy show that in solution all three dialdehydes exist as the enol forms *(1a)*–*(1c)* (Z configuration) which are stabilized by intermolecular hydrogen bonds.

Condensation of fluoromalonaldehyde with heterocyclic *N*-alkylimmonium salts gives novel γ-fluoropentamethinecyanine dyes; coupling with aryldiazonium salts proceeds *via Japp-Klingemann* cleavage to give 2-fluoroglyoxal 2-phenylhydrazone *(3)* whose structure and configuration

(3)

were established by ^1H- and ^{19}F-NMR spectra of a [α-^{15}N]-labeled compound.

A ^{19}F-^{15}N coupling constant of 11 Hz extending over three bonds was observed for the first time in the ^{19}F-NMR spectrum of labeled *(3)*.

Halomalonaldehydes are important starting materials for the production of halogen-substituted heterocyclic compounds. Condensation of *(1b)* and *(2b)* with suitable bifunctional reactants leads to a large number of fluorine heterocycles that were previously not easily or not at all accessible: 4-fluoropyrazoles; 2-substituted 5-fluoropyrimidines (R^2 = H, CH_3, C_6H_5, OH, SH, NH_2); 3-fluoro-2*H*-indazolo[2,3-*a*]pyrimidine from *(1b)* and 3-aminoindazole; and 1,4-diphenyl-6-fluoro-2,3-dihydro-1,4-diazepinium salts from *1b)* and 1,2-dianilinoethane.

Reactivity of the Double Bond in Higher Olefins Depending upon Position and Geometrical Configuration

By *Friedrich Asinger*[*]

The nine isomers of *n*-undecene were first prepared and their purity investigated. The reactivity of these different olefins was then examined by studying their reaction with hydrogen bromide and with bromine, as well as their hydrogenation in a homogeneous system, epoxidation, addition of thioacetic acid, methoxymercuration, production of lubricants by the action of anhydrous aluminum chloride, and finally hydroalumination with diisobutylaluminum hydride.

It was observed that in some cases α-olefins react faster, in other cases those with nonterminal double bonds. *trans*-Olefins generally react more slowly than *cis*-olefins. A decline in the quality and yield of the lubricating oils obtained by polymerization of the olefins with aluminum chloride is observed practically only with *trans*-olefins the nearer the double bond is to the center of the molecule.

The α-olefins react about 240 times faster than those having nonterminal double bonds on addition of diisobutylaluminum hydride. Catalytic amounts of titanium tetrabutoxide, however, accelerate the addition of diisobutylaluminum hydride to olefins having nonterminal double bonds to such an extent that they react just as fast as α-olefins in the absence of a catalyst. The titanium alkoxide promotes isomerization of the organoaluminum compound at elevated temperatures (100—120 °C). The aluminum-containing group migrates to the end of the molecule where it is irreversibly bonded. Olefins with nonterminal double bonds thus yield primary straight-chain alcohols in good final yields after air-oxidation of these aluminum compounds to aluminum alkoxides and subsequent hydrolysis.

Since mixtures of higher olefins having statistically distributed or symmetrically positioned double bonds are nowadays readily available on an industrial scale

Development of a New Type of Polyamide

By *Gerhard Bier*[*]

Until recently only purely aliphatic polyamides, such as perlon, nylon 6,6, nylon 11, *etc.*, have been produced for thermoplastic processing techniques. Completely aromatic polyamides like polymetaphenyleneisophthalamide (raw material of NOMEX fibers) or aliphatic-aromatic polyamides like that formed from hexamethylenediamine and terephthalic acid (m.p. 370 °C) cannot be processed thermoplastically in practice.

Preliminary work by *R. Gabler* was taken up at Dynamit Nobel and a polyamide was subsequently synthesized from a branched-chain aliphatic hexamethylenediamine and terephthalic acid and tested for possible applications. The polyamide (which has been given the trade name TROGAMID T®) is amorphous and has a glass transition temperature of about 150°C. It can readily be processed by thermoplastic techniques. The influence of the aromatic component, of the methyl side chain, and of the carboxamide group on crystallinity and glass transition temperature was studied in detail with the aid of model compounds. It was found, *inter alia*, that for a constant formula weight the positions of the carboxamide groups have a considerable effect on the glass transition temperature. In spite of the amorphous nature of the polymer a high degree of structural order must exist for almost all the carboxamide groups are linked by hydrogen bonds. Above the glass transition temperature the number of NH groups not participating in hydrogen bonding rapidly increases.

TROGAMID T® is characterized by a high tensile strength and dimensional stability as well as resistance to tracking currents, resistance to attack by chemical reagents, resistance to cracking when subjected to a pulsating compression and by transparency. These properties, in conjunction with the low shrinkage in processing, make TROGAMID T® suitable for uses in the automobile industry and for electronics and electrical engineering, filter manufacture, the dairy industry, watch- and clockmaking, production of umbrellas, and measurement and control engineering. Examples include shock absorber pistons, switch knobs, casings for high performance switchgear, caps for ends of cables, transparent filter units, parts for milking machines, filter cups, watch glasses, umbrella frames, and flowmeters for gases and liquids.

New Aspects of the Structure of Randomly Branched Macromolecules

By *Walther Burchard*[*]

In contrast to unbranched chain molecules little is known about the structure of randomly branched macromolecules. The reason may be seen in the difficulties resulting from the large width of the molecular weight distributions (M_w/M_n *ca.* 100–150) and the extreme variety of isomeric structures. The current practice of approximating the physical properties by results obtained for fixed structures (star and comb polymers) holds out of relatively little promise because these structures are probably not representative of the randomly branched chain molecules.

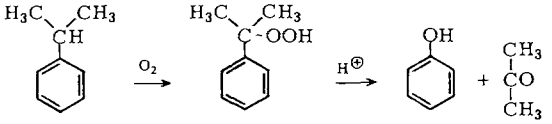
The difficulties can be largely overcome by two techniques novel to polymer science:

1) Branched molecules can be regarded as "trees". After choice of an arbitrary chain element as root, the resulting tree exhibits practically all the characteristics of a family tree which can be unequivocally divided up into different generations. From this results a clear system of ordering and numbering.

2) Methods common in the statistical treatment of population growth processes (demographic methods) can be applied to these "trees". Particular mention should be made in this context of the generating functions which have properties similar to a Fourier transformation of a probability distribution. The advance in the treatment of randomly branched structures results essentially from two properties of generating functions:

a) Straightforward differentiation of the generating functions with respect to the auxiliary variable yields physically meaningful average values that are accessible to measurement and cover both molecular-weight and isomer distributions.

b) The generating functions can be boxed into one another in the form of a cascade (1st, 2nd, 3rd... generation); structures of trees are thereby reproduced which are characteristic of the branched molecules.



In this way it was possible to calculate for a number of branching types the weight- and number-average molecular weights as well as the z-averages of the mean square radius of gyration and of the particle scattering factor for light scattering. The linear chain is always included in the cascade process as a limiting case. Details were given of measurements on alternating copolymers of decamethylene glycol and benzene-1,3,5-triacetic acid as well as of measurements on star molecules having glycogen as nucleus.

"Selected Abstracts", a part of the journal previously containing summarized versions of primary publications of topical interest, will in future be devoted exclusively to abstracts of publications of a more comprehensive nature (reviews, progress reports, *etc.*). The editorial staff will make every effort to ensure that this modification of the "Selected Abstracts" section will provide readers of "Angewandte Chemie — International Edition" with an even more representative and up-to-date survey of current developments in each of the branches of chemistry than heretofore.

Kinetics of autoxidation of hydrocarbons in the liquid phase is the theme of an article by *J. Betts*. In contrast to combustion, autoxidation is taken to mean oxidation by molecular oxygen under mild conditions; practical applications include the atmospheric drying of linseed oil paints and the manufacture of phenol and acetone from cumene *(1) via* the hydroperoxide and its decomposition with strong acids:

(1)

The reaction involves free radicals. The author discusses, *inter alia*, autoxidation chains and the determination of rate constants, relationships between structure and reactivity, autoxidation of polymers and carbanions, reactions with singlet oxygen, and the action of antioxidants. [The Kinetics of Hydrocarbon Autoxidation in the Liquid Phase. Quart. Rev. Chem. Soc. *25*, 265—288 (1971); 94 references, 4 tables]

[Rd 420 IE –K]

Properties of clean metal surfaces and reactions thereon are surveyed by *R. P. H. Gasser*. Such work must be conducted in ultrahigh vacuum at pressures no higher than 10^{-9}, or better at 10^{-10} torr. The following steps of the reaction are of interest: a) adsorption; b) reactions on the surface; c) desorption. During the reaction either the composition of the gas or changes in a property of the metal are monitored. Apart from the theory of adsorption, the article considers, *inter alia*, application of the flash filament method, field-emission and field-ion microscopy, diffraction studies with slow electrons (LEED), and mass spectroscopy. [Properties and Reactions of Clean Metal Surfaces. Quart. Rev. Chem. Soc. *25*, 223—238 (1971); 12 references, 6 figures]

[Rd 418 IE –K]

How are metal atoms formed in flames? This question of analytical importance is posed in a paper by *D. T. Coker, J. M. Ottaway*, and *N. K. Pradhan*. Among other effects, the concentration dependence of ground-state atoms (determining generally the signal strength in atomic absorption spectrophotometry) on the oxygen content of fuel lean flames points to the fact that the dissociation energy of the metal monoxide plays an important role. The influence of anions in the sample solution (halides or oxy-anions) and of the nature of the flame constituents (hydrogen-air, acetylene-air, acetylene-nitrous oxide) lead to the same conclusion. [Metal Atom Formation Processes in Flames. Nature Phys. Sci. *233*, 69–71 (1971). 13 references, 6 figures.]

[Rd 430 IE –H]

The absorption spectra of tetragonal fluorides from the first transition metal series are discussed by *D. Oelkrug*. Complex ions that would have an orbitally degenerate ground state in a ligand field of regular octahedral symmetry are known to be distorted from this symmetry in a way removing that degeneracy (Jahn-Teller effect). The structures of fluorides with Jahn-Teller sensitive ground states are considered using "ionic" and "covalent" bonding models, and their absorption spectra are interpreted under these aspects. [Absorption Spectra and Ligand Field Parameters of Tetragonal 3d Transition Metal Fluorides. Structure and Bonding *9*, 1–26 (1971); 91 references, 8 figures, 4 tables.]

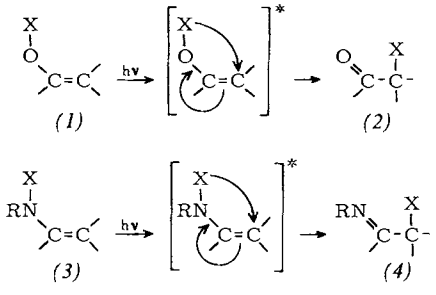
[Rd 431 IE –H]

Structures and bonding properties of β-diketone chelates are reported by *D. W. Thompson*. The different geometries of such compounds, *e.g.* of metal pentanedionates (acetylacetonates) are discussed, and a detailed account is given of the electronic structure of such complexes. Special attention is paid to the question of the "aromatic" character of the chelate rings. [Structure and Bonding in Inorganic Derivatives of β-Diketones. Structure and Bonding *9*, 27–47 (1971); 69 references, 3 figures.]

[Rd 432 IE –H]

The coordination chemistry of metalloporphyrins is reviewed by *P. Hambright*. Introductory sections about structures and acid-base equilibria of metal-free porphyrins are followed by a list of metal ions forming porphyrin compounds, together with selected structures, magnetic properties, and stability constants. The review concludes with discussions of mechanisms of metal ion incorporation, the stability of the complexes against demetalation, and substitution and electron transfer reactions on metalloporphyrins. [The Coordination Chemistry of Metalloporphyrins. Coord. Chem. Rev. *6*, 247–268 (1971); 145 references, 3 figures, 1 table.]

[Rd 433 IE –H]



The stereochemistry of the halocarbonylphosphanes and arsanes of molybdenum and tungsten is summarized by *R. Colton*. The main emphasis is on complexes with bidentate phosphanes and arsanes. Preparative methods are outlined briefly; in the main part, the influence of different ligands on the coordination numbers and the geometries of the complexes is depicted, with special reference to the results of NMR and IR measurements. [Steric Effects in Substituted Halocarbonyls of Molybdenum and Tungsten. Coord. Chem. Rev. *6*, 269–284 (1971); 29 references, 1 figure, 1 table.]

[Rd 434 IE –H]

How many solvent molecules are nearest neighbors to a metal ion in solution? This question is discussed in a review by *S. F. Lincoln*. The problems of a sound definition of the "first coordination sphere" and the methods to measure coordination numbers, *e. g.*, X-ray diffraction, ion exchange, and NMR methods are considered. "Indirect" methods, *i. e.*, methods evaluating coordination numbers from measurements of bulk solution properties, are also mentioned. The results of investigations on solutions in single and mixed solvents are discussed; a chapter about contact ion pairs concludes the review. [Solvent Coordination Numbers of Metal Ions in Solution. Coord. Chem. Rev. *6*, 309–329 (1971); 133 references, 5 figures, 1 table.]

[Rd 435 IE –H]

The photo-Fries rearrangement and related photochemical [1,j]-shifts (j = 3, 5, 7) of carbonyl and sulfonyl groups have been reviewed by *D. Belluš*. Characteristic of all these rearrangements is the 1,3 (or 1,5- or 1,7-) migration of a group X in compounds of the type *(1)* or *(3)* in which the double bond can be isolated, conjugated or aromatic.

Examples of type *(1)* are aryl esters of carboxylic acids and sulfonic acids, and enol esters of carboxylic acids; examples of type *(3)* are *N*-arylamides of carboxylic acids and sulfonic acids, and *N*-aryl lactams. [Photo-Fries Rearrangement and Related Photochemical [1,j]-shifts (j = 3, 5, 7) of Carbonyl and Sulfonyl Groups. Advan. Photochem. *8*, 109–159 (1971); 118 references, 8 tables]

[Rd 437 IE –M]

The use of radioisotopically labeled analytical reagents in organic chemistry is comprehensively reviewed up to the end of 1969 in a paper by *G. Ayrey, D. Barnard*, and *T. H. Houseman*. The examples described cover the quantitative and near-quantitative reaction of a labeled reagent with a special group of the molecule to be determined. An introduction to analytical methods, including, *inter alia*, isotope dilution analysis and isotope derivative analysis, is followed by a discussion of the labeled reagents themselves. The analyses of hydroxy, carbonyl, carboxy, thio, and amino compounds, and of radicals and compounds having metal-polymer bonds serve as examples. [Use of Radioisotopically Labeled Analytical Reagents in Organic Chemistry. Chem. Rev. *71*, 371—393 (1971); 230 references]

[Rd 449 IE –M]

Isomerizations of metal β-diketone chelates are reviewed by *J. J. Fortman* and *R. E. Sievers*. Conceivable reaction mechanisms are first discussed: intramolecular processes with or without bond rupture and intermolecular processes with primary dissociation or bimolecular substitution processes. An account is then given of investigations on individual compounds; the bulk of the data concerns 6-coordinate compounds. Since all these reactions proceed rather rapidly, NMR spectroscopy is almost exclusively used for following the kinetics of such processes. [Optical and Geometrical Isomerization of β-Diketonate Complexes. Coord. Chem. Rev. *6*, 331—375 (1971); 133 references]

[Rd 441 IE –H]

Methods for calculation of stability constants of metal complexes in solution are critically evaluated by *A. M. Bond*. Examples are presented of the way in which different calculation methods using the same experimental data can give substantially different stability constants. There is no "best" method of calculation; on the contrary, it is always a necessity to chose critically between several methods. A preliminary graphic analysis of the experimental data is always helpful for this purpose. [Some Suggested Calculation Procedures and the Variation in Results Obtained from Different Calculation Methods for Evaluation of Concentration Stability Constants of Metal Ion Complexes in Aqueous Solution. Coord. Chem. Rev. *6*, 337—405 (1971); 43 references]

[Rd 442 IE –H]

Infrared spectra of pseudo-halide complexes (thio- and isothiocyanate, seleno- and isoselenocyanate, cyanate, and fulminate) are reported on by *R. A. Bailey, S. L. Kozak, T. W. Michelsen*, and *W. N. Mills*. The spectra in the region of internal ligand frequencies are discussed extensively; the review concludes with chapters about metal-ligand vibrations, which have been investigated to a lesser extent, and about the spectra of mixed complexes. Among other topics, all vibrational frequencies are evaluated with respect to the possibilities they offer to discern coordination of the different ends of the ligand ions. [Infrared Spectra of Complexes of the Thiocyanate and Related Ions. Coord. Chem. Rev. *6*, 407—445 (1971); 90 references]

[Rd 443 IE –H]

The electronic spectra of the hexafluoro complexes of the first transition series are discussed by *G. C. Allen* and *K. D. Warren*. An introductory chapter about the basic theory of interpretation of spectra including a fairly extensive account of LCAO-MO theory of complexes is followed by an appraisal of diffuse reflectance spectroscopy as the most important measuring tool. After discussion of the individual spectra, comparisons are made with those of hexachloro compounds and of complexes from the higher transition series. In the concluding chapters, optical electronegativities, vibrational structures, and the influence of the Jahn-Teller effect are reviewed. [The Electronic Spectra of the Hexafluoro Complexes of the First Transition Series. Structure and Bonding *9*, 49—138 (1971); 137 references]

[Rd 444 IE –H]

Unusual electrophilic aromatic substitutions of preparative interest are reviewed by *D. E. Pearson* and *C. A. Buehler*. Examples are enhancement of *p*-substitution in the formation of aromatic ketones, sulfonic acids, alkylbenzenes, nitroanilines, and nitroarenes as a result of bulkiness of substituent and reagent, and of thermodynamic control in compounds containing *meta*-directing substituents; a further example is *ortho* enhancement in the case of

phenols, aromatic ethers, arylamines and anilides, alkylbenzenes, and benzoic acid by coupling of reagent and substituent before entering the *o*-position. Increased *m*-substitution in aniline and its derivatives, alkylbenzenes, aromatic ketones, substituted phenols, aromatic halides, naphthalenesulfonic acids, and [2.2]metacyclophanes is usually achieved by protonation. [Unusual Electrophilic Aromatic Substitution in Synthesis. Synthesis *1971*, 455 to 477; 73 references].

[Rd 440 IE –M]

Influence of non-bonded H atom repulsions in bis-chelates of 2,2'-bipyridyl and 1,10-phenanthroline on the configuration of the complexes formed is treated by *E. D. McKenzie*. The possibilities of minimizing the van der Waals repulsions in different coordination polyhedra are discussed, and the use of physical methods (X-ray diffraction; electronic, vibrational, and magnetic resonance spectra; Mössbauer effect) for configuration assignments is evaluated very critically. Finally, configurations of known compounds are discussed. [The steric effect in bis(2,2'-bipyridyl) and bis(1,10-phenanthroline) metal compounds. Coord. Chem. Rev. *6*, 187—216 (1971); 145 references, 7 figures, 4 tables]

[Rd 424 IE –H]

The melting of d(T-A) oligomers as a model reaction for the melting of DNA forms the subject matter of a report by *R. L. Baldwin*. $d(T\text{-}A)_n$, $5 \leq n \leq 25$, consists of deoxythymine and deoxyadenine; "melting" is defined as the transition of the helix form to a form devoid of base pairing. Particular interest was commanded by the behavior of hairpin loops formed on base pairing within a strand. The smallest possible loop contains four bases. Methods are described for determining the parameters required for calculation of melting curves. In the presence of high counter-ion concentrations the melting curves of linear oligomers are as predicted by theory, while at lower concentrations the length of the oligomer must be taken into account. The article closes with remarks concerning the kinetic behavior of hairpin helices. [Experimental Tests of the Theory of Deoxynucleic Acid Melting with d(T-A) Oligomers. Accounts Chem. Res. *4*, 265—272 (1971); 38 references, 4 figures]

[Rd 417 IE –L]

The calculation of vibrational frequencies and force constants without the aid of empirical data *(ab initio)* is treated in a review by *C. J. H. Schutte*. Firstly, the basic assumptions underlying this kind of calculation are discussed; among them, the Born-Oppenheimer approximation (independence of electronic and nuclear movements) is common to all present computational procedures. Various approaches to the determination of vibrational frequencies of diatomic molecules, characterized by the introduction of further approximations in different stages of the calculation, are outlined in the major part of the review. Finally, reference is made to calculations of polyatomic molecules, where, in some cases, symmetry considerations can lead to a simplification of the huge problems encountered generally. [The Ab-Initio Calculation of Molecular Vibrational Frequencies and Force Constants. Structure and Bonding *9*, 213—263 (1971); 160 references]

[Rd 447 IE –H]

The assessment of the interelectronic repulsion parameter of ligand field theory is commented on by *E. König*. The report is confined to the evaluation of spin-allowed bands in electronic configurations d^2, d^3, d^7, and d^8, these being easier accessible to theoretical treatment. Different procedures of fitting ligand field parameters to the band maxima measured are compared and reasons are discussed for the differences in the results obtained. The most important reason is that band maxima do not correspond to transitions between minima of potential hypersurfaces of the electronic states involved, as the transitions take place between states of different ligand field configurations. [The Nephelauxetic Effect. Calculation and Accuracy of the Interelectronic Repulsion Parameters. I. Cubic High-Spin d^2, d^3, d^7, and d^8 Systems. Structure and Bonding *9*, 175—212 (1971); 64 references, 9 tables]

[Rd 446 IE –H]

The interaction of protons and metal ions with ribonucleic acid, deoxyribonucleic acid, and their constituent bases, nucleosides, and nucleotides are examined in a review by *R. M. Izatt, J. J. Christensen*, and *J. H. Rytting*. The literature is covered up to August 1970. Special consideration is given to the coordination sites of the ions, alkali and alkaline earth metal ions, and ions of Cr, Mn, Fe, Co, Ni, Cu, Zn, Ag, Cd, Pb, Hg, U, and the lanthanoids. Tables of thermodynamic data for the interactions are also given. [Sites and Thermodynamic Quantities Associated with Proton and Metal Ion Interactions with Ribonucleic Acid, Deoxyribonucleic Acid, and Their Constituent Bases, Nucleosides, and Nucleotides. Chem. Rev. *71*, 439—481 (1971); 229 references]

[Rd 451 IE –M]

The physical chemistry of iron(II) complexes with ligands containing the structural element N=C—C=N is reviewed by *P. Krumholz*. Accounts are given of the magnetochemistry, electronic and vibrational spectra, and of the thermodynamics and kinetics of formation and dissociation of such complexes. A special chapter is devoted to the importance of "back coordination" for understanding the properties of this class of compounds. [Iron(II) Diimine and Related Complexes. Structure and Bonding *9*, 139 to 174 (1971); 233 references]

[Rd 445 IE –H]

Preparation, properties, and applications of vitreous carbon are surveyed by *V. D. Chekanova* and *A. S. Fialkov*. Vitreous carbon possesses a number of specific properties not exhibited by the better known modifications. Its high mechanical strength, its resistance to corrosive agents, and its impermeability to gases are being increasingly exploited. The article deals not only with the preparation of vitreous carbon but also with its physical and chemical properties. [Vitreous Carbon (Preparation, Properties, and Applications). Russ. Chem. Rev. *40*, 413—428 (1971); 97 references, 10 tables, 18 figures]

[Rd 427 IE –M]

Modern Electrochemistry. An Introduction to an Interdisciplinary Area. Vol. 1. By *J. O'M. Bockris* and *A. K. N. Reddy*. Macdonald Technical and Scientific, London and Plenum Press, New York 1970. 1st edit., lx, 622 pp., 245 figures, 119 tables, $ 19.50.

It is the authors' declared intention that this book should provide readers from many different disciplines with as complete as possible an introduction to present-day electrochemistry. In order to achieve these ambitious aims, they have based their approach upon a series of key ideas: clarity is striven for even at the cost of brevity; frequent repetitions thus have to be accepted. Each individual section begins at a simple level and works its way up to the current viewpoint. The background knowledge required for comprehension is given in full. The presentation should be modern in form and content; out-of-date concepts are therefore eliminated. Each phenomenon is discussed on the basis of only one theory, and that is the one which appears to reproduce the facts most consistently. For the sake of clarity the book is kept to the style of a lecture, which in the last analysis is what it is (rather in the sense of "The Feynman Lectures on Physics").

The literature references are limited to fundamental original work (about 300) and more advanced monographs and review articles (about 150) from recent years, generally up to 1968. Each block of references, arranged in chronological order, comes at the end of the appropriate subsection, which is usually about 25 pages long. Unfortunately, there is no explicit reference to them in the text. The search for papers on a given topic would have been considerably simplified if their titles had also been given, or if specific reference had been made to them at the appropriate points. The mathematical derivations, which can break up the flow of a text, are also separated off as appendices to the corresponding chapters (11 in all in the two volumes). Each volume contains a detailed contents list and there is a subject index (with about 2500 entries) for the two volumes. There is no author index, nor is there a list of symbols used. The work contains some 800 illustrations, in the form of line diagrams, figures, and schematic representations. Numerical material is summarized in about 200 tables.

Apart from a brief introduction to the subject as a whole, the shorter volume 1 is concerned with ions in liquids. This topic is called "ionics", in contrast to "electrodics" which is the subject of volume 2. First of all the ion-solvent interaction is dealt with, initially without and then with reference to structure. Here the central position is occupied by the ion-dipole and the ion-quadrupole interaction. Further subsections are concerned with the solvation number, the dielectric constant, and the effect of dissolved non-electrolytes. The next chapter is on ion-ion interactions. The Debye-Hückel theory is critically examined, and the influence of the solvent on the activity coefficients is studied; ion associations, the quasilattice treatment of concentrated electrolyte solutions, and experimental methods are also discussed. The subsequent chapter on ion transport relates principally to aqueous solutions. Separate chapters are concerned with protons in solution and with melts, in which simple models oriented toward the lattice or the gas are discussed and transport phenomena and mixed phases are dealt with.

There is no difficulty in using this volume independently of volume 2, which, considering the high price, is an advantage. It provides a detailed introduction into the present state of knowledge on ions in liquids.

Hermann Göhr [NB 998a IE]

Modern Electrochemistry. An Introduction to an Interdisciplinary Area. Vol. 2. By *J. O'M. Bockris* and *A. K. N. Reddy*. Macdonald Technical and Scientific, London and Plenum Press, New York 1970. 1st edit., lxi, 810 pp., 446 figures, 83 tables, $ 22.50.

Volume 2 of this large-scale textbook on electrochemistry is devoted to "electrodics", *i. e.* the phenomena in the boundary layer between electronic and ionic conductors. Since the character of the overall work was described in the review of the first volume, the present review will be concerned mainly with volume 2.

The first of the five chapters is concerned with electrified interfaces. The fundamental concepts of electrodics are critically discussed. In reading this it becomes very clear how little we still know about double layers on solid metals (in contrast with mercury). Here there are also sections on double layers on semiconductors, electrokinetics, and colloid chemical phenomena. The next two chapters deal with electrode reactions; the first with charge-transfer kinetics, the second with mechanisms. Next a selection of specific types of electrode reactions are described: electrocatalysis, metal electrocrystallization, hydrogen and oxygen evolution. In the final chapter on systems of technological interest, corrosion and related phenomena, electrochemical energy conversion (fuel cells), and storage devices (accumulators and cells) are discussed in detail.

This volume, too, can be used by itself. The arrangement of the field of electrodics is mainly governed by teaching considerations. However, despite the pleasing overall impression, I cannot overlook one or two defects. Experimental methods of investigation are certainly mentioned, but any critical discussion—which one might well expect in a book of this scope—is missing. In the tables and diagrams there are no indications of the experimental or theoretical routes by which the data are obtained. In many of these cases even a literature reference would have helped. There are also several minor errors, such as incorrect signs in equations (*e. g.* in (7.40) to (7.46)) or a reference to a non-existent appendix (A 7.2); however, these shortcomings are no worse than one might expect to find in a first edition.

The two-volume work taken as a whole is a modern, comprehensive textbook on electrochemistry. Since it is written clearly, in detail, and at an elementary level, it is fairly easy to read. To this extent it may be described as an "Introduction". But who, other than an enthusiast, could be expected to read a work of some fifteen hundred pages? The very size of the work prevents it from fulfilling its function of really acting as an introduction.

Hermann Göhr [NB 998b IE]

Standard Methods of Clinical Chemistry, Vol. 6. By *R. P. MacDonald*. Academic Press, New York–London 1970, 1st ed., xiv, 281 pp., bound, $ 14.50.

Six volumes of Standard Methods of Clinical Chemistry have now appeared since 1953 under the auspices of the

American Association of Clinical Chemists. The aim has been the same throughout the series, namely to provide a critical collection of the scattered methods used in clinical chemistry, and this aim has been achieved. In appearance, these volumes remind one of two other series: Organic Synthesis and Methods of Enzymology. The sixth volume, which has just been published, is just as much of a standard work as the previous ones, and belongs on the shelves of any library where this subject is covered at all.

The sixth volume gives a wide variety of methods, determinations, and general topics of interest to clinical chemists, examples being the handling of toxicological problems in the laboratory, the subject of standardizing enzyme activity determinations, and proposals for the nomenclature of quantities and units used in clinical chemistry. The discussion of these very topical questions with such clarity is of great value. It is sufficient to think how much diagnostic information may be lost if we do not soon accept rules for the standardization of enzyme activity determinations. Of course, the difficulties of reaching international agreements are well known.

One hesitates to accept as standard laboratory methods some of the determinations proposed here, for example *Babson*'s color reaction for the GOT activity (p. 149). It is true that this method needs only simple equipment, and for this reason it may be discussed here, but it uses an unstable reference substance, oxalacetate. Another example is the triglyceride determination (p. 215), which comprises no fewer than twelve steps and is therefore certainly unsuitable as a standard method for routine use. A better method was devised for this purpose by *Eggstein* in 1966.

The interference by dextran-type plasma extenders is not taken into account in the description of the *o*-toluidine-glacial acetic acid method for the determination of blood sugar (p. 159), although it can give erroneously positive results with all its consequences, as is well known.

All this, however, does not detract from the fact that this volume too offers very useful analytical methods (*e.g.* for the determination of hemoglobin in the plasma; cf. p. 107) that can be used in large routine laboratories and in research laboratories. Even the "Notes" in small print offer much technical help in laboratory work. The subject index on eight pages is sufficiently extensive to permit anything to be found quickly and easily.

W. Wahlefeld [NB 1 IE]

Autoradiographie (Autoradiography). By *H. A. Fischer* and *G. Werner*. Walter de Gruyter & Co., Berlin 1970. 1st edit., ix, 214 pp., 93 figures, 14 tables, bound, DM 42.—.

Autoradiographic methods have been successfully used in almost every field of science. The collection of people concerned with this technique is therefore a heterogeneous one, and up to now there has been no comprehensive and complete presentation in German of the theoretical and practical fundamentals of this wide-ranging topic. The present book should fill this gap. The authors intend it primarily as a guideline for those interested in the method and as an introduction for those who are unfamiliar with autoradiographic techniques.

After a short explanation of the physical foundations and the method of labeling with radioactive isotopes, there is a survey of the autoradiography of macroscopic, microscopic, and electron-microscopic objects; this section contains a wealth of practical examples from a wide range of applications. To name but a few: studies of metals, applications to chemical and biochemical analysis, biology (autoradiography of whole animals, *etc.*), criminological investigations, mass transport in earth samples, and many others. The techniques of operating with stripping film and "liquid" emulsions are discussed, together with their advantages and limitations. One section is specially devoted to the very important and difficult topic of the autoradiography of dislocatable substances. The possibilities for the autoradiography of electron-microscopic objects are critically discussed on the basis of numerous examples. In each individual section there are separate notes on the selection of the suitable film material and the photographic technique. The objectivity of the presentation can be seen from the numerous notes on artefacts, which all too often lead to misinterpretations of autoradiograms. The book closes with a chapter on the use of autoradiography as a quantitative method; there is a comprehensive bibliography including recent publications.

The fact that some of the captions have been applied to the wrong picture does not detract much from the quality of the book. A further point to be noted in a new edition would be a standardization of the units of measurement, taking the SI units into consideration.

Over and above its value as a guide for the beginner, this book will also offer to the worker familiar with this topic many useful suggestions and a highly informative insight into other specialist fields, which in turn will contribute to an enrichment of his own field. In closing, it may be mentioned that the book is very attractive in outward appearance, but the reproduction of some of the original autoradiograms could have been better.

Hans-Martin Kellner [NB 2 IE]

Chemie der Metall-Olefin-Komplexe (Chemistry of Metal-Olefin Complexes). By *P. Heimbach* and *R. Traunmüller*. Chemische Taschenbücher Vol. 10. Verlag Chemie GmbH, Weinheim/Bergstr. 1970. ix, 180 pp., 85 figures, 30 tables, paperback DM 20.—.

The present monograph is devoted to one of the most interesting fields, and probably also the most topical, of organometallic chemistry. The authors, who are themselves active in this field, have tried to select the results that seem most important to them from the wealth of available material, and to throw light on the chemistry of metal-olefin complexes from various angles.

After an introductory chapter with a very brief discussion of bonding models known at present, the first part of the book describes a number of important preparation methods, mainly those giving isolable, kinetically stable metal-olefin complexes. Syntheses of alkylmetals and metal hydrides are also mentioned, though these do not strictly fall within the realm of the subject proper. Chapters 5 and 6 ("Effects of complex formation on olefin and allyl ligands" and "Olefins and allyl groups as complex ligands") survey the methods and results of structural investigations and also take bonding problems into account. The second part of the monograph presents a very detailed discussion of catalytic processes in which metal-olefin and metal-allyl complexes play a part, usually as kinetically labile intermediates. This discussion is centered on the work of *G. Wilke* and the Mülheim school. It is in these chapters that it becomes very plain

that the authors are approaching the chemistry of metal-olefin complexes primarily from the standpoint of the organic chemist, which will undoubtedly please a wide readership.

As to criticisms, the reviewer was surprised to find almost more on metal-allyl complexes than on metal-olefin complexes in a book with the above title. A longer and more detailed title would have been better. Another notable shortcoming is that though the relationships between olefin and allyl complexes are rightly emphasized, there is no reference to similar relationships between olefin and aromatic complexes (*e.g.* between $C_5H_6ML_n$ and $[C_5H_5ML_n]^+$, $C_7H_8ML_n$ and $[C_7H_7ML_n]^+$). The discussion of the extremely interesting olefin-metal compounds with "fluctuating structures" is also much too short.

Despite these objections, the monograph, which is a true pocket book, fulfills its purpose. It is recommended in particular to those who wish a general picture rather than special information and who are interested in particular in the use of organometallic complexes for synthetic problems.

Helmut Werner [NB 11 IE]

An Introduction to the Chiroptical Methods in Chemistry. By *P. Crabbé*. P. de Aguinaco, Mexico 1971. 1st edit., 121 pp., 54 figures, $ 4.00.

P. Crabbé, who has also written an extensive monograph on the same topic, here presents a brief introduction to chiroptical methods (circular dichroism (CD) and optical rotatory dispersion (ORD)). Of course, it cannot be regarded as a substitute for a detailed textbook, but is a means of bringing oneself up to date with the recent literature, using the index which is arranged by chromophores. After a brief description of the fundamental concepts, the individual groups capable of bringing about a Cotton effect are enumerated, together with the more important rules applying to them; a critical comparison is lacking here. The topic of biopolymers is not dealt with in quite so much detail, but the book does include details on both inorganic complexes and the Faraday effect. This small book, which is printed on extremely hard-wearing paper, contains an extraordinary wealth of literature references, which actually extend into the early part of 1971 and is thus a valuable addition to this branch of spectroscopy which up to now has received only sporadic attention.

Günther Snatzke [NB 3 IE]

Messung radioaktiver Nuklide (Measurement of Radioactive Nuclides). By *K. Bächmann*. Verlag Chemie GmbH, Weinheim/Bergstr. 1970. 1st Edit., xii, 187 pp., 194 figures, 30 tables, bound DM 58.—.

This book is a comprehensive account of methods for the detection of nuclear radiation. It provides the scientist, the engineer, or the student with a detailed guide to the execution and evaluation of radioactivity measurements. Numerous measuring arrangements and methods for this purpose are described, and their usefulness for the solution of particular measurement problems is assessed.

The layout and arrangement are very clear. The first few chapters describe the construction of radiation detectors and the interactions of nuclear radiation with matter that are necessary for an understanding of the detectors. A chapter on electronic aids unfortunately deals mainly with tube circuits (cathode follower, coincidence stage, Schmitt trigger) and omits the transistor circuits that are now in common use. This is followed by detailed chapters on the detection of the various types of radiation and the determination of their energy. A useful section is included for practical workers on the evaluation of γ spectra. A chapter on the relationship between count rate and activity is important to the evaluation of results. The book ends with practical advice on measuring arrangements, standard preparations, and the dosimetry of nuclear radiation.

The practical value of the (relatively expensive) book is enhanced by bibliographies to the various chapters and a reliable subject index.

Helmut Müh [NB 12 IE]

Gmelins Handbuch der anorganischen Chemie (Gmelin's Handbook of Inorganic Chemistry). 8th, fully revised edition. Issued by the Gmelin-Institut für anorganische Chemie und Grenzgebiete of the Max-Planck-Gesellschaft zur Förderung der Wissenschaften under the direction of *Margot Becke-Goehring*. Verlag Chemie GmbH, Weinheim/Bergstr.

System No. 46. Zinn, Teil A (Tin, Part A).
Historical. Occurrence. Chief editor: *Wolfgang Müller*. 1971. vi, xiii, 451 pp., 32 figures, bound. DM 532.—.

Together with gold, silver, and copper, tin is one of the first few metals used by man. The first chapter of the present volume is a 172-page presentation of the history of tin, and at the same time is a form of cultural history of the last five millenia, woven around the use of this metal. Although this undoubtedly makes interesting reading, it would seem to the present reviewer that it is extending the scope of this chapter too far to devote several pages to the origin of the name of the element, and finally to consider the problem of whether the *Publius Crassus* mentioned in a report by the geographer *Strabo* (of Amasia in Pontus) was the younger son of the member of the 1st triumvirate, who subdued Aquitania under *Caesar* in 57 BC, or whether he was the Spanish proconsul in 97 BC, although it is not known whether the latter "undertook any exploratory travels". This is not to criticize the presentation of the history of tin, which among other things contains many detailed quotations from ancient sources that are not readily accessible, but only to ask whether this amount of detail in a handbook of inorganic chemistry, which in general will only be consulted by chemists and representatives of closely allied disciplines, is not paid for at too high a price. There is no doubt that the presentation would be of interest to a very wide circle of readers. The present reviewer would therefore suggest that such detailed historical presentations should in future be published as separate volumes, which could be offered to a much wider circle of readers, with a possible reduction in cost.

After the sections on names and symbols, tin in early cultures, tin in east Asia, India, Africa, America, and tin in the Arab civilization, there are sections concerned with tin ores and their extraction and processing. Detailed descriptions are given of tinning processes, particularly with regard to the manufacture of tinplate. Special attention is given to the various regions where the tinplate industry

has developed, in various parts of Germany as well as in other European countries and America. In the final section of the "Historical" chapter a number of tin compounds that have been known and used for many centuries are described.

The second part contains a chapter on the geochemistry of tin and also a chapter on minerals and workable deposits. The chapter on cosmochemistry gives information on the frequency of occurrence of tin in the universe and its occurrence in the solar spectrum, in star spectra, and in meteorites. The up-to-date nature of the material is particularly clear from a short section on the tin content of moon rocks (for the entire volume, the literature has been scanned up to 1970). The chapters on geochemistry and minerals occupy a large amount of space (160 pages), and describe the behavior of tin in rock and deposit formation, and also the paragenesis and the chemical and physical properties of the tin minerals. Information on the deposits, as far as they are used, is to be found in the final chapter. This also gives the major producers, the production figures for individual countries over the last few decades, tin reserves, and a survey of the price variations of the metal, both in general and in detail.

System No. 61. Silber, Teil B 1 (Silver, Part Bl). Compounds with the inert gases, hydrogen, oxygen, nitrogen, fluorine, and chlorine. Chief editor: *Rudolf Keim*, 1971, vi, xxiv, 542 pp., 154 figures, bound. DM 648.—.

It is only a short while since part A of System No. 61, dealing with the history and occurrence of silver and also with the element as such, was published[1], and now we have here the first section of Part B, which deals with the compounds of silver. As in some of the other recent volumes of this series, in many places the strictly systematic approach is allowed to break down in order to give a chemically clearer picture. Alkali metal and alkaline earth metal double compounds with the same silver-containing anions are handled at the same time as the corresponding silver compound. For example, the description of Ag(II) fluoride is followed by a description of all the fluoroargentates(II). In general, this will be welcomed by the chemist. However, anyone for whom the topic in question is completely unfamiliar will find literature searching more difficult, and this is even more true for the non-chemist. It is therefore hoped that the alphabetical subject index announced for the final volume of "Silver—B" will help to reduce this difficulty.

The present volume begins with a description of the sorption of the inert gases and hydrogen by silver, and also of their solubility and diffusion in silver. Although no well-defined compounds between silver and the inert gases are, as yet, known, silver does react with hydrogen to form a compound with the composition AgH, which exists at any rate in the gaseous state. Solid silver hydrides have certainly been described, but their existence is uncertain. In the silver-oxygen system, Ag_2O occupies the most space. In addition, oxides are known in which silver occurs in the oxidation states of +2 and +3. In the silver-nitrogen system, the description of silver nitrate occupies 37 pages. A further 66 pages are taken up with solutions of $AgNO_3$ and systems containing silver nitrate and alkali metal and alkaline earth metal nitrates. More interesting and stimulating for the chemist, however, are the sections on "Berthollet's silver fulminate", the main component of which is Ag_3N, and on silver azide, silver amide, silver imide, and the silver salts of the lower nitrogen oxy-acids. Most of the papers on the silver-fluorine system are of recent date, if one ignores those on the binary silver fluorides Ag_2F, AgF, and AgF_2. In particular, the fluorine compounds of Ag^{II} and Ag^{III} have become known due to the work of *R. Hoppe*, mainly over the past two decades.

In the silver-chlorine system, AgCl is the only binary silver-chlorine compound whose existence has been definitely proved at present. The AgF_2 analog $AgCl_2$ may exist in the gas phase. AgCl is one of the most thoroughly investigated of all chemical compounds, among other things because of its photochemical properties. The formation and the crystallographic, mechanical, magnetic, electrical, optical, and chemical properties of the pure compound occupy 147 pages, and the description of AgCl-containing systems takes another 30 pages. The rest of the volume is concerned with the silver salts of chlorine oxy-acids.

The literature is covered up to the end of 1969, and in some cases (*e.g.* $KAgF_3$, $RbAgF_3$, and $CsAgF_3$) as far as 1970.

Although recent Gmelin volumes have contained more tables than previously, the present reviewer feels that still more information should be presented in tabular form, thus making the rest of the text easier to read. This would be of particular assistance to users who cannot read German.

Ekkehard Fluck [NB 14 IE]

Survey of Organic Syntheses. By *C. A. Buehler* and *D. E. Pearson*. John Wiley & Sons Ltd., Chichester 1970. 1st Edit., ix, 1166 pp., bound £ 13.00.

The book presents a survey of the principal methods for the preparation of organic compounds. The discussion of each reaction is headed by a general reaction scheme which is followed by a description of the possible uses and the limitations of the method in question. Corresponding to the entirely practical orientation of the book, reaction mechanisms are considered in only a few instances. Finally, the uses of the method are illustrated by well-chosen examples with the relevant literature references. The arrangement of the book is based consistently on the type of compound being prepared. The 20-chapter book begins with the methods for the synthesis of alkanes and ends with those for nitro compounds.

I must confess that the incongruity of the book's claim that it presents a substantially complete account of the methods of practical importance and its relatively small size made me skeptical at first, particularly since the book is aimed both at students and at research chemists. However, a close examination provided a pleasant surprise.

The authors have been very successful in their presentation of the subject matter with special concentration on what is essential. All the methods that have proved useful in laboratory practice are presented briefly but without omission of any essential points. Important experimental data are given in every case. The selection of the methods, the examples, and the references reflect critical judgment of a high order. The use of the book is greatly facilitated by a comprehensive author and subject index.

[1] Cf. Angew. Chem. internat. Edit. *10*, 526 (1971).

In conclusion, it can be said that the book succeeds in providing a really useful survey of methods for the preparation of organic compounds. It is of great practical value, and should soon become a standard work for the organic laboratory.

H. Stetter [NB 16 IE]

Chemie der Pflanzenschutz- und Schädlingsbekämpfungsmittel (Chemistry of Plant Protection Agents). Edited by *R. Wegler*, Springer Verlag, Berlin–Heidelberg–New York, 1970, 1st ed., vol. 1: Einführung, Insektizide, Chemosterilantien, Repellents, Lockstoffe, Akarazide, Nematizide, Vogel- bzw. Säugetierabschreckmittel, Rodentizide (Introduction, Insecticides, Chemosterilizers, Repellents, Attractants, Acaricides, Nematicides, Chemicals Repelling Birds and Mammals, Rodenticides). xxiv, 671 pp., 23 figures, bound, DM 180.—. Vol. 2: Fungizide, natürliche Pflanzenwuchsstoffe, Rückstandsprobleme. (Fungicides, Natural Plant Growth Substances, Residue Problems). xxix, 550 pp., 24 figures, bound, DM 148.—.

This work will "enable students and young industrial chemists to become thoroughly familiar with the field of plant protection, while offering advice and help to specialists". In addition, it helps to fill a gap as a textbook and a survey of this field. The authors are chemists and biologists working mainly in industry (23 for Farbenfabriken Bayer AG, one for Shell Research Ltd., one for Farbwerke Hoechst AG, and two for the Department of Ecological Chemistry, Gesellschaft für Strahlenforschung mbH). The authors "tried to mold the large mass of data into a coherent whole. They also aimed to present the material in homogeneous sections, but primarily in a form dictated by the subject". The biological background is given "whenever it is needed for understanding the subject".

After the Introduction, devoted to the scientific significance of plant protection (17 pp., 22 refs.), volume 1 deals with the development of new plant protection agents (25 pp., 22 refs.), commercial formulations (14 pp., no refs.), and in the chapter on Insecticides—with the general aspects of the biology and testing of insecticides and acaricides (19 pp., 23 refs.), the combatting of the emergence of resistance (19 pp., 14 refs.), naturally occurring insecticides (33 pp., 353 refs.), chlorinated hydrocarbons (98 pp., 553 refs.), carbamates (27 pp., 160 refs.), insecticidal phosphoric esters (205 pp., 810 refs.), insecticides belonging to other groups (10 pp., 30 refs.), and contact insecticides (9 pp., 25 refs.). It also covers chemosterilizing agents (11 pp., 65 refs., alkylating agents, antimetabolites, *etc.*), insect repellents (9 pp., 33 refs.), insect sex attractants (25 pp., 73 refs.), acaricides (44 pp., 248 refs.; biology, historical, active substances), nematicides (10 pp., 27 refs.), bird and mammal deterrents (13 pp., 152 refs.), and rodenticides (43 pp., 1000—1200 refs.).

This comprehensive book gives an excellent survey of the fields mentioned above, and the extensive references permit these fields to be studied in depth. Stock protecting agents and the chemical analysis of active substances receive a somewhat cursory treatment. Questions of nomenclature, which are so important, are dealt with in the chapter on phosphoric esters.

The second volume is particularly valuable because it surveys the important fungicides (166 pp., 440 refs.) and herbicides, and comprises an excellent chapter on the residues of plant protection agents which can be detected in food and in the environment. The textbook nature of this work is enhanced by the color pictures of the main fungal plant diseases in the general part of the chapter on fungicides (40 pp., 43 refs.), and by color pictures of the main weeds in the section on herbicides. There is a very interesting section on phytohormones or natural plant growth substances (30 pp., 300 refs.). These two volumes can altogether be warmly recommended, and should not be missing from the bookshelves of any laboratory dealing with residue problems.

Konrad Pfeilsticker [NB 4 IE]

Experimentelle Einführung in die Anorganische Chemie (Introduction to Experimental Inorganic Chemistry). By *H. Biltz, W. Klemm*, and *W. Fischer*. Walter de Gruyter u. Co., Berlin 1971, 63.—70. Revised edition, 228 pp., 28 figs., 1 table, bound, DM 21.—.

The revised edition of Biltz, Klemm, and Fischer differs from the previous one principally in that the theoretical chapters have been considerably enlarged. The section on chemical bonding gives a concise and up-to-date treatment of the atomic structure of elements, and then describes the three types of bonding (ionic, covalent, and metallic). Although this only takes 7 pages, nothing essential has been omitted, and the topic is presented in a clearly understandable fashion. Appropriately, the most recent definition of the acid-base concept is also given, and the concept of pK is introduced.

The text is amplified with tables of data on the most important indicators (with end-point range and color of the indicator acid or base), solubilities, pK_A and pK_B values for the more important acids and bases, and oxidation and reduction potentials. Such data are very important for the quantitative description of chemical processes.

Despite these improvements, the size of the book has increased only slightly, if at all, due to the deletion of some data from the analytical section and certain sections, *e.g.* "Electronegativity".

The book, which is very attractive typographically and in its general appearance, is a considerable improvement over the previous edition, and will certainly please those who are already Biltz, Klemm, and Fischer enthusiasts. It can be recommended without reservations to all first-year chemistry students and to any student who is taking inorganic chemistry as a subsidiary subject.

Alois Haas [NB 22 IE]

Isonitrile Chemistry. Organic Chemistry, a Series of Monographs, Vol. 20, By. *I. Ugi*. Academic Press, New York, 1971. 1st Edit., xii, 278 pp., numerous illustrations, 8 tables, bound $ 14.50.

Despite the fact that review articles have appeared recently on individual aspects of isonitrile chemistry *(B. Zeeh; L. Malatesta)*, the present book deserves a warm welcome for the way in which it summarizes the information on the structure, syntheses, and reactions of isonitriles (isocyanides) in a single monograph of 256 pages. Not only does this book provide an introduction to the chemistry of isonitriles, but it also takes the trouble to present the position as it exists today.

The material is divided into the following chapters: 1, The Structure of Isonitriles; 2, Isonitrile Syntheses; 3, Kinetics

of the Isonitrile-Nitrile Rearrangement; 4, Simple α-Additions; 5, Cyclization Reactions; 6, The Reaction of Isonitriles with Boranes; 7, The Passerini Reaction and Related Reactions; 8, Four-Component Condensations and Related Reactions; 9, Peptide Syntheses; and 10, Coordinated Isonitriles. This arrangement leads, of necessity, to a certain amount of overlap. For example, many reactions are found both in Chapter 4 and in Chapter 5.

In some of the chapters the material is subjected to a critical review, but in others this review is rather too short. Nevertheless, this monograph can be highly recommended, since it enables the chemist to obtain a quick and comprehensive insight into the chemistry of isonitriles.

Kurt Lev [NB 15 IE]

Komplexchemie (The Chemistry of Complexes). By *M. Becke-Goehring* and *U. Hofman*. Springer Verlag, Berlin–Heidelberg–New York 1970. 1st edit., viii, 245 pp., 104 figures, bound, DM 18.80.

This book is an up-to-date introduction to the chemistry of complexes from the chemist's viewpoint. After an explanation of the meaning of the "chemistry of complexes" and a short historical introduction, the first part of the book deals systematically with the phenomenology of complex compounds. The types of isomerism are described, with particular reference to stereoisomerism, which is of great importance when establishing structural formulas. One chapter is devoted to chelate complexes. All the important classes of complexes (metal carbonyls, hydrido complexes, *etc.*) are considered in relation to their importance, as also are the very recent developments in the field of complex chemistry (*e.g.* complexes with N_2 as the ligand and the electron donor-acceptor complexes). A consideration of the stability of complexes, particularly in aqueous solutions, closes the second part of the book. In the third part are described the structures of complex compounds with the central atoms having coordination numbers of 2 to 9.

In Part 4 the authors go into the theories of bonding between the central atom and the ligands. First of all the valence bond theory is described and its achievements are demonstrated. Any discussion of the chemistry of complex compounds which did not involve ligand field theory would now be unthinkable. The authors have successfully accomplished this far from easy task without recourse to the development of mathematical foundations. The use of the ligand field theory is clearly explained.

Finally, the authors deal with the substitution reactions of complexes of octahedral and quadratic structure, and also with the *trans* effect and the chelate effect. The concepts of "hard and soft acids or bases" which have been much used recently, bring the book to a close.

The book gives an extremely good overall picture of the chemistry of complexes. It is distinguished by a strictly systematic approach and by a clear and precise style of writing. Practically all the viewpoints and principles which are in any way of importance in complex chemistry have been taken into consideration. However, the present reviewer would welcome it if when a new edition appears there could be some mention of the approach of *Magnus*, with its electrostatic basis. Whether or not a complex exists and and is stable in the solid crystalline state depends on the energy of complex formation and, under certain circumstances, also on the lattice energies of the substances involved. It is striking that in recent books on the chemistry of complexes the ligand field theory gets its due mention, but Magnus' electrostatic approach, which permits a simple energetic interpretation of the coordination number, is left out in the cold.

Finally, I should like to emphasize that this excellent introduction to the chemistry of complexes can be warmly recommended to students of chemistry. The expert will read the book with pleasure and be stimulated by the way in which the information is conveyed. The use of extensive literature references is particularly valuable.

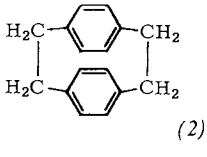
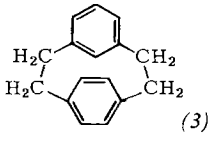
Stereochemistry of [2.2]Metacyclophanes



By Fritz Vögtle and Peter Neumann[*]



Increasing numbers of investigations have been carried out on bridged aromatic compounds, the independence of which was very recently acknowledged in the class name "phanes". Special attention is being attracted by the [2.2]metacyclophanes, whose molecular architecture raises many interesting theoretical questions, mainly with regard to intramolecular steric and electronic interactions. In the present progress report, a short description of the classification and nomenclature of the phanes is followed by a discussion of new physical and chemical aspects of the stereochemistry of [2.2]metacyclophanes and a number of related [2.2]phanes with other aromatic nuclei.

1. Introduction

In addition to demanding synthetic problems, the [2.2]phanes, the best-known of which are [2.2]metacyclophane *(1)*, [2.2]paracyclophane *(2)*, and [2.2]metaparacyclophane *(3)*, present interesting and varied theoretical aspects. This is true in particular of the stereochemistry and the resulting intramolecular steric and electronic interactions, as well as the transannular reactions. The [2.2]metacyclophane system, which will be considered more fully here, is particularly suitable for use as a model system for the investigation of such questions, owing to

(1)

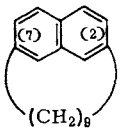
(2)

(3)

the possibility of introducing a wide range of substituents into the interior of the ring. For example, it is possible to investigate interactions of fixed atomic groups with one another or with aromatic systems, the influence of extraannular substituents on such processes, and transannular ring closure reactions in compounds with comparatively simple structures. In view of the abundance of data available, a critically selective survey of the developments of recent years seems appropriate[1]. Since the situation is not very clear at present, the nomenclature and classification of bridged aromatic compounds will first be briefly described[2].

1.1. Classification of the Phanes

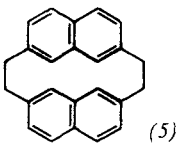
The class designation "phanes"[3] embraces all bridged aromatic compounds, provided that the following conditions are satisfied:



1. The *bridge* satisfies the IUPAC definition[4] in Rule A-31.1, Footnote: "A bridge is a valence bond or an atom or an unbranched chain of atoms connecting two different parts of a molecule."

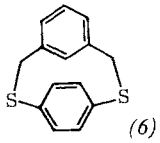
2. The aromatic nuclei (or heteroaromatic nuclei) must be capable of being named in accordance with IUPAC Rule A-21.1 to A-22.5 (or B-1 to B-4).

The definition of phanes is as follows. *Phanes are any compounds containing at least one aromatic nucleus and at least one bridge.* The compound *(4)* is a simple example of a "phane".

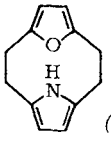


An important advantage of this group designation is that *e.g.* compounds such as *(5)* to *(8)* can be designated briefly and as a class by the name "[2.2]phanes", since this

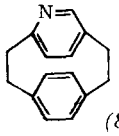
[*] Prof. Dr. F. Vögtle and Dipl.-Chem. P. Neumann
Institut für Organische Chemie der Universität
87 Würzburg, Landwehr (Germany)



(4)



name unambiguously defines the common structural characteristic, *i.e.* the presence of two aromatic nuclei and two bridges of two atoms each[*].



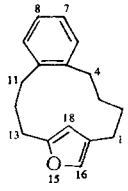
(5)

(6)

(7)

(8)

Moreover, the phanes can be divided into groups and subgroups according to the nature of their structural elements. Thus phanes such as *(5)* and *(6)* with carbocyclic aromatic nuclei (benzene, naphthalene, *etc.*) are called carbophanes, and those with heteroaromatic nuclei such as *(7)* are called heterophanes. If the character of the bridge is taken into account in the name, the prefixes carba- and hetera- show whether the bridge contains only carbon atoms or also contains hetero atoms. A phane such as *(6)* with carbocyclic nuclei and bridges containing hetero atoms thus belongs to the subgroup of hetera-carbophanes.



1.2. Phane Nomenclature

According to the basic rules of phane nomenclature[2b], the number of bridge atoms [*e.g.* 9 in *(4)*] between the bridgehead atoms in the aromatic ring [2 and 7 in *(4)*] is first given in square brackets. The bridgehead positions are then given in round brackets according to the IUPAC numbering of the aromatic nucleus. This is followed by the IUPAC name of the aromatic nucleus, to which the suffix -phane is attached with insertion of the letter o. *(4)* is thus [9](2,7)naphthalenophane. On historical grounds, however, an exception is made in the case of bridged benzene rings; these are called ortho-, meta-, or paracyclophanes.

If there are several aromatic nuclei and hence several bridges in the molecule, the start of naming and numbering is determined by the longest bridge [cf. *(9)*]. For bridges of equal length, as in the case of the [2.2]phanes, the aromatic nuclei are arranged alphabetically; in the case of the cyclophanes, the order is ortho, meta, para.

[*] The name "[*n.m*]phanes" unambiguously indicates compounds with two bridges and two nuclei even when *n* and *m* are large. It does not include compounds having two bridges and only one nucleus; these are called "[*n*][*m*]phanes" [2b]. In the latter designation the square brackets are not separated by the name of any aromatic nucleus. This is in marked contrast to the designations of the compounds *(6)*—*(8)*.

The phane designations for the compounds *(5)* to *(9)* are thus [2.2](2,7)naphthalenophane, 1,10-dithia[2.2]metaparacyclophane, [2](2,5)furano[2](2,5)pyrrolophane, [2]paracyclo[2](2,5)pyridinophane, and [4]orthocyclo[3](2,4)furanophane respectively. If the aromatic nuclei differ

(9)

only in the linkage positions, the two expressions in square brackets may be combined for simplicity [cf. *(6)*]. The same is true for identical linkage positions as in *(7)*: [2.2](2,5)furanopyrrolophane[**].

The phane concept will be further illustrated by the examples in the text.

2. Molecular Geometry and Physical Properties

2.1. [2.2]Metacyclophanes

The geometry of the [2.2]metacyclophane skeleton is known in detail from an X-ray structural analysis[5]. The crystal consists of discrete molecules, each of which has a center of symmetry. The two halves of the molecule form a stepped system (see Fig. 1). It is interesting to note that the benzene rings are not planar, but have a boat conformation (cf. Fig. 2), with the result that the molecule evidently avoids the steric interaction of the central carbon atoms C-8 and C-16 and of the attached hydrogen atoms. The C(8)—C(16) distance (a in Fig. 1) is 2.689 Å. The average length of the aromatic C—C bond was found to be 1.386 Å, and that of the aliphatic bond 1.543 Å. It is remarkable that the normally hexagonal, planar benzene ring suffers such a pronounced deformation with no appreciable change in the interatomic distances[6].

The X-ray structural analysis of 8,16-dimethyl[2.2]metacyclophane *(10)* confirms the results obtained for the

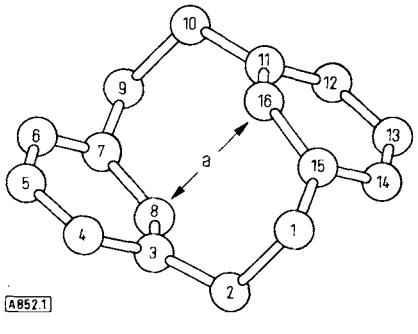


Fig. 1. Geometry of [2.2]metacyclophane *(1)*.

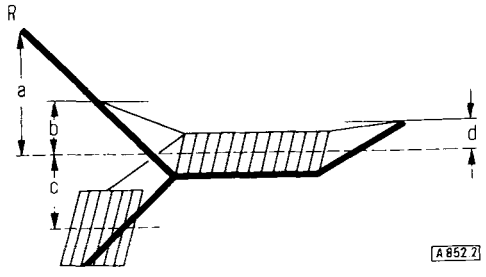
[**] It should be expressly mentioned that the numbers in square and in round brackets must not be omitted, since the number of similar aromatic nuclei (and naturally the number of bridges and atoms in them) can in many cases be deduced only from these figures [cf. *(4)* and *(5)*; see *(74)* and *(76)* in Section 4].

parent compound[7]. The increased strain in the molecule *(10)* as compared with that in the parent hydrocarbon *(1)* can be seen in particular in the distance between C-1 and C-2 (1.573 Å). It is also remarkable that the two methyl carbon atoms lie in one plane together with the carbon



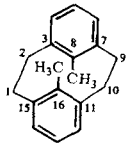


Fig. 2. Deviation of the benzene rings from planarity in *(1)*, *(10)*, and *(11)*. Only one half of the molecule is shown [5—8].

	R	a (Å)	b (Å)	c (Å)	d (Å)
(1)	H	—	0.143	0.368	0.042
(10)	CH_3	0.585	0.187	0.417 (0.453)	0.088
(11)	CH_2Br	0.494	0.178	0.367 (0.481)	0.080

atoms 8,7, and 3 and 16, 11, and 15 (cf. Figs. 1 and 2). The C(8)—C(16) distance is increased from 2.689 Å in *(1)* to 2.819 Å in *(10)*. The rotation of the methyl groups (which are fixed above the aromatic rings) about their axes appears to be hindered, if not blocked. However, proton resonance measurements down to −20 °C show no rotation barrier for the molecule in solution (see below).

(10)

The steric structure of 8,16-bis(bromomethyl)[2.2]metacyclophane *(11)* as found by X-ray structural analysis[8] largely corresponds to that of *(10)*; the benzene rings are deformed to a similar degree [C(8)—C(16) is 2.77 Å]. The C—Br bond length (1.981 ± 0.005 Å) is slightly greater than the usual values for aliphatic compounds (1.937 Å); this is attributed to steric factors. The CH_2—Br group is oriented in such a way that the bromine atom is on the side remote from the other benzene ring (Fig. 3).

The numerous ^{1}H-NMR investigations on dissolved [2.2]-metacyclophane *(1)*[9-17] agree excellently with the assumption of a "stepped" conformation such as is found in the crystal. Figure 4 shows the proton resonance spectrum of *(1)*[17]. The methylene protons of the two bridges are nonequivalent, since they have a fixed, staggered arrangement, and they therefore appear as an AA'BB' system[9]. A particularly striking feature is the absorption of the intra-annular protons H_i at unusually high field strengths ($\tau = 5.75$); this is explained by the fixation of their steric positions above the aromatic rings.

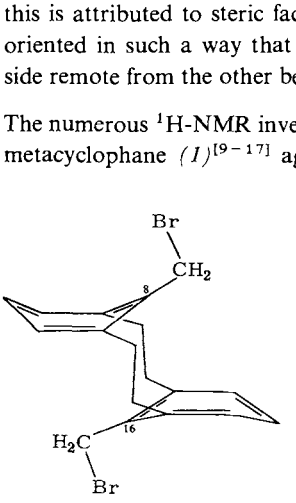

Fig. 3. Geometry of 8,16-bis(bromomethyl)[2.2]metacyclophane *(11)*.

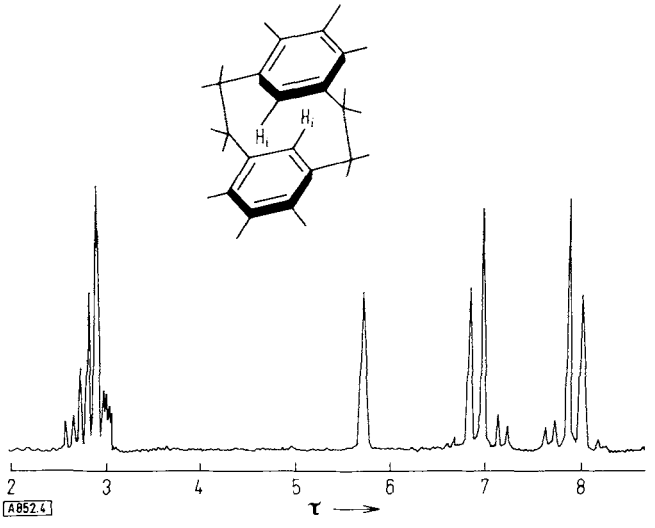

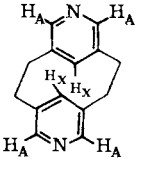

Fig. 4. ^{1}H-NMR spectrum of [2.2]metacyclophane *(1)* in $CDCl_3$ (60 MHz).

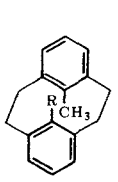
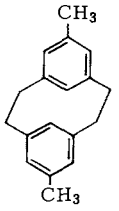
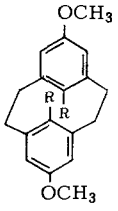


As is shown by the temperature-independence of the methylene resonance of *(1)* between −80 and +190 °C[12], the molecule is also perfectly rigid in solution; in agreement with molecular model considerations, ring inversion can be ruled out.

The molecular structure of [2.2](3,5)pyridinophane *(12)*, according to proton resonance results, agrees with that of *(1)*[18]. The protons of the pyridine nuclei absorb as an A_2X system, and the resonance of the intraannular protons H_X appears at a slightly lower field strength ($\tau = 5.49$) than in the case of *(1)* ($\tau = 5.75$); the same tendency is found for the protons of the methylene bridge, which form an AA'BB' system.



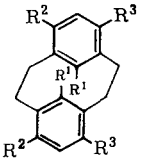
(12)



The anisotropy effect of the benzene nuclei is particularly evident in intra-annularly substituted [2.2]metacyclophanes. It is most pronounced in the case of 8-methyl[2.2]-metacyclophane *(13)*[19]. The absorptions of the intra-annular proton and also of the CH_3 group occur at the highest field strength so far found for such systems ($\tau = 6.28$ and 9.52 respectively; in $CDCl_3$). In 8,16-dimethyl[2.2]-metacyclophane *(10)*, on the other hand, the CH_3 resonance is displaced slightly less in relation to that of toluene [$\tau = 9.44$ for *(10)*, while $\tau = 7.68$ for toluene][9, 20].

(13), R = H
(10), R = CH_3

(14)



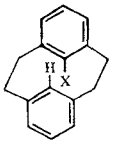
(15a), R = H[9]
(15b), R = CH_3
(15c), R = C_2H_5
(15d), R = C_3H_7

It is possible that each CH_3 group in *(10)* is more strongly removed from the sphere of influence of the opposite benzene ring than the methyl group in *(13)*, to compensate for the greater total strain. An X-ray structural analysis would be of value in clarifying this problem.

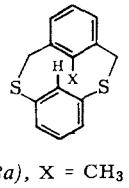
In 5,13-dimethyl[2.2]metacyclophane *(14)*, which also has a rigid conformation, the CH_3 groups absorb "normally" at $\tau = 7.64$, since they are not exposed to the shielding effect of the diamagnetic ring current of the benzene nuclei[9].

The rotation of intra-annular alkyl substituents about C—C single bonds does not appear to be hindered. For example, the CH_3 signal of *(10)* shows no broadening at $-20\,^{\circ}C$[9]. The ^{1}H-NMR spectra of *(15b)*[21], *(15c)*[22], and *(15d)*[23] also give no indication of hindered rotation.

The ^{1}H-NMR spectra of other [2.2]metacyclophanes of the type *(16)* with extra-annular substitution on the benzene rings were discussed by *Sato et al.*[24,25].

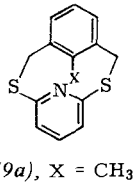


(16a), $R^1 = R^3 = H$, $R^2 = CH_3$
(16b), $R^1 = H$, $R^2 = R^3 = CH_3$
(16c), $R^1 = R^2 = R^3 = CH_3$
(16d), $R^1 = R^3 = H$, $R^2 = COOH$



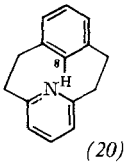
Further evidence of the rigid conformation of the [2.2]-metacyclophane system was provided by the resolution of *(16a)* and *(16d)* into optical antipodes as complexes with (−)-α-(2,4,5,7-tetranitro-9-fluorenylidenaminooxy)-propionic acid and as the quinine salts[12].

In the unsymmetrically substituted phanes *(17a)* and *(17b)*[26], which recently became available by the pyrolysis of suitable sulfones, both the protons of the methylene bridges (ABCD system) and the inner aromatic protons absorb at characteristically high field strengths [$\tau(H_i) = 5.63$ and 6.06 respectively].

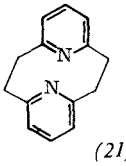


The chemical shifts of the methyl protons of *(18a)* and *(18b)* and of *(19a)* and *(19b)* show[27a] that the replacement of CH_2 groups in the bridges by sulfur atoms also leads to considerable upfield shifts; the $\tau(CH_3)$ value found for *(18a)* (9.41) is almost equal to that of *(10)* (9.44).

(17a), X = F
(17b), X = Cl



(18a), X = CH_3
(18b), X = OCH_3
(18c), X = CN[27b]



(19a), X = CH_3
(19b), X = OCH_3

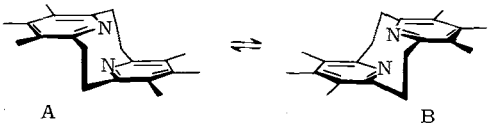
The influence of the pyridine ring in *(19a)* leads to a rather smaller shift of the methyl signal to higher fields ($\tau = 8.41$). The signal of the intra-annular hydrogen atom H_i is shifted ($\tau = 5.05$) in the same way as the signal of the methyl group in *(18a)*. The effect is not so pronounced in *(18b)* and *(18c)* [$\tau(H_i) = 4.80$ and 4.93 respectively].

If the benzene nuclei in [2.2]metacyclophane are successively replaced by pyridine rings linked in positions 2 and 6, the products are [2]metacyclo[2](2,6)pyridinophane *(20)* and [2.2](2,6)pyridinophane *(21)*. In the ten-membered rings, one and both respectively of the intra-annular hydrogen atoms of [2.2]metacyclophane have been formally replaced by the lone pair of electrons of the pyridine N atom. The ^{1}H-NMR spectrum of *(20)*[28] shows an AX_2 system for the protons of the pyridine ring and an AB_2 system for the extra-annular protons of the benzene ring. The intra-annular proton in position 8 again appears at a specifically high field strength ($\tau = 5.60$). The methylene protons of the bridge absorb as an ABCD system, which is unchanged even at 200 °C. *(20)*, like [2.2]metacyclophane itself, thus exists as a rigid, *anti*-staggered ring system up to high temperatures. The free energy of activation for the ring inversion as calculated from the experimental data is >27 kcal/mole.

(20)

(21)

For *(21)* in solution[29] on the other hand, an inversion process of the type A⇌B (Fig. 5) must be assumed on the basis of the temperature-independence of the ^{1}H-NMR spectrum.



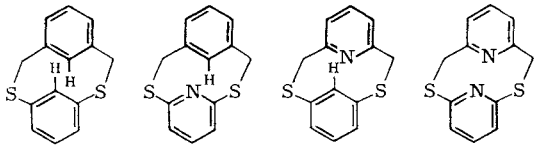


Fig. 5. Ring inversion process for *(21)*; schematic.

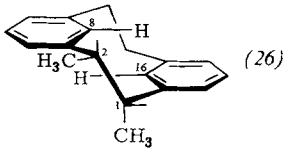
The free energy of activation ($\Delta G_C^{\ddagger}$) for this process was found to be 14.8, and the Arrhenius energy (E_A) is 15.3 kcal/mole. On the assumption of identical ring inversion mechanisms for *(1)*, *(20)*, and *(21)*, the steric hindrance in the transition state is evidently least in *(21)*, in which interaction occurs between two lone pairs of electrons on atoms that are not directly bonded to each other. It was therefore concluded that the space occupied by the lone pair of electrons on the nitrogen atom of pyridine is smaller than that occupied by a hydrogen atom attached to an aromatic nucleus.



Detailed ^{1}H-NMR studies on a series of [2.2]phanes of the types *(22)*—*(25)*[30] have confirmed these results, and at the same time impressively demonstrated the value of the

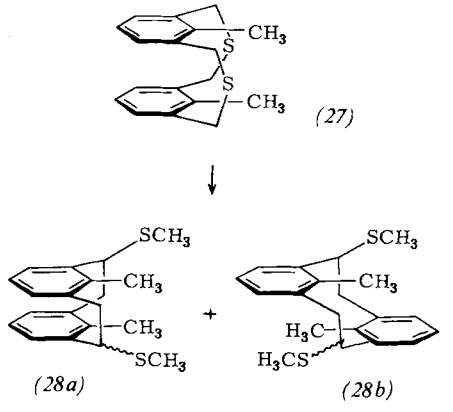
study of the dynamic stereochemistry of the phanes for the qualitative and quantitative determination of steric and electronic effects ("non bonded interactions").

(22) (23) (24) (25)

The intra-annular hydrogen atoms of 1,2-dimethyl[2.2]-metacyclophane *(26)*[31] are magnetically nonequivalent. Whereas H-8 has the same chemical shift as the intra-annular protons of [2.2]metacyclophane ($\tau = 5.75$), the H-16 resonance is displaced to lower fields ($\tau = 5.50$). This displacement could be due to the influence of the methyl group on C-1 ($\tau = 9.15$), whereas a considerably weaker interaction is to be expected between H-8 and the equatorial CH_3 group ($\tau = 8.52$) on C-2. Double resonance experiments also confirm that the axial proton on C-2 couples with the protons of the equatorial CH_3 group.

(26)

The UV spectrum of [2.2]metacyclophane[14] has as its longest-wave absorption that at $\lambda_{max} = 272$ nm ($\log \varepsilon = 2.64$), with three inflections, which are displaced in relation to the reference substance 3,3'-dimethylbibenzyl. MO calculations taking the deformation of the benzene rings into account show satisfactory agreement with the spectroscopic findings[10].



Transannular charge-transfer interactions between [2.2]-metacyclophane and tetracyanoethylene are regarded as the reason for the appearance of a band at 490 nm, which is characteristically displaced to longer wavelengths in relation to that of the corresponding complex with *m*-xylene[16]. Transannular charge-transfer interactions mean in this context that the benzene ring of [2.2]metacyclophane that is turned away from the tetracyanoethylene strengthens the donor action of the nucleus adjacent to the acceptor. However, the long-wave absorption of the [2.2]paracyclophane-tetracyanoethylene complex ($\lambda_{max} = 521$ nm)[32] is not attained.

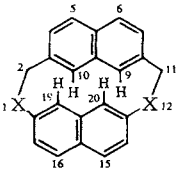
Bands appearing between 1400 and 400 cm^{-1} in the IR spectrum of [2.2]metacyclophane, which are absent or are not present with comparable intensities in the spectra of the reference substances *m*-xylene, [2.2.2]metacyclophane, and [2.2.2.2]metacyclophane, are attributed to the deformation of the benzene nuclei[16].

The mass spectra of [2.2]metacyclophane and higher metacyclophanes have been discussed by *Jenny et al.*[14, 33] and by *Flammang et al.*[16].

Whereas the [2.2]metacyclophanes described so far, according to the spectroscopic findings, have the *anti* conformation with staggered benzene rings, the existence of a *syn* form for a [2.2]phane has recently also been detected[34].

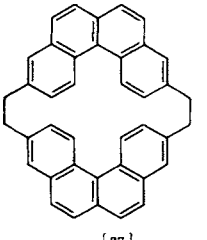
Ring contraction (Stevens rearrangement) of the bis(sulfonium tetrafluoroborate) of *syn*-9,18-dimethyl-2,11-dithia[3.3]metacyclophane *(27)* led to a 3:1 mixture of *syn* and *anti* isomeric substituted [2.2]metacyclophanes *(28a)* and *(28b)*.

(27)



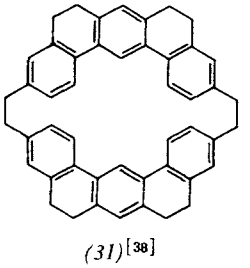
(28a) *(28b)*

The assignment of the isomers is based on the ^{1}H-NMR spectra. The *C*-methyl protons of the *syn* form *(28a)*, as expected, absorb at a very much lower field strength ($\tau = 8.0$) than those of the *anti* form *(28b)* ($\tau = 9.3$).

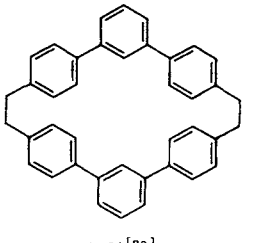


2.2. Compounds Analogous to [2.2]Metacyclophane

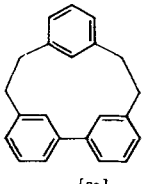
2.2.1. [2.2]Carbophanes



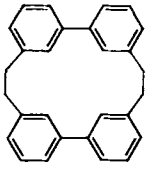
The molecular geometry of the [2.2]phanes *(5)* and *(29)* to *(31)* may be expected to be very similar to that of



(5), X = CH_2[35]
(29), X = S[36]



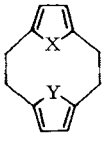
(30)[37]



(31)[38]

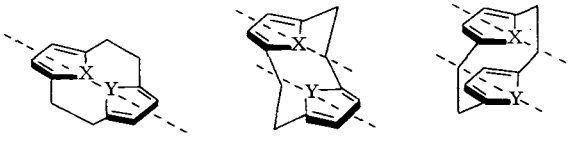
(32)[38]

(33)[39]



(34)[39]

[2.2]metacyclophane, since the two C_{Aryl}—CH_2 bonds from the aromatic nuclei enclose an angle of approximately 120° in each case. Rigid, stepped, *anti* conformations were in fact found in all cases, the unusually high field strength of the absorptions due to the intra-annular hydrogen atoms being taken as an important indication. The compounds *(32)*—*(34)* may also be regarded as metacyclophane analogs.



2.2.2. [2.2]Heterophanes with Five-Membered Aromatic Rings

In view of the entirely different geometry of "aromatic" five-membered rings, the [2.2](2,5)heterophanes *(35)* cannot be compared directly with [2.2](1,3)cyclophanes and [2.2](1,3)pyridinophanes[40]. On the basis of the Raman and IR spectra, *Winberg et al.*[41] proposed the *anti* conformation B with C_{2h} symmetry for [2.2](2,5)furanophane

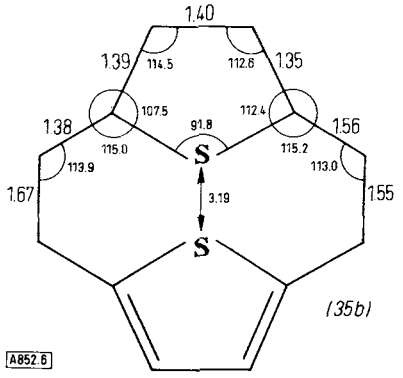
(35a), X = Y = O
(35b), X = Y = S
(35c), X = O; Y = S .
(35d), X = Y = NCH_3

(35a) and [2.2](2,5)thiophenophane *(35b)*, and ruled out the *syn* form C and the coplanar conformation A. A staggered *(anti)* arrangement of the pyrrole nuclei can also be deduced for *(35d)* from ^{1}H-NMR observations[42].

A B C

In the course of a study on benzotrifuroxane *(36)*, *Kamenar* and *Prout*[43] carried out an X-ray structural analysis of a 1:1 π complex of this compound with *(35b)*. As in the case of [2.2]metacyclophane, the length of the C—C bonds of *(35b)* in this complex are practically the same as the normal values. However, the normally planar thiophene rings are appreciably deformed; they are in a sort of boat form. The bridgehead atoms C-2 and C-5 of each thiophene ring project 0.08 to 0.10 Å above the plane of the other ring atoms. However, the planes laid through each thiophene ring by the method of least squares are almost exactly parallel. The distance between two bridgehead atoms of the same CH_2—CH_2 bridge (2.80 and 2.82 Å) is exactly the same as in [2.2]paracyclophane *(2)*[44]. The S—S distance (3.19 Å) is about 1 Å greater than expected for an undistorted model molecule, but is still about 0.5 Å smaller than the van der Waals distance. The distances between the S atom of one thiophene ring and a bridgehead atom of the second thiophene ring (2.93—3.02 Å) are also considerably shorter than the sum of the van der Waals radii.

Even within this series of bridged heterocyclic five-membered rings, it is not entirely safe to draw conclusions regarding the space required by intra-annular atoms or electron pairs from the ring inversion barriers, since the bond lengths and



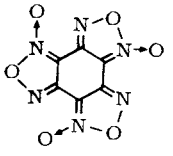


Fig. 6. Molecular geometry of [2.2](2,5)thiophenophane *(35b)* in the 1:1 adduct with benzotrifuroxane *(36)*.

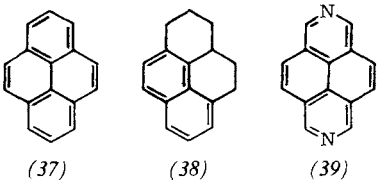
(36)

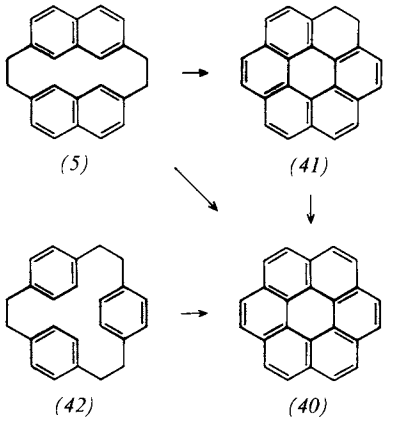


angles differ widely. The considerable difference between the conformational mobilities of the thiophenophane *(35b)*, the molecules of which are perfectly rigid, and of the furanophane *(35a)*, which is flexible, is certainly not due only to the difference in the bulks of the S and O atoms in the five-membered heterocycle. Unfortunately, there is no known X-ray structural analysis of *(35a)*, from which the influence of the bond angle might be estimated.

3. Molecular Geometry and Chemical Properties

3.1. Transannular Reactions

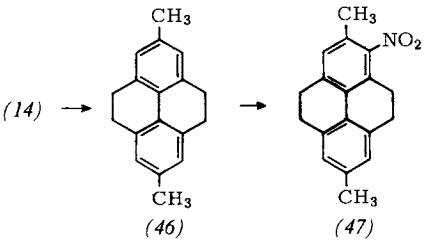
In the course of transannular (ring closure) reactions, one or more additional bridges, and hence new rings, are formed by linkage usually of atoms that lie opposite each other in the ring system, possibly with simultaneous or subsequent further changes in the carbon skeleton.



In the [2.2]metacyclophane system, such reactions normally lead to the pyrene skeleton *(37)*. Dehydrogenation of [2.2]metacyclophane *(1)* itself with palladium/charcoal at about 300°C leads to pyrene *(37)* in 60% yield; when *(1)* is heated with $AlCl_3$ in CS_2, however, only isomerization to the hexahydropyrene *(38)* takes place[45]. *Jenny* and *Holzrichter*[46] obtained 2,7-diazapyrene *(39)* in 30% yield from [2.2](3,5)pyridinophane *(12)* by heating with Pd/C (290°C) in triethylene glycol.

(37) *(38)* *(39)*

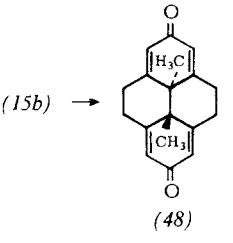
The coronene system *(40)* should be obtainable from the metacyclophane analog [2.2](2,7)naphthalenophane *(5)* by two transannular ring closures. However, the catalytic



dehydrogenation of *(5)* leads only to traces of coronene, whereas treatment with $AlCl_3$ in boiling CS_2 in this case leads in good yields to a mixture of coronene *(40)* and 1,2-dihydrocoronene *(41)*. The compound *(41)* can be dehydrogenated to coronene with palladium in 87% yield[47]. [2.2.2]Paracyclophane *(42)* also gives coronene on oxidation[45b].

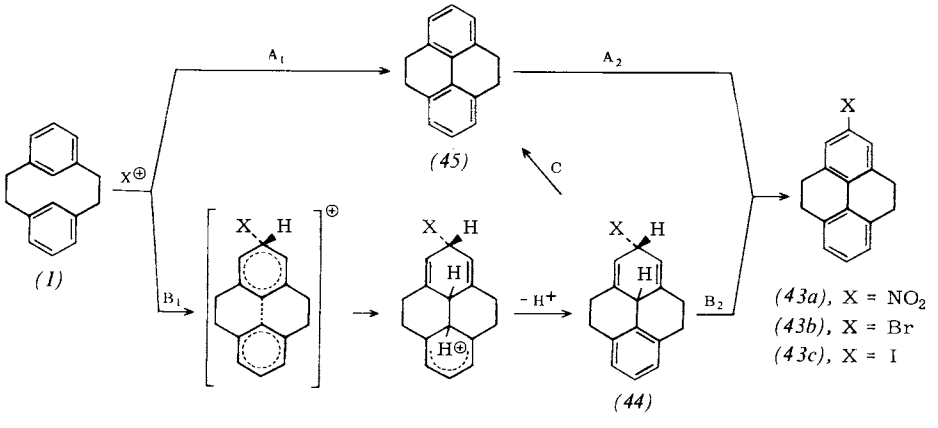
(5) *(41)* *(42)* *(40)*

It is interesting to note that the electrophilic substitutions investigated so far on [2.2]metacyclophanes[48] are associated with transannular ring closures.



According to *Allinger et al.*[15], the nitration of [2.2]metacyclophane *(1)* probably proceeds *via* the tetrahydropyrene *(45)* (path A_1A_2), and not as a concerted transannular aromatic substitution (addition-elimination process B_1B_2), as had previously been assumed by the same group of workers[10]. *Sato et al.* also concluded that the 2-nitro-4,5,9,10-tetrahydropyrene *(43a)* that occurs as the nitration product of [2.2]metacyclophane even under mild conditions is formed not from *(44)*, $X=NO_2$, but from *(45)*[13]. The dimethyltetrahydropyrene *(46)* was in fact detected and isolated as an intermediate in the nitration of 5,13-dimethyl[2.2]metacyclophane *(14)*[15,24]. On the other hand, the intra-annularly substituted 4,6,8,12,14,16-hexamethyl[2.2]metacyclophane *(16c)* gave the 5-nitro derivative, which contains the metacyclophane structure, as is shown by its ^{1}H-NMR spectrum[24].

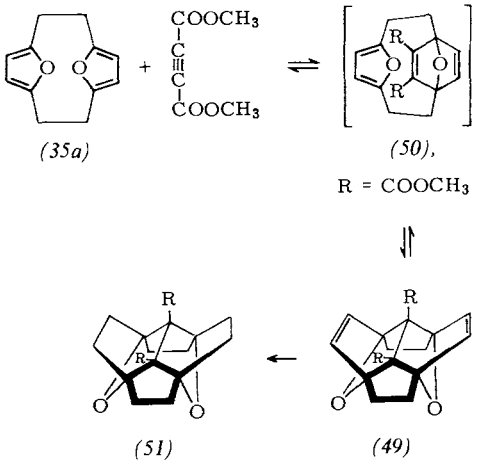
(14) → *(46)* → *(47)*



analogous to the nitration product[15], whereas *Sato et al.*, as in the iodination (with $I_2/AgClO_4$), obtained only 4,5,9,10-tetrahydropyrene *(45)*[49]. *Sato et al.*[49] therefore did not rule out the path B_1C for this reaction. On the other hand, the iodination of *(1)* with I_2/HNO_3, which leads to 2-iodo-4,5,9,10-tetrahydropyrene *(43c)*, is assumed to proceed by path B_1B_2.

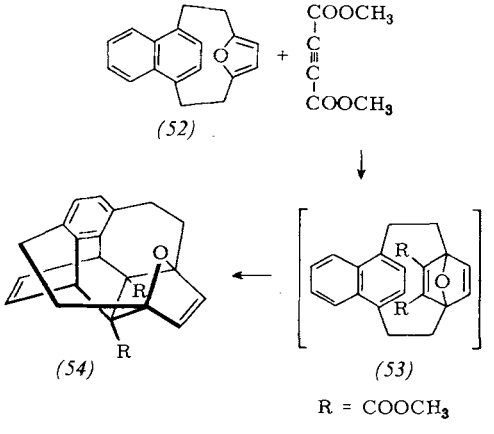
The tendency of the [2.2]metacyclophanes to undergo transannular ring closure even under mild reaction conditions was used by *Boekelheide* for the preparation of 10b,10c-dialkylated dihydropyrene derivatives, which are of interest because of their aromaticity[21]. The transannular ring closure occurs surprisingly readily in the case of *(15b)*. The bis-dienone *(48)*, which is stable to acids, is obtained in practically quantitative yield on oxidation of *(15b)* with $FeCl_3$ in chloroform or with CrO_3/H_2SO_4 in acetone. The ethyl-substituted and *n*-propyl-substituted compounds *(15c)*[22] and *(15d)*[23] react in the same manner.

(15b) → *(48)*



Interesting transannular reactions of some furanophanes have been described. Equimolar quantities of [2.2](2,5)-furanophane *(35a)* and dimethyl acetylenedicarboxylate, when heated at 105 °C, give a 1:1 adduct *(49)*, which decomposes back into the components at 165 °C[50]. The

(1) → *(45)* → *(44)* → *(43a)*, X = NO_2; *(43b)*, X = Br; *(43c)*, X = I

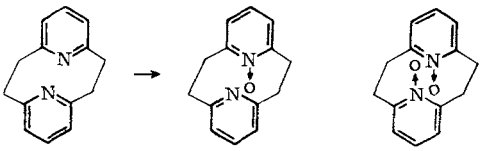


The situation is more complicated in the halogenation of [2.2]metacyclophane *(1)*. In the bromination, *Allinger et al.* obtained the 2-bromo-4,5,9,10-tetrahydropyrene *(43b)* formation of the symmetrical adduct can be explained by a plausible two-step mechanism. In the first step, an intermolecular Diels-Alder reaction leads to the intermediate

(50), which reacts further in a second Diels-Alder reaction, which is intramolecular in this case, to give *(49)*. The assignment of the structure *(49)* was based on spectroscopy (particularly ^{1}H-NMR spectroscopy) and on the formation of *(51)* on hydrogenation with H_2/Pd.

(35a) *(50)*, *(51)* *(49)*

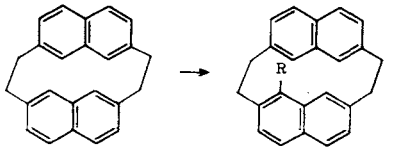
In the case of the "mixed-nucleus" compound [2](2,5)-furano[2](1,4)naphthalenophane *(52)*, the furan ring, as the more active diene component, reacts first with dimethyl acetylenedicarboxylate, again in an intermolecular Diels-Alder reaction, to give *(53)*. The intramolecular 1,4-addition to form *(54)*, as can be deduced from mass-spectroscopic and ^{1}H-NMR-spectroscopic results, then takes place on the unsubstituted nucleus of the naphthalene grouping[51].



(52) *(54)* *(53)*

3.2. Intra-annular Reactions

Ideal intra-annular reactions occur exclusively in the interior of ring systems without subsequent reactions such as transannular linkage.



The mono-*N*-oxide and the di-*N*-oxide [*(55)* and *(56)*] of [2.2](2,6)pyridinophane *(21)* were obtained without difficulty[52].

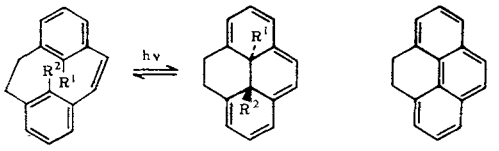
Whereas electrophilic substitutions on [2.2]metacyclophane proceed with transannular ring closure (cf. Section 3.1), the nitro group is introduced into the interior of the ring in the nitration of [2.2](2,7)naphthalenophane *(5)* in

(21) *(55)* *(56)*

benzene/glacial acetic acid; 9-nitro[2.2](2,7)naphthalenophane *(57a)* is formed in 55% yield[35b]. The amine *(57b)* can be obtained by reduction of the nitro compound.

(5) *(57a)*, R = NO_2 *(57b)*, R = NH_2

3.3. Photochemical Reactions



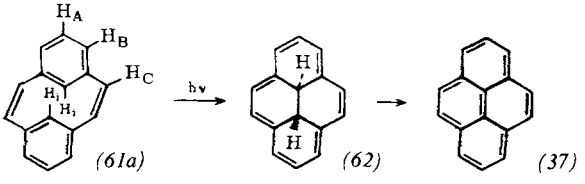
3.3.1. [2.2]Metacyclophanes

Transannular ring closure reactions of [2.2]metacyclophanes to form dihydropyrene derivatives can also proceed photochemically. After irradiation of a solution of [2.2]-metacyclophane *(1)* in cyclohexane in the presence of iodine and sodium hydrogen carbonate, *Sato et al.*[53] were able to isolate 4,5,9,10-tetrahydropyrene *(45)* in 86% yield. Since the starting material was simply recovered unchanged in the absence of iodine, the authors postulated free radicals containing iodine as intermediates in the reaction. Under comparable conditions, 5,13-dimethyl-[2.2]metacyclophane *(14)* similarly gave 2,7-dimethyl-4,5,9,10-tetrahydropyrene *(46)* in 26% yield; 4,6,8,12,14,16-hexamethyl[2.2]metacyclophane *(16c)*, on the other hand, exhibited no reaction[24].

3.3.2. [2.2]Metacyclophanes with Alkene Bridges

On irradiation with light of wavelength around 300 nm, the three metacyclophan-1-enes *(58a)*—*(58c)* undergo photoisomerization to form the colored 4,5,10b,10c-tetrahydropyrenes *(59a)*—*(59c)*[54, 55]. The equilibrium can be displaced back to the side of the [2.2]metacyclophan-1-enes both by irradiation with visible light (wavelength around 500 nm) and by thermal reaction (allowing the irradiated solution to stand in the dark). The equilibration and the kinetics of the dark reaction *(59)* $\rightleftharpoons$ *(58)* were investigated by UV spectroscopy. The reactions are first order. The reaction rate is greater for *(59c)* $\rightleftharpoons$ *(58c)* than for *(59b)* $\rightleftharpoons$ *(58b)* and *(59a)* $\rightleftharpoons$ *(58a)*. This surprising result is partly interpreted as a ring strain effect and partly attributed to a mass effect of the two methyl groups. *(59a)* and *(59b)* are extremely sensitive to oxygen, and are oxidized to 4,5-dihydropyrene *(60)*.

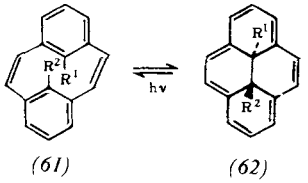
Because of the planarity of the valences at C=C double bonds, the stepped structure cannot be so pronounced in the [2.2]metacyclophane-monoenes and [2.2]metacyclophane-dienes as in the [2.2]metacyclophanes themselves. The absorptions of the intra-annular protons of [2.2]meta-



(58) (59) (60)

(a), $R^1 = R^2 = H$
(b), $R^1 = H$, $R^2 = CH_3$
(c), $R^1 = R^2 = CH_3$

cyclophan-1-ene *(58a)* and its 8-methyl derivative *(58b)*[19] occur at much lower field strengths ($\tau = 4.38$ and 5.10 respectively) than those of [2.2]metacyclophane *(1)* ($\tau = 5.75$) and of the monomethyl compound *(13)* ($\tau = 6.28$). Since the molecules *(58)* differ considerably in their overall geometry, it can hardly be assumed that this effect is entirely due to a deshielding action of the 1,2-double bond.

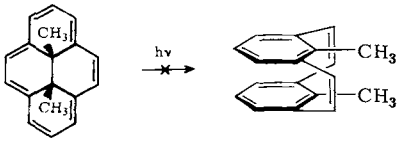


[2.2]Metacyclophane-1,9-diene *(61a)* has recently been prepared[56]. The structure of the compound was verified spectroscopically and by conversion into *anti*-[2.2]metacyclophane *(1)* and *trans*-10b,10c-dihydropyrene *(62)*.

(61a) (62) (37)

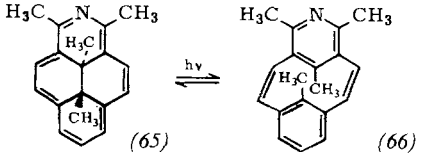
In the ^{1}H-NMR spectrum, the resonance of the intra-annular protons H_i ($\tau = 2.10$) appears at a much lower field strength than those of the other aromatic hydrogen atoms (AB_2 system). The olefinic protons (H_C) absorb as a singlet at $\tau = 3.78$.

The stability of *(61a)* is striking in comparison with that of the intra-annularly substituted [2.2]metacyclophane-1,9-dienes *(61b)*—*(61d)*. The 8,16-dialkyl[2.2]metacyclophane-1,9-dienes undergo spontaneous valence isomerization in the dark at room temperature to form the more stable aromatic *trans*-10b,10c-dialkyldihydropyrenes *(62b)*—*(62d)*[57,21-23]. The unsubstituted compound *(61a)*, on the other hand, gives a mixture of *trans*-10b,10c-dihydropyrene *(62)* and pyrene *(37)* only on irradiation.



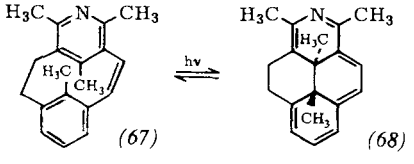
(61) (62)

(b), $R^1 = R^2 = CH_3$
(c), $R^1 = R^2 = C_2H_5$
(d), $R^1 = R^2 = n\text{-}C_3H_7$



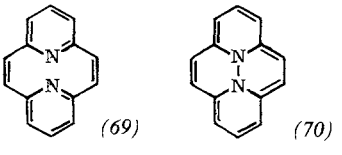
The dark reaction *(61)* $\rightleftharpoons$ *(62)* of the dienes follows first order kinetics. The rate is strongly dependent not only on peripheral substituents but also on the nature of the inner groups. For example, *(61c)* isomerizes six times as rapidly as *(61b)*, while the rate of rearrangement of *(61d)* lies between the values for *(61b)* and *(61c)*[23].

Whereas the reversible photoisomerization of *trans*-10b,10c-dimethyldihydropyrene *(62b)* to the valence-tautomeric *anti*-[2.2]metacyclophane-1,9-diene *(61b)* could be followed spectroscopically, attempts to achieve a photoequilibrium between *cis*-10b,10c-dimethyldihydropyrene *(63)* and *syn*-8,16-dimethyl[2.2]metacyclophane-1,9-diene *(64)* have so far been unsuccessful[34].



(63) (64)

On the basis of the ^{1}H-NMR spectrum, *Boekelheide* and *Pepperdine* assigned the structure of 8,12,14,16-tetramethyl-[2]metacyclo[2](3,5)pyridinophane-1,9-diene *(66)* to the product formed on UV irradiation of *trans*-1,3,10b,10c-tetramethyl-2-azadihydropyrene *(65)*[58]. The hydrochloride of *(66)* exhibits the fastest dark reaction known so far in the dihydropyrene series. The presence of a charge in one of the aromatic rings evidently promotes the formation of a bond to the other ring.

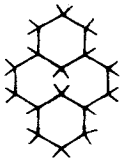


(65) (66)

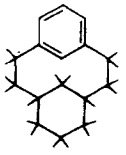
Irradiation of the monoene *(67)*, as in the case of the compounds *(58)* described above, leads to a photoequilibrium with the dihydropyrene derivative *(68)*.

(67) (68)

The question which of the isomers, *i.e.* [2.2](2,6)pyridinophane-1,9-diene *(69)* or 10b,10c-diaza-10b,10c-dihydropyrene *(70)*, is present was decided spectroscopically (^{1}H-NMR, UV) in favor of the diene *(69)*[52]. No isomerization of *(69)* was observed.



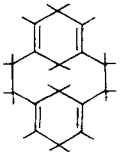
(69) (70)



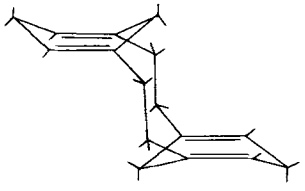
The conformational mobility in the molecule *(69)* would be difficult to investigate. Since the ^{1}H-NMR spectrum varies only slightly with the temperature, *Boekelheide* and *Lawson* assume that the molecule is not flexible[52].

3.4. Reduction of the [2.2]Phanes

The catalytic hydrogenation of [2.2]metacyclophane with platinum in glacial acetic acid leads in 91% yield to perhydro[2.2]metacyclophane *(71)*. If the hydrogenation is stopped after the uptake of 3 moles of hydrogen, the relatively strain-free 3,4,5,6,7,8-hexahydro[2.2]metacyclophane *(72)* can be isolated[10].

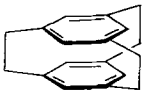


(71)

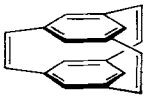


(72)

Birch reduction at −75 °C led to 5,8,13,16-tetrahydro[2.2]-metacyclophane *(73)*, for which *Reiner* and *Jenny*[59] postulated the mobile *anti* conformation *(73a)*.



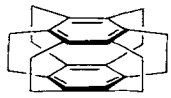
(73)



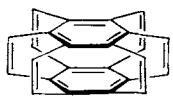
(73a)

4. Outlook

Though a large volume of experimental material on [2.2]-metacyclophanes already exists, as has been shown in this progress report, the investigations in this field, particularly with regard to the *syn*-[2.2]cyclophanes, the hetera[2.2]-cyclophanes, the [2.2]heterophanes, and the [2.2]cyclophanes with alkene bridges, can by no means be regarded as complete. However, the intensive stereochemical studies on [2.2]metacyclophanes have made a decisive contribution to our understanding of chemical and physical interactions in strained or sterically hindered ring systems of medium size. It was only on the basis of the experience and knowledge gained with the doubly bridged [*n.n*]cyclophanes that it also became possible to synthesize cyclophanes with larger numbers of bridges, among which [2.2.2](1,3,5)cyclophane *(74)* and the corresponding triene *(75)*, which have recently been prepared[60], merit attention.



(74)



(75)

The ultimate achievement of work in the cyclophane field would be the synthesis, in the foreseeable future, of the fully bridged [2.2.2.2.2.2]-(1,2,3,4,5,6)cyclophane *(76)* and its hexaene *(77)*.

ESCA: Electron Spectroscopy for Chemical Analysis[**]

By Carl Nordling[*]

A substance on which X-rays fall emits photoelectrons and Auger electrons. The energy spectra of the electrons emitted provide information about the electronic structure in the specimen, ranging from the innermost atomic levels and their dependence on the chemical environment to the molecular orbitals of the valence electrons and the band structure in solids. Electron spectra of this nature can now be recorded with high-resolution instruments; their analysis offers new aspects for investigation of chemical composition. The method of electron spectroscopy developed for this purpose, which has now been developed to a high degree of perfection, will be referred to in the following discussion as ESCA (Electron Spectroscopy for Chemical Analysis).

1. Introduction

For spectroscopic investigations on the structure of atoms and molecules and on the dynamics of atomic processes, one can either analyze the electromagnetic radiation emitted or one can measure the kinetic energy of the electrons emitted as a result of various processes in the electron clouds of the atoms. In certain cases, *e.g.* in NMR and Mössbauer spectroscopy, the atomic nucleus is also used as a source of information about the electron cloud. Whereas the spectroscopy of electromagnetic radiation has been widely used since *Newton*'s time, the behavior of the electrons liberated from the electron clouds has only rarely been investigated. The development of precision instruments for the analysis of electron spectra has nevertheless led to very notable results during the past few years, which show that a spectroscopy based on the direct observation of electrons is a very valuable method for the study of atomic and molecular systems and of solids. Electron spectroscopy also yields information that is not obtainable by other methods, and so offers numerous interesting possibilities *e.g.* for applications in chemistry.

The following article is a report on the ESCA method (Electron Spectroscopy for Chemical Analysis) and on the results obtained with its aid by our research group at Uppsala. (A more detailed report covering the situation up to 1969 may be found in refs. [1, 2].)

2. Excitation of the Electron Spectra

Electron spectra can be induced in various ways. The main agent used for this purpose is characteristic X-rays, though UV light and electron bombardment are also employed. The energy analysis of the emitted electrons is carried out in double-focusing spectrometers of the electrostatic or

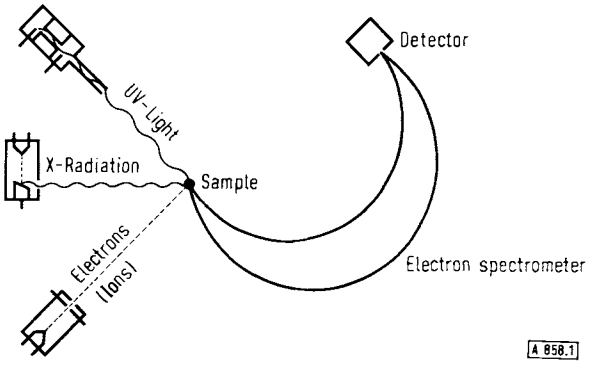

Fig. 1. Methods of exciting electron spectra for recording in high-resolution instruments.

magnetic types. The experimental arrangement is shown schematically in Figure 1, with an indication of the various modes of excitation. One of the magnetic instruments, with the ancillary electronic equipment, is shown in Figure 2.

as well as the molecular orbitals in free molecules and the energy bands in solids.

Excitation with *UV light* has the advantage of a small natural line width, but this process is restricted to the outermost parts of the electron clouds.

Electron bombardment can transfer the system under investigation into a highly excited state, which then decays with emission of an electron. This process, which is known as autoionization, thus produces a positively charged ion and an electron, whose kinetic energy is given by the formula

$$E_{\text{autoionization}} = E^* - E^+ = E^* - E_b \qquad (2)$$

In cases where the electron bombardment itself leads to an ionized initial state, the system becomes doubly ionized on decay. This transition from a singly ionized to a doubly ionized state with emission of an electron is known as the Auger effect, and the energy of the emitted Auger electron is given by

$$E_{\text{Auger}} = E^+ - E^{++} \approx E_b(1) - [E_b(2) + E_b(3)] \qquad (3)$$

Auger electrons can be liberated by high-energy light quanta. When X-rays act on a specimen, therefore, photoelectrons and Auger electrons are obtained together.

Fig. 2. View of an ESCA instrument.

In photoionization, the kinetic energy of the photoelectrons is equal to the difference between the energy $h\nu$ of the stimulating light quantum and the binding energy (ionization energy) E_b of the liberated electrons.

$$E_{\text{kin}} = h\nu - E_b \qquad (1)$$

X-rays of sufficiently high energy can liberate electrons from all levels, *i. e.* the inner atomic shells can be investigated

3. Chemical Shifts in the Spectra of the Inner Electrons

The binding energies E_b are not purely atomic quantities, but change slightly with the chemical environment. This property is manifested in the kinetic energies of the emitted electrons; it can be detected in the electron spectra by modern high-resolution instruments.

Figure 3 shows an ESCA spectrum of *N*-(2-pyridyl)-*p*-nitrobenzenesulfonamide. On excitation of the sample with $Mg_{K\alpha}$ radiation, photoelectrons were emitted, *inter alia*, from the K shells of the nitrogen atoms. Each of the three nitrogen atoms in the molecule has a different chemical environment; three different lines therefore appear in the electron spectrum.

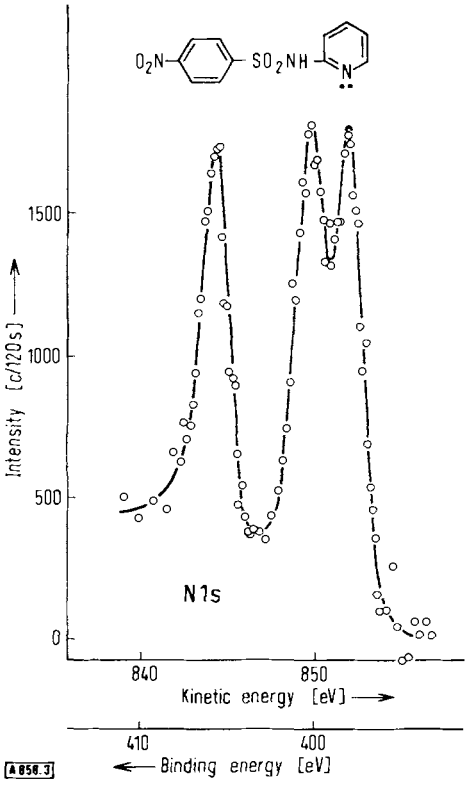

Fig. 3. ESCA spectrum for nitrogen (the 1s electrons) in *N*-(2-pyridyl)-*p*-nitrobenzenesulfonamide.

It is important to note that the electrons involved here are not the valence electrons, *i.e.* the electrons that are actually involved in the chemical bonding, but the electrons of the innermost parts of the electron cloud, which are usually "forgotten" by the chemist.

3.1. Calculation of Chemical Shifts

The binding energies E_b of the inner electrons in free molecules and their chemical shifts can be determined very accurately from quantum-mechanical calculations. In the best possible approximation method of the *ab initio* type for the solution of the Schrödinger equation, *i.e.* the Hartree-Fock (SCF) approximation, the binding energy is obtained as the difference between the total energies for the neutral molecule and the molecule-ion with a vacancy in the inner electrons. The shifts calculated so far by this method correspond to an accuracy of a few tenths of an electron volt, even though correlation effects and relativistic effects were disregarded. However, since the latter are independent of changes in the chemical environment in the case of the inner electrons, they do not affect the calculated chemical shifts.

Electron binding energies and chemical shifts can be obtained more easily from Hartree-Fock calculations with the aid of Koopmans' theorem. In this case the total energy of the neutral and the ionized systems is not calculated, but the binding energies are equated to the individual orbital energies for the neutral system; thus it is additionally assumed that the other electrons in the ion can be described by the same orbital wave functions as in the neutral molecule. The binding energies obtained in this way are systematically 10—20 eV higher than those found experimentally. They are also strongly dependent on the magnitude of the basis set used to describe the wave functions and on its optimization. However, they can be used for a comparison of theoretically calculated *shifts* in the binding energies and those found experimentally. Systematic calculations based on Koopmans' theorem are now available for the chemically induced shifts of the energies of the inner electrons; we have correlated them with the shifts observed experimentally[2].

Figure 4 shows a comparison of the measured chemical shifts for the 1s level of carbon in some small molecules with the orbital energy shifts from *ab initio* MO-LCAO-SCF calculations[3]. The method of least squares gave a straight line having a slope of 1.09. It was found in this case that the agreement of the calculated and the experimental shifts improves, *i.e.* the slope of the line becomes closer to 1, with increasing proximity to the Hartree-Fock limit.

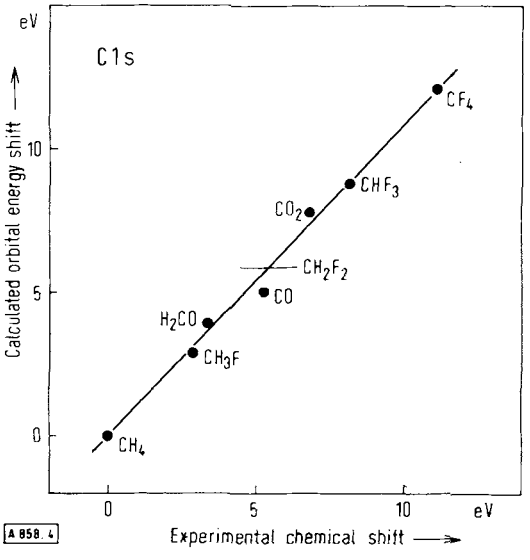

Fig. 4. Correlation between calculated orbital energy shifts for the 1s level of carbon in some small molecules and the experimentally determined shift.

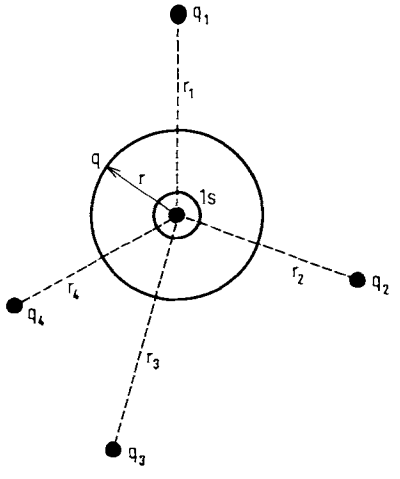
3.2. The Potential Model

A simplification of the theoretical calculation of shifts in the binding energy can be achieved with an electrostatic potential model[1,2]. In this model, the shifts in the binding energy are correlated with the electron distribution in the neutral molecule. The model is entirely classical, but can also be described and applied in quantum-mechanical terms.

In the potential model, the chemical shift for the energy E_b of an inner electron is determined by a change in the potential of the inner electrons. This potential is obtained as the superposition of two potentials, one due to the electron distribution in the atom in question and one due to the charge distribution in the remainder of the molecule. The latter contribution, which we call the molecular potential, is easy to calculate if the charges of the other atoms in the molecule are imagined to be concentrated in point charges q_i (see Fig. 5). The contribution to the shift that is due to the charge distribution in the atom under consideration can be mainly attributed to the valence electrons. If we assume that these form an electron shell of radius r, and if the effective charge q of the atom is placed in this shell, the corresponding contribution to the potential is given by q/r. A theoretically better estimate of this contribution is given by the electrostatic interaction integral J between the inner electron orbital under examination and a valence electron orbital in the same atom. The expression for the chemical shift in the energy level of the inner electron then becomes:



$$\Delta E = Jq + V + l$$

where the molecular potential is given by

$$V = \sum \frac{1}{r_i} \times q_i$$

and the constant l depends on the choice of the reference level. It is found that J is approximately equal to the expectation value $\langle 1/r \rangle$ for a valence electron.

Figures 6 and 7 illustrate the correlation between experimental chemical shifts for the 1s level of carbon and shifts calculated from the potential model with *ab initio* wave functions and with CNDO/2 wave functions respectively[3].

$$\Delta E\,(1s) = q/r + \Sigma q_i/r_i + l \qquad \boxed{A858.5}$$

Fig. 5. In the potential model, the chemical shift of E_b for an inner electron (*e.g.* 1s) is divided into a contribution from the interaction with the valence electrons of the atom in question and a contribution from the other atoms of the molecule. If the valence electrons of the atom in question are assumed to be concentrated in a spherical shell of radius r and having a net charge q, the first contribution is q/r. If the (net) charges of the other atoms are regarded as point charges q_i at distances r_i from the nucleus of the atom under investigation, the second contribution, *i.e.* the molecular potential, is $\Sigma q_i/r_i$.

The charges obtained from the *ab initio* wave functions are *Mulliken*'s "gross atomic charges". The constants J and l were determined in both cases by fitting the least square of $E - V$ to $Jq + l$; the values for J, 18.3 eV from the *ab initio* calculations and 23.5 eV from the CNDO/2 calculations, agree relatively well with the repulsion integrals J calculated for the 1s-2p electrons in a carbon atom.

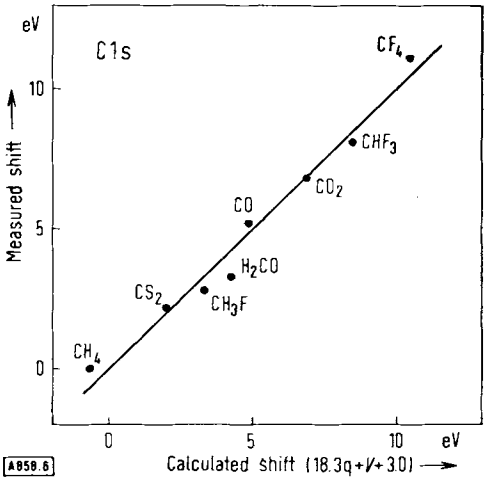


Fig. 6. Correlation between measured chemical shifts for the 1s level of carbon and the shifts calculated from the potential model, the charges being obtained from *ab initio* calculations.

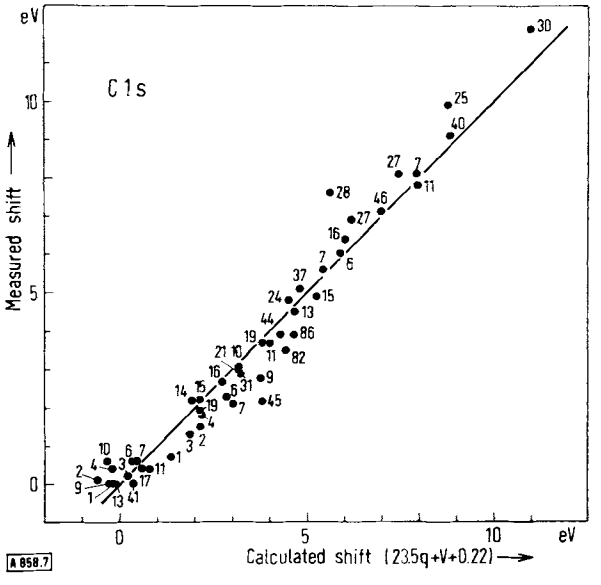

Fig. 7. Correlation between measured chemical shifts for the 1s level of carbon and shifts calculated from the potential model, the charges being obtained from CNDO/2 calculations. (For the assignment of the numbers, cf. [3].)

It can be seen with the aid of the simple potential model that the binding energy E_b of an inner electron increases (and the electron thus becomes increasingly difficult to remove from the electron cloud) with increasing positive charge on the atom. This can be demonstrated by the ESCA spectrum for carbon and oxygen in acetone (Fig. 8). The most strongly positive carbonyl C atom has the highest binding energy (left-hand line). The methyl C atoms (right-

hand line) are more nearly neutral. It can also be seen that the intensities of the lines reflect the relative abundances of the two different types of carbon atoms in the molecule. The intensities of the electron lines are proportional to the abundances of the elements, and can therefore be used for a quantitative elemental analysis, while information on the valences of the elements is obtained simultaneously.

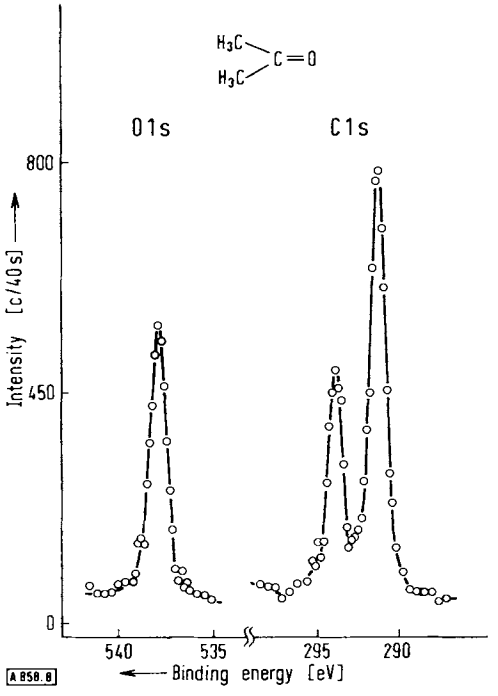

Fig. 8. ESCA spectrum for the 1s electrons of carbon and of oxygen in acetone.

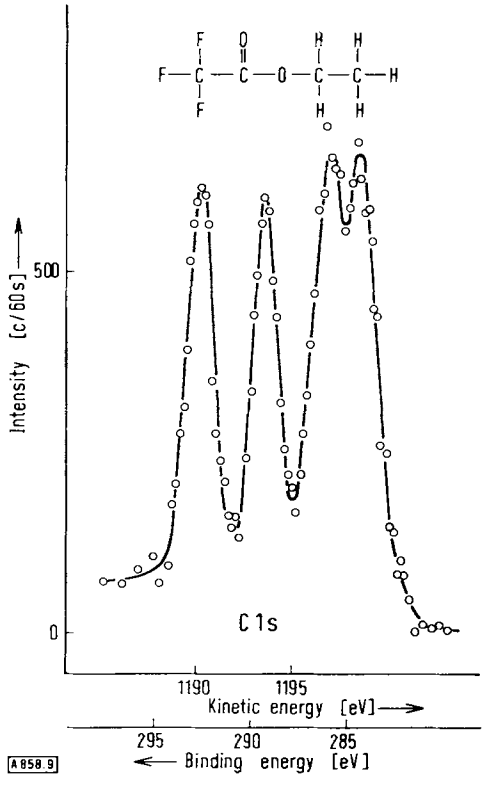

Fig. 9. ESCA spectrum for the 1s electrons of carbon in ethyl trifluoroacetate.

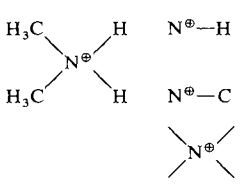
The carbon atoms in ethyl trifluoroacetate (Fig. 9) carry substituents having different electronegativities. The increasingly positive charge is clear from the positions of the lines in the ESCA spectrum of the compound. The lines, in order of excitation energy, are due to the four C atoms of the molecule in accordance with the notation used in Figure 9.

3.3. Charge Correlations



When ESCA is applied to chemical problems, it is often desirable to be able to interpret the chemical shifts in simple language that is understandable to any chemist. This has been found possible with the aid of the electronegativity concept. We have empirically established correlations between measured chemical shifts and an atomic charge parameter q_p. This charge parameter is obtained as the sum of the formal charges on the atom and the partial ionic characters of its bonds with neighboring atoms:

$$\underset{\text{charge}}{q_p} = \underset{\text{formal charge}}{Q} + \underset{\text{contribution of ionic character}}{\Sigma I}$$

The ionic bonding component, according to *Pauling*, can be expressed as a function of the electronegativity difference between the atoms of a bond.

$$I_{AB} = 1 - \exp[-0.25(\chi_A - \chi_B)^2]$$

The procedure can be illustrated *e.g.* by the calculation of the charge on the nitrogen in an alkylammonium ion, which carries a positive formal charge:

	$\Delta\chi$	I
$N^{\oplus}$—H	1.2	−0.30
$N^{\oplus}$—C	0.8	−0.15
$N^{\oplus}$		Q 1.00

$$q_p = 1.00 + 2(-0.30) + 2(-0.15) = +0.10$$

In this way it was possible to correlate shifts found in the ESCA spectra for a large number of compounds having very different structures with a calculated charge parameter q_p. Figure 10 shows the result for a series of sulfur groups, based on measurements of the 2p energy for about 100 sulfur compounds. Similar correlations are found for other elements, and this confirms the hypothesis of the charge-dependence of the binding energies. They have proved to be particularly useful in the application of the ESCA method. Some examples of the application of ESCA to special problems in chemistry are described in the following section.

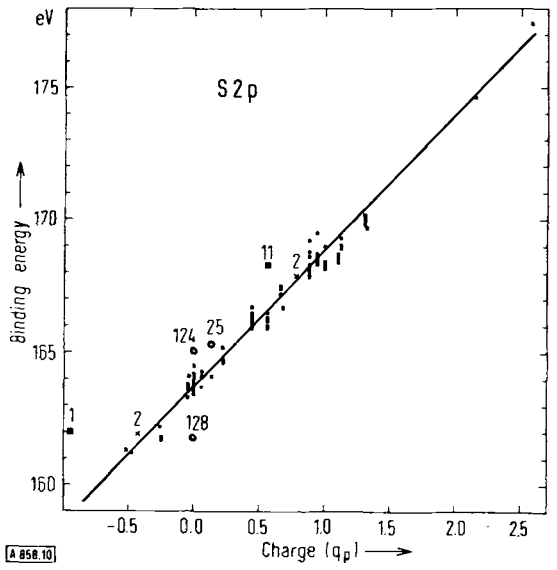


Fig. 10. Correlation of the ESCA shifts for the 2p level of sulfur in various sulfur groups with a charge parameter calculated as the sum of the partial ionic contributions in the bonds. (For assignment of the numbers, cf. [4].)

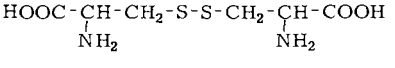
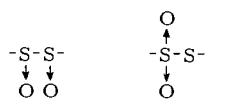
4. Selected Examples

4.1. Polarity of Chemical Bonds

The charge-dependence of the shifts makes electron spectroscopy particularly suitable for the study of the polarity of chemical bonds. It is possible in this way to investigate the polarity without knowing the bond lengths and bond angles.



S—O bonds in many sulfur compounds have been intensively studied[4]. The polarity has been found to be fairly structure-dependent for sulfoxides. Its average value lies roughly between the values calculated on the basis of model substances and charge correlations for the two limiting structures.



A comparison with the carbonyl group shows that the sulfinyl group has approximately the same polarity. These experimental results help to answer the question whether sulfur expands its valence shell by making use of d orbitals.

4.2. Oxidation of Cystine

The example of doubly oxidized cystine can be used to show how the chemical shifts in the ESCA spectra can help to solve structural problems[5]. The cystine molecule contains two equivalent sulfur atoms and two possible structures

had to be considered for the dioxide, *i.e.* disulfoxide and *S*-thiosulfonate.

Disulfoxide *S*-Thiosulfonate

Analysis of the IR and NMR spectra had yielded no definite answer regarding the occurrence of these isomers. The ESCA spectrum of the dioxide clearly shows, on the other hand, that the compound has a thiosulfonate structure (Fig. 11).

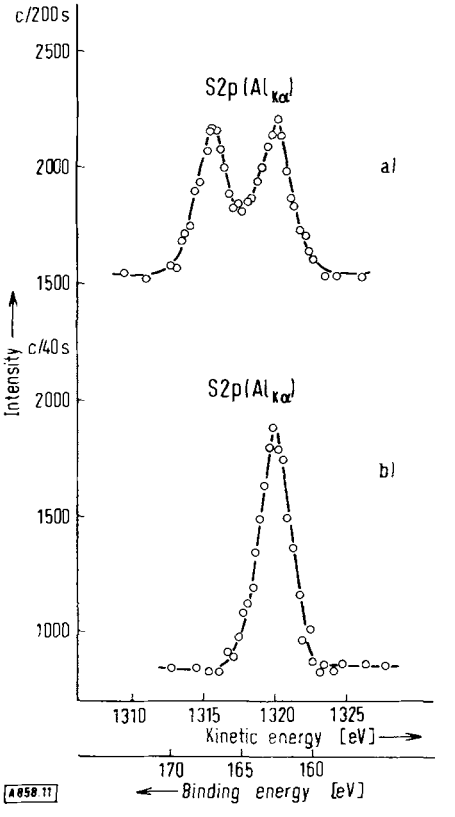


Fig. 11. Structure determination by ESCA. A comparison of the electron spectra from the 2p level of sulfur in cystine *S,S*-dioxide (a) and in unoxidized cystine (b) shows that the dioxide has a thiosulfonate structure.

Instead of a single line, as in the case of unoxidized cystine, two lines are observed for the 2p level of sulfur, one of these showing no shift and the other a shift of 4.0 eV to a more highly oxidized state. The disulfoxide would have given only one line, with the relative intensity doubled and with a shift of ≈ 2 eV.

More complicated structural problems have also been elucidated by the ESCA technique, and it is likely that the further development of the instruments used will lead to increasingly valuable conclusions.

4.3. Valence Problems

The problem of the electron transfer between the metal and the carbon in transition metal carbides was disputed for a long time. For lack of reliable experimental data, no decision could be reached in favor of any of the various theories proposed. ESCA measurements of the energy

shifts for the inner electrons in such compounds and other model substances have now shown that an electron transfer takes place from the metal to the carbon in these carbides (Fig. 12)[6].

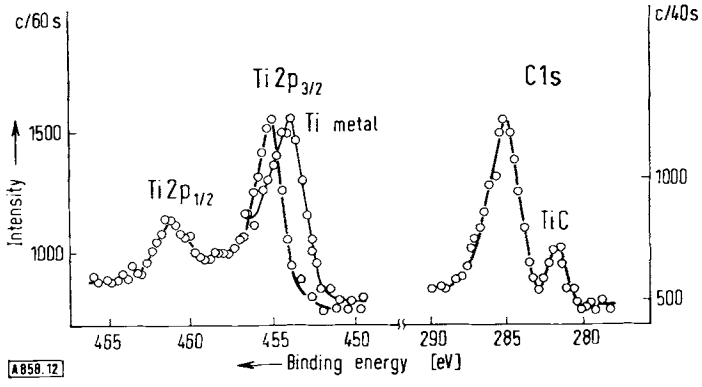

Fig. 12. ESCA spectra of TiC and Ti metal. The line shifts yield information on the charge transfer between the metal and the carbon in the carbide.

In an investigation of the reduced ternary phases in the W—V—O system, the problem of the oxidation state of the tungsten and vanadium atoms was examined. This is associated with the question of the order or disorder of the two types of metal atoms in the crystal structure. The ESCA spectra showed the following distribution of the oxidation states in $W_3V_5O_{20}$ and WV_2O_6, which had already been suggested on the basis of various structures[7]:

$$W^{VI}V^{V}(W^{VI}_{0.25}V^{IV}_{0.75})_2O_{10} \qquad W^{VI}V^{III}_2O_6$$

Figure 13 shows the spectra of vanadium ($2p_{3/2}$) and of tungsten ($4f_{5/2,7/2}$) in $W_3V_5O_{20}$. The positions of the lines obtained with model substances for various oxidation numbers are indicated. It can be seen that tungsten is present exclusively in the hexavalent state, whereas vanadium is present both in the tetravalent and in the pentavalent states.

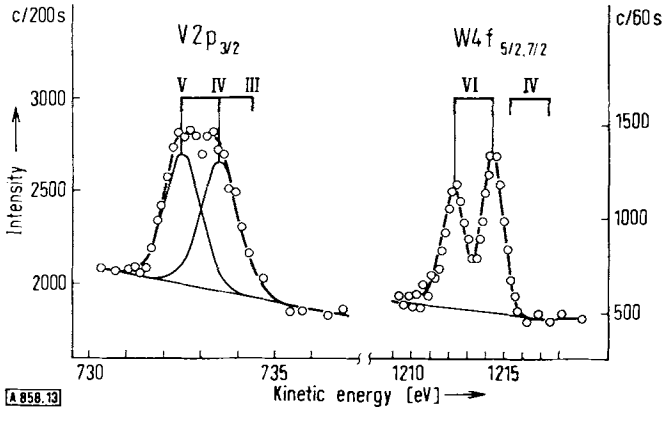

Fig. 13. It can be seen from this ESCA spectrum of $W_3V_5O_{20}$ that tungsten is present as W^{VI} and vanadium in two oxidation states, *i.e.* as V^{IV} and V^{V}.

In the study of many catalytic reactions, the main point of interest is the bonding of the metal in organometallic complexes. We have recently investigated some platinum complexes in which the metal is present in a low formal oxidation state[8]. On the basis of the ESCA data, it was possible to assign relative oxidation states to the central metal, and the investigation confirmed that the coordination of "neutral" ligands can lead to a considerable charge transfer from the metal to the ligands. Figure 14 shows the position of the $4f_{7/2}$ level of platinum in such complexes.

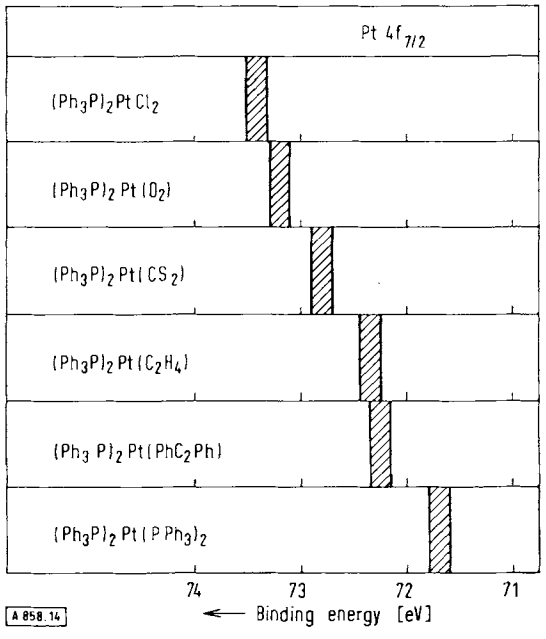

Fig. 14. Chemical shifts for the $4f_{7/2}$ level of platinum in some complexes.

5. Electron Spectra of Free Molecules and Solids

As was mentioned in Section 2, if X-rays are used to excite the electron spectra, the behavior of both the inner electrons and the valence electrons can be investigated. Figure 15 shows an ESCA spectrum of gaseous tetrafluoromethane stimulated with $Mg_{K\alpha}$ radiation. The two lines for binding energies of 696 and 302 eV correspond to the 1s electrons of the fluorine and of the carbon respectively. The K-Auger spectrum of fluorine is observed between kinetic energies of 630 and 660 eV. Molecular orbitals of the valence electrons, which are formed mainly from the atomic 2s and 2p orbitals of the carbon and the fluorine in the CF_4 molecule, are "seen" in the range of binding energies below 50 eV (kinetic energy 1200—1254 eV). The 32 valence electrons of CF_4 are distributed over 16 molecular orbitals, but because of the high symmetry of the molecule, several of the orbitals are degenerate, so that only 7 ionization energies can be distinguished in the spectrum of the valence electrons. Three of these states were investigated earlier on the basis of UV-excited spectra; they can be essentially assigned to non-bonding molecular orbitals.

For a deeper understanding of the chemical bonding, it is necessary also to study the bonding orbitals. These are shown in Figure 15. We used semiempirical (CNDO) and *ab initio* calculations of the valence electron configuration and of the atomic parentage of the molecular orbitals for the interpretation of the MO spectra. A property of the X-ray excited electron spectra that is particularly useful

in this connection is that the cross section for photoemission from a given orbital is strongly dependent on the symmetry of the orbital.

An interesting line splitting is observed in the spectra of the inner electrons of paramagnetic molecules. This splitting is shown in Figure 16 for molecular oxygen in air. The

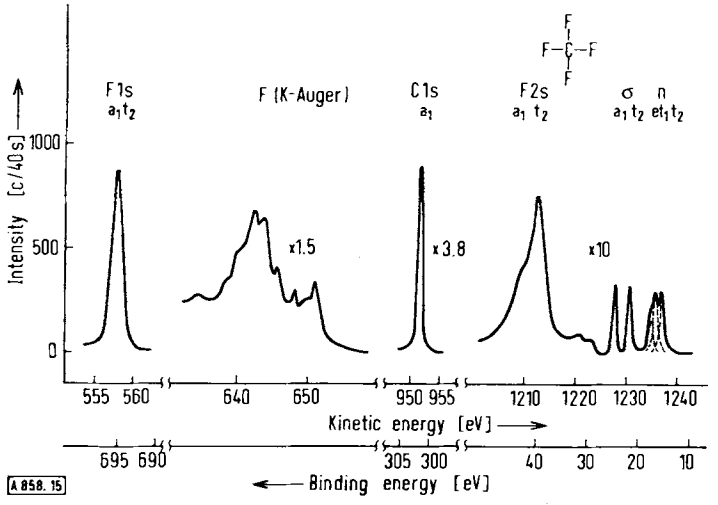

Fig. 15. ESCA spectrum of CF_4. This spectrum shows both the inner electron levels F1s and C1s and the energy levels for the molecular orbitals of the valence electrons. It also shows the K-Auger electrons of fluorine.

spectrum contains the 1s lines of the oxygen and of the nitrogen in the air, as well as the 2p spin doublet of argon, which had a partial pressure of 10^{-3} torr in this case. The 1s line of oxygen is split into two components, with a distance of 1.1 eV between the lines and with an intensity ratio of 1:2. This splitting can be explained as follows. On photoemission of an electron from the 1s level, it is necessary to take into account the interaction between a 1s state with spin $\frac{1}{2}$ and the MO state ($\pi_g 2p$) of oxygen, which is responsible for its paramagnetic properties.

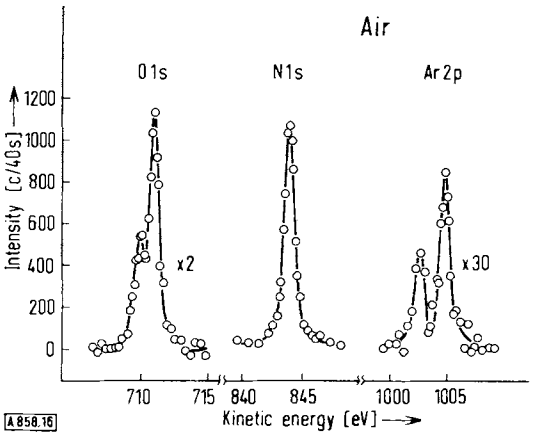

Fig. 16. ESCA spectrum of oxygen, nitrogen, and argon in air. For oxygen, which is paramagnetic, one observes a splitting of the 1s line into two components.

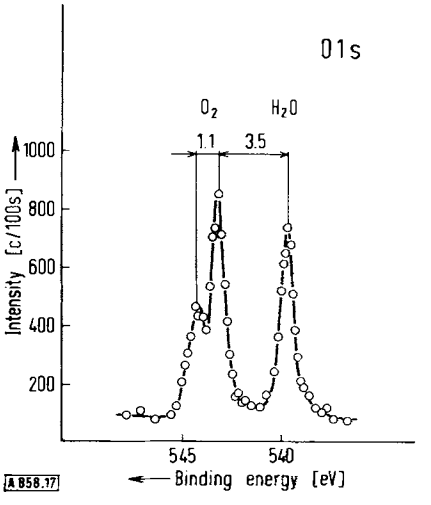

Fig. 17. 1s lines of oxygen in O_2 and H_2O. The line splitting observed for the paramagnetic oxygen molecule disappears when the oxygen is chemically bonded in water vapor. This is accompanied by a considerable chemical shift of the 1s level.

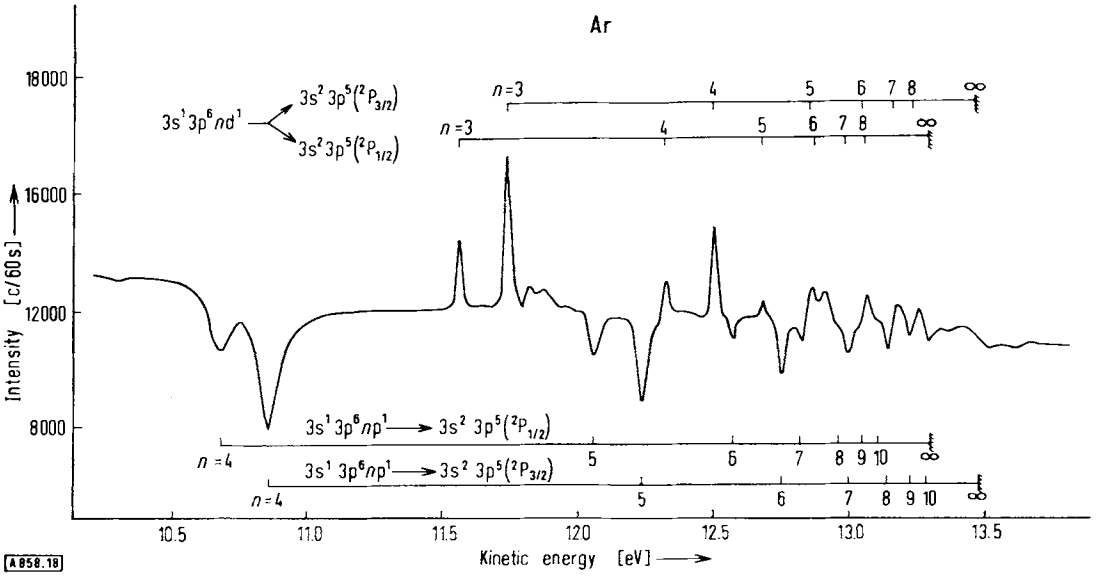

Fig. 18. Autoionization electron spectrum of argon, excited by electron bombardment.

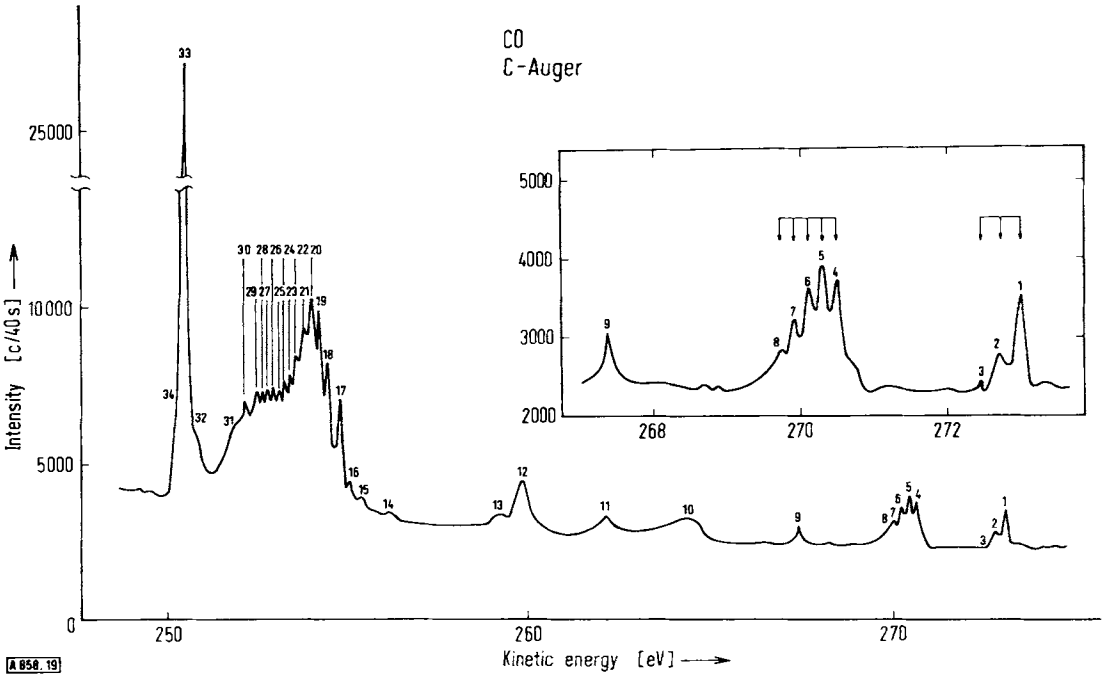

Fig. 19. Auger and autoionization electron spectrum of CO with vibrational structure.

The resultant spin of the two electrons with parallel spin in this orbital is 1. The total spin of the molecule after the emission of a 1s electron will therefore be $\frac{1}{2}$ or $\frac{3}{2}$, *i.e.* the molecule passes into a doublet or quadruplet state. The intensity ratio of the lines thus becomes 2:4, and the calculated magnitude of the energy splitting agrees with that in the electron spectrum (Fig. 16).

This "spin (or exchange) splitting" disappears when the oxygen is chemically bonded to other atoms in diamagnetic molecules, as can be seen from the spectra of O_2 and H_2O (Fig. 17). As discussed earlier, it is replaced by a "chemical shift", which has a magnitude of 3.5 eV in this example between (the quadruplet state of) molecular oxygen and the oxygen bound in H_2O.

The autoionization and Auger electron spectra (cf. Section 2) of free atoms and molecules have not yet been investigated very extensively. We have obtained highly resolved spectra of the inert gases and of molecules by electron bombardment excitation. These spectra contain very large numbers of lines, and can be compared in part with transitions in UV spectra. The autoionization spectrum of argon (Fig. 18) contains several Rydberg series with a series limit that corresponds to the complete separation of a 3s electron in the initial state. The Auger spectrum and the autoionization spectrum of carbon in the CO molecule are shown in Figure 19. The left-hand part of the spectrum is the Auger portion, which shows a pronounced vibration structure in the region around 253 eV. Further to the right in the spectrum, one finds a number of groups of autoionization lines with clearly resolved vibrational components.

We have also extended the scope of the ESCA technique to investigations on solids. Thus the angular distribution of elastically scattered electrons ejected by $Mg_{K\alpha}$ radiation from various levels in an NaCl crystal has recently been

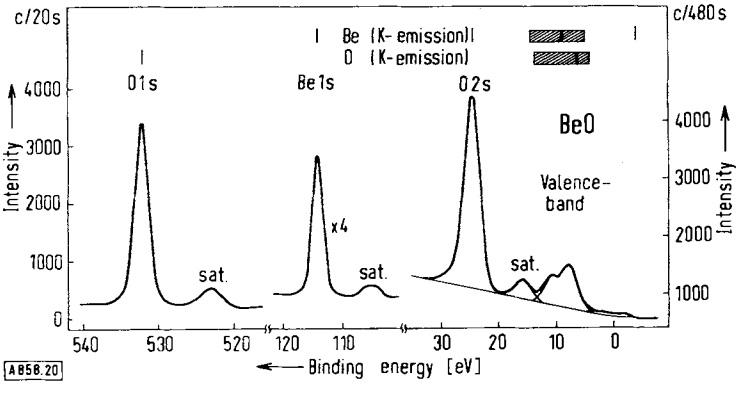

Fig. 20. ESCA spectrum of BeO, excited with $Mg_{K\alpha}$. This spectrum shows both the inner electron levels and the valence bands of the oxide. A comparison with X-ray emission data is shown in the upper part of the figure.

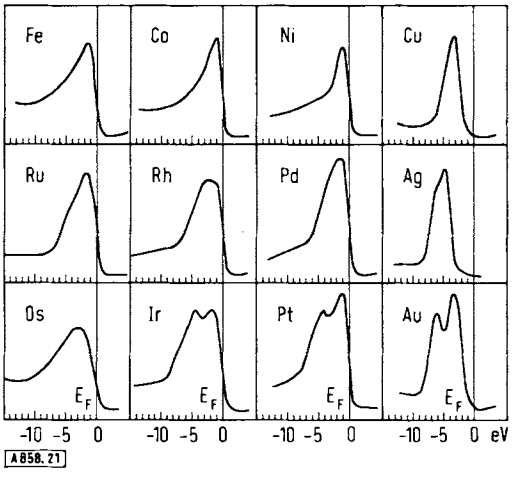

Fig. 21. Band spectra of the transition metals of the first, second, and third series.

investigated[9], and the "escape depth" for electrons liberated from a metal by the action of X-rays has been determined experimentally[10]. The valence bands in LiF, BeO, BN, and graphite have also been studied, and the results compared with X-ray spectroscopic data[11]; see Figure 20.

We have also studied the valence bands in transition metals and other solids[12, 1]. Figure 21 shows electron spectra from the valence bands of twelve transition metals. After certain corrections, these ESCA spectra provide a very good description of the energy distribution in the bands.

It is my pleasure to thank Professor Kai Siegbahn and all the other members of our research group in Uppsala for their contribution to the work that led to the results presented here.

The Electronic Properties of Diradicals

By Lionel Salem and Colin Rowland[*]

A review of the various possible definitions of diradicals leads the authors to describe these systems as having two odd electrons in degenerate or nearly-degenerate molecular orbitals. A study of the wave-function for the two odd electrons shows that its form depends entirely on whether the diradical is homo- or heterosymmetric. Energy schemes are given in these two cases, as well as in the intermediate "non-symmetric" case. The extent of zwitterionic character in diradical states is also investigated. This is followed by a discussion of intersystem crossing between singlet and triplet diradical states via spin-orbit coupling and other mechanisms. The electronic matrix elements for spin-orbit coupling are calculated and evaluated numerically for various model cases. It is then possible to establish general rules for favorable (electronic) intersystem crossing. In 1,3 or 1,4 diradicals its efficiency is estimated to be comparable with that in aromatics. The role of the electron-nuclear hyperfine interaction in mixing singlet and triplet states, particularly in CIDNP, is explained.

Finally the question of whether diradicals actually occur as secondary minima on potential energy surfaces is examined. Recent quantum-mechanical calculations, in contradiction to some thermochemical and kinetic evidence, lead to flat singlet surfaces without significant minima.

1. Introduction: What is a Diradical?

The purpose of this article is to study the qualitative and quantitative properties of those molecular species which Organic Chemists call diradicals. The recent progress in the understanding of concerted reactions[1] has been accompanied by an increased interest in the Chemistry of species with non-concerted behavior[2]. Although, as we shall see, it is difficult to rigorously define the boundaries of the "diradical" family, it is possible to specify fundamental electronic properties which are typical of this family (Section 1). Following that, we shall study successively the wave functions of diradicals and their covalent *versus* ionic character (Section 2), general rules for the spin-orbit induced intersystem crossing between singlet and triplet states (as a function of geometry) and other mixing mechanisms (Sec-

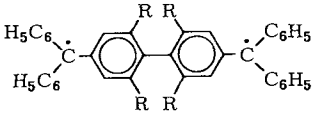
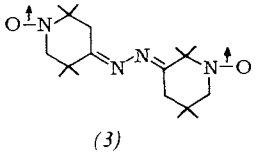
tion 3), and finally the kinetic and thermochemical *versus* quantum-chemical evidence for diradicals as "intermediates", *i.e.* metastable species in secondary minima on the potential energy surface (Section 4).

The term diradical has generally been used loosely to describe systems which can be formally written with two unpaired electrons. A closer look shows that this concept includes a wide variety of species and that the degree of "non-pairing" depends on the type of experiment which is being performed.



1.1. "Two Odd Electrons Far Apart"

The ESR spectroscopist might strictly call a "diradical" any single species which gives an ESR spectrum characteristic of two doublet states, rather than one characteristic of a triplet state. This is true if the interaction between odd electrons is smaller than the hyperfine interaction between odd electron spin and nuclear spin. Thus it escapes measurement by the ESR probe (see Section 3.5). The simplest way to weaken the electronic interaction to this extent is to push the two electrons very far away from each other. For instance bisgalvinoxyl *(1)* shows an ESR spectrum characteristic of two doublet states[3].



Chichibabin's hydrocarbon[4] (R = H) was long considered to be borderline between the case where the system can be described as two doublet states and where the interaction is sufficient so that triplet and singlet states are well defined. The two electrons interact weakly *via* a small residual con-

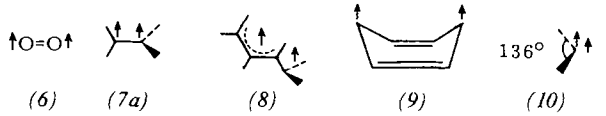
(1)

(2)

(3)

(4)

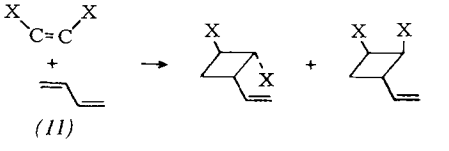
jugation. However, in the nitroxide *(3)* the odd electron interaction is already greater than the hyperfine interaction and the ESR spectrum is that of a well-defined triplet state[5]. In *o*-dihydrobenzene *(4)* the odd-electron interaction is finally so large that the ground state is probably best described as a closed-shell singlet[6].



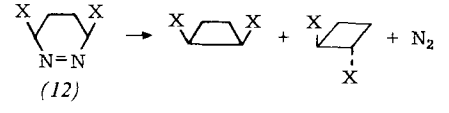
(5)

In this line of thought the simplest diradical of all would be a greatly stretched H_2 molecule *(5)*.

1.2. "Two Odd Electrons with Parallel Spins"



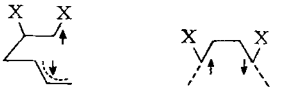
A second common way of thinking of unpaired electrons is to give them parallel spins. It was suggested long ago[7] that the triplet states responsible for phosphorescence should be identified with diradical species familiar to Organic Chemists. Triplet diradicals have been invoked in innumerable photochemical reactions[2c]. Outstanding triplet diradicals are oxygen *(6)*, the ground state of twisted ethylene[8] ("dimethylene") *(7a)*, the lowest $\pi \rightarrow \pi^*$ triplet states of dienes *(8)* and of benzene *(9)* and the ground state of methylene[9] *(10)*.



(6) *(7a)* *(8)* *(9)* *(10)*

1.3. "Non-polar Bifunctional Species in which Loss of Configuration Arises from Internal Rotation"

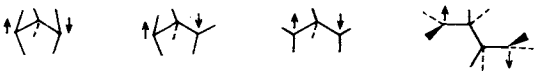
The Organic Chemist generally recognizes a biradical[2b] by the loss of configuration such as occurs in reactions of molecules *(11)* and *(12)*. A total loss of configuration such



(11)

(12)

as shown would imply the formation of intermediate species such as *(13)* or *(14)* in which rotation about the terminal



(13) *(14)*

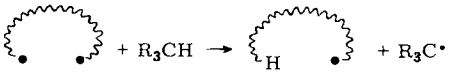
single bonds is faster than carbon-carbon bond reclosure. In fact the extent of approach to equal proportions of product isomers is often used to measure the extent of diradical pathway in the reaction—although it is recognized[2b] that a diradical may be created, but configuration still maintained, if there is a large steric barrier to internal rotation. Triplet diradicals, for which spin inversion is required before closure, are often chosen as reference systems for the loss of configuration. Singlet diradicals are expected to exhibit at least some facets of triplet diradical behavior.

Typical diradicals which have been invoked in this family are trimethylene *(15)*—in several possible geo-

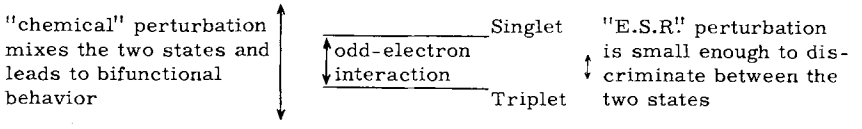
metries[10–14][*]—tetramethylene *(16)*, 1-hexenylene *(13)*, *etc.*

(15a) *(15b)* *(15c)* *(16)*

1.4. Limitations of the Previous Viewpoints



The previous definitions all carry a certain degree of arbitrariness. As concerns the first point of view it is clear that in many cases the two electrons are not totally uncoupled; they conserve a weak residual interaction. The appropriate states are then the singlet, triplet pair. Furthermore, to obtain such weak interaction it is not necessary that the electrons be far apart. Singlet ethylene twisted at 90°, *(7b)*, is a case in point. Thus distance does not seem to be a useful criterion.

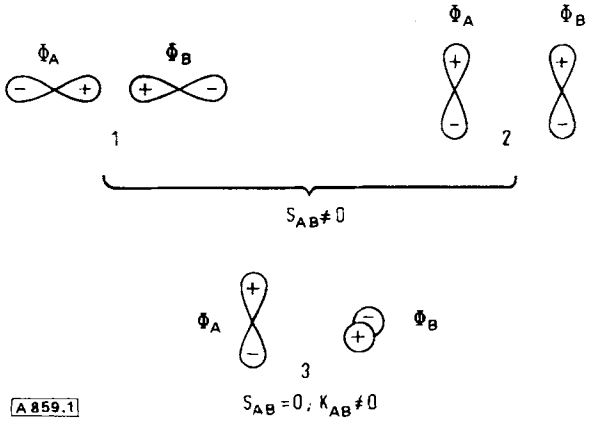


(7b)

The restriction of diradicals to a single spin state—the second point of view—is also a severe limitation. Bifunctional behavior occurs equally well in singlet diradicals and in triplet diradicals, even though the former species have generally a much shorter life-time. Finally the third viewpoint is also arbitrary insofar as it describes the behavior of the intermediate system from an observation of the reaction products. Borderline cases, in which the percentage of isomers lies between that expected for a concerted process and that expected for a diradical process are often interpreted in terms of two competing pathways whereas they may reflect the behavior of some single species in which two electrons are only partially unpaired.

Let us try then and sort out the common features of the diradical species described so far. In only one extreme—molecule *(1)*—is there rigorously no interaction left between the odd electrons. Such a species is truly a "double radical"[**] in the sense that the spin states observed by ESR spectroscopy are those for the separate electrons (doublets) rather than those for the pair (singlet and triplet). In the great majority of systems, however—*(3)* to *(16)*—the odd electron interaction is *sufficient* at least for two distinct states to be recognized by the electron-nuclear hyperfine probe of ESR spectroscopy. At the same time it is expected that it is *not so large* that gross chemical perturbations (such as the approach of a reactant) will discriminate entirely between the two states. Rather, the chemical perturbation will create a "mixture" of the two states, with typical bifunctional behavior. For instance, in the abstraction reaction:

the perturbation due to R_3CH effectively leads to two totally uncoupled odd electrons. This uncoupling is brought about by the mixing of the singlet and triplet states of the starting diradical, leading to two doublet states. Scheme 1 summarizes the relative sizes of the various interactions.



Scheme 1. Relative sizes of various interactions.

Thus systems *(3)* to *(16)* share the common feature of two weakly interacting electrons (*nearly* independent). Another characteristic is that the two electrons have similar energy. Both these properties appear to be required of a system in which two radical centers can effectively behave as if they were independent and equally reactive in the presence of an external reagent. We shall now try and establish a better theoretical understanding of these properties.

1.5. A Localized Picture

The simplest way of describing the odd-electron pair is to assign each electron to a *localized* (for instance, atomic) orbital. Let ϕ_A and ϕ_B be respectively the localized orbitals occupied by the two electrons. These orbitals can interact in varying manners, as shown in Figure 1: *via* a weak one-electron overlap integral S_{AB}, or *via* a two-electron exchange

A 859.1

Fig. 1. One- and two-electron interactions between odd electrons in ϕ_A and ϕ_B.

[*] The role of these different diradical configurations in the geometrical and optical isomerization reactions of cyclopropane is established and the transition state for geometrical isomerization is described in [14].

[**] Molecule *(2)* with R = Cl is also a double radical [16].

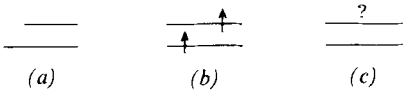
integral[*] K_{AB}. Case (1) occurs in face-to-face trimethylene *(15a)* and in face-to-face tetramethylene *(16a)*[15]. Similarly, case (2) occurs in edge-to-edge trimethylene *(15c)* and in edge-to-edge tetramethylene *(16c)*[17]. Case (3), in which the interaction is of bielectronic nature, occurs in *(7)* or *(15b)*.

(16a) *(16c)*

In all cases, therefore, a weak interaction is conserved between the two odd electrons. The *type* of interaction (one-electron or two-electron) is irrelevant as far as diradical *character* is concerned—although the chemical behavior will vary from one case to another.

This simple picture of weakly interacting, equi-energetic odd electrons is lost:

1. if the overlap integral S_{AB} becomes too large (bond formation)



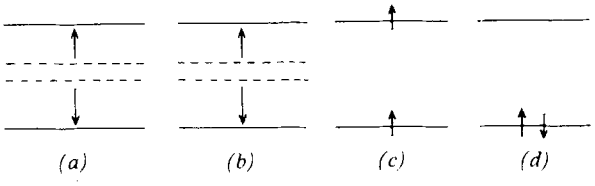
2. if the energy difference between ϕ_A and ϕ_B is too large (localized electron-pair formation in the lower orbital).

These points will be developed further in Section 1.6 (see Figure 2).

1.6. A Delocalized Picture: "Two Odd Electrons in Degenerate or Nearly-Degenerate Molecular Orbitals"

In the previous Section we gave a classical picture of two weakly interacting odd electrons localized in two atomic orbitals. The size of the interaction was measured by K or S. These quantities are very sensitive to geometry and there is no simple way to define limiting values of S, and eventually K, beyond which diradical character is lost. A useful measure of such interactions, which avoids all reference to geometry, is based on *energetic* considerations. This measure is provided by the energy difference between the molecular orbitals occupied by the two electrons or between the lowest triplet and singlet states.

In Section 2.1 and 2.2 we shall see that cases (1) to (3) can be conveniently described by a molecular orbital picture in which the odd electrons are distributed in a pair of molecular orbitals, which are generally delocalized over ϕ_A and ϕ_B (Section 2.1) but which are sometimes nearly localized (Section 2.2). *If* the overlap between ϕ_A and ϕ_B is very weak and *if* the local energies E_A and E_B of ϕ_A and ϕ_B are nearly the same, these two orbitals are degenerate or nearly degenerate (Scheme 2)[18][**].



(a) *(b)* *(c)*

Scheme 2. (a) Non-bonding molecular orbitals; (b) triplet; (c) singlet [***].

The lowest states of the system are a (triplet, singlet) pair with nearly equal energies[***]. Both states describe the diradical; they differ only in the manner in which the electron spins couple. If the separation of the molecular orbitals is sufficiently small, Hund's rule requires the triplet to be the ground state.

Now if the overlap between ϕ_A and ϕ_B increases, the two molecular orbitals cease to have non-bonding character: one orbital becomes bonding and is lowered, while the other becomes anti-bonding and is raised. A lowering of the local energy E_A, while E_B is raised, would lead to similar consequences: one molecular orbital acquires essentially ϕ_A character and is stabilized, and the other one is raised:

(a) *(b)* *(c)* *(d)*

Scheme 3. (a) Increase overlap; (b) increase difference in local energies; (c) triplet; (d) singlet.

In both cases the induced splitting causes a reversal in the ordering of states. The triplet state rises while the system tends to adopt as ground state the closed-shell singlet configuration in which the two electrons are paired in the lower orbital. Thus the nature of the singlet wave function changes progressively from "open-shell" to "closed-shell". Figure 2 illustrates the variation of the state energies for both cases.

In case (a)—increase of overlap—the singlet state acquires covalent bonding character; in case (b)—increase of local energy difference—the singlet state acquires ionic character.

As one advances along the x axis of both diagrams, diradical character is lost. The region where the triplet becomes strongly destabilized and where the singlet becomes a closed shell is of course ill-defined (shaded region). It is reasonable to restrict the diradical region proper to that portion of the diagrams, where the triplet-singlet spacing is small and, *a fortiori*, where the molecular orbitals are reasonably close[19][****] (see also Section 1.4).

We would like to emphasize that strong overlap between ϕ_A and ϕ_B, with the singlet well below the triplet, preclude diradical character even in the triplet state. Consider for instance planar triplet ethylene *(7c)*.

[*] There is a two-electron Coulombic interaction, but it does not discriminate between triplet and singlet. The integrals $S_{AB}=\int\phi_A\phi_B d\tau$ and $K_{AB}=\int\phi_A(1)\phi_B(1)\frac{1}{r_{12}}\phi_A(2)\phi_B(2)d\tau_1 d\tau_2$.

[**] The lower of the two molecular orbitals need not be that in which ϕ_A and ϕ_B overlap positively. The negative combination may be stabilized by through-bond interactions [18].

[***] In the triplet state, of course, one electron occupies each orbital. The singlet state, however, may be either a single configuration with the same spatial occupation (Section 2.2) or a mixture of configurations (Section 2.1).

[****] *G. R. Freeman* [19] has suggested a maximum value of kT for the singlet-triplet energy difference.

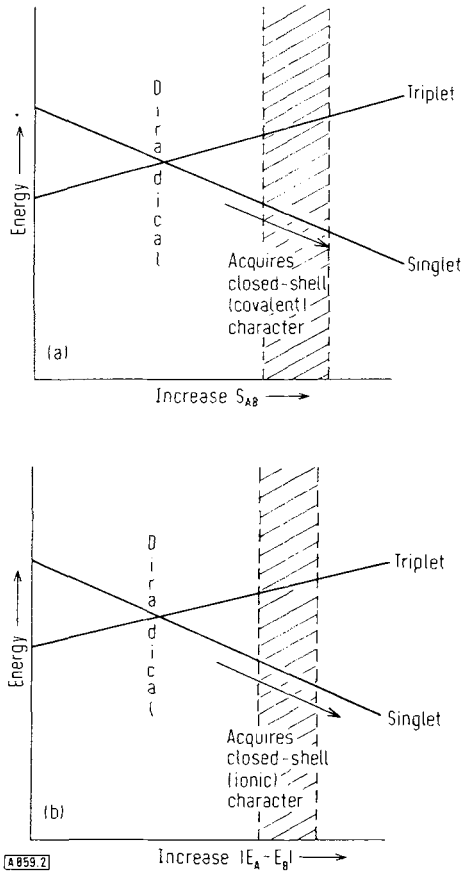


Fig. 2. Energies of (triplet, singlet) pair as the molecular orbital splitting increases. Cases (a) and (b), see text.

Because of the large overlap between the atomic pπ orbitals, the bonding molecular orbital ($\phi_A+\phi_B$) is much more stable than the antibonding orbital ($\phi_A-\phi_B$). In the triplet state one electron occupies each orbital, so that the antibonding electron should be much more labile than the bonding one. Such a system is at best a diradical *precursor*

(7c)

since the more stable electron would be expected to react only after an initial step involving the excited electron. It may be difficult to conceive of triplet ethylene as being a diradical in some phases of its twisting vibration [*(7a)*] and not in others [*(7c)*][*]. Yet clearly *(7a)* can have bifunctional behavior whereas *(7c)* can have only monofunctional behavior. Similarly, H_2 or Li_2 are closed shells in some phases of certain stretching vibrations and open-shell diradicals in others. Also, it is doubtful whether triplet cyclobutene will show bifunctional behavior of the type described in Section 1.3. Even the two odd electrons in a highly bent ($\approx 90°$) methylene triplet [cf. *(10)*] would cease to be equally available, and it could be argued at some length whether it is proper to call such a system a diradical. The electronic characteristics of diradicals may be summarized as follows:

A) Localized Description

a) Weak, but non-zero, interaction between the odd atomic orbitals (*nearly independent* electrons).

b) Similar energy of the odd atomic orbitals (*equally available* electrons).

B) Delocalized Description

a) Degenerate or nearly-degenerate molecular orbitals for the odd electrons.

b) A pair of lowest triplet and singlet states ("diradical" states) with a small separation. Diradical states occur in pairs or not at all.

In the following, the Organic Chemist should constantly remind himself *that the description of diradicals is that of states and two-electron properties rather than orbitals and one-electron properties.* The one-electron model is no longer sufficient (Section 2). Furthermore *these states may represent strongly distorted molecular geometries, not necessarily stable minima* (Section 4).

2. Wave Functions for Diradicals. Covalent *versus* Zwitterionic Character

We now turn to the accurate quantum-mechanical description of diradicals. This description is relatively simple in the "valence-bond" approach: for two odd electrons localized on ϕ_A and ϕ_B the appropriate wave functions are:

$$\begin{aligned} &\text{singlet:} \quad (2 + 2S_{AB}^2)^{-\frac{1}{2}}[\phi_A(1)\phi_B(2) + \phi_B(1)\phi_A(2)] \\ &\text{triplet:} \quad (2 - 2S_{AB}^2)^{-\frac{1}{2}}[\phi_A(1)\phi_B(2) - \phi_B(1)\phi_A(2)] \end{aligned} \tag{1}$$

Similarly two ionic states exist which can serve to describe zwitterions:

$$\begin{aligned} &(2 + 2S_{AB}^2)^{-\frac{1}{2}}[\phi_A(1)\phi_A(2) + \phi_B(1)\phi_B(2)] \\ &(2 - 2S_{AB}^2)^{-\frac{1}{2}}[\phi_A(1)\phi_A(2) - \phi_B(1)\phi_B(2)] \end{aligned} \tag{2}$$

However the vast majority of quantitative calculations of molecular systems are based on molecular orbitals. It is therefore useful to obtain the proper diradical wave functions in the molecular orbital framework. The main difficulty will arise from the requirement that several molecular orbital configurations be *superposed*[20] to obtain functions such as (1) or (2). We shall study successively three limiting cases.

2.1. Homosymmetric Diradicals

We call "homosymmetric" diradical any species in which the odd orbitals ϕ_A and ϕ_B are related by some symmetry element (axis, or plane). The two orbitals may overlap [*(4)*, *(5)*, *(15a)*, *(15c)*, *(16a)*, *(16c)*] or be orthogonal [*(7a)*, *(7b)*]. In either case the proper normalized molecular orbitals are

$$\begin{aligned} \psi_+ &= (\phi_A + \phi_B)/\sqrt{2 + 2S_{AB}} \\ \psi_- &= (\phi_A - \phi_B)/\sqrt{2 - 2S_{AB}} \end{aligned} \tag{3}$$

[*] This feature has been humorously called an "ugly fact" by *G. S. Hammond* (private communication to the authors, 1970).

in a first approximation in which only the through-space interaction of ϕ_A and ϕ_B is considered[18], cf. Footnote [**] on p. 95). From eq. (3) can be constructed the three configurations[*]

$$\psi_+^2, \quad \psi_+\psi_-, \text{ and } \psi_-^2$$

The first and third configurations correspond to singlet spin states. For the configuration $\psi_+\psi_-$ we will specify whether the spin state is a singlet ($^1\psi_+\psi_-$) or a triplet ($^3\psi_+\psi_-$). The spatial symmetry of these three configurations relative to the symmetry element relating ϕ_A and ϕ_B is respectively $+$, $-$, and $+$. The triplet has spatial symmetry $-$.

Configuration ψ_+^2 is a good description of the ground singlet state function when ϕ_A and ϕ_B are strongly bound. (In the following we assume $S_{AB}>0$.) However, if ϕ_A and ϕ_B overlap only weakly or not at all, ψ_+^2 ceases to describe the ground state correctly. Indeed, in terms of the basic atomic orbitals

$$(2+2S_{AB})\psi_+^2 \equiv [\phi_A(1)\phi_B(2)+\phi_B(1)\phi_A(2)] + [\phi_A(1)\phi_A(2)+\phi_B(1)\phi_B(2)] \quad (4)$$

Because of the ionic terms in (4), the energy of the single configuration ψ_+^2 rises much faster than does the true energy of the ground state when the overlap S_{AB} decreases. The correct manner to decrease—and eventually eliminate—the weight of the ionic terms is to mix with ψ_+^2 the second configuration of *same symmetry*

$$(2-2S_{AB})\psi_-^2 \equiv -[\phi_A(1)\phi_B(2)+\phi_B(1)\phi_A(2)] + [\phi_A(1)\phi_A(2)+\phi_B(1)\phi_B(2)] \quad (5)$$

in such a manner that the ionic terms subtract. This is done by taking the negative combination

$$\lambda\psi_+^2 - \sqrt{1-\lambda^2}\,\psi_-^2 \qquad (1 \geq \lambda \geq 1/\sqrt{2})$$

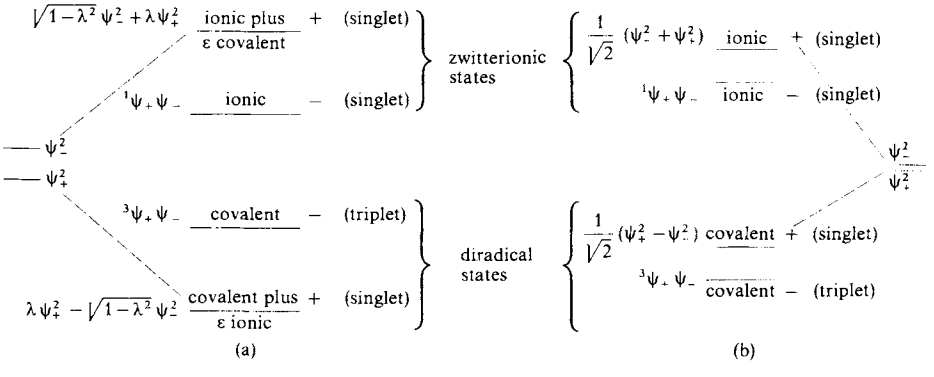
This mixture still contains a small fraction of ionic character. At the limit where the two configurations have *equal energy*, $\lambda = 1/\sqrt{2}$. This can happen in two cases:

a) $S_{AB}=0$. Then we recover the purely covalent singlet (1)

$$\frac{1}{\sqrt{2}}(\psi_+^2-\psi_-^2) \equiv 2^{-\frac{1}{2}}[\phi_A(1)\phi_B(2)+\phi_B(1)\phi_A(2)] \qquad (S_{AB}\equiv 0) \quad (6)$$

b) the degeneracy is *accidental*. This can occur in systems such as *(4)*, *(15a)*, *(15c)* or *(16a)*, *(16c)* where the orbital description (3) is only approximately valid, other components mixing in to ψ_+ or ψ_- *via* through-bond interactions[18]. Then the residual ionic character can easily be verified to be roughly proportional to S_{AB}, which is not necessarily zero.

In a similar fashion ψ_-^2, which is an appropriate representation of the doubly excited state in a closed-shell system, becomes inappropriate for small S_{AB} and the correct description is



$$\sqrt{1-\lambda^2}\,\psi_+^2 + \lambda\psi_-^2$$

which still contains some covalent character. At the limit $S_{AB}=0$ we have:

$$\frac{1}{\sqrt{2}}(\psi_+^2+\psi_-^2) \equiv 2^{-\frac{1}{2}}[\phi_A(1)\phi_A(2)+\phi_B(1)\phi_B(2)] \qquad (S_{AB}\equiv 0) \quad (7)$$

As to the other two configurations, $^1\psi_+\psi_-$ and $^3\psi_+\psi_-$, they remain appropriate descriptions of the singly-excited singlet state and of the lowest triplet state whatever the value of S_{AB}. The reason is that their spatial and spin symmetry is different from that of the two other configurations. The configuration $^1\psi_+\psi_-$ is purely ionic, *whatever* the value of S_{AB}:

$$^1\psi_+\psi_- \equiv (2-2S_{AB}^2)^{-\frac{1}{2}}[\phi_A(1)\phi_A(2)-\phi_B(1)\phi_B(2)] \quad (8)$$

Scheme 4. Homosymmetric diradical: Electronic configurations and energies (for the zwitterionic states see Footnote [***] on p. 98). (a) $S_{AB}>0$ ($1 \geq \lambda \geq 1/\sqrt{2}$); (b) $S_{AB}\approx 0$ ($\lambda = 1/\sqrt{2}$).

while the triplet configuration $^3\psi_+\psi_-$ describes correctly the triplet state (1):

$$^3\psi_+\psi_- \equiv (2-2S_{AB}^2)^{-\frac{1}{2}}[\phi_A(1)\phi_B(2)-\phi_B(1)\phi_A(2)] \quad (9)$$

The orbital energies, energy levels of the states, appropriate wave functions and spatial symmetries ($+$ or $-$) are summarized below (Scheme 4) for a homosymmetric diradical a) with $S_{AB}>0$; b) with $S_{AB}\approx 0$ (degenerate molecular orbitals). The covalent and/or ionic character is also indicated.

[*] In the following, the notation $\psi_\pm^2$ will be used to denote both the conventional configuration and the singlet wave function $|\psi_+\bar{\psi}_-|$. In the case of the open-shell configuration $\psi_\pm\psi_-$ we denote $^1\psi_+\psi_- \equiv (|\psi_+\bar{\psi}_-|+|\psi_-\bar{\psi}_+|)/\sqrt{2}$ and $^3\psi_+\psi_- \equiv (|\psi_+\bar{\psi}_-|-|\psi_-\bar{\psi}_+|)/\sqrt{2}$.

For negative overlap ([18], cf. Footnote [**] on p. 95) the character of the states is the same but the role of the configurations ψ_+^2 and ψ_-^2 is reversed. Cases (a) and (b) are illustrated in Figure 3 by a) a stretched H_2 molecule; b) the twisting of ethylene to 90°.

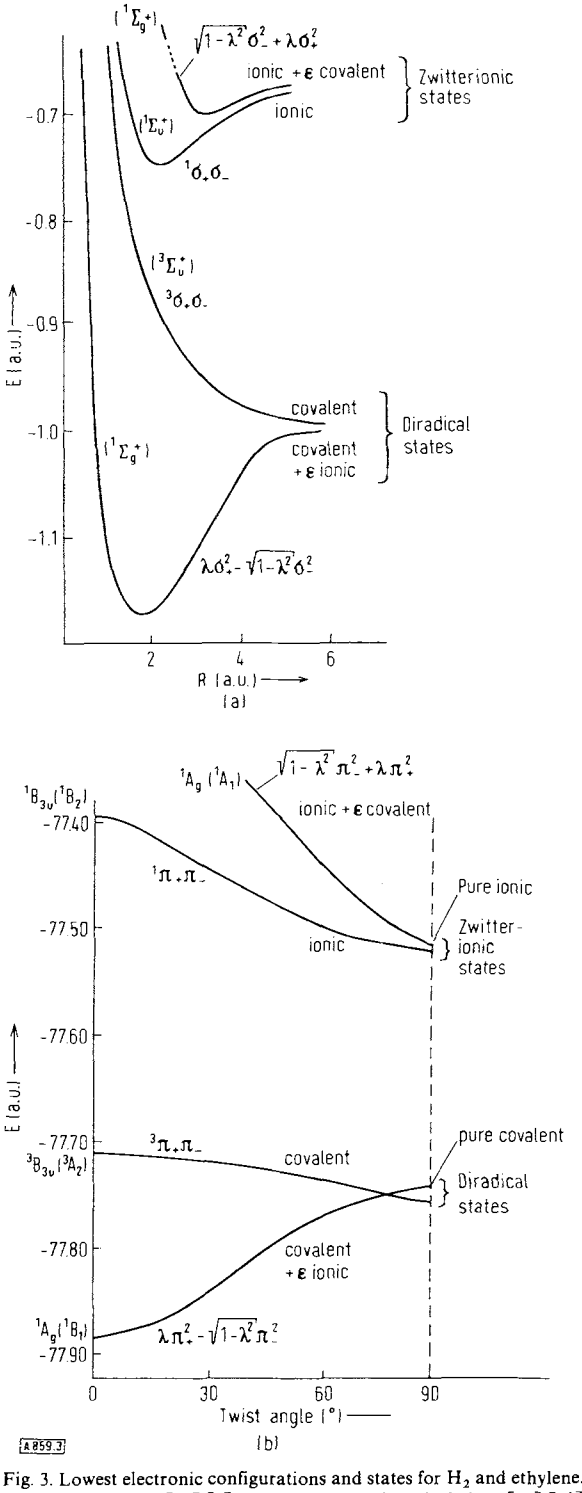


Fig. 3. Lowest electronic configurations and states for H_2 and ethylene. a) Stretching of H_2 [21] [*] ($S_{AB}>0$), b) Twisting of ethylene [22] [**] ($S_{AB}=0$ at 90°).

