This progress report ends with the sentence: In the opinion of many experts, we are entering an "age of inorganic fibers". An attempt is made in the article to outline the present stage of development and the outlook for one of the most interesting fields of modern materials science.

1. Introduction

The technology of fiber-reinforced materials is one of the fastest-expanding fields of modern materials science. From the number of publications and patents, it can be seen that interest in these materials has avalanched during recent years. This development is based on a wide range of inorganic fibrous materials with extraordinary properties, a large part of this range being constituted by polycrystalline inorganic fibers.

2. Definitions

Certain mechanical properties will often arise in the following discussion. It is therefore convenient to recall the meanings of the various physical properties (Fig. 1).

Tensile strength: σ_B [kp/mm²]
Specific strength: $\frac{\sigma_B}{\varrho}$ [km], ϱ = density
Specific modulus: $\frac{E}{\varrho}$ [km], $E = \frac{\sigma}{\varepsilon}$ = modulus of elasticity
Bending moment of a round rod: $M \sim \frac{E \pi d^3}{32}$; d = diameter
A900.1

Fig. 1. Stress-strain diagram of solids. Hooke's law, definitions.

If a body is stressed by application of a tensile stress σ, an elongation ε occurs. σ and ε are proportional to each other in the range of validity of Hooke's law, and the slope of the linear plot is the proportionality factor, the elastic modulus E. E is a material constant. Materials having low elastic moduli, such as synthetic resins, are less able to withstand elongation than materials having high elastic moduli, such as Al_2O_3, SiC, or steel. The maximum tensile stress that can be withstood by a brittle body is its tensile strength σ_B. σ_B, unlike E, is not a material constant, but may have lower or higher values according to the quality of the structure of the material. The rigidity of a body depends not only on its geometric shape but also on its elastic modulus, and can be described by the bending moment M required to produce a certain bending: $M \sim \pi E d^3/32$, *i. e.* of two bodies with identical cross sectional areas and the same shape of cross section, the one with the higher elastic modulus is the more rigid. As the diameter *e. g.* of a round rod is reduced, its rigidity decreases and its flexibility increases. Inorganic fibers consisting of materials with high elasticity moduli, *e. g.* SiC fibers, can therefore have the same flexibility as *e. g.* man-made organic fibers if their diameter is made correspondingly smaller. Since many polycrystalline inorganic fibers are intended for use as light structural materials, it is not only the absolute values of σ_B and E that are of interest, but also the specific values σ_B/ϱ, the specific tensile strength, and E/ϱ, the specific modulus (cf. Fig. 1).

The mechanical properties of some materials are given for comparison in Table 1[1-3].

Table 1. Mechanical properties of materials.

	Material	σ_B [kp/mm²]	E [kp/mm²]	ϱ [g/cm³]
I	Pine wood	7.8	1000	0.6
	Synthetic resins	4–10	300–500	0.9–1.5
II	Al_2O_3	26	36000	3.99
	SiC	11	49000	3.2
III	Titanium	50–90	11200	4.5
	Steel	40–90	21000	7.8

3. Classification of Inorganic Fibers

To obtain a general picture of the many inorganic fiber materials and to be able to arrange the polycrystalline fibers in a logical manner, it is convenient to divide these materials into three groups according to their internal structure, *i. e.* amorphous, monocrystalline, and polycrystalline fibers (Fig. 2)[4].

The amorphous fibers include glass, quartz, and alumina silica fibers, rock wool and slag wool, and carbon fibers that have not been subjected to graphitization or that can be crystallized only with difficulty if at all (vitreous carbon).

[*] Dr. G. Winter, Bayer AG
415 Krefeld-Uerdingen, Rheinuferstrasse (Germany)

[**] Based on a lecture to the "Solid State Chemistry" group of the GDCh on September 14, 1971, in Karlsruhe.

The monocrystalline fibers are represented by "whiskers", many of which exhibit outstanding mechanical properties because of their monocrystalline, defect-free structure.

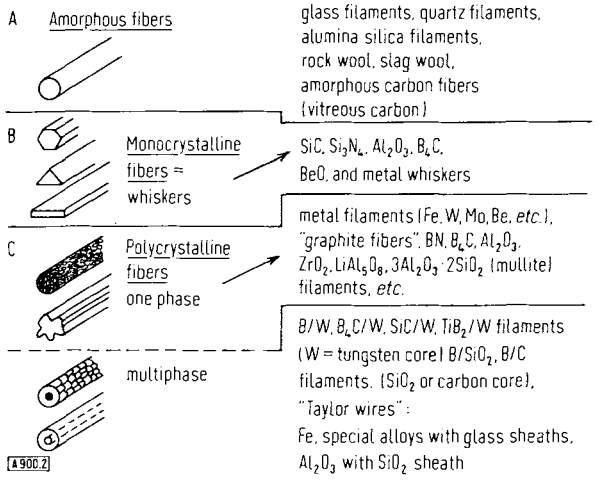

Fig. 2. Classification of inorganic fibers [4].

The third group comprises all other inorganic fibrous materials, which consist either entirely or mainly of countless small, firmly intergrown crystallites. Polycrystalline inorganic fibers consisting of only one phase include the metal fibers (Fe, W, Mo, Be, *etc.*), the "graphite fibers", BN and B_4C fibers, and the group of polycrystalline oxide fibers consisting of Al_2O_3, ZrO_2, Li-Al spinel, mullite, *etc.* The multiphase fibers contain either a core or a sheath of another material. The former include B, B_4C, SiC, or TiB_2 filaments deposited on a tungsten filament and boron filaments with carbon or SiO_2 filaments as cores, while the second group includes "Taylor wires" produced in a glass or quartz sheath, the crystalline inner part consisting of iron, special metal alloys, or oxides such as Al_2O_3.

4. Production

Many different methods are used for the production of inorganic fibers (Table 2).

1. The melt-spinning method, which is extensively used for the production of glass fibers, has so far been applied with only slight success to polycrystalline inorganic fibers. The main difficulties are the sharp viscosity changes that occur on solidification of molten oxides, the high melting points, and the problem of finding suitable containers and spinning nozzles. The production of boron and oxide fibers by this method is therefore still in the experimental stage.

ZrO_2 and Al_2O_3 fibers have been obtained in experimental quantities from rods rotating at a high speed in solar or arc furnaces[5]. On the other hand, a technical solution appears recently to have been found for the spinning of liquid steel to obtain filaments having a diameter of about 75 μm[6].

2. In the extrusion process (Fig. 3), gel or oxide particles, possibly with the aid of a plasticizer, are extruded in the form of filaments and then consolidated by sintering. The products obtained in this way have so far had only low tensile strengths, are relatively thick, and will probably be difficult to process because of the resulting low flexibility[7].

Table 2. Processes for the production of polycrystalline inorganic fibers.

1. Melt-spinning process:
   amorphous glass, quartz, and alumina silica filaments, rock and slag wool, polycrystalline boron, Al_2O_3, and ZrO_2 filaments, steel filaments.
2. Extrusion process:
   BeO and Al_2O_3 filaments.
3. Spinning process with organic supports:
   TiO_2, SiO_2, SiO_2/C, and SiC filaments.
4. Spinning of sols:
   Al_2O_3, ZrO_2, $LiAl_5O_8$, and $3Al_2O_3 \cdot 2SiO_2$ filaments.
5. Impregnation process ("relic fibers"):
   ZrO_2, Ta_2O_5, Al_2O_3, TiO_2, and BN filaments and webs.
6. Precursor conversion:
   cellulose, PAN filaments $\xrightarrow{\text{pyrolysis}}$ C filaments,
   B_2O_3 filaments $\xrightarrow{NH_3}$ BN filaments,
   C filaments $\xrightarrow{BCl_3/H_2}$ B_4C filaments.
7. Chemical vapor deposition on an existing filament:
   B/W, SiC/W, B_4C/W, TiB_2/W, B/SiO_2, and B/C filaments.
8. Wire bundle drawing process:
   Superalloys.
9. Taylor process:
   Fe, special alloy, and Al_2O_3 filaments.
10. Deposition from the gas phase:
    Fe and Fe-containing short fibers with a shell structure.

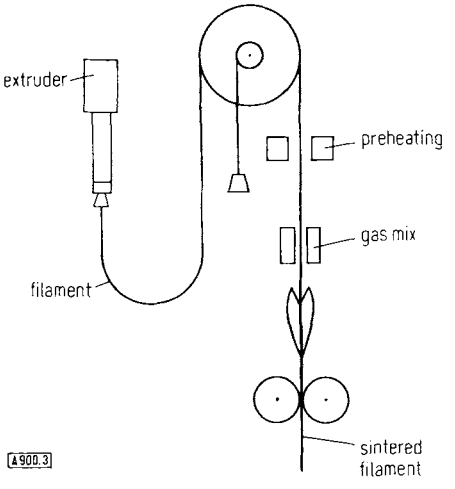

Fig. 3. Scheme of the extrusion process [7].

3. Spinning process with organic supports: Many inorganic substances, which exhibit no spinnability, cannot themselves be spun into fibers and require a spinnable organic support. For example, viscose rayon dope can be used for the production of fibers containing SiO_2; the viscose rayon dope is mixed with water glass, spun, and after coagulation of the rayon fibers in the acid precipitant bath, the products are heated in air to obtain SiO_2 fibers or in an inert atmosphere to obtain SiO_2 fibers containing carbon (Fig. 5). Under certain conditions, it has been found possible to convert the latter into β-SiC filaments without loss of flexibility by an *in-situ* reaction (Fig. 6)[8].

Fig. 4. Fracture surface of a flame-sintered Al_2O_3 filament produced by the extrusion process [7].

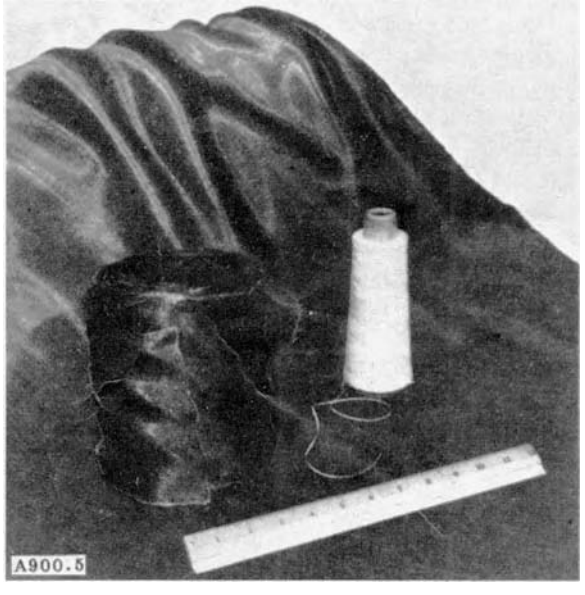

Fig. 5. SiO_2 and SiO_2/C filaments [8].

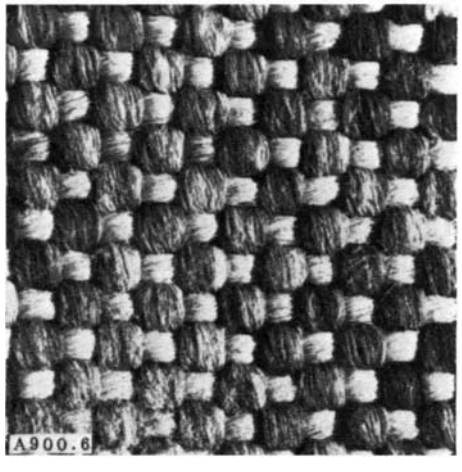

Fig. 6. SiC fiber web [8].

4. Some inorganic sols can be brought into a spinnable state by certain procedures. These sols are then suitable for the production of inorganic fibers by conventional spinning methods. The spun sol fibers are converted into gel fibers by drying in a spinning shaft, the volatile components are eliminated by heating, and the oxide skeleton is sintered. In this way, filaments with good mechanical properties in some cases have been obtained, examples being Al_2O_3, $LiAl_5O_8$, $MgAl_2O_4$, ThO_2, TiO_2, ZrO_2, and $3Al_2O_3 \cdot 2SiO_2$ (mullite) filaments[9].

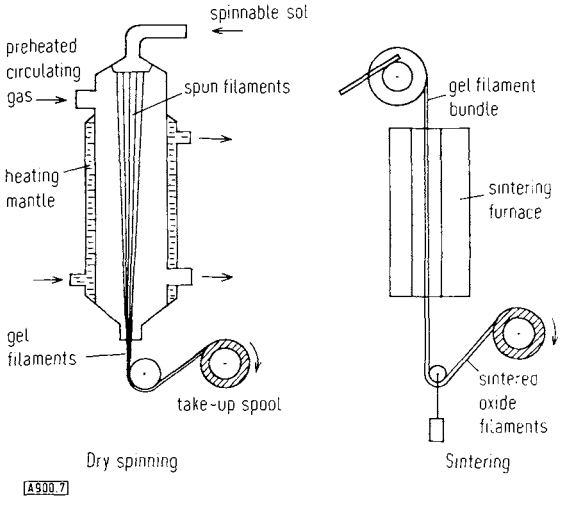

Fig. 7. Spinning of sols (schematic).

5. Relic fibers can be produced by a process developed by Union Carbide, in which single rayon filaments or entire webs are impregnated for a long time with inorganic salt solutions and then subjected to controlled pyrolysis and sintering, in the course of which the organic components are burnt off. Unlike in the similar process for the production of Welsbach gas mantles, where relatively brittle webs are produced, it was possible by this method to obtain

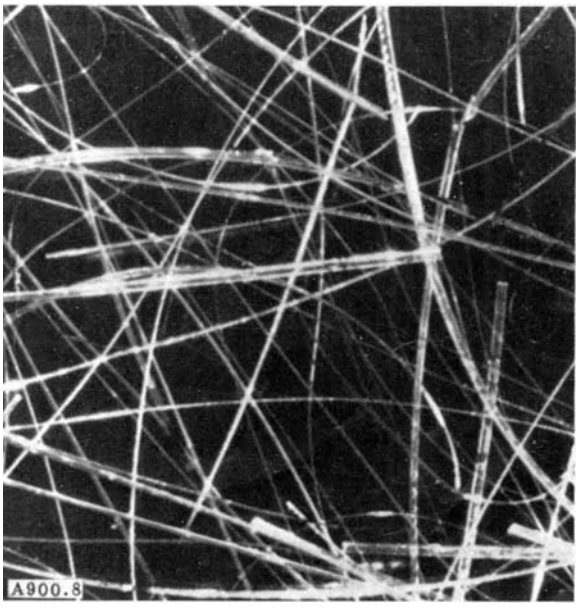

Fig. 8. ZrO_2 filaments, produced by the sol spinning process [5].

fibers and entire webs having useful tensile strengths. Single fibers of ZrO_2 also have useful properties for reinforcing purposes. BN fabrics are also reported to be obtainable in this way[10].

6. By precursor conversion, existing non-fusible organic filaments, which are usually obtained by conventional methods of the fiber-spinning industry, are transformed into carbon or graphite fibers, which are particularly interesting for reinforcing purposes. The source of carbon in this method is cellulose or polyacrylonitrile (PAN) fibers. The American process starts with cellulose fibers, which must be carbonized and stretched by up to 50% of their length at temperatures above 2400 °C in order to orient the graphite crystallites in the fiber direction, to give the fibers the high elastic modulus required for reinforcement. The British process (Fig. 9), which is superior, avoids this difficult step and begins with PAN fibers, which are first subjected to an oxidizing pretreatment below 300 °C, the shrinkage of the fibers (and this is the decisive step) being prevented by firm clamping so that preorientation in the direction of the fiber axis is provided for the graphite crystallites to be formed later. This is followed by a carbonization step at 1000 °C. For the production of graphite fibers with particularly high tensile strengths (type HT = high tensile) the fibers are then heated at 1600—2000 °C, while for the production of fibers with high moduli (type HM = high modulus) they are heated at 2600—2800 °C[11].

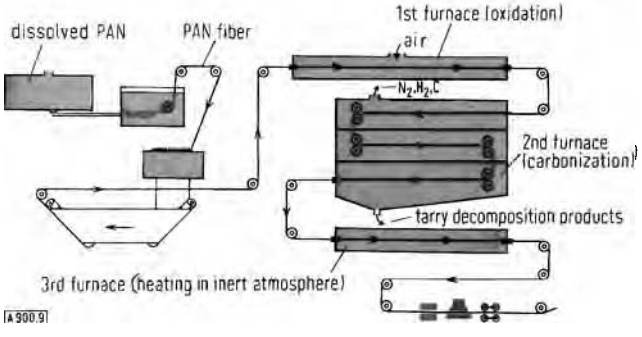

Fig. 9. Process for the production of carbon fibers (schematic) [11].

Numerous efforts have been made to replace the relatively expensive starting fibers rayon and PAN by cheaper materials. However, attempts to spin tar, pitch, lignin, *etc.* into fibers and to carbonize the fibers gave amorphous carbon fibers with low elastic moduli. Crystalline fibers with high elastic moduli were obtained only by the difficult and once again expensive step of graphitization under stress at 2600—2850 °C just below the breaking strength of the fibers[12].

BN filaments (Fig. 10) are produced by reaction of B_2O_3 filaments spun from the melt with NH_3. On reaction of B_2O_3 fibers having a diameter of about 10 μm at temperatures below the melting point of B_2O_3, complete conversion into BN can be achieved in this way. The fibers are stabilized by high-temperature treatment[13]. Carbon filaments can be converted into B_4C in a similar manner by reaction with a BCl_3/H_2 mixture.

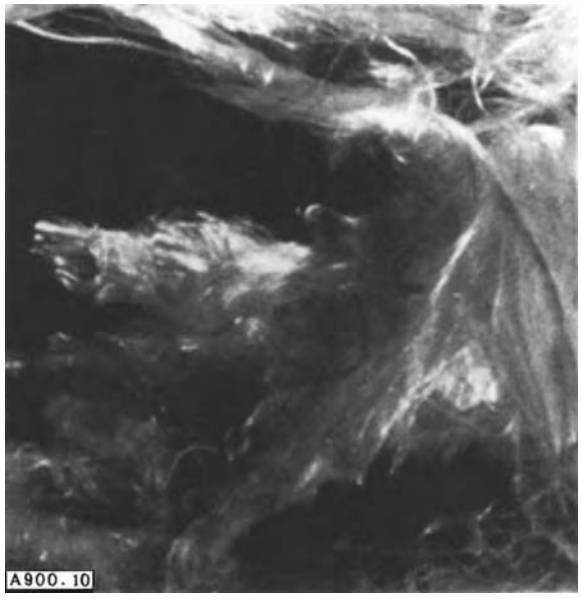

Fig. 10. BN fibers [5].

7. A number of filaments can be produced by chemical vapor deposition on heated tungsten wires approximately 15 μm in diameter at temperatures around 1200 °C. For the deposition of boron or of SiC, mixtures of BCl_3/H_2 or CH_3SiCl_3 are passed over the hot wire. Because of the high specific gravity of the tungsten core, the filament thickness must be built up to about 100 μm to obtain a filament having a low density. At this diameter, however, the filaments are very rigid and difficult to process. Similarly, this method (Fig. 11) can also be used for the production of B_4C and TiB_2 filaments, starting with $BCl_3/H_2/CH_4$ or $BCl_3/H_2/TiCl_4$ mixtures respectively. Attempts are also being made to replace the heavy tungsten core by a cheaper and lighter filamentary substrate. One step in this direction is the deposition of boron from B_2H_6 on carbon-coated, heated SiO_2 filaments or the deposition of boron on carbon filaments[14].

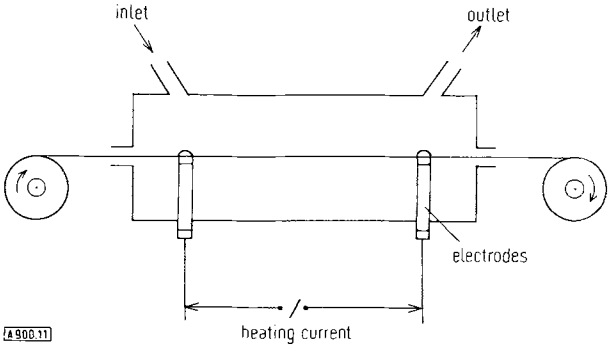

Fig. 11. Scheme of the chemical vapor deposition method [8].

8. For the production of metal filaments, methods have been developed that enable complete bundles of metal wires, which are either coated or embedded in a soft matrix, to be drawn through series of dies with decreasing diameters. A bundle of up to 100 wires made of superalloys, such as Chromel R or René 41, can be drawn in this way to a diameter of 12.7 μm[8].

9. Another process for the production of metallic microwires is the Taylor process, which was developed further *inter alia* by *Nixdorf* at the Battelle Institute. In this process, metals or alloys are melted in glass or quartz tubes and drawn out to extremely fine capillaries. The glass

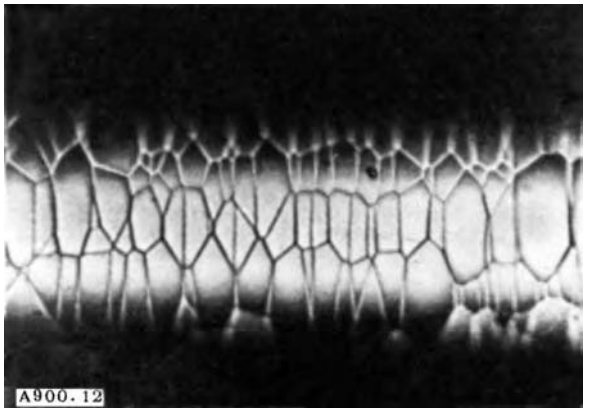

Fig. 12. Surface of a boron filament.

sheath can be removed by ultrasonic radiation, chemical etching, or mechanical crushing, and very fine metal filaments with high tensile strengths are obtained. Under certain conditions, filamentary single crystals can also be produced in this way. It is even possible to melt Al_2O_3 in a quartz tube, which is then drawn out to form a filament with an SiO_2 skin.

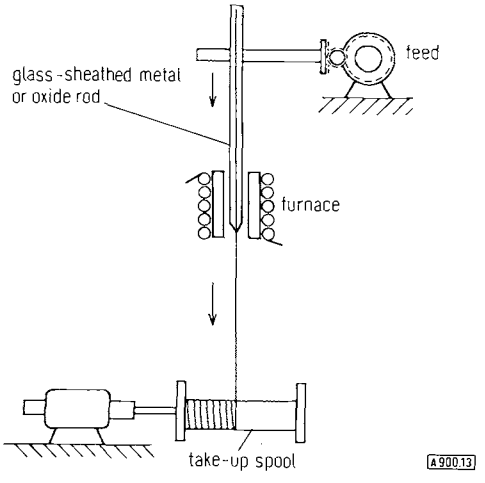

Fig. 13. Scheme of the Taylor process [15].

10. According to *Schladitz*, polycrystalline iron fibers having surprisingly high tensile strengths can be produced in the form of a felt by decomposition of pentacarbonyliron in a magnetic field. These short, polycrystalline metal fibers can be produced in many modifications, *e. g.* with a shell structure of various metals and non-metals. The process is reminiscent of the production of whiskers from the gas phase, but has the advantage of a much higher yields per unit time and volume[16].

The majority of the processes described can be carried out continuously and proceed with relatively high yields per unit time and volume, so that reasonable prices may be expected with mass production. Moreover, most of the filaments can be obtained in any desired lengths, so that the production of wound components or the parallel alignment of the fibers for components with anisotropic properties becomes much simpler than when whiskers are used. These advantages have gained a lead in development for polycrystalline inorganic fibers over whiskers, with which they cannot compete in many of their properties.

5. Properties

The properties of particular interest in polycrystalline inorganic fibers are their tensile strength, their elastic modulus, and the dependence of these properties on temperature, as well as their density and their thermal and chemical stability.

If one considers the tensile strength of compact ceramic bodies and compares this with the values calculated from the bond strengths, one finds that the strengths attained in practice are often two to three orders of magnitude lower than the theoretical values. To this fact, which has been known for a long time as the "crystal paradox", is added another remarkable observation, *i. e.* that macro single crystals of many substances have a lower mechanical strength than polycrystalline bodies of the same material. In the course of time, the search for an explanation of these phenomena produced many findings that have been of the utmost importance to the production of high-tensile polycrystalline inorganic fibers with high elastic moduli, and that have contributed in general to our understanding of the mechanical properties of solids.

One of the first attempts to calculate the theoretical strength of ionic crystals was made by *Polanyi* in 1921[17]. His formula for the calculation of the maximum tensile strength σ_{max}:

$$\sigma_{max} = \sqrt{\frac{4E\gamma}{L_0}} \qquad (1)$$

γ = surface energy,
E = elastic modulus,
L_0 = elongation necessary to cause fracture

was later modified by various workers, and can be expressed in its simplest form by eq. (2).

$$\sigma_{max} \approx \frac{E}{10} \qquad (2)$$

The strengths found from this formula (*e.g.* a value of approximately 4000 kp/mm^2 as the tensile strength of α-Al_2O_3) are not even approached in practice (cf. Table 1). An explanation for this is provided by *Griffith*'s fracture theory[18]. When a tensile stress is applied to a body, the externally acting force is not uniformly distributed in the interior, but gives stress concentrations at flaws in the

crystal structure, *e.g.* at a notch. At the tip of a notch, a stress σ_k of

$$\sigma_k = 2\sigma\sqrt{\frac{C}{r}} \tag{3}$$

σ = overall applied stress,
σ_k = stress at the notch tip,
C = half the length of an internal crack or depth of a surface crack,
r = radius of curvature at the notch tip

is reached. The greater C and the smaller r, the more easily will the tensile stress σ_k reach or exceed the theoretical strength value, whereupon breakage will occur in the case of a single crystal. For a polycrystalline body, however, the fracture of one crystallite does not necessarily lead to breakage of the entire body. The break will certainly extend over the entire crystallite, but it is fairly difficult for a growing crack to pass over into the differently oriented neighboring crystallites, and the fracture process consequently stops here. It is thus clear that the strength of polycrystalline bodies is partly dependent on the crystallite size; this is expressed in eq. (4).

$$\sigma = k \times K^{-a} \tag{4}$$

K = crystallite size,
k, a = empirical constants

High tensile strengths are therefore obtainable in polycrystalline bodies only if the crystallites are very small and if the surface is practically perfect and free from notches. The crystallite sizes of polycrystalline inorganic fibers are mostly less than 300 Å, and often even less that 100 Å.

The pores in the structure of a polycrystalline body have an effect similar to that of notches and cracks. They considerably reduce the tensile strength; this is expressed quantitatively by

$$\sigma = \sigma_0 \, x e^{-bP} \tag{5}$$

σ_0 = tensile strength at $P = 0$,
P = porosity,
b = empirical constant.

Whereas no clear dependence exists between the crystallite size and the elastic modulus, pores also considerably decrease the elastic modulus.

$$\sigma = k \times K^{-a} \times e^{-bP} \tag{6}$$

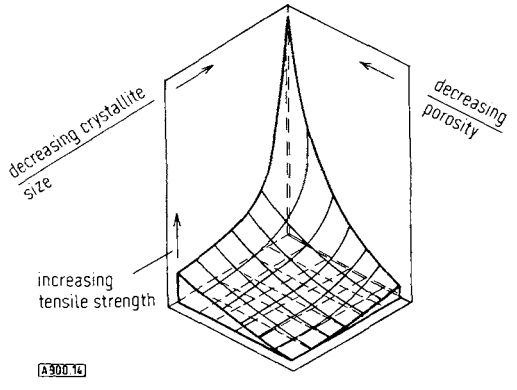

Fig. 14. Tensile strength as a function of crystallite size and porosity [19].

The combined influence of crystallite size and porosity on the strength of a polycrystalline inorganic body can be expressed, according to *Knudsen*, by eq. (6)[19], and is represented graphically in Figure 14.

However, this by no means completes the description of the factors affecting the strength of polycrystalline inorganic fibers. In the discussion of the *Griffith*'s fracture theory, mention was made of flaws in the crystal structure. According to *Seeger*, these defects can be divided into three groups:

1. Zero-dimensional defects *e. g.* lattice vacancies, interstitial atoms, atoms in incorrect lattice sites, foreign atoms.

2. One-dimensional defects (flaws that extend along open or closed lines in the crystal), *e. g.* dislocations (Figure 15) or acicular precipitations.

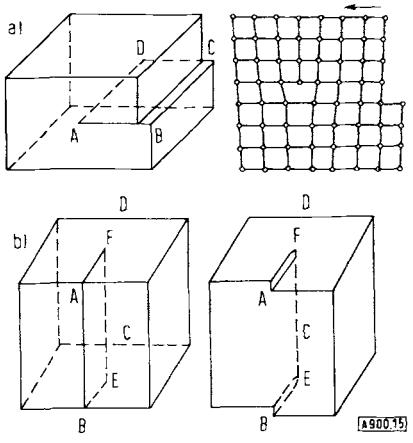

Fig. 15. Scheme of a) edge and b) screw dislocations [20].

3. Two-dimensional defects, *e.g.* grain boundaries or twin boundaries.

The structure of a real crystal, with its vacancies, foreign atoms, dislocations, *etc.*, is reproduced very vividly by a two-dimensional soap bubble model (Fig. 16)[20].

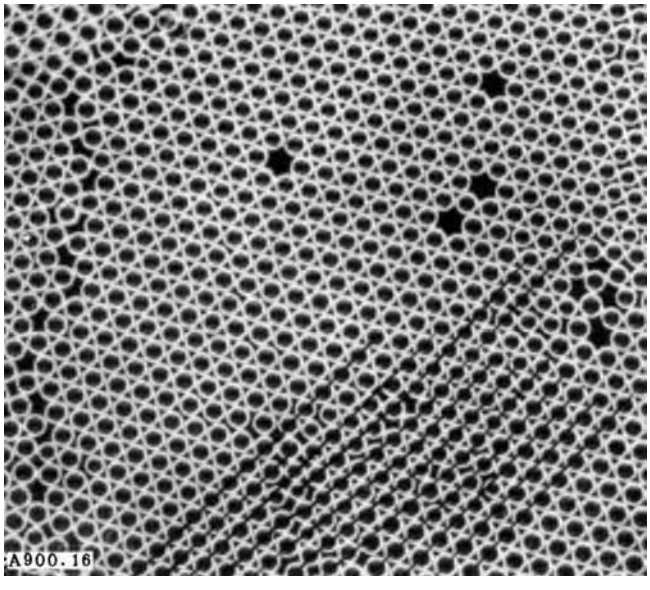

Fig. 16. Soap-bubble model of the defects in a crystal [20].

The dislocations are defects in the crystal lattice that begin to migrate under a tensile stress, and that can thus lead to slip processes and hence also to fracture. There are two fundamental ways of preventing this. Either one tries to produce bodies that are totally free from dislocations, or one tries to inhibit the movement of the dislocations.

The first method is used in the production of whiskers, where an effort is made to produce practically dislocation-free single crystals. The second method is the only one that can be used in the case of polycrystalline inorganic fibers. Several alternatives are available. Dislocations may be anchored by strong lattice distortions such as those resulting from vacancies or foreign atoms in lattice or interstitial sites. The number of dislocations also influences their mobility. Thus the dislocation density can be increased to such a degree by quenching heated bodies (freezing the flaws) or by cold deformation of metals that the dislocations anchor one another and their mobility is thus reduced.

It has already been mentioned that crystallite boundaries present obstacles to the propagation of cracks and to the migration of dislocations. The smaller the crystallite, the smaller is the length of the dislocation source to be activated, and the greater is the work required to set the dislocation in motion. Finely dispersed precipitates of a foreign substance, which can prevent the passage of a dislocation line when separated by certain distances, also present obstacles to dislocations[21].

Attempts are being made, with greater or lesser success, to bring these mechanisms into play in polycrystalline inorganic fibers. As can be seen in Table 3, the transition from the compact material to the fiber with high surface and internal perfection, taking into account the relationships discussed above, is accompanied by a considerable increase in strength. An impressive practical example for which many of these theoretical considerations have been confirmed is provided by the polycrystalline Fe fibers produced by *Schladitz* by decomposition of pentacarbonyliron in a magnetic field. These fibers contain crystallites having a size of 80 Å, and have a dislocation density of 1.5×10^{12} dislocation per cm^2, compared with about 10^6—10^8 in pure iron. The formation of the ideal lattice is suppressed by precipitation of Fe_3C crystallites at short distances from one another, and the dislocations are anchored by precipitation of 1.2% of carbon in interstitial sites. The fibers have tensile strengths of up to 700 to 800 kp/mm^2, *i.e.* approximately 60% of the tensile strength of good iron whiskers ($\approx$ 1300 kp/mm^2)[16].

Table 3. Comparison of mechanical properties of compact and fibrous materials [2,3].

	Compact material		Fiber	
	σ [kp/mm^2]	E [kp/mm^2]	σ [kp/mm^2]	E [kp/mm^2]

For comparison organic synthetic fibers		1.1—1.5	10—125	200—1500		

Table 4 shows a survey of the tensile strengths and elastic moduli obtained with polycrystalline inorganic fibers in comparison with those of other fibers. It can be seen that polycrystalline inorganic fibers have extraordinarily high tensile strengths, which are superior even to those of organic fibers and glass fibers, and are exceeded only by those of whiskers. They normally also exhibit the high elastic moduli found for the corresponding compact ceramic materials. In this respect, they are only slightly inferior to

whiskers. Fine metal filaments also stand comparison in this respect; however, with the exception of Be, when one considers the specific tensile strengths and specific moduli, they immediately lose ground because of their high specific gravity. These specific values, however, are decisive for use in light structural components, *e. g.* for aircraft and space applications.

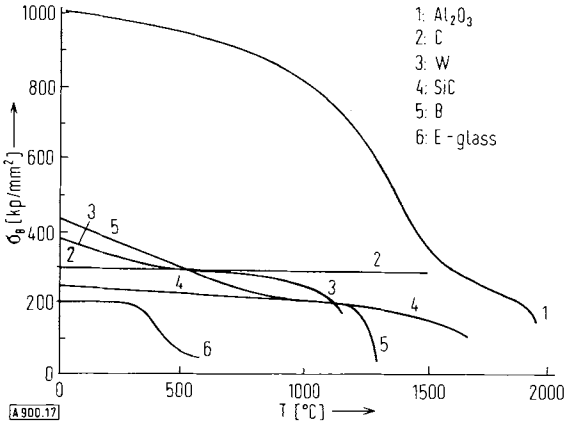

Fig. 17. Temperature dependence of the tensile strength of inorganic fibers [4]. Al_2O_3 as whiskers, all others as endless fibers.

Polycrystalline inorganic fibers naturally have extremely high melting points. However, this does not mean that they can be used up to these temperatures. Recrystallization at temperatures far below the melting point may lead to structural changes that drastically impair the mechanical properties. Moreover, the strength values decrease at higher temperatures because of the greater ease with which creep and slip processes occur.

Nevertheless, polycrystalline inorganic fibers are the strongest materials known at these temperatures, apart from whiskers. As can be seen from Figure 17, for example, graphite fibers still have a greater strength at 1500 °C than steel at room temperature.

6. Applications

The materials in common use can be roughly divided into three groups according to their properties (cf. Table 1). Materials of group I, which include, *e.g.* synthetic resins, are thermally unstable, easy to process, light, tough, impact-resistant materials having low strengths. Because of their low elastic modulus, they have little rigidity, and consequently cannot be used for the production of large load-bearing structural components. The ceramic materials of group II, *e.g.* Al_2O_3 or SiC, are relatively light and thermally stable, have very high elastic moduli and are therefore very rigid, but they are also very brittle and sensitive to impact, and have low strengths. They are also unsuitable for use alone as construction materials. The third group of materials, which within certain limits combines in itself the desirable properties of the other two groups (rigidity, strength, toughness, thermal stability), are the solid metals; however, these have the important disadvantage that, with few exceptions, they are too heavy.

The ideal situation would be achieved if the positive properties of groups I and II could be combined. This can be achieved in a composite material, in which fibers of a material from group II are embedded in a matrix of a material from group I; it is necessary to ensure good adhesion between the fiber and the matrix and good transfer of force. As will be shown later, however, other combinations are also possible.

The strengthening and stiffening mechanism that can act in such fiber-reinforced materials can be seen from the stress-strain diagram (Fig. 18). If a fiber-reinforced material with good adhesion between the fiber and the matrix is subjected to an elongation *a* by application of a tensile stress, the fiber with the high elastic modulus will bear most of the load (σ_f), while the matrix, because of its low elastic modulus, will bear the smaller share (σ_m); the function of the latter is to hold the fibers together and to transfer the tensile stress to the fibers. This combination principle has been followed in nature since the earliest times, examples being the strength and rigidity of bone material or of bamboo cane.

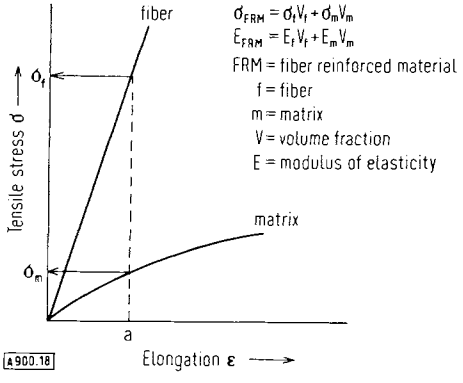

Fig. 18. Stress distribution in a fiber-reinforced material.

In the ideal case, the tensile strength of a fiber-reinforced material (FRM) σ_{FRM} is made up additively from the products of the tensile strength of the fiber σ_f and its volume fraction V_f on the one hand and the tensile strength of the matrix σ_m and its volume fraction V_m on the other. The same is true of the elastic modulus, and hence of the rigidity of the reinforced material.

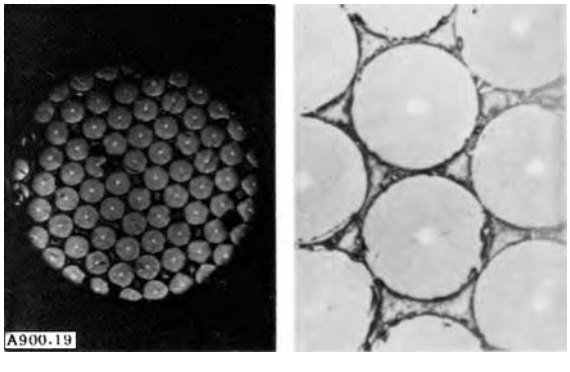

Fig. 19. Cross section through a boron-fiber reinforced material.

The most common case is the reinforcement and stiffening of synthetic resins. As can be seen from Table 5, it is possible in this way to obtain materials whose strength and rigidity is similar to that of steel, but which are lighter by a factor of four to five.