[*] The higher $^1\Sigma_g^+$ state actually has a second minimum at short R due to the mixing of σ_-^2 with the σ_+2s configuration [21].

[**] The energy curves are obtained from *U. Kaldor* and *I. Shavitt*, J. Chem. Phys. *48*, 191 (1968). The nomenclature of states in parentheses corresponds to the 90° situation (D_{2d} symmetry). For the ionic *vs.* covalent character of the excited states of ethylene, see also [22].

In the first case the overlap remains non-zero though very weak; in the second case S_{AB} is 0 for a twist of 90°.

The common feature in both cases is the existence of a *(singlet, triplet)* low-lying pair of degenerate *diradical* states of covalent nature, together with a second *(singlet, singlet)* pair of states of ionic nature. The latter pair of states, with high energy, are the "zwitterionic"[***] states for the system. For H_2 they correspond to the interaction of the classical structures

$$(H^{\oplus}\ H^{\ominus}),\quad (H^{\ominus}\ H^{\oplus})$$

In twisted ethylene, the zwitterionic states correspond to the mixing of the structures[22][**].

The relative triplet-singlet spacing of the diradical states is an interesting feature which discriminates between stretched H_2 (Fig. 3a) and twisted ethylene (Fig. 3b). In H_2, even at infinite distance, the singlet state lies under the triplet state[23, 24]. A naive explanation is that the one-electron energy terms dominate the two-electron exchange terms at all distances. Thus Hund's rule can never be satisfied. In 90° twisted ethylene, however, the triplet state is the ground state. The overlap S_{AB} vanishes so the two-electron exchange integral automatically puts the triplet state (two-electron energy: $J_{AB}-K_{AB}$) under the singlet state (two-electron energy: $J_{AB}+K_{AB}$). The relative energies of the diradical states and of the zwitterionic states are shown in Scheme 5 below for the case $S_{AB}=0$.

This pattern is also valid for $S_{AB}\neq 0$ in those cases where the molecular orbitals ψ_+ and ψ_- are accidentally degenerate [see the discussion of eq. (6)].

We have not dealt with the magnitude or sign of the singlet-triplet separation. It depends on the relative size of the one-electron energy difference between ψ_+ and ψ_- (approximately measured by S_{AB})—a large difference favoring the singlet—and of the two-electron exchange energy K_{AB}, which favors the triplet (Scheme 5). Generally, when ϕ_A and ϕ_B are strictly localized on different centers, K_{AB} is very small and the triplet never falls more than ≈ 5 kcal/mol below the singlet. The difference calculated for ethylene—8.5 kcal/mol—seems to be an upper limit. In other types of diradicals, however (Section 2.2), the singlet-triplet energy difference can become larger.

To summarize, the lowest singlet state of a homosymmetric diradical is a mixture of two configurations. The triplet state generally does not fall more than a few kcal/mol below this singlet state.

[***] In the "zwitterionic" states the homosymmetric species (H_2 or ethylene) has *no net dipole moment*. The term "zwitterionic" is used because one of these states is the correct description of the ground state of true zwitterions (Section 2.4). Similarly loose language is used in describing "1.3 dipoles", in which there is also resonance between two polar structures but where the net dipole moment is *small* and the polar characteristics revealed only during reaction processes.—The authors are grateful to Professors *E. Heilbronner* and *R. Huisgen* for discussions on this point.

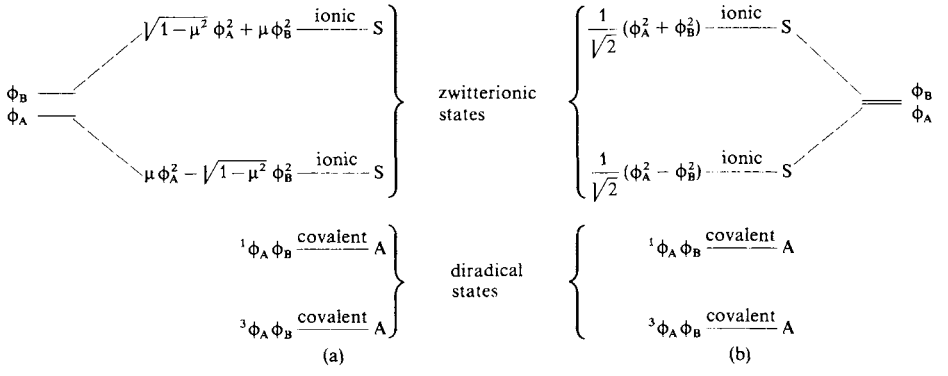
J_{AB} = Coulomb repulsion integral between ϕ_A and ϕ_B
J_{AA} = Self-repulsion integral for ϕ_A
K_{AB} = Exchange integral between ϕ_A and ϕ_B.

2.2. Heterosymmetric Diradicals



In "heterosymmetric" diradicals the orbitals ϕ_A and ϕ_B, though not necessarily localized, belong to different symmetry representations of the molecular point group. Typical examples are *(8)*, *(10)*, and *(15b)*, which all have a plane of symmetry, and where one odd electron occupies a σ orbital while the other one occupies a π orbital. It follows immediately that ϕ_A and ϕ_B can be used as such to construct the diradical and zwitterionic states in the same manner that ψ_+ and ψ_- were used previously. Thus the starting configurations are:

ϕ_A^2, $\phi_A\phi_B$, and ϕ_B^2

with ϕ_A^2 and ϕ_B^2 representing paired electrons respectively on A and B and $\phi_A\phi_B$ (singlet or triplet) representing one electron on each orbital.

tions are defined by a mixing parameter $\mu(1\geq\mu\geq 1/\sqrt{2})$ similar to λ. For $\mu=1/\sqrt{2}$ (Scheme 6b)—this can only occur accidentally since the local fields surrounding ϕ_A and ϕ_B are generally different in a heterosymmetric species—the two-electron energies of all four states are identical to those at the end of Section 2.1 (Scheme 5). Indeed the wave functions of Scheme 4b and 6b are identical when expressed in terms of the local orbitals ϕ_A and ϕ_B. Even if $\mu>1/\sqrt{2}$, the ground state is a triplet, since the configuration $^3\phi_A\phi_B$ always lies below $^1\phi_A\phi_B$. Note that the symmetries in Scheme 6 have been written by assuming one orbital to be S and the other A.

There is an exceptional heterosymmetric diradical—methylene—where the large size of the interorbital repulsion energy J_{AB} (between two atomic orbitals on the same center) together with the significant exchange energy K_{AB} cause the covalent singlet state to rise above the lower ionic

Scheme 6. Heterosymmetric diradical: Electron configurations and energies. (a) $E_A-E_B<0$ $(1\geq\mu>1/\sqrt{2})$; (b) $E_A=E_B$ (accidental degeneracy) $(\mu=1/\sqrt{2})$.

The difference with the homosymmetric case is the manner in which the configurations are used to build the correct wave functions. The negative combination of ϕ_A^2 and ϕ_B^2 gives directly the same ionic state which was obtained previously from the single configuration $^1\psi_+\psi_-$. Similarly, configuration $^1\phi_A\phi_B$ describes the covalent diradical state which previously required combining ψ_+^2 with ψ_-^2. Thus the energy pattern in Scheme 6 resembles that in Scheme 4 for the nature of the states but not for the number of configurations involved in describing each one. Furthermore, the weights of ϕ_A^2 and ϕ_B^2 in the two ionic wave functions are not necessarily the same: although $S_{AB}=0$, the local energies of ϕ_A and ϕ_B are generally different and the orbitals not perfectly degenerate (Section 1.6). The proper combination of singlet state. For an HCH angle of 140° the ordering of states in methylene is roughly[25,26] as given in Scheme 7.

$(^1A_1)$ $\sqrt{1-\mu^2}\,\sigma^2+\mu\pi^2$	ionic	zwitterionic states
$(^1B_1)$ $^1\sigma\pi$	covalent	
$(^1A_1)$ $\mu\sigma^2-\sqrt{1-\mu^2}\,\pi^2$	ionic	diradical states
$(^3B_1)$ $^3\sigma\pi$	covalent	

Scheme 7. Ordering of states in methylene [25, 26]. (Note that σ and π are localized on the same center.)

The triplet lies well below the lowest singlet. The energy difference is 24 kcal/mol between the minima of the two states, 31 kcal/mol for linear methylene[25]. Similarly the ground $^3\Sigma_g^-$ state of O_2 lies 22 kcal/mol below the first

[*] See Footnote [***] on p. 98.

singlet $^1\Delta_g$ because of the large one-center exchange terms between π_x^* and π_y^* orbitals.

We note finally that, whereas in the homosymmetric diradical the extent to which λ deviates from $1/\sqrt{2}$ is roughly a measure of the overlap S_{AB}[*], in heterosymmetric diradicals the deviation of μ from $1/\sqrt{2}$ measures the extent to which the local energies E_A of ϕ_A and E_B of ϕ_B differ.

2.3. The "Non-symmetric" Case

The question now arises as to the behavior of the wave function and energies along a geometrical transformation which brings a homosymmetric diradical into a heterosymmetric diradical. Consider, as an example, the internal rotation of a methylene group which transforms edge-to-edge trimethylene *(15c)* into edge-to-face trimethylene *(15b)*:

(15c) *(15b)*

Clearly along the "reaction" coordinate—except at the start and at the end—the system has no symmetry whatsoever. Thus at any intermediate point the orbitals ϕ_A and ϕ_B overlap but there are no symmetry restrictions on the way in which they combine. The two non-bonding molecular orbitals, which we call ψ and ψ', have different weights on A and B. Orbital ψ localizes more and more on A while ψ' localizes on B, as the reaction proceeds. Furthermore during the rotation *both* molecular orbitals develop an in-plane component (formally called σ) and keep an out-of-plane component (formally called π)[**]. The initial, intermediate and final forms of ψ and ψ' are shown in Figure 4.

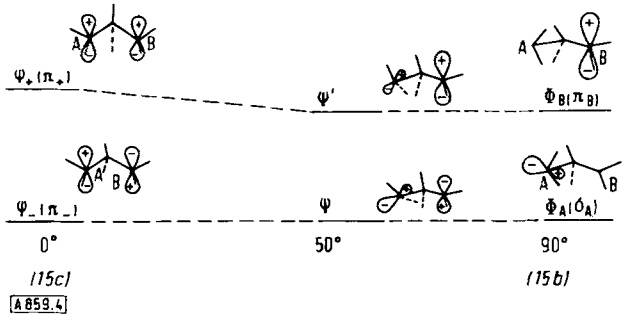


Fig. 4. Transformation of *(15c)* into *(15b)* *via* methylene rotation.

At the intermediate point shown (rotation of 50°) ψ and ψ' are given approximately by

$$\begin{cases} \psi \approx (0.72\sigma_A + 0.55\pi_A) - 0.45\pi_B \\ \psi' \approx (0.34\sigma_A + 0.26\pi_A) + 0.87\pi_B \end{cases} \quad (10)$$

[*] One can even think of $2(1-\lambda^2)$ as a "measure" of diradical character; see [27].

[**] Hence to describe the evolution of both molecular orbitals by perturbation theory would require other than the two initial orbitals themselves.

where the terms σ and π refer to partial in or out-of plane components.

The most interesting feature is the manner in which the energy scheme of 4a is transformed into an energy scheme of type 6a. We will restrict ourselves to the three singlets, for which the configurational description varies along the path. Essentially:

1. There is a cross-over (Fig. 5) of the energies of configurations ψ^2 and ψ'^2 with that of configuration $^1\psi\psi'$. Indeed

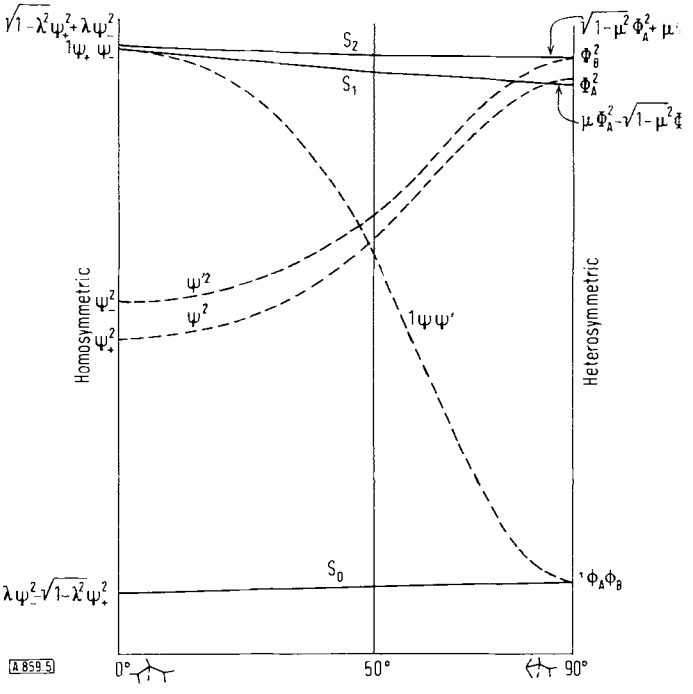

Fig. 5. Singlet configurations and singlet states for internal rotation in the trimethylene diradical [28].

this "open-shell" configuration describes a highly excited ionic state of the starting diradical *(15c)* (Scheme 4a) but correlates with $^1\phi_A\phi_B$ which describes the low-lying covalent diradical state in the final system *(15b)* (Scheme 6a). Thus its energy decreases steadily. Similarly the pair of nearly-degenerate, relatively low-lying configurations ψ_+^2 and ψ_-^2 which initially served to build the ground singlet and top singlet by configuration interaction correlate with the ionic configurations ϕ_A^2 and ϕ_B^2 which interact weakly to give the two ionic states of *(15c)*.

2. The energy levels of the *states* stay nearly constant.

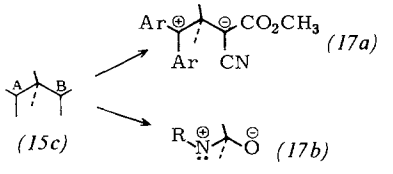
3. The coefficient λ at the start ≈ 0.74 (*i.e.* ψ_+^2 and ψ_-^2 mix almost equally). However the energy difference between ϕ_A^2 and ϕ_B^2 and their weak mixing *via* K_{AB} are such that μ is nearly equal to 1.

Let us write out the wave functions of the three states at 50°, near the crossing point of the three configurations. The three states are:

$$\begin{cases} S_0 = -0.60\,(^1\psi\psi') + 0.58\,(\psi^2) - 0.55\,(\psi'^2) \\ S_1 = -0.69\,(^1\psi\psi') - 0.72\,(\psi^2) - 0.01\,(\psi'^2) \\ S_2 = -0.40\,(^1\psi\psi') + 0.37\,(\psi^2) + 0.84\,(\psi'^2) \end{cases} \quad (11)$$

Although the ground singlet S_0 appears as a nearly equal mixture of all three configurations, at this intermediate

stage, it is possible to show that it actually retains nearly *pure covalent* character. Indeed expansion of (11) in terms of (10) gives:



$$S_0 = 0.55\,[\sigma_A(1)\pi_B(2) + \pi_B(1)\sigma_A(2)] + 0.42\,[\pi_A(1)\pi_B(2) + \pi_B(1)\pi_A(2)] + \text{terms with coefficient} \leq 0.03$$

At the same time S_1 and S_2 remain nearly purely ionic. Thus the three states keep their covalent, or ionic character throughout, and Scheme 4 goes smoothly into Scheme 6.

To summarize, in the "non-symmetric" case the diradical singlet state is generally a mixture of *three* configurations.

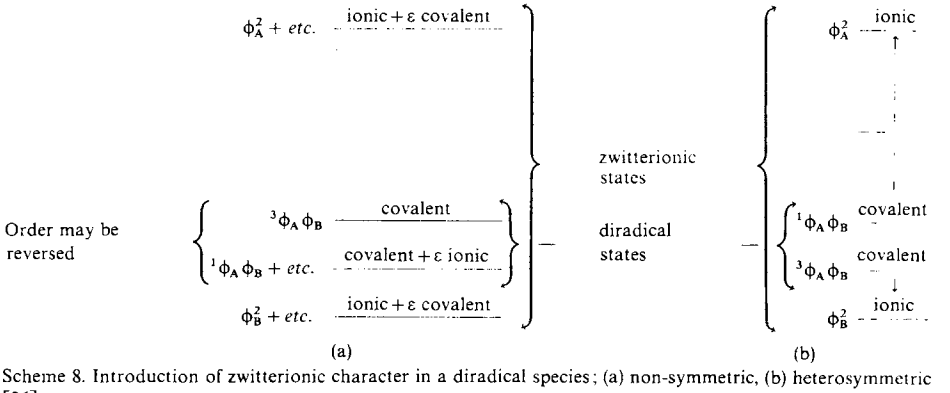
2.4. Introduction of Zwitterionic Character in a Diradical

An important conclusion of our study in 2.2 and 2.3 is that to each pair of diradical states is associated a pair of zwitterionic states. Now it is well-known to Organic Chemists that, for instance, a diradical such as *(15b)* or *(15c)* can be transformed into a zwitterion either by appropriate substitution on the terminal carbon atoms [*(17a)*][29] or formally by exchange of the C atoms with suitable heteroatoms [*(17b)*].

What do such changes imply as to the behavior of the pairs of diradical and zwitterionic states of Schemes 4 or 6? Substitution of a hydrogen atom attached to C_A by an electropositive substituent while an electron attracting substituent is put at C_B, or formal replacement of C_A by N and C_B by O lowers the local energy E_B relative to the local energy E_A.

In the homosymmetric case the ionic component

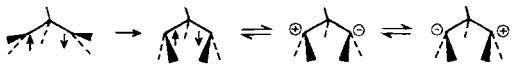
$$\phi_B(1)\phi_B(2)$$



is significantly stabilized while the other component

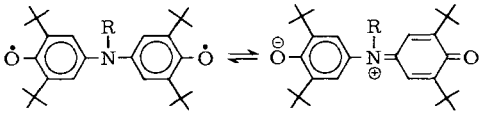
$$\phi_A(1)\phi_A(2)$$

is destabilized. The proper ionic wave functions are no longer given by (2). One ionic wave function has essentially ϕ_B^2 character and little ϕ_A^2 character ($A^+ B^-$), with a very low energy[30]. The other wave function, which contains nearly all the ϕ_A^2 character ($A^- B^+$), has a high energy. The final energy pattern is shown in Scheme 8. The ground *state*, which was nearly purely covalent, has built in more and more ionic character to become nearly ionic. The second singlet state, which was ionic, is now the diradical state. Not only has the energy pattern changed, but also the characteristics of the singlet wave functions. Indeed substitution on species *(15c)* destroys the symmetry element which related ϕ_A and ϕ_B. The situation becomes similar to that in the "non-symmetric" case (Section 2.3) with all three singlet configurations being allowed to mix. Actually the lower configuration is strongly localized on ϕ_B and the highest one on ϕ_A so that the mixing will be relatively small. Hence there will be only residual mixing between the lowest configuration $\psi^2 (\approx \phi_B^2)$, the intermediate one $^1\psi\psi' (\approx \phi_A\phi_B)$ and the upper one $^1\psi'^2 (\approx \phi_A^2)$.



In the heterosymmetric case the components ϕ_A^2 and ϕ_B^2 are of course affected in the same manner as in the homosymmetric case. The only difference lies in the nature of the singlet states: the substitution does not necessarily destroy the element of symmetry which caused ϕ_A and ϕ_B to belong to different representations. Thus all states can remain "pure" ionic or "pure" covalent.

In Scheme 8 we have drawn the zwitterionic state as the ground state of both systems. The nature of the ground state depends on several factors: the difference $E_A - E_B$ of course, but also the extent of overlap between ϕ_A and ϕ_B. Strongly asymmetric substitution on A and B may reduce this overlap by introducing a difference in size in the lobes of ϕ_A and ϕ_B, thereby helping to raise the covalent singlet.



Scheme 8. Introduction of zwitterionic character in a diradical species; (a) non-symmetric, (b) heterosymmetric [26].

The reader will not fail to observe that in the general, non-symmetric case, *the lowest zwitterionic state involves some covalent character just as the lowest diradical state involves some ionic character*. Thus, the familiar terms "diradical" or "zwitterion" are only simplifications of the real situation. Sometimes the "unmentioned" character can become important or predominant *via* a simple geometric change. Thus a significant increase in zwitterionic character of the ground diradical state can occur in face-to-face trimethylene *(15a)*[10] by simple inwards pyramidalization of the terminal methylene groups:

(15d) *(15a)*

An interesting case is the interconversion of a homosymmetric species with a diradical ground state into a species with a zwitterionic ground state *via* a change in hybridization at a single atom, again obtained *via* a simple pyramidalization or depyramidalization process[31]:

(18a) *(18b)*

Diradical *(18a)* has a triplet ground state and is paramagnetic, while the closed-shell species *(18b)* is diamagnetic. The kinetics of the interconversion can be investigated by studying the variation in the line width of the NMR peaks of the zwitterions.

3. Geometrical Selection Rules for Intersystem Crossing between Singlet and Triplet Diradical States *via* Spin-Orbit Coupling

3.1. Introduction: Conditions for Perfect Vibronic Degeneracy between Triplet and Singlet States

It is well known that singlet and triplet states are not proper stationary states of a system when certain intramolecular magnetic interactions are allowed for. In the presence of these interactions the proper states are mixtures of the "pure" spin triplet and singlet states. Time-dependent perturbation theory shows that a system prepared in one of the pure states—as would be a singlet diradical by bond rupture—can evolve by an appropriate interaction, into an oscillatory *mixture* of the two (singlet and triplet) states. If the triplet component can further be stabilized energetically, the entire system can end up in the triplet state[*]. This process is known as intersystem crossing and is illustrated in Figure 6.

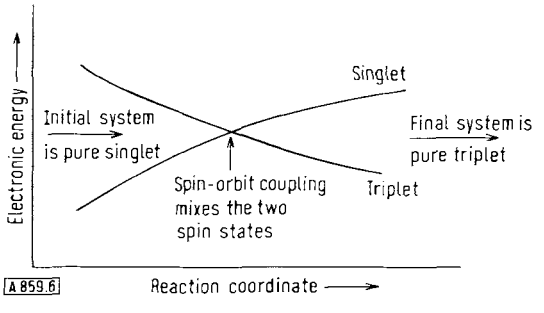


Fig. 6. Intersystem crossing.

[*] For an interesting discussion of intersystem crossing in diradicals, see [32].

Spin-orbit coupling is the most common mechanism *via* which intersystem crossing can occur. The two fundamental prerequisites for the crossing to be effective are:

1. There must be non-zero mixing, *via* the appropriate operator, of the *electronic* wave functions. Essentially the orbital transition between the electronic wave function for the singlet and the electronic wave function for the triplet must create a torque which can flip the electron spin. We shall return to this electronic factor in great detail in the further sections.

2. The separation between the singlet and triplet levels must not be larger than the size of the interaction. In the carbon atom, for instance, the spin-orbit induced splitting between $^3P_1$ and $^3P_0$ states is 16.4 cm^{-1}[33]. Since this is significantly smaller than vibrational spacings in molecules, intersystem crossing will require nearly perfect degeneracy between the vibronic (*i. e.* electronic plus vibrational) levels of singlet and triplet states.

Let us discuss the conditions under which such vibronic degeneracy can occur. Figure 7 shows the calculated spacings for the vibrational levels of the lowest singlet-triplet

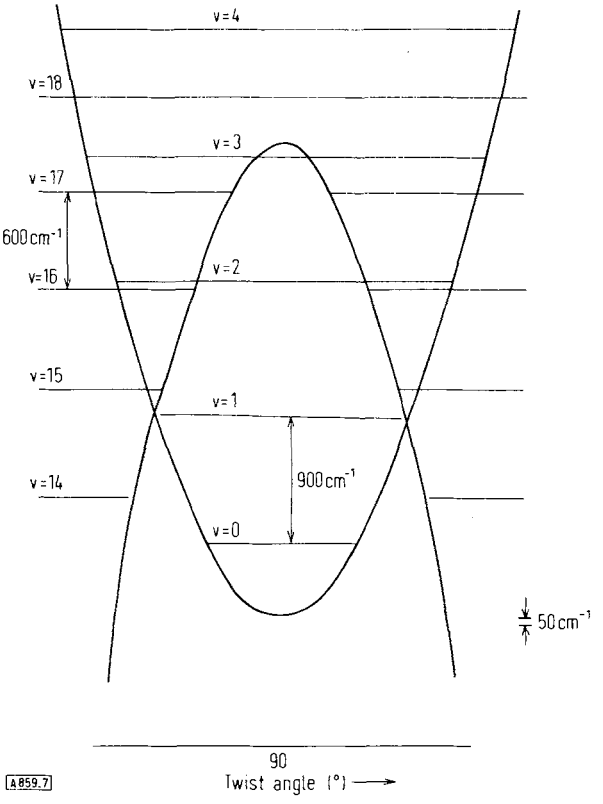

Fig. 7. Estimated vibrational spacings in twisted ethylene. (The electronic energy difference of 3000 cm^{-1} at 90° is obtained from Ref. [**] on p. 98.)

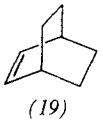
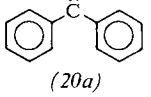
pair of states in twisted ethylene. We have calculated the spacings between the singlet vibrational levels by solution of Mathieu's equation for a barrier height of 16000 cm^{-1} (the value of 45 kcal/mol required to fit the experimental separation of 1023 cm^{-1}[8] between the two lowest twisting levels in planar ethylene). For the triplet the spacings are obtained by using the potential energy curve of Ref. [**] on p. 98.



Clearly the coincidence of vibrational levels is insufficient to ensure that singlet ethylene can cross to triplet ethylene. Although there are pairs of vibrational levels which are relatively close, and which may in fact be nearly perfectly degenerate, the chances of creating singlet ethylene in just the appropriate high vibrational level [for instance v = 16, which coincides with the triplet (v = 2)-level] are extremely small. A much greater density of vibrational levels would be required for a significant probability of intersystem crossing.

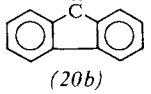
What is required for efficient intersystem crossing is that the levels of the initial state interact, not with a sparse manifold (as in Fig. 7) of highly discrete vibrational levels, but with a dense continuum of vibrational levels[34]. It is well-known that in the equilibrium regions of bound states (triplet in Fig. 7) such a dense continuum exists only for sufficiently large molecules, of the size of benzene say[35].

Thus for *small isolated diradicals*—for instance *(7)*, *(8)*, *(10)*, *(15)*, *(16)* in a rigid matrix—*intersystem crossing should not be efficient*. However, the necessary continuum of energy states may be provided in different ways for the *non-isolated* system:



1. By collision with a rare gas. *Eder* and *Carr* have shown[36][*] that singlet methylene intersystem-crosses efficiently in the presence of inert gases. The collision partner effectively couples singlet methylene with the required continuum of states. Similarly the conversion of triplet ethylene to *cis* and *trans* singlet products follows bimolecular kinetics[37a].

2. By linking the small diradical in which intersystem crossing is sought to a large chain which plays the role of a collisional "solvent" with a vast number of vibronic levels. The facile intersystem crossing to the ground singlet state in triplet-sensitized olefins such as bicyclo[2.2.2]oct-2-ene *(19)*[37b] can probably be explained in this manner. In certain cases the continuum which is provided may involve



(19)

internal rotational levels. For instance diphenyl carbene *(20a)* decays very efficiently from singlet to triplet while *(20b)*, in which the rotation of the phenyl groups is blocked, arrives much less efficiently in the triplet state[38], judging by its reactivity.

(20a)

(20b)

[*] It has been suggested that the collision also serves to enhance the electronic coupling proper *via* methylene spin-gas orbital angular momentum interactions (*M. Y. Chu* and *J. S. Dahler*, Chem. Phys. Lett. *8*, 369 (1971)). However (Section 3.4) the electronic factor in isolated methylene is already very large and, although it is difficult to assess the importance of the large collision-induced orbital distortions, it is doubtful that the collision does anything but actually decrease the electronic term.

3. Even in gaseous "unimolecular" reactions collisions are required to activate and deactivate the reactant molecules; these collisions may suffice to ensure intersystem crossing in small diradicals such as *(15)* or *(16)*.

In the following sections we shall assume that the problem of level degeneracy has been taken care of in some manner. It must therefore be kept in mind that the electronic factors which we shall calculate can be used for meaningful predictions only if this degeneracy is *effectively* ensured.

3.2. The Electronic Factor in Homosymmetric Diradicals

Let us first consider the mixing induced by the spin-orbit coupling operator $H_{sp.orb.}$, between the singlet diradical wave function:

$$S_0 \equiv \lambda\psi_+^2 - \sqrt{1-\lambda^2}\,\psi_-^2 \tag{12}$$

(see Scheme 4a) and the triplet diradical wave function

$$T_0 \equiv {}^3\psi_+\psi_-$$

The orbitals ψ_+ and ψ_- are given by eq. (3). Thus the matrix element is

$$\langle\lambda\psi_+^2 - \sqrt{1-\lambda^2}\,\psi_-^2 | H_{sp.orb.} | {}^3\psi_+\psi_-\rangle \tag{13}$$

In the triplet state *all three spin components* must be considered; there are three matrix elements.

In a first approximation in which two-electron terms are neglected the spin-orbit operator $H_{sp.orb.}$ can be reduced to a sum of one-electron terms each involving a product of orbital angular momentum **l** and spin angular momentum **s**[39][**].

$$H_{sp.orb.} = \frac{e^2}{2mc^2}\sum_{\substack{\text{nuclei}\\ i}}\sum_{\substack{\text{electrons}\\ k}}\frac{Z_i}{r_{ik}^3}\,\mathbf{l}_k\cdot\mathbf{s}_k = H_x + H_y + H_z \tag{14}$$

where H_x is the x component of the operator, H_y its y component and H_z its z component. The calculation of the matrix elements of $H_{sp.orb.}$ between two determinantal functions such as ψ_+^2 and $\psi_+\psi_-$ is straightforward[39][**] and leads to Table 1 for the matrix elements between S_0 and T_0. In the present case

$$H'_{lx} = \frac{\hbar e^2}{4m^2c^2}\left(\frac{Z_A|_x^A}{r_A^3} + \frac{Z_B|_x^B}{r_B^3}\right) \tag{15}$$

with $Z_A = Z_B = Z$.

We now assume that the symmetry element relating ϕ_A and ϕ_B is either a $C_2(x)$ axis or a $\sigma(xz)$ plane as shown in Figure 8. Finally in the matrix elements of Table 1 we restrict our-

[**] The numbers in the Table 5.4 of *McGlynn et al.* [39], which refer to an open-shell singlet configuration, must be multiplied by $\sqrt{2}$ to give correct results for a closed-shell configuration such as ψ_+^2. For the doubly-excited configuration ψ_-^2, a minus sign must be introduced. Note that eq. (5.42) of *McGlynn et al.* is incorrect: the numerical factor should be 1 rather than $1/\sqrt{2}$ (the latter would be correct only if |a c| were to replace (a c)). The equations which follow, however, are correct.

Table 1. Spin-orbit coupling matrix elements between S_0 and T_0.

Component of $H_{sp.orb.}$	$\langle S_0\|H_{sp.orb.}\|T_0^{(1)}\rangle$	$\langle S_0\|H_{sp.orb.}\|T_0^{(0)}\rangle$	$\langle S_0\|H_{sp.orb.}\|T_0^{(-1)}\rangle$
H_x	$\lambda\langle\psi_+\|H'_{ix}\|\psi_-\rangle + \sqrt{1-\lambda^2}\langle\psi_-\|H'_{ix}\|\psi_+\rangle$	0	$-\lambda\langle\psi_+\|H'_{ix}\|\psi_-\rangle - \sqrt{1-\lambda^2}\langle\psi_-\|H'_{ix}\|\psi_+\rangle$
H_y	$i[\lambda\langle\psi_+\|H'_{iy}\|\psi_-\rangle + \sqrt{1-\lambda^2}\langle\psi_-\|H'_{iy}\|\psi_+\rangle]$	0	$i[\lambda\langle\psi_+\|H'_{iy}\|\psi_-\rangle + \sqrt{1-\lambda^2}\langle\psi_-\|H'_{iy}\|\psi_+\rangle]$
H_z	0	$-\sqrt{2}[\lambda\langle\psi_+\|H'_{iz}\|\psi_-\rangle + \sqrt{1-\lambda^2}\langle\psi_-\|H'_{iz}\|\psi_+\rangle]$	0

Table 2. Spin-orbit-coupling matrix elements between singlet and triplet in a homosymmetric diradical: These matrix elements must be multiplied by the proportionality constant $\hbar e^2/(4m^2c^2)$ [see (19)]. $N=(4-4S_{AB}^2)^{-\frac{1}{2}}$.

The coefficients a, b, c give the orientation of the odd orbitals ϕ_A and ϕ_B [eq. (16)]; λ is a measure of the degree of ionic character [eq. (12)]; the integrals ξ_{AB}^{σ} and ξ_{AB}^{π} are defined in eq. (17) and are tabulated in Table 3. The overall singlet-triplet splitting is obtained by solving the 4-by-4 secular determinant involving the overall matrix elements of $H_{sp.orb.}$ between S_0, $T_0^{(1)}$, $T_0^{(0)}$, and $T_0^{(-1)}$ [see (20)].

Component of $H_{sp.orb.}$	$\langle S_0\|H_{sp.orb.}\|T_0^{(1)}\rangle$	$\langle S_0\|H_{sp.orb.}\|T_0^{(0)}\rangle$	$\langle S_0\|H_{sp.orb.}\|T_0^{(-1)}\rangle$
	Case I (C_2 axis)		
H_x	0	0	0
H_y	$-4NZ\hbar ac(\lambda-\sqrt{1-\lambda^2})(2\xi_{AB}^{\pi})$	0	$-4NZ\hbar ac(\lambda-\sqrt{1-\lambda^2})(2\xi_{AB}^{\pi})$
H_z	0	$4\sqrt{2}NZ\hbar abi(\lambda-\sqrt{1-\lambda^2})(\xi_{AB}^{\sigma}+\xi_{AB}^{\pi})$	0
	Case II (C_s plane)		
H_x	$4NZ\hbar bci(\lambda-\sqrt{1-\lambda^2})(\xi_{AB}^{\sigma}+\xi_{AB}^{\pi})$	0	$-4NZ\hbar bci(\lambda-\sqrt{1-\lambda^2})(\xi_{AB}^{\sigma}+\xi_{AB}^{\pi})$
H_y	0	0	0
H_z	0	$4\sqrt{2}NZ\hbar abi(\lambda-\sqrt{1-\lambda^2})(\xi_{AB}^{\sigma}+\xi_{AB}^{\pi})$	0

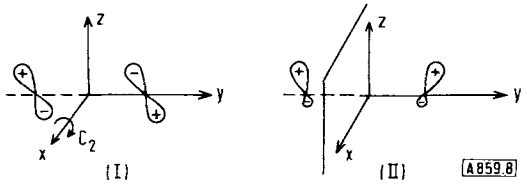


Fig. 8. Symmetry elements which couple ϕ_A and ϕ_B: (I) $C_2(x)$ axis, (II) $\sigma(xz)$ plane.

selves to the p_x, p_y, and p_z components involved in ϕ_A and ϕ_B. (The expectation value of l_x, l_y, and l_z acting on an s orbital is zero.) Then we can write, for (I) and (II):

$$\text{I}\begin{cases}\phi_A = ax_A + by_A + cz_A\\ \phi_B = ax_B - by_B - cz_B\end{cases}\qquad \text{II}\begin{cases}\phi_A = ax_A + by_A + cz_A\\ \phi_B = ax_B - by_B + cz_B\end{cases}\tag{16}$$

where $x \equiv p_x$, *etc.* The only non-vanishing matrix elements of $(1/r_A^3)l_x^A$, for instance, involve coordinate components on the same atom or coordinate components on both A and B:

$$\begin{cases}\left\langle z_A\left|\frac{1}{r_A^3}l_x^A\right|y_A\right\rangle \equiv -\left\langle y_A\left|\frac{1}{r_A^3}l_x^A\right|z_A\right\rangle;\ \left\langle z_B\left|\frac{1}{r_A^3}l_x^A\right|y_B\right\rangle \equiv -\left\langle y_B\left|\frac{1}{r_A^3}l_x^A\right|z_B\right\rangle\\ \left\langle z_B\left|\frac{1}{r_A^3}l_x^A\right|y_A\right\rangle \equiv -\left\langle y_A\left|\frac{1}{r_A^3}l_x^A\right|z_B\right\rangle \equiv i\hbar\xi_{AB}^{\pi}\\ \left\langle y_B\left|\frac{1}{r_A^3}l_x^A\right|z_A\right\rangle \equiv -\left\langle z_A\left|\frac{1}{r_A^3}l_x^A\right|y_B\right\rangle \equiv -i\hbar\xi_{AB}^{\sigma}\end{cases}\tag{17}$$

where ξ_{AB}^{π} and ξ_{AB}^{σ} are parameters which we will discuss later. Similar results hold for $(1/r_A^3)l_z^A$ and for $(1/r_A^3)l_y^A$, except that for this last operator only ξ_{AB}^{π} intervenes.

Simple algebra shows that, in terms of the ϕ's, only the off-diagonal elements between ϕ_A and ϕ_B are non-zero. The results are:

$$\left\langle\phi_A\left|\frac{1}{r_A^3}l_x^A\right|\phi_B\right\rangle = \left\langle\phi_B\left|\frac{1}{r_A^3}l_x^A\right|\phi_A\right\rangle^* =$$

$$-i\hbar bc(\xi_{AB}^{\sigma}-\xi_{AB}^{\pi}) = \left\langle\phi_B\left|\frac{1}{r_B^3}l_x^B\right|\phi_A\right\rangle \quad \text{(case I)}$$

$$-i\hbar bc(\xi_{AB}^{\sigma}+\xi_{AB}^{\pi}) = -\left\langle\phi_B\left|\frac{1}{r_B^3}l_x^B\right|\phi_A\right\rangle \quad \text{(case II)}$$

$$\left\langle\phi_A\left|\frac{1}{r_A^3}l_z^A\right|\phi_B\right\rangle = \left\langle\phi_B\left|\frac{1}{r_A^3}l_z^A\right|\phi_A\right\rangle^* =$$

$$i\hbar ab(\xi_{AB}^{\sigma}+\xi_{AB}^{\pi}) = -\left\langle\phi_B\left|\frac{1}{r_B^3}l_z^B\right|\phi_A\right\rangle \quad \text{(cases I, II)}\tag{18}$$

$$\left\langle\phi_A\left|\frac{1}{r_A^3}l_y^A\right|\phi_B\right\rangle = \left\langle\phi_B\left|\frac{1}{r_A^3}l_y^A\right|\phi_A\right\rangle^* =$$

$$-i\hbar ac(2\xi_{AB}^{\pi}) = -\left\langle\phi_B\left|\frac{1}{r_B^3}l_y^B\right|\phi_A\right\rangle \quad \text{(case I)}$$

$$0 = \left\langle\phi_B\left|\frac{1}{r_B^3}l_y^B\right|\phi_A\right\rangle \quad \text{(case II)}$$

The final results for the singlet-triplet matrix elements in cases (I) and (II) are shown in Table 2. All these results must be multiplied by the proportionality constant written in (15), *i.e.* $\hbar e^2/(4m^2c^2)$. The product of this constant by $\hbar$ is the conversion factor

$$\frac{\hbar^2 e^2}{4m^2c^2} \rightarrow 2.9\ \text{cm}^{-1}\tag{19}$$

if ξ is calculated in atomic units.

3.3. General Rules for Favorable Intersystem Crossing

Table 2 yields the favorable conditions for intersystem crossing. Consider for instance a system of type (II), where ϕ_A and ϕ_B are related by a symmetry plane. The extent of spin-orbit coupling induced by the *x component* of the Hamiltonian is proportional

1. To bc, *i.e.* to the product of the y and z components of ϕ_A (or ϕ_B). The maximum value of bc occurs when ϕ_A points parallel to the diagonal of the yz axis system (Figure 9). It is clear that a transition of an electron from ϕ_A to ϕ_B in-

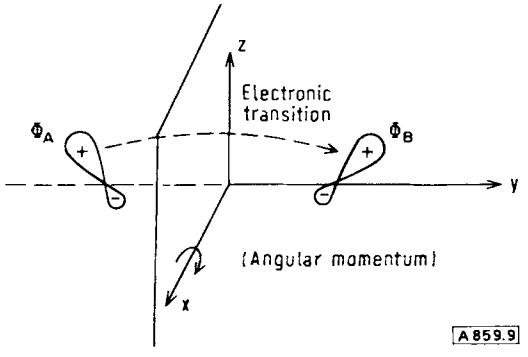

Fig. 9. Creation of orbital angular momentum by electronic transition from ϕ_A to ϕ_B (case II).

volves a rotation of 90° of (the p component of) the orbital which the electron occupies. This is precisely what is required to create an orbital angular momentum around the x axis which can "flip" the electron spin. This situation cannot occur, however, if ϕ_A and ϕ_B were to be related by the x axis as C_2 axis—whence the 0 matrix elements for H_x in case (I). (Similarly in case (II) H_y yields 0.)

In general, therefore, *the orbital axes must be orthogonal to each other and to the axis around which orbital angular momentum is being created.* Figure 10 shows the three different possible favorable cases illustrated for pure p orbitals.

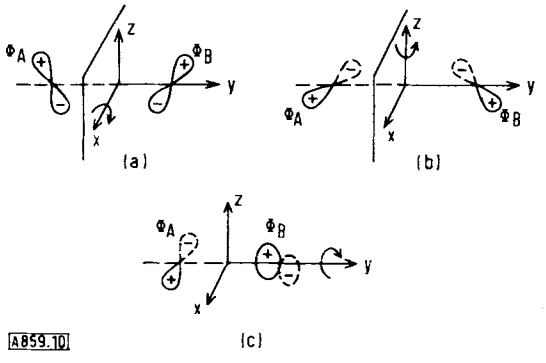

Fig. 10. Favorable orbital orientations for intersystem crossing in diradicals. Arrow shows angular momentum which is created.—The favorable orientation is not enough to ensure intersystem crossing. (a) Case II, C_s symmetry, orbitals in the yz plane; (b) cases I, II, $C_2^{(x)}$ or C_s symmetry, orbitals in the xy plane; (c) $C_2^{(x)}$ symmetry, orbital directions parallel to xz plane.

For angular momentum around z, the optimum value of the matrix element in Table 2 corresponds to a common situation for C_2 symmetry and C_s symmetry. Thus *orbital orientation* is an essential factor for intersystem crossing in diradicals. A triplet diradical in which the odd orbitals point straight at each other is in an unfavorable situation for rebonding.

2. To $\lambda - \sqrt{1-\lambda^2}$, *i.e. to the degree of ionic character* in the singlet wave function (16). Indeed, if the singlet is purely covalent, with one electron on each atomic orbital at all instants, the triplet to singlet transition cannot take one electron from ϕ_A into ϕ_B since the triplet is always purely covalent. No torque can be created to flip the spin since each electron stays in the *same* atomic orbital. Intersystem crossing is effective only if there is some probability of finding both electrons on the same orbital in the singlet. In homosymmetric diradicals the degree of ionic character increases with overlap; thus this second factor is roughly proportional to S_{AB} (see below). In the light of paragraphs 1 and 2, molecule *(15c)*—which is the transition state for optical isomerization of cyclopropane[12, 14]—is hardly prone to intersystem crossing and should remain in the singlet manifold. On the one hand the orbitals ϕ_A and ϕ_B are parallel, and on the other hand the singlet state is nearly covalent.

3. To the sum $\xi^{\sigma}_{AB} + \xi^{\pi}_{AB}$ of two-center integrals. From (17) it is clear that these integrals decrease rapidly with increasing distance AB or decreasing overlap.

Good overlap S_{AB} would therefore seem to be a favorable factor for two reasons [see (2) and (3)]. However, too strong an overlap automatically destroys the degeneracy between the singlet and triplet diradical states (see for instance Figure 3a) and often implies a poorer orbital axis orthogonality. This is illustrated below for ethylene, where we have plotted triplet-singlet energy difference, ionic character and orbital axis orthogonality (ac) against twist angle[*]. The maximum value of the matrix element of H_y is found to occur near 60°. A numerical estimate can

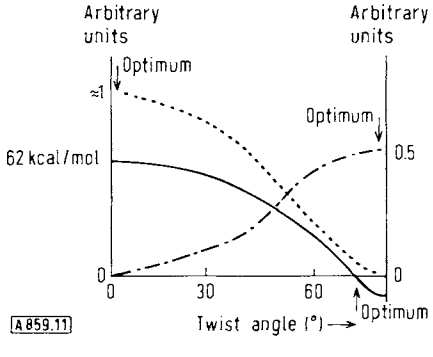

Fig. 11. Terms involved in the H_y induced spin orbit coupling in twisted ethylene (y axis = CC axis; x axis = C_2 axis relating the orbitals). The component ac behaves as $\frac{1}{2}\sin\theta$. —: $E_T - E_S$; ···: $\lambda - \sqrt{1-\lambda^2}$; — · — ·: ac.

be obtained for the intersystem crossing matrix element at this angle by using the values:

[*] In ethylene, in which the spin-orbit coupling is induced by H_y (case I) the integral ξ^{π}_{AB} is insensitive to twisting. Thus the overlap intervenes through λ and through the product ac.

$$(Z=3.25,\text{ effective value})\quad\begin{cases} Z\xi^{\pi}_{AB}=0.7186\,cm^{-1}\,[40][*] \\ S_{AB}\ =0.1321 \\ \lambda\ =0.93 \\ ac\ =\tfrac{1}{2}\sin 60^\circ \end{cases}$$

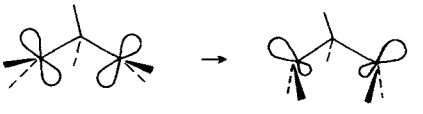
in Table 2 (Case I, H_y).

We find for the matrix elements of H_y between S_0 and $T_0^{(-1)}$ or $T_0^{(+1)}$ $A=0.70\,cm^{-1}$. Whence, by solving the 3 by 3 secular determinant

$$\begin{vmatrix} -E & A & A \\ A & -E & 0 \\ A & 0 & -E \end{vmatrix}=0 \qquad (20)$$

the splitting between singlet and triplet is:

$$\text{Singlet-triplet splitting}=\sqrt{2}A=1\ cm^{-1} \qquad (21)$$



This value is an upper limit for the actual electronic factor in the intersystem crossing since our calculation assumes that the vibronic degeneracy can still be maintained or induced for an electronic energy difference already as large as 1.1 eV. If this is not the case, the actual optimum mixing will occur for larger angles and thereby smaller values of the overall matrix element. Of course (20) will have to be multiplied by a Franck-Condon factor to yield the overall intersystem crossing probability.

Table 3. Values of $Z\xi^{\sigma}_{AB}$ and $Z\xi^{\pi}_{AB}$ for various distances R_{AB} ($Z=3.25$) [40] [*]. Values in cm^{-1} [the conversion factor (19) has been included].

R_{AB}	$Z\xi^{\sigma}_{AB}$	$Z\xi^{\pi}_{AB}$
0	13.5	13.5
1 Å	1.99	1.98
1.5 Å	1.37	0.528
2 Å	0.498	0.133
2.5 Å	0.152	0.032
3.0 Å	0.042	0.0076

Table 3 shows that in 1,3 or 1,4 diradicals the intersystem crossing matrix element drops to 0.5—0.1 cm^{-1}. By comparison the matrix elements for intersystem crossing between the low-lying excited states of benzene are 0.3 cm^{-1}[41]. A tentative comparison of the overall intersystem crossing rates in aromatics and in small diradicals requires knowledge of the vibrational overlap factors. In aromatics the vibrational interaction is characterized by overlap between the lowest level of the higher electronic state and a dense but *strongly oscillatory* manifold of levels from a lower state of similar geometry. In diradicals the situation is similar insofar as the flat or even convex nature of the singlet surface also creates a manifold of *oscillating* vibrational wave functions which must mix with those of the triplet. In aromatics intersystem crossing requires 10^{-8} to 10^{-6} seconds; intersystem crossing rates in diradicals should be of the same order. Only for a singlet diradical lying in a secondary minimum, for which the Franck-Condon overlap with triplet levels (that of two displaced oscillators) might be significant, could the intersystem crossing be enhanced.

Thus introduction of significant overlap occurs at the expense of the intersystem crossing probability, because of the destruction of diradical state pair degeneracy and orbital axis orthogonality. There are, however, cases where ionic character can be significant even though the overlap is small or zero, and in spite of the triplet-singlet proximity. These cases correspond to zwitterionic states (Section 2.4) which are not too far removed from the covalent triplet. One such example is pyramidalized face-to-face trimethylene *(15a)*. The pyramidalization does not destroy the singlet-triplet degeneracy[10] and introduces ionic character into the ground-state singlet. Unfortunately, however, the odd orbitals axes now point nearly toward each other, a less favorable orientation than in *(15d)* trimethylene (compare with Figure 10b).

(15d) good orbital orientation, poor ionic character → *(15a)* poor orbital orientation, good ionic character

A second obvious example is the one-center heterosymmetric diradical methylene where ionic character is predominant in the lowest singlet, the odd orbitals are orthogonal, and where the matrix element ξ^{π}_{AB} is a large one-center term (see Section 3.4).

3.4. The Electronic Factor in the Heterosymmetric Case

In the heterosymmetric case (Section 2.2) the spin-orbit coupling matrix elements vanish between the covalent diradical singlet and the covalent diradical triplet. The reason is simply (Section 3.2) that no angular-momentum-inducing electronic transition is possible from ϕ_A to ϕ_B. For instance in the face-to-edge trimethylene *(15b)*, even though the orbital orientation is favorable, the lack of ionic character in the singlet forbids intersystem crossing.

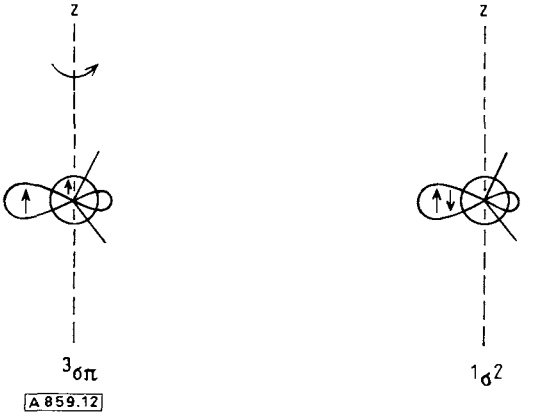


Fig. 12. Spin orbit coupling in methylene.

[*] This value has been calculated according to the procedure of *Coulson* [40] (see also Table 3). The constant (19) is included in this value of $Z\xi^{\pi}_{AB}$.

Non-zero matrix elements occur only between the diradical triplet and a *zwitterionic* singlet. Thus intersystem crossing should be relatively facile in species such as *(17a)* and *(17b)* in an edge-to-face configuration [similar to *(15b)*, see Scheme 8b].

A particularly favorable situation holds in methylene, where the lower singlet has strong ionic character (Scheme 7) and where the orthogonality of the σ and π odd orbitals ensures the creation of angular momentum around the axis which is perpendicular to both orbital directions. We chose this axis as z axis (Figure 12). A calculation similar to that in Section 3.2 then yields (see Table 2, H_z) a spin-orbit coupling matrix element

$$A = 2\sqrt{2}\,Z\hbar(\mu - \sqrt{1-\mu^2})\,\xi_{AA} \tag{22}$$

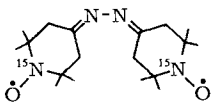
where $100\,\mu^2$ is the percentage of σ^2 character in the lowest singlet and where the one-electron integral

$$\xi_{AA} \equiv \left\langle x_A \left| \frac{1}{r_A^3} l^A \right| y_A \right\rangle$$

is equal to $\zeta^3/3$ for a Slater 2p orbital with exponent ζ. For $\mu \approx 1$ and choosing for Z the effective value $2\zeta = 3.25$ we get, with (19),

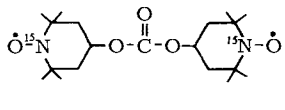
$$A = 37.9\ \mathrm{cm}^{-1} \tag{23}$$

for the singlet-triplet mixing, which is in good agreement with previous results[42]. This large mixing relative to the two-center case [eq. (21)]—compare the relative sizes of ξ_{AA} and ξ^{π}_{AB}—has led *Basch* and *Chang* to predict[43] that triplet and singlet methylene could equilibrate in 10^{-12} s. However, their calculation depends on a doubtful coincidence of vibronic states[36]; furthermore such rapid mixing seems to be at variance with the fact that singlet and triplet methylene have distinct chemistries[44].



3.5. Other Mechanisms for Intersystem Crossing

In the absence of spin-orbit coupling matrix elements larger than $\approx 0.001\ \mathrm{cm}^{-1}$ (30 MHz)—for instance for extremely weakly coupled electrons of the type studied in Section 1.1—other mechanisms can induce intersystem crossing. The most common mechanism is the hyperfine interaction between the electron spins and nuclear spins, which arises from the Hamiltonian [eq. (24)]. This Hamiltonian describes the scalar product of the spin $\mathbf{I}_i$



$$H_{hyp} = \sum_{\substack{\text{nuclei} \\ i}} a_i \mathbf{I}_i (\mathbf{S}_1 + \mathbf{S}_2) \tag{24}$$

of nucleus i with the spins $\mathbf{S}_1$ and $\mathbf{S}_2$ of both electrons. The factor a_i is the isotropic electron nuclear hyperfine coupling constant for nucleus i. Its order of magnitude is 30 MHz for carbon or nitrogen. Equation (24) represents the so-called Fermi contact term, which is responsible for nuclear spin-spin coupling as measured by NMR coupling constants and for the hyperfine structure of ESR spectra of radicals. It can also directly induce singlet-triplet mixing. This effect can be observed most simply in electron spin resonance, but also occurs in the now widespread phenomenon of chemically induced dynamic nuclear polarization or CIDNP.

The form of the ESR spectrum of a diradical such as *(21)* or *(22)* depends on the relative magnitude of a_N, the coupling constant for the ^{15}N nucleus, and of the *singlet-triplet energy separation J*. This energy difference J appears in another term of the Hamiltonian[45]:

(21)

(22)

$$H_{exchange} = -J\,\mathbf{S}_1 \cdot \mathbf{S}_2 \tag{25}$$

This term, which accounts for the exchange between the two electrons (*Dirac*'s "vector coupling model") is valid only for weakly coupled electron spins. In the approximation of weak overlap, the singlet-triplet energy difference J is equal to the valence-bond exchange integral[46]. This integral involves both the Coulombic repulsion of the electrons and their attraction for the opposite nuclear center. Now, if J is much larger than a, the ESR spectrum of two odd electrons coupled to a triplet and located on two ^{15}N nuclei shows 3 lines (Figure 13). The spectrum of *(21)* is of this type.

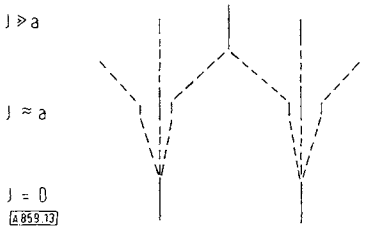


Fig. 13. ESR spectrum of two odd electrons centered on two ^{15}N nuclei [47]. $J \gg a$: triplet state; $J \approx a$: triplet-singlet mixing; $J = 0$: two doublet states.

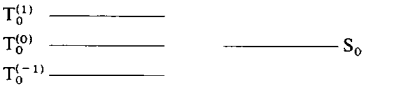
If the singlet-triplet separation is no larger than a, then the spectrum divides into 6 lines (Figure 13, case $J \approx a$). Such a spectrum is shown by diradical *(22)*, in which the odd electrons are on the average further apart than in *(21)*. One can interpret the additional lines as being due to the admixture of singlet character into the originally pure triplet *via* the hyperfine interaction operator. Ultimately, if the odd electrons are even further apart, one has two totally independent odd electrons (a truly "double" radical); each electron contributes equally to the two ESR lines.

The same hyperfine-induced singlet-triplet mixing is responsible for the *dynamic nuclear spin polarization* (CIDNP) observed in chemical reactions proceeding *via* radical pairs[48]. The main features of CIDNP are:

1. The formation of a radical pair by thermal decomposition or photolysis. This radical pair can be derived either from a triplet state or a singlet state precursor:

$$T_{precursor} \rightarrow [A^{\bullet} \cdots {}^{\bullet}B] \qquad S_{precursor} \rightarrow [A^{\bullet} \cdots {}^{\bullet}B]$$



2. An alternative for the radical-pairs, either

a) diffuse with eventual secondary recombination to give products; or

b) collapse in a primary cage-recombination to give products.

While the diffusion process is independent of the nuclear spin states[49][*], the primary collapse process is not: *the intersystem crossing to a singlet electronic configuration, which is necessary to form a bound product occurs more efficiently for certain nuclear states.* NMR transitions involving these states will therefore be enhanced. It can be shown[50][**] that the net polarization observed for collapse of a pair derived from an S precursor is of opposite sign but of similar magnitude to that for a pair derived from a T precursor. Here we will treat the simplest possible case of a caged radical pair produced from a triplet state precursor with both odd electrons coupled to two neighboring protons.

In the presence of the external magnetic field of the NMR spectrometer the three triplet sublevels are largely split (Scheme 9) and one need consider only the (first-order) mixing of S_0, the singlet state, with $T_0^{(0)}$ the $(\alpha_1\beta_2+\beta_1\alpha_2)$ component of the triplet state. The effect of the nuclear spin-electron spin coupling is to induce transitions between the *overall* (electron + nuclear) spin components. If the total

Scheme 9. States of a very loose diradical pair in an external magnetic field.

spin is $\mathbf{R}=\mathbf{S}+\mathbf{I}$, the selection rule is

$$\Delta R_z = 0 \tag{26}$$

for a magnetic field pointing along the z axis. Whence

$$\Delta\left(S_z + \sum_{\text{nuclei}} I_z^i\right) = 0 \tag{27}$$

Since S_z is zero in both states S_0 and $T_0^{(0)}$, $\Delta S_z = 0$ and eq. (27) yields

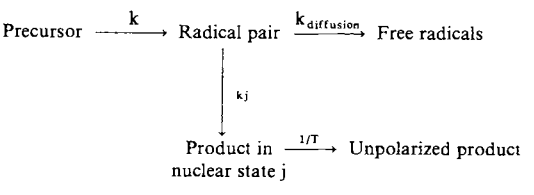
$$\Delta\left(\sum_i I_z^i\right) = 0 \tag{28}$$

[*] The true picture is actually complicated by the fact that the secondary encounters of radicals ($A^{\bullet}$, $B^{\bullet}$) with uncorrelated electron spins can also yield nuclear-polarized products [49a]. For the experimental discrimination between primary combination of a T pair and the combination from secondary encounters of free radicals, which has the same sign, but which could actually have originated from an S precursor, see [49b].

[**] The state of the diradical pair is a time-dependent singlet-triplet mixture; it is assumed that product formation at time t is proportional to the extent of singlet character at time t—itself a function of the situation at t = 0.

For two nuclei with spins 1/2 the only possibility is

$$\begin{cases} (I_z^1) & 1/2 \rightarrow -1/2 \\ (I_z^2) & -1/2 \rightarrow 1/2 \end{cases} \quad \text{or} \quad \begin{cases} -1/2 \rightarrow 1/2 \\ 1/2 \rightarrow -1/2 \end{cases}$$



No transition is feasible if I_z^1 and I_z^2 are both equal to 1/2 or both equal to $-1/2$. The net result is a higher rate of formation of nuclear states with

$$I_z^1 + I_z^2 = 0$$

in the final product.

This result alone would not be sufficient to ensure a nuclear polarization. A competitive process which does not depend on the nuclear states is required. If the radical pairs can also separate by diffusion, the following kinetic scheme—in which k_j is the rate of formation of products in the j^{th} nuclear state—shows that the stationary concentration of product in nuclear state j is:

$$[P]_j = \frac{T k_j k [\text{Precursor}]}{k_j + k_d} \tag{29}$$

If k_d were zero, this concentration would clearly be independent of k_j and there would be no nuclear polarization.

Can CIDNP not then occur in an isolated molecular biradical species for which diffusion does not exist? The answer seems to be[51] that in those diradicals where S_0 lies slightly below $T_0^{(0)}$ and is accidentally degenerate with $T_0^{(-1)}$, the selection rule (27) allows a *direct flip of the overall nuclear spins via* the condition

$$\Delta S_z = 1, \qquad \Delta\left(\sum_i I_z^i\right) = -1 \tag{30}$$

Condition (30) can be satisfied if the triplet-singlet mixing in the diradical is accompanied by a $+1/2$ to $-1/2$ nuclear spin flip for only one proton. Thus the product is created with excess $-1/2$ nuclear spins, and NMR emission is observed[51] although there is no competitive kinetic process.

4. Evidence for and against Singlet or Triplet Diradicals as Secondary Minima ("Reaction Intermediates") on Potential Energy Surfaces

The idea that the formation of a diradical by bond breakage is accompanied by electronic rearrangement in the new species, with concomitant energy stabilization, is a common one in Organic Chemistry. Diradicals have been thought to represent small energy minima on the potential energy

surface from the mother-species to the ultimate product. Thermochemical estimates of the heats of formation of diradicals generated by small hydrocarbon ring pyrolysis are consistently smaller than the experimental activation energies for the reactions[52]. The diradical could therefore be a "resting point" which would immediately follow the transition state. The failure to intercept any such diradical by radical scavengers could be accounted for by its short life-time (10^{-10} s) and high local monoradical concentration (10 mol/l)[19].

Kinetic schemes using intermediate diradicals, such as

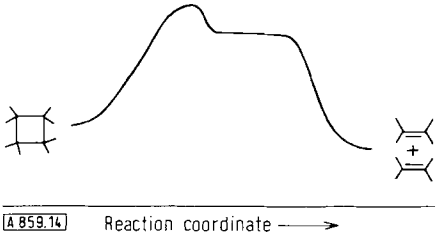
Ring ⇄ Diradical → Decomposition products
(Structural isomerization)

or

cis-Substituted ring ⇄ Diradical ⇄ *trans*-Substituted ring
(Geometrical isomerization)

give reasonable agreement with experiment[52, 53]. (Such schemes would be meaningless if there were no steady-state concentration of diradicals in the process.) Similarly, for bimolecular reactions, the evidence from reaction order measurements for intermediates accompanied by "dips in the energy profile" is impressive[54][*]. It is therefore tempting to believe that diradicals do lie in secondary minima on the potential energy surfaces which lead to their recombination products, with a "barrier to reclosure" to these products.

The first blow to this well-accepted implication came from the calculations by *Hoffmann et al.* on the tetramethylene diradical[55]. These extended Hückel calculations yield a smooth potential surface with only *one* maximum between cyclobutane and the ethylene decomposition products (Figure 14). No secondary minimum is found on the many-



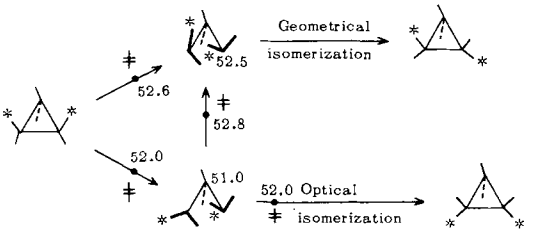


Fig. 14. Energy profile along the reaction coordinate for decomposition of cyclobutane [55].

dimensional potential energy surface. However, the computations do show a very *flat* region in many-dimensional space. This flatness would induce the system in this region—coined "twixtyl"—to spend a relatively long time "exploring" its way out. Such a large, energetically flat region of coordinate space might be "operationally indistinguishable, in its effects on the rate constant, in the possibilities it offers for interception and diversion, from a true minimum"[55]. These results are of course quite startling. However, in view of the approximate nature of the calculations, their failure to discriminate between singlet and triplet, and the low thermochemical estimate (<4 kcal/mol[52]) for the "barrier" to decomposition these novel features awaited confirmation in other cases[**].

Such confirmation now seems to be forthcoming[14][***]. "*A priori*" self consistent field calculations with a minimal basis set of Slater orbitals have been carried out on the potential energy surface for geometrical isomerization of cyclopropane. Both the singlet surface and the triplet surface in the region of the trimethylene diradicals *(15a)* to *(15d)* have been investigated. The reaction path from the closed ring to its geometrical isomer through the region of the resolved transition state climbs monotonically and then goes down again. No energy dip of significance (>0.5 kcal/mol) has been found on the *singlet surface*[14]. Since there is little reason to believe that intersystem crossing occurs in *(15a)* (Section 3.3) or *(15b)* (Section 3.4) which are typical configurations adopted by the molecule along this pathway, it must be concluded that the geometrical isomerization of cyclopropane is a *one-step* reaction.

It is true that structure *(15c)* is found to be in a shallow (≈1 kcal/mol) minimum on the path to optical isomerization, in agreement with *Hoffmann*'s previous calculations[12]. However, the path leading from *(15c)* to *(15b)*—which is required to obtain geometrical isomerization—seems at best just competitive with the direct pathway from cyclopropane to *(15b)*, as shown in Figure 15.

(15c)

Fig. 15. Pathways and energies for geometrical and optical isomerization of cyclopropane [14]. The numbers refer to "*a priori*" calculated energies; ‡ indicates a transition state. The lowest-energy conformations of *(15b)* and *(15c)* have been drawn.

Thus the system does not seem to be required to "stop and rest" in an energy dip. In analyzing these results, however, it is essential to keep in mind that the calculated energies have been obtained in a minimal basis set calculation. Improved "*a priori*" calculations may be seriously at variance with ours, with significant changes in the location and geometry of the extrema.

On the triplet state surface, things seem to be entirely different. The trimethylene diradical in its various conformations corresponds to the region where the triplet state energy is lowest (for a comparison with ethylene, see Figures 3b and 7). It is found[14] that this minimal region lies

[*] *Note that in* [54a] *none of the quoted intermediates is a diradical;* but there are numerous cases of zwitterions, see also [54b].

[**] *R. Hoffmann*, Yale Symposium on Theoretical Analysis of Reaction Pathways (December 1970), was confident that a secondary minimum would be found for trimethylene, in spite of his own results on tetramethylene [55].

[***] *P. J. Hay, W. A. Goddard III*, and *W. J. Hunt*, J. Amer. Chem. Soc., in press, have independently obtained evidence against a secondary minimum in the geometrical isomerization of cyclopropane.

consistently below the singlet surface by 3.5 to 4.5 kcal/mol both for structures *(15b)*, *(15c)* and for intermediate conformations. This is no surprise (Section 2.1, end) since the molecular orbitals of *(15c)* are nearly degenerate[12] while *(15b)* is a heterosymmetric diradical obeying Scheme 6. The overall energy profile along the reaction coordinate for geometrical isomerization can then be described as in Figure 16.

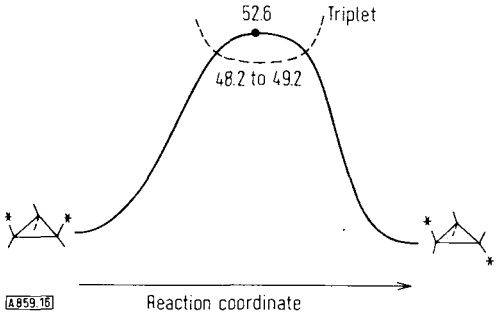

Fig. 16. Energy profile along the reaction coordinate for geometrical isomerization of cyclopropane [14].

If the reactant were to fall onto the triplet surface after reaching the transition state it would certainly become a "reaction intermediate" in the usual sense. But in the absence of favorable intersystem crossing it will simply ignore this lower pathway[*].

In the light of the results for both tetramethylene and trimethylene, what is left of the earlier interpretation of diradicals as reaction intermediates? In our view, the thermochemical estimates of diradical energies and kinetic properties seem to remain valid *only if applied to triplet states*. In trimethylene, for instance, the energy difference of 4.4 kcal/mol between the lowest triplet conformation (48.2 kcal/mol) and the transition state (52.6 kcal/mol) is in not unreasonable agreement with *Benson*'s estimate of 8.2 kcal/mol—which may be somewhat too generous[19]—for the "barrier to reclosure" of the trimethylene intermediate. Thus the thermochemical calculations remain useful if one is careful to keep this spin restriction in mind. Triplet intermediates may actually be quite common in non-concerted reactions of the "anti-Woodward-Hoffmann" type. *Pople* has shown that the lowest energy route through an orbital energy crossing region is *via* the triplet state[56].

Finally, what are the chances of finding a diradical *singlet* in a secondary minimum? We regard these chances as slim[**].

A lowering of energy in the singlet state of a diradical requires that the system be able *to achieve electron pairing without recombination of the radical termini*. In appropriate systems this can occur by acquisition of zwitterionic character[54] *via* electron-pairing on one of the termini. However, the energy minimum is then a zwitterionic state (Scheme 8) or a mixture rather than a true diradical state. In unsubstituted neutral hydrocarbons for which such zwitterionic pairing is costly, the best potential candidates as intermediates should resemble *(15c)*, in which the odd orbitals ϕ_A and ϕ_B are poorly oriented for direct bond closure and in which some ionic character subsists in the ground state (Scheme 4a). However, the energy stabilization of *(15c)* is probably restricted by the fact[12] that the lower of the two molecular orbitals, in which the electrons would tend to pair, is actually antibonding between ϕ_A and ϕ_B. In most cases, therefore, and unless appropriate substituents induce zwitterionic character, one can expect rather flat singlet surfaces without significant minima.

The authors are extremely grateful to the numerous colleagues and friends who did not begrudge them either advice or wisdom: Paul Bartlett, Mustafa El-Sayed, Bill Gelbart, George Hammond, Roald Hoffmann, Martin Karplus, Luitzen Oosterhoff, John Pople, and Stuart Rice. They are also greatly indebted to Dr. H. H. Westen for critical reading of the German and English manuscripts.

[*] There is some evidence for the cyclopropane surface *that the geometry corresponding to the equilibrium structure of the triplet state is very close to that for the transition state on the singlet surface.* We suspect that this may be generally true for diradicals. Some justification can be given as follows: the transition state and the triplet both belong to a family of structures in which some bond is totally broken. By definition the transition state is the lowest energy member of that family (*i. e.* that structure for which all other energy contributions, such as steric effects, which are not involved in the reaction coordinate, are optimized)—apparently within the singlet manifold; whereas the equilibrium triplet is the lowest energy member of the family in the triplet manifold. Since these other factors should not be very spin-dependent, the two geometries—transition state and equilibrium triplet—should be very similar. The authors are grateful to Dr. *Warren Hehre* for a discussion of this point.

[**] We exclude from this discussion the possible stabilization of the two odd electrons *via* delocalization over adjacent unsaturated bonds.

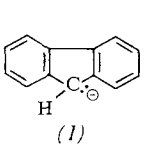
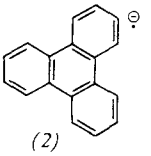
Structure of Ion Pair Solvation Complexes[**]

By Johannes Smid[*]



In solvents of low polarity, salts containing a carbanion, e.g. fluorenylsodium, or a radical anion, e.g. coronenesodium, can exist as contact ion pairs or as solvent separated ion pairs. Particular interest attaches to the complexes of ion pairs with the strongly solvating, polydentate polyglycol dimethyl ethers (glymes) and with crown compounds. These systems can be studied by optical spectroscopy, NMR spectroscopy, and other methods.

1. Introduction



Ionic reactions in media of low dielectric constant often show a complex behavior, largely because of the variety of forms in which the reacting ionic species can exist; *e.g.*, free ions, ion pairs, triple ions, quadrupoles, and higher aggregates. Each of the species may react with its own characteristic rate constant and stereospecificity, and frequently a rapid dynamic equilibrium may exist between two or more ionic species. Such equilibria are often strongly affected, not only by the structure of the reacting ion, but also by the type of counterion, the solvent polarity, the presence of ion-coordinating additives, and the temperature.

Unraveling the complex reactivity behavior of ionic reactions in low polarity media requires, therefore, a knowledge of the structure and solvation state of the existing ionic species. A variety of techniques such as electron spin resonance, nuclear magnetic resonance, electrolytic conductance, ultraviolet, visible, infrared, and Raman spectroscopy and still other methods have been used over the past decade to study the structure of ion pairs and their solvation complexes. The most detailed information has probably been obtained from electron spin resonance studies, particularly as it relates to dynamic phenomena involving the association of ions or solvation of ion pairs. Ultraviolet and visible spectroscopy, on the other hand, is not limited to paramagnetic molecules like the ESR methods, and is also attractive because of its simplicity. Furthermore, high concentrations of reagents are not required, which is often a limiting factor in infrared and nuclear magnetic resonance studies.

In this discussion we shall mainly concern ourselves with the optical and nuclear magnetic resonance spectra of solvation complexes of ion pairs of carbanions and radical anions. It should be pointed out at this stage that a solvent may affect the optical spectrum of a neutral molecule or ionic species in a variety of ways. For example, spectra of pyridinium iodides are very sensitive to a change in solvent polarity, and *Kosower* has shown that the solvent sensitive transition involves a transfer of negative charge from the iodide anion to the pyridinium cation[1,2]. The solvent stabilization of the ground state is therefore lost in the excited state, leading to blue shifts in the more polar solvents. Optical spectra of inorganic and quaternary ammonium iodide salts were studied by *Symons*[3-5] and found to be solvent sensitive. The transition involved appears to result from the transfer of an electron from the iodide anion to the surrounding solvent cage. In another interesting case the optical spectrum of retinylpyrrolidinium perchlorate was shown to be strongly affected by polarizable solvents such as pyridine or dichlorobenzene, but not by a change in polarity of nonpolarizable solvents[6]. The bathochromic shift in the more polarizable solvents was attributed to a stabilization of the greatly delocalized excited state of this conjugated chromophore. The Frank-Condon principle disallows stabilization of the excited state by the much slower solvent-solute reorganization, and polarity itself, therefore, does not affect the transition.

(1)

(2)

The spectra of carbanions and radical ions, when present as free ions, are generally very little affected by a change in solvent polarity. For example, the absorption maxima of the free fluorenyl anion are identical in tetrahydrofuran, pyridine, dimethyl sulfoxide, and hexamethylphosphoramide. However, spectral changes are observed when the radical ions or carbanions are present as ion pairs, due to the perturbation caused by the counterion. The extent of this perturbation depends on the nature of the counterion and its solvation. The observed spectral changes can therefore be utilized to study the interaction of solvents or complexing agents with the counterion and to shed more light on the structure of the ion pair solvation complexes.

The salts of fluorenyl anions are particularly suitable for these types of investigations, as their optical spectra are characterized by sharp absorption bands, and the association with a cation causes a considerable hypsochromic shift, dependent on the cation radius. Moreover, the fluorenyl carbanion not only functions as a convenient optical probe for studying ion pair solvation, it also can be used

[**] The following abbreviations will be used:
DME = dimethoxyethane
DMSO = dimethyl sulfoxide
2-Me-THF = 2-methyltetrahydrofuran
THF = tetrahydrofuran
THP = tetrahydropyran
TMEDA = tetramethylethylenediamine
TMS = tetramethylsilane.

in nuclear magnetic resonance studies. A complexing agent coordinated to the cation will be in the proximity of the aromatic fluorenyl anion, and its protons, therefore, are considerably shifted upfield due to the diamagnetic anistropy. Even more interesting shifts are observed with solvation complexes of certain aromatic radical anion pairs; some of these cases will also be discussed.

In our discussion of ion pair structures we shall frequently use the terms contact and solvent separated ion pairs or tight and loose ion pairs. The latter terminology suggests that more than two kinds of ion pairs may be visualized. For example, the average interionic distance in a contact ion pair may vary depending on the temperature and the type of solvent. Different structures can also be visualized for separated ion pairs, depending on the size and geometry of the complexing molecule. In fact, the distinction between a tight and loose ion pair may depend on the method of investigation.

An interesting example of this was recently found in the behavior of the solutions of triphenylenesodium in 2-methyltetrahydrofuran[7] which contain the radical anion *(2)*. This radical anion pair reveals a sodium coupling in its electron spin resonance spectrum, but the coupling disappears below $-50\,^{\circ}C$, implying a change to a loose ion pair structure. However, the optical spectrum of the ion pair salt remains identical down to $-80\,^{\circ}C$, but changes to that characteristic of the loose ion pair below this temperature. This example points to the necessity of using a variety of methods when studying the structure and properties of ion pairs.

2. Ion Pairing in Fluorenyl Salts

One of the earliest reports on shifts in optical spectra arising from ion pairing concerns a study of the spectra of alkali and alkaline earth salts of ketyls by *Warhurst et al.*[8], who observed bathochromic shifts on increasing the radius of the cation. Similar effects were reported by *Hogen Esch* and *Smid*[9, 10] for fluorenyl and other carbanion salts and by *Zaugg* and *Schaefer*[11] for alkali salts of phenols and enols. Tight ion pairs are involved in all these cases, and the bathochromic shifts can be rationalized by assuming that an enlargement of the cation size causes a greater destabilization of the ground state than of the excited state. A redistribution of charge occurs on excitation, and the cation, while close to the carbon of highest charge density in the ground state, is not allowed to readjust itself on account of the Frank-Condon principle. The transition frequency, therefore, becomes larger as the cation decreases in size. Since the perturbation of the molecular orbital levels of the anion by the cation is largely electrostatic in nature[8], it is not surprising to find that the transition frequencies are roughly proportional to the reciprocal of the cation radius r_c. This is depicted for fluorenyl salts in Figure 1. A similar relationship was observed for enols[11], while for ketyls a linear correlation of the frequency is found with the reciprocal of the function $r_c + 2$, the constant being the contribution of the anion to the interionic distance[8].

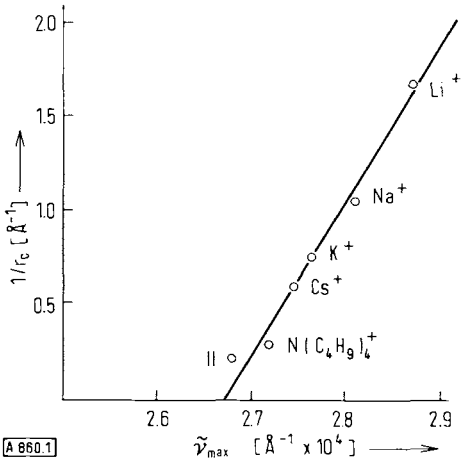

Fig. 1. Correlation between wave number and the inverse of the cationic radius for contact fluorenyl ion pairs in THF at 25 °C. || = solvent separated ion pair.

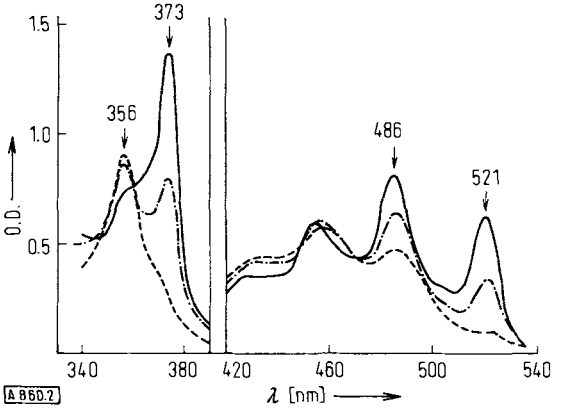

Fig. 2. Optical absorption spectrum of fluorenylsodium in THF at 25 °C (– – –), −30 °C (–·–·–), and −50 °C (——). Cell length 0.0283 cm (left-hand part of spectrum) and 0.208 cm (right-hand part).

Spectrophotometric evidence for the existence of two kinds of ion pairs was first obtained for fluorenyl salts in ethereal solvents. The spectrum of fluorenylsodium in THF at 25 °C (Fig. 2) shows a sharp absorption band at 356 nm, which is replaced at lower temperatures by a new band emerging at 373 nm. Similar changes are observed in the visible region of the spectrum. The change is reversible, and the ratio of the peak heights is independent of the carbanion concentration and is not affected by addition of Na^+ ions. The spectral changes can only be rationalized by postulating a dynamic equilibrium between tight ion pairs (fluorenyl$^-$,M$^+$) and loose ion pairs (fluorenyl$^-$||M$^+$), with the latter being favored at low temperatures[10]:

$$F^-, M^+ + nS \rightleftharpoons \text{fluorenyl}^-\|M^+ \qquad (1)$$

The driving force for the formation of the separated ion pairs is essentially the coordination of solvent molecules, S, with the cation. It makes this ion pair equilibrium a particularly suitable probe for quantitative studies of cation interactions with solvating molecules and their effects on ion pair structures and reactivities.

2.1. Effect of Cation

The ion pair equilibrium (1) is strongly affected by the nature of the cation[10]. Figure 3 shows spectra of fluorenyllithium, -sodium, and -cesium in THF at −30 °C. Solvation of the large Cs^+ ion is weak, and only contact ion pairs are found, even at −70 °C; a similar behavior is observed for the potassium and tetrabutylammonium salts. The sodium salt has approximately equal fractions of the two kinds of ion pairs at −33 °C, while the Li salt is found to exist as a separated ion pair below 0 °C. Usually, the proportion of separated ion pairs decreases along the series Li, Na, K, Cs, but this may change for polydentate solvating species such as polyglycol dimethyl ethers or macrocyclic polyethers.

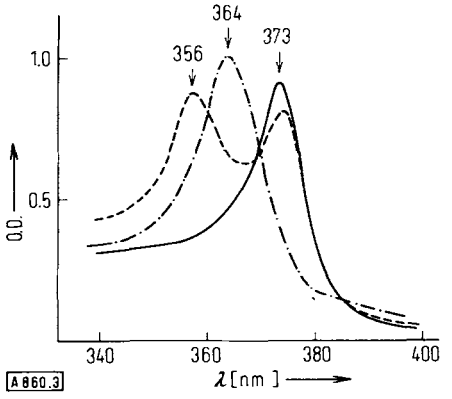

Fig. 3. Absorption spectrum of fluorenyl salts in THF at −30 °C as a function of counterion Li^+ (——), Na^+ (– – –), and Cs^+ (–·–·).

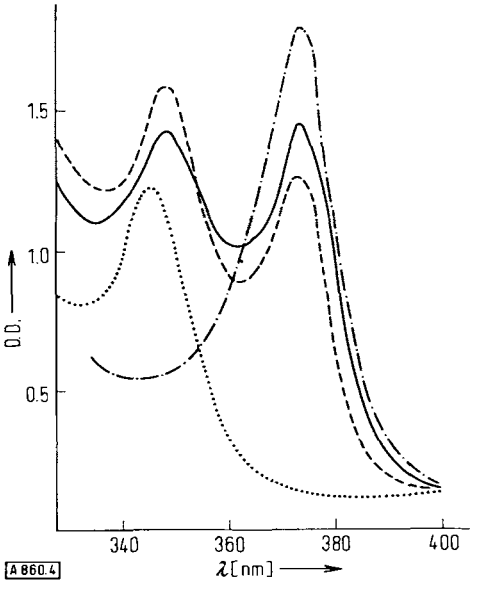
2.2. Effect of Polarity and Structure of Solvent

The equilibrium between tight and loose ion pairs is often drastically affected by the polarity and structure of the solvent[10, 12]. Typical examples are given in Figure 4.



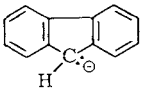


Fig. 4. Optical spectra of contact and separated ion pairs of fluorenyllithium *(1)*Li^+ at 25 °C in 3,4-dihydropyran (·····), 3-methyltetrahydrofuran (– – – –), 2,5-dihydrofuran (——), and hexamethylphosphoramide (–·–·–).

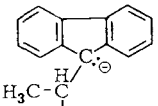

Generally, the separated ion pair maximum at 373 nm is unaffected by a change in solvent polarity. For example, no change is found where tetrahydropyran is replaced by dimethyl sulfoxide or hexamethylphosphoramide. The carbanion transition as such appears, therefore, unaffected by solvent polarity, and the spectral changes can be entirely attributed to the solvent induced separation of the ions. In certain amines[13] changes in the absorption maximum of the separated ion pair have been found, and carbanion solvation may be responsible here[14].

Small bathochromic shifts in the contact ion pair maxima are often noticeable when the solvent polarity is increased, especially with strong complexing agents such as hexamethylphosphoramide or macrocyclic polyethers. External solvation of the contact ion pair is the probable cause of this phenomenon, and it will be discussed in more detail when dealing with the polyethers (Section 4).

The ratio of the concentrations of the two types of fluorenyl ion pairs in a given solvent at a fixed temperature can be calculated from a knowledge of the absorption spectra of the individual ion pairs. This quantity K_i^* provides a measure of the effectiveness of the solvent in complexing the respective cations. Values of K_i^* for a series of unsubstituted cyclic ethers and substituted tetrahydrofurans are given in Tables 1 and 2, respectively. Fluorenyllithium [*(1)*Li^+] and 9-(1-methylpentyl)fluorenyllithium [*(3)*Li^+] were employed as the ion pair salts.

(1)

(3)

For the unsubstituted cyclic ethers the effectiveness of forming separated ion pairs appears to be directly related to the basicity of the respective ring oxygen atom, with the exception of oxepane. The latter compound is reported to be more basic than THF[15] but it appears to be less effective in forming solvent separated ion pairs. When bulky substituents are present close to the coordination site, as in certain substituted tetrahydrofurans, packing in the solvation shell becomes a critical factor. Basicity, as measured by the proton affinity of the ether, is less affected by the structure of the ether since only one solvent molecule is involved. The alkali ion in the solvent separated ion pair, however, is coordinated to several solvent molecules, and steric factors like those observed with substituted tetrahydrofurans become important and are amplified when small cations are used. For example, in 3,3-dimethyloxetane the ratio of separated to contact ion pairs for fluorenyllithium and fluorenylsodium are 1.2 and 0.6 respectively, while in THF the values are much farther apart, *viz.*, 4.6 and 0.05. In oxetane itself both salts exist as loose ion pairs. The lower value in oxepane as compared in THF is also most likely due the larger molar volume of the former solvent.

The behavior of 2-(methoxymethyl)tetrahydrofuran and *o*-dimethoxybenzene exemplifies the importance of chelation. This appears to be most effective when the oxygen atoms are separated by two carbon atoms[16] as in the

Table 1. Solvent separated ion pair formation for fluorenyllithium *(1)*Li^+ and 9-(1-methylpentyl)fluorenyllithium *(3)*Li^+ in unsubstituted cyclic ethers at 25 °C. K_i^* is the ratio of loose to tight ion pairs.

Solvent	K_i^* for *(1)*Li^+	K_i^* for *(3)*Li^+
Oxetane [a]	> 50	—

Hexamethylphosphoramide	> 50	

linear polyglycol dimethyl ethers. These solvating agents will be discussed later.

Shatenshtein[17,18] has shown that the formation of biphenyllithium from biphenyl and lithium in a series of ethers decreases in the order DME ≈ THF > THP > dioxolane > dioxane. The order of decreased formation of the sodium salt of biphenyl or naphthalene is DME > THF > dioxolane > 2-MeTHF ≈ THP > dioxane. In the method developed by *Shatenshtein* the solvation involves both tight and loose ion pairs. On the other hand, the method involving the ion pair equilibrium of fluorenyl salts measures the difference in solvation state between the two kinds of ion pairs. Steric factors may affect the solvation state of the two ion pairs in a different way, and one anticipates that different approaches of measuring the solvating power of organometallic reagents will not always give identical results.

The higher basicity of the amines as compared to that of ethers facilitates ion pair separation in the former solvents and certain amines can therefore be classified as powerful alkali metal complexing agents. Small quantities of ethylenediamine can convert fluorenyllithium and -sodium contact ion pairs into amine separated pairs[13]. In pyridine both salts exist as loose ion pairs at room temperature[10], and the same is observed for the lithium salt in cyclohexylamine[19]. Tetramethylethylenediamine (TMEDA), known as an excellent complexing agent for organolithium reagents in hydrocarbon solvents[20,21], turns out to be a poor solvent separating agent[13]. Apparently it easily complexes externally to the contact ion pair, as indicated by the much higher solubility of fluorenyllithium in TMEDA as compared to hydrocarbon solvents. But the bulky methyl groups hinder the ion pair separation, which probably requires two TMEDA molecules.

2.3. Effect of Temperature and Pressure

The formation of separated ion pairs of carbanions or radical anions from the contact ion pairs is usually exothermic[10,22]. An example of this is found in Figure 5, showing the transformation of 9-(1-methylpentyl)fluorenyllithium *(3)*Li^+ in 2,5-dimethyltetrahydrofuran from a predominantly contact ion pair structure at −20 °C to that of a loose structure at −40 °C. Although there appears to be an isosbestic point, it is usually not expected for temperature dependent ion pair transformations, because on lowering the temperature the extinction coefficients of the absorption maxima of the two kinds of ion pairs often increase in a different way while simultaneously the two spectral bands are narrowed. Calculation of the ion pair fractions as a function of temperature must take these changes into account.

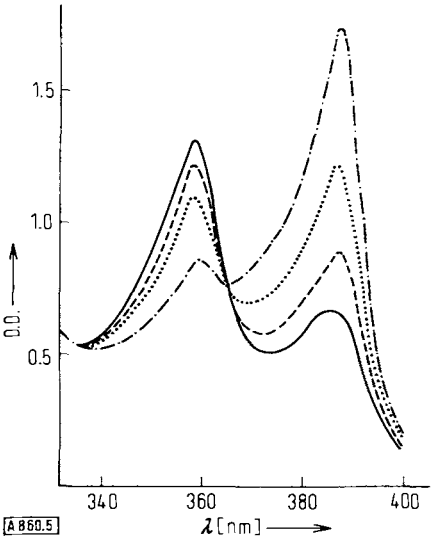

Fig. 5. Temperature dependence of the equilibrium between contact and solvent separated ion pairs of 9-(1-methylpentyl)fluorenyllithium in 2,5-dimethyltetrahydrofuran at −20 °C (——), −26 °C (– – –), −31 °C (···), and −41 °C (–·–·).

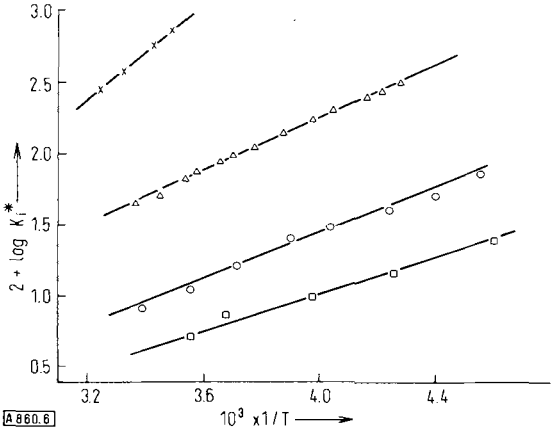

Fig. 6. Plots of log K_i^* *versus* $1/T$ for fluorenyllithium *(1)*Li^+ in tetrahydrofuran (×–×), tetrahydropyran (□–□), 1,3-dioxolane (○–○), and 2,5-dimethoxytetrahydrofuran (□–□).

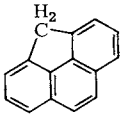
The enthalpy change ΔH_i for a number of solvents (as calculated from the respective slopes of plots of $\log K_i^*$ *versus* $1/T$, some of which are shown in Fig. 6) are collected in Table 3[40]. In the absence of specific ion-solvent interactions the enthalpy change for the separation of two ions is given by

$$\Delta H = Ne^2(1 + d\ln D/d\ln T)/aD$$

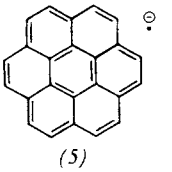
a being the ion pair distance before separation and D denoting the macroscopic dielectric constant[23]. The ion pair separation is expected to be exothermic for a negative value of $(1+d\ln D/d\ln T)$. This is the case in THF, DME, and 2-Me-THF, the respective $d\ln D/d\ln T$ values being -1.16, -1.28, and -1.12[24, 25]. But the calculated exothermicities would amount to only a few kcal/mol, even at a comparatively short interionic distance. Moreover, the separation in THP is expected to be essentially thermoneutral, as $d\ln D/d\ln T = -0.97$[22]. The observed ΔH_i values imply, therefore, that specific ion pair solvation must be the major contributing factor to the exothermicity of the ion pair separation equilibrium. Once the ion pair is in the solvent separated state, further dissociation into free ions is usually described reasonably well by the above Denison-Ramsey relationship[24, 26]. For example, the dissociation of the macrocyclic polyether separated ion pair of fluorenylsodium in THF is found to be thermoneutral[27].

Table 3. Enthalpy and entropy changes for solvent separated ion pair formation from the contact ion pairs, considered for fluorenyllithium *(1)*Li^+ and 9-(1-methylpentyl)fluorenyllithium *(3)*Li^+.



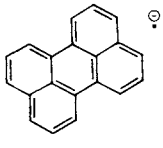
Solvent	*(1)*Li^+		*(3)*Li^+	
	$-\Delta H_i$ (kcal/mol)	$-\Delta S_i$ (e. u.)	$-\Delta H_i$ (kcal/mol)	$-\Delta S_i$ (e. u.)
2,5-Dimethoxy-tetrahydrofuran	2.9	16	—	—
2,5-Dimethyl-tetrahydrofuran	2.0	14	10.0	50
Dioxolane	3.5	17	—	—
3,4-Dihydropyran	3.0	16	8.2	33
Tetrahydropyran	6.6	28		
Tetrahydrofuran	7.5	22		
2-Methyl-tetrahydrofuran	7.5	27	9.8	32
Dioxane-tetrahydrofuran (50%)	3.6	14		
Dioxane-tetrahydrofuran (28%)	—	—	11.0	36
Oxepane	4.3	16		

No simple relationship between ΔH_i and solvent structure is to be expected. The total enthalpy change is determined by the coulombic interactions between the two ions in both the tight and loose ion pair, and by physical and specific solvation of the two ion pair species. The extent of specific solvation is closely related to the structure of the solvent molecules, and the latter may affect the solvation of the two ion pairs in a different way (*e.g.*, the solvation of fluorenyllithium by tetramethylethylenediamine). Also, dielectric saturation must be taken into account in calculating coulombic interactions. Generally, tighter contact ion pairs are expected in less polar solvents, resulting in lower exothermicities. Steric hindrance in the contact ion pair would also lead to small enthalpy values. It is therefore surprising to find such high negative ΔH_i values for the 9-alkylfluorenyllithium *(3)*Li^+. The corresponding sodium salt gives—ΔH_i values which are less than those of fluorenylsodium. An explanation for the peculiar behavior of the lithium salts may be the possible existence of higher aggregates for the planar fluorenyllithium ion pairs in ethereal solutions[12, 28].



Increased pressure was found to shift the ion pair equilibrium to the separated pair[29, 30]. The observed volume contraction, -16.4 ml/mol for fluorenyllithium in THF and -24.2 ml/mol for fluorenylsodium, results from a tight binding of solvent molecules around the cations in the loose ion pairs. The smaller value for the lithium salt was interpreted to indicate a higher degree of solvation for the tight lithium ion pair as compared to that of the sodium salt[30].

2.4. Effect of Anion Structure



The simultaneous existence of tight and loose ion pairs has been observed spectrophotometrically for many carbanions and radical anions. In some cases, as with salts of the triphenylmethyl anion, only an absorption shift rather than distinctly separated absorption bands are observed. Such shifts cannot always be taken as evidence for the existence of chemically distinct ion pairs. *Szwarc et al.*[31] have pointed out that the fluctuating environment of the solvating molecules affects the vibrational motion of the ions in the ion pair. A broad potential energy well may be visualized with the two ions vibrating between the two extreme interionic distances characterizing the tight and loose ion pair. The potential energy as function of the interionic ion pair distance is temperature dependent, and while tight ion pairs may exist at high temperature, more favorable solvation at lower temperature can gradually increase the interionic distance. Physical properties of the ion pairs depending on this distance, such as the optical spectra, will then undergo a gradual change with temperature, and do not result from the superposition of the properties of two distinct species. This type of ion pair behavior may often be encountered in systems with large counterions, with steric hindrance in the contact ion pair, or in low polarity solvents, *i.e.*, in cases where the potential energy barrier separating the tight and loose ion pair is expected to be low.

(4)

(5)

(6)

Charge delocalization facilitates ion pair separation, and this accounts for the higher fraction of separated ion pairs found for the benzofluorenylsodium salts (derived, *e.g.* from benzo[*b*]- and benzo[*c*]fluorene) as compared to fluorenylsodium[10]. The same is observed with 4,5-methano-

phenanthrene (≡ benzo[*def*]fluorene) *(4)*. Studies carried out on salts containing the anion of this fluorene derivative[32] show effects of solvent, counterion, and temperature which closely parallel those obtained for the fluorenyl salts. Other examples of the effect of charge delocalization on ion pair separation can be found in the behavior of the aromatic radical anion salts. Both optical and conductance data clearly reveal a strong increase in the fraction of separated ion pairs as the hydrocarbon structure allows more charge delocalization in the radical anion. Salts such as triphenylenesodium *(2)* Na^+[7, 22, 33], coronenesodium *(5)* Na^+[34], and perylenesodium *(6)* Na^+[22] are separated ion pairs in THF at 25 °C, while the salts of naphthalene and biphenyl are contact ion pairs[10, 35].

Large substituents on the anion lower the stability of the contact ion pair. A typical example can be found in the behavior of the sodium salt of the monoradical anion of tetraphenylethylene[36–38] where the four phenyl groups are twisted out of the plane of the double bond, preventing a close approach of the Na^+ ion. The optical spectra and conductance behavior of this salt in THF demonstrate that separated ion pairs exist between 25 and −70 °C. The structure of the dianion of this hydrocarbon, however, permits a close contact between positive and negative ion, as free rotation around the single bond puts the two $C(C_6H_5)_2$ groups in two mutually perpendicular planes. The dianion is a tight ion pair in THF at 25 °C, with the proportion of loose ion pairs increasing rapidly at lower temperature. Its behavior resembles that of the dianion of 1,1,4,4-tetraphenylethylene[10] and that of the diphenylhexyl anion[39]. Steric hindrance in the triphenylmethyl anion contact ion pair results in higher fractions of separated ion pairs than found with salts of the diphenylmethyl anion[40].

Tight ion pairs are expected to be stable in ethereal solutions of alkoxides, even in solvents such as dimethoxyethane. Solvents of high dielectric constant would favor free ion formation more than that of separated ion pairs, as the latter process is less dependent on dielectric constant. Cation complexing reagents such as macrocyclic ethers or DMSO could possibly induce formation of loose ion pairs in solvents such as THF. However, the tendency of alkoxides to aggregate[60] complicates the study of these systems.

3. Complexation of Polyglycol Dimethyl Ethers to Ion Pairs

In solvents such as ethylenediamine, hexamethylphosphoramide, or polyglycol dimethyl ethers, most fluorenyl salts form only separated ion pairs. The complexation of these powerful solvating agents to ion pairs can be studied by adding small quantities of the complexing agent to a solution of the fluorenyl ion pair in a solvent in which the salt predominantly exists as a contact ion pair.

Because of their polydentate structure, polyglycol dimethyl ethers or glymes of the general formula $CH_3O(CH_2CH_2O)_xCH_3$ are of special interest as coordinating agents of ion pairs[35, 41–43]. Their ability to complex with alkali metal ions depends on the number of available

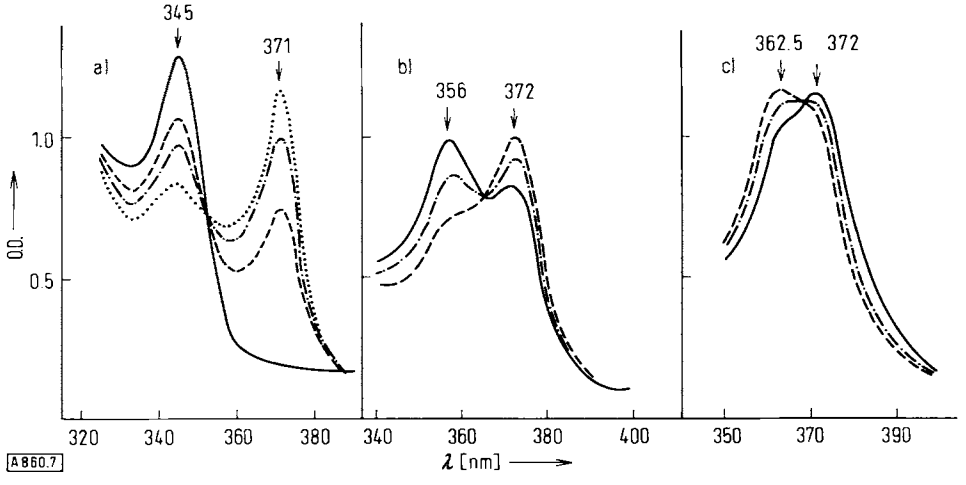


Fig. 7. Spectral changes on addition a) of glyme-4 to fluorenyllithium (≈ 1.5×10^{-3} M in dioxane), b) of glyme-6 to fluorenylsodium (≈ 2×10^{-3} M in THF), and c) of glyme-7 to fluorenylpotassium (5×10^{-4} M in THF).
$[glyme\text{-}4]_0 = 0.0$ (——), 6.46×10^{-3} (– – –), 11.3×10^{-3} (–·–·–), and 24.3×10^{-3} mol/l (·····)
$[glyme\text{-}6]_0 = 1.34 \times 10^{-3}$ (——), 2.64×10^{-3} (–·–·–), and 4.32×10^{-3} mol/l (– – –)
$[glyme\text{-}7]_0 = 1.02 \times 10^{-3}$ (– – –), 2.78×10^{-3} (–·–·–), and 4.8×10^{-3} mol/l (——).

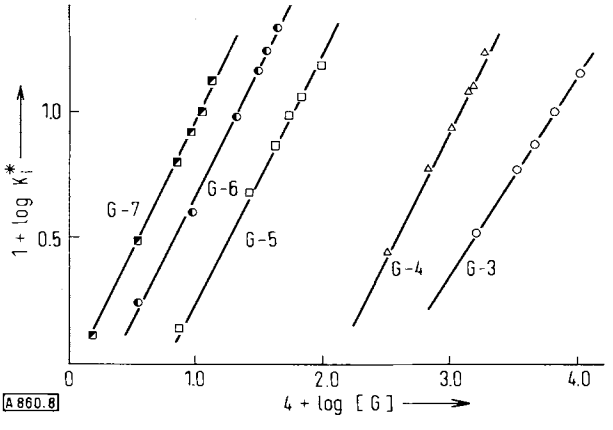

Fig. 8. Glyme separated ion pair formation of fluorenylsodium in THF at 25 °C with glyme-3 (G-3) to glyme-7 (G-7).

coordination sites. The spectral changes which one observes on addition of small amounts of glymes to a dioxane solution of fluorenyllithium or to a THF solution of fluorenylsodium or -potassium are shown in Figure 7. The glyme separated ion pair has an absorption maximum identical with that of the solvent separated ion pair. Plots of log K_i^* (K_i^* being the ratio of separated over contact ion pairs) *versus* log [G] ([G] being the concentration of glyme) for fluorenylsodium are shown in Figure 8, the slopes being equal or close to unity. The same linear relationships are observed with fluorenyllithium, and both results point to a simple complexation mechanism:

$$\text{fluorenyl}^-,M^+ + G \rightleftharpoons \text{fluorenyl}^-,G,M^+ \quad (K_i)$$

However, when the measurements are carried out under conditions such that the concentration of glyme is much greater than that of the fluorenyl ion pair (this is the case for the systems fluorenyl$^-$,Na$^+$-glyme-3, fluorenyl$^-$,Na$^+$-glyme-4, and fluorenyl$^-$,Li$^+$-glyme-3)[*], one cannot exclude the possibility that the contact ion pair is already coordinated to a glyme molecule, *i.e.*, fluorenyl$^-$,M$^+$,G. We will return to this point when discussing the results for fluorenylpotassium.

with combinations of five consecutive oxygen atoms linked by ethylene bridges[16], one expects an increase in the K_i for fluorenyl$^-$,Na$^+$ by a factor of 3 when glyme-7 is used instead of glyme-5[42,43]. The observed increase by a factor of 4.5 is slightly higher, and appears to accelerate for glymes of longer chain length such as glyme-9 and glyme-22 (average molecular weight 1000). There may be certain preferred conformations in the longer glymes which are favorable for cation complexation. Moreover, it is likely that combinations of coordination sites other than those involving consecutive oxygen atoms can form stable complexes with fluorenylsodium. It is also interesting to note that on addition of a tenfold excess of fluorenylsodium to glyme-22 the ratio of fluorenyl$^-$,G,Na$^+$ ion pairs to glyme-22 does not exceed the value two, indicating a maximum of two such pairs per chain[44].

The dielectric constant of the solvent usually does not affect K_i to any great extent, probably because dielectric saturation makes the effective dielectric constant considerably less than the macroscopic one. Also, while a less polar solvent yields a tighter contact ion pair, the removal of solvent molecules by the glyme will cost more energy in a polar solvent, and the two effects apparently largely compensate one another. On the other hand, the glyme

Table 4. Equilibrium constants for glyme-separated ion pair formation in solutions of fluorenylalkali metal salts at 25 °C. $K_i = [\text{fluorenyl}^-,G,M^+]/[\text{fluorenyl}^-,M^+]\,[G]$

Glyme	x	K_i [a] for fluorenyllithium [b]	K_i [a] for fluorenyllithium [b]
DME	1	0.055 ($n=2.4$)	[c]
2-(Methoxymethyl)-THF		0.25 ($n=2$)	[d]
Glyme-3	2	3.1	1.2
Glyme-4	3	130	9.0
Glyme-5	4	240	170
Glyme-6	5		450
Glyme-7	6		800
Glyme-9	8		4800 [44]
Glyme-22	21, average		~25000 [44]

[a] All K_i values were calculated by taking $n=1$, except for DME ($n=2.4$) and 2-(methoxymethyl)tetrahydrofuran ($n=2$).
[b] Dioxane was used as solvent for the lithium salt, THF for the sodium salt.
[c] No titration carried out; proportion of solvent separated ion pairs at 25 °C is about 90% in pure DME.
[d] At room temperature only solvent separated ion pairs in the pure solvent.

The complexation constants for fluorenyllithium and -sodium are given in Table 4. For the lithium salt, the constant K_i strongly increases with the number of oxygen atoms in the glyme up to glyme-4, and then appears to level off. This may indicate that a maximum of four oxygen atoms coordinate with one lithium ion. The K_i for the sodium salt levels off above glyme-5. Apparently, the weaker interaction with the larger Na$^+$ ion requires at least five oxygen atoms to give a complexation constant comparable with that found for the system fluorenyl$^-$,Li$^+$, glyme-4.

As the chain length increases beyond glyme-5, the complexation constant is expected to further increase for purely statistical reasons. Assuming that coordination only occurs

complexation constants may be entirely different in solvents where the ion pairs wholly or partially exist as loose ion pairs. An example can be found by comparing the complexation constants of glyme-4 with the following salts (all referring to THF as solvent, except fluorenyllithium, which was measured in dioxane):

fluorenyl$^-$,Li$^+$ + G-4 $\rightleftharpoons$ fluorenyl$^-$,G-4,Li$^+$	K =	130 l/mol
fluorenyl$^-$,Na$^+$ + G-4 $\rightleftharpoons$ fluorenyl$^-$,G-4,Na$^+$	K =	9 l/mol
coronene$^-$‖Li$^+$ + G-4 $\rightleftharpoons$ coronene$^-$,G-4,Li$^+$	K =	1 l/mol
coronene$^-$‖Na$^+$ + G-4 $\rightleftharpoons$ coronene$^-$,G-4,Na$^+$	K =	$>10^4$ l/mol

Both the lithium and sodium salt of the coronene radical anion exist as separated ion pairs in THF (the complexation constants in these cases were obtained from NMR measurements[34]). This leads to a high complexation constant for the sodium salt (as in sodium tetraphenylborate), whereas the removal of THF from the lithium ion requires a considerable amount of energy.

[*] The number behind each glyme refers to the number of oxygen atoms present in the molecule $CH_3O(CH_2CH_2O)_xCH_3$. This notation particularly emphasizes the analogy between the glymes and the crown compounds (Section 4). Names such as di- and triglyme, in which the multiplying prefix refers to x, are more commonly used.

The enthalpy change of glyme separated ion pair formation amounts to between -5 and -9 kcal/mol, and does not differ much from that found in THF, *i.e.*, -7.6 kcal/mol[42]. The effectiveness of glymes in solvating cations is clearly a result of a more favorable entropy change. In pure THF the change is about -30 e.u.[10], while only -14 to -18 e.u. for the glymes.

Complexation of glymes to fluorenylpotassium appears to be more involved. Plots of $\log K_i^*$ *versus* $\log[G]$ are strongly curved[42]. For glyme-6 and -7 the ratio $K_i^* = [\text{fluorenyl}^-,G,K^+]/[\text{fluorenyl}^-,K^+]$ reaches a constant value at higher glyme concentration. This behavior can be rationalized by postulating two competitive modes of complexation (also observed with mixtures of certain radical anion salts and glymes, see ref. [35]) producing glymated contact ion pairs and glyme separated ion pairs, respectively[42]:

$$\begin{array}{lll} \text{fluorenyl}^-,K^+ + G \rightleftharpoons \text{fluorenyl}^-,K^+,G & K_1 \\ \text{fluorenyl}^-,K^+ + G \rightleftharpoons \text{fluorenyl}^-,G,K^+ & K_i \\ \text{fluorenyl}^-,K^+,G \rightleftharpoons \text{fluorenyl}^-,G,K^+ & K_2 \end{array}$$

The experimental quantity $K_i^* = [\text{fluorenyl}^-,G,K^+]/[\text{fluorenyl}^-,K^+ + \text{fluorenyl}^-,K^+,G]$ is now given by

$$\frac{1}{K_i^*} = \frac{1}{K_2} + \frac{1}{K_1 K_2 [G]}$$

Plots of $1/K_i^*$ *versus* $1/[G]$ for the systems fluorenyl$^-$,K$^+$ with glyme-6 and glyme-7 are indeed linear, as shown for glyme-6 in Figure 9, their slopes and intercepts yielding the complexation constants K_1 and K_2.

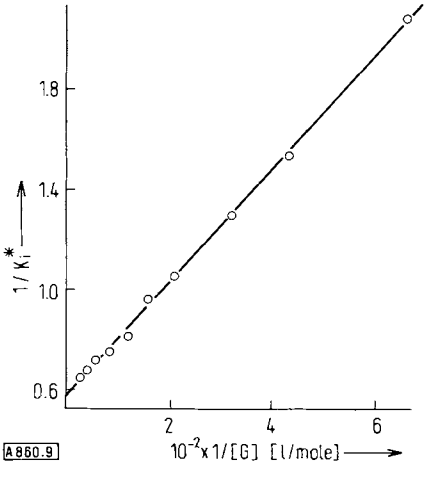

Fig. 9. Plots of $1/K_i^*$ *vs* $1/[\text{glyme}]$ for fluorenylpotassium in THF with glyme-6.

Similar plots for glyme-4 and glyme-5 are curved and extrapolate to the origin, *i.e.* $K_i^* \rightarrow \infty$ for sufficiently large glyme concentration. (This must also be true for glyme-6 and -7, as in the pure glymes only separated ion pairs are found.) This behavior can be explained by postulating a third complexation step in which the glymated contact ion pairs are converted to glyme-separated ion pairs by addition of a second glyme molecule:

$$\text{fluorenyl}^-,K^+,G + G \rightleftharpoons \text{fluorenyl}^-,G,K^+,G \quad (K_3)$$

The quantity K_i^* is now given by

$$K_i^* = \frac{K_2 + K_3[G]}{1 + 1/K_1[G]}$$

which reduces for $K_1[G] \gg 1$ to

$$K_i^* = K_2 + K_3[G]$$

Plots of K_i^* *versus* $[G]$ are indeed linear for glyme-4 and -5 in both THF and THP (see Fig. 10). This also means that in the concentration range of glyme needed to form glyme-separated ion pairs all fluorenylpotassium ion pairs are already externally coordinated with glyme-4 or glyme-5 (*i.e.*, $K_1[G] \gg 1$).

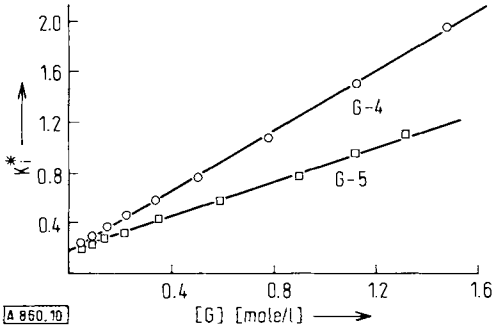

Fig. 10. Plots of K_i^* *vs* [glyme] for fluorenylpotassium in THF at 25 °C with glyme-4 and glyme-5 (G-4 and G-5) respectively.

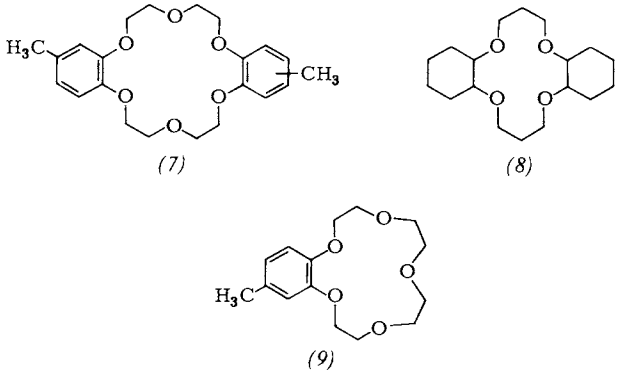
Values of the various complexation constants K_1, K_2, K_3 of fluorenylpotassium with four glymes are collected in Table 5. Although only a lower limit for the K_1 values can be obtained for glyme-4 and glyme-5, it is probable that they are close to those observed for glyme-6 and glyme-7. Four or five oxygen atoms may be the maximum number that can be coordinated with a K$^+$ ion which is shielded on one side by a fluorenyl anion, and K_1 will only increase by a statistical factor on changing to glyme-6 or glyme-7.

Table 5. Equilibrium constants for glyme-coordinated ion pair formation of fluorenylpotassium in THF and THP at 25 °C. The concentration of fluorenylpotassium lies between 1×10^{-4} and 5×10^{-4} mol/l.

Glyme	Medium	K_1 (l/mol)	K_2	K_3 (l/mol)
Glyme-3	THF	—	0	0.21
Glyme-4	THF	>50	0.24	2.27
	THF [a]	>50	0.30	2.2
	THP	>50	0.18	1.2
Glyme-5	THF	>50	0.35	1.07
	THF [a]	>50	0.28	0.92
	THP	>50	0.18	0.69
Glyme-6	THF	250	1.75	—
Glyme-7	THF	530	2.5	—
	THP	1700	2.7	—



[a] Concentration of fluorenylpotassium $\approx 6 \times 10^{-3}$ mol/l.

The constant K_2 describing the equilibrium between glymated fluorenylpotassium contact ion pairs and glyme-separated ion pairs is small for glyme-4 and glyme-5 but sharply increases for higher glymes. Apparently, at least six oxygen atoms are needed to accomplish separation with the weakly interacting K$^+$ ion, and with glyme-4 and

glyme-5 this can be accomplished when two molecules are coordinated with the potassium ion. It is likely that at high glyme-6 or glyme-7 concentrations the fluorenylpotassium ion pair also contains two glyme molecules, as the ratio K_i^* does eventually increase to ∞. No values for the complexation constant K_3 were determined in these cases, but they may be even lower than the value found for glyme-5 if steric repulsion between the two complexed glyme molecules becomes an important factor.

4. Ion Pair Interactions with Macrocyclic Polyethers

Macrocyclic polyethers or crown compounds are much more effective in binding cations than the linear glymes due to their cyclic structure. A large number of crown compounds of different structure have recently been synthesized by *Pedersen*[45, 46] and some of them are shown below, *i.e.* dimethyldibenzo[18]crown-6 *(7)*, perhydrodibenzo[14]crown-4 *(8)*, and 4-methylbenzo[15]crown-5 *(9)*[*].

Crown compounds considerably improve the solubility of inorganic salts in low polarity solvents[45] and are known to affect the rate and stereochemistry of organometallic reactions[47]. They also are used as model compounds for ion carriers across biological membranes[48].

The stability of cation-crown complexes depends on the diameter of the cation relative to that of the polyether hole, the charge of the ion, the number of ring oxygen atoms, their basicity, coplanarity and symmetrical placement, steric hindrance in the polyether ring, and the nature of the solvent[45]. In most studies, methanol and water have been used as solvents[45, 48, 49] and the cations are not associated with the anions. With fluorenyl salts in ethereal solvents, the addition of crown compounds changes the ion pair structure, and generally the interaction follows the mechanism outlined for polyglycol dimethyl ethers (glymes)[50].

Ion pairs separated by crown compounds ($\lambda = 373$ nm) are formed on mixing of equimolar quantities of fluorenylsodium with dimethyldibenzo[18]crown-6, perhydrodibenzo[18]crown-6, and 4-methylbenzo[18]crown-6 in THF or THP[50]. The complexation constants are all higher than 5×10^6 l/mol, compared with a value of only 450 l/mol for the linear glyme-6. With 4-methylbenzo[15]crown-5 *(9)*[51], both separated fluorenyl$^-$,*(9)*,Na$^+$ ion pairs and contact ion pairs are formed (the latter species have their absorption maximum at 359 nm as compared to 354 nm for fluorenylsodium in THP). The ratio

$$K_i^* = [\text{fluorenyl}^-,(9),\text{Na}^+]/[\text{fluorenyl}^-,\text{Na}^+,(9)]$$

increases only slowly on addition of more *(9)*. This behavior is similar to that observed with fluorenylpotassium and glyme-6 or glyme-7, and is again indicative of two competing modes of complexation. Plots of K_i^* *versus* [C] (concentration of the crown compound) are shown in Figure 11, the intercept giving the complexation constant K_2 of the transformation

$$\text{fluorenyl}^-,\text{M}^+,\text{C} \rightleftharpoons \text{fluorenyl}^-,\text{C},\text{M}^+$$

The two isomers A and B of perhydrodibenzo[18]crown-6[49] also give a K_i^* value with fluorenylpotassium which is nearly independent of the crown concentration[51]. The

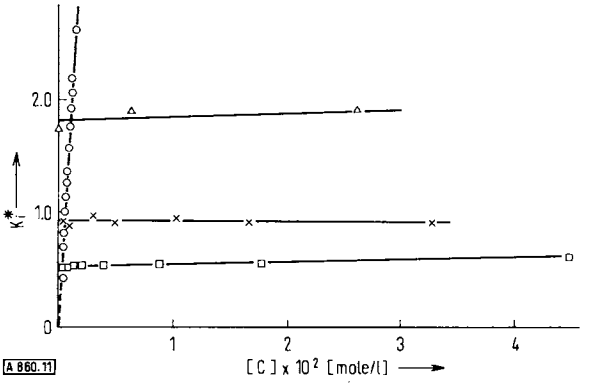


Fig. 11. Plots of K_i^* *vs* [crown] for the systems 4-methylbenzo[15]crown-5 *(9)*-fluorenylsodium in THF (△–△) and THP (□ – □), *(9)*-fluorenylpotassium in THF (○–○), and dimethyldibenzo[18]crown-6 *(7)*-fluorenylpotassium in THF (×–×); fluorenyl salt concentration $\approx 6 \times 10^{-4}$ mol/l.

system fluorenylpotassium-*(9)* deviates significantly from all other systems, and the strong rise in K_i^* with increasing concentration of *(9)* is evidence that a second molecule of *(9)* is complexed to fluorenyl$^-$,K$^+$,*(9)* forming the separated [fluorenyl$^-$,*(9)*,K$^+$,*(9)*] ion pair, similar to that observed with glyme-4 and glyme-5.

The respective complexation constants derived from plots of $1/K_i^*$ *versus* $1/[C]$ and plots of K_i^* *versus* [C] (for the pertinent equations see Section 3) are collected in Table 6. The solvent dependency of K_2, also found with glymes, can largely be attributed to solvent participation in the equilibrium

$$\text{fluorenyl}^-,\text{K}^+,\text{C} + n\text{S} \rightleftharpoons \text{fluorenyl}^-,\text{C},\text{K}^+,\text{S}_n$$

where S denotes a solvent molecule. Due to its planar conformation, complexation of a crown with fluorenyl$^-$,M$^+$

[*] The number preceding the word crown refers to the total number of atoms in the polyether ring, and the second number corresponds to the number of oxygen atoms—*(8)* is often incorrectly termed dicyclohexyl-14-crown-4.

ion pair does not necessitate removal of the entire solvation shell if the interaction leads to a separated ion pair (*i.e.*, if the cation occupies the center of the polyether hole). Hence, more polar solvents will shift the above equilibrium to the separated ion pair.

A smaller polyether ring favors formation of externally complexed contact ion pairs, particularly when the cation barely fits the hole of the crown. For example, with fluorenylsodium and the [15]crown-5 derivative *(9)*, the Na^+ ion may slightly protrude from the plane of the ring, with the oxygen atoms most probably in a nearly planar conformation such that an electron rich environment exists just above the ring. Such a structure would resemble that of the solid complex between perhydrodibenzo[18]crown-6 and rubidium thiocyanate[52, 53].

The existence of 2:1 complexes of [15]crown-5 compounds with fluorenylpotassium is in agreement with potentiometric measurements by *Frensdorff* who found 1:1 and 2:1 complexes of perhydrobenzo[15]crown-5 with free K^+ ions in methanol[49]. Moreover, this compound was shown to form a solid 2:1 complex with potassium iodide[54].

5. Competitive Complexation in Ion Pair Mixtures

When ion pair complexation constants are too high to measure spectrophotometrically (such as those of fluorenylpotassium and fluorenylsodium with dibenzo[18]crown-6), the use of ion pair mixtures can still yield information on the cation selectivity of the complexing agent. For example, when fluorenylsodium ($\lambda_m = 356$ nm) in THF is mixed with an equimolar quantity of the complex formed from fluorenylpotassium and dimethyldibenzo[18]crown-6 ($\lambda_m = 373$ nm), the polyether is immediately transferred to the fluorenylsodium ion pair as evidenced by the appearance of the fluorenyl$^-$,K^+ contact ion pair maximum at 362 nm:

fluorenyl$^-$,C,K^+	+ fluorenyl$^-$,Na^+	⇌ fluorenyl$^-$,C,Na^+	+ fluorenyl$^-$,K^+
λ_m = 373 nm	356 nm	373 nm	362 nm

The selectivity order of dimethyldibenzo[18]crown-6 as measured from this type of experiment was found to be $Na^+ > K^+ > Cs^+ > Li^+$[50]. A different order was found by *Pedersen*[45] and others[48, 49] in methanol and water for perhydrodibenzo[18]crown-6, *viz.* $K^+ > Cs^+ > Na^+ > Li^+$. Clearly, the selectivity order is solvent dependent, as can be shown by repeating the above experiment in oxetane, which is more basic than tetrahydrofuran. In oxetane, fluorenylsodium is a solvent separated ion pair ($\lambda_m = 373$ nm), and addition of fluorenyl$^-$,C,K^+ (C being dimethyldibenzo[18]crown-6) does not lead to a transfer of the polyether to the fluorenylsodium[50]. It apparently costs too much energy to remove the oxetane solvation shell around the Na^+ ion.

Table 6. Complexation constants [a] of macrocyclic polyethers with fluorenyl ion pairs in ethereal solvents at 25 °C.

Ion pair	Crown Compound	Solvent	K_1 $\times 10^{-3}$ (l/mol)	K_2	K_3 (l/mol)	K_i $\times 10^{-3}$ (l/mol)
Fluorenyl$^-$ Na^+	4-methylbenzo-[15]crown-5 *(9)*	THF	9.2	1.8	3.5	16.5
		THP	>20	.52	2.8	>10
	dimethyldibenzo-[18]crown-6 *(7)*	THF				>20000
		THP				>40000
	perhydrodibenzo-[18]crown-6	THP				>40000
Fluorenyl$^-$ K^+	4-methylbenzo-[15]crown-5 *(9)*	THF	≈ 5	≈0.2	1840	≈1
	dimethyldibenzo-[18]crown-6 *(7)*	THF	>10	0.93		>9
		THP	>10	0.55		>5.5
	perhydrodibenzo-[18]crown-6 A	THF	>30	1.80		>54
	perhydrodibenzo-[18]crown-6 B	THF	>40	0.80		>32

[a] Complexation constants refer to the following equilibria:

fluorenyl$^-$,M^+ + C ⇌ fluorenyl$^-$,M^+,C (K_1)
fluorenyl$^-$,M^+ + C ⇌ fluorenyl$^-$,C,M^+ (K_i)
fluorenyl$^-$,M^+,C ⇌ fluorenyl$^-$,C,M^+ (K_2)
fluorenyl$^-$,M^+,C + C ⇌ fluorenyl$^-$,C,M^+,C (K_3)

Recent studies[55] on the cation binding properties of polymers containing crown-5 groups demonstrated a pronounced increase in the efficiency of complexing large cations such as K^+ and Cs^+, compared to that of monomeric methylbenzo[15]crown-5. Cooperative effects between neighboring crown-5 groups enhance the formation of 2:1 complexes with the cations. It was also shown that the maximum number of fluorenylpotassium ion pairs that can be bound to the polymer is close to half that of the total number of available crown-5 units, whereas with fluorenylsodium each crown-5 unit can bind an ion pair[56].

The selectivity could also reverse on changing the temperature. For example, fluorenylsodium changes in THF from a contact ion pair at 25 °C to a separated ion pair at −70 °C, while the fluorenylpotassium ion pair remains a tight ion pair over this temperature range. Hence, the observed selectivity of the dibenzo[18]crown-6 with respect to the two fluorenyl salts (*i.e.*, $Na^+ \gg K^+$) may be reversed at low temperature.

It should also be realized that optical spectra may not always give correct information regarding the selectivity behavior of complexing agents. One can visualize reactions of the type

$$\text{fluorenyl}^-,C,M^+ + \text{fluorenyl}^-,M'^+ \rightleftharpoons \text{fluorenyl}^-\|M^+ + \text{fluorenyl}^-,M'^+,C$$

in which the complexing agent C is transferred to fluorenyl$^-$,M'^+ by external complexation while the fluorenyl$^-$,M^+ ion pair remains separated by acquiring a solvation shell of solvent molecules. No change in optical spectrum would be observed, except when fluorenyl$^-$,M'^+ and fluorenyl$^-$,M'^+,C have different absorption maxima.

Where ion pair solvation does not lead to changes in the optical spectra (*e.g.*, the tight and loose ion pair may have almost identical spectra) competition experiments are often useful. For example, information on complexation of glymes or crown compounds with salts such as sodium tetraphenylborate can be obtained by adding the salt to the glyme- or crown-separated ion pair of a fluorenyl salt:

$$\text{fluorenyl}^-,C,Na^+ + Na^+\|B(C_6H_5)^- \rightleftharpoons \text{fluorenyl},Na^+ + Na^+,C,B(C_6H_5)_4^-$$

when C is dimethyldibenzo[18]crown-6, one observes a change in the optical absorption maximum from 373 nm to 356 nm[50], the latter one being characteristic of the fluorenylsodium ion pair. Sodium tetraphenylborate is a separated ion pair in THF[58], and the crown compound, by removing (at least partially) the solvation shell of the Na^+ ion, now becomes associated with the $NaB(C_6H_5)_4$. The equilibrium constant for this reaction was found to be 2. The same experiment would fail in oxetane, since fluorenylsodium is a separated ion pair in this solvent. Hence, even if transfer of the crown to sodium tetraphenylborate took place, there would be no change in optical spectrum. In such cases, changes in the NMR spectrum of the bound complexing agent can give the desired information (see Section 7).

Other inorganic salts show similar effects, *e.g.*, addition of sodium perchlorate to the fluorenyl$^-$,C,Na^+ complex produces the fluorenyl$^-$,Na^+ ion pair. However, the equilibrium constant is only 0.04. Sodium perchlorate is a tight ion pair in THF (its conductance in THF is very low as compared to that of sodium tetraphenylborate[57, 58], and an efficient binding with the crown compound may require a considerable increase in the interionic distance in the ion pair.

6. Ion Pair Solvation of Fluorenyl Salts of Divalent Cations

The fluorenyl anion again provides us with a convenient system to study solvation and complexation to ion pairs of divalent cations. The salts can be prepared in liquid ammonia[14], but are also directly obtainable in THF (at least difluorenylbarium and -strontium) by reaction of a mixture of 1,1-diphenylethylene and fluorene in THF with a clean metal mirror under vacuum[59]. A THF solution of the barium salt shows a sharp absorption maximum at 347 nm (see Fig. 12) and even at −70 °C the proportion of

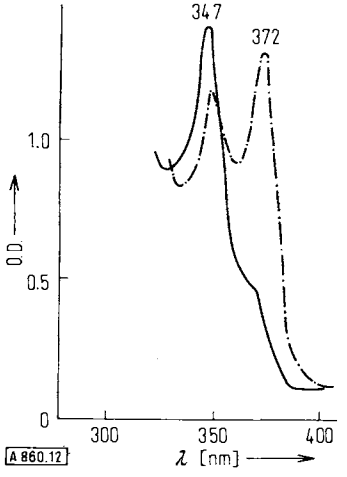

Fig. 12. Optical absorption spectrum of difluorenylbarium (——) and its 1:1 complex with dimethyldibenzo[18]crown-6 (–·–·) in THF at 25 °C.

loose ion pairs appears to be less than 10%. Since in the divalent salt the positive ion is probably sandwiched in between the two fluorenyl rings, the solvation of the cation is hindered, especially the external solvation of the contact ion pair. This is also reflected in the low dissociation constant for the equilibrium

$$Ba^{2+},(\text{fluorenyl}^-)_2 \rightleftharpoons (Ba, \text{fluorenyl})^+ + \text{fluorenyl}^-$$

the value in THF being 3×10^{-9} mol/l at 25 °C[59], compared to 6.2×10^{-7} mol/l and 1.6×10^{-7} mol/l, respectively, for the sodium and potassium salt[26]. The difluorenylbarium ion pair is probably a tighter ion pair than those of the alkali salts, and dissociation produces again a tight $(Ba^{2+},\text{fluorenyl}^-)^+$ ion pair which is only solvated on one side of the barium ion.

Higher fractions of separated ion pairs in THF are obtained with difluorenylstrontium. At −25 °C two absorption maxima of approximately equal height are observed at 344 nm and 373 nm[61]. The results show that the following equilibrium is established:

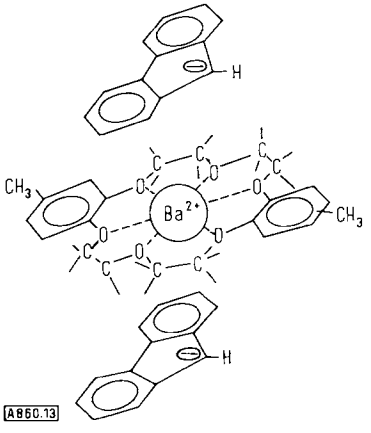
$$\text{fluorenyl}^-,Sr^{2+},\text{fluorenyl}^- \rightleftharpoons \text{fluorenyl}^-\|Sr^{2+},\text{fluorenyl}^-$$

the ΔH being about −12 kcal/mol. The free ion dissociation constant changes from 1.8×10^{-7} mol/l at 20 °C to 2×10^{-6} mol/l at −20 °C, the ΔH_d at 25 °C being close to −13 kcal/mol. The second ion pair solvation step, *i.e.*

fluorenyl$^-$||Sr^{2+},fluorenyl$^-$ ⇌ fluorenyl$^-$||Sr^{2+}||fluorenyl$^-$

probably occurs at a considerably lower temperature.

Ion pair separation can also be accomplished by adding complexing agents such as glymes or macrocyclic polyethers. The addition of dimethyldibenzo[18]crown-6 to difluorenylbarium in a 1:1 ratio in THF at 25 °C produces an optical spectrum of equal fractions of separated and contact ion pairs (see Fig. 12), and no change in this spectrum occurs on addition of more crown compound. A similar behavior is observed with glyme-6. Apparently the solvation with the crown compound or glyme is asymmetric, leading to species of the type fluorenyl$^-$,Ba^{2+},C,fluorenyl$^-$. It is also possible that the Ba^{2+} rapidly vibrates through the hole of the polyether ring as shown in Figure 13, with the ring conformation changing accordingly during the motion.



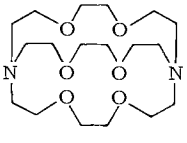


Fig. 13. Possible structure of the difluorenylbarium-dimethyldibenzo-[18]crown-6 complex in THF or pyridine.

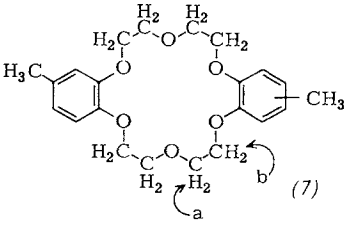
Stable 1:1 complexes with difluorenylbarium and -strontium are formed on addition of the bicyclic amino polyether *(10)*, a powerful cation binding reagent, which has been synthesized recently by *Lehn et al.*[62,63].



(10)

The spectra of these complexes in THF show only one absorption peak at 373 nm. This is not surprising since the cation is symmetrically surrounded by the amino polyether. Similar separated ion pair spectra of difluorenylbarium are found on addition of ethylenediamine or hexamethylphosphoramide, but it is not known whether a multistep solvation mechanism is involved.

7. NMR Studies of Ion Pair Complexation

Interactions of solvent molecules or complexing agents with ion pairs can also be studied by nuclear magnetic resonance. Only a few selected examples will be discussed, particularly those that provide supporting evidence for the spectrophotometric studies discussed in the previous sections. Ion pairs of fluorenyl salts and certain salts of aromatic radical anions are convenient systems for NMR investigations, since the complexing agents are brought into the close proximity of ions that will strongly affect their proton chemical shift. The use of NMR is particularly helpful in cases where complexation to the ion pair does not lead to changes in optical spectra, as in the complexation of glymes to ion pairs of coronenesodium in THF (see Section 3).

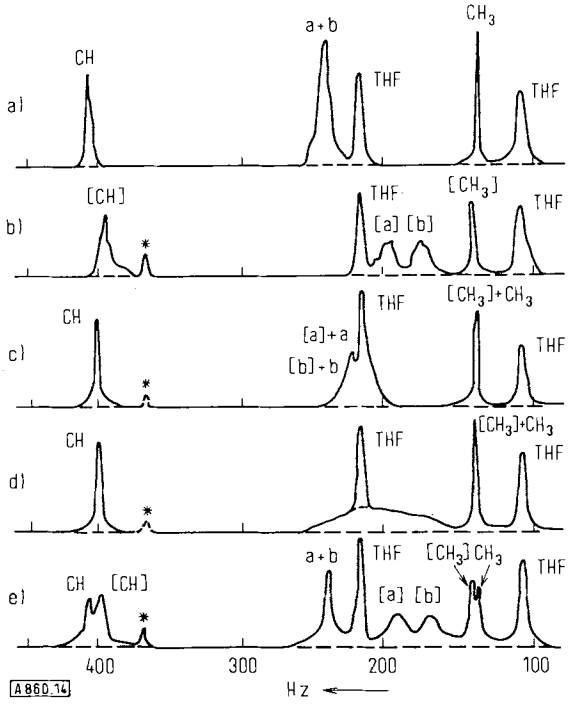


Fig. 14. NMR spectrum of the methyl derivative of dibenzo[18]crown-6 and its complex with fluorenylsodium in perdeuterated THF. The [ ] symbol signifies that the proton peaks belong to complexed *(7)*; * denotes fluorenyl protons. a) *(7)* at 40 °C; b) complex with *(7)* at 40 °C, *(7)*: fluorenylsodium ≈1; c) complex at 40 °C, *(7)*: fluorenylsodium ≈2; d) complex at 2 °C, *(7)*: fluorenylsodium ≈2; e) complex with *(7)* at −40 °C, *(7)*: fluorenylnatrium ≈2.

Strong upfield shifts of the protons of THF and of DME molecules complexed to fluorenyllithium dissolved in deuterated benzene were found by *Dixon et al.*[64]. For a 1:1 fluorenyllithium-DME mixture the CH_2 protons are shifted upfield by 1.22 pm and the CH_3 protons by 0.76 ppm. Similar shifts are found on complexation of glymes or macrocyclic polyethers to fluorenyl ion pairs[42,50]. An example is shown in Figure 14, which depicts the NMR spectrum of dimethyldibenzo[18]crown-6 and its 1:1 and 2:1 mixtures with fluorenylsodium, all recorded in deuterated THF. The complexation of the crown compound leads to a splitting of the polyether ring protons into two

peaks of equal intensity, the upfield shifts being 1.1 ppm and 0.75 ppm, respectively (selective deuteration showed the inner "a" CH_2 protons to undergo the largest shift). The upfield direction is due to the diamagnetic anisotropy exerted by the aromatic fluorenyl ring. This is partially compensated by a downfield shift that is expected on coordination of the crown to the Na^+ ion, as observed in ethereal solutions of certain alkali metal salts[65]. The aromatic protons of the crown are shifted upfield by 0.2 ppm, but the CH_3 protons show a downfield shift of 0.07 ppm, probably because they are located on the periphery of the fluorenyl ring.

A rapid exchange spectrum is observed with 2:1 mixtures of the crown compound and fluorenylsodium (Fig. 14c), but a slow exchange spectrum is obtained at low temperatures. The coalescence temperature for the polyether ring protons was found to be 2 °C (Fig. 14d). The concentrations of complexed and free crown being equal, one may calculate the rate constant of the reaction

$$\text{fluorenyl}^-, C, Na^+ + C^* \rightarrow \text{fluorenyl}^-, C^*, Na^+ + C$$

(C and C* representing the same crown compound) at the coalescence temperature from the equation

$$k = 1/2\tau[C]_{free}$$

with the relaxation time[66]

$$\tau = \sqrt{2}/2\pi(\gamma_A^0 - \gamma_B^0)$$

This expression can be applied at the respective coalescence temperatures of the polyether ring protons ($t_C = 2$ °C, $\Delta\gamma = 56$ Hz), the aromatic CH protons ($t_C \approx -18$ °C, $\Delta\gamma = 10$ Hz), and the CH_3 protons ($t_C \approx -27$ °C, $\Delta\gamma = 4$ Hz). The rate constants thus calculated are 3200 (2 °C), 550 (−18 °C), and 220 l mol^{-1} s^{-1} (−27 °C), giving an activation energy for the exchange process of 12.5 kcal/mol. The actual exchange process may be more complex, and could conceivably involve the free ions, with the rate determining step being the dissociation of the complex into the free cyclic ether and the contact ion pair fluorenyl$^-$, Na^+, followed by a rapid association step leading to the exchange.

The exchange rate is considerably faster with fluorenylpotassium, and even down to −60 °C a 2:1 mixture of dibenzo[18]crown-6 and fluorenylpotassium gives a rapid exchange spectrum. This confirms the results obtained by optical spectroscopy, namely, that this crown ether is more strongly bound to Na^+ than to K^+, at least in THF.

Upfield shifts are also observed for the fluorenylsodium-crown complex in other solvents such as pyridine. In this solvent fluorenylsodium is a separated ion pair, but addition of the dibenzo[18]crown-6 replaces the pyridine molecules around the Na^+ ion. The large proton shifts observed for the complexed crown compound also imply that the fraction of free ions at 0.1 mol/l salt concentration in pyridine ($D = 14.0$) must be small. Dissociation should remove the Na^+-crown complex from the fluorenyl moiety, and a downfield, rather than an upfield shift is then anticipated.

Sandwiched in between two fluorenyl rings, the crown complex of difluorenylbarium (see Fig. 13) shows an even stronger upfield shift for the polyether ring protons (0.5 and 1.4 ppm). The rate of the exchange reaction

$$\text{fluorenyl}^-, Ba^{2+}, C, \text{fluorenyl} + C^* \rightarrow \text{fluorenyl}^-, Ba^{2+}, C^*, \text{fluorenyl}^- + C$$

in pyridine at 60 °C (the solubility of the complex in THF is only $\approx 10^{-2}$ mol/l) is of the order of 500 l mol^{-1} s^{-1}. The (extrapolated) value of this rate constant at 60 °C for the fluorenylsodium-crown complex in THF is close to 10^5 l mol^{-1} s^{-1}. The exchange reaction involving the barium complex is probably sterically hindered. Also, the barium ion is more tightly bound to the crown compound than Na^+, as evidenced by the fact that on addition of difluorenylbarium to the fluorenylsodium-crown complex the crown compound is completely transferred to the barium salt.

Interesting NMR patterns are observed on complexation of glymes to certain paramagnetic ion pairs. It has frequently been observed that the NMR solvent shift for solutions of aromatic hydrocarbon radical anions is considerably less than the value predicted theoretically for solutions of paramagnetic species[67, 68]. Apparently, those solvent molecules which are bound to the radical anion pairs acquire spin density, due to their close proximity to the unpaired electron. This produces a downfield shift of the solvent protons, and partially balances the upfield paramagnetic bulk susceptibility shift[33].

A striking example of this effect is observed for 1:1 complexes of coronenesodium and glymes[34]. In the absence of glyme a 0.1 M solution of coronene$^-$, Na^+ in THF shows a solvent shift of only 0.05 to 0.07 ppm upfield with respect to pure THF. However, addition of an equivalent amount of glyme-5 causes both the α and β protons of THF to acquire their theoretically predicted solvent shift value of 0.25 ppm at 33 °C for a 0.1 M solution of paramagnetic species of spin ½. Apparently the glyme-5 has replaced the THF solvation shell around the Na^+ ion by forming the separated ion pair coronene$^-$, G-5, Na^+.

The high complexation constant ($> 10^4$ l/mol) excludes the presence of any free glyme. The change in the solvation shell is most clearly demonstrated by the NMR spectrum of the complexed glyme. At 120 °C, four absorption peaks can be observed at $\delta = 9.5$, 8.8, 7.5, and 5.5 ppm downfield from the α-THF peak with intensity ratios of 8:4:4:6 (a total of 22 protons). For a solution of glyme-5 in THF, only two glyme peaks are observed, 0.08 and 0.35 ppm upfield from the THF peak.

A similar downfield shift is found for the glyme protons of the 1:1 coronene$^-$, Na^+, glyme-4 complex (18 protons) at 33 °C. The NMR spectrum of this complex is depicted in Figure 15, and shows four well resolved peaks with intensity ratios 4:4:4:6. In this complex, the THF solvent protons still do not give their theoretically predicted solvent shift values, indicating that a few solvent molecules remain bound to the Na^+ ion.

Addition of two glyme-4 molecules per coronenesodium ion pair results in a shift of the glyme protons which is considerably larger than that calculated on the basis of a rapid exchange process for a 1:1 complex. Apparently, a second glyme-4 is coordinated to the coronenesodium ion

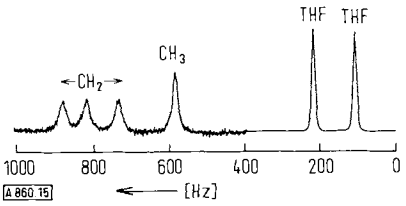

Fig. 15. ^{1}H-NMR spectrum (60 MHz) of the 1:1 complex of coronene-sodium with glyme-4 in tetrahydrofuran at 33 °C. The four signals on the left-hand side are due to glyme protons.

pair, a conclusion which is supported by the NMR data obtained for glyme-4 complexes of fluorenylsodium[42].

A concentration dependent shift of the glyme protons is observed in a 0.1 M mixture of glyme-4 and coronenelithium in THF at 33 °C[34]. The glyme-4 is only partially bound to coronenelithium under these conditions, the equilibrium constant for

$$\text{coronene}^-, \text{Li}^+ + \text{G-4} \rightleftharpoons \text{coronene}^-, \text{G-4}, \text{Li}^+$$

being approximately 1.0 l/mol (see Section 3).

The glyme proton shifts most probably result from a Fermi contact interaction between the glyme protons and the unpaired electron. The g factor for radical anion pairs is nearly isotropic, which makes it unlikely that dipolar interactions between the unpaired electron and glyme protons are causing the downfield shift. The contact shifts are actually larger than the observed downfield shift, since they are partially balanced by an upfield shift of approximately 0.8 ppm caused by the diamagnetic anisotropy of the aromatic ring, similar to that observed for the fluorenyl-sodium-crown complexes (see Fig. 14).

The protons showing the smallest downfield shift are the CH_3 protons. Using a partially deuterated glyme-5[69] it was found that at least in this glyme the eight protons of the two ethylene groups adjacent to the center oxygen atom undergo the largest chemical shift. The difference in chemical shift for the various CH_2 protons of the complexed glyme indicates that the glyme-coordinated Na^+ ion does not rotate indiscriminately above the plane of the coronene molecule, as this would produce the same average shift for all CH_2 protons.

The contact shifts are small for glyme complexes of the radical anion salts of naphthalene, triphenylbenzene, and anthracene, but with triphenylenesodium the CH_2 glyme protons are shifted by about 3.3 ppm[33]. Apparently, an effective overlap between electron orbital and glyme protons only occurs when the spin density is high at the periphery of a comparatively large aromatic molecule. The glyme complex may have a structure in which the glyme is bound to Na^+ in a ring type conformation parallel to the aromatic ring. This provides for a maximum coulombic attraction between the two oppositely charged ions, and should bring the glyme protons close to those coronene atoms which possess the higher spin density.

The large proton shifts for the glyme complexes of coronene radical anion pairs are reminiscent of those often observed for diamagnetic cations in the presence of paramagnetic anionic transition metal complexes. The latter shifts have frequently been utilized to detect ion pairing and to measure equilibrium constants for ion pair formation. For example, *LaMar*[70] observed strong upfield shifts for the protons of the tetrabutylammonium cation in the paramagnetic complex $[(C_4H_9)_4N]^+[(C_6H_5)_3PCoI_3]^-$, and large downfield shifts for the same protons in the corresponding nickel complex. Other systems for which large shifts are observed include tetraalkylammonium ion pairs of tris(2,4-pentanedionato)cobalt(II) and -nickel(II) complexes[71] and ion pairs of tetrahalometalates[72]. Also mixed cations like butyltriphenylphosphonium have been used[73]. The above shifts are usually interpreted in terms of a "pseudo contact" mechanism, *i.e.*, a direct dipolar interaction between the unpaired electron and the protons of the cation. Such an interpretation is plausible since the g factor is often anisotropic for these transition metal complexes.

Other approaches have been used to study ion pairing by nuclear magnetic resonance. While finding no effect of the cation on the coupling constants of the fluorenyl carbanion protons in THF, *Cox*[74] observed downfield shifts with increasing radius of the cation, the lithium salt being an exception. For example, the respective chemical shifts for H-9 in fluorenyllithium, sodium, potassium, and rubidium are 7.21, 7.37, 7.27, and 7.25 ppm downfield from TMS. The downfield trend is caused by a change in charge distribution in the contact ion pair. The deviation shown by the fluorenyllithium is to be expected, since this ion pair is predominantly a separated ion pair in THF at 25 °C[10], hence the cation should have little effect on the chemical shift. Similar studies were carried out by *Chan*[40] who arrived at the same conclusions. Since the effects are small, quantitative data on ion pairing may not be very reliable, particularly since some of the observed changes in chemical shifts could be caused by ion pair aggregation at the high salt concentrations employed.

Interactions between solvent and ion pair can be conveniently studied in the alkali metal tetraalkylaluminates. $NaAl(C_4H_9)_4$ is soluble in most hydrocarbon solvents, which means that ion solvent interactions with coordinating species such as ethers can be studied with a minimum of interference by the medium itself. *Schaschel* and *Day*[75] measured the proton shifts of tetrahydrofuran in cyclohexane in the presence of sodium tetrabutylaluminate as a function of the THF: $NaAl(C_4H_9)_4$ ratio. Up to a ratio of 1:1, the shift relative to the unperturbed THF in cyclohexane is nearly constant at 0.22 ppm, indicating formation of a complex THF/$NaAl(C_4H_9)_4$. Whether this constitutes a THF-separated ion pair or an externally solvated contact ion pair cannot easily be decided, although the authors favor a separated ion pair because of observed shifts in the $Al\cdots CH_3$ proton signal. As more THF is added, the shift difference with respect to unperturbed THF decreases, with a distinct break noticeable at THF: $NaAl(C_4H_9)_4 = 4:1$. This was interpreted as evidence for the presence of $NaAl(C_4H_9)_4 \cdot 4$ THF species. A similar study by *Wuepper* and *Popov*[76] for the system $NaAl(C_4H_9)_4$ and DMSO in dioxane showed a probable solvation number of six for the DMSO-solvated Na^+ ion, but no conclusions can be drawn about possible structures of the ion pair solvation complexes.

Ion pair equilibria may also be studied from the NMR line shapes. An interesting application was reported by *Gore* and *Gutowsky*[77], who studied the NMR spectra of lithium- and sodium tetramethylaluminate in ether, THF, and DME. In the solvent separated ion pair the electric field gradient at the ^{27}Al nucleus is small because of a nearly tetrahedral symmetry of the electric field. The spin lattice relaxation rate of the ^{27}Al is therefore small enough to cause indirect spin-spin splitting by the Al nucleus ($I=\frac{5}{2}$), and the CH_3 group appears as a sharp sextuplet. On the other hand, the electric field gradient at the Al nucleus is large for an intimate ion pair and the resulting high rate of relaxation causes the CH_3 sextuplet to collapse into a singlet. In DME only separated ion pairs were observed for both the Li and Na salts, while in diethyl ether only contact ion pairs were found. However, mixtures of the two ion pairs were found in THF. The thermodynamic parameters for the equilibrium

$$Li^+Al(CH_3)_4^- \rightleftharpoons Li^+\|Al(CH_3)_4^-$$

were calculated to be $\Delta H = -6.5$ kcal/mol and $\Delta S = -11$ e. u. at 40 °C. The ΔH value is close to that found by *Hogen Esch* and *Smid* for fluorenyllithium in THF[10]. The equilibrium constant for the sodium ion pair at 40 °C is about ten times less than for the lithium salt, which is at least qualitatively in agreement with that observed for fluorenyl salts.

Extensive proton and alkali metal NMR measurements on ion pairs of radical anions of biphenyl and naphthalene were reported by *de Boer et al.*[78, 79]. However, a thorough discussion of their interesting work falls outside the scope of this review. There is little doubt that alkali metal NMR measurements can provide very useful information on interactions of complexing agents with alkali metal ions. An example is found in recent work of *de Boer, Grotens,* and *Smid*[80] which shows that the ^{23}Na-NMR line width strongly increases when the THF solvation shell around Na^+ in $NaB(C_6H_5)_4$ is replaced by glyme-7 or dimethyldibenzo[18]crown-6, largely because of an increase in the field gradient at the ^{23}Na nucleus. Solvents will also affect the chemical shift of the ^{23}Na-NMR line[81] and this can often be correlated with the solvating ability of the solvent.

Part of the work described in this review was carried out at the Chemistry Department, College of Forestry, Syracuse, New York, and the author gratefully acknowledges the financial support of the National Institutes of Health (Grant GM 15965) and the Petroleum Research Fund, administered by the American Chemical Society. He is grateful to his many co-workers, in particular Dr. T. E. Hogen Esch, who has pioneered much of the work on fluorenyl ion pairs, and also for many stimulating discussions with Dr. M. Szwarc and Dr. E. de Boer.

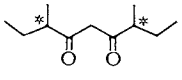
Synthesis of the Lithium Enolate of (*S*)-(+)-*sec*-Butyl Methyl Ketone and Formation of Chiral 1,3-Diketones by Acylation

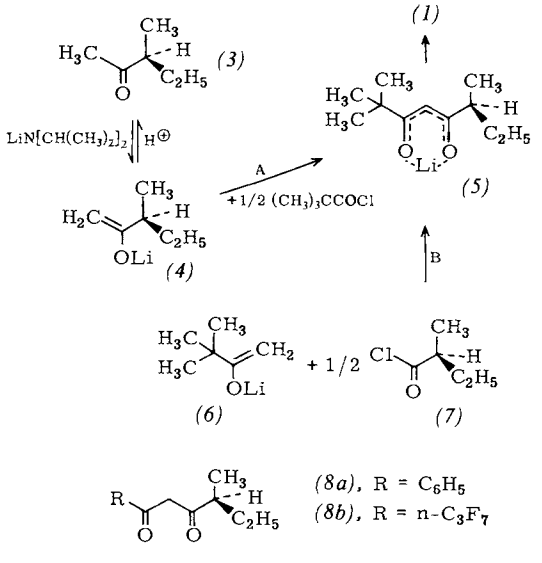
By *Dieter Seebach* and *Volker Ehrig*[*]



In connection with our studies on lanthanoid complexes of chiral 1,3-diketones suitable for determining the purity of enantiomers[1] we were confronted with the problem of synthesizing dipivaloylmethane-(DPM-)like ligands such as *(1)* and *(2)*.

DPM

(1)



(2)

For a synthesis of *(1)*, the enolate *(4)* of the optically active 3-methylpentanone *(3)*[2] has to be *C*-acylated. Amine-free solutions of (*S*)-*(4)* in toluene/THF could be prepared by modification of the procedures given by *Schlosser*[3] and *House*[4] for preparation of lithium enolates. "Neutralization" with the calculated amount of acid regenerates the ketone *(3)* with less than 5% loss of optical activity; addition of one half equivalent of pivaloyl chloride at −80 °C proceeds according to reaction A to give the lithium salt *(5)* from which 2,2,6-trimethyl-3,5-octanedione *(1)* is liberated.

Neither the NMR spectrum nor the gas chromatogram of the diketone *(1)* isolated in 83% yield by molecular distillation gives any indication of contamination by *O*- or α′-*C*-acylated product. Compound *(1)* was also prepared by acylation of the lithium enolate *(6)* of pinacolone with optically active α-methylbutyryl chloride *(7)* (route B).

The ketone *(3)* used for route A had $[\alpha]_D^{25} = +17.8°$ (neat), was at most[2,5] 60% optically pure, and gave diketone *(1)* of $\alpha_D^{25} = +19.0°$ (1 dm, neat); the (*S*)-(+)-acid chloride *(7)* used for route B was at least[6] 89% optically pure and afforded compound *(1)* having $\alpha_D^{25} = +27.5°$; a value of +31° for optically pure diketone was calculated from both experiments.

The diketone *(2)* having two centers of asymmetry and the compounds *(8)* were obtained similarly (see Table); accord-

Table. Starting materials for synthesis and physical data of the diketones *(1)*, *(2)*, and *(8)*; physical data of the diketone complexes CuL_2 and EuL_3. The acylation yields lie between 70 and 90%, based on starting acid chloride.

Li enolate + $^1/_2$ acid chloride	diketone	b.p. (°C/torr)	n_D^{20}	$[\alpha]_D^{25}$ (°) [a] (1 dm, neat)
(4) + $(CH_3)_3C$—COCl	(*S*)-*(1)*	95/15	1.4610	+31
(6) + *(7)*				+31

(*S*)-*(8a)*	EuL_3	206–210 (decomp.)	−170 (5.7)
(*S,S*)-*(2)*	EuL_3		+67 (10)

[a] Based on sample of *(3)* having the highest extrapolatable rotation ($[\alpha]_D = +30°$ (neat)) [5] and optically pure *(7)* ($[\alpha]_D = +17.8°$ (neat)) [6].

ing to their NMR spectra (CCl_4) they all exist to the extent of >90% in the enol form.

The above experiments show that under suitable conditions open-chain ketones that are asymmetric, enolizable, and therefore subject to racemization in the α position relative to the carbonyl group, can be "enolatized" at the less substituted α′-carbon and acylated in high yields without extensive racemization[7].

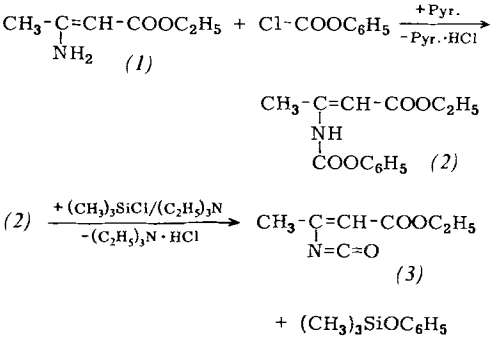
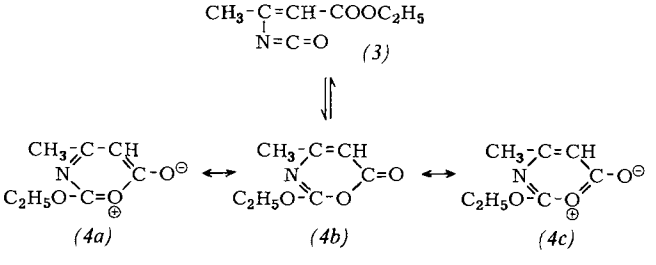
[7] On formation of the enolate and subsequent trimethylsilylation of 2-butanone, 2-heptanone, and 2-methyl-3-pentanone, *House et al.* [4] observed less regiospecificity and up to 40% aldol formation from the ketone.



Reversible Isomerization in β-Isocyanatocrotonic Esters

By *Hans R. Kricheldorf* [*]

Ethyl β-isocyanatocrotonate *(3)* could be synthesized by conversion of ethyl β-aminocrotonate *(1)* into the *N*-phenoxycarbonyl derivative *(2)*, which on treatment with trimethylchlorosilane is cleaved into *(3)* and phenoxytrimethylsilane (cf. Ref. [1, 2]).



[*] Dr. H.-R. Kricheldorf
Institut für makromolekulare Chemie der Universität
78 Freiburg, Stefan-Meier-Strasse 31 (Germany)

The isocyanate *(3)* boils at 82—83 °C/12 torr; it is a colorless liquid with a penetrating, lacrimatory odor. It undergoes rapid reaction with aniline at 0 °C to give the same urea that is formed in the reaction of *(1)* with phenyl isocyanate.

The IR spectrum contains bands for the isocyanate group (2270 cm^{-1}), the ester carbonyl group (1695 cm^{-1}), and the CC double bond (1610 cm^{-1}). The NMR spectrum shows signals for the ethyl groups at τ = 8.72 (t) and 5.82 (q), for the methyl group at 8.09 (s), and for the C—H group at 4.44 (s) (3:2:3:1).

At temperatures below 30 °C an isomer having m.p. 68 to 70 °C crystallizes from pure *(3)*; on the basis of previous investigations this isomer was assigned the structure of a 2-ethoxy-4-methyl-1,3-oxazin-6-one *(4)*. *(4)* can be isolated and stored at 0 °C, but in solution regeneration of *(3)* takes place; in carbon tetrachloride at 20 °C equilibrium is established within 4 days, the ratio of *(3)*:*(4)* being 1:1. The proportion of *(3)* increases on increasing the temperature (at 70 °C in CCl_4 *(3)*:*(4)* = 3:1).

The IR spectrum of *(4)* contains a carbonyl band at 1770 cm^{-1} as well as the band at 1610 cm^{-1} which also occurs in the spectrum of *(3)* and which can be due to a CC or CN double bond. The NMR spectrum of *(4)* shows the same signals as that of *(3)*, but with a larger paramagnetic shift throughout: τ = 8.59 (t), 7.89 (d), 5.57 (q), and 4.38 (d), (3:3:2:1). The signals of the C—H and CH_3 groups occur as doublets (J = 1 Hz), as is to be expected for an allyl *cis* conformation. In accord with the presence of three conjugated double bonds, the UV spectrum of *(4)* shows an intense absorption at 274 nm.—*(4)* does not react with aniline at 0 °C if *(3)* is not present.

Ethyl β-isocyanatocrotonate (3)

Phenyl chloroformate (157 g, 1 mol) is added dropwise to a mixture of *(1)* (127 g) and pyridine (79 g, 1 mol) in ethyl acetate (1 l). The resulting solution is heated to boiling for 30 minutes, then cooled, washed with dilute hydrochloric acid, and finally dried with Na_2SO_4. On evaporation under

vacuum, *(2)* crystallizes out (m. p. 70—72 °C after recrystallization from ethyl acetate/petroleum ether); yield *ca.* 95%.

A mixture of *(2)* (249 g, 1 mol), trimethylchlorosilane (108 g, 1 mol), and triethylamine (101 g, 1 mol) in toluene (1.2 l) is heated to boiling for 2 h, allowed to cool and then filtered. *(3)* is isolated from the filtrate by fractional distillation in a 20 cm packed column; yield 30—50%. For isolation of *(4)*, *(3)* is allowed to stand for 2 weeks at 0 °C and the crystals which separate are filtered off, thoroughly washed with petroleum ether, and finally dried under vacuum; yield 70—85%.

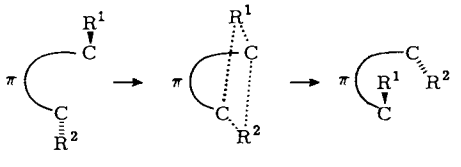
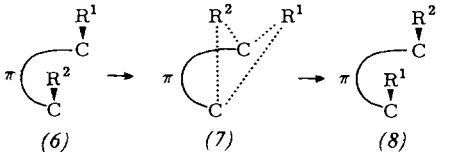
Dyotropic Rearrangements, a New Class of Orbital-Symmetry Controlled Reactions. Type I



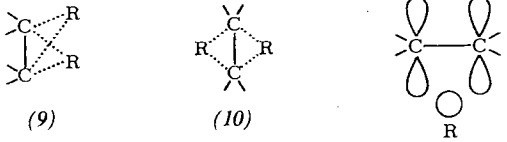
By *Manfred T. Reetz*[*]

A *dyotropic*[1] reaction can be defined as an uncatalyzed process in which two σ-bonds simultaneously migrate intramolecularly. Reactions in which the two σ-bonds interchange their positions are of Type I. In Type II processes no direct positional interchange occurs. This communication treats only Type I reactions[2].



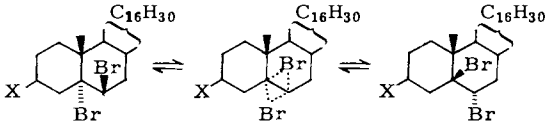
A dyotropic reaction in a conjugated polyene with $m-2$ ($m=2,3,4$) double bonds *(1)*→*(2)* has the order[3] [*m*,*m*] and can proceed out of two distinct conformations, *anti (3)* and *syn (6)*.

(1) *(2)*



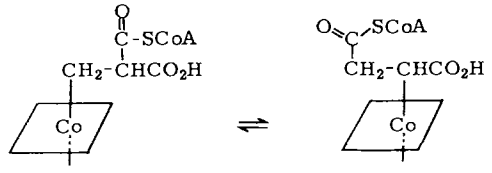
(3) *(4)* *(5)*

(6) *(7)* *(8)*



If both substituents remain on their initial side of the π-system during the reaction, *(supra, supra)*, two transition states result: *anti (4)* and *syn (7)*. The *anti* rearrangement necessarily leads to inversion of configuration of both *stationary* terminal atoms, whereas the *syn* reaction results in double retention. Four additional transition states not shown here are conceivable: *anti(supra, antara)*, *anti(antara, antara)*, *syn(supra, antara)*, *syn(antara, antara)*.

The principle aspects of this reaction type can be illustrated by considering rearrangements of the order [2,2] in which both groups migrate suprafacially. Assuming retention of configuration at the *migrating* groups, application of the formal orbital-symmetry rules[4] leads to the following prediction: The *syn (9)* as well as the sterically more favorable *anti* rearrangement *(10)* are $[_\sigma 2_s + _\sigma 2_s]$ processes and are therefore thermally forbidden. If one of the R groups has a p-orbital available, it can migrate with inversion *(11)*, whereby the reaction would become a thermally allowed $[_\sigma 2_s + _\sigma 2_s]$ process[5].

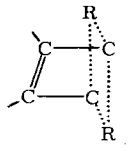


(9) *(10)* *(11)*

Several reactions in which two σ-bonds interchange positions have already been reported[6]; however, few stereochemical studies have been carried out. The long known mutarotation of dibromocholestane *(12)*⇌*(14)*[7] may be a [2,2] dyotropic shift in which one of the bromine atoms utilizes a p-orbital according to *(11)*. In a mechanistic study *Grob* and *Winstein*[8] showed that the reaction rate is unaffected by addition of radical initiators or inhibitors, and that in non-ionizing solvents (such as heptane) a four-membered transition state *(13)* best explains the stereochemical and kinetic data.

(12) *(13)* *(14)*

A similar exchange of substituents has been postulated for a number of coenzyme B_{12} mediated isomerizations[9]. Thus, the equilibrium *(15)*⇌*(16)* in the isomerization of methylmalonyl-CoA to succinyl-CoA[9] represents a formal dyotropic [2,2] rearrangement in which —COSCoA and cobalt participate as migrating groups.



(15) *(16)*

It has been suggested that in this step of the isomerization the —COSCoA group migrates intramolecularly and that the cobalt moiety does not become detached from the substrate[9]. In case of a dyotropic rearrangement, d-orbitals of cobalt would necessarily have to participate.

In dyotropic reactions of higher order, for example a [4,4] shift, the two stationary terminal atoms are connected by one or more π-systems. In the transition state *(17)* of the

[*] Dr. M. T. Reetz
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

[4,4] reaction, a four-membered cyclic orbital array prevails in which the added double bond is not directly involved. This as well as any additional π-system must be treated as a perturbation. As a first approximation, shifts of order [m,m] should behave much like the [2,2] case. Whether a π-system will stabilize the four-membered orbital array, will depend on its symmetry properties and can be analyzed from case to case using the frontier-orbital method[10, 11].

(17)

Three additional points deserve attention:

1. The selection rules are reversed for photochemical reactions.
2. Application of the Dewar-Zimmerman method[4] leads to the same results[10].
3. Since two σ-bonds are being broken simultaneously, the activation energy of dyotropic reactions could be high. A given system may thus choose alternative reaction paths.

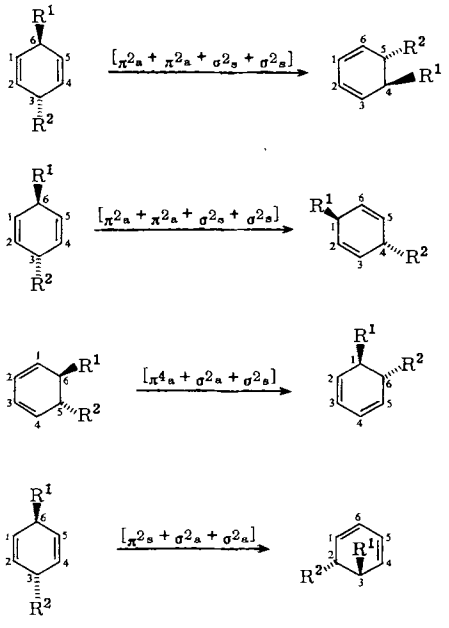
Dyotropic Rearrangements, a New Class of Orbital-Symmetry Controlled Reactions. Type II

By *Manfred T. Reetz*[*]

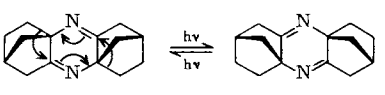


A dyotropic reaction of Type II was defined[1] as an intramolecular process in which two σ-bonds migrate in such a way as not to interchange positions. In this paper it is proposed that a wide variety of structurally different molecules may undergo such reactions and that for a given system several dyotropic reaction paths are conceivable.

Substituted cyclohexadienes serve as illustrative models. The migration of both R groups with retention of configuration as in (1) represents a dyotropic rearrangement of Type II.

(1)

The analysis of this reaction with the aid of a correlation diagram using a two-fold axis of symmetry shows that orbital symmetry[2] is not conserved in a thermal process. Four additional[3] dyotropic reaction modes are shown in (2), (3), (4), and (5). Application of the orbital symmetry rules[2] leads to the prediction that (2), (3), and (4) are thermally forbidden[4], unless one of the R groups migrates with inversion. In (5) one of the double bonds is not directly involved in the reaction, so that the rearrangement is already thermally allowed. In photochemical rearrangements the predictions are reversed.



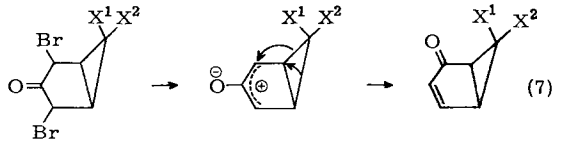
(2)

(3)

(4)

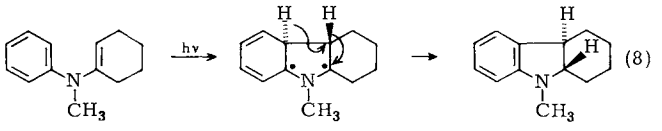
(5)

Dyotropic reactions have not yet been reported for cyclohexadiene itself. However, *Farnum* and *Carlson*[5] have studied a system analogous to (3). In order to explain the photochemically induced racemization of the dihydropyrazine shown below, they postulate a rearrangement (6) in which, like (3), two σ-bonds migrate simultaneously.



(6)

A reaction analogous to (4) in which one σ-bond migrates to a new position while the second one follows synchronously in its "tracks" has been recently described: In order to account for the stereochemistry of the Favorski reaction of bicyclo[3.1.0]hexanone derivatives, *Zimmerman*[6] invokes a sigmatropic [1,4] rearrangement with inversion of configuration. In the same publication *Zimmerman* proposes



[*] Dr. M. T. Reetz
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

an alternative view in which both σ-bonds of the cyclopropane ring "slither" simultaneously along the C_5 framework (see arrows). This represents a thermally allowed $[{}_{\pi}2_s + {}_{\sigma}2_s + {}_{\sigma}2_s]$ dyotropic reaction.

(7)

Chapman[7] has recently considered, *inter alia*, a double hydrogen shift according to (8) in the photocyclization of *N*-aryl enamines; this corresponds to a photochemically allowed $[{}_{\pi}4_s + {}_{\sigma}2_a + {}_{\sigma}2_a]$ dyotropic rearrangement.

(8)

These few examples show that dyotropic rearrangements should be considered principally as possible reaction modes. However, since the simultaneous breakage of two σ-bonds generally requires high activation energies, it is difficult to predict the generality of dyotropic reactions.

[3] *Syn* reaction paths are not illustrated here. As far as orbital symmetry is concerned, they behave qualitatively just like the above discussed *anti* rearrangements. Two "simultaneous" sigmatropic [1,3] reactions have also not been considered.

[4] Besides the possibility of a dyotropic reaction, (2) also represents a sequence of two sigmatropic shifts, [1,3] and [1,5].

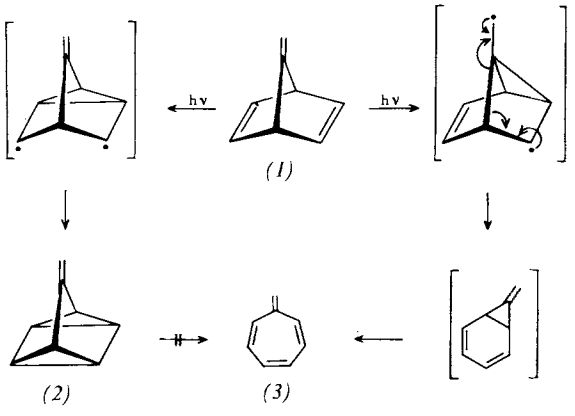
Vinylogous Heptafulvenes from Vinylogous Fulvenes[1][**]

By *Horst Prinzbach*, *Hans-Jürgen Herr*, and *Walter Regel*[*]



According to an undoubtedly naive working hypothesis, selective photoexcitation of the endo- and exocyclic partial chromophores in the methylenenorbornadiene system *(1)*, which are only formally independent[2], leads selectively to quadricyclane *(2)* and heptafulvene derivatives *(3)*[3] respectively.

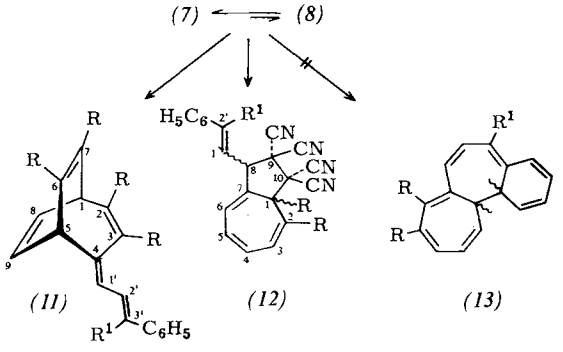
[a] In acetonitrile. [c] Acetone-sensitized. [d] Possibly partly dissociated.
[b] *(5a)* in $CDCl_3$, 60 MHz; *(5b)* in CCl_4, 60 MHz; *(7a)* and *(10b)* in CCl_4, 220 MHz; *(7b)*, *(11a)*, *(11b)*, *(12a)* in C_6D_6, 220 MHz; *(8a)* in CCl_4, 100 MHz; *(8b)* in C_6D_6, 100 MHz; *(9b)* in C_6D_6, 60 MHz; *(12b)* in $CDCl_3$, 220 MHz. – The coupling constants in the 220 MHz spectra are ±0.5 Hz.



(7a) [90% *(7a)*, 10% *(8a)*]. The quadricyclane *(6a)* cannot be detected[7].

Under the same conditions compound *(5b)* gives only 25% of *(7b)* (amethyst prismatic crystals) and 4% *(8b)*, the photoequilibrium mixture[6] contains 87% *(7b)* and 13% *(8b)*. Chromatography with benzene on SiO_2 also gave 20% of a mixture of the dihydroazulenes *(9b)* and *(10b)* (1:2), *(10b)* actually being formed from *(9b)*: on heating, *(9b)* is quantitatively regenerated. Control experiments show that *(9b)* is not formed from *(7b)* or *(8b)*; it is not yet clear when ring closure takes place[9].

Direct irradiation of *(5a)* and *(5b)* (CH_3CN; otherwise identical conditions) yields only the products *(7a)* and *(8a)* and *(7b)* and *(8b)* respectively with slightly varying relative proportions of components[11]. In this case too

no isomers of *(7)* and *(9)*, *i.e.* reaction products of the diradical formed by 6/7 bridging in *(5)*, could be detected.

The structures *(5)*, *(7)*, *(8)*, *(9)*, and *(10)* are characterized by elemental analysis and by mostly typical spectral data (Table); they were further confirmed by addition reactions or oxidation to the corresponding azulenes[10]. Reaction of *(7a)* and *(7b)* with dimethyl acetylenedicarboxylate only occurs in a temperature range in which their thermal rearrangement[10] is already very fast; the adducts which were consequently isolated in only small yields were shown by spectroscopy to have the structures *(11a)* and *(11b)* resulting from a [4+2]-addition. Tetracyanoethylene adds rapidly and almost quantitatively at 20°C to give the [8+2]-adducts *(12a)* and *(12b)*[12]. $[{}_{\pi}2_s+{}_{\pi}10_a]$-addition to the *s-cis* conformations, which appears sterically reasonable and would give heptalene derivatives, does not occur. A further expectation based on the synthesis of the vinylogous heptafulvenes was not fulfilled either: no photochemical cyclization to give fused heptalene derivatives [*e.g. (13)*] could be achieved under a variety of conditions.

Sesquifulvalenes from Dihydrofulvalenes[1][**]

By *Horst Prinzbach* and *Hubert Sauter*[*]

Suitably substituted sesquifulvalenes have become of preparative significance as polyene reactants in the synthesis of σ-bridged annulenes[2]. We have now opened up a new route to this class of compounds in the preparation of 1,2-bis(methoxycarbonyl)-8,9-diphenylsesquifulvalene *(8)* by a method developed on the basis of the photoisomerization of vinylogous methylenenorbornadienes to vinylogous heptafulvenes[3].

Condensation of hydroxydiphenylcyclopentenone *(3)*[4] with cyclopentadiene under standard conditions[5] affords the dihydrofulvalene *(4)* in 70% yield. Mild dehydration over Al_2O_3 yields 2,3-diphenylfulvalene *(1)* pure in solution[6]; however, owing to the rapid dimerization of the fulvalene[7] and the formation of 1:2 adducts addition of dimethyl acetylenedicarboxylate to *(1)* gives an insufficient yield of cyclopentadienylidenenorbornadiene *(2)*. In contrast, *(4)* reacts with dimethyl acetylenedicarboxylate to give at least 90% of a mixture (*ca.* 1:1) of the adducts *(5)* and *(6)*; the latter can be separated by chromatography [Al_2O_3, basic, deactivated with 10% H_2O (Woelm), benzene/CH_2Cl_2 (1:1)]. Acid-catalyzed dehydration to *(2)*, which is isolated as yellow crystals, proceeds in 60 to 70% yield.

Previous studies have shown that the electronically excited polyene *(2)* avoids substantial conversion into *(8)* by undergoing side reactions. While *direct* irradiation (ether, Pyrex filter, Hanau Q 81 high-pressure mercury arc lamp) furnishes only traces of *(8)* alongside products of high molecular weight, the *sensitized* reaction (acetone) affords about 10% of *(8)*. Rearrangement of *(5)* and *(6)*, individually or together, proceeds almost quantitatively on irradiation in acetone (Hanovia 2000-W high-pressure mercury arc lamp, Pyrex filter); a 3:1 mixture (photoequilibrium) of the isomeric dihydrosesquifulvalenes *(9)* and *(10)* is formed in each case. On treatment with acid *(9)* and *(10)* lose water to yield the sesquifulvalene *(8)* which crystallizes as violet needles from ether. At 20°C, *(8)* rapidly adds one equivalent of tetracyanoethylene in positions 7/10; however, the resulting adduct is not stable but slowly rearranges *via* the product of α,ω-([12+2])-addition[6,8] to *(7)*.