Despite the steady improvement of the heat resistance of synthetic resins, full use cannot be made of the outstanding high-temperature properties of polycrystalline inorganic fibers with synthetic resins as the matrix materials. As is shown by the example B/polyimide, the medium-temperature range is attainable, but metallic matrices will play a part in future for the high-temperature range. The metals offer higher heat resistance, higher elastic moduli, and in some cases toughness and hardness, as valuable properties in fiber-reinforced materials.

Table 5. Mechanical properties of fiber-reinforced materials [4].

Composite	Fiber content [vol.-%]	Density [g/cm³]	σ_B [kp/mm²]	E [kp/mm²]	Remarks
C/epoxy	59	1.5	140	14000	
B/epoxy	55	2.1	145	21000	
B/polyimide	69	2.1	200	24000	— tensile strength at 315 °C 130 kp/mm²
B/Al	50	2.7	125	24000	— tensile strength at 500 °C 70 kp/mm²
For comparison:					
Epoxy resin	0	1.2	10	300	
Aluminum	0	2.7	10	7000	
Building steel	0	7.8	50	21000	

Polycrystalline inorganic fibers above all improve the tensile strength at higher temperatures and reduce the density of the metals, with the result that the specific properties are improved. It is clear that such materials will find use wherever great strength is required at high temperatures, as in pressure vessels, in reactor engineering, and above all where weight saving is important, *i.e.* in aerospace technology where resistance to high temperatures is necessary. As can be seen from Figure 20, *e.g.* aluminum reinforced with boron fibers has a strength at 500 °C similar to that of steel at room temperature.

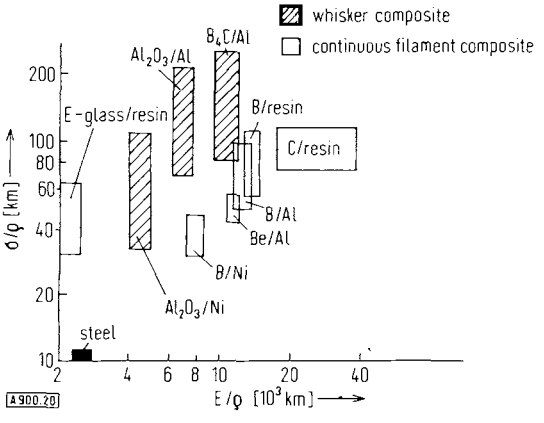

Fig. 20. Specific properties of various composite materials [4].

It is mentioned only to complete the picture that fiber reinforcement of ceramic materials is also possible, and can lead to improved properties. This field of application is still in its infancy, but amazing properties have already been obtained, *e.g.* in the reinforcement of glass with carbon fibers.

In addition to mechanical reinforcement, another important application of inorganic fibers is thermal insulation at high temperatures. However, since extreme mechanical properties are less important here than resistance to high temperatures, low thermal conductivity, resistance to thermal shock, and low embrittlement, this field is dominated not by polycrystalline inorganic fibers but by the amorphous SiO_2 and alumina silica fibers.

Certain polycrystalline inorganic fibers have special fields of application. The steel filaments produced by Monsanto by melt spinning are intended for tire cord. Fabrics made from polycrystalline oxide filaments can be used as filters for hot corrosive gases, liquids, or molten metals. BN fibers, for example, are suitable for electrical insulation at high temperatures; these fibers are also unaffected by boiling alkalis and acids or by molten Fe or Al, and even withstand an atmosphere of chlorine at 700 °C.

Synthetic resins reinforced with polycrystalline inorganic fibers may be expected in the future to find a spectrum of application similar in breadth to that existing at present for glass-fiber reinforced plastics. The former class of composite materials currently seems particularly attractive in aircraft and space applications, since they allow a reduction of weight without loss of strength and rigidity, and hence greater ranges and lower fuel consumptions. However, the weight saving is economically justifiable only if the cost does not exceed a certain limit. This limit is around \$ 60 per kg of weight saved for conventional light aircraft, and around \$ 600 for supersonic aircraft. The cost of saving 1 kg of structural weight by the use of *e.g.* carbon-fiber reinforced materials is at present between \$ 350 and \$ 1900. By 1975, these costs should have fallen to approximately \$ 90 to \$ 500. A considerable saving would thus be possible in particular for supersonic aircraft[22]. For the near future, the addition of small proportions of polycrystalline inorganic fibers to glass-fiber reinforced plastics may be expected; in this way, their rigidity and their fracture energy can be increased, so that they are better suited to the construction of tanks, silos, pipelines, vehicles, containers, *etc.* Other applications of polycrystalline inorganic fibers will become interesting as prices fall. Conceivable applications include lighter bridges with higher carrying capacities and load-bearing structural components in tall buildings in construction engineering, underwater buildings in the exploitation of the sea, rigid but lighter, corrosion-resistant structural components in shipbuilding and boatbuilding, and corrosion-resistant pressure vessels, tanks, and reactors in chemistry and in reactor engineering. The applications that have already been successful in sports (fiber reinforced components in racing cars, racing canoes, yacht masts, *etc.*) are likely to be extended to skis, boat hulls, golf

clubs, *etc.* In the opinion of many experts we are entering an "age of inorganic fibers".

Cathodic Dimerization[**]

By Fritz Beck[*]

The technical, electrochemical, and preparative aspects of cathodic dimerization, which leads to bifunctional compounds, are reviewed. With the hydrodimerization of acrylonitrile as an example, the effects of the reaction parameters and the mechanism are discussed in detail. In addition to the hydrodimerization of activated compounds, the coupling can also proceed *via* elimination of halide or *via* the discharge of cations. Processes of special preparative interest are those in which two different molecules are coupled, which can yield *e.g.* esters, alcohols, or ketones with cyano groups, as well as asymmetric diols. The reductive dimerizations of acrylonitrile, β-chloropropionitrile, acetone, acetylpyridine, nitrobenzene (→ benzidine), and pyridinium salts have already found industrial use.

1. Introduction

The field of cathodic dimerization has developed particularly rapidly in recent years. This is no accident, since this area of organic electrosynthesis involves aspects of great preparative, technical, and mechanistic interest. The object of this progress report is to present a comprehensive survey, with special emphasis on industrial and electrochemical possibilities. Only recently, *Baizer* (together with *Petrowitsch*), who played an extremely important part in the development of the field, published a brilliant survey of the synthetic and mechanical aspects[1]. This topic is also discussed at length in a recent review on organic electrosynthesis[2]. Overlapping with these publications cannot be entirely avoided, but will be kept to a minimum.

In cathodic dimerization, the organic molecule takes up an electron directly at the electrode. It thus passes through the intermediate stage of a radical-ion. The negative charge is compensated in accordance with Scheme 1 by uptake of protons ("hydrodimerization"), by elimination of halide ions, or by the positive charge on the substrate when the latter is a cation. Each of these cases can in principle be further subdivided into the dimerization of two identical molecules, which yields a symmetrical product, the coupling of two different molecules, and intramolecular reactions leading to cyclic products.

If the monomer contains one or more functional groups, bifunctional or polyfunctional dimers are formed. Cathodic dimerization is therefore a valuable method for the synthesis of such compounds. Since only one electron is taken up per monomer in every case, the energy consumption is comparatively low. This is extremely favorable in industrial uses.

The formation of a symmetrical dimer is only one of several possible reactions. In principle, the molecule could also be

[**] Based, in part, on a lecture at the 1st EUCHEM Conference on Organic Electrochemistry at Ronneby Brunn, Sweden, on June 9, 1971.

hydrogenated (possibly in several stages), add on an acceptor molecule instead of the second substrate molecule, form oligomers by addition of a third molecule, a fourth *etc.*, or finally form organometallic compounds with the cathode metal. The fact that cathodic dimerization nevertheless often occurs, with extremely high yields in many cases, shows that this reaction is often favored in electrochemistry. An article by *Knunyants* and *Gambarian*[3] on hydrodimerization clearly shows that electrochemical reduction (or the equivalent reduction with Na amalgam, Zn/glacial acetic acid, or the like) generally leads to hydrodimers,

$2X + 2H^{\oplus} + 2\ominus \longrightarrow HX{-}XH$
hydrodimerization of two molecules of the same type

$X + X' + 2H^{\oplus} + 2\ominus \longrightarrow HX{-}X'H$
hydrodimerization of two different molecules

$X{-}X' + 2H^{\oplus} + 2\ominus \longrightarrow HX{-}X'H$
cyclizing hydrodimerization

$2X\text{-Hal} - 2Hal^{\ominus} + 2\ominus \longrightarrow X{-}X$
dimerization with elimination of halogen

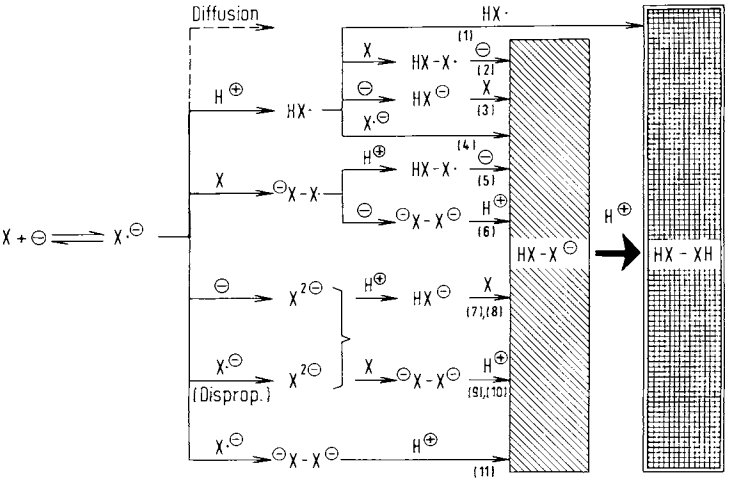
$2X^{\oplus} + 2\ominus \longrightarrow X{-}X$
dimerization of cations

Scheme 1. Survey of cathodic dimerization. (Strictly speaking the second and third variants are not dimerizations.)

whereas catalytic hydrogenation yields such products only in exceptional cases. This may be connected with the strong adsorption of the intermediate products on the catalyst surface, which is unfavorable for the dimerization step. In the electrochemical method, on the other hand, the intermediate products generally interact only weakly with cathodes having high hydrogen overvoltages (exceptions: formation of organolead, organomercury, or organozinc compounds).

2. General Mechanistic Considerations

What intermediates are involved in cathodic hydrodimerization? Scheme 2 shows all the possibilities that are found on application of the following conditions:



a) The primary step is the transfer of an electron to the substrate X with formation of the radical-anion. This reaction is reversible in most cases; surprisingly high exchange current densities are found for this primary process, *e. g.* for aromatic compounds[4]. In exceptional cases, this primary electron transfer may be preceded by a chemical reaction, such as the protonation in strongly acidic solution that has been proposed for ketones[5,6] or for acrylonitrile[7] The unusual increase in basicity is attributed to a field effect[8].

b) The second protonation can occur only *after* the dimerization step, since the hydrogenated monomer would otherwise result.

c) A total of two electrons and two protons is taken up.

The initially formed radical-anion, in (rare) cases in which its stability is high, will diffuse in part into the interior of the solution, where it can be detected *e. g.* by ESR spectroscopy[9]. In general, however, it will react where it is formed, *i. e.* in the electrochemical double layer in front of the electrode. In this case, it reacts in a strong electric field ($\approx 10^7$ V/cm); the subsequent reactions are therefore generally different from those of the same radical-ion formed, *e. g.* by a homogeneous redox process. However, it should be noted that the electric field strengths in the atomic range, *e. g.* in the vicinity of a (small) ion or a dipole, could quite easily be of the order of magnitude mentioned above.

According to Scheme 2, the second reaction step (proceeding toward the hydrodimer) may be the uptake of a proton or combination with a second substrate molecule, *i. e.* the radical-*anion* reacts as a nucleophile. The *free-radical* nature of the primary product becomes evident in the uptake of a second electron or in the (electrostatically improbable) reaction with a second radical anion, which

Scheme 2. Reaction paths in cathodic dimerization. For the figures under the reaction arrows see also Scheme 3.

can also lead to disproportionation. The possibility that the free-radical function directly causes the abstraction of a hydrogen atom, *e. g.* from the solvent, is not shown in Scheme 2.

The secondary intermediates formed can react further as shown in Scheme 2. The intermediate product HX· (or $HX^{\ominus}$) cannot *e. g.* be protonated since this would be contrary to rule b). The intermediate product $^{\ominus}X{-}X^{\ominus}$ or $^{\ominus}X{-}X\cdot$ cannot take up further monomer, and the intermediate $X^{2\ominus}$ has already taken up both possible electrons.

In this way one obtains eleven reaction paths to the hydrodimer, which are summarized once again in abbreviated form in Scheme 3 (in the same order as in Scheme 2). (The actual dimerization step in practically every case is the formation of a C—C bond.) It can be seen that the first reaction step, as required (rule a), is an electron transfer, and the last [except in case (1)] is a protonation; in (1), (4), and (11), the dimerization follows a free-radical course. For electrostatic reasons all mechanisms involving doubly negatively charged dimeric and particularly monomeric

particles are relatively unlikely [(6)–(11)]. Of the remaining first five possibilities (1) and (4) are free-radical, (3) and (5) are ionic, and in (2) the monomer reacts with a free radical. (1) occurs *e. g.* in the hydrodimerization of ketones, and (3)

or (5) in the hydrodimerization of activated olefins. According to *Bard*[272], however, two radical-ions dimerize to give the dimeric dianion in the case of dimethyl fumarate.

3. The Cathodic Hydrodimerization of Acrylonitrile

3.1. Industrial Importance

The cathodic dimerization of acrylonitrile (AN) leads directly in one step to adiponitrile (ADN), which is an important intermediate for 6,6 nylon. The fact that the monomer could be obtained relatively cheaply by a new petrochemical process (Sohio process = ammonoxidation of propylene) drew the attention of the polyamide manufacturers to this electrochemical process about a decade ago. This process had the fundamental advantage that it requires one step less than the conventional industrial syntheses.

cyclohexane $\xrightarrow{O_2}$ cyclohexanol $\xrightarrow{HNO_3}$ adipic acid $\xrightarrow{NH_3}$ ADN

butadiene $\xrightarrow{Cl_2}$ 1,4-dichloro-2-butene $\xrightarrow[-NaCl]{NaCN}$ 1,4-dicyano-2-butene $\xrightarrow{H_2}$ ADN

The hydrodimerization carried out by *Knunyants*[10–12] in the 1950's with Na amalgam initially gave the desired product in a material yield of only 65% and in an amalgam yield of 35%. It was the work of *Baizer* at Monsanto[13–15], who was able to obtain almost quantitative material and current yields, that gave the decisive thrust that led to the construction of an industrial plant at Monsanto. The outstanding purity of the product was a strong argument in favor of the polyamide synthesis. Another advantage was the absence of stoichiometric by-products.

This development helped to bring about an unexpected renaissance in the field of organic electrochemistry, which appeared even around the turn of the century[16,17] to be on the way to becoming an established chemical reaction technique. The earlier view that the use of organic electrosynthesis in industry was to be expected at most for valuable products on a fairly small scale had thus turned out to be wrong. An early review on the hydrodimerization of acrylonitrile was published by *Tomilov et al.*[18].

3.2. Electrolysis Conditions

The choice of the optimum electrolysis conditions will be discussed for the case of acrylonitrile, since data on this reaction is particularly abundant because of its technical importance, and since these considerations can be applied to the hydrodimerization of other compounds. The problem is to optimize the numerous important parameters for the electrosynthesis so that under acceptable industrial conditions of temperature, pressure, *etc.*, the desired reaction

$$\underset{\text{AN}}{2CH_2{=}CH{-}CN} + 2H_2O + 2\ominus \longrightarrow \underset{\text{ADN}}{NC(CH_2)_4CN} + 2OH^{\ominus} \quad (12)$$

clearly predominates over electrochemical side reactions such as

$$CH_2{=}CH{-}CN + 2H^{\oplus} + 2\ominus \longrightarrow CH_3{-}CH_2{-}CN \quad (13)$$

$$2H^{\oplus} + 2\ominus \longrightarrow H_2 \quad (14)$$

$$n\,CH_2{=}CH{-}CN + H_2O + 2\ominus \longrightarrow \text{oligomers} \quad (15)$$

$$2CH_2{=}CH{-}CN + 2H^{\oplus} + 2\ominus + Sn \longrightarrow Sn(CH_2CH_2CN)_2 \quad (16)$$

and chemical side reactions such as the hydrolysis of the nitrile group (in acidic media), cyanoethylation of water to form β-hydroxypropionitrile and β,β'-dicyanoethyl ether (in alkaline media), and free radial initiated polymerization.

3.2.1. Cathode Material

Figure 1 shows the polarographic current-voltage curve of acrylonitrile in aqueous solution. The half-wave potential is strongly negative (−1.96 V against the saturated calomel electrode). This has two immediate consequences. Cathodes with high hydrogen overvoltages are required to suppress the simultaneous liberation of hydrogen in accordance with reaction (14). Furthermore, the discharge potential of the cation of the carrier electrolyte must be as negative as possible. Quaternary ammonium salts satisfy this condition, as has been known for some time from polarography. Mercury and above all lead have proved to be excellent cathode metals. Cadmium is unsuitable, since it is attacked with formation of bis(cyanoethyl)-cadmium[19]. Carbon is also a good cathode material, which differs in important respects from Pb and Hg (see below). The hydrodimer is formed even on platinum, though in poor yields[20]. This is probably due to substantial inhibition of (14) by adsorbed organic products.

3.2.2. Acrylonitrile Concentration

The number of electrons found from the wave height of the polarographic current-voltage curve (Fig. 1) with the aid of the Ilkovič equation is 2. At low acrylonitrile concentrations, therefore, only propionitrile is formed. *Baizer*

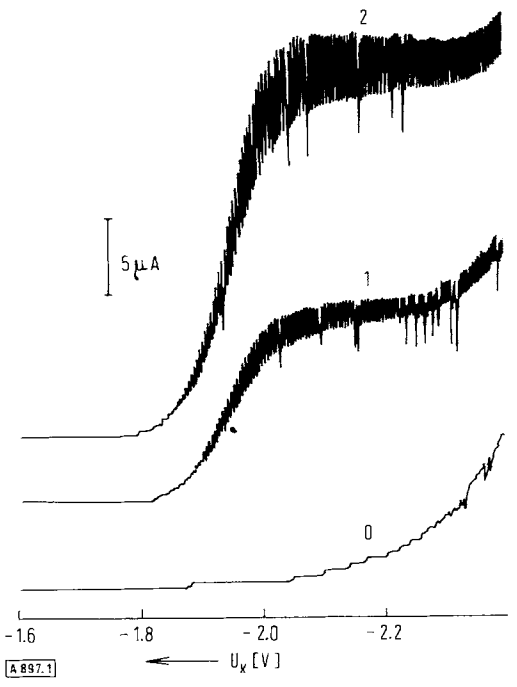

Fig. 1. Polarographic current-voltage curves of acrylonitrile in the presence of 0.1 mol/l of tetramethylammonium chloride. The numbers by the curves indicate the content of acrylonitrile (in mmol/l). For conditions see text.

emphasized in his first reports that ADN is formed in high yields only if the acrylonitrile concentration is higher than 10%[13,15]. The yield of ADN was almost quantitative at an initial AN concentration of 20%, but decreased to 7% with 10% AN and to 2% with 5% AN. At the same time, the yield of propionitrile increased. The reaction mixture also contained a high concentration of quaternary ammonium salt and water. The cathode consisted of mercury.

We have reacted mixtures of 28% of isopropanol, 16% of water, 1% of tetraethylammonium ethyl sulfate,

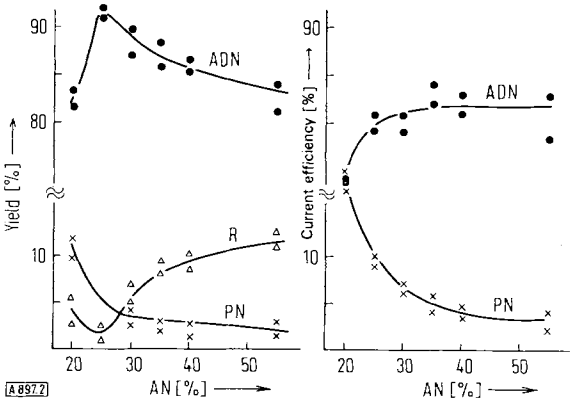

Fig. 2. Dependence of the yield on the acrylonitrile concentration. PN = propionitrile, R = oligomer. For conditions see text.

remainder AN + acetonitrile on graphite cathodes in undivided cells (cf. Fig. 10)[21]. As can be seen from Figure 2, the AN concentration has a strong influence on the ADN yield. An optimum is found for an initial AN concentration of 25 wt.% (the formation of oligomer R has decreased to a minimum). At lower AN concentrations, as in *Baizer*'s experiments, the yield decreases because of the formation of increasing quantities of propionitrile PN. The current yield shows a corresponding decrease[22].

The decrease in the formation of ADN at low monomer concentrations is reasonable in itself. The point beyond which an appreciable decrease occurs depends on the reaction conditions. *Tomilov et al.*[23] obtained high yields of ADN on an Hg cathode at AN concentrations as low as about 2.5% when the ratio of water to dimethylformamide in the reaction mixture was adjusted to an optimum value. It was also shown later[24,25] that high yields of ADN are obtained on lead cathodes in 2 to 5% solutions of acrylonitrile in the presence of *non*-lyotropic carrier salts such as tetramethylammonium sulfate. These carrier salts reduce the solubility of acrylonitrile in water, which is around 7% (at 25°C), by the salting-out effect.

These observations can be best explained if one considers that the solution compositions in the bulk of the electrolyte and at the interface are quite different. Salt effects in particular play an important part here, as is shown in Section 3.2.8.

3.2.3. Current Density

The current density plays a minor part in the hydrodimerization of acrylonitrile. Thus constant yields of ADN were observed in the range between 1 and 30 A/dm²[26] and even in the range between 14 and 128 A/dm²[27]. This suggests that the reaction does not have a free-radical mechanism, in which the yields should decrease greatly at low current densities. Since hydrogenation and hydrodimerization cannot be distinguished in the current-voltage curve in the case of acrylonitrile (both processes have the same rate-determining step), there is no prospect of increasing the selectivity by electrolysis at a constant potential (or indirectly with the aid of the current density). To obtain a good space-time yield in industry, one should not use excessively low current densities[28].

3.2.4. Water Concentration

If the water concentration is too high, the formation of proprionitrile increases, while at excessively low water concentrations, the oligomerization[29,30] becomes very pronounced. Figure 3 shows some examples for Hg cathodes from the literature[23,31], together with our own results (obtained on vibrating lead mesh cathodes, cf.[27,32]). It can be seen that the optimum water concentration depends on the AN concentration, and increases with the latter. The nature of the second solvent, on the other hand, is of minor importance.

3.2.5. pH

The pH should have a considerable influence on the yield of ADN, since excessively low pH values lead to propionitrile formation and liberation of hydrogen at the cathode, as well as to hydrolysis of the nitrile group, while excessively high pH values lead to cyanoethylation. It is therefore recommended in the first Monsanto patents that weakly alkaline solutions should be used.

It can be seen from Figure 4, in fact, that the ADN yield at an Hg cathode greatly decreases even in the weakly acidic range[13]. The situation changes when a graphite cathode

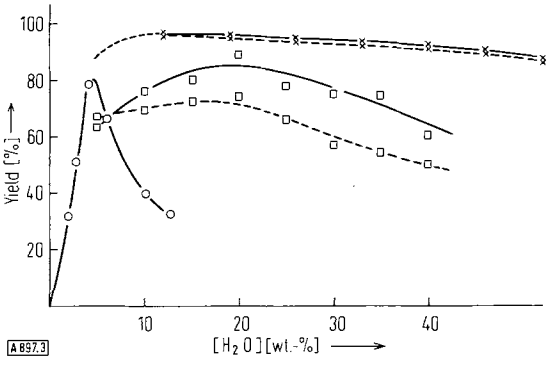

Fig. 3. Dependence of the ADN yield on the water concentration. (——) material yield, (----) current efficiency. Conditions:

	○ [23]	× [31]	□
AN [%]	≈ 3	15	50
NR_4X [%]	≈19	33	1
Auxiliary solvent	Dimethyl-formamide	Acetonitrile	Isopropanol
j [A/dm²]	1	30	20

is used, practically no change in yield being observed in this case over a wide pH range down to pH 1[22]. In conjunction with a "wick cell", electrolysis is possible even in up to 5.5 M H_2SO_4[33]. It is also possible to work at pH values above 14 if the cyanoethylation is sufficiently retarded by cooling to 0 °C[34].

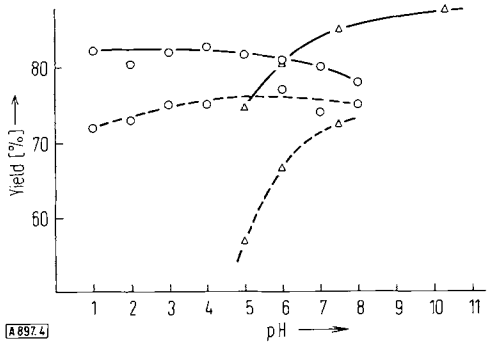

Fig. 4. Dependence of the ADN yield on the pH. (——): material yield, (---) current efficiency. Conditions: (△) 40% AN, 26% H_2O, 34% NR_4X, mercury cathode. (○) 55% AN, 16% H_2O, 28% isopropanol, 1% NR_4X, graphite cathode.

We now know that the pH can no longer be regarded as critical in this electrosynthesis. During optimization, it should be noted that a pronounced increase in pH may occur in the diffusion boundary layer in front of the cathode, particularly where convection is inadequate.

3.2.6. Temperature

The conductivity of the electrolyte increases with rising temperature, and the dissipation of the Joule heat becomes technically easier. However, the rates of chemical side reactions and the vapor pressure also increase. The range between 30 and 40 °C may be regarded as a good compromise. As was mentioned, electrolyses have been carried out even at 0 °C[34]. We have also electrolyzed acrylonitrile on Pb and Hg cathodes (in water/McKee salt[*]) at 20—50 and 80 °C (boiling point of the catholyte), and found that the yield and the current efficiency decrease rapidly with rising temperature; increasing quantities of cyanoethylation products and propionitrile are formed[35].

3.2.7. Second Solvent

A solubilizing agent is necessary in order to obtain higher acrylonitrile concentrations without excessively low water concentrations. Suitable solubilizing agents include lyotropic supporting electrolyte, *e.g.* tetraethylammonium ethyl sulfate[36,37]. Additional solvents such as acetonitrile (which is present in any case in crude AN from the Sohio process), dimethylformamide, or isopropanol have also been used. The use of acrylonitrile-in-water emulsions has also been suggested[38,25].

3.2.8. Supporting Electrolyte

As can be seen from Table 1, optimum material yields and current yields are obtained only with supporting electrolytes containing higher quaternary ammonium ions[15,39]. A decrease in the yields occurs even with tetramethylammonium salts, and this decrease becomes more pronounced with the use of tertiary ammonium salts and in particular of alkali metal salts. This cannot be due to an

Table 1. Dependence of the ADN yield on the cation of the carrier electrolyte. Anion: tosylate. The solution contains 40% of AN, 26% of H_2O, and 34% of carrier electrolyte. The deposition potential is based on a current density of 10 mA/cm².

Cation	ADN Current Efficiency [%]	ADN Yield [%]	U_K [V]
$N(C_4H_9)_4^{\oplus}$ $N(C_2H_5)_4^{\oplus}$	90	87.5	−2.89
$N(CH_3)_4^{\oplus}$ [a]	≈55	≈75	−2.72
$N(C_2H_5)_3H^{\oplus}$	16	34.3	−2.39
$Li^{\oplus}$	6	15	−2.28

$CH_2{=}CH{-}CN$	—	—	−1.80

[a] Calculated from experiments with low salt concentrations.

[*] In this case McKee salt is NEt_4 tosylate.

excessively positive deposition potential of the cations, since even $Li^{\oplus}$ is reduced only at a potential about 0.5 volts more negative than that at which acrylonitrile is reduced. On the other hand, triphenylmethylphosphonium salts give good material yields with only slightly depressed current yields, though the cation is partly discharged on electrolysis.

These observations can be readily explained as "double-layer effects". The ions of the supporting electrolyte not only serve for the transport of current and possibly for the solubilization of the substrate, but also produce many important effects at the phase boundary, which are indicated schematically in Figure 5. They influence the course of the potential in the rigid and diffuse parts of the double layer, and hence indirectly the rate of the electrode reaction. They can also compete as adsorbents for the substrate molecule. As counterions to the ionic intermediates formed, they influence the reactivity of the latter in the subsequent reactions. Thus the ionic function of a radical-anion can be so extensively shielded by a *small* cation (ion-pair formation) that it behaves as a free radical, whereas with a large cation the anionic function has a chance to act as a nucleophile. *Baizer* recently studied these relationships with the aid of cyclic voltammetry[40].

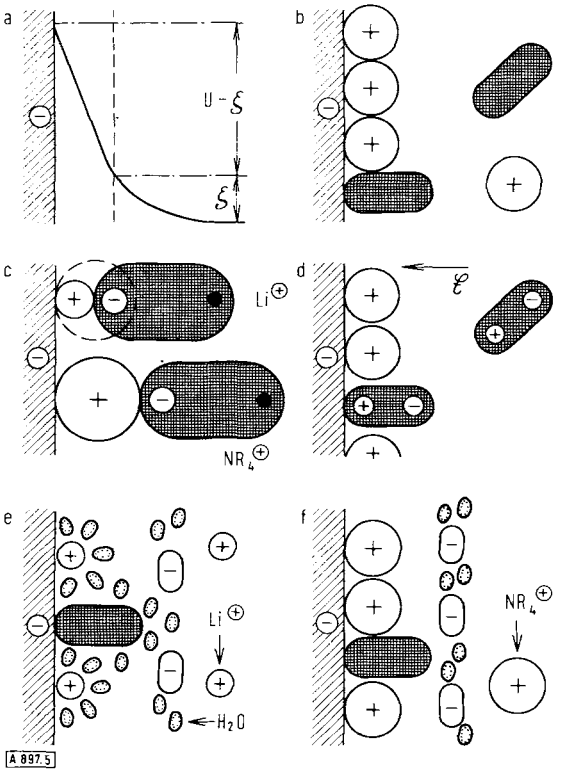

Fig. 5. Salt effects at the phase boundary, schematic. a) Influence on the rate of the electrode reaction, b) adsorption, c) action of counterions, d) orientation and polarization, e), f) action of water at the phase boundary.

Moreover, an organic molecule with a dipole moment may be oriented in the high electric fields at the phase boundary, and the dipole moment may also be considerably increased by polarization. Finally, the rate of the proton-consuming steps is extremely strongly dependent on the water concentration in the double layer. This in turn is determined by the hydration sheath of the cations, so that larger quantities of water reach the vicinity of the phase boundary in the case of alkali metal ions, but practically none in the case of the hydrophobic higher quaternary ammonium ions. This immediately explains the results in Table 1[23,41,39].

Current-voltage measurements as a function of the concentration of quaternary ammonium salt clearly show that the cations influence mainly the ζ potential (Fig. 6a), whereas they have practically no action as competing adsorbents[39]. The hydrodimerization proceeds in high yields even at very low carrier salt concentrations; the electrolysis can be carried out at industrial current densities with a carrier salt concentration of only 0.1% in special cells with a short distance between the electrodes[22,27,39]. Even in these dilute electrolyte solutions, the carrier salt cations are accumulated in the rigid part of the double layer. However, acrylonitrile has also been electrolyzed in concentrated carrier salt solutions (*e.g.* 55 wt.% of tetramethylammonium methyl sulfate)[13]. In the presence of high concentrations of lyotropic salts, the separation of the components is complicated, and requires a multi-stage extraction and distillation process[42].

In the presence of a mixture of tetramethylammonium and tetraethylammonium salts, the hydrodimer is formed in higher yields than in the presence of either of the components alone[43]. Hydrodimerization of acrylonitrile is also possible in the presence of alkali metal salts such as $NaClO_4$ or KSCN if the water concentration is kept below 10% and the reaction is carried out in the presence of high concentrations of aprotic solvents such as DMF or DMSO[44]. Under these conditions, the alkali metal ions appear to be largely resolvated.

3.2.9. Convection

As in any electrolysis, convection must be so strong that transport processes cannot become rate-determining. Moreover, the diffusion boundary layer in front of the electrode must not become too thick, since the phase boundary concentration of acrylonitrile otherwise becomes too low, and that of $OH^{\ominus}$ ions too high (Fig. 6). Particularly strong stirring is necessary in the emulsion procedure[23,38], in order to accelerate the mass transport at the AN/solution

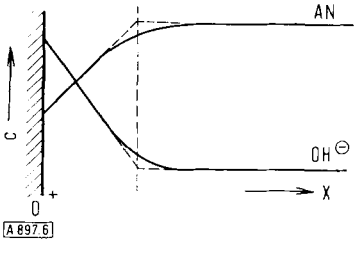

Fig. 6. Diffusion layer in the hydrodimerization of acrylonitrile, schematic. c: concentration; x: space coordinate.

and solution/electrode phase boundaries. The increased power required for stirring in this case may be of the same order of magnitude as the electrolysis power.

3.3. Mechanism

There has been a great deal of speculation on the mechanism of the hydrodimerization of acrylonitrile; however, few measurements of kinetic value have so far been carried out. Measurements at low acrylonitrile concentrations are of limited value (polarography, cyclic voltammetry), since only the hydrogenation occurs under these conditions.

Knunyants originally tried to explain his observations in the reduction with amalgam by a free-radical mechanism of the type (1) (see Schemes 2 and 3)[11].

Exclusively free-radical mechanisms are also discussed in an earlier article on electrochemical dimerizations[45]. Strong adsorption of the intermediates is suggested in an attempt to explain why free-radical initiated polymerization does not occur.

Systematic current-voltage measurements with variation of the principal parameters[26] led to a result that could not be reconciled with this free-radical mechanism, which was also opposed by the fact that the yield of hydrodimer is independent of the current density[26,27]. Figure 7

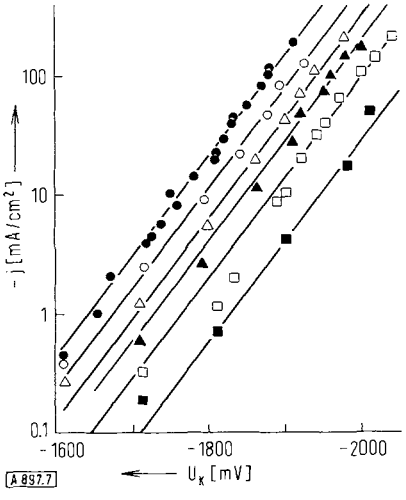

Fig. 7. Tafel lines at various acrylonitrile concentrations [26]. Electrolyte (25 °C, pH = 0): x % AN, (40 − x)% acetonitrile, 26% H_2O, 34% NR_4 tosylate. Concentration of acrylonitrile: ● 40%, ○ 20%, △ 10%, ▲ 5%, □ 1%, ■ 0.2%.

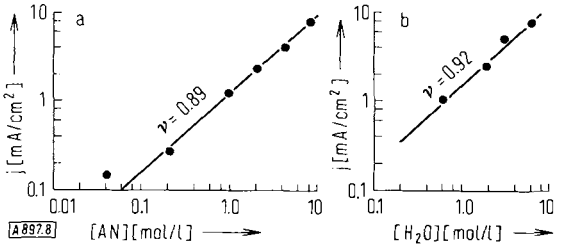
shows a semilogarithmic current-voltage plot for a series of measurements with solid cathodes, in which the acrylonitrile concentration was varied by more than two orders of magnitude. At a constant potential, the current density, *i.e.* the reaction rate at the phase boundary, increases with increasing acrylonitrile concentration. The following relation is also valid at a constant potential in the electrochemical kinetics:

$$j = k \cdot c_{AN}^{\nu}; \quad \log j = \log k + \nu \log c_{AN}$$

where ν is the reaction order with respect to acrylonitrile. A corresponding evaluation (Fig. 8) gives a reaction order $\nu_{AN} \approx 1$. Similar measurements at various water concentrations also lead to a reaction order $\nu_{H_2O} \approx 1$.

It follows from the slope of the "Tafel lines" of 120 mV, assuming a value of 0.5 for the transfer coefficient[46], that one electron is transferred in the rate-determining step.



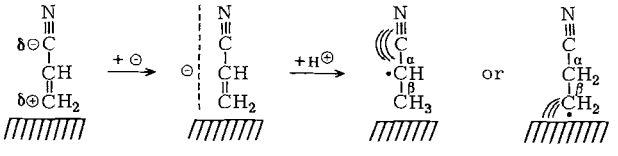


Fig. 8. Reaction order ν with respect to a) acrylonitrile and b) water [28]. Potential against saturated calomel electrode: −1.750 V, 25 °C carrier salt: tetraethylammonium tosylate. a) 26% H_2O, 34% carrier salt, acetonitrile; b) 40% acrylonitrile, 34% carrier salt, acetonitrile.

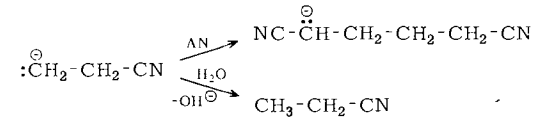
These kinetic observations were later fully confirmed by other workers[47]. Since it is not possible, as was mentioned earlier, to decide from the current-voltage curve whether hydrogenation or hydrodimerization has occurred, the slow step must be the same for both reaction paths. The only possibility was

$$CH_2{=}CH{-}CN + \ominus + H_2O \xrightarrow{\text{slow}} \cdot CH_2{-}CH_2{-}CN + OH^{\ominus}$$

The initially formed radical-anion is thus simultaneously protonated. Controversy exists regarding the site of the protonation (or of the unpaired electron). LCAO calculations for the free radical-anion show[48] that the protonation should occur on the β-C atom rather than on the α-C atom; the α radical would then be stabilized by the π system of the nitrile group.

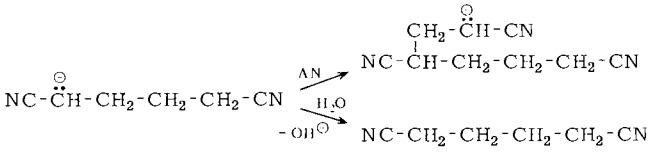
However, these considerations ignore the fact that the reaction steps take place at the phase boundary, with the dipole oriented as illustrated. The stabilization of the β radical by the π-electron system of the metal should be much more effective than the stabilization of the α radical by the nitrile group (cf. Ref. [41]). The protonation of the radical-anion in the α position is also indicated by the argument that the proton migrates first to the position of maximum basicity, with intermediate formation of $\cdot CH_2{-}CH{=}C{=}\ddot{N}H$, which then undergoes prototropic rearrangement to form the β-C radical[15].

The cyanoethyl radical is rapidly reduced further at the prevailing potential[*], so that the steady-state free-radical concentration is extremely low. This explains why a free radical initiated polymerization does not occur.



$$^{\bullet}CH_2{-}CH_2{-}CN + \ominus \xrightarrow{\text{rapid}} [{:}CH_2{-}CH_2{-}CN]^{\ominus}$$

[*] If the cyanoethyl radical is produced by cathodic dehalogenation of β-iodopropionitrile



$$I{-}CH_2{-}CH_2{-}CN + \ominus \rightarrow I^{\ominus} + \cdot CH_2{-}CH_2{-}CN$$

the reduction proceeds at a much more positive potential [49].

The carbanion formed either combines with a second acrylonitrile molecule to form the anion of the dimer or is protonated to form propionitrile.

The anion of the hydrodimer is less reactive than the anion of the monomer, since the negative charge is distributed over the α-C atom and the nitrile group[50]; oligomers are therefore formed only in systems with very low water concentrations.

The first protonation step may even fail to occur at very low water concentrations, an anionic polymerization being initiated by the resulting radical anion[30].

The two other possible anionic mechanisms, starting from the radical-anion $[CH_2{=}CH{-}CN]^{\bullet\ominus}$[48,51] or from the dianion $[CH_2{=}CH{-}CN]^{2\ominus}$[7,13,23,52,53] do not agree with our kinetic findings. With increasing lifetime of the radical anion, the probability of direct dimerization of this species should increase. Some diactivated olefins form relatively long-lived radical-anions, and appear to favor this reaction path[54]. Two possibilities are available: a free-radical mechanism of type (11) or an ionic mechanism of type (5) or (6) (cf. Schemes 2 and 3); the free-radical mechanism should be favored if the anionic function is shielded by a small cation[40]. *Bard*[272] found this mechanism for dimethyl fumarate; in the case of acrylonitrile, the lifetime of the intermediates is too short for the measuring methods used. In the cathodic hydrocyclization of diactivated olefins, a "concerted" mechanism of type (5) has been proposed, *i.e.* the electron transfer and the formation of the C—C bond are closely coupled[55].

The mechanism *via* the dianion of the monomer, which has been considered by a number of authors (see above), is relatively improbable for energetic reasons. However, the two charges may move as far apart as possible after the dimerization step.

3.4. Processes in Divided Cells

The first process in divided cells that allowed the direct electrohydrodimerization of acrylonitrile to adiponitrile in high yields was developed by Monsanto[13]. A diaphragm was necessary, since lyotropic quaternary ammonium salts (such as tetraethylammonium ethyl sulfate), which undergo oxidative degradation at the anode, were used in high concentrations. An example of a typical catholyte composition is as follows: 40% of acrylonitrile, 34% of tetraethylammonium tosylate, 26% of H_2O; the anolyte consists of dilute sulfuric acid. The industrial cells have a cross section of about one square meter, and are of the filter press type.

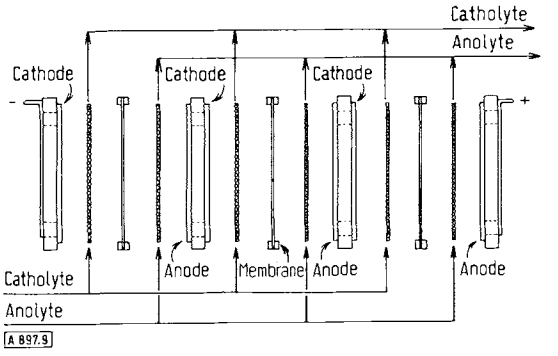


Fig. 9. Filter press cell [58].

Figure 9 shows a diagram of a cell block. The (internally cooled) bipolar electrodes consist of lead on the cathode side and lead alloy on the anode side, the latter becoming passive during operation through the formation of a PbO_2 layer. An ion exchange membrane based on polystyrenesulfonic acid is used as the diaphragm[56]. Membranes of this type have been steadily improved since the development of this industrial organic electrosynthesis, so that they now have a satisfactory lifetime[57]. The advantages over a porous diaphragm are less mixing of the anolyte with the catholyte and an improved acid/base balance in the cell. The catholyte and the anolyte are circulated separately; the Joule heat is eliminated internally *via* the internally cooled bipolar plates. The entire process was described in detail some years ago[58].

The plant in Decatur, Alabama (USA), has been in operation since 1965, and was expanded in 1969 (for economic data see Ref. [59]). The industrial importance of the process is underlined by a series of patents on technological details such as the separation of the quaternary ammonium salt from the material removed from the cell[42] (the salt must be recirculated as quantitatively as possible to maintain economy), the production of the quaternary ammonium hydroxide used for pH control in the catholyte by electrodialysis[60], the preparation of quaternary ammonium salts[61], the separation of by-products[62], the removal of traces of metal from the catholyte (these may reduce the hydrogen overvoltage of the lead cathodes during continuous operation)[63], the removal of oligomers of acrylonitrile[64], the extraction of nitriles from the anolyte by higher amines to reduce corrosion of the anode[65], the improvement of the ion exchange membrane[66], and the stabilization of the anode by lead alloys[67].

The Japanese company Asahi Chemical Industries, which, like Monsanto, has large acrylonitrile plants, has also developed a process having divided cells; a plant of this type is soon to be put into operation[68]. The company's experience in the field of ion exchange membranes proved very useful in this development[69]. The main difference from the Monsanto process is that the concentration of dissolved acrylonitrile in the aqueous phase is kept low (<5%) by nonlyotropic salts such as tetramethylammonium

sulfate[24]. Excess of AN forms an emulsion[25]. The solubility of the reaction products in the organic phase is good, while that of the salt is low, so that subsequent treatment is relatively simple. A typical catholyte composition (aqueous phase) is as follows: 5% of AN, 10% of salt, 85% of H_2O[24]. Here again, numerous patent applications, *e.g.* on problems of working up[70, 71] and on the removal of metallic impurities by carbonate precipitation[72], are indicative of the industrial development.

The Badische Anilin- & Soda-Fabrik has proposed the use of very low concentrations of quaternary ammonium salts in homogeneous solutions[73]. To be able to operate with industrial current densities under these conditions, special cells were developed, in which the liquid-permeable electrodes (meshes, sieves, or expanded sheet) are in direct contact with the ion exchange membrane. The low carrier salt concentrations facilitate working up. An additional solvent is used to homogenize the catholyte, a typical composition of which is: 77% of AN, 10% of H_2O, 10% of DMF, 3% of tetraethylammonium tosylate. It would be possible, in principle, to omit the use of carrier salts in these cells; however, low concentrations are favorable because of the salt effects, which are already pronounced. It has also been suggested[74] that these salt effects should be produced by introduction of insoluble compounds containing $-\overset{\oplus}{N}R_3$ groupings into the pores of the graphite cathode.

The Belgian Company UCB has shown[44] that good yields are also possible in the presence of Na or K salts (in divided or undivided cells) if mixtures containing low water concentrations are used. A typical reaction mixture, which is treated at 20 °C with graphite cathodes, has the composition 39% of DMSO, 27% of AN, 26% of $NaClO_4$ and 8% of H_2O.

Despite the progress in the technology of ion exchange membranes, an electrosynthesis is technically easier to carry out in a diaphragm-free cell. The better the yields and the qualities of the products, therefore, the more this process will be able to compete with the processes discussed in Section 3.4.

It has been shown that the supporting electrolyte is preferentially decomposed at the anode in the McKee system[22]. Cells with very small distances between the electrodes ($d \approx 0.2$ mm) in the form of liquid-permeable stationary[75] or vibrating[32] pairs of electrodes and capillary gap cells[21] enabled the electrolysis to be carried out at BASF at industrial current densities, despite a carrier salt concentration of only 0.5 wt.%. The product was formed in yields of 90%, with current yields of 80%. The cell voltages were so favorable that the energy consumption was less than 3 kWh per kg of product. A typical electrolyte composition is 55% of AN, 28.5% of isopropanol, 16% of H_2O, and 0.5% of tetraethylammonium ethyl sulfate. The isopropanol completely protects the acrylonitrile, which is itself fairly stable, against oxidation at the PbO_2 anode, and is itself oxidized to acetone, CO, and CO_2. The isolation of the product is greatly facilitated by the small quantities of carrier salt.

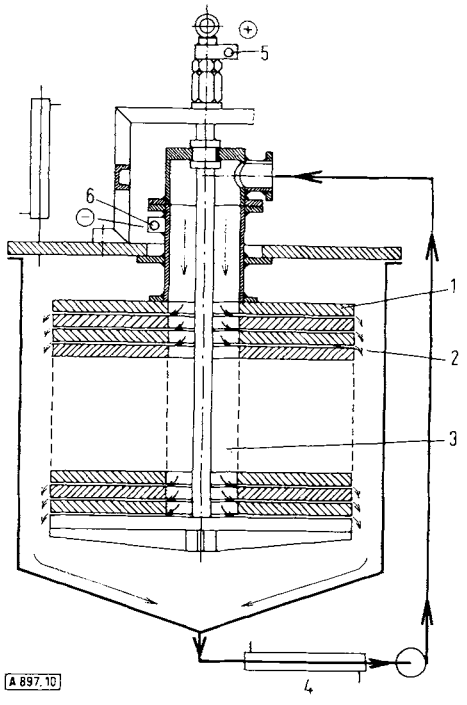

Fig. 10. Capillary gap cell. 1) Bipolar circular electrode plates; 2) capillary gap; 3) bore in the center of the stack; 4) heat exchanger; 5), 6) current leads.

Figure 10 shows one form of the capillary gap cell. It consists of a stack of circular graphite disks, which are connected bipolarly in series. The anode side is covered with PbO_2. The distance between the disks is 0.2 mm. The reaction mixture is pumped in a loop, and flows radially through the capillary gaps. The Joule heat is removed in an external heat exchanger. (The development of these cells is described in[22, 27].) The isolation of the product is simple, and consists essentially of distillation steps. Processes for the production of quaternary ammonium hydroxides[76], the improvement of the yields by the use of carrier salt mixtures[43] or by the addition of small quantities of polyacids[77], and the production of PbO_2/Ti composite electrodes[100] may be mentioned in this connection.

Knunyants has proposed the electrolysis of AN on graphite cathodes in aqueous sodium hydroxide solution[34]. The cyanoethylation of water[78] which, at 35 °C has a half-life of 20 minutes at pH = 14 and of 40 hours at pH = 12[79], is strongly retarded by the use of an electrolysis temperature of 0 °C. The yield of ADN is less than 80%, even when a neutral electrolyte (Na_2SO_4) is used[80].

Tomilov et al.[38] emulsified acrylonitrile in an aqueous phosphate buffer (1 M K_2HPO_4) containing approximately 1% of quaternary ammonium salt. The emulsion was pumped turbulently through a cell with graphite cathodes and magnetite-covered iron anodes. Despite the high water concentration and the low acrylonitrile concentration, the dimer was formed in a yield of about 90%. The process was developed further by the Belgian Company

UCB. The internal surfaces of a drilled graphite block were used as graphite cathodes, the cylindrical magnetite anodes being inserted coaxially in the drillings[51]. The corrosion of the anode was reduced by a factor of 10 on addition of polyphosphates[81]. The isolation of the product appears to be greatly simplified in this process and consists essentially of distillation of the organic phase. The electrolysis temperature must be kept at the relatively low level of 18—20 °C to minimize corrosion of the magnetite anode.

Rhône-Poulenc solved the problem of the supporting electrolyte in the undivided cell by the use of quaternary ammonium salts with anions that are stable at the anode[82]. Examples are sulfates, borates and carbonates.

3.6. Processes with Alkali Metal Amalgam

As was mentioned earlier, the industrial development in this field was started by the pioneering work of *Knunyants*[10-12], who was able to show that an approximately 10% solution of acrylonitrile in dilute mineral acid can be hydrodimerized with Na amalgam to adiponitrile in material yields of 65% and with "amalgam yields" of 35%. Though these results were not good enough to allow the process to be carried out economically, they showed the fundamental possibility of the reaction.

Katchalskii was later able to increase the yield to 75% by the addition of polymerization inhibitors[83]. This value was regarded for a long time as the maximum obtainable, until it was shown in the middle 1960's, mainly through work carried out at ICI, that yields and current efficiencies of more than 90% are quite feasible if the reaction with amalgam is carried out under the following conditions: buffering with CO_2 instead of with mineral acid[84], addition of quaternary ammonium or phosphonium salts[85], of dimethyl sulfoxide, *etc.*[86], and of hexamethylphosphoroamide[87]. Particularly good results were obtained when solutions strongly diluted with acetonitrile were used[88]. It was suggested that the actual reducing agent was not the Na amalgam but quaternary ammonium amalgam formed as an intermediate[89, 90]. The quantitative separation of the very finely divided sodium hydrogen carbonate formed proved to be very difficult on the industrial scale. Elimination of Hg from the products was also a problem. These investigations have not yet progressed beyond the pilot-plant scale.

A series of further patent applications by other workers all claim certain additives as "catalysts". They probably all act by producing an optimum water concentration in the double layer. Examples are dimethylurea[91, 92], biuret[93], diethylacetamide[94], hexamethylenetetramine[95], and tetraalkylarsonium salts[96]. It has also been suggested that the reaction should be carried out in liquid ammonia[97] or in DMSO/H_2O without buffering with acid, so that alkali metal hydroxide is obtained at the same time[98]. In a process developed by UCB to the semi-industrial scale, a mixture of AN/H_2O/formamide is allowed to react with K amalgam[99]. Dilute H_2SO_4 is added for buffering. The K_2SO_4 formed appears to be easier to separate than Na_2SO_4, and is a commercial product.

Regarding amalgam processes in general, they have the disadvantage with respect to the direct process that they are two-step processes. Large quantities of dilute (0.1%) alkali metal amalgam must be circulated. The separation of the alkali metal salt and of the mercury from the organic compounds can be problematic. We shall not discuss here whether these disadvantages can be offset by the advantage that it is industrially easier to construct an amalgam reactor than an electrolytic cell for a direct electrosynthesis. From the point of view of mechanism, the direct synthesis at an Hg cathode is substantially equivalent to the indirect synthesis with Na amalgam.

3.7. Chemical and Catalytic Processes

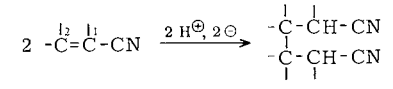
Attempts have been made to carry out the industrially important synthesis of ADN by catalytic hydrogenative dimerization with the addition of molecular hydrogen. Ru catalysts (at 100—200 °C and 400—500 atm) appear to be the most suitable, but the yields are still low at present because of the predominant hydrogenation to form propionitrile[101, 102].

The catalytic hydrogenation generally proceeds by a free-radical mechanism, and the surface concentration of the intermediate HX· is very low[103, 104]. Its dimerization is therefore unlikely. Ionic mechanisms have also been suggested, *e.g.* for polar substances such as nitrobenzene or quinone[105, 106]. Moreover, with decreasing coverage with H_{ad}, the mechanism is reported to change into an ionic mechanism[107], in which dimerization should be more likely.

The homogeneously catalyzed hydrodimerization of AN in the presence of carbonylmetal compounds[108, 109], in some cases with exposure to light[110], also does not proceed very selectively. The by-products include the head-to-tail dimer 1-methyleneglutaronitrile.

The hydrogenolysis of the cyclic dimer 1,2-dicyanocyclobutane, which is formed in high yields in the thermal dimerization of acrylonitrile to form adiponitrile has not yet been achieved with satisfactory yields[111]. The hydrodimerization with metals as reducing agents is of no industrial importance, owing to the stoichiometric formation of heavy metal salts. Almost quantitative yields have been obtained with Mn in DMF[112].

4. Preparative Aspects



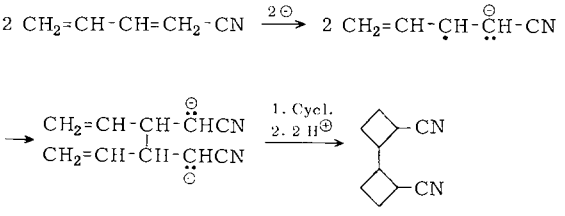
Following the classification shown in Scheme 1, this section presents the preparative aspects. Though it is not possible to go into experimental details, the essential conditions are briefly indicated, and the result is given, if possible, as the current efficiency (quantity of product as a fraction of the quantity to be expected according to *Faraday*'s law), which is more important to the electrochemist, and the yield (based on the quantity of monomer that has reacted).

4.1. Activated Olefins[113]

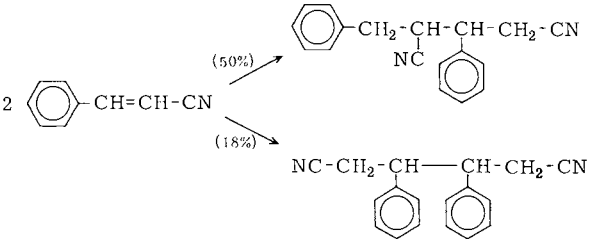
4.1.1. α,β-Unsaturated Nitriles

A number of results are shown in Table 2. Acrylonitrile itself was discussed very fully in Section 3. Because of the industrial importance of the reaction, this dimerization has probably been investigated more thoroughly by many authors than any other. It can nowadays be carried out with almost quantitative yields, even under industrial conditions. In other reactions, which have not been so thoroughly investigated, a poorer reported yield may be due to failure to optimize. In comparison with the direct dimerization on an Hg cathode investigated by *Baizer* and *Anderson*[114], the indirect amalgam method described by *Knunyants*[10-12] appeared to give much poorer yields. However, these results have now been optimized and good results are also obtained in the presence *e.g.* of quaternary ammonium salts[96].

Table 2. Cathodic dimerization of α,β-unsaturated nitriles. The numbers in brackets refer to the amalgam method.



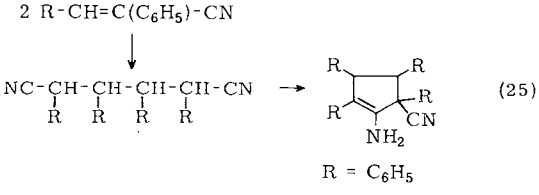
Reaction	Compound	Current Efficiency [%]	Yield [%]
(17)	$CH_2=CH-CN$	90	95 (65)
(18)	$CH_2=C(CH_3)-CN$	75 (0) [a] +10 [b]	
(19)	$(CH_3)_2C=CH-CN$	90	(37)
(20)	$CH_3-CH=CH-CN$	90 [a] + 1 [b]	
(21)	$CH_2=CH-CH_2-CN$	—	
(22)	$CH_2=CH-CH=CH-CN$		70
(23)	$NC-CH=CH-CH_2-CH_2-CN$		
(24)	$C_6H_5-CH=CH-CN$		18 [a] +50 [b]
(25)	$C_6H_5-CH=C(C_6H_5)-CN$		15 [c]
(26)	$C_6H_5-CO-CH=CH-CN$	55	



[a] 2,2-linked product.
[b] 1,2-linked product.
[c] 15% of 2,2-linkage; main product: 2-amino-1,3,4,5-tetraphenyl-2-cyclopentene-1-carbonitrile.

In the case of methacrylonitrile [reaction (18)], the dimerization does not proceed exclusively in the 2,2 position, 10% of 1,2-dimerization also taking place[115]. In the case of crotononitrile [reaction (20)] this fraction is only 1%. A patent has been granted for the hydrodimerization of allyl cyanide[116]; the reaction [(21)] is inhibited, since in the presence of 10% of crotononitrile, only the hydrodimer of the latter is formed[117]. The hydrodimerization of allylamine, which would lead directly to hexamethylenediamine, has not been achieved in H_2O/tetraethylammonium tosylate on Hg cathodes[118]. 1-Cyano-1,3-butadiene, the vinylog of acrylonitrile, has been dimerized *via* position 4 in good yields [reaction (22)] to form the dinitrile, which gave sebacic dinitrile on hydrogenation of the two remaining C=C double bonds[119,120]. Polarographic findings led to a different interpretation of the dimerization[121], according to which 2,2'-dicyanobicyclobutyl is formed.

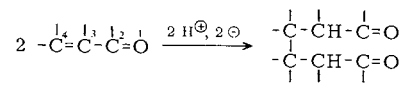
Tetranitriles were formed by hydrodimerization of 1,4-dicyano-1-butene [reaction (23)][122,123].



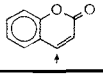
1,2-Diactivated olefins exhibit a number of peculiarities. Cinnamonitrile [reaction (24)] reversibly takes up an electron on polarography in DMF to form a stable radical-anion[121], which, according to investigations by *Baizer et al.*[54b], dimerizes mainly in the 1,2-position.

(24)

The substituents on the C=C double bond stabilize the radical-ion formed in the following order[54a]: $C_6H_5 < COOC_2H_5 < CN < C_6H_5CO$, so that this intermediate is formed at potentials that become increasingly positive in the above order. However, the species containing nitrile groups are much more reactive than any others in the subsequent reactions[54a]. Benzoylacrylonitrile dimerizes exclusively in the 1,1 position [reaction (26)]. 1-Phenylcinnamonitrile gives the 2,2-dimer (2,3,4,5-tetraphenyladiponitrile) only as a by-product, while the main product is the cyclization product, which occurs in the enamine form [reaction (25)][124]. The course of the dimerization again depends on the size of the counterion[40].



(25)



The nitrile group is generally stable to reduction; in acrylonitrile, however, selective reduction to allylamine has been observed under certain conditions (Pb, sulfuric acid solution)[125,126]. The dimerization on the C=C double bond appears to proceed best in the presence of quaternary ammonium salts, possibly with the addition of an auxiliary solvent.

4.1.2. α,β-Unsaturated Carbonyl Compounds

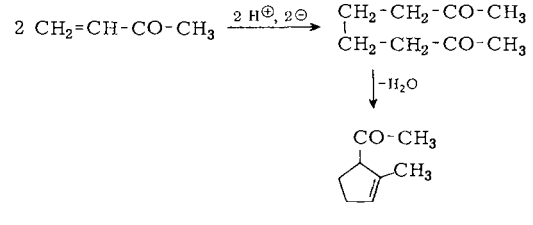


Table 3 shows some representative examples of the hydrodimerization of α,β-unsaturated ketones, esters, acids, and amides (for other ketones and aldehydes, see Section 4.2.). Though reduction of the C=O group cannot be entirely ruled out here, coupling in the 4,4-position, corresponding to the normal scheme, occurs in most cases; coupling in the 2,2 or even the 2,4 position occurs only to a small extent. *Pasternak*[127] pointed this out at an early date on the basis of polarographic results. The "pinacones" found for these compounds in the earlier literature were therefore 1,6-diketones in most cases.

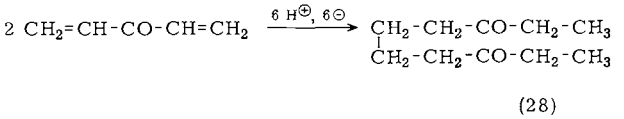
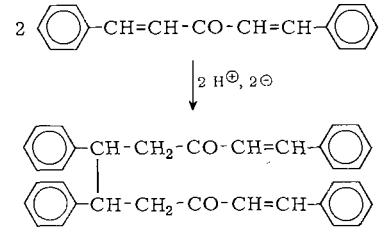
Table 3. Cathodic dimerization of α,β-unsaturated carbonyl compounds.



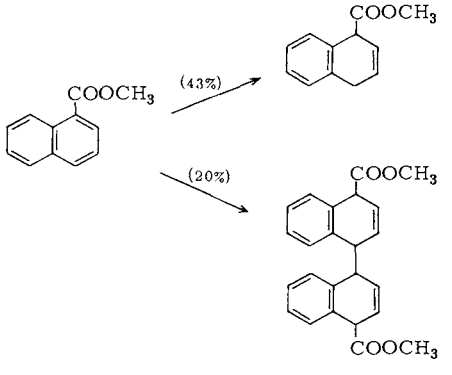
Reaction	Compound	Current Efficiency [%]	Yield [%]
(27)	$CH_2=CH-CO-CH_3$		80
(28)	$CH_2=CH-CO-CH=CH_2$		45
(29)			80
(30)	$(CH_3)_2C=CH-CO-CH_3$		up to 90
(31)	$C_6H_5-CH=CH-CO-CH_3$		74
(32)	$CH_2=CH-COOC_2H_5$	87	
(33)	$H_5C_2OCO-CH=CH-COOC_2H_5$	62	
(34)	$C_6H_5-CH=CH-COOH$		70
(35)			93
(36)	$CH_2=CH-CON(C_2H_5)_2$		73
(37)	$C_6H_5-CH=CH-CON(CH_3)_2$		40

In the past, the electrolysis was often carried out in acidic solution, and followed a free-radical course. More recently, the use of a neutral solution with quaternary ammonium salts has again been found to be advantageous, but the difference in the yields is much smaller than in the cases of nitriles[128]. *Wiemann* and *Bouguerra*, for example, found[129] that on reduction of methyl vinyl ketone on Hg cathodes at approx. —1.4 V (against the saturated calomel electrode), the diketone was formed as the main product [reaction (27)], irrespective of whether the reaction was



carried out in aqueous-alcoholic alkali metal acetate buffer or with tetraethylammonium tosylate in acetonitrile/water. Under these last conditions, the diketone partly cyclized to give a cyclopentene derivative.

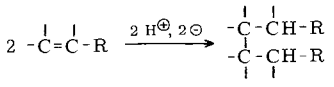
Simonet has suggested the intermediate formation of Hg compounds[130]. Divinyl ketone with Zn/acetic acid yields 3,8-decanedione as the main product, *i.e.* the second vinyl group is hydrogenated[131]. In the case of the analogous dibenzylideneacetone, two double bonds are retained[132, 133].



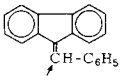
(28)

The reductive dimerization of cyclohexenone [reaction (29)][134a] or of 4,4-dimethylcyclohexenone[134b] also proceeds predominantly by the 4,4 scheme, as does the hydrodimerization of mesityl oxide[130, 135b–135d], which has been known since the work of *Law* (1912)[135a]. *Wiemann* and *Bouguerra*[135b] were also able to isolate furan derivatives in large quantities. Benzylideneacetone [reaction (31)][135a, 127] and dibenzoylethylene[54b] are further examples.

Ethyl acrylate [reaction (32)][114, 136a, 136b] and methyl acrylate[136c] have been hydrodimerized in high yields to the esters of adipic acid. The dimerization of acrylic acid has now also been achieved[137]. The reaction of free cinnamic acid [reaction (34)] was achieved in good yields in acidic aqueous alcoholic solution as early as 1943 by *Wilson* and *Wilson*[138, 139]. Coumarin, as an unsaturated lactone, dimerizes almost quantitatively in the 4,4 position [reaction (35)][140, 141]. *Misono*[142, 143] has reported on the dimerization of α,β-unsaturated aldehydes, which proceeded relatively nonuniformly. The reaction of α,β-unsaturated amides, such as diethylacrylamide [reaction (36)][114], cinnamic acid dimethylamide [reaction (37)][154b], or cyclohexenecarboxamide[144], proceeded selectively in the 4,4 position.



(38)



An example of a vinylogous reaction is the reaction of methyl 1-naphthoate [reaction (38)]. In addition to the 1,4-dihydro compound, the 4,4 hydrodimer is formed on reduction with Na amalgam[145].

4.1.3. α,β-Unsaturated Hydrocarbons

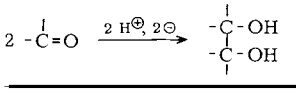
Unsaturated hydrocarbons are generally reduced only at very strongly negative potentials. The radical-anions formed are extremely strong bases, so that even when the proton activity of the solvent is very low, protonation to give the hydrogenation product is favored over dimerization. There are consequently only a few known examples in this series (Table 4).

Table 4. Cathodic dimerization of α,β-unsaturated hydrocarbons.

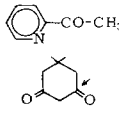
Reaction	Compound	Current Efficiency [%]	Yield [%]
(39)	C_6H_5—CH=CH—C_6H_5		30
(40)		82	
(41)		66	

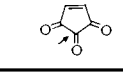
Wawzonek[146] was able to hydrodimerize stilbene in a yield of 30% in DMF [reaction (39)] (but not in acetonitrile) on Hg cathodes in the presence of tetrabutylammonium iodide. The hydrodimerization of phenanthrene was also achieved under similar conditions[147]. *Baizer*[148] dimerized 9-benzylidenefluorene in accordance with reaction (41) in a yield of 66%; only 8% of hydrodimer could be obtained with 2-phenyl-1,3-butadiene. 2-Vinylpyridine and 4-vinylpyridine can again be converted into dimers in high yields[149]. The electrolytic dimerization product of *N*-vinylcarbazole is formulated as a cyclobutane derivative[150].

4.2. Ketones and Aldehydes

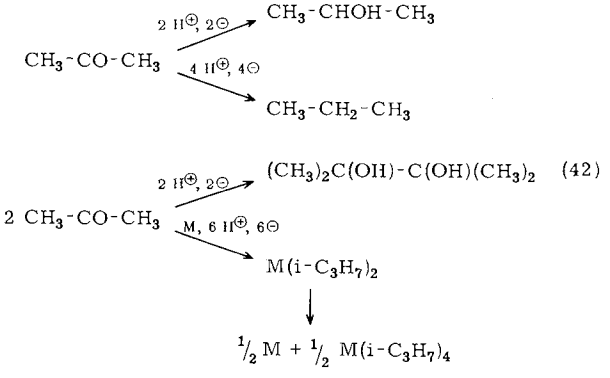


The hydrodimerization of ketones and aldehydes, which has been known for some time, leads to pinacols, *i.e.* derivatives of ethylene glycol. As can be seen from Table 5, there is a considerable difference even in the yield between the aliphatic and the aromatic series (for α,β-unsaturated carbonyl compounds see Section 4.1.2).





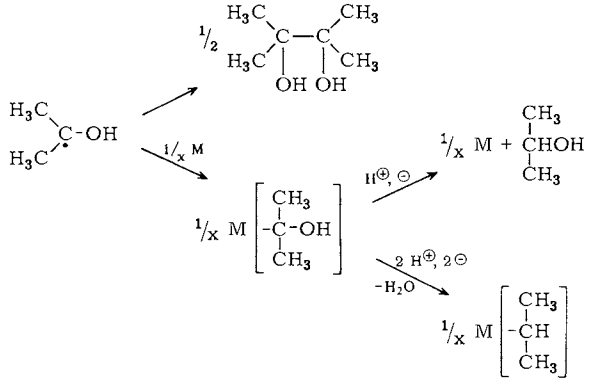
4.2.1. Aliphatic Ketones and Aldehydes



Despite many investigations, some of which were carried out a long time ago, no clear picture has yet emerged regarding the hydrodimerization of acetone. The reason for this may lie in the large number of possible reaction paths.

A free radical mechanism is certain on the basis of polarographic measurements, which have been carried out in particular on aromatic ketones. A central intermediate is the radical anion of the ketyl type, which is formed in acidic solution at relatively positive potentials, and which arises *via* e p or p e, depending on the pH value. A comprehensive description of the complicated situation has

Table 5. Cathodic dimerization of ketones and aldehydes.



Reaction	Compound	Cathode	Current Efficiency [%]	Yield [%]
(42)	CH_3—CO—CH_3	Pb/Sn, Pb/Cu, C(H_2SO_4)	13	60
(43)	C_2H_5—CO—CH_3	Zn (NaOH)	8	25

(42)

been published by *Zuman et al.*[6] (see also[5, 127]). It has been suggested that isopropanol is formed on Hg or Pb mainly *via* the organometallic compound, since the quantities of the two by-products are interdependent[151].

A characteristic feature is the extremely strong dependence of the results on the nature and state of the cathode material. The most suitable materials for pinacol formation appear to be Hg, Pb, Pb/Cu[151] and Pb/Sn alloys[152], which were recommended even in early patents[153]. However, the current efficiencies are poor, with values of 13%[151, 152]; the high values reported in the early publications could not be reproduced. Graphite is also suitable[154, 155]; this material has the advantage that the formation of organometallic compounds is impossible. A patent on the synthesis of pinacols with Na amalgam (80% material yield) actually describes an electrolysis on graphite, since carbon is in simultaneous contact with the Na amalgam and with the alkaline reaction mixture[156]. A yield of 60% was also found on Hg in alkaline media[157].

The strong interaction of acetone with the cathode can be seen from Figure 11. The cathodic current-voltage curve in the base electrolyte has been recorded for several metals. Evolution of hydrogen is observed. After the addition of acetone at a constant current density, the potential is displaced in the negative direction in most cases, and the evolution of H_2 stops. After a few minutes, a new steady-state value is reached. This unexpected displacement of the current-voltage curve, which has also been observed by Japanese authors[158], can be explained by strong adsorption of intermediates, which completely blocks the evolution of hydrogen and allows the further reactions of the intermediates to proceed only at negative potentials.

Slotterbeck[159] was able to obtain a material yield of 60% with a current yield of 50% for short periods on copper electrodes freshly electroplated with lead, but these values decreased considerably after only one day. It was found[160] that with cathodes electroplated with zinc, the result depends on the support; this may be due to orientation effects.

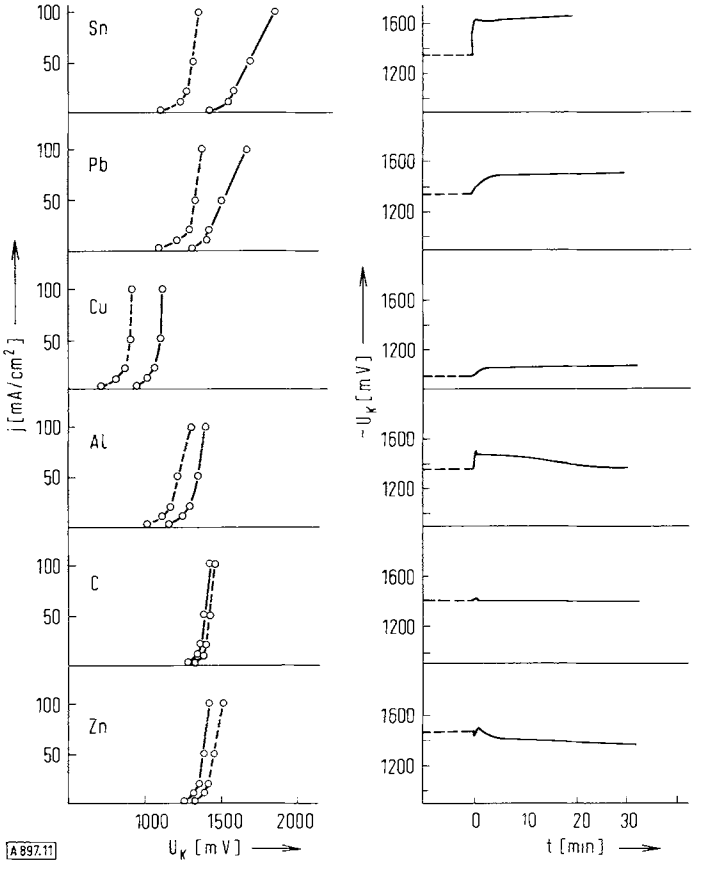

Fig. 11. Electroreduction of acetone in aqueous sulfuric acid. Left: current-voltage curves, right: voltage-time curves. (---) 1 N H_2SO_4; (——): 1 N H_2SO_4 + 1 mol/l of acetone. Current density $j = 50$ mA/cm².

The electrosynthesis of pinacol was of industrial interest for some decades, since it allowed direct access to 2,3-dimethyl-1,3-butadiene, an intermediate for the production of methyl rubber. The many early patents testify to the development work carried out. An original cell with an overlayered catholyte, in which no diaphragm is needed, is the subject of one of these patents[161]. Other aliphatic ketones such as methyl ethyl ketone [reaction (43)][162], diethyl ketone[163], diisopropyl ketone [reaction ((44)][164], or cyclohexanone [reaction (45)][165] also give the pinacols only in moderate yields.

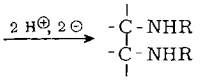
This is also true of aliphatic aldehydes such as acetaldehyde and propionaldehyde [reaction (46)][166]; according to a Russian patent[167], however, glyceraldehyde can be hydrodimerized in high yields to the hexitol [reaction (47)]. Glyoxylic acid (which can be obtained electrochemically from oxalic acid) can be converted into tartaric acid[168].

4.2.2. Aromatic Ketones and Aldehydes

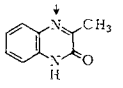
In the aromatic series, the ketyls formed as intermediates in the reduction are stabilized by the aromatic system. The tendency to form organometallic compounds is much smaller than in the aliphatic series, but the reactivity is just high enough for the dimerization to proceed preferentially. The ketyl of benzophenone can be readily detected and followed kinetically by ESR spectroscopy[169], with the rotating ring-disk electrode[170], by cyclic voltammetry, and even polarographically[171].

Almost quantitative yields are obtained for acetophenone [reaction (48)][172-174], propiophenone[175,176], and the higher alkylphenones[176]. *Stocker et al.*[174] investigated the stereoselectivity of the pinacol formation for acetophenone. In alkaline media, it was possible to increase the DL/*meso* ratio to 3, irrespective of the cathode material. Further examples are 2-acetylfuran[177], 2-acetylthiophene[178], and 2- and 3-acetylpyridine[179][*], which has also been synthesized industrially as a pharmaceutical intermediate[180]. The same is true of *p*-hydroxypropiophenone[181,182], which has been dimerized industrially to the glycol with a material yield of 50%.

Diketones, such as dimedone [reaction (51)][183], 1,3-diphenyl-1,3-propanedione [reaction (52)][184] and phenyl glyoxylate[185] are also dimerized smoothly because of the mutual activation of the CO groups. Keto groups in crossed conjugated systems such as cyclohexadienone[186] or croconic acid [reaction (54)][187] (cf. Table 5) also react to give the pinacol in high yields. Because of the double activation of the CO group, the dimerization takes place in the 2,2 position and not in the 4,4 position.



Benzaldehyde gives hydrobenzoin, which is also formed on reduction of the product obtained by chemical condensation. The DL/*meso* ratio can be as high as 3.25[188]. With vanillin as the starting material, the pure *meso* form of hydrovanilloin is obtained for steric reasons[189]. Salicylaldehyde also gives the pinacol[190]. The yield increases with increasing substrate concentration.



4.3. Azomethines

The cathodic hydrodimerization of azomethines leads to derivatives of ethylenediamine (cf. Table 6). The hydrolysis of the monomer must be suppressed by the use of low temperatures and neutral or alkaline solution[191]. *N*-Benzylideneaniline gives medium yields on Hg cathodes [reaction (56)][192] but almost quantitative yields on reduction with alkali metal[193]. Asymmetric optical induction was observed in the reduction of *N*-(α-methyl benzylidine)-benzylamine on Hg cathodes in the presence of chiral supporting electrolyte [reaction (57)][194]. On lead cathodes, the hydrodimer is formed above all in alkaline solution[195]. Quinazoline is a cyclic compound with an activated C=N bond[196]. The 4,4-dimer formed [reaction (58)] can be readily cleaved again by oxidation. In the case of quinoxalones alkylated in position 3, the dimerization occurs by formation of an N—N bond [reaction (59)], which can also be readily broken again[197].