Correct elemental analyses were obtained for all new compounds. The characteristic spectral data are presented in the Table. Assignment of the isomeric pairs *(5)/(6)* and *(9)/(10)* is not yet definite.

1,2-Bis(methoxycarbonyl)-8,9-diphenylsesquifulvalene (8)

(4) (14.9 g, 50 mmol) is refluxed with dimethyl acetylenedicarboxylate (7.8 g, 55 mmol) in anhydrous benzene (100 ml) for 4 h. After removal of the benzene the residue [*(5)*/*(6)*] is dissolved in acetone (1.7 liter) and irradiated in a Pyrex vessel (0 °C) with the light from a Hanau TQ 2024 2000-W lamp until reaction is complete (6 h, NMR monitoring). The acetone is distilled off and conc. HCl (20 ml) is added to a solution of the residue in CH_2Cl_2 (2 liter). After 15 min the reaction mixture is neutralized by addition of sodium hydrogencarbonate solution, and the organic phase is dried and chromatographed with benzene on Al_2O_3 [basic, deactivated with 6% H_2O (Woelm)]. The deep red zone that is first eluted gives 8.2 g of *(8)* [39% based on *(4)*] on recrystallization from ether.

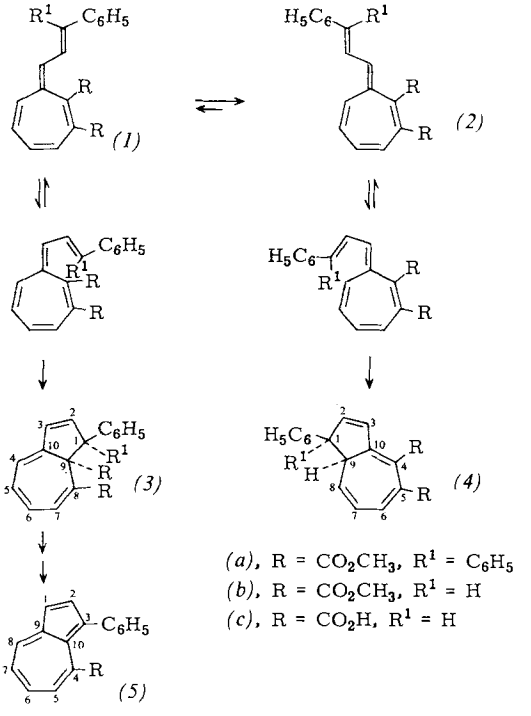
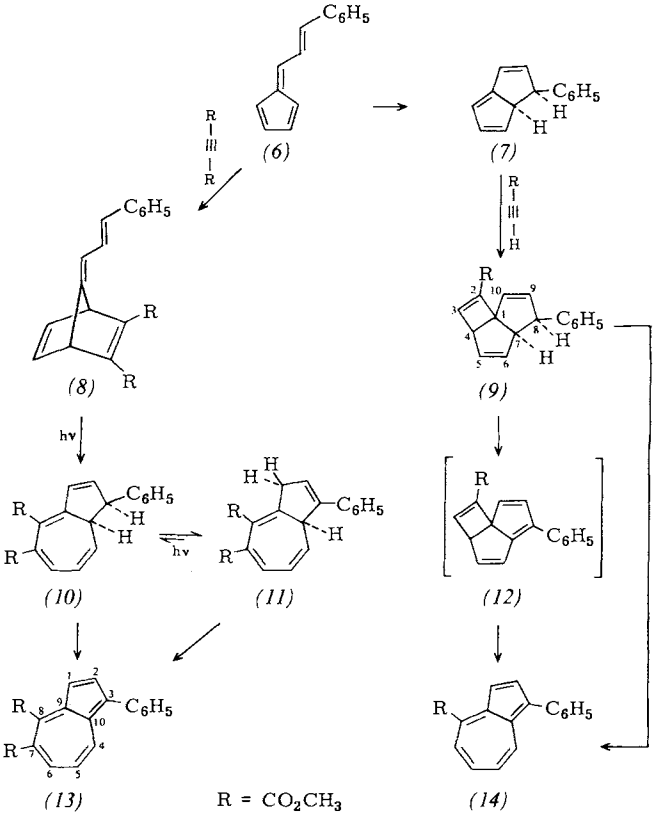
New Routes to the Azulene System[1][**]



By *Horst Prinzbach* and *Hans-Jürgen Herr*[*]

The most important synthesis of azulenes, which has repeatedly been modified[2], involves cyclization of doubly vinylogous fulvenes to form seven-membered rings. We have now found that the azulene system is also accessible by formation of the five-membered ring from vinylogous heptafulvenes.

If a solution of *(1a)* or *(2a)*, or *(1b)* or *(2b)*[3], (1.5 mmol) in pure perchlorobutadiene (5 ml) is heated to 170 °C the *cis/trans* equilibrium *(1a)*⇌*(2a)* or *(1b)*⇌*(2b)* (*ca.* 1:9 in each case) is rapidly established (*ca.* 5 min). NMR and UV spectroscopy show that *(4a)* is formed selectively in the slower electrocyclic reaction of *(1a)*⇌*(2a)* (*ca.* 60 min, 80% colorless needles), while *(1b)*⇌*(2b)* yields *(3b)* (90% yellow prisms).



Treatment of *(3b)* (2.5 mmol) with dilute caustic potash (10 mmol of KOH in 40 ml of H_2O; 100 °C) gives the

(a), R = CO_2CH_3, R^1 = C_6H_5
(b), R = CO_2CH_3, R^1 = H
(c), R = CO_2H, R^1 = H

azulenecarboxylic acid *(5c)* by way of hydrolysis, decarboxylation, and oxidation; *(5c)* reacts almost quantitatively with diazomethane to give methyl 3-phenylazulene-4-carboxylate *(5b)*.

It is most improbable that the dihydroazulene *(10)*, formed in photoequilibrium with *(11)* from the vinylogous methylenenorbornadiene *(8)* on acetone-sensitized irradiation[3], arises *via (1b)* or *(2b)*. *(10)* and *(11)* are readily oxidized by 2,3-dichloro-5,6-dicyanoquinone (in benzene or CCl_4) at 20 °C to blue-black crystals of dimethyl 3-phenylazulene-7,8-dicarboxylate *(13)*[4].

[a] In acetonitrile. [b] In ethanol.

[c] *(3b)*, *(4a)*, and *(14)* in C_6D_6, 220 MHz; *(5b)* in $CDCl_3$, 220 MHz; *(9)* in C_6D_6, 60 MHz; *(13)* in $CDCl_3$, 60 MHz. – The coupling constants in the 220-MHz spectra are ±0.5 Hz.

The synthesis of methyl 3-phenylazulene-8-carboxylate *(14)* also follows a rather unusual route that is not yet clear in all details. Reaction of the vinylogous fulvene *(6)* with methyl propiolate (1:3, toluene, 110°C) yields, in addition to the norbornadiene derivative analogous to *(8)*, an isomeric 1:1 adduct (20–25%) that is not the product of an [8+2]addition[5] but, according to monitoring experiments, results from the dihydropentalene *(7)*[6]. The tricyclic compound, which is stable up to at least 80°C, is oxidized by dichlorodicyanoquinone in boiling benzene to *(14)* in 60% yield. Mainly for this reason we tentatively assign structure *(9)* in preference to the alternative structure from a [4+2] addition to *(7)*. There is evidence for the occurrence of an intermediate, possibly *(12)*, which is unstable under the reaction conditions.

The spectral data collected in the Table for the new compounds prepared[7] need no further explanation. It should be mentioned that the electronic spectrum of *(4a)* closely resembles that of the analogous monophenyl compound[3] and that the absorption maxima of the azulenes *(5)*, *(13)*, and *(14)* are as expected[8]. The positions of the substituents are also established unequivocally by the NMR data.

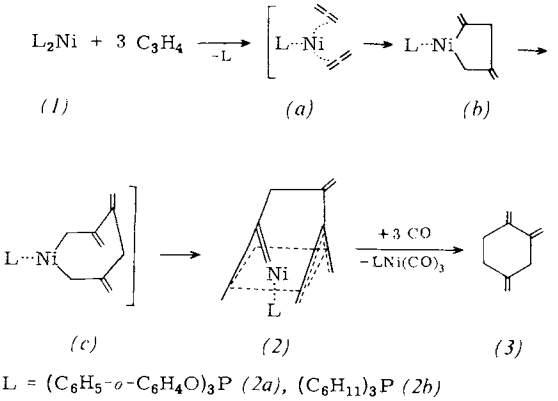
Reaction of a $L_2Ni(0)$ System with Allenes

By *M. Englert*[**], *P. W. Jolly*, and *Günther Wilke*[*]

Nickel(0) complexes having phosphane or phosphite ligands (Ni:P = 1:1) catalyze the dimerization of butadiene to 1,5-cyclooctadiene[1]. Allene undergoes oligomerization

[*] Prof. Dr. G. Wilke, Dr. M. Englert, and Dr. P. W. Jolly
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Lembkestrasse 5 (Germany)

[**] Part of Doctoral Dissertation, Universität Bochum 1971.



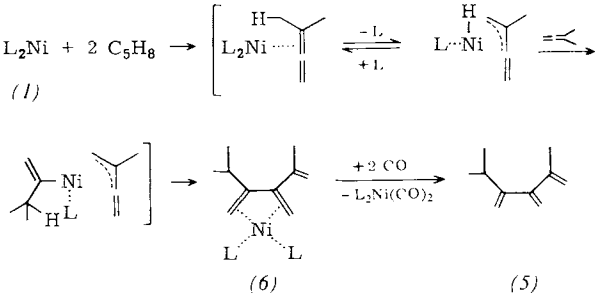
giving dimers to pentamers in the presence of similar Ni(0) complexes[2–4]. An intermediate with a ligand system consisting of three allene molecules was recently described[5]. In the present communication we report findings that led eventually to a complete structure analysis of such an intermediate by three-dimensional X-ray methods.

Our studies on bis(tri-2-biphenylylphosphite)nickel *(1)*[6] have shown that this complex containing coordinately unsaturated nickel(0) can be used to trap intermediates in the oligomerization of allene.

Allene reacts with *(1)* (3:1) in toluene at 20 °C to give an orange crystalline product *(2a)* of composition $C_9H_{12}NiL$ [$L=(C_6H_5\text{-}o\text{-}C_6H_4O)_3P$], which reacts quantitatively with triphenylphosphane or carbon monoxide to yield 1,2,4-trimethylenecyclohexane *(3)*. The ^{1}H-NMR spectrum of *(2a)*, which resembles that of the analogous Pd complex[7], indicates the presence of a free C=C bond and of a *cis*-bis(π-allyl)nickel system: τ = 5.3 (1H), 5.6 (1H), 7.40 (2H), 7.56 (2H), 7.63 (2H) [8.60d (2H); J = 10.4 Hz], [8.68d (2H); J = 9.7 Hz].

A completely analogous preparation yields the corresponding compound *(2b)*, containing tricyclohexylphosphane as additional ligand, whose structure was proved by the ^{1}H-NMR spectrum—τ = 4.84 (1H), 5.26 (1H), 6.90 (2H), 7.05 (4H), [8.13d (2H); J = 10 Hz], [8.21d (2H); J = 9 Hz] and by X-ray structure analysis[8].

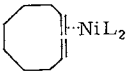
We assume that *(2)* is formed in a multi-step reaction proceeding *via* the following intermediates:



(1) *(a)* *(b)* *(c)* *(2)* *(3)*

L = $(C_6H_5\text{-}o\text{-}C_6H_4O)_3P$ *(2a)*, $(C_6H_{11})_3P$ *(2b)*

Intermediate *(a)* corresponds to a LNi-bis(olefin) complex in which two allene molecules are bonded, as in an analogous bis(ethylene) system[9], through one C=C double bond to the LNi group in such a manner that the four carbon atoms and the L·Ni group are practically coplanar. Carbon-carbon coupling leads to *(b)* containing two C—Ni bonds of which the metal-vinyl bond again adds to allene furnishing *(c)*. The ligand in *(c)* then inverts to give a *cis*-bis(π-allyl)nickel system containing formally five-coordinated nickel. At elevated temperatures or in the presence of donors the allyl groups in *(2)* couple and 1,2,4-trimethylenecyclohexane *(3)* is liberated. *(2)* contains asymmetric allyl groups[8]; and in particular that lying opposite the "*exo*" methylene group should be written as having a C=C bond and a C—C bond.



Reaction of *(1)* with 1,1-dimethylallene (1:2) in toluene follows a different course to yield, at 20 °C, a pale yellow, sparingly soluble substance *(4)* having the composition $C_{10}H_{16}NiL_2$ [$L=(C_6H_5\text{-}o\text{-}C_6H_4O)_3P$], which reacts with carbon monoxide at −78 °C or with triphenylphosphane at 80 °C to give 2,5-dimethyl-3,4-dimethylene-1-hexene *(5)* in 90—95% yield. At 60 °C this triene is formed catalytically on the $L_2Ni(0)$ system. It is not possible to decide whether the allene molecules are already joined in (4) or whether such linkage actually happens on displacement. A complex of *(5)* corresponding to *(6)* is probably present which is possibly formed *via* a π-allyl intermediate that is produced in an equilibrium similar to that found for a propylene·NiL complex[10]:

(1) *(6)* *(5)*

(6) corresponds to the complex formed from *(1)* and butadiene[6].

The simplest intermediate was found in the reaction of *(1)* with 1,2-cyclononadiene (1:1) in which a cyclononadiene·NiL_2 complex *(7)* is formed.

(7)

1,2-Cyclononadiene is displaced unchanged from *(7)* by triphenylphosphane. At 60 °C, however, catalytic oligomerization with *(1)* occurs; mass spectrometry shows the product to contain trimers to hexamers.

Molecular Structure of a Bridged *cis*-Bis(π-allyl)nickel System

By *Bobby L. Barnett, Carl Krüger*, and *Yi-Hung Tsay*[*]

Although the presence of *cis*-bis(π-allyl)nickel in equilibrium with *trans*-bis(π-allyl)nickel has been established by spec-

[*] Dr. C. Krüger, Dr. B. L. Barnett, and Dr. Y.-H. Tsay
Max-Planck-Institut für Kohlenforschung
433 Mülheim-Ruhr, Lembkestrasse 5 (Germany)

troscopy, the former has defied all attempts at isolation and characterization[1]. The complex of nickel(0) with tricyclohexylphosphane and a trimerization product of allene as ligands described in the preceding communication[2] forms triclinic crystals (unit cell: $a=14.443(9)$, $b=11.406(5)$, $c=13.151(9)$ Å; $\alpha=95.97\pm0.04$, $\beta=135.65\pm0.04$, $\gamma=100.32\pm0.03°$; space group $P\bar{1}$; $Z=2$; $d_{calc}=1.195$ g cm^{-3}) and thus allows a three-dimensional X-ray structural analysis to be performed.

The structure was solved by the heavy atom method with 4533 diffractometer data collected in the space group $B\bar{1}$ ($\lambda=1.5418$)[3]. It was found that one molecule of solvent (toluene) is disordered about a center of symmetry in the crystal lattice. Anisotropic least-squares refinement including isotropic hydrogen atoms and a disordered toluene with partial occupancy factors gave a final $R=8.9\%$. Anomalous scattering of the heavy atoms was used in these calculations[4].

The structure of the complex is illustrated in Figure 1; the geometry of the ligands of interest is shown in Figure 2 (distances in Å, angles in °).

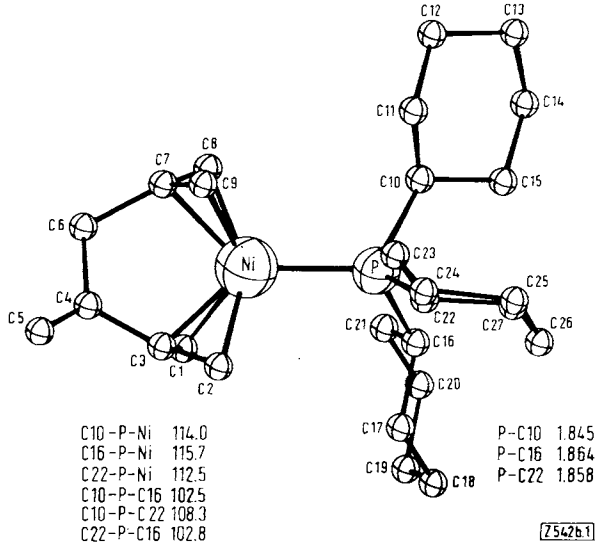

Fig. 1

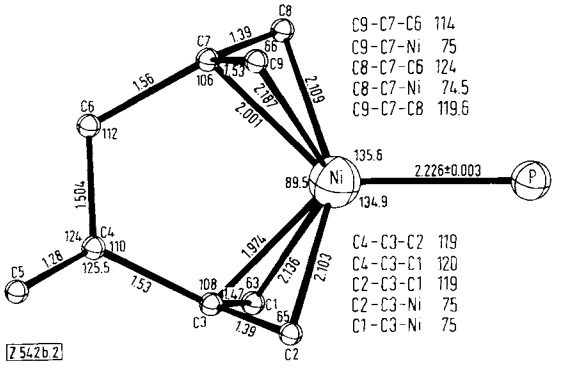

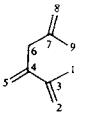

Fig. 2

As we have also found for numerous other examples[5] the coordination of the central atom is trigonal planar with respect to the centers of gravity of the allyl groups; each of the two π-allyl groups occupies a coordination position of the nickel, as does the distorted tricyclohexylphosphane tetrahedron. If the allyl group is considered to occupy two coordination positions as a bidentate ligand there results a square pyramid. The equation of the best plane through C3, C7, Ni, P is

$$-9.671x - 5.911y + 5.180z + 5.425 = 0.$$

All cyclohexyl rings are equatorially bonded and in the chair form; the mean C—C bond length is 1.52 Å, the mean bonding angle 112°.

The interesting asymmetry of the C—C bonds, which is in the same sense in the two π-allyl groups, seems to justify formulation of the ligand as the possible canonical structure *(1)*.

(1)

The allyl group, conjugated with the extremely short (1.28 Å) double bond between C4 and C5, exhibits a tendency towards symmetrization. The angle at C4 shows the metal-ring system of the ligand to be highly strained. The planes through the two allyl groups subtend a dihedral angle of 29.6°.

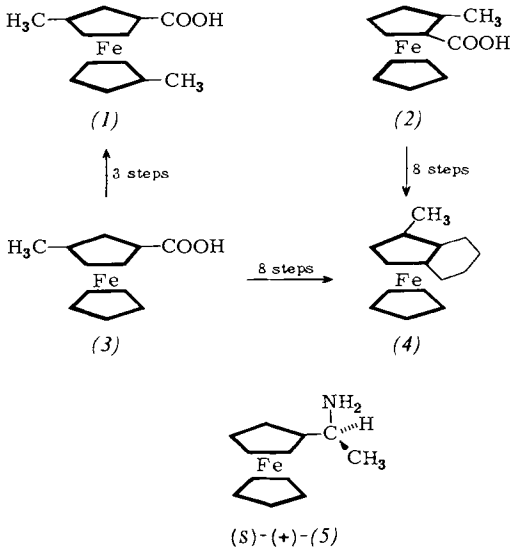
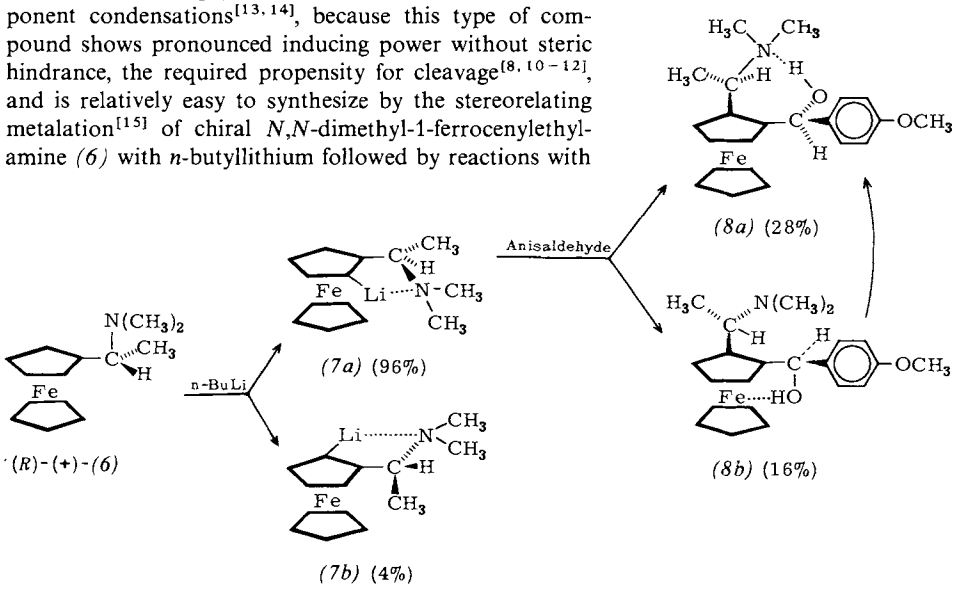
Absolute Configuration of a 1,2-Disubstituted Ferrocene Derivative with Two Different Chiral Substituents[1]

By *Linda F. Battelle, Robert Bau, George W. Gokel, Ray T. Oyakawa,* and *Ivar Ugi*[*]



Neither the absolute configuration of a chiral 1,2-disubstituted ferrocene derivative, nor the configuration of a central chiroid with a ferrocenyl ligand has hitherto been determined by X-ray methods. We wish to report the results of such a determination.

The only optically active ferrocene derivative whose configuration has been established by X-ray crystallography is (*S*)-3,1′-dimethylferrocene-1-carboxylic acid *(1)*[2]. Its configuration has recently been correlated with that of (*S*)-2-methylferrocene-1-carboxylic acid *(2)* by converting *(2)* and (*S*)-3-methylferrocene-1-carboxylic acid *(3)* both into the same 1-methyl-2,3-tetramethyleneferrocene *(4)* by sequences of eight steps[3], and by transforming *(3)* into *(1)* by a sequence of three reactions[4]. By this and a pre-



[*] L. F. Battelle, M. A., Prof. Dr. R. Bau, Dr. G. W. Gokel, R. T. Oyakawa, B. S., and Prof. Dr. I. Ugi

ceding series of chemical interconversions[5], the configurations of chiral 1,2-disubstituted ferrocene derivatives with *achiral* substituents are now unambiguously known.

The configurations of central chiroids with a ferrocenyl ligand have not yet been assigned with the same degree of reliability. For example, both the (*R*)-[6] and the (*S*)-configurations[7,8] have been assigned to (+)-1-ferrocenylethylamine *(5)* by optical methods[6] and by stereoselective reactions[7,8], respectively.

Some 1,2-disubstituted ferrocene derivatives show great potential as asymmetrically inducing[9] amine components for stereoselective peptide syntheses[10-12] by four component condensations[13,14], because this type of compound shows pronounced inducing power without steric hindrance, the required propensity for cleavage[8,10-12], and is relatively easy to synthesize by the stereorelating metalation[15] of chiral *N*,*N*-dimethyl-1-ferrocenylethylamine *(6)* with *n*-butyllithium followed by reactions with

suitable electrophiles[15-17] and subsequent retentive nucleophilic substitutions[18-20].

The main product *(7a)* of the metalation of *(6)* reacts with anisaldehyde to form *(8a)* (m.p. 110—111 °C; $[\alpha]_{589}^{22} = -20.8°$, $c = 1.6$, ethanol) and *(8b)* (dark oil, characterized by NMR and IR) which can both be isolated by chromatography (silica gel, J. T. Baker, no. 3405, 60 to 200 mesh; ligroine-acetone (1:1) as eluent); in aqueous solvents *(8b)* rearranges to form *(8a)*, presumably *via* a highly stabilized carbonium ion[18-20].

In order to assign the absolute configurations of the above class of chiral compounds and also in order to prove in an unambiguous manner the assumed stereorelating nature[15] of the metalation of *(6)*, we determined the absolute configurations of all elements of chirality of *(8a)* by X-ray crystallography (see Figure).

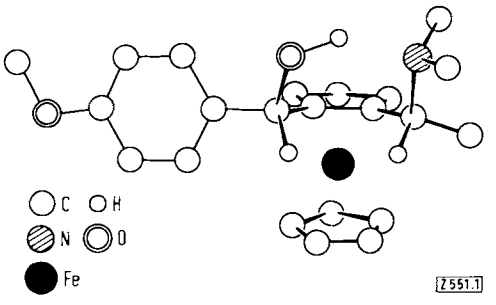

Fig. Molecular structure of *(8a)*.

Crystal data: Monoclinic, space group $P2_1$, $a = 9.77$, $b = 11.15$, $c = 10.56$ Å, $\beta = 120.6°$, $V = 603$ Å^3; d_{calc} (for $Z = 2$) = 1.96 g/ml, d_{exp} (flotation in an aqueous ZnI_2 solution) = 1.92 g/ml. Two quadrants of data were collected on a Nonius CAD-3 automated diffractometer using $Mo_{K\alpha}$ radiation. The structure was solved by conventional heavy-atom techniques[21] and refined to an *R* factor of 6.5%. The opposite configuration refined to an *R* factor of 7.2%. The ratio between the two *R* factors indicates that the probability of the first configuration being correct is better than 99.5%[22]. The configuration about the amine-substituted carbon is (*R*) and that about the hydroxyl-substituted carbon is (*S*). The configuration of the molecule as a whole, with respect to the plane of chirality, is (*S*)[16]. The conformations about the two asymmetric carbons are apparently determined by the hydrogen bond formed between the hydroxyl and amino groups (see Figure). The fact that *(8a)* is the more stable compound seems to be due to this O—H···N hydrogen bonding; an analogous hydrogen bond in *(8b)* is not possible for steric reasons.

Since the stereoselective metalation[15-17], in combination with retentive nucleophilic substitution[18-20], permits the convenient synthesis of a wide variety of ferrocene deriva-

tives having combined planar and central elements of chirality with known configurational relations, the above X-ray result provides access to a large number of optically active ferrocene derivatives with known absolute configurations.

Polarographic Reduction of Oxygen in the Presence of Phthalocyanine Complexes

By *Werner Beyer* and *Ferdinand von Sturm*[*]

Although the accelerating action of phthalocyanines on oxidations has been known for a long time[1, 2] they have only recently been exploited as catalysts for electrochemical reactions taking place in fuel cells[3–6]. The mechanism of their catalytic effect on the electrode reaction, however, has hitherto remained unknown.

Since the polarographic reduction of O_2 at a mercury electrode occurs in two distinctly separate steps it should be possible to determine the point of attack of the catalyst phthalocyanine, provided that the sparingly soluble compound can be obtained in a solution preferably resembling water that can be subjected to polarographic measurements.

In fact, adequate solubility was found in alkaline alcohol. The measurements reported in the present communication were mainly recorded with a 0.1 M solution of LiOH in methanol as supporting electrolyte with addition of monomeric phthalocyanine.

As is apparent from Figure 1, the catalyst acts already during the first wave of the DC polarogram which is assigned to the reduction of O_2 to H_2O_2. A pronounced maximum is observable with low catalyst concentrations (in the range between 10^{-7} and 10^{-4} M). It is not until a concentration of more than 5×10^{-4} M is reached that the current minimum is suppressed; the four-electron reduction of the O_2 then takes place in a single polarographic wave in contrast to the action of hemin, hemoglobin, and Fe^{3+}[7] (cf. Fig. 1, i). The catalytic effect is displayed by the complexes with Fe, Pt, Mn, and Ni as central atom but not those with Li, Mg, Zn, VO, Co, Ag, nor by metal-free phthalocyanine. The effectiveness decreases along the above series, with the Fe complex exhibiting the highest activity.

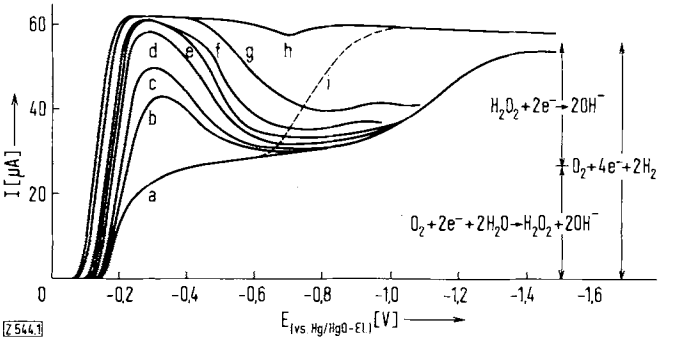

Fig. 1. Polarographic current-voltage curves for oxygen reduction in the presence of the iron(III)-phthalocyanine complex (0.1 M LiOH in methanol, air-saturated, 25 °C).
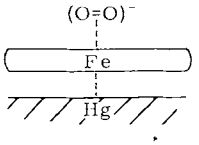
Fe^{III} concentration: 0 (a); 2.5×10^{-7} M (b); 5.0×10^{-7} M (c); 2.5×10^{-6} M (d); 5.0×10^{-6} (e); 9.5×10^{-6} (f); 5×10^{-5} M (g); 5×10^{-4} M (h); Fe^{3+} concentration: 10^{-3} M (i).

The Co-tetraazaannulene recently described[8] as an electrocatalyst merely increases the steepness of the first polarographic wave. The activity of Fe-tetraazaannulene (for whose preparation we are indebted to Dr. *Todt*), on the other hand, is comparable with that of Fe-phthalocyanine.

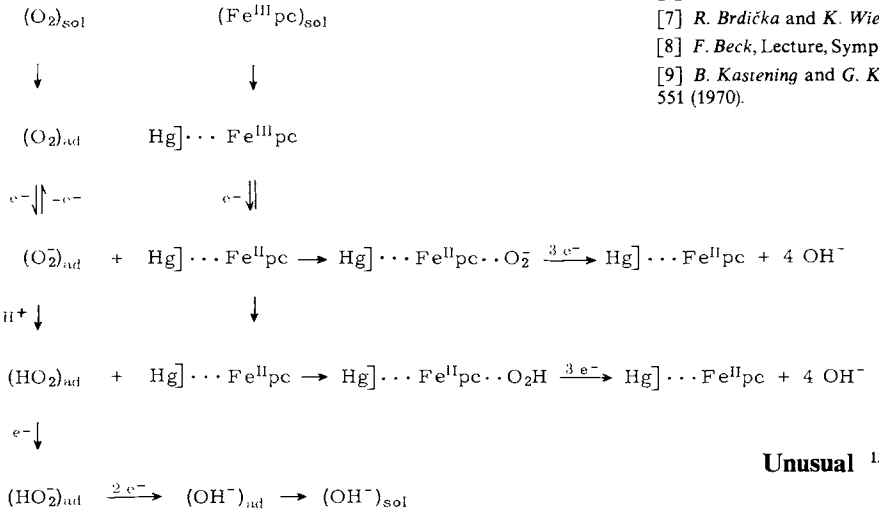
The reason for the current minimum after the catalytic wave (see Fig. 1, b to g) was first suspected to lie in an inhibiting adsorption. However, no adsorption-desorption processes could be detected in the potential range of the minimum by electrocapillary curves or by tensammetric studies.

For all the compounds studied two conditions had to be fulfilled before a catalytic reaction took place:



1) The central atom had to be present in the lower valence state (in some cases after a preceding electrochemical reduction);

2) The first electron already had to have been taken up by the oxygen molecule with formation of the peroxide ion O_2^-.



It is therefore assumed that the catalyst actually reacts with partially reduced oxygen, *i.e.* with O_2^-, to form a complex that favors rapid electron exchange. The oxidant remains bound to the electrode surface by way of the same complex molecule until reaction is complete.

[*] Dr. F. von Sturm and Dipl.-Chem. W. Beyer
Forschungslaboratorien der Siemens AG
852 Erlangen 2, Postfach 325 (Germany)

The drop in current after attainment of the current maximum parallels the taking up of the second electron in the uncatalyzed process. This removal of the O_2^- ion or the

protonated HO_2 radical with increasing negative potential in the competing electrode reaction uses up the starting material for the catalytic process. The overall reaction course is envisaged as shown in the following scheme:

In aqueous solution the product of the first incorporation of an electron can only be stabilized by inhibition of the subsequent protonation (*e.g.* by triphenylphosphane oxide) and thus of the taking up of the second electron[9]. In methanolic electrolytes the two steps can be resolved, without the need for an inhibitor, by square-wave polarography (see Fig. 2).

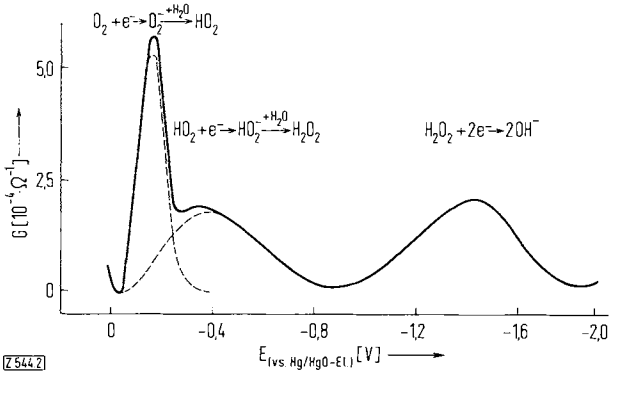


Fig. 2. Square-wave polarogram of oxygen reduction (0.1 M LiOH in methanol), air-saturated, 25 °C; square-wave amplitude 2 mV).

The first step is fast and gives rise to a well developed peak in the square-wave polarogram at −0.175 V. The second electron can only be taken up after completion of the inhibited reaction of peroxide-anion protonation; here the square-wave polarogram exhibits a flat wave at −0.36 V. Addition of water shifts the second wave into the first, thus indicating acceleration of HO_2 formation.

Addition of CN^- ions ($>10^{-6}$ M) deactivates the iron-phthalocyanine complex. This poisoning can be understood in terms of the bridging complex as a displacement of O_2^- by CN^- from the sixth coordination position.

Unusual ^{13}C Chemical Shifts of Transition Metal-Carbene Complexes

By *Cornelius G. Kreiter* and *Victor Formáček*[*]

In order to update our knowledge of the nature of the bonding in transition metal-carbene complexes[1] we have recorded the Pulse-Fourier-Transform ^{13}C-NMR spectra[2] of a few typical compounds. The complexes to be investigated were so chosen that both M as well as X^1 and X^2 in the general formula

(1)-(5)

could be varied to give a comparative series (see Table).

As can be seen from the table the carbene carbon atoms in *(1)—(5)* are extremely deshielded and their signals lie far outside the range in which the ^{13}C-NMR signals of the more common organic compounds appear[2]. The strong deshielding compares very well with the electron deficiency found from other NMR measurements and dipole studies on a complexed carbene carbon[1].

The ^{13}C-NMR signal of the carbene carbon also shifts quite characteristically on changing M, X^1, and X^2 in *(1)* to *(5)*. If the chromium in *(2)* is replaced by tungsten, compound *(3)* is obtained in which the carbene carbon

[*] Priv.-Doz. Dr. C. G. Kreiter
Anorganisch-chemisches Laboratorium
der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)
Dr. V. Formáček
Bruker-Physik A.G., 7501 Karlsruhe-Forchheim (Germany)

is much more shielded. The presence of the *C*-phenyl group in *(1)* instead of the *C*-methyl group in *(2)* has the same effect, since the delocalized aromatic π-electron system of the phenyl group interacts with the vacant p-orbital of the carbene carbon, whose electron deficiency can thus be more effectively lowered than by the methyl group, which only acts inductively[3]. Similarly, a dependence between degree of shielding and nature of heteroatom is observed in compounds *(3)*, *(4)*, and *(5)*. The less electronegative nitrogen in *(5)* clearly confers more negative charge on the carbene carbon than does the more strongly electronegative oxygen in *(3)*.

In the case of *(5)* measurements were carried out on a mixture of the *cis-trans* isomers[4] (65:35). The isomers, which differ from each other only in the orientation of their *C*- and *N*-methyl groups, exhibit different ^{13}C-NMR spectra. The signals for *cis*- and *trans-(5)* in the table were assigned on the basis of intensities. The ^{13}C-NMR signals of the two isomers appear in the same sequence as do the *N*-methyl signals in the ^{1}H-NMR spectrum, *viz.* the signal of the *cis* isomer appears at higher field than that of the *trans* isomer.

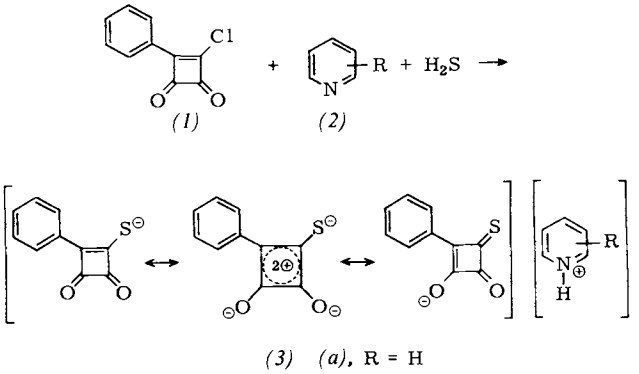

Table. ^{13}C chemical shifts of phenylmethoxycarbenepentacarbonylchromium *(1)*, methylmethoxycarbenepentacarbonylchromium *(2)*, methylmethoxycarbenepentacarbonyltungsten *(3)*, methyl(methylthio)carbenepentacarbonyltungsten *(4)* and methyl(methylamino)carbenepentacarbonyltungsten *(5)*. Measurements on *ca.* 20% solutions in [D_6]-benzene with a Bruker-Multikern Spectrometer HX 90/8 at 22.63 MHz. The chemical shifts are given in ppm relative to TMS as internal standard.

Cpd.	M	X^1	X^2	δC(Carbene)	δC(CO) *trans*	δC(CO) *cis*	$\delta C(X^1)$	$\delta C(X^2)$
(1)	Cr	OCH_3	C_6H_5	−351.42	−224.57	−216.67	−66.62	−153.82 (C-1) −130.26 (C-4) −128.38 (C-2, C-6) −122.89 (C-3, C-5)
(2)	Cr	OCH_3	CH_3	−360.23	−223.76	−216.93	−66.08	−48.10
(3)	W	OCH_3	CH_3	−332.90	−203.62	−197.60	−69.67	−51.51
(4)	W	SCH_3	CH_3	−332.54	−207.40	−198.05	−26.43	−47.11
cis-(5)	W	$NHCH_3$	CH_3	−255.67	−203.44	−198.86	−33.71	−46.39
trans-(5)				−258.73	−203.44	−199.40	−36.68	−41.62

It is worth noting that the $\delta C_{carbene}$ values for *(3)* and *(4)* are virtually equal, thus indicating an almost equivalent degree of charge transfer in the case of oxygen and sulfur. An explanation for this could be the unfavorable overlapping of the large filled p-orbital of the sulfur with the smaller vacant p-orbital of the carbene carbon[5].

In all the carbene complexes investigated, the signal of the *trans* CO-ligands is found to appear downfield from that of the *cis* CO-ligands. It is also observed that most of the ^{13}C-NMR signals of the X^1 and X^2 groups of *(1)*—*(5)* lie outside the range in which signals for these groups in organic molecules characteristically appear. Some of the signals are shifted about 2 ppm downfield; once again the strong electron withdrawing power of the carbene carbon is also apparent.

3-Mercapto-4-phenyl-3-cyclobutene-1,2-dione[***]

By *Arthur H. Schmidt, Walter Ried, Peter Pustolemsek,* and *Hans Dietschmann*[*]

We wish to report on the synthesis and properties of 3-mercapto-4-phenyl-3-cyclobutene-1,2-dione (PCB—SH) *(5)*, the first thio analog of the well-known PCB—OH[1].

Because of its expected high acidity and its capability of being transformed into the novel 4-phenyl-3-thiolatocyclobutenediylium 1,2-diolate system[2], compound *(5)* proves to be a very important representative of the phenylcyclobutenedione series.

Dropwise addition of a benzene solution of *(1)* into pyridines *(2)* saturated with hydrogen sulfide leads to formation of the pyridinium salts *(3)*[2], which have been characterized chemically and spectroscopically (see Table).

In agreement with the salt structure, no peaks for the molecular ions appear in the mass spectra of *(3a)*—*(3c)*. On the other hand, a peak due to the anion whose mass is increased by one unit (*m/e* 190) and the peak of the cation both appear with high intensity.—The absence of an IR

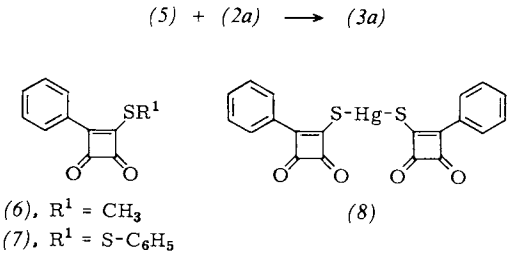
band at about 1600 cm^{-1} (C=C in the four-membered ring) and the shift of the C=O absorptions to lower wave numbers support the given structure.

(3a) reacts with *(1)* to give the thioether *(4)*[3]. We isolated PCB—SH *(5)* from a suspension of *(3a)*—*(3c)* in concentrated hydrochloric acid. *(5)* forms pale yellow

(4)



(5)

crystals which are readily soluble in methanol, $CHCl_3$, and CH_2Cl_2 and less readily soluble in CCl_4 and H_2O. According to preliminary measurements, *(5)* is more acidic than PCB—OH, whose pK_a has been determined as 0.37 ± 0.04[1a]. The mass spectrum of *(5)* contains characteristic fragments at $m/e = 162$ ($M^+ - CO$) and $m/e = 134$ ($M^+ - 2CO$) in addition to the molecular ion ($m/e = 190$).

The ^{1}H-NMR spectrum[4] contains two multiplets at $\delta = 7.9$—7.75 ppm (2H) and $\delta = 7.5$—7.4 ppm (3H), assigned to the aromatic protons, and a broad signal at $\delta = 4.18$ ppm whose position is characteristic for SH groups of thiocarboxylic acids[5]. The IR spectrum (KBr) shows the SH band at 2490 cm^{-1} (s) (in CCl_4 at 2530 cm^{-1}) and C=O bands at 1770 (s) and 1750 (s) cm^{-1}. Further bands appear at the following wave numbers: 1810 (w), 1590 (m), 1535 (m), 1480 (m), 1265 (s), 1128 (m), 768 (m), 685 (m) cm^{-1}[6].

The following absorptions occur in the UV spectrum of *(5)* (cyclohexane): $\lambda_{max} = 322$ ($\varepsilon = 16350$), 308 (19100), 298 (shoulder), 276 (shoulder), 267 (shoulder), 248 (5200). In ethanol, absorptions occur whose position and intensity compare with those observed in the UV spectrum of pyridinium salt *(3c)* (see Table), thus indicating the presence of an anion of *(5)*. On the other hand, the spectroscopic findings do not provide any definite proof for the occurrence of a tautomeric hydroxy form of *(5)*.

The acidic character of PCB—SH *(5)* is demonstrated by the formation of the pyridinium salt *(3a)* and by the ready conversion into the *S*-methyl ester *(6)* on reaction with diazomethane. Reaction of *(5)* with phenylsulfenyl chloride leads to the unsymmetrical disulfide *(7)*.

(6), $R^1 = CH_3$
(7), $R^1 = S\text{-}C_6H_5$

(8)

When a solution of *(5)* in THF is treated with an aqueous solution of $HgCl_2$, the mercury salt *(8)* precipitates immediately as fine, pale-yellow crystals. (The properties of the new compounds are summarized in the following Table.)

Table. A few properties of the compounds *(3c)* and *(6)*—*(8)*. Correct elemental analyses and mass spectra have been obtained for all compounds excepting *(8)*.

Dehydro *N*-Mannich Bases[***]

By *Alfred Kreutzberger* and *Mehmet Umran Uzbek*[*]

In the Mannich reaction an active compound is allowed to react with formaldehyde and an amine. If the active component contains a nitrogen atom bearing a reactive hydrogen, *N*-Mannich bases are formed. Compounds containing a primary amino group, such as urea[1] or benzamide[2], have also found special use in this type of reaction.

We have now found that when *s*-triazine *(2)* is employed instead of formaldehyde, an analogous condensation takes place with formation of *N*-Mannich bases *(5)* having two hydrogen atoms less. This finding is based on the results of a series of investigations on the aminomethinylation reaction, in which *e.g.* anthranilic acid can be converted into 4-quinazolone by reaction with *s*-triazine[3].

[**] As guest from the Institute of Pharmaceutical Chemistry of the University of Istanbul (Turkey).

[***] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

If 2-aminothiazoles or -thiadiazoles of type *(1)* are used in place of anthranilic acid and its derivatives, either no reaction takes place or, as in the case of 2-amino-4-phenylthiazole *(1a)*, only small yields of the expected *N*,*N'*-disubstituted formamidine derivatives are obtained. When, however, attempts were made to increase the yields by addition of excess amine, *e.g.* piperidine or morpholine, the dehydro *N*-Mannich bases *(5)* were formed, presumably *via* the route shown in the reaction scheme.

2-Aminobenzothiazoles *(6)* can be converted in an analogous way into the dehydro *N*-Mannich bases *(7)*.

The previously described three-component reactions in which the parent compound or derivatives of phenylacetonitrile[4], of picoline *N*-oxides[5], aniline[6], fluorene[7], and phenylhydrazine[7] contain the active hydrogen atom, can also be classed under the present, general type of reaction leading to dehydro Mannich bases.

Tetraorganofluorophosphoranes

By *Hubert Schmidbaur*, *Karl-Heinz Mitschke*, and *Johann Weidlein*[*]

Of the four conceivable organofluorophosphoranes R_nPF_{5-n} having $n=1$—4 only the types RPF_4, R_2PF_3, and R_3PF_2 are adequately known[1]. Hitherto only scattered references have appeared in the literature[2] concerning tetraorganofluorophosphoranes, which may be assumed to exist only in a ionic isomeric form, as phosphonium fluorides $R_4P^+F^-$. It would appear that $[(C_6H_5)_4P]F$[3] and $[(C_6H_5)_3PC_2H_5]F$[2] are the only representatives ever to have been obtained in a pure state (by halogen exchange from other phosphonium salts in both cases). However, this technique usually runs into considerable experimental difficulties.

Syntheses of pure, salt-free ylides[4, 5] and their silylated derivatives[6] have now opened up a direct route to compounds of formula R_4PF. Addition of anhydrous hydrofluoric acid to corresponding ylides gives the desired products just as smoothly as desilylation of the silyl ylides with subsequent HF addition *in situ*, as formulated for tetramethylfluorophosphorane *(1)*:

[*] Prof. Dr. H. Schmidbaur and Dipl.-Chem. K.-H. Mitschke
Institut für Anorganische Chemie der Universität
87 Würzburg, Landwehr (Germany)
Doz. Dr. J. Weidlein
Institut für Anorganische Chemie der Universität
7 Stuttgart 1, Schellingstrasse 26 (Germany)

$$(CH_3)_3P{=}CH_2 + HF \xrightarrow{-70\,^\circ C} (CH_3)_4PF \quad (1)$$

$$(CH_3)_3P{=}CH{-}Si(CH_3)_3 + 2\,HF \xrightarrow{-40\,^\circ C} (CH_3)_4PF + (CH_3)_3SiF \quad (2)$$

(1)

The second reaction is another example of the preparative significance of desilylation reactions[7]. Reaction occurs at about $-70\,^\circ C$ in diethyl ether to give a high yield (>90%) of a crystalline product that was purified by sublimation at 20 °C/0.1 torr.

Compound *(1)*, which is extremely sensitive to moisture, also sublimes in a sealed tube without melting above 100 °C. The mass spectrum of the sublimate recorded at an excitation energy of 18 eV contains a peak for the ion of greatest mass and intensity at *m/e* 95 which corresponds to the fragment $(CH_3)_3PF^+$. This result confirms the presence of discrete molecules having direct P—F bonds in the gaseous state. A complete redissociation into the components $(CH_3)_3PCH_2$ and HF on sublimation can be ruled out. A similar situation is known to prevail in (molecular) $(CH_3)_4SbF$[8] whose mass spectrum is dominated by the ion $(CH_3)_3SbF^+$

The infrared and Raman spectra of crystalline *(1)* at 25 °C indicate that the substance must be largely ionic in the solid state. A pronounced symmetrical PC_4 stretching vibration at 660 cm^{-1}, which is only observable in the Raman, and a correspondingly strong antisymmetric IR vibration at 783 cm^{-1}, which is seen in the Raman spectrum at the same frequency but at very low intensity, provide clear evidence of ionic structure, as does the absence of a characteristic PF band. However, if $(CH_3)_4PF$ vapor is condensed at 10^{-6} torr on to a AgCl disk cooled to $-160\,^\circ C$ and an IR spectrum is recorded without warming the sample, new bands are observed that are most probably ascribable to a molecular compound or its aggregate. The spectrum of the ionic form appears again on heating.

Apart from water, in which dissociation occurs, the only other suitable solvent for *(1)* is CH_2Cl_2, the resulting solutions also undergoing decomposition. The ^1H-NMR spectrum of freshly prepared solutions contain a doublet at $\delta = -2.2$ ppm (TMS) with $^2J(HCP) = 15$ Hz. This spectrum is unchanged at $-85\,^\circ C$. It appears that *HCPF* coupling, as well as the possibility of distinguishing between differently bonded methyl groups, is ruled out by a rapid fluoride ligand exchange. As expected, the ^{19}F-NMR spectrum contains only a singlet at -4.0 ppm (CF_3COOH, external), thus indicating considerable "fluoride" character.

The molecular nature of a R_4PF compound is seen much more clearly in the case of tri(*n*-butyl)methylfluorophosphorane $(n\text{-}C_4H_9)_3(CH_3)PF$ *(2)* prepared from $(n\text{-}C_4H_9)_3P{=}CH_2$ and HF as a colorless liquid that can be distilled without decomposition (m.p. 11—13 °C; b.p. 74—76 °C/0.1 torr) and also dissolves in nonpolar solvents, in which it is found to have unit molecular weight. Triphenyl(methyl)fluorophosphorane $(C_6H_5)_3(CH_3)PF$ *(3)*, m.p. 116—118 °C, b.p. 150 °C/0.1 torr, which can be prepared in an analogous fashion, exhibits similar properties. No *HCPF* coupling is recorded for these compounds either, even in nonpolar solvents, since intermolecular fluorine exchange apparently has to overcome only a very low activation barrier.

Tetramethyl(methoxy)phosphoranes and Related Compounds

By *Hubert Schmidbaur* and *Herbert Stühler*[*]

Although compounds of the type $R_nP(OR')_{5-n}$ have been known for a long time and have been the object of intensive study in recent years, no reliable data have yet become available concerning the existence of simple tetraalkyl(alkoxy)phosphoranes, to say nothing of a knowledge of their structure and bonding. The classical publications by *Ingold et al.*[1] give detailed accounts of the action of alkoxide on phosphonium salts and the resulting degradation—phosphorus analog of the Hoffmann degradation—but the phosphonium alkoxides defied all attempts at isolation, as in numerous other studies[2]. In contrast, there is a wealth of information about prototypes of the formulas $P(OR')_5$, $RP(OR')_4$, $R_2P(OR')_3$, and $R_3P(OR')_2$.

We have now found that tetramethyl(methoxy)phosphorane *(1)* and its homologs are readily available in quantitative yields from the pure, salt-free ylides[3] and alcohols. Thus *(1)* is formed by addition of anhydrous methanol to trimethyl(methylene)phosphorane in diethyl ether or benzene at room temperature as a colorless distillable liquid (m.p. -46 to $-44\,^\circ C$; b.p. 48 °C/30 torr) that gradually decomposes above 130 °C.

$$(CH_3)_3P{=}CH_2 + HOCH_3 \rightleftharpoons (CH_3)_4POCH_3 \quad (1)$$

(1)

The compound hydrolyzes very readily and reacts with halohydrocarbons, carbonyl compounds, and nitriles. It is found to have unit molecular weight in benzene (cryoscopic). Only fragments are seen in the mass spectrum, mainly $(CH_3)_3PO^+$ and its degradation products. This is not very surprising since polyalkoxyphosphoranes have been observed to behave similarly[4].

Under normal conditions, the ^1H-NMR spectrum of toluene solutions shows only two singlets in the expected area ratio; the larger signal is very slightly broadened. At low temperatures the expected doublet splitting is observed ($^2J(HCP) = 14$ Hz). It appears that just enough of the starting materials is in equilibrium with *(1)* at room temperature for rapid proton exchange (NMR time scale) on the $(CH_3)_4P$ group. This is in accord with the finding that the process is decelerated on addition of an excess of methanol. No coupling $^3J(HCOP)$ was observed. This interaction does not occur because the process shown in eq. (1) is accompanied by an exchange of the methoxy groups between the $(CH_3)_4P$ groups, similar to that of the fluorine atoms of $(CH_3)_4PF$[5].

[8] *H. Schmidbaur, K.-H. Mitschke*, and *J. Weidlein*, Chem. Ber. *102*, 4136 (1969). Mass spectra: *H. Schmidbaur*, unpublished.

The IR spectrum of liquid *(1)* is complex owing to the low C_s symmetry assumed for each of the possible structures. However, it does rule out an ionic structure $[(CH_3)_4P]^+OCH_3^-$, as well as significant concentrations of free ylide and methanol, whose presence could be expected from eq. (1). In contrast, real analogies to (covalently bonded) $(CH_3)_4SbOCH_3$[6] are apparent.

With a large excess of methanol, *(1)* gives a colorless crystalline adduct of composition $(CH_3)_4POCH_3 \cdot 2CH_3OH$ and of unknown structure (m. p. 62—64 °C).

$(CH_3)_3P{=}CH_2$ and ethanol give the colorless distillable compound tetramethyl(ethoxy)phosphorane (b. p. 50 °C/30 torr) which exhibits similar spectroscopic properties to *(1)*. The reaction products from isopropanol and *tert*-butanol decompose slowly at room temperature to give phosphane oxides. Similar reactions occur in the case of trimethylsilanol. The last-named alcohols, however, also give highly stable adducts having a greater alcohol content:
$(CH_3)_4POC_2H_5 \cdot 2C_2H_5OH$;
$(CH_3)_4POCH(CH_3)_2 \cdot (CH_3)_2CHOH$; and
$(CH_3)_4POC(CH_3)_3 \cdot (CH_3)_3COH$.

Addition of phenol to $(CH_3)_3P{=}CH_2$ gives crystalline $(CH_3)_4POC_6H_5$ (m. p. 71—75 °C, decomp.) whose NMR spectrum contains a doublet for the $(CH_3)_4P$ group at 25 °C in CH_2Cl_2. The proton exchange analogous to eq. (1) obviously becomes slower with increasing acidity of the alcohol. In contrast, the exchange is accelerated with increasing stability of the ylide: solutions of colorless crystalline triphenyl(methyl)methoxyphosphorane formed on addition of CH_3OH to $(C_6H_5)_3P{=}CH_2$ are weakly tinged with the yellow color of the starting ylide, and the CH_3P doublet in the ^1H-NMR has coalesced to a singlet.

Nature of the "Silicon β-Effect" in Allyltrimethylsilane[1]

By *Ulrich Weidner* and *Armin Schweig*[*]

Allylsilanes, $R_3Si{-}CH_2CH{=}CH_2$, exhibit unusual spectral properties and a high reactivity towards electrophiles; furthermore, like other alkylsilanes having β-functions, they are readily fragmented with breakage of the Si—C bond[2]. This "silicon β-effect" has been interpreted in terms of two qualitative models, *viz.* pd conjugation and Si—C hyperconjugation[2]. In the present communication we derive a clear argument in favor of Si—C hyperconjugation from the photoelectron (PE) spectra of trimethylvinylsilane *(1)* and trimethylallylsilane *(2)* and approximate quantum-chemical calculations (CNDO/2 method)[3].

Fig. 1 shows the PE spectra of *(1)* and *(2)*[4] and Fig. 2 the experimental vertical ionization potentials *(IP)* and the

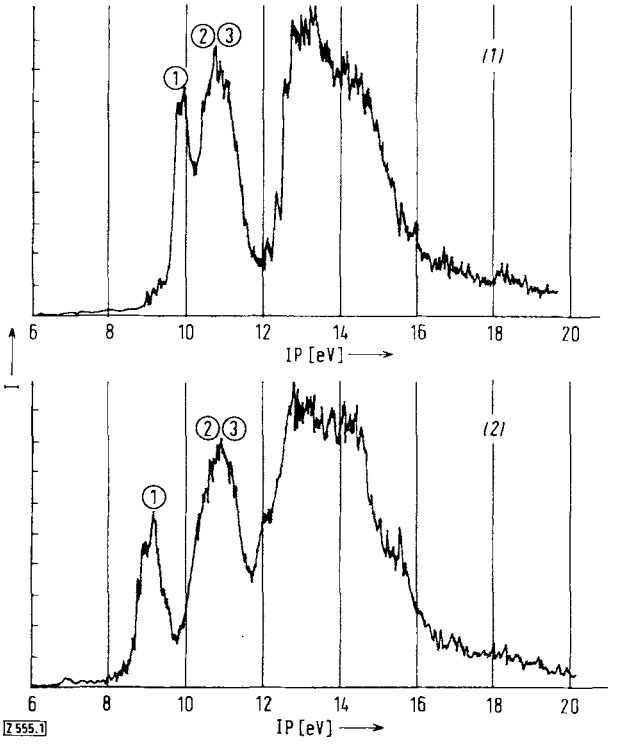

Fig. 1. Photoelectron spectra of trimethylvinylsilane *(1)* and trimethylallylsilane *(2)*.

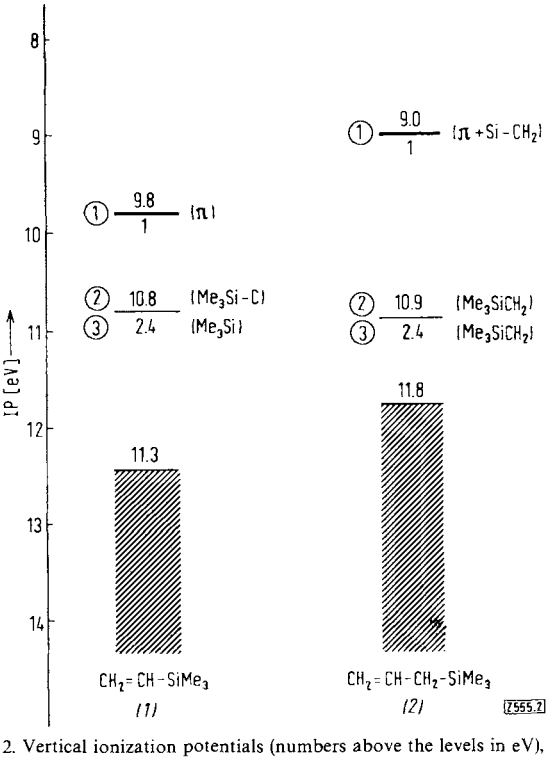

Fig. 2. Vertical ionization potentials (numbers above the levels in eV), relative intensities (numbers under the levels), and assignment of the bands ① and ②③ in the spectra of Fig. 1.

[*] U. Weidner and Prof. Dr. A. Schweig
Physikalisch-chemisches Institut der Universität
355 Marburg, Biegenstrasse 12 (Germany)

relative intensities of the first two bands ① and ②③. A comparison with other vinylsilanes suggested that the HOMO in *(1)* is the π MO having a node between the ethylene π system and the Me_3Si substituents[5]. The band ②③ is due to ionization of the σ MO linking Me_3Si and C, and of a second σ MO localized in the Me_3Si group. The shift of ① by 0.8 eV can be regarded as a characteristic difference between *(2)* and *(1)*[6]. The maximum of the band ②③ remains almost constant in the case of *(2)*. This band is due to ionization of two MOs localized in the σ skeleton of the Me_3SiCH_2 groups[8].

The reason for the unexpected raising of the HOMO in *(2)* is understandable with the aid of Figure 3 which shows the calculated orbital energies for one conformation of *(1)* and two conformations of *(2)*. In *(2a)* the CH_2-Si bond is perpendicular to the ethylenic π-electron clouds but practically parallel to them in *(2b)*; the two conformations undergo mutual interconversion on rotation about the $—CH_2—CH=$ bond. CNDO/2 model calculations were performed for each of the three conformations with and without inclusion of d AOs on the silicon atom (spd and sp basis set respectively). They show that *(2b)* is more stable

Since all three properties that characterize the β-effect—unusual spectral properties (above all bathochromic UV shifts), high reactivity towards electrophiles, and ready fragmentation with breakage of the Si—C bond—are connected with the high energy of the HOMO and the participation of the Si—C bond in the π system we can deduce that the "silicon β-effect" has to be interpreted in terms of Si—C hyperconjugation.

than *(2a)* by 5.1 kcal/mol (sp basis set) or 3.3 kcal/mol (spd basis set); *i.e.* the conformation permitting CH_2-Si hyperconjugation is the more stable. It may be seen that the observed elevation of the HOMO can only be explained by conformation *(2b)*. This elevation arises from a coupling of the π-type CH_2-Si σ MO with the ethylenic π system having a node between $—CH_2—CH=$. According to these findings, the elevation of the HOMO on going from *(1)* to *(2)* can be explained unequivocally by Si—C hyperconjugation but not by pd conjugation.

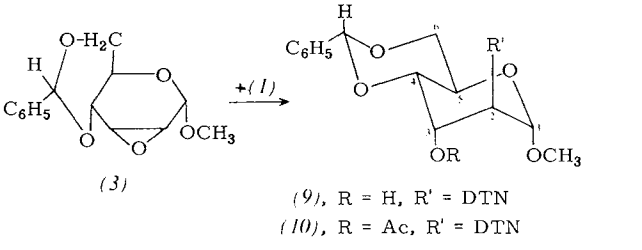
[8] Note added in proof: A more detailed study of the second band in the spectra of *(1)* and *(2)* has revealed that this band probably should be attributed to three MOs.

Synthesis and Pulse Fourier Transform ^{13}C-NMR Spectra of Branched-Chain Carbohydrates[**]

By *Anne-Marie Sepulchre, Gabor Lukacs, Georges Vass,* and *Stephan Dov Gero*[*]



Although much progress has been made recently toward the preparation of branched-chain antibiotic sugars[1], further synthetic approaches seem desirable in this area. Our attention was drawn to the possible exploitation of 2-lithio-1,3-dithiane *(1)*[2] for the synthesis of branched-chain sugars and also for their chain extension. The 1,3-dithianyl side chain allows a variety of chemical modifications leading to functional groups such as CHO, CH_2OH, CH_3, CO, *etc.*

We report here the reaction of *(1)* with methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside *(2)*, methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside *(3)*, and 5,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranoside *(4)*. Reaction of *(2)* with equimolar quantities of *(1)* (R = H) in dry THF solution for three days afforded the highly crystalline methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-(1,3-dithian-2-yl)-α-D-altropyranoside *(5)* in 50% yield, m. p. 195–197 °C, $[\alpha]_D$ +112° (*c* = 2.27; $CHCl_3$). The structure

(4) *(11)* *(12)*

of *(5)* was established from the mass, ^{1}H-NMR, and ^{13}C-NMR spectral data (Table) of its 2-*O*-acetate *(6)*.

Treatment of *(5)* with HgO and BF_3 · ether in aqueous THF[3] gave methyl 4,6-*O*-benzylidene-3-deoxy-3-*C*-formyl-α-D-altropyranoside *(7)*, m. p. 125—130 °C, $[\alpha]_D$ +67.4° (*c* = 0.94; $CHCl_3$), 80% yield, which was characterized as its crystalline *p*-nitrophenylhydrazone *(8)*, m. p. 122—124 °C, $[\alpha]_D$ +49.5° (*c* = 0.77; ethyl acetate).

When a solution of *(3)* was treated with equimolar quantities of *(1)* in dry THF solution for three days, followed by direct acetylation of the reaction mixture, methyl 3-*O*-acetyl-4,6-*O*-benzylidene-2-deoxy-2-*C*-(1,3-dithian-2-yl)-α-D-altropyranoside *(10)*, m. p. 78—80 °C, $[\alpha]_D$ +33° (*c* = 0.94; $CHCl_3$), was obtained in 30% yield; the product exhibited a molecular ion peak in the mass spectrum at *m/e* 426. Unreacted epoxide *(3)* was recovered (45%) before acetylation. The structure of *(10)* was deduced unequivocally from its ^{1}H-NMR and ^{13}C-NMR spectral data (Table). Because of the poor solubility of *(3)* and *(1)* in ethereal solvents optimization of the yield of *(10)* was not attempted.

Table. Assignments of the signals in the ^{1}H-broad band decoupled 25.15-MHz PFT ^{13}C-NMR spectra of *(6)* and *(10)*. Accumulation of 700 pulses, pulse width 15.1 μs, pulse interval 1.5 s. δ-values relative to TMS = 0.

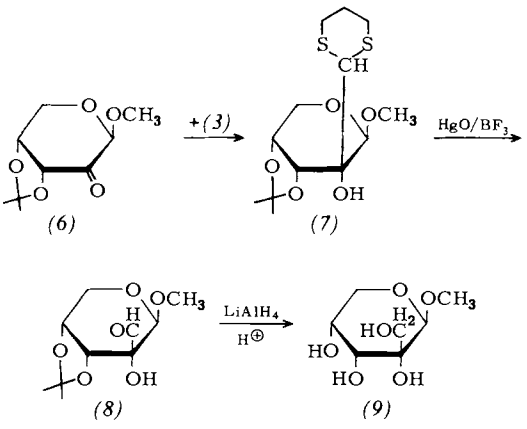
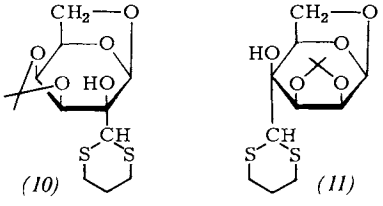
Synthesis of Branched Carbohydrates with Aldehyde Side-Chains.—Simple Synthesis of L-Streptose and D-Hamamelose



By *Hans Paulsen, Volker Sinnwell,* and *Peter Stadler*[*]

Hitherto, the synthesis of branched sugars with aldehyde or keto groups in the side-chain has remained a problem in the field of carbohydrate chemistry that has not been solved satisfactorily. We have now found that the reagent described by *Seebach*[1], 1,3-dithian-2-yllithium *(3)*, proves to be very useful for the preparation of compounds of this type. Blocked cyclic hexuloses react with *(3)* in good yields to give branched sugars in which the side-chain contains an aldehyde group blocked by mercaptal; *e.g.* reaction of 1,2;5,6-di-*O*-isopropylidene-α-D-glucofuranos-3-ulose with *(3)* gives *(1)* (m.p. 97°C, $[\alpha]_D^{20} = +32.1°$) in 62% yield. As a rule the reaction proceeds stereoselectively and favors formation of the isomer in which the large 1,3-dithiane group is least hindered. Since 1,3-dithiane compounds form excellent crystals they can be prepared in a highly pure state prior to use in the following desulfurization step:



The reaction sequence is probably best illustrated by using the synthesis of L-streptose as example: reaction of the 3-ulose *(2)*[2] with *(3)* affords the dithiane-sugar *(4)* (m.p. 141°C, $[\alpha]_D^{20} = -3.0°$, 89%), which can be desulfurized with HgO/BF_3-ether[3] in THF to give *(5)* (m.p. 80—82°C, $[\alpha]_D^{20} = +43°$, 65%) which crystallizes as the hydrate. Acid hydrolysis of *(5)* yields the free L-streptose (syrup, $[\alpha]_D^{20} = 17.9°$, 90%)[2]. A critical step in the reaction sequence is the desulfurization, *e.g.* *(4)* → *(5)*, which must always be carried out under carefully controlled conditions. The blocked streptose derivative *(4)* is a valuable starting material *e.g.* for the synthesis of glycosides.

The 2-ulose *(6)*[4] reacts with *(3)* stereoselectively to give *(7)* (m.p. 102°C, $[\alpha]_D^{20} = -74.3°$, 78%). Desulfurization of *(7)* leads to the aldehyde-sugar *(8)* (syrup, $[\alpha]_D^{20} = -192°$, 75%), which can be converted by reduction with $LiAlH_4$ in THF and subsequent acid hydrolysis (Amberlite 120 $H^{\oplus}$) into the methyl glycoside of the D-hamamelose *(9)* (m.p. 133°C, $[\alpha]_D^{20} = -149.3°$, 70%)[5]. In the 1,6-anhydro series, reaction of *(3)* with 1,6-anhydro-3,4-*O*-isopropylidene-β-D-lyxohexopyranos-2-ulose[6] leads

to the dithiane-sugar *(10)* (m.p. 158°C, $[\alpha]_D^{20} = +98°$); reaction with 1,6-anhydro-2,3-*O*-isopropylidene-β-lyxo-hexopyranos-4-ulose[6] yields the sugar *(11)* (m.p. 161°C, $[\alpha]_D^{20} = +4.5°$) with a side chain on C-4.

Acyclic blocked aldehyde-sugars also react, but in this case a mixture of isomers is formed. 2,3;4,5-Di-*O*-isopropylidene-D-arabinose affords a crystalline mixture of the corresponding dithiane compounds of D-glucose and D-mannose, the major component being D-glucose, which can be separated by fractional crystallization.

Dithiane derivative (4)

A solution of *(2)* (1.7 g, 10 mmol) in THF (10 ml) is added dropwise with stirring at −78°C to a freshly prepared solution of *(3)* from 1,3-dithiane (1.25 g, 10.5 mmol) in THF (10 ml). The reaction mixture is warmed to room temperature, stirred for 1 hour, and then poured into ice-water (50 ml). The aqueous solution is repeatedly extracted with chloroform. The combined washings are dried over $MgSO_4$, concentrated by evaporation, and the residue remaining after removal of excess 1,3-dithiane by sublimation is recrystallized from ethyl acetate/petroleum ether. *(4)* is obtained in 89% yield (2.6 g) [m.p. 141°C, $[\alpha]_D^{20} = -3.0°$ ($c = 1$ in acetone)].

1,2-O-Isopropylidene-L-streptose (5)

A solution of *(4)* (1.46 g, 5 mmol) in THF (7 ml) is added dropwise with vigorous stirring to a mixture of red HgO (3.9 g, 18 mmol) and BF_3-ether (15 mmol) in aqueous THF (30 ml; 15% H_2O). Cleavage of dithiane is complete after 50 hours' stirring at room temperature. The mixture is

then treated with 15 ml H_2O and 30 ml acetone. The precipitate that is formed is removed by centrifugation and the centrifugate is concentrated by evaporation and subsequently extracted several times with chloroform. Concentration and drying of the chloroform phase yields a syrup, which, on treatment with a little water and ether, affords *(5)* as the crystalline hydrate. Recrystallization from acetone yields 650 mg of *(5)* (65%), m.p. 80—82°C, $[\alpha]_D^{20} = +42.8°$ ($c = 1.0$ in dioxane).

"Electron Lone Pairs" in Organic Sulfides and Disulfides[1]

By *Hans Bock* and *Gerhard Wagner*[*]

Dedicated to Professor O. Glemser on the occasion of his 60th birthday

Hydrogen sulfide is more readily ionized than water; the difference between the first ionization potentials ($IE_1(H_2S) = 10.48$ eV; $IE_1(H_2O) = 12.61$ eV)[2] reflects the more effective screening of the 3p electrons from the positive nuclear charge. The next σ molecular orbital (C_{2v}:$3a_1$) is more strongly bonding in H_2S (∢HSH 92.2°) than in H_2O (∢HOH 104.5°)[3]. The band assigned to the lone pair n_S in the photoelectron (PE) spectrum of hydrogen sulfide[2] is isolated and therefore well suited for the study of intramolecular interactions in organic sulfides: Any substitution on the H_2S molecule must lead to delocalization of the lone pair n_S and thus to a reduced ionization potential IE_1. From a formal viewpoint the following effects can be considered (Fig. 1): Antibonding admixture of σ components (1); n_-/n_+ combination with additional electron pairs (2); and π conjugation (3).

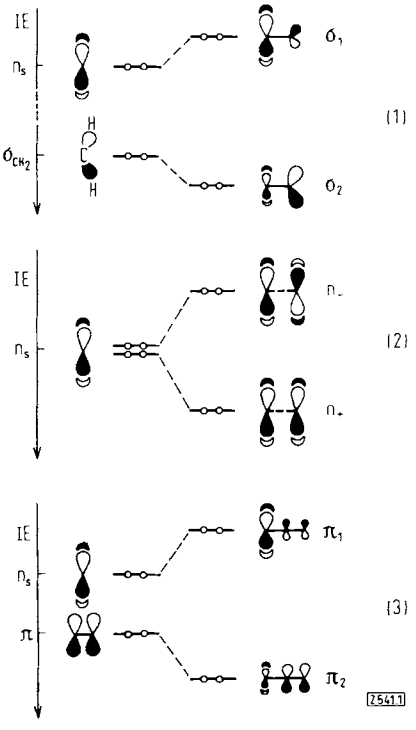

Fig. 1. Qualitative MO schemes for n_S/σ_{CH_2}, n_S/n_S, and n_S/π splitting.

[*] Prof. Dr. H. Bock and Dr. G. Wagner
Institut für Anorganische Chemie der Universität
6 Frankfurt 70, Ludwig-Rehn-Strasse 14 (Germany)

(1) As a result of inductive donor effects and of antibonding admixture of σ_{CH} components in the three-dimensional molecular skeleton (Fig. 1, (1)), alkyl groups lower the n_S ionization energy (Table 1).

Table 1. Vertical PE ionization potentials IE_1 (eV) of sulfides.

	R	IE_1
HSH		10.48 [2]
RSH	CH_3	9.44
RSR	CH_3	8.67
	C_2H_5	8.44
	C_3H_7	8.34
	$CH(CH_3)_2$	8.26
	$C(CH_3)_3$	8.07

Growing chain length and increasing degree of branching of the substituent R further raise the highest molecular orbital with predominating n_S character. These energy changes can also be deduced for dialkyl sulfides from the charge transfer (CT) excitation energies of their σ complexes with tetracyanoethylene (TCNE)[5] according to[4]

$$IE_v\,(\text{eV}) = 3.209 + 2.661 \cdot 10^{-4} \tilde{\nu}_{max}^{CT}\,(\text{cm}^{-1}); \quad SE = 0.011\ \text{eV} \qquad (1)$$

(2) Spatial interaction between sulfur lone pairs in dithiaalkanes (Table 2) causes splitting into an n_- and an n_+ combination (Fig. 1, (2)).

Table 2. Vertical PE ionization potentials $IE_{1,2}$ (eV) of dithiaalkanes [11].

	R	IE_1	IE_2	ΔIE
RSSR	CH_3	8.97	9.21	0.24
	C_2H_5	8.70	8.92	0.22
	C_3H_7	8.62	8.87	0.25
	$CH(CH_3)_2$	8.54	8.76	0.22
	$C(CH_3)_3$	8.17	8.82	0.65
		8.36	9.31	0.95
$RS-CH_2SR$	CH_3	8.65	8.90	0.25
		8.33	8.76	0.43
		9.69	10.16	0.47
$RS-(CH_2)_2-SR$	CH_3	8.64	8.90	0.26
		8.46	8.95	0.49

For a constant interatomic distance S ··· S the splitting is dependent upon the dihedral angle ω. In the case of coplanarity (ω = 0°, 180°) the difference between the first two ionization potentials ΔIE, and also the electronic repulsion neglected in the one-electron MO scheme (Fig. 1, (2)), would reach a maximum. The dihedral angle in dimethyl disulfide is ω = 84.7°[6] and the n_-/n_+ splitting (with admixture of σ_{CH}) therefore amounts to only $\Delta IE = 0.24$ eV. Larger values of ΔIE (Table 2) are observed when the angle is increased by bulky *tert*-butyl groups (ω ≈ 110°) or when it is decreased by fixation in a six-membered ring (ω = 60°[7]). A value of $\Delta IE > 2$ eV can be estimated for ω = 0°.

An increase in the interatomic distance S ··· S by insertion of a CH_2 group reduces the "through-space" interaction between the sulfur lone pairs (Fig. 1, center); at the same time, "through bond" interactions[8] with orbitals of the same symmetry class (Fig. 1, above) should be operative.

Such reasoning provides a qualitative explanation of the varying ΔIE values of the 1,3-dithia compounds (Table 2) on the basis of Figure 2.

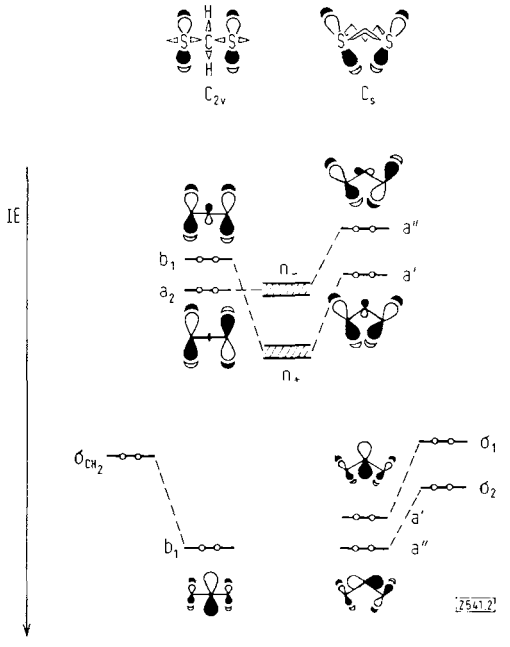

Fig. 2. Qualitative MO schemes for n_S/n_S and n_S/σ interactions in 1,3-dithia compounds.

EHT calculations on the open-chain compound 2,4-dithiapentane in the C_{2v} conformation show the n_+ MO to lie above the n_- MO whose symmetry properties (asymmetric with regard to both mirror planes) rule out admixture of σ_{CH_2} orbitals. In the 1,3-dithiane (C_s) and in bis(thiophosgene) (D_{2h}), however, combinations with molecular orbitals σ_n are symmetry allowed for both n_+ and n_- so that the sequence $IE(n_-) < IE(n_+)$ is retained. Similar differences between the lowest PE ionization potentials are observed (Table 2) in 1,4-dithia compounds, in spite of the large S···S distance ($d_{S\cdots S} \geq 3.5$ Å[9]); this can be interpreted in terms of predominating "through bond" interaction[8].

(3) The delocalization of the sulfur "lone pairs" is particularly clear in thio-substituted π systems[1,4]. The n_S/π conjugation can be described quantitatively by SCF calculations[10] (Fig. 1, (3)) and discussed qualitatively as a perturbation of the π systems. Comparison of the first ionization potentials of dimethyl sulfide (Table 1: 8.67 eV) and of unsubstituted as well as thio-substituted π systems (Table 3) shows, *e.g.*, that the perturbation increases with the number of substituted centers and decreasing energy difference $|IE_\pi - IE_{n_S}|$.

Table 3. Vertical PE ionization potentials IE_i (eV) of π systems and their methylthio derivatives.

	IE_i(X = H)	IE_i(X = SCH_3)
	10.51 [2]	8.45
	10.51	7.96
	9.24	8.07
	9.08 [2]	7.48
	8.55	8.75
	8.15	7.71

The PE ionization potentials IE_1 can only be correlated with the CT excitation energies of the TCNE complexes by the regression

$$IE_v\,(\text{eV}) = 5.769 + 1.335 \cdot 10^{-4}\,\tilde{\nu}_{max}^{CT}\,(\text{cm}^{-1}); \quad SE = 0.017\ \text{eV} \qquad (2)$$

which differs from (1) and which is calibrated with other π systems. Yet more convincing evidence for the delocalization of the sulfur "lone pairs" is provided by the increased ionization energies in the PE spectra which completely confirm, *e.g.* for *trans*-1,2-bis-(methylthio)ethylene, the splitting scheme (Fig. 3) deduced from a symmetry-allowed combination of π- and n orbitals.

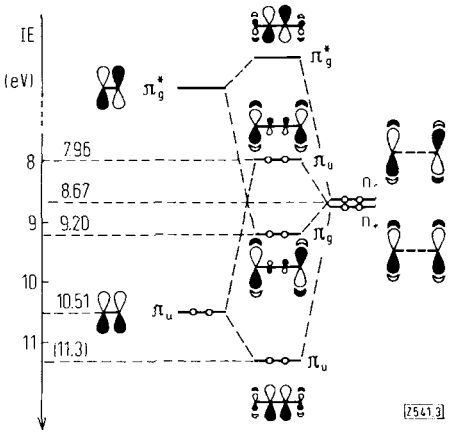

Fig. 3. Qualitative MO scheme for n_S/π interaction in *trans*-1,2-bis-(methylthio)ethylene.

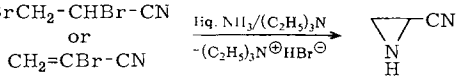
2-Cyanoaziridine



By *Klaus Burzin* and *Klaus Enderer*[*]

Dedicated to Professor Franz Broich on the occasion of his 65th birthday.

Whereas the synthesis of *N*-substituted 2-cyanoaziridines has been reported on a number of occasions[1,2], unsubstituted 2-cyanoaziridine *(1)* has only been postulated

[*] Dr. K. Burzin and Dr. K. Enderer
Forschungslaboratorien der Chemischen Werke Hüls
Aktiengesellschaft
437 Marl (Germany)

as an intermediate in the reaction of 2,3-dichloropropionitrile and of 2-chloro-3-methoxypropionitrile with ammonia[3]. *Gundermann et al.* reported an unsuccessful attempt at synthesizing *(1)*[2]. We have synthesized *(1)* by reaction of 2,3-dibromopropionitrile or 2-bromoacrylonitrile[4] with liquid ammonia[5] in the presence of triethylamine.

The structure of *(1)* follows from elemental analysis and the following spectral data: NMR ($CDCl_3$): $\tau = 8.56$ (1H/broad s), 7.86 (2H/d), 7.44 (1H/q); IR (film): ν(N—H) = 3300 cm^{-1}, ν(C≡N) = 2230 cm^{-1}. Reaction of *(1)* with *p*-nitrobenzoyl chloride in ether in the presence of triethylamine gives 1-*p*-nitrobenzoyl-2-cyanoaziridine [pale yellow crystals, m.p. 95 °C (isopropanol)] in 96% yield. Elemental analysis, IR spectrum, and NMR spectrum are in accord with the given structure.

2-Cyanoaziridine (1)

2,3-Dibromopropionitrile (0.5 mol) or 2-bromoacrylonitrile (0.5 mol) is added dropwise with stirring to liquid ammonia (800 ml) at −30 to −40 °C. After two hours, triethylamine is added in an amount equivalent to the hydrogen bromide released and the resulting mixture is stirred for a further 15—20 hours at −30 to 35 °C. The mixture is then allowed to warm to room temperature, and gently heated to remove last traces of ammonia. The residue is extracted with anhydrous ether (2 × 300 ml). The ethereal solution is concentrated to *ca.* 80 ml and filtered through aluminum oxide (20 g, activity III, neutral). After removal of ether, the residue is distilled[6] at 38—39 °C/0.1 torr through a 10 cm Vigreux column to a colorless oil (yield 65—70%).

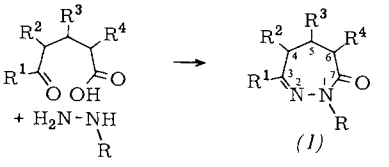
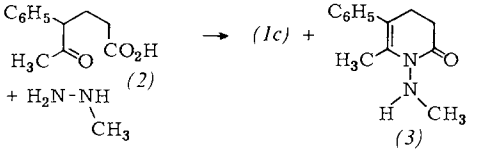
[5] A number of 2-alkoxycarbonylaziridines have been prepared by the same method: *E. Kyburz*, *H. Els. St. Majnoni*, *G. Englert*, *C. v. Planta*, *A. Fürst*, and *Pl. A. Plattner*, Helv. Chim. Acta *49*, 359 (1966); *A. Fürst*, *E. Kyburz*, and *St. Majnoni*, German Pat. 1126879 (1962), Hoffmann-La Roche.



[6] When carrying out the distillation care must be taken to ensure that the bath temperature does not exceed 65 °C, otherwise spontaneous polymerization and consequent destruction of apparatus is likely to take place.

Synthesis of New Diazepinones[**]

By *Camille-Georges Wermuth* and *Jean-Jacques Koenig*[*]



In connection with our studies on pharmacologically active diaza heterocycles[1,2] we have been able to show that the tetrahydrodiazepinones *(1)* are easily prepared by the action of hydrazine on δ-keto acids.

To the best of our knowledge this is the first reported synthesis of these 5,6-dihydro-4*H*-1,2-diazepin-7(1*H*)-ones. Some related compounds, namely a hexahydro derivative[3], a dihydro derivative[4] and a few analogs from the benzodiazepine series[5], have been mentioned in the literature.

(1)	R^1	R^2	R^3	R^4	R	Yield (%)	M.p. (°C)
a	C_6H_5	H	H	H	H	43	157 (C_6H_6)
b	C_6H_5	H	H	CH_3	CH_3	62	89 (hexane)
c	CH_3	C_6H_5	H	H	CH_3	32	55 (pentane)
d	C_6H_5	H	CH_3	H	H	61	161 (C_6H_6)
e	2-Thienyl	H	H	H	CH_3	76	108 ($AcOC_2H_5$ + hexane)

The cyclization represents a general reaction; however, the free δ-keto acids and not the esters must be used. The reaction of unsubstituted hydrazine with δ-keto acids, in which R^1 and R^2 are aliphatic groups leads to a mixture of inseparable compounds. As expected, the cyclization of 4-phenyl-5-oxohexanoic acid *(2)* with methylhydrazine gives the diazepinone *(1c)*; the isomeric 3,4-dihydro-5-phenyl-6-methyl-1-methylamino-2-pyridone *(3)* is formed as by-product [*(1c)*:*(3)* = 4:1]. This side reaction can be explained by the lability of the benzylic hydrogen in *(2)*.

The structure of the products *(1)* was confirmed by spectral analysis and by analytical data: Molecular peak at *m/e* = 188 in the mass spectrum of *(1a)*. UV (C_2H_5OH): 249 nm (ε = 10000) and 292 nm (7900); IR ($CHCl_3$): 3400 cm^{-1} (N—H), 1655 cm^{-1} (C=O), 1600 and 1580 cm^{-1} (C=N and C=C); NMR ($CDCl_3$): δ = 2.4 (4H) for $—CH_2—CH_2—CO$, 2.99 (2H) for CH_2, 7.3 (3H) and 7.5 (2H) for C_6H_5, and 8.83 (1H) for NH (disappears with D_2O). *(3)* is readily differentiated by NMR spectroscopy from the isomer *(1c)* by the absence of the benzyl proton (δ = 4.22 ppm) and presence of a NH proton (δ = 5.1 ppm, exchangeable with D_2O).

[**] The diazepinones *(1)* can also be named as 5,6-dihydro-4*H*-1,2-diazepin-3(2*H*)-ones, 7-oxo-4,5,6,7-tetrahydro-1*H*-1,2-diazepines, or 1,2-diaza-7-cyclohepten-3-ones.

Experimental:

A solution of δ-keto acid (0.1 mol) in xylene (500 ml) is heated to boiling under reflux in a two-necked flask fitted with reflux condenser and dropping funnel. Hydrazine (0.11 mol) is then added and the mixture heated under reflux for 4—5 hours, after which time the water is distilled off as xylene/H_2O azeotrope. The solvent is removed by evaporation under vacuum and the residue taken up in chloroform. The chloroform phase is washed twice with 10% $KHCO_3$ solution, then with water, and finally dried over $MgSO_4$. After removal of solvent, the residue is purified by distillation, recrystallization or chromatography.

Comparative Studies of the Topography of the Membranes of Mitochondria and Chloroplasts

By *Günter Hauska*[*]

In *Racker's* laboratory at Cornell University, U.S.A. the reconstitution, from its component parts, of the respiratory chain of mitochondria from succinate to oxygen has been achieved (see[1]). However, it was disappointing that the energy in this artificial electron transport system could not be obtained in chemical form as ATP. Evidently, a specific arrangement of the components in the membrane is necessary for ATP synthesis which is coupled to the electron flux. This topography must be known precisely before one can contemplate the construction of a "synthetic mitochondrion" which might possibly lead to the elucidation of one of the most important energy transformations in nature.

The fact that both surfaces of the membrane can be made accessible was a great help in *Racker's* investigations[1]. In isolated mitochondria the surface which carries the coupling factor 1 (F_1, a reversible ATPase) is on the inside directed towards the matrix, whereas membrane vesicles obtained after ultrasonic treatment have this coupling factor outside, accessible from the medium. These two surfaces have been studied systematically. For example, attempts were made to strip components from the surface without disrupting the membrane structure and then to reattach them. Further, the reaction of the bound components with hydrolytic enzymes, with radioactive, impermeable reagents and, finally, with antibodies was investigated.

The results so far can be summarized in a model (Fig. 1). The coupling factors F_1 to F_6 and succinate dehydrogenase (SDH) are accessible from the M-side (M for matrix). The C-side bears the cytochromes c and c_1. Cytochrome c oxidase (a,a_3) is accessible from both sides. It was assumed that cytochrome b and ubiquinone (Q) extend through the membrane. Protons are pumped from the M- to the C-side when the membrane is excited. Both succinate oxidation and oxygen reduction occur on the M-side (Fig. 1).

The membrane of the chloroplast is similar to the mitochondrial membrane in structure and function (in

[*] Dr. G. Hauska

der Universität Bochum
463 Bochum-Querenburg, Postfach 2148 (Germany)

chloroplasts the excitation of electrons in two photosystems occurs in addition to the electron flux). A few of the differences in the morphology of the two organelles disappear after treatment with ultrasonics or detergents, which also yields vesicles which have the coupling factor 1 of photophosphorylation (CF_1) on the outside and the

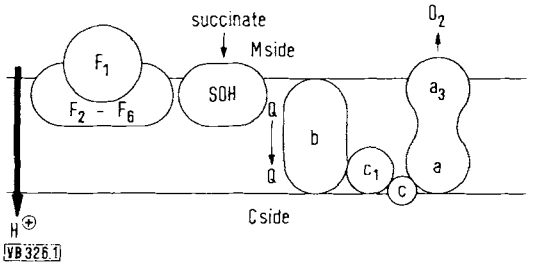

Fig. 1. Model of the mitochondrial membrane.

proton pump directed to the inside. (Bacteria form similar vesicles.) Unfortunately, only one surface of the membrane can be studied directly in chloroplasts since the coupling factor faces the medium immediately after isolation from leaves. It is unclear whether the chloroplast membrane exists *in vivo* with this polarity or whether this is an artifact of isolation. The M-side of the chloroplasts was studied, in the same manner as the mitochondria surfaces. The results are summarized in Fig. 2.

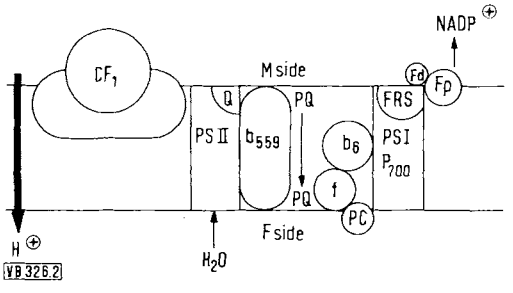

Fig. 2. Model of the chloroplast membrane.

It was assumed that components that are inaccessible are located on the inner surface of the membrane. This seems to be justified, particularly for the hydrophilic plastocyanin (PC)[2]. Coupling factor 1 is found on the M-side[3]. Furthermore, the groups of *Menke* and *Trebst* have found that ferredoxin (Fd)[4], ferredoxin-NADP reductase (Fp)[5] and the reducing end of photosystem I (FRS) (PS = photosystem) are located on this surface. Conversely, cytochrome f and plastocyanin sit on the inside (F-side). It was further assumed that the reaction centers of both photosystems extend through the membrane such that oxygen is formed on the F-side and the reducing end (Q) of photosystem II is located on the M-side. Cytochrome b_{559} is thought to extend through the membrane and plastoquinone (PQ), like ubiquinone, to be dissolved in it. Cytochrome b_6 appears to be tightly linked to photosystem I.

It is obvious that this speculative model is very similar to that for the mitochondrial membrane. In both cases the protein complexes are embedded in layers of lipid.

An analogy between cytochrome c and plastocyanin should also be mentioned. Both of them can react from the M-side with the oxidase and photosystem I respectively, but this artificial electron flux is not accompanied by a phosphorylation. A coupled electron flux is found only when cytochrome c sits on the C-side and plastocyanin on the F-side.

Genetic Organization of the Fatty Acid Synthetase Complex of Yeast

By *Eckhart Schweizer*[*]

The multienzyme complex fatty acid synthetase (M.W. 2.3×10^6) can be dissociated into its protein components by denaturing agents but reassociation of the individual components to yield an active complex again has not yet been achieved[1]. What brings about the ordered association of the components *in vivo*? Is it a process which occurs spontaneously or is it specifically controlled, possibly by a particular organization of the genes involved?

On the basis of the meiotic recombination frequency (tetrad analysis) of appropriate mutants it could be shown that the six known fatty acid synthetase *(fas)*genes[2] are located at three unlinked DNA regions on the yeast genome. The first region consists of one gene, the second of three linked genes and the third of two linked genes.

In the course of a systematic biochemical investigation of representative *fas* mutants we have found that the genes for the enoyl reductase and the dehydratase lie in one of the three *fas* regions and the genes for two of the proteins participating in the condensation reaction as well as that for the β-ketoreductase lie in the second *fas* region. Surprisingly, mutants in the DNA region comprising only one *fas* gene yielded a fully active fatty acid synthetase complex in both the overall fatty acid synthetase reaction as well as all the partial reactions studied. Apparently, acetyl CoA carboxylase activity is not impaired in this mutation.

Pleiotropic polar mutations are also encountered in the *fas* regions 2 and 3, in addition to simple structural gene mutations. Evidently, the proteins of both regions are encoded in a polycistronic mRNA. No synthetase-CRM is to be found on immunological assay of a homogenate of pleiotropic *fas* mutants. The activity of other constituent enzymes which are not primarily affected by the polar mutation may also be missing. It is still not known whether this is due to an allosteric inactivation of the protein in question or to a failure of its synthesis.

Since no linkage of functionally related genes has previously been found in yeast or eucaryotes generally, the linkage of the genes of the fatty acid synthetase complex

[*] Doz. Dr. E. Schweizer
Institut für Biochemie der Universität
87 Würzburg, Röntgenring 11 (Germany)

in two or three polycistronic segments of the genome may be of special significance. It is conceivable that a genetic organization of this kind is a necessary requirement not only for aggregate formation but, particularly, for the formation of the "right" protein complex, *i.e.* it is needed to control its stoichiometry and/or architecture. According to this notion the fatty acid synthetase complex of yeast would be assembled from two to three dissimilar component complexes, the synthesis of which is subject, in each case, to the particularly critical control implied in a linked arrangement of their respective genes. It is possible that the synthesis of the component complexes is also subjected to some kind of mutual co-ordination. This could take the form of typical eucaryotic control mechanisms at the translation level.

New Aspects of the Hydroformylation Reaction

By *Jürgen Falbe*[*]

The catalytic reaction of olefins with carbon monoxide and hydrogen to give aldehydes was discovered in 1938 by *O. Roelen* (Ruhrchemie). It has become known as hydroformylation, the oxo synthesis, or the Roelen reaction. The development of the petrochemical industry, through which lower olefins have become available in sufficient quantities at reasonable prices, provided the basis for the world-wide exploitation of the oxo synthesis in large production plants. In 1970 the annual world capacity for oxo products amounted to about 2.7×10^6 t.

The initially formed aldehydes are hydrogenated to alcohols that are used primarily as solvents and as starting materials for the production of plasticizers and detergents.

[*] Dr. J. Falbe
Ruhrchemie AG
42 Oberhausen-Holten, Postfach 35 (Germany)

About 80% of available production capacity is utilized for conversion of propylene into butyraldehydes.

However, only about two thirds of the propylene is actually transformed into the desired *n*-butyraldehyde, the rest giving isobutyraldehyde as well as other by-products and further reaction products. The reasons for by-product formation were studied and mechanistic interpretations offered. In order to increase the selectivity of the reaction, the tetracarbonylhydridocobalt used as catalyst was modified by replacing the complexed carbon monoxide by compounds of trivalent phosphorus. Although the use of phosphanes[1] does reduce the amounts of isobutyraldehyde and various higher boiling compounds, hydrogenation of the olefin to the paraffin is promoted. Diphosphacyclopentenones[2] that have been investigated at Ruhrchemie lessen the formation of higher boiling compounds, esters, and alcohols and increase the yield of *n*-butyraldehyde; however, they bring about no reduction in the proportion of isobutyraldehyde. Moreover, the increased catalyst costs incurred by catalyst modification counteract the economic advantages of enhanced selectivity.

Attempts were therefore made to cleave isobutyraldehyde into products that can be used again in the oxo synthesis. It was found that partial oxidation or steam reforming affords a synthesis gas that can be re-used in oxo plants[3]. Isobutyraldehyde can also be cleaved into propylene, carbon monoxide, and hydrogen[4] (reversal of the oxo synthesis) on a fixed-bed noble metal catalyst at 250—350 °C. The reaction products can be recycled into the oxo synthesis. This process has been developed on a pilot-plant scale.

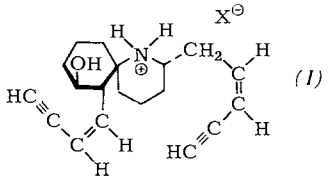
SELECTED ABSTRACTS

Paramagnetic anisotropy of transition metal and rare earth compounds and some minerals is surveyed in a paper by *W. deW. Horrocks jr.* and *W. deW. Hall*. Introductory sections on the theory of diamagnetism and paramagnetism are followed by a fairly detailed description of the most simple and versatile method of measuring magnetic anisotropy: *Krishnan*'s critical torque method. Finally, a documentation of compounds is given for which paramagnetic anisotropy data were available up to 1969 and partly into 1970, together with the pertinent references. [Paramagnetic Anisotropy. Coord. Chem. Rev. *6*, 147 to 186 (1971); 228 references, 4 figures, 1 table]

[Rd 423 IE –H]

The photochemistry of α-dicarbonyl compounds in oxygen-free solutions is the subject of a review by *B. M. Monroe*. Cleavage of a C—C bond is favored in the vapor phase, whereas in the condensed phase hydrogen abstraction preferably takes place. Only sufficiently strained compounds or compounds which can afford sufficiently stable radicals give decarbonylation products. The review deals, *inter alia*, with the excited states of α-dicarbonyl compounds and with photochemical reactions of α-diketones, α-keto acids, and α-keto esters. [The Photochemistry of α-Dicarbonyl compounds. Advan. Photochem. *8*, 77–108 (1971); 120 references]

[Rd 438 IE –M]



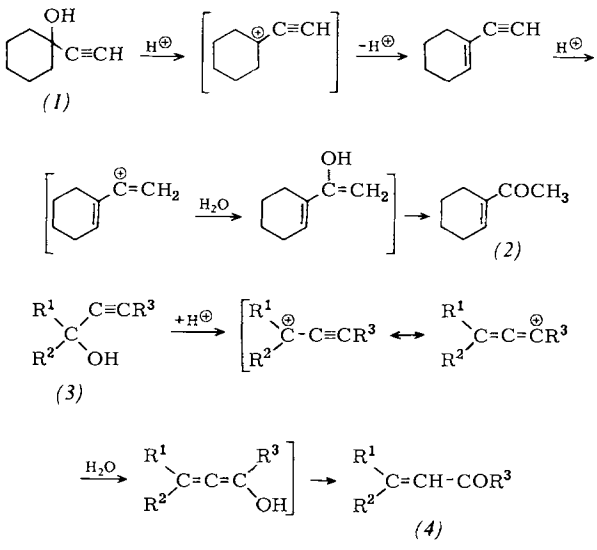
The photochemical and spectroscopic properties of organic molecules in the adsorbed state or in other perturbing polar environments are tabulated by *C. H. Nicholls* and *P. A. Leermakers*. The photochemical behavior of many organic molecules is changed when they are bonded to solid surfaces. This permits the investigation of primary and secondary processes of photochemical reactions. The topics dealt with include, in addition to adsorption itself, the spectra of adsorbed molecules (benzene and derivatives, polycyclic hydrocarbons, ketones, carotinides) and, *inter alia*, their photochemical reactions. [Photochemical and Spectroscopic Properties of Organic Molecules in Adsorbed or other Perturbing Polar Environments. Advan. Photochem. *8*, 315–336 (1971); 60 references, 5 tables]

[Rd 439 IE –M]

Complications in photosensitized reactions are summarized in a report by *P. S. Engel* and *B. M. Monroe*. Choice of sensitizer is very important, since almost all the compounds used as sensitizers are likely to cause complications. The authors give a few rules regarding such a choice. Examples of the complications met with are decomposition of the sensitizers (α- and β-cleavage of ketones, photoenolization, dissociation of halogen compounds), interactions of sensitizer molecules with one another and with substrate (oxetane formation, addition to aromatic hydrocarbons, hydrogen abstraction, reversible energy transfer), and the transfer of energy from a state other than the lowest triplet state (participation of singlet and higher triplet states). [Complications in Photosensitized Reactions. Advan. Photochem. *8*, 245–313 (1971); numerous references, 12 tables, 8 figures]

[Rd 436 IE –M]

New directions of the chemistry of natural products, with particular consideration of the author's own work is the subject of a review by *B. Witkop* in the 13th Paul Karrer lecture. A highlight of the review is a report on histrionicotoxin *(1)*, a component in the poison of the Columbian frog *Dendrobates histrionicus*. *(1)* is the first animal alkaloid containing acetylene residues. Another component, dihydroisohistriotoxin, has one side chain containing an acetylene residue and one containing an allene group; it is the first animal alkaloid with an allene residue.



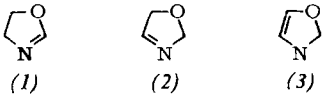
(1)

Other topics dicussed include: batrachotoxin as an auxiliary material in the investigation of Na transport in cell membranes; significance of selective bromocyanide cleavage for the elucidation of protein structure; arene oxides as labile metabolites of aromatic metabolism and their importance as regards long-term toxicology of aromatic medicines and carcinogenic hydrocarbons. [New Directions of the Chemistry of Natural Products: The Organic Chemist as a Pathfinder for Biochemistry and Medicine. Experientia *27*, 1121—1248 (1971); 109 references]

[Rd 448 IE –M]

The Rupe and Meyer-Schuster rearrangements are dealt with by *S. Swaminathan* and *K. V. Narayanan* in a review covering the literature up to the middle of 1968 and in part up to the middle of 1970. The Rupe rearrangement is the acid-catalyzed rearrangement of tertiary α-acetylene alcohols *(1)* to, predominantly, α,β-unsaturated ketones

R^1, R^2 = $C(CH_3)_3$, Aryl; R^3 = H, Alkyl, Aryl



(2); the Meyer-Schuster rearrangement is the isomerization of secondary and tertiary α-acetylene alcohols of type *(3)* to α,β-unsaturated carbonyl compounds *(4)*. A descriptive account of the mechanisms of both rearrangements is supplemented by a discussion of, *inter alia*, substrates and catalysts, and normal and abnormal reaction products. [The Rupe and Meyer-Schuster Rearrangement. Chem. Rev. *71*, 429—438 (1971); 183 references]

[Rd 450 IE –M]

Adsorption and colloidal properties of radioactive elements in trace concentrations are reviewed by *F. Kepák*. Adsorption and colloid formation play a significant role at trace concentrations in solution so that methods of colloid chemistry come to the fore in the study of such small quantities. The author deals, *inter alia*, with ultracentrifugation, ultrafiltration, ion exchange and adsorption, as well as self-diffusion and dialysis. [Adsorption and Colloidal Properties of Radioactive Elements in Trace Concentrations. Chem. Rev. *71*, 357—369 (1971); 170 references]

[Rd 452 IE –M]

A survey of the chemistry of oxazolines from 1949 to 1969 has been authored by *J. A. Frump*. The oxazoline ring, and particularly the 2-oxazoline structure *(1)*, permits the preparation of a large number of derivatives of wide interest.

(1) *(2)* *(3)*

The article considers the preparation of *(1)* from amino alcohols, amides, halo amides, aziridines, epoxides, and Grignard reagents, as well as by the action of $SOCl_2$ on hydroxy amides. Halo-, vinyl-, amino-, mercapto-, and alkoxycarbonyl-oxazolines, as well as oxazolines related to

chloramphenicol and threonine, are discussed in detail. 3-Oxazolines *(2)* and 4-oxazolines *(3)* can also be prepared. Apart from treating stereochemical problems and reactions, the author also goes into technical applications, *e.g.* as protective layers, surface-active agents, fuel and lubricant additives, corrosion inhibitors, textile chemicals, pharmaceuticals, adhesives, and binders. [Oxazolines. Their Preparation, Reactions, and Applications. Chem. Rev. *71*, 483—505 (1971); 398 references]

Rd 453 IE –M]

The function of sulfur in living organisms is the subject of a review by *Z. M. Bacq*. The essential element sulfur is utilized in many forms—ranging from sulfate ions to the mercapto group in amino acids and coenzymes. In seawater and in the soil, sulfur is available as SO_4^{2-} which serves as a suitable source of the element for the synthesis of the sulfur-containing amino acids of proteins.—Space is devoted not only to the utilization of sulfur by plants and animals but also to the general biochemical reactivity of thiols and the mode of action of sulfur-containing compounds that afford protection against radiation. [Some Considerations on the Role of Sulfur in Living Organisms. Internat. J. Sulfur Chem. *6*, 93—101 (1971); 13 references]

[Rd 454 IE –M]

Kinetic data on water exchange between aquo complexes and solvent water are compiled by *J. P. Hunt*. The reactions were followed by monitoring shifts and broadenings of ^{17}O-NMR lines. A compilation of all data available is followed by an attempted systematization of the numerous data on cobalt(II) and nickel(II) complexes. In the author's opinion, there is lack of sufficient data for mechanistic considerations. [Water-Exchange Kinetics in Labile Aquo and Substituted Aquo Transition Metal Ions by Means of ^{17}O-NMR Studies. Coord. Chem. Rev. *7*, 1—10 (1971); 29 references]

[Rd 464 IE –H]

Photochemical reactions of solid coordination compounds are treated in a review by *E. L. Simmons* and *W. W. Wendlandt*. General information about methods of measurement and evaluation of results is followed by sections on redox and ligand substitution reactions. The review concludes with a comparison between thermal dark reactions and photochemical reactions. [Solid-State Photochemical Reactions of Transition-Metal Coordination Compounds. Coord. Chem. Rev. *7*, 11—27 (1971); 88 references]

[Rd 465 IE –H]

Metal complexes of thio-β-diketones are the subject of two reviews, one by *M. Cox* and *J. Darken*, the other by *S. E. Livingstone*. Sections about preparation, structure, and physical properties of the free ligands are followed by descriptions of their metal complexes, including formation, physical and chemical properties, and short accounts of substitution reactions in the chelate ring. Both reviews are written independently and stress different points of their coverage. [Metal Complexes of Thio-β-Diketones. Coord. Chem. Rev. *7*, 29—58 (1971); 99 references. Monothio-β-Diketones and Their Metal Complexes. Coord. Chem. Rev. *7*, 59—80 (1971); 73 references]

[Rd 466 IE –H]

Conductivity measurements in organic solvents are reported by *W. J. Geary* with respect to the electrolytic dissociation of coordination compounds. There are general suggestions about choice of the most suitable solvent and the experimental procedures; detailed accounts (with references to methods of purification) are given of the solvents nitromethane, nitrobenzene, acetone, acetonitrile, dimethylformamide, methanol, and ethanol. Some other solvents are mentioned briefly. A special section is devoted to the toxicity of the various solvents. [The Use of Conductivity Measurements in Organic Solvents for the Characterization of Coordination Compounds. Coord. Chem. Rev. *7*, 81—122 (1971); 377 references]

[Rd 467 IE –H]

BOOK REVIEWS

Organische Chemie (Organic chemistry). By *O. Runquist*. R. Oldenburg Verlag, Munich–Vienna 1970. 1st edit.,
Part 1: Eine programmierte Einführung. Reaktionen I (Programmed introduction. Reactions I), 90 pp., DM 9.80.
Part 2: Reaktionen II (Reactions II), 120 pp., DM 14.80.
Part 3: Nomenklatur (Nomenclature), 101 pp., DM 9.80.

The original American title "Programmed Review of Organic Chemistry" has been incorrectly translated as "Organische Chemie – Eine programmierte Einführung (Organic chemistry—programmed introduction)". Anyone who expects these three volumes to act as an introduction to organic chemistry is thus in for a disappointment. However, if they are regarded (in accordance with the original American title) as a means of testing the knowledge one has gained through reading or attending lectures, then these books will prove to be a useful collection of exercises.

Part 1 (Reactions I) deals with hydrocarbons, alcohols, alkyl halides, Grignard reagents, *etc.* Part 2 (Reactions II) describes more complicated reactions, such as the Hofmann degradation, the Fries rearrangement, the Reformatsky reaction, *etc.* Part 3 (Nomenclature) tests the reader on his ability to assign the correct IUPAC name to an organic formula, and to write out the correct structural formula when given the name. In my opinion this section should have come first.

These books are essentially a series of exercises, a sort of "chemical quiz book". First a fact of general validity (usually an empirical rule) is given, and this is followed by examples of its application. It is thus in no sense a true teaching program. There are also no indications as to the preliminary knowledge expected of the reader. The level of difficulty is about that suitable for chemistry under-

graduates. For such readers it is not important that stoichiometry is not taken into account (*e.g.* in A-13/Part 1).

The presentation of the exercises is lacking in variety, particularly in Part 2. In the answers to Parts 1 and 2, I occasionally missed any consideration of unstable intermediates (*e.g.* in A-242/Part 1).

Sometimes the question bypasses the problem, and the answer appears irrelevant (*e.g.* the answer to question F-206/Part 2, which is very good but not at all what its readers will be expecting).

Despite the deficiencies mentioned, this collection of exercises in organic chemistry is recommended.

Siegfried Nöding [NB 5 IE]

Der Absatz in der Chemischen Industrie. (Marketing in the Chemical Industry). By *H. Köbel* and *J. Schulze*. Springer Verlag, Berlin–Heidelberg–New York, 1970, 1st edit., 732 pp., 259 figures, 156 tables, bound, DM 128.—.

The chemical industry is now showing an increasing tendency to do what other industries have been doing for some time: to align all entrepreneurial activities toward the marketing side. With growing competition resulting from increasing maturity in this industry, the sales prospects have become more and more the bottleneck of commercial success. The development of demand and the situation of markets thus become the most important basis for shaping management decisions from research and development projects to the erection of new plants and the successful opening of markets.

In this book, *Kölbel* and *Schulze* provide for the first time a comprehensive treatment of marketing in the chemical industry. The book is divided into eight main sections, which are based on the practical experience of the authors and their long years of work in the Industrial Chemistry Section of the Institute for Technical Chemistry at the Technische Universität Berlin. The marketing system in the chemical industry is presented by means of branch characterization, classification of products according to marketing aspects, marketing factors as determinants of the marketing system, and the development of chemical marketing. The section on marketing organization and distribution channels shows the possibilities for incorporating the sales function into the company's organization and gives a detailed description of the normal distribution channels in chemistry.

The central point of the whole study is formed by the two sections on the problems and methods of chemical market research, analysis, and forecasting. Particular attention is devoted to the topic of market research for production goods, which so far has received little attention in the literature. The section on forecasting also deals with problems of anticipating trends of technological development.

In the main section on product and program formulation the relationships between research, development, and marketing are studied, together with problems of coordination, followed by details on the determining factors of product development, packaging, quality standards, product marking, and patent and licensing policies. The section on the marketing program formulation is somewhat short, though it includes the problems and aspects of the development of the range of products. In my opinion it does not show sufficiently the relation to the method of direct costing—described in the section on pricing policy—as an instrument for finding the optimal range of goods.

A further section, devoted to application techniques and market development, presents the organization and methods of application techniques in great detail. Examples are shown of the use of the network planning technique for the solution of market development problems. After the section on chemical advertisement, which deals with the fundamentals, advertising factors, target groups, and advertising media, there follows the final section on pricing policy. Emphasis is given here to the determination of prices by costing and pricing in chemical markets.

The comprehensive treatment of the broad marketing field does not allow detailed treatment of special problems. This deficiency is overcome by the extensive lists of lieterature references, mainly of American origin, which have been evaluated by the authors, and which appear at the end of each main section. The clear, detailed arrangement, the large number of illustrative and explanatory examples, and the very detailed subject index should ensure the book's usefulness both for those involved in the fields of marketing, market research, and advertising, and for chemists working in research, development, and production.

Chemistry and Biochemistry of Branched-Chain Sugars

By Hans Grisebach and Rolf Schmid[*]

Branched-chain sugars have recently been isolated in larger numbers from microorganisms and higher plants as glycoside components of antibiotics or phenolic compounds. They also occur in plants in cell wall polysaccharides. Sugars with methyl, hydroxymethyl, formyl, hydroxyethyl, and glycoloyl branches have so far been found in nature. Many new methods have been developed for the synthesis of these sugars. With one exception, the branched sugars known at present can be divided biogenetically into three groups. Sugars with methyl branches are formed by C_1 transfer, sugars with hydroxyethyl branches by C_2 transfer to a hexose chain, and sugars with hydroxymethyl or formyl branches by rearrangement of a hexose or pentose chain.

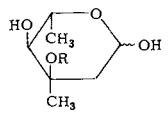
1. Introduction

In the flavone glycoside apiin from parsley *(Apium petroselinum*, synonomous with *Petroselinum hortense)*, *Vongerichten* in 1901 found an unknown sugar, which he named apiose[1]. By oxidation of apiose with bromine, he obtained tetrahydroxyvaleric acid. On reduction with hydriodic acid and phosphorus, this gave a fatty acid, which was regarded as isovaleric acid[2]. *Vongerichten* therefore assumed that apiose has a branched carbon chain. The exact structure of apiose as 3-*C*-hydroxymethyl-D-glyceroaldotetrose was shown later by *O. Th. Schmidt*[3]. A few years after the discovery of apiose, *E. Fischer* and *Freudenberg* discovered a sugar, which they named hamamelose[5], in the hydrolysate of the tannin hamamelitannin[4] from the bark of *Hamamelis virginiana*. *Schmidt et al.* elucidated the constitution and configuration of hamamelose as 2-hydroxymethyl-D-ribose[6].

The discovery of apiose and hamamelose in higher plants attracted little attention at first. These two branched sugars were evidently regarded as rare and unimportant members of the sugar family.

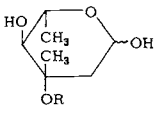
A change came with the start of antibiotic research. More than a dozen branched deoxy sugars have now been discovered as components of antibiotics. The fact that the occurrence of these sugars appears to be confined to the genera *Streptomyces* and *Micromonospora* is probably only a consequence of insufficient investigation of other potentially suitable organisms. It can probably be assumed that sugars of this type will also be found in future in other types of microorganisms; the first example is the discovery of a nucleotide with a branched sugar in *Azotobacter vinelandi*[19].

Apiose and hamamelose have in the meantime been identified in several species in the plant kingdom. A particularly interesting finding is the occurrence of apiose in polysaccharides.



The synthetic chemistry of branched sugars has developed very rapidly during the past few years. One reason for this is the discovery that nucleosides with branched sugars can exhibit cytostatic or virostatic activity.

Some aspects of the chemistry and biochemistry of branched sugars have already been reviewed[7–11]. The present article will be concerned mainly with more recent work.



2. Occurrence and Constitution

The branched-chain sugars are best divided on biogenetic grounds into three groups (see Section 5), *i.e.* methyl-branched sugars, hydroxymethyl-branched and formyl-branched sugars, and hydroxyethyl-branched sugars. Only pillarose [2,3,6-trideoxy-2-glycoloylhexopyranos-4-ulose, see *(35)*], does not fit into this scheme.

2.1. Methyl-Branched Sugars

The structure and occurrence of the known methyl-branched sugars are listed in Table 1. Sugars of this type have so far been isolated only from microorganisms as glycoside components of antibiotics. They include amino sugars and the nitro sugar L-evernitrose *(9)*. The methyl branch is situated on position 3, 4, or 5 of the hexose chain.

The position of the branch can be deduced from the mass spectrum[24, 25]. The tertiary methyl group is shown by a singlet in the NMR spectrum[26]. Difficulties arise, however, in the determination of the configuration at the branching position.

Indications of the configuration are provided by the IR frequencies of the *tert*-OH group[27], the kinetics of the periodate oxidation[26], chromatographic and electrophoretic mobilities in solvent systems with borate buffer[26, 28] or phenylboric acid[27], formation of cyclic carbonates[26], degradation reactions[29–31], partial stereospecific synthesis (see Section 3), and the formation of bicyclic hemialdals[26, 28]. In the case of nitroalkyl-branched sugars or sugar alcohols, the configuration can be deduced from the ORD and CD spectra[32–34a].

For sugars having a tertiary acetoxy group, the NMR signals of the CH_3CO protons of axial and equatorial acetoxy groups differ by about 0.1 ppm. According to *Lichtenthaler*, this is also true of sugars having a methyl group on the same C atom of the ring. This method can probably also be applied to the methyl signals of the acetamido group of *C*-methyl-branched amino sugars[35].

(10)

In the case of *O*-isopropylideneglycopyranosides *(10)*, the configuration at the branching position can be deduced from the signal of the *endo*-methyl protons of the isopropylidene residue[36]. The signal has a fairly constant position at about $\tau = 8.53$ if the substituent at the branching position is *cis* to the isopropylidene ring [*(10)*, $R^2 = e.g. CH_3$], but lies at $\tau = 8.42$ if the substituent is *trans* to the isopropylidene ring.

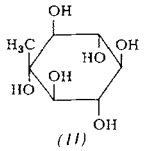

Table 1. Structure and occurrence of methyl-branched sugars.

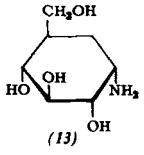
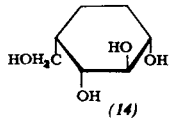
	Trivial name	Systematic name	Occurrence [12]
(1a)	L-Mycarose	2,6-Dideoxy-3-*C*-methyl-L-*ribo*-aldohexopyranose	A few macrolide antibiotics [11] Angolamycin [13] Aureolic acid [16a]
(1b)	L-Cladinose	2,6-Dideoxy-3-*C*-methyl-3-*O*-methyl-L-*ribo*-aldohexopyranose	Erythromycin A, B [14]
(2a)	L-Olivomycose	2,6-Dideoxy-3-*C*-methyl-L-*arabino*-aldohexopyranose	Olivomycin [16]
(2b)	L-Chromose B	2,6-Dideoxy-3-*C*-methyl-3-*O*-acetyl-L-*arabino*-aldohexopyranose	Chromomycin A_3 [18]
(3)	L-Arcanose	2,6-Dideoxy-3-*C*-methyl-3-*O*-methyl-L-*xylo*-aldohexopyranose	Lankamycin [15]
(4)	D-Evermicose	2,6-Dideoxy-3-*C*-methyl-D-*arabino*-aldohexopyranose	Everninomycin [17, 22a]
(5)	L-Noviose	6-Deoxy-3-*O*-carbamoyl-5-*C*-methyl-4-*O*-methyl-L-*lyxo*-aldohexopyranose	Novobiocin [23]
(6)	L-Nogalose	6-Deoxy-3-*C*-methyl-2,3,4-tri-*O*-methyl-L-*manno*-aldohexopyranose	Nogalomycin [20, 20a]
(7)	L-Vinelose	6-Deoxy-3-*C*-methyl-2-*O*-methyl-L-(*altro*, *galacto* or *talo*)-aldohexopyranose (R may be CH_3OCH_2CO too)	As Cytidine diphosphate derivative from *Azotobacter vinelandii* [19]
(8)	L-Garosamin	3-Deoxy-3-methylamino-4-*C*-methyl-L-*arabino*-aldopentopyranose	Gentamycin C [21] Sisomicin [21a]
(9)	L-Evernitrose	2,3,6-Trideoxy-3-*C*-methyl-4-*O*-methyl-3-nitro-L-*ribo*-aldohexopyranose	Everninomycins [22, 22a]

2.2. Methyl-Branched Inositols

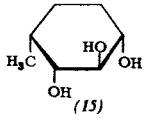
In addition to *C*-methyl-branched sugars, the *C*-methyl-inositols laminitol *(12)* and mytilitol *(11)* also occur in nature.



Laminitol was first isolated from the brown alga *Laminaria cloustoni*[37]. This compound was later found in numerous



(11)

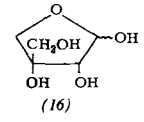


(12)

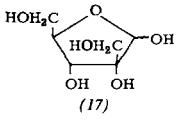
other red and brown algae[38] and in the green alga *Chlorella fusca*[39]. Mytilitol has been detected in mussels[40] and in red[41] and green algae[39].

Other branched inositols have recently been found in the validamycin antibiotics from *Streptomyces hygroscopicus*

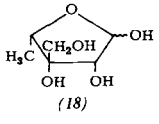
(13)



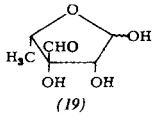
(14)



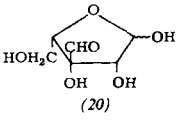
(15)



var. limoneus[39a]. These are validamine *(13)*, validatol *(14)*, and deoxyvalidatol *(15)*.

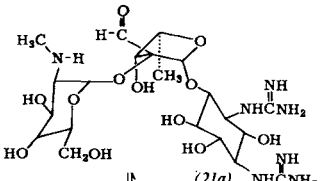


2.3. Sugars with Hydroxymethyl or Formyl Branches

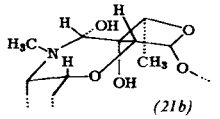


Known sugars of this type are D-apiose *(16)*, D-hamamelose *(17)*, L-dihydrostreptose *(18)*, L-streptose *(19)*, and L-hydroxystreptose *(20)*. The last three of these sugars have so far been found only in members of the streptomycin family[42,43].

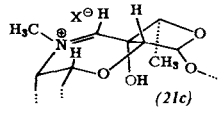
(16)



(17)



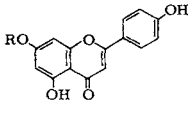
(18)



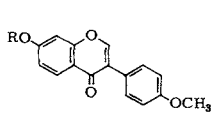
(19)

(20)

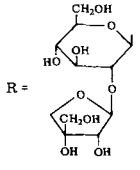
The NMR spectrum of streptomycin *(21a)* in D_2O contains no characteristic signal for the aldehyde proton of the streptose between $\tau=0$ and $\tau=2$, but has a sharp one-proton singlet at $\tau=4.98$. It is assumed from these results and from model considerations that the aldehyde group of the streptose forms a carbinolamine *(21b)* with the secondary amino group of *N*-methyl-L-glucosamine[44].



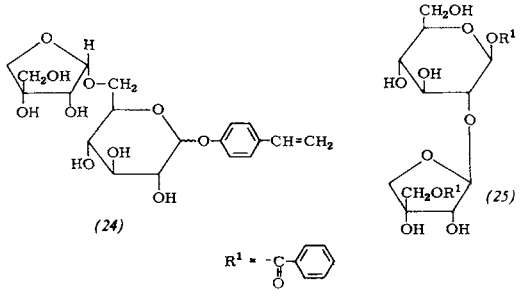
(21a)



(21b)



(21c)

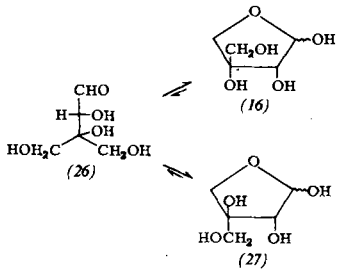


The immonium form *(21c)* that is postulated in equilibrium with *(21b)* is held responsible for the precipitation of polyanions by streptomycin and for its action against certain bacteriophages[44].

As far as is known at present, the occurrence of apiose and hamamelose is confined to plants. D-Apiose is surprisingly widely distributed in the plant kingdom. This sugar is found in the glycosides apiin *(22)* from parsley[1] and Capsicum species[45], lanceolarin *(23)* from *Dahlbergia*

(22)

(23)



(24)

(25)

lanceolaria[46], furcatin *(24)* from *Viburnum furcatum*[47], and *(25)*, a bitter principle from the leaves of *Daviesia latifolia*[48]. Homoflavoyadorinin B from the leaves of mistletoe *(Viscum album)* is 7,3'-di-*O*-methyl-5,7,3',4'-

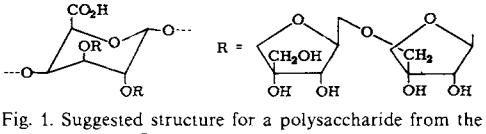
tetrahydroxyflavone 4'-*O*-D-glucoapioside[49]. Kaempferol (3,5,7,4'-tetrahydroxyflavone) 3-β-glucoapioside has been isolated from the chick pea *(Cicer arietinum)*[50].

On formation of the furanose ring of D-apiose from the open-chain structure *(26)*, C-3 becomes asymmetric; the two isomers D-apio-D-furanose *(16)* and D-apio-L-furanose *(27)* can be formed.

By permethylation of apiin and comparison of the 2,3,4-tri-*O*-methyl-D-apiofuranose obtained by hydrolysis with a synthetic compound whose configuration on C-3 was known, it was possible to show that apiose is present in apiin in the D-furanose form *(16)*[51].

The occurrence of D-apiose in polysaccharides from aquatic plants is particularly interesting. An almost identical pectin-like polysaccharide (zosterin), which contains D-galacturonic acid, D-galactose, D-xylose, mono-*O*-methyl-D-xylose, L-arabinose and D-apiose, has been found in several grass-wracks (Zosteraceae)[52]. However, it seems doubtful whether this is a single polysaccharide. The action of pectinase on zosterin gave an apiogalacturonan, in which the apiose residues are probably bound to a polygalacturonan. The polysaccharide nucleus of zosterin therefore probably has a structure similar to that of the apiogalacturonans from *Lemna* (see below). In *Helobiae*, walls containing apiose appear to occur mainly in submerged species in salt or brackish water[53].

Apiose also occurs in the cell wall in the genus *Lemna* (duckweeds)[54,55]. Apiogalacturonans from the cell wall of *Lemna minor* have been particularly intensively studied. As was found by *Beck*[56] and by *Kindel et al.*[57,58], the basic skeleton of these polysaccharides consists of an α (1→4)-bound, practically unesterified polygalacturonic acid chain with an apiobiose on C-2 or C-3 of the galacturonic acid (Fig. 1). Since the apiobiose side chains can be removed extremely readily, transannular participation of the free carboxyl group of D-galacturonic acid is assumed in the cleavage of the glycoside linkage[57].



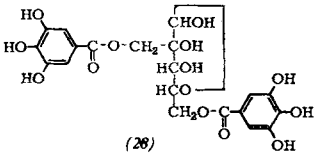


Fig. 1. Suggested structure for a polysaccharide from the cell wall of *Lemna minor* [57].

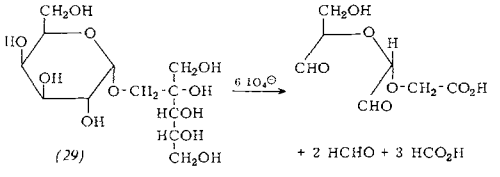
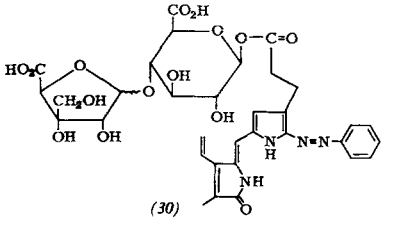


The polysaccharide fractions having a high apiose content are not degraded by pectinase. This may be part of the reason for the high resistance of Zosteraceae to natural decomposition[58].

As well as in aquatic plants, apiose has also been found in a polysaccharide from the lime tree[59].



D-Hamamelose *(17)* and the corresponding sugar alcohol D-hamamelitol (2-*C*-hydroxymethyl-D-ribitol) are very widely distributed in the plant kingdom. Hamamelitannin *(28)*[60] has been isolated not only from witch hazel but also from the bark of the sweet chestnut *(Castanea sativa)*[61] and from the bark of the American red oak *(Quercus rubra)*[60].

Free hamamelose also occurs in these plants. This sugar is of general occurrence in genera and orders related to Hamamelis and Castanea[62]. D-Hamamelitol is found in the leaves of *Primula clusiana* as the predominant carbohydrate[63]. Another substance isolated from these leaves is a non-reducing disaccharide named clusianose, which yields D-galactose and D-hamamelitol on hydrolysis. From the results of periodate degradation, it was identified as 1-*O*-α-D-galactopyranosyl hamamelitol *(29)*[64].

Clusianose *(29)*, as well as hamamelitol, is also found in some sections of the genus *Primula*, and can be accumulated in the leaves in quantities comparable with those of sucrose. Since clusianose is formed only very slowly during photosynthesis in $^{14}CO_2$ and undergoes practically no decomposition in the course of four days in the dark, this disaccharide, unlike sucrose, does not appear to be a true storage substance[65].

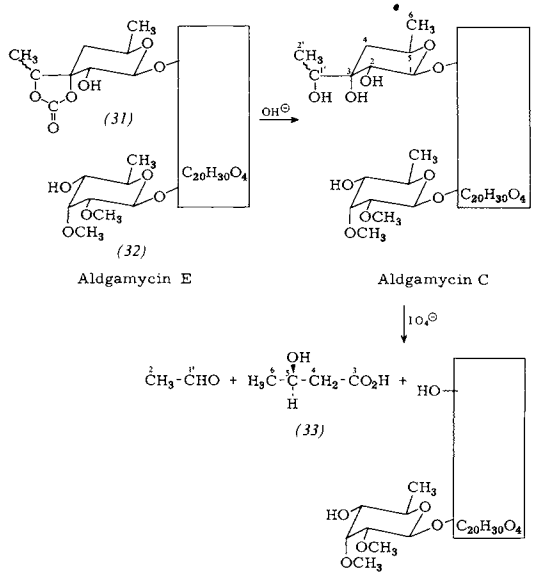
Branched sugars may also occur in man. Mainly on the basis of mass-spectrometric data, *Kuenzle* proposed the structure *(30)* for a bilirubin conjugate isolated from human bile as the phenylazo derivative[66].

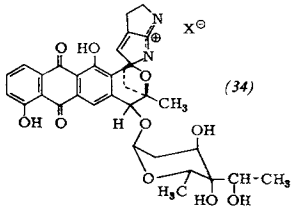
If the structure of this sugar is confirmed, it will show interesting biogenic relations with apiose (see Section 5).

2.4. Sugars with Hydroxyethyl or Glycoloyl Branches

Aldgamycin E, an antibiotic of the macrolide group[67] in which the structure of the macrolide ring is still partly un-

known, has as glycoside component in addition to mycinose *(32)* a 4,6-dideoxy-3-*C*-1'-hydroxyethyl-D-*ribo*-hexose in the form of a cyclic carbonate, D-aldgarose *(31)*[68,69]. The five-membered cyclic carbonate can be recognized from the carbonyl absorption at 1800 cm^{-1} in the IR spectrum. The carbonate group can be readily removed with dilute barium hydroxide. Cleavage of aldgamycin C with periodate (Fig. 2) gives acetaldehyde from the ethyl branch and D-(−)-3-hydroxybutyric acid[69] *(33)* from C-atoms 3—6 of the sugar. The stereochemistry was determined from the NMR spectrum of aldgarose, and only the configuration on C-1' is still unknown[68]. The antibiotic action against *Bac. subtilis* is lost on removal of the aldgarose from the lactone ring[70].





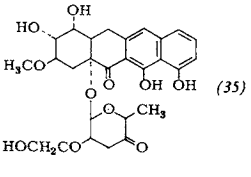


Fig. 2. Partial degradation of aldgamycin E.

The antibiotic isoquinocycline A *(34)*, the constitution of which has been established by X-ray analysis, also contains a sugar with a hydroxyethyl branch. The branch in this case is situated on C-4 of the hexose[71].

Pillarose (2,3,6-trideoxy-2-glycoloylhexopyranos-4-ulose), a keto sugar with a glycoloyl branch, was recently found[73] in pillaromycin A *(35)*[72].

3. Synthesis of Branched-Chain Sugars

Since the publication of the latest reviews[7–10,74,75,124], many new reports on the synthesis of branched sugars have appeared. The preparation of keto sugars, which are very often used as starting compounds, has already been reviewed[9,75a].

The steric course of additions to carbonyl groups or double bonds is particularly important for such syntheses. Whereas it is possible to predict with some certainty which diastereoisomer will be formed in the addition of Grignard compounds to keto sugars (see Section 3.1.1), this is not yet possible for the stereoselective alkylations.

We shall first discuss methods that lead to the formation of sugars of the type RCOH. This will be followed by methods for the formation of deoxy sugars of the types RCNH and RCH. Finally, the synthesis of sugars containing a cyclopropane ring will be discussed. The methods for the synthesis of naturally occurring branched sugars and their diastereoisomers are listed in Table 2.

Table 2. Synthesis of naturally occurring branched sugars and inositols by alkylation of keto sugars.

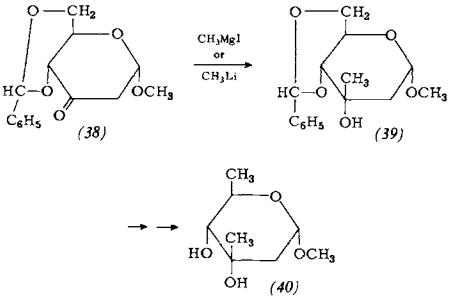
[a] Total syntheses.

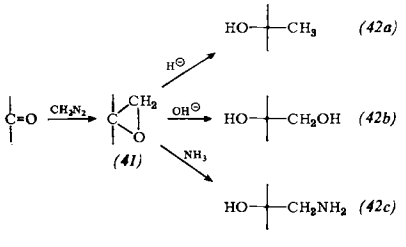
3.1. Synthesis of Sugars of the Type RCOH



3.1.1. Addition of Organometallic Compounds to Keto Sugars

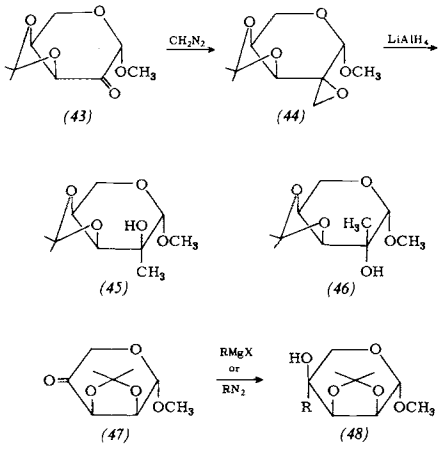
The reaction of keto sugars with organolithium or organomagnesium compounds proceeds stereoselectively in high yields, and in very many cases even stereospecifically[8–10]. Since this addition leads in a predictable manner to asymmetric products, it has become a standard method for the synthesis of branched sugars and their nucleosides[76–92] (Table 2).

Whereas it was reported earlier that the addition of organolithium compounds[78] can follow a sterically complementary course to the addition of Grignard compounds[79] and lead to diastereoisomers, the *allo*-products *(37)* were isolated in the reaction of *(36)* with both types of reagents[93].



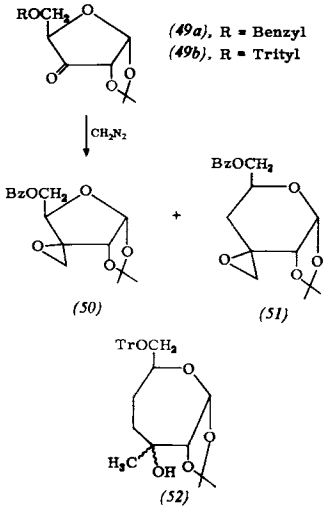
The reaction of *(38)* with methylmagnesium iodide or methyllithium also yields the *ribo*-product *(39)*, which can be converted into D-mycaroside *(40)*[80].

The yields and (within narrow limits) the stereoselectivity of the Grignard reactions depend on the solvent[80,81] and on the halide[81].

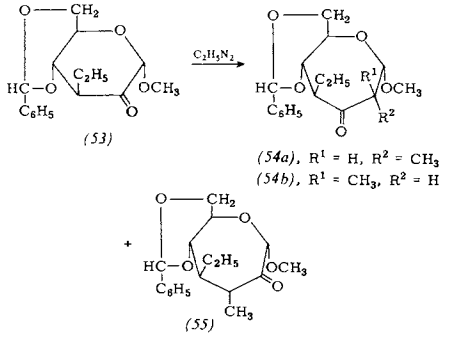


3.1.2. Addition of Diazomethane to Keto Sugars

The reaction of a keto sugar with diazomethane leads to the formation of an epoxide *(41)*, which can be converted into the C-methyl compound *(42a)* by reduction, into the *C*-hydroxymethyl compound *(42b)* by hydrolysis, and into the *C*-aminomethyl compound *(42c)* by ammonolysis.

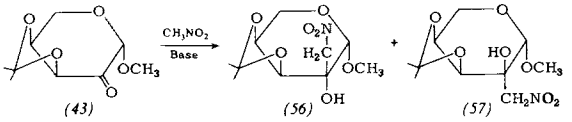


This addition proceeds stereoselectively, and has also frequently been used in recent years for the synthesis of branched-chain sugars[95–98].

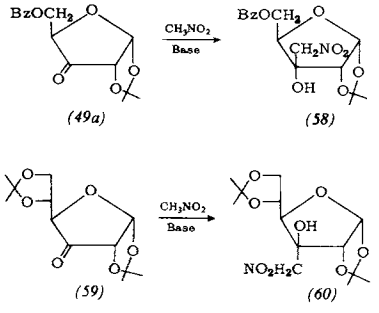


Investigations on the stereochemistry of the reaction led to the following results: Whereas the addition of diazomethane to the keto sugar *(43)* leads mainly to the epoxide *(44)*, which can be reduced to the 2-*C*-methyl compound *(45)* with the *ribo*-configuration[99] (the reaction follows a complementary course to the reaction with methylmagnesium iodide, in which the arabino-compound *(46)* is formed[79]), the reaction of *(47)* both with phenylethynylmagnesium bromide and with diazomethane leads mainly to the *ribo*-compound *(48)*[77].

The reaction can also proceed with ring expansion. Whereas the epoxide *(50)* is formed in the reaction of *(49a)* with diazomethane in ether, the reaction in methanol/ether yields the hexopyranoside *(51)* as the principal product[100].

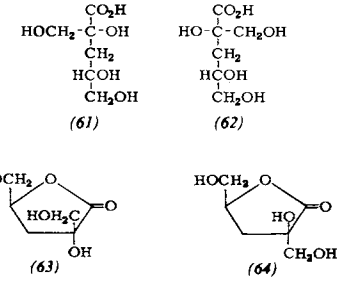


The reduction of the anhydro sugars *(50)* and *(51)* with $LiAlH_4$ yields the 3-*C*-methyl sugars having the *xylo*-configuration. On reaction of the 5-*O*-trityl compound *(49b)* with diazomethane in methanol/ether, a small quantity of the *C*-methylheptose *(52)* formed by double ring expansion was obtained among other products[101]. The addition of diazoethane to the keto sugar *(53)* gave only the ring expansion products *(54a)*, *(54b)*, and *(55)*, but not the expected compound with two ethyl branches[102].



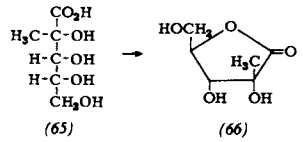
3.1.3. Addition of Nitromethane to Keto Sugars

The base-catalyzed addition of nitromethane to keto sugars leads in good yields to the *C*-nitromethyl compounds, which can be converted into aminomethyl and aminodeoxymethyl sugars[32-34, 103, 104, 138a]. The reaction leads to a mixture of the two anomers. Thus a mixture of the *arabino*-compound *(56)* and the L-*ribo*-compound *(57)* was obtained in the reaction of *(43)* with nitromethane and sodium methoxide[105].



A certain steric control was possible by variation of the temperature. Whereas the isomers *(56)* and *(57)* were formed in a ratio of 1:1 at 0°C, the ratio at 20°C was 3:1. The configuration on C-2 was determined by assignment of the NMR signal of the *endo*-methyl protons of the *O*-isopropylidene residue (see Section 2.1).

Whereas the *ribo* compound *(58)* is formed on addition of nitromethane to *(49a)*, the reaction of the keto sugar *(59)* leads to the *gluco*-isomer *(60)*[33].

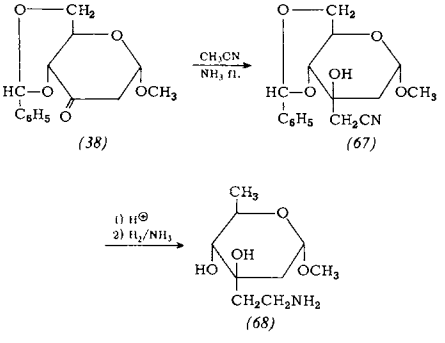


3.1.4. Rearrangements

The treatment of reducing sugars with alkali leads to the formation of saccharic acids[106, 107]. Under the action of calcium hydroxide, 4-*O*-methyl-D-glucose, D-lactose, or D-maltose gives roughly equal quantities of the "α"- and "β"-D-glucoisosaccharic acids *(61)* and *(62)*, from which the γ-lactones *(63)* and *(64)* are readily formed[108].

The configuration of the "α"-glucoisosaccharic acid *(61)*[109] and its lactone *(63)*[110] has been established by X-ray analysis; both were found to be *erythro*-compounds.

When calcium hydroxide is allowed to act on D-fructose, the α-glucosaccharic acid *(65)* is formed in good yields; this compound can also be readily converted into the γ-lactone *(66)*. The β-isomer cannot be detected[108].

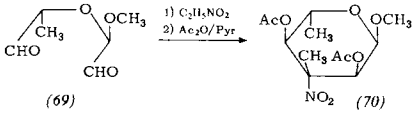


Chemical methods showed the *ribo*-configuration for *(65)*[111], and *(66)* was correlated with the same configuration of D-hamamelose[112].

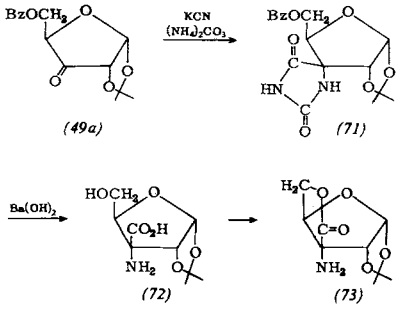
The lactone *(66)* has been used as a starting material for the synthesis of nucleosides with branched sugars[113-115].

3.1.5. Other Reactions

C-Methyl groups can also be introduced by nucleophilic attack of dimethylsulfoxonium methylide on a keto sugar[96, 116-118].



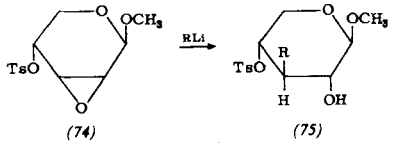
A promising new reaction is that of a keto sugar with acetonitrile in liquid ammonia. Thus reaction of *(38)* leads in very good yields to the *arabino*-cyanomethyl compound *(67)*, which gave the β-aminoethyl compound *(68)* on acid hydrolysis and catalytic reduction in the presence of ammonia[119].



The formation of a branched heptosulonic acid by the cyanohydrin synthesis was described by *Kiliani* as early as 1885[120]. Only occasional use has recently been made of this method[121]. The reason for this is the formation of a mixture of diastereoisomers, the separation of which is time-consuming except in a few cases[122].

3.2. Synthesis of Sugars of the Type $R\overset{|}{C}NH_2$

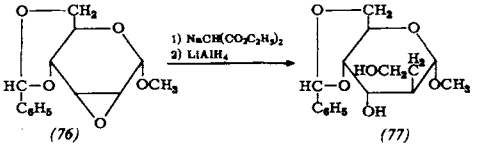
On reaction of the dialdehyde *(69)* with nitroethane followed by acylation, the methyl-branched nitro sugar *(70)* was isolated in small yields[105, 123]. Reviews on this type of reaction have been published by *Baer*[75] and by *Lichtenthaler*[124].



The addition of cyanide to the keto sugar *(49a)* yields the 3-*C*-spiro-5′-hydantoin *(71)* as the principal product. This compound can be converted into the α-amino acid derivative *(72)* by basic hydrolysis. The *ribo*-configuration of *(72)* is shown by the formation of the lactone *(73)*[125].

3.3. Synthesis of Sugars of the Type RCH

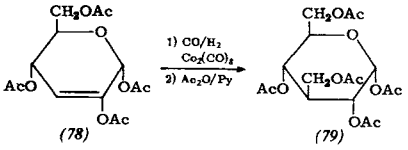
3.3.1. Addition of Nucleophiles to Anhydro Sugars[126]



The reaction of *(74)* with phenyllithium, isopropyllithium, or phenylethynyllithium yields only 3-*C*-substituted products having the *xylo*-configuration *(75)*[127].

As expected, therefore, the cleavage of the epoxide ring leads to the product having the substituents on C-2 and C-3 *trans* to each other.

The reaction of 2,3-anhydro sugars with alkyl Grignard compounds can lead to unsaturated halogenated sugars and to 2-C or 3-C-alkylated sugars. The relative yield depends largely on the halogen used[128].

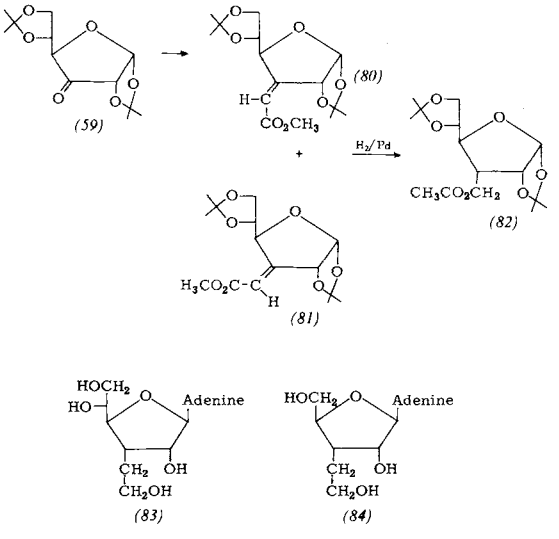


The action of cyanide on 2,3-anhydro sugars leads to a mixture of 2-C- and 3-C-substituted compounds. *trans*-Cleavage of the epoxide ring is normally observed, but the *cis*-product may be formed by subsequent isomerization of the tertiary C atom in the presence of bases[129]. If one of the primary products can be stabilized, this product is preferentially formed[130]. The use of a triethylaluminum-HCN complex in ether favors a stereoselective reaction course[131].

The reaction of the anhydro sugar *(76)* with malonic ester in strongly basic solution followed by reduction with $LiAlH_4$ leads to the hydroxyethyl-branched sugar *(77)* with the *altro*-configuration[132].

3.3.2. Oxo Reaction (Hydro-hydroxymethylation)

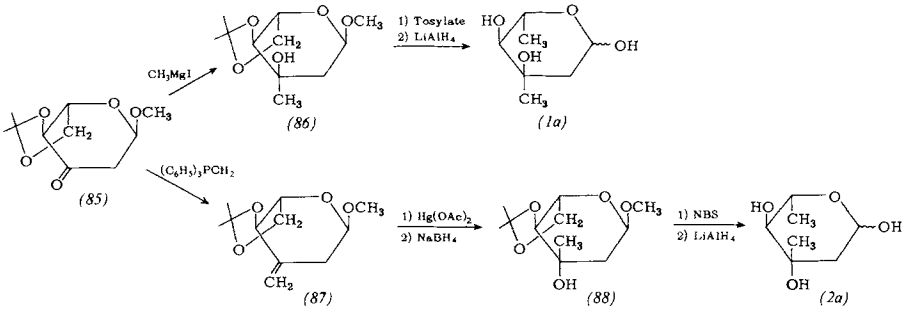
Since this reaction was recently reviewed[74], only one example will be mentioned here. If CO and H_2 are allowed



to act on the glycose-ene *(78)* under drastic conditions in the presence of $Co_2(CO)_8$, the *gluco*-compound *(79)* can be isolated in moderate yields after acylation.

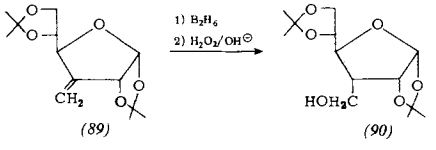
3.3.3. Formation of the Branch by Wittig Reaction

Since *Rosenthal* and *Nguyen* first prepared a *C*-alkylated sugar by reaction of a keto sugar with an organophosphorus compound in 1967[133], this method has found increasing use in the synthesis of branched deoxy sugars and their nucleosides[94, 134–141].



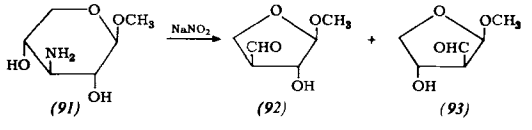
The reaction of *(59)* with methyl dimethoxyphosphonoacetate and potassium *tert*-butoxide at low temperature leads in high yields to the *cis*- and *trans*-methylene sugars *(80)* and *(81)*. The *allo*-product *(82)* is formed on reduction of this mixture with H_2/Pd. The *gluco*-isomer was not detected[133].

It was possible to convert *(82)* into the *allo*- and *ribo*-nucleosides *(83)* and *(84)* by standard methods[142].



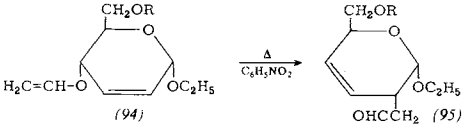
Whereas the branched sugar *(86)* having the L-*ribo*-configuration is formed from the keto sugar *(85)* on reaction with methylmagnesium iodide[91], reaction with triphenylmethylenephosphorane followed by treatment with mercury(II) acetate and sodium tetrahydroborate leads to the branched sugar *(88)* having the *arabino*-configuration. Reaction with tosylate or *N*-bromosuccinimide and reduction led from *(86)* to L-mycarose *(1a)* and from *(88)* to L-olivomycose *(2a)*[143].

The methylene compounds obtained by the Wittig reaction with keto sugars as intermediates allow numerous further reactions[143a]. Thus a hydroxyl group can be introduced



into the compound *(89)* by hydroboration, the product formed being the *allo*-compound *(90)*[135].

Reaction of a methylene sugar with nitryl iodide (NO_2I) leads to nitromethyl-branched sugars[144].

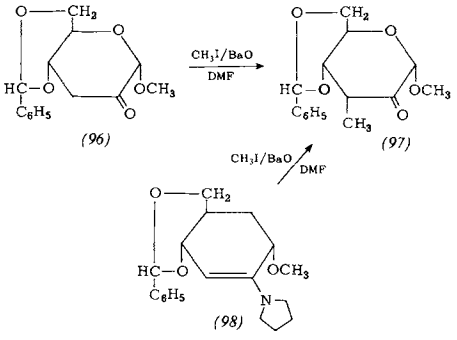


3.3.4. Rearrangements

On treatment of the amino sugar *(91)* with sodium nitrite, the branched aldehyde *(92)* is formed as the main product and *(93)* as a by-product[145].

In earlier attempts to achieve ring contraction by diazotization of amino sugars[146–148] or by thermolysis of *O*-(nitrobenzyl-*p*-sulfonyl)-substituted sugars[148], only the 3-*C*-branched products were identified.

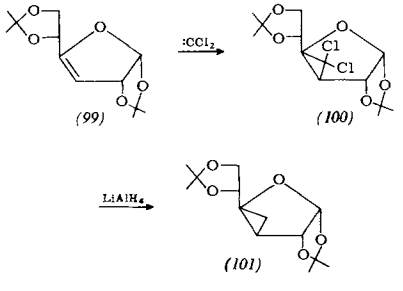
Heating of the unsaturated sugar of the type *(94)* in nitrobenzene leads by allyl shift to the branched aldehyde *(95)*[149].



3.3.5. Other Reactions

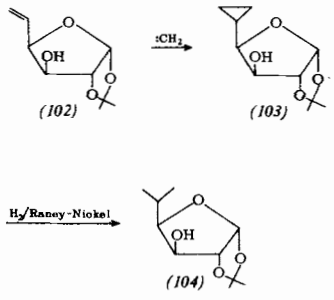
Methyl iodide can add in good yields to the keto sugar *(96)* with base catalysis to give the compound *(97)*[150]. Epimerization takes place on C-3 even in weakly basic solution. If the enamine *(98)* is used instead of the keto sugar *(96)*, almost quantitative yields are obtained.

Branched sugars can also be obtained by reaction of unsaturated sugars with dienes after the manner of a Diels-Alder reaction[151,152]



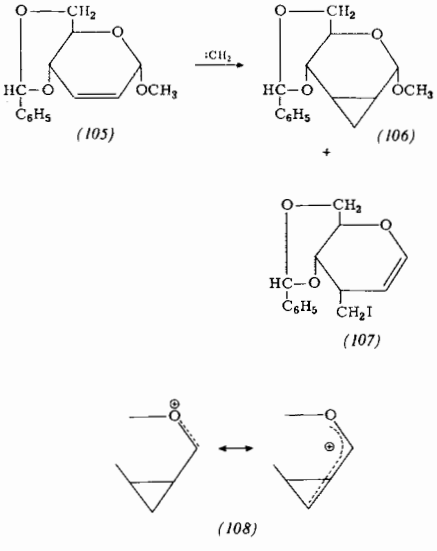
The interesting possibility of using the stereospecificity of enzymatic reactions for the synthesis of branched sugars has so far been realized in only one case. The enzyme 2-deoxy-D-ribose-5-phosphate aldolase (E.C. 4.1.2.4.) can use

propionaldehyde as the substrate instead of the acetaldehyde. Condensation with D-glyceraldehyde-3-phosphate yields 2-methyl-2-deoxy-L-xylose-5-phosphate[153].



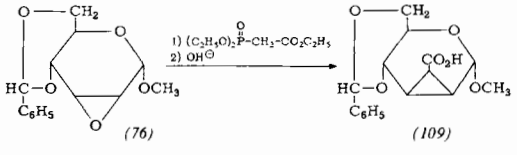
3.4. Synthesis of Sugars Containing a Cyclopropane Ring

The expression "sugars containing a cyclopropane ring" is used here to denote sugars in which two neighboring C atoms are joined by a methylene bridge.



Brimacombe et al. observed the formation of the sugar *(100)* as the only product of the reaction of the unsaturated furanose *(99)* with dichlorocarbene[154]. Reduction of *(100)* with $LiAlH_4$ gave the cyclopropane sugar *(101)*.

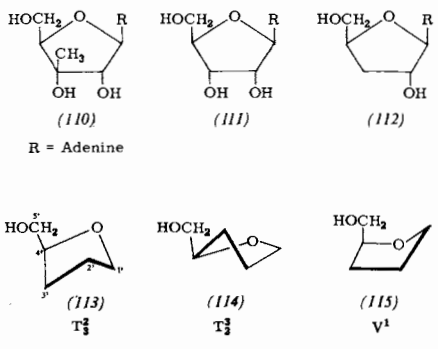
The analogous reaction fails to occur with other unsaturated sugars. However, the carbene addition can be achieved in these cases by the use of methylene iodide and zinc/copper in ether (Simmons-Smith reagent)[155]. This reaction leads with *(102)* to the cyclopropyl compound *(103)*,



which gives exclusively the isopropyl compound *(104)* on hydrogenation in the presence of Raney nickel. The cyclopropane ring is stable to H_2/Pd, sodium in liquid ammonia, bases, and dilute acids[156].

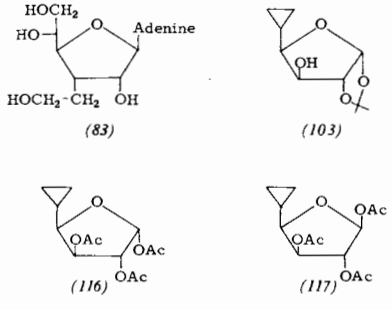
On addition of carbene to *(105)* by the Simmons-Smith method, the cyclopropyl compound *(106)* having the *allo*-configuration is formed, with the allal *(107)* as a by-product[157]. The ion *(108)* is formed in this reaction as an intermediate.

Another method for the synthesis of sugars containing cyclopropane rings is the reaction of an anhydro sugar with organophosphorus compounds. Thus the reaction of



(76) with ethyl diethoxyphosphonoacetate followed by hydrolysis leads to the compound *(109)*, which can undergo many further transformations[158].

4. Conformation of Branched-Chain Sugars



No systematic studies have so far been carried out on the conformation of branched pyranoses. On the other hand, a number of results for branched furanoses have been reported.

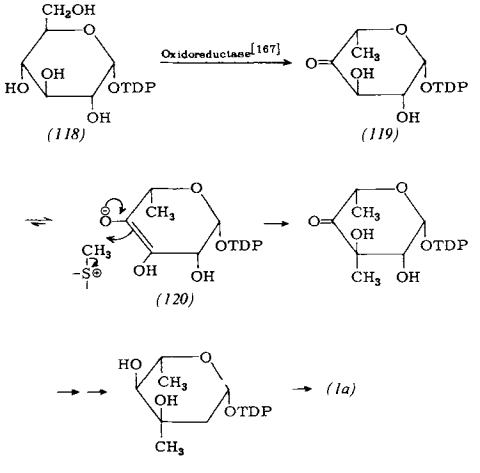
The NMR spectrum of 3′-*C*-methyladenosine *(110)* gives a value of 8.2 Hz for the coupling constant $J_{H\text{-}1'—H\text{-}2'}$, whereas the values for adenosine *(111)* and for 3′-deoxyadenosine *(112)* are 6 Hz and 2.3 Hz respectively[76]. The steric interaction in the furan ring decreases in this order. The dihedral angles found for H-1′—H-2′ with the aid of a modified Karplus equation were 151° for *(110)*, 138° for *(111)*, and 116° for *(112)*. These results indicate increasing deformation of the furanose ring on substitution with bulky groups. It can be shown with the aid of a model that *(110)* probably assumes a T_3^2 conformation *(113)*, *i.e.* a twist conformation, in which C-3′ lies below the plane formed by C-4′—O—C-1′, while C-2′ lies above this plane[164].

The size of the dihedral angle H-1′—H-2′ in *(110)* and the correspondingly large angle between the hydroxyl groups on C-2′ and C-3′ are in agreement with the observation that the (quasi-planar) 2′,3′-*O*-isopropylidene ring is formed with much greater difficulty in *(110)* than in *(111)*[76].

In contrast with these results, coupling constants $J_{H\text{-}1—H\text{-}2}$ and $J_{H\text{-}1'—H\text{-}2'}$ of between 0 and 3.5 Hz were found for methyl-3-*C*-methyl-β-D-ribofuranoside[76] and for the 3′-*C*-(2-hydroxyethyl)adenosine derivative *(83)*[142]. The dihedral angle between H-1 and H-2 and between H-1′ and

H-2′ is thus smaller in these cases than in adenosine *(111)*, and the furanoses are probably in the T_2^3 conformation *(114)*.

In the case of the cyclopropane sugars *(103)*, *(116)*, and *(117)*, the coupling constants $J_{H\text{-}1-H\text{-}2}$, $J_{H\text{-}2-H\text{-}3}$, and $J_{H\text{-}3-H\text{-}4}$ indicate a T_2^3 conformation *(114)* for *(103)* and *(117)* and a T_3^2 or v_1 conformation *(115)* for *(116)*[156].

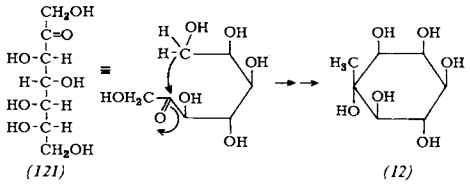


5. Biosynthesis

5.1. Methyl-Branched Sugars

The initially surprising observation that the methyl branch of mycarose *(1a)* comes from the *S*-methyl group of L-methionine (probably *via* *S*-adenosyl-L-methionine) is probably valid for all methyl-branched sugars[111]. This has also been shown experimentally for cladinose and noviose[10, 11].

After incubation of *Streptomyces fradiae* (tylosin former) with methionine deuterated in the *S*-methyl group, mycarose thioacetal was isolated. In the mass spectrum of this compound, the signals of the molecular-ion and of all the fragment ions containing the methyl group on C-3 were accompanied by signals with three mass units higher[165]. It follows that the intact methyl group of methionine is transferred to the hexose chain.



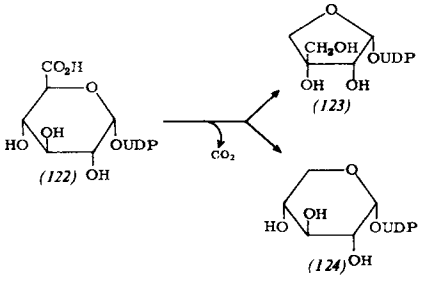
The sugar chain is probably methylated at the stage of a nucleotide-bound 4-keto-6-deoxyhexose, with "active methionine" as the methyl group donor. The formation of thymidine diphosphate 4-keto-6-deoxyhexose *(119)* from TDP-D-glucose *(118)* has been detected in cell-free extracts of *S. fradiae*. Mycarose is also formed with these extracts if *S*-adenosyl-L-methionine and TDP-D-glucose or TDP-4-keto-6-deoxyhexose are present as substrates[166]. The first steps in the biosynthesis of mycarose can therefore be formulated as indicated.

The substitution of *(119)* by the electrophilic methyl group of *S*-adenosylmethionine is formulated here *via* the enol form *(120)*. However, it has not yet been shown that enolization of *(119)* occurs.

5.2. Methyl-Branched Inositols

In contrast with the biosynthesis of methyl-branched sugars, no incorporation of C_1 units was found in the biosynthesis of the *C*-methylinositol laminitol *(12)*. The "best precursor" for laminitol at present is L-*gluco*-heptulose *(121)*[168]. This heptulose has also been detected in small quantities by dilution analysis after application of $^{14}CO_2$ to

Porphyridium[168]. It may therefore be assumed that the methyl group of laminitol comes from C-7 of the heptulose. Experiments with specifically labeled precursors, which would be necessary to confirm this hypothesis, have not yet been carried out.



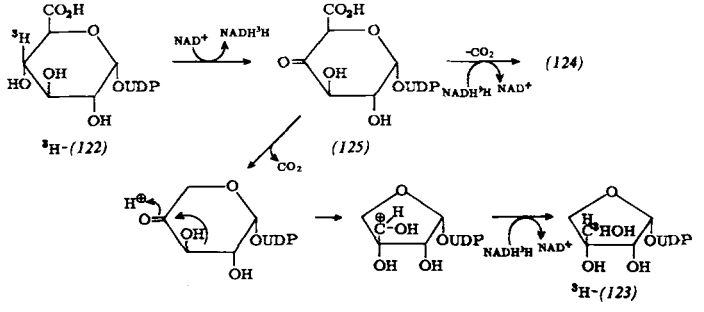
Mytilitol *(11)* appears to be formed in *Chlorella fusca* by epimerization of *(12)*[168a].

5.3. Hydroxymethyl-Branched or Formyl-Branched Sugars

Both hydroxymethyl-branched and formyl-branched sugars are formed by rearrangement of the sugar chain, one C atom being reoriented to form the branch[111]. The biosyntheses of apiose *(16)*, hamamelose *(17)* and streptose *(19)* have been investigated so far. Since no new reports on hamamelose and streptose have been published since the last review[111], only the biosynthesis of apiose will be discussed here.

The biosynthesis of apiose proceeds *via* nucleotide-bound intermediates. The precursor is uridine diphosphate D-glucuronic acid *(122)*; loss of the carboxyl group and branching at C-3 gives UDP-apiose *(123)*[111]. The enzyme that catalyzes this reaction has been partially purified from *Lemna minor*[169, 170] and from cell cultures of parsley[171]. The reaction is NAD^+-dependent.

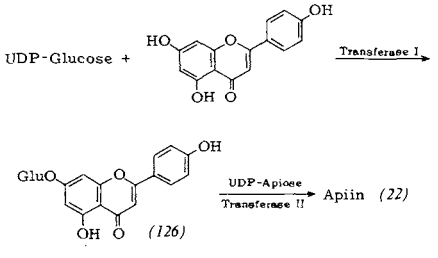
All the enzyme preparations obtained so far also catalyze the formation of UDP-D-xylose *(124)*. None of the modern separation methods for proteins (chromatography on



DEAE cellulose, polyacrylamide gel electrophoresis, and electrofocussing) has so far succeeded in separating the two enzymatic activities. They could therefore be due to a multifunctional enzyme.

The activity of this enzyme in parsley and cell cultures is drastically increased by light[172]. Ammonium ions in-

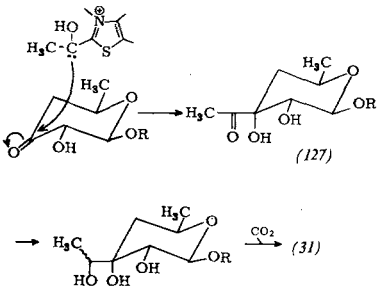
hibit the formation of apiose and stimulate the formation of xylose[170].



Cell cultures of parsley contain a second enzyme, which catalyzes the reaction UDP-glucuronic acid → UDP-xylose without simultaneous formation of UDP-apiose. This enzyme differs considerably in its properties from the apiose/xylose-forming enzyme. For example, it is not influenced by light[173].

When UDP-glucuronic acid labeled on C-4 with tritium is incubated with the apiose/xylose-forming enzyme, the tritium in the UDP-apiose *(123)* is found entirely on the branch C atom[174]. This result can be explained by a hydride transfer involving NAD^+ in the course of the biosynthesis. This is in agreement with our earlier suggestion that the 4-keto compound *(125)* functions as a common intermediate for apiose and xylose[175].

A variant of the rearrangement to apiose, which starts with the same 4-keto compound, was suggested by *Picken* and *Mendicino*[176].



An enzyme that catalyzes the transfer of apiose from UDP-apiose *(123)* to 7-glucosylapigenin *(126)* with formation of apiin *(22)* was partially purified from parsley[177] and cell cultures of this plant and separated from the UDP-glucose: apigenin-7-*O*-glucosyl transferase[178]. According to these results, the two sugars glucose and apiose are linked stepwise to the flavone in the biosynthesis of apiin.

Apiose occurs in polysaccharides in *Lemna* but not in parsley. The transferase responsible for the formation of the polysaccharide containing apiose in *Lemna* (see Section 2.3) is not yet known.

5.4. Hydroxyethyl-Branched Sugars

Among biosyntheses of sugars of this type, that of D-aldgarose *(31)*, a component of aldgamycin, has been investigated. Methionine, ethionine, acetate, and glucose have been ruled out as precursors of the hydroxyethyl branch. On the other hand, specific incorporation of [2-^{14}C]- or [3-^{14}C]-pyruvate into the side chain of aldgarose has been demonstrated[70], while the hexose skeleton comes from D-glucose[69]. It is postulated on the basis of these results that the precursors for the hydroxyethyl branch could be hydroxyethylthiamine pyrophosphate ("active acetaldehyde"), the reaction of which with a 3-ketohexose leads to the intermediate *(127)*. Reduction of the carbonyl group

in *(127)* and formation of the cyclic carbonate would then give aldgarose *(31)*. According to results with [^{14}C]-hydrogen carbonate, the cyclic carbonate is formed at the stage of aldgamycin C by a carboxylation reaction[69, 179].

6. Physiological Action of Branched-Chain Sugars

Very little is known as yet about the physiological action of branched sugars.

Adenosine analogs that are not deaminated to inosine derivatives by adenosine deaminase are of interest as inhibitors of the nucleic acid biosynthesis. It is therefore interesting that 3'-*C*-methyladenosine and 2'-*C*-methyladenosine are not deaminated, or are deaminated very slowly, by adenosine deaminase[113] or by Ehrlich ascites cells[180]. Both adenosines branched in the ribose part inhibit the growth of KB cells[*] in cultures[181].

It is also interesting that 3'-*C*-methyladenosine is phosphorylated to the 5'-triphosphate (the ATP analog) by Ehrlich ascites cells, whereas 5',5'-dimethyladenosine is not[180]. *Walton et al.* have reported on the synthesis and antiviral properties of 2'-*C*-methylcytidine and 3'-*C*-methylcytidine[181]. A number of other nucleosides of branched sugars have been synthesized on the basis of these findings (cf. Section 3), but nothing is yet known about their physiological action.

It is uncertain whether the numerous branched sugars of the antibiotics contribute directly to the antibiotic action[182].

Since some aquatic plants are characterized by apiose-rich cell walls, such cell walls could be connected with the particular conditions of life in the water[53]. Reference has already been made to the resistance of polysaccharides containing apiose toward pectinase (see Section 2.3)[58].

[*] KB cells are human tumor cells from the pharyngeal region.

Our own work in this field has been supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

Mechanisms of Reactions in the Solid State

By Kurt Hardel[*]

The reaction of two solid phases X and Y to give a solid compound XY_ν is taken as an example for the discussion of transport mechanisms and reaction steps. The following methods of investigation are discussed: determination of the rate law, marker experiments, and calculation of the reaction rate. It is pointed out that the investigation of powder reactions leads to problematic conclusions.

1. Introduction

If a solid phase X is in contact with a solid phase Y at a temperature at which the mobilities of the particles in the solid state are sufficiently high, X and Y can react to form one or more solid reaction products $XY_{\nu 1}$, $XY_{\nu 2}$, *etc.* which separate the reactants from each other. A process of this kind is a solid-state reaction. The reactants X and Y may be elements or compounds. Generally the reaction is exothermic, since the entropy of reaction of solids is low. Similar features are valid for reactions between several solid phases, X_1, X_2, *etc.* and several solid phases Y_1, Y_2, *etc.* to form one or more solid reaction products.

If one considers only the reaction of a single solid phase X with a single solid phase Y, the following reaction types can be distinguished:

1. Formation of one or more compounds;

2. Formation of a continuous series of solid solutions between the reactants;

3. Formation of a series of solid solutions with a miscibility gap;

4. Double reaction, *e.g.* $PbS_{(s)}+CdO_{(s)}\rightarrow PbO_{(s)}+CdS_{(s)}$[1];

5. Superposition of the solid-state reaction by an additional decomposition of one reactant with formation of a gas, *e. g.*

$$BaCO_{3(s)} + WO_{3(s)} \rightarrow BaWO_{4(s)} + CO_{2(g)}$$

Only the relatively well-studied reaction type 1 will be discussed, specifically the formation of a single compound XY_ν with a small homogeneity range. X and Y will be binary ionic compounds having the same anion, and XY_ν will be a ternary ionic compound. The reaction mechanisms and the principal methods of investigation are discussed for this simple case. Examples may be found in the literature cited.

2. Reaction Mechanisms

At the beginning of the reaction, the following reaction step may be assumed:

(I) Exchange processes of particles at the interface between the two reactants and formation of the reaction product (phase boundary reaction).

If the reaction product is a ternary compound and if the contact between the solids is ideal, there are three conceivable transport mechanisms after the formation of a homogeneous, pore-free reaction layer; these mechanisms, which

[*] Prof. Dr.-Ing. K. Hardel
Institut für Anorganische und Analytische Chemie der Technischen Universität
1 Berlin 12, Strasse des 17. Juni 135 (Germany)

should be regarded as limiting cases, are shown schematically in Figure 1 for spinel formation from the oxides. A distinction is to be made between the migration of cations and anions through the reaction product in the same direction and countertransport of cations[2]. For the case in which the cations and anions of the substance AO migrate in the same direction through the reaction product to the reactant B_2O_3 (Fig. 1), further reaction steps are as follows:

(II) Transfer of the particles through the interface 1 between the reactant AO and the reaction product (phase boundary reaction).

(III) Diffusion of the cations and anions of the substance AO through the reaction product, specifically volume diffusion or diffusion *via* grain boundaries and dislocations of the crystallites of the reaction product.

(IV) Reaction of the cations and anions of the substance AO at the interface 2 with the reactant B_2O_3 to form the reaction product (phase boundary reaction).

Analogous reaction steps may be assumed for migration of the cations and anions of the substance B_2O_3 through the reaction product in the same direction and for countertransport of cations (Fig. 1).

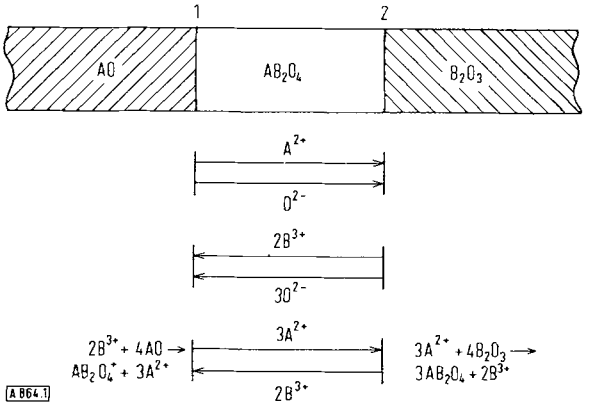

Fig. 1. Transport mechanisms with ideal contact between the solids.

If the contact between the reactants or between one of the reactants and the reaction product is insufficient, or if the reaction layer contains pores, other transport mechanisms are possible; these are the transport of one reactant *via* the gas phase or the transport of the nonmetallic component *via* the gas phase with simultaneous migration of cations and of electrons or defect electrons through the reaction layer (Fig. 2).

Exchange processes of particles at the interface at the beginning of the reaction have been confirmed by LEED investigations[3].

The mechanism of the formation of the reaction product in steps (I) and (IV) has not yet been sufficiently elucidated. It is to be supposed that because of the limited solubility of the reaction product in the reactant, supersaturation of the reactant with the reaction product can occur in the phase boundary reaction (I) or (IV), with consequent heterogeneous nucleation and crystal growth. The heterogeneous nucleation is possible at the interface and in the vicinity of the interface at two-dimensional and one-dimensional defects, at vacancies, or at impurities[4]. In the spinel formation from the oxides, the following mechanism has been proposed for the case of countertransport of cations and for the structural relationship between the reaction product and one of the reactants[5]: After transfer through the interface between the reaction product and the reactant (Fig. 1), the small cations diffuse into the reactant and occupy the sites of the cation lattice of the reaction product, while the anion lattice of this reactant is transformed into the anion lattice of the reaction product by alteration of the stacking sequence of the lattice planes. This occurs by migration of partial dislocations.

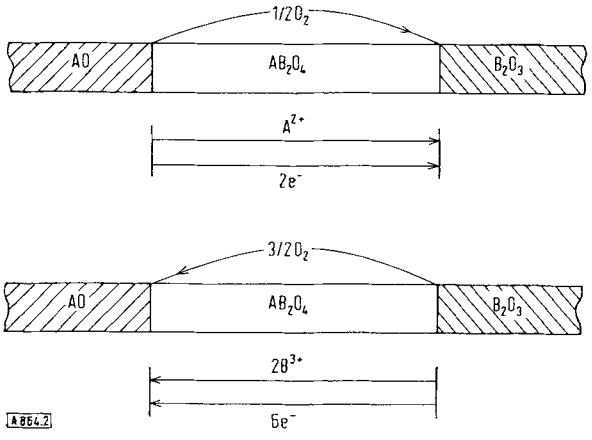

Fig. 2. Transport mechanisms for the case in which contact between the solids is inadequate and the partial pressure of the nonmetallic component is sufficiently high.

Reaction step (II), *i.e.* the finite rate of the transfer of the particles through the interface between one reactant and the reaction product (Fig. 1), can be detected[6]. Deviations from thermodynamic equilibrium at the interface may inhibit the transfer of the particles through the interface, with the result that this becomes the rate-determining step of the reaction.

The volume diffusion through the reaction product, which depends only on the concentration of point defects, has been extensively studied. Reaction layers that are at least several μm thick, and in which the volume diffusion is often the rate-determining step of the reaction at sufficiently high reaction temperatures, are relatively easy to investigate. If the reaction product is a ternary compound and if it is assumed that the particles migrate independently of one another and that the ion currents are related only by the electroneutrality condition, it is possible to distinguish the three diffusion mechanisms shown schematically in Figure 1. Since the component diffusion coefficients of the various types of ions are generally different, the rate of the solid-state reaction is determined by the type of ion whose mobility lies between the mobilities of the other two types. With counterdiffusion of cations, for example, the mobility of the type of cation that diffuses more slowly is rate-determining[7].

If the reaction temperature is not so high that volume diffusion predominates, the diffusion of the particles *via* the

grain boundaries and dislocations ("dislocation pipes") of the crystallites of the product can become the rate-determining step of the reaction. In this case, the reaction rate depends on the relative orientation of neighboring crystallites of the product[8] and on the size of the coherent crystal regions. The reaction rate increases with decreasing average crystallite size or with decreasing average size of the coherent regions of the product[9-11]. If the product is a ternary compound, it is possible, in analogy with volume diffusion, to discuss diffusion of cations and anions in the same direction or counterdiffusion of cations.

If it is established that the formation of the reaction product in step (IV) is coupled throughout the reaction with nucleation processes at the interface between the product and the reactant (Fig. 1), it is possible that the average crystallite size of the reaction product depends on the rate of nucleation of the product at this interface. If grain boundary diffusion through the reaction product is rate-determining, it is thus necessary to check whether factors that affect the rate of nucleation of the reaction product at the interface between the reactant and the product lead to a change in the average crystallite size of the product, and hence to a change in the reaction rate. Such factors would be the crystal structure, the crystallographic orientation, and the defect structure of the reactant, as well as contamination of the reactant with impurities[12-14]. The mechanism has not yet been proved beyond doubt[9].

Where contact between the solid substances is inadequate, the influence of the gas phase on the solid-state reaction must be taken into account. If gaps in which a certain partial pressure of the reactant is produced remain between one of the reactants and the reaction layer during the reaction, and if the reaction temperature is so high that this partial pressure is not negligible, the mass transport takes place *via* the gas phase. For sufficiently thin reaction layers, the evaporation of the reactant, the transport in the gas phase, and the condensation on the reaction product may become rate-determining[5]. This can also be observed[15]. With thick layers of reaction product, however, diffusion through the product is the rate-determining step of the reaction.

If partial conductivity of electrons or defect electrons in the reaction product is not negligible, and if the partial pressure of the nonmetallic component is sufficiently high, the nonmetallic component may be transported *via* the gas phase in cases of insufficient contact between the solid substances or in cases where the reaction layer contains pores, while electroneutrality is maintained by an electron or defect electron current through the reaction product. For the example of spinel formation from the oxides, Figure 2 shows schematically the transport of oxygen through the gas phase with simultaneous transport of the cation A^{2+} or B^{3+} and of electrons through the spinel layer. It is assumed that the particles migrate independently of one another and that the ion and electron or defect electron currents are coupled only by the condition of electroneutrality. The rate-determining step is the diffusion of the cations A^{2+} or B^{3+} through the reaction product. If the oxygen partial pressure is decreased to such an extent that there are no longer sufficient oxygen molecules available for the reaction at the interface, another transport mechanism must come into effect[16].

With good contact between the solid substances, if the partial pressure of the nonmetallic component is sufficiently high, one may find the special case that the reaction product is formed not only between the reactants but also on part of the surface of one of these substances[17]. It is then possible that counterdiffusion of cations occurs in the interior of the reaction layer (Fig. 1), whereas in the zones near the surface, cations and electrons or defect electrons migrate through the reaction product, and the nonmetallic component is simultaneously transported *via* the gas phase (Fig. 2).

The rate-determining step of these reactions depends mainly on the experimental conditions under which the solid-state reaction takes place. The transport mechanism is mainly determined by the experimental conditions, the mobilities of the various types of ions in the reaction product, and the electronic properties of the product.

3. Methods of Investigation

It is assumed in the following discussion that the reaction is isothermic. This condition is satisfied if the mass fraction of the reaction product formed per unit time is relatively small. This assumption is generally permissible in solid-state reactions of the type specified in Section 1.

The principal methods used to investigate the mechanisms of such solid-state reactions are the following:

1. determination of the rate law to establish the rate-determining step of the reaction;

2. marking the interface between the reactants before the beginning of the reaction to establish the transport mechanism;

3. calculation of the reaction rate if the volume diffusion through the product is the rate-determining step. It is possible in this way to decide which of the diffusing types of ions determines the rate of the reaction.

3.1. Determination of the Rate Law

If the phase boundary reaction (II) or (IV) is the rate-determining step, the reaction rate is independent of the thickness Δx of the reaction layer; one obtains a linear rate law, which can be expressed in the form

$$\Delta x = l' t \tag{1}$$

if the reaction cross section remains constant and if the growth of the reaction layer can be treated as a one-dimensional problem. l' is the rate constant and t is the reaction time.

If nucleation is the rate-determining step, one can again obtain a linear rate law, which is the first approximation of the exponential law of nucleus formation, and which can be represented, after the formation of a homogeneous reaction layer, in the form of equation (1). The exponential law is the frequently used equation for the rate of nucleation.

To establish whether the rate-determining step is the phase boundary reaction (II) or (IV) or the nucleation of the reaction product, it is necessary to use further methods of investigation. In the case of nucleation, it may be possible to use microscopy or electron microscopy as the additional method of investigation, if it is possible to separate the reaction layer from one of the reactants without destruction.

If volume diffusion through the reaction product is rate-determining, the reaction rate decreases with increasing thickness Δx of the reaction layer. The process then follows the parabolic rate law, which can be expressed, for a constant reaction cross section, *i. e.* for one-dimensional growth of the single-phase reaction layer, in the form

$$\Delta x^2 = 2k't \qquad (2)$$

k' is the rate constant and t is the reaction time.

Equation (2) also describes the growth of the reaction layer if, instead of the volume diffusion, the rate-determining step is the diffusion *via* the grain boundaries and dislocations of the crystallites of the product, provided that the flux equation[18] can be applied to the ion currents[19].

It is possible to decide between rate-determining volume diffusion and rate-determining diffusion *via* the grain boundaries and dislocations if the reaction rate is found to depend on the average crystallite size or on the average size of the coherent regions of the reaction product. The average crystallite size can be determined with the aid of the microscope or the electron microscope; the average size of the coherently scattering crystal regions can be determined from X-ray line broadening. An indication which of the two diffusion mechanisms predominates can also be obtained by comparison of the activation energies of the two processes. The activation energy of the diffusion *via* grain boundaries and dislocations of the crystallites of the product is relatively low.

Deviations from the parabolic rate law (2) at the beginning of the reaction, *i. e.* if the reaction layer is thin, can also be attributed, in cases of insufficient contact between one of the reactants and the reaction layer, to the evaporation, condensation, or transport of one of the reactants in the gas phase[5]. With sufficiently thin reaction layers, transport *via* the gas phase becomes rate-determining, and a linear rate law (1) is to be expected if the diffusion path in the gas phase remains constant during the reaction[15].

3.1.1. Investigation of Powder Reactions

Though powder reactions are of great importance in preparative solid-state chemistry and in industry, the definite establishment of a rate law for these reactions is difficult, since the growth of the reaction layer is a three-dimensional problem, the thickness of the reaction layer cannot be measured directly, and the reaction cross section changes during the reaction. The investigation is further complicated by other parameters, such as the grain size, the grain size distribution, the porosity of the grains, and the packing density. The determination of the mechanism of powder reactions is therefore problematic[20], even when diffusion processes through the reaction product are rate-determining and the frequently used equations of *Jander*[21] and of *Serin* and *Ellickson*[22] can be applied.

3.1.2. Investigation of Reaction Layers with Plane-Parallel Interfaces

If the reactants are used in compact form, specifically as a single-crystal or as a sintered specimen with plane contact surfaces, the reaction product is formed between the reactants as a layer with a constant reaction cross section and with plane-parallel interfaces. In this case, the growth of the reaction layer may be treated as a one-dimensional problem. For reaction layers whose thickness Δx is at least several μm, Δx can be measured directly by microscopic observation of sections normal to the reaction cross section, and the rate law can thus be determined. This procedure is frequently used.

Using one reactant single-crystalline or as a sintered sample and the second reactant as a cover layer deposited onto the plane substrate, *e. g.* by evaporation *in vacuo* or by sputtering, optimum contact between the reactants can be achieved under suitable experimental conditions. The reaction product is then generally also formed under the cover layer as a homogeneous layer with a constant reaction cross section and plane-parallel interfaces, so that the growth of the reaction layer may be treated as a one-dimensional problem. Since only a thin cover layer is applied to the substrate in this method, the procedure is suitable for the determination of the rate law for thin reaction layers up to a maximum of a few 10^4 Å thick. This method yields information about the initial stages of a solid-state reaction, for example about the reaction steps (I) to (IV) that can become rate-determining in the case of thin reaction layers. Very little is known about the initial stages of solid-state reactions[9, 15], apart from the problematic results obtained by the investigation of powder reactions.

However, the thickness of the thin reaction layers cannot be measured microscopically. In some cases, the cover layer of one of the reactants can be quantitatively removed from the reaction layer by means of a suitable solvent; if the density of the reaction product and the cross section of the reaction layer are known, the thickness Δx of the single-phase reaction layer can then be found by weighing, and the rate law can be determined. In other cases, it is possible to use a procedure[23] based on the measurement of the thickness Δx of the thin reaction layer XY_ν (maximum thickness several 10^3 Å) between the substrate X of one reactant (at least a few millimeters thick) and the thin cover layer Y of the other reactant by X-ray fluorescence analysis (Fig. 3).

The intensity of the X-ray fluorescent radiation of an element in the sample is determined before the beginning of the reaction, *i. e.* without the reaction layer XY_ν, and after the reaction time t, *i. e.* with the reaction layer XY_ν, with monochromatic X-rays; the thickness Δx of the reaction layer after the reaction time t can then be found from the change in intensity, and the rate law can be determined. The intensity I of the X-ray fluorescent radiation is obtained by

surface measurement without destruction of the sample. The following conditions must be satisfied:

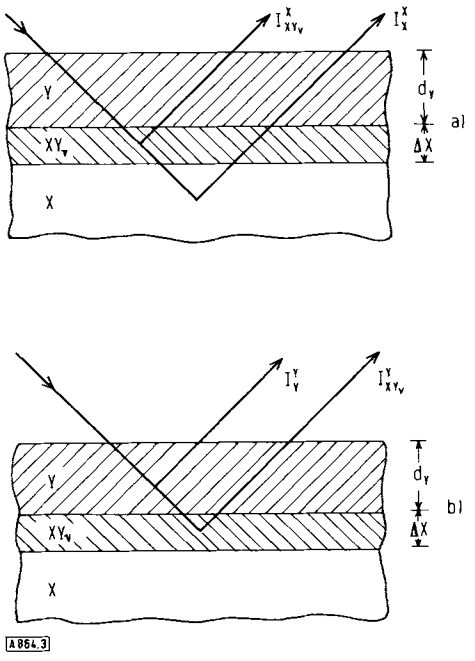

Fig. 3. Excitation of X-ray fluorescent radiation in the sample.

1. The reaction layer is in the form of a homogeneous layer with plane-parallel interfaces. The roughness of the phase boundaries is disregarded.

2. In the quasi-binary system of the reactants X and Y, only one compound XY_ν is formed, or the layer thicknesses of any other compounds formed in this system are negligible. The homogeneity ranges of the reactants and of the reaction product are small.

3. The cover layer Y contains an element Y that does not occur in the substrate X, or *vice versa*.

4. The X-ray fluorescent radiation of the excited element is sufficiently absorbed by passage through the sample.

Two methods of measurement can then be distinguished, depending on whether the X-ray fluorescence of the element X is excited in the substrate X and in the reaction layer XY_ν under the cover layer Y (Fig. 3a) or whether the X-ray fluorescence of the element Y is excited in the cover layer Y and in the reaction layer XY_ν (Fig. 3b). For both cases, it is possible to give functions for the determination of the thickness Δx of the reaction layer under the cover layer[*] if the absorption coefficient of the X-rays can be determined by investigation of the cover layer Y without the reaction layer XY_ν and of the reaction layer XY_ν without the cover layer Y. The more favorable of the two methods (Fig. 3a or Fig. 3b) is chosen for experimental studies. It is advisable to excite the element in the sample whose X-ray fluorescent radiation is most strongly absorbed on passage through the sample, in particular an element with a relatively low atomic number that emits long-wave X-rays.

[*] Cf. eq. (12) or (6) in Ref. [23].

The method has been successfully tested by measurement of the thickness Δx of thin layers of Pb_2SiO_4 up to several 10^3 Å thick[24]. The Pb_2SiO_4 layer was situated between a quartz single crystal or a quartz glass substrate and a thin cover layer of PbO. The Δx values found by X-ray fluorescence analysis agreed with those found by weighing after the removal of the PbO cover layers.

3.2. Marker Experiments

If the reactants are used as single crystals or as sintered samples with plane contact surfaces, it is possible to determine the transport mechanism on which the solid-state reaction is based by marking the interface before the beginning of the reaction with wires or foils of inert material, *e.g.* platinum, a few μm thick (Fig. 4a). By microscopic observation of the position of these markers after the reaction in sections normal to the reaction cross section, it is possible to distinguish the cases shown in Figures 4b to 4d for spinel formation from the oxides. If the position of these markers after the reaction is assumed to indicate the position of the interface between the reactants before the reaction and if the homogeneity ranges of the reaction product and of the reactants may be disregarded, the experiments can be interpreted as follows:

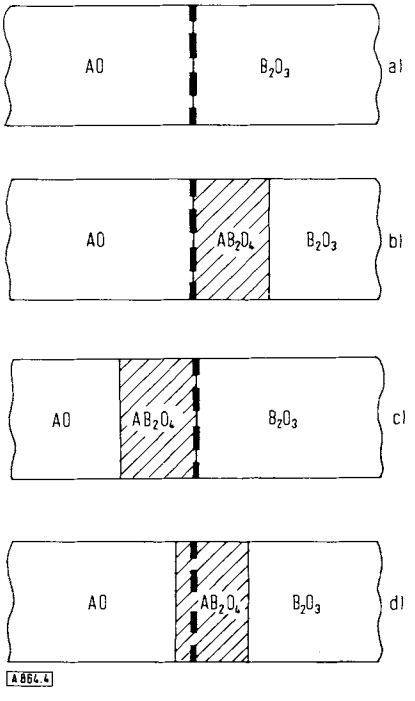

Fig. 4. Position of the markers before (a) and after (b to d) the reaction.

1. If the inert markers are situated in the interface between one reactant and the reaction product (Figs. 4b and 4c), this indicates transport of the cations and anions of this reactant in the same direction through the reaction product (Fig. 1) or migration of cations and of electrons or defect electrons through the reaction layer in conjunction with transport of the nonmetallic component *via* the gas phase (Fig. 2).

2. If the inert markers are situated inside the reaction layer (Fig. 4d), this points to countertransport of cations (Fig. 1). In spinel formation from the oxides, the marker then divides the spinel layer in the ratio 1:3, since according to Fig. 1 only 1 mole of spinel is formed at interface 1, while 3 moles are formed at interface 2.

If the transport of a reactant *via* the gas phase is involved, a reaction layer is formed on one of the reactants even when the compact reactants are separated before the reaction by platinum wires a few hundred μm thick and when this separation is maintained during the reaction.

However, the condition that the position of the interface before the reaction is still indicated by the inert markers after the reaction is frequently not satisfied. It is better to use natural markers. For example, one of the reactants may be used single-crystalline, the cross section of this sample being large in relation to the cross section of the compact sample of the other reactant; the parts of the surface of the single crystal on which no reaction has occurred can then be used as a natural marker. If the reactants differ in their porosity or if one is monocrystalline and the other polycrystalline, the change in porosity or the monocrystallinity or polycrystallinity of the reaction layer may be used as a natural marker.

Experiments with markers are not possible if the reaction layers are less than a few μm thick. In such cases, the results of marker experiments with thick reaction layers must be used to obtain information about the transport mechanism. The same is true of powder reactions.

3.3. Calculation of the Reaction Rate

If the volume diffusion through the product is the rate-determining step, the transport mechanism found from marker experiments can be checked and confirmed by comparing the rate constant of the parabolic rate law calculated on the basis of this transport mechanism with the measured rate constant. The rate of such a solid-state reaction can be calculated for a small spinel phase width[18] if the following conditions are satisfied:

1. The reaction is isothermal and isobaric. The partial pressure of the nonmetallic component is constant, so that the disorder type of the reaction product does not change.

2. The homogeneity ranges of the reactants and of the single-phase reaction product are small.

3. The reactants and the reaction product contain no pores. The contact at the interfaces is ideal.

4. Local thermodynamic equilibrium exists within the reaction layer. This means that the point defects are responsible for the transport of the particles through the reaction layer. The reaction temperature must therefore be so high that the diffusion *via* the grain boundaries and dislocations of the crystallites of the product is negligible.

5. Thermodynamic equilibrium is maintained at the interfaces during the reaction, so that the transfer of the particles through the interfaces is not inhibited. This condition is generally satisfied for sufficiently thick reaction layers.

6. The particles migrate independently of one another. The ion and the electron or defect electron currents are coupled only by the condition of electroneutrality.

If the mobilities of the various types of ions in the lattice of the product differ sufficiently from one another, certain diffusion mechanisms occur.

If the oxygen ions have the lowest mobility in the spinel lattice, counterdiffusion of cations (Fig. 1) occurs when contact between the solids is ideal. The diffusion of the type of cation having the lower mobility is then the rate-determining step. If this is *e.g.* the ion A^{2+} and if the homogeneity range of the spinel is small, the rational reaction constant k can be calculated from the following equation[18]:

$$k = \gamma c_A n_A^{-1} D_A(a_{AO} = 1) \quad [1 - \exp(n_A \Delta G^0 / RT)] \tag{3}$$

γ is a numerical factor of the order of 1, c_A is the molar concentration of the ion A^{2+} in the reaction product, R is the gas constant, and T is the absolute temperature. $D_A(a_{AO}=1)$ is the self-diffusion coefficient of the ionic species A^{2+} in the reaction product when the activity of the reactant AO in the reaction product is 1. ΔG^0 is the standard free energy of the reaction $AO + B_2O_3 = AB_2O_4$. The reaction constant k is related to the rate constant k' of the parabolic rate law (2), which can be determined experimentally by $k = k'/\tilde{V}$, where $\tilde{V}$ is the equivalent volume of the reaction product.

ΔG^0 can be measured with the aid of galvanic solid-state cells. $D_A(a_{AO}=1)$ must be determined for the case where the reaction product is in equilibrium with AO, *i.e.* the activity of AO in the reaction product is unity. n_A can be determined from the equation[18]

$$\frac{D_A(a_{AO}=1)}{D_A(a_{B_2O_3}=1)} = \exp(n_A \Delta G^0 / RT) \tag{4}$$

where $D_A(a_{B_2O_3}=1)$ is the self-diffusion coefficient of the ions A^{2+} in the reaction product if the reaction product is in equilibrium with B_2O_3, *i.e.* the activity of B_2O_3 in the reaction product is unity. n_A has also been calculated for a number of disorder types[18, 25].

4. Closing Remarks

The transport mechanisms and reaction steps discussed here are also valid in principle when several ternary compounds are formed instead of one in the quasi-binary system of the two reactants.

The knowledge of the mechanisms of solid-state reactions can lead to new synthetic pathways in preparative solid-state chemistry. However, our knowledge of the kinetics of

these reactions is still limited. In particular, the following problems are to be clarified:

1. the initial stages of solid-state reactions;
2. the mechanisms of reaction types 4 and 5 in Section 1.

Chemistry of the Positron and of Positronium[1]

By Hans J. Ache[*]

In this progress report, the properties and behavior of the positron ("positive electron", anti-electron) and of the positronium, a "hydrogen atom" containing a positron instead of a proton, are considered from the chemist's viewpoint. Examples are given to demonstrate the development of positronium chemistry, in aqueous solution and in the gaseous, liquid, and solid phases, with its problems and possibilities.

1. Introduction

The reactions of the hydrogen atom and of the proton have been the subject of numerous investigations and must be familiar to every chemist. The reactions of deuterium and of tritium, the heavy hydrogen isotopes with masses 2 and 3 respectively, which are often used as "labeled" hydrogen atoms for the investigation of reaction mechanisms, are also extensively known.

It is probably not so well known, however, that there is an "atom" that can be regarded as an analog of the hydrogen atom, but in which the proton is replaced by a positron, and which thus represents the lightest isotope of hydrogen. This particle, which is known as a positronium, has a very limited lifetime (of the order of 10^{-7} to 10^{-10} s) before it decays with emission of two or three photons.

Despite this short lifetime, which rules out conventional product analysis as used *e.g.* in the reactions of deuterium or tritium, it is an excellent "labeled" hydrogen atom for the investigation of chemical and physical processes in matter; this is because its lifetime and the mechanism of its decay process are determined by the chemical and physical state of the environment. The positron-electron annihilation process is one of the few known nuclear processes whose course depends in a characteristic manner on the chemical and physical structure of the environment. These elementary particles can therefore serve as nuclear probes, and can provide a great deal of information about the properties of the surrounding matter.

At present there are essentially four nuclear processes that satisfy these conditions: 1. the Mössbauer effect; 2. the positron-electron annihilation process; 3. the angular distribution between two successive γ quanta in the emission of γ cascades; and 4. the depolarization of muons and muonium formation.

Whereas *e.g.* the Mössbauer effect has had a firm place in analytical chemistry for several years, the part that the positron or positronium can play in the solution of chemical problems is still largely unknown.

The physico-chemical aspects of the interaction between the positron and matter will therefore be examined below,

[*] Dr. H. J. Ache, Professor of Chemistry
Department of Chemistry
Virginia Polytechnic Institute and State University
Blacksburg, Virginia 24061 (USA)

and some examples will be given to demonstrate the importance of this new nuclear method to chemistry[2–5]. The fact that a positronium atom occurs as an intermediate in many cases before the final annihilation of the positron also allows the study of a series of interesting reactions of this unusual "atom".

2. Annihilation of the "Free" Positron

The positron, which is sometimes also referred to as a positive electron or anti-electron, has the same mass and electric charge as the electron, but the sign of its charge is positive. Its spin, like that of the electron, is $1/2\,\hbar$; it belongs to the class of leptons and obeys the Fermi-Dirac statistics.

It is preferentially formed in the radioactive decay of nuclides in which the proton/neutron ratio is greater than one.

The fate of the positron in matter is determined by the fact that sooner or later it interacts with an electron, resulting in annihilation of both particles. The energy liberated in this process generally appears in the form of "annihilation radiation". The number of photons emitted is determined by the orientation of the spins of the positron and the electron at the instant of annihilation.

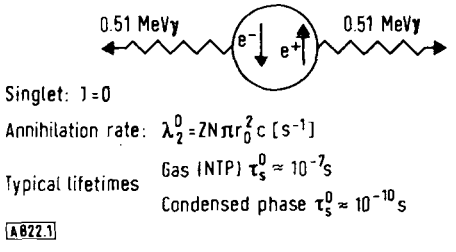

Fig. 1. Two-quantum annihilation of a positron (schematic). J = total spin momentum; Z = atomic number; N = number of particles per unit volume; r_0 = classical electron radius; c = velocity of light.

If the spins of the positron and of the electron are antiparallel, *i.e.* if a singlet system exists ($^1S_0$), the selection rules for the conservation of energy, momentum, and

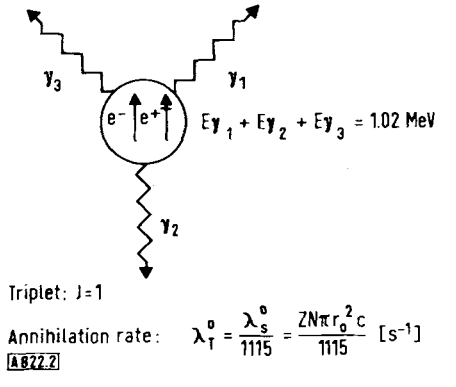

Fig. 2. Three-quantum annihilation of a positron (schematic).

parity require the emission of two γ quanta, each having the energy mc^2 (m = rest mass of the electron, c = velocity of light) or 0.51 MeV. The angular distribution between the two γ quanta depends on the kinetic energy of the positron-electron system (Fig. 1). If the system is at absolute rest at the instant of annihilation, the two photons are emitted in exactly opposite directions; in practice, however, the system usually still has a small content of kinetic energy, which can lead to deviations of a few milliradians (mrad) from the ideal angular distribution of 180°.

If the spins are parallel [triplet system ($^3S_1$)], the selection rules can be satisfied only by the emission of an odd number of photons (usually three). The distribution of the angles between three γ quanta and the distribution of the annihilation energy of 1.02 MeV over the three γ quanta are much more complicated than in two-quantum annihilation (Figs. 2 and 3).

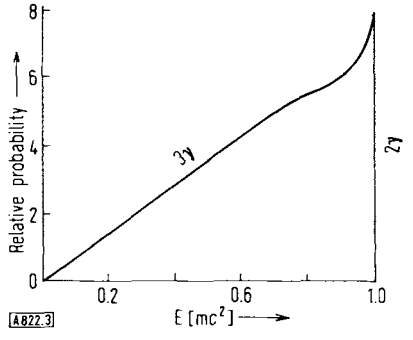

Fig. 3. γ-Energy spectrum of the positron-electron annihilation as a function of the alternatives: two-quantum or three-quantum decay [11].

The cross section for the two-quantum annihilation of a free positron having velocity v with a free electron at rest was calculated by *Dirac*[6]:

$$\sigma_D = \sigma_{2\gamma} = \frac{\pi r_0^2}{\gamma+1}\left[\frac{\gamma^2+4\gamma+1}{\gamma^2-1}\ln(\gamma+\sqrt{\gamma^2-1}) - \frac{\gamma+3}{\sqrt{\gamma^2-1}}\right] \quad (1)$$

$$\gamma = 1/\sqrt{1-\beta^2}\,; \qquad \beta = v/c \quad (2)$$

r_0 = classical radius of the electron or positron = $e^2/mc^2 = 2.8\cdot10^{-13}$ cm

If v is small in relation to c, equation (1) simplifies to:

$$\sigma_D = \frac{\pi r_0^2}{\beta} = \frac{\pi r_0^2 c}{v} \quad (3)$$

from which it is easy to see that the probability of annihilation of the positron increases with decreasing velocity of the particle. The annihilation constant of the free positron in matter ($\lambda_{2\gamma}$) and its average lifetime (τ_D) are found from equation (3), for the case of two-quantum annihilation, to be:

$$1/\tau_D = \lambda_{2\gamma} = ZN\pi r_0^2 c = ZN\sigma_D v\ [s^{-1}] \quad (4)$$

(Z = atomic number of the substrate; N = number of atoms per cm³; τ_D = Dirac lifetime)

Better agreement with the experimental findings can be obtained if Z in equation (4) is replaced by the quantity Z_{eff} (the number of electrons in the outer shells).

The ratio of the three-quantum to the two-quantum annihilation constants was calculated by *Ore*[11], and is:

$$\lambda_{3\gamma}/\lambda_{2\gamma} = 1/1115 \qquad (5)$$

Since the relative probabilities of the formation of triplet or singlet states on meeting of a positron and an electron are given by the number of possible quantum states in the two systems, which is $2J_T+1$, *i.e.* 3, in the case of the triplet (parallel spins, total momentum $J_T=1$) and $2J_S+1$, *i.e.* 1, in the case of the singlet (anti-parallel spins, $J_S=0$), the ratio of the cross sections of the two annihilation modes is given by the equation:

$$\sigma_{3\gamma}/\sigma_{2\gamma} = \frac{\lambda_{3\gamma}}{\lambda_{2\gamma}}\frac{2J_T+1}{2J_S+1} = \frac{1}{1115}\cdot 3 = 1/372 \qquad (6)$$

Positrons formed as a result of a nuclear decay process generally have kinetic energies of several hundred eV to a few MeV, which they lose by successive collisions with atoms or molecules of the environment.

A schematic representation of the fate of positrons in argon as a function of their kinetic energy is shown in Figure 4[7].

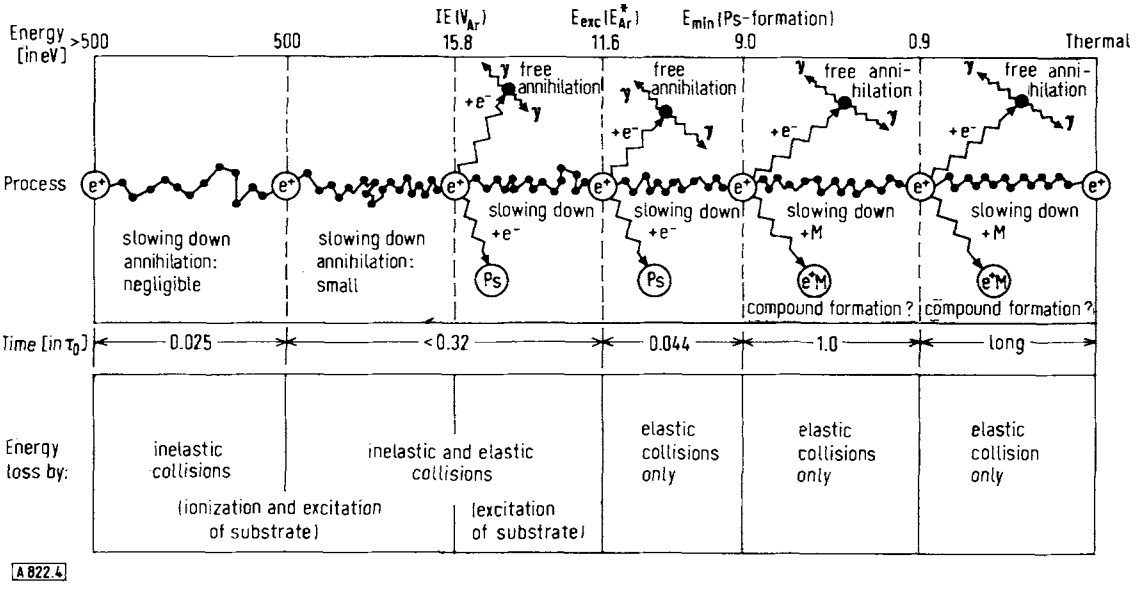

Fig. 4. Fate of positrons in argon as a function of their kinetic energy.

The cross section for the annihilation of positrons is extremely small in comparison with the cross sections for energy transfer *via* ionization or electron excitation in collisions with substrate molecules or atoms; less than 5% of all positrons are annihilated before reaching an energy level of about 5—10 eV.

A comparison of the "Dirac" lifetime calculated from equation (4) with the time required by the positrons to reduce their kinetic energy from an initial value of 0.5 MeV to thermal energies leads to the same result. If τ_D is compared with the time scale in Figure 4, it is found that positrons in argon require only about 8.74×10^{-8} s or 0.32 τ_D for their kinetic energy to fall below 20 eV, *i.e.* only a small fraction of all positrons is annihilated at higher energies.

3. Positronium Formation

The experimentally observed ratio of three-quantum to two-quantum annihilation usually differs considerably from the value of 1/372 found from quantum mechanics [equation (6)]. It follows that the annihilation of the *free* positron cannot be the only process that leads to the disappearance of positrons.

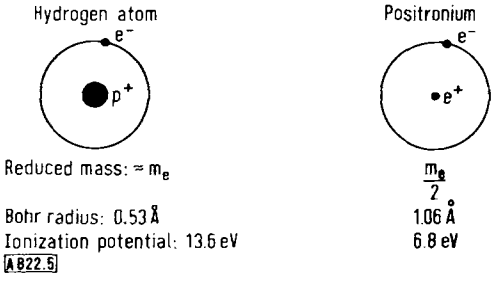

Fig. 5. Characteristics of hydrogen and positronium atoms.

The possibility that the positron could enter into combination (though only very short-lived) with an electron was considered by *Mohorovic*[8] as early as 1934. However, it

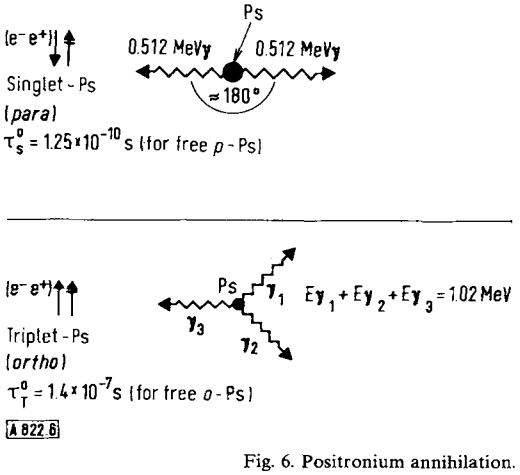

Fig. 6. Positronium annihilation.

was not until 17 years later that *Deutsch*[9, 10] was able to detect the combination, which is known as positronium (e^+e^- or Ps), experimentally.

The properties of positronium can be best described if it is considered as an analog of the hydrogen atom in which the proton has been replaced by a positron. On the basis of the simple Bohr model of the atom, the Ps atom has half the reduced mass of the H atom, so that in comparison with the H atom, the Bohr radius is doubled (1.06 Å) and the ionization potential is halved (6.8 eV) (Fig. 5).

Positronium can exist in two ground states, *i. e.* as a triplet (*ortho*-Ps), with parallel orientation of the positron and electron spins, and as a singlet (*para*-Ps), with antiparallel spins (Fig. 6). The ratio in which *o*-Ps and *p*-Ps are formed is again determined by the number of possible quantum states in which the two systems can occur (see Section 2), with the result that *o*-Ps is formed in 75% of cases and *p*-Ps in 25%.

Corresponding to the annihilation of the free positron, the rules for the conservation of energy, momentum, and parity require a three-quantum annihilation on decomposition of *o*-Ps and a two-quantum annihilation for *p*-Ps.

The average lifetime of *free* *p*-Ps is $\tau_S^0 = 1.25 \times 10^{-10}$ s, while that of *free* *o*-Ps is $\tau_T^0 = 1.4 \times 10^{-7}$ s[11].

The relatively long lifetime of *o*-Ps makes it possible to follow both its formation and its reactions and to use it as a "labeled" hydrogen atom for the elucidation of chemical and physical processes in matter.

4. The "Ore Model"

As was indicated in Figure 4, positronium formation takes place in an energy range of a few eV. This process can be illustrated by the example of a gaseous system, where it is easiest to follow.

The formation of Ps can be formulated as follows:

$$e^+ + M \longrightarrow Ps + M^+ \tag{7}$$

If the ionization potential V of the substrate molecule (M) is greater than 6.8 eV, the bonding energy of the positron and the electron in the ground state of the Ps atom, the formation of Ps is an endothermic reaction with a threshold energy of $Q = (V - 6.8)$ eV, *i. e.* only positrons having a kinetic energy $E_{kin} > (V - 6.8)$ eV can form positronium in this way. This determines the lower energy limit, $(V - 6.8)$ eV, of the Ps formation.

However, if E_{kin}, the kinetic energy of the positrons, is greater than V, the probability of Ps formation is low in comparison with the cross section of reactions that lead to ionization of the substrate molecule, *e. g.*

$$e^+ + M \longrightarrow e^+ + M^+ + e^- \tag{8}$$

and only a few Ps atoms will therefore be formed.

A further reaction that competes with the Ps formation is the electronic excitation of the substrate molecules by the positron, which can occur as long as E_{kin} is greater than E^*, the energy of the first excitation potential of M.

$$e^+ + M \longrightarrow e^+ + M^* \tag{9}$$

It follows that in gases, the major part of the positronium is formed from positrons with kinetic energies between the first (electronic) excitation potential of the substrate molecule (upper limit) and $(V - 6.8)$ eV (lower limit).

This model of the Ps formation was first developed by *Ore*[12], and the energy range in which the Ps formation is most probable is named the "Ore gap" after this author.

The fraction of Ps-forming positrons will be largely dependent on the number of collisions with the substrate molecules within this energy range, *i. e.* it will be a function of the width of the Ore gap. On the basis of the following greatly simplified assumptions:

1. all positrons reach the upper energy limit for Ps formation, E_{max}, without being annihilated;

2. statistical distribution of the kinetic energy of the positrons in the range between E_{max} and $E = 0$;

3. all positrons whose kinetic energy lies in the Ore gap form Ps,

the fraction of these positrons is given by

$$P^0 = \frac{E_{max} - E_{min}}{E_{max}} \tag{10}$$

$E_{max} - E_{min}$ = width of the "Ore gap".

Depending on whether the first excitation potential or the ionization potential of the substrate is taken as the upper energy limit, one obtains for P^0, the fraction of Ps formed:

$$6.8/V > P^0 > (E^* - (V - 6.8))/E^*$$

The validity of the simple Ore model is limited in the case of condensed phases, since the limits of the Ore gap are then determined not only by the ionization and excitation potentials but also by dissociation energies and intermolecular forces, such as dipole-dipole interactions.

For example, *Ferrell*[13] calculated that the upper limit of the Ore gap for the solid phase is $E_{max} = E^* - Q_{e^-}$ and the lower limit is $E_{min} = V - 6.8 - Q_{Ps}$, where E^* = lower limit of the conductivity band; $V - E^* = Q_{e^-}$ = electron affinity; Q_{e^+} = positron affinity; Q_{Ps} = positronium affinity; Δ_0 = Ore gap, calculated for the same substance in the gas phase.

The Ore gap in the solid phase is thus defined as

$$\Delta = (E^* - Q_{e^+}) - (V - 6.8 - Q_{Ps}) = \Delta_0 - (Q_{e^+} - Q_{Ps}) \tag{11}$$

For ionic crystals of the metal halide type (NaCl, KBr, *etc.*), where $Q_{e^+} = 3$—5 eV and $Q_{Ps} < 0$, we find $\Delta = 0$, *i. e.* Ps formation is thermodynamically impossible in such crystals.

The interaction between the positron (or positronium) and matter can be investigated on the basis of two fundamental phenomena: 1. inhibition of Ps formation and 2. reactions of the Ps atom formed (quenching).

5. Inhibition of Positronium Formation

All processes that reduce the formation of Ps will be included in this category. The Ore model is based on the simplified assumption that all positrons whose kinetic energy lies in the Ore gap produce Ps. In practice, however, the Ps formation process in the Ore gap has to compete with all other processes that can cause moderation of the positron to energies below the lower Ore limit. The most important of these are elastic and inelastic collisions with substrate molecules, the energy transferred in the second case possibly stimulating molecular vibrations and rotations. This category also includes processes that lead to positron capture by addition of positrons to the substrate molecule AB.

$$e^+ + AB \longrightarrow e^+AB \text{ or } A + e^+B \qquad (12)$$

If the compound formation occurs above or within the Ore gap, the captured positrons are no longer available for the formation of Ps, the yield of which is therefore decreased (Fig. 7). (The positron bound in the complex is annihilated mainly with emission of two quanta with an annihilation constant that is characteristic of this complex.)

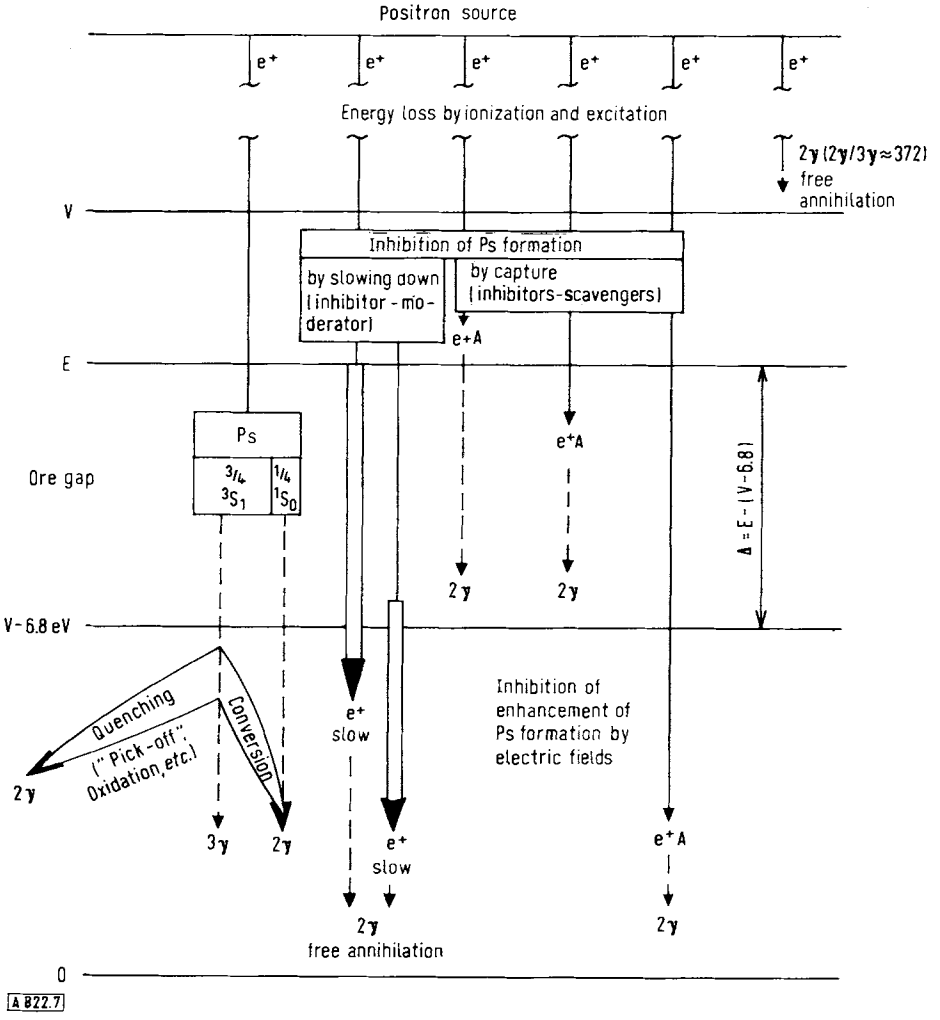
Little is known at present about the fraction of the po that form complexes in the Ore range. From the inv tion of the annihilation of positrons in argon, *Tao e* conclude that approximately 18 to 23 % of all positron an e^+Ar complex in the Ore range.

Since the processes mentioned here, such as elastic s ing, stimulation of molecular vibrations and rotati the eV range, and the addition of low-energy electr positrons) to molecules, are of the greatest importa the understanding of elementary processes in rac chemistry, the study of Ps formation should be capa yielding valuable new knowledge in this little-invest field.

6. Reactions of the Positronium Atom (Quen

The average lifetime of *free o*-Ps, *i.e.* 1.4×10^{-7} s, is re ly long, but only a small fraction of all *o*-Ps atoms r this age in condensed matter, since the positrons car into a series of reactions in the substrate, all of whic to a decrease in their average lifetime. These include

1. annihilation of Ps with "foreign" electrons on co with substrate molecules (pick-off annihilation);



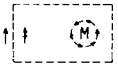


Fig. 7. Schematic survey of the processes of positronium formation and annihilation to illustrate the Ore model and possible deviations from it [3].

2. *ortho-para*-conversion: under the influence of paramagnetic particles, *e.g.* paramagnetic ions in solution, a spin conversion from *ortho* to *para* or *vice versa* can occur;

3. chemical reactions of Ps; addition, substitution, oxidation, compound formation.

The above reactions and their effects on the various annihilation parameters are shown schematically in Figure 8.

Reaction	Mechanism	Average lifetime of products [s]	Photons emitted	Average lifetime of *o*-Ps appears to be
"Pick-off"		—	$2\gamma/3\gamma = 372/1$	shorter [a]
Conversion		1.25×10^{-10} (*p*-Ps)	2γ	shorter [a]
Oxidation		$\approx 0.5 \times 10^{-10}$ [b]	$2\gamma/3\gamma = 372/1$	shorter [a]
Compound formation		$\approx 0.5 \times 10^{-10}$ [c]	$2\gamma/3\gamma = 372/1$	shorter [a]

[a] Intrinsic lifetime $\tau_T^0 = 1.4 \times 10^{-7}$ s. [b] Free positron in condensed phase. [c] Complex

A822.8

Fig. 8. Reactions of *ortho*-positronium (quenching).

6.1. Pick-Off Annihilation

The pick-off annihilation of *o*-Ps atoms can be best described by assuming that at some instant after the formation of *o*-Ps, the positron is removed from the *o*-Ps under the influence of the "electron cloud" of a substrate molecule, and is then annihilated as a free positron together with an electron of the substrate molecule. The result is a decrease in the lifetime of Ps in relation to the characteristic value τ_T^0. Since the same rules apply in this annihilation process as in the annihilation of the free positron, two-photon emission predominates here in contrast with the three-quantum decomposition of *o*-Ps. Increased pick-off annihilation therefore results in a decrease in the three-quantum annihilation probability (Fig. 8).

p-Ps atoms can naturally also be annihilated by pick-off. However, since their average lifetime τ_S^0 is only 1.25×10^{-10} s, they usually undergo self-annihilation before they can enter into any reactions.

The pick-off annihilation of Ps is a process that can generally occur in all substances. The experimental observation[3] that the pick-off annihilation constant in gaseous systems or even in solutions is determined mainly by the molar density of the substance, and not by the average electron density, confirms the view that on collision of Ps with a molecule, the entire "electron cloud" of the molecule enters into interaction with the Ps before an electron of the substrate molecule is annihilated together with the positron.

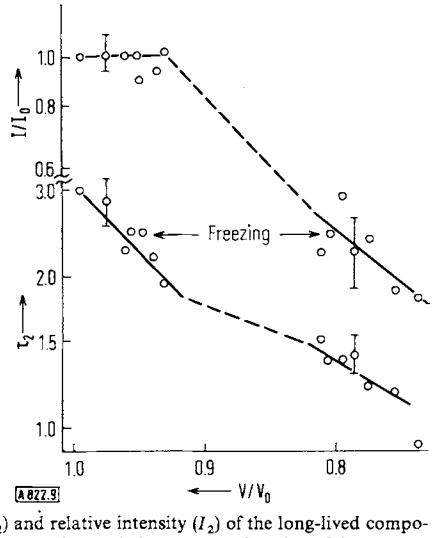
The kinetics of the pick-off annihilation of *o*-Ps in gases corresponds to the relation[3]:

$$1/\tau_T = \lambda_T = \lambda_T^0 + \sigma_p n v \qquad (13)$$

τ_T = average lifetime of *o*-Ps in the substrate [s]
λ_T = experimental annihilation constant of *o*-Ps in the substrate [s^{-1}]
λ_T^0 = self-annihilation constant of *free* *o*-Ps [s^{-1}]
n = molecular concentration of the substrate [cm^{-3}]
v = velocity of *o*-Ps in the substrate [cm s^{-1}]
σ_p = characteristic cross section for pick-off annihilation of *o*-Ps per collision with a substrate molecule [cm^2].

The lifetime of positronium therefore decreases with increasing molar density of the substance. Since it is also a function of the velocity v, it decreases with rising temperature.

In gases, where $\lambda_T^0 \gg \sigma_p n v$ under normal conditions (1 atm, 25 °C), pick-off annihilation is only of minor importance, and the average lifetime of free *o*-Ps is usually found, *i.e.* when no other reactions lead to faster annihilation. The contribution of pick-off to the annihilation process as a whole increases only at higher pressures or temperatures, and it may then considerably decrease the average lifetime of *o*-Ps.



In the condensed phase, on the other hand, the temperature dependence is reversed. This observation is the basis of the free volume model[15-18], which correlates the lifetime of positronium with the "free volume" available in the lattice for the formation and accommodation of the Ps atom.

Brandt, *Berko*, and *Walker* have calculated the lifetime of Ps in molecular crystals, and found the following relation[15]:

$$\tau = \tau_0 [1 + F(P_0 r_0^2, V^*)] \qquad (14)$$

τ_0, P_0 = characteristic constants for lattice type and compound
r_0 = classical electron radius
$V^* = V_1/V_0$ = reduced free cell volume
V_1 = volume of the lattice cell (at temperature T_1)
V_0 = volume of the lattice cell at $T_0 = 0$ °K

In this model, V_0 is regarded as the volume that is not accessible to the Ps; the "free volume" available to the Ps at a given temperature T_1 is calculated as $V_1 - V_0$; F is a function of V^*, and increases linearly with V_1. The lifetime of Ps in a given substance is therefore inversely proportional to the density of this substance, as is confirmed by experiments[19] in which the density of the material was altered by compression (Fig. 9). Since a temperature rise is usually accompanied by a decrease in density, it leads in many condensed systems to an increase in the lifetime of Ps.

A822.9

Fig. 9. Lifetime (τ_2) and relative intensity (I_2) of the long-lived component of the positron annihilation in benzene as a function of the pressure (V_0 = volume at 30 °C/1 atm) [19].

In addition to this density effect, a separate temperature effect, which shortens the lifetime of Ps, was also observed[20]. Such a temperature effect can be explained by the

increase in the thermal vibrations of the atoms in the crystal lattice at higher temperatures, which leads to density variations; the volume available to the Ps atoms is thus reduced, and their lifetime is shortened. The density effect and the temperature effect act in opposite directions, and may lead to maxima in the lifetime, as shown in Figure 10, where the observed lifetime of *o*-Ps in Teflon is plotted as a function of V^*.

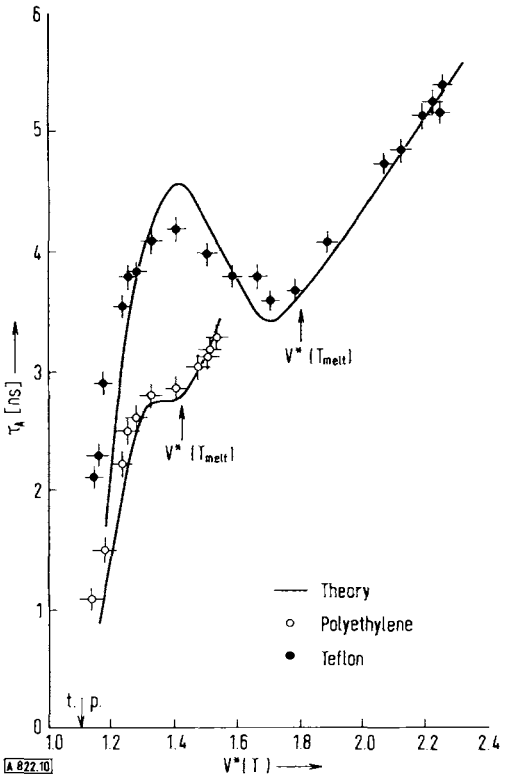


Fig. 10. Lifetime (τ_A) of the long-lived component (*o*-Ps) of the positron annihilation in Teflon and polyethylene as a function of the reduced free cell volume V^* [cf. eq. (14)].

However, it must be pointed out that the free volume model is valid only when no other reactions occur apart from pick-off.

6.2. *ortho-para* Conversion

Under the influence of a magnetic field, such as is produced *e.g.* by the presence of paramagnetic ions in solution, conversion of *o*-Ps into *p*-Ps or *vice versa* can occur.

In its simplest form, the spin conversion can be formulated as a direct spin exchange:

$$\uparrow M + {}^3S_1(\downarrow\uparrow) \rightleftarrows \downarrow M + {}^1S_0(\uparrow\downarrow) \qquad (15)$$

In this case, the *ortho-para* conversion is associated with a reversal of the spin of the paramagnetic particle. However, *Ferrell*[21] was able to show quantum-mechanically that the only condition for such a spin conversion is the encounter of the *o*-Ps or *p*-Ps with an atom or molecule having unpaired electrons; spin flip or electron exchange are not absolutely essential ingredients of the *o-p* or *p-o* conversion of positronium. For example, oxygen molecules in the triplet state can initiate the *o-p* conversion of Ps without themselves undergoing a simultaneous triplet-singlet transition.

$$O_2\uparrow + {}^3S_1(\uparrow\uparrow) \rightarrow O_2\uparrow + {}^1S_0(\downarrow\uparrow) \qquad (16)$$

The result of an *o*-Ps → *p*-Ps conversion is again a decrease in the lifetime of the positron, since it is now in the form of the much shorter-lived *p*-Ps ($\tau_S^0 = 1.25 \times 10^{-10}$ s), which decays with emission of two photons.

The detection of the *ortho-para* conversion can be used as a highly sensitive detection method for the presence of free radicals and other paramagnetic species, particularly in gaseous systems.

Thus on the basis of results in the system Ar—NO, *Goldanskii et al.*[3] were able to show that as little as about 10^{13} radicals or atoms per cm^3 of gas can be detected by this method.

6.3. Chemical Reactions of Positronium

The chemical reactions of the Ps atom will be discussed at length in Sections 8—11. For the present, it is sufficient to point out that they all lead to a decrease in the lifetime of *o*-Ps. The oxidation of *o*-Ps, for example, leads to the formation of a free positron, whose average lifetime in any medium is shorter than that of *o*-Ps in the same medium. This is also true of the lifetimes of the positron or positronium compounds with substrate molecules or fragments; these decompose mainly by two-quantum annihilation (Fig. 8).

7. Experimental Methods for the Observation of the Annihilation of Positrons

As indicated earlier, there are two parameters, *i.e.* the positronium yield (P^0) and the average lifetime of the positron (τ), whose observation can yield information about the interaction of positrons with matter. Three different experimental methods are available.

7.1. Determination of the Probability of Three-Quantum Annihilation

Direct measurement of the probability of three-quantum annihilation is possible with the triple-coincidence arrangement shown in Figure 11[22]. This arrangement ensures that only γ quanta that reach all three detectors simultaneously, as in the emission of photons by three-quantum annihilation, are recorded.

The method can therefore detect the presence of *o*-Ps, but does not enable one *e.g.* to decide which factor (τ_T, the lifetime of *o*-Ps, or P^0, the Ps yield) is responsible for the change in the three-quantum annihilation rate ($R_{3\gamma}$), since these quantities are related as follows:

$$R_{3\gamma} \approx 3/4 P^0 \frac{\tau_T}{\tau_T^0} + \frac{1}{372}(1 - P^0) \qquad (17)$$

This means that experimental data obtained in this way do not show whether a change in $R_{3\gamma}$ is due to reactions of Ps or to inhibited Ps formation.

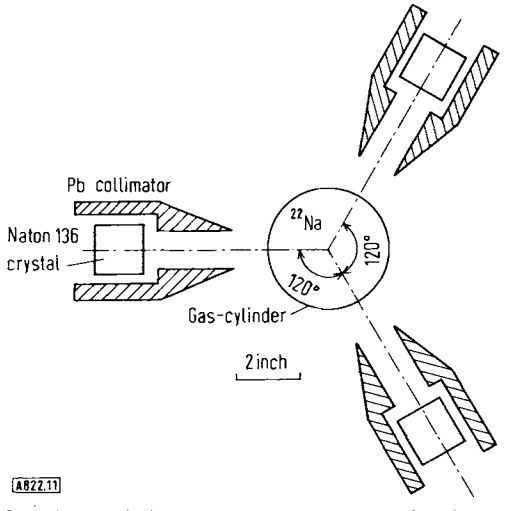

Fig. 11. Typical experimental arrangement for determining the frequency of 3γ coincidences [22].

7.2. Determination of the Angular Distribution in Two-Quantum Annihilation

It can be shown that in two-quantum annihilation the deviation of the angle between the emission directions of the two 0.51 MeV photons from 180° corresponds to

$$\Delta\theta \sim 2\,v/c \qquad (18)$$

where c is the velocity of light and v is the velocity of the center of gravity of the electron and the positron in the system in question[23–25].

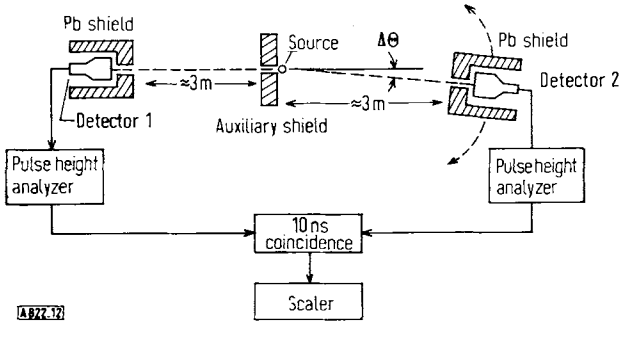

Fig. 12. Typical experimental arrangement for determining the angular distribution (Δθ = deviation from 180°).

The deviation, which is only a few milliradians in all practical cases, can be measured with the aid of the system outlined in Figure 12. The 0.51 MeV photons produced in the same act of annihilation are recorded in this system as a function of Δθ. The form of such angular distribution curves provides a basis for conclusions both regarding the various annihilation mechanisms and regarding the reactions of Ps and its formation.

Free positrons usually still have low kinetic energies when they are annihilated; the angle between the two annihilation quanta therefore differs considerably from 180°, and leads to the "broad" component in the angular distribution curves (Fig. 13). The heavier *para*-positronium, on the other hand, loses most of its kinetic energy very rapidly after its formation, and at the instant of annihilation, it is close to or in thermal equilibrium with its environment; the photons emitted in this case deviate only slightly from 180°, and are responsible for the occurrence of the "narrow" component in the angular distribution curves. Ps formation can therefore be very readily recognized from the presence of the "narrow" component (Fig. 13).

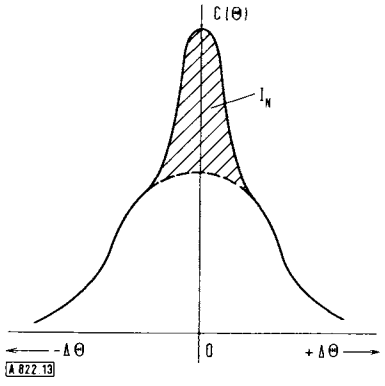

Fig. 13. Angular distribution in two-quantum annihilation: frequency of 2γ coincidences (C(θ)) as a function of Δθ (cf. Fig. 12). The "narrow" component (I_N) is shaded.

However, this method is not confined to the detection of Ps, but can also be used to follow its various reactions. Increased *ortho-para* conversion, for example, causes more positrons to be annihilated in the form of *p*-Ps, and this can be detected by a *relative* increase in the intensity of the narrow component. Oxidation and pick-off of *o*-Ps, on the other hand, cause increased two-quantum annihilation, with a relatively wide angular distribution; the intensity of the "broad" component increases, while that of the "narrow" component does not change. However, if *p*-Ps is also involved in the chemical reaction or in the pick-off (this is generally possible only if these reactions are much faster than the self-annihilation of *p*-Ps), the result is an *absolute* weakening of the "narrow" component instead of a *relative* weakening.

7.3. Determination of the Average Lifetime of the Positron

A direct method that can be used to obtain both the lifetime of the positron or positronium and in most cases the positronium yield P^0 makes use of the "delayed coincidence" technique[26].

The positron source most commonly used for this purpose is ^{22}Na. This decays with a half life of 2.58 years with emission of a positron to give an excited ^{22}Ne nucleus, which passes to the ground state with emission of a 1.28 MeV photon (Fig. 14). Since the excited ^{22}Ne nucleus has an average lifetime of only about 3 ps, it is justifiable, for the purposes of the present investigation, to assume that the two particles are emitted simultaneously. To determine the

lifetime of the positron, one first observes the appearance of the 1.28 MeV photon, and waits until the annihilation of the positron takes place, as indicated by the 0.51 MeV annihilation photons (two-quantum annihilation). The time difference corresponds to the lifetime of the positron. Since the time intervals involved are in the region of a few nanoseconds (ns), the principle of "delayed coincidence" is used for their measurement. A typical arrangement is shown schematically in Figure 15[27].

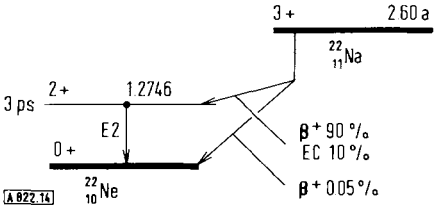

Fig. 14. Decay scheme for ^{22}Na.

The 1.28 MeV photon is observed with a plastic detector (*e.g.* Naton 136). The output signal from the anode of the attached photomultiplier serves as the starting signal for the time-pulse height converter (TPHC). The second similar detector observes one of the two annihilation photons (0.51 MeV). The signal from this detector serves as the stop signal for the TPHC. The amplitude of the output signal of the TPHC is thus proportional to the time difference between the arrival of the start signal and that of the stop signal in the TPHC. The time calibration of the system is effected by a built-in delay unit. The signal from the TPHC passes into a multichannel pulse height analyzer, and is recorded in one of the channels according to its pulse height, provided that the instrument has been activated by a signal from the "slow" coincidence unit (see below).

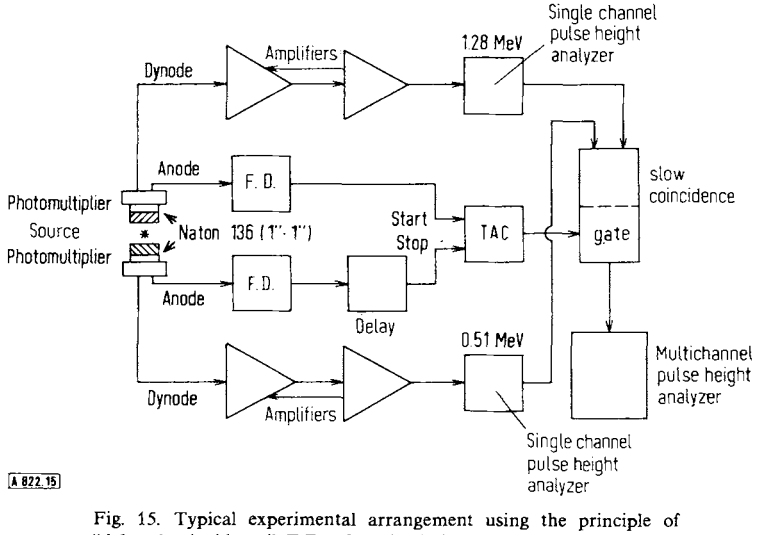

Fig. 15. Typical experimental arrangement using the principle of "delayed coincidence". F.D. = fast discriminator.

To reduce the number of "random coincidences" and to improve the time resolution of the measuring equipment, it is recommended that a second "slow" coincidence circuit be incorporated. For this purpose, a signal from the dynode of the photomultiplier, after passage through a preamplifier and a main amplifier, is led into single-channel pulse height analyzers, one of which passes only signals corresponding to a photon energy of 1.28 MeV, while the other passes only signals corresponding to a photon energy of 0.51 MeV. If two signals filtered in this way by the two single-channel pulse height analyzers enter the "slow" coincidence unit within a specified period (usually 1 μs), they activate the multichannel pulse height analyzer (see above) for a short time and allow the signals arriving from the TPHC during this time to be recorded.

Since the electronic time measurement begins when a positron is formed, the situation is the same as if a large number of positrons was present at a time $t=0$ and decayed with the annihilation constant λ. This is a first order reaction: $T(t)$. The number N of coincidences observed can be plotted logarithmically as a function of time t, and if only one annihilation mechanism is operating, the result should be a straight line whose slope is determined by λ or $1/\tau$ (Fig. 16a). Because of the inadequate time resolution of the measuring arrangement, however, each point on this line is "blurred". The degree of "blurring", and hence the quality of the time measurement, can be found from the "prompt" time spectrum, which can be recorded with the aid of a ^{60}Co source. On radioactive decay, ^{60}Co emits a 1.31 MeV and a 1.17 MeV photon practically simultaneously. The coincidence measurement of these two photons should therefore exhibit no delay, and should give a sharp line at $t=0$. In practice, however, one obtains the spectrum shown in Figure 16b, which exhibits a Gaussian distribution: $P(t)$. The resulting "blurring" of the function $T(t)$ by the measuring arrangement with a resolution function $P(t)$ is finally shown in Figure 16c.

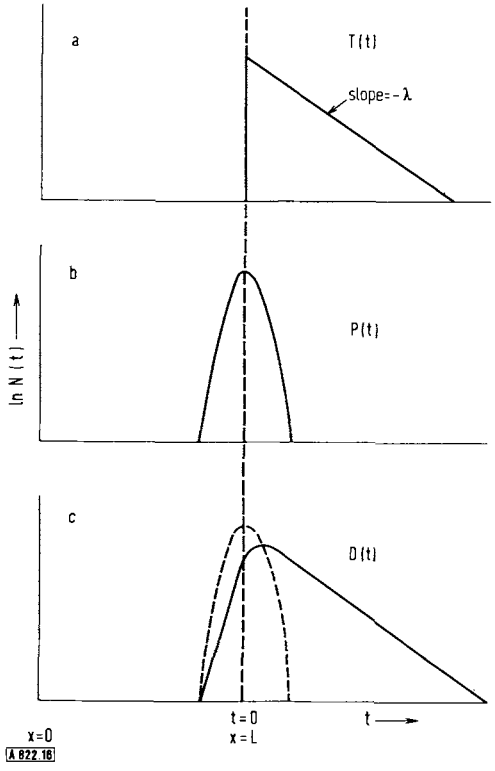

Fig. 16. a) Theoretical $T(t)$ curve for positrons that are annihilated in a first order reaction in the interval between t and $t+dt$; b) "prompt" time spectrum (^{60}Co): $P(t)$ curve; c) "blurring" of the $T(t)$ function in a measuring arrangement with the resolution function $P(t)$: $D(t)$ curve.

A positron lifetime spectrum recorded in this way, which can be resolved into two components, is shown in Figure 17. The number of coincidences (ordinate) is plotted logarithmically as a function of the time that elapses between the start and stop pulses in the TPHC (abscissa). It can be shown mathematically that the right-hand part of the spectrum can be interpreted as a multiexponential function of the form:

$$D(x) = Ae^{-\lambda_1 t} + Be^{-\lambda_2 t} \qquad (19)$$

where λ_1 and λ_2 are the annihilation constants for the various modes of annihilation of the positron or of positronium, and A and B are constants. These quantities can be determined either graphically from the curve or by suitable computer programs. The relative number of positrons or Ps atoms that disappear with one of these annihilation constants is given by the area (I) under the corresponding component in the time spectrum, integrated from $t=0$ to $+\infty$, compared with the total area of the time spectrum.

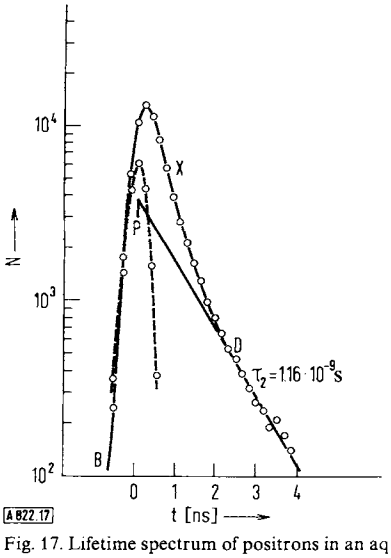

Fig. 17. Lifetime spectrum of positrons in an aqueous $KMnO_4$ solution (0.01 M; pH = 11), resolved into two components. Broken curve: "prompt" spectrum (^{60}Co). N = number of coincidences.

The time $t=0$ is given by the position of the center of the "prompt" spectrum. Details of the evaluation of such a spectrum will be described in the next section.

In most cases, two components can be isolated from the time spectrum. It is usual to attribute the short-lived component to the decomposition of the free positron and the annihilation of *p*-Ps, whereas the long-lived component is attributed to the annihilation of *o*-Ps. This seems justifiable if only a simple pick-off mechanism is involved. If, on the other hand, other reactions of *o*-Ps take part in the process, the relation between τ_2 and λ_2 and the annihilation constants and the *o*-Ps yield is much more complicated, and must be established separately for each individual case (see Section 8).

8. Positronium Chemistry in Aqueous Solutions

The fact that Ps atoms can exist in condensed matter and have proved to be relatively stable in the chemical sense led at an early date to investigations on the reactions of Ps with H_2O molecules and with ions in aqueous solutions.

Since the structure of positronium is very similar to that of the hydrogen atom, its reactivity should also be comparable with that of the H atom. However, as will be shown, there are a number of fundamental differences in the manner in which they react.

Whereas the reaction of Ps in pure water can be best described by a reaction scheme in which the *o*-Ps atoms formed decompose by pick-off annihilation with emission of two photons, other reactions besides the pick-off process can also cause the decomposition of *o*-Ps in aqueous solutions of salts (cf. Fig. 18).

It is admittedly difficult to correlate the many possible reactions and their reaction constants with the quantities obtainable by experiment (P_T^0, the *o*-Ps yield, and τ, the lifetime of the positron or positronium). By careful investigation of these experimental quantities as a function of the

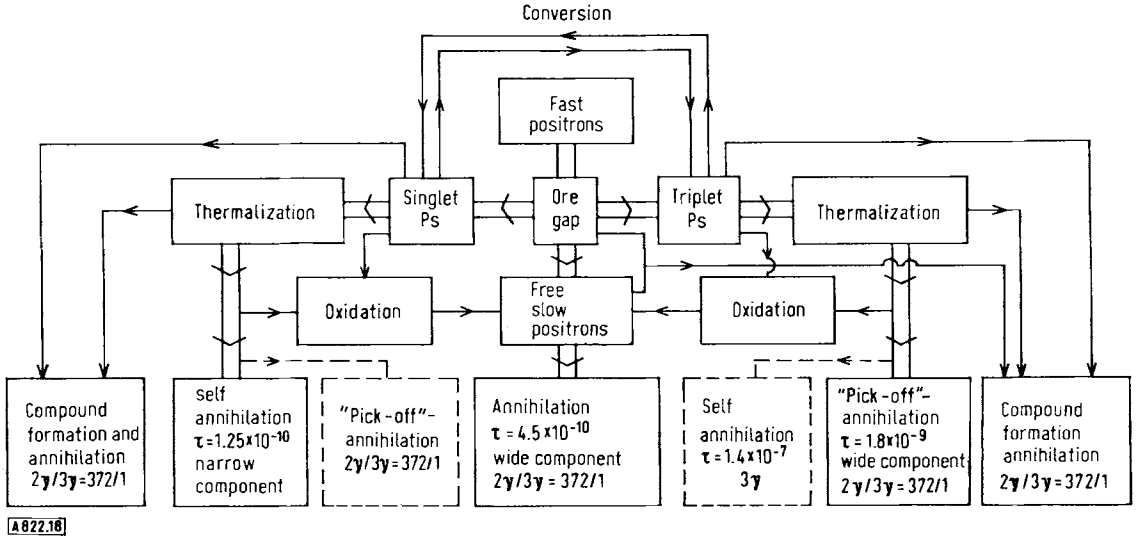

Fig. 18. Flow scheme of the possible reactions of positrons in aqueous solutions.

concentration or of the temperature, however, it is possible in many cases to distinguish the various reaction types and to measure the reaction rate constants.

The evaluation of the results of positron lifetime measurements can be demonstrated by the example of two investigations by *Horstman*[29] and by *Williams* and *Ache*[27].

A relation had been observed in earlier investigations[30] between the chemical oxidation potential of the dissolved compound and the *o*-Ps annihilation constant in the solution. This indicated that the oxidation of Ps should have an activation energy (which should lead to a temperature dependence of the oxidation rate), provided that the observed decomposition of *o*-Ps does in fact proceed by an oxidation mechanism.

The authors therefore investigated the temperature dependence of the *o*-Ps annihilation in aqueous solutions of $HgCl_2$, $SnCl_4$, $SbCl_3$, $PdCl_2$, and $KMnO_4$. These compounds are not paramagnetic; spin conversion is therefore very unlikely, and it was possible to confine the analysis of the results to the pick-off annihilation and to the possible oxidation of *o*-Ps in the solution.

The kinetics will first be considered in general for a solution in which both the annihilation of free positrons and the pick-off annihilation and the oxidation of positronium with regeneration of a free thermal positron are possible[27,29,31]. If the formation of a positron is denoted by $t=0$ and if the probabilities of finding this positron in the various states at a time t are P_S=*p*-Ps, P_T=*o*-Ps, and P_F=free positron, the time dependence of these quantities can be expressed by:

$$dP_S/dt = -(\lambda_S + \lambda_P + \lambda_O)P_S \quad (20)$$

$$dP_T/dt = -(\lambda_T + \lambda_P + \lambda_O)P_T \quad (21)$$

$$dP_F/dt = -\lambda_F P_F + \lambda_O(P_S + P_T) \quad (22)$$

λ_S and λ_T = rate constants for self-annihilation of *p*-Ps and of *o*-Ps respectively;
λ_P = rate constant for pick-off annihilation of Ps;
λ_O = rate constant for oxidation of Ps;
λ_F = rate constant for annihilation of the free positron.

It will be assumed below that λ_O is the only temperature-dependent quantity, and that λ_T may be regarded as negligible. Solution of the above equations then gives:

$$P_S = P_S^0 \exp[-(\lambda_P + \lambda_O + \lambda_S)t] \quad (23)$$

$$P_T = P_T^0 \exp[-(\lambda_P + \lambda_O)t] \quad (24)$$

$$P_F = \left(P_F^0 - P_T^0 \frac{\lambda_O}{\lambda_F-(\lambda_O+\lambda_P)} - P_S^0 \frac{\lambda_O}{\lambda_F-(\lambda_O+\lambda_P)-\lambda_S}\right)\exp[-\lambda_F t] + \frac{P_T^0 \lambda_O}{\lambda_F-(\lambda_P+\lambda_O)}\exp[-(\lambda_P+\lambda_O)t] + \frac{P_S^0 \lambda_O}{\lambda_F-\lambda_S-(\lambda_P+\lambda_O)}\exp[-(\lambda_P+\lambda_O+\lambda_S)t] \quad (25)$$

The coincidences observed in the time spectra, because of the experimental arrangement used, are exclusively the result of two-quantum annihilation. If one disregards the small fraction of free positrons that decay with emission of three photons, the two-quantum annihilation rate $R_{2\gamma}$ is found to be:

$$R_{2\gamma}(t) = \lambda_S P_S + \lambda_F P_F + \lambda_P(P_S + P_T) \quad (26)$$

This is a multiexponential function of the form:

$$R_{2\gamma}(t) = A\exp[-\lambda_F t] + B\exp[-(\lambda_S + \lambda_O + \lambda_P)t] + C\exp[-(\lambda_P + \lambda_O)t] \quad (27)$$

Since in general $\lambda_S \gg \lambda_O + \lambda_P$ and $\lambda_S \simeq \lambda_F$, the first two terms of equation (27) cannot be distinguished experimentally; they will occur together in the short-lived component of the time spectrum, τ_1 (Fig. 17).

On the other hand, the observed rate constant of the second, long-lived component of the time spectrum, λ_2, is determined by the sum of λ_P and λ_O [third term in eq. (27)].

$$1/\lambda_2 = \tau_2 = 1/(\lambda_P + \lambda_O) \quad (28)$$

Separate experiments in pure water, where only pick-off annihilation of Ps occurs, gave $\lambda_P = 0.65\ ns^{-1}$[27,29]. No temperature dependence was observed between 25 and 100 °C, and this value was taken as the pick-off annihilation rate in the dilute solutions investigated here. It was thus possible to determine λ_O from the experimentally observed temperature dependence of τ_2 (for $KMnO_4$; see Table 1), and to find the activation energy for the oxidation from the Arrhenius equation (Table 2). The activation energies found were between 0.05 and 0.2 eV.

P_T^0, the *o*-Ps yield, can be obtained by integration of the part of eq. (26) that contains the exponent $\exp[-(\lambda_P+\lambda_O)t]$ over all times. This leads to the following relation between the intensity of the long-lived component I_2 and P_T^0:

$$I_2 = [1 + \lambda_O/(\lambda_F - \lambda_2)]\,P_T^0 \quad (29)$$

Though I_2 exhibits the temperature dependence shown in Table 1, the *o*-Ps yield calculated in this way remains constant over the entire temperature range investigated (Table 2).

The temperature dependence of the oxidation rate in the solutions investigated indicates that the *o*-Ps atoms, which are formed with kinetic energies of a few eV, are oxidized only after they have reached thermal equilibrium with their environment. This can also be deduced from the linear dependence of $1/\lambda_O$ on the viscosity η of the solution (Fig. 19) and from the low activation energy of the oxidation reactions (0.05—0.2 eV), which differ only slightly from the activation energy for the viscosity in water (0.06 eV). All these findings point to a diffusion-controlled oxidation process in the solutions.

In aqueous $KMnO_4$ solutions, the chemical oxidation potential is a function of the pH. In our investigation[27], however, the oxidation constant λ_O showed no dependence on the pH of the solution, which was varied between 2 and 11 (Table 1). This is in agreement with the results obtained by *Goldanskii*, who carried out angular distribution measurements in the same system and was also unable to find any dependence on the pH.

Table 1. Average lifetime of *o*-Ps in aqueous $KMnO_4$ solutions at various temperatures, concentrations, and pH values [27].

Jackson and *McGervey*[32], who investigated the oxidation of Ps in solutions of MnO_4^-, IO_3^-, and Hg^{2+}, pointed out important differences between the chemical oxidation potential and the ability of an ion to oxidize Ps atoms. Both the short lifetime and the low concentration of Ps in solution rule out the establishment of an equilibrium such as occurs in conventional chemical reactions. It follows that

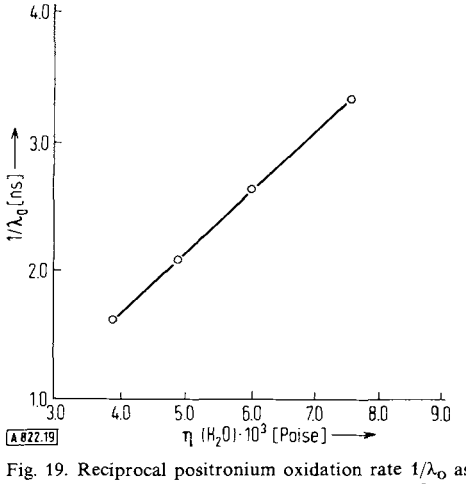

Fig. 19. Reciprocal positronium oxidation rate $1/\lambda_O$ as a function of the viscosity of an aqueous solution (0.01 M $KMnO_4$; pH = 11).

chemical and physical parameters determined by equilibrium measurements can have at most only limited application in positronium chemistry. It is therefore probably more appropriate to regard the oxidation of Ps as a kinetic process, *i.e.* the observed oxidation constants reflect the ability of a single ion to abstract an electron from Ps.

Kinetic equations can be established for spin conversions and other reactions of Ps in solution in the same way as for the oxidation of Ps, and can be used to determine the reaction rate constants for spin conversion *etc.* from the experimental data. A number of ions and compounds that can cause oxidation, spin conversion, or both are listed in Table 3 together with the rate constants for the corresponding reactions[3]. It should be pointed out that λ_O is related to the conventional reaction rate (k) l mol^{-1} s^{-1} by: $\lambda_O = k[s]$ (s = substrate concentration (in mol/l)). It is interesting to note that ions such as U^{4+}, Ti^{3+}, and Ce^{3+}, though paramagnetic, do not appear to cause spin conversion.

Table 3. Reaction rate constants for reactions of positronium in aqueous solutions [3].

Acceptor	K_R (cm^3/s)	Acceptor	K_R (cm^3/s)
Fe^{3+}	2×10^{-11}	$Cr_2O_7^{2-}$	1.5×10^{-10}
Cu^{2+}	8×10^{-12}	CrO_4^{2-}	1.5×10^{-11}
Ti^{4+}	3.3×10^{-12}	MnO_4^-	2.7×10^{-11}
UO_2^{2+}	1.2×10^{-11}	Fe^{2+}	3.5×10^{-12}
Ce^{4+}	2.8×10^{-11}	Mn^{2+}	2.5×10^{-12}
Sn^{4+}	0.9×10^{-11}	Ni^{2+}	2.75×10^{-12}

U^{4+}	$<10^{-14}$	H_2SO_4	$<10^{-14}$
Ti^{3+}	$<10^{-14}$	Na_2SO_4	$<10^{-14}$
Ce^{3+}	$<10^{-14}$	NaCl	$<10^{-14}$
Pb^{2+}	$<10^{-14}$	$Fe(CN)_6^{4-}$	$<10^{-14}$
Nd^{3+}	$\approx 10^{-13}$		

Goldanskii[3] compared the reaction rate constants of the reactions of Ps with Fe^{3+} and Fe^{2+} (see Table 3) with data for the reactions of hydrogen atoms with the same ions in aqueous solution (Fe^{3+}: 1.5×10^{-13} cm^3/s; Fe^{2+}: 3.3×10^{-14} cm^3/s), and found that positronium reacts about one hundred times as fast as the hydrogen atom in both cases.

An explanation for this difference will be largely dependent on whether one assumes that the observed reaction rate constant K_R is controlled by diffusion (diffusion rate constant K_D), *i.e.* by the number of collisions between the solvent cells containing the Ps or the Fe ion, or by the reaction probability per collision of the two reactants (kinetic rate constant K_k) within a solvent cell. Since these quantities are related as follows:

$$1/K_R = 1/K_D + 1/K_k \qquad (30)$$

$K_R \approx K_D$ in the first case, and $K_R \approx K_k$ in the second.

If the highest observed value for K_R from Table 3 ($Cr_2O_7^{2-}$: 1.5×10^{-10} cm^3/s) is taken as the diffusion constant K_D, the "true" kinetic constant of the ($Ps + Fe^{3+}$) reaction is

found to be 2.3×10^{-11} cm^3/s. If it is also assumed that the difference between the kinetic constants for the (Ps+M) and (H+M) reactions (M = Fe^{2+} or Fe^{3+}) is determined only by the difference in the activation energies E, and that the number of collisions of the reactants is the same in both cases, it is found that $E_H - E_{Ps} \approx 3$ kcal/mole, which in *Goldanskii*'s opinion[3] could point to a "tunnel effect" for the Ps reaction. However, if the ratio of the number of collisions in the two systems is given by v_{PsM}/v_{HM} or $\sqrt{m_H/m_{Ps}} \approx 30$, the result would be practically perfect agreement of the activation energies of the reactions of H and Ps with Fe^{2+} or Fe^{3+}. It is not possible at present to decide between these alternatives. In general, however, it can be said that the determination of the true kinetic constants K_k of Ps reactions, *e.g.* by extrapolation to extremely low viscosities ($K_D \gg K_k$), offers interesting possibilities for the study of the reaction mechanisms in conjunction with collisions of solvent cells.

The influence of complex formation and the accompanying spin delocalization or "blurring" of the electron density in the outer sphere of complexes (in solution) on the reactions of positronium was also investigated by *Goldanskii et al.*[33].

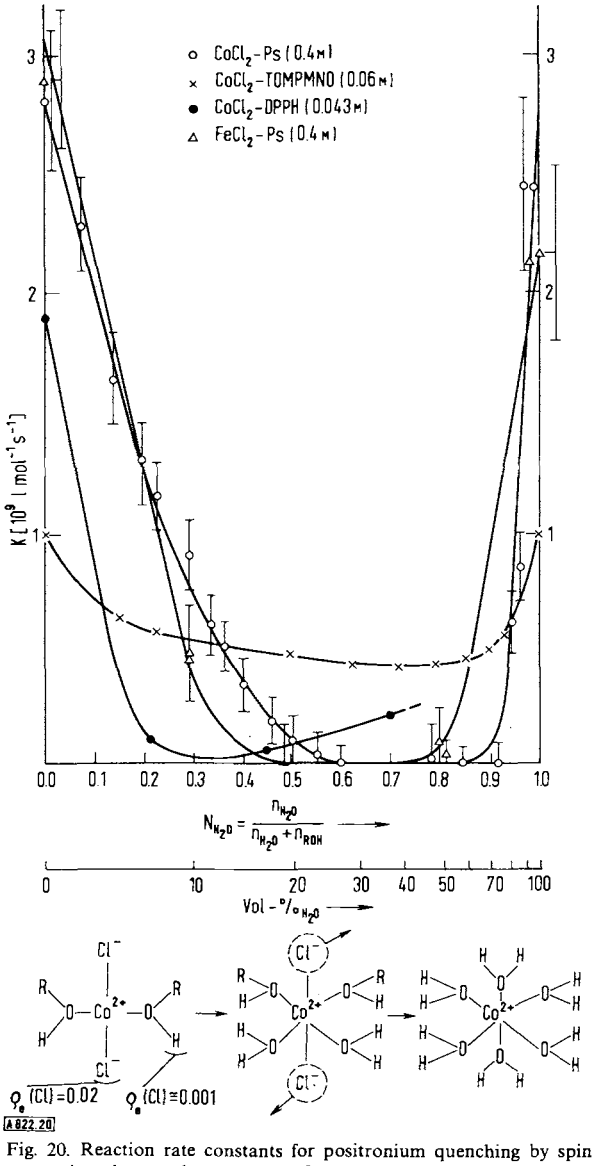

Fig. 20. Reaction rate constants for positronium quenching by spin conversion due to the presence of paramagnetic centers in water-propanol mixtures (0.01 M $CoCl_2$ or $FeCl_2$) as a function of the composition of the solvent; action of tetraoxymethylpentamethylene-nitroxide (TOMPMNO) or diphenylpicrylhydrazyl (DPPH) on the substrate [3]. $K = \lambda_0$/[solute conc. (mole/l)].

These authors determined the reaction rate constants for spin conversions caused by the presence of paramagnetic centers in Co^{2+} or Fe^{2+}-water-propanol mixtures having various compositions. A selection of the results are shown in Fig. 20 as a function of the solvent composition, the complex present in each case being indicated. The authors conclude from these investigations that the unpaired electrons of the paramagnetic central atom are blocked by the coordination sphere, and cannot affect the Ps reaction. The reaction rate constant of the spin conversion is therefore essentially determined by the concentration of the unpaired electrons in the ligands, *e.g.* on chlorine when the solvent is the alcohol, or on oxygen when the solvent is water. As can be seen from Fig. 20, the reaction rate constant reaches a maximum in the pure solvents, whereas the spin conversion is practically suppressed in mixtures containing between 50 and 80% of water. A possible explanation is that in mixtures having the composition mentioned, the electrons, which are concentrated on the oxygen of the solvate groups in this case, are blocked by formation of intermolecular hydrogen bridges with solvent molecules, and can no longer interact with the Ps.

The influence of the delocalization of unpaired electrons on Ps reactions in the system $Co(ClO_4)_2 \cdot 6H_2O$-water-propanol can be explained in a similar manner[3] (Fig. 21). In this case, the reaction rate constant is relatively small even in pure propanol, since, unlike in the case described above, no chlorine atoms function as carriers of unpaired electrons, and the oxygen atoms of the alcohol groups are accessible only with difficulty as sites of unpaired electrons. On replacement of the alcohol groups by water groups, in which access to the oxygen is sterically less hindered, the rate constants increase considerably.

On the other hand, complex formation and spin delocalization appear to have little effect on the oxidation of Ps. *Goldanskii et al.*[34] compared lifetimes and intensities of the long-lived components in time spectra of Fe^{III} compounds, some of which exhibited no complex formation in aqueous solution (*e.g.* perchlorate), while others exhibited partly strong complex formation (sulfates, cyanoferrates); however, they were unable to find any dependence of the oxidation constants on the complex that was present.

Special interest has been shown in recent years in the question of the existence of positronium compounds in aqueous solutions.

Green and *Bell*[35] observed a large decrease in I_2, the intensity of the long-lived component, with increasing ion concentration in the positron time spectra of aqueous nitrite and nitrate solutions, whereas the corresponding lifetime τ_2 was practically unchanged. The explanation given for this effect calls for a mechanism in which the NO_2^- or NO_3^- ions capture positrons, and so compete with the Ps formation. However, it was not very clear why such a capture should be confined to these two ions if other anions showed no effect of this nature. *McGervey* and *Jackson*[32] therefore considered the possibility that the Ps is oxidized by these ions before it has reached thermal energies. In this case, its lifetime would be shortened to such a degree that

it would appear together with the result of the *p*-Ps annihilation and the annihilation of the free positron in the short-lived component of the time spectrum τ_1. The only visible result of this would be a decrease in the number of *o*-Ps atoms that reach thermal energies and then react, which would be seen mainly in a change in I_2 while τ_2 remained constant. The results of angular distribution measurements[36], on the other hand, indicate that some of the positrons annihilated in these solutions decompose *via* a state that is not identical either with that of the free positron or with that of *o*-Ps; this would support the hypothesis of a positronium compound.

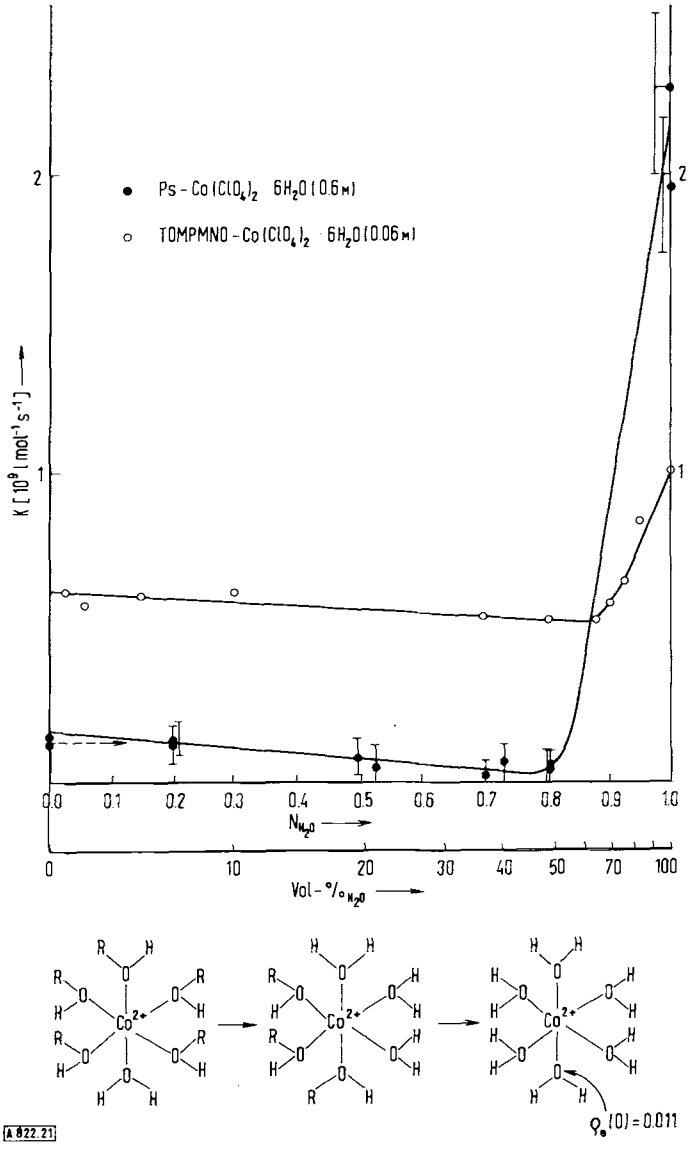

Fig. 21. Reaction rate constants for positronium quenching with $Co(ClO_4)_2 \cdot 6H_2O$ (0.6 M), with and without TOMPMNO, as a function of the composition of the solvent water-propanol [3]. $K = \lambda_0/$[solute conc. (mole/l)].

A similar possibility was suggested by *Tao* and *Green*[37], who recently reinvestigated the problem of Ps compound formation by recording the positron lifetime spectra for a series of oxy acids such as H_3PO_4, H_2SO_4, $HClO_4$, and HNO_3 and for HCl, HF, NH_3 (all in aqueous solution), and H_2O. The observed intensities I_2 for the aqueous oxy acids are shown in Figure 22. They exhibit a pronounced dependence on the acid concentration, whereas the corresponding lifetime τ_2 is practically constant. Linear extrapolation of these curves (to an acid mole fraction of 0) leads in every case to a value of 17% for I_2, which differs considerably from I_2 in pure water. The authors therefore assume a common mechanism for the change in I_2, which is effective at low acid concentrations, *i.e.* the oxidation of "hot" (not thermal) *o*-Ps atoms by H^+ ions *via* simple electron transfer.

$$Ps + H^+(aq.) \rightarrow Ps^+(or\ e^+) + H(aq.) \tag{31}$$

It can also be seen from the same figure that the I_2 values remain approximately constant in the concentration range between $n_{acid} = 0.3$ and 0.7. However, the plateau values which I_2 reaches at this concentration range in the various systems differ markedly. Changes in the "Ore gaps" as a result of the acid addition in these systems could be ruled out as an explanation for this effect, since this could not justify the observed decrease in I_2 in $HClO_4$—H_2O and HNO_3—H_2O. (One would normally expect the presence of an additive to widen the Ore gap, since Ps can then be formed not only in the Ore range of the solvent, in this case H_2O, but also in that of the additive, in this case the acid, with the result that the Ps yield should be increased; cf. also the remarks in Section 9.) The other possibility, *i.e.* that positron capture, as originally postulated by *Green* and *Bell*[35] in the case of NO_3^-, is the reason for the relative position of the I_2 plateaus in the various systems in Figure 22, is opposed by the fact that, by analogy with the corresponding hydrogen compounds, one would then expect the formation or the stability of $e^+ClO_4^-$, $e^+HSO_4^-$, and $e^+H_2PO_4^-$ to be much higher than that of $e^+NO_3^-$, since HNO_3 is much more strongly dissociated than the other acids. The tendency of the I_2 values should thus be the reverse of that shown in Figure 22. *Tao* and *Green* were therefore convinced that the reaction mechanism that occurs in these systems includes the formation of a Ps compound, *e.g.*:

$$Ps + H_2PO_4^- \longrightarrow PsO + H_2PO_3^- \tag{32}$$

For the formation of a stable Ps compound to be possible in a reaction of the type

$$Ps + AB \longrightarrow PsA + B \tag{33}$$

in general, the dissociation energy of the Ps compound (D_{PA}) must be positive. Moreover, the minimum energy that must be supplied by the positronium to enable the reaction to take place is determined by $D_{AB} - D_{PA}$, where D_{AB} is the dissociation energy of the compound AB.

If $D_{AB} - D_{PA} > E_{therm.}$, the reaction cannot take place with thermal Ps atoms. $D_{AB} - D_{PA}$ is thus the lower energy limit for these reactions if the activation energy can be disregarded. In the case $D_{AB} - D_{PA} < 0$, on the other hand, the reaction can also proceed at thermal energies.

The following reaction is found for the intensity of the long-lived component, I_2[32]:

$$I_2 \sim \frac{D_{AB} - D_{PA}}{V} \tag{34}$$

V = ionization potential of AB.

In the present example, values are known for D_{AB} (H_2PO_3—O, *etc.*). D_{PA} for PsO can, in the opinion of the

authors, be estimated by an empirical method. The values for D_{AB} are plotted as a function of I_2 (Fig. 23), I_2 being measured in the constant region of the curves in Fig. 22. According to equation (34), I_2 assumes the value 0 when $D_{AB}=D_{PA}$. D_{PA} can therefore be obtained by extrapolation of the curve in Figure 23 to $I_2=0$. The numerical evaluation

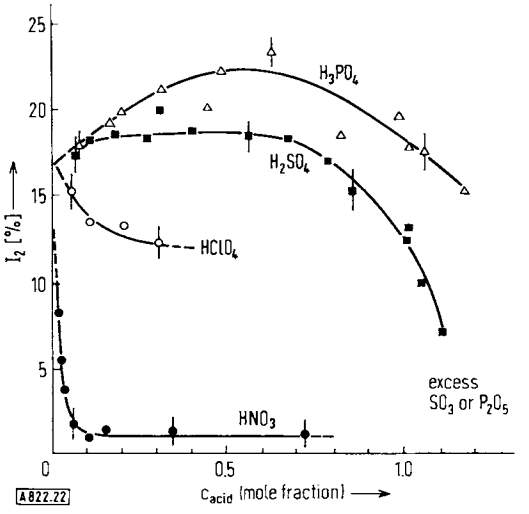

Fig. 22. Intensity I_2 of the long-lived component in positron lifetime spectra of some oxy acid-water systems [37].

gives $D_{PA}=2.2$ eV (dissociation energy of Ps—O) if the activation energy of the reaction is neglected. Since $D_{AB}-D_{PA}>0$, therefore, these compounds should be produced only by reactions of "hot" Ps atoms. The bond energies of a series of other Ps compounds were determined in a similar manner; they are listed in Table 4.

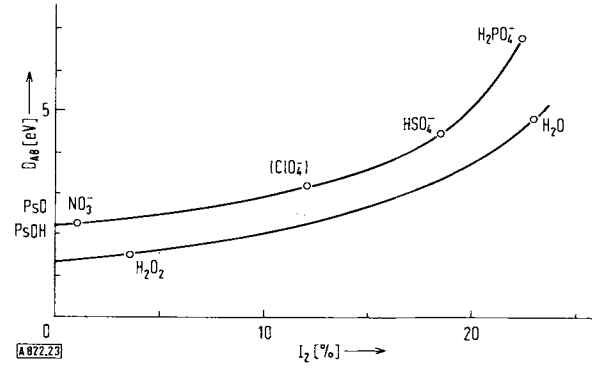

Fig. 23. Empirical relation between the values of D_{AB} and I_2.

Though the theory outlined above certainly corresponds to the experimental findings, it is not clear *e.g.* why the Ps—OH bond should be weaker than the Ps—O bond, since the corresponding hydrogen compounds exhibit the reverse trend (H—OH 5.0 eV; H—O 4.5 eV). There is no doubt that further investigations in this field will be necessary before any final and general explanation of the phenomena observed in aqueous solutions will be possible.

Table 4. Bond energies in positronium compounds [37].

Compound	D_{PA} (eV)
Ps—O	2.2±0.5
Ps—OH	1.3±0.5
Ps—Cl	2.0±0.5
Ps—F	2.9±0.5
Ps—CH_3	≈0.0
Ps—NH_2	≈0.0

9. Positronium Chemistry in the Gas Phase

A number of recent investigations have been carried out on the formation of positron compounds in gases below the "Ore gap".

Positrons whose kinetic energy has fallen below the lower Ore limit can be re-accelerated to the energies of the Ore gap in electric fields. It should theoretically be possible in this way to obtain practically 100% yields of positronium. However, if compound formation occurs below the Ore gap, these positrons are lost from the Ps formation, since they are annihilated rapidly in the bound form. The occurrence of e^+ compound formation can therefore be recognized by a decrease in the Ps yield superimposed on an increase under the influence of an electric field (cf. Fig. 7). The Ps yield was equated here, as in many other cases (not entirely correctly) to the intensity I_2 of the long-lived component in the time spectrum. *Hughes et al.*[39-40] observed that the presence of an electric field leads to the expected increase in I_2 in inert gases (He, Ne, Ar) and in H_2 and N_2, whereas no increase is observed in a number of other gases, such as CO_2, CH_4, C_2H_6, and $C_2Cl_2F_2$. Small quantities of this last group of gases, when added to argon, suppress the increased Ps formation found in pure Ar under the same experimental conditions. The authors explain these findings by compensation, or even over-compensation, of the effect of the electric field (acceleration of the positrons to Ore energies and hence increased Ps formation) by positron capture processes with compound formation in CO_2, CH_4, C_2H_6, and $C_2Cl_2F_2$.

Leung and *Paul*[41] reported interesting observations on argon-propane mixtures in the gaseous and liquid phases. The I_2 values increase considerably on transition from liquid to gaseous, and pass through a maximum at a propane content of 7—10% (Table 5). This would agree with the idea that Ps, if formed in the Ore range, has a greater probability in the liquid phase than in the gas phase of decomposing again in one of the next few collisions or of being destroyed by pick-off. C_3H_8 molecules could stabilize the Ps atoms by energy transfer in inelastic collisions; this effect should be smaller in the gas phase, which would explain the small changes found for I_2 as a function of the C_3H_8 concentration in this case.

Table 5. Positronium yields in gaseous and liquid argon-propane mixtures [41].

Substrate	I_2 (gas phase) (%)	I_2 (liquid phase) (%)
Ar	35.2±3.5	10±1
Ar+ 0.2% C_3H_8	(relative: P=1)	20±2
Ar+ 0.5% C_3H_8	(relative: P=0.96−0.97)	27±2
Ar+ 7 % C_3H_8		64±3
Ar+10 % C_3H_8	52.8±3.7	
Ar+22 % C_3H_8	45.1±5.0	
C_3H_8	43.0±2.7	39±2

Brandt and *Feibus*[42] calculated the influence on the Ps yield of small quantities of an additive whose ionization potential, and hence also its Ore gap, is lower than that of the substrate. They considered the possibility that positrons that have not been captured in the Ore gap of the substrate with Ps formation now produce positronium in the Ore gap of the additive. According to these calculations, even very small quantities of impurities cause considerable changes in the Ps yield. This model also appears to offer a very convincing explanation of the processes found in the argon-propane system.

The positron compounds postulated in the course of these investigations present an interesting phenomenon, not only in the sense that a positron shell would be present in the atom or molecule, but also because entirely new types of interatomic bonds and types of compound could occur. It is to be hoped that further investigations will soon contribute further to their characterization. No theoretical treatment of the positron compounds of the type e^+ He *etc.* will be given here, since this is discussed *e.g.* in[3,4].

10. Positronium Chemistry in the Liquid Phase

In simple hydrocarbons, where the *o*-Ps atoms formed can be annihilated mainly by the pick-off mechanism, a good estimate of the extent of Ps formation in the liquid phase can be obtained from the intensity of the long-lived component I_2 in the time spectra. Though the Ore model was developed especially for gaseous systems, good agreement is found here between the P^0 values calculated by *Ore* and the experimental values for I_2[2].

Table 6. Observed and calculated (after *Hatcher*) *o*-Ps yields in halogenated hydrocarbons [38, 43].

Substrate A-B	V(eV) [a]	D_{A-B} (eV)	I_2 (calculated) (%) [b]	I_2 (observed) (%)
C_6H_5—F	9.19	4.98	21	24±2
C_6H_5—Cl	9.07	3.72	12	14±7
C_6H_5—Br	8.98	3.07	7.4	6±2
C_6H_5—I	8.73	2.47	4.6	4±2
C_3H_7—Cl	10.7	3.4	<0	16±2
C_3H_7—Br	10.29	3.0	<0	10±2
C_3H_7—I	9.41	2.5	<0	4±2

[a] Ionization potential of AB.

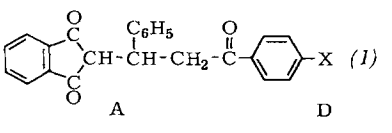
[b] $I_2 = \frac{3}{4} \cdot \frac{D_{A-B} - (V - 6.8)}{V}$.

On the other hand, the experimental results differ considerably from the Ore values in alcohols and particularly in halogenated benzene derivatives. *Hatcher*[43] was able to show that better agreement can be achieved in the case of monohalogenated aromatic compounds if the dissociation energy of the weakest bond in the molecule (C-halogen) is taken as the upper limit of the Ore gap instead of the first excitation potential (Table 6). However, on application of this modified Ore model to the monohalogenated propanes, one would expect practically no Ps formation in such systems, whereas the experimental values, as in the case of the monohalogenated aromatic compounds, are found to be $I_2 = 16$—4% (Table 6). This appears to suggest that the probability of Ps formation is a function of the nature of the halogen rather than a property of the molecule as a whole.

Tao and *Green*[38] have systematically investigated the problem of Ps formation in the liquid phase and have concluded that the Ps yield, as required in the original Ore model, is determined by the ionization potential V of the substrate (upper limit) and $[V - 6.8\ \text{eV}]$ (lower limit). They found that a relation exists between the true Ps yield, P^0, and the measured intensity, I_2, this relation being very strongly dependent on the type of reaction undergone by the Ps, such as pick-off, spin conversion, oxidation, compound formation, or reduction. Whereas in simple pick-off, for example, I_2 is proportional to the width of the Ore gap, a dependence in accordance with equation (34) is found for I_2 in the case of Ps-compound formation with subsequent decomposition in accordance with equation (33).

If the reaction between Ps and the monohalogenated hydrocarbons proceeds by compound formation with subsequent decomposition,

$$\text{Ps} + \text{R—Cl} \longrightarrow \text{PsCl} + \text{R}^\bullet \qquad (35)$$

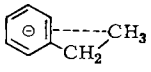


the trend observed in Table 6 is easily explained. The bond energies of the C-halogen and Ps-halogen bonds (Table 4) are predominantly a function of the halogen atom, and it follows that the threshold energy $D_{AB} - D_{PA}$ also depends only on the nature of the halogen. Since V varies only slightly within this series, I_2 is determined by the halogen atom. $D_{AB} - D_{PA}$ assumes positive values in these systems, *i.e.* the reaction should be possible only with "hot" Ps atoms.

An alternative to the above views was proposed by *Hatcher et al.*[44], who attempted to attribute the observed decrease in the I_2 values with increasing dipole character of the substrate molecule to "self-suppression" of the Ps formation by the competing positron capture reaction.

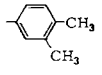
$$\text{R—X} + e^+ \longrightarrow \text{R}^\bullet + e^+\text{X} \qquad (36)$$

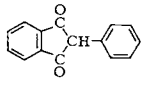
This is supported by the fact that this trend for I_2 is not restricted to the halogen derivatives and alcohols since a corresponding variation is found in the xylene system (*o*: 32%, *m*: 25% and *p*: 16%), where the inductive effect of the methyl groups leads in the order $o > m > p$ to a decrease in the negative charge on the substituents.

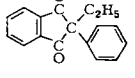


An interesting result in this connection was reported by *Zalukaev et al.*[45]. The anti-vitamin K activity in compounds of the type *(1)* is determined exclusively by the

(1)







substituent X, which is separated from the indan-1,3-dion-3-yl reaction center by at least two saturated carbon atoms. The influence of the substituent X on the hypocoagulation activity was explained by the existence of an intramolecular charge transfer complex between the indan-

dionyl and the aroyl components of the molecule, the β-diketone part acting as the acceptor (A) and the carbonyl group plus the alkylphenyl component acting as the donor (D). The authors found that in the series of alkylbenzenes and in the series of indanyl derivatives of the type *(1)* that contain the end group $-C_6H_4X$ (X = H, CH_3, C_2H_5, C_3H_7, and C_4H_9), I_2 reaches a minimum at $X = C_2H_5$, which coincides with a maximum in the anticoagulant action or a minimum in the prothrombin index (Table 7). They attribute this to the formation of an additional charge transfer complex between the ring and the ethyl group, which strengthens the electron donor property of the ethylbenzene group:

An interesting relation thus appears to exist between the Ps yield and the electron density distribution in the molecule, and hence also the stability of charge transfer complexes, which ultimately have a decisive influence on the biological activity of certain compounds.

Table 7. Prothrombin index and positron annihilation in indan-1,3-dione derivatives [45].

Aryl in *(1)*	Prothrombin-index	Positron-annihilation I_2 (%)	τ_2 (10^{-10} s)
	8	0	0
	50	0	0
	63	—	—
	71	—	—
	90	19.2 ± 5.8	7.3 ± 2.2
	100	15.2 ± 4.5	6.6 ± 2
	40	0	0
	100	18.8 ± 5.6	4.8 ± 1.4

As was mentioned earlier, a decrease in I_2 with no simultaneous increase in the corresponding lifetime τ_2 can result either from inhibited Ps formation or from chemical reaction of the Ps before it has reached thermal energies.

The question whether inhibited Ps formation or reactions of "hot" Ps atoms are responsible *e.g.* for the drastic decrease in I_2 in benzene on addition of CCl_4 (Fig. 24) was recently answered by *Chuang* and *Tao*[46] by measurement of the time spectra of silica gels on which small quantities of the substrates under investigation were adsorbed.

Brandt and *Paulin*[47] had been able to isolate three components in the time spectra in the investigation of the dependence of positron annihilation on the particle size of solids such as SiO_2, Al_2O_3, and MgO. The first two components, with average lifetimes of $\tau_1 = 0.4$ ns and $\tau_2 = 2$ ns, are due as usual to the annihilation of the free positron and of *p*-Ps (τ_1) and to the annihilation of *o*-Ps (τ_2). The lifetime of the third component, however, is close to the theoretical lifetime of free *o*-Ps, *i.e.* 1.4×10^{-7} s. The intensity of this component (I_3) increases at the expense of I_2 with decreasing particle size of the substrate. These observations were interpreted as resulting from diffusion of the *o*-Ps formed (up to 95% of all Ps atoms) from the solid phase into the cavities of the substrate, where the *o*-Ps is subsequently trapped.

By using this "*o*-Ps source", *Chuang* and *Tao*[46] found that the lifetime (τ_3) and intensity (I_3) of this component are very strongly influenced by the presence of small quantities of iodine (Fig. 25), whereas much greater quantities of CCl_4 must be adsorbed to produce the same effect (Fig. 26).

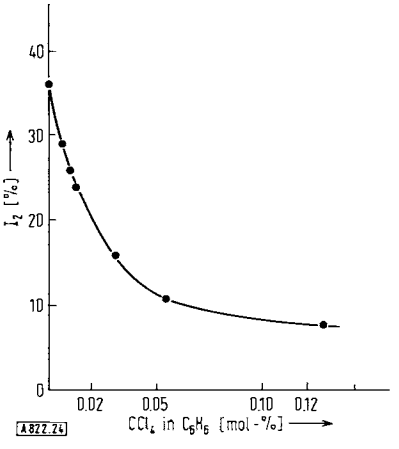


Fig. 24. Inhibition of positronium formation in benzene in the presence of small quantities of carbon tetrachloride [49].

The attraction between an *o*-Ps atom and the pore surface of the adsorbent is mainly due to van der Waals forces. The probability of annihilation of Ps, as in the "free volume"

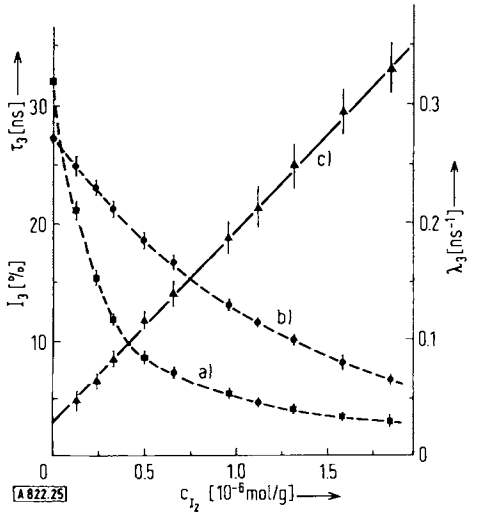

Fig. 25. Lifetime (τ_3) and intensity (I_3) of the third (long-lived) component in positron lifetime spectra of silica gel as a function of the quantity of adsorbed iodine [46]: a) τ_3; b) I_3; c) $\lambda_3 = 1/\tau_3$.

model (cf. Section 6.1), is thus given by the extent of the resulting overlap of the Ps wave function with the electron density function of the molecules on the surface of the SiO_2. If an adsorbate is a species with which positronium can react chemically (compound formation, *etc.*), chemical forces of attraction occur in addition to the van der Waals forces. This leads to an increase in the overlap of the wave functions and an increase in the Ps annihilation constant, as in the case of the adsorption of I_2. On adsorption of

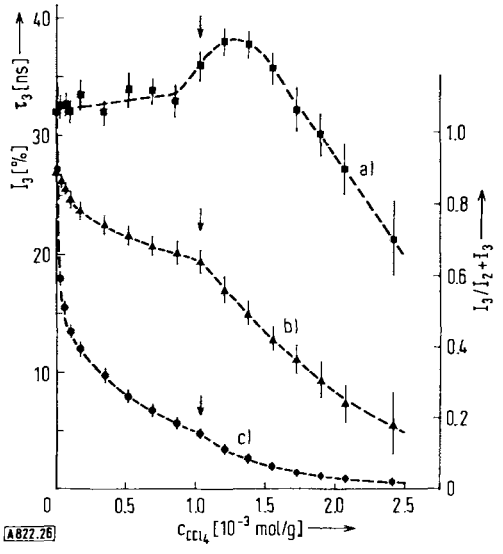

Fig. 26. τ_3 and I_3 in positron lifetime spectra of silica gel as a function of the quantity of carbon tetrachloride adsorbed [46]: a) τ_3; b) I_3; c) I_3/I_2+I_3.

CCl_4, on the other hand, the lifetime of *o*-Ps (τ_3) and the intensity I_3 remain constant, or even increase, over a wide concentration range. It can be concluded from these findings that iodine is very reactive toward positronium, and probably forms Ps-compounds in accordance with

$$Ps + I_2 \rightarrow PsI_2 \text{ or } PsI + I \qquad (37)$$

This is in agreement with investigations[48] on mixtures of hydrocarbons and iodine, in which it was found that iodine seems to react very rapidly with Ps, but only slightly inhibits the Ps formation. The role of CCl_4, whose classical Ore gap is 0, appears on the other hand to consist mainly in the inhibition of Ps formation, though it is not certain whether this is due to positron capture reactions, as suggested by *Ormrod* and *Hogg*[49], or to moderation to energies below the Ore range as a result of energy transfer in inelastic collisions.

11. Positronium Chemistry in the Solid Phase

The discussion of the chemistry of positronium in the solid phase will be confined to three areas.

11.1. Investigation of Radiation-Induced Polymerizations in the Solid Phase by Positron Lifetime Measurements

Tabata et al.[50] used this method to investigate the γ-radiation-induced polymerization of diethyl itaconate (diethyl methylenesuccinate) in the solid phase. The time spectra show that τ_2 remains practically constant over the entire range investigated, while I_2 exhibits the dependence on the radiation dose shown in Figure 27. In these circumstances, two factors should determine the lifetime of the *o*-Ps. These are the number of free radicals and other paramagnetic species produced by the γ radiation, which shorten the *o*-Ps lifetime by spin conversion, and the "free volume" available for the accommodation of *o*-Ps, which undoubtedly changes during the polymerization. However, it is possible that, as appears to be the case in the present example, these two effects balance each other, so that τ_2 remains constant. The change in I_2 during the polymerization can be attributed to the transition from the monomeric to the polymeric phase. The *o*-Ps yield is evidently lower in the monomer (f_M) than in the polymer (f_P). Since I_2 increases linearly with the polymer yield at conversions of more than 10%, the following equation can be given for the *o*-Ps formation

$$f_{total} = cf_P + (1-c)f_M \qquad (38)$$

where c is the polymer content of the system. Numerical evaluation gives $f_M = 0.13$ and $f_P = 0.36$. However, this linear dependence is not found in the initial stage of the polymerization. This interval appears to reflect the time taken for the nucleation process. 10% of polymer is always found experimentally during this period, irrespective of the experimental conditions; this agrees well with the observed linear dependence of I_2 starting at a conversion of 10%. It appears that the polymer is suspended in the crystal during this period, and that no phase separation has occurred.

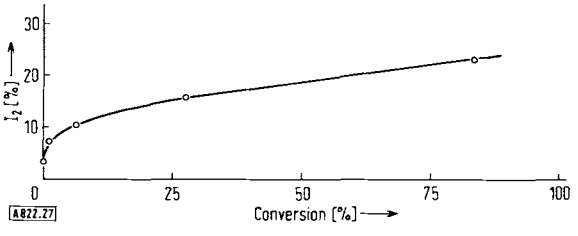

Fig. 27. Relation between I_2 in the positron lifetime spectrum and degree of polymerization (% conversion) in the γ-induced polymerization of diethyl itaconate in the solid phase [50].

Tabata et al. have also used this method to investigate the polymerization of *N*-vinylcarbazole[51, 52]. Unlike in the diethyl itaconate system, the τ_2 values here increase rapidly with the degree of polymerization, whereas I_2 exhibits a characteristic minimum at radiation doses of 12—13 Mrad (Fig. 28). The authors distinguish four regions: I and II are the induction periods, III is the propagation period, and in IV the polymerization has reached its saturation value. In I and II, where τ_2 is practically constant, the lifetime-shortening effect of the free radicals and other active centers is evidently compensated by the effect of the "free volume"; in III, however, the latter effect predominates, and τ_2 increases. In IV, where the "free volume" becomes constant, τ_2 is again shortened by Ps reactions with the free radicals. ESR measurements confirm the linear increase in the free-radical concentrations with the radiation dose. A clue to the cause of the observed minimum of I_2 in the propagation

period III was obtained in experiments in which the substances colored green by the irradiation were bleached by UV light. The same decoloration takes place in III. The intense color under these circumstances is an indication of the presence of ions. *Tabata et al.* therefore conclude that positrons react to form compounds with the ions, which are evidently present in increased quantities during III (as is indicated by the green color), and that the positrons are therefore not available for Ps formation. When most of the ions have disappeared, as in period IV, I_2 again increases.

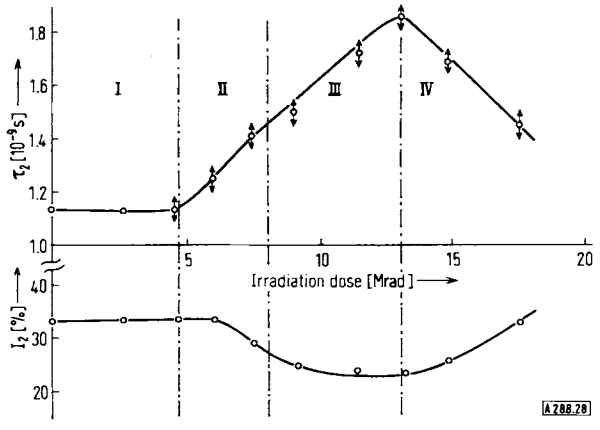

Fig. 28. τ_2 and I_2 of the long-lived component in positron lifetime spectra of solid *N*-vinylcarbazole as a function of the γ radiation dose at 23 °C (7.2×10^6 rad/h) [51].

Post-polymerization has also been investigated by this method[53].

Incomplete as they still are in some respects, such investigations clearly show that this technique offers a possibility of studying the detailed mechanism of polymerization in the solid phase, both the nucleation process and the nature of the active particles in the crystals that initiate and carry on the polymerization.

11.2. Investigation of Phase Transitions by the Positron Annihilation Technique

The dependence of the lifetime of *o*-Ps in solids on the density of the substance can generally be explained very satisfactorily by the "free volume" model[16–18]. However, this model cannot explain the drastic changes in τ_2 that have been observed in many phase transitions.

A particularly interesting example is the liquid crystal system, which was first investigated by *Cole* and *Walker*[54], and which very clearly demonstrates the effect of the intermolecular forces and the internal structural arrangement of the molecules on the lifetime of *o*-Ps. The results, which are summarized in Figure 29, show that a change in τ_2 is found only in transitions that involve a sudden change in the intermolecular dipole-dipole forces; such a change occurs in the transition from the solid to the smectic phase or from the smectic to the nematic phase, but not from the nematic or smectic to the liquid (isotropic) phase. The dipole-dipole interaction is undoubtedly strongest in the solid phase, and this would explain the shortening of τ_2 observed there. From the observation that no *o*-Ps is formed in solid *p*-azoxyanisole, it was concluded that the same effect also leads to inhibition of Ps formation. This is opposed by the observation by *Nicholas* and *Ache*[55] that I_2 changes only slightly in the region of the phase transitions in cholesteryl benzoate and myristate, *i.e.* the Ps yield is

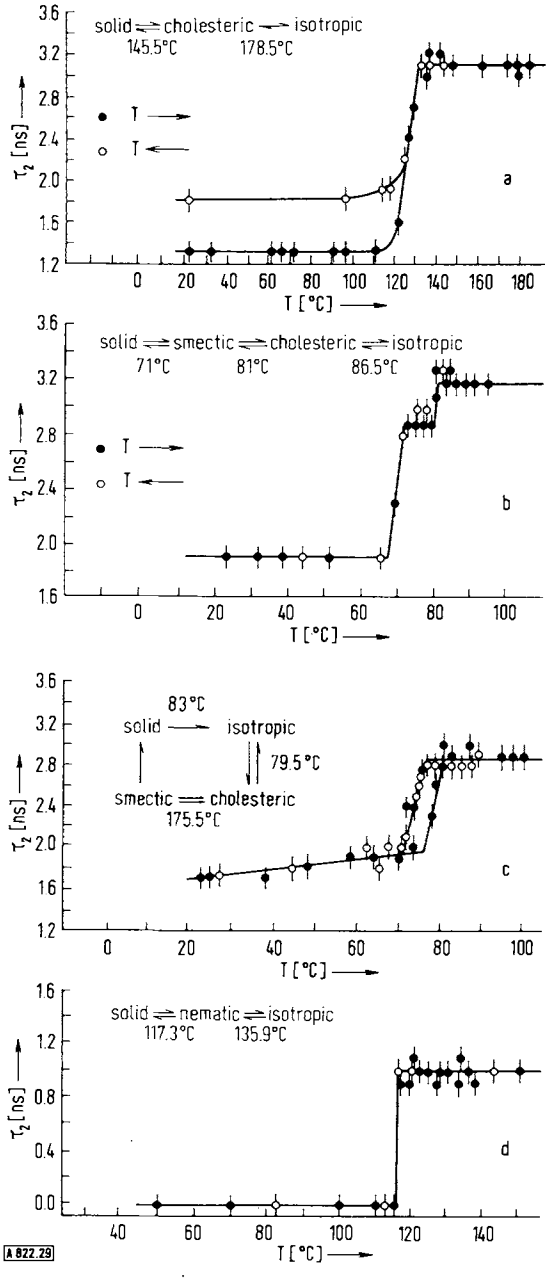

Fig. 29. Temperature dependence of τ_2 for some liquid crystals [54]: a) cholesteryl benzoate; b) cholesteryl myristate; c) cholesteryl stearate; d) *p*-azoxyanisole.

only slightly influenced by the phase transition in these systems. There thus appears to be no obvious connection between the Ps yield and the phase change. Recent angular distribution measurements[56] support the view that *ortho-para* spin conversion processes are responsible for the shortened lifetime of *o*-Ps in the solid phase in such systems.

11.3. Positron Interactions with Crystal Defects (in Ionic Crystals)

Though Ps formation in ionic crystals such as NaCl was ruled out by *Ferrell*[13] on the basis of thermodynamic considerations, the time spectra of the alkali metal halides can be resolved into at least two components[57-61], *i.e.* in addition to the annihilation of the free positron, at least one other annihilation mechanism must be active. *Goldanskii* and *Propokev*[62-64] discuss three positron states through which annihilation could take place, *i.e.* e^+-anion, polaron-e^+, and e^+-crystal defect. *Brandt*[65] developed the view that positrons that are annihilated in cation vacancies could be the reason for the appearance of the long-lived component in the time spectra.

The first indication that crystal defects could influence the lifetime and intensity of the long-lived component was provided by *Williams* and *Ache*[60] as a result of investigations on the dependence of these quantities on the defect concentration in proton-irradiated and γ-irradiated NaCl and NaF crystals. The I_2 values increase considerably on irradiation. However, thermal annealing of the crystals brings I_2 back to the original value for the unirradiated crystals. τ_2 changes only slightly. Since the high proton and γ doses undoubtedly lead to a series of different defects, these results provide no indication of the exact nature of the defects. Recent investigations by *Singru et al.*[66] and particularly by *Brandt*[67], who produced cation vacancies by plastic deformation of the crystals, indicate that such vacancies cause an increase in I_2. This is also indicated by a study on the temperature dependence of τ_2 and I_2[61].

These studies as well as more recent investigations by *Brandt*[68-69] and *Ache*[70] led to the development of a model, in which the positrons are assumed to annihilate either in the bulk of the crystal at a typical rate $\lambda_0 = 1/\tau_0$ or to be captured in crystal-defects, most likely cation-vacancies, at a rate K_1 which is proportional to the number of the defects (n_v). Since in these "positron traps" there is less overlapping between the positron wave function and the wave functions of the electrons of the surrounding atoms, the annihilation process is delayed. The result is an increase in the lifetime of the positron. The kinetic treatment of the various annihilation processes involved results in the following relation between the defect concentration n_v and the experimental quantities τ_1, τ_2 and I_2:

$$K = \text{Const.} \times n_v = I_2 (1/\tau_1 - 1/\tau_2)$$

τ_1 and τ_2 are lifetimes of the short- and long-lived components in the observed positron lifetime spectra; I_2 is the intensity of the long-lived component.

Since the lifetimes of the two components that appear in the time spectra are close to each other and are both very short, considerable difficulties are still often encountered in the evaluation. However, it is to be hoped that an improvement in the resolving power of the instruments will allow more detailed investigation of the individual components in the spectra, so that this technique can be developed into a method for the identification and measurement of crystal defects of types that are little known at present.

A first practical application has been reported by *Kelly* and *Merrigan*[71], who studied the properties of chemically light-sensitized AgCl crystals. Among other things, they found that the degree of light sensitivity of these specially prepared crystals can be correlated to the relative intensity, I_2 of the long-lived component in the time spectra.

12. Summary and Outlook

In this progress report, which is not claimed to be complete, an attempt has been made to discuss the problems of positronium chemistry that have arisen in recent years from the viewpoint of the chemist.

It is clear that the chemical applications of the positron annihilation process are still in their early stages; however, a number of areas already stand out where this new nuclear technique will be able to contribute most to the solution of chemical problems. The most important of these are probably:

1. the detection of free radicals and other paramagnetic species in gases, where this technique, with its high sensitivity, should be superior to most conventional methods;

2. the investigation of spin delocalization in complexes;

3. the determination of the true kinetic parameters of chemical reactions in solution;

4. the study of the physico-chemical processes in phase transitions and the accompanying changes in the nature and strength of the intermolecular forces;

5. the detailed elucidation of the mechanism of polymerization processes in the solid phase (duration and course of the nucleation process, nature and role of free radicals and ions in radiation-induced polymerization);

6. the determination of the effect of parameters such as ionization potentials, dissociation energies, and charge distributions on the additions of positrons (or electrons) with subsequent decomposition of the compound (fundamental processes that occur in radiation chemistry and may determine the radiation-chemical stability of the compound);

7. the identification and measurement of various types of defects in solids.

It seems certain that as this nuclear method becomes increasingly widely used, it will find interesting new applications in chemistry.

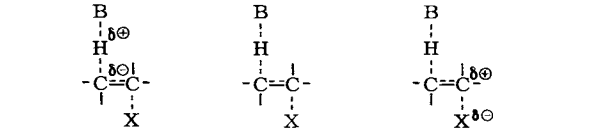
The *syn* and *anti* Steric Course in Bimolecular Olefin-Forming Eliminations

By Jiří Sicher[*]

Earlier evidence led to the view that in bimolecular olefin-forming eliminations the anti steric course is generally preferred over the syn. Recent experiments, however, show that in some common bimolecular elimination reactions, notably those involving onium bases, syn- and anti-eliminations proceed side by side, the former preferentially leading to the trans- and the latter to the cis-olefins.

1. Introductory

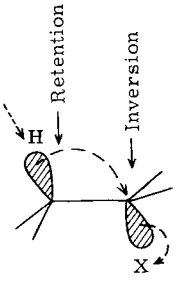
One of the features essential for the description of the mechanism of a concerted 1,2-elimination process is the torsion angle about the C^{α}—C^{β} bond in the activated complex. In principle, this angle can posses any value between 0 and 180°. However, it is suggested by theory (*e.g.* the principle of maximum orbital overlap) and supported by experiments on mono- and bicyclic ring systems that arrangements in which the C^{α}—X and the C^{β}—H bond are antiperiplanar (*anti*-elimination, torsion angle 180°) and synperiplanar (*syn*-elimination, torsion angle 0°) will be greatly preferred in the transition state of an HX elimination reaction (Scheme 1)[1-4].



Scheme 1.

Accepting this view one must next ask what the situation is with respect to a possible preference of the one steric mode of elimination over the other[**]. Until recently there seemed to be universal agreement that whenever the molecule was "free to choose" between the 0° and the 180° torsion angle to effect elimination it would definitely prefer the latter.

2. The Case for Preferred *anti*-Elimination

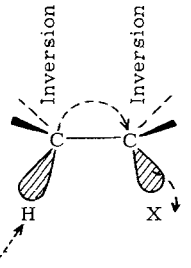


2.1. Theoretical Considerations

Frequently, the problem of the steric course is discussed in terms of eclipsing effects. In *syn*-elimination all three pairs of groups attached to C^{α} and C^{β} are eclipsed or nearly so; by contrast, the transition state for *anti*-elimination, barring cases with highly developed double bond character, permits a staggered arrangement. These conformational differences led to an estimated factor of 10^2 or 10^3 in favor of *anti*-elimination[6]. In the non-synchronous, yet concerted elimination processes [E1-like *(paene-carbonium ion)* or E1cb-like *(paene-carbanion)*[7], cf. Scheme 2] the advantage accruing from maximum orbital overlap is not as great as in the fully synchronous process, and, as a result, the *syn*-elimination transition state need not be fully eclipsed. It was suggested that this feature could lead to a lowered preference of *anti*- over *syn*-elimination[6].

Scheme 2.

An alternative treatment, stressing electronic effects[8-11], is based on a conceptual dissection of the elimination process into two components, *viz.* a "nucleophilic substitution" on C^{α}, through the electrons on C^{β}, and the complementary "electrophilic substitution" on C^{β} by C^{α} (Scheme 3). An S_N2 substitution invariably proceeds with inversion of configuration, and the stereochemistry of S_E2 is generally retention: this combination thus results in overall *anti*-elimination.



Scheme 3.

In 1962, *Ingold*[11] added the following important reservation. If C^{β}—H bond fission in a concerted elimination were considerably progressed in the transition state (as in an E1cb-like process; Scheme 2), sufficient ionicity could develop on C^{β} for the charge to spread on both sides of this carbon and thus for the S_E2 component to proceed with

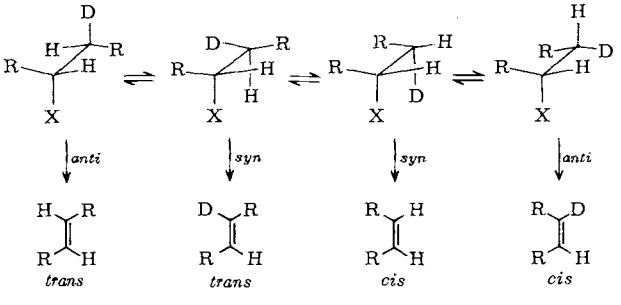
[**] This discussion relates only to bimolecular processes; processes in which the leaving group acts as an internal base must be *syn*-eliminations. For a review of these reactions, see ref. [5].

inversion; the elimination could then exhibit *syn*-stereospecificity (Scheme 4).

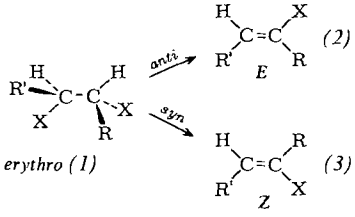


Scheme 4.

Fukui and others[12–14] have provided a quantum mechanical rationale for preferred *anti*-elimination in open-chain systems but a recent qualitative analysis in molecular orbital terms was taken to suggest that either elimination mode may be preferred, depending on the relative timing of the bond changes[15]. Application of the principle of least motion[16] also indicates a general preference for *anti*-elimination.

2.2. Experimental Evidence

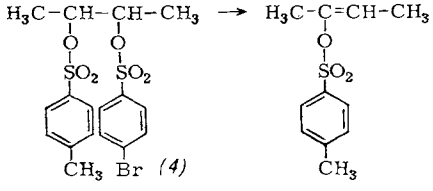
2.2.1. Open-Chain Compounds



In their pioneering investigations on the steric course of elimination, *Skell* and his co-workers[17,18] made use of the mono-deuterated derivatives of 2-butyl bromide and 2-butyl tosylate (Scheme 5). Starting from the β-deuterated substrates of known configuration, information about the steric course of the elimination can be deduced directly from the deuterium content of the individual olefinic products.

Scheme 5.

It was found that the elimination of both hydrogen bromide and toluenesulfonic acid using potassium ethoxide in ethanol proceeds exclusively by *anti*-elimination[*].

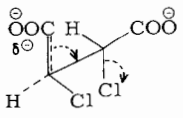


Stereochemical analysis of the course of elimination becomes simpler when the reactant exists as diastereomers without having to be labeled. Thus hydrogen chloride elimination from an *erythro*-dihalide of type *(1a)* (R = R′ = alkyl, X = halogen) can give rise to either *Z*- or *E*-vinyl halide [*(2a)* or *(3a)*], depending on whether the elimination proceeds by an *anti*- or a *syn*-elimination mechanism (Scheme 6).

Scheme 6.

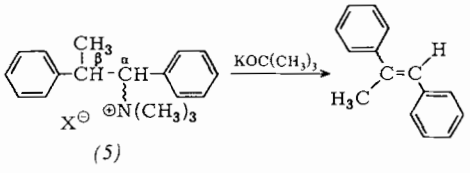
It was reported[19] that the reaction of *erythro*-2,3-dichloropentane *(1b)* (R = CH_3, R′ = C_2H_5, X = Cl) and homologous *erythro* and *meso vic*-dichloroalkanes with potassium hydroxide in *n*-propanol gives exclusively the *E*-vinyl chlorides *(2)*, showing that the elimination proceeds by the *anti* mechanism.

Likewise, the elimination of *p*-bromobenzenesulfonic acid from the two diastereoisomers of 2-brosyloxy-3-tosyloxybutane *(4)* [$N(C_2H_5)_3$/50% aqueous dioxane] leads exclusively to the isomers expected from an *anti*-elimination course[20].



Caution is sometimes required when dealing with earlier results. For example, with the aid of modern analytical instrumentation it has been shown that elimination of HBr from *erythro*-4,5-dibromooctane with piperidine at reflux temperature does not give solely 4-bromo-*cis*-4-octene (*E*-isomer), as previously assumed[21], but also 15% of the *Z*-isomer[22][**].

However, at least two cases have long been on record in which two open-chain diastereoisomers give rise to the same olefin isomer (stereoconvergent elimination). *meso*- and dl-α,α-Dichlorosuccinic acid react with aqueous alkali to give chloromaleic acid. The formation of chloromaleic acid from *meso*-dichlorosuccinic acid was assumed to proceed through a non-synchronous, yet concerted E1cb-like mechanism with approximately *syn*-coplanar geometry. In the transition state the excess charge should reside mainly on the carboxylate group. Consequently, the lone pair that displaces the chlorine atom from its bond to the carbon comes more from the direction of the carboxylate—and elimination is therefore in reality *anti*-coplanar—than from the direction of the leaving hydrogen atom (Scheme 7)[23–25].

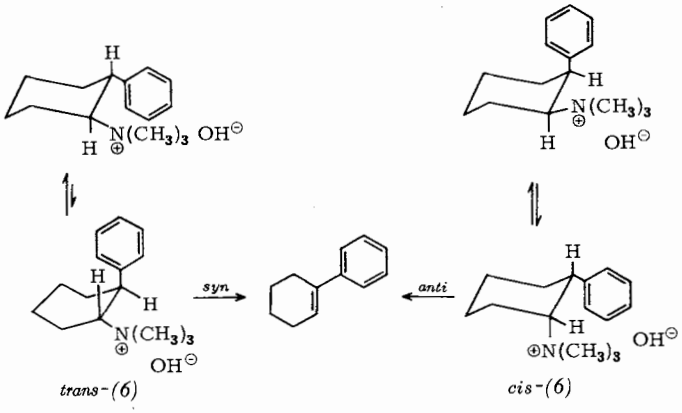


[*] Actually, for the hydrogen bromide elimination the "reverse" argumentation had been employed: *anti*-elimination was assumed as being *given* and the eliminations were run in order to establish the relative configurations of deuterium and bromine in the reactants and also their configurational purity. However, the results are self-consistent to such a degree that the evidence may be considered to have established both aspects.

[**] It appears from unpublished work (*J. Sicher* and *J. L. Schwitzguebel*, Université de Lausanne 1970) that the *Z*-isomer is not actually formed by *syn*-elimination but in a subsequent partial isomerization of the *E*-isomer.

Scheme 7.

Likewise, both the *threo* and the *erythro* isomers of the (1,2-diphenylpropyl)trimethylammonium salt *(5)* react with *tert*-butoxide in *tert*-butanol to give the same olefin isomer, *viz.* α-methyl-*trans*-stilbene[25].



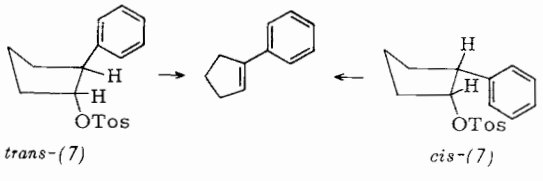
(5)

The two diastereoisomers were found to react at very similar rates and this was taken to indicate that the reaction is an E1cb process, the rate-determining step being deprotonation at C^{β}. An alternative explanation, *i.e.* that the process involves rapid isomerization at C^{α} followed by concerted elimination, was also considered. Subsequent isomerization of the reaction product was ruled out in this (and similar) cases by control experiments: α-Methyl-*cis*-stilbene is stable under the above reaction conditions[26].

Significantly, with ethoxide in ethanol, *threo-(5)* gave α-methyl-*trans*-stilbene, and *erythro-(5)* gave α-methyl-*cis*-stilbene, both processes thus being *anti*-eliminations, and the ratio $k_{threo}/k_{erythro}$ was rather high (*i.e.* 57). The reactions of the corresponding bromides and chlorides *(5)*, Cl or Br instead of $\overset{\oplus}{N}(CH_3)_3$, with a variety of base/solvent combinations were also found to be *anti*-eliminations[26].

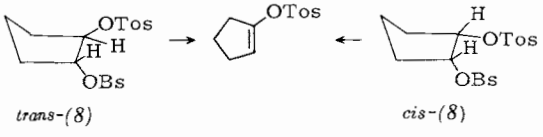
2.2.2. Cyclohexyl Compounds

As is well known, bimolecular eliminations take place smoothly in this system only if the two vicinal bonds involved are configurationally *trans*, and, in addition, diaxially disposed; *cis*-placed substituents will not undergo



trans-(6) *cis-(6)*

concerted elimination, or will do so only reluctantly. Thus, even though both *trans*-2-phenylcyclohexyltrimethylammonium hydroxide *(6)* and the corresponding *cis*-isomer[30] give 1-phenylcyclohexene[27–29], the reaction is some 140 times slower in the former case.

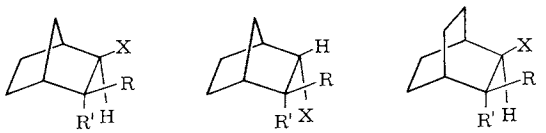


It seems that it was not always appreciated that results such as these are not necessarily relevant to the question of preference of *anti*- over *syn*-elimination. The lower reactivity of *trans-(6)* could be taken to mean that *syn*-elimination is generally less favorable than the *anti* mode. The influence of other important factors on the reaction rate should, however, not be overlooked. While the *trans*-diaxial arrangement in one of the two chair forms of *cis-(6)* corresponds ideally to the geometric requirements of *anti*-elimination, the conditions for *syn*- or near-to-*syn*-elimination cannot be fulfilled in the chair form. Conversion of the chair into the sterically less favorable boat form requires strain energy, even though the energy differences in the case of *trans-(6)*, and in similar systems capable of undergoing *syn*-elimination[31,32], are estimated to be lower than for unsubstituted cyclohexane itself, since the bulky *gauche* groups [*e.g.* C_6H_5 and $\overset{\oplus}{N}(CH_3)_3$ in *trans-(6)*] tend to destabilize the chair conformation relative to the boat[33].

2.2.3. Cyclopentyl, Bicycloheptyl, and Bicyclooctyl Compounds

In the five-membered ring a torsion angle close to zero practically pre-exists for *cis*-placed groups, while for *trans*-placed groups a true *anti*-planar arrangement is hardly attainable[*]. It is therefore not altogether surprising that examples of bimolecular *syn*-eliminations should have been found in this system. Thus, on treatment with *tert*-butoxide in *tert*-butanol and trimethylamine in 50% aqueous dioxane, respectively, the *trans*-isomers *(7)*[34] and *(8)*[20] eliminate *p*-toluenesulfonic acid and *p*-bromobenzenesulfonic acid by what must be a *syn*-elimination. However, the rates of *anti*-elimination from the corresponding *cis*-isomers were found to be higher by factors of 9.1 and 1.3 respectively.

trans-(7) *cis-(7)*



trans-(8) *cis-(8)*

Derivatives of bicyclo[2.2.1]heptane *(9)* and bicyclo[2.2.2]-octane *(10)* possess geometric features which are expected to be especially favorable for *syn*-elimination. Several such compounds have been studied from this point of view (Table 1), and *syn*-elimination has indeed been found to be the preferred reaction mode for the bicyclo[2.2.1]heptyl system provided that the anionic leaving group X occupies

[*] The existence of the *trans*-hydrindan (perhydroindene) system demonstrates, however, that such an arrangement cannot be ruled out entirely.

the *exo* position. The corresponding *endo*-substituted compound [*endo-(9)*] undergoes *anti*-elimination, regardless of the unfavorable torsion angle of 120°. This "lower reactivity" of the *endo*-hydrogen may be a result of steric hindrance to the access of base, or of some other effect.

Several other important conclusions follow from an analysis of the data in Table 1. Thus, the bicyclooctyl system *(10)* exhibits a somewhat greater tendency for *syn*-elimination than the bicycloheptyl system *(9)*. Further, the tendency to react by *syn*-elimination decreases on going from the trimethylammonium to other leaving groups, particularly halogen or tosylate. Finally, the proportion of *syn*-elimination decreases with the polarity of the solvent.

(14) k_{anti} = 0.02 *(15)* k_{syn} = 1.6

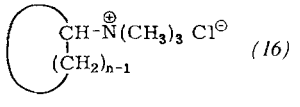
Scheme 8.

follows the same trends. A further important finding is that the dichlorides show a greater proclivity toward *syn*-elimination than the dibromides. The relative rates of these eliminations are apparent from Scheme 8.

2.3. Conclusions from Studies Prior to 1966

Theoretical considerations largely predicted a general preference of the *anti*-elimination mode, although the possibility of a genuine bimolecular *syn*-elimination was also envisioned. The available experimental evidence appeared to be in full accord with the prevailing view that "any system having the possibility of free choice will prefer the *anti*- over the *syn*-elimination path". The *syn*-elimination mechanism was considered to operate only in more rigid systems in which the torsional arrangement required for *anti*-elimination cannot be attained.

That many of the model compounds studied simply do not permit definite conclusions to be drawn was largely overlooked. Cyclopentyl and bridged bicyclic systems, which favor *syn*-elimination, are counterparts of the cyclohexyl derivatives in which *anti*-elimination is torsionally enforced. Interesting and significant as these results are, neither the one nor the other bears directly on the question of the general preference of the one or the other elimination mode.



There were, nevertheless, several aspects of E2 reaction data which were difficult to understand on the basis of this simple picture of a sterically homogeneous elimination behavior. One of these was the frequent lack of correlation between the relative stabilities of *cis-trans* olefin pairs and the ratio in which the two isomers were formed in certain elimination reactions[43]. Moreover, reservations could be held against the significance of some of the evidence. This concerns, as we have just seen, some of the ring systems frequently employed. Also, the point could be made that the range of base/solvent systems employed in some of the studies was not sufficient to justify the generalizations made.

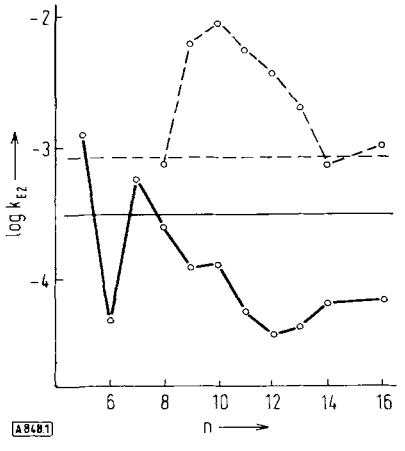
3. Recent Investigations: Evidence for *syn*-Elimination as a Frequent Reaction Mode

3.1. Rate Profile Studies on Eliminations from Cycloalkane Derivatives

The study of the variation of rate with ring size of a reaction in a homologous series of ring compounds ("rate profile") can provide useful mechanistic and stereochemical information[44-49]. By relating the "rate profile" of the process under investigation to that of a reaction of known mechanism one may hope to obtain evidence on its course, the argument being that reactions which are similar with respect to their salient geometric features should also be similar as regards rate profile.

In the case of bimolecular eliminations rate profiles were first determined for base-induced degradation of cycloalkyltrimethylammonium compounds[50-53]. Fig. 1 shows an example.

(16)



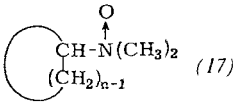


Fig. 1. Effect of ring size n on rates of formation k_{E2} of *cis*- and *trans*-cycloalkenes from cycloalkyltrimethylammonium chlorides *(16)* with potassium *tert*-butoxide in *tert*-butanol at 55 °C [50, 51]. – – –: *trans*-cycloalkenes, ——: *cis*-cycloalkenes.

The immediately obvious feature of these results is the very marked difference in the rate profiles for *cis*- and *trans*-cycloalkene formation. Provided one accepts the tenet that processes possessing similar salient stereochemical features will exhibit rate profiles of similar type[45], one also has to accept the converse of this statement, namely that rate profiles of different types may indicate the operation of stereochemically different mechanisms. Accepting this view, one is forced to conclude that two geometrically distinct mechanisms are operating in the present reaction, the one being mainly, or even exclusively, the route of choice for *trans*-olefin formation, the other for *cis*-olefin formation.

A similar rate profile study for a *bona fide syn*-elimination process, the thermolysis of amine oxides (Cope elimination) (Fig. 2), provides further information.

It is clearly apparent that the rate profiles for *trans*-cycloalkene formation from the onium base elimination and the amine oxide elimination are closely similar, and must therefore both be *syn*-eliminations. By contrast, the rate profiles of *cis*-olefin formation in the two processes are very different, suggesting that *cis*-olefin formation from the onium compounds does not proceed by a *syn* route, and hence must proceed by an *anti*-elimination mechanism[50, 54-57], at least largely, if not exclusively.

(17)

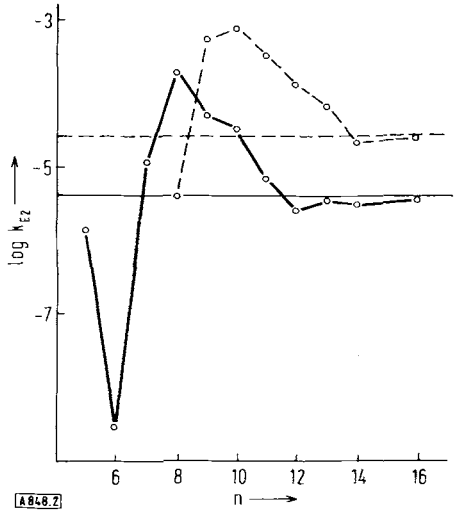

Fig. 2. Effect of ring size n on rates k_1 of *cis*- and *trans*-cycloalkene formation from cycloalkyldimethylamine oxides *(17)* in *tert*-butanol at 20.6 °C [54]. – – –: *trans*-cycloalkenes; ——: *cis*-cycloalkenes.

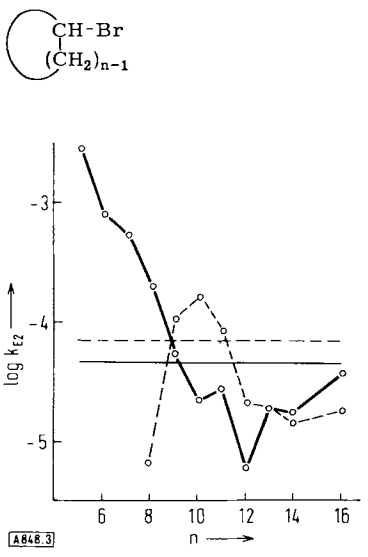
These studies thus not only revealed the operation of the hitherto stigmatized *syn*-elimination mechanism but they also led to the discovery of an unexpected mechanistic dichotomy. By means of the rate profile approach we cannot decide how rigorous the observed mechanistic stereoselectivity actually is: some *anti*-elimination in *trans*-olefin formation, or, again a certain proportion of *syn*-elimination in *cis*-olefin formation would not necessarily be revealed by this procedure.

This approach was extended to other base/solvent systems. Eleven combinations were investigated and the data obtained led to the same fundamental conclusions. Initial studies on eliminations from cycloalkyldimethylsulfonium salts are consistent with the data for the ammonium compounds[52, 53].

An analogous study on cycloalkyl bromides revealed that in the base/solvent systems *tert*-butoxide/*tert*-butanol and *tert*-butoxide/benzene, *trans*-cycloalkene formation probably also proceeds, either largely or exclusively, by *syn*-elimination (Fig. 3)[58, 59]. By contrast, for the process of *trans*-cycloalkene formation with the base/solvent systems ethoxide/ethanol and *tert*-butoxide/dimethylformamide the rate profiles were found to be quite different from those known to be characteristic for *trans*-olefin formation by *syn*-elimination. In the latter two systems the *syn* → *trans* reaction thus appears to play a subordinate role, if it occurs at all.

In *cis*-cycloalkene formation from cycloalkyl bromides, the *anti*-elimination pathway seems to be obligatory, regardless of the reaction conditions.



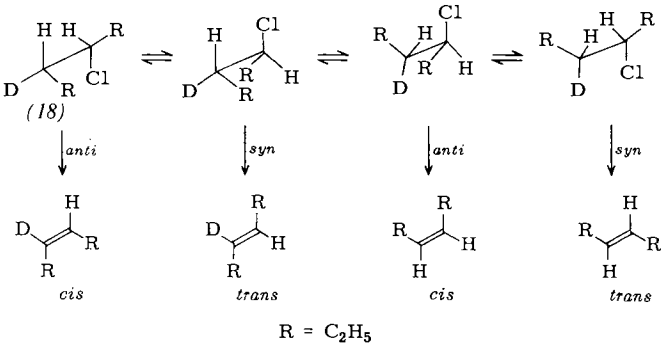


Fig. 3. Plot of log k_{E2} for *cis*- and *trans*-cycloalkene formation from cycloalkyl bromides and potassium *tert*-butoxide in *tert*-butanol at 82.5 °C *versus* the ring size *n*. The horizontal lines indicate the rate of formation of *cis*- and *trans*-4-nonene from 5-bromononane. – – –: *trans*-cycloalkenes; ——: *cis*-cycloalkenes [59].

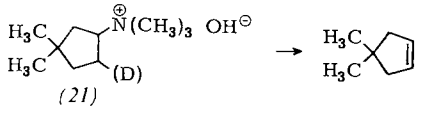
3.2. Studies Employing Diastereoisomerically β-Deuterium-Labeled Substrates

As already mentioned in Section 2.1.1, deuterium-labeled compounds can be used to determine the relative contributions of the competing *syn* → *cis*, *anti* → *cis*, *syn* → *trans*, and *anti* → *trans* processes to the overall reaction. The procedure entails separate isolation of the two isomeric olefins and determination of their deuterium content[*].

More simply, qualitative or even semiquantitative information concerning the steric course of an elimination may be obtained by comparing the olefin composition obtained from the stereospecifically β-deuterium-labeled reactant with the olefin composition obtained from the non-deuterated "parent" compound. The principle is illustrated in the following example. The reaction of, *e.g.*, [4D]-*threo*-3-hexyl chloride *(18)* to give *trans*-3-hexene by the *syn* route involves rupture of the C—D bond, whereas formation of the same olefin by the *anti* route does not: the formation of *trans*-3-hexene from the *threo*-β-deuterated reactant by the *syn* route is hence slowed down by the operation of a primary deuterium isotope effect, its formation by the *anti* route is not. Consequently, if, relative to the competing formation of *cis*- and *trans*-2-hexene, the proportion of *trans*-3-hexene resulting from the *threo*-β-deuterated reactant is found to be practically the same as that obtained from the parent compound, we must conclude that *trans*-3-hexene formation from *(18)* has taken place by *anti*-elimination. If, on the other hand, the proportion of *trans*-3-hexene from the *threo*-β-deuterated substrate is substantially lower than from the "parent" compound we must conclude that *syn*-elimination is in part, or wholly, responsible for the reaction.

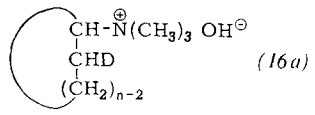


Thus the ratio of the rate constants of the formation of *trans*-3-hexene from non-deuterated and monodeuterated hexyl chloride is available directly from the product composition data. This ratio is an apparent kinetic isotope effect[60][**].

3.2.1. Cycloalkyl Onium Compounds

Degradation of selectively deuterated cyclooctyltrimethylammonium hydroxide *(16a)*, $n = 8$[61, 62], and of selectively deuterated tetramethylcyclodecyltrimethylammonium salts *(19)*[63, 64] confirm the results obtained from rate profile studies (Tables 2 and 3). *trans*-Cyclooctene and 5,5,8,8-tetramethyl-*trans*-cyclodec-1-ene are formed exclusively by *syn*-elimination.

The same technique was used to elucidate the stereochemical course of the formation of *cis*-cycloalkenes having small and medium-sized rings (Table 2). As expected, cyclobutene formation from the cyclobutyl onium hydroxide under "dry" pyrolytic conditions proceeds predominantly by *syn*-elimination[65]. Cyclopentene formation from the onium base using *tert*-butoxide in *tert*-butanol or on "wet" pyrolysis (in steam) at 190 °C is largely an *anti*-elimination reaction[66]; however, "wet" pyrolysis at 110 °C was reported[65] to proceed to approximately equal extents by *syn*- and *anti*-elimination.

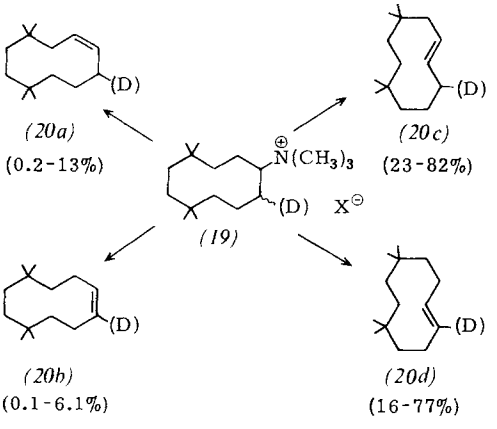


Pyrolysis of 3,3-dimethylcyclopentyltrimethylammonium hydroxide *(21)* to give 4,4-dimethylcyclopentene was found from labeling studies to proceed to the extent of 76% by *syn*-elimination[65]. Since the methyl groups are in a 1,3-relationship to the bulky onium group such a difference seems understandable.

Under pyrolytic conditions, decomposition of cyclohexylammonium hydroxide proceeds to at least 96% by *anti*-elimination[65–67]. In contrast, *cis*-cycloheptene and *cis*-

[*] *Secondary* isotope effects are neglected; this is perfectly legitimate in such cases.

[**] The "apparent" kinetic isotope effect $(k_H/k_D)_{app}$, determined from product composition data will be equivalent to the true deuterium isotope effect k_H/k_D solely when the reaction is exclusively *syn* or exclusively *anti and* this reaction mode requires removal of deuterium. The value of the "true" deuterium isotope effect of the elimination can only be calculated when the deuterium content in the olefinic product is known.



(16a)

No incursion of *syn*-elimination could be detected in the formation of the ten-membered *cis*-olefin *(20b)* from *(19)* using methoxide/methanol[64] (Table 2). Unfortunately, the experiments could not be extended to base/solvent systems which favor *syn*-elimination since the *cis*-olefin *(20b)* is then formed in amounts below 2%. This does, however, indicate that the *syn* → *cis* reaction cannot be of great importance in the cyclodecyl system[*].

3.2.2. Cycloalkyl Tosylates

Data are so far available only for ten- and twelve-membered ring systems. The picture for the ten-membered ring derivatives is gratifyingly simple. Both the position isomeric *trans*-cyclodecenes *(23)* and *(24)* appear to be formed by *syn*-elimination almost exclusively, under all the reaction conditions investigated. On the other hand, the *cis*-cyclodecene derivative *(25)* is formed by *anti*-elimination[68].

Table 3. Steric course of formation of *cis*- and *trans*-tetramethylcyclodecenes *(20b)* and *(20c)* from the cyclodecyltrimethylammonium compounds *(19)* [63, 64].

[c] Deuterium content as determined by mass spectrometry on isolated individual olefin and corrected for incomplete deuteration of *(19)*.
[d] Decomposition at 50°C/10^{-7} torr, X = OH.

cyclooctene formation by pyrolysis of the corresponding quaternary onium hydroxides has been found to involve about 34 and 51%, respectively, of *syn*-elimination[65]. Data for the steric course of elimination in homogeneous solution are unfortunately not available.

[*] The following reactivity sequence seems to hold for the ten-membered ring system: *syn* → *trans* ≫ *anti* → *cis* > *syn* → *cis* ≈ *anti* → *trans* (*J. Sicher, G. Jan,* and *M. Schlosser,* Angew. Chem. *83*, 1012 (1971); Angew. Chem. internat. Edit. *10*, 926 (1971)).

For the formation of the *trans*-olefin *(27)*, *syn*-elimination is now no longer the sole reaction path, and the proportion of *syn*- relative to *anti*-elimination using *tert*-butoxide as base falls off sharply on going from the solvent benzene to *tert*-butanol and still more to dimethylformamide[68] (cf. Table 1).

3.2.3. Acyclic Onium Compounds

As already observed in the alicyclic series, acyclic *cis*-olefins of type *(30)* are also formed predominantly or exclusively by *anti*-elimination.

As regards *trans*-olefin formation, however, the situation is distinctly less uniform than in the case of the corresponding alicyclic compounds. *syn*-Elimination does again operate and in many of the cases studied it represents the predominant, if not the sole, route to the *trans*-olefin. However, in other cases it plays only a subordinate role and in one or two instances it appears to be practically absent (Table 4).

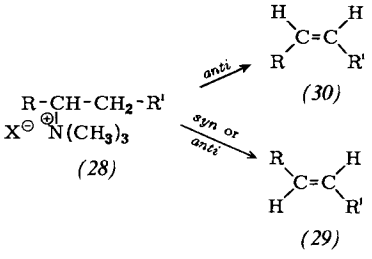

Table 4. Steric course of formation of *trans*-olefins *(29)* and *cis*-olefins *(30)* from ammonium compounds *(28)*.

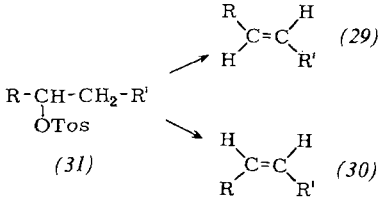
[a] Determined in a *cis*-*trans* mixture obtained from unlabeled *(28)*.
[b] Percentage *syn*-elimination (*syn* + *anti* = 100) in formation of *(29)* and *(30)* respectively.
[c] Evaluated from deuterium analyses on products from *threo*- and *erythro*-β-deuterated *(28)* corrected with assumed $(k_H/k_D)_{syn}$ and $(k_H/k_D)_{anti}$; for details see original papers.
[d] Estimated from $(k_H/k_D)_{app}$, the apparent isotope effects, calculated from product proportions.
[e] X = OH.

Two regularities clearly emerge from this picture. The first is the tendency, encountered previously (Table 1), for the *syn* → *trans* route to become appreciably more important than the *anti* → *trans* route as the base becomes stronger (bulkier) and the solvent less dissociating. Thus, in the case of *trans*-3-hexene formation from 2-hexyltrimethylammonium hydroxide, *syn*-elimination accounts for only 9% of the *trans*-olefin formed in aqueous sodium hydroxide; on addition of dimethyl sulfoxide the contribution of *syn*-elimination increases, accounting for 53% of the *trans*-3-

hexene formed when the hydroxide contains 62 mole-% dimethyl sulfoxide[70].



The proportion of *syn*-elimination is only small on reaction of 3-hexyl- and 5-decylammonium salts with primary alkoxide in primary alcohols but definitely becomes the principal reaction mode with tertiary alkoxides in tertiary alcohols or with tertiary alkoxides in an aprotic solvent such as benzene or a polar solvent like dimethyl sulfoxide.

A second remarkable and distinct trend is also apparent from the data in Table 4. It may be seen that the contribution of the *syn* → *trans* reaction increases significantly with the length and degree of branching of the aliphatic chain R, while the choice of steric course is less sensitive to the nature of the group R'. It is informative to compare the formation of *trans*-2-hexene (15 and 69% *syn* route) and *trans*-3-hexene (83% *syn*) from 2- and 3-hexyltrimethylammonium salts [*(28)*, $R=CH_3, R'=C_3H_7$; $R=C_3H_7, R'=CH_3$; $R=R'=C_2H_5$] on treatment with potassium *tert*-pentoxide in *tert*-pentanol.

The case of *trans*-2-butene formation is of particular interest in this context; the evidence is still fragmentary but the available information is consistent with the view that the tendency for *syn*-elimination is very small[69].

3.2.4. Acyclic Alkyl Tosylates

As in the cyclic series, the tendency towards *syn*-elimination is again lower than for the corresponding onium derivatives. The dependence on base/solvent character appears to follow the already familiar pattern. Thus, in DMSO and

3.3. Acyclic Alkyl Halides

As already mentioned (see Section 2.2.1) a direct insight into the stereochemical course of base-induced dehydrohalogenation was provided by studies with selectively deuterated diastereoisomeric alkyl halides[17].

In the meantime, some attempts have also been made to derive qualitative information from less direct evidence. Thus it has been found[76] that the ratio of *trans*- to *cis*-2-pentene obtained in the elimination of 2,2,4,4-tetradeuterio-3-pentyl halides using *tert*-butoxide in *tert*-butanol is significantly lower than that obtained under the same conditions from the "non-deuterated" halide. Since the deuterium isotope effect of *anti*-elimination is now known to be significantly greater for *anti*- than for *syn*-elimination, the observed situation is thus compatible with a dichotomous elimination pattern.

Similarly, it has been suggested that differential contributions by *syn*- and *anti*-elimination could be partly responsible for the characteristic effect of the base/solvent system used upon the *trans/cis* olefin ratios formed in the dehydrohalogenation of 2-hexyl halides[7].

3.4. Eliminations Leading to Trisubstituted Ethylenes: The *syn-anti* and the Hofmann-Saytzeff Dichotomies

Hardly any other aspect of elimination reactions has been discussed as extensively as that of orientation in olefin formation. The discovery that *syn*-elimination is a common reaction mode in the formation of disubstituted olefins places the problem of orientation in a new light. In particular, the question arises whether a relationship exists between the two aspects: steric course and orientation.

That there is indeed such a relationship is suggested by the course of the degradation of *threo*- or *erythro*-(6-methyl-5-decyl)trimethylammonium bromide *(32)* under various conditions[77]. The steric course of formation of the isomeric Saytzeff products *(33)* and *(34)* follows directly from a configurational correlation between reactant and product. Although no direct experimental evidence is available on the steric course of the formation of the disubstituted (Hofmann) ethylenes *(35)* and *(36)*, consideration of earlier findings (Sections 3.1, 3.2.1, 3.2.3) leads to the conclusion that the *trans*-isomer *(35)* arises mainly or exclusively by

Table 5. Steric course of formation of *trans*-olefins *(29)* and *cis*-olefins *(30)* from tosyl compounds *(31)*.

when the substrate bears a short, straight-chain substituent *syn*-elimination makes no, or very little, contribution to *trans*-olefin formation. However, *syn* participation increases when the solvent is changed to *tert*-butanol, or even more so in the case of benzene, and also on transition to branched systems (Table 5). Furthermore, *syn*-elimination participates only slightly, if at all, in the formation of the *cis*-olefin.

syn-elimination and the *cis*-olefin *(36)* by *anti*-elimination. It is then possible to draw the following conclusions from the data presented in Table 6: The contribution of *syn*-elimination to the formation of both the disubstituted and the trisubstituted ethylene increases steeply on going from a protic solvent (methanol) to a less protic one (*tert*-butanol), a polar one (dimethyl sulfoxide), or especially to an aprotic, non-polar solvent (benzene). In some cases, this

4. Tentative Rules Regarding the Steric Course of E2 Reactions

The results discussed in the preceding Section have shown that *syn*-elimination is a more frequent reaction mode than has previously been assumed. Both *anti*- and *syn*-elimination should be looked upon as "normal", *i.e.* frequent,

difference is very pronounced, *e.g.* where the Hofmann-Saytzeff dichotomy appears as a reflection of the *syn-anti* dichotomy, the Hofmann olefin, if our analogy is correct, being formed predominantly by *syn*-, and the Saytzeff olefin predominantly by *anti*-elimination. However, such a situation is clearly not general, as a consideration of the elimination using *tert*-butoxide in benzene shows. Here elimination both in the Hofmann as well as in the Saytzeff direction proceeds by *syn*-elimination.

modes in bimolecular reactions, the operation of the one or the other process depending on the structural features of the reactants (substrate and base), as well as on the nature of the solvent. The following incomplete and tentative rules can be given.

Table 6. Formation of the Saytzeff products *(33)* and *(34)* and of the Hofmann products *(35)* and *(36)* from the ammonium compound *(32)*.

[a] OH in place of Br.

Reactant structure: Conditions for *syn*-elimination appear to be favorable in bicyclic systems, such as bicyclo[2.2.1]-heptane and bicyclo[2.2.2]octane, and in the monocyclic systems cyclobutane and cyclopentane and then again in

the medium sized rings (8—14 ring members). In open chain alkyl systems, the tendency for H—X elimination to proceed by the *syn* rather than the *anti* pathway is greater when the alkyl groups are long or branched.

The tendency for *syn*-elimination is greater in eliminations leading to 1,2-disubstituted ethylenes than in those yielding trisubstituted ethylenes.

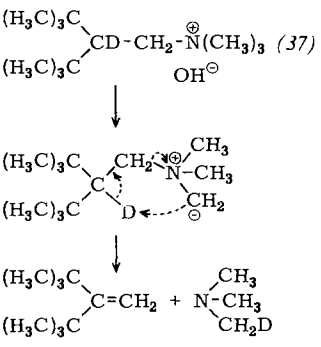
Olefin configuration: *syn*-Elimination is more likely to be encountered, if at all, in the formation of the *trans*-alkene (or *trans*-cycloalkene). The *cis*-alkenes are formed almost exclusively by an *anti* process.

Leaving group: Other factors being equal, *syn*-elimination is more likely to be encountered when the leaving group is an ammonium or sulfonium group. Chlorine, bromine, and tosyloxy leaving groups are more likely to cause *anti*-elimination.

Base: For alkoxide bases, the tendency of the elimination to prefer the *syn*-pathway increases in the order $^{\ominus}OCH_3 < {}^{\ominus}OC_2H_5 < {}^{\ominus}O\text{-}n\text{-}C_4H_9 < {}^{\ominus}O\text{-}sec\text{-}C_4H_9 < {}^{\ominus}O\text{-}tert\text{-}C_4H_9$.

Solvent: Other factors being equal, *syn*-elimination is more likely to be encountered in weakly dissociating solvents, *e.g.* benzene or *tert*-butanol than in solvents such as dimethyl sulfoxide or methanol, which favor *anti*-elimination.

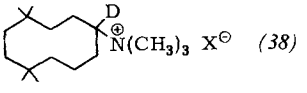
5. Mechanism of *syn*- and *anti*-Elimination



The problem of bimolecular elimination mechanisms has been treated in detail in monographs[78] and several reviews[6, 79–81]. We therefore do not have to survey the problem extensively; nevertheless since all these treatments, except one[81], are based on the view of generally preferred *anti*-elimination it will be useful to discuss here certain new, or novel, aspects which follow from the discovery of the facility of *syn*-elimination.

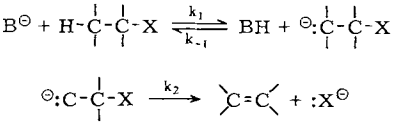
5.1. Is *syn*-Elimination a One-Step Process?

The strong "prejudice" against bimolecular *syn*-elimination has in the past led some authors to consider alternative, sometimes circuitous, reaction paths for products whose formation could more simply be accounted for by *syn*-elimination, according to the motto "*nicht sein kann, was nicht sein darf*"[82]. One of the questions which, however, it is undoubtedly necessary to consider is whether *syn*-elimination is actually a true single-step process.



For onium compounds, a two-step *syn*-elimination mechanism is indeed well known[83]. This mechanism, referred to as α′,β-elimination, is normally followed when an organometallic reagent, such as phenyllithium, is employed as base. In such a case, it involves, in the first step, proton removal from a nitrogen-bound methyl group, followed, in a discrete second step, by intramolecular proton transfer from the β position of an ethyl or a longer alkyl group to the carbanion of the intermediate *N*-ylide.

With alkoxides and related bases a substantial contribution of this mechanism has thus far been found for a single instance only[84], namely the pyrolysis of [2D]-2-*tert*-butyl-3,3-dimethylbutyltrimethylammonium hydroxide *(37)*. The replacement of the *tert*-butyl groups by other alkyl groups brings the contribution of the α′,β-mechanism down to zero or a very low percentage at most[85].

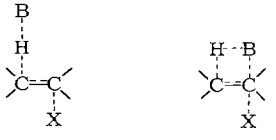


(37)

The α-deuterium labeled ammonium derivative *(38)* was found to give olefins practically without loss of label[64]. No exchange has thus taken place with solvent, and this clearly excludes the α-elimination mechanism, which would pass through a carbene and is very unlikely here anyway.

(38)

The possibility has to be considered that the elimination could be a two-step process of the type E1cb, involving, as the first step, removal of a proton in the β position, followed by release of the leaving group X from C^{α} in a second step (Scheme 9)[86].



Scheme 9.

Good arguments have been given that substrates of the type considered in this review are unlikely to give rise to a carbanion intermediate which would regenerate the reactant by reaction with external solvent faster, or at a comparable rate, than it gives olefin (reversible E1cb, $k_{-1} \geq k_2$)[81, 87].

On the other hand, the formation of a carbanion intermediate which either does not revert to reactant (irreversible E1cb, $k_{-1} < k_2$) or one that does so in an invisible reaction cannot be rigorously excluded. In the latter case ("E1cb-HBA"[89]) the intermediate could be visualized as a complex between the anion and the alcohol molecule which arose through proton removal[88, 89]. Such a species (a hydrogen bonded anion) would thus revert to reactant without change in configuration and would be suitably set up for *syn*-elimination. As recently pointed out[90], this mechanism would be consistent with the very low deuterium isotope effect found for most *syn*-eliminations ($k_H/k_D \approx 2$). Whether a mechanism of this kind is operating or not is difficult to prove experimentally; it is important to note, however, that the argument given in the sequel for one-step *syn*-elimination would—*mutatis mutandis*—apply to this mechanism also.

5.2. Role of the Base in *anti*-Elimination (E2C and E2H Mechanism)

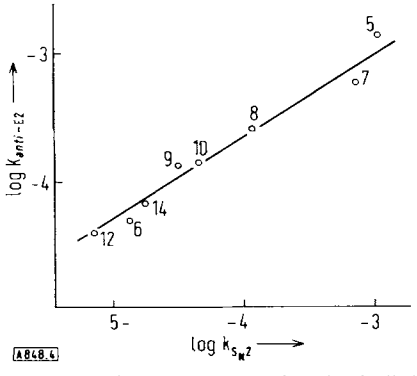
It was recognized only relatively recently that in bimolecular *anti*-elimination reactions the base could fulfil two functions: in addition to attacking the hydrogen on C^{β}, it could accelerate the reaction by nucleophilically assisting C^{α}—X bond fission (Scheme 10)[83,91].

E2H E2C

Scheme 10.

Simultaneous attack by the base on the C^{α} atom and the β-hydrogen atom is now termed an E2C reaction, and the mechanistic alternative of exclusive interaction between the base and the β-hydrogen atom is denoted E2H.

It may be significant in this context that a reasonably good correlation has been found between the rates of *cis*-cycloalkene formation (presumably largely or entirely by *anti*-elimination) in reactions of homologous series of cycloalkyl onium bases[51] or cycloalkyl bromides[59] and those of an S_N2 reaction on cycloalkyl bromides (Fig. 4).



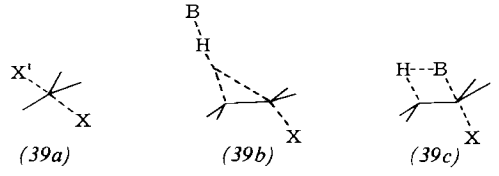


Fig. 4. Plot of log k_{S_N2} of the reaction of cycloalkyl bromides with potassium iodide in acetone, against log $k_{anti-E2}$ of *cis*-cycloalkene formation from cycloalkylammonium chlorides with potassium *tert*-butoxide in *tert*-butanol (numbers in Figure represent ring size).

We have suggested[51,59] that this correlation could be a consequence of a similar geometry around the C^{α} carbon in *anti*-elimination and bimolecular substitution, and thus form evidence for a "double engagement" of the base in the elimination[*].

[*] In private discussions the author accepted a slightly modified concept: The similarity of the rate profiles primarily suggests a comparable electronic environment of the C^{α} atom in the transition state of substitution *(39a)* and in that of *anti*-elimination. However, this would apply

(39a) *(39b)* *(39c)*

just as well to an elimination transition state *(39b)* in which the CH bonding pair has already partly migrated to the α carbon atom, as in the case of the E2C transition state *(39c)*.

Other evidence for the E2C mechanism has been provided by other authors[92-94] in rather different systems. The whole E2C/E2H concept has, however, recently also been criticized[7,95,96].

5.3. Mechanistic Information from the Effects of Variables on the *syn-anti* Ratio in E2 Reactions

5.3.1. The Timing of Bond Changes

A poor leaving group X will favor an E2 transition state in which the process of C^{β}—H bond breaking is considerably progressed while C^{α}—X is largely intact. It has also been assumed that with stronger bases the process of C^{β}—H bond breaking will become more important, but this point of view has recently been challenged[97].

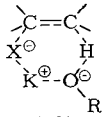
An explanation of the enhancement of *syn*- relative to *anti*-elimination by poor leaving groups and strong (bulky) bases would therefore lie in extensive C^{β}—H bond breaking, assumed to be characteristic of the transition state of a *syn*-elimination. Such an assumption would also account for the notoriously low hydrogen isotope effects, the low Hammett ρ constants[34], and the modest k_{Br}/k_{OTos} ratios[34]. This conclusion would, indeed, be consistent with the concept of a *syn*-elimination mechanism involving an "inversion" on C^{β} (Scheme 4), made possible by the fact that "sufficient ionicity has developed on both sides of this carbon"[11].

According to an alternative view[70,71], the increased tendency for *syn*-elimination with poorer leaving groups and stronger bases results from the fact that in the "more reactant-like transition state" the stereoelectronic constraints towards *anti*-elimination are less pronounced, thus giving the *syn*-mechanism a better chance to compete.

The difference between these two points of view is not merely of a semantic nature. According to the first, the suitable timing of the bond changes actually leads to a lowering of energy for the *syn*-elimination process compared to a (hypothetical) synchronous mechanism; according to the second, *syn*-elimination is not accelerated *absolutely* but merely *relatively* because the usual advantages of *anti*-periplanarity are largely lost.

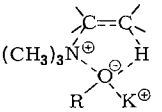
The entire problem of the timing of the bond changes in elimination reactions may turn out to be even more complex. There is some evidence already that the extent of C^{α}—X and C^{β}—H bond breaking need not necessarily be complementary: thus, there are data which may be interpreted as suggesting that in certain eliminations extensive C^{β}—H bond breaking is accompanied by extensive C^{α}—X bond breaking, a situation referred to as the "E1cb-paradox"[98]. There is also the question whether a spectrum of transition states, analogous to that believed to exist for *anti*-elimination, should not also be considered for *syn*-eliminations[7].

So far in this discussion we have largely stressed the electronic properties of the base and the leaving group. It must be kept in mind that for the alkoxides base "strength" goes parallel with "steric bulk"; similarly, for the departing group X some parallelism may be discerned between "leaving group capacity" and bulk, the onium group being both



bulkier as well as a "poorer" leaving group than halides or tosylates. We return to this point in Section 5.3.3.

The electronic and steric points of view are, at any rate in this instance, not mutually exclusive: effects of both types could operate and contribute to the observed behavior.

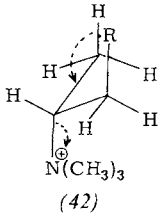


5.3.2. Solvent and Ion-Pair Formation

Solvents such as benzene or *tert*-butanol which favor *syn*-elimination enhance the base strength of the alkoxide ion and this alone could, in the light of the effects discussed above, be responsible for the observed high *syn-anti* ratio. If this were the case, use of the solvents dimethylformamide or dimethyl sulfoxide, in which alkoxide is a very strong base, should further enhance *syn*-elimination. In practice the very opposite is true.

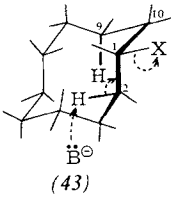
The effect which makes the non-polar solvents favorable for *syn*-elimination may thus be that they support an ion pair association. Such an association will tend to enhance *syn*-elimination since it makes possible a cyclic mechanism. The same feature is clearly unfavorable for *anti*-elimination because it would require separation of charged species.

(40)



(41)

An analogous formulation is possible for onium base elimination: here one can visualize an association between the ammonium ion and an alkoxide ion. Again, a solvent which would stabilize an ion pair of this type would enhance *syn*-elimination [transition state *(41)*].

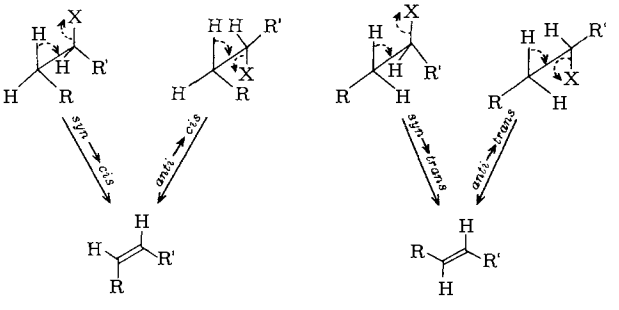


Cyclic multi-center mechanisms were invoked some years ago[99] to explain the occurrence of *syn*-eliminations and recently also of *cis*-eliminations leading to triple bonds[100].

5.3.3. Carbon Skeleton of the Reactant

We have noted (see Section 4) that long-chain and branched alkyl groups promote the *syn* mode. An explanation has been given on the basis of steric hindrance to approach of the base in the *anti* process[70][*].

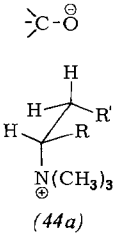
(42)



(43)

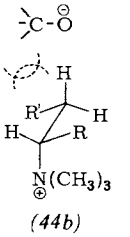
The argumentation makes use of the reasonable assumption that a *sec*-alkyl-trimethylammonium compound will prefer the conformation *(42)* in which the alkyl group R and the bulky trimethylammonium group are separated by the greatest possible distance. It can then readily be seen that the group R can effectively obstruct attack by the base on the *anti* β hydrogen, and this is why—when R≠H—*anti*-elimination is suppressed and *syn*-elimination gets a chance to compete.

The stereochemical situation is similar in cyclic reactants[71]. Assuming for the ten-membered ring the conformation *(43)* we see that the hydrogen atom *anti* to the leaving group X is in an encumbered 1,3-relationship to the C^9—C^{10} bond and, moreover, in an intraannular position; it is hence not accessible to attack by base. The unusually high ratio of *syn*- to *anti*-elimination in the formation of medium sized *trans*-cycloalkenes[53] thus becomes understandable, although other factors are certainly also involved[57].