[*] For 2-acetylpyridine, unlike for acetophenone, the DL/*meso* ratio is found to depend on the electrode material.

Table 6. Cathodic dimerization of azomethines.

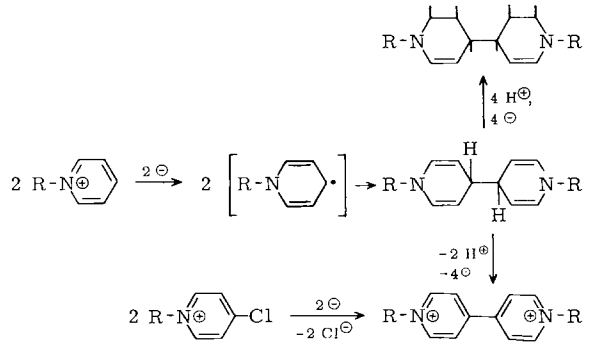
(59)		

4.4. Cations

4.4.1. Immonium Ions

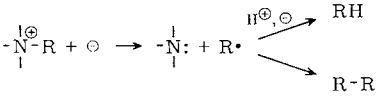
The hydrodimerization of immonium ions is similar to the hydrodimerization of azomethines. *Andrieux* and *Savéant*[198,199] have investigated this field very thoroughly.



(60)

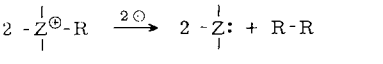
On discharge, free radicals are formed, and can be detected by cyclovoltammetry[199] and ESR spectroscopy[200]. In most cases, *e.g.* in reaction (60), the primary electron transfer is irreversible, and a free radical mechanism leads to the dimer. Cations highly substituted with aromatic groups are reversibly discharged to form stable radicals. The electrolysis must be carried out in acetonitrile owing to the ease of hydrolysis of the immonium ions.

4.4.2. Pyridinium (Quinolinium) Ions



This type of cathodic dimerization is also similar to the reaction with azomethines. *Emmert* was able to show that in the reduction of pyridinium or quinolinium salts on lead in sulfuric acid solution, tetrahydrobipyridyl or tetrahydrobiquinolyl is formed[201], the reaction proceeding *via* deeply colored radicals as intermediates. The dimerization takes place in the 4,4 and 2,2 positions, and to a small extent in the 2,4 position. Tetrahydrobipyridyl can be reduced further to the octahydro product, but can also be oxidized *e.g.* with air to the dication; because of the herbicidal activity of these compounds, both the reduction of pyridinium salts with alkali metal amalgam or cathodic

reduction on lead in alkaline solution[202,203] and the oxidation to the dication[204] have been subjects of recent development work. By reversible uptake of an electron, the dication can be reduced to a radical-cation[205,206]. It has also been obtained in one step, by reduction of 4-chloro- or 4-cyanopyridinium salts; the substituents are eliminated as anions[207,208].

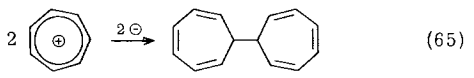


4.4.3. Other Cations

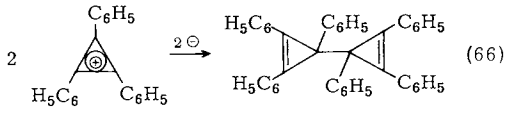
The reductive cleavage of quaternary ammonium ions was discovered by *Emmert*[209]. *Horner* later constructed a cleavage series for the groups removed[210]. Only the hydrogenated product is formed in aqueous solution[210].

In DMF[211] and hexamethylphosphoramide[212], on the other hand, the formation of dimers was observed (cf. Table 7). Ylides are also obtained with phosphonium-[213]

Table 7. Cathodic dimerization of ammonium, phosphonium, and sulfonium ions.



Reaction	Compound	Yield [%]
(61)	$C_6H_5-\overset{\oplus}{N}(CH_3)_2-\underset{\uparrow}{CH_2}-C_6H_5$	35
(62)	$(CH_3)_3\overset{\oplus}{N}-\underset{\uparrow}{CH}(CH_3)-C_6H_5$	30
(63)	$(C_6H_5)_3\overset{\oplus}{P}-\underset{\uparrow}{CH_2}-C_6H_5$	31
(64)	$(CH_3)_2\overset{\oplus}{S}-\underset{\uparrow}{CH_2}-C_6H_4-NO_2(p)$	

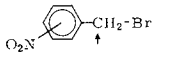


and sulfonium salts[214]. The cleavage of the dimethyl-*p*-nitrobenzylsulfonium ion occurs at such positive potentials (0.7 V) that the nitro group is not attacked, and the dimeric product *p,p'*-dinitrobibenzyl can be isolated[215].

4.4.4. Cyclic Cations

As can be seen from reactions (65) and (66), cyclic cations such as the tropylium ion[216,217] and the triphenylcyclopropenylium ion[218,219] dimerize quantitatively when discharged cathodically or with reducing agents.

(65)

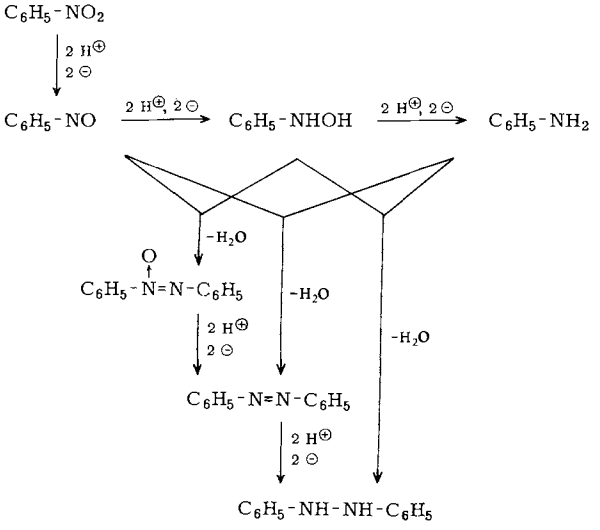


(66)

4.5. Halogen Compounds

The electrochemical reduction of halogen compounds can lead, with elimination of halide ions, to dimeric products. The frequently observed formation of organometallic compounds points to a free-radical mechanism. The industrially important dimerization of β-chloropropionitrile [reaction (67)] to form adiponitrile either with Na amalgam[220,221] or cathodically[222,223] is the subject of several patents. One disadvantage is the chloride that is always formed. The dimerizations of benzyl bromide[224] and of nitrobenzyl bromide [reaction (68)][225] have also been intensively studied. The latter reaction was carried out in acetonitrile with tetraethylammonium perchlorate.

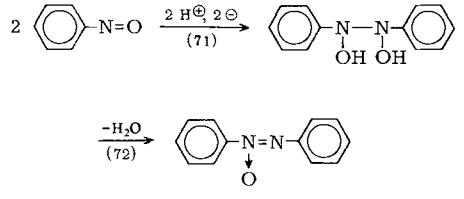
Table 8. Cathodic dimerization of halogen compounds.



Reaction	Compound	Yield [%]
(67)	$NC-\underset{\uparrow}{CH_2}-CH_2-Cl$	90
(68)		
(69)	$R-CO-\underset{\uparrow}{CH_2}-CH_2-Cl$	
(70)	$(p\text{-}H_3C-C_6H_4)_2CH-\underset{\uparrow}{CH_2}-Cl$	

In earlier work[226], the dimer of 1,1-di-*p*-tolyl-2-chloroethane was obtained [reaction (70)] (cf. Table 8). β-Chloro ketones give diketones[227].

4.6. Nitroaromatic Compounds



The classical reductive dimerization of aromatic nitro compounds[228] to form azoxybenzene, azobenzene, and hydrazobenzene derivatives (cf. Scheme 4) can be formally regarded as a condensation of the intermediates. The best yields are obtained in alkaline solution; the intermediate azoxybenzene can be intercepted in aqueous solution, since it is sparingly soluble, and is therefore withdrawn from the further reduction. However, as was shown by *Haber* in his fundamental investigation[229], azoxybenzene is also formed in alcoholic aqueous solution (with a current yield of 76%) if the electrolysis is carried out at a constant potential ($U_K = -0.84$ V). Hydroxylamine reacts very

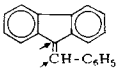
rapidly with nitrosobenzene to form azoxybenzene. An electrochemical mechanism, *e.g.* in accordance with reactions (71) and (72), thus does not seem to be ruled out. Trifluoronitrosomethane can be dimerized cathodically[273]. The formation of an N—N bond *via* the hydrodimerization of a C=N bond was mentioned in Section 4.3.

Scheme 4. Cathodic dimerization of nitroaromatic compounds, with nitrobenzene as the example.

Hydrazobenzene has been produced on the industrial scale with a current efficiency of 90% as an intermediate for the production of benzidine. The divided cells were fitted with steel cathodes covered with spongy lead[230–232].

4.7. Mixed Dimers with Identical Activated Groups

The mixed dimerization of two activated olefins or two ketones A and B should lead preferentially to the mixed dimer AB if the reaction is carried out close to the potential of the more easily reducible component (A), with introduction of a large excess of the other component (B)[233]. In most cases, an ionic mechanism appears to occur. A reacts at the cathode to form an anionic intermediate ($A^{\bullet\ominus}$, $AH^{\ominus}$), which reacts as a nucleophile with the acceptor molecule B. Free-radical mechanisms cannot be ruled out, *e.g.* in the case of the ketones.



Some characteristic examples are shown in Table 9. Ethyl acrylate and acrylonitrile, whose reduction potentials differ by only 0.1 volt, react to give the cyano ester in a material yield of 60% [reaction (73)] at a cathode[222, 234], or with sodium amalgam[235]. This electrolysis has also been carried out in undivided cells[236]. In the coreduction of diethyl maleate and acrylonitrile, whose reduction potentials differ considerably (0.5 V), *Baizer* made the interesting observation that the yield of mixed dimer increases rapidly as the potential becomes more negative [reaction (74)][237]. This observation has been confirmed by other examples[238]. Even when the reaction was carried out at the potential of the less easily reducible compound, a large quantity of mixed product was obtained. To explain this, it is assumed that the reactivity of the acceptor increases with increasing potential as a result of a field effect. The concentration of the acceptor in the diffusion layer is also much higher than that of the electroactive particle, which can react even at the limiting current density. The specific adsorption of the acceptor may also play some part.

Other examples are the reaction of acrylonitrile with 1,4-dicyano-1-butene[239], vinylpyridine[240], and mesityl oxide [reaction (76)][241]; with the last of these combinations, several cyclic products are also formed[242]. With 9-benzylidenefluorene [reaction (77)][243], acrylonitrile acts as the donor; an interesting feature here is the double addition, in which 9,10-dicyanoethylbenzylidenefluorene is formed.

Table 9. Cathodic codimerization of compounds with identical activated groups.

Donor (A) Acceptor (B)

Reaction	Donor	Acceptor	Yield [%]
(73)	$H_5C_2OCO—CH=\underset{\uparrow}{C}H_2$	$\underset{\uparrow}{C}H_2=CH—CN$	60
(74)	$H_5C_2OCO—CH=\underset{\uparrow}{C}H—COOC_2H_5$	$\underset{\uparrow}{C}H_2=CH—CN$	23
(75)	$NC—\underset{\uparrow}{C}H=CH—CH=CH_2$	$\underset{\uparrow}{C}H_2=CH—CN$	55
(76)	$CH_3—CO—CH=\underset{\uparrow}{C}(CH_3)_2$	$\underset{\uparrow}{C}H_2=CH—CN$	
(77)	$NC—CH=\underset{\uparrow}{C}H_2$		
(78)	$(CH_3)_2N$-C6H4-$CO-CH_3$	CH_3O-C6H4-$CO-CH_3$	35
(79)	$C_6H_5—CO—C_6H_5$	$CH_3—CO—CH_3$	18

In series of ketones, *Allen* mentioned a number of mixed hydrodimerizations, *e.g.* of *p*-dimethylaminoacetophenone and *p*-methoxyacetophenone [reaction (78)][244]. *Nicolas* and *Pallaud* recently combined acetone with benzophenone [reaction (79)][245].

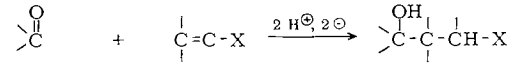
4.8. Mixed Dimers with Different Activated Groups

Most investigations in this field are concerned with the reaction of acetone with an activated olefin (cf. Table 10). As was shown earlier, acetone itself dimerizes only with poor yields. As early as 1965, *Sugino* and *Nonaka* reported that acetone and acrylonitrile give the mixed hydrodimer in good yields in sulfuric acid solution [reaction (80)][246,247]. *Brown* and *Lister* were able to detect a free-radical mechanism by kinetic measurements[248]; even at $U_K = -1.3$ V, ketyls are formed, and these add to the acrylonitrile.

In neutral solution in the presence of quaternary ammonium salts, *Baizer* recently obtained the mixed hydrodimer in a material yield of 85%[238]. Since unprotonated acetone is reduced only at $U_K = -2.4$ V, the roles are reversed in this case.

Nicolas and *Pallaud* coelectrolyzed acetone with hydrocarbons such as styrene [reaction (81)], butadiene, and cyclohexene, and obtained tertiary alcohols in moderate yields[236,249]. Similar coelectrolyses of acetone with pyridine [reaction (82)][250] and benzophenone[240] have been described. Reaction with allyl alcohol leads to very good yields of 4-methyl-1,4-pentanediol, which is cyclized with dilute sulfuric acid to 2,2-dimethyltetrahydofuran[251,252].

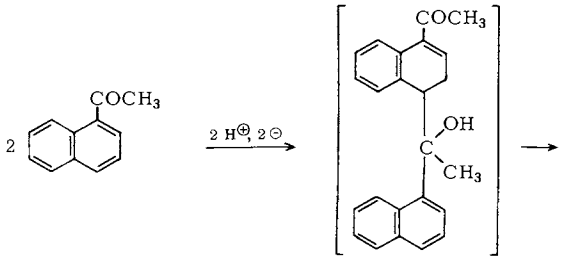
The mixed dimerization of acrylonitrile with halogen compounds such as β-chloropropionitrile (→ adiponitrile) [reaction (85)][220,253] or chloro ketones[254] has already been examined in detail.



The intermediates formed on cleavage of quaternary phosphonium ions [reaction (86)][255,256] and tertiary sulfonium ions[257] can add to acrylonitrile and similar compounds.

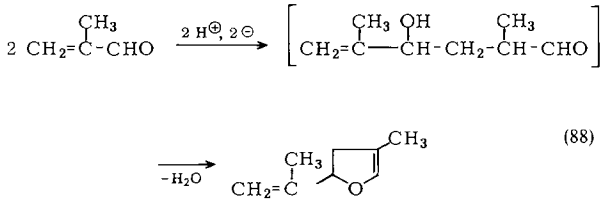
The mixed coupling of activated olefins with azomethines or azo compounds leads to cyclic products[113,258].

A Japanese patent describes the mixed dimerization of acrylonitrile and acetonitrile to form glutaronitrile[259].



Two examples that prove only on closer inspection to belong to this section are the hydrodimerization of 1-acetylnaphthalene [reaction (87)][260] and the hydrodimerization of methacrolein [reaction (88)][261].

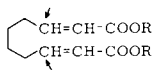
Table 10. Cathodic codimerization of compounds with different activated groups.

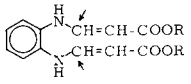


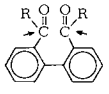
Donor (A) Acceptor (B)

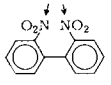
Reaction	Donor	Acceptor	Current Efficiency [%]	Yield [%]
(80)	$CH_3-CO-CH_3$	$CH_2=CH-CN$	70	70
(81)	$CH_3-CO-CH_3$	$CH_2=CH-C_6H_5$	25	42
(82)	$CH_3-CO-CH_3$			73
(83)	$CH_3-CO-CH_3$	$CH_2=CH-CH_2OH$	70	95
(84)	$C_6H_5-CO-C_6H_5$	$CH_2=CH-CN$		15
(85)	$Cl-CH_2-CH_2-CN$	$CH_2=CH-CN$	90	90
(86)	$(C_6H_5)_3\overset{\oplus}{P}-CH_2-CH_2-CN$	$CH_2=CH-C_6H_5$		10

(87)



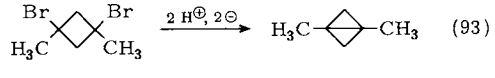






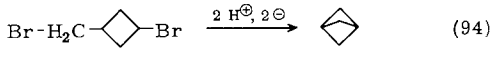
(88)

4.9. Cyclizations



In electrochemical cyclizations, any of the dimerization reactions discussed so far can in principle proceed *intramolecularly* if the steric conditions in the molecule allow this. Some examples are shown in Table 11; a detailed review of this subject was published in 1969[262].

Table 11. Cathodic cyclizations. R = alkyl.



Reaction	Compound	Current Efficiency [%]	Yield [%]
(89)		90	
(90)		86	
(91)			50
(92)			95

The ring closure can be carried out on some activated bisolefins with high yields [cf. reaction (89) and (90)][263-265]. The pinacol formation between two keto groups has also been used for cyclization [reaction (91)][266]. It was similarly shown at a very early date that the dinitro compound gives the cinnoline (N=N linkage) in accordance with reaction (92)[267].

(93)

(94)

The cathodic elimination of halogen has often been used for ring closure reactions; whereas dibromodimethylcyclobutane can be smoothly reduced to the bicyclic compound (material yield 94%) in accordance with reaction (93)[268-270], bicyclo[1.1.1]pentane is formed from bromo(bromomethyl)cyclobutane [reaction (94)] in a material yield of only 4%. The main product is 1,4-pentadiene, which is formed by ring cleavage[271].

5. Concluding Remarks

Whereas the investigation of electrochemical "homodimerizations" has been brought to some sort of conclusion through the rapid developments of the past ten years, the investigation of the "heterodimerizations" is just beginning (cf. Sections 4.7 and 4.8). The number of possible variations is immense. The use of the principle of "coelectrolysis", in which at least two organic substrates are allowed to react together in an electrolytic cell, one of these substrates being converted at the electrode into reactive intermediates, which react further with the second component, will lead to many valuable preparative results in the future. Specific electrochemical factors such as supporting electrolyte effects, concentration profiles in the diffusion layer, and adsorption will lead in this work to unexpected products. Together with the undeniable technological advantages of this reaction technique, this will help greatly toward the advance of organic electrosynthesis.

Organic Syntheses in the Plasma of Glow Discharges and Their Preparative Application

By Harald Suhr[*]

It is only during the last few years that reactions of organic substances as a result of electron collisions in the cold plasma of glow and corona discharges have been developed into a preparatively useful method with a wide range of possibilities. Its basic principles and development prospects are discussed in the present progress report on the basis of the research results that are known at present.

1. Introduction

In the continuous search for new methods of syntheses, the possibility of using the plasma[**] of spark, arc, and glow discharges for this purpose was examined by chemists at an early date[2][***]. However, many of the earlier efforts met with only slight success. This is easy to understand nowadays, since the early experimental techniques were unfavorable, and gave only low yields and nonuniform reaction products. The organic compounds investigated in this way decomposed in the plasma, largely with formation of tarry or polymeric products. Despite the numerous efforts to make preparative use of reactions in plasmas, therefore, the only processes of this type that have achieved any industrial importance are the formation of ozone in silent discharges and the formation of nitrogen oxides and of acetylene in an arc. Apart from these, a few syntheses of inorganic compounds on the laboratory scale[3a] and the modification of oils[3b] have also been developed. It is only in the last few years that organic syntheses on the preparative scale have been successfully carried out in plasma. These results and the possible applications of plasma chemistry with organic compounds form the subject of the present report.

[**] Plasma = partly ionized gas.

[***] A large number of publications (cf. [1g]) report successful attempts to synthesize fairly complicated systems from very simple starting materials and to break down or isomerize organic compounds by plasma reactions. However, the present review deals only with those that are closely concerned with preparative applications.

2. Forms of Discharge

The various types of electric discharge are best illustrated with the aid of a current-voltage diagram (Fig. 1)[4]. A current flows between two electrodes that project into a vessel having a low gas pressure and that are connected to a source of direct current. Various regions with different types of discharge, depending on the current strength, are clearly discernible. At currents of less than 10^{-12} A, the current flow is unsteady, and occurs only when charged particles are produced in the vessel by cosmic radiation or light quanta. At higher current strengths, the production of electrons by external agencies is no longer necessary. The self-supporting dark discharge occurs in the region of $10^{-12}-10^{-5}$ A, and this is followed by a region in which the passage of current is associated with luminous phenomena. The weakly luminous glow discharge appears first between 10^{-4} and 10^{-1} A, and the bright arc occurs at current intensities of more than 1 A. Whenever the current is switched on, the discharge passes through all the stages in a short time (approx. 1 ms) until the type determined by the magnitude of the resistance is reached. If low-frequency alternating current of up to about 1000 Hz is used instead of direct current, a new discharge builds up in each half cycle. The decay of a discharge takes approximately 0.5 ms. At frequencies of more than 1000 Hz, therefore, the time between two half cycles is no longer sufficient for the ionization to decay completely. Numerous electrons are therefore already available for the ignition process in the next half cycle.

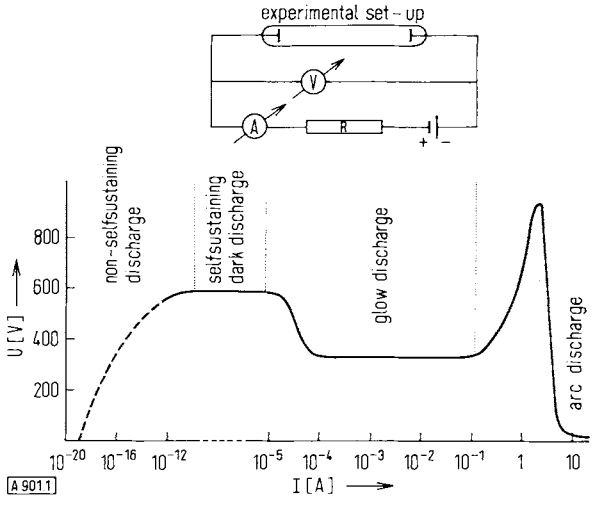

Fig. 1. Plot of a current-voltage curve in a vessel 50 cm long filled with neon at 1 torr. The various types of discharge appear at various resistance values.

At higher frequencies, discharges can be maintained even if the electrodes are situated outside the low-pressure vessel (capacitive coupling). Energy can be equally easily supplied to the plasma by induction if a coil is wound round the vessel and connected to a high-frequency generator.

The elementary processes of electric discharges[4] can be most simply described as follows. Individual electrons, formed *e.g.* by cosmic radiation, are accelerated by the electric field, and can excite or ionize atoms or molecules with which they collide. Since a new electron is released in each ionization, the number of electrons avalanches until it reaches an equilibrium value determined by the rates of the electron-supplying and electron-consuming processes. The main electron-consuming process is recombination in the gas phase or on the wall of the vessel.

The possibilities of using the various forms of discharge in chemistry depend on the thermal stabilities of the starting materials and of the final products, since extremely high temperatures sometimes occur in the discharges. It is necessary here to distinguish between the temperatures of the electrons, of the ions, and of the neutral molecules. A temperature can be formally assigned to each particle on the basis of its velocity:

$$\frac{m}{2}v^2 = \frac{3}{2}kT.$$

In a discharge, electrons and ions acquire additional velocity through the electric field, and hence a higher "temperature" than the neutral particles. Because of their high mobility, the electrons reach a particularly high temperature. In a neon tube, for example, the temperature of the electrons is about 25000 °C, whereas that of the neutral particles and ions differs only slightly from the ambient temperature. Systems of this type in which the temperature of the electrons is much higher than that of the neutral particles and of the ions are known as cold or nonequilibrium plasmas; if the temperatures of the electrons, ions, and neutral particles differ only slightly from one another, one speaks of hot or equilibrium plasmas. Typical examples of cold plasmas are glow discharges and corona discharges, while arcs are typical of hot plasmas.

Arc discharges with gas temperatures above 1000 °C can be used for chemical syntheses only if the reaction products are thermally very stable. Carbides, borides, and nitrides have been prepared in arc discharges. Only a few organic compounds, such as HCN, C_2N_2, C_2H_2, and CO, can withstand such temperatures without decomposing. Larger molecules are broken down under these conditions[5-7].

In glow and corona discharges, the gas temperatures are so low that thermal decomposition of organic substances can be avoided. They should therefore be suitable for many syntheses. Despite intensive efforts, however, only a few syntheses (mainly inorganic) have been achieved with cold discharges[2, 8]. Apart from the formation of ozone, which was mentioned earlier, the most important of these are the syntheses of hydrazine[9-12], sulfur monoxide[13], and halides and hydrides[8] of boron, silicon, germanium, phosphorus, and arsenic. Experiments with organic substances did not lead to any preparatively useful syntheses. Though it was possible to show that most organic compounds undergo chemical changes in cold discharges, the products were mainly polymeric material or low molecular weight decomposition products. The reasons for the earlier failures have been revealed only by recent investigations. Most organic compounds have only a low stability in the plasma, must not be exposed to excessively high energies, and must be removed quickly from the reaction zone to avoid complete decomposition. These facts impose a very narrow

range of experimental conditions in which syntheses can be carried out with preparatively useful yields.

3. Execution of Reactions in Cold Plasmas

Since glow discharges occur only under reduced pressure, all arrangements that make use of this form of discharge show some resemblance to vacuum distillation apparatus (cf. Fig. 2).

A particularly simple arrangement is a glass apparatus with metal electrodes, across which a DC or low-frequency AC voltage of 20—50 V/cm is applied (Fig. 2a). Experimental arrangements of this type are very suitable for the preparation of atomic hydrogen, nitrogen, or oxygen[14,15]. For the reaction of organic compounds, the electrodes must be protected by an inert gas, since they otherwise rapidly become coated with decomposition products[16]. Apparatus of this type is cheap and robust, but is dangerous because of the high voltages required.

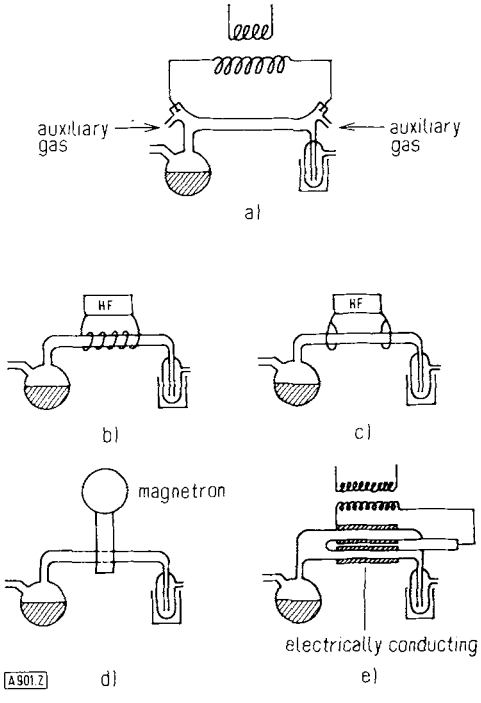

Fig. 2. Simple forms of apparatus for reactions in glow discharges.

No electrode problems arise in short-wave and microwave units. The short-wave energy is coupled inductively or capacitively to the plasma (Fig. 2b and 2c). For microwave discharges (Fig. 2d), quartz[*] reaction tubes are passed through the wave guides or through resonance cavities. Microwave and short-wave generators are commercially available. Short-wave generators can also be constructed in the laboratory at low cost. Even the simplest push-pull oscillators give good results. Multistage oscillators have the advantage of high stability of frequency and power output independent of load conditions. After matching the high-frequency energy in both cases can be easily carried from the oscillator to the reaction vessel by coaxial cables. This separation of the electronic from the chemical apparatus greatly facilitates operation.

For corona or silent discharges, DC or low-frequency AC current flows through a glass wall (Fig. 2e). In this way, one obtains low-current discharges, which are uniformly distributed over the entire surface. The advantage of this form of discharge is that operation at normal pressure is possible. Against this it has the disadvantage that high voltages must be used, and that very large surface areas are necessary for high conversion rates.

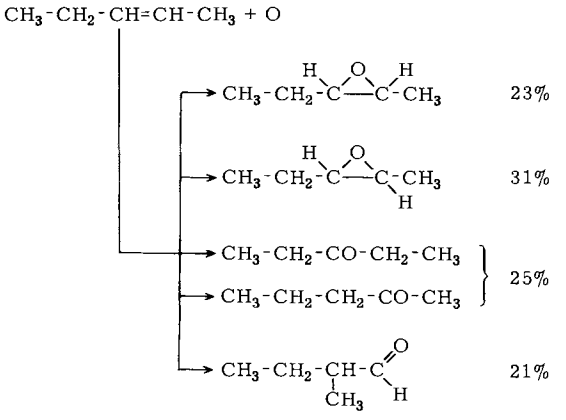
Experience gained so far in organic plasma chemistry shows that the result of the reaction depends mainly on the field strength, pressure, and vessel dimensions, so that similar results can be obtained with various types of discharge. Short-wave apparatus is therefore recommended for laboratory work because of the ease of operation, while the simpler high-voltage types of equipment are recommended for larger units.

4. Applications

4.1. Reactions of Atomic Gases with Organic Compounds

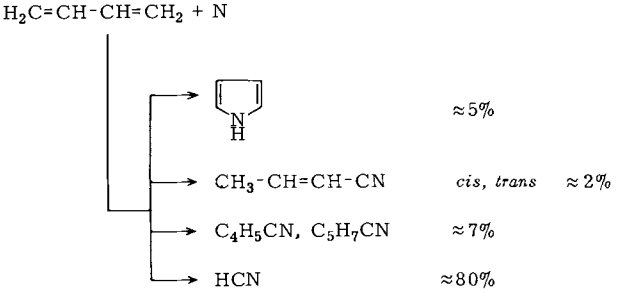
Glow discharges are excellently suited for the dissociation of molecular hydrogen, oxygen, or nitrogen into atoms. Since the atoms recombine mainly on the wall, high yields are obtained only if the walls are "poisoned" with certain substances such as water, phosphoric acid, Dryfilm, or Teflon[17-22].

The atomic gases can react with many organic compounds[23-25]. Atomic hydrogen abstracts hydrogen atoms from saturated compounds[26] and adds to unsaturated compounds[27]. In both cases free radicals are formed, and these can give a variety of further products by decomposition, disproportionation, combination, or rearrangement:



$$\left.\begin{array}{l} H\cdot + H_3C\text{-}CH_3 \rightarrow H_2 + CH_3\text{-}CH_2\cdot \\ H\cdot + H_2C{=}CH_2 \rightarrow CH_3\text{-}CH_2\cdot \end{array}\right\} \rightarrow \text{Products}$$

Atomic oxygen abstracts hydrogen from saturated compounds. With unsaturated compounds, the first reaction step is the formation of an epoxide, which then partly rearranges to form carbonyl compounds[27-30]. Thus 2-pentene gives approximately 50% of *cis-trans*-pentene oxide, 25% of diethyl and methyl propyl ketones, and 20% of 2-methylbutanal. A synthesis of particular industrial interest is that of propylene oxide from propene and atomic oxygen. Mixtures of oxygen and propene give good yields of propylene oxide in silent discharges. With a conversion of 20%, approximately 30% (corresponding to 100 g/kWh) of propylene oxide was obtained[31].

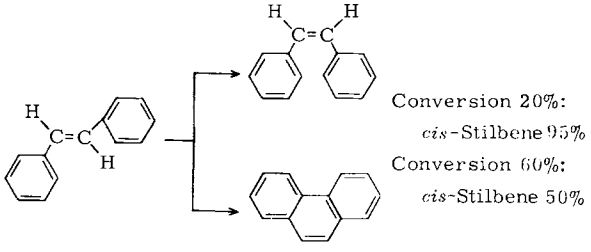


Nitrogen atoms react very vigorously with organic compounds[32-35]. Irrespective of the type of compound, the

[*] Because of the high dielectric losses, glass would heat up too much and might soften.

reaction always yields large quantities of hydrogen cyanide as well as some cyanogen and ammonia. In some cases the yields are so high that the formation of hydrogen cyanide can be used for the determination of atomic nitrogen[36].

Only a few cases are known at present in which active nitrogen was incorporated into organic compounds. In the reaction with butadiene, however, in addition to a large quantity of hydrogen cyanide (about 80%), a mixture of pyrrole, crotononitrile, and cyanobutadiene is formed[37, 38]. Isoprene similarly gives methylpyrrole[39] in yields of about 10%. A reaction was recently achieved between atomic nitrogen and aqueous solutions of organic compounds. However, no products containing nitrogen are formed; the atomic nitrogen merely has a dehydrogenating action, and so converts *e.g.* alcohols into aldehydes[40].



Whereas atomic hydrogen often effects interesting reductions with inorganic compounds, and many substrates can be converted into nitrides with active nitrogen, no preparatively useful syntheses with atomic hydrogen or nitrogen are known as yet for organic compounds.

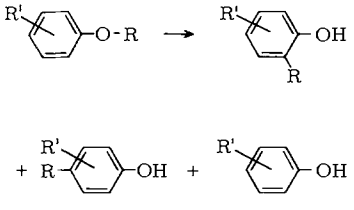
4.2. Reactions of Organic Compounds

Several hundred organic compounds have already been investigated in glow discharges. The findings are very diverse. The number of results that have been reported so far is not yet sufficient to show any clear patterns, but a typical plasma behavior of certain classes of compounds is already discernible. Some typical plasma reactions of this type will be described in the following sections.

4.2.1. Isomerizations

Olefins can be isomerized even under very mild reaction conditions. Thus *trans*-stilbene is converted into the *cis* form[41]. At high flow rates and a correspondingly low conversion, 95% of the reaction product is *cis*-stilbene. If the distillation rate is reduced to increase the conversion, the content of *cis*-stilbene decreases, while the content of phenanthrene increases. Similar isomerizations have been observed for cinnamonitrile, crotononitrile, and stilbazole[42].

Another typical plasma reaction is the change in the position of substituents. In some cases this is only a side reaction. Xylene, for example, in addition to a large quantity of the synthetic product bixylyl (cf. Table 4), gives about 1% of rearranged xylenes[*]. The migration of the sub-



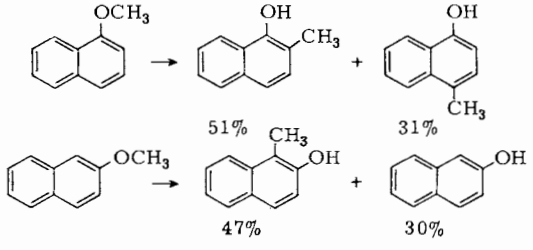


Table 1. Products and yields of rearrangement reactions [45—47].

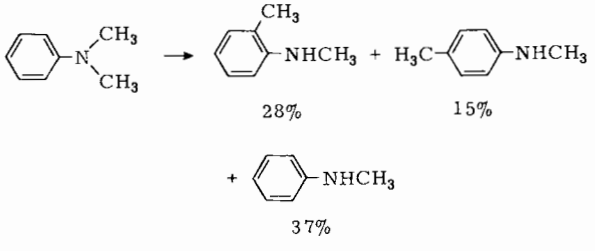
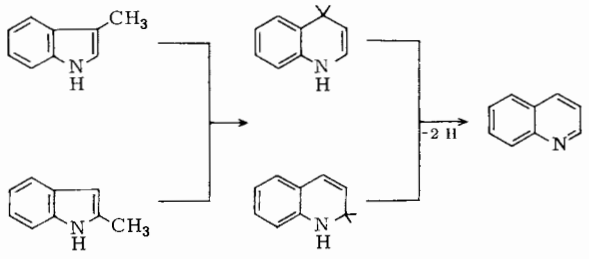
Starting compound	Yields of rearrangement products [mol.-%]				[g/kWh]
Anisole	*o*-cresol	44	*p*-cresol	27	50
Phenyl isopropyl ether	*o*-isopropylphenol	36	*p*-isopropylphenol	22	25
p-Tolyl methyl ether	2,4-dimethylphenol	59			58
1-Naphthyl methyl ether	2-methyl-1-naphthol	51	4-methyl-1-naphthol	31	55
2-Naphthyl methyl ether	1-methyl-2-naphthol	47			58
Diphenyl ether	2-phenylphenol	53	4-phenylphenol	18	180
N,*N*-Dimethylaniline	*N*-methyl-*o*-toluidine	28	*N*-methyl-*p*-toluidine	15	23

[*] In experiments with *p*-xylene that was free from the *ortho* isomer, the xylene component recovered at conversions of 20—50% contained about 1% of *o*-xylene; small proportions of *m*-xylene could not be separated from the *para* isomer under these conditions. Similarly, about 1% of *o*-xylene is formed from *m*-xylene. *o*-Xylene gives approximately equal quantities of the *meta* and *para* isomers [43].

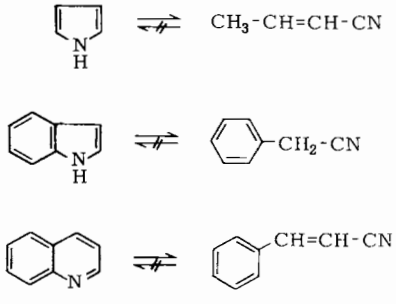


stituents often becomes the main reaction, as in the rearrangement of aryl alkyl ethers to alkylphenols[44]. Methyl ethers and ethers of primary alcohols isomerize as readily as ethers of secondary and tertiary alcohols[45] (Table 1).

Anisole gives a mixture containing 95% of *o*-cresol, *p*-cresol, and phenol. *m*-Cresol, benzene, toluene, and cyclopentadiene are also formed in small quantities. The ratio of *o*-cresol to *p*-cresol can be varied only slightly, whereas the content of phenol in the reaction products is strongly dependent on the experimental conditions. It increases with increasing power, and can ultimately exceed the content of cresol. The rearrangements of other ethers[45, 46] are very similar to those of anisole, but cleavage of the migrating alkyl group sometimes occurs as a side reaction. If the *ortho* or *para* positions are blocked by other substituents in these arrangements, the proportion of the corresponding "phenol" always increases. In the case of the naphthyl methyl ethers[46], the 1-naphthyl derivative gives a mixture of 2- and 4-methyl-1-naphthol, while the 2-naphthyl derivative gives only 1-methyl-2-naphthol.