5.4. Speculations on the Cause of the Stereoselectivity in *syn*- and *anti*-Elimination

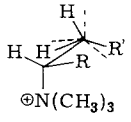
So far the discussion has been concerned with the distinction between the overall *syn*-elimination process and the overall *anti*-elimination process. We now have to consider in more detail the stereochemical course of those reactions which lead to *cis/trans* isomeric olefins and to distinguish between the four routes possible for a coplanar process, *viz. cis*- and *trans*-olefin forming *syn*-elimination *(syn → cis* and *syn → trans)* and *cis*- and *trans*-olefin forming *anti*-elimination *(anti → cis* and *anti → trans)* (Scheme 11).



Scheme 11.

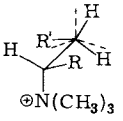
It is not difficult to find a simple steric explanation for the tendency of *syn*-elimination to lead preferentially to *trans*-olefins. Since the *syn → cis* route requires an eclipsed or near-to-eclipsed arrangement of two neighboring alkyl groups (R, R') it is clearly at a disadvantage.

(44a)



(44b)

It is less simple to give an explanation for the complementary observation, *i.e.* that *anti*-elimination leads preferentially to the *cis*-olefin. An explanation has been proposed based on the model already discussed (see Section 5.3.3)[70]. It is pointed out that (particularly if R is bulky) the hydro-



[*] Steric hindrance to solvation of the leaving anion may also play an important role (cf. *J. Sicher, G. Jan,* and *M. Schlosser,* Angew. Chem. *83,* 1012 (1971); Angew. Chem. internat. Edit. *10,* 926 (1971)).

gen on C^{β} is "shielded on both sides" in conformation *(44b)* while in conformation *(44a)* it is "relatively open to attack" on one side. If now "non-linear approach of the base is energetically feasible, *cis*-olefin could form faster than *trans*-olefin, especially with the bulkier bases".

A somewhat modified picture[101] of the transition state may make the above interpretation more readily acceptable. The basic argument is to be found in the assumption that the dihedral angles between vicinal bonds do not necessarily have to be exactly 60° but would, on the contrary, deviate from the idealized staggered arrangement if this were to lead to an overall drop in intramolecular repulsion. Since the dominating *gauche* interaction in the molecule is that between the alkyl group R′ and the trimethylammonio group, the conformers *(44a)* and *(44b)* would adopt the more favorable arrangements *(45a)* and *(45b)*.

(45a)

(45b)

This alteration of the dihedral angle could also apply to the elimination transition state since it probably possesses only very slight double bond character. The base would then encounter the hydrogen to be eliminated in a congested environment in the transition state *(45b)* for *trans*-olefin formation, whereas the hydrogen attacked in *cis*-olefin formation in *(45a)* would be readily accessible.

The above arguments refer specifically to base-induced ammonium salt degradation; however, an analogous situation ($k_{anti \rightarrow cis} > k_{anti \rightarrow trans}$) is encountered in certain tosylate eliminations presumably again under conditions where the transition state has only little double bond character. Thus, 2-butyl tosylate with *tert*-butoxide in *tert*-butanol gives more *cis*- than *trans*-butene[102, 103] although the elimination presumably proceeds largely, or exclusively, through the *anti* process. Following the above arguments, we should have to assume that under these conditions the steric effects are not large enough to suppress *anti*-elimination, yet sufficient to direct *anti*-elimination preferentially into the *anti* → *cis* channel[*].

According to an alternative interpretation of the stereoselectivity of the two elimination modes[104], the observed trend could be rationalized on the grounds that the two hydrogens on C^{β}, being diastereotopic, differ intrinsically in reactivity—in any rotational conformation[**]. Inspection of the four alternative rotameric arrangements depicted in Scheme 11 shows that the rapidly occurring elimination processes *syn* → *trans* and *anti* → *cis* involve removal of the *pro-threo* hydrogen, while the less favorable elimination routes *syn* → *cis* and *anti* → *trans* necessitate removal of the *pro-erythro* hydrogen. This is, of course, a *post hoc* argument and plausible interpretations of the chemical nonequivalence of the hydrogen atoms on C^{β} cannot be given without the postulation of new effects.

Received: April 24, 1970 [A 848 IE]
German version: Angew. Chem. *84*, 177 (1972)

[*] Neither previous arguments to account for preferred *cis*-olefin formation in open-chain tosylate elimination [102, 103] nor the fascinating yet difficult problem of the relationship between *trans-cis* olefin composition in elimination reactions and the relative thermodynamic stabilities of the two isomers, which has recently been treated elsewhere [43], will be discussed here.

[**] This is reminiscent of the differential proton mobilities found for the diastereotopic hydrogen atoms of several sulfoxides ([105], see, however, [106]).

Photooxidation of 3,4-Diethyl-2,5-dimethylpyrrole[1][**]

By *David A. Lightner* and *Gary B. Quistad*[*]

Investigations of the photooxidation of pyrroles have been largely confined to pyrrole itself[2, 3] and to various phenyl-substituted pyrroles[4, 5] which have been studied extensively. Until recently[2, 6] no studies on the photooxidation of alkylpyrroles had been reported. Alkylpyrroles are unstable to air and light[7]; however, only their autooxidation had been examined[8]. We have found the dye-sensitized photooxidation[9] of 3,4-diethyl-2,5-dimethylpyrrole *(1)* in methanol proceeds *via* loss of one or both α-methyl groups to give *(6)* and *(7)*. This novel dealkylation, as well as other reactions leading to *(8)* and *(9)*, have not heretofore been observed.

Synthesis of *(1)* was accomplished from the conveniently obtained pyrrole *(10)*[10] in three steps by treating *(10)* at 230 °C in diethylene glycol/hydrazine/KOH to give 3,4-diethyl-2-methylpyrrole[11] in 67% yield which was converted into 3,4-diethyl-2-formyl-5-methylpyrrole[12] in 83% yield by a Vilsmeier-Haack reaction and then in into *(1)*, in 72% yield, by Wolff-Kishner reduction.

A dilute (0.1—0.2% w/v) methanolic solution of *(1)* containing 0.03‰ Rose Bengal ($^1O_2$ sensitizer) was photolyzed[13] for four hours while bubbling a slow stream of oxygen through the reaction vessel. After evaporation of the methanol *in vacuo* at room temperature, the crude photolyzate was chromatographed on alumina (E. Merck; neutral, Act. V). Ethyl acetate eluted six components (54 weight % of the total photolyzate) which were separated by preparative thin layer chromatography (Silica gel F, M.

Woelm Eschwege, 1 mm, ether). The structures of five products were characterized by a combination of spectroscopic methods and also—in the case of *(7)* and *(8)*—by comparison of melting points with those of authentic material.

The formation of *(6)* and *(7)* from *(1)* constitutes the first reported examples of dealkylation by photooxygenation of an heterocycle. Similar dealkylation or dearylation reactions have not been observed for phenyl-substituted pyrroles[4, 5] or for alkylated furans[14–16].

We assume that the products *(3)*, *(6)*, *(7)*, and *(8)* are formed in the manner quoted. The postulated route *(5)*→*(7)* is supported by the decomposition of the *tert*-butoxy radical to acetone and methyl radical[17]. We formulate *(4)* on the basis of the hydroperoxide[16] isolated in the photooxygenation of 2,5-dimethylfuran[15]; however, it has not been reported to demethylate to an analog of *(6)*. *(3)* and *(8)* could be formed in the same way as their analogs in the photooxygenation of 2,3,4,5-tetraphenylpyrrole[4]. We cannot as yet ascribe a simple mechanism to the formation of the rather surprising structure *(9)*. Mechanistic details of these reactions are currently under investigation.

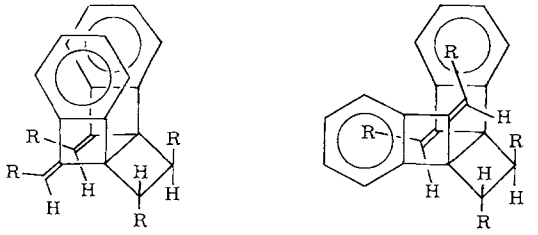
The Photochemistry of Dimethyl 1,2-Dihydrocyclobutabenzene-1,2-diylidenediacetate[**]

By *Richard J. Spangler* and *J. Curtis Sutton*[*]



The interesting photochemistry of compounds *(1)* and *(2)* has already been described[1, 2]. We have now obtained a crystalline mixture of two photodimers in 25% yield by ultraviolet irradiation of a dilute methanol solution of dimethyl 1,2-dihydrocyclobutabenzene-1,2-diylidenediacetate *(3)*[3, 4] for 40—50 hours. Separation by preparative thick layer chromatography on alumina and eluting with chloroform yielded the two pure dimers, melting at 260 to

(1), $X^1 = X^2 = O$
(2), $X^1 = CH\text{-}CO_2CH_3$, $X^2 = O$
(3), $X^1 = X^2 = CH\text{-}CO_2CH_3$

265 °C and 304—305 °C. Based on considerations of the spectral data and the likely mechanistic pathways[5–8] we have assigned structures *(4)* and *(5)* to the photodimers.

The parent peak in the 70-eV mass spectra of both photodimers at *m/e* 488 and the close resemblance of the mass spectra below *m/e* 244 to that of the monomer *(3)* indicate that there has been no rearrangement during the photo-

(4) R = CO_2CH_3 *(5)*

dimerization. Furthermore, a small but significant peak at *m/e* 344 ($M-CH_3OCOCH{=}CHCO_2CH_3$) in the mass spectra of both dimers is consistent with the head-to-head arrangements *(4)* and *(5)* but would not be expected from a head-to-tail photodimer.

The 100-MHz NMR spectrum of the higher melting dimer *(5)* indicates a symmetrical structure: the two methine protons ($\delta = 4.26$), the methyl protons of the two saturated ester groups ($\delta = 3.52$), the two α,β-unsaturated ester groups ($\delta = 3.78$), and the two vinyl protons ($\delta = 6.15$) each give only one signal. In contrast, the NMR spectrum of the lower melting compound *(4)* shows two separate methine signals (an apparent AB quartet centered at $\delta = 4.21$ in which only the middle two peaks of the quartet are visible), a separate signal for each of the four methyl ester groups ($\delta = 3.46, 3.61, 3.76, 3.80$), and two signals in the vinyl region ($\delta = 5.91$ and 6.05). The aromatic protons of *(4)* and *(5)* give signals at $\delta \approx 7.31$ and $\delta \approx 7.75$ (6:2). Two deshielded aromatic protons indicate that the stereochemistry about the double bonds in *(4)* and *(5)* is *anti*, as it is in the monomer *(3)*[4]. IR and UV spectra are also in accord with the proposed structure assignments.

These results indicate that the photochemistry of *(3)* is markedly different from that of the analogous compounds *(1)* and *(2)*. The latter compounds both suffer cleavage of the four-membered ring first[1, 2], while in the case of *(3)*, $[2_\pi + 2_\pi]$ photodimerization, not ring cleavage, is the observed reaction pathway. To the best of our knowledge this represents the first example of a dihydrocyclobutabenzene whose photochemistry has not been dominated by ring opening. This process finds analogy with the recently

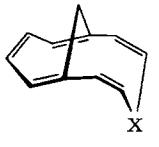
Bridged Hetero[11]annulenes[1]

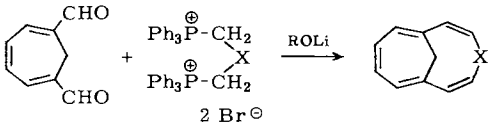
By *Emanuel Vogel, Rainer Feldmann, Helmut Düwel, Hans-Dieter Cremer*, and *Harald Günther*[*]



Advances in annulene chemistry have recently encouraged a number of research teams to take up the study of heteroannulenes having medium and large rings, especially the homologs of furan, pyrrole, and thiophene[2]. Since the members of homologous heteroannulene series, like the simple annulenes, differ considerably in conformation and mobility of the ring skeleton, attempts to establish correlations between physical and chemical properties of the respective compounds meet with difficulties. In the case of heteroannulenes having medium-sized rings, a planar skeleton desirable for comparative studies seems attainable only by introduction of bridges or triple bonds.

(1a), (1b)
a: X = S
b: X = O

(2a), (2b)
syn



(3a), (3b)
anti

The present communication describes the bridged hetero[11]annulenes 4,9-methanothia[11]annulene *(1a)* and -oxa[11]annulene *(1b)*, which can be regarded as potential 12π-electron systems. These compounds can adopt conformations with an approximately planar heteroannulene ring while incurring only a moderate degree of ring strain; however, owing to lack of resonance stabilization they are likely to prefer the almost strain-free conformations with the hetero atom *syn* or *anti* to the bridge [*(2a)* and *(2b)*; *(3a)* and *(3b)*].

4,9-Methanothia[11]annulene *(1a)* was synthesized by a Wittig reaction: Cycloheptatriene-1,6-dialdehyde *(4)*[3] in dimethylformamide was allowed to react for 24 h at room temperature with thiodimethylenebis(triphenylphosphonium bromide) *(5a)* and lithium methoxide as a base (added in methanol to the reaction mixture). Compound *(1a)*, isolated in 30% yield as red crystals (m. p. 27—28 °C, from ethanol), underwent a fairly rapid change above 50 °C, partly decomposing to 1,6-methano[10]annulene *(8)* and sulfur[4] and partly polymerizing.

4,9-Methanooxa[11]annulene *(1b)* could be obtained similarly to *(1a)*, albeit in only 2% yield, by reaction of *(4)* with *(5b)*; the oxa compound is an air-sensitive yellow liquid (b. p. ≈70 °C/0.1 torr) best kept in an argon atmosphere.

(4) *(5a), (5b)* *(1a), (1b)*
a: X = S
b: X = O

The hetero[11]annulene structures *(1a)* and *(1b)* of the two compounds were proved by their NMR spectra, which also provided evidence favoring the *syn* conformations *(2a)* and *(2b)*[5].

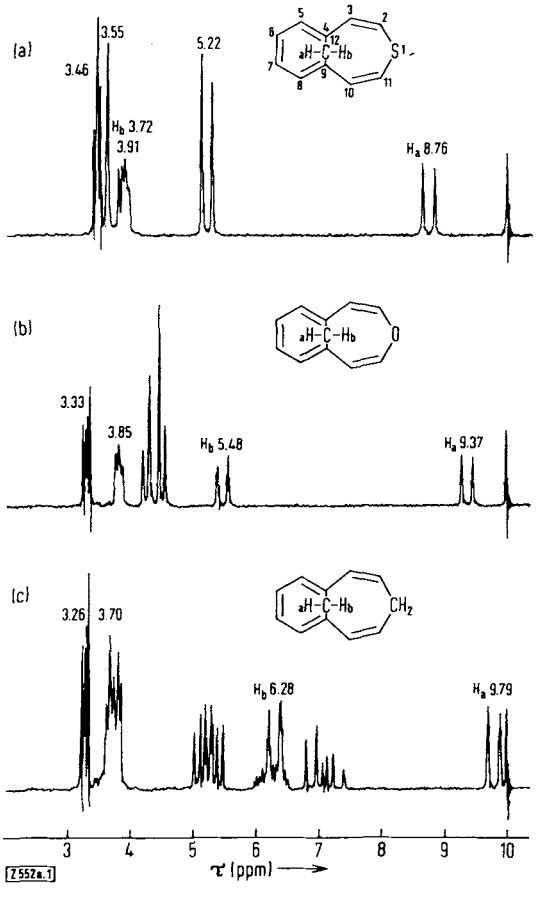
The NMR spectrum of *(1a)* (in CCl_4) (Fig. 1a) shows an AA'XX' system at $\tau = 3.46$ (H-6, H-7) and 3.91 (H-5, H-8) for the heteroannulene protons of the cycloheptatriene part of the molecule, an AX system at $\tau = 3.55$ (H-3, H-10) and 5.22 (H-2, H-11) with $J = 9.6$ Hz[6] for those in the vicinity of the sulfur atom, and an AX system at $\tau = 3.72$ (H-12b) and 8.76 (H-12a) with $J = -11.5$ Hz for the bridge protons. The A part of the bridge-proton AX system, which is superposed on the absorption of the heteroannulene protons (see Fig. 1a), was located by double resonance. The possibility of *(1a)* being in rapid equilibrium with a significant quantity of its 1,6-methano[10]annulene 3,4-episulfide valence tautomer *(7)* can be ruled out since a) the NMR spectrum shows no temperature dependence and b) the heteroannulene protons of the cycloheptatriene part exhibit practically the same chemical shifts and coupling constants ($J_{5,6} = 5.78$, $J_{6,7} = 10.38$, $J_{5,7} = 0.30$, $J_{5,8} = 1.29$ Hz) as the corresponding protons of the hydrocarbon bicyclo[5.4.1]dodeca-2,5,7,9,11-pentaene *(6)*[3,7] (Fig. 1c). From the remarkable agreement in chemical shifts shown by the protons of the cycloheptatriene parts of *(1a)* and *(6)* it follows that *(1a)* does not sustain a significant paramagnetic ring current. The resonance of the bridge proton H-12b at exceptionally low field—difference in chemical shifts between H-12b and H-12a = 5 ppm!—is only in apparent discord with the above observations and is readily explained by the combined effects of the diamagnetic anisotropy of the S—C bonds[8], the field effect of the sulfur atom[9], and possibly also a steric compression[10] of the sulfur atom and the bridge proton H-12b, assuming that the molecule adopts the *syn* conformation *(2a)*.

The UV spectrum of *(1a)* with maxima at 233 ($\varepsilon = 31\,200$), 284 (27000), and 395 nm (427) (in cyclohexane) differs markedly from that of the hydrocarbon *(6)*, thus indicating that the sulfur atom electronically interacts with the double bond system in spite of the clearly non-planar arrangement of the heteroannulene ring.

In its NMR spectrum (CCl_4) (Fig. 1b), and specifically with regard to the bridge-proton absorption, 4,9-methanooxa[11]annulene *(1b)* occupies an intermediate position between *(1a)* and *(6)*. The spectrum of the oxa compound

[*] Prof. Dr. E. Vogel, Dr. R. Feldmann, Dr. H. Düwel, Dipl.-Chem. H.-D. Cremer, and Prof. Dr. H. Günther
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

contains an AA'XX' system at $\tau = 3.33$ (H-6, H-7) and 3.85 (H-5, H-8) ($J_{5,6} = 5.96$, $J_{6,7} = 10.54$, $J_{5,7} = 0.08$, $J_{5,8} = 1.51$ Hz), an AX system at $\tau = 4.29$ (H-3, H-10) and 4.52 (H-2, H-11) with $J = 6.2$ Hz, as well as another AX system at $\tau = 5.48$ (H-12b) and 9.37 (H-12a) with $J = -10.4$ Hz. Remarkably,



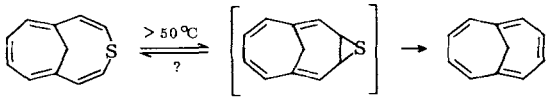


Fig. 1. NMR spectra of a) 4,9-methanothia[11]annulene *(1a)*, b) 4,9-methanooxa[11]annulene *(1b)*, and c) bicyclo[5.4.1]dodeca-2,5,7,9,11-pentaene *(6)* in CCl_4 (60 MHz; TMS as internal standard).

the difference between the chemical shifts of the bridge protons decreases by 1.2 ppm on going from *(1a)* to *(1b)*. From analogies with comparable compounds[11] the magnitude of this decrease suggests that *(1a)* and *(1b)* have similar conformations[12].

The UV spectrum of *(1b)*, which exhibits maxima at 248 ($\varepsilon = 39200$) and 328 nm (2450) (in cyclohexane), is almost superimposable with that of the hydrocarbon *(6)*. It therefore follows that *(1b)* and *(6)* definitely belong to the same

(1a) *(7)* *(8)*

conformational type and, furthermore, that the oxygen function in *(1b)*—as in oxonin[2a]—does not transmit cyclic conjugation.

Elimination of sulfur from *(1a)*[4] above 50 °C most probably proceeds *via* the hitherto undetected 1,6-methano-[10]annulene 3,4-episulfide *(7)* formed by a symmetry allowed electrocyclic process. Attempts to trap *(7)* with dienophiles were unsuccessful[13].

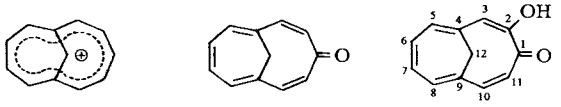
[12] The large difference in the resonances of the bridge protons, which is also observed in the NMR spectrum of *(6)*, appears unusual. A discussion of the spectrum will appear elsewhere.

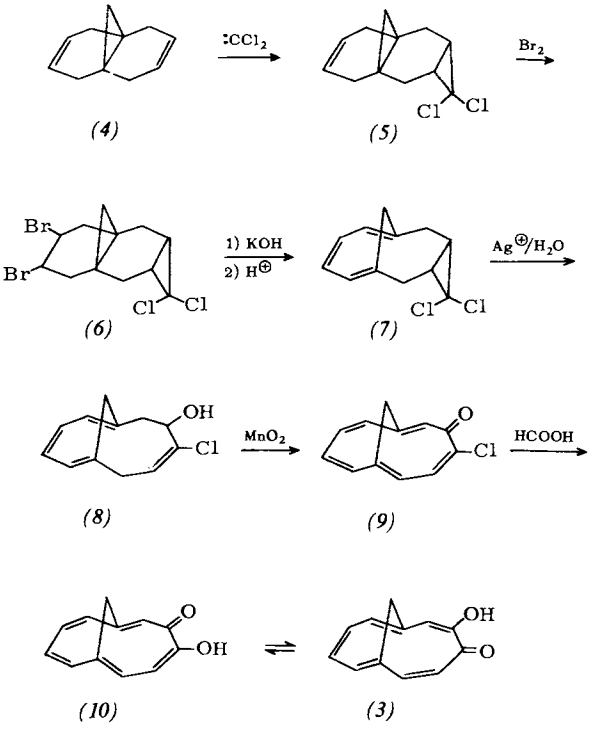
[13] After completion of the present manuscript, Dipl.-Chem. *M. Mann* succeeded in synthesizing 1,6-methano[12]annulene, an orange-red compound of m. p. 30—31 °C that is isoelectronic with *(1a)* and *(1b)*. The NMR spectrum (CCl_4) of the hydrocarbon shows an AA'XX' system at $\tau = 3.85$ and 4.29 as well as a narrow multiplet at $\tau = 4.52$ for the annulene protons and an AX system at $\tau = 3.00$ and 7.72 with $J = -11.4$ Hz for the bridge protons.



2-Hydroxy-4,9-methano[11]annulenone, a 10 π-Electron Analog of Tropolone[1]

By *Josef Reisdorff* and *Emanuel Vogel*[*]

Identification of the 1,6-methano[11]annulenium ion *(1)*[2] as an aromatic 10π-electron analog of the tropylium ion suggested the interesting possibility that keto- and ketohydroxy derivatives of *(1)* might exhibit physical and chemical properties similar to those of tropone and tropolone, respectively. As recently reported, this expectation was impressively confirmed for the keto derivatives of *(1)* (five structural isomers in all) by the synthesis of 4,9-methano[11]annulenone *(2)*[3] and of the isomeric 3,8- and 2,7-methano[11]annulenones[1]. We now wish to describe the preparation of 2-hydroxy-4,9-methano[11]annulenone *(3)*, one of 36 possible isomers, whose properties justify its being regarded as a 10π-electron analog of tropolone.

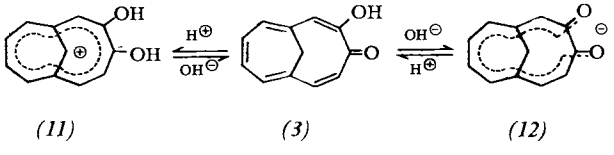


[*] Dr. J. Reisdorff and Prof. Dr. E. Vogel
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

The starting point of the route to *(3)* was the readily accessible tricyclo[4.4.1.$0^{1,6}$]undeca-3,8-diene *(4)*, an intermediate of the synthesis of 1,6-methano[10]annulene[4]. On reaction with a slight excess of chloroform and potassium *tert*-butoxide the hydrocarbon affords a uniform monoadduct of m.p. 45—46 °C (yield 37%; 78% based on reacted diene) which most probably has the *anti* configuration *(5)*. Treatment of *(5)* with bromine in the cold readily gives the dibromide *(6)* (yield 93%; m.p. 140 °C after repeated recrystallization from ethyl acetate). Heating of *(6)* with potassium hydroxide in methanol/dioxane followed by treatment of the resulting crude dehydrobromination product with dilute perchloric acid in dioxane/water

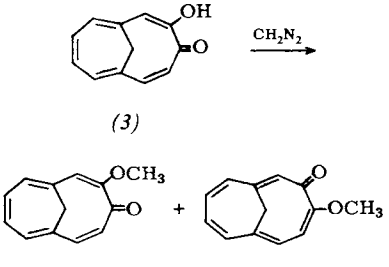
(1) *(2)* *(3)*

furnished an 88% yield of a compound having m.p. 98 °C which was unequivocally shown to be the cycloheptatriene derivative *(7)* by its NMR spectrum. Subsequent hydrolysis of *(7)*, preferably with silver nitrate in a boiling mixture of water and 1,2-dimethoxyethane in the presence of a small amount of pyridine, effected the desired disrotatory opening of the cyclopropane ring, with formation of the rather unstable alcohol *(8)* (yield 76%; m.p. 92—93 °C after repeated recrystallization from hexane/ethyl acetate). According to the NMR spectrum, that alcohol isomer appears to be formed in which the OH group is *syn* to the CH_2 bridge. Treatment of *(8)* with activated manganese dioxide in boiling 1,2-dimethoxyethane led not only to the



(4) *(5)* *(6)* *(7)* *(8)* *(9)* *(10)* *(3)*

expected conversion of the allylic hydroxyl into a carbonyl group but also to dehydrogenation; as a result 11-chloro-3,8-methano[11]annulenone *(9)* was obtained as orange-red prisms of m.p. 133—134 °C (yield 25—30%). Substitution of the chlorine atom in *(9)* by hydroxyl was best accomplished by heating *(9)* to 145—150 °C in anhydrous formic acid in the presence of sodium formate. There resulted a TLC-homogeneous, stable ketohydroxy compound (yield 60%) which crystallizes as orange prisms of m.p. 99 °C (from diisopropyl ether) and is either compound *(10)* or the tautomer *(3)*—or (in solution) an equilibrium mixture of the two forms.



The 60-MHz NMR spectrum (in CCl_4) of the compound, which displays no temperature dependence, contains: an AB system at $\tau = 2.59$ (H-10) and 3.21 (H-11) with $J = 11.5$ Hz, a weakly resolved triplet at 2.65 (H-3), and a multiplet at 2.5—3.2 (H-5 to H-8) for the olefinic protons; an AB system at $\tau = 9.13$ (*anti*-H-12)[5] and 9.83 (*syn*-H-12) with $J = -10.9$ Hz for the bridge protons; and a broad singlet at $\tau = 1.44$ for the hydroxyl proton. This spectrum, and in particular with regard to the chemical shift of the bridge protons, closely resembles those of 4,9-methano[11]-annulenone *(2)* and the methyl ether *(13)* derived from *(3)*, but differs pronouncedly from those of 3,8-methano-[11]annulenone and the methyl ether *(14)*[6]. In parallel herewith the UV spectrum of the compound with maxima (in cyclohexane) at 247 ($\varepsilon = 11\,700$, shoulder), 270 (14900, sh), 304 (40500), 330 (10100, sh), 381 (5980), and 430 nm (3500, sh), is of the same type as the spectra of *(2)* and *(3)*; no marked resemblance is seen, however, to the spectra of 3,8-methano[11]annulenone and the methyl ether *(14)*[6]. The IR spectrum [characteristic absorptions (in KBr): 3290 (OH), 1577, 1558, 1536, 1518 cm^{-1} (C=O and C=C)] does not appear suitable as a basis for distinguishing between *(3)* and *(10)*.

The above comparisons between the NMR and UV spectra permit the assumption that the ketohydroxy compound exists predominately, if not exclusively, as the tautomer *(3)*. This conclusion is in full accord with the prediction made on the basis of the pK_a values[7] of -0.6 ± 0.1 and $+0.5 \pm 0.1$ found for *(2)* and 3,8-methano[11]annulenone. Since 3,8-methano[11]annulenone exceeds the isomer *(2)* by 1.1 pK_a units in its basicity, *(3)* should definitely be the preferred form in the equilibrium between the two keto-hydroxy tautomers.

(11) *(3)* *(12)*

The most important chemical feature of *(3)* is its tropolone-like ability to form salts both with acids and with bases. As readily demonstrated by spectroscopy, *(3)* is protonated by acids to the 8,9-dihydroxy-1,6-methano[11]annulenium ion *(11)*. In the NMR spectrum (in CF_3COOH) the transition from *(3)* to *(11)* is manifested in a considerable down-

(3) *(13)* *(14)*

field shift of the resonances of the olefinic protons (multiplet at $\tau = 1.2$—2.0) and a concomitant upfield shift of the bridge-proton AB system ($\tau = 9.87$ and 11.05 with $J = -10.7$ Hz). The UV spectrum of *(3)* recorded in ethanolic perchloric acid, like that of protonated *(2)*, exhibits excellent agreement with the spectrum of the ion *(1)*[8]. As an acid *(3)* reacts with alkali metal hydroxides to give salts *(12)* that afford dark red aqueous solutions. A pK_a value of 8.25 is measured for *(3)* by potentiometric titration in water. *(3)* is thus not quite as strong an acid as α-tropolone (7.00)[9] but is more acidic than benzo[*d*]-tropolone (10.2)[10].

The acidity of *(3)* permits methylation of the compound with diazomethane in the absence of a catalyst, the ethers *(13)* (m. p. 122 °C) and *(14)* (m. p. 143 °C) being formed in the ratio 6:1 (total yield 64%). Since *(14)* can be synthesized independently by reaction of *(9)* with sodium methoxide, the structural assignments of both ethers are proved beyond doubt. Diazomethane methylation of *(3)* probably proceeds *via* an intimate ion pair[11] formed from the methyl diazonium ion and *(12)*, thus precluding any assessment of the equilibrium mixture of *(3)* and *(10)* from the ratio of *(13)* and *(14)*.

Geometry and n-Ionization Energies of Alkyl-Substituted Triketones[**]

By *Jürgen Kroner* and *Walter Strack*[*]

The dimethyl derivative (pentanetrione) *(1)* was selected as a model compound for the study of the hitherto unknown molecular geometry and the photoelectron (PE) spectra of open-chain triketones.

A MINDO/2 minimization[1] as a function of the torsional angles ω_1 and ω_2 about the CC axes reveals the most stable form to be a non-planar conformation *(2)* (cf. Fig. 1) with an equal and opposite deviation of the two acetyl groups from the C—CO—C plane ($\omega_1, \omega_2 \approx \pm 90°$); the difference in energy between the conformations *(1)* and *(2)* is calculated as 21.8 kcal/mol, the staggered arrangement of methyl groups appearing only marginally more favorable (≈0.4 kcal/mol) than the eclipsed one. Kerr effect measurements[2] and electronic spectra[3] indicate deviations from planarity in biacetyl and triketones, respectively; according to these results the torsional angles in dimethyltriketone should be $\omega_1, \omega_2 \approx 0°, 90°$. Further evidence for a possible non-planar arrangement of the three carbonyl groups in *(1)* is provided by CNDO CI calculations of excitation energies; MINDO/2 (1.95 D) and CNDO/2 dipole moments (1.67 D)[4] are in good agreement with the experimental value of 1.93 D.

(1)

Assuming the validity of the MINDO/2 model in which the acetyl groups protrude in opposite directions from the C—CO—C plane we found a preference for a helix conformation in tri- and tetraketones[5] (Fig. 1).

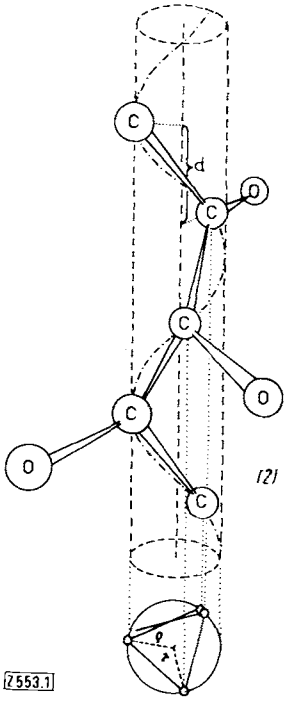

Fig. 1. Helix model of dialkyl-substituted triketones [6].

According to *Shimanouchi* and *Mizushima*[7] the spatial arrangement of the carbon centers can be described in terms of the angle of rotation (τ) about the helical axis, the distance (ρ) from the axis, and the chain lengthening *(d)* per CC segment (Fig. 1). Values of $\tau = 107°$, $\rho = 0.62$ Å, and $d = 1.08$ Å are obtained for dimethyltriketone with $\omega_1, \omega_2 = \pm 90°$. Dimethyltriketone thus proves to have a significantly larger helix radius than, *e.g.*, polyethylene ($\omega = 0°$, $\rho = 0.45$ Å) and polytetrafluoroethylene ($\omega = 18°$, $\rho = 0.45$ Å)[7, 8]. An increase in the torsional angle along the series dimethyl-, diisopropyl-, di-*tert*-butyltriketone, owing to competitive steric interactions of the alkyl groups with each other and with the central carbonyl oxygen, should lead to an increase in the helix radius (ρ) with a concomitant compression of the helix cylinder (*d*).

[*] Dr. J. Kroner and Dipl.-Chem. W. Strack
Institut für Anorganische Chemie der Universität
8 München 2, Meiserstrasse 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

The n-ionization energies[9] of alkyl-substituted triketones, as determined by photoelectron spectroscopy, can also be discussed on the basis of the calculated geometry of dimethyltriketone.

The considerable energy difference between orbitals of "nonbonding" (n)-electron pairs in α-diketones[10-12] and α,β-triketones[12] has its origin in their through-bond interaction[13] by way of the σ skeleton. The first bands in the PE spectrum of the simplest open-chain triketone *(1)* are found at 9.52, 10.97, and 12.30 eV; they can be assigned to ionization from "nonbonding" orbitals (n_1, n_2, n_3).

Combination of the orbitals $n_1(-)$, $n_2(+)$, and $n_3(-)$[14], which are threefold degenerate under conditions of slight through-space interaction[10], with lower lying asymmetric and symmetric CCC σ orbitals having the correct symmetry properties yields the highest occupied energy levels which, for C_{2v} symmetry, correspond to the irreducible representations b_1, a_1, and b_1 (Fig. 2). These n-splittings will be discussed with the aid of the simpler planar model.

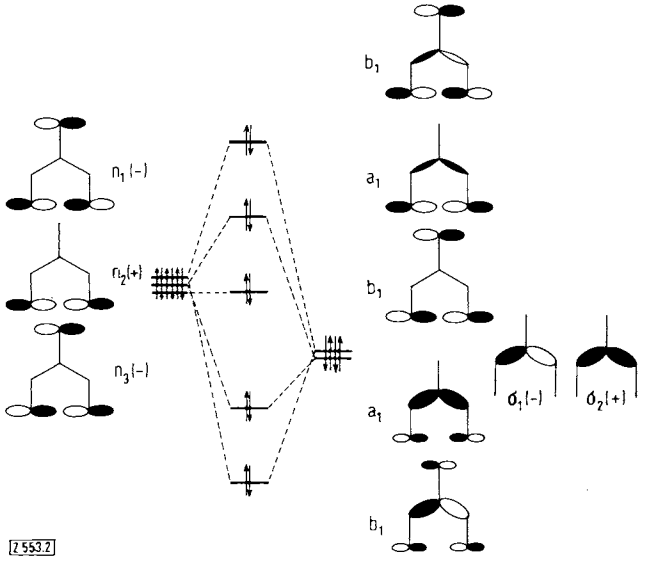

Fig. 2. Qualitative representation of the n-orbital interactions in planar triketones.

The orbital sequence results from the differing number of antibonding and bonding n/σ interactions. According to model calculations no significant admixture of antibonding CCC σ* contributions is to be expected in the range of highest occupied energy levels considered in the present case. The MOs corresponding to the first three ionizations do show a preference for n-components but they also undergo strong delocalization over the σ skeleton.

Table. Vertical ionization energies IE_v (eV), calculated n-orbital energies (eV) and n-splitting of dimethyltriketone.

Orbital type Symmetry [a]	n_1 b_1	n_2 a_1	n_3 b_1	$\lvert\Delta(n_1-n_3)\rvert$
IE_v	9.52	10.97	12.30	2.78
MINDO/2 [b]	−9.25	−11.27	−12.14	2.89
CNDO/2 [b, c]	−9.22	−11.45	−12.30	3.08
MINDO/2 [d]	−9.58	−11.00	−12.24	2.66
CNDO/2 [c, d]	−9.29	−11.03	−12.66	3.37

[a] Based on (planar) C_{2v}-geometry; [b] ω_1, $\omega_2 = 0°$ [16]; [c] energy zero at 1 eV; [d] ω_1, $\omega_2 = \pm 90°$ [16].

Assuming the validity of Koopmans theorem[15] the vertical ionization energies of dimethyltriketone, as measured by PE spectroscopy, are compared with the orbital energies calculated for $\omega_{1,2} = 0°$ and $\pm 90°$ by the MINDO/2 and modified CNDO/2 methods (Table).

As in diketones[10-12], the energies of the n-orbitals and their splitting in triketones proves to be only slightly dependent upon the torsional angle, thus offering some justification for a discussion on the basis of the planar model.

In contrast to dimethyltriketone, Δn is found by experiment to be 2.78 eV ($n_1 = 9.04$, $n_2 = 10.48$, $n_3 = 11.82$ eV) for diisopropyltriketone, and 2.59 eV ($n_1 = 9.00$, $n_2 = 10.28$, $n_3 = 11.59$ eV) for di-*tert*-butyltriketone. A decrease in the splitting would correspond to an increase in the torsional angle and an enlargement of the helix radius along the series $R = CH_3 \approx CH(CH_3)_2 < C(CH_3)_3$ if the differing electronic effects of the alkyl groups on n_1 and n_3 are neglected. The observed splittings are also in good agreement with theoretical predictions (2.72 eV)[10] for a hypothetical cyclopropanetrione. Increasing n-splitting is observed within the series of di-, tri-, and tetraketones[5].

PE spectroscopy is still in its infancy[2]. The reason for this state of affairs is to be found in the fact that the orbitals localized in CC and CH bonds are strongly bonding and have similar energies; in molecules of low symmetry they consequently undergo extensive mixing. Even in the case of medium sized molecules, such as *n*-pentane, ionization therefore leads to a multitude of broad, contourless, strongly overlapping bands whose identification runs into considerable difficulties.

The PE spectrum of neopentane should be free from such complications. The MOs of a molecule of the point group T_d are largely dictated by symmetry and can be deduced without the need for explicit calculations. An EO model[3] is admirably suited for this purpose since it takes full account of the specific requirements of PE spectroscopy: It can readily be parametrized with the aid of PE data for compounds having known orbital sequences and facilitates the analysis of the spectra of molecules whose orbital sequence is still unknown. Alkanes are particularly attractive objects of investigation since they contain only two kinds of chemically nonequivalent bonds (CC and CH)[4].

The starting point for neopentane is provided by the four equal-energy CC EOs and the twelve mutually degenerate but more stable CH EOs (Fig. 1, far left and far right respectively). The first-named orbitals form the basis for a representation Γ_{CC} which can be broken down into the following irreducible representations: $\Gamma_{CC}=a_1+t_2$. The CH EOs also provide the basis for another representation Γ_{CH} which can be reduced as follows: $\Gamma_{CH}=a_1+e+t_1+2t_2$.

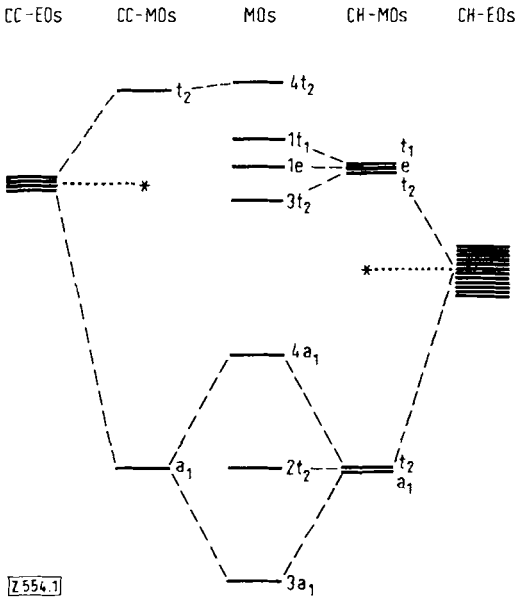

Fig. 1. Qualitative energy level scheme for neopentane (point group T_d). The localized, two-center EOs are seen on the far left and far right, the completely delocalized MOs in the middle, and the semilocalized CC and CH MOs in between.

In order to obtain MOs of correct symmetry that are localized in the CC and CH bonds the CC and CH EOs must each be allowed to interact separately. Since the s and p AOs of the central C atom have different transformation properties and differ in energy the t_2 CC MO is raised and the a_1 CC MO lowered while retaining the mean energy of the system (Fig. 1, left); the splitting probably amounts to about 9 eV, as in methane[5]. Similar arguments lead to the splitting pattern shown on the right-hand side of Figure 1 for the CH EOs.

The semilocalized MOs obtained in this way are still not the "true", completely delocalized MOs since some of them belong to the same irreducible representation and can therefore mix with each other. The extent of this interaction is very sensitive to the choice of parameters; however, it is probably not very large and results only in a lifting of the degeneracy of the (t_1, e) and t_2 CH EOs. The through-space interaction of the methyl groups has to be accounted for by a parameter η which is estimated at about -0.6 eV on the basis of the PE data for propane and *n*-butane[4]. A glance at a group table will reveal that $3t_2$ is stabilized by 2η while $1t_1$ is destabilized by the same amount. In contrast, the 1e MO exhibits the remarkable property of being completely devoid of interaction; its energy, as determined by PE spectroscopy, would therefore represent (within the limitations of Koopmans' theorem) an ideal standard for a strictly localized "CH_3" orbital comprising only C 2p and H 1s AOs.

The PE spectrum reproduced in Figure 2 fulfilled our expectations. It shows four clearly separated bands[6], of which the first (centered at about 11.3 eV[7]) is assignable to ionization from the $4t_2$ MO which is primarily involved in CC bonding. The facts that the splitting pattern of the three CH-bonding MOs $1t_1$, 1e, and $3t_2$ is completely symmetrical and that the centroid of the three bands (*ca.* 14.1 eV) has exactly the same value as we have found for other hydrocarbons[4] indicate a very slight interaction between the CC and CH MOs.

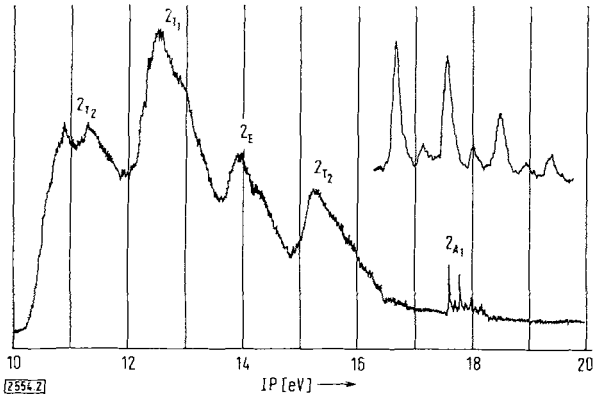

Fig. 2. High-resolution He I-PE spectrum of neopentane (Perkin-Elmer PS 16 spectrometer). Above right: Expanded recording of the band starting at 17.56 eV.

Further justification for this conclusion is also provided by the observation that only the $^2T_2$ ground state of the ion shows a pronounced Jahn-Teller (JT) instability. A comparable JT instability in all $^2T_2$ states would have indicated extensive mixing of the CC and CH MOs. The separation between the two intense JT components of the first band (*ca.* 0.4 eV; the third component can be seen at *ca.* 11.7 eV on an expanded scale) is smaller than that found in the first band of methane (*ca.* 0.7 eV[5]). This is probably due to the smaller degree of repulsion between neighboring CC EOs in neopentane.

The first vertical ionization potential of neopentane is higher than that of *n*-pentane; thus branching does not necessarily lower the ionization potential[8]. This finding is in accord with the present EO study (and also with our *ab initio* calculations) but contradicts current concepts of organic chemistry.

The EO method also readily explains the origin of the band exhibiting fine structure which starts at 17.56 eV: its low intensity, the exceptional sharpness of the vibrational components, and the dominance of the O—O transition leave no doubt that it is to be correlated with the totally symmetric partner of the t_2 CC MO which, for reasons of orthogonality, is largely localized in the 2s AO of the central C atom and is only weakly bonding. The fact that it is mainly the CH_3 deformation mode that is excited (frequency in ion *ca.* 1310 cm^{-1}, in the neutral molecule[9] 1368 cm^{-1}) on ionization while the likewise totally symmetric CC stretching frequency (ion *ca.* 650 cm^{-1}, molecule[9] 734 cm^{-1}) is less intense is presumably attributable to the strong internal strain of the molecule which also manifests itself in the unexpectedly high value of the parameter $\eta = -0.7$ eV. This interpretation is in agreement with the excitation of the SiC stretching mode on ionization from the a_1 SiC MO in tetramethylsilane where these steric problems have largely been solved. It cannot, however, be ruled out that the a_1 CC MO undergoes extensive mixing with the CH MO of the same symmetry (the *ab initio* calculations support this view; cf. also Fig. 1). A further possibility is that both progressions belong to the CC stretching frequency and that the alternation of intensities is due to an accidental equality of the equilibrium geometries of the ion and the neutral molecule. We hope to be able to solve this question by combined use of He I and He II spectroscopy with the perdeuterated compound.

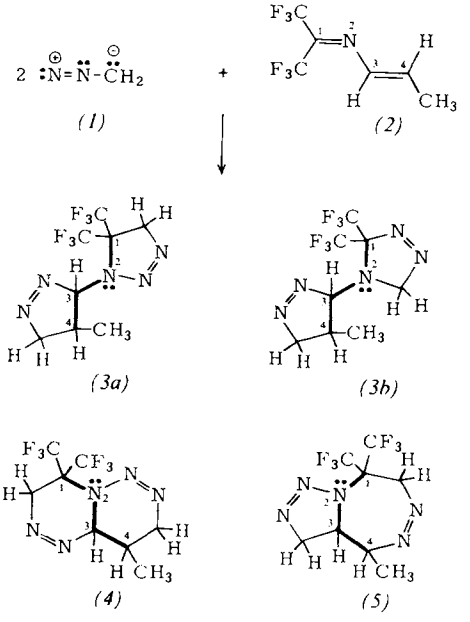
Structure of the 2:1 Cycloaddition Product of Diazomethane and 1,1,1-Trifluoro-2-trifluoromethyl-3-aza-2,4-*trans*-hexadiene



By *Alfred Gieren*[*] together with *Klaus Burger* and *Josef Fehn*[**]

Reaction of diazomethane *(1)* with 1,1,1-trifluoro-2-trifluoromethyl-3-aza-2,4-*trans*-hexadiene[1] *(2)* gives both a 1:1 cycloaddition product[2] and a 2:1 adduct.

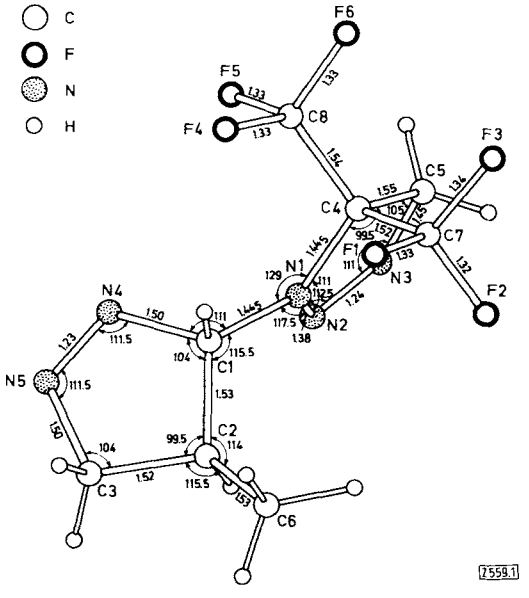
In the latter case the addition must, in principle, have followed one of three alternative routes giving (i) two linked five-membered rings *(3)* [1,2; 3,4-addition], (ii) two condensed six-membered rings *(4)* ["criss-cross" addition, 1,3; 2,4-addition], or (iii) a 5,7-bicyclic system *(5)* [1,4; 2,3-addition]—the numerals refer to the 2-aza-1,3-*trans*-butadiene skeleton present in *(2)*; see formula scheme). Each addition mode could give four structural isomers depending upon the position at which the 1- and 3-positions of the 1,3-dipole diazomethane add to the dipolarophile. IR and NMR measurements reduced the number of possibilities from twelve to three, *viz.* *(3a)*, *(3b)*, *(4)*. An X-ray structure analysis was performed to decide between these three possibilities and to determine the configuration and conformation of the compound.



The three-dimensional X-ray structure analysis was carried out with orthorhombic crystals obtained from diethyl ether. Crystallographic data: $a = 19.83_9$, $b = 12.98_5$, $c = 8.82_6$ Å; $d_{exp} = 1.69_5$ g cm^{-3}; space group Pbca. The asymmetric unit contains one molecule $C_8H_9N_5F_6$ ($d_{calc} = 1.68_9$ g cm^{-3}). 2154 reflections (254 not observed, $I < 2\sigma_I$; $\vartheta \leq 70°$, $\vartheta/2\vartheta$ scan; 5 point measurement) were measured with $Cu_{K\alpha}$ radiation on a Siemens diffractometer.

The signs of 294 structure factors could be determined by direct methods[3]. All atoms except the hydrogen atoms were visible in an *E*-Fourier synthesis. The identities of the N and C atoms followed unequivocally, partly from the *E*-Fourier synthesis and partly after the first cycles of refinement on the basis of the bond lengths. Least-squares refinement (full matrix), initially with isotropic and then with anisotropic temperature factors, was carried out until an *R* factor of 9.1% was reached. The nine greatest maxima of a difference Fourier synthesis calculated at this stage indicated the proton positions. Refinement was then pursued including the H atoms (H atoms isotropic, all other atoms anisotropic); the *R* factor has now been reduced to 6.7%. The structure of the molecule is shown in the Figure; it corresponds to that of *(3a)*, 5,5-bis(trifluoromethyl)-1-(4-methylpyrazol-1-in-3-yl)-1,2,3-triazol-2-ine.

The short N1—N2 single bond length in the triazoline ring (1.38 Å) and the angle at N1 indicate rehybridization at N1 from sp^3 to sp^2. The lone pair on N1 undergoes reso-

nance with the N=N double bond. In agreement with the rehybridization at N1, the C—N single bonds emanating from this atom are shortened from 1.47[4] to 1.44$_5$ Å (sp^3—sp^2) and are thus of the same length as the isotypic bond C5—N3. In contrast, the sp^3—sp^2 single bonds (C1—N4, C3—N5) in the pyrazoline ring are lengthened to 1.50 Å. The N=N double bonds (1.24 Å) and C—C (1.53 Å) and RF_2C—F single bonds (1.33 Å) correspond to the expected values.

Both five-membered ring systems are in the "envelope" conformation, the "flap" being provided in both cases by the C atoms lying opposite the N=N double bond. Rehybridization of N1 leads to a significant flattening of the triazoline ring. While C2 protrudes from the plane of the rest of the pyrazoline ring by 0.49 Å, C4 projects from the triazoline ring by only 0.11 Å. The best planes through all five atoms of the two rings enclose an angle of 86°.

Angles (°):

F1–C7–F2: 107.5	F4–C8–F5: 107
F2–C7–F3: 106.5	F5–C8–F6: 107.5
F3–C7–F1: 106.5	F6–C8–F4: 107
C4–C7–F1: 113.5	C4–C8–F4: 113.5
C4–C7–F2: 111.0	C4–C8–F5: 109.5
C4–C7–F3: 111.5	C4–C8–F6: 112
C7–C4–N1: 110.5	C8–C4–N1: 112.5

Fig. Molecular structure of 5,5-bis(trifluoromethyl)-1-(4-methylpyrazol-1-in-3-yl)-1,2,3-triazol-2-ine *(3a)*.
The bond lengths are given to the nearest 0.01 Å and the angles to the nearest 0.5°; the mean standard deviations for these quantities are 0.005 Å and 0.3°, respectively.

The adjacent substituents on the pyrazoline ring—triazolinyl and methyl—are *trans*-dipseudoequatorial. The pyrazoline ring also occupies a pseudoequatorial position as a substituent on the triazoline ring. The marked asymmetry of the external angle at the bridge atoms N1 and C1 (129 against 117.5°; 115.5 against 111°) relieves the conformative strain between the two ring systems. The conformation is largely determined by the steric interactions in the molecule.

The angles in the CF_3 groups indicate a distortion of the tetrahedra that appears to be typical for these groups.

Photofragmentation of Spiropyrazoles.—Stable Norcaradienes and Spiroheptatrienes[**]

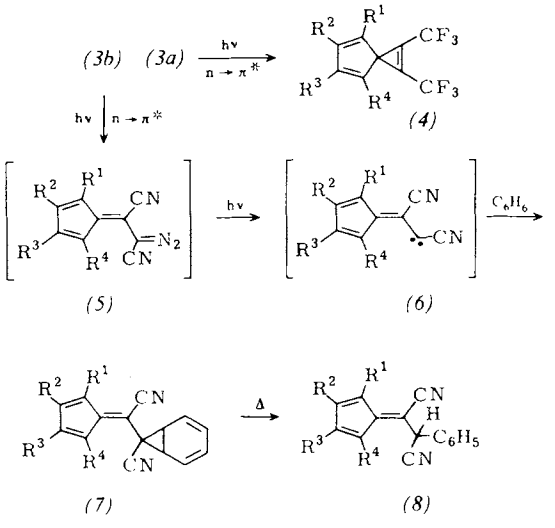
By *Heinz Dürr, René Sergio,* and *Willy Gombler*[*]

1,3-Dipolar addition of diazocyclopentadienes *(1)* to alkynes *(2)* affords spiropyrazoles *(3)*[1]. Substituted spiropyrazoles *(3)* undergo photochemical fragmentation to give benzocyclopropenes in excellent yields[2]. We have now found that dibenzo derivatives of *(3)* react in a completely different way.

The cycloaddition of diazofluorene *(1a)* to the highly reactive hexafluorobutyne *(2a)* (at −30°C) and dicyanoacetylene *(2b)* (at 20°C) readily affords the spiropyrazoles *(3a)* and *(3b)*[1], respectively, in 91 and 85% yield. The ^{19}F-NMR spectrum of *(3a)* contains two quartets at 57.6 and 62.1 ppm ($CFCl_3$ as internal standard) with $^5J_{FF}$ = 6.8 Hz. In the IR spectrum the stretching vibrations of the CF_3 groups are observed at 1325 and 1365 cm^{-1}, along with the peaks due to the spiro skeleton.

(1) *(2)* *(3)*

(a), R^1–R^2 = R^3–R^4 = benzo, R^5 = CF_3
(b), R^1–R^2 = R^3–R^4 = benzo, R^5 = CN



Photolysis (Hg high pressure lamp) of *(3a)* in benzene (Pyrex filter) leads to spiro[2.4]heptatriene *(4)* in 86% yield. The IR spectrum of *(4)* exhibits the typical cyclopropene band at 1900 cm^{-1}, as well as the bands due to the trifluoromethyl groups as 1325 and 1365 cm^{-1}. The only signal in the ^{19}F-NMR spectrum is a singlet at 59.0 ppm which is typical for the highly symmetrical structure of *(4)* (C_{2v} symmetry). Some mono- and dialkoxycarbonyl derivatives of *(3)* react similarly[2–4].

Photolysis of *(3b)* in benzene follows a completely different route. Under the conditions used above for *(3a)*, reaction of *(3b)* furnished an 85% yield of the fulvenylnorcaradiene

[**] Photochemistry of small rings, Part 26.—Part 25: *H. Dürr, P. Heitkämper,* and *P. Herbst,* Synthesis, in press.

(7), the *first representative of this type of compound*. In the presence of ether *(3b)* gives a mixture of insertion products. The structure of *(7)* follows from the spectroscopic data. CN stretching vibrations appear at 2200 and 2230 cm^{-1} in the IR spectrum. Further unambiguous evidence for a norcaradiene structure is provided by the ^{1}H-NMR spectrum: $\tau(CDCl_3)=2.2$—2.8 (m), 3.70 (m, vinyl H), and 6.95 (br. s, cyclopropane H) in the ratio 8:4:2.

(7) definitely exists as the norcaradiene; even at 110 °C it is not converted into the cycloheptatriene valence isomer (NMR) but instead rearranges to the phenylfulvene *(8)* (m. p. 183—184 °C; correct elemental analysis; see ref. [5]). The synthesis of the first fulvenylnorcaradiene *(7)* proceeds *via* the diazofulvene *(5)* to the fulvenylcarbene *(6)* which gives *(7)* in an intermolecular cycloaddition. This course has also been established for the photolysis of 5-cyano-3*H*-pyrazoles[6].

7-Cyano-7-(6-cyanodibenzofulvenyl)norcaradiene (7)

A solution of *(3b)* (1.00 g, 3.73 mmol) in anhydrous benzene (200 ml) is irradiated under N_2 with a Philips HPK 125-W lamp for 15 min. After removal of the benzene *in vacuo*, the yellow residue was treated with chloroform to give 1.00 g (85%) of yellow crystalline *(7)*.

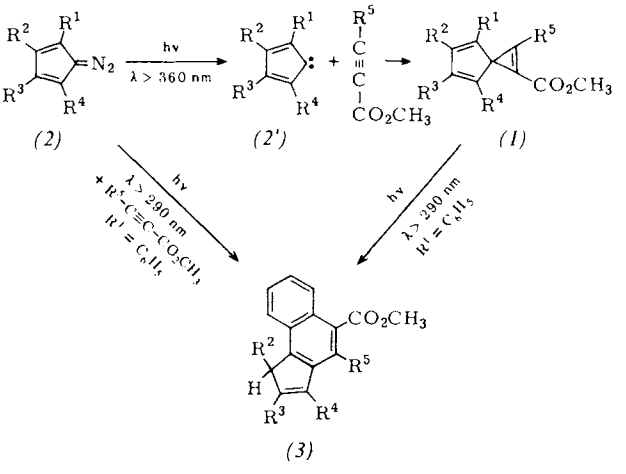
Spiroheptatrienes by [1+2]-Cycloaddition[1]

By *Heinz Dürr* and *Bernd Ruge*[*]

Spiro[2.4]heptatrienes of type *(1)*[2] are of interest for two main reasons:

1. The spiro bracket introduces additional ring strain into the highly strained (Baeyer strain) cyclopropene group, which should endow these compounds with a relatively low stability or a high reactivity.



2. Because of their mutually perpendicular π systems, the spiroheptatrienes *(1)* lend themselves for a critical examination of the concept of "spiro conjugation"[3].

The synthesis of these compounds has so far been accomplished in isolated cases only[2,4]. In the present communication we report a general synthesis:

The method involves photolysis of diazocyclopentadienes *(2)* (Hg high pressure lamp) in alkynes such as dimethyl acetylenedicarboxylate or methyl propiolate. Long-wave UV light must be used (GW_v filter: $\lambda > 360$ nm) in the case of phenyl-substituted diazocyclopentadienes in order to avoid possible photorearrangement of *(1)* to benzindenes *(3)*[5].

After removal of the alkyne, chromatography of the photolyzate on silica gel gave medium yields of spiro[2.4]heptatrienes *(1)* (see Table).

Photolysis of the diazocyclopentadiene leads initially to a carbene *(2')* which undergoes [1+2]-cycloaddition with the alkyne to give *(1)*.

	R^1	R^2	R^3	R^4	R^5	Yield (%) *(1)*	Yield (%) *(3)*	IR (cm^{-1}) [a]
(a)	Cl	Cl	Cl	Cl	CO_2CH_3	22	—	1895
(b)	Cl	Cl	Cl	Cl	H	25	—	1795
(c)	C_6H_5	C_6H_5	benzo		CO_2CH_3	26	9	1855
(d)	C_6H_5	C_6H_5	benzo		H	29	—	1775
(e)	C_6H_5	C_6H_5	C_6H_5	C_6H_5	H	9	12	1778
(f)	C_6H_5	C_6H_5	C_6H_5	C_6H_5	CO_2CH_3	40 [5]	—	1865

[a] Cyclopropene band of *(1)*.

The structure of the spiro[2.4]heptatrienes follows from elemental analysis and spectroscopic data. Being very simple, the NMR spectra support the symmetrical structure given. Thus the NMR spectrum of *(1d)* contains a singlet

at $\tau = 6.19$ ppm for the methoxycarbonyl group, a singlet at $\tau = 1.83$ for the vinyl proton, and a multiplet at $\tau = 2.45$ to 3.13 ppm for the aromatic protons. The signal areas are in the ratio 3:1:14. The characteristic IR spectra of *(1)* exhibit the C=C stretching mode for 1,2-disubstituted cyclopropenes at 1850—1900 cm^{-1} and for 1-substituted cyclopropenes at 1750—1800 cm^{-1} (see Table).

When $R^1 = C_6H_5$, small amounts of benz[*e*]indenes *(3)* are also formed. Use of high-energy UV light ($\lambda > 290$ nm) for the photolysis of *(2c)*—*(2e)* in alkynes leads exclusively to benz[*e*]indenes[5] which are formed from *(1)*. For example, the photolysis of *(1c)* (Hg high pressure lamp, Pyrex filter: $\lambda > 290$ nm) gave an 80% yield of *(3c)* *via* a 1,7 sigmatropic shift and subsequent rearomatization (cf. also ref. [5]), *i.e.* under these conditions *(1)* underwent direct rearrangement to *(3)*.

An attempt was made to deduce information about ring strain in *(1)* from the $^1J_{^{13}C-H}$ coupling constant of *(1b)*. A 49.6% s component of the cyclopropene C—H bond was calculated from $^1J_{^{13}C-H} = 248$ Hz[6, 7]. Studies on the effect of spiro conjugation in *(1)* are currently in progress.

3-Methoxycarbonyl-2',3'-diphenylspiro[cyclopropene-1,1'-indene] (1d)

Compound *(2d)* (2.50 g, 8.5 mmol) is irradiated in methyl propiolate (155 ml) for 2.5 h with the light from a Philips HPK 125-W lamp (GW_v filter: $\lambda > 360$ nm). 85% of the calculated amount of N_2 were evolved within this time. The propiolate was then distilled off at 40 °C/30 torr and the residue chromatographed on silica gel. Elution with benzene/$CHCl_3$ (19:1) gave 1.70 g of a brown oil, from which 0.87 g [29% yield based on reacted *(2d)*] of *(1d)* crystallized on using ether as a solvent; m.p. 118—119 °C after recrystallization from ether; IR: νC=C (cyclopropene) = 1775; νC=O = 1705; νC—H (cyclopropene) = 3110 cm^{-1}.

Infrared Rotatory Dispersion (IRD)[**]

By *Bernhard Schrader* and *Ernst-Heiner Korte*[*]

According to the theory of rotatory dispersion[1] it is to be expected that anomalous optical rotation can occur in the infrared owing to molecular vibrations. The amplitude of the anomalies is inversely proportional to the mass of the particles participating in the transition. Effects are therefore predicted that are about four orders of magnitude smaller than those recorded for electronic transitions. Moreover, the components of an IR spectral polarimeter (Nernst glower, polarizer, thermocouple) have less favorable properties than the corresponding components of a UV instrument. The search for anomalies has hitherto been unsuccessful[2].

Previous measurements of the rotatory disperison of molecules covered only the near infrared down to 2500 cm^{-1}. However, the greatest and most informative effects are to be expected in the range of skeletal vibrations. Our studies in this spectral region with a single beam spectral polarimeter[3] having a sensitivity of 0.01° (at 1000 cm^{-1}, 2 cm^{-1} slit width, and 60% absorption) on both antipodes of carvone *(1)*, α-pinene *(2)*, phenylethylamine *(3)*, and 2,3-diphenyldinaphtho[2,1-*e*;1,2-*g*]-[1,4]-diazocine[4] *(4)* show no measurable anomalies apart from the normal drop in rotation with the wave number.

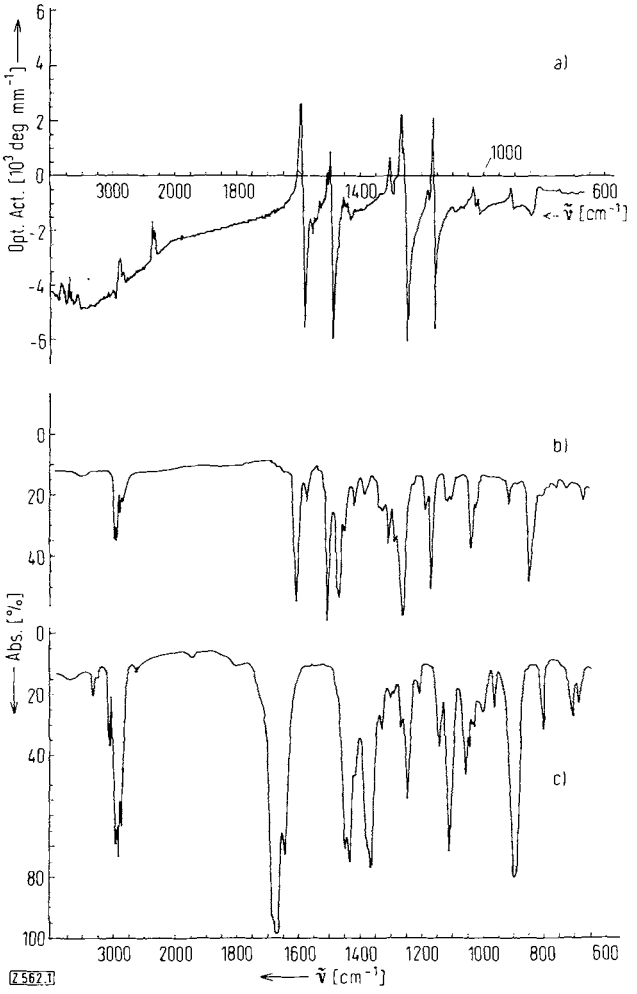

Fig. 1. a) IRD curve of 2 mol-% d-carvone *(1)* in Licristal® *(5)*, layer thickness 13 μm, NaCl windows; b) IR absorption spectrum corresponding to a); c) IR absorption spectrum of d-carvone *(1)*, layer thickness 50 μm.

46 Dortmund-Hombruch, Postfach 500 (Germany)
Dipl.-Phys. E. H. Korte
Institut für Spektrochemie und angewandte Spektroskopie
46 Dortmund, Postfach 778 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We also wish to thank Dr. *E. Steigner*, Frankfurt, for the preparation of the antipodes of *(4)*.

Anomalies do occur, however, when the molecules *(1)* to *(4)* are dissolved in a nematic liquid crystal. This optically inactive mesophase is transformed into the optically active cholesteric phase by addition of small amounts of chiral molecules[5]. We have found that a solution of 2 mol-% d-carvone in Licristal® *(5)* (eutectic mixture of the isomeric *N*-oxides of *p*-methoxy-*p'*-*n*-butylazobenzene) as a 13-μm layer between NaCl windows gives the rotatory dispersion curve reproduced in Figure 1a with anomalies having an unexpectedly large amplitude of *ca.* 7000 deg/mm. A corresponding curve of opposite polarity is recorded for a solution of l-carvone. Solutions of *(2)*, *(3)*, and *(4)* in *(5)* give curves having anomalies at the same frequencies but of different magnitudes and forms. Solutions of *(1)* to *(4)* in a mixture of *N*-(*p*-methoxybenzylidene)- and *N*-(*p*-ethoxybenzylidene)-*p'*-butylaniline *(6)* produce similar curves. The frequencies at which rotational anomalies are observed agree with the IR absorption bands of the *host* molecules—*(5)* and *(6)*—while vibrations of the *guest* molecules—*(1)* to *(4)*—are not seen in anomalies of the dispersion curves (see Fig. 1).

We assume that the steric form of the chiral molecules determines the pitch of the cholesteric phase. Anomalies of the rotatory dispersion are to be expected when the effective wavelength in the cholesteric phase λ_{eff} (vacuum wavelength λ_{opt} divided by the refractive index n) is equal to the pitch. The appearance of several anomalies in the IRD curve can be explained by the fact that $\lambda_{eff} = \lambda_{opt}/n$ is equal to the pitch for various values of λ_{opt} since n is subject to wide variations in absorption bands.

Studies are in progress to determine in how far the sign and degree of helicity of molecules can be ascertained with the aid of this new effect.

Amino Acid Analysis on the Picomole Scale[**][1]

By *Norbert Lustenberger*, *Hans-Walter Lange*, and *Klaus Hempel*[*]

In an alkaline medium, amino acids *(1)* and pyridoxal *(2)* undergo condensation to Schiff bases *(3)* which can be converted into pyridoxyl amino acids of type *(4)* by catalytic reduction[2, 3] or by reduction with sodium tetrahydroborate. We have found that pyridoxyl amino acids can be detected extremely readily. After separation by column chromatography, approx. 2×10^{-8} mol of an individual pyridoxyl amino acid can be detected by spectrophotometry and approx. 5×10^{-10} mol by fluorometric methods. Reduction with radioactive $NaBT_4$ offers particular advantages since the tritiated pyridoxyl amino acids *(4)* can be quantitatively determined on a picomole scale (1×10^{-12} mol).

In order to ascertain the sensitivity of this amino acid analysis we have examined: a) the chemical reaction; b) the isotope effect of the $NaBT_4$-reduction of the Schiff bases *(3)*; c) the separation of the pyridoxyl amino acids by column chromatography; as well as d) the possible methods of determination.

a) The yields (Table) were determined by reaction of 25-μmol portions of ^{14}C-labeled amino acids of known specific activity followed by column-chromatographic separation from the pyridoxyl ^{14}C-amino acid. The highest yields were obtained with 0.2 M solutions of pyridoxal in phosphate buffer (pH = 9.3). To the best of our knowledge pyridoxylcysteic acid, -glutamine, -proline, and -hydroxyproline have not previously been described.

The formation of pyridoxylprolines was unexpected since the intermediacy of a Schiff base *(3)* can be ruled out in this case. We suspect that the reaction proceeds *via* a keto enimine intermediate[4, 5]. Cysteine and histidine do not give pyridoxyl amino acids of type *(4)* since the Schiff bases of these compounds undergo spontaneous cyclization to products that cannot be reduced[2]. Use of radioactive pyridoxal recommends itself in this case; investigations are in progress.

b) Considerable isotope effects have been recorded[6] in reactions with mixtures of hydrogen isotopes. For a given series of pyridoxyl amino acids *(4)* we therefore determined the yield and the ^3H activity after reduction of the Schiff bases *(3)* with $NaBT_4$ (spec. activity 10 mCi/mg-atom) and calculated the specific ^3H activities (Table) from these results. Deviations from the value expected with no isotope effect (10 mCi/mmol) lie within the limits of experimental accuracy. The fact that no isotope effect was detected could possibly have something to do with our using $NaBT_4$ diluted with $NaBD_4$.

[a] Pyridoxyloxopyrrolidinecarboxylic acid.
[b] Schiff base *(3)* cyclizes to an imidazopyridine derivative that cannot be hydrogenated [2].
[c] More than 70% of the amino acid resists reaction; yields increased by repeated treatment with pyridoxal and $NaBH_4$.
[d] Dipyridoxyllysine.
[e] Reduction of *(3)* with a $NaBT_4/NaBD_4$ mixture of spec. activity 10 mCi/mg-atom; produced by dilution of $NaBT_4$ (spec. activity 900 mCi/mg-atom) with $NaBD_4$.
[f] Mean value calculated from three to six individual determinations.
[g] Dissolved in 0.2 N NaOH; fluorescence measurements at E_{max} 306 nm/F_{max} 370 nm.

c) We were able to separate the pyridoxyl derivatives of synthetic mixtures of all biologically important amino acids on ion-exchange resins. The Figure illustrates the analysis of an amino acid mixture (1×10^{-11} mol per amino acid), which had been converted into the radioactive pyridoxal derivatives *(4)*. For optical detection a further 0.5 μmol of each pyridoxyl amino acid was added prior to analysis. Extinction, fluorescence, and radioactivity of the column eluate were measured. In order to ensure that these measurements were performed at similar pH values (pH 5) for all amino acids an aliquot of eluate was diluted with four parts of sodium citrate buffer (pH 5.28) for the extinction measurements and with 49 parts for the fluorescence determinations.

d) Owing to the chromophoric pyridoxyl group, pyridoxyl amino acids of type *(4)* have spectra resembling that of pyridoxamine (absorption maxima at 255 nm and 328 nm) and also exhibit a characteristic pH-dependent fluorescence (E_{max} 332 nm/F_{max} 400 nm) suitable for detection of these compounds (Table). The molar fluorescence of most pyridoxyl amino acids lies in the same range. On excitation (332 nm) the intensity of fluorescence falls off within minutes.

Detection with the aid of radioactivity measurements is most sensitive. We found about 2000 counts per min for each 1×10^{-12} mol of pyridoxyl amino acid after reaction with $NaBT_4$ of specific activity 3600 mCi/mmol. The specific activity of carrier-free $NaBT_4$ is 116 Ci/mmol.

Pyridoxyl derivatives are suitable not only for the detection of amino acids and amines. On use of pyridoxamines in place of pyridoxal *(2)*, carbonyl compounds can be determined quantitatively with the same degree of sensitivity. The α-keto acids yield the corresponding pyridoxyl amino acids.

We believe that the above method is the most sensitive available for the quantitative determination of amino acids. On use of ninhydrin in automatic amino acid analysis[9], 10^{-9} mol can still just be detected by colorimetry. The sensitivity of the ninhydrin reaction can be enhanced 10 to 100-fold by addition of phenylacetaldehyde and fluorescence measurements[10, 11]. The dansyl method[12] can be used to identify 10^{-12} mol[13] of any amino acid after separation by thin-layer chromatography. However, this test cannot be automated and is limited to amino acids and amines.

Experimental

Solutions of amino acids in 0.5 M phosphate buffer (pH 9.3) are mixed with an equal volume of a freshly prepared 0.4 M pyridoxal solution whose pH has been adjusted to 9.3, and allowed to stand at 8 °C. The molar ratio of pyridoxal and amino acid should be > 5:1. After 30 min the yellow reac-

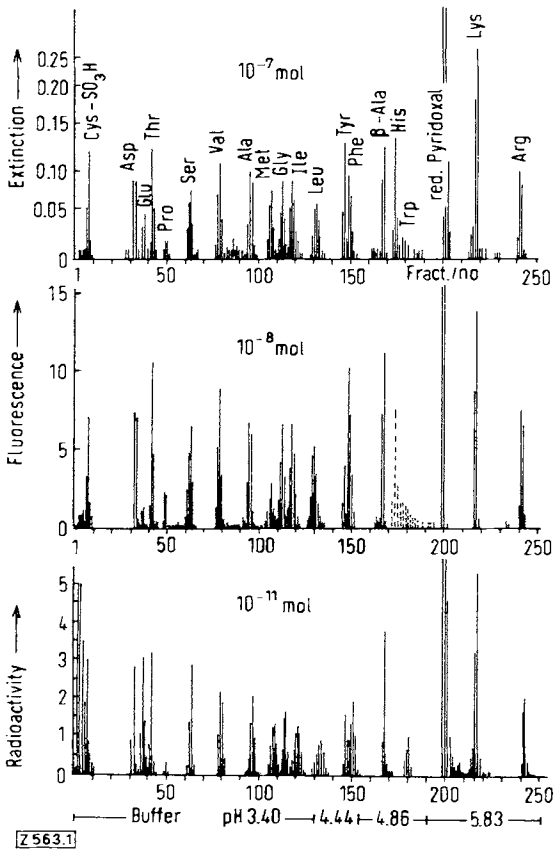

Fig. Column chromatography of a pyridoxyl amino acid mixture and detection of the amino acids. Conditions: Ion-exchange resin Aminex A 5 (BioRad, Richmond, California 94804 (USA)), column 100 × 0.6 cm, packed height 90 cm, temperature 70 °C, flow rate 33 ml/h, pressure 30—35 at, fraction volume 3 ml, elution with 0.2 N (pH 3.40—4.86) and 0.35 N (pH 5.86) sodium citrate buffer.

UV determination (328 nm): 1×10^{-7} mol of each amino acid. Pyridoxyltryptophan partially decomposed.

Fluorometric determination ($E_{332\,nm}/F_{400\,nm}$; relative units): 1×10^{-8} mol of each amino acid. Dashed fractions were adjusted to pH 12 with conc. NaOH and measured at $E_{306\,nm}/F_{370\,nm}$ to achieve better determination of the histidine derivative. Pyridoxyltryptophan partially decomposed.

Radioactive determination (counts/min × 10^{-2}). Activity measurements with liquid scintillation counter (Tri-Carb model 3380, Packard, Downers Grove, Illinois 60515 (USA)), yield 5%. 1×10^{-11} mol of each amino acid; reduction with radioactive $NaBT_4$ of spec. activity 3600 mCi/mmol (= 900 mCi/mg-atom). Pyridoxyltryptophan partially decomposed. No radioactivity at position corresponding to the histidine derivative.

tion mixture is decolorized by addition of $NaBH_4$ solution (100 mg in 1 ml 0.1 N NaOH). The excess of $NaBH_4$ is decomposed by acidification with HCl (pH 1—2) prior to column chromatography.

Carbodiimidium Compounds as Reagents in Organic Chemistry[**]

By *Rolf Scheffold* and *Emil Saladin*[*]

Carbodiimidium compounds of general structure *(1)* (R′ = H) play an important role as intermediates in acid-induced addition reactions of carbodiimides. To the best of our knowledge no reports have so far appeared in the literature describing the isolation of carbodiimidium compounds in substance. According to *Hartke* and *Rossbach*[1], attempts to synthesize them by reaction of aliphatic carbodiimides with anhydrous tetrafluoroboric acid in methylene chloride or by reaction with dimethyl sulfate lead exclusively to dimeric cyclic products.

We have now found that *N,N′*-dicyclohexylcarbodiimide can be alkylated by prolonged heating in pure alkyl bromides or iodides[2]. Treatment with methyl iodide, for example, leads to 75% yields of *N,N′*-dicyclohexylcarbo-

diimidium iodide *(1a)*, which crystallizes as colorless needles having m. p. 111—113 °C. Assignment of structure is based on elemental analysis, the IR spectrum [($CHCl_3$): bands at, *inter alia*, 2119 (ν N=C=N) and 1667 cm^{-1}], and the NMR spectrum [($CDCl_3$): δ = 3.50 ppm (s, 3H of N—CH_3); 3.3—3.6 ppm (broad accumulation of signals, 2H on the α-C of the cyclohexyl groups); 1.0—2.1 ppm (broad accumulation of signals, 20H on the β-C, γ-C, and δ-C of the cyclohexyl groups)].

Carbodiimidium compounds of general structure *(1)*[3] are of interest in many respects as reagents in organic chemistry. To illustrate this we report first on their use in the conversion of alcohols into iodides:

Aliphatic primary and secondary alcohols (including such types as homoallyl and neopentyl alcohols) react with *N*-methyl-*N,N′*-dicyclohexylcarbodiimidium iodide *(1a)* in solvents such as tetrahydrofuran, benzene or hexane at 35°—50 °C to give the corresponding iodides, usually in high yields.

Stereochemistry: The reaction involves inversion of the configuration at the C atom bearing the OH group[4]. For example, in the case of 3β-cholestanol, thermodynamically

[*] Prof. Dr. R. Scheffold and Dipl.-Chem. E. Saladin

[**] This work was supported by the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung, Project No. 4783.

less stable 3α-iodocholestane is formed in more than 84% yield. Particularly noteworthy is the fact that cholest-5-en-3β-ol (cholesterol, as a typical representative of the homoallyl alcohols) is converted in one step into the previously unknown 3α-iodocholest-5-ene[5].

Table: Examples of typical reactions of alcohols with *N*-methyl-*N*,*N'*-dicyclohexylcarbodiimidium iodide *(1a)*.

Educt	Product	Conditions [a]	Yield (%) [b]
1-Octanol	1-Octyl iodide	3 h/35 °C	89
dl-2-Octanol	dl-2-Octyl iodide	2 h/35 °C	81
1,3-Dihydroxypropane	1,3-Diiodopropane	15 h/35 °C	72
3β-Cholestanol	3α-Iodocholestane	15 h/35 °C	84
Cholest-5-en-3β-ol	3α-Iodocholest-5-ene	15 h/35 °C	38
		15 h/35 °C [c]	40
13-Isopropyl-podocarpa-8,11,13-trien-15-ol	13-Isopropyl-15-iodo-podocarpa-8,11,13-triene	48 h/50 °C	18
17β-Hydroxy-androst-4-en-3-one	17α-Iodoandrost-4-en-3-one	62 h/60 °C	38

[a] Each mol of alcohol treated with 2 moles of *(1a)*. Solvent: THF unless otherwise stated.

[b] The yields relate to analytically pure product. The yields of crude iodides are sometimes much higher.

[c] In hexane.

Steric hindrance: Even extremely sterically hindered alcohols such as neopentyl alcohols can be converted under mild conditions, albeit in low yields, into the corresponding iodides. As examples may be mentioned the conversion of 13-isopropylpodocarpa-8,11,13-trien-15-ol (dehydroabietanol) into 13-isopropyl-15-iodopodocarpa-8,11,13-triene[6] and of 17β-hydroxyandrost-4-en-3-one (testosterone) into 17α-iodoandrost-4-en-3-one[7].

Limitations: Substrates containing nucleophilic substituents other than the OH group of the alcohol, *e.g.* amino groups or carboxy groups, cannot be converted directly into the iodides without prior protection.

It seems reasonable to assume that the primary reaction step involves addition[8] of one mol of alcohol RR'CHOH to the highly reactive carbodiimidium system with formation of an isourea as trigonal intermediate, which, under the conditions given, is protonated[9]. The second and usually rate-determining step consists of the nucleophilic substitution of the positively charged urea group by the iodide ion. This substitution proceeds with inversion of configuration at the carbon atom (see Figure).

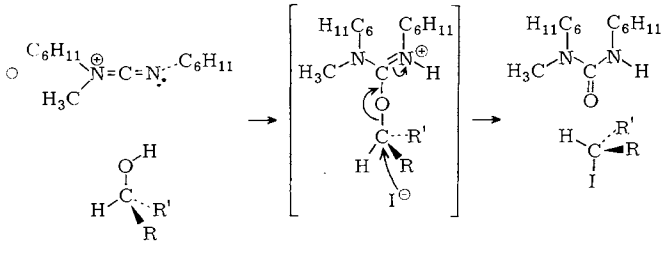

Figure. Schematic representation of the course of the reaction.

N-Methyl-N,N'-dicyclohexylcarbodiimidium iodide (1a)[*]

Freshly distilled *N*,*N'*-dicyclohexylcarbodiimide (42 g, 0.204 mol) was dissolved in methyl iodide (90 ml, 1.45 mol) under nitrogen at room temperature in a 250 ml round-bottom flask fitted with magnetic stirrer, reflux condenser, and a nitrogen bulb. The colorless reaction mixture was stirred for 72 h at a bath temperature of 70 °C. The excess of methyl iodide was then removed from the pale-brown solution by distillation under reduced pressure and the viscous, brown residue thus obtained was dissolved in anhydrous toluene (150 ml) at 40 °C. The crystalline mass which separated out within a few hours was separated from the mother liquor in an inert atmosphere by filtration on a glass Buchner filter fitted with a nitrogen bulb; the reaction flask was then rinsed three times with 25 ml portions of ice-cold anhydrous toluene. The pale-yellowish crystalline mass recovered on the filter was washed with ice-cold anhydrous toluene until colorless crystals were obtained. After 20 hours drying at room temperature/0.1 torr, a total yield of 53 g (75%) of colorless crystals, m. p. 111—113 °C, was obtained. For analysis, the product was recrystallized three times from methyl iodide/hexane and dried at 20 °C/0.005 torr for 48 hours, m. p. 111—113 °C.

Typical example of a alcohol → iodide conversion: 3α-iodocholestane

A mixture of 3β-cholestanol[10] (1.940 g, 5 mmol) and *(1a)* (3.475 g, 10 mmol) was dissolved in tetrahydrofuran (50 ml) in a 100 ml round-bottom flask fitted with a nitrogen bulb. The colorless solution was allowed to stand for 15 hours at 35 °C. The solvent was then removed at reduced pressure in a rotary evaporator. The residue was taken up in 50 ml hexane, transferred to a separatory funnel, and washed three times with 25-ml portions of methanol/water (4:1) to remove *N*-methyl-*N*,*N'*-dicyclohexylurea. The combined washings were extracted three times with 25 ml portions of hexane; the combined hexane phase was dried over sodium sulfate and then filtered through silica gel (*ca.* 10 g). The clear filtrate, after removal of solvent under reduced pressure and subsequent drying at 20 °C/0.1 torr, yielded 2.359 g (95%) of crude iodide. Recrystallization of the crude product from anhydrous acetone (40 ml) afforded 2.086 g (84%) of pure 3α-iodocholestane, colorless needles, m.p. 111—111.5 °C[11].

Revised: December 1, 1971
German version: Angew. Chem. *84*, 158 (1971)

[*] *Note added in proof* (February 8, 1972): A dimer of *(1a)* cannot be ruled out on the basis of the available data.

[1] *K. Hartke* and *F. Rossbach*, Angew. Chem. *80*, 83 (1968); Angew. Chem. internat. Edit. *7*, 72 (1968).

[2] It had been established as long ago as 1925 that *N*,*N'*-di-*n*-propylcarbodiimide does not add methyl iodide: *H. Lecher*, *F. Graf*, *C. Heuck*, *K. Köberle*, *F. Gnädinger*, and *F. Heydweiller*, Liebigs Ann. Chem. *445*, 35 (1925).

[3] *(1a)* is a crystalline, colorless, slightly hygroscopic compound that can be stored in the refrigerator for several months. Variation of R,R', and X⁻ in *(1)* can be realized by suitable choice of carbodiimide and alkylating reagent. The anion I⁻ in *(1a)* can be replaced by X⁻ by treatment with AgX.

[4] Although, strictly speaking, the reaction proceeds with inversion of configuration, it is possible that a certain amount of the iodoalkane shows retention of configuration. This part of the product arises by nucleophilic substitution of the initially formed iodoalkane by iodide ions in solution. Consequently a decrease in stereoselectivity is always observed, if the reaction conditions are too vigorous (too high a temperature, too long a reaction time, too great an excess of reagent).

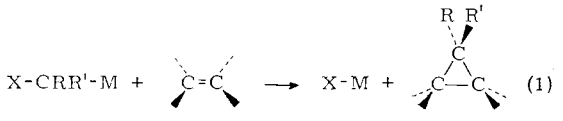
[5] Recrystallized from acetone three times and dried at 0.01 torr; m. p. 130—130.5 °C. In the NMR spectrum in $CDCl_3$, the signal of the β proton on C-3 appears as a multiplet at δ = 4.90 and that of the olefinic proton on C-6 as a multiplet at δ = 5.30 ppm (TMS = 0).

[6] Colorless, viscous oil. NMR spectrum in $CDCl_3$: δ = 1.09 (s, 3H); 1.20 (s, 3H); 1.22 (d, J = 7 Hz, 6H); 1.45—1.76 (accumulation of signals, 9H); 2.0—3.0 (m, 2H); 2.91 (septet 1H); AB system with 3.20 (d, J = 11 Hz, 1H) and 3.33 (d, J = 11 Hz, 1H); 6.9—7.1 (m, 3H) (TMS = 0).

[7] Recrystallized from anhydrous acetone and dried at 0.01 torr; m. p. 154—155 °C. IR spectrum in chloroform: 1670 cm^{-1} (ν C=O). In the NMR spectrum in $CDCl_3$ the signal of the β-proton on C-17 appears as the X part of an ABX system at δ = 4.40 (q, J_{AX} = 2 Hz, J_{BX} = 6 Hz, 1H) and the signal due to the olefinic proton on C-4 occurs at δ = 5.77 (d, J = 1.5 Hz, 1H).

[8] The isourea hydroiodide formulated as intermediate in the reaction of 2,2-dimethylpropanol (neopentyl alcohol) with *(1a)* in THF can in fact be isolated as colorless crystals after a few hours at 35 °C. This shows that sterically hindered alcohols also undergo smooth addition to the C=N double bond of carbodiimidium system.

[9] The pK^{*}_{MCS} of the isourea hydroiodide formed from *(1a)* and neopentyl alcohol is 9.5. (For the definition of pK^{*}_{MCS} value cf. *W. Simon*. Helv. Chim. Acta *41*, 1835 (1958).



[10] The 3β-Hydroxycholestane used was obtained from Fluka AG, Buchs; its melting point after one recrystallization was 140—142 °C.

[11] The melting point and all spectroscopic data are identical with the values quoted for 3α-iodocholestane by *J. P. Verheiden* and *J. G. Moffat*, J. Org. Chem. *35*, 2319 (1970) and by *A. V. Bayless* and *H. Zimmer*, Tetrahedron Lett. *1968*, 3811.

Organomercury Carbenoids for the Synthesis of Cyclopropane Derivatives[**]

By *Rolf Scheffold* and *Urs Michel*[*]

Organometallic compounds of general structure *(1)* can be used for the synthesis of cyclopropanes[1].

(1) *(2)* *(3)* *(4)* (1)

X = leaving group, *e.g.* halogen

M = metal or metal complex cation

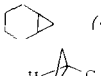
R,R' = H, organic group, halogen, *etc.*

Zinc(II) and copper(I) carbenoids of type *(1)*, with R = R' = H, are of particular importance in preparative organic chemistry; they are unstable and must be prepared *in situ*—from diiodomethane and zinc/copper couple[2] or diethylzinc[3] or from diazomethane and zinc iodide[4]—or they are formed as an intermediate, *e.g.* as in the synthesis of cyclopropane by Cu(I)-catalyzed decomposition of diazomethane[5].

In contrast, the corresponding mercury(II) compounds are considerably more stable and can be isolated in substance. *Seyferth et al.*[6] shown that mercury(II) carbenoids are suitable reagents for the synthesis of 1,1-dihalogenocyclopropanes. Similar methods[7] for the preparation of the cyclopropanes *(4)* (R = R' = H) are, however, comparatively less satisfactory since the mercury(II) carbenoids seem to be insufficiently reactive.

We have investigated the organomercury(II) carbenoids regarding their suitability as reagents for a mild, versatile, and selective synthesis of cyclopropane and alkylcyclopropane derivatives. As first example we report here on the synthesis and reactions of benzylmercurioiodomethane *(1a)*[8].

Addition of an ethereal solution of diazomethane to a solution of benzylmercury iodide *(3a)* in tetrahydrofuran at 0 °C leads to immediate formation of the carbenoid *(1a)*[9] in quantitative yield. This compound, a colorless oil, is so stable towards heat that it remains unchanged for several hours in benzene at 90—100 °C under nitrogen.



$$\underset{(3a)}{C_6H_5\text{-}CH_2\text{-}Hg\text{-}I} + CH_2N_2 \xrightarrow[\text{quantitative}]{Et_2O,\ THF,\ 0\,^{\circ}C} \underset{(1a)}{C_6H_5\text{-}CH_2\text{-}Hg\text{-}CH_2\text{-}I} + N_2 \qquad (2)$$

IR (CCl_4): Bands at 1500—1600 (broad), 1490 (s), 1450 (s), 690 (s) cm^{-1}.

^{1}H-NMR ($CDCl_3$): δ = 2.25 ppm, singlet (2 H of the methylene group, satellite signals $J_{^1H-^{199}Hg}$ = 47 Hz[10]); 2.65 ppm, singlet (2 H of the benzyl group, satellite signals $J_{^1H-^{199}Hg}$ = 154 Hz[10]); 7.1—7.2 ppm, multiplet (5 H of the aromatic ring).

Benzylmercurioiodomethane *(1a)* reacts with olefins (molar ratio 1:1) under mild conditions to give benzylmercury iodide *(3a)* and cyclopropane derivatives *(4)* (R = R' = H) in accordance with eq. (1); duration of reaction a few minutes to a few hours at temperatures of 0—90 °C. Depending on the nature of the olefin (solid or liquid) the reaction can be carried out without or with solvent,

Table. Examples of typical cyclopropane syntheses with benzylmercurioiodomethane *(1a)*.

Olefin	Reaction conditions [a]	Product	Yield [b]
 *(2a)*	30 min/50	 *(4a)*	94
 *(2b)*	4 h/70	 *(4b)*	90
 *(2c)*	4 h/80	 *(4c)*	70
 *(2d)*	4 h/90	 *(4d)*	80
 *(2e)*	6 h/90	 *(4e)*	6
	several h/90		no reaction

[a] Molar ratio olefin : carbenoid *(1a)* = 1:1, no solvent. Quoted after the oblique is the bath temperature (°C).

[b] Referred to pure product in reactions using quantities of the order of 10 mmol.

e.g. benzene or tetrahydrofuran. The yield of regenerated *(3a)* is usually about 90%; the yield of *(4)* depends on the nucleophilic reactivity of the olefin *(2)* (Table).

The relative reactivity of the olefins increases with increasing nucleophilic character of the C=C bond. Up to now, no such reactions have been observed in the case of α,β-unsaturated carbonyl compounds and benzene.

The stereochemistry of the products is compatible with a *syn*-[1,2] addition on the unhindered side of the olefin.

Side reactions: So far, no insertions have been observed to take place into C—C or C—H bonds.

Experimental:

(All organomercury compounds are to be regarded as being very toxic. It is therefore recommended that relevant safety precautions should be taken).

Benzylmercury iodide

Benzylmercury bromide[11] (62.0 g, 0.167 mol) is dissolved in tetrahydrofuran (200 ml, previously distilled over CaH_2) at 40°C; to this solution is added a solution of pure sodium iodide (27.6 g, 0.184 mol) in anhydrous methanol (100 ml). The color changes to yellow and a white precipitate is formed. The solvent is removed from the mixture by evaporation in a rotary evaporator at a water-bath temperature of 30°C, and the residue thus obtained is taken up in benzene (400 ml, previously distilled over Na). After separation of undissolved sodium bromide (17.0 g), the filtrate is concentrated to 200—300 ml. On cooling, pale-yellow to orange crystals separate from the supersaturated solution. Yield 62.0 g (89%); m.p. 114—115°C; ^{1}H-NMR ($CDCl_3$): δ = 3.32 (s, 2H; no satellite signals), 7.2 (s, 5H).

Benzylmercurioiodomethane

A solution of benzylmercury iodide (4.19 g, 0.01 mol) in tetrahydrofuran (30 ml, previously distilled over KOH and $LiAlH_4$) is cooled to 0—5°C and a cold solution (*ca.* −10°C) of freshly distilled diazomethane in ether[12] is slowly added until liberation of nitrogen ceases. After five minutes the excess of diazomethane and solvent is removed by distillation in a rotary evaporator. After drying (18 h at room temperature/0.3 torr) there remains 4.33 g (100% yield) of a clear colorless oil.

Cyclopropane derivatives

Equimolar amounts of the liquid carbenoid *(1a)* and an olefin *(2a)*—*(2e)* are homogeneously mixed and heated under nitrogen. The progress of the reaction can be estimated from the amount of benzylmercury iodide which crystallizes out on cooling the mixture to room temperature; in the case of complete conversion the cooled reaction mixture is usually solid.

Readily volatile cyclopropanes such as 1-methoxybicyclo-[3.1.0]hexane *(4a)*, tricyclo[3.2.1.0^{2,4}]octane *(4b)*, and bicyclo[4.1.0]heptane *(4d)* can be recovered directly by distillation at 0.1 torr. Towards the end of the distillation the reaction mixture is warmed up (*ca.* 90°C). The benzylmercury iodide melts and further products are liberated. The residue consists of only slightly impure benzylmercury iodide *(3a)*, which can be recrystallized from benzene and re-used.

In the case of less volatile cyclopropanes such as tricyclo-[4.4.1.0^{1,6}]-3,8-undecadiene *(4c)* and *trans*-1,2-diphenylcyclopropane *(4e)* the reaction mixture is eluted with warm hexane. The less soluble benzylmercury iodide is not eluted, and the cyclopropane can be recovered from the eluate in pure form by distillation or chromatography.

X-Ray Photoelectron Spectroscopy of Iron-Containing Proteins—The Valency of Iron in Ferredoxins

By *Dieter Leibfritz*[*]

Determination of the valency of a metal ion in metal-containing proteins still presents difficulties. Investigation of such complexes by chemical reactions frequently leads to ambiguous results, and ESR and Mössbauer spectroscopy often prove to be of little use where these complexes are diamagnetic or Mössbauer-inactive. X-ray photoelectron spectroscopy (XPE spectroscopy or ESCA)[1], however, has no such limitations and can be used to investigate all metals and elements except hydrogen. For inorganic iron compounds, for example, the chemical shift of the

[**] Thanks are due to Prof. *E. Bayer*, Tübingen, Prof. *H. B. Gray*, Pasadena, and Dr. *M. P. Hagenmaier* for the supply of samples, to Dr. *W. Proctor*, Varian, Palo Alto, for the use of an IEE spectrometer, and to the Deutsche Forschungsgemeinschaft for a research stipend.

binding energy of the L_{III} level ($2P_{3/2}$) varies within a range of 6 eV[2]. The line-width also depends very much on the number of unpaired electrons[3]. The following is a report on the use of XPE spectroscopy in the investigation of biochemically important iron complexes.

Solutions of the ferredoxins *(1)*, *(2)*, and *(3)* from *Clostridium pasteurianum (C. pasteurianum)*, *Clostridium acidi-urici (C. acidi-urici)*, and Chromatium (high potential iron protein, HIPIP) were frozen onto the sample holder of the spectrometer, freeze-dried in the apparatus, and immediately measured to ensure that the oxidation state of the iron would not undergo any changes. The ionization energies obtained are listed, together with data for some model compounds, in the following table.

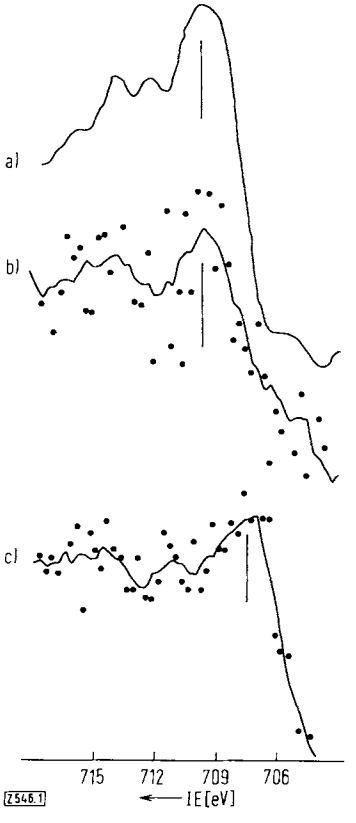
	Compound	IE [eV]	Oxidation State Fe
(1)	*(C. pasteurianum)*	710.0	+3
(2)	*(C. acidi-urici)*	709.9	+3
(3)	(HIPIP)	708.2	+2
(4)	Iron phosvitin	711.0	+3
(5)	Hemin chloride	710.2	+3
(6)	Salen	710.1	+3
(7a)	(oxidized)	710.3	+3
(7b)	(reduced)	707.9	+2
(8)		708.5	+2
(9)		711.8	+3

The iron in the bacterial ferredoxins *(1)* and *(2)*, which occur on isolation in the oxidized form[4], has an ionization energy approximately 2 eV higher than the iron in the reduced form of *(3)*. Even though the absolute values of the ionization energies yielded little information (the various influences of the ligands on lower energy levels cannot generally be determined quantitatively) they should still agree with the ionization energies of model complexes if their structural and physical properties are similar to those of the ferredoxins. The dimeric "dithiolene"-iron complexes, *e.g. (7)*, are often used as suitable model compounds[5].

(7)

The oxidized form of compound *(7)*, *i.e.*, *(7a)*, is in the formal oxidation state +3 (reduced form *(7b)*: +2). The ionization energy of *(7a)* agrees, within experimental error, with the ionization energies of the bacterial ferredoxins, while *(7b)* corresponds closely to the reduced form of HIPIP *(3)*.

Regarding arrangement of the 6—8 Fe atoms in Clostridian-ferredoxins, two models are discussed here: A linear arrangement of the metal ions with iron of different valency at the ends[6], or a cluster-like arrangement of the iron (two clusters having similar properties[7] or only one cluster[8]). According to the XPE spectra (see Figure), compounds *(1)* and *(2)* contain Fe ions of only one type with the identical, or almost identical, ionization energies as required by a cluster model. This is also in agreement with previous X-ray structural investigations[9]. Although the ionization energies of the ferredoxins *(1)* and *(2)* are relatively low for a formal iron(III) complex they are nevertheless in good agreement with a valence tautomeric cluster model, as proposed by *Bayer et al.*[10]. As previously shown by X-ray structural analysis[11], compound *(3)* also contains only one type of iron. (The peaks at 712 eV and higher in the spectrum of bacterial ferredoxin (see Figure) can be ascribed to plasma excitation and impurities.)



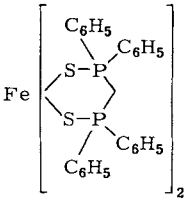


Fig. X-ray electron spectroscopy of the iron $2p_{3/2}$ level in the ferredoxins a) *(1)*, b) *(2)*, and c) *(3)*.

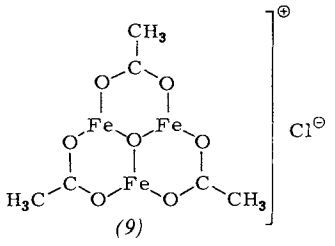
Generally, one can say that Fe^{III} with "soft" ligands[12] (sulfur, porphyrin skeleton) exhibits IE values of about 710.0 ± 0.5 eV (*(1)*, *(2)*, *(5)*, *(6)*, *(7a)*), whereas the values for Fe^{II} are about 708.0 ± 0.5 eV (*(3)*, *(7b)*, *(8)*).



(8)

If Fe^{III} is bound to "hard" ligands (*e.g.* oxygen), the IE values are shown to be 711.0 ± 0.5 eV—cf. "trimeric iron acetate" *(9)* or iron phosvitin *(4)*, where Fe^{III} is tetrahedrally surrounded by oxygen[13].

Considering the low proportion of iron (with reference to the molecular weight), the line-width in the spectra of ferredoxins is somewhat larger than in those of low-molecular iron compounds; nevertheless, it can be deduced that iron

must certainly be present in the low-spin state, for high-spin iron(III) exhibits considerably larger energy half-widths[2] (>1 eV). This is in agreement with magnetic susceptibility determinations[14] and Mössbauer spectroscopic investigations[6].

(9)

The sulfur spectra of *(1)*—*(3)* contain two lines (≈164.0 and ≈162.8 eV), the former being due to cysteine sulfur, the latter to labile sulfur.

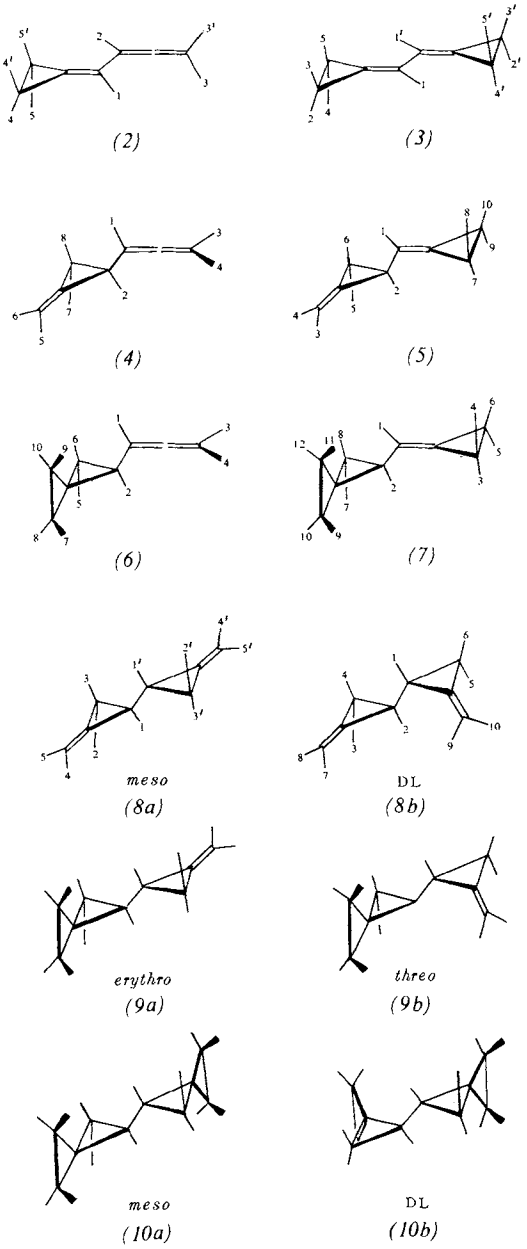
Cyclopropanation Products of Biallenyl

By *Friedrich Heinrich* and *Wolfgang Lüttke*[*]

In the course of our studies on the electronic interactions between conjugated double bonds, between directly linked three-membered rings[1], and between three-membered rings and double bonds[2] our interest was directed towards the compounds *(2)*—*(10)*. All these compounds should be directly accessible from a single starting material, *viz.* biallenyl[3]. All three kinds of interaction listed above are present: thus *(2)* and *(3)* contain the butadiene system, *(4)*—*(7)* a vinylcyclopropane moiety, and *(8)*—*(10)* the bicyclopropyl system.



[*] Dipl.-Chem. F. Heinrich and Prof. Dr. W. Lüttke
Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

In order to synthesize these novel hydrocarbons we have carried out the reaction of biallenyl *(1)* with diazomethane in the presence of copper(I) chloride. All twelve possible cyclopropanation products could be isolated by preparative gas chromatography.

(1)

Conversion of biallenyl was almost quantitative; about 10% of the resulting hydrocarbon mixture consisted of polymer. The relative yields of compounds *(2)*—*(10)* depend upon the excess of diazomethane used. With diazomethane and biallenyl (solution in *n*-pentane) in the molar ratio 5:1 the nonpolymeric portion of the reaction mixture was shown by gas chromatography to contain (in mol-%): 8% *(2)*, 3% *(3)*, 13% *(4)*, 9% *(5)*, 15% *(6)*, 13.5% *(7)*, 4.5% *(8a)*, 3.5% *(8b)*, 17% *(9a)* and *(9b)*[5], 11.5% *(10a)* and *(10b)*[5].

[a] Characteristic IR frequencies, measured with the neat liquids except for *(3)* (CCl_4 solution).
[b] Cf. UV data for dicyclohexylideneethane: λ_{max} = 259, 250, 241 [11].
[c] Assignment supported by double resonance experiments.
[d] The retention times of the diastereoisomers are utilized in assigning the compounds to the *meso* or DL forms: *(8a)* exhibits a longer retention time than *(8b)* on non-polar columns but a shorter retention time on polar GC columns. This tentative assignment is to be checked in a conformational analysis of *(8a)* and *(8b)*.

A mixture of *(10a)* and *(10b)* was prepared independently by oxidative dimerization of spiropentylmagnesium bromide with copper(II) chloride. NMR and IR data were identical with those given in the Table.

Satisfactory C, H analyses were obtained for all new compounds. The structures were assigned on the basis of their NMR, IR, UV, and mass spectra[6]; reference data were taken from the spectra of biallenyl[3], methylenecyclopropane[7], spiropentane[8], 1-bromomethylenecyclopropane[9, 10], 1-bromo-2-methylenecyclopropane[9, 10], and spiropentyl bromide[10]. The most important spectroscopic data for our compounds are summarized in the Table.

Compounds *(2)*—*(10)*, with the exception of *(3)*, are all liquids at room temperature; *(3)* is a solid. *(2)*, *(3)*, *(4)*, and *(5)* undergo polymerization when stored neat or in solution in a refrigerator; they are stable, however, at −70 °C.

Investigations of the thermal and photochemical properties, as well as a complete analysis of the spectra (with the aim, *inter alia*, of studying conformational equilibria), are currently in progress.

Experimental:

In a cyclopropanation reactor constructed according to *Gaspar* and *Roth*[4] were placed 5 g (0.064 mol) of biallenyl, 5 ml of pentane and 300 mg of cuprous chloride. Diazomethane was generated from nitrosomethylurea [a total of 47 g (0.46 mol) of nitrosomethylurea was used within 7 hours] and blown, by means of a steady stream of nitrogen, into the reaction mixture, which was cooled in an ice/water bath. The reaction mixture was trap-to-trap distilled

under vacuum and separated by preparative scale gas chromatography using a Varian Aerograph Model 90 P4 gas chromatograph [columns: 3 m 10% SE 30 on Chromosorb W DMCS (60/80 mesh) and 3 m 15% 1,2-bis(β-cyanoethoxy)ethane on Chromosorb W DMCS (80/100 mesh)].

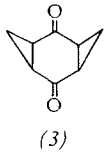
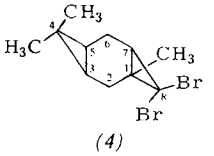
Synthesis and X-Ray Structure Analysis of *anti*-1-Bromotricyclo[5.1.0.0^{3,5}]octane-2,6-dione (*anti*-1-Bromobishomoquinone)

By *Jürg Heller, André S. Dreiding, Rita Grieb,* and *Alfred Niggli*[*]



In a preliminary communication[1] we described the synthesis of *anti-* and *syn*-bishomoquinone *(2)* and *(3)*. In connection with certain calculations[2] and with a study of their spectroscopic properties (NMR, IR, UV) as well as those of *anti*-1-bromobishomoquinone *(1)* it was of interest to confirm the previously assigned configurations and to establish the preferred conformations.

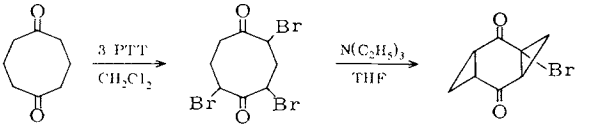


(1)

(2)

(3)

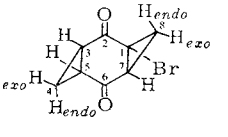
(4)



In the bishomoquinone series the conformation of the central ring is of special significance, since the possibility exists that a multi-conjugative interaction can take place between the cyclopropane units and the carbonyl groups[3,4]. It follows from theoretical considerations[4,5] and from experimental observations[6] that the torsional angle about the single bond between a carbonyl and a cyclopropane group influences the magnitude of the conjugative effect between these groups. In the bishomoquinones four such torsional angles are determined by the conformation of the central ring.

If two opposite pairs of adjacent C-atoms in a six-membered ring are each doubly bonded or form part of a three-membered ring, then the six-membered ring assumes a very flat boat conformation[7]. This was shown, with certain reservations (instability of the crystal in the X-ray beam), in a recent X-ray structure analysis by *Reck*[8] of *anti*-8,8-dibromo-1,4,4-trimethyltrichloro[5.1.0.0^{3,5}]octane *(4)*, which crystallizes with three molecules in the unit cell, each molecule having a slightly different conformation: The two mean planes, one defined by C1, C2, C6, and C7, and the other by C2, C3, C5, and C6 in the three conformations enclose a dihedral angle of 180.5, 186.1 or 177.7°, ±4.6°, showing a maximum deviation from coplanarity of about 6.1°.

Since the C—C—C angle at carbonyl groups is larger than the C—C—C angle at methylene groups in equally strained systems an even higher degree of flattening of the six-membered ring is to be expected in the bishomoquinones than in saturated tricyclo[5.1.0.0^{3,5}]octanes such as *(4)*. In the case of *anti*-bishomoquinone *(2)*, however, the measured dipole moment of 1.4 D excludes the possibility of the central ring having a planar conformation[9]. We therefore subjected compound *(1)* to an X-ray structural analysis and found that there is a small, but significant deviation from planarity in the six-membered ring (Fig. 2). In Table 1 the positions of the atoms in *(1)* are described with reference to a mean ring plane in order to permit a direct comparison with the results obtained by *Reck*[8] for *(4)*. The dihedral angle between the two mean planes in *(1)* as defined by *Reck*[8] (see above) is about 5.8° (mean error not determined).



Synthesis of anti-1-bromobishomoquinone (1)

In the bromination of cyclooctane-1,5-dione *(5)*[10] with three equivalents of phenyltrimethylammonium tribromide (PTT)[11] in methylene chloride (25 °C, 1 h) a non-crystal-

(5) *(6)* *(1)*

lizable mixture of products is formed which presumably consists of the stereomeric tribromides *(6)* contaminated with dibromo- and tetrabromo-derivatives of *(5)*. Reaction of this mixture with ten mole equivalents of triethylamine in tetrahydrofuran (THF) (25 °C, 1 h) brings about a double 1,3-dehydrobromination to *anti*-1-bromotricyclo-[5.1.0.0^{3,5}]octane-2,6-dione *(1)*, m. p. 166—167 °C, in 30% yield based on *(5)*.

The IR spectrum ($CHCl_3$) shows a weak absorption at 3020 cm^{-1} corresponding to the C—H stretch in the cyclopropane groups and a strong carbonyl band at 1707 cm^{-1}. The 100-MHz NMR spectrum in C_6D_6 solution consists of three groups of signals (integral ratio 1:3:3) and is interpreted as follows: $\delta = 1.94/d \times d$ (10.6, 6.4) (H—C7), 1.45 – 1.05/m (H—C3, H—C5), 1.09/d × d (10.6, −6.8) (*exo*-H—C8), 0.73 – 0.40/m (*exo*-H—C4, *endo*-H—C4), 0.65/d × d (6.4, −6.8) (*endo*-H—C8); ppm (Hz). The 100-MHz NMR spectrum in $CDCl_3$ solution contains four groups of signals (integral ratio 1:3:2:1) and is interpreted as follows: $\delta = 2.50/d \times d$ (10.6, 6.4) (H—C7), 2.40 – 2.05/m (H—C3, H—C5), 200/d × d (10.6, −6.8) (*exo*-H—C8), 1.76/t × d (9.4, −5.6) (*exo*-H—C4), 1.72/d × d (6.4, −6.8) (*endo*-H—C8), 1.44/t × d (5.5, −5.6) (*endo*-H—C4); ppm (Hz). The mass spectrum contains, in addition to the molecular ion peak with $m/e = 214$ (4%), the following important fragments: 146 (3.5) $M^+ - C_4H_4O$, 135 (24) $M^+ - Br$, 68 (21) $M^+ - C_4H_3OBr$, 67 (14) 146 – Br, 27 (100); *m/e* (%).

Compound *(1)* prepared by the above method is identical with the by-product of another reaction to which the *anti* configuration was assigned on chemical grounds[12].

X-ray structure analysis of (1)[13]

The compound crystallizes in the orthorhombic, non-centrosymmetric space group $Pca2_1$ with $a = 11.16$, $b = 8.69$, $c = 8.02_5$ Å; $d_{calc} = 1.834$ g/cm³: $Z = 4$.

Suitable crystals of *(1)* were examined with a Picker four-circle single crystal X-ray diffractometer; a total of 642 reflections were measured, of which 248 had intensities less than three times the standard deviation[14].

respectively (a difference within the range of experimental error). The angles C2—C1—Br, C7—C1—Br, and C8—C1—Br are 113.1, 117.5, and 117.3° (±1.1°) respectively.

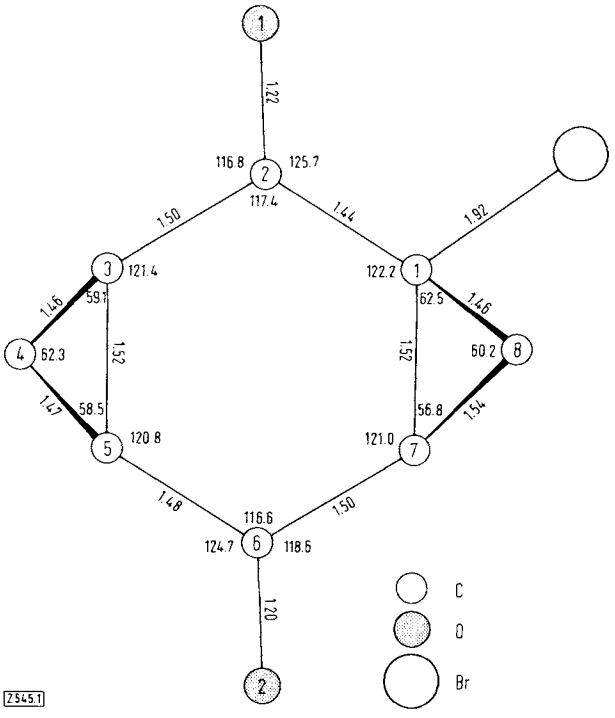

Fig. 1. Bond lengths and angles (average error 0.02 Å and 1.0—1.6° resp.).

Table 1. Deviations of the positions of the atoms of the central ring with respect to a least squares ring plane.

	Δ in Å referred to the least squares plane			
	(1)	*(4)* mol. I [8]	*(4)* mol. II [8]	*(4)* mol. III [8]
C 1	−.014	+.001	+.030	−.035
C 2	+.039	+.003	−.046	+.049
C 3	−.020	−.003	+.012	−.041
C 5	−.029	−.001	+.038	+.019
C 6	+.047	+.005	−.052	−.004
C 7	−.023	−.006	+.018	+.012
χ^2	27.69	0.04	4.41	3.28
ω (%) [a]	<0.05	>99.5	20–25	30–40

[a] ω is the percentage probability that a planar arrangement of the six atoms would give as large an χ^2 as that calculated (three degrees of freedom).

The special position of the bromine atom in the unit cell was unambiguously located by means of a Patterson synthesis. A subsequent three-dimensional Fourier synthesis by the heavy atom technique gave a quadruplication of the C- and O-positions due to the special position of the bromine atom, which, however, could be assigned unambiguously on the basis of the supposed architecture of the molecule.

Fig. 2 shows that the six-membered ring is almost planar. C2 and C6 protrude from the least squares plane of the six C atoms; this deviation from planarity is beyond the range of experimental error.

The angles between the least squares plane of the six-membered ring and those of the three-membered rings C1—C7—C8 and C3—C4—C5 are 75.28° and 77.25°

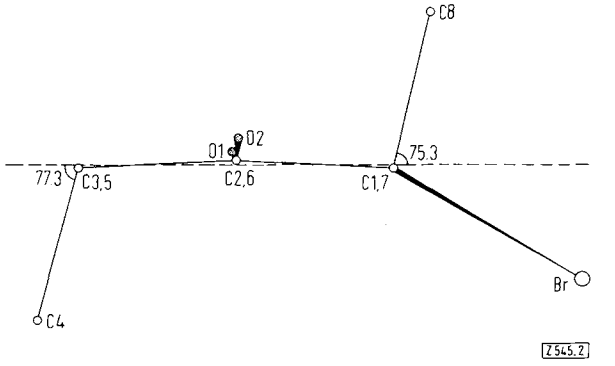

Fig. 2. Deviation of central six-membered ring from planarity (true to scale).

The small, but significant difference between the two O—C—C angles of each carbonyl group can be explained in terms of the intra- and intermolecular steric effects of the large bromine atoms (Fig. 1).

Transition Metal Carbene Complexes as π-Ligands—[Ethoxy-(2,6-dimethoxyphenyl)carbenetetracarbonyliron(0)]tricarbonyliron(0)[1]

By *Ernst Otto Fischer, Eberhard Winkler, Gottfried Huttner,* and *Dieter Regler*[*]

During our studies on the preparation of carbenecarbonyliron complexes we allowed pentacarbonyliron to react with 2,6-dimethoxyphenyllithium (molar ratio 1:1) at low temperature in tetrahydrofuran. After ethylation of the resulting acyl metalate, chromatography of the reaction

$$Fe(CO)_5 \xrightarrow[2.\ [(C_2H_5)_3O]BF_4/CH_2Cl_2]{1.\ C_6H_3(OCH_3)_2Li/THF} Fe_2C_{18}H_{14}O_{10}$$

product gave a small yield of deep red crystals whose total analysis showed them to have the composition $Fe_2C_{18}H_{14}O_{10}$ (m. p. 98 °C).

In accord with the above composition, the molecular ion appears at *m/e* 502 (based on ^{56}Fe) in the mass spectrum (50 eV, Atlas CH4). The fragmentation behavior of the compound indicates the presence of seven CO ligands. Correspondingly, the IR spectrum (KBr) contains seven ν_{CO} absorptions at 2083 s, 2025 vs, 2004 vs, 1981 vs, 1965 vs, 1935 s, 1895 m cm^{-1} which point to a low symmetry of the $Fe_2(CO)_7$ group. The band at 1895 cm^{-1} evidences a CO ligand having partial bridging character. ^{1}H-NMR studies unexpectedly show that a solution of the crystals contains two components, presumably in equilibrium. The spectrum ([D_6]acetone) shows a strongly split group of signals for the phenyl protons at 3.5—4.0 τ, three singlets at 5.59, 6.02, and 6.00 τ in the ratio 1:2:1, which can be assigned to the methoxy groups, and two triplets at 8.67 and 9.00 τ in the ratio 1:1 for the methyl protons of the ethoxy group. The signals of the methylene protons are masked by the very intense singlets of the methoxy groups.

These data were not sufficient to deduce the structure of the new compound. An X-ray structure analysis[2] indicated the geometry shown in the Figure.

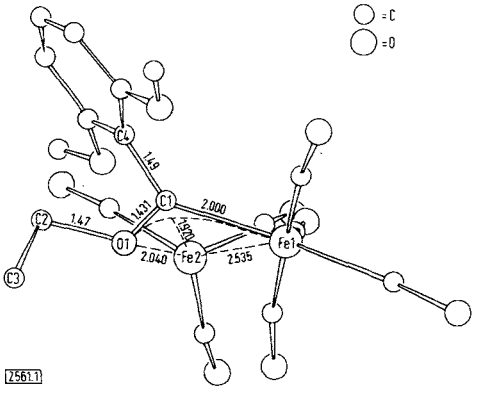

Fig. Structure of $Fe_2C_{18}H_{14}O_{10}$.

The molecule contains a tetracarbonylethoxy-(2,6-dimethoxyphenyl)carbeneiron moiety (central metal: Fe 1) that is linked to an $Fe(CO)_3$ group by the carbene system Fe1—C1—O1. In contrast to mononuclear carbene complexes, the carbene group is not strictly planar: The carbene carbon atom C1 protrudes by 0.197 Å from the best plane through the atoms Fe1, C1, C4, and O1. Nevertheless, the arrangement of the substituents on C1 is much closer to a trigonal-planar configuration than to a tetrahedral one. As a result of the π bonding to Fe2, the C1—O1 bond length, which is of the order of 1.33 Å in mononuclear carbene complexes[3], is increased to that of a C—O single bond. The compound can therefore be regarded as the first example of a complex in which the four-electron three-center π system located on the carbene system Fe1—C1—O1 acts as a π ligand towards the acceptor $Fe(CO)_3$. Further investigations on $Fe_2C_{13}H_{12}O_9$, a yellowish brown compound having m. p. 39 °C, are currently in progress to elucidate the ligand properties of carbene complexes.

Experimental:

1,3-Dimethoxybenzene (4.14 g, 30 mmol) in ether (50 ml) and *n*-butyllithium (30 mmol) in *n*-hexane (15 ml) are mixed at room temperature and stirred for 3 h. The resulting turbid yellow solution is added dropwise at −50 °C to $Fe(CO)_5$ (5.83 g, 30 mmol) in tetrahydrofuran (100 ml).

[*] Prof. Dr. E. O. Fischer, Dr. E. Winkler, Dr. G. Huttner, and Dipl.-Chem. D. Regler
Anorganisch-chemisches Laboratorium der Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

After removal of the solvent at −20 °C the deep red reaction mixture is dissolved in methylene chloride (20 ml) and treated at −20 °C with $[(C_2H_5)_3O]BF_4$ (5.70 g, 30 mmol) in methylene chloride (20 ml). The solvent is removed in a vacuum, the residue extracted with *n*-hexane, and the extract filtered and concentrated to a volume of 20 ml. Elution with *n*-hexane on a chromatographic column (2 × 55 cm; Merck silica gel) prepared with hexane and maintained at −10 °C gives unreacted $Fe(CO)_5$ and $Fe_3(CO)_{12}$, as well as a yellow unstable oil that has not yet been investigated. The next, deep red zone containing the novel complex is eluted with hexane/benzene (3:1). Recrystallization from pentane gives 250 mg of $Fe_2C_{18}H_{14}O_{10}$ (yield 1.6%).

The Universities of Aarhus, Hamburg, Kiel, Copenhagen, and Odense organised a German—Danish Symposium on Organic Chemistry at Odense (Denmark) on September 4 and 5, 1971.

From the lectures:

Structural Studies on Constituents of Umbelliferae[**]

By *Bent Eichstedt Nielsen*[*]

Coumarins, polyacetylenes, monoterpenoids, and sesquiterpenoids are examples of secondary plant constituents that frequently occur in Umbelliferae.

The coumarins found in Umbelliferae include numerous optically active compounds. The centers of chirality are usually situated in the isoprenoid side chains, which are linked either directly or *via* ether bonds to the aromatic skeleton. Isoprenoid C_5 side chains may also be incorporated into a condensed heterocyclic ring system, as *e. g.* in the dihydrofurocoumarins and dihydropyranocoumarins. Side chains and ring systems of this type are also found in other naturally occurring compounds, *e. g.* chromones, isoflavones, and quinoline alkaloids. Accordingly, investigations of the stereochemistry of these systems are of general interest. Furthermore, knowledge of the stereochemistry of the optically active coumarins is of interest for the study of their biosynthesis.

Chemical correlations have been used for the stereochemical investigations on coumarins. Either optically active degradation products were isolated and their configuration determined by synthesis and comparison with compounds of known configuration, or stereospecific syntheses were carried out.

A number of dihydrofurocoumarins and dihydropyranocoumarins contain two centers of chirality in the basic skeleton. One of these centers is at a benzylic carbon atom carrying either a hydroxyl or an acyloxy group which can be removed upon hydrogenolysis. The product of hydrogenolysis can be compared with corresponding compounds containing only one center of asymmetry whose configuration has been determined by degradation reactions. For the compounds with two centers of chirality, it is then only necessary to determine the relative configurations. This is achieved *e. g.* by spectroscopic studies on synthetic epimers or by observation of the thermal stability and of the reactivity toward mineral acids.

From our work on acetylenes and terpenoids, mention may be made of the determination of the configuration of the naturally occurring alkyne falcarinol and the isolation and structural elucidation of some monoterpene esters having a cyclohexadiene skeleton.

Catalysis by Phthalocyanine Complexes

By *Heinz Kropf*[*]

The phthalocyanine (Pc) complexes of Cu, Zn, Pd, Pt, Ag, Hg, Ni, Fe, Co, and Mn catalyze the initial step in the autoxidation of benzene hydrocarbons, *i. e.* chain initiation in the absence of hydroperoxide, by reaction of a metal-Pc—O_2 complex with the hydrocarbon. As soon as hydroperoxide is formed, other catalysis mechanisms are observed:

1. In the autoxidation of phenylalkanes and phenylcycloalkanes in the presence of the Pc complexes of Cu, Zn, Pd, Pt, Ag, and Hg, the metal-Pc—O_2 complex reacts with dimeric hydroperoxide to form alkylperoxy radicals; at higher temperatures, the Pc complex itself reacts with dimeric hydroperoxide. In the autoxidation of diphenylcycloalkanes, the bimolecular collision of the dimeric hydroperoxide on the catalyst surface can be detected. The relative reactivities of the phenylcycloalkanes and diphenylcycloalkanes can be explained by an extended I-strain theory.

2. The Pc complexes of Fe, Co, and Mn are deactivated by monomeric hydroperoxide as a result of the formation of a

[*] Prof. Dr. H. Kropf
Institut für Organische Chemie und Biochemie der Universität
D-2 Hamburg 13, Papendamm 6 (Germany)

Pc-hydroperoxide addition product. The known secondary catalysis occurs at the same time.

3. Ni-Pc is poisoned by chemisorption of products formed by a special chain termination reaction.

VO-Pc, on the other hand, catalyzes autoxidation entirely by decomposition of the dimeric hydroperoxide on the catalyst surface. In the presence of alkali metal-Pc, a base-catalyzed autoxidation occurs after a metal-hydrogen exchange with hydroperoxide.

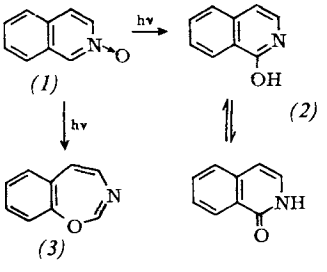
In the decomposition of cumyl hydroperoxide in the presence of Pc complexes, three groups of Pc complexes can be distinguished:

1. Fe, Co, and Mn complexes: the Pc complexes are attacked during the fast reaction.

2. Ni, Cu, Zn, Mg, and Al(OH) complexes: reaction proceeds much more slowly, and the Pc complexes remain unchanged.

3. VO-Pc: decomposition proceeds autocatalytically.

Finally, Pc complexes (Ni > Fe > Co > Cu) have been found to be hydrogenation, dehydrogenation, and hydrogenolysis catalysts in the system allyl alcohol/*n*-propanol/propionaldehyde/acrolein; the products formed on hydrogenolysis are propane, propene, and allene or propyne, depending on the Pc complex used. In the case of Cu-Pc, sudden changes in activity occur at 280—290 °C; these may be explained by phase transformations.



Photochemistry of Aromatic Amine Oxides

By *Christian Lohse*[*]

The photoisomerization of isoquinoline *N*-oxides such as *(1)*[1] to isocarbostyrils *(2)* in polar solvents and benz[*f*]-[1,3]oxazepines *(3)* in non-polar solvents could be shown to proceed *via* singlet excited states.

Earlier reports have explained the solvent effect on the product distribution in these rearrangements in terms of a possible oxaziridine intermediate. This compound could not be observed, in fact laser experiments showed the formation of isocarbostyril from isoquinoline *N*-oxide within the time of a laser pulse (20 ns)[2].

A triplet excited state of isoquinoline *N*-oxides was observed, and it could be shown that this state is responsible for the deoxygenation of the *N*-oxides to the parent amines. This process can be used for oxidation of organic compounds in their excited state to yield products different from those obtained by ground state oxidations.

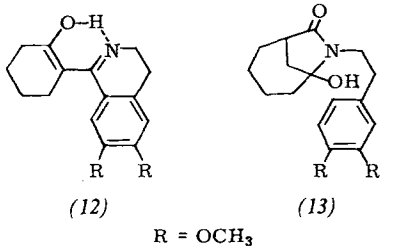
Rearrangements of Spirolactams with Synthetic *cis*- and *trans*-Erythrinanes as Example

By *Albert Mondon*[*]



Wolff-Kishner reduction of the bromo keto lactam *(1)* gives not only compounds having the erythrinane skeleton[1] but also products with rearranged ring systems, such as *(2)* and *(5)*. The structure of *(2)* is shown by the UV spectrum with $\lambda_{max} = 348$ nm ($\log \varepsilon = 4.28$), which is similar to that of 6-phenyl-α-pyridone and agrees with that of the synthetic structural isomer *(3)*[2]; an independent synthesis of *(2)* has recently been achieved[3], so that the structure of the rearrangement product has now been fully verified.

	X^1	X^2
(5)	H	OH
(6)	OAc	OAc
(7)	OAc	OMs
(8)	H	H

	X
(9)	COOH
(10)	H

R = OCH_3

Closely related to the structural elucidation of *(5)* are comprehensive studies on a phenomenon that was first observed for the dihydroxy lactam *(4)* and its diacetate *(6)*[4]. Though the acetylation and hydrolysis are trivial reaction steps, they each involve a rearrangement of the skeleton, which can be detected only through the NMR spectra. Whereas *(4)*, as a typical *trans*-erythrinane, gives two widely separated singlets for the two aromatic protons[5], *(6)* gives only one singlet for two protons at a relatively high field strength.

[*] Prof. Dr. A. Mondon
Institut für Organische Chemie der Universität
D-23 Kiel, Olshausenstrasse 40/60 (Germany)

Since the NMR spectra of *(5)* and its acetate agree with that of *(6)* in the region of the aromatic protons, *(5)* and *(6)* should have the same basic skeleton. The interconversion of these compounds has not yet been achieved, but the new ring system has been confirmed for *(6)* by degradation reactions and for *(5)* by independent synthesis of the compound containing no hydroxyl groups.

Degradation of the mesylate acetate *(7)* corresponding to the diacetate *(6)* to give the carboxylic acid *(9)* was recently reported[4]. Thermal decarboxylation leads to the saturated lactam *(10)* and to the unsaturated lactam *(11)*, which is formed by cleavage of the C—N bond and a hydrogen shift. An interesting reaction is the extensive rearrangement of *(9)* by dilute sulfuric acid, which leads on gentle heating to the excellently crystallizing yellow chelate *(12)*. The amide obtained from homoveratrylamine and 2,2-ethylenedioxy-1-cyclohexanecarboxylic acid also gives *(12)* on Bischler-Napieralski ring closure, and so confirms its structure.

The ring system of *(5)* can also be synthesized directly from 3-oxo-1-cycloheptanecarboxylic acid and homoveratrylamine *via* the hydroxy lactam *(13)* by ring closure with hydrofluoric acid[6]; the excellently crystallizing cyclization product *(8)* is found to be identical with the compound containing no hydroxyl group that is obtained from *(5)* on reduction of the tosylate[3].

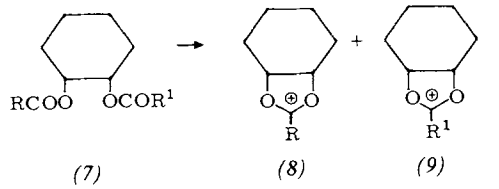
Rearrangement of Carbohydrate Esters with Anhydrous Hydrofluoric Acid

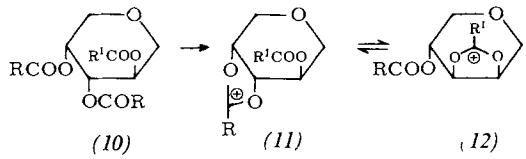
By *Christian Pedersen*[*]

Carbohydrate esters form glycosyl fluorides after reaction for a short time (approximately 15 min) with anhydrous hydrofluoric acid; longer exposure leads to further reactions. These reactions have been followed with the aid of the NMR spectra in hydrofluoric acid as the solvent.

(1) *(2)* *(3)*



(4) *(5)* *(6)*



[*] Prof. Dr. C. Pedersen
Organisk-kemisk Laboratorium
Danmarks tekniske Højskole
DK-2800 Lyngby (Denmark)

After reaction with HF for 24 hours, tetrabenzoylarabinopyranose *(1)* gives the benzoxonium ion *(2)*, which is converted into *(3)* on reaction for a further 3 to 4 days. The inversion on C-2 is thus followed by a ring contraction. When tetrabenzoylxylopyranose *(4)* is dissolved in HF, the very stable dibenzoxonium ion *(5)* is formed in the course of 24 hours, with inversion on C-2 and C-3.

Many other carbohydrate esters also react with inversion and/or ring contraction on treatment with anhydrous hydrofluoric acid. Thus some glucofuranose, mannofuranose, and glucopyranose derivatives give the same stable dioxolanylium ion *(6)* on treatment with HF for 24 to 48 hours.

(7) *(8)* *(9)*

(10) *(11)* *(12)*

To gain a better understanding of these reactions, the behavior of some model compounds toward HF was investigated. Esters of *cis*-1,2-cyclohexanediol react with HF to form dioxolanylium ions. If the mixed esters *(7)* are used as the starting materials, the isomeric ions *(8)* and *(9)* may be formed. Our investigations have shown that this reaction is kinetically controlled, and that the less stable ion is often formed. Thus the acetate nitrobenzoate *(7)*, $R=CH_3$, $R^1=p\text{-}NO_2C_6H_4$, yields only the nitrobenzoxonium ion *(9)*, $R^1=p\text{-}NO_2C_6H_4$, whereas the acetate methoxybenzoate *(7)*, $R=CH_3$, $R^1=p\text{-}CH_3OC_6H_4$, yields only the acetoxonium ion *(8)*, $R=CH_3$. *cis*-1,2-Cyclopentanediols behave similarly.

To determine the thermodynamic stability of the dioxolanylium ions, the reaction between esters of 1,5-anhydroarabinitol *(10)* and HF was investigated. *(10)* reacts with HF to give mainly the ion *(11)*, which exists in equilibrium with the isomeric ion *(12)*. The position of this equilibrium is an expression of the relative stabilities of these two ions. When *(10)*, $R=CH_3$, $R^1=C_6H_5$, is dissolved in HF, only the benzoxonium ion *(12)* is obtained (NMR spectrum). Only the acetoxonium ion *(11)*, on the other hand, is formed from *(10)*, $R=CH_3$, $R^1=p\text{-}NO_2C_6H_4$. From these and other experiments it can be concluded that the stabilities of the dioxolanylium ions vary as follows with the substituent on C-2: $p\text{-}NO_2C_6H_4 < CH_3 < C_6H_5 < p\text{-}CH_3OC_6H_4 = p\text{-}CH_3C_6H_4$.

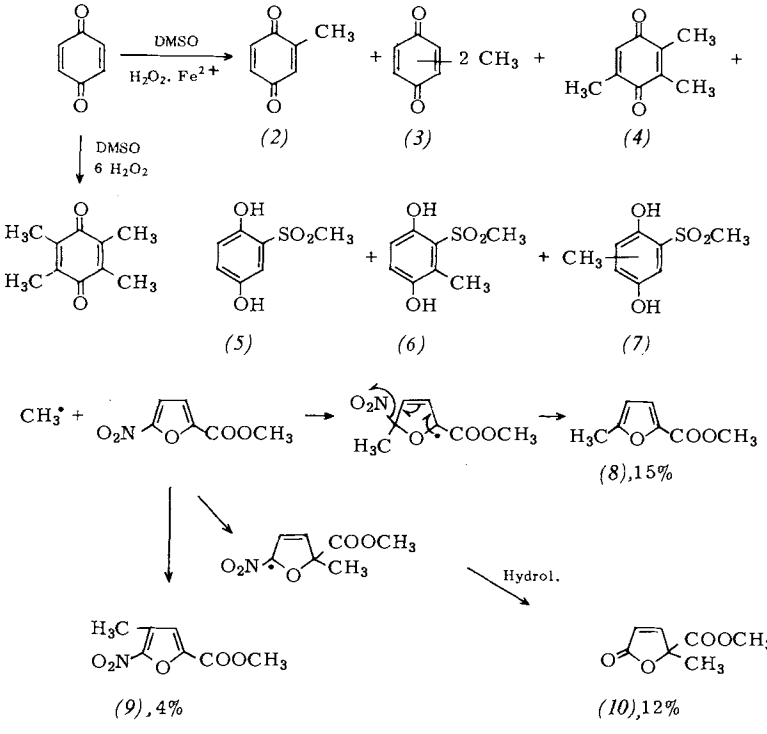
Free-Radical Alkylation with Sulfoxides and Fenton's Reagent

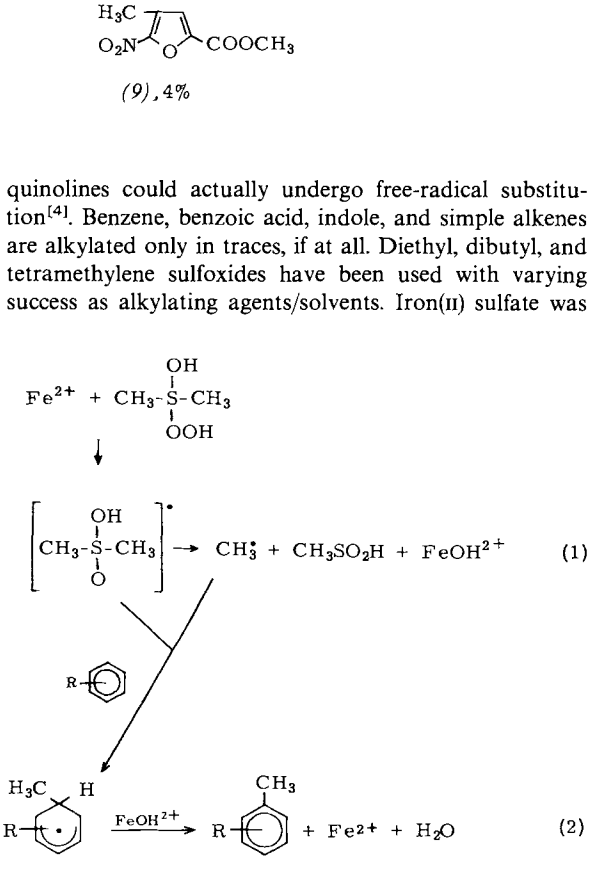
By *Kurt Torssell*[*]

Methyl radicals *(1)* are formed in the Fe^{3+}-induced decomposition of hydrogen peroxide in DMSO[1]. They have

[*] Prof. Dr. K. Torssell
Chemical Institute, University of Aarhus
DK-8000 Aarhus C (Denmark)

also been detected[3] by the nitroxide method[2], in a quantity so large that we found it interesting to check the reaction on a preparative scale.





(1)

The nitroxide method has been largely used in our laboratory for the detection and structural elucidation of radicals, and it is also suitable for use as a kind of "synthetic spectroscopy" for the interpretation of free-radical reactions. It was found that reactive substrates such as quinones, nitroaromatic compounds, thiophenes, furans, pyridines, and quinolines could actually undergo free-radical substitution[4]. Benzene, benzoic acid, indole, and simple alkenes are alkylated only in traces, if at all. Diethyl, dibutyl, and tetramethylene sulfoxides have been used with varying success as alkylating agents/solvents. Iron(II) sulfate was found to be most suitable as the catalyst. On photolysis of hydrogen peroxide in DMSO, the alkylated product was formed in a lower yield.

Trinitrobenzene gave *e.g.* trinitrotoluene (25 °C, 1.5 equivalents of H_2O_2, 0.2 equivalents of $FeSO_4$, 1 hour) in 67% yield. The products *(2)*—*(7)* were formed from benzoquinone. Methyl 5-nitrofuran-2-carboxylate gave the products *(8)*—*(10)*, the formation of which can be explained by free-radical attack on C-5, C-4, and C-2 respectively. The replacement of the nitro group by methyl is remarkable.

The reaction course can be represented by the reaction sequences (1) and (2).

EPR Spectroscopy as a Method of Conformational Analysis

By *Jürgen Voss*[*]

On the basis of the Heisenberg uncertainty principle

$$\Delta t \times \Delta H \geq 5.7 \times 10^{-8} \text{ gauss s}$$

it is shown that the EPR time scale allows the observation of states with lifetimes of the order of microseconds. Thus species that are converted into one another by rotation

[*] Dr. J. Voss
Institut für Organische Chemie und Biochemie der Universität
D-2 Hamburg 13, Papendamm 6 (Germany)

about formal single bonds appear as distinct isomers, and it is difficult to differentiate conceptually between conformers and configurational isomers.

This phenomenon is illustrated by the radical-anion of terephthalaldehyde. Its EPR spectrum shows the presence of a *cis* form and a *trans* form together, the lifetimes of these forms being 5×10^{-7} s[1]. Similarly, the preparation of biacetylsemidione yields a mixture of isomers in which the *trans* form predominates in a ratio of 95:5. The configuration can be assigned on the basis of steric considerations and particularly of the complex-forming properties (only the *cis* form gives a Li chelate)[2].

Conformation analysis in the true sense is possible by EPR spectroscopy with the aid of the relation

$$a_{CH}^{H} \approx B\,\rho_c \times \cos^2\theta$$

a_{CH}^{H} = HFS coupling constant

B = constant of proportionality $\quad\quad$ ρ_c = spin density

For example, from the coupling constants of the alkyl protons in the radical-anions of oxalic esters ("dialkoxysemidiones"), it is possible to determine the time-averaged dihedral angle θ between the C—H bond and the z axis of the π-electron system[3]. For primary alkyl groups, $\theta = 47°$, while for secondary alkyl groups, $\theta = 60°$; these values can be shown to be plausible by estimation of the space requirements from Newman projections. This also provides an explanation for the surprisingly small value $\theta = 42°$ for the neopentyl ester, while the deviation from the normal in the case of the cyclobutyl derivative ($\theta = 49°$) is attributed to ring strain.

An example of the determination of a dynamic quantity is the calculation of the activation energy $E_a = 8.6 \pm 0.5$ kcal/mole for the rotation of the angled NO group of the nitrosobenzene radical-anion from the temperature dependence of its EPR spectrum[4].

Reactions and Compounds with Molecular Nitrogen

By *Wilhelm Preetz*[*]

It has recently been shown that molecular nitrogen, which was previously considered to be very inert, can undergo a number of chemical reactions under mild conditions. Because of the importance of nitrogen assimilation in Nature, a great deal of interest has been shown in the search for models displaying the ability to bind nitrogen. Since transition metal ions appear to play a key role in the enzymatic fixation of nitrogen attention has mainly been directed to the following two possibilities:

1. Complexes with elements of the higher sub-groups, *i.e.* of the type $[Ru(NH_3)_5(N_2)]Cl_2$, which were discovered by *Allen* and *Senoff*[1];

2. The binding of nitrogen by Ziegler catalysts, *e.g.* Cp_2TiCl_2 (Cp = π-cyclopentadienyl), and reduction to ammonia in the presence of organomagnesium compounds, as was first reported by *Volpin* and *Shur*[2].

Comparison of the electronic structure of the N_2 molecule with those of the isoelectronic ligands CO, CN^-, C_2H_2, and NO^+ reveals only slight differences. Because of its stable triple bond, low polarizability, and weak donor properties, the N_2 molecule is the least conducive to bonding. The best partners prove to be metal ions having a fully occupied t_{2g} level (d^6 system) in which the electrons are not too firmly bound. The most favorable of such partners are, therefore, low-valency transition metals of the higher groups which are able to effect back-bonding on donation of electrons to the unoccupied π^*-state of the N_2 molecule. A maximum stability seems to occur with Os^{II}.

In the complexes previously isolated and characterized by structural analysis, the nitrogen is bound to the metal ion in the direction of its molecular axis ($M \leftarrow :N \equiv N:$; "end on"). In the case of enzymatic nitrogen fixation, however, bonding *via* the π-system perpendicular to the molecular axis ($M \leftarrow \overset{\ddot{N}}{\underset{\ddot{N}}{|||}}$; "edge on") must be taken into consideration since, *e.g.*, C_2H_2 inhibits uptake of N_2. All mononuclear nitrogen complexes (the known symmetrical binuclear complexes[3] of the type M—N≡N—M are excluded here) show an intense, sharp IR band in the range 2050—2150 cm^{-1}, which is indicative of an "end on" bonded N_2 molecule. Compared with the known stretching vibration at 2331 cm^{-1} in the Raman spectrum of free N_2, a long-wave shift of about 200—250 cm^{-1} is observed in the case of nitrogen complexes, corresponding to the loosening of the bond between the N atoms; simultaneously the N—N bond length, which is 1.098 Å in the free molecule, increases by about 0.02 Å. The degree of loosening of the bond—as shown by IR spectroscopic investigations—is very much dependent on the nature of the nearest and near neighbors.

All nitrogen complexes are reactive and therefore suitable for planned substitution reactions. Much preparative work remains to be done to establish the most favorable metal ions for bonding to N_2 and the most suitable ligand environment, thus opening a wide new field of study in coordination chemistry.

Lecture at Kiel on October 28, 1971 [VB 332 IE]
German version: Angew. Chem. *84*, 267 (1972)

[*] Prof. Dr. W. Preetz

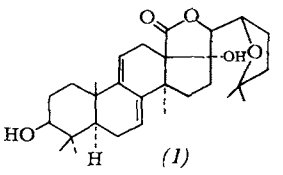
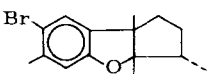
Structure of coordinated nitrate groups in complexes with specific metal-nitrate interactions is considered by *C. C. Addison, N. Logan,* and *S. C. Wallwork.* The ligand NO_3 can engage in several different kinds of bonding: it can act as a monodentate to terdentate, in each case symmetrical or unsymmetrical, ligand or assume a bridging function. Thus $Co(NO_3)_3$ contains symmetric and $[Co(NO_3)_4]^{2-}$ unsymmetric bidentate NO_3 groups. Monodentate NO_3 ligands are present in $[Au(NO_3)_4]^-$ while α-$Cu(NO_3)_2$ contains NO_3 bridges. Apart from the factors that could be responsible for the kind of coordination in a given compound, the authors discuss the stereochemistry of the compounds and their vibrational spectra. [Structural Aspects of Co-ordinated Nitrate Groups. Quart. Rev. Chem. Soc. *25*, 289—322 (1971); 85 references, 14 figures, 13 tables with numerous examples]

[Rd 421 IE -E]



The chemistry of disulfur monoxide is reviewed by *A. R. Vasudeva Murthy, T. R. Narayanan Kutty,* and *D. K. Sharma* (up to 1970). Sulfur combines with oxygen to give a variety of oxides, the formation of those having high sulfur contents of the formula S_xO, $x = 2$—7, having been studied relatively little. Such lower oxides probably tend to undergo polymerization. Studies of the sulfur-oxygen system under varying conditions of temperature and pressure could possibly also provide an insight into atmospheric pollution by sulfur oxides.—S_2O can be prepared by combustion of S in O_2 at reduced pressure, by reaction of sulfur vapor and SO_2 in an electric discharge, by reaction of a metal oxide with S, and from sulfur-halogen compounds. Its properties are discussed in detail. [Chemistry of Disulfur Monoxide. Internat. J. Sulfur Chem. *6*, 161—175 (1971); 76 references]

[Rd 456 IE -M]



The UV spectroscopic properties of simple compounds having N—N and N—O bonds are surveyed by *J. Kuhn, W. Hug, R. Geiger,* and *G. Wagnière.* The electronic structure of NO, aminoxyl, nitrosomethane, azomethane, trimethylamine oxide, azomethane *N,N'*-dioxide, NO_2, nitromethane, nitroethylene, and methyl nitrite was determined by a SCF CI calculation including all valence electrons that was performed by the CNDO method; essential agreement was obtained between the calculated and measured spectrum. Furthermore, predictions could be made regarding the symmetry and relative energy levels of nonbonding orbitals. [Die elektronische Struktur einfacher stickstoff- und sauerstoffhaltiger Verbindungen. Helv. Chim. Acta *54*, 2260 to 2277 (1971); 28 references]

[Rd 457 IE -M]

Toxins from marine invertebrates, *i.e.* from echinoderms and mollusks, are the subject of a review by *P. J. Scheuer.* Heightened interest in this field became apparent about ten years ago; nevertheless, our knowledge of the chemical constituents of marine organisms is incomparably more sketchy than the information available about those of terrestrial fauna and flora. The physiologically active substances of the echinoderms are mainly triterpenoid glycosides: holothurins [aglycones: holothurinogenins, *e.g. (1)*] and asterosaponins. The active constituents of

(1)

(2)

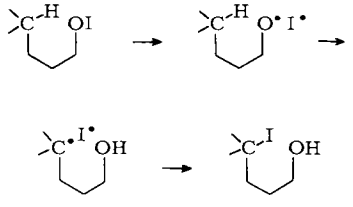
the mollusks are primarily sesquiterpenes; aplysins, *e.g. (2)*, constituents of the digestive gland. [Toxins from Marine Invertebrates. Naturwissenschaften *58*, 549—554 (1971); 48 references]

[Rd 458 IE -M]

Aromatic amino acids in the metabolism of higher plants are discussed in an article by *H. Kindl.* The metabolism of higher plants is characterized by a great variety of reactions and by a remarkable specificity with regard to species. Aromatic amino acids and their derivatives undergo, *e.g.*, chain lengthening by one C atom or are degraded to benzoic acid derivatives, phenols, and aliphatic compounds. The hydroxylation reactions differ considerably from those in mammalian tissues. The genus- and species-specificities of numerous reaction sequences are so pronounced that chemical-taxonomic demarcations can often supplement morphological findings. [Aromatische Aminosäuren im Stoffwechsel höherer Pflanzen. Naturwissenschaften *58*, 554—563 (1971); 157 references]

[Rd 459 IE -M]

The use of polyphosphoric acid for the synthesis of polymeric aromatic heterocycles by cyclopolycondensation reactions is reviewed by *N. Yoda* and *M. Kurihara.* The new types of polyheterocycles which can be prepared by these methods are discussed in detail, as is also the mechanism of macromolecular syntheses in phosphoric acid solutions. Examples of such polymeric aromatic heterocycles which can be prepared by these methods are: polybenzoxazinones, polyquinazolinediones, poly-4-phenyl-1,2,4-triazoles, polybenzimidazoles, and polybenzothiazoles. Polyimidazopyrrolones, polybenzimidazobenzophenanthrolines, polyisoindoloquinazolinediones, and spiropolyimides can be prepared by double cyclization. [New Polymers of Aromatic Heterocycles by Polyphosphoric Acid Solution Methods. Macromol. Rev. *5*, 109—193 (1971); 111 references]



[Rd 468 IE -M]

Oxidation, reduction, and addition reactions of sulfenyl halides are reviewed by *E. Kühle.* The recent increase in the number of publications concerned with this topic is due partly to the industrial availability of trichloromethanesulfenyl chloride and its derivatives and to the synthesis of new types of sulfenyl halides. Addition takes place with multiple bonds (C=C, C≡C, C=N, C≡N, C=O, C=S) and small rings (oxiranes, thiiranes), *etc.* Addition-elimination reactions are also considered, *e.g.* to diazo compounds with elimination of N_2 and to C=S and P=S bonds with elimination of alkyl halide. Preparative examples are given for the reaction discussed. [One Hundred Years of Sulfenic Acid Chemistry. Oxidation, Reduction, and Addition

Reactions of Sulfenyl Halides. Synthesis *1971*, 563—586; 176 references]

[Rd 463 IE –M]

The hypoiodite reaction, a versatile method for intramolecular substitution of non-activated centers, is discussed in a review by *J. Kalvoda* and *K. Heusler*. The reaction permits, *e.g.* the synthesis of tetrahydrofuran, lactone, and γ-cyano ketone groupings, even on complicated skeletons such as steroids. Essential features of the reaction are the *in situ* formation and homolysis of a RO—I bond and subsequent reactions of the resulting alkoxy radicals. Several reaction schemes are discussed and a series of experimental examples is given. The course of the reaction can be represented by a reaction scheme formulated by *D. H. R. Barton:*

Compounds containing, *e.g.*, ONO, OCl, OBr, or NHI in place of OI react analogously. [Die Hypojodit-Reaktion (Verfahren zur intramolekularen Substitution an nicht-aktivierten C-Atomen). Synthesis *1971*, 501—526; 152 references]

[Rd 461 IE –M]

The occurrence of polychlorobiphenyls and their environmental significance are reviewed by *R. Edwards*. The chlorinated hydrocarbons used as pesticides and the polychlorobiphenyls have many common properties; however, the latter are considerably more stable, both chemically and thermally. They have been widely used industrially since about 1930 and are carried into rivers and the sea in waste water. An increasing number of studies are concerned with their occurrence in the environment and with their toxicology, particularly regarding possible long-term effects. The pronounced resemblance to a number of pesticides causes interference in analyses. [The Polychlorobiphenyls, their Occurrence and Significance: A Review. Chem. Ind. (London) *1971*, 1340—1348; 70 references]

[Rd 460 IE –M]

Oxidation of alkenes with mercury(II) salts is the topic discussed in a review by *H. Arzoumanian* and *J. Metzger*. Alkenes react with Hg(II) salts in an addition reaction (solvomercuration) or in a redox reaction with oxidation of the alkene and reduction of the mercury. The oxidation products vary widely with the substrate: α-alkenes give α,β-unsaturated carbonyl compounds; alkenes having no terminal methylene group (linear disubstituted alkenes, cyclic alkenes, phenyl-substituted alkenes) afford various oxidation products depending upon the substituents; and conjugated dienes yield α,β-unsaturated carbonyl compounds and unsaturated cyclic ethers. [Oxidation of Olefins with Mercuric Salts. Synthesis *1971*, 527—536; 69 references]

[Rd 462 IE –M]

The polymerization of vinyl- and related compounds in the presence of sulfur compounds is dealt with in a review by *P. Ghosh*. For example, peroxy compounds, diazothioethers, sulfonyl azides, organic sulfoxy compounds, sulfuric acid, sulfuryl chloride, salts of reducing sulfoxy compounds, and thioureas are suitable as polymerization initiators. Compounds that can be used as initiators and/or modifiers for the polymerization are, *inter alia*, sulfur, organic sulfides, and H_2S. Dimethyl sulfoxide can be used as both initiator and solvent for the polymerization. The author also discusses the copolymerization of sulfur chlorides with diolefins and the synthesis of polymers containing sulfoxy groups. [Participation of Sulfur Compounds in Vinyl and Related Polymerization. Macromol. Rev. *5*, 195—227 (1971); 131 references]

[Rd 469 IE –M]

The coordination chemistry of scandium is treated comprehensively in a review by *G. A. Melson* and *R. W. Stotz*. The known coordination compounds are arranged in groups according to the donor atoms oxygen, nitrogen, and halogen. Generally scandium prefers the coordination number six, *i.e.*, the stereochemistry of an (often distorted) octahedron. However, the occurrence of coordination numbers other than six is not ruled out. Very few details of structures and bonding properties are known. [The Coordination Chemistry of Scandium. Coord. Chem. Rev. *7*, 133—160 (1971); 225 references, 6 tables]

[Rd 476 IE –H]

The application of magnetic resonance methods in the elucidation of bonding properties of transition metal compounds is reviewed by *D. R. Eaton* and *K. Zaw*. Electron spin resonance (ESR) and nuclear spin resonance (NMR) provide the investigator with complementary information, since ESR measures modifications of central ion energy states caused by the ligands, whereas NMR sees shifts of ligand transitions caused by the central ion. The theory of ESR and NMR and results on selected transition metal compounds are given. [Magnetic Resonance Methods in the Study of the Electronic Structures of Transition Metal Complexes. Coord. Chem. Rev. *7*, 197—227 (1971); 189 references, 3 figures, 5 tables]

[Rd 478 IE –H]

Leitfaden der Farbstoffchemie (A Guide to Dyestuffs Chemistry). By *P. Rys* and *H. Zollinger*. Chemische Taschenbücher Vol. 13. Edited by *W. Foerst* and *H. Grünewald*. Verlag Chemie GmbH, Weinheim/Bergstr. 1970. 1st Edit., xi, 220 pp., 16 illustrations, 16 tables, paperback DM 22.—.

The present book classifies dyes according to their chromophore systems into azo, nitro and nitroso, polymethine, aza-[18]annulene, di- and triarylcarbonium, sulfur, and carbonyl dyes. Each group has its own chapter and comprehensive introductions are given.

The more general and theoretical chapters give details of reaction mechanisms, the relationship between chemical composition and color, color measurements, and the thermodynamic and kinetic principles of application.

The text is concise but clear and ample references are given. The book is a valuable and useful piece of work, based on the principles of modern organic and physical chemistry.

Udo Mayer [NB 25 IE]

Kleines Chemisches Praktikum (Small Chemical Laboratory Manual). By *E. Dane* and *F. Wille*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. 7th Edit., xii, 189 pp., 23 illustrations, paperback, DM 19.80.

Significantly, the student will often refer to much used textbooks or laboratory manuals simply by the names of their authors. This also applies to "Dane/Wille", which is now in its 7th revised edition. In 190 pages, this attractive, handy, and well-produced book deals with about 400 experiments and explanations, inculcating a basic knowledge of inorganic chemistry. The subject matter is arranged according to classical principles: in the inorganic section according to the periodic system, supplemented by chapters on atomic structure, chemical bonding, equilibrium, electrolytes, oxidation and reduction, acids and bases, and qualitative and quantitative analysis; and in the organic section according to the sequence of compounds by functional groups (still usual in the majority of basic textbooks), supplemented by chapters on plastics, chromatography, qualitative organic analysis, resonance and substitution in aromatic substances.

When it first appeared (1960) "Dane/Wille" heralded a new approach for books of this type: its concise presentation of the subject matter and its description of experiments pointed a new way to the reform of chemistry teaching for medical students (the methods used then varied much more from university to university than they do now).

However, "Dane/Wille" can nowadays really be appreciated only from the historical point of view; as shown by the new regulations for the certification of doctors, since the book was first published the modern concept of "concentrating" the subject matter has taken precedence over the classical principle of "spreading out" the material, because this is the only way of bringing the teaching of fundamental physical and chemical principles in the preclinical part of a medical course into line with the further biochemical, physiological-chemical, and general practical needs of the student. Thus, for a practical course it would seem essential to open up well-defined and specific fields of interest by means of appropriate experimental work and to teach critical assessment of the results—if possible by further experiments. This, however, tends to shift the emphasis of the practical and theoretical teaching of a very wide subject to an in-depth examination of specific problems.

In this connection it should be mentioned that the above approach has already found expression in another book, "Chemie für Mediziner" (Chemistry for Medical Students) by *K. Beyermann*. A similar approach was adopted even earlier in the brochures on laboratory work for medical students written by *K. Dimroth* and *C. Mahr* or by *G. Hartmann* and *S. Hünig* on the Marburg and Würzburg models respectively. If we go by the criteria that form the basis of the above concepts of medical training—and these have for several years proved very successful—then "Dane/Wille" can no longer meet the requirements for a modern laboratory manual, in spite of the services it has rendered in the past.

Theophil Eicher [NB 26 IE]

Gmelin-Durrer: Metallurgie des Eisens (Metallurgy of Iron). Fourth fully revised edition, continued by *G. Trömel*. Supplement to Gmelins Handbuch der anorganischen Chemie, 8th Edit., System No. 59, "Iron", Part A, Volumes 3 to 5, Verlag Chemie GmbH, Weinheim/Bergstr. 1968. Volume 2. General Requirements for the Industrial Reduction of Iron Ores. Raw Materials. The Industrial Processes Apart from the Blast Furnace, Volume 2a: Text Part, vi, 350 pp., Volume 2b: Figure Part, iv, 188 pp., 452 figures cloth, together DM 492.—.

The present volume concludes the discussion of the raw materials for the reduction of iron ores and their preparation prior to smelting. The industrial reduction methods are then discussed, apart from those that are carried out in the blast furnace. As in the other volumes of the 4th edition, the text part and the figure part are separate in volume 2, which was produced with the aid of data from the European Coal and Steel Community.

The first part contains the following sections: Physico-Chemical Principles of the Reduction; Survey of Raw Material Requirements; Survey of the Principal Deposits of Iron and Manganese Ores; Properties of Iron Ores and Iron Ore Agglomerates that are Important for the Industrial Reduction; Survey of the Production of Coal and Lignite Cokes. The second part contains the sections Reduction in the Low Shaft Furnace; Reduction in the Electric Furnace; The Direct Reduction Processes; The Uses of Pre-Reduced Materials.

A very comprehensive subject index in German and English makes it easy to find the various processes.

The literature is evaluated up to, and in some cases beyond, Spring 1967.

Ekkehard Fluck [NB 29a IE]

Gmelin-Durrer: Metallurgie des Eisens (Metallurgy of Iron). Fourth fully revised edition, continued by *G. Trömel* and *W. Zischkale*. Supplement to Gmelins Handbuch der anorganischen Chemie. 8th Edit., System No. 59, "Iron",

Part A, Volumes 3 to 5, Verlag Chemie GmbH, Weinheim/Bergstr. 1971. Volume 3, Part 1. Blast-Furnace Installations. Blast-Furnace Operation. Pig Iron and By-Products. World Pig-Iron Production Situation. Volume 3a: Text Part, vi, vii, 320 pp., Volume 3b: Figure Part, vi, i, 137 pp., 304 figures, cloth, together DM 487.—.

The present volume of "Gmelin-Durrer" has been written by engineers from West German ironworks and from the Verein Deutscher Eisenhüttenleute in collaboration with the Institut für Eisenhüttenwesen der Technischen Universität Clausthal and the Gmelin-Institut in Frankfurt. Together with Volume 4, which is still in preparation, it deals with blast furnace installations. As can be seen from the sections described below, Volume 3 is also concerned with iron production practice, blast furnace products, and world iron production data.

The first section deals with the blast furnace installation and the topics discussed include furnace types, blast furnace profiles, the refractory lining of blast furnaces and hot metal ladles, the cooling of blast furnaces, blast production and air heating, monitoring of the blast furnace operation, the casting bay, and finally the purification of blast furnace gases. Blast furnace operation, *i.e.* the practice of pig-iron production, the production of special steels, and the treatment of the pig iron outside the blast furnace, forms the subject of the second section. Considerable space is given in this section to the processes for the removal of phosphorus and sulfur from the liquid pig iron. The products from the blast furnace, *i.e.* pig iron, blast furnace slag, blast furnace gas, and blast furnace flue dust, are described in the third section. The final section begins with a comparison of blast furnace operating results, and continues with a discussion of world pig iron production, locations of ironworks, raw material supply, raw material treatment, characteristic running parameters *etc.*

As in the earlier volumes of the 4th edition, the text part and the figure part of the present volume are separate.

The literature is evaluated up to, and in some cases, beyond 1968/1969.

Ekkehard Fluck [NB 29b IE]

Knauers Buch der modernen Chemie (Knauer's Textbook of Modern Chemistry). By *J. Rudolph*. Droemersche Verlagsanstalt Th. Knauer Nachf., München 1971. 1st Edit., 360 pp., 285 illustrations (mostly in color), bound, DM 22.—[*].

This book serves two purposes. On the one hand it provides a comprehensive introduction to the fundamentals of chemistry and hence is a useful tool for the layman who, perhaps as a student, is trying to learn some chemistry or to refresh his memory on what he once knew but has now forgotten. On the other hand, it guides the reader quickly and very skilfully *via* the basic principles of the subject to many modern problems which are being actively pursued in research laboratories or which, because of their importance in our everyday life, are felt to be in urgent need of solution.

Among the subjects treated are atomic structure, new elements, orbitals, Hückel theory, cyclopropenylium ion and cyclobutadiene, metal complexes, nitrogen fixation, Ziegler catalysts, fuel cells, lead and sulfur dioxide in the air, inert gas compounds, cyclohexasulfur, the Merrifield method, vitamin B_{12}, fast reactions, and of course the genetic code and survival of the fittest.

[*] An English translation will be published by Ruppert Hart-Davis, London.

The book has no bias toward any one particular field, nor is any attempt made to give the impression that everything is attractive and childishly simple. The reader himself has to make the effort to understand the meaning of orbital diagrams, how spectra arise (also in the field of nuclear resonance), and how the properties of alloys are described by phase diagrams.

On the whole, the author places more value on an understanding of physical principles than on burdening the memory with facts. For example, he attempts to explain the procedure of X-ray structure analysis and to clarify the phase problem. While he mentions the highly developed art of stereospecific synthesis of complex organic molecules, he does not adduce concrete examples or describe individual steps in detail. His treatment of chemical reactions and mechanisms is comparatively simple.

The book not only imparts a knowledge of facts, methods, and applications, it also takes a stand on many modern problems. It criticizes and gives food for thought on matters concerning universities, research, industry, and advertising. The author expresses sound opinions on many subjects. He is objective and clearly has at his command an astonishing wealth of information. Only occasionally is a scientific or technical problem misrepresented: for example, the reasons for the decline of coalmining (p. 143) or the use of enzymes in detergents (p. 331). In some places one might perhaps have expected more precise descriptions, in comparison with other parts of the book (*e.g.* hydrophobic bonding, p. 306). There are many small points, for example in the field of chemical pedagogy (p. 161) and the training of students with physical equipment (p. 236), but these should not be taken too seriously because they are generalizations based on isolated instances. It would have been better, too, if the author had refrained from expressing opinions on nonchemical subjects. Notable examples of this are his statements about the type of men which had in earlier times erected great cathedrals (p. 151), about the church itself (pp. 157, 221), and about soldiers marching in step (p. 244). On the other hand, the reviewer was glad to find common sense being brought to bear on reports concerning the reputed evil intentions on the part of some chemists and companies (*e.g.* plant protection and war gases, p. 177).

The book is manageable in size, readable, and very clearly written. It has many excellent diagrams and illustrations, although these unfortunately do not always appear at the proper places. Even the specialist who finds that his particular field has not been dealt with in sufficient detail will have to admit that the treatment of complex topics and the introduction of the reader to the problems of today are exemplary from the didactic point of view. A conscious attempt has been made to avoid the style of *Schenzinger*'s "Anilin", which in its time was very successful. In the way it is written the book is more reminiscent of *Watson*'s "Double Helix", with its open, critical, and relaxed approach.

Although the work is in the nature of a textbook, the anti-authoritarian *Zeitgeist* can be detected in places. This is by no means designed simply to attract and please the younger reader. On the other hand, the author loses no opportunity to point out the achievements of individual scientists, and the text is liberally provided with short historical and biographical interludes.

This book has been written for a very wide readership. Every enlightened person from the age of 14 upward should read it. Many people who in their professional lives seem to be far removed from the sphere of chemistry (teachers of

Greek, for example, or judges or politicians) will realize how much their existence depends on chemistry and how much joy and wonder can be derived from a knowledge of nature. Specialists too may benefit from an overall view of a large part of the field of modern chemistry, from seeing their own particular subject within the context of chemistry as a whole.

Hans Musso [NB 32 IE]

Catenanes, Rotaxanes and Knots. By *G. Schill.* Academic Press, New York–London, 1971. 1st Edit., vii, 192 pp., numerous figures, bound $ 11.00.

This book is no. 22 in the series "Organic Chemistry; A Series of Monographs", edited by *A. T. Blomquist*, which has quickly acquired a high reputation through many excellent monographs on interesting and topical fields from the pens of experts.

The book opens with a brief account of the history, structure, nomenclature, and stereochemistry of the types of compounds named in the title. The general part (19 pages) ends with a few words on their natural occurrence. The second part begins with the fundamental methods for the synthesis of [2]-catenanes. This is followed by a detailed description of experimental efforts to solve this problem, which is fascinating for any preparative chemist (about 100 pages). Special emphasis is placed on the characterization and proof of structure of the compounds and the demonstration of their structure by mass spectroscopy. The subsequent sections on [3]-catenanes and [2]-rotaxanes are similarly arranged (about 10 pages each). The last section presents concepts and investigations on knots and on doubly twisted and higher catenanes and rotaxanes (11 pages). A table containing all compounds of this type so far isolated concludes the text (10 pages).

The book is clearly, sensibly, and critically written. It is not a distilled extract of the existing material, with a straightforward description of the successes, but rather a systematically arranged account of all syntheses and approaches, including those that were unsuccessful, abandoned, or unpublished. Once the reader has worked his way into the book (which will not be without effort to some), he will be caught up in the dramatic development of every single step, with all its disappointments and difficulties. Impressed by the experimental work and the tenacity with which the aim has been pursued, he will be unable to lay the book aside. The drive of the initiator and the author's independent contribution can be discerned in many places. It is not intended as a textbook for younger students; however, the advanced chemist will learn much from it, even if he is not, and does not intend to become, involved in this particular field. This type of presentation demonstrates how a clear and simple, but experimentally very difficult concept can be empirically realized in the end by classical methods.

The printing and the numerous, sometimes large formulas are generally free from errors and very good. In places, the reader could progress more easily if the text dealing with a certain compound and its formula were closer together. It is often necessary to interrupt one's train of thought to search for a formula on the preceding or following page. The steric structures of many compounds are shown very clearly by the figures in a number of places (*e. g.* pages 1, 3, and 60). It would also have been useful in many other formulas of the twisted structures to indicate the parts of the molecule that lie in front and those that lie behind by means of thicker and thinner lines in order to enhance the perspective impression. It would certainly be useful, once the summit is reached on p. 120, to recapitulate briefly the straightforward path from the simple starting material to [2]-catenane, *e. g.* for readers who wish to prepare a lecture on the basis of this book. In view of the many pages carrying little or no print (about 15), it should have been possible to reproduce some mass spectra in connection with the proof of the structure on p. 122.

This book should find a place in every chemical library; every chemist is recommended to read it, including those who are not concerned with organic compounds.

Carrier-Bound Biologically Active Substances and Their Applications

By Hans Dieter Orth and Wolfgang Brümmer[*]

Stable catalysts can be obtained by fixation of enzymes on suitable supports. The principal methods for their preparation and their properties are described. The use of supported enzymes in routine biochemical analysis as "insoluble reagents" for automatic analyzers and for enzyme electrodes appears particularly interesting. For preparative transformations and syntheses, the supported enzymes offer the advantage that many processes that were formerly operated batchwise can be run continuously to give protein-free products. The use of supported proteinases as specific adsorbents provides a simple method for the isolation of various naturally occurring inhibitors. This principle, which is the basis of affinity chromatography, has now also been adapted to the purification of enzymes and other biologically active substances on suitable supported effectors.

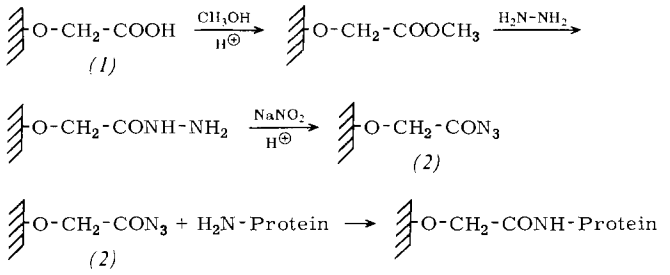
1. Introduction

Recent years have seen the development of a field of biochemistry known as "enzyme engineering", the aim of which is to extend the use of the specific catalytic properties of enzymes. Efforts were made at first to stabilize enzymes by inclusion in or by fixation on water-insoluble supports so that they could be used repeatedly. Polymer-bound enzymes of this type can be used not only as specific catalysts but also as selective adsorbents, *e.g.* for naturally occurring inhibitors. Conversely, this new technique, which is known as affinity chromatography, also allows the isolation of many enzymes in a very pure state by selective adsorption on suitable insolubilized inhibitors or other specific effectors (substrate or coenzyme analogs, antibodies).

The object of the present progress report is to illustrate the possible applications of supported enzymes for transformations and of supported effectors for isolations with the aid of selected examples.

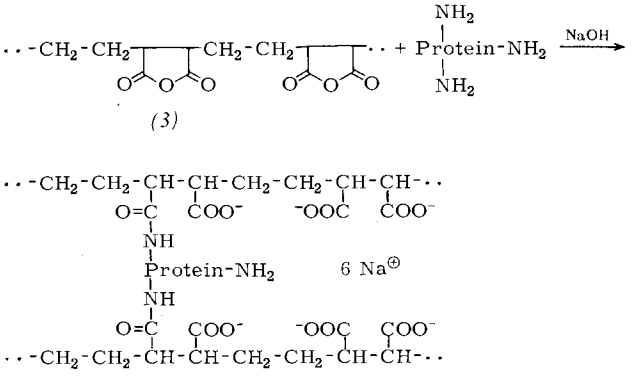
2. Binding of Proteins to Supports

2.1. Methods



Numerous publications dealing with the binding of biologically active proteins to insoluble supports have appeared during the past few years. Important contributions to the development of this new field of enzymology have been made by the research groups of *Katchalski*, *Goldstein*, *Manecke*, *Porath*, *Axen*, *Kay*, *Hornby*, *Lilly*, *Crook*, *Cuatrecasas*, and *Anfinsen*. (For reviews see [1—15].)

There is no standard method for the preparation of supported proteins. Special reaction conditions, and in many cases special "tailor-made" supports are required to ensure substantial retention of the biological activity of the individual protein to be bound. There are three principles in common use at present for the fixation of proteins, and particularly of enzymes:



1. Ionic binding on hydrophilic ion exchangers[16–20]. As long as certain physical conditions are maintained, such as ionic strength and pH value, enzymes having a relatively high content of acidic amino acids, *e.g.* the aminoacylase from *Aspergillus oryzae* (see later), remain firmly bound to DEAE-cellulose or DEAE-Sephadex even at relatively high substrate concentrations[16, 17].

2. Entrapment in hydrophilic gels by photocatalytic copolymerization of acrylamide and *N,N'*-methylenebis(acrylamide) in the presence of the enzyme[21–23]. However, this method is suitable only for enzymes transforming low molecular weight substrates, since those of high molecular weight cannot pass through the pores of the gel to reach the enzyme molecules enclosed in the gel matrix. A critical discussion of the method, based on investigations on immobilized cholinesterase, has been published by *Degan* and *Miron*[23].

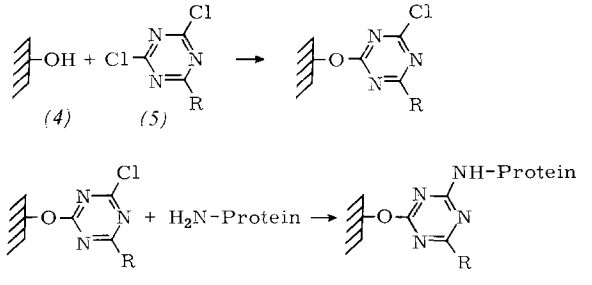

Scheme 1. Conversion of carboxymethyl cellulose *(1)* into the reactive azide form *(2)* and reaction with proteins [29, 39, 40].

Scheme 2. Binding of proteins to a copolymer of ethylene and maleic anhydride *(3)* (EMA) [31, 32].

Scheme 3. Activation of polysaccharides *(4)* such as agarose and cellulose with BrCN and reaction with proteins [25].

Scheme 4. Activation of polysaccharides *(4)* such as agarose and cellulose with cyanuric acid derivatives *(5)*, R = *e.g.* NH_2 (2-amino-4,5-dichloro-*s*-triazine), and reaction with proteins [28, 29].