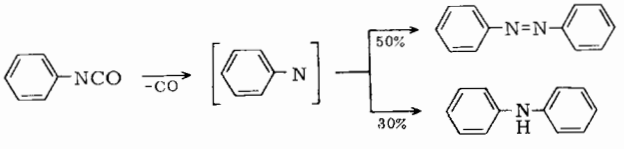


Purely aromatic ethers exhibit similar rearrangements. Diphenyl ether gives a mixture of *o*- and *p*-phenylphenol together with some phenol[47]. The *ortho* compound partly cyclizes to dibenzofuran[47]. Finally, the same reaction can also be detected for vinyl ethers. Ethyl vinyl ether isomerizes to 1-butenal or decomposes to form vinyl alcohol which is isolated as the tautomeric aldehyde[46].



Behavior similar to that of the ethers is shown by the analogous nitrogen compounds[47]. *N, N*-Dimethylaniline gives *o*- and *p*-*N*-methyltoluidine as rearrangement products and *N*-methylaniline as a degradation product (cf. Table 1). When *N*-methylaniline is used as the starting material, *o*- and *p*-toluidine and aniline are found. Other reactions take precedence over the rearrangement in the cases of phenyl esters and acetanilides.

Other types of isomerization in glow discharges are ring contractions, ring expansions, and ring cleavages. Some cycloolefins, such as cycloheptatriene and cyclooctatetraene, rearrange readily in the plasma to form the more stable aromatic compounds toluene and styrene[48]. On the other hand, ring expansions, which are frequently assumed to occur in mass spectroscopy, are unusual in the plasma. The only example observed so far is the rearrangement of 2- or 3-methylindole into quinoline[42].

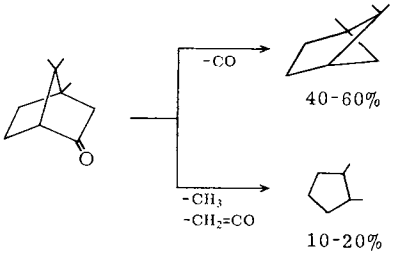


Interesting preparative possibilities are offered by ring-chain isomerizations found for various heterocyclic systems[42]. In glow discharges, pyrrole gives crotononitrile and polymeric material having the same elemental composition. Similarly, indole decomposes to give phenylacetonitrile, and quinoline forms cinnamonitrile. Attempts to

isomerize nitriles to heterocycles, on the other hand, have been unsuccessful[42].

4.2.2. Eliminations

Another type of reaction that proceeds preferentially in glow discharges is elimination. Single atoms or small groups can be removed from many compounds in the plasma without disruption of the rest of the molecule. Eliminations of carbon monoxide, carbon dioxide, and nitrogen proceed particularly smoothly. Thus isocyanates are decarbonylated to nitrenes, which then dimerize or undergo other nitrene reactions. Azobenzene and diphenylamine have been obtained in this way from phenyl isocyanate[49].



Aldehydes and ketones can also be readily decarbonylated (Table 2). The resulting radicals are stabilized by hydrogen abstraction or by dimerization. Thus benzene and biphenyl are formed from benzaldehyde, thiophenecarbaldehyde is converted almost entirely into thiophene[49], and 2-pyridinecarbaldehyde gives pyridine and 2,2'-bipyridyl[42].

The mildness of this decarbonylation is evident in the case of thiophenecarbaldehyde, since no desulfurization occurs at low conversions. Many ketones are decarbonylated in high yields, and so offer interesting synthetic possibilities.

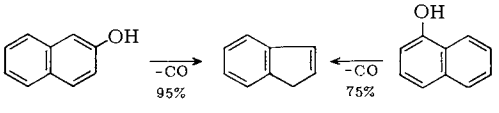


Table 2. Products and yields of some decarbonylation reactions [42, 49, 50].

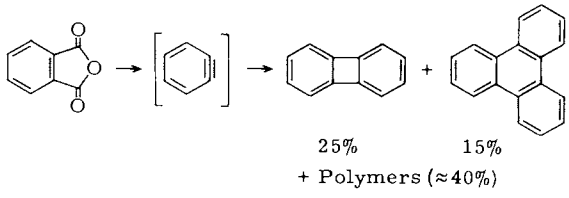
Starting compound	Conversion [%]	Product	Yield [mol-%]	[g/kWh]
Benzaldehyde	63	benzene	81	93
		biphenyl	16	18
Thiophenecarbaldehyde	4	thiophene	99	24
	40	thiophene	86	46
2-Pyridinecarbaldehyde	25	pyridine	70	
		2,2'-bipyridyl	20	
Benzophenone	68	biphenyl	27	18
		fluorenone	36	24
		biphenylene	36	24
Benzil	18	biphenyl	98	27
Fluorenone	20	biphenylene	99	43
	50	biphenylene	99	63
Camphor	76	trimethylbicyclo-[2.1.1]hexane	76	24

Benzophenone gives biphenyl, and in the decomposition of benzil, the formation of biphenyl is almost quantitative[49]. Fluorenone undergoes ring contraction to form biphenylene[50]. Aliphatic cycloketones react nonuniformly, and give only a small quantity of ring-contraction product. The decarbonylation of bicyclic ketones, such as camphor and norcamphor, on the other hand, leads to very good yields of bicyclic hydrocarbons resulting from ring contraction[43, 49].

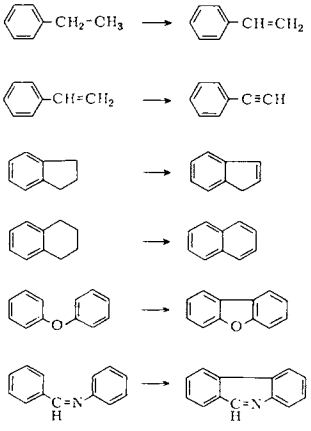


Decarbonylations are also observed for aromatic hydroxy compounds. 10—15% of cyclopentadiene is formed from phenol, while cresols give methylcyclopentadiene in a similar reaction[45]. The yields are considerably higher in the naphthalene series. 1-Naphthol gives up to 75%, and 2-naphthol up to 95%, of indene[51].

The same reaction occurs for 1-nitronaphthalene[48]. This compound decomposes with loss of nitric oxide and subsequent decarbonylation to form the indenyl radical, which is stabilized by formation of indene.

Yields similar to those obtained on decarbonylation are also found on decarboxylation. Carboxylic acids are converted almost quantitatively into the corresponding hydrocarbons. The reaction course is less uniform in the case of esters, but these also preferentially form hydrocarbons[51].

On decomposition of acid anhydrides, carbon dioxide is eliminated first, followed by carbon monoxide. The intermediate carbonyl compounds can be detected in some cases on the basis of the reaction products[51]. The main



product of the reaction is an unsaturated compound. For example, phthalic anhydride decomposes to give dehydrobenzene, which can react further in various ways. If no other reactant is present, biphenylene, triphenylene, or "polyphenyl" is formed[52, 53].

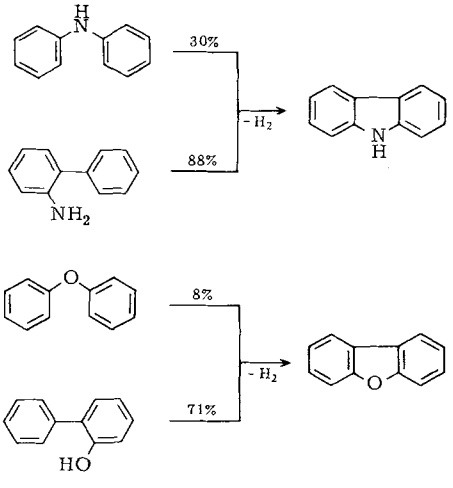
The decomposition of azo compounds in the plasma has so far been investigated only for azobenzene, which is converted in high yields into biphenyl. The isoelectronic compounds benzylidenaniline and stilbene behave differently; they decompose mainly into benzonitrile or cyclize to form phenanthrene, while the formation of biphenyl is only of minor importance.

Many plasma reactions result in the formation of atomic hydrogen or free radicals[17, 54, 55], which then usually react with other molecules with hydrogen abstraction. For

Table 3. Typical dehydrogenation reactions in the plasma [43, 57].

this reason, dehydrogenations in the plasma are very common. They sometimes occur as side reactions, but can also become preparatively useful principal reactions[57]. Alkanes can be converted into alkenes and alkenes into alkynes in this way. Cycloalkanes and cycloalkenes are aromatized with dehydrogenation (Table 3).

Some aromatic systems form 5- or 6-membered rings in the plasma with elimination of hydrogen[43]. In favorable cases, as in the formation of carbazole[56] or dibenzofuran[47], the yields are so high that they offer interesting preparative possibilities.



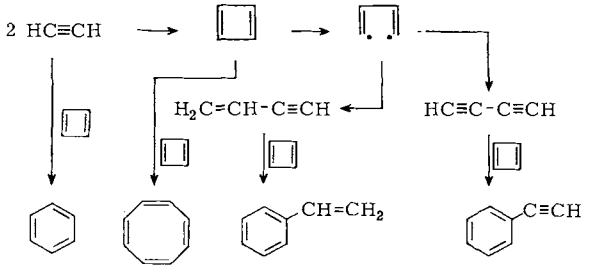
mostly require more elaborate apparatus, and have therefore been investigated in only a few cases.

A bimolecular reaction that very often occurs in the plasma and makes no demands regarding equipment is the dimerization of a compound with removal of hydrogen or other groups. Particularly good yields are obtained with aromatic starting compounds. Thus biphenyl is formed from benzene[44, 58-61], and 1,2-diarylethanes are formed from toluene and other methylaromatic compounds[59, 62-64] and from benzyl halides or benzyl alcohols[43] (Table 4). Substituted ethanes are also formed from aromatic com-

Table 4. Products and yields of dimerization reactions.

Starting compound	Product	Yield [mol-%]	Yield [g/kWh]	Ref.
Benzene	Biphenyl	40	45	[58]
Toluene	Bibenzyl	90	8	[63]
p-Xylene	Bixylyl	90	70	[43]
Durene	Bisdurene	77	43	[43]
Isopropylbenzene	2,3-Diphenylbutane	—	34	[44]
tert-Butylbenzene	2,3-Dimethyl-2,3-diphenylbutane	90	38	[44]
1-Methylnaphthalene	1,2-Di(1-naphthyl)ethane	48	129	[43]
p-Methylbenzonitrile	1,2-Di(4-cyanophenyl)ethane	90	170	[64]

The ease of removal of water or hydrogen halide can also be used for the preparation of olefins[57]. The elimination of other groups has not yet been very extensively studied.



The removal of halogen, hydroxyl, methoxy, or amino groups has been observed in some cases. The yields are mostly low, and the reactions are of little preparative interest.

4.3. Bimolecular Processes

The last section was concerned only with unimolecular reactions, but chemistry in glow discharges is by no means confined to such processes. However, bimolecular reactions

pounds having straight-chain or branched alkyl groups, with C-C bond cleavage in the α position.

Trimerizations and tetramerizations occur only rarely in the plasma. An exception is acetylene, which can also trimerize and tetramerize. Because of its simplicity and its industrial importance, the behavior of acetylene in plasmas has often been investigated[65-67]. In these experiments, in addition to small quantities of vinylacetylene, diacetylene, and benzene, the main product isolated was always a yellow polymer (cuprene). Under certain reaction conditions, however, entirely different results can be obtained[48]. If the surface area of the vessel is greatly increased, the reaction can be stopped at an intermediate stage. Polymer formation can be almost totally suppressed in this way, and compounds containing eight carbon atoms are formed instead, together with vinylacetylene and diacetylene (Table 5). The reaction thus corresponds formally to a tetramerization of acetylene, which can be plausibly explained by the intermediacy of cyclobutadiene:

If the reaction is not stopped at the tetramer, it proceeds to yield high molecular weight compounds. The IR spectra

of the polymerization products from acetylene are very similar to those of polystyrene[60].

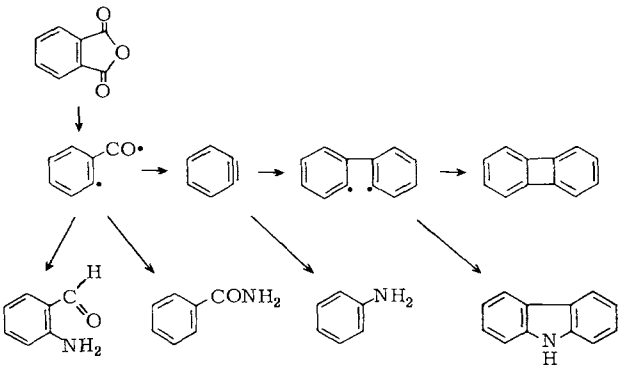


Table 5. Liquid products of the plasma reaction of acetylene [48].

Product	Yield [mol-%]
Styrene	30—70
Phenylacetylene	15—50
Cyclooctatetraene	1
Benzene	5—10
Naphthalene	10—20

Polymerizations are observed much more frequently than oligomerizations in the plasma. In addition to the usual monomers, such as styrene and butadiene, compounds exhibiting no tendency to polymerize under normal conditions can also be polymerized in the plasma[68-73]. For example, under drastic conditions, benzene gives a polymeric material, presumably "polyphenyl", as the only product[59, 60]. A high molecular weight substance, presumably "polyphenyl", is similarly obtained from phthalic anhydride. A series of compounds containing nitrogen, such as pyrrole, pyridine, and aniline, are converted in the plasma into unsaturated nitriles, which can be readily polymerized[42].

In bimolecular reactions of two different components, the range of favorable operating conditions is very narrow. Outside this range, at most only one of the components reacts. Under suitable reaction conditions, propylene oxide has been prepared from propene and oxygen[31], and styrene oxide from styrene and oxygen[48]. Mixtures of benzene and oxygen give phenol[51, 74], and mixtures of benzene and ammonia can be converted into aniline[42, 75]. The yields in such reactions are often unsatisfactory. Systematic attempts to optimize the processes have so far been made only for propylene oxide[31].

Another interesting possibility for carrying out bimolecular reactions is to produce reactive intermediates in the plasma and to intercept these with suitable reactants. This possibility has been investigated in the case of phthalic anhydride[53]. In the first reaction step, the compound loses carbon dioxide, and carbon monoxide is then eliminated to form dehydrobenzene. Two molecules of dehydrobenzene can then combine to form a biphenyl diradical, which cyclizes to biphenylene or reacts with another molecule of dehydrobenzene to form triphenylene. The reaction can be stopped at any of the intermediate stages by means of interceptor reagents. The addition of hydrogen reduces the yields of biphenylene and triphenylene in favor of biphenyl formation. Sulfur atoms also react with the biphenyl diradical to form dibenzothiophene. Dehydrobenzene can be intercepted by the addition of acetylene, and the main reaction product in this case is phenylacetylene. Finally, all the intermediates react with ammonia. The benzoyl radical gives aminobenzaldehyde and benzamide, dehydrobenzene gives aniline, and the biphenyl diradical reacts to form carbazole:

Preparative organic plasma chemistry is still at an early stage of development. The results obtained so far have already shown many possibilities for specific reactions and preparative applications. Most of the investigations have been carried out on simple model compounds, but the results obtained can be readily applied to other, preparatively more attractive systems.

More complicated compounds can often react in several ways, and in such cases the reaction with the lowest energy requirements usually occurs preferentially. To be able to predict the reaction course, the reactivities of the various groups must be known. For this purpose, one still has to rely largely on experience and estimates based on bond energies. If the molecules contain only relatively strong bonds, they react only with difficulty in the plasma. C-C and C-H bonds in aromatic compounds and double and triple bonds are therefore particularly stable. C-C bonds in aliphatic systems are moderately stable, and C-C bonds in benzyl or allyl positions are particularly easily broken. Most functional groups react readily in the plasma. Aldehyde, carboxyl, nitro, and azo groups are most readily attacked. Carbonyl, hydroxyl, alkoxy, amino, and alkyl groups as well as halogens also react under rather more drastic conditions. Only cyano and ethynyl groups and fluorine have been found to be stable substituents.

5. Reaction Mechanisms

In a plasma reaction, the starting materials are known and the end products can be determined by analysis. However, the reaction path is usually unknown. The reaction course can be influenced only by variation of pressure, electron energy, and residence time. Interception reactions or other means for the identification of intermediates are only rarely possible. Views on the mechanisms of organic plasma reactions are therefore largely based on a discussion and critical consideration of the various possible elementary processes and on an interpretation based on the reaction products.

Elementary processes of very different types can occur in the plasma. 1 cm^3 of the plasma zone normally contains about 10^{10}—10^{12} electrons and ions as well as 10^{16} neutral particles. Though the charged particles are present only in a low concentration, it is the presence of these particles that makes the plasma reactions possible. The electrons

absorb energy in the electric field and transfer it to the neutral particles in elastic or inelastic collisions.

The transfer of energy by elastic collisions depends on the relative masses of the colliding particles. On collision of an electron with a molecule of mass 100, only 1/100000 of the energy of the electron is transferred to the larger molecule. In the usual preparative plasma experiments, 0.1—1 mol of starting material is passed through the plasma per hour. Each molecule thus spends only about 0.1 s in the plasma, and the quantity of energy that it receives through elastic collisions during this time is so small that neither chemical reaction nor appreciable heating of the neutral gas occurs. The influence of the elastic collisions is therefore extremely small.

The chemical reactions in the plasma are undoubtedly results of inelastic collisions. Various processes can occur in such collisions, depending on the energy of the colliding electrons. Electrons with low energies may be trapped by the molecules to form negative ions. Somewhat higher electron energies lead to the formation of short-lived collision complexes, whose lifetime is sufficient in many cases for part of the kinetic energy of the electrons to be transferred to the molecules. Vibrationally or electronically excited molecules are formed in this way. If electrons with still higher energies collide with the molecules, they may produce positive ions, possibly in a vibrationally or electronically excited state. Since the kinetic energy in an ionizing collision is distributed over three particles, the probability of the formation of electronically excited positive ions is small.

Vibrationally or electronically excited molecules are undoubtedly crucial intermediates in many plasma processes. The role of the ions is less clear. Despite the low degree of ionization, many of the molecules may be temporarily ionized during their passage through the plasma, since the exchange of charge *via* ion-molecule reactions takes place extremely rapidly[77]. However, it is necessary in every case to investigate whether the structural changes in the molecule take place in the ionic state.

The ions revert to the uncharged state by charge transfer or by neutralization. The recombination of a positive ion with an electron can take place only in a three-body collision or on the wall. Though the energy (approx. 10 eV) is distributed between two particles here, the single molecule receives so much energy that it may decompose. There is less danger of decomposition for larger molecules, since these can absorb more energy through their numerous vibrational modes. Many positive ions form complexes with neutral molecules[78–80]. If such a complex recombines with an electron, or a positive ion with a negative ion, the energy liberated can be distributed over several particles and numerous bonds.

The negative and positive ions and the excited molecules may rearrange or decompose. They or their further reaction products, which are often free radicals, may form new species by reaction with unexcited particles. Only by detailed investigations is it possible to establish which of these numerous possibilities predominates in a given reaction. For this purpose, the electron density and energy distribution and the nature and concentration of the positive and negative ions, the excited molecules, and the intermediates should be determined by sonde measurements or by mass, electron spin resonance, emission, or absorption spectroscopy. Investigations of this nature have already been carried out for simple systems, and have demonstrated the possibilities of determining the elementary processes in the plasma in this admittedly very laborious way[81–87].

A much simpler method is the comparison of the plasma reaction products with the products of related reactions. Some classes of substances, on reaction in the plasma, exhibit similarities to pyrolysis, photolysis, or mass spectroscopy. If analogies are found in the products, it may be assumed that the reaction mechanism is also analogous.

Aliphatic hydrocarbons are converted into a variety of paraffins, olefins, or acetylenes in the plasma by decomposition and degradation reactions[88]. A similar mixture of products is formed on pyrolysis of hydrocarbons, and it can therefore be concluded that the two processes have the same (free-radical) mechanism for this class of compounds. Similarities between glow discharges and pyrolyses occur only occasionally, since the two methods differ in important respects. In pyrolysis, many particles have a high energy, while in the plasma only isolated molecules receive an energy through electron collision that can appreciably exceed the energy involved in pyrolysis. These "hot molecules" react, but are then immediately deactivated again by collisions with the less excited neighboring molecules.

Some plasma reactions yield the same products as photochemical reactions. It cannot be assumed that the reactions in the plasma proceed indirectly *via* photons, since only a small proportion of the photons produced in glow discharges are absorbed by the gas molecules. The "photochemical reactions" in the plasma are due to the fact that the same states can be excited by collision with electrons as by absorption of a photon. Since there are no selection rules and no forbidden transitions for collisions with slow electrons, they can also lead to other states, which are not directly accessible by photochemical processes.

In some classes of compounds, pronounced similarities are found between the behavior in the plasma and in the mass spectrometer. An impressive example is provided by anisole (Table 6). For all the plasma products of anisole[45], there are decomposition paths leading to similar products in the mass spectrum[89]. The only difference is that reactions requiring large amounts of energy, such as the elimination of formaldehyde or of $CH_3 + CO$, are important in the mass spectrometer, whereas the reaction with the lowest energy requirement, *i.e.* the rearrangement to the cresols, is particularly favored in the plasma. The analogy between plasma chemistry and mass spectroscopy is not surprising, since the reactions are induced in both cases by collisions with electrons. However, there are differences with respect to the electron energies and the pressure. Because of the higher pressures in the plasma, bimolecular processes such ion-molecule reactions can readily proceed, whereas these reactions occur only rarely if at all in the mass spectrometer.

Reactions are occasionally found in the plasma for which no analogies are known. One such case is that of nitro-

benzene[90]. In the plasma, this compound gives numerous products, which are almost without exception derived from three intermediates, *i.e.* the phenyl radical, the phenoxyl radical, and dehydrobenzene. The decomposition of nitrobenzene to form the phenyl radical requires 57 kcal/mol, and the elimination of nitric oxide presumably

Table 6. Comparison of the reaction products of anisole (H_5C_6—O—CH_3 = M) in the plasma with the fragmentation processes in the mass spectrometer.

Plasma products	[mol-%]	Mass spectra	Rel. intensities
		M^+	100
Phenol	22—26	$M^+ - CH_3$	15
Benzene	0.4—4	$M^+ - CH_2O$	56
		$M^+ - H—CH_2O$	16
Cyclopentadiene	1—3	$M^+ - CH_3—CO$	63
Cresols	62—70	$M^+ - H$	2 [a]
		$M^+ - H - CO$	10 [a]

[a] Typical cresol band.

requires rather less energy. Both reactions also occur in photolysis[91], pyrolysis[92], and mass spectroscopy[93]. It is surprising that in addition to these readily occurring reactions, the energetically much less favorable elimination of HNO_2 (energy requirement approx. 200 kcal/mol) plays such an important part in the plasma. This surprising observation suggests that an appreciable proportion of the nitrobenzene molecules have been ionized, and the energy of approx. 10 eV liberated on recombination has allowed aryne formation.

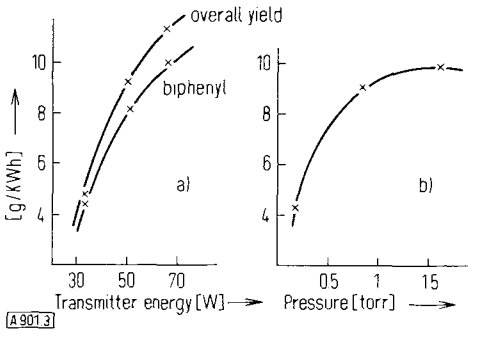
The mechanisms of plasma reactions have so far been thoroughly investigated in only a few cases. The results obtained are extremely interesting, but the picture of the organic plasma that can be drawn on the basis of these findings is still too incomplete for any pattern to emerge.

6. Possibilities and Limitations of Organic Plasma Chemistry

The preparative use of a plasma reaction depends on the conversion (in %) and the yield (in g/kWh). Other decisive factors are whether the reaction leads uniformly to the desired product and what trouble is involved in the separation of any by-products, whether the reaction product is also obtainable by another route, and whether the value of the product justifies the outlay on equipment.

The yield and the selectivity of a plasma reaction depend on the experimental conditions, and can be optimized by series of experiments. Figure 3 shows such a dependence for the formation of biphenyl from benzene[47]. With increasing field strength, the total yield increases, but the percentage of biphenyl in the reaction products decreases.

With increasing pressure, the yield of biphenyl passes through a maximum. The first result is due to the fact that secondary processes and fragmentations also occur to an increasing extent with increasing energy. As to the pressure dependence, an increase in the bimolecular reaction rate is opposed here by the decrease in the average electron energy and hence in the number of chemically effective collisions[94]. In many reactions, the selectivity increases with increasing pressure because of the lower electron energy.



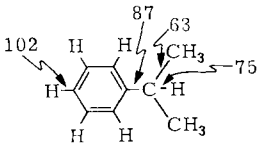


Fig. 3. Yields of biphenyl in the plasma reaction of benzene [47]: a) at constant pressure (0.8 torr) and with varying transmission energy; b) at constant transmission energy (52 W) and with varying pressure.

The rules for the control of plasma reactions are not yet sufficiently known, and it is therefore necessary to determine the optimum conditions experimentally for each new reaction by variation of the pressure, field strength, tube diameter, and flow rate. Moreover, the transfer of experimental data from one plasma apparatus to another is often not directly possible, and a number of further optimization experiments are then necessary. A direct transfer of data will become possibly only when the plasma properties required for a given reaction have been established[95].

The yields of plasma products vary widely. Rearrangements give approx. 1 mol/kWh and dimerizations approx. 1—2 mol/kWh; eliminations usually proceed with yields of 0.1—0.5 mol/kWh. These data relate to experiments in which the field strength, the pressure, and the flow rate have been optimized. If the tube diameter is also varied and the high-frequency coupling optimized, it should be possible to increase the yields further.

Plasma chemistry is confined to the gas phase, and for preparatively useful mass throughputs it requires a vapor pressure of 1 torr or more. In principle, therefore, all compounds that can be distilled without decomposing at pressures of at least 1 torr should be suitable for use in plasma reactions. However, the number of preparatively useful reactions is much smaller, since product mixtures can occur with molecules for which several energetically equivalent reactions are possible. Only if one of the possible reactions has a much lower energy requirement than any of the others can the reaction be controlled in such a way that only a single product is formed. In the case of isopropylbenzene, in which the bond energies differ by almost 30 kcal/mol[96] the reaction can be carried out in such a way as to obtain 2,3-diphenylbutane almost quantitatively by the use of mild conditions. Reactions that require the cleavage of a stronger bond become important only at higher electron energies, but are then accompanied by the formation of 2,3-diphenylbutane.

The mass throughput is decisive to the economy of plasma reactions. The laboratory equipment developed so far operates at pressures of 1—5 torr and distillation rates of

Bond energies in kcal/mol

about 0.1 mol/h. If the pressure is increased to raise the throughput, the field strength must be simultaneously increased, since the ratio of the two quantities should be kept approximately constant. However, this often leads to such high gas temperatures that starting compounds or final products undergo thermal decomposition. It may be possible to overcome these difficulties with pulsed plasmas, in which there is no excessive heating of the neutral gas up to the region of about 50 torr[95].

7. Future Developments

The transformation of organic substances by collision with electrons, which has been known for some time, has been developed in recent years into a preparative method offering a wide range of possibilities. Many technological problems still have to be solved before the processes elaborated so far on the laboratory scale can be applied to industrial production. Owing to the considerable cost of plasma equipment, plasma chemistry is not very likely to be considered for large-scale syntheses. Its future use will presumably lie in the production of compounds that are unobtainable or obtainable only with difficulty by other methods. Though organic plasma chemistry is still in the early stages of development, it is likely, from the very recent preparative successes, that plasma-chemical methods of synthesis will be introduced into laboratory chemistry and industrial production in the near future.

Energy Metabolism in Mitochondria

By Hans Walter Heldt[*]

Mitochondria are separate metabolic compartments within the cell. The functional boundary of the mitochondrial compartment is the inner membrane. This membrane contains the enzymatic apparatus for the electron transport and oxidative phosphorylation. The substrate breakdown cycles are localized in the mitochondrial matrix space. Specific carriers are responsible for the exchange of ADP, ATP, phosphate, and intermediates of the citric acid cycle between the matrix space and the extramitochondrial space. The particular importance of the adenine nucleotide transport to the regulation of the energy metabolism of the cell is discussed in detail.

Mitochondria occur in the cytoplasm of all aerobic eukaryotic cells. They are the site of cell respiration, and have therefore been referred to as the "power plant of the cell". The energy liberated on oxidation of the substrate hydrogen drives the endergonic synthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and orthophosphate (P). This process is known as oxidative phosphorylation[**]. The energy liberated on hydrolysis of ATP to ADP and phosphate covers the energy-consuming processes of the cell (*e.g.* mechanical, chemical, osmotic, and electric work).

There are two important metabolic compartments in the animal cell, *i.e.* the extramitochondrial compartment, which comprises the ground cytoplasm and the nuclear space, and the mitochondrial compartment. Coordination of the metabolic processes requires the specific transport of substrates and products through the membranes that separate the two compartments. The present report is concerned with the structure of the mitochondrial compartment. Details of specific transport processes between the two compartments should provide an insight into the regulation of the oxidative metabolism.

[**] A comprehensive article on the mechanism of oxidative phosphorylation has been published in this journal by *Schatz* [1].

1. Morphological Structure of Mitochondria

Mitochondria were observed with the aid of the optical microscope in the middle of the last century[2–5], but a precise elucidation of their structure (Fig. 1) became possible only with the advent of electron microscopy[6–8]. A particularly striking feature of mitochondria is the high membrane fraction. They have two types of membrane (Fig. 2), which differ in their fine structure, lipid composition, and protein content. The *outer membrane* surrounds the mitochondrion. The *inner membrane* extends more or less densely packed in an endlessly folded or in a tubular arrangement in the interior of the mitochondria. It has a very large surface. The mitochondrial matrix that it sur-

rounds consists of a dense protein gel. Apart from the membrane phases, therefore, there are two compartments in the mitochondria, *i.e.* the *intermembrane space* between the outer and the inner membranes and the matrix space.

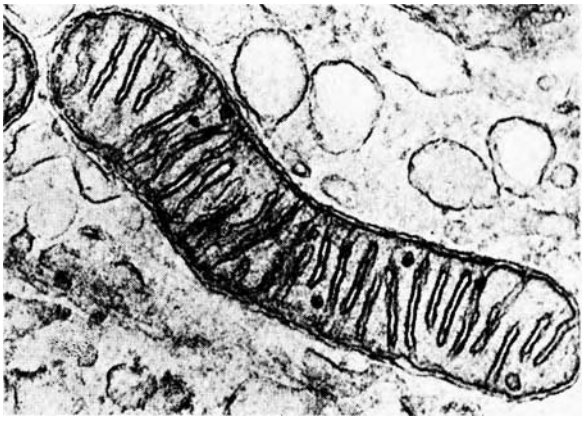

Fig. 1. Mitochondrium from the epididymal epithelium of the mouse. 61000-fold magnification [9].

With the aid of the electron-microscope technique of negative staining[***], characteristic round "knobs" having a diameter of about 90 Å were observed on the side of the

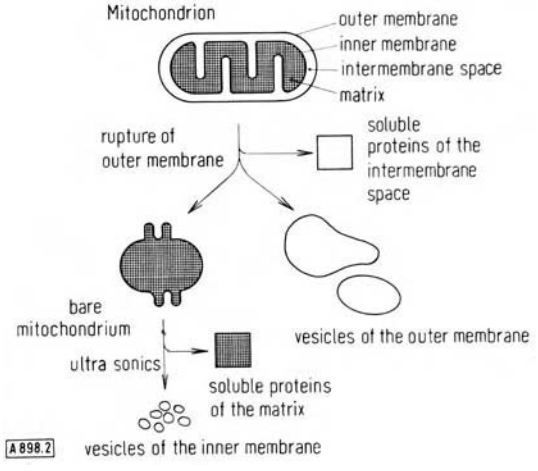

Fig. 2. Scheme of the structure and the fractionation of mitochondria.

inner membrane turned toward the matrix[10]. The outer membrane does not show these knobs. There is now evidence that these knob-shaped subunits are identical with the cold-labile ATPase, an enzyme that catalyzes a step of the oxidative phosphorylation[11]. However, it is doubtful whether these subunits that can be seen in the electron-micrograph are also evident in the intact membrane. It is possible that they were formed from a pre-existing structure on treatment with the reagent. The fact that these structures are observed only on the inside of the inner membrane points to the asymmetric structure of this membrane.

[***] In "negative staining", the sample is spread on a liquid film by surface tension. Phosphotungstate is then applied to the layer. On examination in the electron microscope, cell structures give a negative contrast.

Characteristic differences between the two membranes are also found in the lipid composition (Table 1). Thus cholesterol is found mainly in the outer membrane, while cardiolipin occurs almost only in the inner membrane[12-14]. The inner membrane also contains more protein than the outer membrane. In its lipid composition the inner membrane resembles a bacterial membrane, and the outer membrane resembles the plasma membrane.

Table 1. Composition of the outer and inner membranes of mitochondria from guinea pig liver [12, 13].

	Outer membrane	Inner membrane
Density	1.13	1.21
Protein : Lipid	1 : 0.829	1 : 0.275
Protein : Cholesterol	1 : 0.030	1 : 0.0051
Percentage of individual phospholipids in the entire phospholipid:		
cardiolipin	3.2%	21.5%
phosphatidylinosite	13.5%	4.2%
phosphatidylethanolamine	25.3%	27.7%
lecithin	55.2%	44.5%

Mitochondria multiply by division[15-17]. All the mitochondria of an organism are thus descended from the mitochondria of the egg cell. The deoxyribonucleic acid (DNA) present in the mitochondria[18-21] differs from the DNA in the cell nucleus; like bacterial DNA, it has a cyclic structure. However, the mitochondrial DNA determines only a few proteins that are essential to the genesis of mitochondria[22]. The synthesis of most of the mitochondrial proteins is controlled by the cell nucleus. It has been speculated that the aerobic cells arose from symbiosis between anaerobic cells and aerobic bacteria phagocytized by them[23]. According to this hypothesis, the mitochondrial outer membrane is derived from the cell membrane, which has been turned inward by phagocytosis, while the mitochondrial inner membrane is derived from a bacterial membrane.

2. Permeation Behavior of Mitochondria

Investigations with isolated mitochondria showed that part of the mitochondrial compartment is freely accessible to low molecular weight substances, such as inorganic ions, nucleotides, amino acids, and sucrose. This space is not accessible, however, to large molecules such as polymeric sugars or proteins. The size of the space that is accessible to sucrose can be influenced by the tonicity of the medium. Under isotonic conditions the sucrose-accessible space roughly corresponds to one third of the total mitochondrial solution space. If the isotonic medium is replaced by a hypotonic medium, the sucrose-inaccessible space increases at the expense of the sucrose-accessible space. In electron microscope studies carried out in parallel with this work, swelling of the matrix space (see Fig. 2) was observed, with a simultaneous decrease in the intermembrane space. A comparison of size between the functionally measured and the morphologically observed spaces showed that the sucrose-accessible space is identical with the intermembrane

space, and the sucrose-inaccessible space with the matrix space[24, 25]. It can be seen from the result that the outer membrane is permeable to low molecular weight substances, while the inner membrane is the osmotically active membrane.

3. Localization of Mitochondria Enzymes

Enzymes contained in the mitochondria may be present in the matrix space or in the intermembrane space. They can also be structure-bound components of the inner or outer membrane. An enzyme of the inner membrane may be directed toward the matrix space or toward the intermembrane space.

Two methods are used for the assignment of one of these positions to a mitochondrial enzyme, *i.e.* functional investigations on intact and disrupted mitochondria, and fractionation of the mitochondria with subsequent measurement of the enzyme activities in the fractions.

The functional investigations are based on the fact that the intermembrane space is freely accessible to substrates and nucleotides. The matrix space, which is not freely accessible, contains the mitochondrial nucleotides and Mg^{2+} ions, among other things. The inner membrane is impermeable to nucleotides, apart from a specific transport for adenine nucleotides, which will be discussed later. This transport is inhibited by atractyloside (Section 7). The localization of an enzyme inside the mitochondria can be determined *e.g.* by measurements of the reactivity with intramitochondrial or extramitochondrial nucleotides, sensitivity to atractyloside, and dependence on added Mg^{2+} ions.

The fractionation of the mitochondria is based on specific opening of the outer membrane. The soluble enzymes of the intermembrane space are liberated and are found in the supernatant. A scheme of this process is shown in Figure 2. One method for selective rupture of the outer membrane is treatment of the mitochondria with hypotonic media[12, 24]. Since the inner membrane is osmotically active, the matrix space swells in the hypotonic medium, and the inner membrane presses against the outer membrane and bursts it open.

Another method of rupturing the outer membrane selectively makes use of the fact that cholesterol occurs mainly in the outer membrane. It is well known that cholesterol forms a compound with digitonin. The addition of digitonin to mitochondria binds the cholesterol of the outer membrane and causes the membrane to break open[26–28]. The fragments of the outer membrane, which are mostly in the form of vesicles, can be separated by centrifugation in a density gradient. The bare mitochondria, consisting of the inner membrane and the matrix enclosed by it, remain behind. In these bare mitochondria the folds of the membrane turn outward. Treatment with ultrasonic radiation leads to destruction of the inner membrane. The membrane fragments form small vesicles, which can be separated from the soluble proteins of the matrix space by centrifugation.

The broad lines of the organization of the mitochondrial metabolism are recognized from the localization of some important mitochondrial enzymes, which are listed in Table 2. The oxidation of the substrates and the associated ATP synthesis take place on or in the inner membrane. The substrate breakdown processes (citric acid cycle, degradation of fatty acids) are localized in the matrix space. The reduction equivalents resulting from these processes (in the form of NADH, succinate, or acyl coenzyme A) diffuse to the inside of the inner membrane, where they are oxidized. The ATP synthesis coupled with the respiratory chain takes place on the inside of the inner membrane, and the ATP formed passes into the matrix space. Carefully prepared bare mitochondria accordingly exhibit all the essential properties of intact mitochondria[26]. On the other hand, the enzyme activities of the intermembrane space (some of which also occur outside the mitochondria) and the membranes of the outer membrane appear to have more of an accessory importance.

Table 2. Localization of mitochondrial enzymes [24, 26—41].

Site	Enzyme
Inner membrane	Respiratory chain NADH-oxidase Succinate-dehydrogenase Fatty acyl CoA dehydrogenase Glycerophosphate-oxidase Pyridine nucleotide-transhydrogenase ATP-synthetase
Matrix	Dehydrogenases of the citrate cycle β-Hydroxyacyl-CoA-dehydrogenase Succinate-thiokinase GTP-dependent fatty acid activation ATP-dependent fatty acid activation (for short-chain fatty acids) GTP-AMP phosphate-transferase Transaminases Citrulline-synthetase Pyruvate-carboxylase
Intermembrane space	Adenylate-kinase Creatine-kinase Nucleoside diphosphate-kinase
Outer membrane	ATP-dependent activation of long-chain fatty acids Phospholipase Enzymes of the lecithin synthesis Monoamine-oxidase

4. Properties of the Inner Membrane

From the functional standpoint, the intermembrane space may be regarded as belonging to the extramitochondrial compartment. The partition separating the mitochondrial and the extramitochondrial metabolic compartments is the inner membrane. Through this membrane the substrates of the mitochondrial oxidation, mainly pyruvic acid and fatty acids, as well as orthophosphate and ADP must pass into the matrix space, and the product ATP must be released from the mitochondria.