3. Binding to hydrophilic natural[24–29] or synthetic[30–34] polymers or to inorganic substances such as glass[35–38] by covalent linkage *via* functional groups of the enzyme protein that are not essential to enzyme activity. This applies not only to the terminal α-amino group(s) of the enzyme molecule, but frequently also to the basic ε-amino groups of the lysines, the hydroxyphenyl side chains of the tyrosines, the guanidyl side chains of the arginines, and the imidazolyl groups of some histidines, and these may therefore be favored as points of attachment[9].

The support usually has to be converted into an active form before the reaction with the proteins. Some typical support substances are listed in Schemes 1—4.

Mention should also be made here of an interesting method that has recently been developed by *Novais* for the coordinate binding of enzymes to surfaces of cellulose or glass that have been activated by treatment with chelate-forming transition metal salts, particularly titanium salts[41].

2.2. Steric Conditions

Mild conditions must be used for the fixation of biological macromolecules in order to preserve their steric structure which is essential to their activity. The support matrix must therefore be hydrophilic and highly porous[25, 40, 42]. The reaction conditions that may be considered are moderate ionic strengths, pH values between about 4 and 10, and temperatures between 0 and about 35 °C. To guarantee the conservation of the steric structure and the free accessibility of the active center, it is also favorable in many cases to attach the macromolecule to the support *via* a side chain ("spacer") instead of attaching it directly. This can be achieved *e.g.* by the use of an α,ω-diaminoalkane or an ω-amino carboxylic acid[14, 15, 42].

For sterically unhindered contact with substrates and effectors, it is also necessary to avoid covalent linkage of too many groups of the macromolecule to the support. Since the binding occurs mostly *via* NH_2 groups and the p*K* values of the terminal NH_2 groups of peptides are lower compared with those of the NH_2 groups in the lysine side chains, it is possible to ensure, by variation of the pH, that binding occurs mainly *via* the terminal α-NH_2 group, provided that this group is not masked by the steric arrangement of the polypeptide chain. Thus immune globulin that had been coupled to activated agarose at pH 9 took up only 7% of the calculated quantity of insulin, whereas immune globulin fixed at pH 6.5 took up 77%[14].

3. Properties of Insoluble Enzymes

3.1. Stability

Most of the supported enzymes described so far are considerably more stable than the corresponding soluble enzymes[9], so that provided a suitable support and mild coupling conditions are used, this property may be regarded as characteristic of supported enzymes. Binding to an insoluble support evidently provides better protection for

the native conformation of the enzyme against denaturing effects. With continuous use, the stability is further increased by the influence of the substrate.

As an example of the stabilization of supported proteinases due to reduced autolysis, Figure 1 shows the variation with time of the residual activity of bovine trypsin in the soluble and bound forms after preincubation at 55 °C[39].

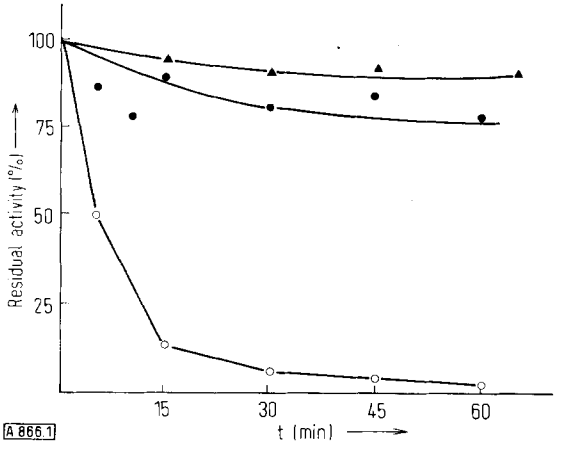

Fig. 1. Residual activity of trypsin (bovine) (○), CMC-bound trypsin (●), and MA-bound trypsin (▲) after preincubation at 55 °C, measured with casein as the substrate [39]. CMC = carboxymethyl cellulose, MA = crosslinked copolymer of 1,4-bis(vinyloxy)butane and maleic anhydride.

3.2. Activity

Supported enzymes are generally less active than the corresponding native enzymes. Enzymes that act on low molecular weight substrates exhibit an average residual activity of 40—80% after fixation[9], while hydrolases bound to polymers retain only 5—40% of their activity for their high molecular weight substrates[25,27]. Higher values have occasionally been reported[24,26]. However, this partial loss of activity is offset by the fact that insoluble enzymes can be used repeatedly. Some reasons for the modified activity of the bound enzymes are discussed below.

4. Parameters Influencing the Properties of Insolubilized Enzymes

4.1. Steric Hindrance

An enzyme molecule is generally fixed to the support, not at one point of attachment, but at several. This results in a certain amount of crosslinking, which, together with possible intramolecular crosslinking of the activated matrix itself, hinders the access of a substrate to a bound or enclosed enzyme molecule. This is particularly true of enzymes such as proteinases, amylases, and nucleases, which degrade high molecular weight substrates[1,4,5,9]. *Cresswell* and *Sanderson*[44] investigated this effect for an insolubilized microbial proteinase (pronase from *Streptomyces griseus*) bound to a diazotized copolymer of leucine and *p*-aminophenylalanine[43]. A linear relation was found between the residual proteolytic activity and the logarithm of the molecular weight of the substrate. The proteolytic activity decreases with increasing molecular weight of the substrate, and a stage is ultimately reached where only the enzyme molecules attached directly to the surface of the porous particles are still active. The same is true of proteinase inhibitors, *i.e.* the fraction of the bound enzyme that they can inhibit decreases as their molecular weight increases[27,32,45]. The situation is similar to that in exclusion chromatography of proteins on crosslinked dextran gels, in which the fraction of the pore volume accessible to a protein depends on the molecular weight of the protein.

4.2. Electrostatic Interactions

Mere steric hindrance is observed only with uncharged supports or uncharged substrates. With ionic supports, it is accompanied by the electrostatic interaction between the support and similarly or oppositely charged enzyme substrates. This effect becomes particularly obvious under conditions where substrate saturation of the bound enzyme cannot be achieved. This has been demonstrated *e.g.* in the activation of chymotrypsinogen A and chymotrypsinogen B by trypsin bound to a support having anionic groups (carboxymethyl cellulose, see Scheme 1)[39]. The two proenzymes have the same molecular weight (25000) but different electric charges (isoelectric points at pH 9.5 and 5.2 respectively). Under the reaction conditions used seven times as much bound trypsin was required for the activation of negatively charged chymotrypsinogen B as for the positively charged chymotrypsinogen A[39]. If the support matrix and the substrate are oppositely charged, a higher substrate concentration occurs on the surface of the support than in the surrounding solution. Conversely, if the support and the substrate carry like charges, electrostatic repulsion leads to a decreased substrate concentration in the microenvironment of the bound enzyme. Inequality of the substrate distribution between the external and internal phase causes the bound enzyme to exhibit apparently a higher or a lower affinity, respectively, for its substrate[4,46].

The $H^{\oplus}$ ions behave similarly. As was shown by *McLaren*, these ions concentrate on negatively charged solid surfaces and cause a "surface pH" that can be up to two units lower than in the external phase[47,48]. These effects and their influence on the pH-activity profiles of bound enzymes were later investigated by *Goldstein et al.*[3,4]. The electrostatic interaction may be advantageous where the support and the enzyme substrate are oppositely charged. Thus if the substrate concentration decreases during an enzymatic reaction, the reaction rate of the supported enzyme decreases to a much smaller degree than that of the free enzyme[49].

4.3. Diffusion

Another factor that influences the substrate concentration in the microenvironment of a bound enzyme, and hence

also the activity of the enzyme, is diffusion. This is shown by the fact that insoluble enzymes exhibit their maximum activity only at sufficiently high stirring speeds in the reaction mixture[50–52]. The influence of diffusion on the activity of a bound enzyme depends on the maximum reaction rate V_{max} of the individual enzyme, the diffusion coefficient of the substrate, and the thickness of the diffusion zone[46].

If, however, instead of merely one-step enzymatic reactions, one considers reaction sequences catalyzed in a cascade by several enzymes, as in physiological processes in the cell, the local accumulation of a metabolite in the microenvironment of a structure-bound enzyme sequence due to limited diffusion can make the system as a whole particularly effective.

Mosbach and *Mattiasson*[53] have investigated this effect for a supported three-component system, in which β-galactosidase, hexokinase, and glucose-6-phosphate dehydrogenase were fixed together on BrCN-activated Sephadex (see Fig. 2). In this system, in which the reaction rate depends on the concentration of the intermediate products, it was found that the supported "multienzyme system" is more effective than the three individual enzymes in solution, since the initially formed glucose does not diffuse away immediately into the external phase, but remains available in high concentrations for the subsequent enzymatic reaction steps.

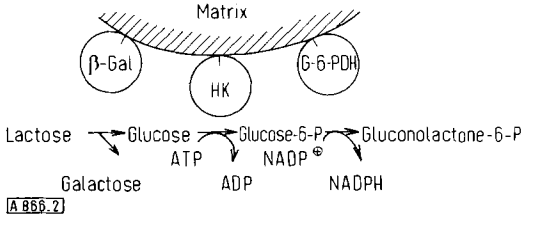

Fig. 2. Schematic representation of a three-step sequence with supported enzymes [β-galactosidase (β-Gal)—hexokinase (HK)—glucose-6-phosphate dehydrogenase (G-6-PDH)] (after [53]).

It can be seen here that the study of the properties of supported enzymes can also contribute to a deeper insight into the physiological mode of action of many cellular enzymes that are bound to membranes and structures.

5. Binding of Enzyme Effectors on Supports

5.1. Formation of the Covalent Bond

The effectors are always linked to the supporting resins by covalent bonds. Binding by adsorption, ionic interaction, or inclusion in porous polymers is not stable under the conditions (high ionic strength, extreme pH values, *etc.*) that are often necessary for the elution of substances purified by affinity chromatography. Under these conditions, physically coated supports bleed, *i.e.* their capacity is reduced, and they ultimately become unsuitable for affinity chromatography.

Amino groups of the effector molecules are used in many cases for covalent binding; the methods described earlier for the binding of proteins (Section 2.1) can be used for this purpose too. Carboxamide linkages are formed not only by the azide method but also in many cases by carbodiimide activation; in addition, the carbonyl group may be situated either on the support (see Section 2.1) or on the effector. Supports having amino groups can be obtained by the introduction of suitable side chains (see Section 2.2). The free end of the side chain may also carry an aromatic amino group, so that an aromatic effector can be attached by diazo coupling. Unlike proteins, low molecular weight effectors need not be bound to the support in aqueous solution, but can also be fixed in organic solvents[5,14,15,54,55].

5.2. Adsorption, Elution, and Influence of the Side Chain

The substance to be purified, *e.g.* an enzyme, may be adsorbed from crude extracts or from prepurified solutions. The affinity resins are used in batch and in column chromatography methods. The batch method can be used only if the dissociation constant of the complex formed by the two reactants is low, *i.e.* if the complex is stable. The column method, on the other hand, can be used even if the dissociation constant of the complex is high. In this case, the dissolved reactant is not fixed during chromatography, but is merely retarded, and elution presents no problems.

The decomposition of complexes having low dissociation constants, on the other hand, usually requires drastic changes in the conditions, such as heating, extreme pH values, high ionic strengths, or high concentrations of denaturing agents. This often leads to irreversible inactivation of the macromolecules to be desorbed[14,15]. Milder elution conditions are sufficient if the stability of the complex can be reduced. This is possible by shortening the side chain by which the reactant is attached to the support. However, the capacity of the treated support simultaneously decreases.

Microbial β-galactosidase is inhibited by *S*-(*p*-aminophenyl)-β-D-1-thiogalactopyranoside. The degree to which the enzyme is retained by the agarose-bound inhibitor varies with the length of the side chains. The retention of the enzyme by support A is practically zero, and that by support B is only slightly better. There is no need for severe elution conditions in either case. If, on the other hand, the columns are packed with support C (Fig. 3), the β-galactosidase is very strongly bound and 0.1 M borate buffer (pH 10) is required for elution[42,56].

The dependence of the support capacity on the length of the side chain has been determined for the agarose-bound Staphylococcus nuclease inhibitor 3'-(4-aminophenylphosphoryl)deoxythymidine-5'-phosphate[42]. With direct binding (corresponding to Figure 3, A), the capacity is 2 mg of nuclease/ml of gel. If *N'*-acetylethylenediamine is introduced as a side chain (corresponding to Fig. 3, B), the binding capacity increases to 8, and with *N'*-succinylbis(aminopropyl)amine as the side chain (corresponding to Fig. 3, C) to 10 mg of nuclease/ml of gel. In all three cases, the columns contained 2 μmole of inhibitor/ml of packed gel.

Elution with effector solution, *e.g.* the elution of L-asparaginase with D-asparagine[57], has also been reported (see also Section 8.1).

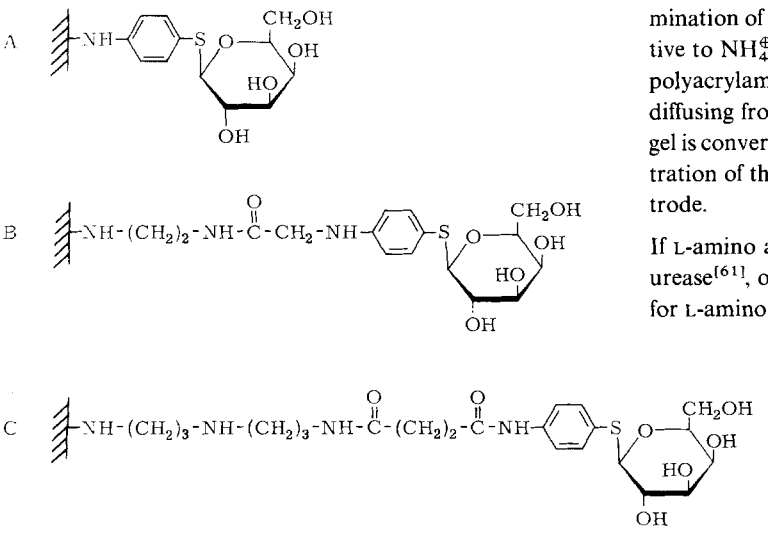

Fig. 3. Agarose-bound *S*-(*p*-aminophenyl)-β-D-thiogalactopyranoside [42]. A directly bound, B bound *via N'*-acetylethylenediamine, C bound *via N'*-succinylbis(aminopropyl)amine.

6. Use of Insolubilized Enzymes in Analysis

6.1. Automatic Analyzers and Enzyme Electrodes

Hicks and *Updike* used insolubilized enzymes entrapped in crosslinked polyacrylamide gel for the determination of oxidizable substrates in an automated analysis system[22]. They used microcolumns packed with granulated enzyme gel, through which the solutions for analysis were passed. The determination of glucose was carried out *e.g.* with insoluble glucose oxidase, corresponding to Scheme 5.

$$\text{Glucose} + O_2 \xrightarrow{\text{GOD}} \text{Gluconic acid} + H_2O_2 \qquad \text{(a)}$$

$$H_2O_2 + \underset{\text{reduced, colorless}}{\text{color indicator}} \xrightarrow{\text{POD}} H_2O + \underset{\text{oxidized, blue}}{\text{color indicator}} \qquad \text{(b)}$$

Scheme 5. Determination of glucose with glucose oxidase (GOD) and peroxidase (POD).

The H_2O_2 formed oxidizes, in the presence of peroxidase, a color indicator such as *o*-tolidine that is colorless in the reduced state. The intensity of the resulting color corresponds to the glucose concentration in the solution under analysis. If a sensitive oxygen electrode is used instead of the indicator reaction (b), a "reagentless" determination of glucose is achieved[58].

To make the process independent of the flow rate, *Hicks* and *Updike* developed an enzyme electrode[59]. This consists of a highly sensitive O_2 electrode encased in a layer of gel 25—50 μm thick containing entrapped glucose oxidase. If this probe is immersed in body or tissue fluid, O_2 and glucose diffuse into the enzyme layer, where the O_2 concentration is reduced by the enzymatic oxidation of glucose, and can be recorded as a change in the electrode potential. The principle is similar to that of the measurement of $H^{\oplus}$ concentrations with the pH electrode.

Guilbault and *Montalvo* have described an enzyme electrode operating on the same principle for the continuous determination of urea[60]. A cationic glass electrode that is sensitive to $NH_4^{\oplus}$ ions is enclosed in a thin layer of crosslinked polyacrylamide gel in which urease is trapped. The urea diffusing from the solution under analysis into the enzyme gel is converted into $HCO_3^{\ominus}$ and $NH_4^{\oplus}$ ions, and the concentration of the $NH_4^{\oplus}$ ions is immediately sensed by the electrode.

If L-amino acid oxidase is entrapped in the gel instead of urease[61], one obtains an enzyme electrode that is specific for L-amino acids.

6.2. Sequence Analysis of Nucleotides and Peptides

Even more complicated analytical investigations, such as the sequence determination of oligoribonucleotides, have been automated with the aid of supported enzymes.

Neu and *Heppel* proposed a method for the sequence analysis of tRNA that, unlike the usual method (enzymatic fragmentation of the RNA with specific endonucleases and exonucleases), allows a stepwise degradation from the free 3'-OH end of the terminal nucleoside[62]. This degradation occurs in two steps. The first step consists in the periodate oxidation of the exposed vicinal OH groups of the ribose of the terminal nucleoside, followed by elimination of the terminal base. In the second step, the newly formed phosphate monoester is split off with alkaline phosphatase; this exposes the vicinal OH groups of the next ribose. The reaction sequence is then repeated, as illustrated in Scheme 6.

Cycle I:

1st step ..ApGpC $\xrightarrow[\text{iodate}]{\text{per-}}$ "oxidized" ..ApGpC

$\xrightarrow[\text{pH 10.5}]{\text{glycine}}$ ..ApGp + cytosine

2nd step ..ApGp $\xrightarrow[\text{phosphatase}]{\text{alkaline}}$ ..ApG

Cycle II:

1st step ..ApG $\xrightarrow[\text{iodate}]{\text{per-}}$ "oxidized" ..ApG

$\xrightarrow[\text{pH 10.5}]{\text{glycine}}$ ..Ap + guanine

etc.

Scheme 6. Stepwise sequencing of an oligonucleotide. A = adenine, G = guanine, C = cytosine (after [62], modified).

However, if the phosphatase is not quantitatively eliminated after the second reaction step, the protective phosphate group of the following nucleoside, which then also reacts, is

partly removed during the first reaction step of the next cycle. Thus after a few reaction cycles the results become ambiguous[63]. *Zingaro* and *Uziel* largely overcame this difficulty by the use of insolubilized phosphatase, which was covalently bound to ethylene-maleic anhydride copolymer (EMA)[64]. The supported enzyme is still sufficiently active toward native RNA. The authors are now trying to construct an automatic RNA sequenator working on this principle[64].

Lee has reported the successful binding of ribonuclease T_1 to BrCN-activated Sepharose[65]. The advantage of using the bound enzyme is that the specific fragmentation of the RNA can be interrupted by simple centrifugation at any time that is favorable for the separation of the fragments or their subsequent sequencing.

This also applies in principle to the hydrolysis of proteins with supported specific endopeptidases and exopeptidases. Promising results were obtained by *Schwabe*[66] in preliminary experiments on the sequencing of peptides with an insolubilized leucine aminopeptidase. This enzyme was not covalently bound to a support, but was used in the form of an adsorbate on calcium phosphate gel.

7. Use of Insolubilized Enzymes to Obtain Reaction Products

7.1. Transformations

Of the 2000 or so enzymes known at present, only a few (mainly hydrolases) have found industrial application. In addition to bacterial proteinases for the detergent industry, proteinases, amylases, and amyloglucosidases are nowadays produced on the ton scale for the food industry[67]. As "industrial chemicals", these technical enzymes must naturally be stable and cheap products. The possibility of the replacement of these enzymes by supported types will depend on economic factors. Only cheap supports and simple methods for the fixation of the enzymes can be considered for these purposes.

7.1.1. Production of L-Methionine

Tosa et al. have developed a process for the continuous resolution of acetylated D,L-methionine by aminoacylase from *Aspergillus oryzae* adsorbed on DEAE-cellulose or DEAE-Sephadex[16, 17]. They use an enzyme column heated to 50 °C, through which the racemate solution flows in the upward direction. The enzyme deacetylates only the L-form, which can then be separated and isolated in the crystalline state. The column loses 40% of its activity only after an operating time of 4 weeks. This loss can be compensated without changing the column by introduction of a suitable quantity of soluble enzyme, which is then fixed. The pilot plant, which is shown schematically in Figure 4, is claimed to allow an output of up to 20 tons per month[68].

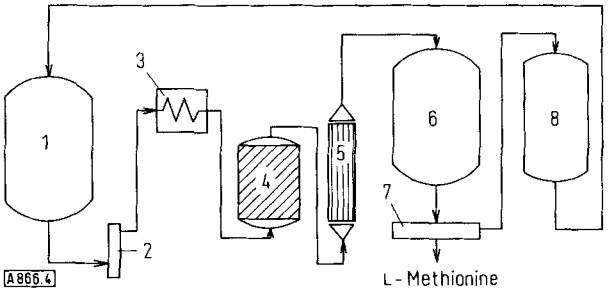

Fig. 4. Scheme of the continuous production of L-methionine from racemic acetyl-D,L-methionine by aminoacylase from *Aspergillus oryzae* adsorbed on DEAE-Sephadex [68].
1, Acetyl-D,L-methionine; 2, filter; 3, heat exchanger; 4, enzyme column; 5, evaporator; 6, crystallization vessel; 7, separator; 8, racemization vessel.

The superiority of the continuous process with the supported enzyme over the batch process with soluble enzyme is shown by the fact that with equal quantities of enzyme and under optimum conditions in each case, ten times as much L-methionine was obtained by the continuous enzyme reaction as by the batch process[17].

7.1.2. Saccharification of Starch and Production of Invert Sugar

Smiley et al. investigated the suitability of insolubilized amyloglucosidase from various species of *Aspergillus* for the continuous saccharification of partly hydrolyzed starch solutions. Since the viscous substrate solutions tend to block the column after a short operating time[19], a continuous feed stirred tank reactor was used. A 30% substrate solution was fed, with stirring at 55 °C, into a reaction vessel containing supported amyloglucosidase, and the glucose solution formed almost quantitatively was removed continuously[20]. The enzyme, which was adsorbed on DEAE-cellulose, showed no loss of activity during an operating time of 3—4 weeks. *Wilson* and *Lilly* used the same enzyme for the saccharification of starch, but in this case the enzyme was covalently bound to DEAE-cellulose activated with 2-amino-4,6-dichloro-*s*-triazine[49] (see also Scheme 4). The process was carried out in a column at 55 °C. A bed volume of insolubilized enzyme of only 5 × 13 cm yielded 3.8 kg of glucose/100 hours operating time, with no decrease in the activity of the bound enzyme. However, this process has not yet been used on an industrial scale. *Smiley* has recently been working on a process for the production of invert sugar by isomerization of glucose with supported microbial glucose isomerase[69]. Since glucose is a cheaper raw material than sucrose, this route could be more economical than *e.g.* the inversion of cane sugar by invertase from yeast.

7.1.3. Production of 6-Aminopenicillanic Acid

6-Aminopenicillanic acid, the starting material for numerous synthetic penicillins, is mainly produced microbiologically in industry by cleavage of benzylpenicillin with the enzyme penicillin amidase, which occurs in *E. coli*[70]. *Self, Kay,* and *Lilly* investigated the possibility of replacing this batch process by a continuous procedure based on the isolated, supported enzyme[71]. This would avoid the need for the complex fermentation process, the reaction would be easier to optimize, and the reaction product would be free from by-products and impurities.

The enzyme, which is easily isolated from *E. coli*, was covalently bound to DEAE-cellulose that had been activated

with a cyanuric acid derivative, 2,4-dichloro-6-carboxymethylamino-*s*-triazine. Unlike the relatively labile native enzyme, the insolubilized enzyme showed no loss of activity even after 11 weeks in the continuous column process at 37 °C. A special advantage of this process is that the 6-aminopenicillanic acid obtained is free from soluble, contaminating enzyme; subsequent purification is therefore unnecessary. The material obtained by microbiological reaction, on the other hand, must be carefully freed from protein impurities, which could lead to allergic reactions on the subsequent therapeutic use of penicillins. An interesting suggestion by *Shaltiel et al.* is that supported nonspecific proteinases may be used to split these proteins into immunologically inactive fragments[72].

7.1.4. Steroid Transformations

Another therapeutically important class of substances in which microbiological transformations play a decisive role is the steroids. However, the use of supported enzymes appears to present much greater difficulties here because of the instability of the steroid-transforming enzymes. *Mosbach* and *Larsson* attempted to use enzymes entrapped in polyacrylamide gel for the 11β-hydroxylation of Reichstein's "compound S" (17α,21-dihydroxy-4-pregnene-3,20-dione, 11-deoxycortisone) to obtain hydrocortisone and for the dehydrogenation of hydrocortisone to form prednisolone (11β,17α,21-trihydroxy-1,4-pregnadiene-3,20-dione)[73].

Since the isolation of the 11β-hydroxylase required for the first reaction from the fungus *Curvularia lunata* was unsuccessful because of the instability of the enzyme, intact cells were polymerized into the gel and used in this form in the reaction. The Δ^1-dehydrogenase required for the second reaction step was concentrated from *Corynebacterium simplex*, but after entrapment in the gel it had only 7% of its original activity.

7.2. Syntheses

7.2.1. Synthesis of Poly-I:C

A particularly successful application of a supported synthesizing enzyme, the polynucleotide phosphorylase from *Micrococcus luteus*, was achieved by *Hoffmann et al.*[74] in the synthesis of the interferon inducer poly-I:C, a substance that is very effective against virus infections. This synthetic ribonucleic acid, consisting of paired homopolymer strands of polyriboinosinic acid (poly I) and polyribocytidylic acid (poly C), was required in large quantities for pharmacological and clinical testing. The two homopolymeric nucleotides are synthesized by enzymatic polymerization of the respective nucleoside-5'-diphosphate with polynucleotide phosphorylase. However, it proved very expensive to obtain large quantities of the enzyme. Moreover, great difficulty was encountered in the isolation of the polynucleotides from large incubation mixtures by exhaustive extraction with phenol, the enzyme being destroyed in every case.

The difficulties were overcome by covalent binding of the enzyme to a support, BrCN-activated cellulose. In the course of six months, during which the insolubilized enzyme was intermittently used for 40 polymerization cycles, there was no decrease in the synthesis output. The enzyme could now be separated from the reaction product by simple centrifugation. The homopolymers synthesized by the cellulose-bound enzyme corresponded in all their properties to those prepared with soluble enzyme.

7.2.2. Synthesis of Trinucleotides

Gassen made use of the synthetic properties of ribonuclease covalently bound to a highly substituted carboxymethyl cellulose to obtain the trinucleotides UAA, UAG, and UGA, which had previously been obtainable only by difficult chemical synthesis[75]. These trinucleotides, which are the termination codons of protein biosynthesis, are required for special investigations on the course of cell-free protein synthesis. Though ribonuclease normally catalyzes only degradation reactions, it can also be used for syntheses in the presence of a cyclic nucleoside phosphate as a donor and a nucleoside as an acceptor[76, 77]. However, it is practically impossible to make preparative use of this effect for the production of oligonucleotides, since the enzyme cannot be quantitatively removed from the reaction mixture[77]. The complete elimination of the enzyme is essential, since the oligonucleotides synthesized would otherwise be hydrolyzed during workup. Ribonuclease firmly bound to the support, on the other hand, is easily removed by centrifugation and can be used repeatedly.

8. Use of Supported Biologically Active Substances as Specific Adsorbents

The adsorbents mentioned are excellently suited for the isolation of proteins by affinity chromatography, which is superior to the usual methods because of its high specificity.

8.1. Purification and Isolation of Enzymes

The first purification of an enzyme by affinity chromatography was described by *Lerman*[78], who is also one coauthor of the first publication on the isolation of antibodies by this method[79]. As early as 1910, *Starkenstein*[80] observed the strong binding of amylase to insoluble starch, and *Holmbergh*[81] in 1933 reported the separation of α- and β-amylase by adsorption onto starch. Relatively few purifications of enzymes by affinity chromatography were described until the introduction of agarose as a support material (1967/68)[82]; examples of these earlier reports are the purification of flavokinase from liver on flavin-cellulose[83], the purification of flavin mononucleotide (FMN)-dependent enzymes on flavin phosphate-celluloses[84], and the purification of DNA polymerase on DNA-cellulose, the DNA having been fixed to the cellulose by UV irradiation[85].

Carboxypeptidase A, α-chymotrypsin, and Staphylococcus nuclease were the first enzymes to be purified by affinity chromatography on agarose derivatives[82]. The bound inhibitors were L-tyrosine-D-tryptophan for carboxypeptidase A, D-tryptophan methyl ester or *N*-ε-aminocaproyl-

D-tryptophan methyl ester for α-chymotrypsin, and 3'-(4-aminophenylphosphoryl)deoxythymidine-5'-phosphate for the nuclease. Diluted acetic acid (pH 3) was used for elution in all three cases.

The high specificity of the method can be seen by the fact that phosphodiesterase from spleen, which, like staphylococcus nuclease, hydrolyzes nucleic acids to 3'-phosphorylated fragments, was not retained by the support carrying Staphylococcus nuclease inhibitor[82]. Since this nuclease inactivated with diazotized 3'-(4-aminophenylphosphoryl)deoxythymidine-5'-phosphate was not adsorbed, it was possible to show with the same column the cause of the residual activity of the inactivated nuclease, *i.e.* a residual content of native enzyme[86].

The adverse effect of strong steric hindrance on the complex formation was demonstrated by the fact that α-chymotrypsin was adsorbed much more strongly by the support to which the inhibitor was bound *via* the ε-aminocaproic acid residue than in the case of direct binding. Here again, the enzyme inactivated with diisopropyl fluorophosphate was no longer adsorbed. If the enzyme was chromatographed at lower ionic strength, it was more strongly bound, but this offered no advantage, since the possibility of non-specific adsorption of other proteins simultaneously increased[82].

Enzymes for therapeutic use cannot generally be administered orally. For successful intravenous application, the purity of these enzymes must be extremely high to minimize immunological defense reactions.

Asparaginase from *E. coli*, which is therapeutically active against several types of leukemia, was isolated by expensive multi-stage purification processes (heat treatment, solvent precipitation, gel filtration, column chromatography). The products obtained had specific activities of 270—400 units/mg[87, 127]. By affinity chromatography on ε-aminocaproyl-D-asparagine-agarose, the asparaginase from *E. coli* extracts can be obtained in a much higher purity in a single step (specific activity 10000 units/mg) (Fig. 5). Elution is carried out with effector solution (1 mmol/l D-asparagine).

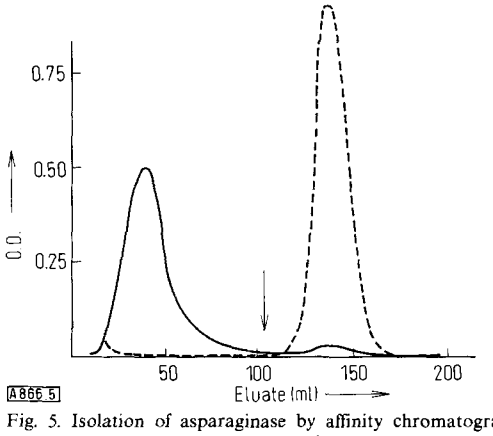

Fig. 5. Isolation of asparaginase by affinity chromatography of an *E. coli* extract on agarose-bound ε-aminocaproyl-D-asparagine. 0.001 M D-asparagine solution in buffer was used for the desorption of the asparaginase (arrow) [57]. ——: protein (measured at 280 nm); – – –: asparaginase (measured at 570 nm).

Though asparaginase hydrolyzes the enantiomorph D-asparagine of the natural substrate L-asparagine at pH 8.6 (pH value in the chromatography) at 5.5% of the rate of hydrolysis of L-asparagine, the D-asparagine-agarose could be used more than ten times without appreciable loss of capacity[57].

Papain was purified by affinity chromatography on an agarose-bound inhibitor peptide[88] and on agarose-bound 4-aminophenylmercury(II) acetate[89]. In this last case, $HgCl_2$ solution was used for elution. Since mercury reacts with SH proteins in general, a mercury resin can be used as a group-specific chromatography resin.

Affinity chromatography on supported coenzymes permits the adsorption of all enzymes whose catalytic activity depends on these coenzymes. Since these enzymes form complexes of different strengths with the bound coenzyme, they are eluted successively by increasing salt concentration in the eluant more or less completely separated from one

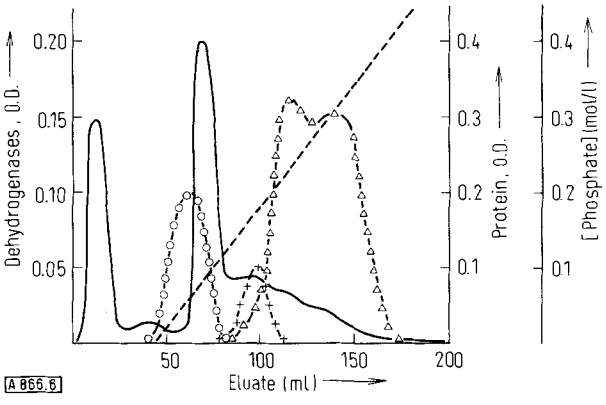

Fig. 6. Isolation of glucose-6-phosphate dehydrogenase (○), lactate dehydrogenase (+), and threonine dehydrogenase (△) by affinity chromatography of a dialyzed *Ps. oxalaticus* extract on NAD-cellulose [90]. Dehydrogenases (see above), (measured at 366 nm); ——: protein (measured at 280 nm); – – –: phosphate gradient (mol/l).

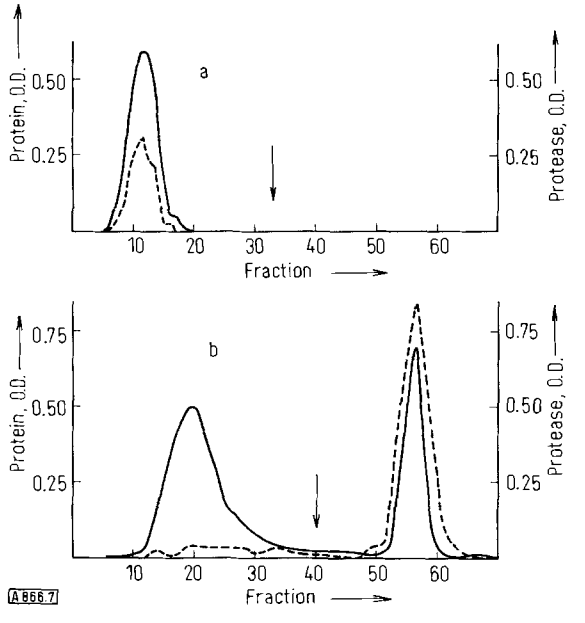

Fig. 7. a) Chromatography of a prepurified wheat malt extract on unsubstituted agarose. b) Isolation of the proteinases from the same wheat malt extract by affinity chromatography on a hemoglobin-agarose column. 0.1 N Acetic acid is used for the elution of the proteinases (arrow) [91].
——: protein (measured at 280 nm); – – –: proteinase (measured at 670 nm).

another. Thus glucose-6-phosphate dehydrogenase, lactate dehydrogenase, and threonine dehydrogenase were adsorbed from a *Ps. oxalaticus* extract on NAD-cellulose and separated from one another by elution with increasingly concentrated phosphate buffer[90]. The NADP-dependent glucose-6-phosphate dehydrogenase was retarded least (Fig. 6).

Difficulty was encountered in the isolation of the proteinases from wheat malt, since the proteinases aggregate with other contaminating proteins. Affinity chromatography on covalently bound substrate (hemoglobin) led to a preparation that showed only proteolytically active bands on disk electrophoresis (Fig. 7)[91].

A survey of communications on this topic is presented in Table 1.

Affinity chromatography can also be used for enzymological problems besides the isolation of enzymes. Pig carboxypeptidase B, in addition to its known specificity against basic amino acids, has a slight specificity similar to that of carboxypeptidase A, which suggests that it is contaminated

Table 1. Isolation of enzymes by affinity chromatography.

Enzyme	Support	Effector	Ref.
On bound inhibitors:			
Acetylcholinesterase	Agarose	4-Ammoniophenyltrimethylammonium dibromide	[92]
	Agarose	4-Ammoniophenyltrimethylammonium dichloride	[93]
	Agarose	Trimethyl-[*N*-methyl-*N*-(4-aminophenyl)-3-carbamoyloxyphenyl]ammonium chloride	[93]
L-Asparaginase	Agarose	D-Asparagine	[57]
Carboxypeptidase A	Agarose	L-Tyrosyl-D-tryptophan	[82]
	Agarose	D-Tryptophan	[94]
	Cellulose	Glycyl-D-phenylalanine	[95]
Carboxypeptidase B	Agarose	D-Alanyl-L-arginine	[96]
	Agarose	D-Tryptophan	[94]
	Carboxymethyl-Sephadex	D-Arginine	[97]
	Carboxymethyl-Sephadex	D-Phenylalanine	[97]
	Cellulose	Glycyl-D-arginine	[95]
Chymotrypsin	Agarose	D-Tryptophan methyl ester	[82]
	Cellulose	Glycyl-D-phenylalanine	[95]
	Ethylene-maleic anhydride copolymer	Trypsin-kallikrein inhibitor	[128]
Dihydrofolate reductase	Agarose	4-Amino-10-methylpteroylglutaminic acid	[98]
	Aminoethyl-Biogel P-150	4-Amino-10-methylpteroylglutaminic acid	[99]
β-Galactosidase	Agarose Polyacrylamide	4-Aminophenyl-β-D-thiogalactopyranoside	[56]
Kallikrein	Ethylene-maleic anhydride copolymer (modified)	Trypsin-kallikrein inhibitor	[129]
Neuraminidase	Agarose	*N*-(4-Aminophenyl)oxamidic acid	[100]
Papain	Agarose	Glycylglycyl-(*O*-benzyl)-L-tyrosine-L-arginine	[88]
Pepsin	Agarose	Poly-L-lysine	[101]
Plasmin	Ethylene-maleic anhydride copolymer (modified)	Trypsin-kallikrein inhibitor	[129]
Plasminogen	Agarose	L-Lysine	[102]
RNase (pancreatic)	Agarose	5'-(4-Aminophenylphosphoryl)uridine 2',3'-cyclophosphate	[103]
Staphylococcus nuclease	Agarose	3'-(4-Aminophenylphosphoryl)deoxythymidine 5'-phosphate	[82]
Thrombin	Agarose	4-Chlorobenzylamine	[104]
Trypsin	Agarose	Ovomucoid	[105, 106]
	Cellulose	4-(4'-Aminophenoxypropoxy)benzamidine	[107]
	Ethylene-maleic anhydride copolymer	Trypsin-kallikrein inhibitor	[128]
Tyrosine hydroxylase	Agarose	3-Iodotyrosine	[108]
On bound substrates:			
DNA polymerase	Cellulose	DNA	[85]
	Agarose	DNA	[109]
Flavokinase	Cellulose	Flavin	[83]
Phosphomonoesterases	Cellulose	Phosphate	[110]
Phosphodiesterases	Cellulose	Glycerophosphate	[110]
Proteases (from wheat)	Agarose	Hemoglobin	[91]
Tyrosinase	Cellulose	Phenol	[78]
On bound coenzymes:			
Glucose-6-phosphate dehydrogenase	Cellulose	NAD	[90]
Glycolate apooxidase	Cellulose	FMN	[84]
Lactate dehydrogenase	Cellulose	NAD	[90]
NADPH-cytochrome c apooxidase	Cellulose	FMN	[84]
Pyridoxine phosphate apooxidase	DEAE cellulose	FMN	[84]
Threonine dehydrogenase	Cellulose	NAD	[90]
On bound allosteric effectors:			
Chorismate mutase	Agarose	L-Tryptophan	[111]
3-Deoxy-D-arabinoheptulonate 7-phosphate synthetase	Agarose	L-Tyrosine	[112]
On bound group-specific reagents:			
Papain	Agarose	4-Aminophenylmercury(II) acetate	[89]

with this enzyme. Purification by affinity chromatography on agarose-bound inhibitor increased the specific activity without removing the carboxypeptidase A-like activity. A control experiment showed that carboxypeptidase A was not retained by the column. We are therefore dealing here with a secondary activity[96].

Ribosomes for protein biosynthesis in cell-free systems can be selected by affinity chromatography to such a degree that a certain protein is synthesized preferentially. The incorporation of radioactive amino acids into tyrosine aminotransferase was increased by a factor of more than ten by the use of ribosomes from hepatoma cells that had been concentrated on pyridoxamine phosphate-agarose, the supported coenzyme of transamination[113].

8.2. Isolation of Naturally Occurring Inhibitors

The isolation of naturally occurring enzyme inhibitors by affinity chromatography from crude extracts or partially purified solutions on covalently bound enzymes has been described by several authors.

Most of the articles on this topic were published by *Fritz*, *Werle*, and others, who purified proteinase inhibitors on insolubilized proteinases[114–118]. Examples of the isolation of proteinase inhibitors with insolubilized trypsin are given in Table 2. A DNase I inhibitor has been isolated from calf thymus extracts on agarose-bound DNase I[119]. RNase bound to CM-cellulose has been used for the purification of an RNase inhibitor from rat liver[120].

Table 2. Preparative isolation of some naturally occurring proteinase inhibitors by affinity chromatography on insolubilized trypsins. EMA = ethylene-maleic anhydride copolymer; CM = carboxymethyl.

Inhibitor from	Support	Ref.
Pancreas (pig)	EMA, modified	[114]
Pancreas (sheep)	EMA, modified	[114]
Lung, liver (ox)	EMA	[114]
Leech	EMA, modified	[114]
Leech	CM-cellulose	[114]
Seminal vesicles (guinea pig)	EMA, modified	[114]
Seminal plasma (boar)	Polyacrylamide	[114]
Seminal plasma (man)	CM-cellulose	[116]
Wheat germs	CM-cellulose	[117]
Peanuts	CM-cellulose	[117]
Sea anemone	CM-cellulose	[118]

8.3. Use in Immunology

Water-insoluble antigens are used for the isolation of the corresponding antibodies, which can be obtained free from other serum components and free from antigens in this way[5]. Unprecipitable, incomplete antibodies and antibodies that cannot be precipitated because of their low concentration in the serum can also be isolated by affinity chromatography and quantitatively determined[5].

Most natural antigens have several centers for complex formation with antibodies. Each center is associated with one specific antibody. The covalent binding of the antigen to the support may render one center or another inaccessible to its antibodies, so that complex formation cannot occur. In this case, affinity chromatography yields an antibody population whose spectrum differs from that of the antibody population in whole blood. Since the various antibodies form complexes of different strengths with the various centers of the antigen, non-uniform elution of antibodies from the insoluble antigen can modify the spectrum of the antibody population too. The easily eluted components are then enriched[5].

Campbell et al.[79] were the first to bind crystalline bovine albumin covalently to an insoluble polymeric support, *i.e.* *p*-aminobenzyl cellulose, by diazo coupling for purification of bovine albumin antiserum from rabbits. After adsorption, the complex was washed with 1% NaCl solution until free from protein, and was then dissociated at pH 3.2. The yield was influenced by the contact time between the antibody and the insolubilized antigen. 86% of the precipitable antibody that had been adsorbed by the insolubilized antigen could be recovered by immediate elution, whereas only 56% could be recovered 12 hours later.

Another example is the purification of insulin antibodies on agarose-bound insulin[121]. It was found that different insulin-agarose derivatives differed in their immunoreactivity:

insulin-Phe(B1)-agarose	38%
insulin-Lys(B29)-agarose	59%
acetylinsulin-Lys(B29)-agarose	72%

Supported haptens have also been used as an immunoadsorbent for antibodies[122]. There have been fewer descriptions of the opposite application, *i.e.* the isolation of an antigen on a covalently bound antibody. One example is the isolation of insulin from serum on agarose-bound insulin antibodies[123].

8.4. Use in Nucleic Acid Chemistry

The interaction known as hybridization between DNA and complementary RNA, between complementary oligonucleotides, and between nucleotides and nucleosides can also be used in affinity chromatography. Thus T_4-specific RNA has been chromatographed on cellulose-bound T_4-DNA[124]. Phe-tRNA and Lys-tRNA have been concentrated on pT- and pU-cellulose and on pA-cellulose respectively[125]. Thymidylate-cellulose retained mainly adenosine and polyadenylate[126][*].

Chemical Plant Protection — Past, Present, and Future[**]

By Klaus Sasse[*]

Dedicated to Professor Richard Wegler on his 65th birthday

Chemical plant protection greatly contributes to ensuring good harvests and is therefore of considerable agricultural and economic importance. After thirty years of systematic research we are now in possession of powerful chemical agents active against most of the significant enemies of cultivated plants, but the constant change in nature always calls for more and better plant protection agents. These agents play a mostly well-known part in environmental pollution and in the overall toxic situation, and one of the aims of future development is to reduce further the dangers to man and the environment.

1. The Causes of Damage to Cultivated Plants

Darwin described the equilibrium in nature in terms of the struggle for survival. When man began to exploit and change nature, he disturbed this equilibrium and took up the fight against the forces that constantly try to re-establish it.

Plants have of course always had their share of natural enemies, because animals (and many lower plants) cannot synthesize organic substances from carbon dioxide and water and must feed on plants or other animals.

Man has long known, therefore, that he cannot reap all that he sows, but he was ignorant of many of the reasons for this failure. The most obvious was the damage done by insects, which constitute the largest zoological class, with over half a million known species, at least 5000 of which cause damage to plants. Besides these, mites, slugs, birds, and rodents have for centuries been uninvited guests to our cultivated crops.

By contrast, the causes of plant diseases remained mysterious for a very long time, although—as many historical documents[1] testify—the diseases themselves were recognized long ago. Thus, blight and mildew of corn belong to the punishments for disobedience under Mosaic law (Deuteronomy, XXVIII, 22). The Romans celebrated a yearly festival, the Robigalia, which was supposed to protect their cereal crops from rust. In his Naturalis Historia (Vol. 17/18), *Pliny the Elder* described in 77 AD several remedies against cereal diseases. While it was known even in ancient times that some human diseases such as leprosy are transmitted by contact or air, only in the last century was it established that parasites cause plant diseases; this emerged from the detailed investigations of *De Bary* on the

[**] Based on a lecture to the General Meeting of the Gesellschaft Deutscher Chemiker at Karlsruhe on September 17, 1971.

biology and physiology of fungi (1853), and those of *Kühn* on the role of fungi in infections and diseases (1858). Not much later, it became possible to attribute numerous plant diseases to bacteria and viruses following the publication of *Pasteuer*'s (1822—1895) and *Koch*'s results (1876).

Besides animal parasites, phytopathogenic fungi, bacteria, and viruses, damage is also caused by weeds, since these take the light, moisture, and nutrients from the cultivated plants. It depends on numerous local factors which of these causes of plant damage are involved, and to what extent, and since nature is dynamic their combination changes all the time both qualitatively and quantitatively whenever a change in the environment, *e.g.* as a result of cultivation and plant protection, favors or disfavors certain species in the ecological community.

Particularly important in this connection are the infection and infestation of previously unaffected areas through trade in seeds, plants, and other produce. Thus, catastrophic damage was caused to French vineyards successively by powdery mildew, phylloxera, and downy mildew in the second half of the last century as new varieties were introduced; the Colorado beetle, which reached Europe from the USA during World War I, spread from France to Germany, and then deep into Eastern Europe; the blue mold of tobacco introduced into Britain from the USA in 1958, swept across Europe to the Middle East and North Africa.

2. Effects of Damage to Agricultural Produce

2.1. The Economic Aspect

A low yield in agricultural countries means a marked drop in the gross national product, threatening the foundations of the economy; this in turn can lead to inflation, disruption of economics, social unrest, and possibly political changes. For example, late blight almost fully destroyed the potato crop in Ireland in 1845/46, which was responsible for the death of 250000 people through starvation and for the emigration of 2.5 million people. The same disease caused a famine in Germany in 1916/17 (rutabaga winter). Around 1870, coffee rust devastated coffee plantations in Ceylon to such an extent that the cultivation of this plant was abandoned altogether and the plantations changed over to tea. The migration of the Mexican boll weevil from Mexico to the southern states of the USA around the turn of the century roughly halved the harvests, so that many farms were abandoned and many people—especially negroes—lost their livelihood. The Panama disease forced farmers in various places in the Caribbean to abandon the cultivation of bananas over large areas in the first half of this century; thus, in 1940, the area producing bananas dropped to about one-half in Jamaica, the greatest banana exporter, this product providing 52% of its export earnings.

2.2. Effect on World Food Supplies

A sufficient amount of wholesome food is essential for health and work. The question arises whether, and if so how, future generations can be assured of a minimum existence level of food intake in view of the population explosion. In the absence of widespread contraception or a rise in the standard of living, which has a similar effect, the population of the world will increase from 3.5 to 6 billions in the next 30 years. According to data released by the Food and Agriculture Organization (FAO) of the UN, 500 million people are at present undernourished and 1.5 billion are incorrectly or insufficiently nourished.

The hunger of the world is protein hunger. Adequate food consists of 25% of food from animal sources and 75% of food from vegetable sources. It seems paradoxical that agricultural productivity is lowest in the agricultural countries (Table 1)[2]. Raising this productivity in such

Table 1. Yields per unit area (in 100-kg units per hectare).

Area	Rice			Wheat	
	1945	1955	1965	1964/65	% of world production
Japan	20	30	50		
India and Pakistan	13	13	16		
USSR				10.9	27.9
Europe (without USSR)				20.9	22.9
North America and Central America				16.4	20.2
Asia (without China and USSR)				8.6	11.9
China				6.9 [a]	6.0

[a] Value for 1953.

Table 2. Means of raising agricultural production.

a) Increasing the cultivated land area
b) Improving the choice of location for certain cultivated plants
c) Treating and improving the soil (loosening, irrigation, drainage, and fertilization)
d) Selection and breeding
e) Rationalizing the agricultural operations
f) Improving the structure of the agricultural sector
g) Combating pests and weeds
h) Correct handling of seeds and harvested produce (transport, storage, and preservation)

countries by the means listed in Table 2 is vital for adequate nutrition of the world. It is estimated that plant protection alone can double the rice yield in Asia.

2.3. The Agricultural (Economic) Aspect

In highly industrialized countries the most important aspect of agricultural production is not whether it can feed the population, but whether it would be profitable to do so. The main factors that ensure profitability are a high yield per unit area, good-quality marketable produce and—since labor is getting scarcer and dearer—rationalization of production methods. The data in Tables 3 and 4 show how much agricultural measures can raise the yield per unit area: in the USA figures doubled for wheat and cotton and trebled for corn *(Zea mays)* in 30 years.

Table 3. Data for potato cultivation in Germany.

Period	Area involved (ha)	Yield (100-kg units/ha)
1901—1905	1262000	61.7
1921—1925	1360000	71.6
1941—1945	1141000	94.7
1947	851000	124.5
1950	684000	170.3

Table 4. Yields of various crops in the USA.

Crop	Yield (100-kg units/ha)			
	1938	1948	1958	1968
Wheat	8.4	11.4	17.4	18.0
Corn	16.3	25.0	30.3	46.1
Cotton	2.6	3.4	5.1	5.6

2.4. The Health Aspect

Contamination of the food by insects, insect excrement, fungi, bacteria, viruses, and other plants or their parts reduces the quality, and—what is more important—can be harmful to human and animal health[3].

The toxic alkaloids of the cereal parasite *Claviceps purpurea* (ergot alkaloids) used to cause a great deal of poisoning (ergotism). In most civilized countries, therefore, the maximum permissible ergot content of cereals or flour is fixed by law. The increased incidence of cirrhosis and cancer of the liver, mainly in Asia, has been ascribed to a disease known as "yellow rice", caused by *Penicillium islandicum* and *P. citrinum*. Aflatoxins, produced by *Aspergillus* species and especially *A. flavus*, are particularly toxic, often causing serious liver damage when consumed by pigs, cattle, and turkeys as impurities in groundnuts, groundnut meal, and corn.

Insects and their fragments in food are not only nauseating, but often a health hazard. The level to which such contamination in flour must be suppressed is therefore also fixed by law in many countries.

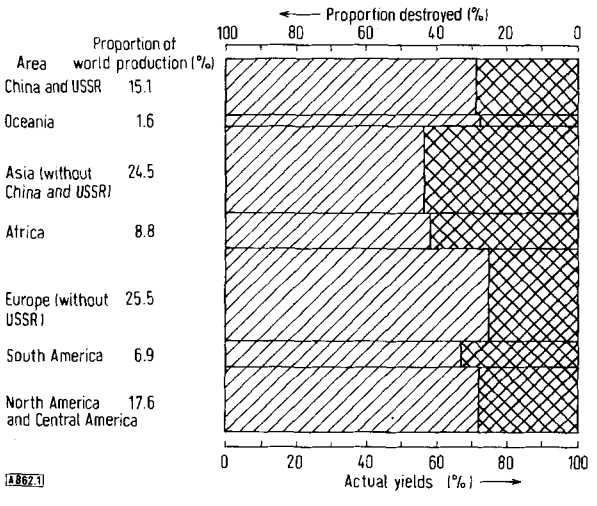

Fig. 1. Regional distribution of the total yields and the proportion of damage to agricultural produce.

Many weeds contain alkaloids and saponins that are poisonous to warm-blooded animals and can therefore cause severe accidents on ingestion.

From all these aspects, making more and better food is one of our greatest tasks. The total damage done by various harmful species amounts to some 35% of the world agricultural production that we would otherwise reach (Fig. 1), *i.e.* it amounts to 70—80 billion dollars.

3. Development of Chemical Plant Protection

Prior to the 19th century there was no etiologically well-founded way of dealing with plant diseases and plant-damaging parasites. The earliest folk methods[4, 5] had a mystical character, and the introduction of mechanical measures first brought some degree of success. As regards chemicals, only inorganic compounds and substances of plant origin could initially be used. Only fragmentary historical records exist of how it was discovered which of these agents were really effective.

3.1. Insecticides

By the middle of the 19th century several insecticides were already known, such as nicotine from tobacco, pyrethrins from the sap of pyrethrum flowers, and rotenoids from the roots of leguminous plants. Petroleum and its fractions were also used against insects at that time. The only other insecticides were arsenic preparations (which are now forbidden in many countries because of their poor biological degradability and high human toxicity) and hydrocyanic acid (which can be used only in enclosed spaces).

The first purely organic and metal-free insecticide, 4,6-dinitro-2-methylphenol (Antinonnin), was put to use in Germany in 1892 against the tussock moth (*Lymantria monacha*), but the low plant tolerance and relatively high toxicity prevented it from gaining wider use. A measure of success was later achieved with aliphatic thiocyanates (1932), phenothiazine (1934), and nitrocarbazoles (1938).

The big breakthrough, leading to a universal contact insecticide, came with *P. Müller*'s discovery of *p,p'*-dichlorodiphenyl-1,1,1-trichloroethane (DDT). Owing to its broad insecticidal spectrum, DDT has had unprecedented success since 1940 in plant protection and in the improvement of hygiene throughout the world. Only this compound has enabled us to combat and in many places fully eradicate the *Anopheles* mosquito, clothing louse, and the tsetse fly, which transmit malaria, typhus, and sleeping sickness, respectively (see Section 7 for the ban on DDT).

The insecticidal properties of other chlorinated hydrocarbons, such as γ-hexachlorocyclohexane, toxaphene, and polycyclic polychloro compounds, were discovered in 1941—45. Since chlorinated hydrocarbons, which are ingestional and contact poisons, generally have a high chemical stability, they exert a prolonged action, but they are dangerous because for the same reason they accumulate in warm-blooded animals and in the environment.

G. Schrader's important work on organic phosphorus compounds, started in the mid-thirties, reached its first peak in 1944 with the discovery of parathion (E 605). Many active organic phosphorus compounds were later found, but none more advantageous and more widely applicable than parathion. In spite of intensive work for the past 30 years, the field of organophosphorus insecticides is still not closed. After 1950 came the development of some systemic preparations (systox group) belonging to this class, which provide plants with internal prophylaxis mainly against harmful sucking insects.

With the development of chlorocarbons and organophosphorus compounds in the past 25 years, man now has the tools needed to keep the main insect pests of almost all cultivated plants under control. These pesticides are supplemented by the cholinesterase inhibitors *N*-methyl- and *N,N*-dimethylcarbamates of phenols, heterocyclic enols, and oximes.

3.2. Fungicides

It was believed for centuries that plants become diseased mainly because the soil is unhealthy for the seeds, and so seed treatment to counteract this started very early. After the use of wine and urine, the salt treatment of cereals began, *e. g.* in Britain, in the 17th century. After about 1760, the salt was replaced by copper sulfate, but this compound proved unsatisfactory, because of its germ-damaging properties. The true importance of copper as a fungicide lies in mixtures of copper sulfate and lime (Bordeaux liquid, *Millardet*, 1885) and copper oxide chloride, which are still used in some fields, mainly in viniculture.

Sulfur as a fungicide has a history at least as long. It served as a cleaning agent over 2000 years ago (it is mentioned in the Iliad and the Odyssey). The first authenticated use of sulfur as a fungicide is associated with *Forsyth* (1803), who recommended a spray mixture of tobacco, sulfur, lime, and elder buds for mildew on fruit trees. Wettable sulfur is still used as a fungicide. Another early fungicide was formaldehyde: it was first used as a disinfectant in 1888 and as a seed-treatment agent in 1895.

In 1910 *Hiltner*, a German phytopathologist, discovered the action of mercuric chloride against the Fusarium wilt of cereals, mercuric chloride having already been known as a bactericide. Attempts to replace this highly toxic compound, having a low plant tolerance, led in 1915 to 3-chloro-4-hydroxymercury(II) hydroxide (Uspulun), the first industrially produced fungicide. This was followed by other alkyl- and arylmercury compounds (Ceresane, 1930), which still have not been surpassed in safety and width of biological activity as seed-dressing agents.

The fungicidal properties of dithiocarbamates and thiuram disulfides were discovered in 1933—1935, but only the metal salts of alkylene-bis(dithiocarbamates) found universal application in orchards, vineyards, and the potato and hop fields (1941). The trichloromethylsulfenyl derivatives of dicarboxylic acid imides set a new standard in the fight against numerous diseases of the green parts of plants (1951), and have made it possible to reduce greatly the use of copper and dithiocarbamate preparations in orchards and vineyards.

After it had thus been found that some broad-spectrum fungicides can be found among the metal-free and purely organic compounds, systematic research led to the discovery of many new useful groups of compounds. Showing a greater variety in morphology, pathogenesis, and site of infection, fungi have to be fought with a greater variety of agents than insects, and therefore more fungicides than insecticides will be needed.

Systemic fungicides were discovered only in the last few years; while the conventional fungicides are purely protective, these systemic fungicides—derivatives of benzimidazole and pyrimidine—confer on plants internal prophylaxis, which is independent of the stability of the surface residues. Some of them, namely oxathiine derivatives, enable one for the first time to combat some plant diseases, such as rust and loose smut of cereals.

3.3. Herbicides

Weed killing in cultivated fields is a difficult form of plant protection, because it calls for substances capable of selecting weeds from the not much more highly evolved useful plants. Neither nature nor early chemistry knew such a substance. Besides, weed-induced damage must have long been underestimated, for it was not thought to be worth any extra cost: until the middle nineteen-forties cheap inorganic compounds available in large amounts were practically the only ones in use as herbicides, the main examples being iron(II) sulfate (since 1900), sulfuric acid (since 1910), ammonium sulfate, and—since 1942—ammonium sulfamate, arsenic(III) oxide, and sodium arsenite. Sodium chlorate and sodium borate were first tried in 1900 and 1930, respectively; they have to be applied in large amounts and have several other disadvantages, but are still used for total weed killing. Sodium 4,6-dinitro-2-methylphenoxide was the first organic herbicide to gain practical application in 1932.

As a result of a systematic search for selective herbicides, starting toward the end of the last war, there were in 1945, 1956, 1963, and 1971 respectively about four, forty, ninety, and over a hundred commercial herbicides with various mechanisms and spectra of action. The main impetus came with the discovery of aryloxy fatty acids in the USA and Britain in 1942—44. These phytohormone-type herbicides kill virtually only dicotyledons, and can therefore be used on cereals; they are still the most important herbicides. Some chlorobenzoic acids and chlorophenylacetic acids also behave like phytohormones.

Herbicides that inhibit photosynthesis form another important group. Since all higher plants rely on photosynthesis for their energy supply and metabolism, these herbicides can, when used in sufficient concentration, terminate plant growth and thus obviously fully eradicate weeds. The surprising fact is that many cultivated plants tolerate some of these herbicides. The most important photosynthesis inhibitors are *N*-aryl-*N'*-alkylureas, diamino-*s*-triazines, carboxylic acid anilides, uracils, and pyrazines.

Differential herbicidal action is exerted against graminaceous plants by *N*-arylcarbamates, *N,N*-dialkylthiolcarbamates, and chloroacetamides. Quaternary bipyridyls interfere with electron transfer during photosynthesis and cause H_2O_2 to accumulate, which destroys the green parts of plants. Increasing economic importance is attached to herbicides of the nitrodiaryl ether type (for rice) and of the type of *N,N*-dialkylanilines carrying three electronegative substituents (for cotton).

It can be said in conclusion that systematic target-oriented research and screening of readily accessible organic compounds have given—and no doubt will continue giving—numerous biologically active agents for the protection of useful plants.

4. Tasks of Chemical Plant Protection for the Near Future

The future development of chemical plant protection depends mainly on the market and the price of produce, and on the overall profile of the substances used for plant protection. The market depends upon the significance of the various plants on the one hand and upon the specific protection problems involved on the other. Most sources of damage can now be combated by quite efficient substances, and large-scale production lowers the production cost. A new agent will be commercially successful only if it has a favorable price/effect ratio, fills a gap on the market, or is particularly advantageous to use.

The trend, aimed at improving profitability and rationalization, will continue to be toward labor-saving measures and single-crop cultivation over large areas. Of crops cultivated over large areas, those with a high yield per unit area (*e.g.* corn) and those with a high-protein yield (*e.g.* soybean) will gain increasing importance. The changing problems of plant protection will call for special care in this field. The need for herbicides will increase, as it has in the past few years (the consumption in the German Federal Republic quadrupled between 1962 and 1969). Over half the money spent in the world on plant protection agents is already spent on herbicides.

There is a worldwide need for agents against parasites that could not previously be combated effectively or at all, examples being bacteria, viruses, and pathogens of systemic and wilt diseases. Furthermore, new agents will be needed in areas or countries where chemical crop protection has not yet started; this is because the existing agents are not always suitable for tackling the problem when one is confronted with different harmful species, their different associations, and different climatic and soil conditions.

Proliferation of certain species, the disturbance of the biological equilibrium, and similar phenomena may lead to such an upsurge of currently insignificant parasites as to call for special measures. The nature and the incidence of harmful species are certainly in constant state of change, mainly because of cultural measures (trend toward large single-crop farms, absence of crop rotation, and cultivation of high-yield varieties), and because most of the common plant-protection agents work toward the biological selection of the less sensitive harmful species, which are then further promoted by the removal of competition, leaving behind a pressure-free biotope. More and more resistant strains of some mites and insects—and sometimes also of parasitic fungi—are emerging and proliferating, which calls for new agents for their control. New agents will also be needed to replace those having disadvantages as regards toxicological properties and environmental pollution.

Expensive labor will promote harvesting aids, and defoliation—necessary before the machine harvesting of cotton—may in the future be extended to orchards and vineyards as soon as suitable chemicals are found for this purpose. Current research suggests that agricultural chemicals will be increasingly used to influence crops, *e.g.* by inhibiting or accelerating their growth, retarding or accelerating the ripening of sap and fruit, reducing or increasing the fruit yield, raising the protein and sugar content of the produce, raising the yield, and improving frost resistance.

5. Biological (Nonchemical) Methods of Plant Protection

It has often been asked, especially recently, whether chemicals could be fully replaced by biological means of plant protection, including all suitable cultural measures such as the choice of the right location, soil treatment, breeding, and crop rotation[6], the breeding of disease-resistant varieties having been particularly successful. In other biological measures, aimed directly at the parasites[7–9], the natural enemies of the harmful species that are present in the locality are promoted, or such enemies of a new type are introduced. The use of specific predatory insects, insect-pathogenic fungi, and bacteria has had some success against certain species of harmful insects, and a virus preparation has been released in the US for restricted use in this field. There is understandable doubt, however, whether these natural agents are entirely harmless to man in the numbers in which they need to be used. Besides, it is difficult to estimate the consequences of disturbing the biological equilibrium in this way.

Other insecticideless methods devised before or under development include sterilization with γ-rays or chemicals and the use of attractants, repellants, antifeedants, and hormones, but only the sterilization of insects has shown any practical success. These methods are efficient only when used on a large scale, and they need extensive organization and management by the government. The release of innumerable additional insects is bound to increase temporarily the damage to cultivated plants. In use over small areas, possibly with toxicologically faultless chemicals, the results are uncertain and take a long time.

Two hormones responsible for insect metamorphosis, namely the molting hormone ecdysone and the juvenile hormone, have recently been isolated and their structure has been elucidated[10–12]. However, attempts to control the reproduction of insects on a large scale through these natural substances or their synthetic analogs have not yet been successful.

An objective assessment of all these methods indicates that today chemical plant-protection agents cannot be fully replaced. However, any feasible method should be fully investigated in view of the emergence of resistance, the problem of chemical residues, the environmental pollution, and the protection of useful species.

In the best combination of chemical and biological means, known as integrated plant protection, the idea is to rely primarily on biological means and to combat the still persisting damage with such chemical means, used in such quantities, that an optimal balance between harmful and useful species is set up. For this purpose the farmer must adopt a systematic and flexible approach, and he must be provided with various crop-specific agents for single-crop systems. Such agents are still rare at the present time. An associated question still to be answered concerns the emergence of resistance when chemicals are deliberately used in subthreshold doses.

6. The Toxicology of Plant Protection Agents

Contrary to a widely held view, plant protection agents are not merely biocides or poisons: most of the modern agents act on one metabolic process, vital only to certain groups of life-forms. Data for what are probably the twenty most commonly used insecticides, fungicides, and herbicides show that only a few—all insecticides—have a high acute oral toxicity for warm-blooded animals (Table 5), *Maier-Bode*[13], and only about 1% of cultivated land is treated with agents belonging to the poison class I. Furthermore, since the most toxic insecticides are quite rapidly decomposed, the user himself is virtually the only person at risk. Though the modern farmer can be familiar with toxic chemicals, it is desirable to replace the highly toxic insecticides by less toxic ones, and much has been done in this direction in the past few years.

Table 5. Acute oral toxicity in rats, of what are probably the 20 most commonly used agents among insecticides, fungicides, and herbicides (some of these substances have other trade names as well).

[e] DDT, Diazinon, Dimethoat, Fenthion.
[f] Nabam, Fentin acetate, trichlorodinitrobenzene.
[g] Diquat, Paraquat, 2,4-D.

A very important question concerns the contamination of food by chemical plant-protection agents and the magnitude of the resulting health hazard. Though we still do not know many of the thousands of substances that make up our food, and of which only relatively few are involved in the energy supply and the body's metabolism, many of them can be assumed to be dangerous in larger amounts. Other substances finding their way to our food come from animal husbandry (hormones, antibiotics, drugs, and other feed additives), preservatives, refining agents, artificial colors and flavoring substances, and possibly also packaging materials.

Improving the quality of the produce obviously must not involve any new health hazard, and this is in fact guaranteed with almost 100% certainty by the tests needed for registering new chemical food additives and by effective observation and control of the safety period and the instructions for use.

The produce rarely comes into contact with plant-protection agents that are applied to the seeds, the soil, or the green parts before fruit formation. The agents are gradually decomposed by chemical and physical action, but the amount left behind on or in the produce in the form of residues or their decomposition products is decisive. The permissible maximum amount of plant-protection agents that is considered safe (tolerance) is fixed by law in many countries (cf. the maximal quantity decree of November 30, 1966, Federal German Food Laws). Tolerances are not toxicological limits whose violation would necessarily damage health; they are values established by law to prevent the abuse of plant-protection agents. They are based on the toxicological tolerance, calculated with a certain safety margin from the maximal nontoxic dose found in chronic toxicity tests on animals. Regrettably, the legally defined tolerances vary quite considerably from country to country, which makes matters difficult for exports and imports.

The stage of chronic toxicity tests is nowadays the costliest part of developing a new plant protection agent: long-term feeding trials with the optimal doses on at least two species of mammals must continue for two years, *i.e.* for almost the whole of the animals' lifetime when rats are used. Only compounds entirely beyond suspicion as to carcinogenic and teratogenic action, embryo toxicity, and damage to organs can be considered safe. According to this criterion, many earlier agents are unsafe, and the law gives their permissible amounts in food at zero (zero tolerance). In Germany at present the law governs four groups of compounds in this field (arsenic compounds, fluoroacetic acid and its derivatives, mercury compounds (except for seed treatment), and selenium compounds), and ten individual agents, including eight chlorocarbon insecticides.

7. The Problem of the Environment

The lack of information about the health aspect of contaminants in air, drinking water, foods, drinks, and tobacco has recently led to widespread anxiety and uncertainty. The great progress in hygiene and public health has been paralleled by a great increase in waste materials, influenced by the growth of the population, rising standard of living, and

increased mechanization; nature's own physical, chemical, and biological purification mechanisms are in some cases already overloaded as a result.

A distinction must be made between acute local side effects and the large-scale spread and accumulation of certain agents in the soil, water, and the food chain. Acute local effects of plant-protection agents on wildlife (*e.g.* deer, birds, and fish) have occurred from time to time, though fewer cases have been really due to these agents than is generally supposed. Such cases are generally caused by rodenticides and insecticides with a high toxicity but short-lived stability. However, they are not direct and inevitable consequences of these agents, but instead are mostly attributable to incorrect use, lack of care, or unfortunate circumstances. The resulting damage to wildlife is local and is soon compensated. Though plant protection agents are used more and more, the number of roes and red deer in the Federal Republic of Germany has increased by a factor of 5—10 since the last world war.

The stability of plant-protection agents and their metabolites requires considerable attention. Except for short-term insecticides, the agents must be stable on plants or in the soil for a considerable time in order to fulfil their function against *e.g.* weeds or fungal diseases. On the other hand, natural decomposition of the agents is desirable in order to minimize residues in food, avoid any unknown long-term effect on the soil, and prevent contamination of the rivers and the ground water.

Of the pollutant metals and metalloids, only mercury, used in seed-dressing preparations, is of general importance here, but even that is used in a small amount in this sector in comparison with the total quantity of mercury used, the amount of mercury used in agriculture in the Federal Republic of Germany in 1969 being only 27 tons or 3.6% of the total 760 tons. Recent work shows that the quantity of mercury thus introduced into the environment is insignificant in comparison with that passing into the atmosphere from other sources and depositing from there. The danger is greater in connection with the seed treated with mercury compounds itself when it is irresponsibly used for feeding livestock. The mercury reaching the food chain *via* fish definitely does not come from plant protection.

The accumulation of plant-protection agents in the soil is dangerous if they cannot be sufficiently decomposed by atmospheric forces or microorganisms. However, this generally causes only local problems, but the use of such agents over large areas and for a long time can admittedly lead to wider environmental pollution, assisted by air, water, and the food chain, which spread them beyond the area of actual use.

The problem of environmental pollution by plant protection agents first arose in connection with DDT. It has since been found that part of the contamination originally blamed on DDT has been due to polychlorobiphenylene, which has been used for various technical purposes for over 40 years, but it cannot be denied that DDT is now present everywhere, partly because it has a high persistence (half-life about 30 months), and partly because large amounts of DDT can be stored by microorganisms (including plankton) and the fatty tissues of higher animals. However, extensive investigations[14] have shown that, apart from a few local exceptions, the present overall DDT concentration need not be feared as a cause of physiological damage in man and wildlife. Nevertheless, health and environment authorities in several countries have banned DDT, except for certain applications, on the grounds of the possibility of unforeseeable damage. The ban has been extended to the other relatively persistent chlorinated hydrocarbon insecticides, for the same reason. To eliminate any new persistent agents at the start, data on the degradability must now be submitted when applying for registration.

8. Future Outlook

Plant-protection agents and growth-regulating agents are at present indispensable if intensive agriculture is to provide enough food. However desirable this might be, it seems that chemical agents cannot be basically replaced by non-chemical and economically feasible methods of plant protection. The nature and the amount of these chemicals should be so chosen as not to damage human health or pollute the environment. For this purpose the users must adhere to guidelines and instructions and be aware of their responsibilities toward their fellow men and nature. They must choose the best agent for each purpose, favor selective agents, minimize the dosage, observe the safety periods, and avoid the use of persistent agents over large areas. No purpose is served by quoting isolated cases—highly regrettable but insignificant within the overall picture—to suggest to the public that people are gradually being poisoned by plant-protection agents. According to the present state of knowledge, the existing laws and the means of their implementation are sufficient to ensure wholesome food.

The development and the use of plant-protection agents are no longer the sole concern of industry and agriculture, and it would be commendable if the cooperation already existing in several areas between industry, the universities, and government bodies were further extended and developed.

The worldwide trade in agricultural produce and the protection of the environment call for international laws on plant-protection agents, based on the relevant national laws. A promising start has been made with the international residue tolerances recommended by the FAO in conjunction with the World Health Organization.

Structure of Porous Adsorbents

By Klaus Unger[*]

Porous solids are gaining in importance as adsorbents and catalysts both for scientific investigations and for industrial applications. Adsorbents having predetermined pore structure can be prepared by specific synthesis. This pore structure can be described in detail and comprehensively by specific parameters, which can be determined by gas adsorption measurements and by other means. Information concerning the bonding state and the concentration of the functional groups on the surface is obtainable by the use of chemical and physical methods of investigation. Other functional groups can be attached to the surface by chemical reactions. It is possible in this way to prepare selective adsorbents.

1. Introduction

Porous adsorbents differ from other solids in that they have a pore structure. The shape and the width of the pores range from macroscopic depressions and cracks having a diameter of about 1 μm to pores with widths of the order of magnitude of molecular dimensions. The large internal surface is responsible for the excellent adsorption properties of porous adsorbents toward gases, vapors, and solutes.

The ability to adsorb substances on the surface is thus the reason for the use of porous adsorbents in various fields, *e.g.* as material for the separation of mixtures on the analytical, preparative, or industrial scale, as catalysts or catalyst supports for chemical reactions, or as materials for the production of a vacuum (adsorption pumps).

Special interest is being shown at present in two problems:

1. the use of porous solids having selective adsorption properties to prevent the pollution of air and of water;

2. the use of porous adsorbents for the storage of biologically active substances.

Adsorbents with specific properties are required for the successful study of these problems. The most important of these properties are the parameters of the pore structure and the chemical composition of the framework and its surface, and also in a wider sense the mechanical properties such as strength, compressibility, and the shape and size distribution of the porous particles.

[*] Prof. Dr. K. Unger
Eduard-Zintl-Institut für Anorganische und Physikalische Chemie der Technischen Hochschule
61 Darmstadt, Hochschulstrasse 2 (Germany)

Porous substances having variable properties were first prepared on a purely empirical basis. It is only during the last decade that systematic investigations have been carried out on certain systems of substances. These investigations were concentrated on the following three aspects:

1. elucidation of the steps in the synthesis of an adsorbent that lead to the formation of its pore structure. If these processes and the quantities that they affect are known, the parameters of the pore structure can be systematically varied;

2. critical examination of known methods and development of new methods for the description of the pore structure of porous adsorbents in order to obtain more detailed information than has hitherto been available;

3. physical and chemical investigations on the bonding state and the reactivity of the functional groups on the surface of an adsorbent; execution of chemical reactions on the surface to effect a systematic modification of the adsorption properties.

The present progress report reviews this development with the aid of some selected examples. It will also show the degree to which scientific problems provide a link between the most diverse disciplines of natural science.

2. Description of the Pore Structure of Porous Adsorbents

For a porous adsorbent, the most important of the properties mentioned above is the pore structure. The width of

the pores determines the rate at which matter is transported to the active centers of the surface. The adsorption and desorption processes take place on the pore walls.

It is usual to characterize the pore structure of porous substances, irrespective of their chemical composition, by the following parameters:

geometric extension of the pore wall surfaces per gram of adsorbent = *specific surface area* s ($m^2.g^{-1}$);

total volume of pores per gram of adsorbent = *specific pore volume* v_p (ml of liquid taken up per gram);

average pore diameter $\bar{d}_p$ (Å);

distribution function $dv_p/d\bar{d}_p = f(\bar{d}_p)$ = *pore size distribution.*

Values for these parameters are obtained mainly from gas adsorption and desorption measurements[1,2]. The adsorptives used are mainly nitrogen, as well as argon and other inert gases and hydrocarbons. The result is an adsorption isotherm, which shows the quantity x_a of gas adsorbed (moles per gram of adsorbent) as a function of the relative pressure p/p_0 in the range $0 < p/p_0 \lesssim 1$ (p = equilibrium vapor pressure of the adsorbate during adsorption, p_0 = saturation vapor pressure of the pure liquid adsorptive).

The experimental results can be evaluated by several methods. These make assumptions either about the process of adsorption or about the state of the adsorbed material, and yield equations that show good agreement with the course of the isotherms in certain regions. They also provide a relation between the quantities actually measured (x_a, p/p_0) and the parameters s, v_p, $\bar{d}_p$ to be determined. The real pore structure is approximated by pore models.

Methods for the measurement of gas adsorption have been greatly improved from the experimental standpoint over the past ten years, and the underlying phenomena of adsorption and capillary condensation have been critically examined with regard to their physical significance to porous solids. The influence of the chemical nature of the surfaces of porous substances on their adsorption properties has also been studied in detail with adsorptives having various polarities[3]. Other methods of characterizing the pore structure of porous substances, which are not based on gas adsorption data, have also been developed; these include small angle X-ray scattering, electron microscopy, permeability measurements with gases, penetration measurements with liquid metals, and radiochemical methods. Consequently, the description of the pore structure of porous solids has been refined and differentiated to a greater degree than was previously possible.

2.1. The Average Pore Diameter as a Classifying Parameter of the Pore Structure

The decisive criterion in the adsorption of gases and vapors on porous solids is the value of the average pore diameter $\bar{d}_p$ and its relation to the size of the adsorptive molecule.

The diameters of the gas molecules used range between 3 and 7 ångström units (nitrogen ≈ 3.0 Å, argon ≈ 3.8 Å, methane ≈ 5.0 Å, benzene ≈ 7.0 Å). If we consider the ratio of the pore diameter to the molecular diameter, we can distinguish two limiting cases:

1. the average pore diameter $\bar{d}_p$ is several orders of magnitude greater than the diameter of the adsorptive molecule. Because of the large pore diameter, the pore wall surface may be regarded, to a first approximation, as a planar surface;

2. the average pore diameter $\bar{d}_p$ is of the same order of magnitude as the diameter of the adsorptive molecule, and therefore lies within the range of dispersion forces.

We may therefore expect that the process of adsorption will proceed differently in the two cases.

In the first case, we have very large pores with a small specific surface area (average pore diameter $\bar{d}_p > 2000$ Å, specific surface area $s < 2\ m^2.g^{-1}$). The adsorptive can diffuse very readily into the pores, and the adsorption equilibrium is established very rapidly. At very low pressures, adsorption occurs first on the most active centers of the surface. With increasing pressure p, the less active centers also become occupied, and a polymolecular adsorption layer is formed. We obtain an adsorption isotherm as illustrated in Figure 1c. It is similar to the isotherm of a non-porous substance (type II of the BDDT classification[4]).

Whereas the activation energy of diffusion is very low in the case of adsorbents with very large pores, a much higher activation energy is required for adsorption in micropores (second case)[5]. The adsorption rate is also strongly dependent on the size of the adsorptive molecule. In such a narrow pore, the gas molecule interacts simultaneously with several surface atoms of opposite pore walls. In contrast with the situation in large pores, we have here an adsorption space instead of an adsorption surface. This

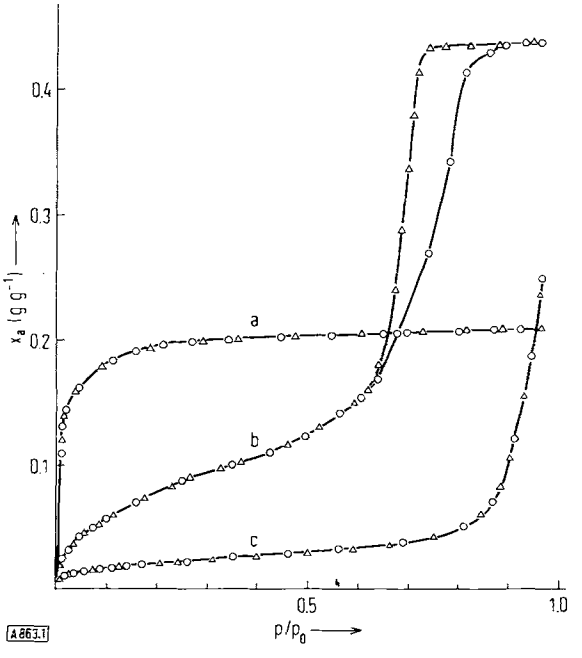

Fig. 1. Adsorption isotherm of an adsorbent with micropores (a), with intermediate pores (b), and with macropores (c). Adsorbent: porous silica; adsorptive: nitrogen; method: gravimetric determination with a Sartorius 4102 electronic vacuum microbalance. ○ = adsorption, △ = desorption.

cavity becomes increasingly packed with adsorbate with increasing pressure p. Once the adsorption space has been saturated, the quantity of gas adsorbed remains constant when the pressure is increased further. Figure 1a shows the corresponding adsorption isotherm (type I of the BDDT classification, Langmuir type). A characteristic of this type is the steep ascent at low p/p_0 values and the almost horizontal course at higher p/p_0 values.

Consideration of the adsorption process on the basis of the relationships discussed necessarily leads to a classification of adsorbents into those with narrow pores (micropores, average pore diameter $\bar{d}_p < 30$ Å) and those with very large pores (macropores, average pore diameter $\bar{d}_p > 2000$ Å)[6]. Adsorbents are then described as microporous or macroporous if the porous solid contains only pores of one of the two sizes. The limiting values indicated for the average pore diameter should not be regarded as rigid limits, but are intended merely as an indication of the order of magnitude.

In the case of microporous adsorbents, the shape of the pores must also be considered. If the micropores have constrictions (ink-bottle pores), they must be characterized by two parameters, *i.e.* the diameter of the narrow neck of the pore and the diameter of the wide body.

In the classification of porous adsorbents according to the average pore diameter, consideration must also be given to the range $30 < \bar{d}_p < 2000$ Å. Pores of this size are known as intermediate pores or mesopores. Adsorbents in which all the pores have diameters in this range are described as intermediate porous adsorbents.

Like microporous and macroporous adsorbents, adsorbents with intermediate pores also exhibit a phenomenon that leads to a characteristic shape for the adsorption isotherm. Intermediate-porous adsorbents are characterized by a hysteresis loop between the adsorption and desorption branch of the isotherm (see Fig. 1d). This can best be explained by the phenomenon of capillary condensation on the basis of the Kelvin equation[1, 7].

$$\log p/p_0 = -\frac{4\sigma V \cos\Theta}{2.3\,RT\,d_K}$$

σ = surface tension of the liquid adsorptive (dyne.cm^{-1})
V = molar volume of the liquid adsorptive (ml.mole^{-1})
Θ = angle of contact between the liquid and the pore walls
d_K = Kelvin diameter (pore diameter) (Å) on the assumption of open cylindrical pores

On adsorption at the beginning of the hysteresis loop, it is assumed that the gas condenses in the pores to form a liquid on the polymolecular adsorption layer already present. At the end of the hysteresis loop and in the subsequent horizontal part of the isotherm, all intermediate pores are filled with capillary-condensed liquid. On desorption (along the upper part of the isotherm in Fig. 1b from higher to lower values of p/p_0) the pores are emptied apart from a polymolecular layer, whose thickness t depends on the value of p/p_0.

The hysteresis between the adsorption and desorption branch of the isotherm is explained by a difference in the mechanism of the filling and emptying of the pores as a function of their shape[7]. No hysteresis is observed with microporous adsorbents.

For macroporous adsorbents, capillary condensation corresponding to the Kelvin equation occurs only at p/p_0 values close to unity. The equilibrium is also established very slowly in this range. For these reasons, capillary condensation in macropores can be determined only with very large errors, if at all.

The classification into microporous, intermediate porous, and macroporous adsorbents was proposed by *Dubinin*[6]. It is a useful classification, since characteristic differences are found in the shape of the adsorption isotherm for the three pore size ranges. With such an approach, however, instead of characterizing the pores present in an adsorbent by the specific total surface area and the specific total pore volume, one must give the characteristic parameters s, v_p, and $\bar{d}_p$ for the pore size range in question.

The knowledge of these specific structural parameters is sometimes important when porous substances are used in adsorption processes. The macropores play only a minor part in adsorption. However, they often provide access to the smaller pores. The rate of diffusion of a gas into the interior of a porous core is therefore decisively influenced by the geometry of the macropores.

The majority of synthetically produced adsorbents have pores with diameters that cover two, and often even all three ranges of pore sizes. The pore size distribution is least often homogeneous. Frequency maxima occur at various pore sizes in many cases. Gas adsorption measurements alone are not enough to characterize the pore system of such adsorbents. They must be supplemented by other methods, such as mercury porosimetry[1, 8, 9] or electron microscopy[10].

The ways in which the specific structure parameters of the three types of adsorbents and the total specific pore volume and the total specific surface area can be determined are briefly described below.

2.2. Determination of the Parameters of the Pore Structure

2.2.1. Determination of the Specific Surface Area

For adsorbents whose pores belong to one one of the three size ranges, we find the following surface area values[6]:

microporous adsorbents	$s > 500$ m^2.g^{-1}
intermediate-porous adsorbents	$10 < s < 500$ m^2.g^{-1}
macroporous adsorbents	$s < 10$ m^2.g^{-1}

Figure 2 presents a brief survey of some methods for the determination of the specific surface area by gas adsorption measurements[11–16]. The most important of these will be briefly described here.

BET Method[11, 17] (Fig. 2a): The specific monolayer capacity x_m of the adsorbent (mole.g^{-1}) is determined with the aid of the BET equation from the region ($0.05 < p/p_0 < 0.35$) of the isotherm of a gas (usually nitrogen). x_m multiplied by a_m (Å^2/molecule), the area of the gas molecule

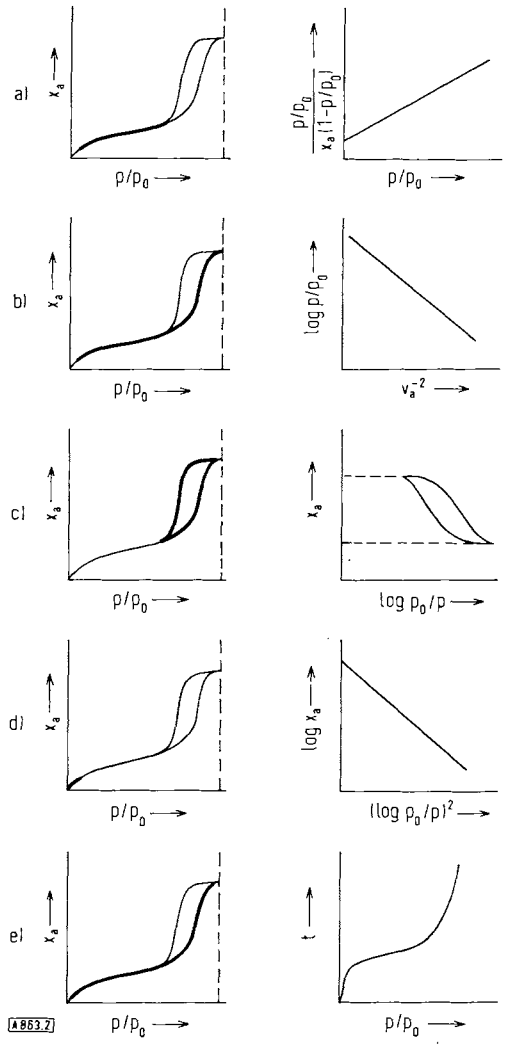

Fig. 2. Survey of methods for the determination of the specific surface of porous adsorbents. The region of the isotherm that is used is given on the left, and the equations of the isotherms are plotted as graphs on the right.

a) BET method [11, 17]:

$$\frac{p/p_0}{x_a(1-p/p_0)} = \frac{1}{x_m \cdot C} + \frac{C-1}{x_m} p/p_0$$

$$s_{BET} = x_m a_m N_L \times 10^{-20}\ (m^2 g^{-1})$$

b) Method of *Harkins* and *Jura* [12]:

$$\log p/p_0 = B - A v_a^{-2}$$

$$s_{HI} = k A^{1/2} \quad k = 4.06 \text{ (for } N_2)$$

c) *Kiselev*'s Method [13, 14]:

$$s' = \frac{2.3\,RT}{\sigma} \int_{x_{a_1}}^{x_{a_2}} \log(p_0/p)\,dx_a$$

d) *Kaganer*'s Method [15]:

$$\log x_a = \log x_m - D\,(\log p_0/p)^2$$

$$D = 2.3\,k R^2 T^2$$

$$s_K = x_m a_m N_L \times 10^{-20}\ (m^2 g^{-1})$$

(valid for the range $1 \times 10^{-5} < p/p_0 < 0.03$)

e) Method of *Lippens* and *de Boer* (*t* method) [16]:

$$t = \frac{v_a}{v_m}\delta = f(p/p_0)$$

$$s_t = 15.47\, v_a/t \text{ (for } N_2)$$

x_a = quantity adsorbed (mole.g^{-1})
x_m = specific monolayer capacity (mole.g^{-1})
v_a = quantity adsorbed (ml of gas.g^{-1})
v_m = specific monolayer capacity (ml of gas.g^{-1})
a_m = molecular cross-sectional area of a gas molecule (Å^2/molecule)
δ = thickness of a monomolecular adsorption layer (Å)
t = statistical thickness of the adsorption layer
For further abbreviations see text.

in a complete monolayer and the factor 6.02×10^3 gives the specific surface area (m^2.g^{-1}).

The two-parameter BET equation used[17] describes the interaction of a gas with a planar surface of the pore walls. Consequently, only the surface of macroporous adsorbents and to a first approximation that of intermediate porous adsorbents can be determined with the aid of this equation. On mathematical consideration of the BET equation, moreover, it is found that the isotherm of the adsorbent used for the evaluation must be concave with respect to the pressure axis, or the value C in the BET equation must be greater than two[17–19].

Purely microporous adsorbents usually give isotherms of the Langmuir type. If the course of the isotherm corresponds to the Langmuir equation, the specific monolayer capacity x_m can be obtained from the following function

$$\frac{p}{x_a} = \frac{1}{B x_m} + \frac{p}{x_m}$$

B = constant of the Langmuir equation

The determination of the specific surface area by the method of *Harkins* and *Jura*[12] (Fig. 2b) will not be discussed here.

Determination of the Specific Surface Area s' of the Adsorption Layer from the Isotherm: According to *Kiselev*[13, 14] (Fig. 2c), the specific surface area s' of the adsorption layer can be determined, on the basis of thermodynamic considerations, with the aid of the following equation:

$$s' = \frac{2.3\,RT}{\sigma} \int_{x_{a_1}}^{x_{a_2}} \log \frac{p_0}{p}\,dx_a$$

σ = surface tension of the pure liquid adsorptive (dyne.cm^{-1})
x_{a_1} = quantity adsorbed (mole.g^{-1}) at the beginning of the hysteresis loop
x_{a_2} = quantity adsorbed (mole.g^{-1}) at the end of the hysteresis loop.

The value of the integral is determined both for the desorption branch and for the adsorption branch of the isotherm from the function

$$x_a = f(\log p_0/p)$$

and the two values are then averaged. It is assumed that at the beginning of the hysteresis loop, corresponding to the lower integration limit x_{a_1}, the adsorbate is present as a condensed liquid phase, and that at the end of the hysteresis loop, corresponding to the upper integration limit x_{a_2}, the pores are filled with capillary-condensed liquid. An indication that these assumptions are permissible was provided by the agreement of the values of s' found for an intermediate porous silica with various adsorptives. The values also agree with the BET surfaces[14].

It can be seen that this method can be used for the determination of the specific surface areas only of adsorbents with intermediate pores, since only these exhibit hysteresis. Unlike the BET method, this method requires accurate determination of the entire isotherm.

Determination of the Specific Surface Area after Kaganer[15] (see Fig. 2d): On the basis of *Dubinin*'s potential theory[1], *Kaganer*[15] derived an equation that represents the course of the isotherm of a porous substance in the monolayer adsorption range ($1 \times 10^{-5} < p/p_0 < 0.03$):

$$\log x_a = \log x_m - D\,(\log p_0/p)^2$$

It differs from the Dubinin-Raduschkewitsch equation (see Section 2.2.2) in the constant and in the replacement of the term $\log W_0/V$ by $\log x_m$. x_m is obtained by extrapolation of the straight line to the value $(\log p_0/p)^2 = 0$. The specific surface area can be calculated with the aid of x_m as follows:

$$s_K = x_m N_L a_m \times 10^{-20}\ (m^2 g^{-1})$$

Determination of the Specific Surface Area after Lippens and de Boer (t Method)[16] (see Fig. 2e): The *t* method developed by *Lippens* and *de Boer*[16] is not an independent method for the determination of the specific surface. When the correct *t* curve is used ($t = f(p/p_0)$), the value of s_t must agree with the specific surface area according to the BET method.

Specific Surface Area from Mercury Penetration Measurements: According to *Rootare* and *Prenzlow*[20], the specific surface area of an adsorbent can be determined from mercury penetration measurements with the aid of the following equation:

$$s = -\frac{1}{\sigma \cos\Theta} \int_{v_0}^{v_{max.}} p\,dv$$

σ = surface tension of mercury (dyne.cm^{-1})
Θ = contact angle between liquid mercury and the pore walls
v = volume of mercury forced into the pores of the adsorbent with increasing pressure
v_0 = volume of mercury at $p = 1$ atm (v assumed to be 0)
v_{max} = volume of mercury forced in at p_{max}

The value of the integral is determined graphically from the experimentally obtained function $p = f(v_p)$. No assumptions are made about the shape of the pores. Measurements on various adsorbents have shown that the surface values obtained in this way agree with the BET values at $s < 100$ m^2.g^{-1}.

2.2.2. Determination of the Specific Pore Volume

The specific pore volume can be determined from adsorption measurements only for adsorbents with micropores and intermediate pores. The specific pore volume of macroporous and intermediate-porous adsorbents can be determined independently by mercury penetration measurements[1, 8, 9].

The total pore volume is determined by mercury and helium permeametry[21], in which the apparent densities ρ_{Hg} (density with respect to mercury) and ρ_{He} (density with respect to helium) of the porous adsorbent are determined in two separate experiments. The reciprocal $1/\rho_{Hg}$ corresponds to the specific volume of the skeletal substance plus the specific volume of pores having $\bar{d}_p < 12$ µm, while $1/\rho_{He}$ corresponds only to the specific volume of the skeletal substance. The difference $1/\rho_{Hg} - 1/\rho_{He}$ is thus equal to the specific total pore volume.

Determination of the Specific Pore Volume from Gas Adsorption Measurements; Gurwitsch Rule: The Gurwitsch rule[1, 22] is based on the assumption that when the isotherm of a gas is parallel to the abscissa in the range $0.95 < p/p_0 \lessapprox 1$, all the pores of an adsorbent are completely filled with liquid adsorbate. In this way, the pore volume of microporous and intermediate-porous adsorbents is found from the equation

$$v_p = x_a \cdot V\ (ml\,g^{-1})$$

x_a = quantity adsorbed (mole.g^{-1}) at $0.95 < p/p_0 \lessapprox 1$
V = molar volume of the liquid adsorptive at the experimental temperature (ml.mole^{-1})

It was found from numerous adsorption experiments with gases and vapors on a wide range of adsorbents (at various temperatures) that the pore volume determined from the Gurwitsch rule is practically independent of the adsorptive used[1].

Determination of the Specific Pore Volume after Dubinin-Raduschkewitsch[1, 6, 24, 25]: On the basis of *Polanyi*'s potential theory[23], *Dubinin et al.* derived a theory of the adsorption of gases in micropores (theory of volume filling of micropores). The result is an equation that represents the course of the adsorption isotherm in the range $1 \times 10^{-5} < p/p_0 < 0.2$:

$$\log x_a = \log \frac{W_0}{V} - B'T^2 (\log p_0/p)^2$$

x_a = quantity of gas adsorbed (mole.g^{-1})
W_0 = total volume of the adsorption space (= specific pore volume v_p) (ml.g^{-1})
V = molar volume of the liquid adsorptive (ml.mole^{-1})
B' = constant ($= 2.3 \times k' R^2 T^2$)

A plot of $\log x_a$ against $(\log p_0/p)^2$ gives a straight line whose intercept on the ordinate corresponds to the ratio W_0/V.

Below the boiling point of the adsorptive, V is equal to the molar volume of the liquid, to a first approximation. For higher temperatures, *Dubinin et al.* describe a method for the calculation of the molar volume[6]. W_0, which corresponds to the micropore volume of the adsorbent in question, can thus be calculated.

2.2.3. Determination of the Pore Size Distribution

The function $dv_p/dd_p = f(\bar{d}_p)$ of a porous adsorbent can be determined experimentally from gas adsorption measurements and from mercury penetration measurements[1]. Gas adsorption measurements yield information only on the pore size distribution in the micropore and intermediate pore range, while mercury penetration measurements give the distribution in the macropore and intermediate pore range provided that $p_{max} \approx 4000$ atm. In the subsequent calculation, the real pore structure is approximated by models[26], or a ratio dv_p/ds is given without assumption of a model[27, 38].

Brunauer[27, 28] described a method by which the pore size distribution of microporous adsorbents can be calculated. In this method, in addition to the measured adsorption isotherm, it is necessary to know the t curve[29, 30], which shows the dependence of the thickness t of the adsorbed layer on the relative pressure p/p_0 on a non-porous adsorbent of the same chemical composition (Fig. 2e).

For adsorbents with intermediate pores, the pore size distribution is calculated from the isotherm in the hysteresis region with the aid of the Kelvin equation[1]. It is assumed that the differences in the shape of the hysteresis are determined by the pore shape. For some pore models, the course of the desorption and adsorption isotherms can be given theoretically[26, 31]. Depending on the model chosen, therefore, the adsorption branch, the desorption branch, or both branches of the isotherm are used. The evaluation can be carried out by various calculation methods, in which the thickness t of the adsorbed layer is assumed to be constant or its dependence on p/p_0 is taken into account[32–38].

The mercury penetration measurements are evaluated on the basis of *Washburn*'s equation[8, 9, 39]

$$p = -\frac{4\sigma\cos\Theta}{d_p}$$

σ = surface tension of mercury (dyne.cm^{-1})
Θ = contact angle between liquid mercury and the pore walls
p = equilibrium pressure

This equation is valid for cylindrical pores. Comparison of the pore size distributions found for porous adsorbents by the mercury penetration method and by gas adsorption measurements shows good agreement in the intermediate pore range[40, 41].

3. Preparation of Porous Adsorbents with Variable Parameters of the Pore Structure by Specific Synthesis

In naturally occurring porous adsorbents, such as kieselgur and kaolin, the pore structure is fixed by geochemical processes spanning millions of years. Most of the adsorbents used today, however, are either prepared synthetically or obtained from natural products by special treatment (examples: active charcoal, cellulose).

Two types of methods can be distinguished in synthesis. In one type, the pore structure is formed directly as a result of consecutive or simultaneous chemical and physical processes, while in the other it may arise indirectly from the removal of one component from a solid having an inhomogeneous composition (example: porous glass).

The direct synthesis is the more interesting method from the standpoint of preparative chemistry. Its object is to produce porous adsorbents having a specific pore structure by variation of the preparation conditions. This requires a knowledge of the processes that lead to the formation of the pore structure of a porous substance, and of the factors that influence them. Systematic studies of this nature have been successfully carried out on only a few substances.

Depending on the average pore diameter of the adsorbent, moreover, quite different processes are responsible for the formation of the pore structure. Micropore formation involves processes that take place in the range of atomic dimensions and lead *e.g.* to a different linkage of atoms or groups of atoms. The pore structure in the range of intermediate pores may result *e.g.* from the packing together of non-porous particles (colloidally dissolved or highly dispersed particles). Macropores, on the other hand, are formed from interstices between aggregated crystallites or arise from cracks and dislocations of crystals.

From the many porous adsorbents, two are selected here for the discussion of the formation of their pore structure and its variation. Example 1 consists of the synthetic zeolites, which have a pronounced micropore structure. Their main importance is in industry, *e.g.* in the separation and refining of hydrocarbon mixtures[42, 43]. Example 2 is porous silica (silica gel). Its average pore diameter can be varied over a much wider range than that of the zeolites. The main use of this adsorbent is in chromatography[44].

3.1. Preparation of Synthetic Zeolites

Zeolites are crystalline aluminosilicates[45, 46] having the chemical composition $M_{2/m}\cdot Al_2O_3\cdot nSiO_2\cdot xH_2O$. The aluminosilicate framework consists of $[SiO_4]$ and $[AlO_4]$ tetrahedra linked to one another by the oxygen atoms. The negative excess charge resulting from the replacement of silicon by aluminum is neutralized by alkali metal and/or alkaline earth metal ions. Fibrous, lamellar, and infinite three-dimensionally crosslinked structures are found[42].

Only the infinite three-dimensionally crosslinked zeolites are suitable for use as adsorbents. Their structure can be imagined as consisting of polyhedra formed from $[SiO_4]$ and $[AlO_4]$ tetrahedra. Linkage of these polyhedra by four-membered, six-membered, eight-membered, or even twelve-membered oxygen rings gives cavities that extend throughout the entire zeolite crystal. In the unactivated state, the cavities are filled with water.

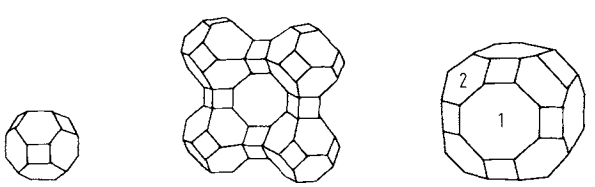

Fig. 3. Formation of the cavity structure in zeolite A by linkage of octahedra (schematic). a) Truncated octahedra. b) Part of the model of the unit cell. c) Large cavity of b (magnified). For 1 and 2 see text.

As an example, Figure 3 shows schematically the formation of the cavity structure in the synthetic zeolite A (faujasite type)[47, 48], which has a cubic crystal structure. The cavity is formed by linkage of truncated octahedra by four-membered rings of oxygen atoms (Fig. 3b). We distinguish a larger cavity (Fig. 3c) bounded by eight truncated octahedra and having a diameter of 11 Å. This cavity is accessible *via* six openings (corresponding to the surfaces such as 1),

each of which is formed from eight oxygen atoms. The diameter of such an eight-membered ring is 4 Å. In each of the eight truncated octahedra, there is also a smaller cavity having a diameter of 7 Å. Each of these smaller cavities is linked to the larger cavity by a six-membered ring of oxygen atoms (diameter 2 Å, corresponding to the surfaces such as 2). It must be pointed out that on adsorption, the entrances to the smaller cavities of the synthetic zeolite A are too narrow for molecules, so that these pass into the cavity only through the larger openings[5].

These cavities are connected to other cavities with the same dimensions by the six-membered and eight-membered openings (corresponding to the surfaces 2 and 1 respectively) to give a system of cavities having extremely regular dimensions. This structure is described as a micropore structure, since the diameters of the cavities (pores) are of the order of magnitude of molecular dimensions.

The micropores of zeolites are characterized by two parameters, *i.e.* the diameter of the entrance to the cavity and the diameter of the cavity. Values for these parameters can be estimated from X-ray structural data. Adsorption measurements give only the total volume of the pores.

What has been said about zeolite A is also applicable to the other synthetic zeolites[49] which differ from zeolite A only in the manner in which the polyhedra are linked, *i.e.* in the lattice constants of the unit cell. In this way one obtains porous solids having cavities with definite diameters, depending on their structure. The diameter of the entrances can be additionally varied by ion exchange[50, 51]. According to *Barrer*[52], the synthetic zeolites can be divided into five types according to the diameter of the entrances leading to the cavities, *i.e.* type 3A (3 Å), 4A (4 Å), 5A (5 Å), 10X (8 Å), and 13X (10 Å).

It can be seen from the above discussions that the pore structure of zeolites is determined by their crystal structure. To obtain reproducible values for the pore structure, it is necessary to adhere exactly to the synthesis conditions that lead to zeolites having definite compositions and crystal structures.

The natural zeolites were formed millions of years ago by the action of basic mineral salt solutions on rocks at 100 to 300 °C under pressure. The conditions of this hydrothermal synthesis have been simulated in the preparation of synthetic zeolites.

The starting materials are aqueous solutions of sodium aluminate and sodium silicate and of sodium hydroxide. When the solutions are mixed, they form a gel, which is then heated under pressure at 50—350 °C. This leads to recrystallization of the amorphous gel. The microcrystalline precipitate is separated from the mother liquor, washed, and dried.

Reproducibility of the composition and crystal structure of the synthetic zeolites can be achieved through the conditions of the hydrothermal synthesis. The most important factors are the molar ratio $SiO_2:Al_2O_3$, the content of alkali metal and/or alkaline earth metal ions, and the crystallization temperature. The influence of these parameters on the crystal structure of the zeolites has been studied in detail by *Barrer*[53] and by *Shdanov*[54].

The zeolites are formed in the synthesis as a microcrystalline powder (range of particle diameters 0.1—10 μm). For industrial use, the zeolite crystals are mixed with a binder (*e.g.* clay) and the material is then pressed into small rods or spheres. This process results in an additional pore structure, which is determined by the size of the crystallites and the molding pressure. The resulting pores are macropores having $\bar{d}_p > 2000$ Å[5].

3.2. Preparation of Porous Silica

In the synthetic zeolites, the parameters of the cavity structure are determined by the crystal structure, *i.e.* by the linkage of the atoms and the distances between them. Porous silica, on the other hand, is an amorphous substance having the composition $SiO_2 \cdot xH_2O$. The framework consists of infinite three-dimensionally crosslinked $[SiO_4]$ tetrahedra. On its surface, porous silica has polar hydroxyl groups and adsorbed water[55].

Because of its amorphous character, we cannot expect such a homogeneous pore structure as in the case of the zeolites. However, the special advantage of porous silica is that samples with highly variable average pore diameters (range $10 < d_p < 10000$ Å) can be prepared. Its properties can thus be adjusted to suit a wide range of applications.

The pore structure of porous silica arises in an entirely different manner from that of the zeolites, and the processes involved in its formation are much more complicated. They will be illustrated by the example of preparation from sodium silicate[55].

On acidification of a sodium silicate solution, the silicate ions are converted into silicic acids, which condense, according to the pH, to give polysilicic acids. The submicroscopic polysilicic acid particles grow into larger particles, which are non-porous, and which are spherical. Their diameter is approximately 100 Å. They are in colloidal solution (polysilicic acid sol). The subsequent aggregation of the polysilicic acid particles finally leads to the formation of a polysilicic acid gel. The reason for the aggregation is the dehydration of surface hydroxyl groups of neighboring polysilicic acid particles. The polysilicic acid gel is an infinite three-dimensionally crosslinked packing of spherical polysilicic acid particles, which still contains immobilized water. The water is removed by subsequent heating, and the dehydration thus proceeds further. The final product is a hard, porous xerogel (silica gel). The walls of the pores are formed by the surfaces of the spherical polysilicic acid particles. Depending on the size and packing density of the particles, we obtain pores of various sizes. The formation of small and large pores is shown schematically in Figure 4.

The parameters of the pore structure are thus determined by the dimensions of the polysilicic acid particles and by their packing density[56]. To obtain given values of these parameters, the size and the growth of the polysilicic acid particles and the gel formation must be controlled. The influence of the preparation conditions in the steps polysilicic acid sol → polysilicic acid gel → xerogel on both processes have been systematically studied in numerous investigations[57-65].

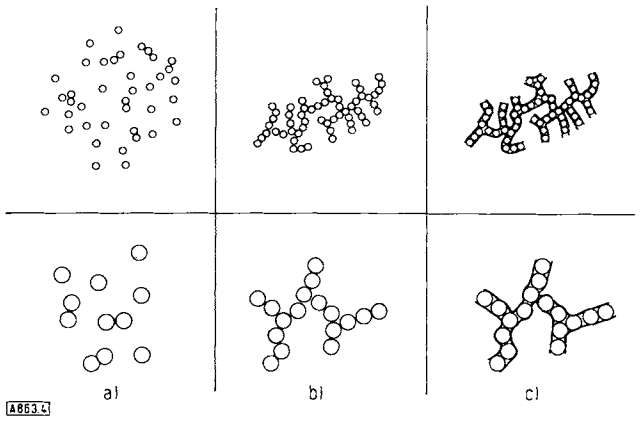

Fig. 4. Development of large and small pores on formation of porous silica (schematic). a) Colloidal solution of polysilicic acid particles, top: small particles, bottom: large particles. b) Aqueous polysilicic acid gel, top: many contact points for small particles, bottom: few contact points for large particles. c) Hard, porous xerogel, top: many small pores and correspondingly large surface area for the small particles, bottom: few large pores and correspondingly small surface area for the large particles.

The growth of the polysilicic acid particles can be inhibited as follows: by a pH of <7 in the polysilicic acid sol[57, 59]; by treatment of the polysilicic acid gel with dilute acids[60, 61, 64]; by replacement of the immobilized water with organic solvents[65]. A pH of >5 in the polysilicic acid sol, on the other hand, favors the growth of the polysilicic acid particles and accelerates the gel formation[59, 60, 63]. The same effect is achieved if the polysilicic acid gel is treated with alkaline solutions or with strong sulfuric acid solutions[62]. The hydrothermal treatment of the polysilicic acid gel at high temperatures in an autoclave is particularly effective[66–68]. Because of the higher solubility of the smaller polysilicic acid particles, larger particles are formed with rising temperature and with increasing treatment time.

Porous silica is generally obtained in the form of hard, irregularly shaped particles, which are crushed and sieved or classified to obtain the desired grain size fraction. However, spherical porous silicon dioxide particles are required for many purposes, *e.g.* for use as stationary phase material in column chromatography[69] or as a catalyst support in moving bed or fluidized bed reactors.

As an example, a new method for the preparation of spherical silica particles is described below[70, 71]. The starting material is a tetraalkoxysilane, *e.g.* tetraethoxysilane. The tetraethoxysilane is dissolved in a solvent, and a slight amount of water containing small quantities of a catalyst is added. A hydrolytic polycondensation now occurs in the homogeneous phase with formation of a high molecular weight polyethoxysiloxane, which still contains ethoxy groups. The polyethoxysiloxane is freed from solvent and from monomer. Its viscosity can be varied by adjustment of the hydrolysis conditions.

In a further reaction, the condensation of the polyethoxysiloxane is completed in a heterogeneous phase by addition of solvent and an excess of water containing a catalyst. This reaction is carried out with stirring. The stirring leads to the emulsification of the polyethoxysiloxane, and the resulting droplets subsequently harden. The spherical particles obtained are porous. Figure 5 shows a photomicrograph of such a product.

The parameters of the pore structure can be systematically varied over a wide range in this method by variation of the nature and concentration of the catalyst in the hydrolytic polycondensation reaction (Table 1). Another advantage

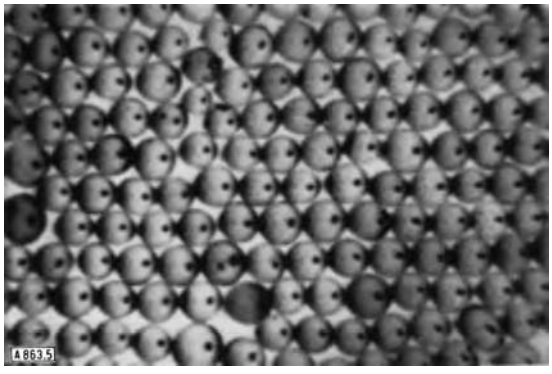

Fig. 5. Photomicrograph of a porous silica consisting of spherical particles (magnification 1:40).

is that very pure silica preparations can be obtained. The droplet size of the polyethoxysiloxane and hence the diameter of the resulting spherical particles, can be varied within wide limits (range about 1—1000 μm) by variation of the viscosity of the polyethoxysiloxane and of the stirring rate during the emulsification.

Table 1. Examples of the variation of the parameters of the pore structure of porous silica prepared from tetraethoxysilane. s_{BET} = specific surface according to BET method, v_p = specific pore volume, $\bar{d}_p$ = average pore diameter.

Sample	s_{BET} ($m^2\,g^{-1}$)	v_p ($ml\,g^{-1}$)	$\bar{d}_p$ (Å)
1	563	0.30	20
2	630	0.63	40
3	311	0.78	100
4	178	0.88	200
5	220	2.20	400
6	215	4.19	800

4. Chemical Modification of the Surface of Porous Adsorbents

Examples of the preparation of porous substances with variable parameters of the pore structures were given in the last section. The adsorption properties of a porous substance are determined not only by the geometry of the pore system but also by the nature and structure of the surface atoms or groups of atoms[3]. This can be seen *e.g.* in the adsorption behavior to different polar gases or vapors.

Methods by which one type of functional group on the surface of an adsorbent can be replaced by others to obtain selective adsorbents are therefore of interest. This is possible by reactions of the existing surface groups with suitable

reactants to form new functional groups, which in turn are chemically bonded to the surface. For such surface reactions to occur, the existing functional groups of an adsorbent must be sufficiently reactive. Moreover, the reactions should be carried out under conditions that give a dense monomolecular surface layer that eliminates as far as possible the influence of the original surface on the adsorption process.

These reactions on the surface of porous solids must be distinguished from chemisorption processes *e.g.* on metal surfaces[72,73]. The latter are carried out with gases such as oxygen, hydrogen, and carbon monoxide on clean, definite surfaces under ultra-high vacuum conditions. Their purpose is to elucidate the elementary steps in the adsorption and the bonding between the adsorbate and the adsorbent. The investigation methods used include field electron and field ion microscopy, mass spectrometry, IR spectroscopy, and low energy electron diffraction (LEED method).

Porous adsorbents have a specific surface area several orders of magnitude greater than that of metals. The effects in surface reactions on porous adsorbents are consequently greater. Moreover, their surface is often contaminated with traces of adsorbed water or oxygen, since the samples are heated at high temperatures before the reaction only in a high vacuum, and not in an ultra-high vacuum. The surfaces before the reaction are therefore not usually clean in the physico-chemical sense. Furthermore, most porous adsorbents have an energetically heterogeneous surface. These facts impose limits regarding the interpretation of such reactions. Their theoretical description is further hindered by the fact that the diffusion and adsorption of the reactants in the pore system is very complicated[5].

The importance of surface reactions on porous adsorbents lies in the preparation of new adsorbents and in their wide practical application. Numerous reactions on adsorbents have already been investigated, *e.g.* on graphite[74,75], synthetic zeolites[45], and oxide adsorbents[70,74]. The problem of surface reactions will be illustrated for an oxide adsorbent, *i.e.* porous silica. This is particularly suitable for use as a model substance, on the one hand because of the possibility to vary the parameter of its pore structure, and on the other because its polar hydroxyl groups allow numerous reactions. Promising reactions are those in which an Si—C bond is formed on the surface. The favorable solid-state properties of porous silica are combined in this way with the many synthetic possibilities of organic chemistry. The attachment of Si-aryl groups to the surface, for example, changes the polarity of the surface, and further reactions are also possible on the aryl groups[76].

4.1. Chemical Structure of the Surface of Amorphous Silica

The surface of both amorphous and of crystalline silica is hydrated[74,77]. Weakly acidic hydroxyl groups attached to silicon atoms are distinguished from siloxane groups on the surface. The concentration of hydroxyl groups can be determined *e.g.* by the following chemical and physical methods: reaction with methyllithium or Grignard compounds followed by quantitative determination of the methane formed[78,79], heterogeneous isotope exchange with D_2O and subsequent mass-spectrometric analysis[80,81], and heterogeneous isotope exchange with tritium-labeled water[79]. The maximum concentration of hydroxyl groups α_{OH} on porous silica at an activation temperature of 200 °C is 8.0—9.0 μmole.m^{-2}[78,82]. α_{OH} is a function of the temperature (Fig. 6). With rising temperature, condensation leads in an increasing degree to the formation of siloxane groups.

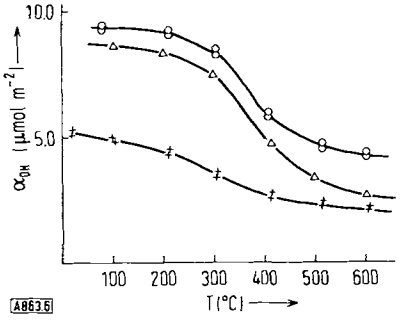

Fig. 6. Dependence of the hydroxyl group concentration α_{OH} (μmole.m^{-2}) of porous and non-porous silica samples on the activation temperature with simultaneous vacuum treatment. ○ = silica gel, $s_{BET} = 35$ m^2.g^{-1}, $\bar{d}_p = 1200$ Å; △ = silica gel, $s_{BET} = 330$ m^2.g^{-1}, $\bar{d}_p = 200$ Å; + = Aerosil, $s_{BET} = 200$ m^2.g^{-1}. Determination method: reaction with methyllithium, followed by determination of methane.

It can be concluded from the course of the curve (Fig. 6) that the hydroxyl groups are bonded in different ways. Further information is provided by IR-spectroscopic studies (transmission measurements, disks)[78,83-85]. Both non-porous and porous silica give a sharp band at 3750 cm^{-1}, which is assigned to the stretching vibration of free hydroxyl groups. A further broad, indistinct band appears in the vicinity of 3550 cm^{-1}, and this is assigned to the stretching vibration of hydroxyl groups which are bonded to one another by hydrogen bonds.

Numerous models have been developed for the bonding of hydroxyl groups on the surface of porous silica. The two most important are:

1. *Concept of free and bound hydroxyl groups:* On a silica surface, one can distinguish free and bound hydroxyl groups. According to *Kiselev*[86], at a total concentration of $\alpha_{OH} = 8.0$ μmole.m^{-2}, 4.3 μmole.m^{-2} is the concentration of free hydroxyl groups and 3.7 μmole.m^{-2} is the concentration of bound hydroxyl groups. *Armistead et al.*[87] give a concentration of 2.5 μmole.m^{-2} of free and 5.2 μmole.m^{-2} of bound or paired hydroxyl groups for a total concentration of 7.7 μmole.m^{-2}.

2. *Concept of paired hydroxyl groups:* According to *Peri*[88], a silica surface has mainly paired (geminal and vicinal) hydroxyl groups, together with isolated free hydroxyl groups. The concentration of each of these species can be calculated as a function of the total concentration.

The course of the curve in Figure 6 can be interpreted as follows on the basis of these models. The hydroxyl group concentration initially decreases slightly as a result of desorption of adsorbed water[78]. At about 300 °C, the con-

centration of adsorbed water is negligibly small in relation to that of the hydroxyl groups. The pronounced decrease in α_{OH} between 300 and 500 °C is attributed to the condensation of bound or paired hydroxyl groups. The condensation of free hydroxyl groups occurs only above 600 °C. The course of the curve differs slightly for each porous silica sample, depending on its preparation.

It is interesting in this connection to note that two sharp, symmetrical IR bands have been found at 3657 cm^{-1} and 3636 cm^{-1} for crystalline quartz (ATR Technique, powder)[89]. These bands are assigned to the stretching vibration of free and relatively free hydroxyl groups. It can be concluded from the results that the surface of crystalline silicon dioxide resembles those of crystalline titanium dioxide (anatase) and of γ-aluminum oxide more than that of amorphous silica.

4.2. Formation of an Si—C_{aryl} Bond on the Surface of Porous Silica[76]

As an example, we shall describe the formation of a surface Si—C_{aryl} bond. The following two methods are possible[90–94]:

1. Reaction of silica with arylchlorosilanes. A siloxane linkage is formed with elimination of hydrogen chloride. The Si—C bond in this case is already present in the reactant.

2. Reaction of silica with silicon tetrachloride or thionyl chloride followed by a reaction of the chlorosilylated or chlorinated products with aryllithium compounds. In the first reaction, a very reactive group is formed on the surface, and in the second, an Si—C bond is formed directly with elimination of lithium chloride.

The kinetics of the reaction and the influence of the reaction temperature on the conversion was investigated first for the reaction of porous silica with the homologs phenyltrichlorosilane, diphenyldichlorosilane, and triphenylchlorosilane[91,92,94]. Because of the diffusion of the reactants into the pores, the times required to reach a constant conversion were very long. The conversion also increased with rising temperature. Above 200 °C, however, no further increase could be achieved. This was taken as evidence that maximum coverage had been reached under these conditions (see Table 2).

On the basis of these results, porous silica was allowed to react under the same conditions with silicon tetrachloride or thionyl chloride[93]. In the subsequent reaction of these modified products with solutions of phenyllithium, α-naphthyllithium, or trityllithium in ether, heating was possible only up to a maximum of 35 °C; however, the aryllithium compounds were used in large excess[93]. The following analytical studies were carried out on the modified derivatives and on the starting materials: elementary analysis for chlorine, carbon, silicon (increase on modification with $SiCl_4$), determination of the hydroxyl group concentration, IR spectroscopic studies (transmission measurements, disks). Results are shown in Table 2.

The values in Table 2 show that the maximum coverage with aryl groups is a function of the size of the molecule offered for reaction. Both with the homologous phenylchlorosilanes and with the aryllithium compounds, the maximum conversion under given conditions decreases with increasing molecular size. This is due to the increasing cross-sectional area of the molecules.

4.3. Influence of the Surface Reaction on the Parameters of the Pore Structure[95]

A surface reaction can cause a total of three effects that can alter the parameters of the pore structure:

1. The reaction leads to a specific increase in weight in relation to the starting material. The specific surface and the specific pore volume of the modified products must therefore be corrected by a corresponding amount.

2. The reaction leads to a change in the polarity of the surface. Since the parameters of the pore structure are determined from adsorption and desorption measurements

Table 2. Maximum surface concentration of Si-aryl groups on porous silica samples (hydroxyl group concentration of the starting material $\alpha_{OH} = 8.0$ μmole · m^{-2}).

Sample modified with	Surface functional groups	Maximum surface concentration (μmol m^{-2})
	—OH	8.0
Phenyltrichlorosilane	$>Si(Cl)C_6H_5$	3.6
Diphenyldichlorosilane	$—Si(Cl)(C_6H_5)_2$	2.6
Triphenylchlorosilane	$—Si(C_6H_5)_3$	1.9
Benzyltrichlorosilane	$>Si(Cl)CH_2C_6H_5$	4.1
Silicon tetrachloride	$—SiCl_3$, $>SiCl_2$	2.3; 2.9
Thionyl chloride	—Cl	6.8
Silicon tetrachloride + Phenyllithium	$\geqslant Si—C_6H_5$	5.4
+ α-Naphthyllithium	$\geqslant Si—C_{10}H_7$	3.4
+ Trityllithium	$\geqslant Si—C(C_6H_5)_3$	1.9

with nitrogen, this can lead to a decrease in the quantity adsorbed and hence to a decrease in s and v_p.

3. The reaction results in the deposition of a layer of thickness t on the original surface. The average pore diameter consequently decreases by $\Delta\bar{d}_p = 2t$. This decrease may lead to a more or less large decrease in the specific surface area s and in the specific pore volume v_p, depending on the $\bar{d}_p$ value of the starting material.

In macroporous silica samples, these effects are negligible, and the parameters s, v_p and $\bar{d}_p$ are not affected. In purely microporous samples, the reactions mentioned lead to total blockage of the pores, since the size of the reacting molecules is of the same order of magnitude as the diameter of the pores. The resulting products are non-porous. In silica samples with intermediate pores, s and v_p were found to decrease by an amount which depends on the size of the reacting molecule. Also the mean pore diameter $\bar{d}_p$ of the modified samples becomes smaller than that of the starting material. These effects are still being investigated.

4.4. Influence of the Chemical Modification of the Surface of Porous Silica on Its Adsorption Properties[94]

On replacement of the acidic protons of the hydroxyl groups by Si-aryl groups, the hydrophilic character of silica largely disappears. The resulting products are hydrophobic, and can no longer be wetted with water. A quantitative measure of the change in the adsorption properties is provided by the heats of adsorption of the modified products for various polar gases (Table 3).

Table 3. Isosteric heats of adsorption ($q_{isost.}$) of benzene and methanol on various modified porous silica samples and the starting material ($s_{BET} = 35\ m^2 \cdot g^{-1}$, $\bar{d}_p = 960$ Å). Determination method: gas chromatography at 190°C.

Surface functional groups	$q_{isost.}$ (kcal mol^{-1}) Benzene	Methanol
—OH	6.9 ± 0.5	12.1 ± 0.5
>Si(OH)C_6H_5	4.6	9.3
—Si(OH)$(C_6H_5)_2$	4.4	7.2
—Si$(C_6H_5)_3$	1.3	1.7
—Si$(CH_3)_3$	1.6	2.2

The heat of adsorption of benzene or methanol, as expected, is highest for the starting material and lowest for the silica modified with triphenylchlorosilane. The latter corresponds in its hydrophobic character to a product obtained by reaction with trimethylchlorosilane. A gradation is found between the two values, the heat of adsorption decreasing with the number of phenyl groups bonded to the silicon atom. The differences are more pronounced in the case of the polar methanol than in the case of benzene. The results also confirm the composition of the surface, which was obtained from analytical data independently of adsorption measurements.

Substitution reactions can be carried out on the surface aryl groups. In this way, it is possible to synthesize porous silica samples having acidic or basic functional groups[96].

5. Closing Remarks

Porous silica and synthetic zeolites have been used as examples to illustrate a number of general lines of development that are currently of interest in the field of adsorbents. The most important aspects are their preparation and the use of chemical and physical methods to describe the geometry of their pore system and the chemical structure of their surface. It is only with the aid of this knowledge that adsorbents having desired properties can be prepared and their mode of action interpreted.

Advances in Acoustical Holography

By K. Preston, Jr.[*]

The most recent branch of holography, acoustical holography employing acoustical radiation, presents a variety of new and highly interesting possible applications: Thus objects can be imaged in a turbid liquid medium (marine research); the technique can be used for non-destructive investigations of the internal structure of objects that are opaque to light (testing of materials) and is possibly also a potential tool for the three-dimensional imaging of biological structures (biomedical diagnosis).

1. Introduction

Optical holography is familiar to all of us. It has opened a new and interesting area of technical endeavor. Although not every reader of this article may have seen holographic images with his own eyes, he will certainly have encountered numerous articles on the subject of holography.

The reader is probably less aware that holography has been used in an entirely different mode during the past five years—in a mode wherein the hologram is made by means of acoustical radiation. After recording an acoustical hologram a holographic image may be formed by means of light so that the image may be examined by the human eye. Images may also be formed from an acoustical hologram by means of a digital computer where the image is displayed using a cathode ray tube. It is the purpose of this article to review the state of the art in the field of acoustical holography and to illustrate the benefits a chemist may derive from use of the technique.

2. Fundamental Properties

Before continuing the discussion of acoustical holography, this article discusses some of the fundamentals of holography by using one or two illustrations from the world of optical holography. Either the optical or the acoustical hologram may be recorded in the form of a transparency which, when illuminated from a monochromatic point source, acts upon the illuminating radiation in such a way as to create a multiplicity of spherical wavefronts each corresponding in strength and apparent source position to all points in the original scene from which the hologram was made. This explains why holographic imaging has been called *wavefront reconstruction*[1]. There is no fundamental restriction in holography as to the particular radiation chosen to create the hologram nor on the radiation used for illuminating the hologram in performing wavefront reconstruction.

2.1. Forming the Hologram

Let us first set holography in perspective by considering the formation of the hologram itself. Construction of the hologram of an object requires that the object be illuminated with monochromatic radiation. To create the hologram, interference fringes are formed between the back-scattered waves of radiation from the object and another wavefront called the *reference*. In most holographic systems the reference is of the same frequency as the illuminating radiation.

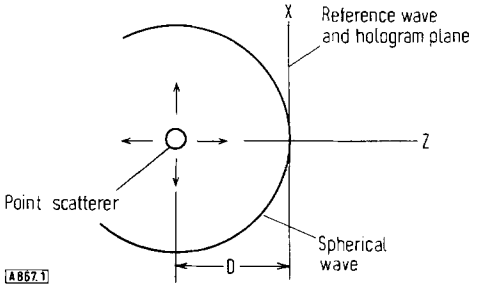

Fig. 1. Schematic diagram showing a spherical wave radiating from a point scatterer and impinging in the hologram plane with a planar reference wave.

The simplest hologram—and the one from which all other holograms may be derived—is the hologram of a point scatterer. Figure 1 shows the spherical wave reflected from a single point scatterer; the $x-y$ plane (perpendicular to this page) is chosen to be the *hologram plane*. It is in this plane that the interference pattern between the back-scattered wave and the reference wave is formed. For simplicity Figure 1 shows the hologram plane parallel to a coplanar reference wave. In this case the interference pattern which constitutes the hologram is the well known *Fresnel zone plate*[2] of classical optics (see Fig. 2). This hologram consists of alternately bright and dark concentric rings. This hologram is dark at the center when the reference wave and the back-scattered wave are out of phase. The rings occur because the reference wave and the back-scattered spherical wave go alternately in and out of phase. The rings are more closely spaced as the distance from the center increases because of the quadratic nature of the phase across a spherical surface.

If D is the distance from the point scatterer to the origin, it is, of course, the radius of the back-scattered wave. The distance from the point scatterer to the $x-y$ plane is given by

$$\sqrt{D^2 + r^2};\ r^2 = x^2 + y^2$$

[*] Dr. K. Preston, Jr.
Optical Group
The Perkin-Elmer Corporation
Norwalk, Conn. 06852 (USA)

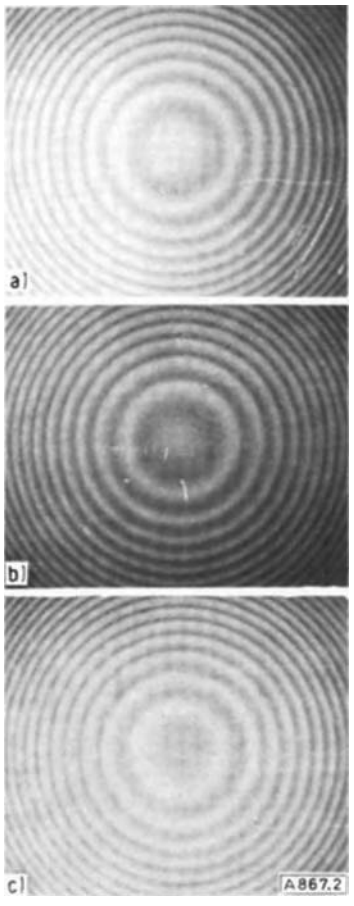

Fig. 2. Three holograms of a point scatterer showing, a) in-phase, b) intermediate phase, and c) out-of-phase conditions on the optical axis.

In order to determine whether the plane reference wave and the back-scattered wave are in or out of phase, we merely divide the difference between these two distances by the wavelength λ as follows:

$$\varphi(r) = \frac{2\pi}{\lambda}(\sqrt{D^2+r^2} - D)$$

If the above quantity is an integral multiple of π, then the difference between the two distances is an integral number of half wavelengths. If the integer is even, an in-phase condition exists yielding a bright ring in the hologram. If the integer is odd, the two waves are out-of-phase and a dark ring exists.

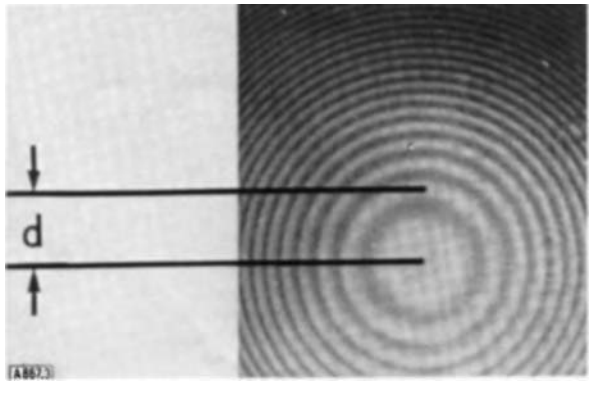

Fig. 3. Hologram of a point scatterer displaced a distance d from the optical axis.

A few simple variations on the Fresnel zone plate hologram will clarify the fundamentals of holography for the reader. For example, if the point scatterer shown in Figure 1 is moved a distance d along the y axis, the interference pattern created in the hologram plane merely shifts off-axis by an amount given by d; otherwise the pattern is unchanged (Fig. 3). It is clear that the position of the center of the hologram remains directly at the intersection of the normal to the reference wave which passes through the point scatterer.

Another example of interest occurs when the point scatterer is moved farther from the $x-y$ plane. Now, of course, the radius of the spherical wave is larger than before. The interference rings, therefore, will become more widely spaced since the quantity D in the above equation is larger. In other words there is less wavefront curvature and the back-scattered radiation goes in and out of phase more slowly as a function of x. The result is shown in Figure 4. Conversely, when the point scatterer is closer to the hologram plane, the interference rings in the hologram become more closely spaced. Thus the distance to the point scatterer is directly related to the spacing of the interference rings in the hologram.

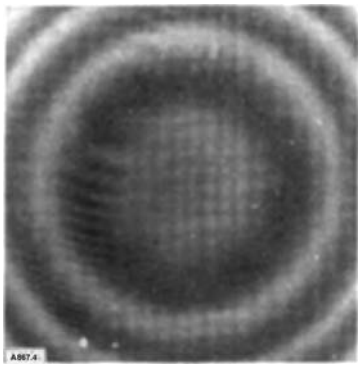

Fig. 4. Hologram of a point scatterer which is at an extreme distance from the hologram plane.

It is simple to extend the above concepts to more general holography. No matter what the configuration of the object being holographed, Huygens principle[3] tells us that it may be considered to consist of a multiplicity of point scatterers having different positions. Thus the hologram becomes a superposition of zone plates. Holograms of more general objects are discussed and illustrated in Sections 4 and 5.

2.2. Forming the Image

So far, this article has only treated the formation of a hologram and its general appearance. Next we discuss how the hologram may be used to produce an image. For simplicity consider the holographic image formed from a hologram created from a single point scatterer, *i.e.*, the Fresnel zone plate. In order to form an image using optical radiation a simple methodology is employed, as illustrated in Figure 5. The hologram is illuminated from a point source of optical radiation. The hologram of a

single point scatterer has the property that it focuses some of the radiation which passes through it to a point. This is because this simple hologram has the properties of a Fresnel lens[14]. The mechanism of focusing is the phenomenon called *diffraction*. Thus the image is formed.

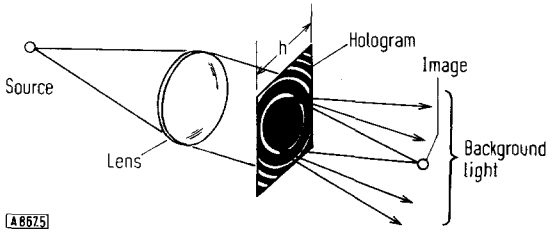

Fig. 5. An optical arrangement for producing an image of a point scatterer from its hologram.

However, this simple zone plate hologram also forms a virtual image. Furthermore it allows some of the illuminating radiation which passes through it to continue with its direction unaltered. Both the unaltered illumination and the radiation from the virtual image serve to corrupt the desired image. This is illustrated in Figure 6, which shows the real image formed from a zone plate hologram surrounded by a halo of illumination produced by the illuminating radiation whose direction is unaltered. Radiation from the virtual image is also present but is more dispersed. Several techniques may be used both in optical and acoustical holography to circumvent this type of image degradation (see Section 3).

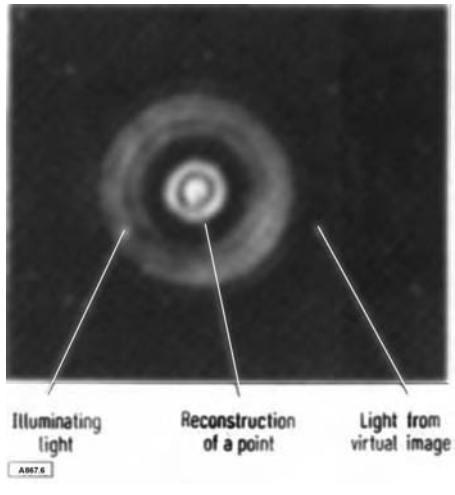

Fig. 6. Image formed from the hologram of a point scatterer showing the encircling halo produced by nondiffracted light from the illuminating source.

3. Methodology for Acoustical Holography

All of the above examples have been taken from optical holography. As we shall see, holograms made by acoustical techniques correspond directly to the holograms and holographic images shown above. The differences between acoustical and optical holography are primarily methodological ones.

The major difference between acoustical and optical holography is that the type of radiation used is sound rather than light. Another important difference is that there is no equivalent in acoustics to the silver halide emulsions used in recording optical holograms. A completely different method must be used for recording. In order to detect acoustical radiation over the hologram plane the user requires a material or device which is sensitive in some manner to acoustical radiation. In the early 1960's when the author was faced with the problem of how to record the acoustical hologram it was elected to scan the hologram plane with a small piezoelectric detector (see Fig. 7).

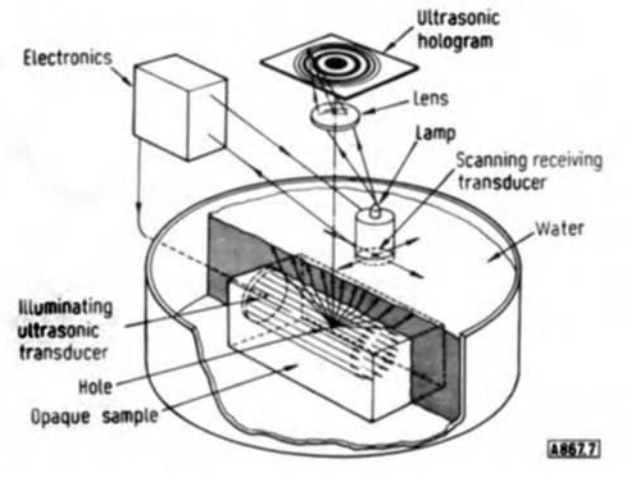

Fig. 7. Diagram of the arrangement utilized for producing an acoustic hologram by means of mechanical scanning.

The apparatus shown in Figure 7 was designed to utilize the fact that acoustical radiation propagates in many materials which are opaque to light. This permits the formation of acoustical holograms of point scatterers, *i.e.*, acoustic discontinuities within these materials. From these holograms images may be formed of the *internal structure* of these materials. In the apparatus shown the acoustical radiation is obtained by connecting a piezoelectric transducer to a block of the material to be examined. The block itself is placed in a tank of water so that there is good acoustical coupling between the back-scattered radiation and the transducer which scans the hologram plane.

The electronic system shown in Figure 7 serves three functions:

1) Generation of the excitation for the transmitting transducer.

2) Amplification and measurement of the back-scattered radiation detected by the scanning transducer.

3) Generation of signals to the lamp which is used to record the hologram.

The recording lamp is mechanically attached to the carrier which moves the scanning transducer. An image of the recording lamp is formed by means of a camera on photographic film.

The electronic system takes advantage of modern pulse techniques. Instead of being continuously energized, the

transmitting transducer is energized by short pulses. Also the acoustical radiation detected by the scanning transducer is amplified by a pulse amplifier. This approach has the advantage that the hologram which is recorded is only produced from acoustical radiation back-scattered from a volume in space selected by the length of the pulse utilized. This approach permits the elimination from the hologram of the effects of unwanted back-scattered radiation (such as that coming from exterior surfaces of the object being examined or from the surfaces of the tank itself). Those readers familiar with radar techniques will immediately see the analogy between this methodology and that used in pulsed radar.

3.1. A Simple Acoustical Hologram

A simple zone plate like those mentioned in Section 2 was formed using the apparatus shown in Figure 7. A small steel sphere was placed in the tank of water and ensonified by the transmitting transducer. The transmitting transducer was placed some distance from the sphere rather than being in contact with it. Thus the major source of back-scattered radiation was the surface of the sphere. The back-scattered radiation produced was picked up by the scanning transducer as it traversed the hologram plane. The resultant acoustical hologram was recorded on photographic film by means of the recording lamp and camera. The result is shown in Figure 8.

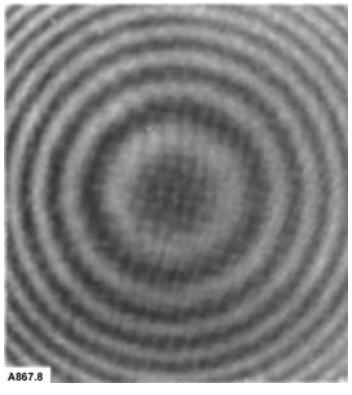

Fig. 8. Acoustic hologram of a point scatterer.

The complete parameters of this experiment are listed below:

Parameter	Value
Acoustical frequency	5 MHz
Pulse duration	100 μs
Pulse repetition frequency	1 kHz
Number of cycles in the transmitting pulse	500
Size of the hologram plane	20 × 20 cm
Distance of the sphere from the hologram plane	1.1 m
Number of scans across the hologram plane	256
Scanning velocity	4 cm s^{-1}
Number of pulses recorded	128 000
Size of hologram	1.0 × 1.0 cm
Recording medium	Eastman Kodak SO–243

3.2. Acoustical Holographic Imaging

To form an image from the acoustical hologram shown in Figure 8 the optical arrangement shown in Figure 9 was utilized. This arrangement differs from that shown in Figure 5 in that the image is no longer corrupted by the halo of illumination produced by light whose direction is unaltered as it passes through the hologram. This improvement is produced by two additional lenses which serve two functions. The first lens causes all illumination whose direction is unaltered by the hologram to impinge on what is called a "zero-order stop". This stop absorbs almost all of the illumination which would add a halo to the image. The second lens (in conjunction with the first one) relays the image formed by the hologram to a focal plane where it may be both observed and photographed. Light from the virtual image is widely dispersed in this focal plane and has essentially no effect on the image. The image itself is shown in Figure 10.

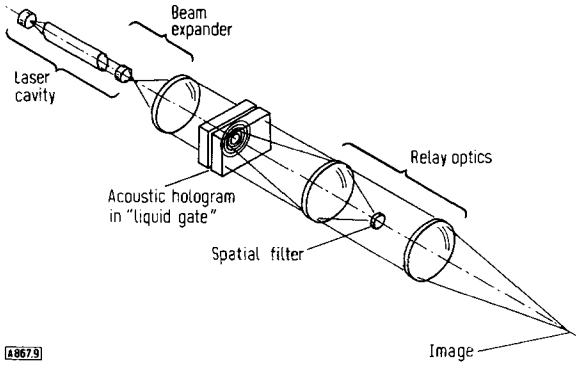

Fig. 9. Optical arrangement for use in producing acoustic holographic images wherein non-diffracted light is eliminated from the image.

Fig. 10. Image formed from the acoustic hologram of a point scatterer using the imaging system shown in Fig. 9.

Another method of forming the image from an acoustical hologram is to compute the image by means of a high speed digital computer. The results of the calculation may then be converted into either graphical or pictorial form. In order to do this the acoustical hologram must first be transferred into a format which is digital. The acoustical hologram shown in Figure 8 is a photographic transparency. An $x-y$ microdensitometer was utilized to read the point by point transmission values of the transparency. These transmission values were digitized and stored on magnetic tape which was then transferred to the computer.

The computer program required to calculate the image must perform the following four functions:

1) Compute a new set of transmission values from the values recorded which have zero mean. This operation is equivalent to the action of the zero-order stop mentioned above.

2) Compute a conjugate quadratic focusing function and apply it to the computed transmission values. This compensates for the focusing action of the hologram acting as a Fresnel lens. The proper focusing function is determined from geometrical considerations which take into account the original size of the hologram and the distance of the object holographed from the hologram plane.

3) Compute the two-dimensional Fourier transform of the resultant complete transmission values. This operation is equivalent to the function of the second lens in Figure 9[5].

4) Compute the intensity of the image by taking the square of the modulus of the resultant Fourier transform. This is the final step in the computational program.

A computer generated graph of the resulting calculation corresponding to the hologram shown in Figure 8 is provided in Figure 11. The z axis of this graph corresponds to the acoustical intensity while the $x-y$ plane is the final focal plane shown in Figure 9.

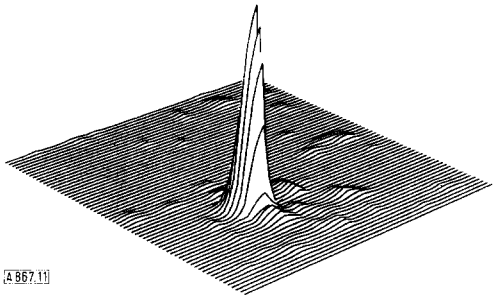

Fig. 11. Graph showing the computer generated acoustic intensity plot corresponding to the image shown in Fig. 10.

3.3. More Complex Holograms

Acoustical holograms have been made at Perkin-Elmer of more complicated structures than that of the simple sphere discussed above. One of the earliest acoustical holograms made is the now famous "bolt-hologram" recorded by *Kreuzer*[6] (Fig. 12). A conventional photograph of the bolt from which the hologram was made is shown in Figure 13. The bolt is approximately 13 mm in diameter with approximately 4 threads to the centimeter.

The acoustical hologram of the bolt has a highly complex structure. Upon observing the hologram it is possible to see a set of essentially parabolic rings which are due to the interference of the cylindrical wave reflected from the main body of the bolt. These rings are interrupted by a certain orthogonal fine structure which is due to the effect of sound back-scattered from the threads of the bolt. Using the optical image forming technique diagramed in Figure 9 the acoustical holographic image of the bolt was formed and photographed. The result is shown in Figure 14.

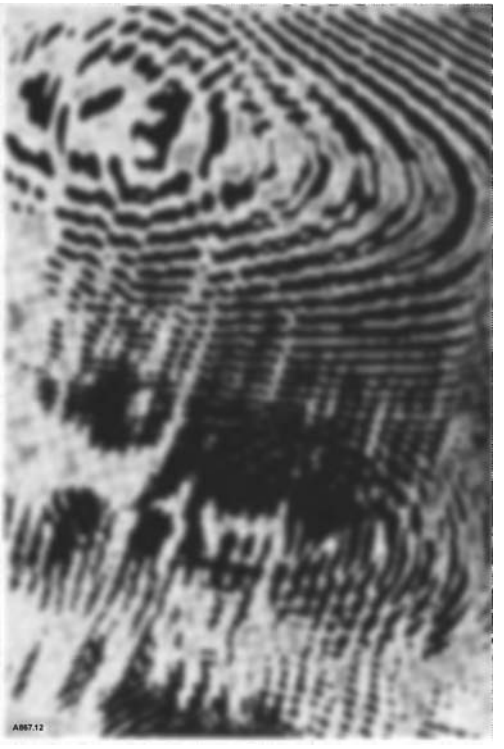

Fig. 12. Acoustic hologram of a 13 millimeter diameter bolt having two threads to the millimeter.

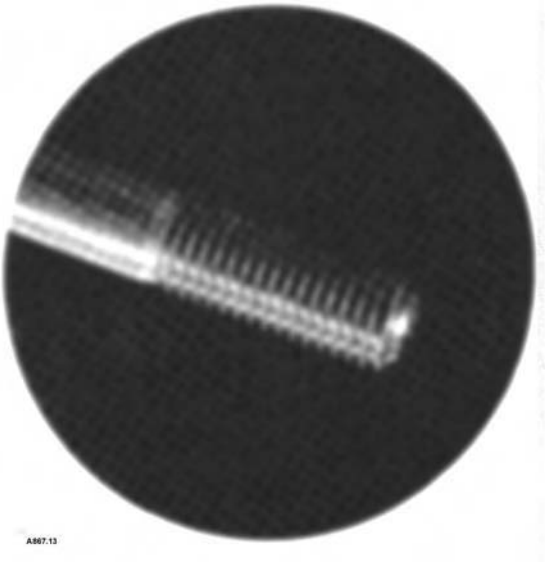

Fig. 13. Ordinary photograph of the bolt whose hologram is shown in Fig. 12.

The acoustic-holographic images shown in Figures 10 and 14 both correspond to objects lying in a plane. The holographic image of the entire object is in focus in this plane. When several objects are holographed, however, it is no longer possible to focus on all of them simultaneously and image interpretation becomes difficult.

Figure 15 shows a configuration of three objects which are at different distances from the hologram plane. The objects are all metal spheres and were simultaneously ensonified (in water) by the transmitting transducer. Two of the spheres shown in Figure 15 are approximately 13 mm in diameter and the third is approximately 25 mm

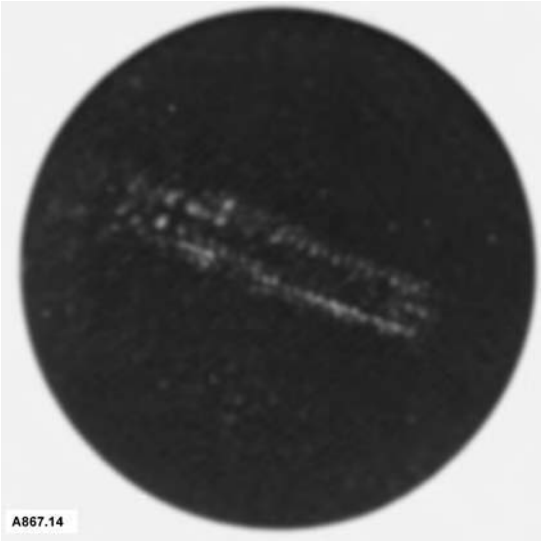

Fig. 14. Acoustic holographic image of the bolt shown in Fig. 13.

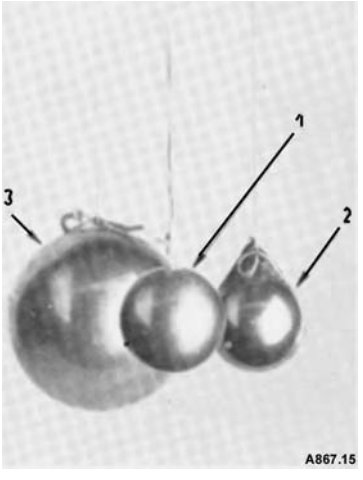

Fig. 15. Photograph of 3 steel spheres 25 mm, 13 mm, and 13 mm diameter placed 114, 118, and 122 cm from the hologram plane, respectively.

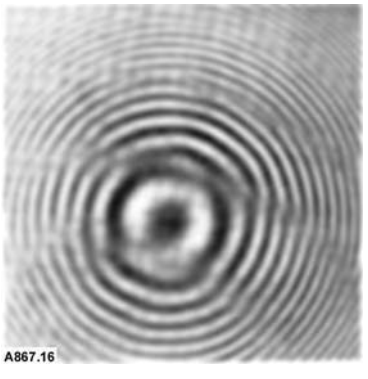

Fig. 16. Acoustic hologram of the three-sphere configuration shown in Fig. 15.

in diameter. Their distances to the hologram plane were 110, 114, and 118 cm, respectively. Using pulses of 5 MHz acoustic radiation having a duration of 150 microseconds a hologram was made of the entire volume containing the three spheres (Fig. 16). Because of the close lateral spacing of the spheres this hologram has the appearance of a single Fresnel zone plate. Close examination, however, shows a pattern of spherical moire fringes. These indicate, as expected, that the hologram consists of three superimposed zone plates. The moire fringes are circular because the three zone plates correspond to objects at different distances from the hologram plane. (Linear moire fringes would occur if the objects were all equidistant from the hologram and displaced laterally.)

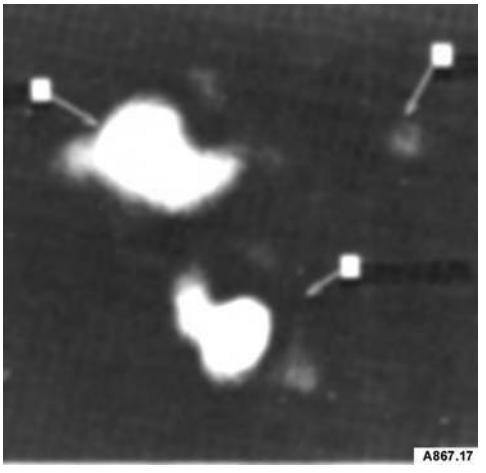

Fig. 17. Acoustic holographic image of the three spheres generated using the imaging arrangement shown in Fig. 9.

Figure 17 shows a holographic image formed from this hologram using the optical imaging arrangement shown in Figure 9. The image of the sphere nearest the hologram plane is in focus. The image of the sphere most distant from the hologram plane is strongly defocused. Surprisingly, the intermediate sphere is scarcely visible. Photometric measurements were made which showed that the in-focus intensity of the image of the intermediate sphere was less than 5% of the in-focus intensity of the other two spheres. This surprising result is assumed to be due to the fact that multiple reflections from the three spheres which arrive simultaneously in the hologram plane produced interference effects which suppressed the Fresnel zone plate corresponding to the intermediate sphere.

In order to confirm the results of optical imaging from the acoustical hologram the hologram shown in Figure 16 was scanned and its transmission values were recorded on

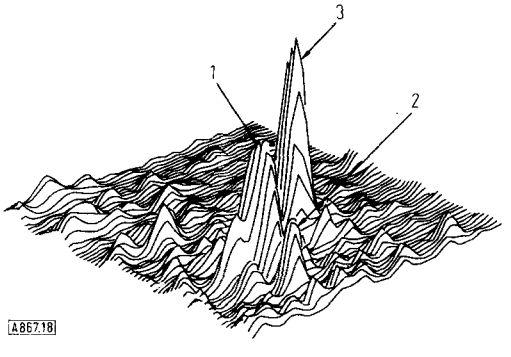

Fig. 18. Computer generated acoustic intensity graph corresponding to the acoustic holographic image shown in Fig. 17.

magnetic tape. The acoustic field intensity at a focal plane corresponding to the position of the intermediate sphere was calculated using the computer program described above. A graph-out of the result is shown in Figure 18. The low intensity of the image of the intermediate sphere is apparent thus confirming the previous results. This demonstrates that the formation of acoustical holograms of objects occupying a volume suffers from two rather serious problems:

1) It is impossible to focus on all portions of the volume simultaneously. The image of the portion of the object which is in focus is corrupted by defocused images of other portions of the object.

2) The true intensity of sound reflected from various portions of the object is not represented properly in the volume hologram due to interference effects.

3.4. Focus Equalization

Recently the author has worked out a method of circumventing most of the problems which are associated with the formation of images from holograms. The approach of holographing the entire volume was discarded. A new approach was taken where a multiplicity of holograms are made of different portions of the volume being holographed. The result is an image which is in focus throughout the volume. This new method is thus called *focus equalization*. Imaging is carried out entirely by computer.

Pulses of acoustical radiation are utilized which are only long enough to permit the production of a complete Fresnel zone plate from point scatterers in each region of the volume ensonified. The resultant computer generated image is then equalized for focus throughout the volume. Returning to the object configuration shown in Figure 15 (3 spheres) the resultant computer graph-out is shown in Figure 19. A comparison of Figure 19 with Figure 18 shows the enormous improvement in volume holographic imaging produced by this new technique of focus equalization.

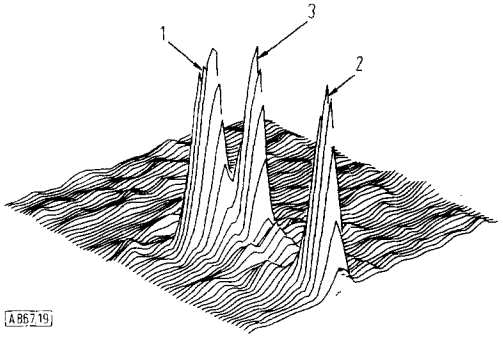

Fig. 19. Computer generated graph of the three-sphere image using focus equalization.

In order to take full advantage of focus equalization it is preferable to create a computer display which is readily interpretable when observed visually. It has already been mentioned in the introduction that it is possible to display images using a cathode ray tube. It is also possible to create photographic transparencies by means of the same technique. In order to record the graph-out shown in Figure 19 as an image on the face of a computer driven cathode ray tube, the electron beam is made to scan the face of the tube and the intensity of the electron beam is modulated according to the calculated values of acoustical intensity. Simultaneously the face of the tube is imaged on photographic film for recording purposes. The photographic transparency corresponding to Figure 19 is shown in Figure 20. This figure readily conveys to the human observer the fact that three objects exist in the volume holographed. This image is far superior to the optical acoustical holographic image shown in Figure 17. As can be seen, the image of each sphere is simultaneously in focus.

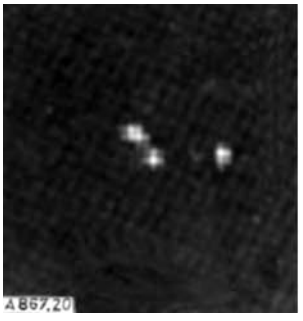

Fig. 20. Computer generated image of the three-sphere configuration using focus equalization.

The one draw-back of this display is that the human observer cannot tell that the three spheres shown are at different distances from the hologram plane. However, since distance information is included in the computer calculations, it may be added to the display. This has been done recently by the author with the result shown in Figure 21. Figure 21 is a stereo-pair which, when observed using both eyes in such a manner that the two images fuse, gives depth to the image. The right hand image of the pair is the same as that shown in Figure 20 while the left hand image was produced by translating the calculated values of acoustical intensity for different regions of the volume with respect to each other by the amount required to produce a left-eye view for an observer located halfway between the hologram plane and the three spheres.

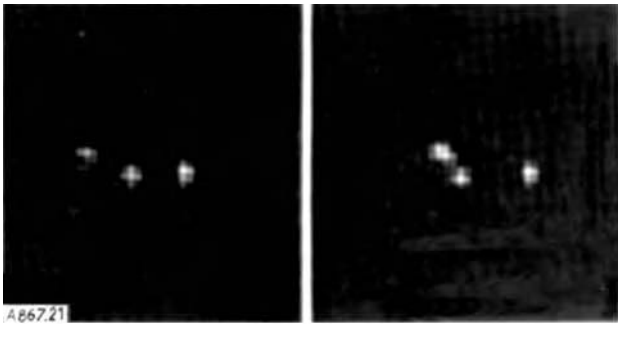

Fig. 21. Computer generated stereo pair of the three-sphere configuration shown in Fig. 15.

Observing the stereo-pair makes it possible for the viewer to ascertain that the central sphere is the nearest, the sphere on the left is the farthest, and that the sphere on the right is at an intermediate distance.

4. Views of Interior Structure

Acoustical holography may be used to form images of the interior structure of objects as well as of their exterior surfaces. Some preliminary experiments in this area were performed by *Kreuzer* in 1968. An example of a typical experiment is illustrated by Figure 22. This figure shows an aluminum block through which a slanted hole 3 mm in diameter has been drilled. In one of *Kreuzer*'s experiments this block was ensonified using a 5 cm diameter transmitting transducer affixed to one face of the block. The pulses of sound which were back-scattered by the hole were picked up by a scanning transducer moving in a horizontal hologram plane. The actual hologram formed is shown in Figure 23. This is a volume hologram where the duration of the pulses was sufficiently long to permit pulses scattered from all points along the hole to be received simultaneously

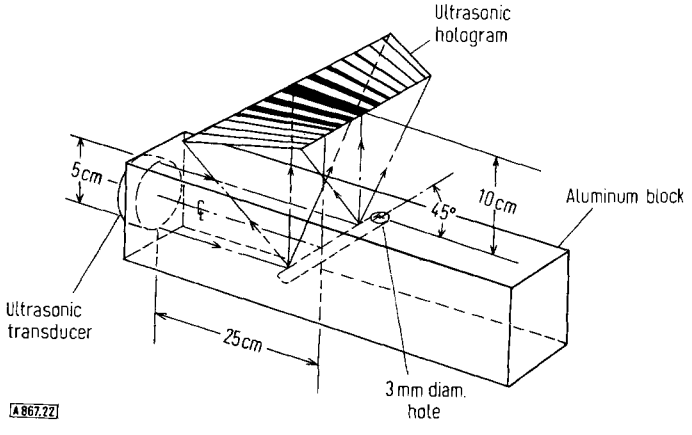

Fig. 22. Schematic diagram showing the arrangement used for creating an acoustic hologram of a hole in an aluminum block.

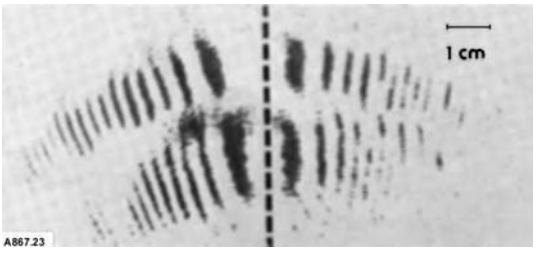

Fig. 23. Actual acoustic hologram of a hole (3 × 80 mm) in an aluminum block.

in the hologram plane by the scanning transducer. An acoustical frequency of 5 MHz produced a wavelength in the aluminum block of approximately 2 mm. The hole in the aluminum block had a diameter only somewhat greater than 1 acoustical wavelength. The hole was about 40 wavelengths long.

Images were formed from the hologram shown in Figure 23 using optical techniques. In this case two approaches were adopted to solve the problem of focusing optically throughout a volume. Figure 24a shows the image of the hole when the focal plane was adjusted to cause the upper end of the image of the hole to be in focus. Only a portion of the entire image of the hole can be seen as in focus. Most of the image is defocused to the point of being invisible. Since the image of the hole lies in a plane, the focusing problem may be solved by placing a tilted surface in the focal plane and by focusing upon this surface. The result is shown in Figure 24b. The result for this special case is quite satisfactory. This is only due to the fact that the hole lay in a plane. In order to completely solve the problem of volume holography for the interior structure of objects it is obvious that the focus equalization technique discussed above would be advantageous. This approach is now being pursued.

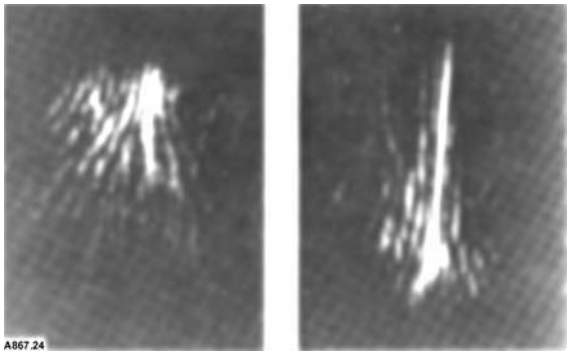

Fig. 24. Acoustic holographic images of the slanted hole shown in Fig. 22 taken a) end-on (left) and b) in the plane of the hole (right).

5. Summary

This paper has surveyed the relatively new field of acoustical holography[*] and has described methods for forming the hologram as well as both optical and digital-computer methods for forming acoustical holographic images. This new field is still in its developmental stages and should progress rapidly now that certain of the limitations which are fundamental to optical imaging from acoustical holograms have been removed by reverting to modern digital-computer methods for calculating and displaying images.

This field offers a technology which permits objects to be imaged in a liquid medium when ordinary photography is impossible. One example of such an application would be that of imaging objects in turbid water, *i.e.*, water filled with particulate matter. Acoustical holography is also of interest to workers in materials testing where it is necessary to observe the internal structure of objects which are opaque to light. The illustration provided where an image was formed of a long hole in an aluminum block gives a dramatic demonstration of this capability. Another

[*] In addition to the references cited in the main body of the article the reader who wishes a broad overview of the entire field should read the three volume survey edited by *Metherell* [9].

application may be in medicine where it might be possible to form three dimensional images of biological structures assuming that the problems associated with the transmission of sound in tissue can be solved.

The fact that systems for use in acoustical holography are rapidly becoming all-electronic (rather than electro-optical) makes instrumentation simpler and suggests that real-time imaging may soon be possible, particularly in view of recent advances in fast Fourier computation[7]. Also the single scanning receiving transducer may soon be replaced by transducer arrays taking advantage of well-known radar techniques in aperture synthesis[8]. The demonstration of stereo displays of acoustical holographic images where all portions of the volume are simultaneously in focus and where depth effects are readily apparent is the most recent advance. All of these innovations appear to be leading us towards extremely practical working systems for use in underwater exploration, materials testing, and perhaps, in biomedical diagnosis.

The author would like to acknowledge support from the US Army Materials and Mechanics Research Agency which permitted our early work to materialize. It should be noted that the first demonstration of acoustical holographic imaging at Perkin-Elmer was made by J. L. Kreuzer working under the direction of the author. Subsequent work, supported by Perkin-Elmer, has benefited from efforts by W. R. Arndt, J. R. Carvalko, and D. DeCava. F. Reizman has conducted the recent quantitative studies in evaluating the defects of optically forming acoustical holographic images. The computer generation of acoustical holographic images has been performed with the assistance of Jeanne Sand and D. Rosenzweig. Gennifer Austin is to be thanked for typing this manuscript and Grace Chew and J. Bannister for assistance with the illustrations.

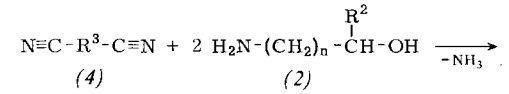
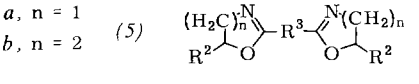
Simple Synthesis of 2-Substituted 2-Oxazolines and 5,6-Dihydro-4*H*-1,3-oxazines

By *Helmut Witte* and *Wolfgang Seeliger*[*]



The methods for preparation of 2-oxazolines *(3a)* and 5,6-dihydro-4*H*-1,3-oxazines *(3b)* in the laboratory are rather cumbrous from the point of view of techniques or apparatus[2] or are limited to highly substituted derivatives[1,3].



(1) *(2)*

(3)

(4) *(2)*

a, n = 1
b, n = 2 *(5)*

We have now found a single-stage synthesis in which heating nitriles *(1)* with α,β- *(2a)* or α,γ-amino alcohols *(2b)* gives, respectively, 2-oxazolines *(3a)* or 5,6-dihydro-4*H*-1,3-oxazines *(3b)* in good yield, provided that catalytic amounts of certain heavy-metal salts are present. Soluble zinc or cadmium salts have proved particularly suitable.

Additions of diamines or amino thiols to nitriles, however, yielding 2-imidazolines, 1,4,5,6-tetrahydropyrimidines, and 2-thiazolines, are known but proceed without metal catalysts[4].

Dinitriles *(4)* can be treated analogously with the amino alcohols *(2a)* and *(2b)*, giving bis(2-oxazolines) *(5a)* and bis(5,6-dihydro-4*H*-1,3-oxazines) *(5b)*, respectively. A selection of the compounds prepared is listed in Tables 1 and 2, where the yields refer to the amounts of nitrile used.

Table 1. Examples of compounds *(3a)* and *(3b)*.

[a] See footnote [a] of Table 1.

General method:
1 mol of nitrile is heated with 1—1.5 mol of amino alcohol per nitrile group and 0.025 mol of catalyst for 25 h under reflux or at 100—130 °C, ammonia being driven off. When aromatic dinitriles are used, 500 ml of chlorobenzene is added as solvent. At the end of the reaction the product is distilled or, if necessary after removal of the solvent, recrystallized.

Thermal Formation of 1-Propenylketene from 2,4-Pentadienal[**]

By *Peter Schiess* and *Paul Radimerski*[*]

As has been recently reported[1], gas phase pyrolysis of 3,4-epoxycyclopentene *(1)* (14 torr/1 s) at 400 °C affords 2-*cis*-penta-2,4-dienal *(2)* and at 500 °C the *trans* isomer *(3)*. Compounds *(2)* and *(3)* were characterized as their dinitrophenylhydrazones[2] which were isolated in 8 and 10% yield, respectively.

We have now been able to show that the pyrolyzate of *(1)* contains not only the above aldehydes *(2)* and *(3)* but also up to 90% of the stereoisomeric propenylketenes *(4)* and *(5)*. When the pyrolysis products of *(1)* are trapped in methanol at −60 °C a mixture of *(2)*, *(3)*, and the stereoisomeric methyl 3-pentenoates *(6a)* and *(7a)*[3] results. Trapping in ethanol leads to the corresponding ethyl esters *(6b)* and *(7b)*[3] while use of an ethereal solution of aniline gives the two anilides *(6c)* and *(7c)* (eutectic mixture m.p. 64—66 °C)[3].

A solution of the products trapped at −80 °C in CS_2 exhibits an intense ketene band in the IR spectrum at 2180 cm^{-1}. In the NMR spectrum the signals of the aldehydes *(2)* and *(3)* (H^1 in *(2)*: 10.23 ppm d, $J = 8$ Hz; H^1 in *(3)*: 9.77 ppm d, $J = 8$ Hz) are accompanied by the signals of the ketenes *(4)* and *(5)*. Two characteristic doublets at 3.93 and 4.05 ppm ($J = 10$ Hz) correspond to the aldoketene H atoms in *(4)* and in *(5)*[4].

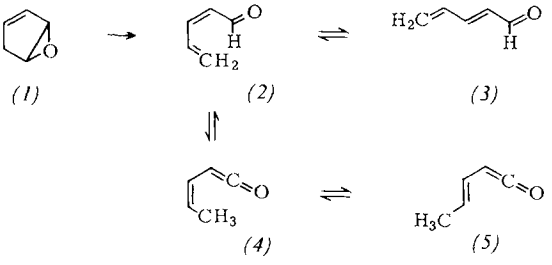
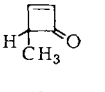
Institut für Organische Chemie der Universität
CH-4056 Basel, St. Johanns-Ring 19 (Switzerland)



[**] This work was supported by the Schweizerischer Nationalfonds (Project No. 2.396.70) and by a contribution from Ciba-Geigy.

It may be seen from the Table that the *cis*-aldehyde *(2)* is formed as primary product on pyrolysis of *(1)* (1 torr/0.1 s) above about 300 °C. Ketene formation starts slightly above 300 °C, the proportion of *cis* isomer *(4)* initially predominating. The product mixture obtained at 600 °C corresponds to equilibration between the isomers *(2)*—*(5)* for at this temperature a product of approximately equal composition is obtained, irrespectively of whether one starts with epoxide *(1)*, *trans*-2,4-pentadienal *(3)*, or *trans*-3-pentenoyl chloride *(7d)*[5]. On the basis of the order in which the compounds *(2)*—*(5)* are found in the pyrolyzate with increasing temperature, it can be assumed that *(4)* is formed from *(2)* and that the *cis*, *trans* equilibria *(2)* ⇌ *(3)* and *(4)* ⇌ *(5)* are established at elevated temperature (see formula scheme).

Table. Composition of the product mixture formed on gas phase pyrolysis (1 torr/0.1 s) [a].



Cpd.	Pyrolysis temp. (°C)	*(1)*	*(2)*	*(3)*	*(4)*+*(5)*	Ratio *(4)*:*(5)* [b]
(1)	290	99	1	—	—	—

[a] Percentages, determined from the NMR spectrum of the pyrolyzate trapped in methanol; [b] determined by gas chromatography of the methyl esters *(6a)* and *(7a)* (capillary column 0.2 mm, 50 m, Castorwax; 60 °C).

CH_3-CH=CH-CH_2-CO-R

cis: (6) *(a)*, R = OCH_3; *(b)*, R = OC_2H_5
trans: (7) *(c)*, R = NHC_6H_5; *(d)*, R = Cl

(8)

Formation of *(4)* from *(2)* can be regarded as a sigmatropic [1,5]shift of the aldehydic proton in *(2)*. We have previously observed a similar reaction on irradiation of a substituted pentadienaldehyde[6]. Reversible [1,5]hydrogen shifts have recently been invoked in the interpretation of thermal isomerization reactions of unsaturated aldehydes[7]. However, as far as we know the present case is the first example of *directly observed* thermal ketene formation from an acyclic unsaturated aldehyde.

The interconversion *(4)* ⇌ *(5)* could possibly proceed *via* 4-methylcyclobutenone *(8)* as an intermediate[8]. However, no cyclobutenone could be detected by spectroscopy in the pyrolysis mixture at −60 °C[9]; nor is any formed

from *(4)* or *(5)* on heating to room temperature—instead complete polymerization of the ketene occurs.

Simple Method for the Synthesis of Some Boc-Amino Acids[1][**]

By *Akhtar Ali, Falk Fahrenholz*, and *Boris Weinstein*[*]

tert-Butyloxycarbonyl (Boc) amino acids are frequently employed as intermediates in the synthesis of peptides, and there are several methods available for their preparation[2]. We have now found that Boc amino acids are also formed in the reaction of 1,1,3,3-tetramethylguanidinium salts of some amino acids *(1)* with *tert*-butyloxycarbonyl azide[3] in dimethylformamide as solvent. The simple procedure outlined here provides a convenient method for the synthesis of a series of Boc amino acids in excellent yields (Table). In the case of Boc derivatives of Ala, Asp, Asn, Glu, and Tyr, the yields are only moderate.

(1)

(2)

Compound	Yield (%)	M.p. (°C) of crude product
Boc-Ala-OCH_3	80	33–34
Boc-Arg(NO_2)	82	122–124
Boc-Cys[*p*-OCH_3(Bzl)]-DCHA [a]	90	132
Boc-Glu(OBzl)-DCHA	87	139–140
Boc-Leu	94	oil [c]
Boc-Lys(Z)-DCHA [b]	82	154–155
Boc-Met	100	syrup
Boc-Phe	78	85–86
Boc-Pro	93	134–135
Boc-Ser(C_4H_9)	100	oil [c]

[a] Bzl = benzyl, DCHA = dicyclohexylammonium.
[b] Z = benzyloxycarbonyl.
[c] Solidifies after a few days.

Experimental

tert-Butyloxycarbonyl azide (21.5 g, 0.15 mol) is added dropwise over a period of 30 minutes to a stirred suspension of proline (11.5 g, 0.1 mol) in dimethylformamide (220 ml) and 1,1,3,3-tetramethylguanidine (23 g, 0.2 mol) in an ice-bath. The resulting solution is stirred for three days at room temperature and then the solvent is removed by evaporation under vacuum. The residue is taken up in ethyl acetate (500 ml) and 20% citric acid solution (200 ml). The aqueous phase is removed and extracted once again with ethyl acetate (300 ml). The combined ethyl acetate extracts are then washed three times with water (200 ml), dried over magnesium sulfate, and finally concentrated by evaporation under vacuum. Crystallization of the residue from ethyl acetate/petroleum ether yielded 20.0 g (93%) of *N-tert*-butyloxycarbonyl-proline.

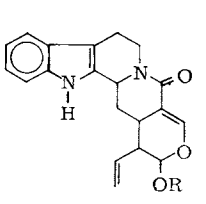
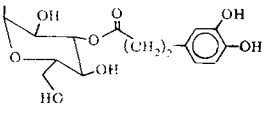
The Biogenetically Oriented Total Synthesis of Camptothecin and 7-Chlorocamptothecin[1]



By *Ekkehard Winterfeldt, Tilman Korth, Dennis Pike*, and *Marlies Boch*[*]



Camptothecin *(1a)* was first isolated by *Wall et al.* in 1966 from *Camptotheca acuminata*[2]; its structure was confirmed by X-ray structure analysis[3]. *Wenkert* has indicated the biogenetic connection between camptothecin and the indole alkaloids[4] and *Brown et al.* have recently announced the isolation and structural elucidation of an indole alkaloid *(2)* having a structure closely resembling that of camptothecin[5].

Since camptothecin was reported to have strong antileukemia and tumor-inhibiting activity, a synthetic route to this compound is of interest. Following a recent com-

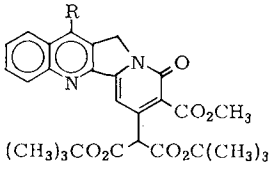
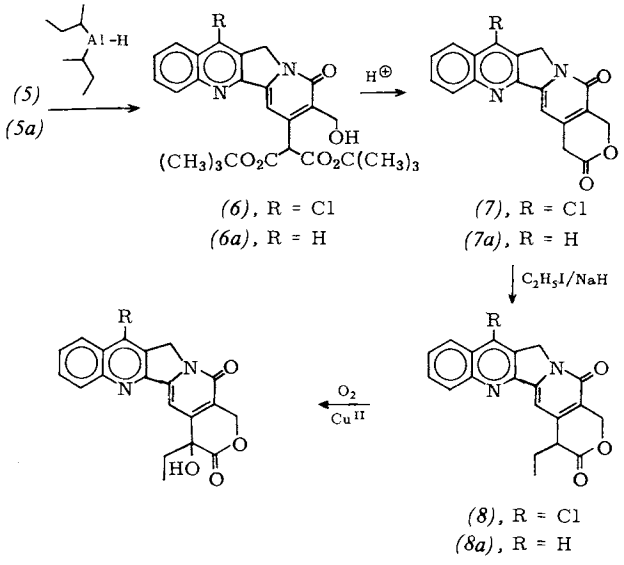
munication on a total synthesis[6] we now publish our results on a biogenetically oriented indole-camptothecin rearrangement.



Using the easily accessible indolic compound *(3)*[7] as starting material, the indole-quinoline conversion could be carried out in two simple steps.

(3)



(4)

(5), R = Cl
(5a), R = H

Autoxidation[8] of *(3)* affords the quinolone *(4)*, which, on treatment with thionyl chloride in dimethylformamide, is converted into the chloroquinoline-pyridone *(5)*. Hydrogenation of *(5)* yields the chlorine-free derivative *(5a)*.

Selective reduction of *(5)* and *(5a)* with diisobutylaluminum hydride[9] affords the alcohols *(6)* and *(6a)*, which, on being allowed to stand at room temperature after addition of trifluoroacetic acid, are converted into the lactones *(7)* and *(7a)* respectively. Alkylation of *(7a)* and *(7)* with ethyl iodide in dimethylformamide yields deoxycamptothecin *(8a)* and the corresponding chloro compound *(8)*, which are converted into camptothecin *(1a)* and its 7-chloro derivative *(1)* respectively in high yields by passing oxygen through a dimethylformamide solution in the presence of copper(II) chloride. The natural product proved to be identical with a sample provided by Prof. *Wall*; all the other substances mentioned above have been characterized by elemental analysis, mass spectroscopy, and NMR spectroscopy.

Stereochemistry of the Cycloaddition of 1,3-Diphenyl-2-azaallyllithium to Alkenes at 0 °C[1][**]

By *Thomas Kauffmann* and *Edgar Köppelmann*[*]

1,3-Diphenyl-2-azaallyllithium[3], which was prepared by reaction of *N*-benzylidenebenzylamine with lithium diisopropylamide, was allowed to react under nitrogen in THF (deep red solution) at 0°C with *trans*-stilbene, with *cis*-stilbene, and with acenaphthylene (molar ratio 1:1 in each case) and the configuration of the pyrrolidines obtained by hydrolysis was determined by NMR spectroscopy[4]. The results are given in the following scheme and table.

(1) *(2)* *(3a)* *(3b)* *(4a)* *(4b)*

Reactant	Pyrrolidine formed	Yield (%)	M. p. (°C)
trans-Stilbene	*(2)*	83	110—111
cis-Stilbene	*(3a)* or *(3b)*	21 [a]	113—114
Acenaphthylene	*(4a)* + *(4b)*	40+40	176 and 194

[a] In the case of *cis*-stilbene, the greater part of which remained unreacted, a brown reaction flask was used owing to the light-sensitivity of the reactant.

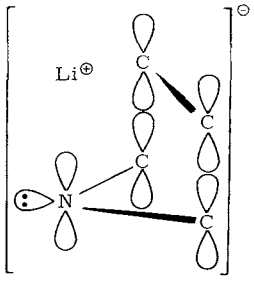
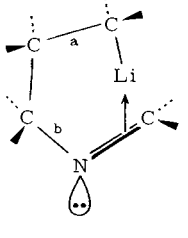
[9] We thank Schering AG, Berlin and Bergkamen for supplying the diisobutylaluminum hydride.

According to the above results the "alkene-created part" of the pyrrolidines obtained by [1,3]-anionic cycloaddition[2] always has the configuration of the alkene used in the reaction, thus indicating stereospecific *cis*-addition of the alkenes (no alternative in the case of acenaphthylene). In the "azaallyl-created part" the phenyl residues of the pyrrolidines always have *cis*-configuration, thus proving that the stereospecific addition always involves the same 1,3-diphenyl-2-azaallyl anion[5]. The findings are best interpreted in terms of a symmetry allowed one-step $[_{\pi}4_{s}+_{\pi}2_{s}]$-cycloaddition of 1,3-*(trans,trans)*- *(1)* or 1,3-*(cis,cis)*-diphenyl-2-azaallyl anion *(5)* according to the principle of conservation of orbital symmetry[7]. The *trans,-trans* configuration of the anion undergoing addition is thus much more probable since the anion of the comparable 1,3-diphenyl-allyllithium in THF at 0°C is always present in this configuration[5,6]. The *trans,trans* configuration of the 1,3-diphenyl-2-azaallyl anion at 0°C can also be deduced from the irreversible, and obviously quantitative configurational rearrangement of 1,3-*(cis,trans)*-diphenyl-2-azaallyl anion *(6)* on warming from −60°C to 0°C[8], since the thermodynamic stability should increase along the series *cis,cis* < *cis,trans* < *trans,trans* (completely coplanar, strain-free conformation is possible only in the case of *trans,trans*). However, confirmation of the *trans,-trans* conformation by direct NMR investigation has not, as yet, been reported.



(5)



(6)

The pyrrolidines obtained from *cis*- and *trans*-stilbenes were free of detectable mutual contamination[9]. A decision between pyrrolidine structures *(3a)* and *(3b)* is still not possible. The pyrrolidines *(4a)* and *(4b)* (ratio *ca.* 1:1) obtained from acenaphthylene have configurations corresponding to those of *(3a)* and *(3b)*. The fact that—in contrast to experiments with *cis*-stilbenes—both possible isomers are formed in reactions with acenaphthylenes, may be due to slight differences in the grouping.

The orbital diagrams of the 2-azaallyl anions resemble those of 1,3-dipolar substances such as azomethine ylides or diazoalkanes. Hence, the MO considerations described

(7)

(8)

by *Huisgen et al.*[10] for 1,3-dipolar cycloadditions can be applied to the analogous reactions of 2-azaallyl anions. Since the cycloaddition processes in the reactions investigated here are one-step processes, they ought to proceed *via* a two-plane orientation complex *(7)*. However, a two-step process *via* an intermediate of type *(8)*, in which rotations about axes a and b are blocked by formation of a strong chelate bridge to the CN double bond or to the N atom, cannot, as yet, be ruled out[11].

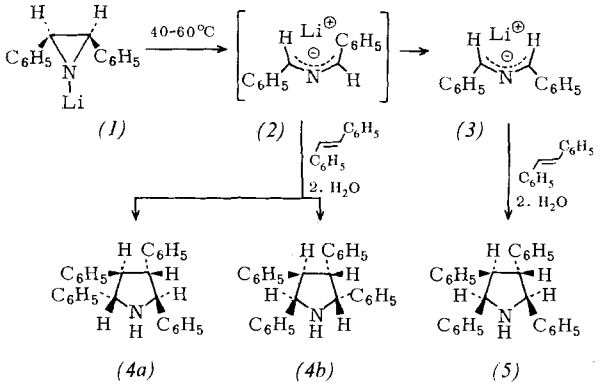
[11] Reaction of 2-azaallyllithium compounds with ketones always leads to non-cyclic adducts; this is also possibly due to ring-opening of the anionic cycloadduct (*Th. Kauffmann, E. Köppelmann*, and *H. Berg*, Angew. Chem. *82*, 138 (1970); Angew. Chem. internat. Edit. *9*, 163 (1970)).

Ring-Opening of *N*-Lithio-2,3(*cis*)-diphenylaziridine to 1,3(*cis,trans*)-Diphenyl-2-azaallyllithium and Its Rearrangement to the *trans,trans*-Form[1][**]



By *Thomas Kauffmann, Kai Habersaat*, and *Edgar Köppelmann*[*]

Some *N*-arylaziridines undergo conrotatory ring-opening with formation of azomethine ylides[3] when heated to *ca.* 100—110°C. We have now found a preparatively interesting analogous reaction, namely the ring opening *(1)* → *(2)*. The initially colorless THF solution turns red at temperatures as low as 40—60°C (nitrogen atmosphere) and the 1,3(*cis,trans*)-diphenyl-2-azaallyllithium *(2)* (regarding ionization cf.[2]) expected according to the principle of conservation of orbital symmetry[4] as intermediate, could be trapped when ring-opening was carried out in the presence of 1 mole of *trans*-stilbene. 2,3,4,5-Tetraphenylpyrrolidine (m.p. 138—140°C) having structure *(4a)* or *(4b)*—*i.e.* a cycloadduct with the two phenyl residues of the "2-azaallyl-created part" in the *trans* position (structural determination by NMR spectroscopy[6])—was formed to the extent of 73%[5]. 2,3,4,5-Tetraphenylpyrrolidine *(5)* (m.p. 110—111°C), which has the *cis*-configuration in the "2-azaallyl-created part" and which has already been reported in a previous communication, was formed as by-product (11%).

[*] Prof. Dr. Th. Kauffmann, Dipl.-Chem. K. Habersaat, and Dr. E. Köppelmann
Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

When the product of the ring-opening reaction of *(1)* was cooled to 0 °C prior to treatment with 1 molar equivalent of *trans*-stilbene, the pyrrolidine *(5)* was the sole end product isolated. This indicates that the primary ring-opening product *(2)* is completely converted, either into the *trans,trans* form or the *cis,cis* form.—Evidence for the existence of the primary ring product in the *cis,trans* configuration by NMR spectroscopic investigation of the lithium compound is still pending.

(1) *(2)* *(3)* *(4a)* *(4b)* *(5)*

The 2,3,4,5-tetraphenylpyrrolidine *(4a)* or *(4b)*, m.p. 138—140 °C, is also formed (11%) as well as *(5)* (35%) when a solution of 1,3-diphenyl-2-azaallyllithium (prepared by reaction of 1 mole of lithium diisopropylamide with *N*-benzylidenebenzylamine) in THF is prepared at −60 °C and treated at this temperature with *trans*-stilbene. The lithiation of *N*-benzylidenebenzylamine leads, at least in part, to formation of the intermediate *(2)*. However, the *cis,trans* configuration is evidently destroyed on warming to 0 °C, since subsequent addition of *trans*-stilbene at this temperature leads to the pyrrolidine *(5)* having a *cis*-configuration in the "2-azaallyl-created part". From the irreversibility of the configurational rearrangement of *(2)* observed in control experiments it can be deduced that *(3)* is also formed. The ring-opening of *(1)* and its sodium analogs[7] provides an alternative route to the 2-azaallylmetal compounds. This method is of particular interest since it leads to solutions of 2-azaallylmetal compounds free of amine and metal amide and thus widens the scope of these organometallic compounds as reagents in organic synthesis[8].

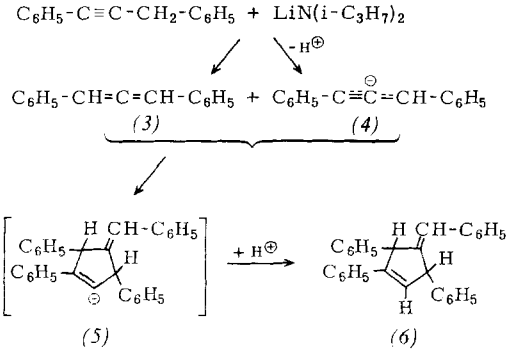
[8] The presence of diisopropylamine and lithium diisopropylamide (in equilibrium with 2-azaallyllithium compounds) interferes in reactions of 2-azaallyllithium compounds with substrates which, like phenyl isocyanates, oxiranes or alkyl halides are able to react with amides (*A. Busch*, Diplomarbeit, Universität Münster 1971; *R. Eidenschink*, Dissertation, Universität Münster, to be presented 1972).

Synthesis of Five-membered Carbocycles by [1,3]-Anionic Cycloaddition[1][**]

By *Rudolf Eidenschink* and *Thomas Kauffmann*[*]



Appreciable driving force for the smooth cycloaddition of 2-azaallyl anions to multiple bonds is believed to lie in transfer of the negative charge from the peripheral C atoms of the 2-azaallyl system to the more strongly electronegative central N atom[2]. The cycloaddition of allyl anions[3] to multiple bonds should therefore be favored by anything that makes it easier for electrons to be taken up by the central C atom. A phenyl group on the central C atom or increase in the electronegativity of this atom by alteration of the degree of hybridization ($sp^2 \rightarrow sp$) should therefore be favorable. This has been tested.

After unsuccessful attempts to prepare the 2-phenylallyl anion *(1)* from α-methylstyrene by treatment with lithium diisopropylamide in THF[4], we brought α-methylstyrene into reaction with lithium diisopropylamide in the presence of one equivalent of stilbene in THF at 45 °C for 150 h. After hydrolysis by water we obtained a 41% yield of a hydrocarbon, m. p. 62 °C, to which the structure of a 1,2,4-triphenylcyclopentane *(2)* (configuration of the phenyl groups not yet determined[5]) is assigned on the basis of analytical values and spectra (IR, NMR, MS). Evidently small amounts of the 2-phenylallyl anion *(1)* are formed in an equilibrium reaction and this undergoes the expected cycloaddition to *trans*-stilbene and is continuously reformed[6].

(1) *(2)*

Further, we have warmed an *n*-hexane solution of equivalent amounts of lithium diisopropylamide, 1,3-diphenylpropyne, and tolan for 24h at 60 °C and, after hydrolysis by water, obtained, together with unchanged tolan (95%),

(3) *(4)* *(5)* *(6)*

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

a hydrocarbon of m.p. 129°C, apparently not hitherto described, which on the basis of analytical values and spectra (UV, IR, NMR, MS) possesses structure *(6)*. The configuration of the phenyl groups has not yet been determined.

We interpret this result as formation of 1,3-diphenylallene *(3)*[7] and the [1,3]-anion *(4)* together from the 1,3-diphenylpropyne and reaction of these products by a [1,3]-anionic cycloaddition (one- or two-stage process) to yield *(5)*. Since the tolan remains unchanged, *(4)* is evidently unable to add rapidly to the C—C triple bond flanked by phenyl groups.

Side-Reactions Arising on Formation of Cyclodipeptides in Solid-Phase Peptide Synthesis[**]

By *Manfred Rothe* and *Jan Mazánek*[*]

During the solid-phase synthesis of oligo-L-prolines[1] we observed a considerable decrease in peptide yield (35—40% under usual condition[2]) in the step from diproline to triproline. From the filtrates of the neutralization reaction (with triethylamine/methylene chloride) after removal of the Boc protective group (with HCl/glacial acetic acid or trifluoroacetic acid/methylene chloride), from the washing operations, and from the coupling reaction with Boc-proline (with the aid of dicyclohexylcarbodiimide) we were able to isolate cyclodi-L-prolyl *(1)*

(1)

in a chromatographically pure state (TLC). Compound *(1)* was identified by melting point and mixed melting point determination (142—144°C), IR spectrum, optical rotation ($[\alpha]_D^{22} = -153.9°$, $c = 1$, H_2O), and mass spectrum ($M^+ = 194$). The amount of *(1)* formed increases on prolonged shaking in methylene chloride suspension of the polymer-bound diproline (90% after 24 h). The cyclization is catalyzed by tertiary amines.

This pronounced tendency to undergo ring closure was also found in the case of polymer-bound dipeptide esters of other *N*-alkyl amino acids, especially with disarcosine and L-prolylsarcosine (61% and 42%, respectively, of the cyclodipeptides [=diketopiperazines] isolated prior to the addition of carbodiimide). It is dependent upon the nature and the sequence of the amino acids; *e.g.* a value of 10% was found for sarcosylglycine, 5% for diglycine, and 2.5% for L-prolylglycine. Cyclodipeptide formation decreases with increasing bulk of the side chain and is hardly significant for most amino acids (cf. ref. [3]).

But even when only a few percent of the dipeptide cyclize, the reaction still represents a source of serious interference. The favorably placed hydroxymethyl groups formed on the polymer during the cyclization can undergo esterification in the subsequent coupling reactions with Boc-amino acids and carbodiimide and thus afford starting points for new peptide chains. For instance, during the synthesis of the antamanide sequence Phe-Phe-Val-Pro-Pro-Ala-Phe-Phe-Pro-Pro-polymer, small amounts of each of the Boc-amino acids used for chain lengthening were fixed to the resin by ester bonds (beginning with the tripeptide) and could be detected by TLC in samples cleaved from the carrier after each coupling step *(R. Pudill)*.

However, the amount of ester formation from *N*-protected amino acids and aliphatic alcohols with carbodiimides as condensing agent is only small in the absence of tertiary amines[4], as could be confirmed during solid-phase synthesis with hydroxymethyl resins[5]. In our own studies with a hydroxymethyl-polystyrene under the usual coupling conditions (reaction twice repeated with a threefold molar excess of Boc-proline, based on polymer-bound hydroxy groups) but for a prolonged reaction time (a total of 20 h) we found only 4% esterification.

Nevertheless, even very small amounts of amino acids bound in this way can possibly lead to peptide mixtures that are not further separable.

During the synthesis of oligoprolines this side-reaction hardly plays a significant role since the newly formed chain containing two proline residues less is removed again by cyclization as the cyclodipeptide at the diproline stage. Formation of hydroxy groups can be completely suppressed if the dipeptide stage is avoided in the synthesis, either by lengthening the prolyl polymer with, *e.g.* Boc-di- or Boc-triproline (no danger of racemization!), or by esterification of the chloromethyl polymer with Boc-triproline instead of Boc-proline.

Intramolecular $[_\pi 4 + _\pi 2]$-Cycloadditions: Preparative and Kinetic Aspects

By *Heinz W. Gschwend* and *Hans Peter Meier*[*]

The intramolecular version of the Diels-Alder reaction[1] represents an elegant high-yield method for the stereocontrolled synthesis of substituted carbo- and heterocyclic 5,6- and 6,6-ring systems. These intramolecular reactions not only proceed stereospecifically, with regard to the symmetry controlled $[_\pi 4_s + _\pi 2_s]$ process[2], and regiospecifically[3,4] (for geometrical reasons), but they also exhibit a much more favorable entropy factor than intermolecular Diels-Alder reactions. In the present communication we report the exceptionally ready formation of substituted isoindolines as well as the kinetic parameters of this reaction.

(a), R = $COOC_2H_5$; *(a')*, R = $COOCH_3$; *(b)*, R = C_6H_5

The reactive intermediate *(2a)* formed on acylation of the amine *(1)*[5] with the acyl chloride of monoethyl fumarate is not isolable at 0°C but gives the bicyclic lactam *(3a)* in 77% yield. The structure of *(3a)* and especially the relative configuration of the four centers of chirality appears to be confirmed by the NMR spectrum. Equilibration of *(3a)* in $CH_3OH/NaOCH_3$ leads cleanly to the thermodynamic product, the *cis*-fused lactam *(4a')*. With both epimerizable centers inverted, the stereochemistry of *(4a')* is identical to that of a kinetic product arising from an *exo*-addition *(4a)*[6].

If the amine *(1)* is acylated with a less reactive dienophile such as cinnamoyl chloride, then the intermediate *(2b)* can be isolated. This amide is an ideal substrate for the determination of the kinetic parameters of the intramolecular [4+2]-cycloaddition. Upon heating of a benzene solution of *(2b)* the *endo*- and *exo*-products *(3b)* and *(4b)* are formed (see Table 1). It may be deduced from the product ratio (15:2) of this kinetically controlled reaction that the activation energy for the *endo* transition state $[(2b) \rightarrow (3b)]$ lies about 1.4 kcal/mol below the *exo* transition state. The rate constants ($k = k_{2\rightarrow3} + k_{2\rightarrow4}$) were determined by NMR[7] and, more accurately, by UV spectroscopy[8] (Table 2).

Table 2. Kinetic data for the first order reaction $(2b) \rightarrow (3b) + (4b)$ [9], as calculated from UV measurements.

T (°C) (±0.1 °C)	k_{obs} (s^{-1})
70.0	0.897×10^{-5}
76.6	1.924×10^{-5}
85.3	3.914×10^{-5}
90.4	6.587×10^{-5}
log A =	9.80 s^{-1}
E_a =	23.3 ± 0.6 kcal/mol
$\Delta H^{\neq}$ =	22.6 ± 0.6 kcal/mol
$\Delta S^{\neq}$ =	−16.0 ± 1.5 e.u.

The most striking deviation from the kinetic data of bimolecular Diels-Alder reactions ($\Delta S^{\neq}$ varying between −30 to −40 e.u. and log A = 4.0 to 7.0)[10] is the higher value of the frequency factor and, accordingly, a significantly less negative entropy of activation. While the parameters of this intramolecular process reflect the increased degree of order of the substrate, the particular geometry of the transition state of this four-center reaction nevertheless manifests itself in a relatively large negative $\Delta S^{\neq}$. However, the value of −16 e.u. is found to be of the same order of magnitude as the entropy observed in the Cope rearrangement ($\Delta S^{\neq} = -11$ e.u. and E_a = 25.8 kcal/mol)[11], which

Table 1. Preparation and properties of the compounds *(3a)*, *(4a')*, *(2b)*, *(3b)*, and *(4b)*.

Oxidative Rearrangement of *C*-Sulfonylthioformamides

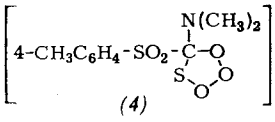
By *Nils Henning Nilsson* and *Alexander Senning*[*]

As previously reported[1], ozonolysis of the *C*-sulfonylthioformamide *(1)* leads to the *C*-sulfonylformamide *(2)*.

$$\underset{(1)}{4\text{-}CH_3C_6H_4\text{—}SO_2\text{—}CS\text{—}N(CH_3)_2} + O_3 \longrightarrow \underset{(2)}{4\text{-}CH_3C_6H_4\text{—}SO_2\text{—}CO\text{—}N(CH_3)_2} + SO_2$$

Meanwhile, further studies on the oxidation of *(1)* have shown that the ozonolysis represents a special case. With other oxidizing agents reaction proceeds *via* rearrangement to give *S*-sulfonylthiourethanes *(3)*.

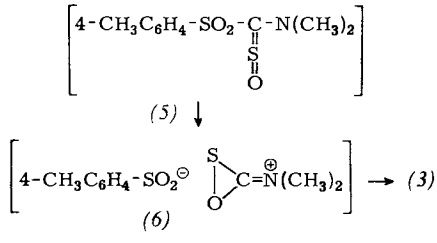
$$(1) + IO_4^\ominus \longrightarrow \underset{(3)}{4\text{-}CH_3C_6H_4\text{—}SO_2\text{—}S\text{—}CO\text{—}N(CH_3)_2} + IO_3^\ominus$$



[*] Amanuensis cand. scient. N. H. Nilsson and Lektor fil. lic. A. Senning
Kemisk Institut
Aarhus Universitet
DK-8000 Århus C (Denmark)

The structure of *(3)* follows from the IR spectrum (in KBr; $\nu_{CO} = 1695\ cm^{-1}$, $\nu_{SO_2} = 1335$ and $1150\ cm^{-1}$), a barrier to rotation about the amide C—N bond as detected by NMR spectroscopy ($\Delta G^\neq = 15.6$ kcal mol^{-1}; the corresponding barrier for rotation about the S—N bond of the isomeric sulfenamide 4-CH$_3$C$_6$H$_4$—SO$_2$—CO—S—N(CH$_3$)$_2$ is expected from our experience with sulfenamides[2] to lie considerably lower), and cleavage with chlorine (in CCl_4 at 25 °C) to give *N,N*-dimethylcarbamoyl chloride and *p*-toluenesulfonyl chloride in quantitative amounts.

Oxidation of *(1)* to *(3)* is possible with hydrogen peroxide, peracetic acid, and *m*-chloroperbenzoic acid, as well as metaperiodate, but not with oxides of nitrogen.



Preparative thin-layer chromatography (silica gel; ether/pet. ether) of the mixture obtained on ozonolysis of *(1)* (in $CHCl_3$ at 25 °C) showed it to contain not only *(2)* (13%) but also *(3)* (4%). Since *(3)* is not attacked by ozone, the reaction sequence *(1)* → *(3)* → *(2)* can be ruled out.

Our findings can be explained by assuming that the ozone attacks the carbon and the sulfur of the thiocarbonyl group simultaneously [*via* the intermediate *(4)* which subsequently decomposes to *(2)* and SO_2] while the other oxidations

(4)

proceed *via* the unstable *S*-oxide *(5)*. The ensuing isomerization of *(5)* to *(3)* can be regarded as a retro-Mannich condensation with subsequent recombination of the ion pair *(6)*. An analogous rearrangement occurs during the oxidation of thiuram sulfides[3].

(5) ↓

(6) → *(3)*

S-Tosyl-N,N-dimethylthiourethane (3)

To a stirred suspension of *(1)* (12.2 g, 0.05 mol) in glacial acetic acid (300 ml) and water (75 ml) is added, over a period of 1 hour, a solution of sodium metaperiodate (13.0 g, 0.06 mol) in water (75 ml). The resulting homogeneous solution is poured onto ice and the volume made up to 800 ml. The pale yellow precipitate of *(3)* is filtered off, washed with two 400-ml portions of water, and recrystallized twice from lukewarm ethanol. The last residue of iodine is washed out with a small volume of CCl_4. Yield: 4.2 g (32%) of *(3)*, m.p. 121—122 °C.

Determination of the Absolute Configuration of (+)-Pentahelicene

By *Hans Jürgen Bestmann* and *Wolfgang Both*[*]

Resolution of pentahelicene *(4)* was recently described[1]. We have now succeeded in the first allocation of absolute configuration to a helicene, namely to (+)-*(4)*.

(−)-(*S*)-*(1)* (+)-(*S*)-*(2)*

(*S*)-*(3)* (+)-(*P*)-*(4)*

The fundamental investigations of *Mislow et al.*[2], later confirmed by X-ray structure analysis[3], have shown that (−)-2,2′-bis(bromomethyl)-1,1′-binaphthyl *(1)* belongs to the (*S*)-series. The optically pure compound (−)-*(1)* with triphenylphosphane in molar ratio 1:2 afford the (+)-*(S)*-bisphosphonium salt *(2)* ($[\alpha]_{578}^{23} = +117.3°$, $[\alpha]_{546}^{23} = +138.7°$, $c = 5.48$ mg/cm³ in chloroform; m. p. 274—277 °C (dec.), m. p. (racemate) 289—290 °C (dec.)[4]), which is converted by $NaIO_4$ into the (*S*)-bisphosphonium periodate *(3)*. With lithium ethoxide at −5 to 0 °C[4], *(3)* gives the (+)-pentahelicene *(4)*, which has absolute conformation of the (*P*)-series[5] because of its preparation from (−)-(*S*)-*(1)*; it has $[\alpha]_{578}^{2} = 2260°$, $[\alpha]_{546}^{2} = 2730°$, $[\alpha]_{436}^{2} = 6820°$, $c = 2.90$ mg/cm³ in chloroform; $[\alpha]_{578}^{26} = -1670°$[1], $[\alpha]_{546}^{26} = -2025°$[1], $[\alpha]_{436}^{26} = -4950°$[1] in isooctane; m. p. 159 to 161 °C; the racemate has m. p. 176—177 °C[4]. Since we started from optically pure (−)-(*S*)-*(1)* and prepared *(4)* at 0 °C—a temperature at which no racemization of the compound can be observed—we assume that the (+)-(*P*)-pentahelicene formed is optically pure.

According to calculations partly based on CD measurements, (+)-hexahelicene[6, 7] and (+)-heptahelicene[7] also belong to the (*P*)-series[8]. We suspect that all (+)-helicenes belong to the (*P*)- and all (−)-helicenes to the (*M*)-conformation[9].

Vinylogous Fulvalene: Synthesis and Electrocyclic Reaction[1][**]

By *Hubert Sauter* and *Horst Prinzbach*[*]

Angularly annelated indacenoid ring systems *(5)* have been the subject of several quantum-mechanical calculations[2] and the aim of preparative studies[3, 4]. We have sought the synthetic precursors *(2)* and *(4)* by α,ω-cycloadditions to the fulvalenes *(1)* (*m*=2, *n*=1; *m*=2, *n*=3; *m*=2, *n*=5)[3] and by electrocyclic ring closure of the vinylogous fulvalenes *(3)*. We report here the first example of the second of these synthetic routes[5]: we have been able to prepare compound *(4a)* (*m*=*n*=2) from *(3a)* (*m*=*n*=2).

(1) *(2)* *(3)* *(4)* *(5)*

1,2-Biscyclopentadienylideneethane *(3a)*, the vinylog of the extremely unstable fulvalene that has hitherto been obtained only in highly dilute solution[6], can be isolated in pure form as violet-red needles from pentane. For this purpose the deep red solution obtained when "glyoxal sulfate" *(6)* reacts with cyclopentadienylsodium (equivalent amounts, THF, −20 °C) in the presence of triethylamine, is chromatographed on Al_2O_3 (neutral, deactivated with 7% of H_2O) at −15 °C with pentane as eluant; *(3a)* crystallizes at −78 °C from the pure fraction (yield 3 to 5%)[7].

Crystalline *(3a)* is quite stable in an inert atmosphere at −20 °C but isomerizes rapidly and quantitatively in solution to tricyclo[7.3.0.0^{2,6}]dodeca-3,5,7,9,11-pentaene *(4a)*; its half-lifetime, determined by UV spectrometry (isosbestic points at 281, 362, 399 nm) in pentane at 30 °C amounts to *ca.* 20 min. Even under the influence of daylight the ring closure *(3a)* → *(4a)* is reversible. On base catalysis *(4a)* affords the known mixture of dihydro-*as*-indacenes obtain-

[a] Satisfactory elemental analyses were obtained for all the compounds isolated. [b] Evaporation temperature below 60°C. [c] In pentane, 0°C. [d] In $CCl_4/CDCl_3$ 5:1, –15°C. [e] In pentane. [f] In $CCl_4/CDCl_3$ 5:1. [g] In ethanol. [h] In C_6D_6.

ed by another route[8], and on pyrolysis at 80°C gives exclusively the isomer *(7)*. On partial catalytic hydrogenation *(7)* and the tautomers are converted into hexahydro-*as*-indacene[9]. The spectroscopic data (Table) are in agreement with structures *(3a)* and *(4a)*.

In the case of *(3a)* special interest attaches to the allowed longest-wavelength π—π^* transition in connection with theoretical papers on the electronic spectra of bisdiphenylenepolyenes[10]. In qualitative agreement with improved HMO calculations the relevant absorption band (λ_{max} = 419 nm) is shifted slightly bathochromically with respect to that of fulvalene[11].

Ring closure of *(3a)*, which without doubt is not planar in the *s-cis*-conformation, should be conrotatory[12], leading to *(4a)* with *trans* geometry. The magnetically equivalent protons H^1, H^2 in *(4a)* would differ in the adduct *(9)*; the vicinal coupling of 12.7 Hz makes the *trans* arrangement probable but does not permit a final decision[13].

(4a) adds dimethyl acetylenedicarboxylate with satisfactory speed at 25°C, without notable isomerization to *(7)*. It thus affords *(9)* or *(10)* according to the reaction conditions[14]; compound *(8)*, the product of $[{}_{\pi}10_a + {}_{\pi}2_s]$-addition, was not found.

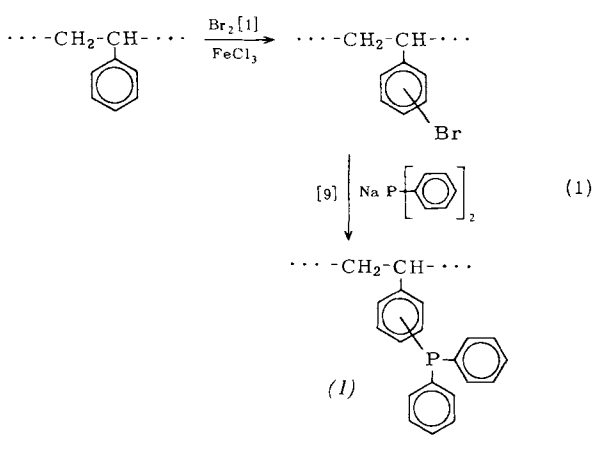
Polymeric Wittig Reagents[1][**]

By *Walter Heitz* and *Rudolf Michels*[*]

"Polymeric reagents" are polymers that carry functional groups. Only those polymers are suitable that can quite easily be removed from a reaction mixture after reaction of their functional groups. Cross-linked polymers can be separated easily by filtration and can thus be used in large excess; linear polymers are in general unsuitable.



Polymeric reagents are especially advantageous when an excess of the analogous low-molecular reagent or its reaction product causes separation troubles or if a quantitative yield is sought; also the formation of by-products can be suppressed in some cases since intermediates, which are now more easily separated, can be removed.

taining 2.1—3.18 mequivalents of triphenylphosphane groups per g of polymer (6.5 or 9.9%, respectively, of P). (A polymer from pure vinyltriphenylphosphane would contain 3.47 mequivalents of triphenylphosphane groups per g of polymer.) The polymers containing triphenylphosphane groups can be used for *Wittig* olefination[2, 11].

Table. Comparison of yields in the conventional *Wittig* olefination and in the preparation of olefins by reaction with polystyrene cross-linked with 2% or 0.5% of divinylbenzene and containing triphenylphosphane groups.

RR′CHBr	Carbonyl compound	Yield (%) polymer 2%	polymer 0.5%	low-mol.	
Geranyl bromide	*p*-Chlorobenzaldehyde	11	48	49	(61 [4])
4-Benzoyl-1-bromobutane		32	26	22	(24 [5])
Ethyl bromide	9-Anthracenecarbaldehyde	—	66	7	(— [6])
Isopropyl bromide	9-Anthracenecarbaldehyde	10	—	16	(28 [6])
9-Fluorenyl bromide	Benzaldehyde	68	86	65	(84 [7])
Butyl bromide	Acetophenone	100	—	100	(100 [2, 8, 10])

According to eq. (1), reaction of polystyrene cross-linked with divinylbenzene affords a cross-linked polymer con-

In the reaction steps (2a) and (2b) the reagent (alkyl halide or butyllithium) can be added in excess, and the excess can be removed by filtration.

The reactions were carried out with polystyrenes cross-linked with 0.5 or 2.0 wt.-% of divinylbenzene. Gel-chromatographic studies[3] showed that only about 75% of the pore volume in a swollen polystyrene cross-linked with 2% of divinylbenzene is accessible to substances with molecular weights of 300—400. This percentage certainly decreases when the bulky triphenylphosphane groups have been introduced. Accordingly the yields obtained when working with the more strongly cross-linked copolymers are certainly considerably less than those obtained by conventional methods (Table). However, by starting with polystyrene cross-linked with only 0.5% of divinylbenzene we obtained at least as good yields as by the usual *Wittig* technique; examples are given in the Table.

In step (2b) the reaction of low-molecular reagents often causes formation of by-products that are not present after reaction of the polymeric reagents and removal of the base by filtration, as can be shown by gas chromatography; however, the by-products are formed even in these cases if the butyllithium is not carefully removed.

2-Phenyl-2-hexene

A copolymer (30 g) prepared according to eq. (1) from polystyrene cross-linked with 2% of divinylbenzene (7.3% of P, corresponding to 0.0705 mol of triphenylphosphane groups) was treated in THF (80 ml) with *n*-butyl bromide (11.6 g, 0.0841 mol). The suspension was stirred under reflux for 24 h, then the polymer was extracted with THF in a Soxhlet for 8 h and dried for 24 h at 40 °C in a vacuum. This afforded the polymeric *n*-butyltriphenylphosphonium bromide (39.0 g, 0.0657 mol of phosphonium groups).

The polymer (19 g), dried and loaded with N_2, was made into a slurry with anhydrous dioxane (40 ml), and 20% butyllithium solution (13 ml) was added at 20 °C. The Gilman test[12] was still positive after 30 min. The supernatant solvent was removed, anhydrous dioxane (30 ml) was added, then stirred and filtered again. The washing procedure was repeated until the Gilman test was negative.

The polymer thus obtained was suspended and vigorously stirred in dioxane (40 ml) at 20 °C and a solution of acetophenone (2.95 g, 0.0247 ml; freshly distilled) in dioxane (10 ml) was added. After 8 hours' stirring at 60 °C the reaction was stopped. The polymer was extracted with 1:1 aqueous THF in a Soxhlet for 12 h, after which the aqueous phase was separated from the eluate, and the residual solution was investigated by gas chromatography and IR spectroscopy (comparison with authentic olefin). Removal of the solvent left 4 g of extract from which distillation in a vacuum afforded pure 2-phenyl-2-hexene (3.85 g, 97%).

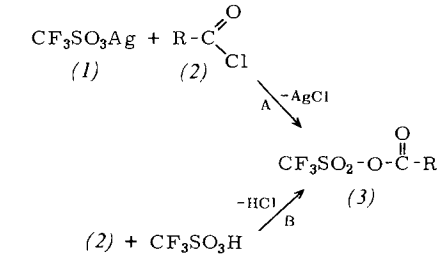
Trifluoromethanesulfonic-Carboxylic Anhydrides, Highly Active Acylating Agents[1]

By *Franz Effenberger* and *Gerhard Epple*[*]

The trifluoromethanesulfonate anion has proved the best leaving group so far in solvolytic displacement reactions[2]. For acylation with carboxylic acid derivatives, however, a straightforward estimate of the influence of the leaving group on the reaction rate is impossible; depending on substrate and reaction conditions, there are several mechanistic pathways with a varying dependance on the nature of the leaving group[3]. Recent investigations have shown, though, that the acylation potential is higher for sulfonic-carboxylic than for carboxylic anhydrides[4, 5]. So, further increased reactivity may be expected with trifluoromethanesulfonic-carboxylic anhydrides *(3)*.

We have prepared the mixed anhydrides *(3)* by treating the silver salt *(1)* with acyl chlorides *(2)* (method A, Table 1); they are also formed, although in lower yields, by reaction of free trifluoromethanesulfonic acid with *(2)* (method B, Table 1).



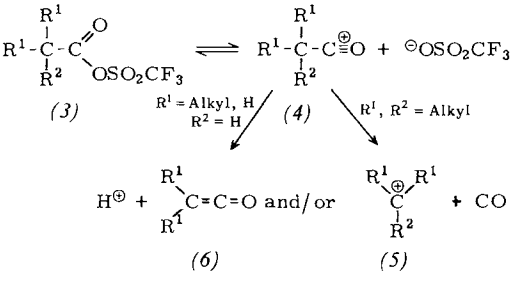


Table 1. Anhydrides *(3)* from *(2)* and *(1)* (method A) or from *(2)* and CF_3SO_3H (method B).

R	Method	B.p. (°C/torr)	Yield (%) [a]
C_6H_5	A	98–101/11	90
p-NO_2—C_6H_4	A	M.p. = 40–53 °C	80
p-CH_3—C_6H_4	A	62/0.3	94
p-Cl—C_6H_4	A	78/0.2	100
$(CH_3)_3C$	A	[b]	66
$(C_2H_5)_2CH$	A	54–58/0.1	36
C_6H_5	B	96–101/11	35
p-CH_3—C_6H_4	B	57–60/0.1	39
p-Cl—C_6H_4	B	73–75/0.1	63

[a] Crude yields are given in each case. Due to extreme sensitivity to water, elemental analyses of the anhydrides *(3)* often gives slightly inexact values. [b] Decomposes on distillation.

In the case of aromatic carboxylic acids [*(3)*, R = aryl], the anhydrides may be distilled without decomposition; the aliphatic members (R = alkyl) are thermolabile, and only a few do not decompose upon distillation. This instability can be rationalized in terms of a dissociation equilibrium of the anhydrides *(3)*: if R is an aliphatic group ($R = CR^1_2R^2$), the acylium cations *(4)* thus formed may either lose CO yielding carbonium ions *(5)* and/or be deprotonated to give ketenes *(6)*.

We have established that carbon monoxide is formed quantitatively in the decomposition of several aliphatic anhydrides; but ketenes have not been observed so far. When R = aryl, ketene formation is impossible, and decarbonylation appears rather unlikely because of the instability of the phenyl cations formed.

The anhydrides *(3)* are the most powerful acylating agents known so far. Whereas xylenes do not react with other

7000 Stuttgart, Azenbergstrasse 14—18 (Germany)

sulfonic-carboxylic anhydrides even if heated for 24 h at 100 °C[5], non-activated arenes such as benzene are acylated smoothly by the mixed anhydrides *(3)*, without addition of Friedel-Crafts catalysts (Table 2). The trifluoromethanesulfonic acid can be recovered almost quantitatively as its barium salt.

Table 2. Acylation of aromatic compounds by anhydrides *(3)*.

Reactants *(3)*, R	Arene	Conditions T(°C)	t(h)	Product [b]	Yield (%)
C_6H_5	Benzene	−20	5	Benzophenone	5
C_6H_5	Benzene	+20	5	Benzophenone	52

with strong Brønsted acids, though in poor yields[3]. However, the trifluoromethanesulfonic-carboxylic anhydrides obtainable from acyl chlorides and CF_3SO_3H do smoothly acylate aromatic compounds without addition of a catalyst[4]; in the course of the reaction, the sulfonic acid is set free again. Therefore, CF_3SO_3H-catalyzed acylation of aromatic compounds with acyl chlorides appeared a possibility.

If a catalytic amount (~1%) of CF_3SO_3H is added to a mixture of acyl chloride *(1)* and aromatic compound *(2)*, hydrogen chloride is evolved more or less violently, depending on the reactivity of the reactants, and aromatic ketones *(3)* (Table 1) are formed.

In many cases carboxylic anhydrides may be made to react under similar conditions, but the yields are then slightly lower.

Catalytic Friedel-Crafts Acylation of Aromatic Compounds[1]

By *Franz Effenberger* and *Gerhard Epple*[*]

For the synthesis of aryl ketones from aromatic compounds and acid chlorides or anhydrides at least one equivalent of Friedel-Crafts catalyst is required[2]. Highly activated arenes such as mesitylene or anisole may be acylated also

Trifluoromethanesulfonic-carboxylic anhydrides[4] formed as intermediates could be assumed to constitute the active acylating agent; on the other hand, the acylating potential of the acyl chlorides may also be increased sufficiently by protonation of the C=O group. We have therefore studied the catalytic efficiency of other strong Brønsted and Lewis acids. As shown in Table 2, catalytic acylation of arenes is possible in principle also with other acids; the yields, though, are of little preparative interest. Perchloric acid which has about the same acid strength as trifluoromethanesulfonic acid[5] is a considerably less effective catalyst. This finding supports our assumption that intermediate

[*] Prof. Dr. F. Effenberger and Dipl.-Chem. G. Epple
Institut für Organische Chemie der Universität
7000 Stuttgart, Azenbergstrasse 14—18 (Germany)

formation of mixed anhydrides is decisive for the catalytic influence of trifluoromethanesulfonic acid; a final decision, however, is not yet possible.

Table 2. Catalytic action of Brønsted and Lewis acids in the acylation of *p*-xylene by benzoyl chloride.

Catalyst	Amount (%)	Conditions T (°C)	t (h)	Yield (%)
CF_3SO_3H	1	138	6	82

C—C-Bond Formation in the α-Position to Nitrogen in Secondary Amines. Lithiodimethylnitrosamine[**]

By *Dieter Seebach* and *Dieter Enders*[*]

In 1970 *Keefer* and *Fodor* published data showing that base-catalyzed H/D-exchange occurs in the α-position of nitrosamines[2]. The synthetic availability of corresponding anions *(2)* would offer a novel type of route to amine molecules. Thus, nitrosation of a secondary amine *(1)*, metalation to give a derivative of *(2)*, reaction with an electrophile to form *(3)*, and denitrosation[3] represent a way of carrying out the valuable electrophilic substitution *(1)* → *(4)* which is not feasible by known methods[4].

We were able to verify the sequence *(1)* → *(2)* → *(3)* using dimethylnitrosamine (DMNA) and a number of electrophiles; there are numerous examples in the literature[3] for the facile last step *(3)* → *(4)* in the above cycle.

In our first metalation experiments with DMNA it turned out that nucleophilic attack at the nitroso group and metalation at the methyl group of DMNA compete when organolithium compounds are employed: sequential addition of *n*-butyllithium and benzophenone to a solution of DMNA in THF at −80 °C furnished a mixture containing both the adduct *(5a)* and butyraldehyde oxime. Similarly, the highest yield of carbinol *(5b)* obtained

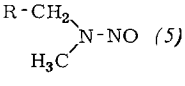

Table. Yields (not optimized), melting- and boiling points of nitrosamines *(5)* from DMNA [a] [the electrophiles were added 10 min after the solutions of DMNA and lithium diisopropylamide had been combined (total volume 40 ml THF/hexane 8:2 per 10 mmol); the mixtures were kept at −80 °C for 5—10 h].

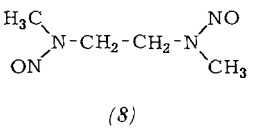
[**] Most nitrosamines are organotropic carcinogens [1]. All manipulations must be carried out with due care. However, cancer research scientists are interested in testing new types of nitrosamines which might become available through organometallic derivatives. We thank Prof. Dr. *H. Druckrey*, Freiburg, and Dr. *R. Preussmann*, Heidelberg, for valuable discussions.—Financial support by the Fonds der Chemischen Industrie is appreciated.



using methyl-, *tert*-butyl-, and phenyllithium for metalation and benzaldehyde as an electrophile was 75% (by NMR spectroscopy of the product mixture).

Quantitative lithiation to give *(6)* can be accomplished, however, with lithium diisopropylamide, as shown by the isolation in more than 95% yield of *(5b)* after successive addition (within 10 min) of the amide and the aldehyde to a solution of DMNA in THF. If the aldehyde is added after a longer period of time the yield of *(5b)* decreases, thus demonstrating the instability of *(6)* (halflife at −80 °C *ca.* 2 h, decomposition product not yet identified). The table contains data about the nitrosamines *(5)* obtained with various electrophiles.

With benzoyl chloride a product (70% yield, m.p. 110 °C) is formed to which we tentatively assign structure *(7)* on the basis of its elemental composition, molecular weight (exp. osmom. 270, calc. 250), and IR spectrum (strong absorption at 3.3 μm). Iodine converts *(6)* into the dimer *(8)* (95% yield, m.p. 57 °C, identical with authentic[7] sample). The

(7)

(8)

scope of the new reaction as applied to further electrophiles and other nitrosamines is currently under investigation[**].

Preparation of *cyclo*-Octasulfur Oxide, S_8O[1]

By *Ralf Steudel* and *Michael Rebsch*[*]

Thionyl chloride reacts with thiols (RSH) and with hydrogen sulfide with elimination of HCl, as follows:

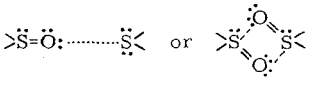
In this way disulfane oxide chlorides RS_2OCl[3] and trisulfane oxides R_2S_3O[4,5] are obtained from RSH, and polysulfane oxides[6] from H_2S. If now $SOCl_2$ is treated with polysulfanes (H_2S_n) in the molar ratio 1:1 by the dilution principle, a ring closure reaction affords cyclopolysulfur oxides:

In this way we have been able to prepare the new sulfur oxide S_8O as the first compound of that class which can be isolated in a pure state; this was effected by condensation of $SOCl_2$ with "crude sulfane" (H_2S_n; $n=3,4,5...$) at −40 °C in $CS_2/(CH_3)_2O$.

S_8O crystallizes from CS_2 as intensely yellow needles some millimeters in length. The solubility in CS_2, *ca.* 8 g/l (25 °C), is large enough to permit osmometric determination of the molecular weight at 0 and 25 °C. This gave values between 270 and 285 with a mean value of 278 (calc.: 272.5). Sulfur and oxygen were determined separately, S acidimetrically after combustion to H_2SO_4, and O iodometrically thus:

The analytical results confirm the molecular composition.

Crystalline S_8O is stable (metastable) for weeks at −20 °C in the dark. At room temperature the substance can be kept for several hours without decomposition, but on longer storage an odor of SO_2 develops. Warming causes spontaneous decomposition with evolution of SO_2 at 78 °C, and at higher temperatures the crystals liquefy. In this process polymeric sulfur (S_n) is formed, which is plastic on cooling:



The same decomposition occurs in boiling CS_2, the intensely yellow solution decolorizing and S_n being precipitated.

In a vacuum thermal decomposition occurs at 80—120 °C, thus:

For this reason no molecular ion was found in the mass spectrum[7] even on variation of the probe and source temperatures and of ionization energy. S_2O^+ and S_8^+, their fragments SO^+ and S_n^+ ($n=1$ to 7), and occasionally S_3O^+ were detected.

IR spectrum[8] of crystalline S_8O (CsCl disc)[9]: 340w, 351w, 383s, 397s, 424w, 440vw, 515w, 1085vs, and 1094w cm^{-1}. In CS_2 solution the SO stretching vibration was found at 1134 cm^{-1}, which corresponds exactly to the value for other compounds containing the —S—SO—S— group[3,4,5]. In the solid state ν(SO) at 1085 cm^{-1} is shifted to somewhat smaller wave number, which can be explained by very weak coordinate bonding of the following type:

On use of known formulas[2] the stretching force constant $f(SO)=7.40$ mdyn/Å obtained from the two-mass model leads to the bond order $b(SO)=1.6$ in crystalline S_8O

[*] Prof. Dr. R. Steudel and Dipl.-Chem. M. Rebsch
Institut für Anorganische und Analytische Chemie der Technischen Universität
1 Berlin 12, Strasse des 17. Juni 135 (Germany)

and the bond length $d(SO) = 1.49$ Å. The structure of the S_8O molecule is probably that of a zigzag S_8 ring with an equatorial or axial O atom (symmetry C_s).

In light from an argon ion laser (488.0 and 514.5 nm) S_8O decomposes slowly into SO_2 and S_8, so that it was impossible to obtain an unambiguous Raman spectrum.

Experimental:

"Crude sulfane"[10] (104 g) of mean composition $H_2S_{6.2}$, dissolved in CS_2 (266 ml), and $SOCl_2$ (62 g), dissolved in CS_2 (290 ml), were added in equimolar amounts simultaneously to a mixture of CS_2 (800 ml) and $(CH_3)_2O$ (200 ml) at −40 °C during 8 h. After being stirred for a further hour the orange solution, from which a yellow precipitate had separated, was concentrated by 100 ml at −50 °C in a vacuum. The solution was then separated from the precipitate and was concentrated to half its volume in a vacuum at temperatures rising slowly from −50 to −20 °C. By then HCl and $(CH_3)_2O$ had been almost completely removed. The solution was next cooled slowly to −60 °C, whereupon a flocculent precipitate separated. This was filtered off, washed with a little ether at 20 °C, dried in a vacuum, and recrystallized three times from CS_2. Further S_8O was isolated from the solid formed in the main reaction. Yield: *ca.* 3 g. All operations were carried out under dry N_2 and with carefully dried solvents.

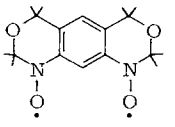
A Stable Aromatic Diradical with Strong Dipolar Electronic Interaction[**]



By *André Rassat* and *Hans Ulrich Sieveking*[*]

Bisnitroxides in which the radical centers are not widely separated have only recently become known[1–5]. Various types of information about the conformation, symmetry, and electronic state of the diradicals can be obtained from their ESR spectra. However, the shape of the ESR spectra is also sensitively influenced by the arrangement and mobility of the environment of such molecules.

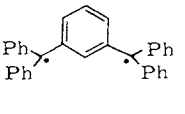
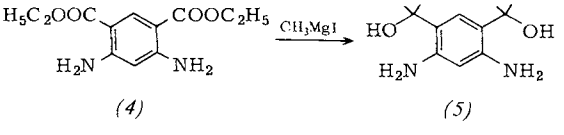
[**] Nitroxides, Part 50. This work was supported by a NATO Fellowship administered by the Deutscher Akademischer Austauschdienst (H.U.S); we thank *H. Lemaire* and *J. Ronzaud* for stimulating discussions.—Part 49: *R. Ramasseul* and *A. Rassat*, Tetrahedron Lett. *1971*, 4623.

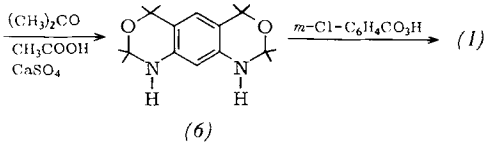


Thus increasing interest attaches to bisnitroxides as spin probes for investigations of isotropic and anisotropic liquids (liquid crystals) and for clarification of the structure and mode of action of biological systems (membranes, enzymes)[3a, 5, 6]. For such purposes stability and as rigid a conformation as possible are particularly important.

(1)



(2)



(3)

The bisnitroxide *(1)* described below contains two nitroxide groups in *meta*-position to one another and is expected to exist as a triplet in the ground state, as is the case in the related diradicals *(2)* and *(3)*[2, 7]. Like *(2)*, it cannot form a quinonoid diamagnetic bisnitrone, in contrast to analogous *ortho*- and *para*-compounds[2, 8]. In comparison with *(2)*, which is only moderately stable, *(1)* has the advantage that the reactive *para*-positions to the radical centers are shielded by tertiary alkyl groups[2, 9]. In contrast to compounds *(2)* and *(3)*, the conformational mobility of *(1)* is only slight since the nitroxide groups are kept in one plane by the condensed benzobisoxazine system.

The synthesis of *(1)* starts from diethyl 4,6-diaminoisophthalate *(4)* which, in analogy to work by *Bogert et al.*[10], is obtained in four steps from 4,6-dinitro-*m*-xylene.

(4) *(5)*

(6)

Reaction of *(4)* with methylmagnesium iodide gives a 40% yield of the diamino dialcohol *(5)* (m.p. 150—152 °C), which is only moderately stable because of its ready elimination of H_2O. *(5)* reacts with acetone as *o*-aminobenzyl alcohol does with ketones[11], yielding the diamine *(6)* by double ring closure. This product was purified (m.p. 144—145 °C, yield 40%) by chromatography. Spectroscopic data for *(5)* and *(6)* are in agreement with expectation.

On oxidation by an excess of *m*-chloroperbenzoic acid in ether, *(6)* affords a *ca.* 10% yield of 1,2,8,9-tetrahydro-2,2,4,4,6,6,8,8-octamethyl-4*H*,6*H*-benzo[1,2-*d*;5,4-*d'*]bis-(1,3-oxazine)-1,9-dioxyl *(1)*, which can be isolated by thin-layer chromatography and forms red needles, dec. 159.5—161 °C. *(1)* is stable for several months in the crystalline state but decomposes slowly in solution.

ESR spectra of *(1)* in dilute solution usually show a single broad band, which indicates the presence of a diradical with large zero-field splitting[2, 5]. In solutions of low

viscosity the ESR spectrum of *(1)* shows a poorly resolved hyperfine structure (six lines), which we ascribe to a diradical whose exchange energy J is large compared with the N coupling constant a_N[12] ($J \gg a_N$; $a_N/2 = 5.5 \pm 1$ G); in addition there is the interaction energy of the electrons with the *ortho*-proton ($a_{H^o} = 3.5 \pm 1$ G); cf. 1,2-dihydro-2,2-dimethyl-4*H*-benz[*d*]-[1,3]-oxazine[13]: $a_N = 10.8$, $a_{H^{o,p}} = 3.1$, $a_{H^m} = 0.95$ G.

In ethanol glass, *(1)* shows the characteristic spectrum of a non-cylindrically symmetrical triplet. The half-field resonance shows the ($\Delta m = 2$) transition. In the ($\Delta m = 1$) spectrum (Fig. 1) there are three pairs of bands from whose

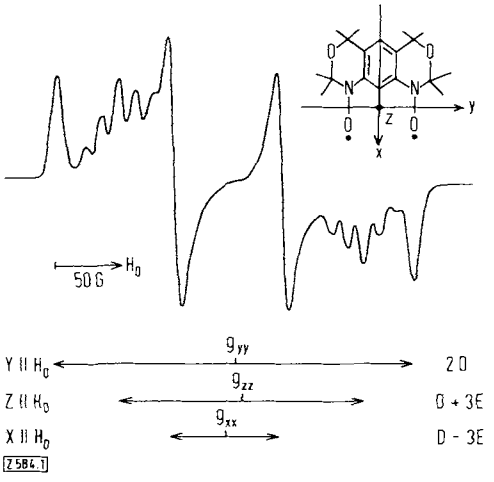


Fig. 1. ESR spectrum of *(1)* in ethanol glass at −130 °C (in definition of the axes the molecular skeleton is assumed to be planar to a first approximation).

separations the zero-field parameters of the dipolar electron-electron interaction can be obtained[1–5]: $D = 140$ G and $E = 18$ G. From the value of D it can be concluded that for the triplet *(1)* the distance between the radical centers in the point-dipole approximation amounts to about 5.8 Å; Dreiding models give the following N—N and O—O separations: double half-chair form, 4.9—5.1 Å; double half-boat form, 5.0—5.8 Å.

That the midpoints of the pairs of bands do not coincide arises from the anisotropic g factor; in agreement with results for mononitroxides[14, 15] we find for the diagonal elements: $g_{xx} > g_{yy} > g_{zz}$ (Fig. 1).

Hyperfine structure due to aniosotropic coupling with the N nuclei can be recognized only for the z components: five equidistant bands with intensity relations 1:2:3:2:1. This corresponds to the spectrum of a diradical with $J \gg D$[16] and $A_{zz}/2 = 12$ G. That the hyperfine structure of the other pairs of bands is not resolved agrees with the fact that the xx and yy diagonal elements of a coupling tensor (assumed to be cylindrically symmetrical) are expected to have appreciably lower values than those observed for the zz element[15, 16].

$$A_{xx} = A_{yy} = \frac{3a_N - A_{zz}}{2} = \frac{33 - 24}{2} = 4.5 \text{ G}$$

Studies of biological systems by means of *(1)* as spin label are in progress.

Simple New Synthesis of N^6-Substituted Adenosines and 2-Aminoadenosines[**]

By *Helmut Vorbrüggen*[*]

Since their isolation from tRNA[1] the N^6-substituted adenosines have become increasingly important as cytokinins[2] and experimental drugs[3].

Up to now, inosine and guanosine were converted in several steps into the free or protected 6-chloro, 6-bromo or 6-alkylthiopurine nucleosides[4], which gave with amines the N^6-substituted adenosines and 2-aminoadenosines respectively. To simplify this reaction sequence in analogy to our new cytidine synthesis[5], we converted the nucleosides into their persilylated derivatives *(1)* in order to protect the alcoholic hydroxy groups and activate the 6-position of the purine moiety. But even on heating with amines for days up to 180 °C the persilylated derivatives *(1)* gave only traces of the N^6-substituted adenosines or 2-amino-adenosines *(2)*.

[**] Synthesis of Nucleosides, Part 6.—Part 5: [5].

As a typical addition-elimination reaction to the imino-trimethylsilyl ether partial structure[6] of the purine moiety the reaction of *(1)* with amines should be accelerated by attack of a proton or a Lewis acid on the basic N^1-nitrogen. We therefore treated *(1)* with amines in the presence of 0.1—0.2 equivalents of amine salts or Lewis acids and obtained in this "one-step reaction" the N^6-substituted adenosines and 2-aminoadenosines *(2)*, often in very good yields. Most effective were stannic chloride, mercuric chloride and mercuric acetate, although the mercuric salts led to considerable oxidation of the amines, which were used in a threefold molar excess and served as solvents.

This reaction can be applied to the corresponding persilylated purines *(3)*[7], which on treatment with amines in the presence of $HgCl_2$ afford the corresponding N^6-substituted purines *(4)* in good yields.

(3) R = H, NH-Si(CH$_3$)$_3$ *(4)* R = H, NH$_2$

A similar activation by Lewis acids, especially by mercuric chloride, was recently described by *E. P. Gracheva et al.*[8] in the reaction of 6-methylthiopurines with amines.

Several examples of this reaction are listed in the following table.

Table. Synthesis of compounds *(2)* and *(4)*.

	(1), R	R^1—NH—R^2	Catalyst	*T* (°C)	*t* (h)	*(2)*, Yield (%)	*(2)*, M.p. (°C)
a	H	homoveratrylamine	$HgCl_2$	145	20	68	122
b	H	β-phenylethylamine	$SnCl_4$	145	22	70	166–167 [9]
c	H	β-phenylethylamine	$(NH_4)_2SO_4$	145	21	50	166–167 [9]
d	H	β-phenylethylamine	BF_3-ether	145	20	41	166–167 [9]

	(3)						*(4)*
a	H	β-phenylethylamine	$HgCl_2$	140	60	62	241–244
b	H	pyrrolidine	$HgCl_2$	120	24	83	297–300
c	NH_2 [a]	pyrrolidine	$HgCl_2$	120	26	50	263–266

[a] Is present in *(1)* and *(3)* in the silylated form as $(CH_3)_3$ SiNH-group.

N^6-(β-Phenethyl)adenosine[9] *(Example (2e))*

Inosine (5.36 g, 20 mmol) was dissolved by 16 hours' refluxing at 155 °C (bath temperature) in 100 ml hexamethyldisilazane and 0.5 ml trimethylchlorosilane. The reagents were then removed under reduced pressure and with exclusion of moisture and the residue stirred with 7.6 ml (60 mmol) β-phenethylamine and 0.638 g (2 mmol) mercuric acetate for 22 h at 145 °C under nitrogen. The dark solution was evaporated in vacuum and the residue thus obtained was refluxed for 3 h in 250 ml methanol, decolorized with charcoal, and filtered. On cooling 6.67 g (90%) of N^6-(β-phenethyl)adenosine was obtained in two crops, m.p. 166—167 °C.

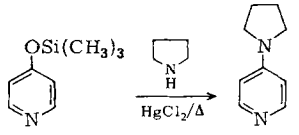
Simple Amination of Aromatic Hydroxy-Nitrogen Heterocycles



By *Helmut Vorbrüggen*[*]

Aromatic hydroxy-nitrogen heterocycles are usually aminated *via* their chloro derivatives[1], which are obtained by treatment with phosphorus oxychloride or phosphorus pentachloride. In some cases, *e.g.* with 4-hydroxyquinoline[2], an amination with higher boiling amines can be achieved directly by acid catalyzed dehydration. However, the reaction of hydroxy-nitrogen heterocycles with tetrakis-(dimethylamino)titanium[3] or with amines and equimolar amounts of titanium tetrachloride[4] gives only low yields of the aromatic amino derivatives.

We have found that our method for the amination[5] of purines and purine nucleosides can be applied to the mono- and poly(trimethylsilyl) ethers[6] of aromatic

[*] Dr. H. Vorbrüggen
Forschungslaboratorien der Schering A.G.
1 Berlin 65, Müllerstrasse 170—172 (Germany).

hydroxy-nitrogen heterocycles, which are easily accessible by reaction with hexamethyldisilazane/trimethylchlorosilane. The silyl derivatives can be reacted with ammonia or primary or secondary amines in the presence of 0.1—0.2 equivalents of Lewis acids at 145 °C to give (generally in good yields) the amino derivatives of the nitrogen heterocycles. The amine was used in threefold molar excess and served as solvent. Thus the trimethylsilyl derivative *(1)* of 4-pyridone afforded the 4-pyrrolidinopyridine *(2)*[7] in 67% yield.

(1) *(2)*

Several further examples are listed in the table.

Table. Amino derivatives of hydroxy-nitrogen heterocycles.

Starting heterocycle	Amine	Catalyst	T (°C)	t (h)	Product	Yield (%)	M.p. (°C)
2-hydroxy-quinoline	benzylamine	$HgCl_2$	145	24	2-benzylamino-quinoline [8]	74	98— 99
2-oxindole	pyrrolidine	$SnCl_4$	120	60	2-pyrrolidino-3*H*-indole	36	134—137

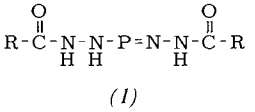
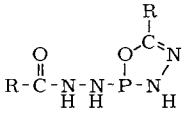
Spirophosphoranes from Acylhydrazines and Phosphorus(III) Compounds[1]

By *Alfred Schmidpeter* and *Jörg Luber*[*]

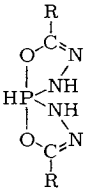


The reaction of carboxylic acid hydrazides with P^{III} compounds has been reported in two patents[2, 3]: from PCl_3 or PBr_3 and a hydrogen halide-acceptor, or from diaminodiazadiphosphetidines, products are formed in which one phosphorus atom replaces three hydrogen atoms of two acylhydrazine molecules. We have found that such compounds are obtained particularly simply by warming the hydrazide with tris(dimethylamino)-phosphane (under the same conditions, however, not by means of trimethyl phosphite).

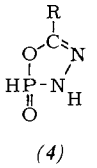
The products were previously assigned structure *(1)* or *(2)*[2, 3]. The formulation *(1)* with two-fold coordinated phosphorus can be excluded straightaway: all phosphorus(III) imide amides have so far proved to be dimeric, with the phosphorus attaining its normal three-fold coordination by formation of a diazadiphosphetidine ring. However, the compounds now in question are monomeric. If the coordination deficiency of the phosphorus in *(1)* is filled by the oxygen of an acylhydrazine group and, to equalize charges, a proton is moved to the neighboring nitrogen, then the other formulation *(2)* is



[*] Priv.-Doz. Dr. A. Schmidpeter and Dipl.-Chem. J. Luber
Institut für Anorganische Chemie der Universität
8 München 2, Meisterstrasse 1 (Germany)



obtained. But this also cannot be correct since the two R groups are then in different environments, whereas the ^{1}H-NMR spectrum (for, *e.g.*, R = CH_3) shows them to be equivalent.



(1)

(2)

(3)

(4)

A symmetrical, spirocyclic structure *(3)* results if the oxygen of the second acylhydrazine group is also coordinated to the phosphorus and, to balance the charges resulting, a proton bonded to nitrogen is transferred to the phosphorus. This can be proved, not only by the equivalence of the R groups, but also by the equivalence of the NH-protons which is recognizable by a triplet splitting of the ^{31}P-NMR signal, by the PH stretching vibration, by the $^1J_{PH}$ coupling, and by the large corresponding coupling constant that is characteristic of pentacoordinated phosphorus[4] (reference-value for a phosphorus atom surrounded by O_2N_2: 765 Hz[5]) and the high ^{31}P shielding (cf. Table).

Table. Characteristic IR and NMR data for *(3)* (shifts to higher field from TMS or H_3PO_4 positive; signal multiplicity in parentheses).

R	νPH	νCN	$\delta^1H \times 10^6$			$\delta^{31}P \times 10^6$	J_{PH}	J_{PNH}
	(cm^{-1})		PH	NH	CH_3		(Hz)	
CH_3	2460	1650	−8.60 (2)	−7.40 (2)	−1.86	+51.9 (2 × 3)	810	35
C_6H_5	2460	1630	−8.61 (2)	−8.73 (2)		+55.5 (2 × 3)	828	36
4-C_5H_4N	2450	1625						

A tautomeric equilibrium between *(2)* and *(3)* does not appear impossible. However, a contribution from the phosphane form *(2)* cannot be detected spectroscopically or chemically; the reactions characteristic of other phosphanes, *e.g.* with boiling CCl_4 or with S_8 in boiling benzene, do not occur; compounds *(3)* are at least comparable in stability under such conditions with the PH-spirophosphoranes[6, 7] derived from unsubstituted α-amino alcohols. On treatment with water in dimethylformamide *(3)* is hydrolyzed to an isolable intermediate that is probably *(4)* (R = CH_3: $\delta^{31}P = +7.8 \cdot 10^{-6}$; J_{PH} = 653 Hz); complete hydrolysis takes place on treatment with boiling water.

2,2'-Spirobi(1,3,4,2-oxadiaza-P^V-phospholines):

A solution of $P(NMe_2)_3$ (0.1 mol) in benzene (50 ml) is heated at the b.p. for some hours with the acylhydrazine (0.05 mol). Compound *(3)* crystallizes in about 90% yield when the solution is cooled. When R = 4-C_5H_4N the product is barely soluble at the boiling point.

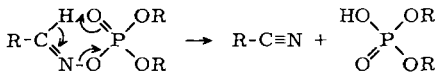
Reactivation of Phosphorylated Acetylcholinesterase—Dependence upon Activator Acidity

By *Ilse Hagedorn, Irmo Stark*, and *Hans Peter Lorenz*[*]

Acetylcholinesterase (AChE) inhibited by phosphorylation can be reactivated by 2- or 4-(hydroxyiminomethyl)-pyridinium halides such as *(13)*[1] or *(9)*[2].

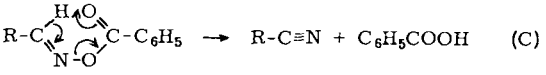


(A)

The first step in the enzyme reactivation is formulated as an equilibrium (A)[3].

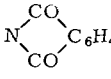
The second step, in which the equilibrium (A) is shifted in favor of the intact enzyme, is a cyclic α, β-*cis*-elimination (B)[4].

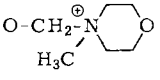
[*] Prof. Dr. I. Hagedorn, Dr. I. Stark, and Dipl.-Chem. H. P. Lorenz
Chemisches Laboratorium der Universität
78 Freiburg, Albertstrasse 21 (Germany)

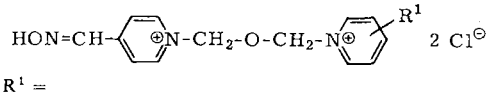


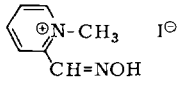
(B)

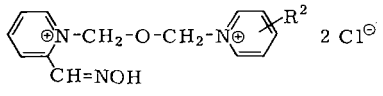
To determine the relations between oxime acidity[5] and enzyme reactivation[6] we have prepared 60 (hydroxyiminomethyl)pyridinium halides, a representative selection of which is shown in Table 1. The acidity of the compounds was determined by potentiometric titration[7].











We found that the optimum of AChE reactivation was attained with oximes whose pK_a values lay at 7.8. Structurally similar substances with $pK_a < 7.5$ and > 8.0 cannot be used (Table 1).

The ineffectiveness of the more acidic oximes *(14)* to *(18)* rests on the fact that the nucleophilicity of their anions is too slight for the primary step (A), as shown by UV spectroscopy: they do not react at pH = 7.8 even during 90 min with triethyl phosphate which was chosen as model for the inhibited enzyme[8]. The reaction between oximate anion and phosphoric acid triesters is in general quite slow, from which it can be assumed that the phosphate group removeable by oximes is attached to the enzyme by an energy-richer, non-ester-like bonding.

(C)

Table 1. Relation between the acidity of (hydroxyiminomethyl)-pyridinium halides and their ability to reactivate phosphorylated acetylcholinesterase [6].

	Compound	pK_a ±0.03	Reactivation (%) at an oxime concentration of (mol/liter)			Ref.
			7.5×10^{-4}	7.5×10^{-5}	7.5×10^{-6}	
						
	R=					
(1)	$O-CH_2-C_6H_{11}$	8.13	0	0	0	[5]
(2)		8.11	0	0	0	[9]
(3)	$O-C_6H_{11}$	8.09	0	0	0	[5]
(4)		8.05	0	0	0	[9]
(5)	$O-CH_2-C_6H_5$	8.01	17	0	0	[5]
(6)		7.89	50	14	0	[8]
						
	R^1 =					
(7)	$3\text{-}CONH_2$	7.83	74	29	0	[10]
(8)	$4\text{-}CONH_2$	7.81	62	40	0	[10]
(9)	4-CH=NOH	7.80	56	49	17	[2, 11]
(10)	$3\text{-}CO-CH_3$	7.79	53	28	0	[10]
(11)	3-CH=NOH	7.78	50	27	0	[10]
(12)	H	7.78	60	50	8	[10]
(13)		7.68	49	14	1	[1]
						
	R^2 =					
(14)	$3\text{-}CONH_2$	7.30	0	0	0	[12]
(15)	$4\text{-}CONH_2$	7.28	0	0	0	[10]
(16)	3-CH=NOH	7.24	20	0	0	[12]
(17)	H	7.20	0	0	0	[12]
(18)	2-CH=NOH	7.09	0	0	0	[12]

The less acidic oximes *(1)* to *(5)* are ineffective because the acidity of their methine-protons is too low to permit reaction (B) to occur sufficiently fast. This effect, which had been observed previously[4], was measured by means of reaction (C).

Table 2. Decomposition constants for benzoylated oximes in aqueous solution at pH 8.1, determined by UV spectroscopy ($\lambda_{max} = 280$ nm).

Benzoate of	*(13)*	*(12)*	*(8)*	*(7)*	*(5)*	*(19)* [a]
$t_{1/2}$ (min)	3	570	700	860	1825	3600
$k \times 10^4$ (min^{-1}) [b]	2310	120	99.0	80	38	19
pK_a value of the oxime group	7.68	7.78	7.81	7.83	8.01	8.34
Reactivation (%) [c]	49	60	62	74	17	0

[a] *(19)* = 4-(Hydroxyiminomethyl)-1-methylpyridinium iodide.
[b] The reaction is pseudo-first order.
[c] At an oxime concentration of 7.5×10^{-4} mol/liter.

Since the rate of the decomposition (C) depends on the kinetic methine acidity the half-reaction time $t_{1/2}$ serves as a measure for this (Table 2).

Rapid enzyme activation occurs only if the nucleophilicity of the oximate anion and acidity of the methine proton have minimum values.

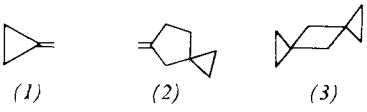
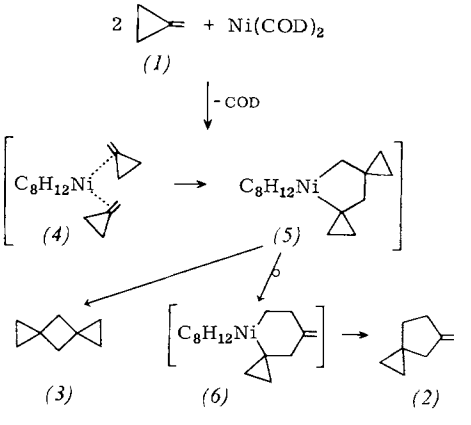
Cyclodimerization of Methylenecyclopropane on a Ni(0) Catalyst



By *Paul Binger*[*]

Methylenecyclopropane *(1)*[1,2], which is now readily available in good yield, is thermally stable up to *ca.* 150 °C, but can be oligomerized by bis(1,5-cyclooctadiene)-nickel $[Ni(COD)_2]$[3] at as low a temperature as −15 °C. Irrespective of whether it is conducted without a solvent or in pentane, benzene, or diethyl ether, the exothermic reaction yields a mixture containing 45% of dimers [65% of *(2)* and 20% of *(3)*], *ca.* 10% of trimers (6 isomers), and about 45% of higher-molecular oligomers with a mean cryoscopic molecular weight of 1100. In these experiments *ca.* 1 mol of pure *(1)* was treated with 1 mg-atom of Ni.

[*] Dr. P. Binger
Max-Planck-Institut für Kohlenforschung
433 Mülheim/Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)



A nickel catalyst freshly prepared in 1,5-cyclooctadiene[4] or in methylenecyclopropane from 2,4-pentanedionato-nickel and ethoxydiethylalane affords an oligomer mixture of the same composition. However, in the presence of a titanium catalyst prepared from 1 mmol of titanium tetrachloride and 10 mmol of chlorodiethylalane[4] higher-molecular oligomers $(C_4H_6)_n$ are formed almost exclusively (>95%).

The dimers separated in pure form by preparative gas chromatography were previously unknown. They could be identified by their spectra as 5-methylenespiro[2.4]heptane *(2)* and dispiro[2.1.2.1]octane *(3)*. [*(2)*: mol. wt. (MS)

108. IR (neat): 1658 ($\nu_{C=C}$), 1010 cm^{-1} (δ_Δ). ^{1}H-NMR (100 MHz, neat): $\tau = 5.31$ (2 H/m), 7.68 (2 H/t), 7.89 (2 H/m), 8.55 (2 H/t), and 9.68 ppm (4 H/s). — *(3)*: Mol. wt. (MS) 108. IR (neat): 3090 ($\nu_{CH\Delta}$) 1000 cm^{-1} (δ_Δ). ^{1}H-NMR (100 MHz, neat): $\tau = 7.80$ (4 H/s) and 9.55 (8 H/s)].

Transition-metal catalyzed syntheses of four-membered rings resembling the formation of *(3)* from *(1)* are known for several dienes[5-7] but have hitherto been observed for monoalkenes in only one isolated case[8]. Presumably *(2)* and *(3)* are formed *via* the same unstable organonickel intermediates *(4)* with π-Ni(C=C) bonds

and *(5)* with σ-NiC bonds. The ring of *(1)* should not open immediately on complex formation with the nickel[9] but, as with the cyclopropylmethyl compounds of several main-group elements (Li[10], Mg[11], and B[1]), only during isomerization to the 3-butenyl group [*(5)* → *(6)*].

Methylenecyclopropane is known to form complexes with nickel(0) using its C=C bond without ring opening[12].

Experimental:

$Ni(COD)_2$ (0.25 g) is treated dropwise at −15 °C during 1 h with *(1)* (40 g, 0.74 mol). The dark red solution is stirred for a further 20 h and volatile constituents (23.2 g) are then removed in a vacuum (0.001 torr, max. bath temp. 120 °C). There remains a dark viscous oil (15.7 g).—Fractionation (spinning band column): 18.5 g (46%) of b.p. 58—62 °C/100 torr [GC: 19% of *(3)* and 67% of *(2)*, residue (14%) containing 15 unknown compounds]; 0.35 g of b.p. 70—90 °C/100 torr [GC: 5.9% of *(2)*, 57.3% of 1,5-cyclooctadiene and 17.1% of C_8H_{10} (mol. wt. (MS) 106), residue (19.8%) containing 16 unknown compounds]; and 3.8 g (9.5%) of b.p. 100—118 °C/20 torr [GC/MS: 96% of $C_{12}H_{18}$ (≧6 isomers; mol. wt. 162).—^{1}H-NMR spectrum of C_8H_{10} (60 MHz, benzene): τ = 3.46 (m), 4.00 (s), 4.8—5.18 (m) and 7.62 ppm (s) in the ratio 0.9:1.1:[4]:4; presumably 3-methylene-1-vinyl-1-cyclopentene, calc. 1:1:[2+2]:4.

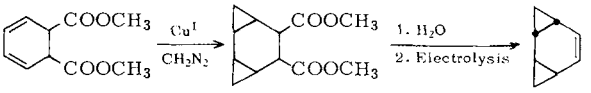
cis,trans-Tetracyclo[6.1.0.0^{2,4}.0^{5,7}]nonane, "*trans*-Trishomobenzene"

By *Martin Engelhard* and *Wolfgang Lüttke*[*]

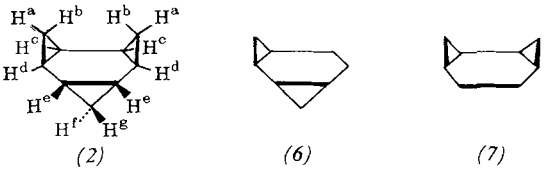


Our investigations of quasiconjugative interactions between three-membered rings have so far been devoted mainly to bicyclopropyl[1,2]. Such effects should be more clearly visible with compounds in which the cyclopropane rings are fixed by cyclic bonding. Particular interest appeared to attach to the system, called occasionally trishomobenzene, that can be constructed formally by adding three methylene groups to a benzene molecule. Two configurations are possible for this system: the completely *cis*-form (C_{3v} symmetry) ("crown") *(1)* and the mirror-plane symmetrical *trans*-form (C_s-symmetry) ("peaked cap") *(2)*.

(1) *(2)*

A bridged *cis*-trishomobenzene was recently obtained by *de Meijere, Kaufmann,* and *Schallner*[3]; heteroanalogous derivatives of *(1)* and *(2)* have been described by *Prinzbach* and *Stusche*[4].

We report here the preparation of the parent hydrocarbon *(2)*. Dimethyl tricyclo[5.1.0.0^{2,4}]octane-5,6-bicarboxylate *(4)* was obtained by cyclopropanation of dimethyl *trans*-1,2-dihydrophthalate *(3)*; hydrolysis of *(4)* and subsequent electrolytic decarboxylation afforded a hydrocarbon previously described by *Roth* and *Peltzer*[5] and identified as *trans*-tricyclo[5.1.0.0^{2,4}]oct-5-ene *(5)* by its IR and NMR spectra.



(3) *(4)* *(5)*

The Cu(I)-catalyzed reaction of *(5)* with diazomethane led to a product to which high-resolution mass spectroscopy assigned the molecular mass 120.093772; for *(1)* and *(2)* (*i.e.* for C_9H_{12}) calculation gives 120.093896. The structure and the "peaked cap" configuration with C_s symmetry *(2)* of the product are further proved by the ^{1}H-NMR spectrum: for the completely *cis*-form *(1)* only three types of proton are to be expected, but for *(2)* seven in the proportions $H^a:H^b:H^c:H^d:H^e:H^f:H^g = 2:2:2:2:2:1:1$.

The NMR spectrum (CCl_4, 100 MHz) confirms configuration *(2)*: τ = 10.1 ($2H^b$/q), 9.9 (H^f/q) (width of the quartets each *ca.* 15 Hz), 9.50 and 9.58 ($2H^a + H^g$/m) (width of the multiplets each *ca.* 20 Hz)[7], 8.9—9.4 ppm ($2H^c$, $2H^d + 2H^e$/m)[6].

The assignment of the secondary protons makes use of the known fact that the coupling constants between *trans*-protons on the cyclopropane ring are smaller than those between *cis*-protons[8]. All the assignments were further strengthened by results of analysis of the NMR spectra of *trans*- and *cis*-tricyclo[4.1.0.0^{2,4}]octane [*(6)* and *(7)*] by *Braun*[9].

1-Formylamino-1-arylsulfonyl Alkenes from α-Metalated Isocyanomethyl Aryl Sulfones and Carbonyl Compounds; Conversion of a Carbonyl Compound into the Next Higher Carboxylic Acid[*]

By *Ulrich Schöllkopf* and *Rolf Schröder*[*]

1-Formylamino-1-arylsulfonyl alkenes *(8)* are formed when α-metalated isocyanomethyl aryl sulfones *(2)*, prepared from isocyanomethyl aryl sulfones *(1)* and bases such as potassium *tert*-butoxide in tetrahydrofuran, are allowed to react with ketones and aldehydes *(3)*. The adducts *(4)*, as well as the oxazolines *(5)* and *(6)* metalated in the 2- and 4-positions and the open-chain anions *(7)*, can be looked upon as intermediates of this "formylaminomethylenation"[2] of the carbonyl compound.

If reaction of the isocyanomethyl aryl sulfone *(1)* with the carbonyl compound is carried out in ethanol in the presence of sodium cyanide as basic catalyst[4], the 4-arylsulfonyl-2-oxazolines *(10)*, which are formed by protonation of the intermediate *(5)*, can be isolated. On treatment with potassium *tert*-butoxide (in tetrahydrofuran at −10 °C) the azolines *(10)* are converted to the alkenes *(8)*. This route to *(8)* is sometimes superior to the direct route. For instance *(8e)* is obtained *via (10)* in 58% overall yield.

We obtained the isocyanomethyl aryl sulfone *(1)* from isocyanomethyllithium and arylsulfonyl fluoride.

Isocyanomethyl p-tolyl sulfone (1), Ar = p-tolyl

Butyllithium (0.08 mol; *ca.* 40 ml of a *ca.* 2.0 N solution in pentane) is added dropwise to a stirred solution of methyl isocyanide (3.28 g, 0.08 mol) in THF (100 ml) at −70 °C such that the temperature never rises above −60 °C. The solution of tosyl fluoride (6.96 g, 0.04 mol) in THF (30 ml) is added dropwise within *ca.* 3 min at −70 °C to the suspension of the isocyanomethyllithium while keeping the temperature below −65 °C. The resultant mixture is stirred for a further 10 min at −60 to −50 °C before addition of glacial acetic acid (2.4 g, 0.04 mol). The mixture is then allowed to warm and the solvent is evaporated off at 25 °C under vacuum. The residue is treated with 50 ml water and the resulting aqueous solution washed with two 75-ml portions of methylene chloride. The organic phase is dried over magnesium sulfate and worked up in the usual way.

Compound *(1)*, Ar = *p*-tolyl, [m. p. 110 °C after recrystallization from benzene/cyclohexane (1:3)] is obtained in 66% yield (based on tosyl fluoride), *i.e.* 5.26 g.

1-Formylamino-1-tosyl-2-methyl-1-propene (8f)

A solution of isocyanomethyl *p*-tolyl sulfone *(1)*, Ar = *p*-tolyl (1.95 g, 0.01 mol) in THF (10 ml) is added dropwise in *ca.* 3 min at 7—10 °C to a stirred suspension of potassium *tert*-butoxide (1.12 g, 0.01 mol) in THF (20 ml). After cooling to −10 °C the solution of acetone (0.58 g, 0.01 mol) in THF (10 ml) is added and the resultant mixture stirred for a further 5 min. Glacial acetic acid (0.6 g, 0.01 mol) is then added and the solvent removed by evaporation at 25 °C under vacuum. The residue is treated with water (25 ml) and the aqueous solution extracted with methylene chloride (50 ml). The organic phase is dried over magnesium sulfate and worked up in the usual way. The yield of *(8f)* (m. p. 100 °C after crystallization from ethanol) is 2.1 g (83%).

	R^1	R^2	Ar	*(8)* [a], Yield (%)	*(8)*, m. p. (°C)	*(9)* [c], Yield (%)
(a)	C_6H_5	H	C_6H_5	72	152 [b]	65
(b)	C_6H_5	CH_3	p-CH_3—C_6H_4	42	145 [b]	
(c)	α-Naphthyl	CH_3	p-CH_3—C_6H_4	50	186 [b]	
(d)	$C(CH_3)_3$	H	p-CH_3—C_6H_4	63	120 [b]	60
(e)	$CH(CH_3)_2$	H	p-CH_3—C_6H_4	10	83 [b]	
(f)	CH_3	CH_3	p-CH_3—C_6H_4	83	100	62
(g)	—$(CH_2)_5$—		p-CH_3—C_6H_4	61	132	55
(h)	C_6H_5—CH=CH	H	p-CH_3—C_6H_4	73	163 [b]	67

[a] Correct analysis for all products. Characteristic IR bands: 1630 cm^{-1} ($\nu_{C=C}$), 1680, 1670 cm^{-1} (ν_{CO}), 1310, 1140 cm^{-1} (ν_{SO_2}).
[b] Mixture of isomers; clear melt at this temperature.
[c] Based on *(1)*.

The synthesis deserves attention since the compounds *(8)* are converted into carboxylic acids *(9)* on heating with, *e.g.*, dilute hydrochloric acid for *ca.* one to three hours[3]; *i.e.* the reaction can be utilized for the preparation of the next higher carboxylic acid *(9)* from a ketone *(3)*, a conversion for which no simple method has previously been reported.

Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

Cyclohexanecarboxylic acid (9g) from cyclohexanone

Cyclohexanone (0.98 g, 0.01 mol) is first treated in the manner described above. The crude *(8g)* thus obtained is heated gently under reflux with 2 N hydrochloric acid (20 ml) for 10 h. The mixture is then cooled, 2 N sodium hydroxide (30 ml) is added, and the whole washed with ether. (The ethereal phase contains *p*-tolyl *p*-toluenethiosulfonate—formed from *p*-toluenesulfinic acid[5].) The aqueous phase is adjusted to pH ≈ 1 by treatment with hydrochloric acid, extracted with ether, and the ether extract dried over magnesium sulfate. The yield of *(9g)* (b. p. 232 °C) obtained is 0.7 g (55%).—Ten hours' heating with dilute hydrochloric acid promotes conversion of *p*-toluenesulfinic acid into the thiosulfonate[5]. In the case of acid-sensitive carboxylic acids *e. g.* α-styrylacetic acid *(9h)*, hydrolysis is interrupted after formation of the acid (*ca.* 1 h) and the *p*-toluenesulfinic acid separated off by treatment with CCl_4 in which it is insoluble.

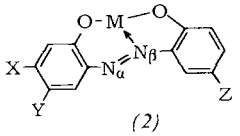
Structurally Isomeric Metal Chelates of Unsymmetrical *o,o'*-Dihydroxy Azo Compounds



By *Helmut Pfitzner*[*]

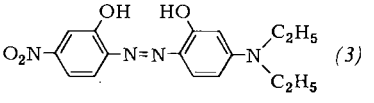
Metal complexes from *o,o'*-dihydroxy azo dyes were first prepared sixty years ago[1]; since then this class of compounds has been intensively investigated and also tested for its industrial applicability[2].

There have been many discussions as to which of the two nitrogen atoms of the azo bridge should be regarded as ligand to the metal bound in the complex; for unsymmetrical *o,o'*-dihydroxy azo compounds two structurally isomeric metal chelates *(1)* and *(2)* are conceivable, which can be designated as N_α and N_β isomers.

(1)

(2)

(a), M = Cu
X = Cl, SO_2NH_2
Y = H, Cl, CH_3, OCH_3
Z = Cl, Br, CH_3, OCH_3, C_6H_5, cyclohexyl

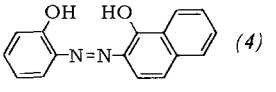


(b), M = Ni
X = H, Cl, OCH_3, NO_2, SO_2NH_2
Y = H, Cl, CH_3, OCH_3, NO_2
Z = Cl, Br, CH_3, OCH_3, $NHCOCH_3$, C_6H_5, cyclohexyl

[*] Dr. H. Pfitzner
Badische Anilin- und Soda-Fabrik, Farbenlaboratorium
67 Ludwigshafen (Germany)

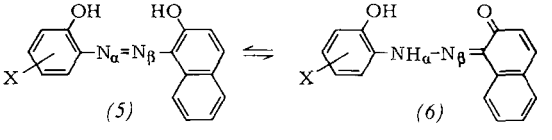
We have studied this question for the 1:1 copper(II) and 1:1 nickel(II) complexes[3] of unsymmetrically substituted *o,o'*-dihydroxyazobenzene.

Chromatographic investigation showed that in many cases the presence of two compounds of the same composition could be proved, which are formed in about 1:1 proportions. The chromatographic separation succeeded with pyridine/benzene (*ca.* 1:9) on silica gel. The colors appeared visually the same; only for the nitro compounds were differences recognizable.



Particularly good separations were given by the metal complexes *(1a)* *(2a)* and *(1b)* *(2b)*. It was striking that the nickel chelates differed more than the corresponding copper complexes in R_F values.

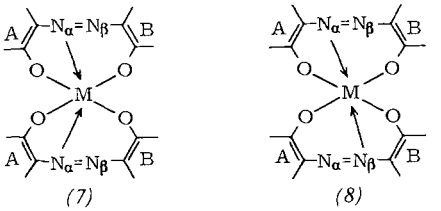
(3)



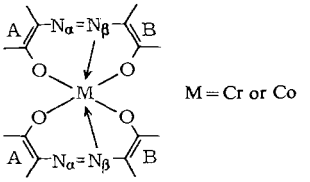
Strong polarization of the molecule, as in *(3)*, led to formation of only one complex.

As expected, no isomers were detected for the symmetrical chelates of *o,o'*-dihydroxyazobenzene (X = H and Y = Z); similarly none were found for the copper and nickel complexes of the symmetrical *o,o'*-dihydroxyazonaphthalenes. However, the complexes from the unsymmetrical parent compound *(4)* and its derivatives could be separated into

(4)



the N_α and the N_β isomer. *o,o'*-Dihydroxy azo dyes of types *(5)* and *(6)*, which contain β-naphthol as coupling component, yield always only one type of complex (N_α) which



(5) *(6)*

is derived from the quinone hydrazone form of this class of compounds[4]; the same is the case for pyrazolone dyes that exist in the ketone hydrazone form[5].

From the homogeneous isomers isolated so far it could be established that the isomerization of N_α to N_β, and vice

(7) *(8)*

(9)

M = Cr or Co

versa, proceeds relatively easily; even gentle boiling in pyridine for a short while is sufficient to produce a mixture of both isomers.

Three isomers, *(7)* to *(9)*, are to be expected in the 1:2 chromium and 1:2 cobalt chelate series in those cases in which N_α and N_β isomers are found in the corresponding copper and nickel complexes. These also can be demonstrated by chromatography.

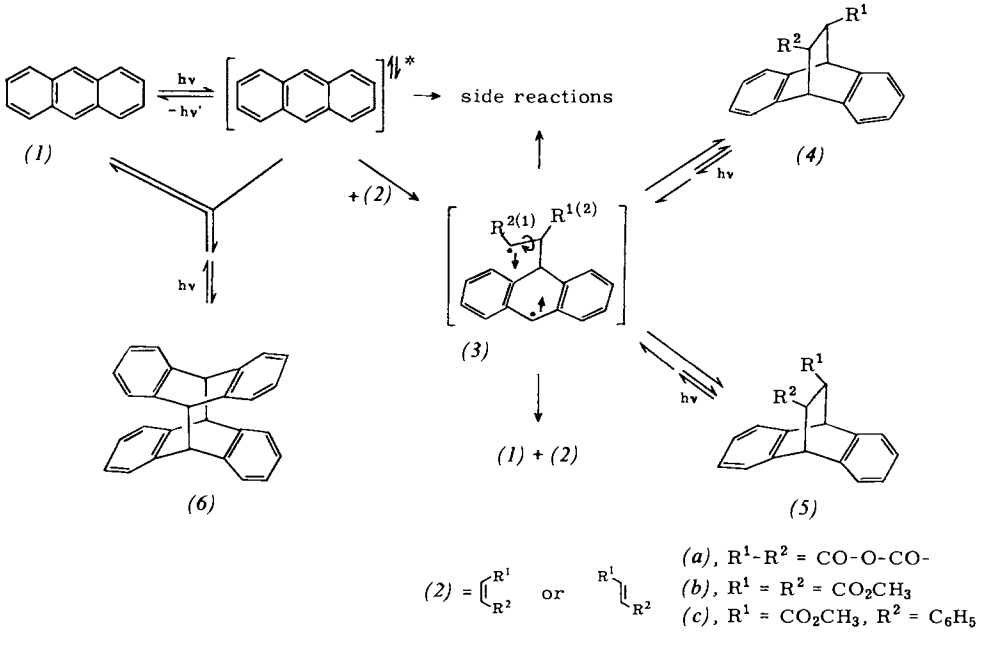
Cyclovinylogous $[2\pi \rightarrow 2\sigma]$ Photoadditions[**]

By *Gerd Kaupp*[*]

In a recent communication[1] kinetic evidence was presented to show that the formally symmetry-allowed $[{}_\pi 2_s + {}_\pi 2_s]$ singlet photoaddition in intramolecular models actually proceeds in two steps. We now report on analogous mechanisms in some cyclovinylogous[2] $[2\pi \rightarrow 2\sigma]$ photoadditions.



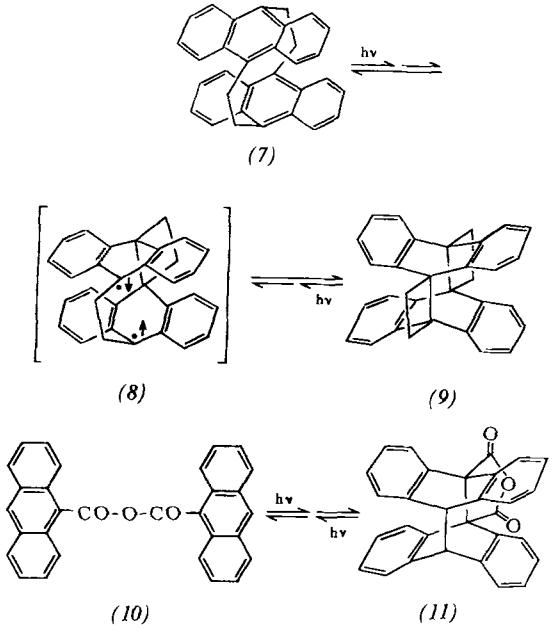
Electron-deficient alkenes *(2)* can undergo photochemical addition to anthracene *(1)* *via* a $[4\pi+2\pi]$-type reaction to give *(4)* or *(5)* (see Table). They thus compete with the $[4\pi+4\pi]$ dimerization of *(1)* to *(6)*. On selective excitation of *(1)* ($\lambda > 330$ nm) in presence of fumaric- and maleic dimethyl esters, [*trans-(2b)* and *cis-(2b)*, respectively], the more stable *trans* adduct *(4b)* is formed as principal product [*(4b)*/*(5b)* ≈ 98/2][2]; with cinnamic methyl ester [*trans-(2c)*] the same product *(4c)* is formed[3] as when the components are heated to 120 °C [*(1)*/*trans-(2c)* = 1/10, 3 days, 67%]. These results rule out symmetry allowed $[{}_\pi 4_s + {}_\pi 2_a]$ processes (cf. *e.g.* Ref. [4]) and lend support to the occurrence of intermediate products *(3)* with rotation about the original CC double bond.

Table. Yields [a] and quenching of fluorescence [b] in the reactions of anthracene *(1)* with alkenes *(2)* in benzene under N_2 at 25 °C.

Alkene	*(2)*, *cis*/*trans* [c]	Product (%) *(4)*	*(6)*	Fluorescence quenching (%)
(2a)	—	72 [d]	13	65
trans-(2b)	4/96	40	12	48
cis-(2b)	92/8	25	65	26
trans-(2c)	18/82	19	34	12

[a] $c_0 = 2.0 \times 10^{-3}$ mol *(1)*/l and 2.0×10^{-2} mol *(2)*/l; $\lambda > 330$ nm.
[b] $c = 2 \times 10^{-6}$ mol *(1)*/l and 2.0×10^{-2} mol *(2)*/l; $\lambda_{ex} = 378$ nm; self quenching of *(1)* can be neglected.
[c] At complete conversion of *(1)*.
[d] *(5a)*.

The data listed in the table show that the sterically less demanding, electron-deficient alkenes *(2)* can compete better with *(1)* for electronically excited singlet anthracene. (However, the amount of quenching of fluorescence cannot be used for the determination of photochemical rate constants because of reverse and side reactions.) In the case of more electron-rich olefins such as cyclopentene, cyclohexene or stilbene neither a quenching of the anthracene fluorescence nor formation of adducts of type *(4)* or *(5)* can be detected under standard conditions.



External heavy atom effects, which detectably favor the formation of triplet anthracene[5], serve as further confir-

mation for the singlet mechanism of the $[4\pi+2\pi]$ photoaddition: In ethyl bromide under standard conditions the yields of *(6)* and *(4)* fall below 5% in all cases, and on terminating the irradiation at standard time the alkenes *(2b)* and *(2c)* are present in more than 99% in the *trans* form[6]. Also as expected, the addition of *(2a)* to *(5a)* is strongly retarded (yield under standard conditions: 26%).

The singlet $[4\pi+4\pi]$-dimerization of anthracene (derivatives)[7] can be interpreted formally as a symmetry allowed $[{}_{\pi}4_{s}+{}_{\pi}4_{s}]$ reaction in which both new σ bonds (bond length *ca.* 1.6 Å) are formed simultaneously from an excimer (typical inter-aromatic distance *ca.* 3.3 Å) with rehybridization at the four *meso* positions (cf. p. 320 in Ref. [5]). An experimental test for these concepts is feasible by measurement of the quantum yields of forward and reverse reactions for a model[1,2] already containing two anthracene nuclei in the molecule.

[2.2](9,10)Anthracenophane *(7)*[8] having a distance of about 3 Å between aromatic nuclei (molecular model; also comparable with [2.2]paracyclophane[9]) reacts uniformly and without detectable fluorescence (start of absorption at *ca.* 550 nm) with a quantum yield $\Phi=0.30$ (CH_2Cl_2 or C_2H_5Br; 450, 365, 334, or 282 nm; N_2 or O_2)[10] to give the polycyclic compound *(9)*[8], which is reconverted into *(7)* by 282 nm-excitation with $\Phi=0.6$; no fluorescence can be detected, although non-uniformly fluorescing by-products are formed on prolonged 282-nm irradiation. The sum of the quantum yields $\Phi_{forward}+\Phi_{rev.}$ remains below the limiting value of 1 and is thus in accord with a common singlet intermediate *(8)*, which is also indicated by the fact that neither oxygen nor ethyl bromide alter the quantum yields. These findings suggest that, contrary to theoretical concepts, a biradical intermediate [analogous to *(8)*] must be assumed in order to explain the kinetic data in the photodimerization of *(1)* and the photocleavage of *(6)*[2].

The almost quantitative formation of intermediate *(8)* from both directions (cf. Ref. [1]) shows that the primary photochemical process requires virtually no activation. Consequently, the photolysis of *(7)* or of *(9)* in a KBr pellet at −190 °C also proceeds without detectable luminescence[11]. By way of contrast, the anhydride *(10)*[12], whose longwave absorption appears up to about 470 nm, behaves mechanistically less clear-cut since several conformations of *(10)* are conceivable and since the photointermediates from *(10)* and *(11)*[12] do not have to be identical.

In absence of moisture, *(10)* reacts uniformly ($8\times10^{-5}-2\times10^{-4}$ mol/l, CH_2Cl_2, 25 °C, 365 or 334 nm, N_2 or O_2, $4\times10^{-7}-5\times10^{-7}$ einstein/min) with a quantum yield $\Phi=0.031$ to give *(11)*; there is competition from a relatively intense yellow-green fluorescence (in CH_2Cl_2, 365 nm, 25 °C: $\lambda_{max}^{corr.}=520$ nm, $\Phi_{Fl}=3.5\times10^{-3}$). At −190 °C ($CH_2Cl_2$) only a 17% conversion of *(10)* into *(11)* can be achieved. The photoreaction can also be carried out intermolecularly in a KBr pellet at 25 °C; however, crystalline *(10)* is *photostable* at −190 °C (IR detection).

As an explanation for the above findings it is assumed that only a small proportion of dissolved *(10)* is present in a conformation favorable for formation of the first σ bond and that further thermal supply of this conformer is frozen-in at −190 °C. The absence of a heavy-atom effect (observed in the dimerization of *(1)*) in ethyl bromide ($\Phi=0.0315$; 25 °C) also discounts the photochemical generation of the reactive conformation.

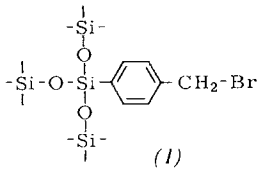
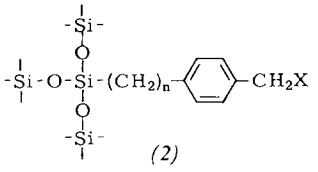
Solid-Phase Peptide Synthesis on an Inorganic Matrix having Organic Groups on the Surface[**]



By *Wolfgang Parr* and *Karel Grohmann*[*]

We have recently shown[1] that an inorganic matrix *(1)* having organic groups located on the surface is suitable for the Merrifield solid-phase synthesis of peptides[2]. The

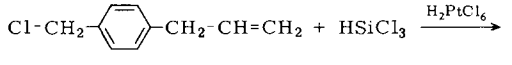


[*] Prof. Dr. W. Parr and Dipl.-Ing. K. Grohmann
Chemistry Department, University of Houston
Houston, Texas 77004 (USA)

[**] This work was supported by the Robert A. Welch Foundation, Houston, and the National Science Foundation.

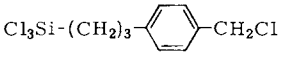
synthesis of the model peptide Pro-Gly-Phe-Ala proceeded satisfactorily, but removal of the peptide from the silicate polymer presented difficulties.

(1)



(2)

n = 1,2,3,...; X = Halogen



These difficulties can be overcome if, as in *(2)*, a short aliphatic chain is inserted between the three-dimensional silicate network and the active benzyl group.

We have now synthesized a matrix of structure *(2)* in which $n=3$ and X = Cl. For this synthesis we required the silicon trichloride derivative *(4)*, which was prepared for the first time using the following procedure:

1,4-Dibromobenzene is converted by a Wurtz synthesis with allyl bromide and magnesium into 1-allyl-4-bromobenzene[3], which can be transformed *via* the Grignard compound with formaldehyde into 1-allyl-4-hydroxymethylbenzene. Reaction of the latter with hydrogen chloride in the presence of anhydrous Na_2SO_4 (6 h, room temperature) yields 1-allyl-4-chloromethylbenzene *(3)* (NMR: $\delta=7.08$ (q), 5.85 (m), 5.06 (m), 4.83 (m), 4.42 (s), 3.28 ppm (d)). *(3)* reacts with trichlorosilane in the presence of chloroplatinic acid as catalyst[4] to give trichloro-[3-(4-chloromethylphenyl)propyl]silane *(4)* in 50% yield. According to NMR data only one isomer is formed (NMR: $\delta=7.15$ (q), 4.45 (s), 2.62 (t), 1.83 (m), 1.30 ppm (m)).

(3)

(4)

Compound *(4)* is allowed to react with the hydroxy groups of the glass surface and the remaining Si—Cl bonds are then hydrolyzed. The silicone layer is then polymerized at 100 °C in vacuum to *(2)*, $n=3$, X = Cl.

As a model peptide we synthesized the dodecapeptide H—(Phe-Ala)$_6$—OH[6], which was required for further investigation of the failure sequences that are formed as a result of incomplete coupling. For the synthesis, inorganic carrier *(2)* (8.9 g, 0.67 mmol Cl) was esterified with Boc-Ala in dioxane in the presence of triethylamine; all together 0.24 mmol Ala was attached to the carrier. The synthesis is then continued in the usual manner[6]. On treatment with HBr in trifluoroacetic acid, 240 mg (≈90%) peptide can be removed from 7 g of carrier. Ninhydrin tests and total hydrolysis of the carrier with 6 N HCl show that removal of the peptide was practically quantitative. According to amino-acid analysis the ratio of the Ala : Phe was 1.01 : 1.00. The hydrolyzate obtained by partial hydrolysis with 12 N HCl (37 °C, 72 h) is esterified with isopropanol and then trifluoracetylated. No dipeptide of the type Ala-Ala or Phe-Phe, *i.e.* no failure sequences, were observed by combined gas chromatography-mass spectrometry. Results of this type, however, are only semi-quantitative since partial hydrolysis yields not only dipeptides and free amino acids but also longer fragments which can not be detected by gas chromatography.

Experimental

A mixture of $HSiCl_3$ (37 g, 0.27 mol) and a 0.1 M solution of H_2PtCl_6 in isopropanol (0.3 ml) is treated with *(3)* (2 ml) and heated under reflux for 20 min. A further 38 ml of *(3)* is then added dropwise to the mixture such that it continues to boil without further heating. After heating under reflux for 3 h the excess of trichlorosilane is removed under vacuum. The oily residue thus obtained is then distilled; Yield: 36 g *(4)* (44%), b. p. 130 °C/0.1 torr.

(4) (2.5 g) is dissolved in anhydrous benzene (50 ml) and shaken together with porous glass beads (10 g, Porasil E, Waters Ass.) for 24 h in a 250 ml vessel. After filtration, the coated glass beads are washed free from unchanged *(4)* with benzene and the remaining Si—Cl bonds are hydrolyzed with water/ethanol (50:50). After further washing with ethanol and benzene the silicone layer is dried under vacuum at room temperature and finally polymerized by heating to 100 °C for 24 h in high vacuum. After washing with benzene and tetrahydrofuran the capacity of the silanized beads was determined by Volhard analysis for chlorine (0.07 mmol Cl/g glass)[5]. The chlorine content varied according to the conditions of preparation from 0.03 to 0.08 mmol/g.

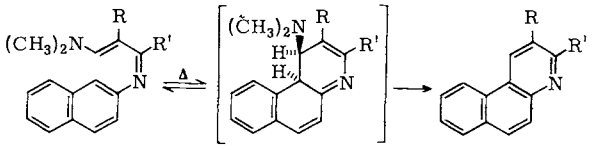
Synchronous Six-Electron Cyclization of Hexatriene Systems as a New Synthetic Principle for Preparation of Aromatic and Heteroaromatic Compounds[**]

By *Christian Jutz* and *Rudolph M. Wagner*[*]

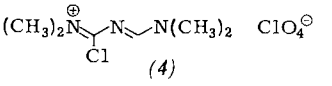


Thermal cyclization of hexatrienes to cyclohexadienes occurs as a disrotatory reversible process[1]. The irreversible conversion of the cyclohexadiene into a six-membered aromatic system can be effected in a subsequent elimination step if the starting hexatriene contains, *e.g.* a dimethylamino group, preferably *trans*, on C-1 and also a *cis*-proton on C-6.

[*] Prof. Dr. Ch. Jutz and Dipl.-Chem. R. M. Wagner
Organisch-Chemisches Laboratorium der Technischen Universität
8 München, Arcisstrasse 21 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Azalogous hexatriene systems occur in (dimethylamino-propenylidene)-*N*-arylamines *(1)* where one of the double bonds is part of an aromatic ring; when heated to *ca.* 150—200 °C these compounds are converted into quinolines *(2)* with loss of dimethylamine.



(1) *(2)*

+ $HN(CH_3)_2$

The thermolysis temperature is determined, *inter alia*, by the localization energy of two π-electrons in the aromatic systems of *(1)* with respect to a double bond of the hexatriene. This explains why with *(1)* from naphthylamines also be achieved in a single operation if equivalent amounts of arylamine and *(3c)* or *(3e)* are heated in pyridine or quinoline, respectively, with one equivalent of sodium ethoxide.

In *(3h)* the reactive chlorine may be replaced nucleophilically by an arylamino group. The 3-(dimethylamino)-acrylamidines isolated [in *(1)* R′ = $N(CH_3)_2$, and R = CN] cyclize particularly easily to quinoline derivatives (Table). Analogously, the azatrimethine *(4)* and arylamines afford finally dimethylaminoquinazolines. For example, 3-(dimethylamino)benzo[*f*]quinazoline,

(4)

m.p. 136—137 °C, is formed in 90% yield from *(4)* and 2-naphthylamine at 180—200 °C.

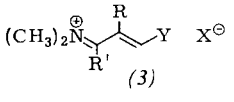


Table 1. Preparation of quinolines of type *(2)* from arylamines and trimethines *(3)*.

Arylamine	Trimethine	Cycln. temp. (°C)	Quinoline	M.p. (°C)	Yield (%)

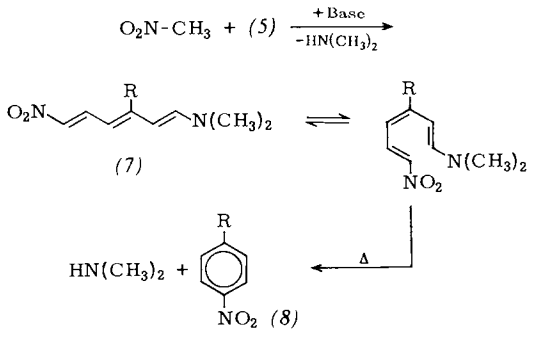
The observation that 2-trifluoromethylbenz[*d*]-[1,3]-oxazin-4-one reacts with enamines (having one more free β position) by cleavage of secondary amine to give 2-trifluoromethylquinoline-8-carboxylic acid[8] even though the intermediate of type *(1)* postulated as being formed at the same time cannot be isolated and the reaction takes place at −40 °C, induced us to investigate the thermally stable *(1)*-bases.

The well-known Conradt-Limpach thermal synthesis of quinolones from β-arylamino acrylic esters[9] belongs

(5)

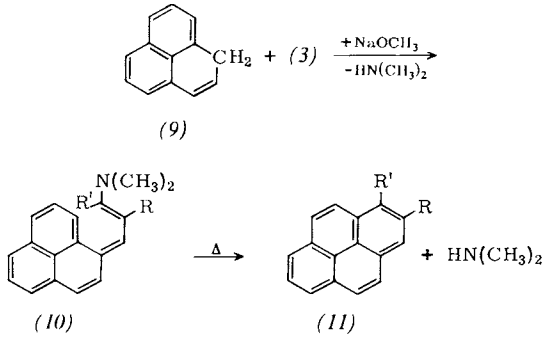


(6)

a, R = H
b, R = C_6H_5

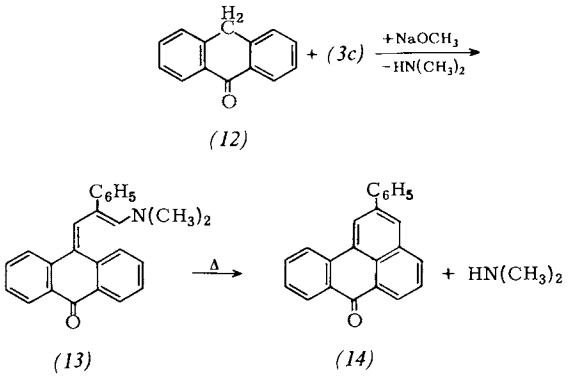
to the class of "aza-hexatriene" cyclizations with elimination. The formation of pyridines by reaction of pentamethinium salts, such as *(5)*, with ammonia (ammonium acetate) is also a nucleophilic substitution only in the first step, which leads to a 1-aza-6-dimethylaminohexatriene *(6)*. Cyclization takes place very readily since no additional localization energy is necessary.

On the basis of previous findings it was expected that the unknown 1-dimethylaminohexatriene should also cyclize very readily with elimination of dimethylamine to give benzene. 6-Substituted 1-dimethylaminohexatrienes *(7)* are obtained by reaction of *(5)* with compounds containing an acidic methyl-group in the presence of a base (triethylamine or sodium methoxide).



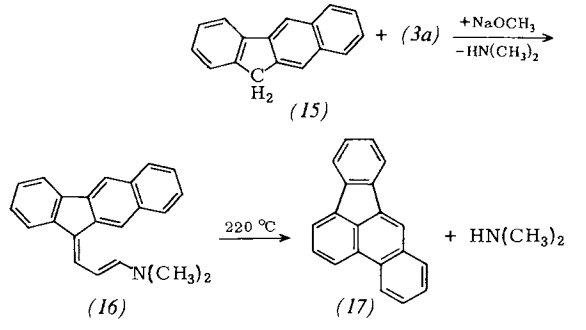
Ring-closure occurs even at 60—90 °C.

a, R = H
b, R = C_6H_5

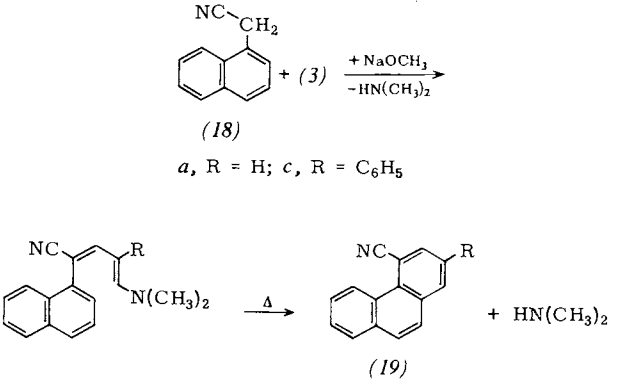


Nitrobenzene *(8a)* is obtained in 73% yield, and 4-nitrobiphenyl *(8b)*, m.p. 111—113 °C, in 66% yield. Acetophenone and 4-acetylpyridine react analogously with *(7b)* in pyridine on addition of one equivalent of sodium methoxide; dimethylaminoheptatrienone is formed as a deep red intermediate, but at 70—90 °C the color fades, dimethylamine is split off, and 4-benzoylbiphenyl, m.p. 100—101 °C (96%), and 4-pyridyl 4-biphenylyl ketone, m.p. 153—154 °C (95%), are obtained as products.

The synthesis of pyrenes *(11)* from the acid phenalene *(9)* and trimethine perchlorates *(3)* by way of the isolable, violet-red enamines *(10)*[7, 10] is an example of the cyclization of 1-(dimethylamino)hexatrienes in which the aromatic system participates. As expected, the thermolysis temperature is again higher in these cases (120—180 °C).

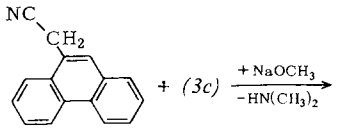


However, other, more easily accessible, starting materials with acidic methylene groups in the aromatic component permit also annelation of a further benzo ring in this way.

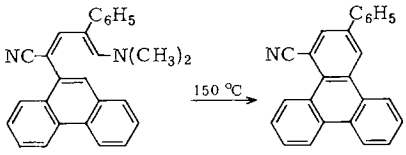


Anthrone *(12)* condenses with *(3c)* to give the orange-red enamine ketone *(13)*, which at 170—180 °C cyclizes to 2-phenylbenzanthrone *(14)*, m.p. 196—197 °C (87%).

With somewhat greater difficulty, fluorenes *(15)* can also be converted by way of aminofulvenes *(16)*[11] into fluoranthenes *(17)*, *e.g.* benzo[*b*]fluoranthene, m.p. 165—167 °C (34%).



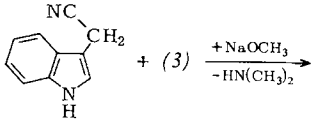
Phenanthrenes with substituents in specific positions can be conveniently built from naphthalene derivatives, *e.g.* 4-phenanthronitrile *(19a)*, m.p. 106—108 °C (91%), or 2-phenyl-4-phenanthronitrile *(19c)*, m.p. 169—177 °C (87%), from 1-naphthylacetonitrile and *(3a)* or *(3c)*, respectively.



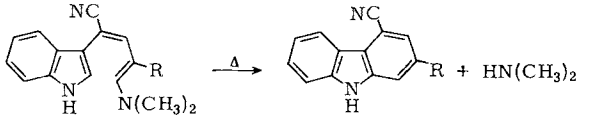
a, R = H; *c*, R = C_6H_5

One can proceed analogously from 9-phenanthrylacetonitrile into the triphenylene series *(21)*, *e.g.* from *(20)* and *(3c)* to 3-phenyl-1-triphenylenecarbonitrile, m.p. 161 to 163 °C (95%).

Indoles can be converted in carbazoles. We obtained 4-carbazolecarbonitrile *(23a)*, m.p. 156—158 °C (68%),



(20)



(21)

2-phenyl-4-carbazolecarbonitrile *(23c)*, m.p. 225—226 °C (91%), and 2-methoxy-4-carbazolecarbonitrile *(23f)*, m.p. 142—143 °C (72%), from 3-indolylacetonitrile *(22)* with *(3a)*, *(3c)*, or *(3f)*, respectively, by way of the orange-red enamine at 160—180 °C.

(22)

(23)

a, R = H; *c*, R = C_6H_5; *f*, R = OCH_3

These few examples suffice to show how the new synthetic principle is capable of generalization.

The known Ziegler-Hafner azulene synthesis and the formation of azuleno[5,6,7-*cd*]phenalene[7,10] constitute an extension of the electrocyclic reaction with elimination into ten-electron systems.

6-Methoxy-3-phenylquinoline

p-Anisidine (1.23 g) is added to a solution of the adduct *(3d)* from dimethyl sulfate (1.26 g) and 3-(dimethylamino)-2-phenylacrolein (1.75 g) in CH_2Cl_2 (25 ml), the solvent is evaporated, and the yellow syrup resulting is dissolved in a little water. On addition of sodium perchlorate the yellow perchlorate is precipitated; it forms yellow needles (3.61 g, 91%), m.p. 180—181 °C, from ethanol. 2N NaOH liberates the base of type *(1)* which is taken up in benzene. After removal of the benzene by distillation, the crude crystalline base (2.5 g) is heated slowly to 200—220 °C in a stream of N_2; dimethylamine is evolved above 180 °C and can be determined acidometrically. After 1 h thermolysis is complete. The dark residue is dissolved in hot benzene and filtered through a short column of Al_2O_3 (activity II, basic). From the eluate the sublimable compound of type *(2)* (1.30 g, 65%) is isolated and forms colorless needles, m.p. 122—123 °C, from *n*-hexane. ^{1}H-NMR ($CDCl_3$): τ = 1.03 (H-2/d), 1.90 (H-4/d), 2.0 (H-8/d), 2.25—2.53 (5 phenyl-H/m), 2.70 (H-7/dd), 2.94 (H-5/d), 6.10 (3 methoxy-H/s); J_{24} = 2.5 Hz; J_{57} = 2.7 Hz; J_{78} = 9.5 Hz.

6-Chloro-2-dimethylamino-3-quinolinecarbonitrile

The salt *(3h)* (2.15 g) is added to a solution of *p*-chloroaniline (1.9 g) in CH_2Cl_2 (20 ml) and the solvent is distilled off. The residue is digested with water containing sodium perchlorate and the solid perchlorate is filtered off; it forms colorless needles (2.25 g, 80%), from ethanol. The liberated base forms colorless needles, m.p. 115 °C, from benzene-hexane. ^{1}H-NMR ($CDCl_3$): τ = 2.7—3.6 (4 phenyl-H/m), 4.75 (1 methine-H/s), 6.9, 7.0, 7.06, 7.3 (12 N—CH_3—H/s). The thermolysis with loss of dimethylamine is already quantitative within 30 min at 180 °C. From 0.55 g of the above base is formed 0.46 g (99%) of the sublimable compound of type *(2)*, forming yellow needles of m.p. 116 °C from hexane. ^{1}H-NMR ($CDCl_3$): τ = 2.05 (H-4/s), 2.52—2.75 (3 H/m), 6.75 (6 N—CH_3—H/s); IR (KBr): ν_{CN} = 2225 cm^{-1}.

4-Biphenylyl 4-pyridyl ketone

A *ca.* 2N methanolic solution (5 mmol) of sodium methoxide is added dropwise to a stirred solution of 4-acetylpyridine (0.6 g) and *(5b)* (1.64 g) in pyridine (25 ml). The mixture at once assumes the intense reddish-violet color of the dimethylaminoheptatrienone. When the mixture is warmed to 90 °C the color fades. After 1 hour's heating, the pyridine is distilled off in a vacuum, the residue is digested with a little water, and the crystalline ketone is sucked off; it forms colorless leaflets (1.23 g, 95%), m.p. 153—154 °C, from ethanol. ^{1}H-NMR ($CDCl_3$): τ = 1.15 (2 H/d), 2.18 (2 H/d); J = 5 Hz (pyridine-H); 1.95—2.6 (9 phenyl-H/m).

2-Methoxy-4-carbazolecarbonitrile (23f)

A *ca.* 2N methanolic solution (10 mmol) of sodium methoxide is dropped into a solution of 3-indolylacetonitrile (1.56 g) and *(3f)* (2.57 g) in anhydrous quinoline (25 ml), and the whole is heated slowly with stirring under N_2 to 125 °C; after 1 h the bath temperature is raised to 160 °C, whereupon the stoichiometric amount of dimethylamine is evolved within 3 h. The quinoline is then largely distilled off in a water-pump vacuum, the residue is dissolved in CH_2Cl_2 with addition of water, and the organic phase is washed with dilute HCl and water. After removal of the solvent the crystalline residue is recrystallized from ethanol, yielding colorless needles of *(23f)* (1.52 g, 72%), m.p. 142—143 °C. ^{1}H-NMR ($CDCl_3$): τ = 1.87—2.06 (H-5/m), 2.5—2.88 (H-6, H-7, H-8/m), 2.95 (H-3/d), 3.13 (H-1/d); J_{13} = 2 Hz; 6.08 (OCH_3-H/s).

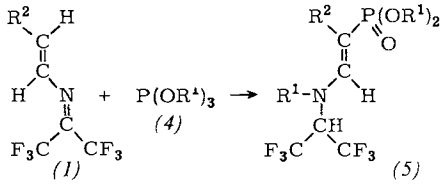
Addition of Phosphanes and Phosphites to Trifluoromethyl-Substituted 2-Aza-1,3-butadienes[**][1,2]

By *Klaus Burger, Josef Fehn, Josef Albanbauer*, and *Josef Friedl*[*]

4-Phenyl-1,1-bis(trifluoromethyl)-substituted 2-aza-1,3-butadiene (1,1,1-trifluoro-2-trifluoromethyl-5-phenyl-3-aza-2,4-pentadiene) *(1a)*[3] reacts with the phosphanes *(2a)* and *(2b)* to give the 1:1-adducts *(3a)* and *(3b)* respectively. The ^{31}P-NMR spectra of *(3a)* and *(3b)* show signals at -15.4 and -34.5 ppm, respectively (85% phosphoric acid as external standard), and thus rule out the product of a [4+1]-cycloaddition to a phosphorus heterocycle containing pentavalent phosphorus, as we have already found for the reaction of *N*-hexafluoroisopropylidenecarboxamides with phosphites[4]; the value is in the range of those found for phosphorus ylides[5]. In the IR spectra absorption occurs in the double-bond region at 1540—1570 cm^{-1}; similar values are observed for α-carbonyl ylides[6]. The coupling constants J_{PH} for the proton on C-2 are 28—35 Hz.



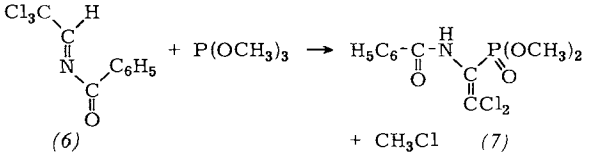
(1a) + PR^1_3 → $R^1_3P{=}C(C_6H_5)$-CH=N-CH$(CF_3)_2$ *(2)* *(3)*

(3)	R^1	Yield (%)	M.p. (°C)	IR (cm^{-1}) [a]
(a)	C_6H_5	62	138 (dec.)	1565 [7]
(b)	$CH(CH_3)_2$	84	84	1560

[a] In KBr with a Perkin-Elmer Infracord.

We assume that nucleophilic attack of the phosphane at position 4 takes place first to give a phosphonium betaine which is subsequently stabilized by 1,4-proton migration to the ylide *(3)*. The signal of the migrated proton appears in the NMR spectrum at $\delta = 3.62$ ppm (CCl_4, TMS); it is split into a septet ($J_{HF} = 7.0$ Hz) by the neighboring CF_3 groups. Similar 1,4- and 1,2-proton shifts are known. Hydrolysis of *(3a)* yields phenylacetaldehyde, which was characterized as dinitrophenylhydrazone.

Phosphites *(4)* also react with the compounds *(1)* to give 1:1-adducts, namely the phosphonates *(5)*. The ^{31}P-NMR spectrum[8] shows signals at -21 to -25 ppm and the ^{1}H-NMR spectrum [*(5a)*, *(5c)*] signals at $\delta = 3.6$ ppm (6 H/d, $J_{PH} = 11.0$ Hz), which are characteristic for a phosphonate grouping[9]. The signal of the migrated proton appears as a septet [$J_{HF} = 7.5$ Hz at $\delta = 6.0$ *(5a)*, 5.4 *(5b)*, and 5.8 ppm *(5c)* (CCl_4, TMS)]. The IR spectrum contains a signal in the double-bond region at 1610—1620 cm^{-1} as well as characteristic absorptions for the phosphonate group at 1250 (P=O), 1180 (P—OCH_3), 1060 and 1025 cm^{-1} (P—O-alkyl). The coupling constants J_{PH} of 18—19.2 Hz are indicative of a *cis*-configuration for the phosphonic group and proton[10]. This assumption is supported by the considerable difference in the chemical shift observed for the *N*-methyl group of *(5a)* ($\delta = 2.5$ ppm) and *(5c)* (3.12 ppm). The reaction *(1)* → *(5)* might proceed in the same way as *(1a)* → *(3)*; however the ylide is dealkylated by the nitrogen[11]. This step is analogous to the last step of the Arbusov reaction[12], for which a bimolecular process has been proved[13].



(1) + $P(OR^4)_3$ *(4)* → *(5)*

(5)	R^1	R^2	Yield (%)	M.p. (°C)	IR (cm^{-1}) [a]
(a)	CH_3	C_6H_5	51	179	1618
(b)	C_2H_5	C_6H_5	38	121	1615
(c)	CH_3	$CH(CH_3)_2$	40	97–98	1610

[a] In KBr with a Perkin-Elmer Infracord.

4,4-Disubstituted derivatives of *(1)* do not react under the conditions chosen; the trimethylphosphite merely rearranges to the phosphonate.

Unlike the analogous *N*-hexafluoroisopropylidenecarboxamides, but like the 2-azabutadiene *(1)*, *N*-(2,2,2-trichloroethylidene)benzamide *(6)*[14] reacts with trimethyl phosphite. The structure of the α-benzoylamino-β,β-dichloroethylenephosphonic acid dimethyl ester *(7)* formed by elimination of methyl chloride is confirmed unequivo-

(6) + $P(OCH_3)_3$ → *(7)* + CH_3Cl

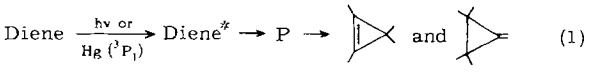
CONFERENCE REPORTS

International Symposium on the Chemistry of Small Rings

A symposium on the chemistry of small rings and activated multiple bonds was held at Louvain (Belgium), September 12—16, 1971.

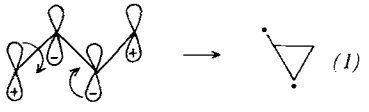
From the lectures:



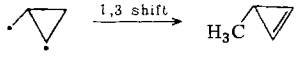
Some Properties of a Three-Membered Cyclic Diradical Intermediate

By *R. Srinivasan* and *S. Boué*[*]

The photoinduced electrocyclization of a conjugated diene to a cyclobutene is a well documented process[1] formally arising from the $\psi_1^2\psi_2\psi_3$ state. It has been shown[2], however, that the driving force is supplied by a significant contribution of the $\psi_1^2\psi_3^2$ state to the total wavefunction and accordingly the reaction obeys[1] the ψ_3 orbital symmetry, *i.e.* it is disrotatory for the ring closure and is specific for the singlet excited state.



Three years ago we discovered[3] that electronic excitation of a linear conjugated diene also yields three-membered ring products, namely cyclopropene and methylene-cyclopropane derivatives. Thus the excited diene can relax through a 1,3-p_π bonding overlap of atomic orbitals and this process was found to be independent of the state multiplicity as it took place on $Hg(^3P_1)$ sensitization as well as on direct irradiation in the vapor phase or in solution[4]. Kinetic analyses[4-6] of quenching measurements have ruled out production of the cyclopropenes by ring closure concerted with a hydrogen migration and have called for a labile precursor P which would be the real primary photoproduct [eq. (1)].



[*] Dr. R. Srinivasan

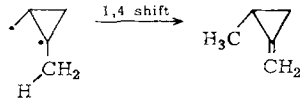
(1)

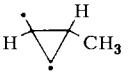
We then surmised that P would have the structure of the previously proposed[1] cyclic diradical *(1)* which can rearrange by hydrogen migrations, as shown in eq. (2) to (4).



(2)

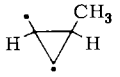
(3)

(4)



This is supported by several facts, the most important being:

1) P [≡ *(1)*] is quenchable by the ground state diene while $\Phi_{cyclobutene}$ is not dependent on the diene concentration.



2) P leads to the final products by a hydrogen shift which is subject to a free activation energy $\Delta G^{\neq}$ obeying the se-

quence 1,3 < 1,2 ≈ 1,4; expectedly, the distribution of products was observed to be strongly influenced by the excess of vibrational energy possessed by P.

3) The S_1 state of *cis*- and *trans*-1,3-pentadienes yields distinctly different precursors interpreted as *(2)* from the *trans* and *(3)* from the *cis*.

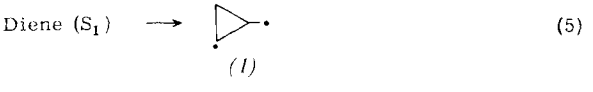
(2)

(3)

4) There is an energy barrier to the formation of P[7], since the cyclopropenes are observed as products on $Hg(^3P_1)$ sensitization ($E_T = 112$ kcal/mol) and on direct irradiation at 253.7 nm but not on sensitization with organic sensitizers ($E_T \leq 75$ kcal/mol) while *cis*⇌*trans* isomerization remains operative under these conditions.

It is proposed that the cyclic diradical species is of primary importance for explaining the $S_1 \rightarrow S_0$ internal conversion in the diene systems. Indeed, while in the T_1 diene the configuration relaxed by a 90° twist of one terminal p_π orbital is energetically degenerate with the correspondingly twisted ground state and thus offers a pathway for $T_1 \rightarrow S_0$ crossover, this is no longer true for the S_1 state[8].

Oosterhoff and *van der Lugt*[2] have shown that the energy profiles for the transformation



in S_1 and in S_0 are degenerate somewhere along the reaction coordinate; hence this would be a mechanism for energy dissipation in the S_1 diene but it can only account for the small proportion of molecules lying in the *s-cis* configuration when excited. A symmetry controlled 1,3-p_π bonding overlap would neither be subject to this restriction nor require a $\psi_1^2\psi_3^2$ contribution to provide the driving force for cyclization which is thus possible for a "hot" T_1^n state (ψ_2 and ψ_3 having the same symmetry with respect to a 1,3 closure), and would explain how internal conversion in S_1 preserves the geometrical configuration up to 90% ($\Phi_{cis \rightleftharpoons trans}$ on direct irradiation is of the order of 10% for the 1,3-pentadienes[4]).

It is therefore assumed that the energy profiles in S_1 and S_0 for the conversion

become degenerate as the reagent progresses along the reaction coordinate, this being the major pathway for energy dissipation in S_1 as well as for *cis*⇌*trans* isomerization about a double bond of the diene. The process

(1) (5)

(6)

(7)

appears to be most unusual since cyclization and ring-opening are both conrotatory. Expressed kinetically in terms of eq. (5) and (6) this is a "no reaction" reaction, involving a transient diradical similar to that invoked by *Turro*[9] to explain the dissipation of electronic energy.

Given the low barrier expected for reaction (6) while activation energies are reported for H migrations corresponding to reactions (7), the mechanism looks quite plausible and accounts for the low quantum yields ($\approx 10^{-2}$) in cyclopropene and methylenecyclopropane formation.

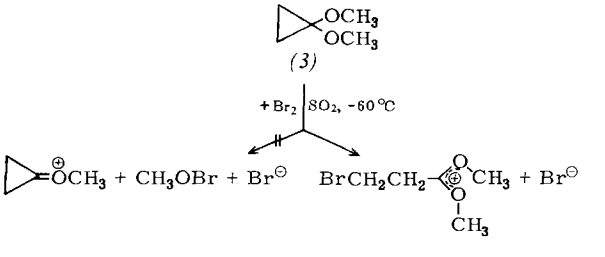
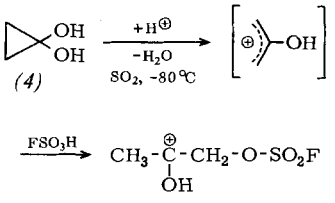
Cations and Radicals from Cyclopropanone Adducts



By *Th. J. de Boer*[*]

Cations: Cyclopropyl cations are highly unstable species, existing only when substituted by a *powerful* electron donor such as the dimethylamino group. Such cations are accessible by reaction of cyclopropanone adducts like *(1)* with Lewis acids (*e.g.* Br_2).

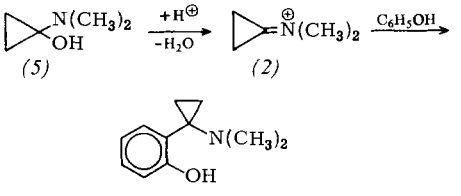
(1) *(2)*



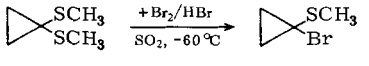
The cyclopropyldimethylimmonium ion *(2)* can be observed clearly in the NMR spectrum. Treatment of the dimethylacetal *(3)* of cyclopropanone with bromine leads exclusively to ring opening. No trace of the closed-ring oxonium ion can be detected, although such ions are easily formed from larger-ring acetals.

(3)

[*] Prof. Dr. Th. J. de Boer
Universiteit van Amsterdam
Laboratorium voor Organische Scheikunde
Nieuwe Achtergracht 129
Amsterdam (The Netherlands)



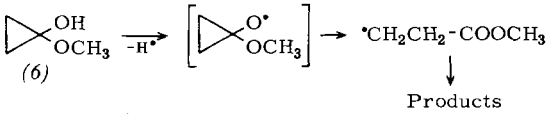
In the cyclopropyl series the tendency to form double bond exocyclic to the positively charged oxygen is apparently extremely low. This is also reflected in the behavior of cyclopropanone [or its hydrate *(4)*] towards strong Brønstedt acids, *e.g.* FSO_3H, at low temperatures. *O*-Protonated cyclopropanone cannot be detected in the



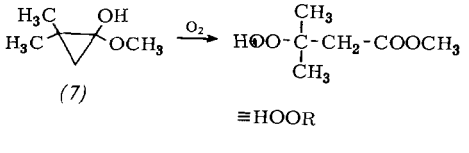
NMR spectrum but ring cleavage again prevails, albeit with rupture of a different C—C bond than in the bromination of the acetal *(3)*.

Disrotatory ring opening of *(4)* leads to the 2-hydroxyallyl cation, not observed in the NMR spectrum because of rapid subsequent reaction with fluorosulfuric acid to give the protonated fluorosulfate of hydroxyacetone[1].

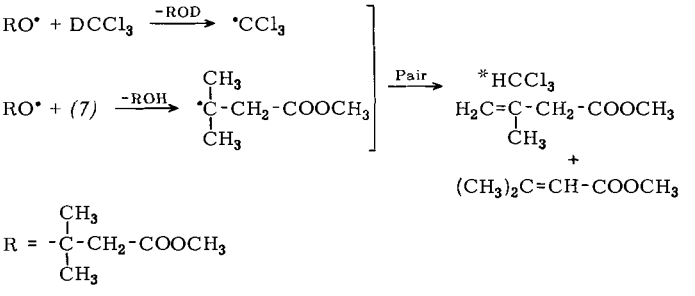
The (mono)-dimethylamine adduct *(5)* of cyclopropanone undergoes Mannich reaction with ketones and (ph)enols, presumably *via* the immonium ion *(2)*.



A (non-planar?) cyclopropyl cation stabilized by neighboring sulfur seems to be an intermediate in the reaction of cyclopropanone dithioacetal with bromine.



This substitution process is in striking contrast with the ring opening of the acetal *(3)*.

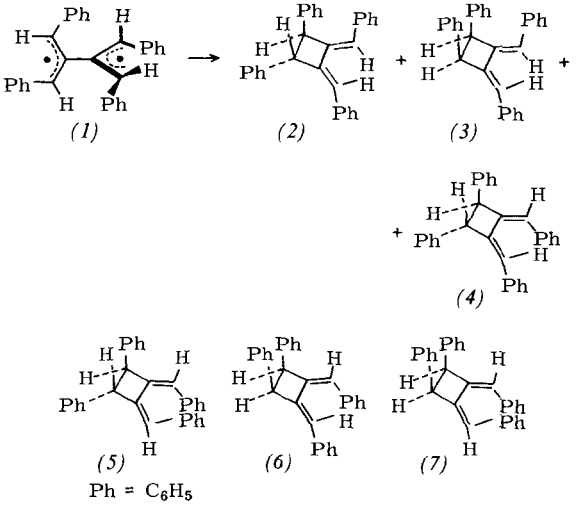


Radicals: Cyclopropanone hemiacetal *(6)* is easily oxidized by metal ions at room temperature, possibly *via* the (never detected) cyclopropyloxy radical.

Reaction of *(6)* with molecular oxygen is slow, but a phenyl group or two methyl groups in the ring [as in *(7)*] have a strong accelerating effect.

When the hemiacetal *(7)* is freshly dissolved in $CDCl_3$ the NMR spectrum shows strong emission signals for $CHCl_3$ after a brief induction period. During this period atmospheric oxygen spontaneously forms a hydroperoxide (ROOH), and this acts as an initiator, generating RO· for various radical processes.

Singlet-triplet mixing within the radical pair explains the emission signal for $CHCl_3$. Under suitable conditions, especially in benzene with added peroxide, absorption/emission multiplets are found for unsaturated products, the nature of which is in full agreement with recent CIDNP theories.



[1] This explanation differs from the one given previously by *G. A. Olah* and *M. Calin*, J. Amer. Chem. Soc. *90*, 938 (1968).

Dimerization of Optically Active 1,3-Diphenylallene

By *E. V. Dehmlow*[*]

Dimerization of allenes to substituted 1,2-bis(methylene)-cyclobutanes is usually formulated as a two-stage process occurring by way of a 2,2'-bis(allyl) radical *(1)* in which the two halves of the molecule are mutually perpendicular[1]. 1,2-Cyclononadiene is the only optically active allene with a high rotation that has been investigated; the results obtained in that case are in line with interpretation as a concerted $[{}_{\pi}2_s + {}_{\pi}2_a]$ reaction[2]. It therefore appeared desirable to study another optically active allene.

The rotation of 1,3-diphenylallene ($[\alpha]_D^{31} = 360°$) in aprotic solvents decreases according to a second-order rate law. The

Ph = C_6H_5

[*] Prof. Dr. E. V. Dehmlow
Organisch-Chemisches Institut der Technischen Universität
1 Berlin 12, Strasse des 17. Juni, No. 135 (Germany)

products are optically inactive; after two half-lives the starting material recovered has unchanged activity. Detailed investigation of the product mixture showed the presence of two new isomers [*(2)* and *(4)*] and clearly higher oligomers as well as the readily crystalline dimer *(3)* previously studied[3,4]. Accordingly, the reaction proceeds through an intermediate of type *(1)*.

A total of six structures *(2)* to *(7)* is possible. Irradiation of the long-known[3] dimer *(3)* in ethereal solution (mercury-vapor high-pressure lamp, Jena glass filter) afforded the three isomers *(5)*—*(7)* still missing. All the structures could be allocated by means of the degradation carried out previously and the NMR spectra. These showed that *(2)*, *(3)*, and *(4)* are formed in approximately equal amounts in the thermal reaction. It is striking that these are the thermodynamically favored isomers, whereas in other cases[1] compounds are obtained with the substituents in sterically unfavorable positions of the exocyclic double bonds. Our results clearly depend on the considerable stabilization of the two halves of the radical in the intermediate *(1)*.

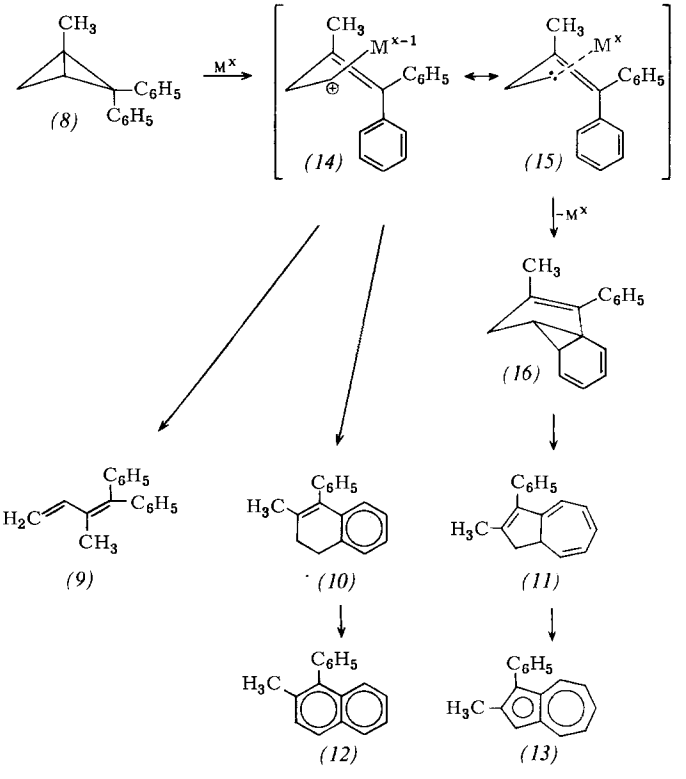
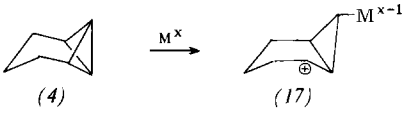
Reactions of Highly Strained Polycyclic Molecules Promoted by Transition Metal Complexes



By *Paul G. Gassman*[*]

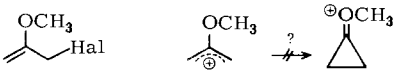
The catalytic isomerization of highly strained ring systems such as bicyclo[1.1.0]butane, bicyclo[2.1.0]pentane, or tricyclo[4.1.0.0^{2,7}]heptane has been shown to proceed at low temperatures in the presence of a variety of transition metal complexes. Examples of these metal-catalyzed rearrangements are the conversion of *(1)* into a mixture of *(2)* and *(3)*, and the isomerization of *(4)* into *(5)*. Both of these isomerizations occur readily at 25 °C in the presence of trace amounts of dicarbonylchlororhodium.



The formation of *(2)* from *(1)* demonstrated that the isomerization involved cleavage of the center (a—c) bond and a side (a—b) bond, accompanied by a hydrogen shift from C_d to C_a. Formally, this transformation can be pictured as occurring *via* the hybrid intermediate represented by the resonance structures *(6)* and *(7)*. Substantial evidence for the carbenoid character of this hybrid intermediate was obtained when 1-methyl-2,2-diphenylbicyclo[1.1.0]butane *(8)* was isomerized by dicarbonylchlororhodium. This rearrangement led to a

mixture of *(9)*, *(10)*, and *(11)*. Addition of chloranil to the crude mixture of rearrangement products converted *(10)* and *(11)* into *(12)* and *(13)*, respectively. Mechanistically, it is assumed that *(8)* is converted into an intermediate represented by the resonance hybrids *(14)* and *(15)*. Carbene type addition to the aromatic ring would then produce *(16)* which on valence tautomerization would furnish *(11)*.

The rearrangement of *(4)* and of its 1-methyl derivative was investigated in detail. It was observed that different metal complexes led to different products. Evidence was obtained which supported the contention that the



initial step in the isomerization of *(4)* was cleavage of a side bond to yield *(17)*. The fate of *(17)* was a function of M^x. Use of a nucleophilic solvent led to the trapping of *(17)* prior to further rearrangement.

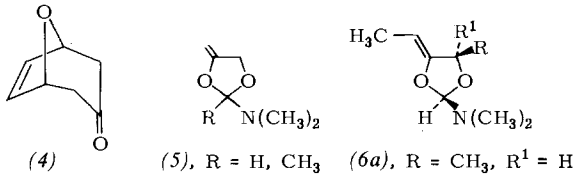
Cycloadditions and Rearrangements of 2-Oxyallyl Systems

By *H. M. R. Hoffmann*[*]

The hitherto unknown 2-methoxyallyl halides *(1a)*—*(1c)* have been synthesized by two independent routes, *viz.* (i) reaction of 2-methoxypropene with *N*-halosuccinimides



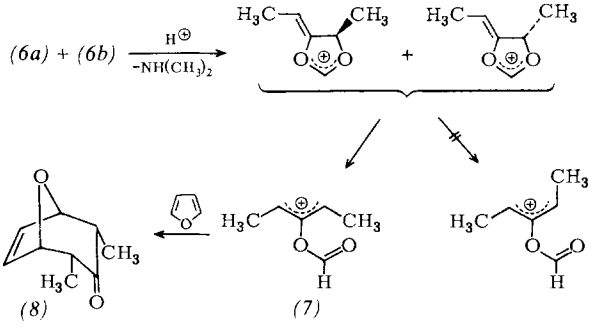
(1a), Hal = Cl
(1b), Hal = Br
(1c), Hal = I

(2)

(3)

and (ii) pyrolysis of 1-halo-2,2-dimethoxypropanes in the presence of a mildly acidic catalyst[1].

Attempts to generate a long-lived 2-methoxyallyl cation *(2)* from *(1b)* under a variety of conditions were unsuccessful owing to the sensitivity of the starting material[2]. However, treatment of 2-methoxyallyl bromide *(1b)* with silver trifluoroacetate in the presence of conjugated dienes and sodium carbonate afforded seven-membered cycloadducts[3]. For example, 8-oxabicyclo-[3.2.1]oct-6-en-3-one *(4)* was obtained in the presence of furan[4]. Reaction of 2-methoxyallyl bromide with



(4)

(5), R = H, CH_3

(6a), R = CH_3, R^1 = H
(6b), R = H, R^1 = CH_3

silver trifluoroacetate in the absence of conjugated diene provided no evidence for an electrocyclic closure to 1-methoxycyclopropyl cation *(3)*.

The debromination of α,α'-dibromoketones with a zinc-copper couple in dimethylformamide and dimethylacetamide yields 2-dimethylamino-4-methylene-1,3-dioxolanes *(5)* in a new and general reaction[5]. The heterocyclics formed, which can be formally regarded as 1,3-dipolar adducts of oxyallyl systems and dimethylformamide, are highly reactive and undergo numerous reactions. For example, on standing at room temperature furan and *(6a)* + *(6b)* furnish exclusively the *cis*-diequatorial adduct *(8)*.

(8)

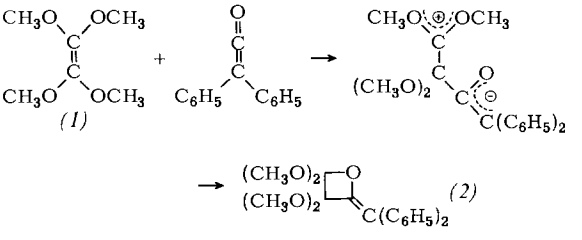
University College
London WC1H OAJ (England)



Hence, the intermediate 1,3-dimethyl-2-formoxyallyl cation is generated stereospecifically in the W configuration *(7)* and then combines with furan in a boat-like seven-membered transition state. 2-Oxyallyl cations have also been generated by an organometallic route in the presence of furan and cyclopentadiene, and a bevy of 8-oxabicyclo-[3.2.1]oct-6-en-3-ones and bicyclo[3.2.1]oct-6-en-3-ones has been prepared[6].

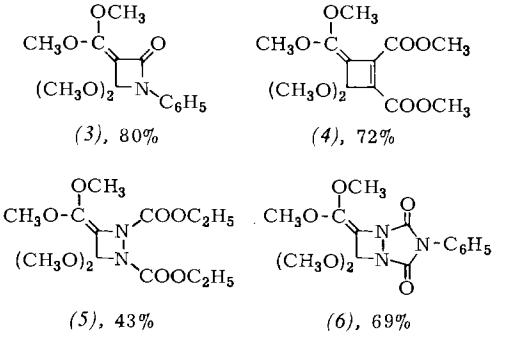
Reactions of Double Bonds Activated by Methoxy Groups

By *Reinhard W. Hoffmann*[*]



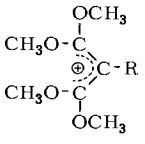
Methoxy-substitution at a π-electron system causes an increase in the π-electron density at the carbon atoms involved. These substances react much more readily with electrophiles than their unsubstituted counterparts. Permethoxy-substitution maximizes this effect, as is demonstrated by the ease with which the electron-rich olefin tetramethoxyethylene *(1)* undergoes cycloadditions to electrophilic double bonds and to heterocumulenes[1]. These [2+2]-cycloadditions appear to be polar two-step processes, as is hinted by the formation of an oxetane *(2)* rather than a cyclobutanone on addition of *(1)* to diphenylketene.

(1)

(2)

These [2+2]-cycloadditions have now been extended to an electron-rich allene, tetramethoxyallene, which had been prepared starting from *(1)*[1]. The following adducts have thus been generated:

(3), 80%



(4), 72%

(5), 43%

(6), 69%

[*] Prof. Dr. R. W. Hoffmann
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

These products most probably also arise in a two-step cycloaddition involving an intermediate tetramethoxyallyl cation *(7)*. Thus the adduct of tetramethoxyallene to tetracyanoethylene equilibrates rapidly at room temperature with the 1,4-dipole *(7a)*[2]. More insight into the behavior of such 1,4-dipoles is provided by a study of the tetramethoxyallyl cation *(7b)* itself, which is generated by protonation of tetramethoxyallene by fluorosulfuric acid. Only one methoxy signal is observed in the NMR spectrum of *(7b)* at 20 °C. Equilibration of the methoxy groups in *(7b)* at −20 °C requires $\Delta G^{+} = 12.7$ kcal. This is probably the barrier to allyl rotation in the cation, rather than that to methoxy rotation.

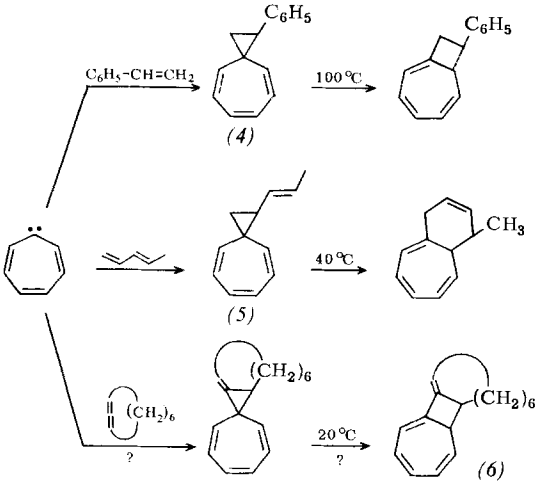
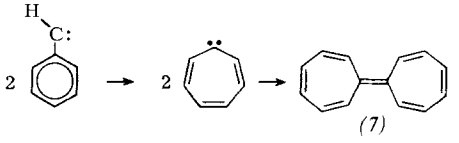
Cycloheptatrienylidene: Structure and Role in Carbene-Carbene Rearrangements

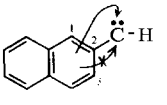


By *W. M. Jones*[*]

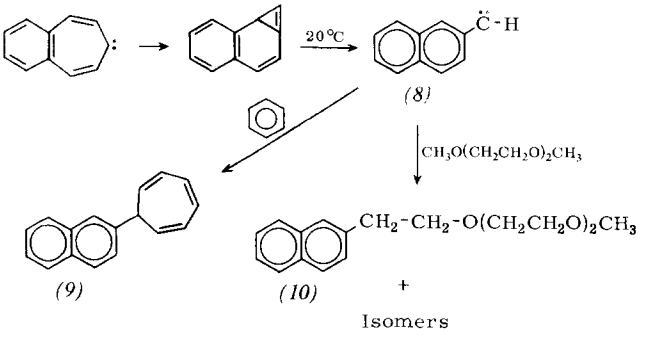
Three structures may be envisaged for the intermediate resulting from the photolytic or thermal decomposition of the sodium salt of tropone tosylhydrazone: the singlet carbene *(1)*, the diradical (triplet) *(2)*, and the allene *(3)*.



(1) *(2)* *(3)*



Although earlier results[1] had pointed to the singlet carbene structure, the recent discovery[2] that the low temperature addition of the intermediate to cyclononadiene gives a cyclobutane product *(6)* re-opened the question. However, it has now been found[3] that the cyclopropane ring of the styrene adduct *(4)* expands to a cyclobutane at 100 °C and that of the 1,3-pentadiene adduct expands at 40 °C (half life, *ca.* 30 min). By extrapolation, the cyclononadiene adduct would be expected to expand to the observed product *(6)* under the reaction conditions, thus vitiating the need for the cycloheptatetraene structure *(3)*.



Singlet cycloheptatrienylidenes are also believed to result from carbene-carbene rearrangements of arylcarbenes. For example, in the gas phase, phenylcarbene gives heptafulvalene *(7)*[4], the formal dimer of cycloheptatrienylidene.

Evidence has how been obtained for the assumed[4] cyclopropene mechanism (in contrast to a Wolff zwitterion mechanism) for this rearrangement. Thus, in the gas phase, 3-methyl-2-naphthylcarbene gives over 70% 2-vinylnaphthalene, the product resulting from a two-step rearrangement with initial migration of C-1 of the naphthalene nucleus to the carbene center and net cleavage of the bond between C-1 and C-2. In contrast, 1-methyl-2-naphthylcarbene gives no vinylnaphthalene, the product that would result from migration of C-3 to the carbene center on C-2 with cleavage of the C-2—C-3 bond.

An additional result that is consistent with the cyclopropene mechanism is the facile rearrangement of benzocycloheptatrienylidene to *beta*-naphthylcarbene *(8)*. This rearrangement is extraordinary in that it takes place at low temperatures (as low as room temperature) in solution. The rearranged naphthylcarbene has been identified by its

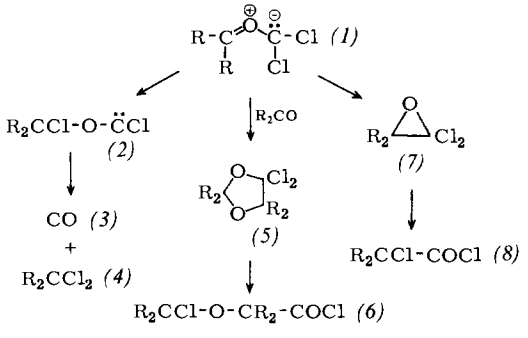
[4] *R. C. Joines*, *A. B. Turner*, and *W. M. Jones*, J. Amer. Chem. Soc. *91*, 7754 (1969); *P. O. Schissel*, *M. E. Kent*, *M. J. McAdoo*, and *E. Hedaya*, *ibid. 92*, 2147 (1970); *C. Wentrup* and *K. Wilczek*, Helv. Chim. Acta. *53*, 1459 (1970).

reaction products with solvent. For example, both thermal (80 °C) and photolytic (20 °C) decomposition of the salt of benzotropone tosylhydrazone in benzene gives *beta*-naphthylcycloheptatriene *(9)* in good yield. In diglyme, the rearranged carbene gives the expected insertion products such as *(10)*. Possible rearrangement of a carbene precursor has been excluded. These results point to a reaction proceeding through a cyclopropene that is thermally so unstable that, even at room temperature, it undergoes facile ring opening, sacrificing a *sigma* bond to give what is normally considered to be a high energy intermediate, an arylcarbene.



Carbonyl Ylides and Dichlorooxiranes in Carbene Reactions

By *John A. Landgrebe, Charles W. Martin,* and *Erich Rapp*[*]

The treatment of phenyl(bromodichloromethyl)mercury with an excess of either benzaldehyde or benzophenone results in the formation of several products which are most easily rationalized by Scheme 1.

Once formed, carbonyl ylide *(1)* can follow three distinctly different paths. The ylide *(1a)* from benzophenone[1] undergoes ring closure followed by a known type of rearrangement of dichlorooxirane *(7)* to produce chloroacetyl chloride *(8)*, the major product. None of product *(6)* and only a few percent yield of products *(3)* and *(4)* were noted.

In stark contrast, the ylide *(1b)* from benzaldehyde[2] gave substantial yields only of products *(3)*, *(4)*, and *(6)*. The ease with which alkoxyhalocarbenes such as *(2)* lose carbon monoxide is well known[3]. The conversion of *(1)* into *(2)* requires a 90° twist of the CCl_2 group followed by 1,3-migration of halogen. Production of acid chloride *(6)* apparently involves initial 1,3-dipolar addition of benzaldehyde to carbonyl ylide *(1b)* followed by rearrangement of the anticipated dichlorodioxolane *(5)* (not isolated). Attempted independent synthesis of *(5)* resulted only in the formation of *(6)*.

Scheme 1. *(1a)*, R_2CO = benzophenone; *(1b)*, R_2CO = benzaldehyde.

The different behavior of benzaldehyde and benzophenone may be due to the unavoidable steric interactions between the *ortho*-hydrogen and halogen in the carbonyl ylide *(1a)* from benzophenone which promotes rapid conrotatory closure to the oxirane followed by rearrangement to *(8)*.

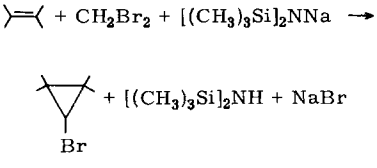
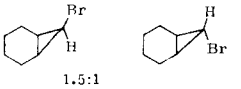
A New Direct Synthesis of Monobromocyclopropanes

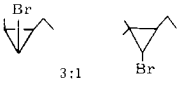
By *Bernard Martel* and *Jean Michel Hiriart*[*]

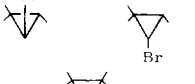
Up until now, the synthesis of monobromocyclopropanes has usually been carried out *via* the reduction of dibromocyclopropanes with tributyltin hydride [eq. (1)][1]; no direct method has been available.

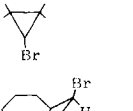
We have now developed a direct method [eq. (2)] using sodium bis(trimethylsilyl)amide which has been shown to be useful in α-elimination reactions[2, 3]. Our results are shown in Table 1.

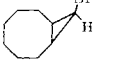


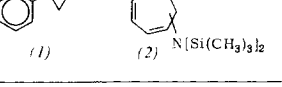












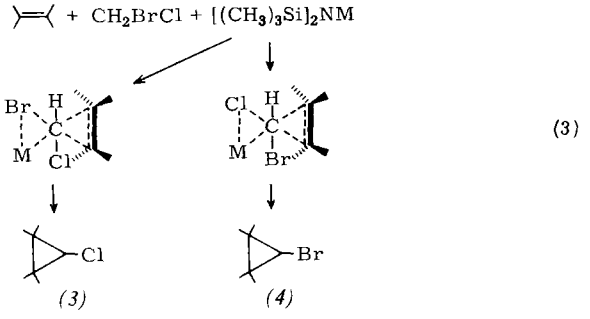


Table 1. Yields of bromocyclopropanes obtained *via* eq. (2).

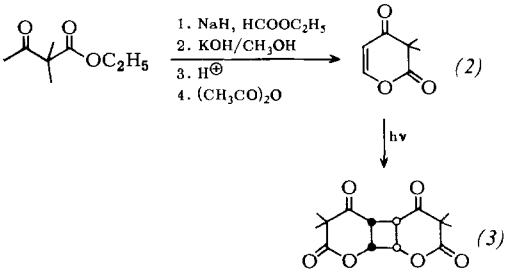
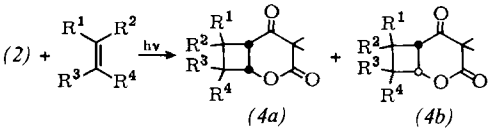
Synthesis and Photochemical Behavior of Enone Lactones

By *P. Margaretha*[*]



Some results pertaining to the synthesis and photochemical behavior of cyclic alkenes substituted as in *(1a)* and *(1b)* will be discussed.

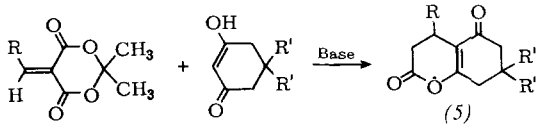
[*] Dr. P. Margaretha
Max-Planck-Institut für Kohlenforschung, Abt. Strahlenchemie
433 Mülheim/Ruhr, Stiftstrasse 34/36 (Germany)



(1a) *(1b)*

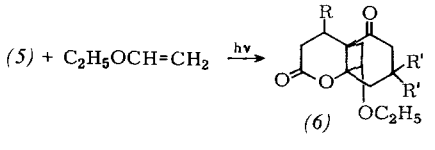
As the simplest non-enolizing compound of the type *(1a)*, compound *(2)* was synthesized as follows:

(2) *(3)*



Irradiation of *(2)* in various solvents leads to only one product, which proves to be the HH *cis-anti-cis* dimer *(3)*. Irradiation of *(2)* in the presence of alkenes leads to *cis-* and *trans*-fused oxabicyclooctanes *(4)*. An evident specificity is observed in the orientation of addition.

(4a) *(4b)*

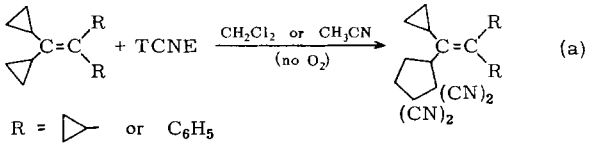


R^1	R^2	R^3	R^4
H	H	OCH_3	OCH_3
H	H	CH_3	CH_3
H	H	H	OC_2H_5
CH_3	CH_3	CH_3	CH_3

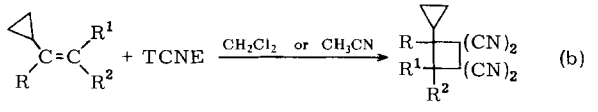
Compound *(5)* [as an example of type *(1b)*] is synthesized as follows:

(5)

In contrast to *(2)*, no dimerization was observed on irradiating *(5)* in solution. Cycloaddition leading to substituted propellanes *(6)* took place only with ethyl vinyl ether. The resulting isomers of *(6)* were separated by chromatography on silica gel; however, no precise assignment of configuration could be deduced from their NMR and IR spectra.



(6)

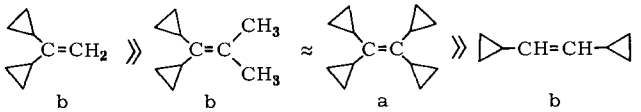


Cycloaddition of Cyclopropylethylenes with Tetracyanoethylene

By *Shinya Nishida*[*]

Cyclopropylethylenes are found to undergo facile cycloadditions with TCNE in two different manners, called type a and type b[1,2]. Type a cycloaddition, observed in the reaction of tetracyclopropylethylene[3] and 1,1-dicyclopropyl-2,2-diphenylethylene, gives a 1:1 cycloadduct formed by cleavage of one of the cyclopropane rings and subsequent incorporation of TCNE. This cycloaddition proceeds smoothly in the absence of oxygen; no charge-transfer color develops in the reaction. Most other cyclopropylethylenes produce charge-transfer color with TCNE and give [2+2]-cycloadducts in high yields (type b cycloaddition).

(a)



(b)

Type a cycloaddition most probably involves an electron transfer process to give TCNE anion radical (characterized both by electronic absorption spectrum and by ESR) and cyclopropylethylene cation radical. Cyclopropane cleavage could take place at this stage to give a five-membered cycloadduct.

On the other hand, type b cycloaddition could involve a charge-transfer complex as an intermediate, from which the [2+2]-cycloadduct is derived. The addition of excess mesitylene to the solution effectively slows down the reaction rate. In the transition state, there must be considerable charge separation because the rates of type b cycloadditions are influenced by the polarity of the solvent (the same adduct is formed as a single isolable product in all solvents studied, however), and 1,1-dicyclopropylethylene is the alkene of highest reactivity while *cis*- and *trans*-1,2-dicyclopropylethylene are those of lowest reactivity. However, the addition is found to be >90% stereospecific for the latter two compounds.

Steric effects cannot be a single major factor controlling the course of these two types of cycloaddition. Although the two olefins which underwent type a are both tetrasubstituted, 1,1-dicyclopropyl-2-methylpropene, which is also a tetrasubstituted ethylene, produces a blue solution with TCNE and yields a [2+2]-cycloadduct as the sole product.

The relative reactivity sequence of representative alkenes

b b a b

shown also supports this conclusion. Tetracyclopropylethylene is moderately reactive in cycloaddition with TCNE, and 1,2-dicyclopropylethylene reacts slowly. The fact that no charge-transfer color can be seen in type a cycloaddition suggests that these particular olefins have substantially low ionization potentials which makes the species formed by electron transfer more stable than a charge-transfer complex. In fact, cyclopropylethylenes are found to be alkenes of notably low ionization potential. For example, 1,1-dicyclopropylethylene has an *IP* of 8.08 eV[4] which is even lower than that of 1,3,5-hexatriene (8.26 eV)[5].

Catalysis of Strained σ-Bond Rearrangements by Silver(I) Ion

By Leo A. Paquette[*]

First recognized in 1969[1], the ability of Ag^+ ion to induce skeletal bond reorganizations of highly strained molecules lacking sites of unsaturation has quickly become established as a viable and fruitful area of research. Appealing because of their mechanistic import and synthetic potential, such transition metal-promoted rearrangements have given evidence of a strong undercurrent of interest.

In the specific case of bicyclo[1.1.0]butane isomerizations, kinetic studies[2] have revealed that bicyclobutane-Ag^+ complexes are definitive intermediates. Several equilibrium constants have now been measured and the experimentally derived values ($K = 0.29$—1.0 *vs.* benzene) reveal that the extent of complex formation is substantial. The activation parameters associated with a typical rearrangement (*e.g.*, of tricyclo[4.1.0.0^{2,7}]heptane *(1)* to 1,3-cycloheptadiene), $\Delta H^{\neq} = 18.5$ kcal mol^{-1}, $\Delta S^{\neq} = -11.5$ kcal mol^{-1}, accord well with subsequent rate-determining isomerization of the complex. Various degrees of alkyl substitution of the bicyclobutane nucleus *(2)* and the specific location of such groups are recognized to promote substantial alterations in which bond cleavages are kinetically dominant[3]. Generally speaking, positioning of substituents at C-2 and C-4 is seen to reinforce the propensity of the parent system for C-1—C-2 and C-3—C-4

(1) *(2)*

("double edge") bond cleavage. Contrariwise, substitution of the bridgehead positions promotes rupture of the central bond and one edge bond. In acuatl fact, the situation is considerably more complex. Structural[4] and deuterium isotope effect considerations[5] give evidence of the fact that "double edge" rupture is reconcilable with a model

[*] Prof. Dr. L. A. Paquette
Department of Chemistry, The Ohio State University
Columbus, Ohio 43210 (USA)

in which Ag^+ inserts oxidatively into one of these bonds, followed by ring opening of the coordinated cyclopropylmethyl cation so produced and loss of Ag^+.

However, when a substituent resides at C-1, the first-formed intermediate now undergoes preferential central bond cleavage to generate a stabilized (tertiary) argento carbonium ion[3–5]. Such entities most frequently suffer subsequent 1,2-hydride shift (where structurally possible) and ejection of Ag^+. In an overall sense, this latter pathway bears many similarities to a reverse carbenoid addition to a double bond. Interestingly, it apparently gains prominence only when the formation of a tertiary argento carbonium ion can be realized.

With certain substitution patterns, cyclobutene derivatives are also produced. This rearrangement mode has been found to be subject to a primary deuterium isotope effect[5]. The magnitude of this effect suggests that such deep-seated chemical changes are triggered by migration of hydrogen (or deuterium) from C-3 to C-1 in the rate-determining transition state. Clearly, additional work is required before all of the mechanistic ramifications of Ag^+ catalysis are thoroughly understood. On the basis of the foregoing, however, there is little doubt that such phenomena will comprise an exciting new area of physical organic chemistry.

Cyclopropanimines

By *Helmut Quast, Rolf Frank*, and *Edeltraud Schmitt*[*]

A high yield synthesis of the cyclopropanimine *(1)* *via* a 1,3-elimination of HBr from *(8)* (X = Br) and several ring-opening reactions of this novel heteroanalog of methylenecyclopropane was reported[1].

Attack on C-1 by nucleophiles (KOH, $LiAlD_4$) is followed by a regiospecific 1,3-bond cleavage: After two days' refluxing two moles of $LiAlD_4$ in ether gave 80—90% of *(4)*. The isomerization *(2)* → *(3)* has a precedent in the cyclopropylmethyl carbanion rearrangement and in the base catalyzed ring opening of cyclopropanones in the Favorskii reaction.

In contrast, reaction with strong acids under mild conditions yields products of 2,3-bond cleavage. One mole of D_2SO_4 in methylene chloride smoothly converted *(1)* into the zwitterion *(7)* in 87—95% yield. Hydrogen halides in CH_2Cl_2 afford (only after addition of HSO_3F in the case of HF) 66—85% yields of the α-halo imines *(8)* and *(9)*, the ratio of isomers [*(8)*:*(9)* = 94:6 (F), 94:6 (Cl), 91:9 (Br), 93:7 (I)] proving to be independent of the nucleophilicity of the anion. This reaction is best rationalized in terms of disrotatory ring opening of *(5)*. Apparently, cyclopropanimines behave as convenient, leaving-group-free precursors of 2-aminoallyl cations [*e.g. (6)*].

Cyclopropanones and the Favorskii Rearrangement. An Unexpectedly Large Secondary Isotope Effect

By *Christoffer Rappe* and *Leif Knutsson*[*]

Some years ago one of us found that treatment of 1,1,3-trihaloacetones with aqueous bases yielded *cis*-3-haloacrylic acids in 60—75% yield[1]. Further details of the reaction and its mechanism were revealed by experiments in a deuterating solvent (D_2O)[2]. We found that both the product and the starting bromo ketone were considerably deuterated. Furthermore, ^{1}H-NMR analyses of the product showed that the amount of deuterium incorporated in the α- and β-positions was unequal. The mean value from eight determinations of recrystallized acid gave α−H/β−H = 0.86. This can be rationalized in two ways:

1) an unsymmetric mechanism in the rearrangement;

2) an α-secondary isotope effect ($k_H/k_D = 1.6$—1.7) in the fission of the monodeuteriodibromocyclopropanone *(1)*.

We have now studied the rearrangement mechanism using ^{13}C-labeled starting compound. [3-^{13}C]-1,1,3-Tribromoacetone was prepared according to known methods

[*] Prof. Dr. C. Rappe and Dr. L. Knutsson
Institute of Chemistry, University of Umeå
S-901 87 Umeå (Sweden)

from sodium [2-^{13}C]-acetate[3]. If we neglect the small $^{12}C/^{13}C$-isotope effect and assume that the symmetric cyclopropanone mechanism is the only mechanism operating, we can predict an equal labeling in the 2- and 3-positions.

^{13}C-NMR spectroscopy provides a reliable method for the determination of the [2-^{13}C]-acid/[3-^{13}C]-acid ratio. The shifts were found to be 62.0 ppm (2-C) and 66.2 ppm (3-C) ($CS_2 = 0$). The ratio [2-^{13}C]/[3-^{13}C] was estimated to be 1.0 ± 0.1. Therefore only a symmetric cyclopropanone mechanism is operating in the rearrangement and the unexpected deuterium labeling can only be rationalized as due to an α-secondary isotope effect in the opening of the cyclopropanone ring. This value, $k_H/k_D = 1.6$—1.7, is an unusually large value for an α-secondary isotope effect with only one deuterium in the molecule[4-6]. One explanation for this could be the special conditions encountered in the cyclopropanone ring system.

We have also investigated the rearrangement using synthetically prepared 3,3-dideuterio-1,1,3-tribromoacetone. In this experiment we obtained the same value for the isotope effect.

Dye-Sensitized Photooxygenation of 6,6-Dimethylfulvene: a New 1,2-Dioxolane Rearrangement

By *W. Skorianetz*, *K. H. Schulte-Elte*, and *G. Ohloff*[*]

The dye-sensitized photooxygenation of 6,6-dimethylfulvene *(1)* in solution at 15—20°C affords mainly (total yield 70%) the products *(2)*, *(3)*, and *(4)*[1].

The proportions in which they are produced depends greatly on the polarity and/or basicity of the solvent. In methylene chloride the enol lactone *(2)* but in pyridine the ketol *(4)* is formed as the main product. The structures of compounds *(2)*, *(3)*, and *(4)* were proved by chemical and physical methods.

A peroxide could be detected (KI/glacial acetic acid) after a photooxygenation carried out at −30°C. Thus *(2)*, *(3)*, and *(4)* are probably obtained by rearrangement of the 6,6-dimethylfulvene *endo*-peroxide *(5)*, which can be considered also as a 1,2-dioxolane. The annexed reaction course is suggested to explain the formation of *(2)*, *(3)*, and *(4)*.

(1) *(5)* *(6)* *(7)* *(2)* *(4)* *(8)* *(3)*

In a basic medium isomerization of *(5)* yields mainly the ketol *(4)* (Kornblum-de la Mare reaction). In an apolar medium (*e.g.* in CH_2Cl_2) *(5)* rearranges, in analogy to other 1,2-dioxolanes[2], with ring opening to afford the allene peroxide *(6)*, which in turn isomerizes to the cyclopropane derivative *(7)*. In a subsequent, new, probably electrocyclic reaction, *(2)* is then produced. *(3)* can arise by cyclization from *(6)* or *(7)* without participation of the aldehyde group. The keto aldehyde *(8)* first formed can be isolated in crystalline form as the enol *(3)*.

Insights into Small Ring Carbocations Provided by MO Calculations

By *P. v. R. Schleyer*[*]

Very little is known experimentally about the detailed structure of carbocations. Molecular orbital calculations provide a means of obtaining such information[1-8] and inspire experimental tests of the conclusions reached[9-13]. A collaborative program of such calculations has been undertaken with Prof. *L. C. Allen*, Princeton[1-4], and especially with Prof. *J. A. Pople* and Dr. *Leo Radom*, Carnegie Mellon University[3,5-8].

Early experience revealed that semi-empirical (valence electron) treatments (CNDO, MINDO, NDDO) artificially favored small ring structures[2]; therefore, such methods were rejected for general use. *Pople*'s *ab initio* (all electron) procedure employs a complete geometry search with a minimal basis set (STO-3G); improved energies are obtained by use of a more extended basis set (4-31G). Results of this procedure, while not perfect, are in good agreement with the available experimental data. Some of the more important of the conclusions reached are the following:

1. Distortion of the methyl species, $(H_a)_2CH_b$, produces a different effect in the cation than in the anion and free radical[1,4]. Going from a 120° to a 90° H_aCH_a angle increases the inversion barrier in the methyl anion, and favors a non-planar structure for the methyl radical. However, such 90° distortion *raises* the out-of-plane $C\text{-}H_b$ bending force constant of the methyl cation.

2. "Classical", rather than proton bridged structures, are preferred for the ethyl and more strongly for the vinyl cations[2,3]. The latter are more stable in linear than bent arrangements[9]. However, the most stable structure for the ethyl cation is distorted, and has a slightly non-planar arrangement at the carbocation center[3]. Despite the strong tendency of carbonium ions toward planarity, this is possible only when symmetry permits.

3. Contrary to the usual literature assumptions, C—C hyperconjugation is appreciably more important than C—H hyperconjugation[5,6,8,10]. Hyperconjugation is

[*] Prof. Dr. P. v. R. Schleyer
Department of Chemistry
Princeton University, Princeton, New Jersey 08540 (USA)

enhanced when the C—C bonds are strained, as in the bisected conformations of the cyclopropylmethyl and cyclobutylmethyl cations. The perpendicular conformation of only the latter is stabilized also[11], and a relatively low rotational barrier results.

4. The isopropyl cation is the most stable $C_3H_7^+$ species[7, 8]. The *n*-propyl cation, corner protonated cyclopropane, and a strange, highly distorted structure with an 83° C—C—C bond angle, all have comparable energies, but only the last is a minimum on the energy surface[7, 8]. These results emphasize the arbitrary nature of "classical" and "nonclassical" designations of carbonium ions. Edge protonated cyclopropane is less stable than any of these structures, and face protonation is very unfavorable[12].

5. Bridged and non-bridged carbonium ions have quite different 1s orbital energies[8], confirming conclusions reached recently by *Olah* from ESCA spectroscopy[13]. This provides the most direct experimental way of distinguishing between these structural types[13].