Closed membranes are fundamentally impermeable both to cations and to anions. Membranes present much less hindrance to the penetration of undissociated acids or bases, since these substances can dissolve to some extent in the lipid layer of the membrane. It is thus possible for anions

and cations to pass through the membrane *via* the undissociated molecules that exist in equilibrium with them. This is probably true of a number of monocarboxylic acids. In the cases of dicarboxylic and tricarboxylic acids and phosphoric acid, on the other hand, the dissociation equilibria in neutral solution lie so far on the side of the anions that membranes are practically inpermeable to these substances[42].

In connection with the permeation properties of membranes it is interesting to note that the most important substrates of the mitochondria *i.e.* pyruvic acid and the fatty acids, are monocarboxylic acids. On the other hand, the intermediates of the mitochondrial substrate breakdown cycles (citric acid cycle and oxidation of fatty acids) are dicarboxylic or tricarboxylic acids or derivatives of coenzyme A (a compound containing phosphate), which cannot diffuse freely through the inner membrane. The same is true of the pyridine nucleotides, which take part in the substrate breakdown, and of the adenine and guanine nucleotides, which take part in the energy conservation.

5. Transport of Substrates

Both the pyruvic acid and the short-chain fatty acids can probably pass through the inner membrane without special carriers[42]. Recent findings concerning the occurrence of a special carrier for the pyruvate anion in the inner membrane[43] require further investigation.

Whereas the short-chain fatty acids are activated (*i.e.* bonded to coenzyme A) in the matrix space, the activation of the long-chain fatty acids, such as palmitic acid, occurs on the outer membrane or on the endoplasmic reticulum[36-39]. The mitochondria are thus faced with the problem of bringing the activated fatty acids into the matrix space through the inner membrane, which is impermeable to coenzyme A and its derivatives. This is achieved by a special transport mechanism, of which all the details have not yet been clarified. Three observations are important to discussions about a possible reaction course (Fig. 3): a) Carnitine [3-hydroxy-4-(trimethylammonio) butyrate] is required for the oxidation of palmitate[44]. b) Neither carnitine nor coenzyme A or its esters can pass through the inner membrane[45, 46]. c) Two different acylcoenzyme A—carnitine transferases have been discovered, one of which is bound in the inner membrane[47]. The acylcoenzyme A outside the inner membrane is assumed to be converted into acylcarnitine by the external transferase (I), with liberation of coenzyme A. The transferase in the inner membrane (II) is thought to be arranged vectorially[45], *i.e.* the bonding sites for carnitine and acylcarnitine are directed outward, and the bonding sites for coenzyme A and acylcoenzyme A toward the matrix. According to this scheme, acylcarnitine passes from outside to the inner membrane, and the acyl residue is "handed through" and reacts with the mitochondrial coenzyme A on the inside of the membrane. This would mean that a functional unit exists here between the chemical reaction and the directed transport through the membrane.

The inner membrane is impermeable to the intermediates of the citric acid cycle. This impermeability is overcome by specific carriers[48-53]. The dicarboxylic acid carrier transports malate and succinate in exchange with these dicarboxylic acids or with phosphate. The transport of citrate and isocitrate by the citrate carrier and the transport of α-ketoglutarate by the α-ketoglutarate carrier occurs in exchange with dicarboxylic acids. There is also evidence of a specific transport of glutamate.

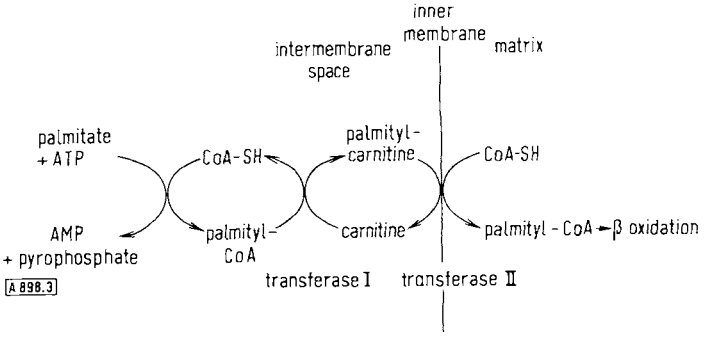

Fig. 3. Scheme of the activation of long-chain fatty acids and of the transport of activated fatty acids into the matrix space [45].

The transport of malate is important to gluconeogenesis. The initial step of this metabolic chain, *i.e.* the carboxylation of pyruvate, takes place in the matrix space[40]. The resulting oxalacetate can be transported out of the mitochondria as malate after reduction. The further synthesis steps of gluconeogenesis then take place outside the mitochondria.

The transport of citrate plays a part in lipogenesis[54]. The starting material for the synthetic chain of lipogenesis is acetyl-coenzyme A, which is formed in the mitochondria *e.g.* from pyruvate. Since the fat synthesis takes place outside the mitochondria, the acetyl-coenzyme A must be carried out of the mitochondria. Since the inner membrane is impermeable to coenzyme A and its thioesters, indirect transport occurs. Acetyl-coenzyme A condenses with oxalacetate in the mitochondria to form citrate, and this is transported into the extramitochondrial space by the citrate carrier, where it is converted back into acetyl-coenzyme A and oxalacetate.

6. Transport of Phosphate

The transport of phosphate by the phosphate carrier takes place in exchange with hydroxide ions or as a co-transport with protons[42, 49, 55]. These possibilities cannot be distinguished experimentally. The transport is inhibited by very low concentrations of compounds that block SH groups[56-58]. The phosphate carrier thus contains free SH groups. The phosphate required for the oxidative phosphorylation can pass into the matrix space through the phosphate transport. Since the transport of phosphate takes place without exchange with anions, apart from hydroxide ions, whereas the transport of dicarboxylic acids occurs in exchange with phosphate and the transport of tricarboxylic acids in exchange with dicarboxylic acids, the phosphate transport has a key function for the uptake of dicarboxylic and tricarboxylic acids into the mitochondria.

7. Transport of Adenine Nucleotides

A carrier transports the ADP into the mitochondria and the ATP formed out of the mitochondria (Fig. 4). This carrier is specific for ADP and ATP. AMP, guanine, and uracil, cytidine, and pyridine nucleotides are not transported[59]. The transport is an obligate exchange: for each molecule of adenine nucleotide transported in, another must be transported out. The carrier probably cannot pass through the membrane in the uncharged state[60]. In this way the total of mitochondrial adenine nucleotides remains constant. The affinity of the carrier is very high. Half of the maximum transport rate is reached at an ADP concentration outside the mitchondrion of only 12×10^{-6} M[42]. Atractyloside, a plant glycoside from the mastic thistle (Atractylis gummifera) and bongkrek acid, an antibiotic, are specific inhibitors of the adenine nucleotide transport[61-63]. Both substances are therefore very powerful poisons.

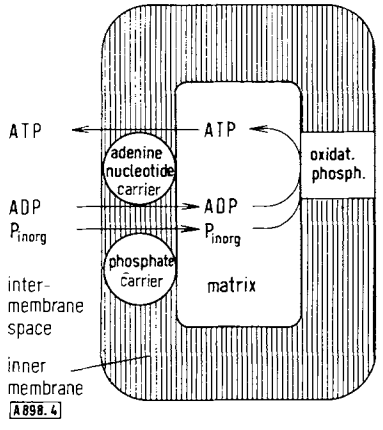

Fig. 4. Functional scheme of the adenine nucleotide transport.

The specificity of the adenine nucleotide carrier is different for the two transport directions. There are no measurable differences between ADP and ATP for the outward transport. For the inward transport, on the other hand, ADP is strongly favored over ATP. However, this is true only of intact mitochondria, in which a coupling exists between the transport of electrons by the respiratory chain and the ATP synthesis. If this coupling is eliminated by "uncouplers" (*e.g.* dinitrophenol), ADP is no longer favored for the inward transport; ATP is then transported as readily as ADP[59, 64]. It can be concluded from these findings that the preference for the transport of ADP requires the consumption of energy. This energy is supplied by the respiratory chain. It has not yet been established in detail how the transport is influenced by the energy. It is assumed that through the transport of electrons by the respiratory chain, a potential is built up across the inner membrane. Since ATP carries one negative charge more than ADP, a membrane potential could allow a discrimination against the transport of ATP through the inner membrane[42].

The asymmetry in the specificity of the transport of adenine nucleotides leads to an asymmetric distribution of ADP and ATP on the two sides of the membrane. The ATP/ADP ratio is greater outside the mitochondria than inside[65]. To check this, ADP was added to a suspension of aerobic mitochondria in the presence of substrate. After the ADP had been phosphorylated and the state of respiratory control had been reached, the mitochondria were centrifuged from the medium through a silicone layer into perchloric acid[66]. It was thus possible to measure the nucleotide concentrations in the matrix space and in the surrounding medium in the same experiment (Table 3).

Table 3. Phosphorylation potential $\Delta G'$ of ATP in mitochondria and in the medium in the state of respiratory control (20 °C) [65].
$\Delta G' = \Delta G'_0 - RT \times \ln([ATP]/[ADP] \times [Phosphate])$
$\Delta G'_0 = -8.8$ kcal/mol [70].

	$\frac{ATP}{ADP}$	Phosphate (mmol/Liter)	$\Delta G'$ (kcal/mol)
mitochondrial	3.9	3.5	−12.9
extramitochondrial	29	0.48	−15.2

The ATP/ADP ratio was found to be about 7 times as high in the medium as in the matrix space. With the aid of the measured phosphate concentrations it is possible to calculate the free energy of the hydrolysis of ATP, which is also known as the phosphorylation potential, for both spaces. The phosphorylation potential found for the ATP in the medium is 2.3 kcal/mol more negative than for the ATP in the matrix space.

Though the phosphorylation potential in the mitochondria certainly cannot be calculated exactly in this way, it can be seen that the energy consumption required for the release of the ATP from the mitochondria may be considerable. This has important consequences for the ratio of the ATP formed to the oxygen consumed (P/O ratio) in the cell. It is well known that a P/O ratio of 3 is found in mammalian mitochondria for substrates that enter the respiratory chain at the NADH stage, and a P/O ratio of 2 for substrates that attack at the flavoprotein, *e.g.* succinate. However these figures are obtained only if the ATP/ADP ratio outside the mitochondria is artificially kept low. This can be achieved by addition of glucose and hexokinase to the medium; the terminal phosphate residue of the extramitochondrial ATP is then transferred to glucose. Lower P/O values are observed without this "ATP trap", since part of the energy gained in the respiratory chain must be used up to release the ATP from the mitochondria[67].

The question arises whether the differences between the ATP/ADP ratios inside and outside the mitochondria in the test tube also occur in the living cell. To answer this question, the reactions occurring in a perfused liver were stopped by sudden cooling to −195 °C, and the frozen liver was freeze-dried and then homogenized in heptane. Mitochondria and nonmitochondrial cell material were separated by centrifugation of the homogenate in a heptane-carbon tetrachloride density gradient, and the adenine nucleotides were determined enzymatically in the resulting fractions. This experiment showed that the ATP/ADP ratio in the intact cell outside the mitochondria was more than 5 times as high as in the mitochondria[68]. Agreement with the results found for isolated mitochondria is therefore good.

8. The Importance of the Adenine Nucleotide Transport to the Energy Metabolism of the Cell

The living cell tends to maintain its ATP concentration at a constant value. A decrease in the ATP concentration on consumption of ATP can be offset for a short time by ATP reserves. Such reserves consist of the ADP that is in equilibrium with ATP and AMP in the presence of adenylate kinase, and creatine phosphate:

$$2\ \mathrm{ADP} \xrightleftharpoons{\text{adenylate-kinase}} \mathrm{ATP} + \mathrm{AMP}$$

$$\mathrm{ADP} + \text{Creatine phosphate} \xrightleftharpoons{\text{creatine-kinase}} \mathrm{ATP} + \text{Creatine}$$

These systems may be regarded as ATP buffers. The ATP consumption is ultimately compensated by ATP synthesis. In the aerobic metabolism of glucose, 95% of the ATP formed is synthesized in the mitochondria. Oxidative phosphorylation is thus the main source of the ATP in the cell.

The ADP-concentration in the matrix space controls respiration. The higher the concentration, the higher the respiration rate and hence also the rate of ATP synthesis. However, half of the maximum rate of oxidative phosphorylation is reached only when about half of the adenine nucleotide in the matrix space is in the form of ADP[69].

If the adenine nucleotide concentrations inside and outside the mitochondria were equal, a relatively large decrease in the cellular ATP concentration would be required to cause a fairly large increase in respiration. In this case the "ATP buffer" would be exhausted before increased ATP synthesis could occur. It has been observed for muscle, however, that after stimulation, a pronounced increase in respiration occurs before the creatine phosphate is exhausted[71]. The adenine nucleotides transport evidently plays an important part here. Because of the energy-dependent preference for the transport of ADP into the mitochondria, a small increase in the ADP concentration in the extramitochondrial space leads to a marked increase in the ADP concentration in the matrix space, with the result that the ATP synthesis in the mitochondria is stimulated. The energy consumption required for the adenine nucleotide transport could thus be regarded as a contribution to the maintenance of a constant cellular ATP concentration.

Self-Organization of Molecular Systems and Evolution of the Genetic Apparatus[**]

By Hans Kuhn[*]

The aim of the work described in this report is to find pathways leading to self-organization of molecular systems. The idea is not to trace the historical pathway of evolution but to describe a model whose experimental verification should help to clarify the important principles of evolution. The difficulty of accepting the origin of living organisms as a physico-chemical phenomenon and the deeply rooted notion that a system of such complexity as the genetic apparatus could never be the outcome of processes based solely on the known laws of physics have influenced philosophical thinking very strongly. This study is also intended as an attempt to overcome this psychological problem by systematic pursuit of a model pathway composed of many, readily comprehensible steps. A process thus becomes understandable which cannot be grasped as a whole, and is therefore alien to our conceptual habits.

1. Presentation of the Problem

A veil of uncertainty still surrounds the formation of the first biological systems from which the great variety of organisms developed during the further course of evolution[1-6]. Such systems must already have had the property of self-reproduction, and this can only have been possible if they were of considerable complexity. They must have had a mechanism employing very sophisticated strategies, comparable with those of the genetic apparatus of present-day organisms. How could this kind of system develop? Do the laws of physical chemistry suffice to explain this process or do we have to postulate principles that are still unknown? Let us suppose that the origin of life can be described as a physico-chemical process: does this process take place wherever appropriate conditions are to be found or is it a process of extremely low probability which nevertheless happened to take place on earth?

[**] Extended version of a lecture given at Marburg on January 29, 1971.

The basic hypothesis of the following is that the origin of life is a physico-chemical process which occurs by necessity under appropriate conditions. The following two problems then require solution: first of all, a basis has to be given for the hypothesis. If it is correct, the intuitive reluctance to accept it is a psychological difficulty, and consequently the second task is to overcome this difficulty.

Possibilities for the formation of self-organizing systems have been considered by the mathematicians *v. Neumann*[7], *Turing*[8], and more recently *Ulam*[9]. The search for general principles that are important for the evolution of self-organizing systems is the topic of studies by *Prigogine*[10] and *Katchalsky*[11] and particularly of *Eigen*'s comprehensive theory on the self-organization of matter and the evolution of macromolecules[12].

We proceed in a somewhat different manner: we try to find a model pathway offering a plausible route for the formation of a mechanism like the genetic apparatus. The model pathway consists of a number of small steps. Each step follows from the preceding one as an answer to the question of which type of behavior seems most likely. Possible ways are invented, the time requirement is estimated, and the fastest possibility is chosen as the next step (Fig. 1).

Thus, by applying legitimate variations one can search out reasonable model pathways and see where the procedure leads and whether the initial concept turns out to be a fruitful one.

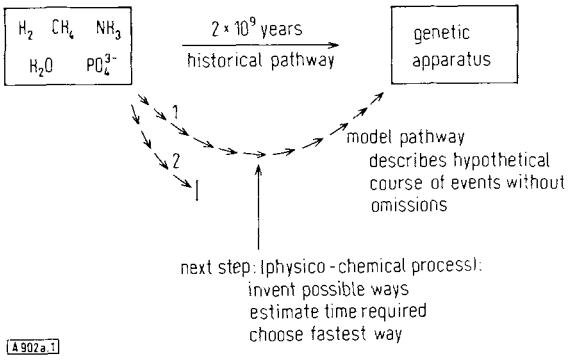

Fig. 1. Historical pathway of evolution and model pathways consisting of many individual physico-chemical steps. A model pathway must describe the hypothetical course of events as an uninterrupted chain of causative events. Otherwise it cannot be judged whether the pathway represents a meaningful approach. Model pathway 1 leads to a system with a genetic apparatus, pathway 2 leads to a dead end.

Each step is a customary physico-chemical process. We make no attempt to find generalizing concepts for self-organization and evolution. However, we do expect to be able to recognize the important aspects especially clearly in the special case of a model system. Using the procedure outlined we hope to arrive at self-organizing and self-reproducing systems so to speak blindly and automatically and to understand how the genetic apparatus, as we know it, could have developed during the available time span of about 2×10^9 years.

Our procedure is analogous to that employed in quantum chemistry where one tries to reach an understanding of the chemical bond by invention of appropriate test functions as approximations of wave functions. In quantum chemistry quite speculative test functions, like *Hückel*'s concept of the π-electron system, have proved to be extraordinarily fruitful. This encourages the discussion of speculative model pathways for a biological problem.

By systematically going through the many individual steps, we try to overcome the psychological difficulty of accepting the idea that an extremely well functioning mechanism like the genetic apparatus should follow solely from the known laws of physics: each individual step can be grasped easily, and the psychological difficulty arises from the fact that in the evolutionary process the chain of causative events can no longer be grasped as a whole because of the great number of steps and the great number of individuals involved. On considering the individual physico-chemical steps *Darwin*'s process of selection (survival of the fittest) seems self-evident. The frequently stated opinion that a system cannot organize itself because thermodynamics requires that a closed system should strive to attain the state of highest disorder is incorrect for a simple model far removed from equilibrium.

A model pathway must describe the hypothetical course of events completely. Many assumptions about individual steps which at first glance seem quite reasonable may lead to a dead end (Fig. 1), which can only be recognized and avoided by consistent pursuit of the causal chain of hypothetical steps.

It cannot be expected that a seemingly reasonable imaginative pathway actually represents the historical route, but even by tracing just one chain of causally linked steps leading to a system with a genetic apparatus it is demonstrated that the development of biological organisms can, in principle, be interpreted on a physico-chemical basis. We can hope that experimental checks of the steps involved in the model will provide some clues regarding the actual development.

A meaningful model pathway must lead to an understanding of the development of the genetic apparatus, an extraordinarily complex system exhibiting the following salient features[13]: The information for the structure and function of an organism is stored in the form of base sequences. The double helix replicates, thus the information is reproduced, and from one organism many others are

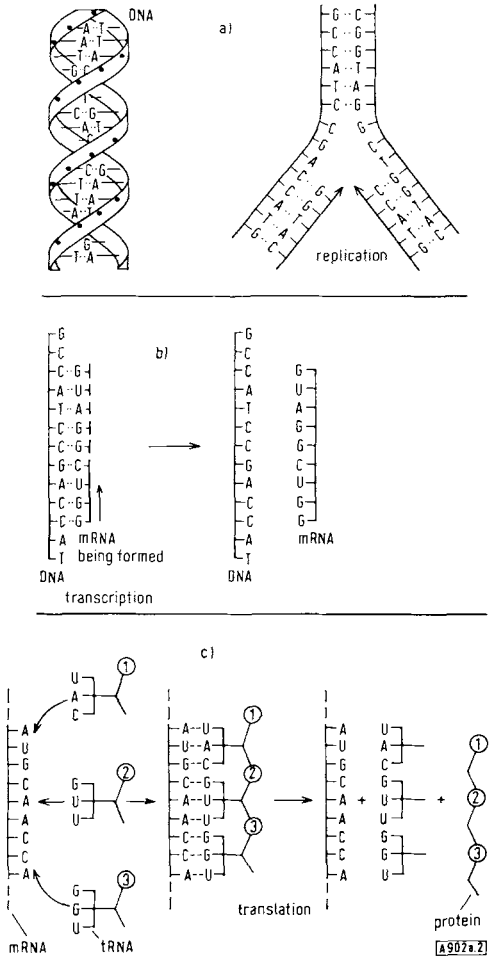

Fig. 2. Genetic apparatus.
a) DNA double strand (C = cytosine, G = guanine, T = thymine, A = adenine). Replication of a DNA strand by an enzyme system (replicase). T and A, and G and C are complementary bases. b) Formation of messenger-RNA (mRNA) on the template of a DNA strand by an enzyme system (transcriptase). In messenger-RNA the base thymine is replaced by uracil (U). c) Protein biosynthesis on the ribosome. Transfer-RNAs (tRNA) for amino acids 1, 2, 3, with anticodon triplet characteristic for the amino acid. Orientation of the triplets on the messenger-RNA, synthesis of the protein, release of tRNAs without amino acids and messenger-RNA.

formed (Fig. 2a). The information present in any one section of DNA is transcribed to messenger-RNA (Fig. 2b), on which the information is translated from a language written in four letters (the four bases A, U, G, C) into one containing 20 letters (the amino acids) (Fig 2c). The amino acid molecules are attached to their own characteristic transfer-RNA molecules which also carry the anticodon triplet, through which the information on the messenger-RNA is read off. On the ribosomes the amino acids thus combine to a protein, whose amino acid sequence is determined by the base sequence of the messenger-RNA. The proteins assume a specific tertiary structure, which is determined by their amino acid sequence and, as enzymes and structural elements, make up an organized functional network resulting in an organism.

2. Model Assumptions Pertaining to the Behavior of RNA

We shall assume that in the model environment an enzyme-free replication of RNA is possible (Fig. 3a) and that the replication error per base is $W = 1/100$, *i.e.* on the average one out of 100 bases is copied incorrectly. This means that in a newly synthesized strand about one out of 100 bases is not complementary to its partner on the template strand. An enzyme-free replication of RNA can be assumed on the grounds of experimental evidence[14], even though for the time being precise statements about the conditions for such a replication are not possible. A value of about $W = 1/100$ follows from the careful analysis by *Eigen*[12] and co-workers[15].

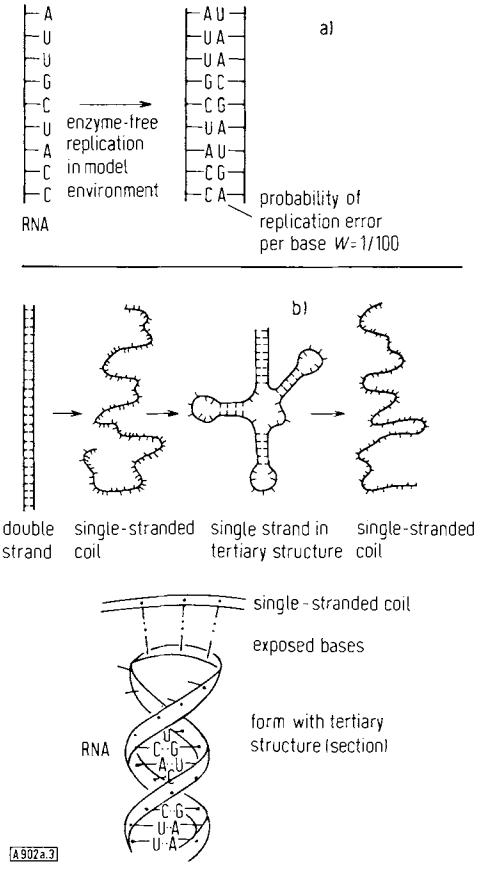

Fig. 3. Model assumptions concerning the behavior of RNA.
a) RNA is supposed to undergo enzyme-free replication under certain conditions: energy-rich mono- or oligonucleotides are supposed to associate with the open chain conformation in such a way that complementary bases form pairs and then proceed to condense. b) Transition of RNA from double strand to single stranded open chain conformation given appropriate changes of environment, from the latter to a conformation with tertiary structure given a suitable base sequence, and then back to the open chain conformation. c) During intervals, in which forms with tertiary structure appear, weak bonding should be possible between exposed bases of these species and the open chain single strands.

Furthermore we shall assume that strong fluctuations of quantities characterizing the environmental conditions take place with time. Such fluctuation may have been due to cycles which have always been present on the earth, for example day and night, the cycle of the seasons, and the rhythm of the tides. They should allow transitions of RNA from an open chain conformation to one with a tertiary structure. Suitable fluctuations may again transform the species exhibiting tertiary structure into an open chain conformation, which in turn may serve as a template for replication (Fig. 3b). Transitions of this type are known from experiments[16].

Finally we assume that under the model conditions loose association between open chain species and the exposed bases of species with tertiary structure may occur during the periods characterized by the appearance of molecules with tertiary structure. This is again in keeping with experimental results[17].

3. Starting Point: Spontaneous Polymerization of Energy-Rich Nucleotides during Phases of Formation; Hydrolysis of Polymers during Phases of Decay

In the early phase of evolution we cannot assume the presence of RNA molecules, but energy-rich nucleotides capable of polymerization may very well have occurred. This follows from the well-known experiments on the simulation of conditions that may once have prevailed on the earth[1-5].

Since we assume strong fluctuations of the environment, a solution of suitable substrates may alternately have been dissolved and evaporated to dryness, and warmed and cooled. This may lead to high concentrations of given substances in certain places or to a situation where energy-rich compounds formed by gas discharge or irradiation alternately appear and disappear. We may assume an alternation between phases during which polymers are formed from phosphonucleotides and those during which they gradually undergo hydrolytic decomposition (Fig. 4).

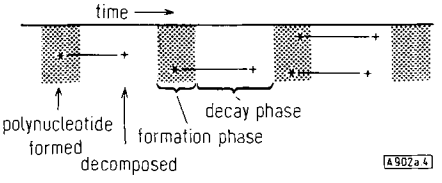

Fig. 4. Starting conditions: periodic fluctuations of the environment: alternation between formation phases (formation of polymers from energy-rich mono- or oligonucleotides) and phases of decay (hydrolysis of polymers).

Nucleic acids contain ribose. We have to assume that d- and l-ribose are present in equal concentrations and are incorporated into the polymer with the same probability.

4. Formation of Replicating Forms of RNA. Development of RNA Molecules of Uniform Chirality

One can imagine the chance formation of an RNA molecule with, say, 21 bases and containing exclusively d-ribose as sugar component (Fig. 5). The probability of the appear-

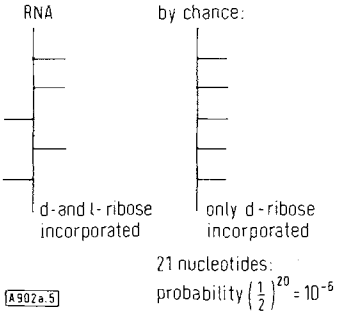

Fig. 5. Formation of RNA molecules having Uniform chirality. Random formation of a sufficiently large molecule containing just d-ribose. The molecule serves as template for the formation of a double helix. Those molecules containing both d- and l-ribose do not have this property because of lacking cooperativity. The double helix is stabilized by cooperative effects, and is thus able to multiply and has a longer life span.

ance of this type of molecule is $(1/2)^{20}$ if the same probabilities are assumed for the condensation of d- with d and d- with l-phosphonucleosides. Among $2^{20} \approx 10^6$ molecules having a degree of polymerization of 21, there is on the average one molecule that happens to contain only d- or only l-ribose. One can expect this type of molecule to have the following three properties lacking in the others (Fig. 6):

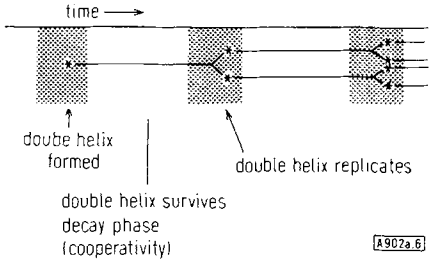

Fig. 6. Double helix molecules multiply and displace all the others. The originally divergent phase (formation of polymers with many different sequences of d- and l-ribose) has thus turned into a convergent phase during which d- or l-ribose is incorporated selectively.

1. During a phase of formation, the molecule may serve as template for the formation of a double helix because it may collect energy-rich mono- or oligonucleotides, which can then link up with one another. This is not possible with other polymeric molecules because of the lack of cooperativity. Incorporation of just one molecule having the wrong chirality destroys the tight packing present in the helix.

2. The cooperative effects holding all parts of the molecules tightly within the double helix make it especially resistant to hydrolysis and therefore able to survive the decay phase.

3. Upon entering a new formation phase one may expect replication of the double helix if the environment changes in a suitable way (entrance into a phase in which the double helix dissociates into single strands, followed by one in which the single strands serve as templates for the formation of new double helices). During following periods more and more double helices will be formed. The energy-rich phosphonucleosides will be used up and the formation of polymers having non-uniform chirality is suppressed.

The random formation of the first double helix initiates the first phase exhibiting a selection process: the initial, divergent phase (spontaneous formation of a large number of polymers having all possible sequences of d- and l-ribose) turns into a convergent phase characterized by selective formation of double helices and suppression of spontaneous polymerization as soon as one molecule with a sufficiently high degree of polymerization and containing only the d- or l-form of ribose is present.

The change from the divergent to the convergent phase is the result of pure chance. But even so, this event sooner or later takes place by necessity: Given a sufficient number of molecules and a sufficiently long time, the probability that *not* a single molecule will be formed containing exclusively d- or l-ribose is extremely small. Thus, the change is a necessity. This effect is typical for evolving systems: In any one case decisive events, although highly improbable, take place by constraint within a large population.

Only d-ribose is present in the nucleic acids we know today. According to our model it was merely by chance that a system capable of reproduction and happening to contain only d-ribose was able to assert itself; *i.e.* that species containing d-ribose happened to develop earlier and was therefore able to displace the species containing l-ribose.

It is conceivable that evolution of organisms with l-ribose could take place in one locality while organisms with d-ribose develop elsewhere. As soon as these two populations come into competition with each other, only that species will survive which happens to have attained the more advanced stage of evolution or which by chance is the first to find a way of inflicting sufficient damage on the other form. Competition may occur either very soon or after the system has already reached a high degree of differentiation, depending on which substrate necessary for development is lacking.

It seems reasonable to assume that the degree of polymerization of double helices capable of selection is about 20. Cooperative regions of this size are frequently encountered in soap- and dye micelles; according to *Debye*[18] this has energetic reasons.

5. Development of a Side-by-Side Existence of RNA Molecules with Differing Tertiary Structures

It is to be expected that identical double helices will from time to time undergo condensation according to Fig. 7a (with omission of the helical conformation of the strands)

thus affording species exhibiting intramolecular pairing of complementary bases. Further condensation yields species of clover-leaf structure—as found in tRNAs (example: tRNA for phenylalanine, Fig. 7b)[19].

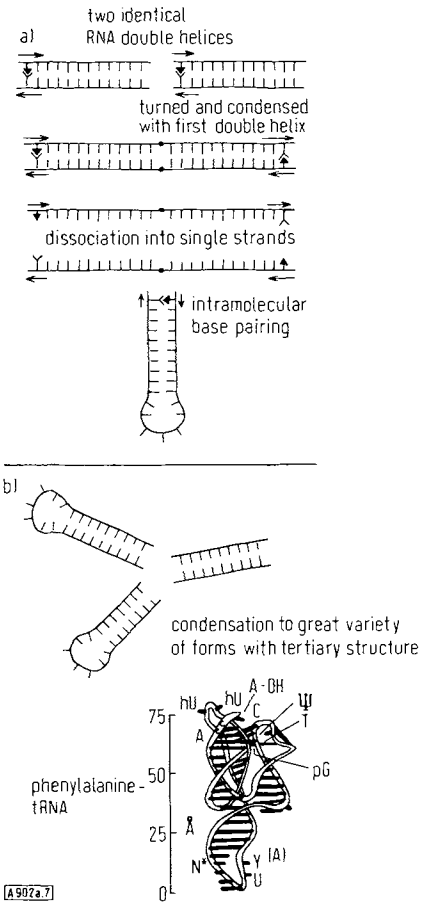

Fig. 7. Formation of RNA molecules by random condensation of double helices (drawn with omission of helical screwing of the strands).
a) Formation of hairpin molecules (from top to bottom): identical double strands: double strand on the right turned by 180° and condensed with the other one; strands separated from each other; bases form intramolecular pairs. b) Condensation of hairpin molecules, and possibly double helices (on the right), to give transfer-RNA-like molecules. Example of a transfer-RNA with a tertiary structure as proposed by *Cramer*.

It may be expected that this permits development of species with quite different tertiary structures. Thus, a divergent phase of evolution is reached again.

6. Selection of Individual Molecules on the Basis of Resistance to Hydrolysis Impossible Because of Too Many Reproduction Errors

RNA species with different tertiary structures will differ in their susceptibility to hydrolysis. More compact species will be more resistant than others and more likely to survive the decay phase. We therefore have to ask whether we can assume a selection of species which are more resistant to hydrolysis than others because of their tertiary structure.

In order to answer this question we shall make the simplifying assumption that only *one* species is initially present and that it replicates without error. During the formation phase replication takes place and, then the tertiary structure is formed; during the decay phase some of the molecules are hydrolyzed while those remaining replicate during the next formation phase (Fig. 8). The number of molecules will increase until saturation is reached and the same number Z of molecules is present at the end of each decay phase (Fig. 8).

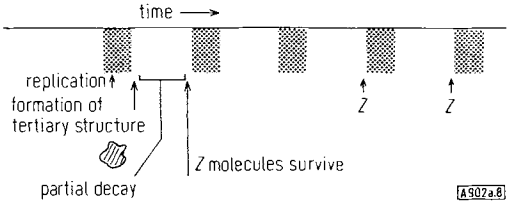

Fig. 8. Behavior of molecules as shown in Fig. 7b in the model environment. Formation phases: replication, transition to a tertiary structure. Decay phases: partial hydrolysis of the molecules. After arriving at a state of saturation at the end of each decay phase there are about Z molecules present.

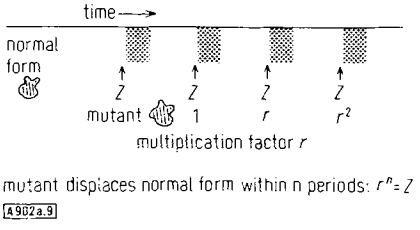
Let us consider that a molecule with a different kind of tertiary structure is now formed as a result of a base copying error occurring randomly during replication (Fig. 9). This mutant shall be somewhat more resistant to hydrolysis than the preceding species (= normal form = most common species of the prevailing population). The multiplication factor r of the mutant is then somewhat larger than 1.



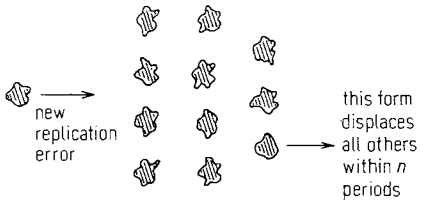


Fig. 9. Appearance of a mutant having the multiplication factor r. Number n of generations during which the mutant displaces the normal form.

(The multiplication factor r is defined as follows: if at the end of any phase of decay *one* individual of the mutant is present, then r is the average number of molecules of the mutant at the end of the next decay phase. At saturation the multiplication factor of the normal form is 1.) After an additional period an average of r^2 molecules will be present, *etc.* The mutant will have displaced the normal form after about n periods and will thus have become the new normal form. At that time about Z individuals of the mutant will be present, *i.e.* $r^n = Z$ (Fig. 9).

Example: if at the beginning we find $Z = 10^6$ molecules of the normal form (*i.e.*, if the advantageous mutant appears once among 10^6 molecules) and $r = 2$ (*i.e.*, if the mutant has twice the chance of surviving the next decay phase compared to the normal form), then $n = 20$. If $r = 1.01$, it follows that $n = 1400$.

After the selection of the mutant, another base copying error will be considered to occur in each individual (Fig. 10). In this way mutants of quite different shapes will be

formed. Most of them will be more susceptible to hydrolysis than the previously selected species. This is because it is highly improbable that a structure which has already proved resistant to hydrolysis, should further improve this property by another chance error. The globular mutant in Fig. 10 is assumed to be a favorable species and after about n periods will have displaced the others. However, this type of selection is only possible if the next error in reproduction does not take place too early. Otherwise, the probability that the favorable mutant will disappear instead of improving is too high. For a selection to occur it is therefore essential that the next error in reproduction should not occur earlier than after n periods, *i.e.* after the favorable mutant has asserted itself and is present in large numbers.

condition for selection: new replication error usually no earlier than after n periods

A902a.10

Fig. 10. Appearance of new mutants after the mutant of Fig. 9 has become prevalent: most of them have no advantage since it is highly improbable that a species which has already proved its value should be further improved by a random replication error. The most favorable mutant (most resistant to hydrolysis) displaces all other species within n periods.

Let P be the probability of a reproduction error occurring in an individual. In order for selection to take place, the number of errors after n successive reproductions may not be larger than 1, *i.e.* $P \times n \leq 1$ (Fig. 11). The reasoning behind this relation is given in Appendix 1. An illustration of the selection process by computer simulation may be found in a paper by *Försterling*, *Kuhn*, and *Tews*[20] appearing in this issue.

If we designate the number of bases in an RNA molecule N and the probability of a replication error per base W then $P = N \times W$ (if P is small compared to 1): the error may occur in the 1st or the 2nd *etc.* or in the n^{th} base. The condition for selection thus follows (Fig. 11):

$$N \times W \times n \leq 1 \quad \text{or} \quad W \leq 1/(N \times n)$$

P = probability of reproduction error of individual

n = number of periods

condition for selection: $P \cdot n \leqslant 1$

N = number of bases

W = replication error per base

$P = N \cdot W$

---

condition for selection

$N \cdot W \cdot n \leqslant 1$

$W \leqslant 1/(N \cdot n)$

Fig. 11. Selection conditions.

In the case considered we can expect about $N = 50$ and $n = 20$. Then W must be smaller than about 1/1000 in order for selection to take place. But as we saw before, $W \approx 1/100$. This means, that RNA molecules with a particularly favorable tertiary structure cannot be selected. Each favorable species is altered adversely by additional reproduction errors in a much shorter time than is necessary for selection. Therefore, a divergent evolution of RNA molecules with different tertiary structures is to be expected.