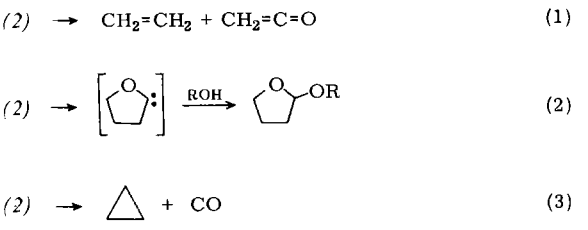
Photoreactions of Cyclobutanones in Solution



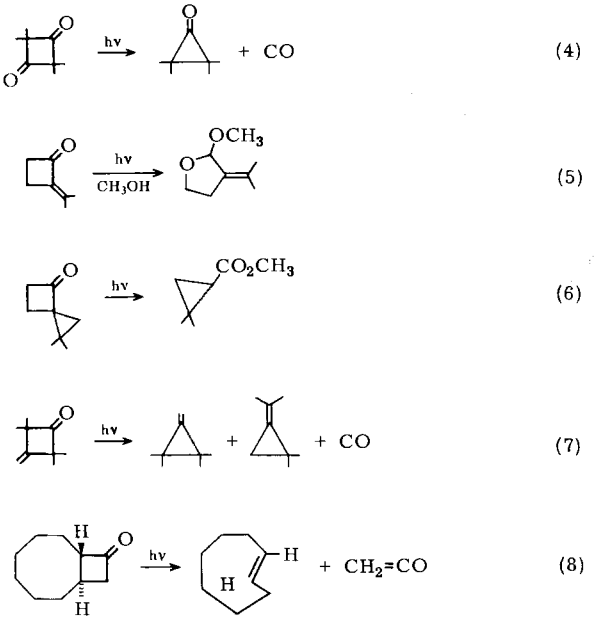
By *Nicholas J. Turro*[*]

The photochemistry of cyclobutanone and its derivatives possesses some unique opportunities for mechanistic and synthetic study. To date, essentially all of the photoreactions of cyclobutanones in solution are understandable on the basis of one primary photochemical process (homolytic cleavage of the bond α to the excited carbonyl) from the singlet state. Thus, for cyclobutanone the biradical *(2)* is produced and the products derived from it are listed

[*] Prof. Dr. N. J. Turro
Department of Chemistry
Columbia University
New York, New York 10027 (USA)

(1) *(2)*

(1)



(2)

(3)

in eq. (1), (2), and (3), namely cycloelimination [eq. (1)], ring expansion [eq. (2)], and decarbonylation [eq. (3)].

Structural-reactivity studies reveal that (a) in asymmetrically substituted cyclobutanones, the most highly substituted α-C—CO bond breaks preferentially; (b) ring expansion is favored by substitution of electron releasing groups on the α-carbon and by the occurrence of an sp^2 carbon on the α-carbon; (c) cycloelimination and decarbonylation, while general reactions, do not display a clear cut structural dependence; (d) each of the processes. cycloelimination, ring expansion, and decarbonylation are stereospecific and stereoselective.

Some examples of special synthetic interest are listed in eq. (4)—(8).

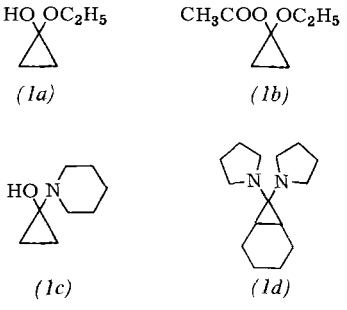
(4)

(5)

(6)

(7)

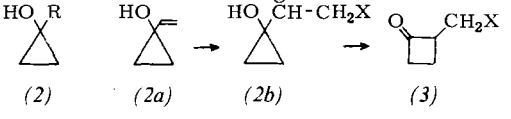
(8)



With respect to the mechanism of these reactions, it is important to note that some of the absorbed photons do not lead to observable reactions. This observation, when coupled with the high stereospecificity of these reactions, leads us to suggest that the biradical *(2)* is indeed formed, but that it closes to regenerate the starting material in competition with cycloelimination, ring expansion, and decarbonylation. All of these processes, however, must be assumed to be faster than bond rotations. The use of the technique of energy balance (*i.e.*, photons in *versus* product molecules out) may thus be employed to detect otherwise "chemically invisible" intermediates, such as *(2)*.

Recent Aspects of Cyclopropanone Chemistry

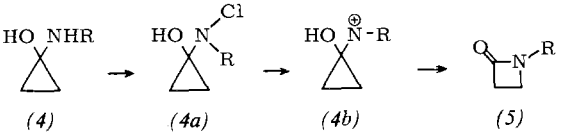
By *Harry H. Wasserman*[*]



Cyclopropanones, incorporating the carbonyl group in a small, strained ring, are reactive compounds of considerable potential use in synthesis. Thus far, exploration of their chemistry has been limited by the inaccessibility of these ketones since they tend to undergo decomposition or polymerization during attempts to obtain them in the pure state.

It is possible, however, to observe reactions of cyclopropanes by generating them *in situ* from pure, isolable, labile intermediates such as hemiacetals, hemiacetal acetates, 1-amino alcohols, or 1,1-diamino derivatives [examples of which are given *(1a)*—*(1d)*].

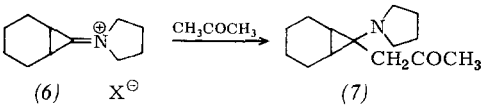
(1a) *(1b)* *(1c)* *(1d)*



Thus, reaction of *(1a)* or *(1b)* with two moles of $LiAlH_4$ yields cyclopropanol, while, with a wide variety of Grignard reagents, 1-substituted cyclopropanols *(2)* can be obtained.

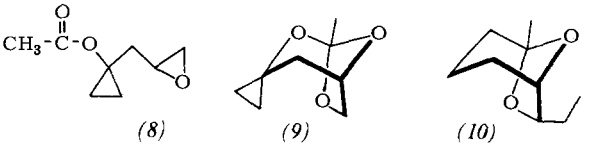
(2) *(2a)* *(2b)* *(3)*

1-Vinylcyclopropanol, prepared in this way, is a particularly useful cyclopropanol derivative since it may react with electrophilic reagents (X^+) including H^+, OH^+, Cl^+, or $CH_2^+—N(C_2H_5)_2$ to form cyclobutanones *(3)*.



By reaction with azide ion at pH 5.5, cyclopropanone precursors such as *(1a)* and *(1d)* yield β-lactams. This ring enlargement reaction has recently been made generally useful for the preparation of *N*-substituted β-lactams by the following modification: Secondary amines are added to the solution containing the cyclopropane (diazomethane and ketene in methylene chloride at −78 °C) to form an intermediate unstable 1-amino alcohol *(4)*, which is then converted into the *N*-chloro derivative *(4a)* by addition of *tert*-butyl hypochlorite. Treatment of *(4a)* with silver ion in acetonitrile yields the lactam *(5)* presumably through the nitrenium ion *(4b)*.

(4) *(4a)* *(4b)* *(5)*

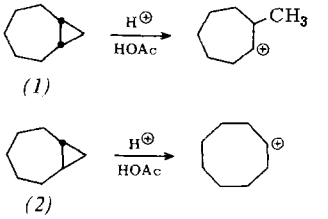


[*] Prof. Dr. H. H. Wasserman
Department of Chemistry
Yale University
New Haven, Connecticut 06520 (USA)

Other reactions of 1-aminocyclopropanes appear to take place *via* highly reactive cyclopropyliminium salts. Thus the fused-ring cyclopropyl derivative *(6)* reacts readily with acetone (or nitromethane) to form condensation products of type *(7)*.

(6) *(7)*

During studies on 1-allylcyclopropanol it was observed that the epoxy acetate *(8)* undergoes ready thermal conversion to the bicyclo[3.2.1]octane derivative *(9)*. This thermal isomerization has been shown to be a general method for the rearrangement of δ,ε-epoxy ketones to dioxabicyclo[3.2.1]octane systems and other hetero analogs, and has been employed in the synthesis of insect pheromones such as brevicomin *(10)*.



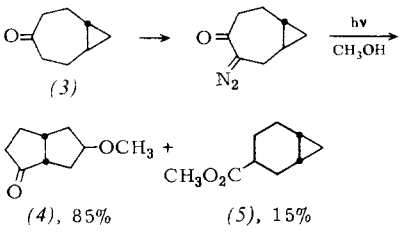
(8) *(9)* *(10)*

Bicyclic and Tricyclic Small Ring Compounds

By *Kenneth B. Wiberg*[*]

The past ten years have provided a number of remarkable examples of angular deformation of bonds to carbon. Two recently studied cases have been the *trans*-fused bicyclo[*n*.1.0]alkanes and the small ring propellanes. In both types of compounds the strain is especially localized at one carbon-carbon bond, and would be expected to lead to unusual reactivity.

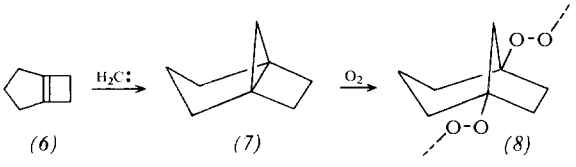
We may first compare *cis*- and *trans*-bicyclo[6.1.0]-nonane with *cis*- and *trans*-cyclooctene. The former have been found to have the same heats of formation[1], whereas the latter differ in energy by 9 kcal/mole[2]. Thus cyclopropane rings are considerably better in tolerating *trans*-fusion than are double bonds. *trans*-Bicyclo[5.1.0]octane *(2)* is considerably more reactive toward electrophiles than *cis*- or *trans*-bicyclo[6.1.0]nonane[3]. Of more significance, whereas *cis*-bicyclo[5.1.0]octane *(1)* undergoes acetolysis with cleavage of one of the external cyclopropane bonds, *(2)* reacts predominantly by cleavage of the central bond.



(1) *(2)*

An attempt was made to prepare a *trans*-bicyclo[4.1.0]-heptane *via* ring contraction of a ketone *(3)* related to *(2)*[4]. However, the products were partially rearranged to a

[*] Prof. Dr. K. B. Wiberg
Department of Chemistry, Yale University
New Haven, Connecticut 06520 (USA)



bicyclo[3.3.0]octane derivative *(4)*, and the resulting bicyclo[4.1.0]heptane *(5)* had a *cis*-ring junction. It is possible that the *trans* derivative is first formed, and rearranges to the *cis* compound *(5)* by a process similar to the interconversion of *cis*- and *trans*-[1,2-D_2]-cyclopropane[5]. Strain energy calculations suggest that the strain

(3) *(4)*, 85% *(5)*, 15%

in *trans*-bicyclo[4.1.0]heptane may be sufficient to permit the *trans-cis* isomerization to occur readily.

The smallest propellane prepared to date is tricyclo-[3.2.1.$0^{1,5}$]octane *(7)*[6]. It was prepared by the addition of a carbene to bicyclo[3.2.0]hept-1(5)-ene *(6)*. The structure of *(7)* is unique in that the bridgehead carbons have an "inverted" tetrahedral geometry[7]. Thus, a plane through the three methylene carbons attached to a bridgehead will intersect the central carbon-carbon bond. It is not surprising that this is one of the most reactive of known C—C single bonds. Thus, *(7)* reacts with oxygen spontaneously at room temperature to form a 1:1 copolymer *(8)*.

(6) *(7)* *(8)*

The hydrocarbon *(7)* also reacts with a variety of electrophiles at high rates even at low temperatures. It is, however, remarkably stable thermally ($t_{1/2}$ = 20 h at 200 °C). This results from a combination of orbital symmetry restrictions and the difficulty of forming double bonds to the bridgehead in a bicyclo[3.2.1]octane.

The propellane *(7)* may be prepared by the reduction of 1,4-dibromobicyclo[3.2.1]octane under dissolving metal conditions. However, attempts at preparing smaller propellanes *via* this procedure failed. It is hoped that the recently prepared bicyclo[2.2.0]hex-1(4)-ene[8] will serve as a satisfactory reactant for the preparation of some of these compounds.

Flash-Vacuum Thermolysis of *p*-Benzoquinones

H. J. Hageman and *U. E. Wiersum*[*]

It was recently found[1] that flash-vacuum thermolysis of phenyl-*p*-benzoquinone *(1)* occurs with loss of two CO molecules. Naphthalene *(2)* was obtained as the major product (54% of converted starting material). The formation of *(2)* was visualized, in analogy with mass spectral data[2], to take place *via* intramolecular trapping of either a butadiene diradical, a cyclobutadiene, or a tetrahedrane by the phenyl group.

(1) *(2)*

The present contribution deals with the flash-vacuum thermolysis of *p*-benzoquinone *(3)* itself[3]. Loss of two CO molecules from *(3)* implies formation of a C_4H_4 species. The structure of such a species is of interest because cyclobutadiene and tetrahedrane are possible candidates, although there is evidence that vinylacetylene is a more stable isomer[4, 5].

If CO molecules are expelled stepwise, cyclopentadienone must also be considered as a transient intermediate. It has been reported[6] that the flash-vacuum thermolysis of *o*-benzoquinone gives a fair yield of 4,7-methano-3a,4,7,-7a-tetrahydroindene-1,8-dione, indicating that in this type of thermolysis the transient cyclopentadienone dimerizes rather than losing a further CO molecule.

The thermolysis of *p*-benzoquinone was carried out by subliming it *in vacuo* (pressure up to 1 torr) through an unpacked quartz tube externally heated to 850 °C. Analysis of the liquid product mixture trapped on a low temperature surface (liq. N_2) showed it to consist of vinylacetylene (70%), benzene (15.6%), styrene (8.8%), phenylacetylene (1.8%), indene (2.0%), and a number of other minor products, of which toluene and naphthalene were identified. No cyclopentadienone dimer was found in any of our experiments with *p*-benzoquinone. This indicates that cyclopentadienone is not an intermediate in the thermolytic degradation of *p*-benzoquinone. The main product vinylacetylene was shown not to arise from dimerization of acetylene that could be formed by direct fragmentation of *p*-benzoquinone.

[8] *H. J. Hageman* and *U. E. Wiersum*, to be published.

(3) (4)

Excluding cyclopentadienone as an intermediate in the thermolysis of *(3)* we feel that the difference in thermolytic fragmentation of *o*- and *p*-benzoquinone can be explained by assuming that primarily a cyclopropanone-type intermediate is formed in the case of *p*-benzoquinone. Bicyclo-[2.1.0]pent-4-en-2-one *(4)* is likely to give a C_4H_4 species (butadiene diradical, cyclobutadiene or tetrahedrane) ultimately leading to vinylacetylene, since it is known[7] that cyclopropanones lose CO under relatively mild conditions. 1,2- and 1,4-Naphthoquinone show a similar difference in their thermal fragmentation patterns[8].

Macromolecular Colloquium

The Macromolecular Colloquium was held at Freiburg/Br. (Germany), March 2—4, 1972.

From the lectures:

Phase Transitions in Polymers

By *S. Blasenbrey, A. Baumgärtner* (lecturer), *W. Dollhopf*, and *W. Pechhold*[*]

Starting with a defect-free bundle of macromolecules (ideal crystal), the real crystal is obtained by the introduction of stable defects (kinks, torsion defects, jogs, and folds) that are compatible with the intramolecular and intermolecular potentials. The cooperative-statistical treatment of this bundle under certain conditions shows a first order phase transition, which is characterized by a sudden change in the defect concentrations. In the case of polyethylene, the transition data (T_m, ΔH_m, ΔV_m), the coefficient of expansion, and the compressibility of the melt, together with their pressure dependences, can be quantitatively explained. The calculated short-range order in the bundle model is in agreement with the X-ray and electron diffraction results for the polyethylene melt. Transition data for polyethylene terephthalate are reported and discussed in the light of the bundle model.

Errors in the Determination of Narrow and Broad Molecular Weight Distributions by Gel Permeation Chromatography and Their Possible Elimination

By *K. C. Berger*[*]

Accurately determined molecular weight distributions are extremely useful sources of information on the formation of a polymer, and are therefore an important aid in kinetic studies. To obtain reliable information, however, it is necessary to recognize and to eliminate possible errors in the method. This was the aim of the experiments described below.

The gel-chromatographic elution curve results from the superposition of flow dispersion and separation on the basis of polymolecularity. By collection of eluate fractions and reintroduction into the gel chromatograph, therefore, it is possible to distinguish two limiting cases. In one case, all fractions now have the same elution volume; the original elution curve was then entirely due to flow dispersion. In the other case, all fractions have the elution volume at which they were collected; in this case, the original elution curve was entirely due to separation on the basis of polymolecularity. The results obtained in practice lie between these limiting cases. The situation becomes particularly clear with trimodal distributions such as may occur in the anionic polymerization of styrene.

The case of pure flow dispersion is important. In the experimental procedure described above, it relates to the system solvent-polymer solution-solvent. On the other hand, the flow dispersion in the system polymer solution-polymer solution-polymer solution, which influences the middle part of the elution curve in the case of broad molecular weight distributions, can be conveniently measured with radioactively labeled polymers, as was shown in the experiments.

On the basis of these measurements, the mathematical concept for the determination of molecular weight distribution from gel-chromatographic elution curves is clearly outlined.

Formation, Structure, and Function of the Flagella of Bacteria

By *W. Bode*[*]

For their active motion most bacteria use thin, often very long, helical filaments. These flagella appear in electron micrographs as sinusoidal waves having a constant and characteristic "wavelength". In addition to mobile bacteria with "normal" flagella, immobile mutants with tightly-coiled or even perfectly straight flagella have also been observed. The helical main filament is built up by non-covalent bonds from identical subunits, the protein flagellin, which has a molecular weight of about 40000. Isolated, dissolved flagellin behaves hydrodynamically and in its X-ray small angle scattering as a very highly elongated particle.

Under suitable conditions, flagellin can aggregate *in vitro* in a cooperative self-assembly process to form filaments that cannot be distinguished from intact flagella in the electron microscope or by X-ray studies. Conflicting results have been found for the growth of the flagella *in vivo*.

Several flagella models have been developed, in which flagellin forms the morphological subunit. The flagellin molecules in these models are arranged in several longitudinal strands, which in turn form a more or less hollow cylinder. As is shown by simple symmetry considerations,

[*] Dr. W. Bode
Max-Planck-Institut
für Eiweiss- und Lederforschung
8 München 2, Schillerstrasse 46 (Germany)

the individual flagellin protomers cannot occupy equivalent positions in the flagellum, owing to the superhelical structure of the flagella of bacteria. According to *Klug*, two different slightly incompatible sets of bonds could be made between the protomers. As a result the tube of the flagellum, which would be linear if only one set of bonds were used, would be deformed to a strained helix. According to *Asakura*, the protomers could be present in a flagellum in two conformations having different lengths, forcing the flagellum into a helical shape whose pitch differs according to the ratio in which the conformations are present. This could also explain the transitions between helices with different pitches that are observed *in vivo* and *in vitro*.

With sufficiently high cooperativity between the protomers within the longitudinal series, a cyclic exchange of the bonding and conformation pattern could be induced from the basal membrane, with a consequent rotational or even springing motion.

Mixtures of Polymers Having Different Tacticities with a Melting Point Maximum

By *W. Borchard* (lecturer), *G. Rehage*, and *E.-P. Uerpmann*[*]

On the basis of earlier investigations in which the association of polymethyl methacrylate mixtures with various tacticities in solutions was interpreted as crystallization, it was possible to measure the isobaric melting diagram of isotactic and syndiotactic polymethyl methacrylate (PMMA), whose mixtures were obtained from solutions. The liquidus curve found from calorimetric and microscopic measurements shows a melting point maximum situated about 30°C above the melting point of the syndiotactic component. The position of the "solidus" curve is strongly dependent on the crystallization conditions.

The characteristics of the melting diagram for high-molecular weight components are discussed in comparison with that of a binary low-molecular weight system with solid solution formation.

The density of pseudoternary solutions of isotactic and syndiotactic PMMA in toluene, determined at a constant solvent concentration, shows a maximum that agrees with mixed crystal formation at temperatures below the liquidus surface.

Neighboring Group Effects in the Ammonolysis of Acetic Esters of Polynuclear Phenolic Compounds

By *V. Böhmer* (lecturer), *K. Wörsdörfer*, and *H. Kämmerer*[*]

In dinuclear phenolic compounds esterified with acetic acid and containing a nitrophenol unit, the ester linkage in this unit has a reactivity similar to that of a mononuclear nitrophenyl ester. The ester linkage is readily broken *e.g.* by ammonia. In 2,2'-dihydroxydiphenylmethane derivatives, however, ammonia also cleaves the ester linkage in that unit which contains no nitro group, though ester linkages in dinuclear compounds containing no nitro group are not attacked under the same conditions.

On the other hand, the second acetyl group suffers practically no attack in 2,4'- and 4,4'-dihydroxydiphenylmethane derivatives, and is removed only extremely slowly in 4,2'-dihydroxydiphenylmethane derivatives. The nitro group is always in the first nucleus, *i.e.* that denoted by unprimed numbers. These results can be explained if it is assumed that the rate-determining step in the ammonolysis of the second acetyl group in the part of the molecule having no nitro group is the removal of a proton from the intermediate compound *(1)* or *(2)*.

(1) *(2)*

R^1 or R^2 or both equal NO_2

This removal takes place intramolecularly under the action of the phenoxide group of the neighboring part of the molecule, which has already been ammonolyzed. A steric arrangement that favors this step is possible only in 2,2'-dihydroxydiphenylmethane derivatives. However, the influence of the first phenoxide group also extends to a third phenol unit, presumably *via* intramolecular hydrogen bonds, if this third unit is also linked by a methylene bridge *ortho* to the phenolic OH group.

The Influence of *N*-Acylation on the Three Dimensional Structure and the Properties of Insulin

By *D. Brandenburg* (lecturer), *H.-G. Gattner*, and *A. Wollmer*[*]

Homogeneous monosubstituted, disubstituted, and trisubstituted derivatives of bovine insulin have been obtained by attachment of aliphatic acyl groups to the amino groups, *e.g.* with *p*-nitrophenyl acetate in dimethyl sulfoxide/triethylamine or acetic anhydride and succinic anhydride in aqueous solution, followed by ion exchange chromatography.

Circular dichroism measurements at pH 8 show that the steric structure of insulin is only slightly modified by acetylation of phenylalanine^{B1} or lysine^{B29}, but undergoes a pronounced change on substitution of glycine^{A1}. In agreement with the CD data, the biological activity *in vitro* (fat cell test, *J. Gliemann*, Copenhagen) was found to be decreased to 30—50% for all derivatives in which the glycine amino group was acetylated; the immunological reactivity (*H. A. Ooms*, Brussels) is also reduced. Full insulin activity is found *in vivo* (hypoglycemia in rats, *W. Puls*, Wuppertal-Elberfeld) see also Ref.[11].

The Turbidimetric Titration of Polymers

By *H.-J. Cantow* (lecturer), *M. Kowalski*, and *S. Krozer*[*]

In conventional turbidimetric titration, the result always depends on the rate of addition of the precipitant, since the relatively slow nucleation process distorts the titration curve in relation to the equilibrium curve obtainable on stepwise addition. One of us achieved a much better separation according to molecular weight by a dissolution titration following the precipitation titration[1], since the dissolution of particles precipitated under suitable conditions proceeds much more rapidly than the phase formation in precipitation.

Advances in the dissolution titration of homopolymers (anionic polystyrenes) are reported first. The turbidity photometer[2] was supplemented for this purpose by a device for automatic correction for the dilution effect. With this arrangement, *e.g.* for a mixture of three preparations having average molecular weights of 0.982×10^5, 4.11×10^5, and 18.0×10^5, all three maxima were satisfactorily obtained. The change in the solubility of the components was detected by comparison with the dissolution curves of the individual preparations.

Initial attempts to determine the molecular weight distribution and the chemical distribution of copolymers by turbidimetric titration are also reported. This is not directly possible either in precipitation titration or in dissolution titration, since the scattering intensity per unit mass of precipitating polymer depends on the particle sizes and the refraction increment (which is generally also influenced by preferential solvation) of the gel droplets in the mixture. For chemically nonuniform copolymers whose structural units have different refractive indices, the analysis for molecular weight distribution and chemical distribution is unsuccessful, since the product of the refraction increment and the mass of the precipitating fraction determines the scattering effect.

We have tried to carry out this analysis of copolymers by making use of the fact that the precipitated gel droplets carry (usually negative) charges. They therefore migrate in a strong electric field and are deposited on the anode[3]. We modified the turbidity titration apparatus by fitting suitably shaped electrodes in the measuring cell.

The titration was carried out by successive addition of small portions of precipitant to this solution and application of a high-tension field after each addition of precipitant to deposit the precipitated gel droplets on the anode. The deposition process takes only a few minutes. The polymer is then removed from the cathode and its chemical composition is investigated spectrophotometrically. The first experiments (initially on mixtures of polystyrene and polymethyl methacrylates) showed that the method is feasible.

Another modification to the photometer will allow analysis for chemical heterogeneity without the need to remove the precipitate from the electrode after each titration stage. A photomultiplier is placed in the primary beam behind the cell, and is used to record the increase in transparency in a suitable spectral range as a result of the deposition of a component (absorbing) of the copolymer. Simultaneous evaluation of scattered light and consumptive absorption then allow deductions concerning the molecular and chemical heterogeneity.

Characterization of the Intermittently Polymerization-Active Species of Soluble Ziegler-Natta Catalysts

By *G. Fink* (lecturer), *D. Schnell, B. Brenner*, and *R. Rottler*[*]

The kinetics of the polymerization of ethylene with soluble Ziegler-Natta catalysts of the type $(C_5H_5)_2TiX_2/AlX_3$ (with X = Cl, C_2H_5, or higher alkyl) both in a flow tube and in a stirred reactor with toluene and cyclohexane as solvents are discussed. Investigations on the complicated behavior of the polymerization rate on transition from the homogeneous to the heterogeneous phase due to precipitating polymer are also discussed. The catalyst concentration in the polymer is correlated with the polymerization rate, taking into account the fact that the active species is an equilibrium product.

The findings in solution are compared with the results of the ethylene polymerization in the gas phase, a "soluble" Ziegler-Natta catalyst system being used without solvents in the latter case, corresponding to its aggregation state at room temperature. The results are used in an effort to explain the relations between the formation, concentration, and lifetime of the active inserting species and peculiarities of the partition function of the oligomers formed.

Possibilities and Limits of the Enzymatic Synthesis of Polynucleotides

By *G. Feix*[*]

Many enzymes that synthesize DNA or RNA have been isolated during the past few years from microorganisms and from cells of higher organisms. Some of these enzymes have been purified to such a degree that

[*] Doz. Dr. G. Feix
Institut für Biologie III
(Genetik und Molekularbiologie) der Universität
78 Freiburg, Schänzlestrasse 9—11 (Germany)

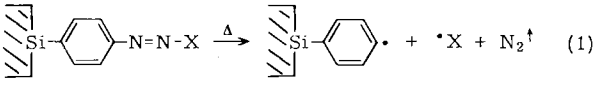
the cell-free synthesis of many polynucleotides that were not obtainable by chemical synthesis became possible with their aid.

The enzymes catalyze the linear linkage of nucleotides, the 3'-hydroxyl group of the ribose or deoxyribose of the growing polynucleotide chain being joined to the 5'-hydroxyl group of the entering nucleotide by a phosphoric acid diester bridge.

The nucleotides are incorporated into the nucleic acid either randomly according to the composition of the substrate nucleotides or in a specific sequence in a template-dependent reaction according to the Watson-Crick principle of base complementarity.

The high specificity of the enzymes on the one hand allows the synthesis of complicated nucleic acids, which are biologically active, but on the other hand constitutes a barrier to the synthesis of nucleic acids from substrates that are not accepted by the enzymes.

The synthesis of new nucleic acids has recently become possible by modification of the enzymes and by suitable adjustment of the incubation conditions of the enzymatic reaction. The preparative use of the enzymatic synthesis of polynucleotides will become increasingly important.



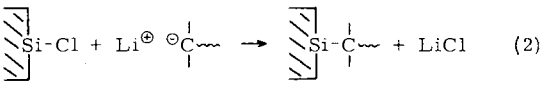
Graft Reactions on SiO_2 Surfaces

By *N. Fery*, *R. Hoene*, and *K. Hamann*[*]

1. *N. Fery* (lecturer): A stable linkage of organic macromolecules to the surface of amorphous SiO_2 is possible *via* the Si—C bond. By reaction with thionyl chloride, the siloxane and silanol groups on the surface of the particle were converted into Si—Cl groups after *Boehm*[1].

Polyfunctional initiators with inorganic skeletons are formed as follows. The Si—Cl groups on the surface are converted with phenyllithium into Si-phenyl groups; diazonium salt groupings are formed by nitration, reduction, and diazotization[2].

By coupling with H-active compounds, *e.g.* thiols, sulfinic acids, and amines, we have now obtained labile diazonium compounds covalently bonded to the SiO_2 surface that initiate the free-radical polymerization of vinyl monomers.



(1)

X = *e. g.* -S-Ar, $-SO_2$-Ar, -NH-Ar

Monomers used for the polymerization were: styrene, acrylamide, acrylic acid, methyl methacrylate, and vinylpyridine. The quantity of polymer grafted, based on silicon dioxide, is 10—60%.

2. *R. Hoene* (lecturer): Linear macromolecules with definite chain lengths can be grafted by reaction of the Si—Cl groups on the particle surface with polymeric carbanions.

The molecular weight of the grafted chains is varied by the ratio of styrene to initiator (butyllithium). An essentially

(2)

linear relation is found between the quantity of grafted polymer and the degree of polymerization of the chains.

Moreover, the number of Si—C bonds formed is smaller than in the reaction with phenyllithium, evidently because of steric effects of the polymer residue.

The properties of the SiO_2 particles are considerably changed by the grafting reaction. Amorphous SiO_2 (specific surface area 200 m^2/g) with about 50% of grafted linear polystyrene, for example, gives practically stable suspensions in aromatic solvents.

Rearrangement and Polymerization Mechanisms of DTE-Amino Acids and 2-Thioxo-5-oxazolidones

By *H. R. Kricheldorf*[*]

α-DTE-Amino acids[1] *(1)*, $n=1$, can be polymerized to polypeptides without racemization of optically active amino acids. *Kato*, *Higashimura*, *Suzuoki*, and *Okamura*[2], who were the first to study these reactions, considered the active monomer to be the α-isothiocyanatocarboxylic acid *(2)*, $n=1$, liberated on decomposition of *(1)*.

(1)

(2)

(3)

The present investigations show, however, that polycondensation is possible for β- and higher ω-isothiocyanatocarboxylic acids, but not for α-isothiocyanatocarboxylic acids. The active monomers in the polymerization of *(1)*, $n=1$, are in fact the 2-thioxo-5-oxazolidones *(3)* formed by cyclization of *(2)*, $n=1$. An ionic mechanism with ring cleavage is proposed for the polymerization of these cyclic monomers.

The Polymorphic Transformations II to I in Poly-1-butene

By *G. Goldbach*[*]

Of the four known crystalline forms of poly-1-butene, the tetragonal modification II and the hexagonal modification I are not only technically important but also of scientific interest. When the melt is cooled, the unstable modification II generally crystallizes out first, and then

[*] Dr. G. Goldbach
Chemische Werke Hüls AG
437 Marl (Germany)

changes more or less rapidly, depending on the experimental conditions, into the stable modification I.

The lecture dealt with the kinetics of the transformation of II into I as a function of the parameters temperature, previous thermal history, additives, and external stresses or elongations. Dilatometric, IR-spectroscopic, and mechanical-dynamic methods were used for the investigations.

The half-time of the transformation from II into I has a complicated temperature-dependence with a minimum. The temperature at which the minimum occurs depends on the chemical nature of the additives, the thermal history, and the magnitude of the applied deformation. The half-life is determined by the mobility of the molecules in the *amorphous* regions and by internal stresses. The participation of the amorphous regions in the transformation is shown by IR-spectroscopic, caloric, and mechanical-dynamic measurements.

The investigations on the influence of mechanical stresses, which were carried out over a wide temperature range extending from −196 °C to the melting point of modification II (approx. 115 °C), showed that the uniaxial deformation below the brittle fracture or yield stress proceeds mainly in the amorphous regions. Appreciable deformation of the crystallites occurs only when the yield stress is reached. There is thus a (lower) critical elongation below which (for a given short time) no transformation from II into I takes place. The critical elongation has a complicated but interpretable temperature dependence.

The Shear-induced Crystallization of Polypropylene

By *H. J. Leugering* (lecturer) and *G. Kirsch*[*]

A melt of isotactic polypropylene oriented by shearing crystallizes in band spherulites, which consist of the pseudohexagonal (β) or of the monoclinic (α) modification, depending on the crystallization temperature. Band spherulites in which both modifications occur are formed at medium temperatures. By crystallization with simultaneous shearing, contents of more than 30% of the β modification can be obtained, as has been shown by differential calorimetry. When such samples are heated, the β components exhibit characteristic melting and transformation phenomena, which are discussed in detail.

The Dynamic Structure of a Synthetic Deoxyribonucleic Acid

By *A. Lezius*[*]

The enzymatic copolymerization of deoxyadenosine triphosphate (dATP) and 4-thiothymidine triphosphate (s^4dTTP) by DNA polymerase from *Bacillus subtilis* yields a polydeoxynucleotide, poly[d(A-s^4T)·d(A-s^4T)] having a high molecular weight [$M_2^{s=0} = 1.2 \times 10^6$; $S_{20,w} = 10-14$ S] and a strictly alternating base sequence[1].

[*] Dr. A. Lezius
Max-Planck-Institut für experimentelle Medizin
34 Göttingen, Hermann-Rein-Strasse 3 (Germany)

The spectra of the optical rotatory dispersion (ORD) and of the circular dichroism (CD) show a strong negative Cotton effect around 400 nm, which can be assigned to an $n \rightarrow \pi^*$ transition of the thioamide chromophore. Since this band has a positive sign in monomeric 4-thiothymidine, it is concluded that the nucleoside is probably in the unusual *syn* conformation in the polymer. A protonated form of the double-stranded polymer, in which the N-1 atoms of the deoxyadenosine act as the proton acceptors, is formed at pH = 4.2 (cooperative transition point). These properties of the polymer are incompatible with a Watson-Crick structure; the alternative is an "reversed" Hoogsteen base pairing [O-2(s^4T)———N-6(A), N-3(s^4T)———N-7(A)].

From model studies, a left-handed double helix can be predicted for this base pairing[2]. A decisive symmetry property of the model has been confirmed by X-ray fiber diagrams[3].

The polymer exhibits cooperative temperature-dependent and salt-dependent helix-helix transitions, in which structure-induced hysteresis phenomena may occur[2]. These transitions are accompanied by changes in the hydrodynamic properties, such as the sedimentation coefficient, the buoyant density, and the partial specific volume.

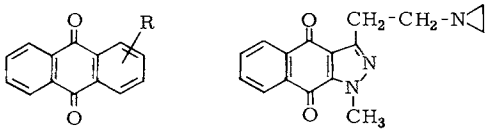
Some New Redox Polymers Containing Nitrogen

By *G. Manecke* (lecturer), *W. Hübner*, and *H.-J. Kretzschmar*[*]

In a continuation of our studies on redox polymers, substituted vinylindazole-4,7-quinones were prepared by 1,3-dipolar addition of vinyldiazomethane to 1,4-benzoquinones. The object was in particular to synthesize quinone systems with higher redox potentials. Systems of the types *(1)*—*(3)* with redox potentials of 340—460 mV were obtained.

(1) *(2)* *(3)*

R^1 = H, Cl, CH_3, OCH_3
R^2 = H, CH_3, $CH{=}CH_2$
R^3 = CH_3, $CH{=}CH_2$

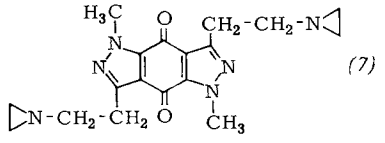


In the free-radical homopolymerization in solution, the vinylindazole-4,7-quinones and the indazolehydroquinone acetates obtained by reductive acetylation exhibited different polymerization properties.

5,6-Dichloro-3-vinylindazolehydroquinone triacetate with 5,6-dichloro-1,3-divinylindazolehydroquinone diacetate as the crosslinking agent gave a copolymer, from which hydrolysis and sulfalkylation gave a chemically and

[*] Prof. Dr. G. Manecke, Dr. W. Hübner, and Dr. H.-J. Kretzschmar
Institut für Organische Chemie der Freien Universität
1 Berlin 33, Thielallee 63—67 (Germany)

mechanically stable redox polymer that was swellable in aqueous media and had a redox capacity of 4.25 mequivalent/g; the redox potential and swellability of the polymer were measured.



Since vinylquinones often polymerize poorly, polymerizable aziridinylquinones with redox potentials of 100—230 mV, *e.g. (4)—(7)*, were prepared by addition of aziridine to the vinyl group.

(4), R = 1-CH_2-CH_2-N△

(5), R = 2-CH_2-CH_2-N△

(6)

(7)

Their cationic homopolymerization was investigated. The monomers *(4)—(6)* were also copolymerized with 1,4-bis[2-(1-aziridinyl)ethyl]benzene as the crosslinking agent in various molar ratios. The redox polymers obtained in this way swelled readily in aqueous acid because of their tertiary amino group. The redox capacities of the chemically stable copolymers were 3.6—5.3 mequivalent/g. The redox potentials and the pH dependence of the bulk density were also investigated.

Chemical Reactions on Polymethyl Methacrylate

By *F. Arranz, J. J. Bourguignon, J. C. Galin*, and *P. Rempp* (lecturer)[*]

When reactions are carried out on high polymers, it is advisable to characterize the resulting products chemically and physico-chemically as far as possible, to establish whether the desired reactions take place on the side groups, and to what extent the reacted side groups can influence those which have not yet reacted. Great importance was placed on these questions in the study of the nucleophilic substitution of polymethyl methacrylate (PMMA).

It was found that bases such as the following carbanions: the dimsyl anion CH_3—SO—$CH_2^{\ominus}$, the dimethylsulfonyl anion CH_3—SO_2—$CH_2^{\ominus}$, and the dimethylaminosulfonyl anion $(CH_3)_2N$—SO_2—$CH_2^{\ominus}$ react with the ester functions of PMMA with conversions of up to about 50%. Cyclizations may occur when the mixture is heated. It should be emphasized that in the case of random copolymers of 54% styrene and 46% methyl methacrylate, the conversion based on the ester functions can be as high as 100%. This shows that the reacted groups protect the neighboring ester functions against substitution.

[*] Dr. F. Arranz, Dipl.-Chem. J. J. Bourguignon, Dr. J. C. Galin, and Prof. Dr. P. Rempp
Centre de Recherches sur les Macromolécules C.N.R.S.
6, rue Boussingault, F-67 Strasbourg (France)

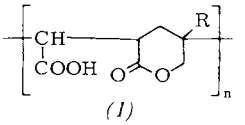
Another feature of the products of this substitution reaction is the great lability of the C—H bond on the C atom between the carbonyl and the sulfonyl or sulfinyl groups. These are true "carbon acids". This can also be seen from the stoichiometry of the substitution reaction: two equivalents of the carbanion are required to substitute one ester group.

High-Impact Plastics Formed by Two Phases. Adjustment of the Degree of Dispersion and of the Interfacial Adhesion by Block Copolymers

By *G. Riess* (lecturer), *J. Periard*, and *Y. Jolivet*[*]

It has been shown that the degree of dispersion in high-impact plastics based on a soft dispersed rubber (*e.g.* polyisoprene) in a hard phase (polystyrene) can be adjusted by block or graft copolymers. This oil-in-oil emulsifier action of a block copolymer A—B for the incompatible homopolymers A and B or for two immiscible solvents depends both on the concentration of copolymer and on its molecular weight, structure, and composition.

It was also found that the block copolymer causes interfacial adhesion in such two-phase systems. In a certain range of particle diameters, therefore, the impact strength is directly dependent on the concentration of the copolymer at the phase boundary.



Several methods have been developed for localizing the copolymer in such two-phase systems. These include interference and UV fluorescence microscopy, analysis after irradiation, and investigations with the electron microprobe.

Cyclocopolymerization with Intramolecular Formation of Lactone Rings

By *G. Sackmann* (lecturer) and *G. Kolb*[*]

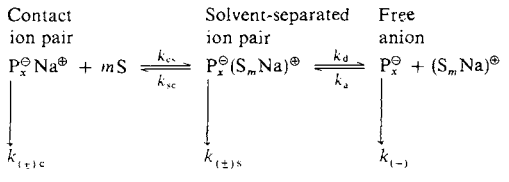
The radical-initiated copolymerization of maleic anhydride with allylic hydroxyl compounds such as allyl alcohol or methallyl alcohol between −10 and +70°C yields linear and soluble (1:1) copolymers. These consist to an extent of about 90% of lactone ring structures, and contain free carboxyl groups.

R = H, CH_3

(1)

The alternating copolymers *(1)* are probably formed under the influence of a free-radical initiator by homopolymerization of EDA complexes formed from maleic anhydride and the allyl compound. Intramolecular esterification then gives the lactone ring structure. By choice of suitable initiator systems, it is possible, *e.g.*

[*] Dr. G. Sackmann and Dr. G. Kolb
Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG
509 Leverkusen-Bayerwerk (Germany)



with methallyl alcohol, to obtain copolymers having molecular weights of more than 100000.

The partial replacement of the allyl or methallyl alcohol by a third copolymerizable compound leads to terpolymers that contain cyclic anhydride groups besides lactone rings.

The Analysis of Narrow Molecular Weight Distributions as an Aid to the Kinetic Investigation of Ionic Polymerization Processes

By *G. V. Schulz* (lecturer), *L. L. Böhm*, and *G. Löhr*[*]

Anionic polymerization processes can be controlled by the flow tube or stop-flow technique in such a way that all the polymer molecules formed have an equally long growth time available under identical conditions. The molecular weight distribution under these conditions should be a Poisson distribution *(Flory)*, whose nonuniformity $U = 1/\overline{P}_n$ (when $\overline{P}_n \gg 1$). Even under the most precise conditions, however, broader distributions are in fact frequently produced. This is because the polymerization has a multipath mechanism, since the reactive end *e.g.* of polystyrylsodium occurs in three forms, which exist in a dynamic equilibrium and add on monomer with very different rate constants $k_{(\pm)c}$, $k_{(\pm)s}$ and $k_{(-)}$, as shown in the following scheme:

Poisson distributions occur only if there is only *one* form of the "living" end present or if the transition is considerably faster than the addition, *i.e.* $k_{sc} \gg k_{(\pm)s}$ or $k_a \gg k_{(-)}$.

If the rates of the transition and of the addition are comparable, multipath mechanisms lead to broadening of the molecular weight distribution, and this broadening can be used to calculate the rate constants k_{sc} and k_{cs} as well as k_a and k_d with the equations given by *Figini*[1] and *Böhm*[2]. Dr. *Chmelíř*[3-5] reported to last year's Colloquium that in a series of solvents (including THP, THF, and DME), the three propagation rate constants and the equilibrium constants $K_{cs} = k_{cs}/k_{sc}$ and $K^*_{Diss} = k_d/k_a$ are known as functions of temperature. A series of experiments will now be reported in which the molecular weight distributions are determined so accurately that the rate constants of the transitions can be calculated.

The kinetic data allow the calculation of the conditions of temperature and ionic strength in which the addition proceeds by the one-path mechanism, *i.e. via* the contact ion pair, and so gives a Poisson distribution. Such polymers can be used for the development of methods for determining the nonuniformity of narrow distributions with the accuracy necessary for our purpose. We use the precipitation chromatography method, the fractions being checked by gel permeation chromatography. The width of the fractions, and hence the effectiveness of the fractionation, can be quantitatively estimated by overlapping experiments. These experiments show that the inhomogeneity of polymers in the range 0.5 to 2.0×10^{-2} can be determined with an error of less than $\pm 0.2 \times 10^{-2}$.

The temperature dependence of the rate constants determined by this method for the transition reactions for polystyrylsodium in THP and THF can be used to find their Arrhenius parameters. In DME, on the other hand, the inhomogeneity is very close to that of the Poisson distribution over the whole temperature range, so that it must be concluded that the transition rates in this solvent are greater than the addition rates.

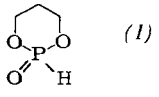
Chemical Reactions on Single Crystals of Copolymers

By *N. Wiemers* (lecturer), *H. J. Sterzel*, *E. W. Fischer*, and *G. Wegner*[*]

Polymer single crystals serve as important models for the solid state of crystalline high polymers. Because of the phenomenon of chain folding, these lamellar single crystals consist of an inner region of high crystallinity and amorphous surface regions in which the chain folds are localized. Chemical reactions proceed more rapidly in the amorphous, liquid-like surface layers than in the crystalline inner regions. This is the basis of experiments by which the structure of the amorphous surface layer can be elucidated.

A problem that can be solved by chemical methods is the structure of single crystals of copolymers. During the crystallization, a sort of phase separation may occur between the comonomer units. To be able to describe the thermodynamic properties of such crystals correctly, it is important to know whether the comonomer units accumulate in the amorphous surface layers or are incorporated into the crystalline regions.

Investigations of this type have been carried out on copolymers of 3,3-bis(chloromethyl)oxetane and propiolactone and on copolymers of L-(−)- and DL-lactide. By selective hydrolysis of ester linkages in the amorphous surface layers, it was possible to determine the number of comonomer units in these regions from a comparison of the analytical data before and after chemical treatment of the suspended single crystals. A correlation is possible between these data and results of X-ray small angle scattering, electron microscopy, and differential calorimetry.



In the copolymers investigated, enrichment of the comonomer units always occurs in the surface layers. There is practically no incorporation into the crystalline regions. The distribution of the uncrystallizable comonomer units can also be investigated under different crystallization and annealing conditions by the methods developed. The application of these methods to the determination of sequence lengths was discussed.

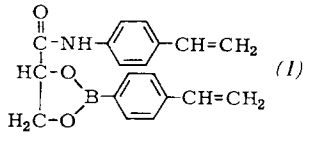
The Polycondensation of Diethyl Phosphite with Aliphatic Diols

By *W. Vogt* and *S. Balasubramanian*[*]

The condensation reaction of diethyl phosphite with aliphatic diols of the type HO—$(CH_2)_x$—OH ($x = 2$—6 and 8) was investigated. It was found that very different products were obtained according to the number x of methylene groups between the two OH groups. Polymers with degrees of condensation greater than 10 are formed only with $x \geqslant 6$. When $x < 6$, the molecular weights are kept low by an ether formation that proceeds simultaneously with the polytransesterification; the formation of an ether linkage is formally equivalent to the removal of a molecule of water, which ultimately appears in the form of acidic P-OH groups, which are incapable of condensation with the diols under the conditions used. This ether formation is particularly pronounced in the reactions with 1,5-pentanediol and 1,4-butanediol, in the course of which large quantities of the cyclic ether tetrahydropyran (approx. 30 mole %) or tetrahydrofuran (approx. 80 mole %) are formed. The use of 1,3-propanediol leads to an entirely different main product, *i.e.* 2-hydro-2-oxoperhydro-1,3,2-dioxaphosphorin *(1)* (approx. 80 mole %).

(1)



The formation of all these reaction products can be readily explained with the plausible assumption that those reactions that can proceed *via* five-membered or six-membered intermediates are always preferred.

The Use of Polymers with Enzyme-Analogous Structures for the Resolution of Racemates

By *G. Wulff* (lecturer) and *A. Sarhan*[*]

A new method has been investigated for the introduction of functional groups into polymers with a fixed, predetermined stereochemistry. The functional groups to be introduced were bonded, in the form of polymerizable vinyl compounds, to a suitable template molecule, and this was copolymerized *e.g.* with divinylbenzene under conditions such that macroporous, non-swellable polymers were formed. It was expected that after removal of the template, the functional groups would be present in a stereochemistry fixed by the template. With chiral templates, the arrangement of the functional groups in the surrounding polymer

(1)

[*] Prof. Dr. G. Wulff and Dr. A. Sarhan
Organisch-Chemisches Institut der Universität
53 Bonn, Meckenheimer Allee 168 (Germany)

cavity should also be asymmetric. A very sensitive method of testing for the stereochemically correct introduction of the functional groups in this case is testing for the ability of such polymers to resolve racemates, *e.g.* of the template used.

For example, the 2,3-*O*-*p*-vinylphenylboronic ester of D-glyceric acid *p*-vinylanilide *(1)* is copolymerized with divinylbenzene in the presence of acetonitrile. At most about 50% of the D-glyceric acid could be split off again. The polymer prepared in this way contained free boronic acid and amino groups, and had a capacity for the uptake of glyceric acid that corresponded to the quantity originally split off. On reaction with D,L-glyceric acid, binding of the D-form was significantly better, so that L-glyceric acid accumulated in the solution. A significant enrichment of the antipodes was also possible in the case of D,L-glyceraldehyde. As expected, the ability to resolve racemates was totally and irreversibly lost in solvents that swell the polymer.

Determination of Kinetic Constants of Homopolymerization by Measurement of Copolymerizations

By *P. Wittmer*[*]

In the determination of *r*-values, the measurements frequently also yield data that can be used for the calculation of the copolymerization rate.

It was shown how copolymerization rates can be calculated from dilatometrically measured volume contraction-time curves. The molar volume contraction consists of three increments for the two homopolymerization steps and the alternation step.

A new equation proposed by *Russo* and *Munari* was used to describe the copolymerization rate. The quantity $k_p/k_t^{1\backslash 2}$ for the homopolymerization of one of the two monomers can be determined from copolymerization rates.

The calculations were illustrated by examples from the copolymerization system ethyl acrylate/styrene.

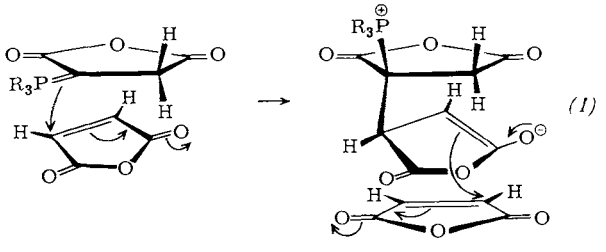
Structural Investigations on Polymethyl Methacrylate and Methyl Methacrylate Copolymers in Solution

By *W. Wunderlich* (lecturer) and *D. Panke*[*]

Light scattering and viscosity measurements were carried out on solutions of copolymers of methyl methacrylate with methyl, ethyl, and *n*-butyl acrylate and *n*-butyl methacrylate, as well as on the corresponding homopolymers. The unperturbed dimensions and the excluded volume (acetone, 20 °C) were calculated from the experimental results. Comparison of the results obtained by the two methods shows that the Flory constant Φ_0 for copolymers is greater than the calculated and experimentally confirmed value for binary polymer solutions. This is also true of solutions of polymethyl methacrylate in a mixed solvent.

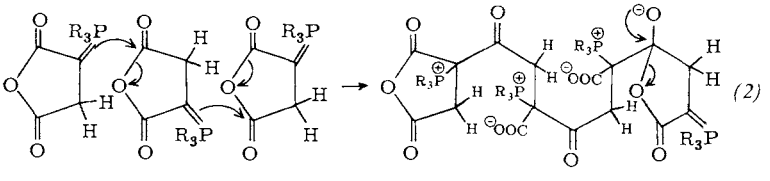
[*] Dr. W. Wunderlich and Dr. D. Panke
Röhm GmbH, Chemische Fabrik
61 Darmstadt, Postfach 4166 (Germany)

In the calculation of chain flexibility (persistence length) of ternary polymer systems, viscosity data evidently yield misleading values. Only the results of scattering experiments should be taken into account.



For the copolymers investigated, these show that the flexibility decreases on combination of an α-substituted monomer with an unsubstituted monomer. The contribution of hetero-contacts to the excluded volume can be determined quantitatively and correlated with the incompatibility of the corresponding homopolymers.

The Anionic Polymerization of Maleic Anhydride with Tertiary Phosphanes



By *H. Zweifel* (lecturer) and *Th. Völker*[*]

Braun et al.[1], *Schopov*[2], and *Zweifel, Völker*, and *Giovannini*[3] found that maleic anhydride polymerizes spontaneously in the presence of *e.g.* pyridine bases and trialkylamines. *Zweifel, Löliger*, and *Völker*[4] investigated this polymerization and formulated two reaction models to explain it on the basis of the experimental findings. Their investigations also included the initiation of the polymerization of maleic anhydride by triphenylphosphane or tributylphosphane, since these phosphanes may be compared with pyridine bases in their reactivity.

The polymerization proceeds *via* zwitterions in accordance with the reactions (1) and (2).

(1)

(2)

Phosphonium groups were detected in the fractions obtained on fractional precipitation, extraction, column chromatography, and gel permeation chromatography, and the structure of the polymers was investigated spectroscopically. Kinetic measurements were also carried out on the polymerization of maleic anhydride with triphenylphosphane in dimethyl sulfoxide.

Mineralogy and Chemistry

The 49th Annual Conference of the German Mineralogical Society (DMG) was held in Kiel, September 6—9, 1971. Eight plenary lectures and 77 short lectures were presented.

Crystal chemistry formed a focal point of the lectures. Problems were dealt with concerning the structure and formation of silicates. *F. Liebau* (Kiel) reported on further progress made in the *Systematic Compilation of Silicate Structures*. They are classified according to chain type and degree of condensation, since in this way their salient characteristics can be readily compared from a crystallochemical point of view.

G. Gottardi (Modena) gave a review of the *Crystal Chemistry of the Zeolites* and their synthetic representatives.

The Feldspars were comprehensively reviewed in a plenary lecture delivered by *F. Laves* (Zürich), this year's DMG prizewinner (A. G. Werner medal), and in a series of short lectures by *H. U. Baumbauer, H. Kroll, G. Voll, H. Pentinghaus, H.-E. Nager*, and *H. H. Steuhl* (all from Münster). The feldspars constitute an important group of silicates having a framework structure of three-dimensionally connected SiO_4 tetrahedra, in which 1/3 to 1/2 of the silicon positions are replaced by aluminum, the charge being balanced by univalent or divalent cations. Ga^{3+}, Fe^{3+}, and Ge^{4+} may also replace Si^{4+}. The more or less random distribution of Al and Si in the tetrahedral sites changes the structural parameters of the univalent and divalent cations, and thus alters the symmetry of the structure. The order/disorder of the feldspars reflects their temperature of formation and can thus be used as an indicator of thermal prehistory. Accurate and detailed investigations of feldspars can be of great value as model studies for other classes of compounds.

In his plenary lecture on the *Formation of New Phases in Lattice Defects*, *E. Hornbogen* (Bochum) showed how recent progress made in the theoretical understanding of internal stress in metals can give renewed impetus to the clarification of complex oxide structures. *G. Voll* (Münster) indicated the *Analogies between the Texture of Metals during Crystallization and the Texture of Rocks*.

Industrial mineralogy commanded a great deal more attention at the Kiel conference than at previous conferences. *J. Petzold* and *K. Schilling* (Mainz) gave an insight into the recent developments that have been made in, and the present state of industrial production of *Glass Ceramics*. *H. G. Kurczyk* and *W. Münchberg* (Hagen) reported on the most promising utilizability of *Synthetic Wollastonite in Ceramics*. *R. Beising* (Karlsruhe), and *R. Singh Dev, H. Kautz*, and *H. Kirsch* (Essen) discussed the problems associated with the combustion of sulfur-containing lignites, and of fuels containing inorganic components, in conventional power stations. Methods for the chemical binding and separation of SO_2 and SO_3 in flue gases were outlined.

R. Kranz (Jülich) dealt with the question of analysis in connection with *Methods of Measuring Radioactive Equili-*

bria. H. Köster (München) reported on the separation of cations on citrate-loaded Dowex 1 anion exchanger. *M. Pavicevic* and *A. el Goresy* (Heidelberg) described the use of the electron microprobe for the *Determination of the Valency of Fe and Ti* in the system Fe—Ti—O; *M. Gramse* (Göttingen) has used the same technique for the investigation of the chemistry of basaltic glasses. *A. Schneider* and *B. Schulz-Dobrick* (Göttingen) reported on the *Use of the ARL 72000 Simultan X-ray Quantometer in Automatic X-ray Fluorescence Analysis.* Scanning electron photomicrographs of the early stages of surface alteration of silicates in presence of supercritical aqueous solutions were shown by *K. F. Riedl* and *K. Jasmund* (Köln). *K. M. Sylla* (Köln) reported the synthesis of iron chrysotile in asbestos-like fibers.

A plenary lecture delivered by *W. Noll* (Leverkusen) was devoted to the future role of the *Mineralogist in Industry.* The various possible openings for the mineralogist in the chemical industry—particularly in the field of solid-state chemistry—were outlined, and it was pointed out that mineralogy is not just an academic discipline but also an integral part of the "industrial sciences" and should receive more recognition as such than hithertofore.

Friedemann Freund [VB 333 IE]
German version: Angew. Chem. *84*, 267 (1972)

REVIEW ABSTRACTS

The mode of action of amino acid antagonists of biological origin is surveyed in a review by *G. Nass, K. Poralla,* and *H. Zähner.* There is a small group of antibiotics whose growth-inhibiting activity can be counteracted by one or more amino acids and which thus act as amino acid antagonists. In some cases the biosynthetic precursors of amino acids or their conversion products also act as antagonists. (Antibiotics inactivated by direct interaction with an amino acid do not belong to the antagonists.) Enzymatic reactions in which antagonists interfere are described. Their modes of action include feedback inhibition, inhibition of cellular amino acid uptake, influence on the incorporation of amino acids into peptide chains and on the function of proteins, and inhibition of oligopeptide synthesis and purine synthesis. [Biogenetic Amino Acid Antagonists. Naturwissenschaften *58*, 603—610 (1971); 110 references]

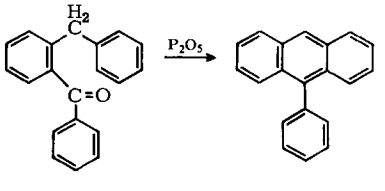
[Rd 472 IE –M]

Some recent trends in the chemotaxonomy of plants are reviewed by *R. Hegnauer.* It is often difficult to assess the significance of chemical characteristics because of our incomplete knowledge about the occurrence, biosynthesis, and function of most phytoconstituents. Three patterns of distribution can be distinguished, namely general occurrence, "asystematic" occurrence, and systematic occurrence, which enable assessment of the taxonomic possibilities and their limitations. By way of preference the natural products of vascular plants are dealt with in order to illustrate these patterns. The comparative chemistry of macromolecules and phytoserology also affords results which can have phytotaxonomical significance. [Pflanzenstoffe und Pflanzensystematik. Naturwissenschaften *58*, 585—595 (1971); 88 references]

[Rd 473 IE –M]

High molecular polyphenylenes, which are of interest with regard to the development of heat-resistant materials, are the subject of a review by *G. K. Noren* and *J. K. Stille.* They can be synthesized, *inter alia,* by oxidative cationic polymerization, dehydrogenation of poly-1,3-cyclohexadienes, metal-catalyzed coupling reactions, and Diels-Alder polymerization. The spectra, crystallinity, solubility and solution properties, semi-conducting properties, irradiation stability, thermal stability, and reactions of polyphenylenes are discussed. Because of their insolubility and since they are difficult to prepare, polyphenylenes have so far found only limited application. [Polyphenylenes. Macromol. Rev. *5*, 385—430 (1971); 129 references]

[Rd 474 IE –M]



Ion binding by synthetic macrocyclic compounds is discussed in a paper by *J. J. Christensen, J. O. Hill,* and *R. M. Izatt.* The existence of macrocycles with hydrophilic cavities containing multiply binding atoms and having exterior frameworks exhibiting hydrophobic behavior, opens up a number of possibilities with regard to the development and synthesis of molecules having specific cation and anion binding properties. The metal-ligand binding in cyclic polyethers appears to be predominantly ionic but the covalent character increases on substitution of sulfur or nitrogen for oxygen atoms. The hydrophobic exterior of the macrocycles can be modified by the addition of side-chains or functional groups to facilitate the solubilization of salts in organic solvents. The macrocyclic compounds serve as models for the investigation of the interaction of metal ions with biological systems. [Ion Binding by Synthetic Macrocyclic Compounds. Science *174*, 459—467 (1971); 50 references]

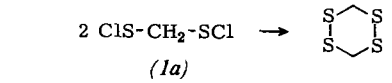
[Rd 475 IE –M]

Recent developments in the synthesis of organic compounds in liquid sulfur dioxide are described in a review by *N. Tokura.* The reactions proceed *via* carbenium ion intermediates. In most cases, SO_2 forms a charge-transfer complex in

$$R\text{-}X + CO + H_2O \longrightarrow R\text{-}COOH + HX$$

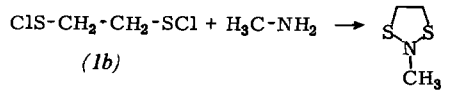
$$R\text{-}OH + H^{\oplus} \longrightarrow R\text{-}\overset{\oplus}{O}H_2 \xrightarrow{+H^{\oplus}} R^{\oplus} + H_3O^{\oplus}$$

which it acts either as an electron acceptor or an electrophile. Typical examples are those given in the accompanying scheme.



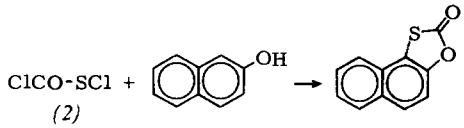
Other examples mentioned are Beckmann rearrangements and rearrangements of epoxides into ketones. [Recent Developments in Organic Synthesis in Liquid Sulfur Dioxide. Synthesis *1971*, 639—645; 56 references]

[Rd 471 IE –M]

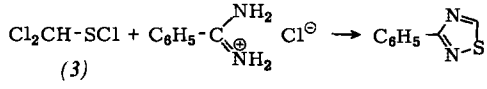


The stereochemistry of cobalt complexes with flexible tetradentate ligands is the subject of a review by *G. R. Brubaker, D. P. Schaefer, J. H. Worrell,* and *J. I. Legg.* The ligands treated are tetraamines and dithiadiamines with their donor atoms located in a straight chain, and ethylenediamine-*N,N'*-diacetate. The preparation of stereoisomers and the determination of their configurations, especially by the measurement of circular dichroism or optical rotatory dispersion, are described in detail. The importance of cobalt complexes of these ligands is due to their comparatively high kinetic stability against substitution reactions; it is conceivable, therefore, that knowledge gained from the study of cobalt complexes can be used for the determination of configurations of other transition metal complexes which cannot be isolated readily. [Complexes of Cobalt(III) with Flexible Tetradentate Ligands. Coord. Chem. Rev. *7*, 161—195 (1971); 102 references, 8 figures, 10 tables]

[Rd 477 IE –H]



Substitution and cyclization reactions of sulfenyl halides are treated comprehensively in a review by *E. Kühle.* The main substitution reactions dealt with are the sulfenylations of hydroxy compounds, sulfinic acids, thioles, amines, NH acidic compounds, organophosphorus compounds, Grignard reagents, active methylene- and methine compounds, aromatics, phenols, and *N,N*-dialkylanilines. Bis(sulfenyl chlorides) such as *(1)*, ω-chlorocarbonylsulfenyl chlorides



(1a)

(1b)

(2)

(3)

such as *(2)*, and substituted chloromethanesulfenyl chlorides such as *(3)* undergo cyclization reactions. Experimental details are given for individual reactions. [One Hundred Years of Sulfenic Acid Chemistry. Substitution and Cyclization Reactions of Sulfenyl Halides. Synthesis *1971*, 617 to 638; 325 references]

[Rd 470 IE –M]

BOOK REVIEWS

Titrationen in nichtwässrigen Medien (Titrations in Nonaqueous Media). By *I. Gyenes.* Ferdinand Enke Verlag, Stuttgart 1970. 701 pp., 206 figs., 108 tables, DM 84.—.

The book opens with an exposition of the various acid-base theories, together with discussions on the problems of acid and base strength and its dependence on the nature of the solvent. This gives a basis on which the processes occurring during titrations in nonaqueous media may be explained (120 pages). Some 70 pages are devoted to the solvents themselves, with particular reference to their properties, their behavior, and their purification; the titrants concerned, both acidic and basic, are dealt with in 35 pages or so.

End-point determination in titrations takes 140 pages. Descriptions are given of visual and photometric methods using color indicators, and also instrumental methods such as potentiometry, conductometry, oscillometry, voltametry, amperometry, and thermometry. In each case particular attention is paid to examples of application, without going into the fundamentals of the method.

The titrations themselves occupy 250 pages. Details are given of the determination of acidic substances, such as acids, acid anhydrides, acyl, alkyl, and aralkyl halides, enolic hydroxy and imide groups, phenolic and alcoholic hydroxy groups, nitro compounds, and acid salts. In the section on basic compounds, aliphatic, aromatic, and cycloaliphatic nitrogen-containing compounds and their salts are discussed. Methods are also given for the titration of carbonyl groups, sulfur-containing compounds, and organometallics.

This book has much of value to offer both to those concerned with theoretical aspects and those concerned with practical aspects. The latter will find very many specific analytical procedures and numerous useful tips. The book can be warmly recommended to anyone concerned with this subject area.

Günther Kraft [NB 17 IE]

Chemistry of Acetylenes. By *H. G. Viehe.* Marcel Dekker Inc., New York 1969, 1st edit., xv, 1298 pp., numerous tables and formulas, bound, $ 59.50.

This brilliantly successful book shows in clear and readily comprehensible form the rich and diverse nature of acety-

lene chemistry, and the extent to which acetylene derivatives occur in many fields of organic chemistry. Though intended primarily for research workers and chemistry students, it can also be used as a wide-ranging source of information to stimulate new ideas and as an easily understandable introduction to the individual topics of acetylene chemistry.

In the production of this book the author had the collaboration of 22 subject specialists from seven countries, and many other scientists. They have succeeded in creating a comprehensive survey of the chemistry of acetylene and its derivatives, thereby meeting a long-felt need of organic chemists. Topics not dealt with in detail in the text are completely covered by the approximately 4150 literature references, which contain practically all that is known and is worth knowing about the chemistry and reactions of acetylenes.

The book consists of 22 chapters, which deal with the following individual themes: theoretical considerations on the structure and physical properties of acetylenic compounds and the nature of the triple bond; preparation of acetylenes and polyacetylenes by dehydrohalogenation and other elimination reactions, and also by substitution reactions, starting with acetylenic compounds; ionic additions to acetylenes; radical additions; partial hydrogenation of acetylenes; rearrangement of alkynes to allenes; synthesis of cyclic and heterocyclic compounds by cycloaddition to acetylenes and cyclization reactions; coupling of acetylenes; preparation of halogenated acetylenes, alkynyl ethers and thioethers; ynamines; acetylene derivatives of elements of Groups III b, IV, and V of the periodic table; description of naturally occurring acetylenes; cyclic acetylenes; dehydrobenzene and dehydrohetarenes.

In order to achieve the desired degree of completeness, the book ought to contain a related section on the work carried out by *Reppe* with acetylene under pressure and a detailed description of *Reppe*'s discovery of the carbonylation of acetylenes. Some of these reactions are carried out today on an industrial scale, and have led to such valuable intermediates as acrylic acid and acrylic esters. The topics concerned are certainly covered by the literature references, but their description in the text would be an added boon for the reader.

Anyone concerned with the practical applications of acetylene chemistry should have this book close at hand. It is therefore to be hoped that this book, which by reason of its arrangement and its content is an irreplaceable reference work for the whole field of acetylene chemistry, will maintain its value in the future by revised editions, each of which will need to be brought up to the current state of the art.

Nikolaus von Kutepow [NB 18 IE]

Milk Proteins. Chemistry and Molecular Biology. Vol. 1. Edited by *H. A. McKenzie*. Academic Press, New York–London 1970, 1st edit., xvii, 519 pp., numerous figs., bound, $ 28.50.

Only about a quarter of this book, the first of a two-volume work, is devoted exclusively to milk proteins, and this consists of a brief historical and a longer chemical survey, which is also concerned with fractionation, nomenclature, biosynthesis, and biological functions, together with an extensive chapter on immunological studies. The main part of the book is concerned with the general chemical and physical methods of protein chemistry, and in particular with elemental analysis, the analysis of the functional groups of the amino acid, peptide, and carbohydrate residues, chromatography and electrophoresis (with particular regard to the interactions between the components of the mixture to be analyzed), spectrophotometry, and the other physical methods used to study changes in the degree of association, conformation, and structure.

The basic problem here is whether there is much point in describing general techniques in a book on specific substances. The answer in this case cannot be an unqualified no, since most of the techniques are illustrated with examples involving milk proteins, and in some (possibly too few) cases there are discussions on the method most applicable in the case in question. For the protein chemist, most of the chapters could have been shortened or replaced by references to appropriate monographs; however, the worker who is only occasionally concerned with proteins will welcome the explanations of the individual methods. For complete information it will be necessary to refer also to the second volume, which, according to the publisher's announcement, will deal with individual milk proteins and also the casein micelles and rennin. If the second volume matches the first in quality and attractive layout, this could be the best and most detailed work on milk proteins. The problems are discussed critically and precisely, and the literature has been surveyed up to 1970. The work is highly recommended.

H. G. Maier [NB 19 IE]

Lehrbuch der Pharmazeutischen Chemie (Textbook of Pharmaceutical Chemistry). By *H. Auterhoff*, with the collaboration of *J. Knabe*, Wissenschaftliche Verlagsgesellschaft mbH, Stuttgart 1971. 6th, revised and amplified edition, xii, 636 pp., 1 fold-out table, cloth-bound, DM 54.—.

This was the first German textbook of pharmaceutical chemistry that attempted to present the fundamentals of general inorganic and organic chemistry, in order to discuss more thoroughly the chemistry of compounds relevant to pharmaceutics, their analysis, and medical applications. The success of this approach is shown by the otherwise inexplicable fact that six editions of *Auterhoff*'s book have appeared within eight years. At present, the work has no rival. The present edition is arranged in the way that has proved so satisfactory in the past. The inorganic section, about 100 pages long, is arranged in accordance with the periodic table. The organization of the organic chemistry section presented considerable problems, and so a compromise has been arrived at; first of all the pharmaceuticals from the simple and more complex chemical classes are dealt with (*e.g.* hydrocarbons, alkyl halides, alcohols, phenols, carboxylic acids, amines, proteins, carbohydrates, steroids, alkaloids), followed by groups of pharmaceuticals arranged by their pharmacological or therapeutic properties (*e.g.* analgesics, psychotropics, coronary dilators, hypnotics, antihypertensives, cytostatics, chemotherapeutics, antibiotics, hormones, vitamins). This brief selection may show how wide a range of compounds is covered.

The sixth edition has not only been amplified to bring it as up to date as possible, but in addition some completely new chapters have been added, *e.g.* on the absorption, distribution, and biotransformation of pharmaceuticals and on enzymatic analysis. Particular care has been taken

with the redrawing of the structural formulas which are used to clarify the stereochemical relationships. In many cases references are also given to literature which will lead the reader deeper into the subject; the increase in this literature will have to be taken into consideration in further editions of this work.

Horst Böhme [NB 20 IE]

Einführung in die Optimierung (Introduction to Optimization). By *U. Hoffmann* and *H. Hofmann*. Verlag Chemie GmbH, Weinheim/Bergstr. 1971. 1st Edit., xvi, 260 pp., 114 figures, 61 tables, paper DM 48.—.

The present book deals with methods for the optimization of parameters. The well arranged subject matter leads through linear programming (*Dantzig*'s simplex method) and dynamic programming *(Bellmann)* to the "hill climbing" methods of optimization, to which considerable space is devoted. Starting with one-dimensional search methods, all the important search methods for several variables with and without secondary conditions are discussed. A chapter on minimizing sums of squares follows.

The book is an explicit textbook. It is up to date and comprehensible, and is intended mainly for those who have no special mathematical knowledge. The material is backed up by simple but appropriate examples from the field of application and by many figures and tables. The student is practically forced to cooperate. Questions are interspersed to enable him to check whether he has understood the material. The flow diagrams of the various methods are also very useful, since the thought processes are repeated here. The necessary mathematical principles are presented in an appendix. This avoids any interference with the intuitive presentation of the problems.

Problems from chemical engineering are discussed at the end of the book in the chapter on examples of applications.

The aim of the authors was to present an intuitive introduction to optimization for the practical user, and in this they have succeeded. The book will undoubtedly win many friends.

The Computer in Chemical Research—An Introduction

By Günther Wilke

With the appearance of this issue of Angewandte Chemie, an anniversary could be celebrated in the Mülheim Institute: twenty years ago the first commercially available IR spectrometer (Perkin Elmer) was put into operation. Presumably in a large number of other research laboratories in Europe, the same date marked the beginning of a new era during which a kind of revolution in chemical research began, initiating fundamental changes in the process of structural determination. Very soon UV and Raman spectroscopy, mass spectroscopy and gas chromatography, NMR and ESR spectroscopy, and finally X-ray structural analysis followed IR spectroscopy. Photoelectron spectroscopy can be cited as the newest development.

In the framework of preparative chemistry, the required tasks can be subdivided into the two fields of synthesis and analysis; clearly, the above physical methods have expedited primarily the secondary field—analysis (*viz.*, in particular, structural determination)—so that it can be approached today with a speed and accuracy that were not imaginable twenty years ago. At the same time it is also clear that in comparison the methods in the primary field of synthesis have developed comparatively little. The time requirements invested in the two areas have often been reversed by these developments, as is readily illustrated by an example of an olefin synthesis leading to a mixture of products. Formerly analytical fractional distillation required days, in some cases, weeks—out of all proportion to the time required for the synthesis—while today the gas chromatographic determination of the composition is obtained in a matter of minutes and much more accurately than was possible by distillation.

One could conclude from this reversal that the chemist is under pressure to produce ideas for new syntheses in faster succession than before. To a certain degree that is in fact the case; however, resources that were earlier dedicated to the second field are now at his disposal. One should not forget, however, that the physical methods not only provide the desired information previously obtained only by tedious chemical steps, but, in addition, yield an abundance of detailed information which must also be processed by the chemist. In any case an increased volume of information is produced which can only be evaluated through close cooperation of scientists from the two fields.

The next step of the development—the use of a relatively large computer in chemical research[*]—is described in the following six reports by different groups of the Mülheim Institute. Out of the structure of the Institute has evolved a system which is occasionally referred to as the "Mülheim System". Thus a few details about the Institute are appropriate. The Max-Planck-Institut für Kohlenforschung consists of two parts, the main institute (founded 1914) and the independent division for radiation chemistry (founded 1958). The principal areas of study concern general organometallic chemistry, electrochemistry, catalysis, photochemistry, as well as theoretical and radiation chemistry. Altogether about 120 scientists (including graduate students) are employed.

The X-ray structural analysis group, which had difficulties in obtaining adequate facilities in computer centers, initiated the discussions about acquiring a computer. A committee was formed including all parties concerned. After considerable discussion the committee established

[*] Prof. Dr. G. Wilke

[*] Determining synthetic routes with a computer will not be discussed here: *E. J. Corey* and *W. Todd Wipke* have already treated this topic in an interesting article (Science *166*, 178 (1969)).

all the demands to be made of the computer in "off-line" and "on-line" operation and finally contacted numerous computer manufacturers. It was soon apparent that one of the manufacturers was able to satisfy the special needs of "on-line" operation at a reasonable price. The decision for this system was made by the members of the committee and the purchase was financed by the Max-Planck-Gesellschaft and, supplementarily, out of the resources of the Institute.

Experience gained with the system since 1968 is described in the following reports from the standpoints of the different groups. The preparative chemist, even though he himself is least directly involved, usually benefits from the advantages of the system. Accordingly, the secondary field defined above was developed further. There are good prospects that the new system will benefit the primary field not only indirectly but directly if it is possible to link the computer with an analytical system (*i.e.*, a gas chromatograph) and reactor to control the reaction process. Such a mode of operation would extend the available laboratory techniques. In the Mülheim Institute the first attempts of this kind have already been successful.

For the theoretician, on the other hand, direct access to a computer installation is absolutely essential for fruitful work.

A few remarks on the following progress reports appear to be in order:

The reports are by no means written only for the specialist. The chemist not familiar with data processing should also take an interest in these problems; even without a detailed knowledge he will quickly appreciate what possibilities exist. A certain amount of repetition was unavoidable. Also, one must become accustomed to computer terminology; a few technical terms are explained in a glossary.

Finally, a word of warning: The methods of experimental analysis available today entice us to work on and to solve problems at great expense which, with regard to the real worth of the knowledge obtained, can in no way be justified. The analytical apparatus can soon become overburdened without really achieving anything new. A critical evaluation and selection of the problems to be treated with these tremendous resources is more important than ever before. In the enthusiasm over our present facilities, we should never forget the outstanding achievements of those who worked without these resources, *i.e.* before 1952.

Computer Systems for Chemical Research

By Engelbert Ziegler, Dieter Henneberg, and Gerhard Schomburg[*]

1. Introduction

As in almost all areas of our daily lives, digital computers have also invaded the field of chemical research. If one thinks of the first successes of *Corey* and *Wipke*[1], who used a computer system for the determination and optimization of synthesis paths in preparative chemistry, or of the development of documentation systems for chemical literature or for molecular spectra, one can imagine the new possibilities which will become available to the chemist in the future through the increased use of computers and how the chemist's way of working could be affected.

The purpose of this paper is not so much to give a picture of future developments in the field but rather to serve as a brief survey of the current uses of digital computers in chemical research and of the corresponding computer systems. The system developed at the Max-Planck-Institut für Kohlenforschung in Mülheim/Ruhr, Germany, is described.

2. Applications in Chemical Research

The customary applications of computers can be divided into two areas:

1. Computational tasks ("off-line" operation) and

2. connection of analytical measuring instruments to a computer system ("on-line" operation).

2.1. Off-line Applications

Calculation problems from theoretical chemistry, such as those arising in the various computational approaches to MO theory or in reaction kinetics, are usually solved in off-line operation. Also falling into this category are the various kinds of computations in the field of spectroscopy and for literature and spectra documentation.

Many of these computer programs place considerable demands on the efficiency and capacity of the computer. A core memory of 32 K 36-bit (or at least 32-bit) words is a typical requirement. Aside from this, extensive computing time requirements are characteristic for such off-line pro-

grams. Even on large computers, computing times of an hour or more are by no means a rarity. (For example, evaluation programs for X-ray structure analysis run particularly long.) A further characteristic of most of these programs (exception: documentation systems) is the relatively low number of input and output operations.

As long as the programs have been tested out and average turn-around times of several hours or even days are considered tolerable, then conventional batch operation, in which the programs are processed one after another, is suitable.

For small calculations of all types, however, like those which can occur in the daily laboratory routine, a faster access to the computer and fast reporting of the results are desirable. An input-output teleprinter terminal located in the laboratory and connected to a computer considerably facilitates the use of the computer for such tasks.

2.2. On-line Applications

A completely different type of use for a computer is the real-time acquisition of data from analytical instruments coupled to the computer. The data occur either in digital form or—more frequently—as analog values, normally a voltage. For computer processing these voltages must first be digitized with an analog-to-digital (A/D) converter. An interface between the A/D converter and the computer allows proper mutual communication.

One could consider it irrelevant whether a card reader, a magnetic tape, or an A/D converter is connected to the computer. Viewed from this angle the interface to an analytical instrument would merely be an additional peripheral unit in a normal computer system such as is used for the previously mentioned off-line computations.

However, whereas conventional peripheral devices like magnetic tapes or card readers transmit data to the computer according to the needs of the program, the data from an analytical instrument must be taken by the computer at the points in time which are determined by the on-line experiment (real-time data acquisition).

The typical demands on an on-line system cannot be specified without going deeper into the individual problems. The structure of an on-line system is essentially determined by:

Data rate (data points per second)

Data volume (number of data points)

Precision of measured values

Reduction of data in real-time

Extent of closed-loop operation

Number of analytical methods to be served simultaneously

Number of analytical devices of the same type to be served simultaneously

Storage and temporary storage of data

Complexity of data evaluation

Type and speed of parameter input and result output

Requisite flexibility of hardware and software

Frequency of changes in problem specifications

Degree of operational reliability required

Existing laboratory structure and the possible extent of reorganization necessary

Available financial means for purchase and maintenance

Available personnel.

Besides the computer, an A/D converter, a real-time clock as an external timer, as well as relay inputs and outputs for registration and control of start/stop events normally make up the hardware of an on-line system. In almost all cases a peripheral data storage medium (preferably disk or tape) is indispensable. Closed-loop systems often also need a D/A converter.

3. On-line Systems for Analysis

Spectroscopic and analytical instruments have been continually improved; they have usually also become correspondingly more complicated and more expensive. The direct connection of these instruments to a digital computer is a further step in this direction. However, for the analyst and the spectroscopist this step is in no way unproblematic. On the one hand they are offered tempting new possibilities; on the other hand they see themselves confronted with, for them, a new and multifariously complicated subject. Moreover, since the purchase costs for an on-line system are at least as high as for a large analytical instrument, one should consider the installation of such a computer system especially thoroughly. For that reason several arguments for the computerization of analytical instruments are enumerated here. Their weights depend on the specific requirements of a laboratory and must be discussed for the individual case:

Increase in the accuracy and precision of analysis

Speeding up of the evaluation

Increase in analysis through-put

Gain of more information

Performing new types of experiments

Control of an experiment

Processing of spectra for documentation purposes

Saving of personnel

Supervision of personnel.

The multiplicity of measuring instruments on the market, the tasks which vary considerably from laboratory to laboratory, the differing forms of organization of the analytical work, and finally the large number of computer types which come into question have brought about the development of many very different on-line systems. Most of the present systems can be placed in one of the following categories:

1. dedicated (single-purpose) systems

2. multi-method systems

3. mixed systems (both on-line and off-line processing), with satellite computers or without.

Table 1. Areas of application for the various types of on-line systems.

System	Typical computer requirements	Especially suited for	Typical environment
Dedicated systems 1. one instrument per computer	small computer, 4—8 K	instrument control, fast data acquisition, long running experiments	largely independent of laboratory type
2. variable-purpose dedicated system	small computer, 4—8 K	alternative connection to one of several instruments	research lab (university)
3. several instruments of the same type per computer	small to medium-sized computer 8—16 K	slow data acquisition, simple evaluation, limited instrument control	routine industrial lab (*e.g.* quality control)
Multi-method systems (small or medium-sized computer)	usually medium-sized computer, 8—16 K		routine lab with essentially unchanging demands
Mixed system (with conversational time-sharing operation)	large computer, 32 K; extensive periphery	real-time data acquisition, processing of large volumes of data, complicated evaluation procedures, limited instrument control functions	research and industrial labs with many analytical methods
Satellite systems (with dedicated satellites)	large computer, 48 K; several small computers; extensive periphery; possibly complicated data transmission	instrument control, many devices with high data rates, complicated evaluation procedures, off-line calculations	large institutions with a wide range of analytical methods, large computer centers with some real-time applications

The areas of application of these three categories of on-line systems are summarized in Table 1. Their essential characteristics will be briefly described below.

3.1. Dedicated Systems

To this group belong the computer systems that serve either one single instrument or several instruments of the same type (such as a group of gas chromatographs). It is essential that the computer work with a uniform programming system ("software").

3.1.1. Computer Systems for a Single Instrument

Measuring devices for fast-running physical events (for instance a Fourier-transform NMR spectrometer or a fast-scan mass spectrometer) produce very many digitized values in a short time (data rates in the kHz region) that have to

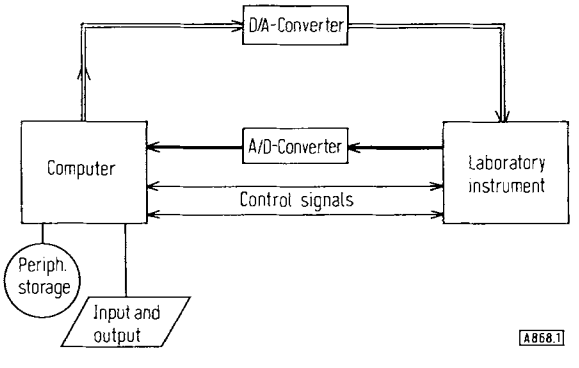

Fig. 1. Block diagram of a single-purpose ("dedicated") system in which a computer is used for the data acquisition and control of a single analytical instrument.

be accepted by the computer and further processed or stored away. In addition to the high data rates, complicated evaluation programs are frequently necessary. Therefore, a small dedicated computer may be necessary for devices with such demands.

Single-instrument computer systems (Fig. 1) can be adapted to the requirements of the respective instruments and are particularly suited for experiments that require many feedback control operations from the computer, for example the computer-controlled single-crystal diffractometer. With this latter application a measurement usually extends over several days; therefore, a particularly high system reliability, usually not achieved by complicated computer systems, is required.

From an economical standpoint such on-line systems are still very unfavorable; normally the computer together with peripherals and interface is more expensive than the measuring instrument itself. However, the development of "integrated" measuring instruments is foreseeable. Here the computer hardware is distributed as an integral constituent over the components of the instrument. This, of course, entails a completely new construction of conventional analytical instruments. As a consequence of continuing further development and reduction in cost of components such instruments with a "built-in" computer need not necessarily be more expensive than the currently existing instrument without computer.

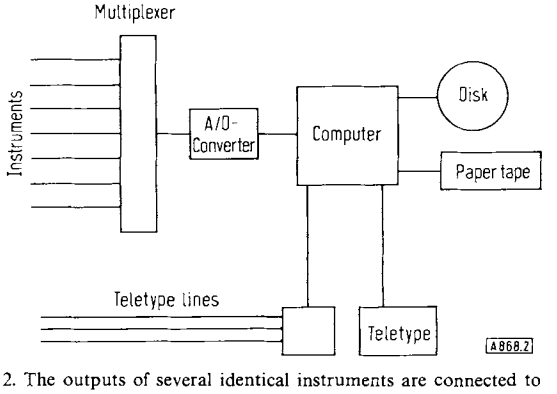

Fig. 2. The outputs of several identical instruments are connected to the computer through a multiplexer.

3.1.2. Multiple Instruments of the Same Type on one System

For economic reasons one would today still try to serve as many instruments as possible simultaneously with one computer (Fig. 2). If it is a question of devices all of one type, like a number of gas chromatographs, then it is relatively simple for all of the instruments to work with the same programming system; this means that only one copy of the data acquisition routines and evaluation programs need be in the computer.

3.2. Multi-method Systems

If different types of instruments (for instance gas chromatographs and IR, NMR, or mass spectrometers) are connected to the same computer systems for simultaneous service, then different evaluation programs and often also different data acquisition programs are required, depending on the application. In such a system a monitor program is necessary; it is reponsible for distributing the central processor time among the programs.

In order to be able also to gather the data from active instruments during data processing, the computer must operate with an "interrupt system" with several priority levels. With this system an external real-time clock can interrupt the currently running program by an electronic impulse. On such an interrupt, the monitor program decides which instrument takes its turn for the acquisition of data next, switches the multiplexer to the corresponding channel, and starts the A/D conversion. Until the completion of this activity (signaled by another interrupt), the computer can return to the previously interrupted program or switch to another one.

The programming effort for such a multi-method system is quite considerable. The parallel measurements must be tuned to each other in relation to memory requirements, external storage demands, data rates, and computing times.

Program maintenance (removal of programming errors, technical programming improvements, installation of new evaluation algorithms) can become quite a serious problem in such a system. During alteration of a program only relatively large "nice" computers prevent any influence (for instance through faulty programming) on parallel running programs. Therefore all program changes must be tested out on the total system, which is frequently quite troublesome. However, the more instruments of different types are connected to the computer system simultaneously, the more frequent such changes will be, which then disturbs the total operation considerably.

For this reason, multi-method systems are not suited for use with small or medium-sized computers, in particular for research laboratories with frequently changing problems. However, such systems could be useful for some industrial laboratories working with a set of tested programs for an extended period.

The advantage of a multi-method system over several dedicated systems lies in a saving of hardware. Only one central processor is required and duplication of some peripheral units (which therefore can be of better quality) is avoided.

3.3. Mixed Systems (Simultaneous On-line and Off-line Processing)

If a computer system serves not only several directly connected analytical instruments, but also concurrently runs one or more off-line programs ("background processing"), then it may be called a "mixed system".

If such a system is to work effectively, then an efficient central computer is required, the hardware of which guarantees that individual programs are completely protected from one another. Since many off-line programs are not completely tested and are therefore potentially faulty, such program protection is indispensable.

A mixed system offers the advantage that the many peripherals usually associated with a large computer, like line printers, card readers, disks and magnetic tapes, offer on-line users possibilities which do not exist with small computer systems.

Besides the large central computer some mixed systems employ several subordinate small computers ("satellites") for the acquisition of data from the connected analytical instruments and for pre-processing of these data. Through the satellite computers the central computer can be relieved of the pure "bookkeeping" tasks and need only occupy itself with the extensive calculations of the data evaluation work.

A variant of the satellite system is the "multi-mini" system in which a small computer (if possible of the same type as the satellites) is used as the central computer, or in which there is no central computer. In the latter case the small dedicated computers are connected with each other in a network fashion. The lack of an efficient central computer means, however, that heavily computational programs cannot be accommodated. In addition, the operating system of the small central computer, which must organize the data communication to the satellites, clearly cannot be so flexible and efficient as is possible with a large computer.

Section 4 presents a general discussion of the advantages and disadvantages of a mixed system taking the Mülheim Computer System as a typical example.

3.4. Failsafe Systems

The computerization of analytical instruments makes analytical laboratories largely dependent on the computer; therefore the greater the number of instruments connected to the system, the more serious a system breakdown can be.

The most certain measure against such "disasters" would be an identical second system that processes the same data in parallel with the first system. However, such an expenditure is normally justified only for some process-control computer installations supervising manufacturing processes. Obviously in this case one would try to keep the duplicate system as small as possible.

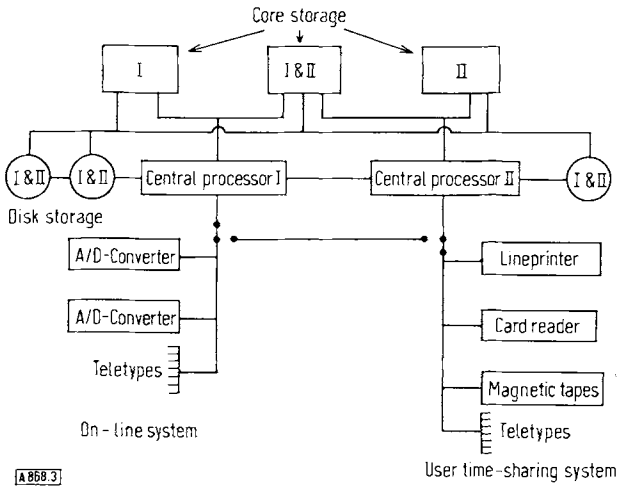

Fig. 3. The Du Pont company's failsafe system. On failure of the central processor responsible for the real-time processing, the other processor automatically takes over the duties of the first one.

For the computerized experiments in the field of chemical research no such high operational reliability is required; partial security against the worst failures is sufficient.

Interesting in this respect is a failsafe-system being built at the Du Pont company's Experimental Station in Wilmington, Delaware, USA[*]. This system consists of two coupled (PDP-10) central processors, one of which normally serves exclusively for the real-time acquisition of data from the analytical instruments, while the other is used for the evaluation of the real-time data and the execution of off-line programs (Fig. 3). Part of the memory and some of the peripheral units are commonly accessible to both central processors. Should the central processor responsible for the real-time data acquisition fail, then the other one takes over this task automatically.

4. The Mülheim Computer System

4.1. Computer Applications at the Max-Planck-Institut in Mülheim/Ruhr

At the Max-Planck-Institut für Kohlenforschung, including the radiation chemistry division, in Mülheim/Ruhr, almost all possible applications for computers in chemical research are represented. Among the off-line tasks programs exist for:

X-ray structure analysis

MO theory

Reaction kinetics

Simulation and iteration of spectra

Evaluation of spectra

Spectra documentation

Literature documentation

Support of the Institute's administration.

[*] Dr. *E. A. Abrahamson*, Dr. *J. Fok*, and Dr. *J. Read*, Wilmington, Delaware, private communication.

In addition to these there are smaller labor-saving programs of all types.

The extensive spectroscopic, analytic, and physical chemistry laboratories of the Institute have at their disposal a large number of analytical instruments, some of which should be connected directly to a computer (for the current state see Section 4.6):

1. "Slow" instruments (data rate *ca.* 20 Hz)

20—30 gas chromatographs

1 mass spectrometer

2—3 NMR instruments

1 IR spectrometer

1 ESR instrument

1 spectral polarimeter

2. "Fast" instruments (data rate 1 to 20 kHz)

2 low-resolution fast-scan mass spectrometers

1 pulse NMR instrument

While the purchase of one or more computer systems for all of these areas of application was under discussion in 1967, two alternatives were open to the Institute:

1. The purchase of a medium to large computer that would be used in batch mode for all off-line computing problems, supplemented by a number of small computers for several dedicated on-line systems for the analytical instruments.

2. The purchase of a single, more capable computer possessing both the hardware and software for a multiprogramming time-sharing system and simultaneous off-line and on-line operation.

4.2. Hardware Configuration of the PDP 10

For financial and organizational reasons the second alternative was chosen.

In December 1968, the first part of a PDP10 installation[*] was put into operation; in April and September 1969, the additional hardware required for the on-line applications was installed; in July 1970, the system was expanded by the addition of 32 K of core memory and a disk pack unit. The present system configuration is represented in Figure 4.

The hardware of the PDP10 central processor includes 366 machine instructions (including floating-point and byte instructions), an interrupt system with seven priority levels, as well as memory protection registers. The present memory capacity is 64 K 36-bit words. Two channels for fast data transmission connect the memory with a fixed-head disk (average access time 17 ms, transmission rate 77 K words/s, capacity 500 K words) and a disk pack (average access time 60 ms, transmission rate 62 K words/s, capacity 5000 K words).

A part of the fixed-head disk is used for temporary copies of the core image of running programs ("swapping" operation) if the memory is not sufficient to hold all parallel

[*] Producer: Digital Equipment Corporation, Maynard, Mass. (USA).

running programs. However, the major portion of disk space serves for storage of programs and data.

Additional peripheral units include a line printer, a card reader, magnetic tape units, a plotter, paper tape reader and punch, as well as 22 input/output teleprinters which serve as user terminals for time-sharing operation.

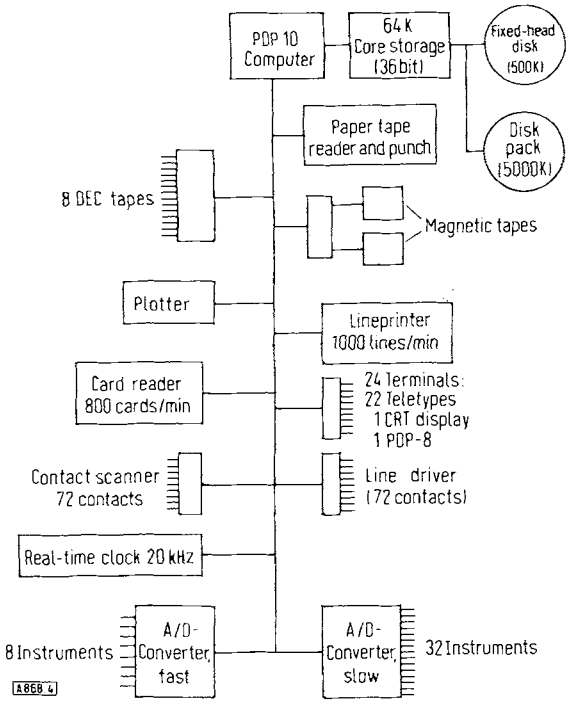

Fig. 4. Hardware configuration of the PDP10 installation at the Max-Planck-Institut für Kohlenforschung in Mülheim/Ruhr, Germany.

Several special units serve as interfaces between the computer system and the directly connected analytical instruments: Up to 32 "slow" instruments can be connected to a high quality A/D converter by means of a multiplexer unit. This A/D converter works with a 13-bit resolution in 11 amplification ranges, and therefore has a dynamic range of nearly 10^7. The total data rate amounts to 3.3 kHz with automatic range selection.

For the "fast" instruments another A/D converter is used that can work with data rates between 1.25 and 20 kHz. The resolution is 10 bits; the dynamic range 2.5×10^5, and is subdivided into three ranges of amplification. Up to eight instruments can be connected to this A/D converter by means of a multiplexer. However, in order not to disturb the normal time-sharing operation and the simultaneous data acquisition from the "slow" instruments only one of the eight possible "fast" instruments is allowed to be active at any one time. Due to the short recording times of about 2—3 seconds for such instruments, this restriction is no serious hindrance.

The clocking of the data for each of the two A/D converters is done by a real-time clock (quartz oscillator, 20 kHz) and two digital counters.

72 contact inputs allow the recognition of the closing and opening of external circuits; 72 relay drivers permit external relays to be opened and closed by the computer. With this equipment the computer recognizes start and stop commands for the real-time data acquisition and can control external events. Non time-linear registering instruments like IR spectrometers notify the operating system of the time for every A/D conversion by closing an external contact.

4.3. Time-sharing Operation

In the current version of the operating system up to 23 jobs can be handled simultaneously. The jobs are initialized by the users at any time from the teletype stations distributed throughout the Institute. The jobs each control the running of one program that the user has started by typing a command at the teletype. Data can be entered and the results printed out *via* the teletype. (Any other peripheral units can naturally also be used for data input/output.)

A868.5

Fig. 5. "Snapshot" of the state of the simultaneously processed jobs in the Mülheim System: SELDAT (Job 1) is the data acquisition program for the "slow" on-line instruments, MSDAT (Job 2) the data acquisition and pre-reduction program for the mass spectrometer; ORGANI (Job 3) is a control program that initializes several programs; REFREP (Job 8) produces outputs of gas chromatograms; PARAM (Job 12) is used to input parameters for on-line runs of "slow" instruments; NMRCAT (Job 18) is a time-averaging program for NMR spectra.

The commands typed in on the teletype are interpreted by the operating system. The operating system also determines the distribution of central processor computing time, the allocation of memory, and the assignment of peripheral units to the individual jobs. Whenever a job begins an input or output operation *via* one of the seven priority levels of the interrupt system, or after the apportioned amount of computing time ("time slice"—from 0.5 to 2 seconds) has run out, the operating system searches for another job to occupy the central computing unit. Figure 5 shows a representative "snapshot" of computer operation.

The time-sharing mode of operation allows a regular dialog between a program and a user. Figure 6 is an example of such a dialog; here the input of parameters for a plotting program is presented. Explanations and warnings for the inexperienced user have been provided in the program.

The scientist who has immediate access to the computer and the banks of data stored there by way of a teletype located at his place of work can use the computer as a constantly available thinking aid just as on a less sophisticated level he uses a slide rule or mathematical tables.

Fig. 6. Example of a programmed dialog: By typing the command "R DATPLT" the user starts a program for plotter representation of a spectrum which was measured on-line; he specifies necessary parameters in a dialog with the program. (For clarity, all user responses appear underlined.)

4.4. Organization of Real-time Data Acquisition

The dynamic time-sharing operation enables on-line and off-line jobs to be run simultaneously. For the real-time data acquisition a common data-job is needed for all "slow" instruments and one data-job for each active "fast" instrument. These are programs which essentially contain data buffers for the individual instruments. The individual data are read in by the computer on one of the interrupt levels, so that the running programs are only interrupted for several microseconds. As long as instruments are actively transmitting data, the corresponding data-jobs must remain in the core, *i.e.*, they may not be moved out to the disk during monitor swapping operations. This feature and a preferential allocation of computing time distinguish the data-jobs from the other user programs.

For the "slow" instruments the data are transmitted buffer-wise to the disk without any pre-processing; separate data sets are used for each device. For the "fast" mass spectrometers a pre-reduction of the data is carried out by the data-jobs; only reduced data reach the disk.

After the stop command the data belonging to each instrument are further processed by analysis programs (which run as separate jobs). If several instruments (for example a group of gas chromatographs) use the same analysis program, then this program can be initialized to check the status of all instruments in question at regular time intervals; on completion of a data acquisition experiment the evaluation is carried out automatically. (For a detailed description of the software organization see [2, 3].)

4.5. Flexibility of the System

The time-sharing system allows a very flexible, stepwise evaluation of the measured data. An evaluation program can be organized in dialog form so that the user can receive intermediate results over the teletype and can be questioned as to further steps in the evaluation. The individual steps of the evaluation can also be carried out with several sequentially callable programs. According to the intermediate results the user can decide freely which programs to use for further processing. For example, for a molecular spectrum, procedures for smoothing and for improving the resolution, peak searching algorithms, and so on, could be used in any sequence depending on the results of the experiment. The freedom of the user is not affected in any way by other users who are working with the computer at the same time—apart from the competition for common peripheral units such as line printers and plotters.

This high degree of flexibility is not only advantageous but necessary for analytical laboratories in a research institute with frequently changing analytical problems[4, 5]. However, a standard program can still be used for certain routine analyses with fixed evaluation procedures. This program needs no parameter input and supplies the final result in the form of a report on the teletype.

The time-sharing mode of operation proves especially advantageous in the development and check-out of new programs. As an example, new evaluation programs can be tested out without the danger of disturbing other users. With text editors it is possible to modify programs over the teletype and to immediately try out the corrected programs —without the long turn-around times associated with batch

systems. This direct contact between the programmer and the computer has considerably accelerated the development of programs for on-line application.

4.6. Current State and Reliability of the Mülheim System

So far, 23 gas chromatographs, an NMR spectrometer, an IR spectrometer, a spectral polarimeter ("Cary 60"), an ESR instrument, and a slow mass spectrometer are connected *via* the "slow" A/D converter; a fast-scan mass spectrometer and a pulsed NMR instrument are connected through the "fast" A/D converter.

Of the currently used computing capacity (in 24 hour operation 20 to 25%) almost 90% are off-line calculations and only about 10% are for the acquisition and processing of on-line data.

Off-line programs requiring more than 28 K of core must run at night, *i.e.* between 5 p.m. and 8 a.m. One reason for this is that they would cause an unreasonable amount of swapping activity during daytime operation; a second reason is that for very large programs the amount of core left free by the resident monitor (presently 41 K) is not sufficient, so a special operating system must be loaded.

The reliability of the operating system has increased through continual improvements in the course of time, so that practically no software crashes occur any more.

However, there are still occasional hardware failures that usually result in down-times of an hour to one or two days (maximum to date).

4.7. Disadvantages of the Mülheim System

A large computer system such as the Mülheim system is always unflexible if changes are necessary in the very complex operating system. Besides the interrupt routines for the real-time data acquisition, all the controlling routines necessary in real-time for a connected instrument must be present as subroutines in the operating system. For this reason it is impossible to provide for real-time control of cases in which the operating system would have to be changed too frequently because of changing experimental requirements. Additionally, the "book-keeping" cost of real-time routines in a time-sharing system is substantial. In particular, however, no real-time experiments that run over very long periods, for example several days, should be connected to a large system; the normal operation can be interrupted not only by regular maintenance work, but also by unforeseeable system failures. For this reason no attempt was made to have the Institute's automatic X-ray diffractometer controlled by the PDP 10[6].

4.8. Personnel Requirements

The Mülheim computer installation is run by a physicist, a mathematician, two programmers, an operator, and a maintenance engineer. This group also developed the major portion of the software for on-line applications. Members of most of the analytical groups of the Institute are also involved to some extent with program development.

Good teamwork between the computer personnel and the analysts proved to be an essential prerequisite for the successful construction of the system. Cooperation is also necessary with the electronics engineers to ensure trouble-free connection of analytical instruments.

5. Comparison of Computer Systems for Chemical Research

Since most research laboratories have access to a large computing center where off-line programs can be run, the main interest is usually focused on the purchase of an on-line system (see however Sections 5.6 and 5.7). The scopes of the various types of on-line systems have already been discussed in Section 3. It is, however, fitting to consider once more the advantages and disadvantages of small dedicated systems and large mixed systems.

5.1. Programming

The parts of programs for real-time data acquisition and possibly real-time control are easier to develop and in most cases also easier to modify in dedicated systems than in large ones with complicated operating systems.

On the other hand, the analysis programs are simpler to produce in large systems because they can usually be written in a high-level programming language such as FORTRAN. Programs for debugging and text editing are available for fast program modification as well as labor-saving peripheral devices (listings, copying programs). (See also Table 2.)

5.2. Computing Capacity

For some evaluation procedures (for example in mass spectroscopy) the greater computing power and larger storage capacity of a large system are desirable and sometimes also essential. In such cases the use of small systems is often limited to pure data acquisition or limited preprocessing, so that the stored data must be evaluated later off-line in a computing center.

5.3. Flexibility

As already emphasized elsewhere, a large mixed system which makes possible a conversational time-sharing mode is in many respects more flexible for the user than a dedicated system.

This holds for the programming as well as for the handling of data. The possibility of modifying programs without great difficulty and adapting them to new demands is especially important for laboratories with frequently changing tasks.

Table 2. Programming of on-line systems.

System	Real-time data acquisition and processing	Evaluation	Testing and editing of evaluation programs	Flexible use of different evaluation programs
Dedicated systems 1. one instrument per computer 2. variable-purpose dedicated system	very simple (no overlapping of different analytical methods)	troublesome (normally done in assembly language)	difficult (small memory, few testing aids, program	possible with extensive periphery
3. several instruments of the same type per computer	simple (but possibly complicated scanning algorithms)	very troublesome (assembly language, several instruments)		
Multi-method systems	difficult (timing correlation)	very difficult (assembly language, different analytical methods)	very tedious (a change for one method influences all the others)	
Mixed systems	very difficult (implementation within a complete operating system); time-sharing operating system from the manufacturer is a prerequisite	very simple (FORTRAN, no overlapping of evaluation programs of different instruments or of data acquisition parts, complicated evaluation procedures can be employed, access to extensive banks of data)	very simple (no influencing of other users, fast work with text editors, efficient testing aids, ease of use because of extensive periphery)	extremely simple (because of possibility of time-sharing dialogs!), stepwise evaluation possible depending on intermediate results
Satellite systems	simple for dedicated satellites, but conflicts with operating system possible			

In contrast, dedicated systems are more flexible in their hardware composition. They are therefore better suited for laboratories tending to experiment with hardware.

5.4. Maintenance and Operation

No maintenance personnel is normally required for a dedicated system and the user need not make allowances for other users. Small systems are also usually more reliable than complicated large systems.

Although failures are more frequent with large systems, they usually do not last so long since a maintenance engineer is invariably close at hand.

5.5. Laboratory Organization

Only dedicated systems come into question for small, individual laboratories. Also laboratories with several analytical instruments but only infrequent analyses can work with a dedicated system connected to one instrument at a time depending on requirements (standard interface essential!). Such a "multi-purpose" small-computer system, which might be transportable between laboratories, is loaded with a different programming system according to the particular analytical instrument connected to it. "Interpreter" languages (BASIC, FOCAL, *etc.*) or languages especially developed for analytical methods can be used for a relatively simple data evaluation.

However, for larger laboratories or for a number of neighboring small laboratories the advantages of a large computer system cannot be ignored.

5.6. The Decision to Buy

The decision to buy a small system is easier to make because of the lower costs and the corresponding lower risks. The purchase of a large system may require the collaboration of many interested parties. Any agreement must be based not only on financing, type, and size of the system to be

Table 3. Management considerations concerning on-line systems.

System	Typical price (DM)	Decision to buy	Operational costs
Dedicated systems 1. one instrument per computer 2. variable-purpose dedicated system 3. several instruments of the same type per computer	80000 100000 200000	easy (low costs, low risk, no organizational difficulties, fast operational capability)	low
Multi-method systems	400000—1500000	not so easy (the mutual interests of several parties must be met, limited system efficiency)	low
Mixed system	2000000	difficult (high costs, many parties concerned, possible reorganization or merging of labs, time-consuming planning and development, consideration of existing computer centers, company politics, or national motives concerning computer manufacturers)	maintenance engineer and highly specialized personnel necessary
Satellite systems	3000000		

purchased, but also on the later organization and manner of operation (see Table 3).

In many cases existing computing centers hinder the purchase of a large mixed system. However, it is often overlooked that many of the existing computer installations, even without scientific or chemical applications, are running near capacity or will be within a few years. Moreover, at least in the industrial area, the computing centers are normally oriented toward commercial applications. Scientific and technical applications, for which other types of computers and other forms of organization of computing operation are more suited, often appear as intruders.

5.7. Future Developments

Large mixed systems are desirable not only because of the requirements of data acquisition and processing for the directly connected analytical instruments: As previously mentioned, the early developments of computer programs for the support of the preparative chemist, the implementation of documentation systems, as well as continuously improved methods of interpretation in spectroscopy stimulate the purchase of large computers for the field of chemical research. Moreover, since many documentation systems and complicated evaluation procedures utilize the data sets from on-line systems, the most intimate possible union—which the mixed system optimally offers—of on-line and off-line systems is desirable.

Because of the relatively low level of exploitation of a large system by on-line tasks alone, such a system becomes economical only with the inclusion of several intensive off-line computations. A similar degree of computer usage could be attained by using the computer for training students.

Computer-Aided Analysis of Organic Mass Spectra

By D. Henneberg, K. Casper, E. Ziegler, and B. Weimann[*]

1. Introduction

After introduction of the sample into the spectrometer, mass spectrometric analysis may be divided into three phases: Measurement of one or more spectra; evaluation or work-up of the data; and finally interpretation with a view to answering the particular question of the analysis. Evaluation means determination of the masses present und their relative intensities as well as determination of metastable ions with the assignment of their possible origins. Data work-up refers to correction of spectra by averaging and/or background subtraction and also the choice of the most suitable representation for the information, *i.e.* bar-graph spectrum, table, mass chromatogram, or element map. The last step, that of interpretation, involves identifying molecular fragments, hetero-atoms, and structural elements responsible for the observed peaks, as well as the recognition of mixtures. It requires further quantitative determinations on mixtures or isotopically labeled compounds and identification or classification by comparison with calibration spectra.

[*] Dr. D. Henneberg, K. Casper, Dr. E. Ziegler, and B. Weimann
Max-Planck-Institut für Kohlenforschung

We wish to demonstrate with a few examples how the use of a computer system can effectively support all three phases of mass spectrometric analysis. In order to be able to show the impressive advantages of computer use, especially in the measurement of spectra, we would first like to give a few illustrations of the possibilities of mass spectrometric analysis with special emphasis on the more recent instrumentation and methods.

Three techniques have made the application of mass spectrometry particularly interesting, and in some cases indispensable, in the analysis of organic compounds.

1. The combination of a gas chromatograph (GC) and a mass spectrometer (MS) is of particular value in the analysis of mixtures of easily vaporizable compounds. In this technique the eluate from a GC is continuously analyzed by mass spectrometry. In the course of a chromatographic analysis it is possible to obtain the mass spectra of all resolved components (see Fig. 4). It is assumed that the spectra are recorded rapidly so that distortion due to changes in the partial pressures is minimized.

2. The direct vaporization of samples having low vapor pressures results in a considerable increase in the types of analyzable compounds. Modern mass spectrometers allow

spectra to be recorded at sample pressures between 10^{-7} and 10^{-5} torr in the ion source. Systems are available where the sample temperature may be chosen as a parameter between -100 and $+500$ °C and thus for many substances a vapor pressure suitable for the ion source can be chosen. By this method it is nowadays possible to obtain spectra of compounds ranging from peptides, with molecular weights of more than 1000, to volatile transition metal complexes which decompose well below room temperature.

In general, after introduction of the sample the temperature is set so that the sample has an insignificant vapor pressure. The temperature is then increased until the vaporization process is complete. In this way, a certain amount of fractionation occurs for mixtures which can afford valuable information for use later in the interpretation. In special cases, the composition of the mixture can be quantitatively determined (Fig. 1).

3. High resolution mass spectrometry allows determination of the empirical formula of molecules and their fragments by means of very precise mass identification. Computers have been successfully used in conjunction with high resolution mass spectrometry for some time[1]. That the method is almost unthinkable without the help of computers is clear from the wealth of data that must be analyzed. Large volumes of many-digit numbers are produced whose processing culminates in the choice of the possible empirical formula from a large number of atomic combinations.

In the following article we shall discuss only the GC—MS combination and direct vaporization techniques with on-line computer operation and direct our attention solely to low resolution spectra. This area is still in its infancy. The application of high resolution mass spectrometry to the sample introduction techniques discussed in 1 and 2 above remains limited to a few special cases due to the particularly large amounts of equipment required.

In order to highlight the effect of computerization on experimental, analytical, and last but not least organizational aspects, a comprehensive description of the available software has been intentionally avoided.

2. Measurement of Mass Spectra in Conjunction with an On-line Computer

Typically, the partial pressures of the components in the ion source change as a function of time for the GC—MS combination and the direct vaporization techniques. This is particularly obvious for gas chromatographic peaks. The partial pressure of the sample changes rapidly, especially during measurements with good chromatographic separation. The first peaks in Figure 4, for example, have widths at half-maximum of about one second. Under normal conditions (fast scan of the magnetic field) it is not possible to obtain good spectra with such peaks.

For the analysis of a total chromatogram, at least one mass spectrum per chromatographic peak is necessary. If overlapping of several components occurs and the background is not constant, then many more spectra must be recorded. At best, 10 to 20 spectra per minute can be recorded with magnetic-scan spectrometers. For a 30-minute chromatogram in which a spectrum is taken every 5 seconds a total of 360 spectra will result. Experience has shown that of these 360 possible spectra only 150 to 200 are necessary to obtain the maximum amount of information. Further reduction assumes prior knowledge of which chromatogram peaks are of interest to the analysis. Two-hundred spectra correspond to about 40 m^2 of paper. It would be simply impossible in an analytical service laboratory to evaluate so many spectra manually, even to the point of deciding which spectra are important and which are not.

However, with data processing this problem is easily solved with a minimum of time and effort. For the cost of recording a single spectrum on UV-paper with a galvanometric recorder it is possible to record and store an entire series of spectra with a computer.

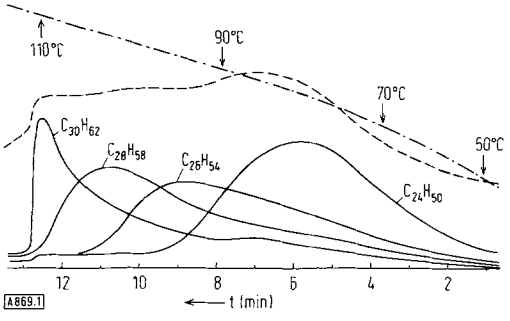

Fig. 1. Fractional vaporization of a mixture of *n*-paraffins.
Changes in the temperature (—·—) and total ionization (pressure) (– – –) were recorded with an X_1—X_2 recorder. During the total vaporization 30 spectra were measured at intervals of *ca.* 25 s. The four vaporization curves given for the separate components are obtained from the intensities of their respective parent peaks in the 30 spectra. For chemically similar compounds, the areas under the vaporization curves agree well with the known composition of the mixture in mol-percent.

Cpd.	Fraction (mol-%)	Area (%)	B. p. (°C)
$C_{24}H_{50}$	28	31	391
$C_{26}H_{54}$	22	23	412
$C_{28}H_{58}$	25	25	432
$C_{30}H_{62}$	25	21	450

The direct vaporization of a mixture of solids is shown in Figure 1. The change in the composition of the mixture with time is clearly recognizable. Although the partial pressure of each component changes relatively slowly a rapid-scan recording of the spectra is recommended. Many substances vaporize irregularly, which can result in a considerable distortion of a single spectrum. For qualitative evaluation of the analytical results shown in Figure 1, it is sufficient to record four spectra provided they are measured at favorable times for the separate components. In order to know when the spectra are best recorded and which corrections must be carried out, a prior knowledge of the shape of the vaporization curve is required. This is obtained by plotting the intensity of a chosen mass from a series of successive spectra. This technique has long been in use with the GC—MS combination and is applied in several

variations: mass chromatograms measured directly with fixed masses[2, 3] or extracted by the computer from a series of complete spectra for arbitrary masses[4]; alternating mass (AVA-technique[5]); or isotope scan[6].

The evaluation of an analysis such as that shown in Figure 1 takes several hours by hand, whereas a computer requires but a few minutes to deliver the corresponding picture.

In order to obtain such a picture for an unknown mixture, it is first necessary to know which masses are characteristic of only one component. An experienced investigator determines this by examining spectra from the beginning, middle, and end of the vaporization. We will attempt, however, to make the optimum choice with the aid of a computer program[4].

The first great advantage of measuring spectra with a computer is the ease with which a large number of spectra can be recorded and stored. Although perhaps only a few spectra are actually utilized for interpretation of the analysis, the recording of unnecessary spectra requires less effort than the repetition of an entire measurement if unsufficient spectra are available to allow interpretation.

The second advantage of using a computer is that the measurement is performed automatically and does not require supervision by a technician. In the case of a GC—MS combination without automatic measurement, the undivided attention of a technician is required to follow the chromatogram in order to measure each desired spectrum at the right moment, *i.e.* at a chromatogram peak maximum. In practice the situation is often simplified by determining the rough form of the chromatogram in a trial run. With direct vaporization prior information cannot be obtained. In this case the vaporization process is followed in successive spectra recorded at short intervals—for example with a storage oscilloscope. In order to record the "right" spectra during the fractionation of a mixture, it is necessary to recognize and interpret continuous changes in the spectra. This is, of course, only superficially possible during an experiment and requires much experience and concentration. On the other hand, with automatic recording of many spectra the technician can devote time during the measurement to other tasks such as the evaluation of previous experiments or preparation for new measurements.

3. Programs for Measurement and Evaluation of Mass Spectra

Two programs, MSDAT and MACO, developed by us, are employed in the recording and evaluation of spectra. The functions of MSDAT and MACO are discussed briefly below.

The program MSDAT facilitates the recording, reduction, and temporary storage of spectra to be evaluated. For recording of spectra it is possible to choose from three modes of operation:

1. Push-button measurement of a single spectrum.

3. Measurement of a single spectrum in a 5-s cycle of the spectrometer consisting of 2 s spectrum and 3 s pause. In this mode the start of computer measurement is synchronized with the spectrometer scan after pushing a button.

3. Automatic computer measurement in a 5-s cycle. By means of a parameter word it can be dictated whether every spectrum in the cycle or every second, third, *etc.* should be measured; in this way, spectra may be recorded every 5, 10, 15 s, *etc.*

Each spectrum is composed of 10000 digital values (2 s recording time for $m/e=20$ to 450, 5 kHz digitization frequency), which during the course of the measurement are reduced by MSDAT to the maxima contained in the spectra. Positions, intensities, and form factors of the maxima together with values for the base line and the total ionization are stored. The latter is a sum of all intensities (ITOT) which is related to the pressure in the ion source.

By comparison of the ITOT value of a spectrum with that of previous spectra MSDAT can, for example, determine whether the spectrum in a GC—MS analysis was measured on the base line or on the tail of a previous peak. In the latter case, temporary storage is pointless so that further handling of this superfluous information is eliminated (see Fig. 4)[15]. The possibility of not evaluating a spectrum can be overridden by means of the parameter word previously mentioned.

The variable operational mode of MSDAT may be adjusted to fit the particular problem:

1. For a normal GC—MS analysis, automatic measurement in 5-s cycles is chosen. Spectra for which the value of ITOT is the same as that of the immediately preceding spectrum are suppressed.

2. For vaporization of a solid sample, recording of spectra at 10-s or 15-s intervals is usually sufficient. The spectrum suppression is eliminated by the appropriate parameter word in order to obtain the complete vaporization curve from a uniform series of data points.

3. In order to obtain a good calibration spectrum of a pure substance, a number of spectra are averaged. For this purpose one chooses the fastest repetitive scan, 5 s. In this mode the spectra suppression must be turned off since it would prohibit recording repetitive spectra of a calibration substance at a constant inlet pressure.

At this point it should be clear how a single program can be flexibly adapted to perform many different tasks.

Program MACO evaluates and summarizes all spectra belonging to a particular analysis. First, the data pertinent to identification of the analysis are fed in, *i.e.* analysis number and sample designation (Fig. 2). Following this, MACO works-up the data stored by MSDAT. Normal mass peaks and metastables are recognized, noise peaks removed, and the masses calculated. In addition, MACO carries out a series of control functions which test the reliability of the mass determinations, signal intensity, position of the base line, and peak shape. Without a computer, it would be impossible to carry out all these checks for each spectrum. From each spectrum MACO stores the following list of information: integral masses; deviations from integral masses; intensities and peak type (*i.e.* sharp peak, metastables, unresolved doublets, or undetermined type of peak).

For each individual spectrum evaluated some preliminary information is printed out immediately containing the number of the spectrum, intensity and mass of the base peak, the total ionization, the largest significant observed mass, and a value which characterizes the reliability of mass determination (Fig. 2). If one of the above-mentioned control functions has discovered an abnormal situation a corresponding comment appears in addition. In Figure 2, for example, a reference is made to overloading for spectra 10 and 11. Thus it is possible to judge the correctness of the measurement from the data given in the control information immediately after the measurement of each spectrum

Fig. 2. Example of a print-out from program MACO. The underlined numbers are input data. RUN DSK MACO starts the program. 875 is the analysis number, SON BA 010 is the sample identification number. Sixteen spectra were evaluated, two of these showing warning comments. The column headings are:
ITOT: = Total ionization
BINT: = Base peak intensity
BMAS: = Mass of base peak
LSM: = Last significant mass in the spectrum
MSH: = Scale factor for mass determination

because the time-sharing operating system allows MACO to run parallel to recording of spectra. In addition to this, the teletype print-out provides a convenient record of the whole experiment.

The mass numbers are obtained with the aid of a mass/time calibration. Slow drift and small fluctuation errors are, within certain limits, corrected by MACO. The calibration table is produced automatically (9 s of computing time) by Program MASCAL from a PFK spectrum. Calibration twice a day is generally sufficient.

The program combination MSDAT and MACO is capable of recognizing peaks of the same order of magnitude as background noice (for fast scan spectra, depending upon the photomultiplier voltage, 3—5 mV). That yields a dynamic range of 3×10^4 relative to the saturation limit of the amplifier (100 V) which can be accepted by the computer. Mass peaks smaller than 0.03% of the base line are suppressed in the case of intense spectra.

In addition, MACO recognizes and evaluates metastable ions. Thus with computer techniques it is possible to obtain and correct all the available information from a spectrum, even on fast scan operation. In our experience both the masses and the intensities are more accurately determined by computer than from typical oscillographic records. This is attributable to the quality of the quartz-controlled time base and the linearity of the analog-digital converter.

We have recently installed a device which automatically switches sensitivity scales and thereby increases the dynamic range to 3×10^5. This is necessary for GC—MS analysis of mixtures whose components are present in widely differing concentrations. Otherwise, several runs with various amounts of the sample must be made.

4. Print-out of Mass Spectra

In the print-out of computerized mass spectra the most suitable form is chosen for the particular application in question. For quantitative determinations in which the composition of a mixture and/or isotope ratios are to be displayed a table is most suitable. For a qualitative interpretation, for example determination of the type of spectra and the characteristic fragmentation pattern, representation as a simple bar-graph is to be preferred. For documentation purposes, however, a bar-graph is not suitable since the dynamic range is often too small and metastable ion peaks are not easily reproduced. Analog spectra are not particularly suitable for any type of further evaluation. It is, therefore, unnecessary to record analog spectra parallel to computer measurement. Analog spectra are possibly of importance only in special analyses dealing with shapes of peaks and metastables.

Spectra evaluated by MACO, as well as any other suitably stored spectra, can be printed-out as tables with Program REMAS. For reasons of clarity and ease of filing, it is important that the print-out has a standard form. An example of such a print-out in tabular form is shown in Figure 3.

The uppermost field contains all pertinent identification information. The main field (left center) gives masses and intensities, which may be normalized to the base line or total ionization as desired. If the signal is not a normal, sharp mass peak, a symbol designating the type of peak appears (see legend of Fig. 3). The metastable ions are tabulated again to the right of the main field along with assignments of their possible origins where possible.

The capability of the program group MSDAT, MACO, and REMAS is clearly evident from the mass peaks $m/e = 86$ and 28 in Figure 3. The star alongside $m/e = 86$ indicates that the peak is broader than normal and hence may ori-

ginate from a metastable ion or unresolved doublet. The $m/e=86$ peak therefore appears once again among the metastable peaks (Fig. 3, center right). There one sees the exact mass of the ion (86.02), a possible formation route

The profile of the reduced spectrum[*] in the lower right field provides certain information important to the qualitative interpretation of the spectrum, since it is characteristic of certain classes of compounds.

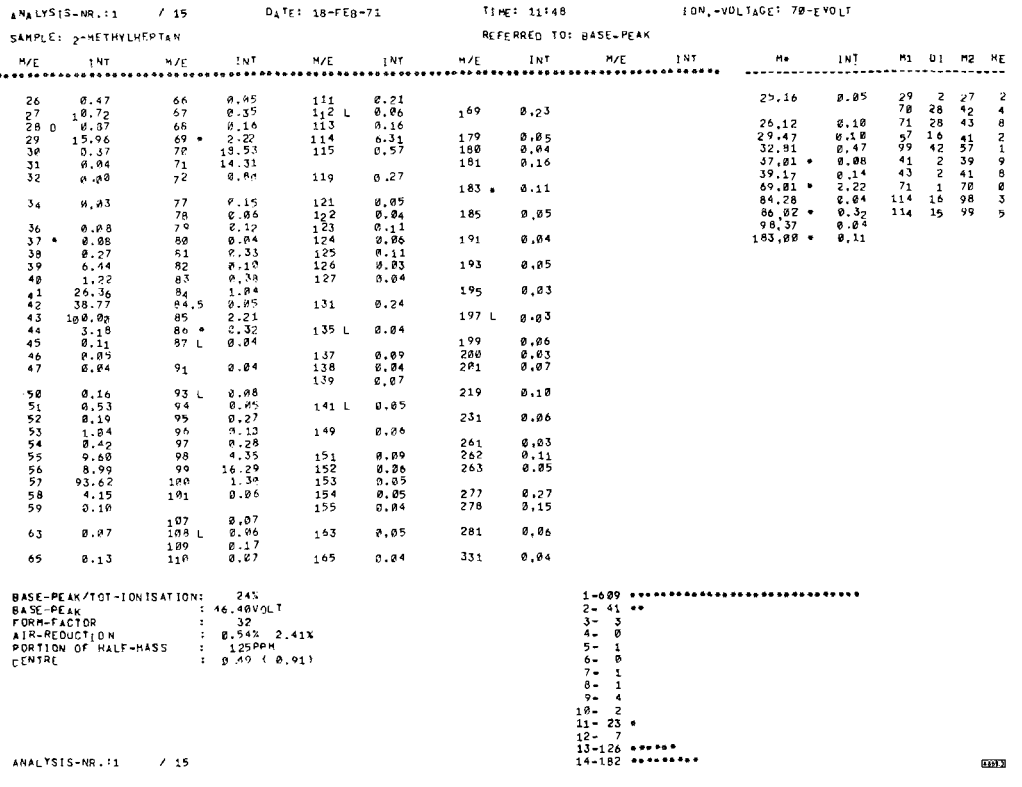

Fig. 3. Standardized print-out of a mass spectrum produced by program REMAS on a line printer. The print-out contains all values from the measured spectrum, as well as some derived information and information on the origin or measurement.
Peak type: D = unresolved doublet
.5 = doubly charged ion
* = possible metastable ion
L = small peak, type undetermined

(*i.e.* 114→99), and the deviation of the measured from the theoretical mass (5/100 mass units). This mode of degradation is resonable (loss of a methyl group from 2-methylheptane). Due to the isotopic distribution, a peak having an intensity of about 0.14% should appear at $m/e=86$ (*i.e.* 9% of $m/e=85$). It is then clear the $m/e=86$ peak arises from the superposition of this isotopic peak and the peak of the metastable ion resulting from the 114→99 decomposition. Without this superposition, the metastable ion would appear only in the metastable ion field of the REMAS print-out. At $m/e=28$ the partially resolved doublet for N_2 and C_2H_4 is shown.

Figure 3, bottom left, shows additional information such as the contribution of the base peak to total ionization, and the absolute magnitude of the base peak. The latter allows assessment of spectrum quality. If a given spectrum is the resultant of an averaging or corrective operation, this field will contain information about the way in which the spectrum was arrived at.

Should one of the control functions have responded in program MACO, the corresponding comment would be given in the blank lower center portion of Figure 3.

If a bar-graph is desired, the spectrum can be drawn by a suitable plotter. Two examples of bar-graph spectra are shown in Figure 6. The plotter requires about 1—2 minutes per spectrum and is therefore not suitable for the reproduction of series of spectra. For this reason we will soon employ a Statos recorder which requires 4 s to plot a spectrum.

5. Treatment of Spectra and Analyses

In the previous sections we have discussed how a series of spectra may be obtained as starting material for a mass spectrometric analysis. It will now be illustrated how the necessary spectra are chosen and corrected during a GC—MS analysis. It is first necessary to obtain an overall view of the chromatogram drawn by the plotter according to program DIPLO. Figure 4 shows the first part of analysis No. 875.

The times at which spectra are recorded and stored are indicated by crosses on the chromatogram. It is evident

[*] "Reduced spectrum" after *Crawford* and *Morrison* [7].

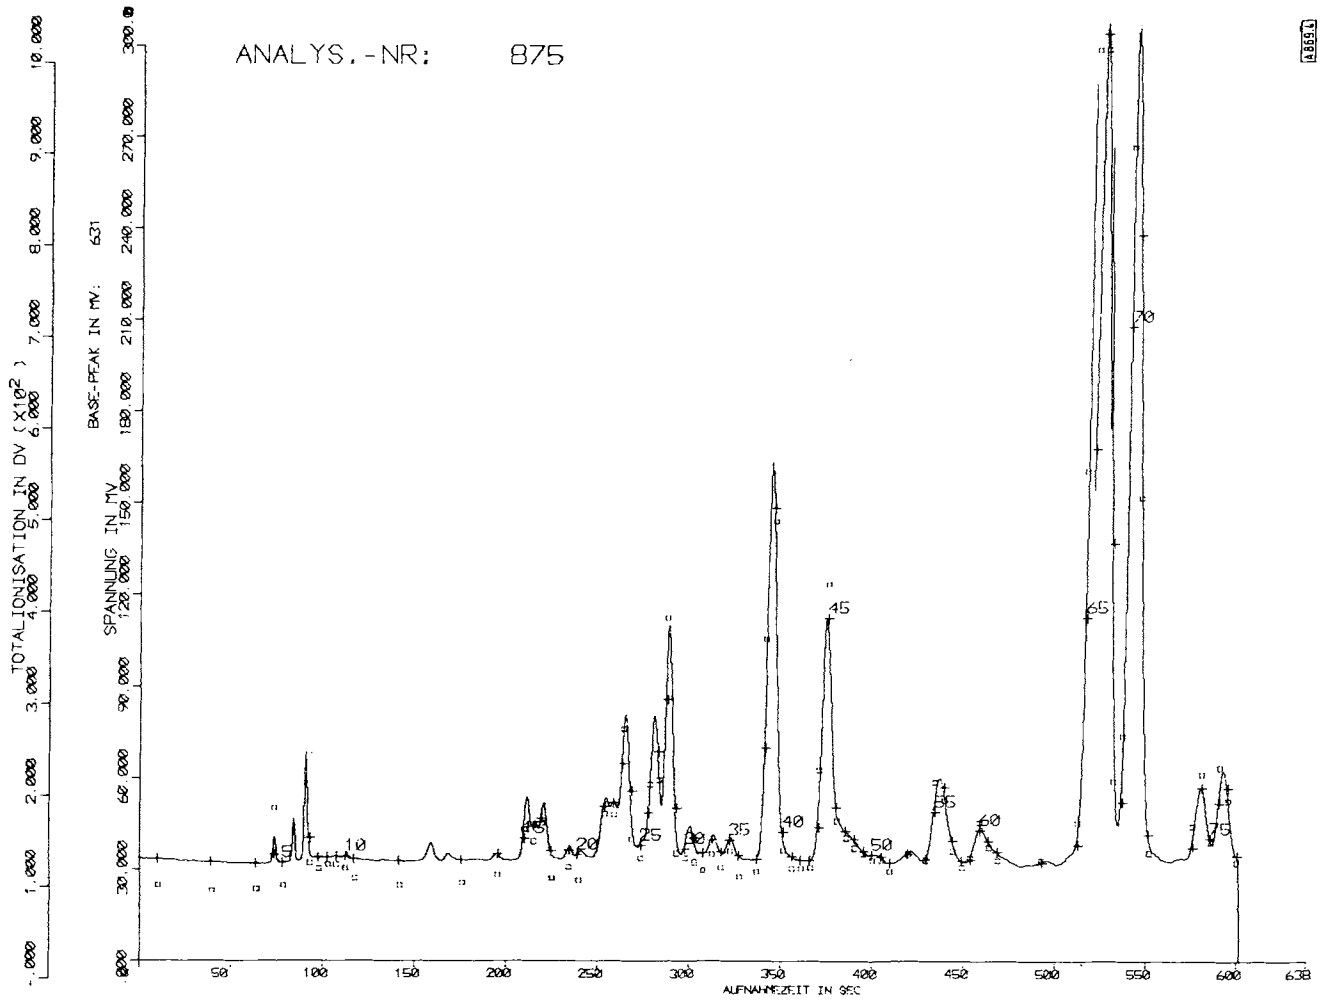

Fig. 4. Overview of the GC-MS analysis No. 875, drawn by program DIPLO with a plotter: ——, chromatogram, measured as the total current from a pressure measuring ion source at 20 eV; +, signifies measurement and storage of a mass spectrum. The number of the spectrum is printed every fifth measurement; □, total ionization values of the mass spectra.
The scale of the chromatogram is so chosen that the smaller peaks are clearly visible. Peaks too large for the chart paper are shown in reduced scale so that the largest signal appears as a full scale deflection. Its height is given alongside the scale.

that spectra recorded in peak-free regions or in flat tailing portions of the chromatogram (for example following spectrum 62) are neither stored nor further evaluated. As seen for spectra 21 and 22, however, if the ITOT value is approximately the same in a region of one or two successive GC peaks, both spectra are stored[15]. The enlargement scale for the illustration of the chromatogram as well as for the ITOT value can be chosen by a dialog after calling the program. With such a diagram, it is possible to find the spectra which are important for a particular analysis, even for a long, complicated chromatogram with many recorded spectra.

An example of a simple, straightforward trace analysis will now be described; the corresponding MACO print-out was depicted in Figure 2. In Figure 5 a portion of the DIPLO picture of the analysis is shown.

During the total running time of 250 s, spectra were measured at intervals of 5 s. Of the resulting 50 spectra, only 16 were stored and evaluated as shown in Figure 5. In this case, the GC—MS combination was connected to the computer only during the time 3 minutes before the elution of the main component until shortly after the appearance of the trace component. This limitation of the measurement was possible due to prior knowledge of the chromatogram.

The trace component is best represented in spectrum 14. As can be seen in Figure 5, about 40% of the total ionization in spectrum 14 results from the constant background and the tail of the main component. In this case, the desired correction is obtained by subtracting the arithmetic mean of spectra 13 and 15. The effect of this correction is shown in Figure 6.

After this correction, a pure hydrocarbon spectrum remains. Apart from the peaks at $m/e=28$ and 32 (due to air) the peaks removed in the corrected spectrum are mainly due to the major component, diisopropylbenzene ($m/e=45$, 59, 73, and 87).

This example shows clearly how it is possible to achieve an optimum stepwise reduction of data and applied operations: Prior knowledge of the chromatogram allowed limitation of the length of the measurement to about 4 minutes. During this time span, at 5-s intervals, a total of 50 spectra were recorded by MSDAT. Of these 50 spectra, 16 were temporarily stored and later evaluated by MACO. For solution of the analytical problem, *i.e.* determination of

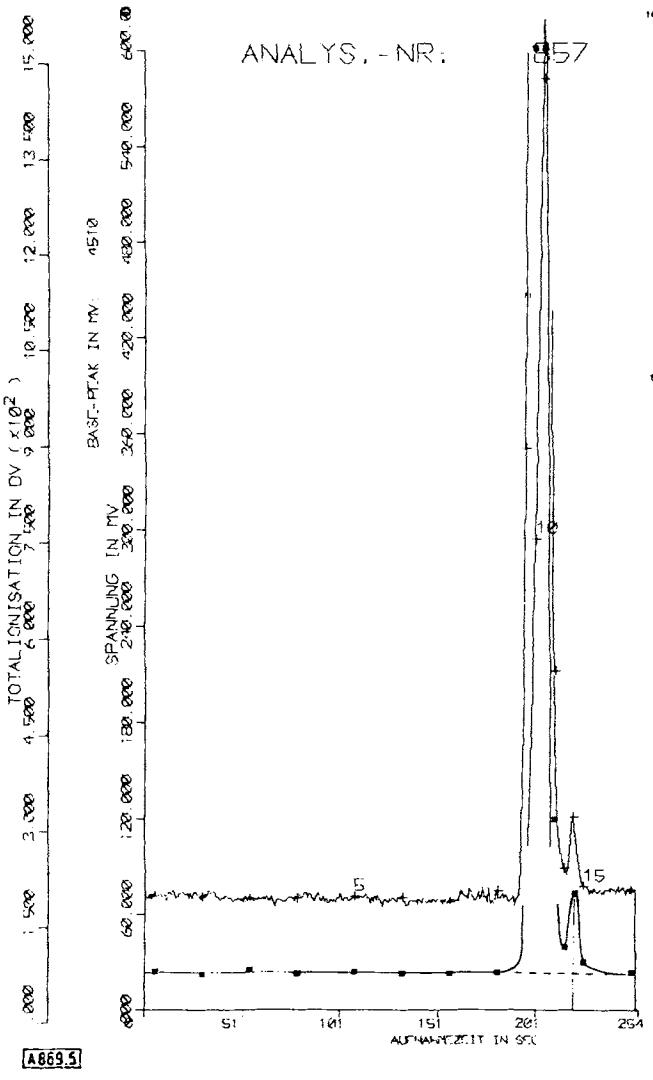

Fig. 5. Excerpt from the DIPLO display of Analysis 875 (cf. Fig. 2). In order to show more clearly how spectrum 14 of the trace component can be corrected the course of ITOT between the squares during the analysis was later added by hand.

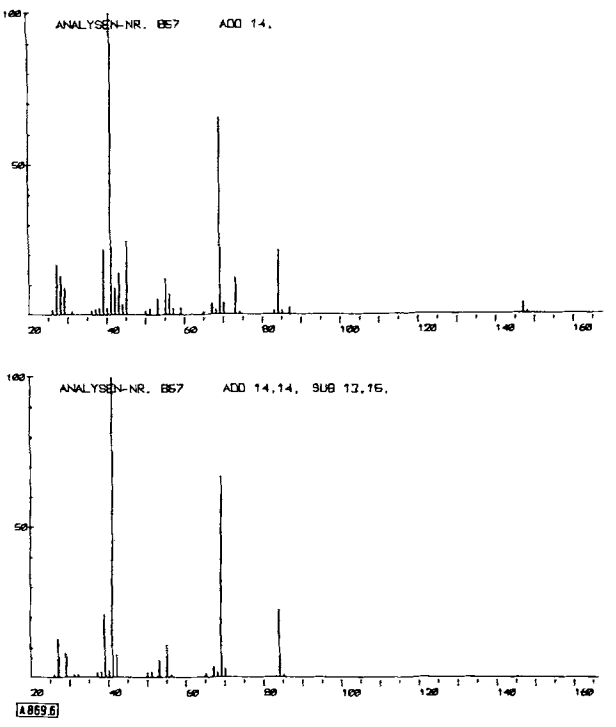

Fig. 6. Mass spectra displayed as bar-graphs drawn by a plotter. Top: Spectrum 14 of Analysis 875. Bottom: Spectrum 14 after subtraction of arithmetic mean of spectra 13 and 15 (Fig. 5).

the trace component, only 3 of the 16 spectra were necessary; apart from the uncorrected spectrum only one spectrum was finally printed out.

Only 3 operations are generally necessary for the correction of spectra: addition; weighted subtraction; and correction of intensity distortions due to pressure changes during the course of measurement (TI-correction). For example, TI-correction would be desirable for spectra 38 and 39 of Figure 4. However, before each TI-correction the constant portion of the background must be subtracted. After correction, the spectra may be compared. If the corrected spectra are not identical, then the chromatogram peak to which they belong is due to more than one component. In the case of spectra 38 and 39, a practically undistorted spectrum is obtained by simple addition since the distortions of the separate spectra tend to cancel when added.

A weighted subtraction must be applied, for instance, in order to obtain the best spectrum of the substance represented by the middle peaks of the group centered at 220 s in Figure 4: certain fractions of spectra 15 and 17 must be subtracted from spectrum 16.

Addition of spectra yields an average which is employed in cases where several weak spectra are available for one component or where a very accurate calibration spectrum of a pure substance is desired. (It is not necessary to divide by the number of spectra added together since this is already accounted for in the output program normalization.)

Without the computer, these arithmetic operations for "correction" of spectra are normally omitted since they are time-consuming and unpleasant tasks. An experienced analyst recognizes part of the "impurities" of a spectrum and disregards them during the interpretation. Since computer programs for interpretation or comparison of spectra are easily disturbed by impurities, computer interpretations therefore require background-corrected spectra.

6. Computer-Aided Interpretation of Mass Spectra

The last step of an analysis, interpretation, is particularly interesting and important. Requisite for the development of suitable methods is the availability of a comprehensive, reliable collection of computer-compatible spectra. The establishment of a collection of required magnitude will be possible in those laboratories in which spectra are directly measured and corrected with a computer. Model studies have already been carried out for limited collections at Stanford University in California[8] with programs attempting to reconstruct the decision-making process employed by an experienced analyst in spectra interpretation (Artificial Intelligence). However, this method soon runs up against the same difficulties which limit non-computerized evaluation of spectra, *i.e.* insufficient knowledge of reliable fragmentation rules.

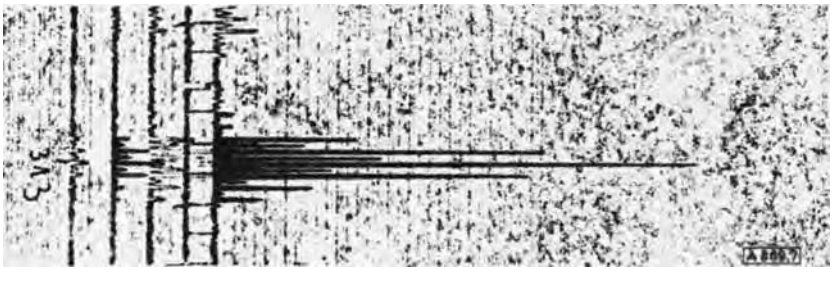

Fig. 7. Print-out from program ISOTOP. Top: Input data are underlined: program start and desired form of the print-out (TABLE AND GRAPH) of the isotope distribution for the formula $C_8H_{18}Br_1Sn_1$. Center: Mass table and bar-graph spectrum. Bottom: Molecular peak group whose hetero-atom content was to be determined.

The employment of decision vectors[9, 10] seems especially attractive where results are expected which would be inaccessible without the aid of a computer. The main task of the computer is to "train" a vector to a set of known spectra, using an iteration process within a learning program. A vector so trained is applied to a spectrum to be evaluated and a "yes—no" decision is obtained. In this way, it would be possible to determine the presence of oxygen, a vinyl group, a ring, *etc.*

An obvious type of interpretation is identification by comparison with a collection of stored spectra. Descriptions of this method have been given in some detail[11, 12]. The trace component analysis problem discussed in the previous section would be largely soluble with this method since practically all C_6H_{12} hydrocarbons are tabulated. The spectrum shown in Figure 6 could only belong to a compound of this formula. There remain, however, three alternatives whose spectra are all quite similar, 2-methyl-4-pentene, 4-methyl-2-pentene, and 2,3-dimethyl-2-butene.

A final decision in favor of 2-methyl-4-pentene is possible only when additional results from another analytical method are considered—for example, chromatographic retention times. This decision could also be made by our computer system. In the signal from the pressure-measuring ion source, the GC—MS combination delivers a chromatogram comparable with a normal chromatogram. The existing programs for evaluation of chromatograms and for determination of retention times can be called for use by the GC—MS analysis, since in the Mülheim computer system it is possible to make use of information stored by other users. These possibilities are exploited between the gas chromatography and mass spectrometry divisions and are especially advantageous for the GC—MS combination. It is possible to envision a general Laboratory Information System which would facilitate the exchange of various analytical results between analysts as well as allow access of chemists to analytical information.

The complete computer interpretation of an analysis is possible in the case of quantitative gas analyses. A program for such analyses has been in use over three years[13]. Calibration spectra of 45 inert gases, hydrocarbons, and volatile solvents are stored. Starting with the mass spectrum of a mixture the program calculates the composition of the

mixture and prints out a control slip for documentation as well as the final analysis results for the researcher. The program utilizes the method of regression analysis.

A final example of computer assistance is provided by a program which computes the isotope distribution associated with a given empirical formula (Fig. 7).

Simple isotope distributions with O, N, and up to 30 C atoms as well as the distribution of Cl and Br may be found in tables. Complicated distributions are not tabulated and cannot be calculated by hand without unreasonable effort. Therefore, such a program is indispensable in cases where isotope-rich hetero-atoms are combined with many carbon or several halogen atoms.

The future holds the promise of particularly interesting developments in the area of computerized spectra interpretation.

7. Organization of Mass Spectrometric Data Processing within the Time-sharing System

In the preceding sections it was shown that measurement and evaluation of spectra are largely automated by the computer. Interpretation of spectra, on the other hand, is accomplished on the teletype in a preprogrammed dialog using a series of programs with which the user is able to carry out only suitable and necessary operations. As a prerequisite for such a mode of operation, all spectra, regardless of origin and previous manipulating processes, must be filed in the same uniform format so that they are available for any kind of further treatment, interpretation, or output.

The logical interrelationships of the operations applied to mass spectra from the initial measurement to the final interpretation are depicted schematically in Figure 8.

In the computer system employed by us[14] all data and programs are stored on a magnetic disk, *i.e.* in a large memory with random access. All operations may be started

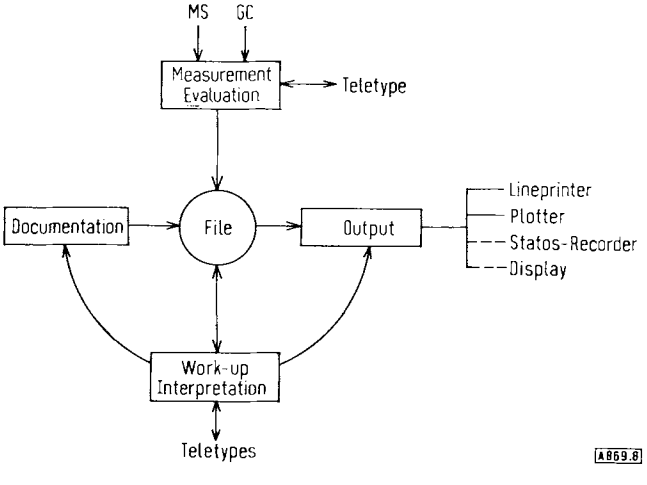

Fig. 8. Organization scheme for processing of mass spectrometric data. The file includes actual parameters, spectra, and programs, to which simultaneous, rapid access from several locations is possible in time-sharing operation.

at arbitrary times, several operations such as measuring, processing, storing, and retrieving of spectra, may be started simultaneously from different teletypes. Such a system makes for optimum flexibility and all tasks, including program development, can be economically distributed.

From the schematic diagram, and above all from the examples presented here, it is clear that the computerization of mass spectroscopic analysis does not aim at becoming a completely automated (black-box) process. Rather, the computer is used as a controllable instrumental aid whose operation is guided by the analyst and thereby adapted to fit each facet of the analytical problem. A completely automatic, combined application of all possibilities for spectral correction and interpretation for each recorded spectrum would quickly lead to the situation where the computer is overloaded with unnecessary work—not to mention the huge expenditure of programming effort. A fully automatic analysis up to the print-out of the final results would only be possible if essentially all conceivable results and associated complications were foreseeable in advance. A special case of this is the quantitative gas analysis already mentioned, *i.e.* a routine analysis the evaluation procedure of which is precisely defined and which occurs frequently enough to make the programming effort worthwhile.

Of decisive importance in the procedure described here, namely, the successive application of several programs or program modules with variable parameters, is the dialog between the program-user on the one side and the program processing the data sets on the other. This dialog takes place at the terminal from where it is possible to start and interrupt programs. The dialog, *i.e.*, the questions and answers, are appropriately preprogrammed. A simple example of such a dialog is the choice of the scales for the drawing made by program DIPLO (Figs. 4 and 5). The program determines and prints the maximum peak height in the chromatogram and the largest value of the total ionization in a given series of mass spectra. From this it is possible to specify the desired scales for the plotter diagram.

Warnings against attempts to carry out illogical operations and the possibility of terminating the program in such a case are of particular importance for a real dialog. If, for example, large negative values were produced by subtraction of background, or during an averaging an incorrect spectrum were used, warnings are issued and modifications of the processing procedure are allowed. This kind of dialog, which permits changing of the program flow during execution, is not to be confused with the input of parameters at the start of a program. These permit variation of the program flow before execution, but do not allow user interactions after the program has started.

The measurement of spectra, evaluation and interpretation of analyses, and program development are separate tasks assigned to different persons within the laboratory. Only a multi-user time-sharing system will permit the execution of these tasks simultaneously from several teletypes, or temporally independently of one another, and in the form of a dialog. Thus an optimized and economical use of a modern mass spectrometer is possible.

The time-sharing operation has worked especially well for program development. Since the use of the computer

normally does not require an operator and programs can be changed, compiled, and started at any time, it is possible to directly test and verify new ideas. Thus the computer becomes a thinking tool for the scientist.

In this connection two special types of programs should be mentioned. First, programs which serve as support for the development of optimum methods. For instance, one of these programs is written so that certain regions or peaks from the original 10000 data points of a spectrum can be quickly found and printed out *via* a teletype. For instance, this allows a user to investigate the effect of various smoothing functions or to test which algorithm or parameters give the optimum signal to noise ratio or optimum differentiation between metastable ions and partially separated doublets.

The second type of program is the test version of a regular measurement and evaluation program. Such programs print out all important intermediate results and thereby permit the location of errors in the program or spectrum.

The construction of our program system for measurement and evaluation is already substantially complete, having begun about three years ago. Two years ago automatic measurement was introduced, and automatic GC—MS analyses have been performed on a routine basis since then. In some cases, automatically measured analyses using direct vaporization are performed with the same program system and the same spectrometer.

On-line connection of additional mass spectrometers is now rapidly accomplished since the basic programs already developed can be used with only minor changes. With the exception of MSDAT, all programs are presently written in Fortran. This is feasible because of the size and speed of the computer system and has the advantage that program improvements may be easily made. Such improvements are always necessary in scientific laboratories since the problems to be solved are constantly changing and it is necessary to take instrumentational advances into account as quickly as possible.

Data Processing in Gas Chromatography

By Gerhard Schomburg, Fritz Weeke, Bruno Weimann, and Engelbert Ziegler[*]

1. Introduction

Data processing in gas chromatography is usually viewed as the execution of a large number of routine analyses—primarily analyses of mixtures whose quantitative and qualitative compositions are subject to only slight variation. However, the interest shown by industry in GC data processing has additional, "natural" motives: The large number of instruments frequently encountered in industrial laboratories and the corresponding demand for operating personnel make rationalization and automation essential for uniformity in routine analytical work.

In contrast, data processing with GC instruments employed in research or development has hitherto attracted less attention or interest. This is probably due to the lower number of instruments connected per laboratory, especially if dedicated systems for gas chromatography only are considered. Gas chromatography, however, is rarely used on its own in research and development but usually in conjunction or even in direct combination with other physical methods of analysis such as mass, NMR, and IR spectroscopy.

In these circumstances, larger computer systems having more peripheral equipment and higher efficiencies should be considered from the viewpoint of higher total cost and a better price/performance ratio. Each of the analytical methods mentioned will undoubtedly make use of electronic data processing in the future, so that each would

[*] Dr. G. Schomburg, F. Weeke, B. Weimann, and Dr. E. Ziegler
Max-Planck-Institut für Kohlenforschung
433 Mülheim/Ruhr, Kaiser-Wilhelm-Platz 1 (Germany)

require its own small computer system if the philosophy of the dedicated system were to be maintained.

We believe that we will be able to show that large computers are desirable or even essential for data processing in scientific analysis, for which flexible software is a prerequisite.

These tasks, together with documentation tasks requiring extensive storage, could also be executed by computer systems consisting of a large background computer with one or more suitable satellites for real-time data acquisition[1]. In any case data acquisition from many instruments at low and high data rates must be accomplished *simultaneously*.

The importance of time-sharing, which implies an interactive or conversational mode, for "scientific" applications cannot be overemphasized because of the frequently changing problems. Such a mode not only permits stepwise data processing, but also enables the operator to make quick changes or adapt subroutines using a "high-level" programming language. Through the teletype, continuous direct contact exists between the computer and its users who thus have full access to a large computing system with all its advantages.

The following report is essentially an account of the application of the Mülheim Computer System[2-4] in the field of gas chromatography[5].

Because of the differences between industrial and scientific analyses special software has been developed for this system. This software permits flexible solution of and adaptation to any analytical problem occurring in gas chromatography with the aid of a large number of auxiliary aud subprograms, without requiring repetitive runs of the chromatogram itself. Furthermore, the data acquired in an analysis can be further processed and put into suitable form by successive application of different programs.

2. Computer Applications in Gas Chromatography

The development of gas chromatographic analysis is characterized by the continuous improvement of performance, *i.e.* resolution, symmetry of the peaks obtained, and separation rate. As the resolution improves, the analysis of complicated mixtures produces an ever-increasing number of separated species, resulting in chromatograms having a higher information content. The qualitative and quantitative interpretation of such chromatograms requires the manipulation of a large volume of data. In order to interpret and evaluate the entire data set it must also be taken into consideration that additional gas chromatographic measurements for calibration and standardization purposes must frequently be made with the same sample. Repetition of the separation with modified separation parameters, such as temperature and carrier gas flow, or in columns with different resolution or polarity of the stationary phase, also increases the amount of data. The same applies to the use of more substance-specific detectors or combined analytical methods, like reaction gas chromatography (*e.g.* on-line hydrogenation) or GC-MS coupling.

The appropriate processing of these large volumes of data is an important task. Its solution must be sought with the same intensity as the above-mentioned development of the gas chromatographic technique. High demands are also placed on the capacity and capability of the laboratory by the monitoring of chemical reactions like those already frequently carried out in industrial process chromatography. We feel that in the future equipment for automated kinetic measurements will have its place in the laboratories of research institutes.

Many chromatograms have to be processed at intervals adapted to the reaction rate. This is especially important when the results of the analysis are to be used for "closed-loop" control of reaction parameters.

The measurement of a series of analyses, where the individual samples are taken manually from the reaction vessel by an operator and transferred to an automatic device for consecutive injection of the samples also belongs to this category. (In the authors' laboratory a combination of a gas chromatograph with an automatic sampling device produced by the Hewlett-Packard company, HP-model No. 7670A and the computer system to be described was tested successfully.)

For control purposes and process chromatography it is advantageous to use small computer systems which are adapted and programmed for specific problems but can also be connected as satellites to large computers. For normal gas chromatographic work, the computing and storage capacity of a large computer is desirable or even essential if, for instance, peak overlapping calculations, comparison of retention values with tabulated data, or documentation work of any kind (including exchange of information with other analytical departments) must be carried out in parallel with data acquisition from many instruments. (For a discussion on the use of "dedicated" or "large" computer systems see [6].)

3. Information Content of Gas Chromatograms

The basic task of data processing in gas chromatography is the "evaluation" of chromatograms in both coordinates *i.e.* intensity and position of peaks. Evaluation of a chromatogram requires extraction of its information content. Essentially all the parameters required for a mathematical description of each peak must be considered, such as start, end, maximum, halfwidth, turning-point, and symmetry factors or other parameters for uncertain mathematical peak shapes, which may be due to deviations from linearity of isotherms or the influence of the geometry of the pneumatic system of the gas chromatograph. Other factors include the signal to noise ratio, base-line drift, and the start and end of the chromatogram. For all more precise analyses and calculations of, *e.g.*, overlapping peaks, it is necessary that the entire digitized chromatograms remain in internal or external storage until completion of all the desired calculation and processing operations.

Evaluation of a chromatogram therefore requires a series of steps:

1. Determination of peak height or, more often, peak area as related to a standard peak, to the amount of sample injected, or to the total quantity of all the substances contained in the chromatogram represented by the sum of the individual peak areas. (These peak areas have to be corrected with respect to detector response for each component.) For the determination of the peak area, the base-line drift and, if possible, also peak overlapping must be taken into consideration.
2. Determination of peak position as defined by the distance of the "correct" maximum from the injection point or, better, from the maximum of the "gas" peak. Automatic determination of the net retention volumes or relative retention volumes and the Kovats index is possible only in the second case.
3. Standardization, normalization, and correction of peak positions and area values; identification of peaks by additional information introduced by the operator or by automatic comparison with tabulated relative retention values.
4. Arrangement of results of series of experiments in tables and summaries, or conversion into graphical representations, *e.g.* in kinetic studies.
5. Combination of several subprograms for automatic tabulation of results of refined analysis in routine work. The operator can choose either one specialized program or a combination of several.

4. Scope of Analytical Problems and Organization of the Chromatographic Laboratories at the Mülheim Institute

Before practical examples are given to illustrate the demands on hardware and software of a computer system in a research laboratory with frequently changing gas chromatographic problems, the organization of the GC laboratories as well as the particular aspects of the analytical problems will be described as an example of centralized instrumental analysis in research and development laboratories.

The Max-Planck-Institut für Kohlenforschung consists of two divisions with different research areas; there is a gas chromatography laboratory for each division and the techniques and methods employed are adapted to the individual applications. The two laboratories—housed in two connected buildings located about 150 meters apart—are operated jointly.

The analytical problems of the divisions are very different. In the chromatography laboratories of the main institute analyses are performed primarily on mixtures of hydrocarbons or their simpler functional derivatives obtained by catalytic reactions. All physical methods are employed for rapid qualitative and quantitative analysis of the usually complicated many-component mixtures of hydrocarbon isomers. (See [7—10] for particulars of analytical problems.)

All types of chromatography including liquid chromatography are used; capillary gas chromatography plays a dominant part in analytical gas chromatography because of the difficulties usually inherent in separation of hydrocarbon isomers. The use of GC-MS combination techniques is particularly important. This method also produces an enormous amount of information. (For related software see [11].)

Finally, besides on-line hydrogenation, reaction gas chromatographic investigations are carried out in the field of heterogeneous catalysis and kinetic measurements on homogeneous catalysis.

In the radiation chemistry division, apart from normal GC analyses, qualitative and quantitative trace analyses frequently have to be done. The formation of only small concentrations of reaction products in radiation-chemical or photochemical reactions is tolerated in order to avoid the formation of secondary products.

In both divisions there is a total of 46 GC instruments (29 in the main institute and 17 in the radiation chemistry division); there are also 8 preparative GC instruments. If necessary, some of these instruments can be set up in other nonanalytical laboratories. All the analytical instruments are connected on-line over the same interface to the computer mentioned above. The interface is called "slow" because its maximum data rate is lower in comparison to the other ("fast") interface. Of the 32 channels available on the slow interface, 15 are used by the chromatography laboratories of the main institute and 7 by those of the radiation chemistry division.

5. Connection of Gas Chromatographs to the Computer

The computer and interface (analog-digital converter, multiplexer, contact-scanner, and line-driver) are separated from the gas chromatographs by about 70 to 100 meters. The analog signals are transmitted over shielded cables and registered by the computer in real time. The dynamic range, the resolution, and the data rate of the interface are sufficient for the requirements of gas chromatography.

Further connections between the GC laboratories and the computer exist with the contact-scanner and line-driver units. This control system allows the transmission of start or stop commands and the operation of relays for control functions at and in chromatographs.

By means of the contact-scanner the computer determines on which channel data acquisition is in progress or completed, while the line-driver controls opening and closing of relays. For example, with the line-driver it is possible to initialize, at pre-set time intervals after the start of a chromatogram, the following instrument operations: 1) start of a temperature program; 2) start of an inlet pressure or flow program; 3) switching of pre- or double column setups for the backflush or cutting-off of uninteresting components. Separate cables are necessary for each of these operations.

Teletypes are located in the laboratories close to the chromatographic equipment and permit the input of measurement parameters, sample identifications, *etc.* in a dialog

mode. By typing corresponding commands various programs can be called, and the computer's peripheral devices such as line printer, plotter, and magnetic tapes can be assigned to the user for convenient data output and storage.

6. Data Flow and Software Structure

An appropriate schematic representation is given in Figure 1. Gas chromatographic data from the interface are stored by the data acquisition program SELDAT in core buffers. As soon as the buffers are full the data are transferred to disk storage. Raw data are processed by the analysis program GCAN, but remain available for processing by other programs such as the plotting program GCPLOT. The use of GCAN is controlled by ORGANI, an organizing program. It checks the operating system's channel-status

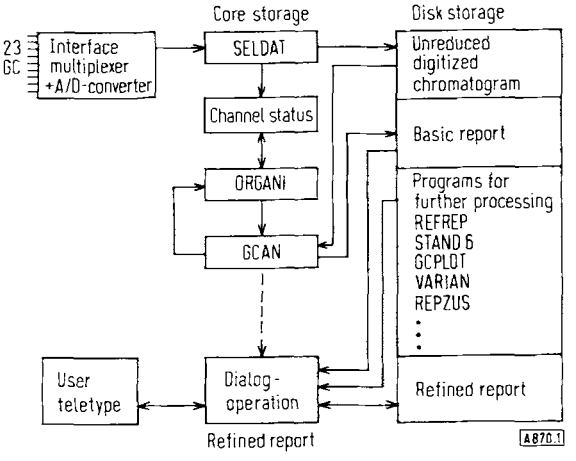

Fig. 1. Data flow and software organization for gas chromatography.

at definite time intervals. When it has detected that the data collection from a chromatograph is complete then the analysis program GCAN is called for this channel. GCAN produces a "basic report" which is written on the disk and remains there as long as desired until eventually used by other programs. While the "basic report" is produced automatically without user interaction, a "refined report" can be obtained by teletype dialog programs, thereby taking full advantage of the interactive time-sharing mode of the computer system.

7. Quantitative and Qualitative Gas Chromatographic Analysis Using Various Methods

7.1. Specification of Data Acquisition Parameters

First the GC instrument and its analog recorder are brought into the "ready" state by selecting suitable GC parameters. Such parameters are, *e. g.*, column type or stationary phase, temperature, carrier gas flow, sample load, input impedance of the amplifier, and recorder attenuation for the analog chromatogram. Subsequently the input of parameters for data acquisition is executed by the program PARAM.

A teletype dialog is used to specify several parameters of data acquisition before the sample is injected: the number of the channel on which the acquisition is to be done, the data rate (maximum of 20 points/sec), the run time (the computer stops data transmission when this time has expired if no stop signal has been given), as well as whether the raw data should be preserved for an extended period or discarded after completion of the *next* run on the same channel.

In addition, a sample identification can be entered. It is encoded to furnish information on the detailed origin of the sample.

If no new parameters are entered before the start signal (pressing the "start" button), the parameters of the previous run are used.

7.2. Data Acquisition

Special routines in the operating system (monitor) process interrupts from the real-time clock and control the analog/digital converter. The data from the A/D converter are stored in the buffers of a data job which is started automatically when the monitor is loaded; this job maintains buffers for all on-line instruments. When one of these buffers becomes full, its contents are transferred into the associated data file on the disk. It is important for the progress of the entire analysis that no data reduction or processing should occur at this stage. The data job cannot be swapped between core and disk like other time-sharing programs because data must be accepted continuously from the A/D converter. It therefore remains in the core, reducing the core capacity available to other users. When data acquisition on a certain channel is ended, either automatically or by a "stop" command, the corresponding data file on the disk is closed and becomes available for further processing.

7.3. Producing the Preliminary Basic Report with the Analysis Program GCAN

The analysis program determines the previously mentioned peak parameters such as start, end, maxima, turning points, shoulders, peak areas, and peak positions. A limit is defined for the first deviation relative to the mean signal noise, which is determined from 128 data points of the base-line before the start of the real chromatogram. Here, as with the real analysis, a special algorithm for the elimination of spikes is used. An unstable zero-line is corrected by a mathematical method in which a new base line is constructed as a polygon with minimal slope from all beginnings and ends of peaks. Peak deconvolution can be performed with special programs now under development since all raw data (unreduced A/D data) can be preserved on the disk. Very small peaks on the tails of other large ones can be treated by repeated evaluation of these data by a special version of GCAN which allows modification of the analysis parameters.

At the end of a chromatogram an organization program (ORGANI) automatically calls the evaluation program (GCAN). This program evaluates the raw data and writes the basic report on disk (Fig. 2). From there it can be recalled

```

Fig. 2. Example of a preliminary report. See text for an explanation of lines 1–10.

by the operator at any time with a simple command (Fig. 2, line 1). In lines 2—9 the following information appears:

line 2: number of reported peaks
line 3: date and time
line 4: channel number on which the data acquisition has occurred
line 5: type of GC instrument and the column used on channel 22
line 6: code for data acquisition. The first figure can be 0 or 1, depending on whether the raw data are to be stored for some time or are to be deleted after the next run. The data rate is coded in the second figure
line 7: actual run-time for the chromatogram in minutes
line 8: information on the use (for the largest peak) of the linear dynamic range of the interface as percentage of full scale
line 9: information about the average noise level in μV

The sample identification is printed out at the end of the report. Many analyses can be measured on the same channel without new parameter specifications and the operator can append the corresponding sample identification at the end of each individual analysis.

The list of all the peaks found by GCAN contains the following information about each individual peak (starting at line 10):

column 1: peak number; shoulders are indicated by *
column 2: peak position as number of points between the chromatogram start and the maximum
column 3: retention time in minutes from the start to the maximum (for faster location in the analog chromatogram)
column 4: information about whether the integration, *i.e.* the determination of peak area, was from base line to base line (BB) or the minimum between two not completely separated peaks was used as the integration limit (BT for between base and valley, TB for between valley and base)
column 5: halfwidth of peak relative to retention time (in the first approximation a constant for isothermal chromatograms)
column 6: absolute area of the peak
column 7: peak area normalized over the total area

(The lines number 1—10 are not actually part of the computer output.)

This basic report serves as the basis for the refined analysis.

7.4. Refined Analysis

Like GCAN, the programs in this group have been written in FORTRAN IV by the analysts themselves, *i.e.* staff members of the chromatography laboratories. The use of a time-sharing computer facilitated their fast production. These programs serve to normalize, standardize, and correct the basic report data according to the wishes of the user, and also to plot the data (Fig. 3) and put them into the proper format. Additional information about the sample (*e.g.* numbers and/or intensities of standard peaks, concentrations and other parameters for response factor determinations, and internal standards, as well as names and response factors of identified peaks) is therefore also introduced by the operator in a teletype dialog. The operator can decide which limits should be set for the elimination of small peaks, *etc.* With the exception of the internal standard program all of these programs are subprograms of a large general program for refined analysis (REFREP) which can be called with the command RUN DSK : REFREP. Then the name of the basic report is typed in, *e.g.* REP 14 for the report for channel 14. Next the computer asks the operator at the teletype for the sample identification in case it is missing from the report. In response to the question "Auswertung" the operator can specify any of the following subroutines of program REFREP: FAKTOR, NAME, DIGFIL, ZUSFAS, NORM, INDEX, RESP.

7.5. Quantitative Analysis with the Basic Report Data

The following Section contains reproductions of teletype output from program REFREP's various subroutines working on the basic report (see Fig. 2). In the first example

(Fig. 4) the operator specifies the peaks by their numbers within the basic report. Response factors are employed for the correction of peak areas.

In this example, the program DIGFIL was used as well as the programs FAKTOR and NAME (for "manual" input of response factors and substance names) to condense the final report; with DIGFIL a limit can be specified for the normalized peak areas in the basic report. All single peak areas which lie below the given value (here 1.0%) are not printed out in the new report; they are added and their sum printed out at the end of the output. After using DIGFIL, the report contains the percentage area values of the unnormalized report obtained after response factor correction.

Subroutine ZUSFAS can also be used in conjunction with REFREP's subroutines NAME and FACTOR; it allows

entire groups of small peaks to be summed as one total area leaving only the main peaks to appear individually (Fig. 5). It is used only when many small unimportant peaks occur in the chromatogram together with very few peaks of interest.

7.6. Quantitative Analysis with Internal Standard(s)

After calling the corresponding program (STAND6—see Fig. 6), the report number, calibration factors, and the names and numbers of the peaks to be identified and evaluated are given. The program asks for the weights of the sample and the standard and specifies the peak numbers of both standards (in this example).

Then the framed portion of Fig. 6 is printed out for the experimenter, the peak areas or concentrations of standards having been eliminated to calculate the concentrations of the components of the original mixture.

7.7. Qualitative Analysis

In order to identify separated species by means of their retention parameters the latter must be available in a standardized form. For this purpose either normal relative retention or Kovats indices can be used. The latter are especially suited, in keeping with the relevant thermo-

Fig. 7. Subroutine INDEX, table look-up.

Considerable progress with regard to precision and rapid evaluation of the measurements has been made in this field by complete computerization of gas chromatography. We feel that the practical application of the Kovats index for qualitative analysis in the past essentially suffered from the fact that its calculation and determination were inaccurate, troublesome, and time consuming.

It will be shown in the following how the Kovats index can be determined from the basic report (Fig. 2).

The determination of Kovats indices of the components of a mixture requires the presence of standard compounds—*n*-paraffins in the right carbon number range—if no extrapolation of standard peak retentions is allowed. In the interests of high precision it is desirable that the standard paraffins should already be present in the sample and that the *n*-paraffin retention values for the index calculation not be determined independently through the measurement of a standard chromatogram.

The program INDEX is a subprogram of REFREP. The program asks for the peak numbers and the retention index of standards found in the mixture. It will also ask for the peak number to which all peak areas whose index values are to be determined should be normalized. The answer to the code inquiry allows different kinds of evaluation procedures, according to which Kovats indices can be calculated from one or more or whole groups of peaks in the basic report.

Fig. 7 shows the teletype output for an identification of isomeric hydrocarbons by the comparison of experimentally determined index values with tabulated ones. In answer to the question "Tabelle:", the number of the corresponding collection of data is given. Two limits are defined in the process. The first limit at the beginning of the report has the same function as the limit in program DIGFIL. All peaks of substances whose concentrations are less than, *e.g.* 1.0% are not evaluated. The second limit is defined as the "window" for data comparison with the values in the tables; *i.e.*, the tabulated index values and names of compounds whose index values are inside the limits of the measured ones are printed out. The table search can be repeated as often as desired with variations of the limits up and down in order to exclude possible isomers or include others in the comparison. Thus each qualitative analysis is accompanied by a quantitative analysis. The standard peaks are not taken into consideration on normalization of peak areas since the standards in most cases are added and do not belong to the sample.

Identification is also possible without any added standard if the sample contains components whose indices are known. The peak numbers and index values of these compounds are then specified during the TTY dialog instead of the index values of the standard *n*-paraffins, and the program calculates the index values from them.

Under the heading "Typ" (see the beginning of the index table), the standard peaks are marked with ST and the others with IN and EX to indicate whether the index values were interpolated or extrapolated. Certain errors for the index determination are to be expected for extrapolated values because of the curvature of the $\log V_R$/C-number plot of the standard paraffins.

7.8. Mean Standard Deviation of Repeatability of Qualitative and Quantitative Analyses

Not only rationalization by saving of service staff and greater analysis through-put are important arguments for the introduction of electronic data processing with on-line operation. Besides the possibility of carrying out completely new experiments (*e.g.*, in process control), a considerable increase in analytical precision and accuracy is obtainable through the elimination of subjective errors and through the use of better instruments (see description of the interface, *etc.*).

Fig. 8. gives an impression of the repeatability of quantitative analyses.

The accuracy of the evaluation of gas chromatographic analyses with such a computer system can be checked only at considerable expense since the systematic errors of sample preparation and of gas chromatographic analysis itself (sample injection, detection, *etc.*) can only be made smaller than the repeatability with extreme effort.

The repeatability of Kovats index measurements is in principle better (for instance, the standard substances are generally contained in the sample) (Fig. 9). The standard deviations of Kovats index determination on an analog diagram using logarithmic scales are three to four times larger than those observed with the computer evaluation. Such a repeatability of index measurement is of great importance for high resolution gas chromatography with capillary columns, since it is better than the resolution (0.2—0.3 IU[*] at best). Thus the full benefit of gas chromatographic separation efficiency in the interests of qualitative identification is assured. Details of the determination of the repeatability of peak areas and retention values will not be reported here. The data acquisition rate and various parameters of the program GCAN employed clearly play a role in such measurements.

7.9. Additional Auxiliary and Subprograms for the Refined Analysis

The following list summarizes additional auxiliary and subprograms and their functions:

REPZUS: Compilation of the most important data of several basic reports into tables

VARIAN: Calculation of mean standard deviation for a large number of measurements

SORT: Program for production, competition, or correction of data tables with corresponding names. A table can be sorted in ascending order of data if so desired

RINGO: Program for the determination of theoretical plate numbers and K values

GCVARI: Program for repeatability measurements for the compilation of values from several basic reports

GCPLOT: Production of an analog chromatogram from the unreduced data, either completely or partially. Arrows show the positions of the peaks (Fig. 3); stars indicate shoulders

The description of the software used in gas chromatographic analysis corresponds to the state as of Summer, 1971.

Use of a Computer in Nuclear Magnetic Resonance Spectroscopy

By Ernst G. Hoffmann, Werner Stempfle, Gerhard Schroth, Bruno Weimann, Engelbert Ziegler, and Josef Brandt [*]

1. Survey

1.1. On-line Data Acquisition and Direct Processing

The NMR spectroscopist has long been familiar with the connection of a computer to his spectrometer.

Specially organized small computers have been employed in on-line operation with NMR spectrometers for many years. Since the advent of spectrometers whose magnetic fields are sufficiently stable over a long period of time with regard to homogeneity and drift, spectroscopists have used multi-channel analyzers, such as were known from nuclear physics, for signal improvement by accumulation of spectra[1]. Indeed one of the greatest weaknesses of the NMR method is its low sensitivity or high sample requirement. By coherently summing the records in digital form, the signal to noise ratio can be improved by at least one order of magnitude.

These improved spectra can then be written out in *analog* fashion, or *digitally* by use of a punched tape output, for further processing in a computer center[2]. The signal averaging computers CAT® (computer for averaging transients) or TAC (time averaging computer) are hardware programmed for their particular purpose[3]. Operating synchronously with the sensor (the spectrometer) they add (or subtract) the analog data (signals) of the periodically repeated runs of spectra. In some types of correlation or signal averaging computers signal integration is also possible.

However, we soon succeeded in using such computers with further spectroscopic methods[4]. Thus, for example, an infrared analysis of complicated mixtures is possible by subtracting, in increments, the spectra of assumed components from the stored spectrum of the mixture, until even strongly overlapping absorption bands may be identified and measured. The above method can also be utilized for solvent compensation when it is impossible to use a comparison cell for optical compensation. Corresponding on-line applications in NMR spectroscopy (compensation of unavoidable solvent impurities becoming significant on accumulation) are restricted by the greater solvent and concentration dependence of the signal positions. Further, Raman spectra can be separated

from a fluorescent background (subtraction of a "spectrum" recorded with an extremely large slit width)[2].

The small number of storage locations (usually 1024) in these now outdated instruments[*] allows full reproduction of the resolution capacity only for limited sections of the spectra. Freely programmable computers extend the on-line uses considerably as will be shown below. In particular they allow immediate flexible processing of the digitized data files.

1.2. Off-line Interpretation Aids and Evaluations

The off-line use of (albeit large) computers in NMR spectroscopy for classification and analysis of strongly coupled systems goes back even further. If the differences in the chemical shifts and the accompanying coupling constants do not differ greatly from one another then the resulting splitting pattern is very complicated and prevents direct extraction of these values. The computer allows quantum mechanical model calculations for larger spin systems too. In these calculations[6-8b] the tentative parameters of the coupled nuclear spins are varied until the simulated spectrum is sufficiently similar to that measured. Iterative calculation programs[6-8b] then optimize the agreement between the calculated and the experimental spectrum, and thus the exact parameters important for spectral assignment and interpretation of topological and stereochemical molecular properties can be determined.

With respect to the kind of assistance that a modern computer can give in *qualitative* analysis, nuclear magnetic resonance spectroscopy assumes a position intermediate between gas chromatography and molecular vibrational spectroscopy:

The parameters of a gas chromatogram can be extracted *directly* from the record in nearly all cases after only simple computational treatment. Its information content for qualitative analysis is small even when account is taken of combinations of different measuring conditions (change of columns *etc.*). In NMR and vibrational spectra, the parameters (chemical shifts and coupling constants, mass and force constants, respectively) are contained *implicitly*, and can be found for example by model calculations. In general, such calculations are practicable as an analytical tool only in NMR spectroscopy. In vibrational spectroscopy such simulations are possible in principle, but except for some useful findings on the characteristic vibrational frequencies, the molecule has to be considered as a *whole* with all the degrees of freedom that the atoms possess within its elastic system. Therefore complete calculations are possible here only for fairly small molecules, and they only yield less reliable approximations of structural parameters. These parameters are closely connected with the frequently quite arbitrary choice of model and require support from other methods. *Routine* application of model calculations when deciding about structural problems does not come into question presently because of the large number of estimated parameters necessary in the calculations. Therefore in gas chromatography as well as in vibrational spectroscopy a computer can generally only help to correlate the measured records or their characteristic data with material previously stored for comparison by use of search and library programs[9, 14].

In contrast to molecular vibrational spectroscopy, the NMR spectrum of a compound hardly depends upon the molecule as a *whole* but may be understood as a superposition of the spectra of its constituent parts because of the very limited transmission of indirect spin-spin coupling within a bond system. Model calculations with seven to nine spins or equivalent spin groups are therefore possible and permit a *unique* assignment of the molecule or a section thereof[16-21].

1.3. The Computer as a Spectrometer Component