7. Formation of Aggregates from Molecules Fitting into Each Other

It is to be expected that, among a large number of different RNA molecules moving around in solution, once in a while one molecule will have a tertiary structure matching that of another very well (Fig. 12a). The resulting aggregates will come apart during phases of multiplication and the individual molecules will replicate. In the following phase each molecule reassumes its tertiary structure and the matching molecules will again form aggregates. The aggregates thus multiply (Fig. 12a).

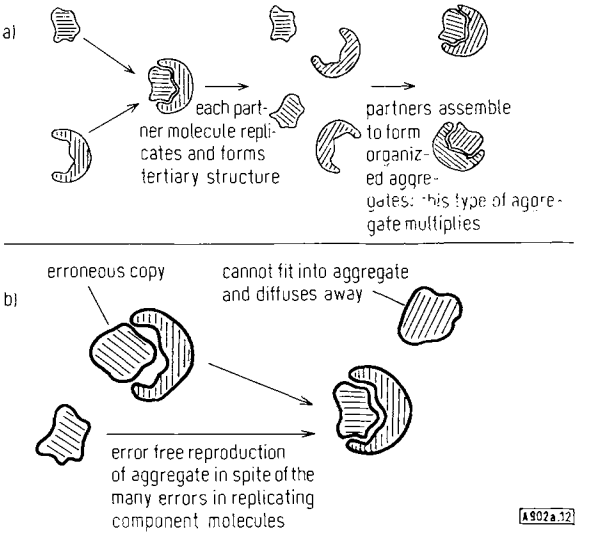

Fig. 12. a) Species of molecules which happen to match form aggregates. During formation phases the individual molecules separate and replicate. Afterwards they reassemble to form aggregates: this particular type of aggregate multiplies. b) Error copy does not fit and is replaced by one that has been reproduced correctly, thus ensuring error free reproduction of aggregate. Condition for selection (Fig. 11) can be fulfilled for aggregates.

During replication a reproduction error may occur. A faultily replicated molecule will assume an altered tertiary structure and no longer fit into the aggregate (Fig. 12b). It will diffuse off and be replaced by a molecule that has been replicated correctly. The result of this mechanism is that the aggregate is reproduced at a low error rate even

though the individual molecules are frequently reproduced erroneously. Since only correctly reproduced molecules may form aggregates, the condition for selection may be fulfilled for the aggregates (Fig. 11) even though it is not fulfilled for their precursors. It is clearly a prerequisite that the aggregates be formed in time and be sufficiently able to survive the decay phase. In other words: the condition for selection (Fig. 11, above) is only fulfilled if n is not too large, *i.e.* if according to Fig. 9 the multiplication factor r exceeds a critical value.

8. Necessity of Compartmentation to Ensure the Condition for Selection Is Fulfilled for the Aggregates

Within the aggregates the molecules protect each other from hydrolysis. We may therefore expect the aggregates to survive the decay phase more frequently than individual molecules. To provide for sufficiently fast aggregate formation, the molecules have to find each other within a time that is small compared to the duration of the decay phase.

This is only possible if we postulate the molecules to be enclosed within a compartment (Fig. 13). The compartment facilitates the agggregation process and may also provide another advantage for the selection of aggregates: by virtue of their size they cannot leave the compartment while the individual molecules unsuitable for incorporation into the aggregates can escape through the pores of the compartmental envelope during the decay phase.

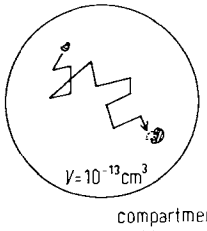

Fig. 13. Compartmentation: aggregates must be formed fast enough to attain the condition for selection: compartmentation prevents matching molecules from diffusing apart.

The maximum size of a compartment that still allows the molecules to find each other reasonably fast is about 10^{-13} cm^3 (for calculation see Appendix 2) provided the duration of the decay phases is of the order of one day. This value is roughly comparable with the volume of a bacterium. Cavities of this size are frequently met, *e.g.* between clay particles.

By the formation of aggregates of matching RNA molecules within these compartments, the transition to a strongly selective, convergent phase of evolution is once more initiated because the condition for selection is again satisfied.

Like the first change from a divergent to a convergent phase (onset of replication) this second change is again triggered off by pure chance (fortuitously matching tertiary structures are brought together by their random thermal motion). Here again an event that seems rather unlikely *per se* takes place sooner or later by constraint, thereby beginning a convergent phase. Looking at this simple case, we may recognize what time and again governs self-organization: the game of chance (the random motion of individual molecules and the chance formation of matching molecular shapes) leads to the formation of increasingly organized structural and functional units.

Because of the high frequency of errors during enzyme-free replication of RNA. *Eigen*[12] considered evolution to occur by cooperation between a system of nucleic acids and a second system consisting of a large number of different protein molecules engaged in mutual syntheses without a nucleic acid template in a reaction cycle which by itself is readily subject to perturbation.

In the model developed here, it is assumed that a system of nucleic acids capable of selection was first present. By forming aggregates the error rate during reproduction is reduced to such a degree that selection of pure RNA systems becomes possible. The assumption of strong periodic fluctuations of the environment is important for this model because they lead to the changes in molecular shapes that we just discussed. Such alterations in shape represent the decisive factor for selection. The other important concept that matching molecules may form self-organizing aggregates has an experimental basis: it has been shown with viruses and ribosomes that highly organized systems can be formed in solution simply upon mixing their constituents[21]. Ribosomes consist of more than 50 macromolecules.

9. Types of RNA Aggregates Capable of Selection: Aggregating Molecules Consist of About 50 Nucleotides

Let us now ask which types of aggregates will undergo selection. Aggregate a in Fig. 14 has no chance of asserting itself. Upon entering the multiplication phase all the molecules must disentangle and after replication and formation of tertiary structure they have to reassemble. This process is very time consuming. Only small isometric aggregates (b) and larger aggregates (c), in which the molecules are joined together in a chain, have any chance of being selected.

The degree of polymerization of those molecules which will displace the others can be estimated quite easily: each molecule capable of selection may consist of about 50 bases. Such a molecule is small enough to frequently replicate without error, since according to Fig. 3a an error in replication occurs in only one out of a hundred bases. On the other hand, molecules that associate to give stable aggregates must be sufficiently large to have a specific tertiary structure. This is the case for molecules of about 50 nucleotides, as we know from the transfer-RNAs (Fig. 7b). According to the concept of this model molecules having just about the same size as a transfer-RNA molecule will select.

Among the aggregates consisting of concatenated molecules, those made up of a nucleation molecule plus many identical line-up molecules must have selectional advan-

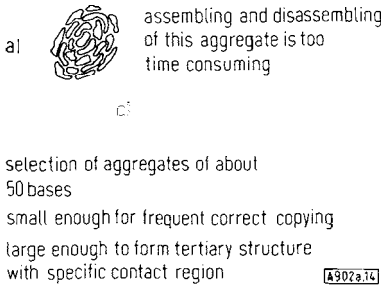

Fig. 14. Considerations on the nature of selecting RNA aggregate types.

tages, *i.e.* those which, like a crystal needle, are formed starting from a nucleation center (Fig. 15). Identical molecules form aggregates much faster than different molecules.

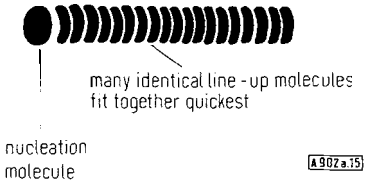

Fig. 15. Aggregates of two types of RNA with definite tertiary structure (nucleation molecule and many identical line-up molecules). This type of aggregate has selection advantages.

The latter need much more time to find each other during random diffusion. However, even with identical line-up molecules aggregate formation is still a relatively slow process (see Appendix 2).

10. Aggregates Consisting of Nucleation Molecule with Collector Strand and Line-Up Molecules

Let us consider a nucleation molecule which has a definite tertiary structure as described so far but in addition possesses a fairly long chain end of random sequence which keeps its open chain conformation (Fig. 16a). Line-up molecules may loosely associate with this chain, called the collector strand, and diffuse back and forth along its length; starting from the nucleation center they may proceed to form an organized associate (Fig. 16b). Thus the collector strand accelerates the collection of line-up molecules and the formation of an organized aggregate. Three-dimensional diffusion is now replaced by one-dimensional diffusion. Perturbations of the system by erroneous entanglement of the complicated forms of fitting elements are thus suppressed; the traffic problem of supplying line-up molecules is solved by the collector strand. The length of the collector strand determines the size of the aggregate. Since base replication errors do not abolish the action of this strand, its length is not dependent on the condition of containing about 50 bases which applies for molecules or parts of molecules having a tertiary structure (Fig. 14).

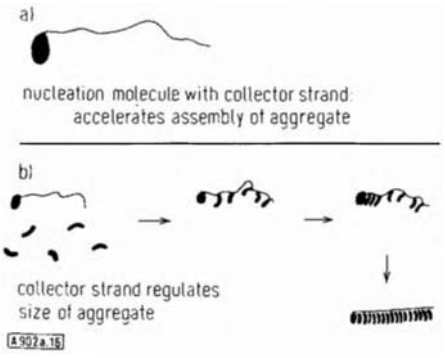

Fig. 16. Nucleation molecule (with tertiary structure) equipped with an open chain strand without tertiary structure (collector strand) represents a selection advantage for the aggregate: the collector strand facilitates construction of an organized aggregate. The collector strand reduces interference by incorrect entanglement of line-up molecules, and thus helps to solve traffic problems arising during formation of aggregates.

We now may expect that, apart from small, isometric aggregates, chain-like aggregates also undergo selection.

The tertiary structure of aggregate-forming molecules is fixed only in their matching regions. In other regions which are not important for the association, however, base reading errors do not influence aggregate replication. The exposed surfaces of the aggregates will thus constantly change during this evolutionary phase (Fig. 17a). Different

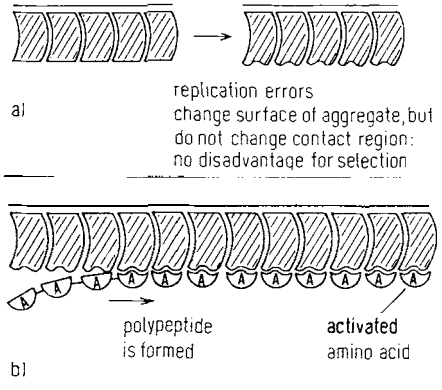

Fig. 17. Gradual alteration of the aggregate according to Fig. 16. Catalyzing properties facilitate, *e.g.*, polymerization of activated amino acids on the surface of the aggregate.

forms will coexist. Since random processes will form structures into which smaller molecules may be fitted, we can expect these structures to be capable of catalyzing reactions.

The catalytically active surfaces will partly disappear again when base reading errors occur and thus have no effect in further evolution. However, as soon as the fitting of foreign molecules becomes one of the crucial factors for the association of the aggregate, the catalytic system stabilizes itself for forthcoming generations. Here again we enter a divergent phase of evolution, in which many systems catalyzing different processes have about equal chances of survival.

12. Formation of Polypeptides on the Surface of an Aggregate Consisting of a Nucleation Molecule and Line-Up Molecules

One can imagine one of the numerous catalytic reactions occurring on surfaces of organized aggregates to be the formation of a polypeptide (Fig. 17b). We may take it for granted that under prebiotic conditions activated amino acids were present in sufficient concentrations. This follows from the experiments of *Miller* and others who obtained many different amino acids upon simulation of such conditions[1-5]. It is quite likely that polypeptides may be made this way: According to the work of *Katchalsky et al.*[22] certain kinds of montmorillonite also serve as catalysts for the formation of polypeptides. Activated amino acids react with one another on the surface of these minerals. Molecules of glycine cetyl ester, brought into contact with each other by forming a monolayer of the substance, react to form the polypeptide[22a], and we may expect a similar reaction in aggregates of corresponding line-up molecules.

Polypeptide-synthesizing systems would be of no importance if their presence did not create a very special situation: it is known that polypeptides obtained by heating dry amino acids form small globules in water. These globules represent polypeptide envelopes and have a diameter of several μm. These microspheres, which have been described by *Fox*[23], can act as semipermeable membranes.

13. Turning Point: Systems Produce Polypeptide Envelopes and Thus Become Independent of a Naturally Occurring Compartment

We now can assume that the polypeptide-synthesizing associates produce their own envelopes. This leads to a turning point: the systems are now independent of naturally occurring compartments; they are no longer confined to the spaces between clay particles and can reproduce whenever the necessary periodical fluctuations occur.

This development again leads into a convergent phase: any system able to complete synthesis of its envelope faster than another has selection advantages. A selection pressure now exists, favoring systems with a more sophisticated protein-synthesizing apparatus.

At this point the isometric aggregates (Fig. 14b) may come into the picture and contribute to peptide synthesis. Nucleation molecule and collector strand have thus become the primitive messenger-RNAs, the line-up molecules have become the primitive transfer-RNAs, and the isometric aggregates have turned into the primitive ribosomes.

The crucial event at the turning point is again highly improbable as an individual process, but in a large enough population it occurs cogently. The mutant is selected because it can now enter new areas. Without the formation of an envelope it would not have been possible to attain a higher degree of evolution. Here again the general direction of evolution seems to be logically predictable.

14. Accelerated Production of Envelope-Polypeptide by More Precise Fitting of Groups at the Site of Peptide Formation. Evolution of the Primitive Ribosome

Any change, even the smallest, leading to an improvement of the polypeptide-synthesizing device offers selectional advantages.

A multistep evolution of the primitive ribosome should now start. The isometric aggregate should gradually change in such a way as to ensure increasingly precise fitting of groups at the site of peptide linkage and to render the supply of amino-acid-carrying tRNA molecules progressively less sensitive to perturbation. To facilitate these improvements, the tRNA molecules must be held in position by a pincer-like device at the time of peptide linkage. This may be accomplished most easily by a primitive ribosome made up of two parts closing in on the reacting molecules. Polypeptide synthesis may be assumed to take place in the following way: to start with the two parts of the primitive ribosome form a complex of precisely fitting elements with the nucleation center and a primitive tRNA molecule. A second molecule of primitive tRNA then fits in at a precisely determined position so that a peptide bond can be formed. The second tRNA molecule can subsequently take the place of the first, the third take the place of the second, and polymerization can thus be sustained.

15. Pairing of Three Bases on the Primitive mRNA with a Base Triplet on the Primitive tRNA

Polypeptide synthesis will proceed with less interference and thus faster the better the amino acids fit together at the site of peptide bond formation. This will largely depend on how well the line-up molecules on the collector strand can be channeled into the primitive ribosome. The development

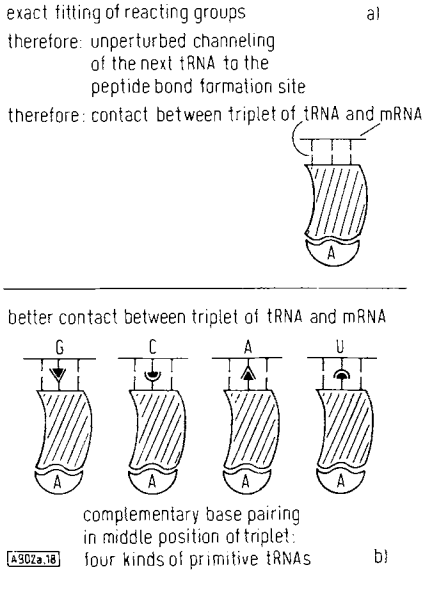

Fig. 18. Improvement of the device for polypeptide synthesis for the purpose of faster production of the envelopes.
a) Linkage between triplets of the tRNA and mRNA. b) Complementary base pairing between the middle position of the triplet and the respective place on the mRNA.

of a mechanism which fits the line-up molecules on the collector strand into the primitive ribosome, so that the next tRNA is transported smoothly to the site of peptide formation, seems to follow inevitably; and one can imagine that *inter alia* a mechanism develops where the bases on the primitive mRNA (collector strand) are paired three at a time with a base triplet on the primitive tRNA (line-up molecule) (Fig. 18a).

Let us assume that initially only the middle bases of the triplets have to fulfil the condition of complementarity (Fig. 18b). If a molecule of primitive tRNA with the wrong base in the middle position comes along, it is unable to form a stable complex with the collector strand inside the primitive ribosome and thus moves on. As soon as a molecule of the right kind comes along it is incorporated. If the RNA molecules are considered to be made up of four bases we have to differentiate between four kinds of primitive tRNAs. They have different bases in the middle position of the triplet but still lack amino acid specificity (Fig. 18b).

Precise and fast polypeptide synthesis provides the systems with such a tremendous selection advantage that the small disadvantage of complementary base pairing is unimportant. The time lost by the line-up molecule having to diffuse to its vacant site can be calculated and is found to be of little significance (Appendix 2).

16. Systems Produce Polypeptides with Specific Sequences. Sequence Cannot be Retained Owing to Excessive Replication Errors

The tertiary structures of the four kinds of primitive tRNAs we have just considered are gradually altered by replication errors. A change resulting in even a slight advantage is carried over to all molecules of the same strain after a few generations. The reasons for this are the same as those for the selection of aggregates with identical line-up molecules in earlier phases. The different tertiary structures lead to a certain specificity in the binding of amino acids, which may have kinetic or thermodynamic reasons. The system then produces a polypeptide with a sequence that is no longer random; however, the code cannot yet be fixed: the base sequence of the primitive mRNA is altered by replication errors before selection has taken place.

As shown in Appendix 3 an error probability during replication of about $W = 1/1000$ would be necessary for fixation of the code while the actual probability is assumed to be $W = 1/100$. Thus, even though a code exists for up to 4 amino acids it cannot be conserved.

We have now again reached a divergent phase of evolution: on the collector strand any number of replication errors may occur without disadvantage and therefore systems evolve that are able to produce polypeptides with different amino acid sequences. A species producing a polypeptide happening to be particularly useful cannot be selected: because of excessive replication errors all the progeny lose the ability to produce this polypeptide.

17. System Produces Polypeptide Reducing Probability of Replication Errors: Code for Four Amino Acids is Fixed

We can now assume that, among a large number of polypeptides in a population, one will evolve which, on account of its amino acid sequence, happens to exert an enzymatic effect on RNA replication and thus reduce the probability of error during replication from $W = 1/100$ to $W = 1/1000$. At the same time the system has to have a direct selection advantage and therefore a higher multiplication factor r. The first property conserves the information stored in the specific amino acid sequence, while the second property enables the individual to displace other individuals. Both properties may be coupled: the enzyme reducing the replication error frequency is simultaneously able to increase the replication rate itself. The code for four amino acids (or four groups of amino acids) thus gradually becomes fixed.

The divergent phase again turns into a convergent one: systems producing polypeptides with a predetermined amino acid sequence can now be selected. Again a selective pressure is present: systems happening to produce polypeptides with favorable sequences assert themselves.

The exact sequence of the following steps is unimportant. It is reasonable to assume the gradual formation of amino acyl synthetases for the four primitive tRNAs, which would increase the specificity for the binding of amino acids. However, the sequence of formation of the individual enzymes is of little importance because many different paths lead to the same result. As soon as the condition for selection is reached, *i.e.* once W falls below a critical value, further evolution of the genetic code occurs by constraint.

We have to bear in mind that no base replication error may occur in the middle of the anticodon triplet of the primitive tRNAs until selection has taken place. A mistake of this type would annul the coding. Once the species having an enzyme guaranteeing a low replication error rate has asserted itself, a replication error in the anticodon is no longer of any consequence: each erroneous individual produces a wrong polypeptide and is therefore eliminated. The code is thus fixed.

This consideration demonstrates a very important principle of evolution: the crucial change was brought about by a selection process which continuously refined an existing mechanism until a system resulted which began to serve an entirely new purpose. [The device for the synthesis of unspecific polypeptides was improved (complementary base pairing) so that the envelopes could be synthesized faster; this resulted in systems with predetermined amino acid sequence and thus in new varieties of chemical behavior.]

The change here again is triggered off by an event of low intrinsic probability (formation of an RNA-replicating enzyme) but which seems to occur by constraint in a favorable environment. It does not seem easy to think of a fundamentally different event likewise able to steer the systems from a divergent into a convergent phase and hence to a higher level of evolution.

Naturally the great demands made on the mutual fitting of groups at the site of peptide linkage can only be met by one chiral form of amino acids and not by the other at any one time. On the basis of this model, the fact that only l-amino acids are found in proteins now becomes intelligible.

After reaching the new level of evolution a vigorous development must set in: replication errors and selection effect improvements in the polypeptides and in their mutual adjustment. Their properties supplement each other increasingly well and the functioning of the system as a whole becomes more and more dependent on the presence of all polypeptides, which now form a functional network. The system of a number of protein synthesizing entities within a common envelope now becomes a primitive organism.

18. Code for Additional Amino Acids

Those systems which synthesize the best enzymes will survive, and good enzymes have a high molecular weight. Sooner or later a selective pressure towards larger proteins with a determined amino acid sequence will therefore occur. Those systems will survive which have the lowest probability of producing "nonsense" proteins, *i.e.* proteins made by skipping one base on the mRNA. This means that systems able to provide the best contact between anticodon and primitive mRNA will be selected. Thus those systems will gradually dominate where not only the middle but also the first base of the triplet bow to the condition of complementarity. The need for a polypeptide-synthesizing apparatus working with increasing precision must again lead to a turning point: the development of a code for additional amino acids. Again a selection process which effectively improves mechanisms already present necessarily leads to a sudden change of direction.

19. DNA Begins to Play a Role in the Genetic Apparatus

A difficulty preventing further evolution is soon bound to arise: aside from the RNA strands constituting the protein-synthesizing device (tRNAs, mRNAs, and ribosomal RNAs), the respective complementary strands are also made during the multiplication phase. They are of no use in protein synthesis and represent waste products giving rise to increasingly serious interference the more complex the systems become.

The formation of these complementary strands can be avoided by participation of DNA in the genetic process: One can imagine the development of two enzymes E_1 and E_2 (see Appendix 4), where E_1 makes the complementary DNA on the RNA template, and E_2 produces RNA on the template of the complementary DNA (Figure 19). One can further imagine that an RNA linking protein is subsequently formed, which permits the assembly of the entire information of the individual in a single strand of DNA. Sooner or later a protein enabling replication of DNA is bound to evolve by chance. Since this kind of system multiplies much faster, there will be a strong selective pressure towards the development of an increasingly

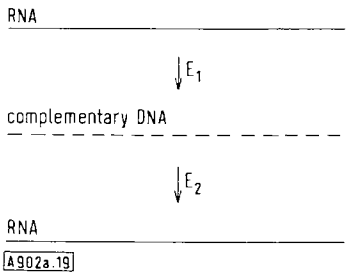

Fig. 19. DNA is beginning to play a role in the genetic apparatus.

precise DNA replicating device. DNA now becomes the carrier of genetic information, E_1 degenerates, and E_2 evolves to become transcriptase.

All the important elements of the genetic apparatus, as known from molecular biology, are now present. Further evolution becomes a necessary consequence: improvement of the ribosome to reduce its sensitivity to interference, the introduction of start- and stop signals; further evolution of the genetic code; and evolution of a replication and transcription device.

20. Time Required for Instruction of an Additional Protein in a System with a Fully Developed Genetic Apparatus

Let us now take a look at a species with a fully developed genetic apparatus. It produces many proteins with well determined functions, which as a group form a highly organized structural and functional network. The system furthermore will be assumed to produce a protein of random sequence which is not yet part of the functional network (Fig. 20a). Each replication error during reproduction, occurring in the instructed part, shall be lethal, *i.e.* the instructed proteins must fit together functionally like the parts of a watch, and practically any mistake stops the whole process.

It may then be assumed that, in a larger population of such systems, that part of the DNA which carries the information for the fully instructed proteins has the same sequence in all individuals. The section for the last protein, on the other hand, has a random distribution of sequences. The species in which this protein happens to have a function conferring the greatest advantage will assert itself. As shown by the estimate in Appendix 5, this takes about $n = 10^3$ generations. We can assume that the systems are optimized with regard to the probability of reproduction errors, *e.g.* according to Fig. 11 the error probability of replication has to be $W = 1/(n \times N)$, N (number of bases for instruction of a protein) being about 10^3. Thus $W \approx 10^{-6}$ (Fig. 20a). The number of generations needed for the instruction of a new protein can now easily be estimated to be about 10^8 (Appendix 5): This corresponds to about

10^5 years if we use an average of one day per generation[*]. For the instruction of the 10^3 proteins of a bacterium, the time requirement now turns out to be about 10^8 years. The entire time requirement for all the preceding steps of evolution of the genetic apparatus is small compared to this value of 10^8 years. This time estimate for the evolution of bacteria is within the limits set by geohistory (about 2×10^9 years). The result shows that the evolution of bacteria may be interpreted in terms of a physico-chemical phenomenon. This type of estimate is not meant to give precise figures on the time requirement for the evolution

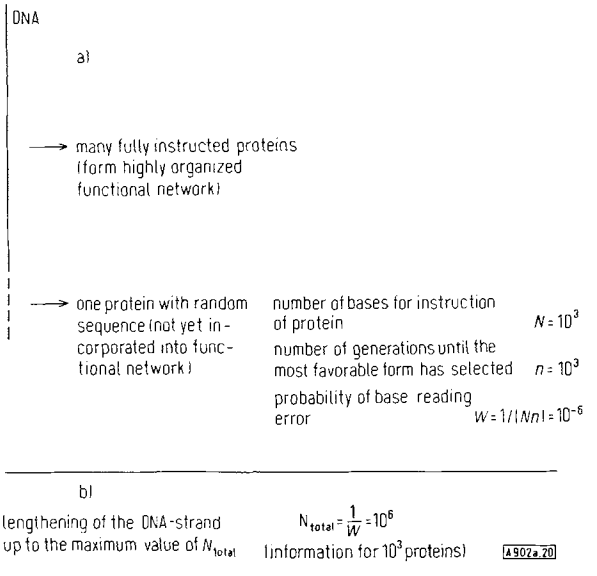

Fig. 20. a) System with fully developed genetic apparatus. Time requirement for the instruction of an additional protein not yet incorporated into the functional network. b) Upper limit of genetic information capacity of model systems. If this limit were exceeded, too many replication errors would occur per generation.

of bacteria, but rather to disprove the frequently voiced claim that the time historically available for development of such systems is much too short.

For the upper limit of the number of bases in the DNA strand, N_{total}, we find (using the value $W \approx 10^{-6}$): $N_{total} = 1/W \approx 10^6$. With higher values for N_{total} an error-free reproduction would rarely take place; a species of that type would soon disappear on account of lethal errors. $N_{total} \approx 10^6$ just about corresponds to the informational content of a bacterium[24] (information for about 10^3 proteins). At this point of the model we again reach a limit (Fig. 20b).

Replication errors occurring in the DNA will sometimes be not lethal but harmless or even useful. A divergent phase thus starts in which many species have comparable chances of survival. With systems having the information content of a bacterium, evolution seems to have come to an end.

However, the model indicates another turning point which may lead to the evolution of higher organisms containing a greater amount of genetic information. (For details see Appendix 6—8.)

21. Final Considerations

21.1. Basic Ideas and Discussion of Results

We started from the hypothesis that the laws of physical chemistry are sufficient to understand the evolution of selforganizing systems. The basic idea of this procedure was to acquire an insight into the principles of selforganization by discussion of a special model. A model pathway was considered as a causative chain of events. Each step results from the previous one by reflecting on how the system might behave under certain conditions. A crucial assumption in the model was strong periodic fluctuation of the environment of the evolving system. This procedure led to the essential mechanisms of the genetic apparatus and no steps of low probability had to be introduced. In an appropriate environment the evolution of selforganizing systems appears to be a normal physico-chemical process.

It may now be asked why this procedure, which is based on free inventions, leads to the genetic apparatus as we know it and not to entirely different systems. This may partly be due to the fact that inventions are based on what one already knows. On the other hand, each important evolutionary step is the solution of traffic- and organizational problems. With many of these steps, very different pathways will presumably lead to similar solutions, which simply represent the best solutions of particular problems.

The model has shown that changes between divergent and convergent phases of evolution repeatedly take place: during divergent phases many forms have similar survival probabilities and thus the population has a great diversity. A gradual improvement of mechanisms occurs. At a turning point, which may be logically predicted, a certain mechanism begins to serve an entirely new purpose. The process leading to this kind of turning point is highly improbable by itself; but even an improbable process sooner or later must take place by constraint in a population of sufficient size. The turning point initiates a convergent phase. It is strongly selective and the selection process has a definite direction: those random mutants survive which serve the new purpose best (Table 1).

For the turning points we endeavored to perform a careful analysis of how the condition for selection can be fulfilled, but we did not look for detailed models of evolution during the convergent phases. During these phases the system must develop in the direction prescribed by the selective pressure, and for the general points of view under discussion it is unimportant to know *exactly* in which way an impending problem of molecular traffic organization is solved.

Since the transitions from divergent to convergent phases may be grasped fairly well by quantitative approximations, it is possible to discern methods for an experimental appraisal of the model. Such an appraisal would be of great importance.

[*] The information on the construction plan of the individual, passed on from one generation to the next, increases by 1 bit in $10^5/(2 \times 10^3)$ years = 50 years (a base pair corresponds to 2 bits).

Table 1. Turning points from divergent to convergent phases of evolution.

Cause	Effect
Polynucleotide molecule uniformly contains d- (or l-)ribose	Molecule is capable of replication. Species multiplies
RNA molecules with tertiary structure fit together and form aggregates	Aggregate can be reproduced with low error rate because incorrect copies of individual molecules do not match. Aggregate species selects
Polypeptide synthesis on surfaces of aggregate	Polypeptide forms envelope, which impedes diffusion of precursors of aggregates. Species multiplies. It is independent of a given compartmentation and thus has new scope for propagation
Complementarity between bases of the triplets of the primitive tRNAs and the primitive mRNA	Protein with certain specificity of amino acid sequence reduces probability of a replication error to 10^{-3} per base. Genetic code. Proteins with specific functions evolve
DNA-RNA tandem	Useless complementary RNA strands are no longer made. Information for organisms merges in the DNA strand. DNA becomes carrier of genetic information. Development up to $N_{total} \approx 10^6$, $W \approx 10^{-6}$
Exchange of genetic material between individuals in addition to an improvement of the replication device, for example by triple storing of information	Evolution of pseudosexual mechanisms. Diminution of W and enlargement of N_{total} up to the limit given by thermal blows or radiation damage. Evolution of higher organisms
Language, writing, and information storage and retrieval technology	More information can be passed on to the next generation than by the genetic apparatus. Thus, evolution of functional networks needing a greater information capacity than given by the genetic apparatus

21.2. Further Possibilities for the Evolution of Selforganizing Systems. Scope of the Presented Conceptual Pattern

In this study the model asumptions were choosen to retain as many connections to known facts as possible in order to keep the hypothetical content as small as possible.

The method described here could also be used in a search for routes to selforganizing systems employing completely different tools than the organisms we know. It would be interesting, for example, to consider the selection possibilities for systems whose genetic information is stored, replicated, and read off in a planar fashion instead of linearly.

It has often been asked whether living systems could, under different conditions (on different celestial bodies), evolve from entirely different compounds. This question is reasonable, because elements like boron, nitrogen, phosphorus, *etc.* in non-aqueous media form a great variety of compounds with each other. Specialists in the field suspect an abundance of compounds comparable with that of carbon chemistry.

Here we also encounter a difficulty which would equally arise in carbon chemistry if we did not know anything about nucleic acids and proteins: a special model for the formation of selforganizing systems would remain speculative because it could not be substantiated at all stages by comparison with what we know.

In principle, after what has already been said, one could imagine the evolution of selforganizing systems according to a comparable sequence of divergent and convergent phases where the carriers of information and function belong to completely different classes of substance from nucleic acids and proteins. With this kind of system also, all the important model steps would be steps to solve problems of traffic regulation and organization on the molecular level, which must likewise occur with other types of substances and under different conditions.

It seems rewarding to apply the described method (conceiving systematically of a hypothetical pathway as a causative chain of events, checking individual steps by quantitative estimates) to later evolutionary steps of an apparently highly teleological nature, for example to the phylogenesis of the bombardier beetle.

Tracing the logical pattern of the evolutionary formation of important biological processes by model considerations should prove to be one of the main applications.

The situation in biology is comparable to that in chemistry: Basically chemical phenomena should be predictable from the Schrödinger equation, but the Schrödinger equation is applicable only if enormous simplifications are introduced. Quantum chemical model systems may serve as a frame, in detail however chemistry is largely based on experience. In biology, the complex structure of each individual and of the evolving populations introduces similar restraints for a strict treatment, and the search for simple models will be an important task.

21.3. Chance and Necessity

The process leading to a turning point from a divergent to a convergent phase of evolution for the individual in question is a random event of very low probability. But in a sufficiently large population even a highly improbable process takes place by necessity. This is similar to the event of throwing 10 sixes in a row which takes place by constraint if the dice is thrown often enough.

In the above discussion only *one* possibility leading to a turning point was found on each occasion. On the level

of the evolution of aggregates, for example, the step leading to the formation of an envelope seemed necessary to provide an escape from the divergent phase. The systems remain captives of their evolutional level until the occurrence of the decisive random event which raises them to the next level. Since this event sooner or later must take place by constraint, not its occurrence as such but the time of occurrence is pure chance. Means of overcoming difficulties impeding further development after a divergent phase has been reached are thus apparently intelligible, and the general lines of the evolutionary process, as determined by the turning points, are not unpredictable. Under appropriate conditions the origin of life and the evolution of increasingly highly organized systems, with respect to the decisive aspects, therefore seems to be a necessity.

The situation does not seem basically different from that in other areas of physics, where individual processes are described by random laws of chance while the overall behavior of large ensembles is deterministic in approximation.

In the model no step of low overall probability has to be introduced. Instead, the evolution of life can be considered to be a process which must occur under suitable circumstances. The triggering process would certainly not appear to be of such low probability that it is unique in the universe.

If the conditions as they have prevailed on earth could be simulated, forms of life would again develop. The inevitable steps leading to higher levels of evolution would occur again, and these steps appear to be replication, formation of aggregates, envelope formation, evolution of the genetic code, the coupling of the genetic material containing the construction plan of an individual, the exchange of genetic material between individuals as well as later steps, such as steps similar to the formation of an envelope enabling the system to find new living space. On the other hand it could be expected that all those steps representing solutions for molecular organization problems of minor importance, *i.e.* problems having different, equally reasonable solutions, would go in different directions if they were repeated. Therefore it can be assumed that the elements of the genetic apparatus (for example the ribosome) would have a different structure and would be part of a different functional network; and it also seems likely that the translation pattern of the genetic apparatus would be different. The development of other metabolic pathways, which happen to have been found earlier and form different functional networks, is conceivable. It may be expected that enzymes with corresponding functions would have a different structure.

The overall course of evolution would be expected to be the same, but in detail the evolving systems would find different functional networks and precursor elements, which would still serve the same general purposes. The random accidents are the triggering elements of evolution and determine the time of occurrence of decisive events and all the details concerning the structure of self-organizing systems, but they do not determine the general features of self organization.

22. Appendix 1: Can a Model Step be Realized? General Considerations for the Estimates

When we discussed Figure 9 we presumed that one individual of an advantageous mutant, formed spontaneously and at random, would be found in the given population. This prerequisite is practically always fulfilled for the following reason: in a large population there will be spontaneous production of many mutants with a slight advantage and a few with a greater advantage. In general, only one specimen of the mutant with the greatest advantage of all will occur at random. Since this mutant is usually the one that asserts itself it is the only one that has to be taken into consideration apart from the normal form.

From the molecular architecture of the system, we can estimate the probability of formation of an imaginary mutant by random reproduction errors. From this probability we are able to derive the size of the population, *i.e.* the number Z of individuals of the respective normal form displaced on selection of the mutant. (Z equals the reciprocal value of this probability.) Furthermore, on the basis of the advantages we assumed for the new mutant, we can estimate by how much its reproduction frequency or its chance of survival has increased compared to the normal form.

We thus obtain a value for r which we can use, according to Figure 9, to determine the number n of generations necessary for selection. Furthermore, we assumed that after having evolved through replication errors the mutant does not suffer another replication error during those n generations, because in a highly differentiated system practically any error would incur a disadvantage. In Figure 11 we then introduced the error probability P, *i.e.* the probability of a new error occurring during reproduction of an individual of this mutant. This means that after $1/P$ generations practically all the progeny of this mutant are afflicted with an error. Simplifying, we may imagine that no error occurs during the $1/P$ generations after the first appearance of the mutant, but after precisely this number of generations an error in reproduction occurs in each individual of the mutant. This simplification does not change the result very much but it makes the situation easier to grasp.

We now have to differentiate between two cases:

$$1/P < n \quad \text{and} \quad 1/P > n$$

n is the number of generations (counting from the first appearance of the mutant) in which the mutant displaces the normal form. If $1/P > n$, the mutant has not asserted itself before the next error occurs. The mutant thus only represents a minute fraction of the population. The probability of finding one individual in this small group which would profit from the error is exceedingly small. The mutant almost certainly dies off.

If $1/P \geq n$, the whole population is made up of the mutated species. The number of individuals suffering a new error is high. However, we can now assume that among the many individuals there is one which has profited from the new error: a new improved mutant develops which again asserts itself.

If $1/P \geq n$, the random error is no longer disadvantageous but is useful instead. The condition for selection as given in Figure 11 applies. As soon as this condition is obeyed, evolution takes place faster the faster the new random error occurs: The time before the occurrence of the next error inducing a new evolutionary step is much too long if the error probability is reduced. The condition for optimal probability of reproduction error is therefore:

$$1/P = n\,.$$

When looking for a meaningful model pathway one thus proceeds in the following manner: Z, r, and P are estimated for an imaginary mutant on the basis of molecular architecture. It is then established whether the condition $1/P > n$ for selection to take place is fulfilled for the step considered. Only those steps may be considered for which this condition holds (Fig. 21).

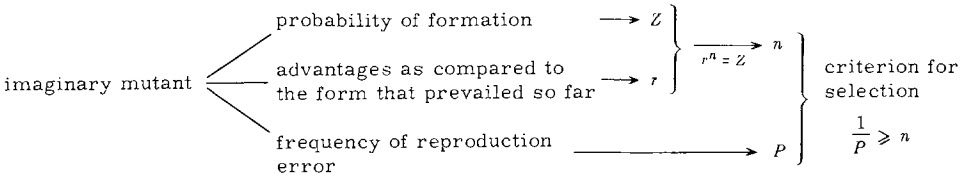

Fig. 21. Test to see if a model step may be realized.

The method will be illustrated for the selection conditions of individual molecules (Fig. 9 and 10). During the multiplication phase a replication error occurs with a probability of $P = N \times W$ (Fig. 11). This is true if the species replicates only once during the entire multiplication phase. Each molecule serves as template for the synthesis of the complementary molecule, and during the next multiplication phase the complementary molecule itself now functions as a template on which the original molecule is synthesized again. Both species have corresponding tertiary structures during the decay phase because intramolecular base pairing occurs at corresponding sites. It can be assumed that because of their complementary tertiary structures both species have a similar chance of survival. Our considerations in Figures 9 and 10 were based on molecules having $N = 50$ bases each, such as are met in tRNAs. Molecules of this size can assume specific tertiary structures and they will have particular selection advantages: larger molecules will be formed too slowly whereas smaller molecules will have poorer chances of survival and will display no significant differences with respect to their resistance to hydrolysis.

Among $Z = 10^6$ molecules with $N = 50$ *one* will be assumed to be twice as likely to survive the decay phase than the great majority of the others because of its tertiary structure. Species even more resistant to hydrolysis will be assumed not to occur. It thus follows that $r = 2$ and $n = 20$ (Fig. 9). Therefore $1/P > 20$ (Fig. 11) must apply in order for selection to take place. In the case considered (only one replication step in the multiplication phase, $P = N \times W$) $W < 1/(20 \times 50)$ is the condition for selection. If in the multiplication phase several (for example s) replications take place in a row, then $P = N \times W \times s$ if $P \ll 1$. With increasing s the portion of error-free individuals is reduced upon entering the phase of decay, and accordingly the value of r becomes smaller. Both effects (increase of P and decrease of r and thus increase of n) make the condition for selection stricter.

As mentioned in Section 6 the condition for selection of individual molecules is not fulfilled even in the most favorable case, *i.e.* $s = 1$, because $W = 1/100$. For aggregates, on the other hand, the condition for selection can be fulfilled, even though $P = N \times W = 50 \times (1/100) = 1/2$ holds for the precursor molecules (see Appendix 2). At the end of the multiplication phase, however, there must be a sufficient number of error-free molecules able to form an organized aggregate. Particular interest therefore attaches to the ratio of the number of error-free copies to the total number of molecules formed by replication in the multiplication phase as a function of s.

In the course of the multiplication phase, one molecule yields $V = 2^{(s-1)}$ molecules of the same type and $V' = 2^{(s-1)}$ of the complementary form. We can now easily calculate numbers v and v' of error free copies:

if $s = 1$	$v = 1$ $v' = 1 - P$
if $s = 2$	$v = 1 + (1-P)^2$ $v' = 2(1-P)$
if $s = 3$	$v = 1 + 3(1-P)^2$ $v' = 3(1-P) + (1-P)^3$
if $s = 4$	$v = 1 + 6(1-P)^2 + (1-P)^4$ $v' = 4(1-P) + 4(1-P)^3$ *etc.*
therefore	$v + v' = [1 + (1-P)]^s$
or	$(v + v')/(V + V') = (1 - P/2)^s$.

In the case $P = 1/2$ under consideration the ratio $(v+v')/(V+V')$ thus amounts to

0.75 (for $s = 1$)
0.56 (for $s = 2$)
0.42 (for $s = 3$)
0.31 (for $s = 4$).

The proportion of error free copies for $s = 4$ is therefore less than half that for $s = 1$.

The selection of aggregates is dependent upon the availability of compartments (Fig. 13). In this case, the selection criterion is somewhat different because selection first takes place within the compartment. Later on the especially

favorable individuals take over the other compartments. The condition for selection then is less stringent than without compartmentation, because the advantageous species has to displace a smaller number of individuals (the individuals within the compartment). The condition for selection here again is given by the equations of Fig. 9 and 11, Z now representing the number of individuals of the normal form in the compartment and n representing the number of generations during which the species becomes dominant in the compartment. The prerequisite here is $Z \gg 1$.

The number of generations needed for the fittest species to becomes dominant in the entire population depends on how quickly the fittest form enters the neighboring compartments. Let us consider the following case: n generations after the favorable species has dominated the compartment it takes over just one more compartment, and this event keeps on occurring after each n generations. After about $g \times n$ generations the fittest form will have displaced the entire population (G compartments). Then $2^g = G$.

23. Appendix 2: Estimate of Time Required for Formation of Organized Aggregates

In order for the macromolecule B to be able to associate with A (Fig. 22a), a and b have to approach each other closer than the critical distance d of about 1 Å. Furthermore, the molecules have to have the correct orientation. Let us assume that molecule A is fixed. We now want to estimate the average time that elapses until part b of molecule B approaches part a of molecule A to within distance d. To simplify the problem, let us further assume

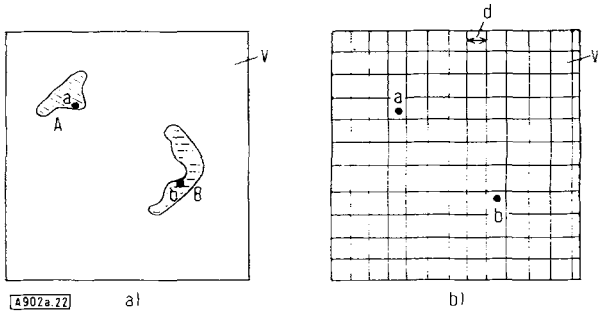

Fig. 22. Estimate of the time requirement for formation of an aggregate of matching molecules.

that part b is in the center of the molecule and therefore only takes part in translational but not in rotational diffusion of the molecule. Let us divide up the volume of the compartment V into cells with an edge length of d (Fig. 22b). According to *Einstein-Smoluchowski*, the average time τ needed by b to reach the next cell is $\tau = d^2/2D$, where D is the diffusion constant of the molecule B. The average time t required for b to reach the cell containing a, is τ times the number of cells of volume V, *i.e.*

$$t = \tau(V/d^3) = V/(2Dd)$$

In order to calculate the time needed for incorporation of molecule B into system A we still have to multiply t by a steric factor α, which makes allowance for the necessity of proper orientation of molecule B.

An RNA molecule of about 50 bases forming a compact tertiary structure has a mean radius of about $R = 40$ Å (Fig. 7b). The diffusion constant is $D = kT/6\pi\eta R$ [(k = Boltzmann's constant, T absolute temperature, η viscosity of the solvent (10^{-2} poise for water)], and thus about $D = 6 \times 10^{-7}$ cm^2/s. For $d = 1$ Å and $V = 10^{-13}$ cm^3, t amounts to 10 s. If we put $\alpha = 1/100$ the time of formation is found to be about 20 min. If there are several identical molecules B which can take each other's place in the aggregate then assembly occurs correspondingly faster. The formation of an aggregate from a nucleation molecule (Fig. 15) and, say, 20 line-up molecules, under the respective conditions takes $(1/20 + 1/19 + \ldots + 1/2 + 1) \times 20$ min $= 1$ hour.

In a system consisting of a nucleation molecule with collector strand and line-up molecules, not only the time for diffusion of line-up molecules to the collector strand (according to the above estimates about one minute), but also the time for arrangement of the molecules to form an organized aggregate becomes crucial. We can assume that the time required for incorporation of an additional molecule is 100 times that for one rotation around the axis of the molecule by diffusion. The latter amounts to $t = (2\pi)^2/2D_{rot}$ where $D_{rot} = kT/8\pi\eta R^3$, from which $t = 10^{-5}$s is derived. Within an aggregate of 20 molecules the matching would take $20 \times 100 \times t$, that is less than one tenth of a second.

In the model considerations the RNA concentrations can be taken to be one quarter of the concentration of transfer RNA in a bacterial cell. In a compartment of 10^{-13} cm^3 there are then about 10^4 RNA molecules, and, for example, 10^2 aggregates could be made, each containing 10^2 RNA molecules. If only one type of aggregate is present, the time required for association of the molecules becomes correspondingly shorter because each molecule can be fitted into any aggregate, provided that it carries no reproduction errors. The probability for this results from the concepts presented in Appendix 1.

24. Appendix 3: Probability Estimate for the Step Triggering the Evolution of the Genetic Code

According to Section 17 we can assume the synthesis of a polypeptide which supports RNA replication in such a way that its own synthesis takes place with sufficient sequence specificity. This results from the following estimate:

A specific contact region, which reduces W from 1/100 to one tenth or one twentieth of this value, can be attributed to the imaginable polypeptide, in order that it may display a sufficient degree of catalytic activity. It seems reasonable to assume that the amino acids must be predetermined in, say, $\nu = 10$ positions. This means that the base also has to be predetermined in 10 places of the collector strand. The probability of this type of polypeptide being

produced by an aggregate at random is then $(1/4)^{\nu} \approx 10^{-6}$, which means that $Z = 10^6$. If it is assumed that the presence of the catalyst increases the multiplication factor by 30% ($r = 1.3$), then according to the equation in Fig. 9: $n \approx 50$. Now from the condition for selection it follows that (Fig. 11) $P \leq 1/50$. In this case P is the probability that during reproduction an error occurs in the first or the second, *etc.*, of these ν positions on the collector strand (replication errors elsewhere in the collector strand have no effect, and if the molecules contain errors spoiling their tertiary structure they are not incorporated into the aggregate). P is dependent upon the frequency W of replication errors and on the numbers of consecutive replications in the multiplication phase (Appendix 1). $P = \nu s W$.

Here s must have a value of at least 2. During the multiplication phase each molecule then functions as template for synthesis of one complementary molecule and the complementary molecule subsequently serves as template for the synthesis of one individual of the original kind. At the end of the multiplication phase there are now two molecules of the original kind instead of one; if $s = 4$ there are four molecules, *etc.* We thus obtain $W = P/(s \times \nu) \leq (1/50)/(2 \times 10)$, which means that $W \leq 1/1000$ for $s = 2$, or $W < 1/2000$ for $s = 4$. W therefore must be 1/1000 to 1/2000 for selection to take place. Systems with the postulated polypeptide therefore must select.

In the preceding considerations we assumed that the contact regions on the four primitive tRNAs are sufficiently specific to guarantee formation of the postulated polypeptide in sufficiently high yield. In the following we shall consider the possibility that this specificity is lacking. The step considered would then require the presence of polypeptides effecting a specific linkage between the activated amino acids and the primitive tRNAs (amino acyl synthetases).

At this particular stage in the model there may be many polypeptide-synthesizing entities within a common envelope. It will be assumed that by chance five of these entities have just that base sequence on the mRNAs which would lead to the synthesis of the four amino acyl synthetases and of the replication enzyme if the four synthetases were present to serve as starters. The difficulty is that these synthetases are not present. It can be easily seen, though, that in this type of system they must gradually be formed in an autocatalytic process. Then the system can select.

The following argument demonstrates that such a system develops with sufficient probability:

A polypeptide acting as synthetase must have a specific recognition site for the amino acid and another one for the tRNA. If it is assumed that for each recognition site five digits have to be occupied in a specific way in order to attain sufficient specificity, then the probability of being produced by one entity is $(1/4)^{10} \approx 10^{-6}$.

According to Appendix 2 it may be assumed that there are, for example, 100 aggregates consisting of 100 RNA molecules in a compartment of 10^{-13} cm^3. The probability of finding one that acts as synthetase among these 100 aggregates is then $100 \times 10^{-6} = 10^{-4}$. The probability of also finding aggregates producing the above mentioned replicase and four different synthetases in one compartment, is then $(10^{-4})^5 = 10^{-20}$. It can thus be assumed that among 10^{20} systems of this kind there is one having this particular property and therefore selects. A population of this size does not seem unrealistic. The volume of 10^{20} compartments of 10^{-13} cm^3 is $10^{-13} \times 10^{20}$ cm^3 = 10 m^3. In a smaller population it would take proportionately longer for such a system to be formed at random.

25. Appendix 4: Interference by Complementary RNA Strands; DNA Evolves

In accordance with Appendix 2, RNA molecules and their complementary strands form tertiary structures, and the question arises whether disturbances are produced by faulty incorporation of complementary molecules into an aggregate. It can be assumed that the molecules in organized aggregates are mainly linked together by complementary base pairing, and that complementary strains are therefore not incorporated but instead form aggregates among themselves. If polypeptide synthesis takes place on an aggregate, the complementary aggregate cannot at the same time serve as template for the matching of the amino acids.

In Section 19 the possibility was considered that production of the enzymes E_1 and E_2 would avoid the formation of useless complementary strands. At that point the further model steps were only hinted at and will now be examined in more detail.

The enzyme for RNA replication becomes superfluous once E_1 and E_2 are formed. The respective section on the primitive mRNA strand degenerates because replication errors in this section are no longer damaging. As soon as this section randomly gives rise to a protein with favorable properties this strain selects, and the properties of the protein are improved by further selection steps: An RNA section that has become superfluous will therefore only degenerate for a short period of time and will invariably be revived again by modification. Modification of an RNA section that has already been instructed will take place much faster than completely fresh instruction of a section with random sequence.

We shall now assume the formation of a protein L which joins up the open-chain RNAs to give a single strand. The polymerization of DNA on this strand as template is catalyzed by enzyme E_1.

At the beginning of the multiplication phase L links all the RNAs together, and the DNA strand thus formed contains the information for the entire individual. Protein L will be linked more tightly to the newly formed DNA strand than to the tail ends of the RNA chains. It then serves as a block for further polymerization of RNA, and all the individual RNA molecules can be produced on the one DNA strand. The merging of the entire information of the individual within the DNA is a selection advantage. Perturbations occurring through the loss of one

or the other messenger RNA from the network of the organized systems are avoided, and traffic problems during construction are alleviated.

We can now assume the formation of a DNA-dependent DNA-polymerase. DNA replication now appears as additional factor in reproduction: the enhanced reproduction effect represents a selection advantage. After each replication the molecules of protein L occupy those sites on the DNA strand where synthesis of an RNA molecule is initiated. They are able to find these sites on account of their recognition region, which enables them to differentiate between complementary DNA strands.

The new reproduction principle replaces the preceding one: enzyme E_1 has become superfluous and degenerates. Apart from DNA, each daughter individual must now be provided by the parent with protein E_2 (for RNA formation on the DNA template) and protein L (for adequate stopping of further polymerization of RNA molecules on the DNA).

26. Appendix 5: Estimate of Time Required for Instruction of 10^3 Proteins (Information Content of a Bacterium)

Regarding Figure 20 it was assumed that each replication error occurring in the DNA section for fully instructed proteins is lethal. This assumption admittedly simplifies matters but has little effect on the results: many errors are disadvantageous but not deleterious. The erroneous copies thus do not disappear immediately but only after a few generations, which clearly has the same overall effect.

Many errors are ineffective because some of the amino acids of a protein are unimportant for its function (substitution of one amino acid by another makes practically no difference). Also, the degeneracy of the genetic code permits exchange of some bases for others without consequences. Errors of this type are taken into consideration by not counting the corresponding bases when determining N_{total} (the fraction of such bases in the total DNA will be considered in Appendix 6).

Errors in the instructed section are ineffective in further evolution as long as their number is small. This is the case, if the critical length of the DNA is not exceeded ($N_{total} < 1/W$), which will be assumed to hold at this point.

Replication errors at the end of the DNA strand, which carries the information for the last protein, are no disadvantage because this protein does not yet have a function. We may therefore assume that a population of individuals is formed whose base sequence at the end of the strand has a random distribution while the base sequence of the remaining strand is practically the same in all individuals.

Noticeable selection advantages will appear in the protein to be instructed as soon as at least v positions are occupied by certain amino acids (one can imagine, for example, that these amino acids may be important for an active site). Then 3v codon digits have to be placed correctly by chance (degeneracy of the code is neglected for simplicity although it could easily be considered; in the extreme case of complete degeneracy of the third digit in the triplet, 2v would have to be put in the place of 3v). The probability of finding a specific base in 3v digits is $(1/4)^{3v}$, because a choice between 4 bases is possible. Thus, among $Z = 4^{3v}$ individuals *one* mutant of this type appears.

For a multiplication factor r,

$$n = \log Z / \log r$$

follows from the equation in Fig. 9. It is assumed that a replication system with optimal error probability W has already been formed. Therefore $n = 1/P = 1/(W \times N)$, where N is the number of bases coding for the protein at the end of the strand; thus

$$W = 1/(N \times n) = (1/N)(\log r/\log Z).$$

It is difficult to estimate the value for r which has adapted the system to an optimal value of W. For $v = 5$, for example, one may assume $r = 1.01$, which, for a protein with five determined amino acids, means a 1% increase in the chance of survival.

In favorable instances higher r values may be obtained with five determined amino acids. The optimal value of W will adjust itself in such a way that even minor improvements of adaptation of the protein to its function will induce selection of this strain. In many positions of the protein, however, the nature of the amino acid will be of such little importance that, even upon the best choice of bases, an r value will result in the DNA which is below 1.01. A selective adjustment is then no longer possible; nor would it be worthwhile. In other words, these areas do not have to be considered in counting the digits of the DNA which are essential for coding.

The value $r = 1.01$ for $v = 5$ follows from the following estimate: it can be assumed that the selection advantages of an additional, fully instructed protein in a simple or complicated organism will become immediately apparent, *i.e.* each additional protein will represent a substantial improvement, increasing the chances of survival for example by 20% ($r = 1.2$). The value of r must increase considerably with the number v of digits occupied by advantageous amino acids. It therefore seems reasonable to assume that the value for r increases exponentially with v:

$$r = e^{v/a}$$

and for $v = 300$ (number of amino acids in a larger protein) comes to the value of $r = 1.2$. It follows that $a = 500$ and for $v = 5$ r amounts to a value of 1.01. With these values for r and v and with $N = 10^3$ (protein of about 300 amino acids), and using the relationship given, we arrive at: $Z = 4^{3\times5} \approx 10^9$; $n = 10^3$ and $W = 10^6$

The instruction of an entire protein is an optimization process, during which the new protein is incorporated increasingly well into the functional network of the others. One can assume that this process takes about

$$k = N/(3 \times v \times W)$$

generations. [This equation is derived by using the following simplification: in $N/3\nu$ consecutive steps, ν amino acids are instructed at a time, and after each step the statistical distribution of the uninstructed amino acids must be allowed to establish itself. (Statistical distribution is reached after $1/W$ generations, *i.e.* after as many generations as are necessary for an average of one replication error to occur at each codon.)]

On the whole the number of selection steps is smaller than $N/3$, because not all N bases are used for coding. $1/W$ is too high an estimate for the number of generations it takes for the next selection step to occur: for each selection step there are many ways of determining ν amino acids, and the first possibility realized at random must occur much earlier than after $1/W$ generations for statistical reasons. On the other hand, sufficient adaptation of the new protein to its functions is attained only after a fairly large number of optimizing steps. These two effects should approximately counterbalance each other.

Minor optimization processes of the instructed proteins will, of course, always be taking place. As already mentioned, almost all errors occurring in the DNA section for these proteins are either ineffective or deleterious. However, useful errors will occasionally occur which then lead to selection of a particular strain.

The DNA strand of the individual concerned is considered to grow by attachment of an additional small element of DNA material so that another protein is produced. If the strand grows too early (before the protein coded for at the end of the original strand is fully incorporated into the functional network) selection disadvantages result; *i.e.* the system cannot afford to have several proteins without specified function because, in general, each useful error in the DNA section of one protein becomes ineffective if disadvantageous errors occur in the section for another protein. On the other hand, a system whose DNA strand grows after the protein resulting from the end of the strand has just been incorporated into the functional network of the other proteins will select, even if the additional protein has only a minor advantage.

It may therefore be assumed that according to this mechanism the systems we considered will grow by $N = 1000$ bases after $k = N/(3\nu W) = 10^8$ generations. It may then be asked how many generations K are necessary for the instruction of $B = 10^3$ proteins (that is about the number of different proteins in a bacterium). The answer is $K = Bk = BN/(3\nu W) = 10^3 \times 10^8 = 10^{11}$

If we take a time requirement of 20 min per generation (doubling time of a bacterium under optimal conditions, which are not fulfilled in its natural surroundings), we arrive at 10^7 years for 10^{11} generations. If we use one day per generation (assuming that the generation time is determined by the day-night cycle during the decisive stages of evolution) the time required is 10^8 years. Thus, within 10^8 years the evolution of a system as complex as a bacterium could have taken place starting from a more simple system having a fully developed genetic apparatus.

The arbitrary value $r - 1 = 0.01$ is uncertain, but according to the estimates given above it cannot be wrong by orders of magnitude. The number K of generations is not very strongly dependent on r:

$$K = (BN^2/3\nu)(\log Z/\log r)$$

and since $Z = 4^{3\nu}$

$$K = BN^2(\log 4/\log r)$$

With $N = 10^3$ and $B = 10^3$ we obtain:

$$K = 10^{10} \quad \text{for} \quad r = 1.1$$
$$K = 10^{11} \quad \text{for} \quad r = 1.01$$
$$K = 10^{12} \quad \text{for} \quad r = 1.001 .$$

The larger the population, the more favorable the mutants occurring with sufficient probability, and the faster the evolution will advance. In a population of $Z = 10^{24}$ (a very large population) $\nu = 11$; if $Z = 10^5$ (a very small population) $\nu = 3$. Since $\log r$ is proportional to ν, K is inversely proportional to ν. If $Z = 10^{24}$ is reduced to $Z = 10^5$, K changes by a factor of only 3/11. An increase in population thus does not reduce the time requirement for evolution decisively.

These considerations were based on the assumption that instruction of all the proteins of an individual must occur one by one. We did not take into account the possibility that information may accumulate in different populations simultaneously, and that these systems evolving parallel to one another may interact and fuse to give an organism containing the information of both. This possibility could reduce the time required for the instruction of proteins considerably. It is highly probable, however, that this type of mechanism, which was certainly important during later phases of evolution (Appendix 6—8), did not play an important role in the instruction of the first 10^3 proteins. This phase saw the evolution of the main biochemical processes necessary for development of the genetic apparatus and the safe delivery of its building blocks. These processes make up such a closely-knit functional network that it seems safe to assume that evolution could only have occurred by stepwise incorporation of single functional elements.

27. Appendix 6: Maximum Information Capacity of Simple Organisms, and Error Frequency During Their Replication

a) Total Number of Base Pairs in DNA Double Strand and Proportion of Instructed Base Pairs

According to Appendix 5 the total number of base pairs of a DNA double helix is larger than the number of instructed base pairs (N_{total}). The proportion of non-instructed pairs depends on (i) what proportion of amino acids can be replaced by others without impeding protein function and (ii) how much of the DNA strand is used for protein biosynthesis. The number of amino acids that may be changed without affecting its function differs considerably from one protein to another. In hemoglobin, whose molecular function is known best[25, 26], 10% of the amino acids can be exchanged for others without producing any significant interference. In histones this proportion is smaller than 0.1%, in cytochrome 3%, in myoglobin 10%, but in fibrinopep-

tides it is almost 100%[27]. The fraction of DNA used for protein biosynthesis in bacteria is probably very large. Thus we may assume that N_{total} represents a considerable portion of the total amount of DNA, which in various bacteria lies between 3×10^6 and 6×10^6 bases[28]. The theoretical result of N_{total} being of the order of magnitude of 10^6 is therefore supported by experimental findings.

b) Frequency of Errors During Replication in Bacteria

According to the frequency of neutral mutations in *E. coli*, the probability of replication errors per base pair is found to be $W = 10^{-8}$[29]. This value is about two orders of magnitude smaller than that in the model of Appendix 5, even though according to Section 27a the value of N_{total} is in agreement with the model. This discrepancy is probably the result of the phenomenon of conjugation in *E. coli*: two bacteria happen to come into contact with each other and exchange genetic material[30]. Thus one individual receives advantageous genetic material from the other. After this conjugation, the bacteria undergo repeated cell division until conjugation again takes place at the next random contact. During the time between two conjugations the progeny of the partner carrying the more favorable genetic material will displace all other strains. This pseudosexual process of conjugation provides for recombination of genes and subsequently for faster accumulation of favorable genetic material by selection. The strain with the best combination of genes probably has a selection advantage which is so great that it only takes a few generations to select. If we assume that $Z = 10^6$ individuals interact with each other, and if the individual with the best gene combination is attributed a survival probability which on average is increased by 20% ($r = 1.2$), then according to Figure 9 the number of generations after which the strain is selected is $n = 10^2$. A maximum of *one* error is allowed in the DNA strand after 10^2 consecutive divisions if the condition for selection (Fig. 11) is to be satisfied, *i.e.*

$$N_{total} \times W \times n \leq 1$$

must hold. Thus, W may not exceed the value

$$W = 1/(10^6 \times 10^2) = 10^{-8}$$

and at about this value we expect the highest rate of evolution. Individuals with this value of W will select. The experimental value of $W \approx 10^{-8}$ may thus be easily understood.

According to the model, the instruction of further proteins has reached a limit at $N_{total} \approx 10^6$. Further evolution is restricted to a rearrangement of the informational DNA already present. At this point any mechanism leading to a faster selection of favorable strains will displace the others. The conjugation mechanism mentioned offers a new possibility for collection and combination of favorable mutants. It needs an improved replication device, because it is subject to the condition $N_{total} \times W \times n \leq 1$ (see Appendix 7, a). The *E. coli* organism thus represents a system that is very different from the systems in Figure 20, and may have developed from these by multiple step evolution.

28. Appendix 7: Considerations of the Limits of Genetic Information Capacity

a) How to Overcome the Limit Reached at $N_{total} \approx 10^6$ and $W \approx 10^{-6}$ by Exchange of Genetic Material

According to Figure 20b a limit of genetic information capacity is reached at $N_{total} \approx 10^6$. If W were smaller than 10^{-6}, N_{total} could become larger and more proteins could be instructed. However, reduction of W would not lead to immediate advantages, and only immediate advantages lead to selection. An individual whose replication device has been changed by random errors in such a way that W has only half the value of that of other individuals will be considered. Even though this strain could now instruct twice as many proteins, it has selection disadvantages because W is not optimized as it is in other strains. It therefore disappears long before it has the chance to instruct more proteins in order to gain selection advantages.

Reduction of W could be an immediate advantage under the following conditions: One can imagine that by chance a strain develops which has the ability of exchanging genetic material by fusion of individuals. According to Appendix 6 this process in itself would not yet provide selection advantages. A strain which, on account of this exchange mechanism, has accumulated particularly favorable genetic material, could not select because too many reproduction errors would occur. For selection to take place, the condition $N_{total} \times W \times n \leq 1$ would have to be fulfilled.

As soon as this type of strand by chance acquires a reduced W so that the above condition is fulfilled a turning point is reached and the direction for selection is now clearly defined. Those systems must evolve whose mechanism for exchange of genetic material becomes increasingly precise. Also the mechanism guaranteeing a reduced value of W must become less prone to interference. It therefore seems easy to understand how pseudosexual processes as discussed in Appendix 6 could arise.

Exchange of genetic material at this point seems to be the only way in which systems with $N_{total} = 10^6$ and $W = 10^{-6}$ can escape from a divergent phase. This turning point is again brought about by a process which is highly unlikely for an individual but becomes necessary in a large population.

It may be that this turning point permits further development of the genetic apparatus leading all the way up to higher organisms by gradual reduction of W and respective increase of n as well as N_{total}. According to Appendix 8 in the highest organisms we have to expect $n \approx 10^3$ and $N_{total} \approx 4 \times 10^7$. These values would give $W = 1/(n \times N_{total}) = 2 \times 10^{-11}$, which is close to the value found.

However, increasing improvement of the genetic apparatus must reach a limit owing to the loss of information by thermal collisions. We have to establish when this limit is reached and how it could be overcome.

b) Loss of Information by Thermal Collisions

In the preceding considerations it was assumed that the information is fully maintained during the time t between consecutive replications. The probability W' of a base on the DNA strand exchanging during this time t was considered to be small as compared to W. During further evolution W can only be reduced until $W = W'$, *i.e.* $W \geq W'$ must hold. Further reduction of W without simultaneous reduction of W' offers no further selection advantages.

Exchange of a base during the time between two consecutive replications can be due to radiation or chemical effects. Here we only consider the inevitable exchange by thermal knocks. As a crude approximation, W' will be given as the probability of dissociation of a bond. It follows that

$$W' = f \times t \times e^{-\Delta E/kT}$$

where ΔE is the activation energy and f the frequency of thermal vibrations of the atoms forming the bond.

From the values $f = 10^{12}\ s^{-1}$, $T = 300°K$, and $t = 2$ hours (estimated time between two divisions of *E. coli* under natural conditions) with $\Delta E = 33$ kcal/mol it follows that $W' = 10^{-8}$. In a system of the complexity of an *E. coli* bacterium ($W + W' \approx 10^{-8}$) the activation energy must be greater than 33 kcal/mol in order for the condition $W' \leq W$ to be fulfilled. In a higher organism [$W + W' \approx 10^{-11}$; $t = 5$ days (Appendix 8)] it becomes $\Delta E \geq 40$kcal/mol, *i.e.* the activation energy must have a value that is only reached when the information (as in natural systems) is fixed by formation of a chemical bond, and if the information carriers are also highly protected by incorporation into a strictly ordered matrix. In this case the simple expression $W' = f \times t \times e^{-\Delta E/kT}$ no longer applies and has to be replaced by one which takes into account that for breakage of a bond a sufficiently large area of the matrix has to be "melted" (relatively high activation energy), but also that the reaction can proceed *via* many different directions, *i.e. via* many different activated states (high activation entropy; f is replaced by a higher value). But this does not basically change the reasoning.

Bacteria have developed mechanisms for repairing damage in cases which do not completely erase an element of information. In this way W and W' are reduced considerably, but again a limit is reached at a certain value of W'. It seems possible that this limit has been reached in higher organisms. The fact that $W + W'$ probably has almost the same value in all higher organisms would point in that direction. However, it is also even possible that this limit has already been reached in bacteria, since the value $\Delta E \geq 40$ kcal/mol calculated for higher organisms seems rather large.

After this limit has been reached, further evolution depends on a basic change in the system of transfer of genetic information. Consideration of this possibility might be interesting for a discussion of imaginable forms of evolution, independent of where the limit is.

c) Development of a System of Information Transfer Based on Multiple Reading

Systems will be considered in which W or W' cannot be reduced. The ability to transfer large amounts of information from one generation to the next in spite of this, logically requires the development of a system based on multiple storing of information. The possibility will now be considered that a system is formed which has both triple storing of information and a mechanism, by which the three double strands of DNA are constantly being repaired so that they always have the same sequence (Fig. 23). In addition, an enzyme system is postulated which constantly

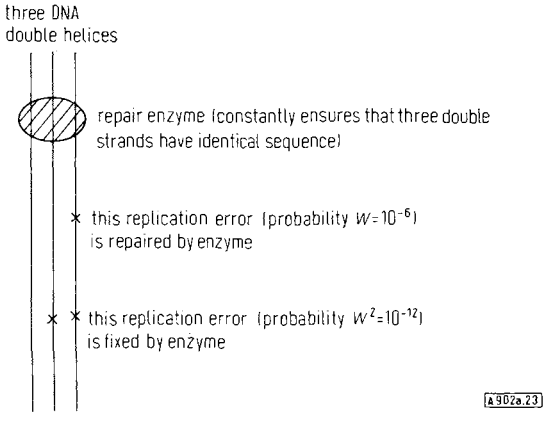

Fig. 23. The limit for genetic informational capacity set by thermal impacts or radiation damage is overcome. Triple coding and repair mechanism ensuring the same base sequence of the three double strands.

runs up and down the three double strands and checks whether the three respective base pairs agree. If they do not agree, the deviating base pair is replaced by the enzyme in such a way that the double strands always have completely identical sequences. For the enzyme to have an unequivocal function and with three different base pairs present, chance is supposed to decide which of the three base pairs remains and which are replaced in the other double strands. The enzyme corrects errors induced during replication by thermal knocks or radiation damage, and only retains them when the same error occurs on the same digit in two of the three double strands. The probability that the same error occurs on one digit in two of the three double strands during replication is $3 \times (W + W')^2$ (the factor 3 appears because the error can occur in strands 1 and 2, 1 and 3, or 2 and 3). Each base pair can be replaced by any of the others with the same probability. The probability that an error is retained under the conditions mentioned is thus $(7/9) \times 3 \times (W + W')^2 = (7/3) \times (W + W')^2$. If, according to Figure 20, the value 10^{-6} is assumed for $W + W'$, we then obtain $(7/3) \times (W + W')^2 \approx 10^{-12}$. The empirical value for the probability of replication errors in higher organisms is about 10^{-11} (see Appendix 8).

The circumstances necessary for this type of mechanism to evolve should be studied more closely. However useful a mechanism may seem, it will have no chance of being found by the selforganizing system if it does not offer an immediate advantage. The three-strand mechanism could

develop during a phase, in which exchange of genetic material takes place between systems with $W = 10^{-6}$ and $N_{total} = 10^6$, and therefore a considerable reduction of the probability of reproduction errors is necessary in order to reach the condition for selection. In a later stage this mechanism would hardly offer any selectional advantage. A lost opportunity will never return.

Biological evolution may possibly have missed this three-strand mechanism, but it does not seem out of place to imagine that bacteria were maneuvered into a dead end by reduction of W and W', and that the three-strand mechanism led to eukaryotes.

d) How to Overcome the Limits of Genetic Information Capacity

Apparently during evolution of eukaryotes the possibility of finding a mechanism working at a lower error rate than $W \approx 10^{-11}$ was missed. This is independent of the fact that one or the other possibility is realized in the genetic apparatus of these organisms. With $N_{total} \approx 10^7$, $n \approx 10^3$ a limit was reached which is determined by $nN_{total}\, W \leq 1$ (Appendix 6). Therefore a divergent phase (development of higher organisms) must have started.

Appearance of the human being meant that another turning point leading to a convergent phase had been reached: language writing, and information storage and retrieval technology represent an additional device for transfer of larger amounts of information from one generation to the next. Thus the evolution of functional networks demanding an information capacity exceeding that of the genetic apparatus became possible. Such a functional network may be seen in the technology of industrial products from which further functional networks, like space technology, evolve. From this viewpoint the evolution of the human is a fundamental biological event because the extent of the functional networks now feasible is no longer limited by the condition of Appendix 6.

Here again the initial missing of an opportunity (formation of a replication device working at an error rate below 10^{-11}) could have triggered the development of larger functional networks. It would be challenging to study the many imaginable courses of evolution more systematically.

One could ask, for example, what possibilities would exist for evolution if the prolonged action of ionizing radiation were to change the minimum value of $W + W'$ to 10^{-5}. In this case, the only way of keeping N_{total} above 10^5 would be multiple storage of information in connection with a repair mechanism. Organisms with $W + W' = 10^{-5}$ could hardly be sufficiently differentiated to be able to form such a mechanism, and evolution would come to an end at this level.

A similar limiting condition must exist for the turning point reached with man and computer: the existence of intelligent beings having a considerably lower degree of differentiation than given by $N_{total} = 4 \times 10^7$, $n = 10^3$ is hardly possible, *i.e.* the probability of replication errors per base pair in one cell generation may only be about 10^{-11} at the most. The intensity of radiation may thus not amount to much more than about 1 rad per cell generation, since 1 rad causes the exchange of 1 base pair in haploid cells with a probability of 10^{-11} [30a].

This also follows from the fact that in *Drosophila* one lethal mutation per gene locus is caused by a dose of 1 Krad with a probability of 10^{-5} [30b], meaning that the error probability per base pair per rad amounts to about $10^{-5} \times 10^{-3} \times 10^{-3} = 10^{-11}$. (It may be mentioned that 0.1 rad is considered to be the maximum radiation intensity permitted per week; that would be 0.1 rad per cell generation.)

29. Appendix 8: Frequency of Reproduction Errors and Genetic Information Capacity in Higher Organisms

a) Frequency of Replication Errors in Higher Organisms

From changes in the amino acid sequence of proteins within phylogenetic series, it was concluded for vertebrates that the probability of base exchange is only dependent on time. It is therefore independent of the time between successive generations of a biological species and amounts to 3×10^{-9} per year, irrespective of whether a quickly evolving organism (mammals) or a "living fossile" (carp) is studied[31]. In order to deduce the probability of replication errors we shall consider a chain of ancestors of cells in which each daughter cell emerges from the parent cell by division. The time between two consecutive cell divisions in this chain will be regarded as constant and of the order of five days. This assumption is realistic: the separation of a sperm from a spermatogonium occurs about once every five days[32]. Separation of an egg cell from its mother cell occurs at a much lower frequency. However, since the chain we are considering involves equal numbers of male and female organisms we can assume the average time per cell division after completion of embryonic development to be about 10 days. During embryonic development a cell division occurs about once every 10 hours[33], and an estimate shows, that the total number of consecutive cell divisions during embryonic development is similar to the number of cell divisions taking place from then on until puberty. Thus on the average a cell division occurs about once every five days (10^{-2} years). The probability of an error in a cell generation is therefore $3 \times 10^{-9} \times 10^{-2} = 3 \times 10^{-11}$. A similar probability is to be assumed in *Drosophila*, as we shall see below.

In *Drosophila* an average of 3×10^{-6} lethal mutations occurs per generation per locus[34]. The probability of base exchange is thus about $3 \times 10^{-6} \times 10^{-3} = 3 \times 10^{-9}$ because each locus corresponds to about 10^3 base pairs, whose alteration leads to lethal mutations. There are about 10^2 cell generations per generation[35], and thus the error probability of base exchange becomes $3 \times 10^{-9} \times 10^{-2} = 3 \times 10^{-11}$. The fact that this value is almost constant, suggests that the replication mechanism and the mechanisms for conservation of information have remained practically unchanged during the course of evolution of

higher organisms. The calculated error probability of replication is comparable with the probability resulting from the model in Figure 23 and Appendix 7.

b) Genetic Information Capacity of Higher Organisms and Chromosomal Structure

The total amount of DNA in a haploid cell of protozoa and algae contains at least 10^7 base pairs, but values 30 times higher than that have also been found (it is suspected that in such cases many copies of the same DNA strands are present)[36]. In mammals this number is about 4×10^9, in *Drosophila* it is 2×10^8. There is evidence that in higher organisms only a small fraction of the total DNA is used for instruction of the amino acid sequence of proteins and thus only this small portion contributes to N_{total}[34,37]. In *Drosophila* there are about 10000 gene loci[34] (therefore $N_{total}\approx10^4\times10^3=10^7$, *i.e.* about 5% of the total DNA). In humans *ca.* 40000 loci are assumed[34] ($N_{total}\approx4\times10^7$, *i.e.* about 1% of the total DNA). Although doubling of genes repeatedly took place during evolution[27,38], which increased the total content of DNA, N_{total} did not apparently increase correspondingly because most DNA sections were no longer used for protein biosynthesis. Such a small value of N_{total} is also required by theory (Appendix 6)[31] because no more than one error per generation (*i.e.* per cell generation) is allowed to occur in the fully instructed part of the DNA; with $W=3\times10^{-11}$ and $n=10^3$, N_{total} can be about $1/(n\times W)\approx3\times10^7$ at the most. On the other hand, if $N_{total}\approx3\times10^7$, n can be 10^3 at the most, or (taking 5 days per cell generation) the time requirement per generation is 10^4 days at the most (the value that has been reached in mammals).

After what we have said, the possibility of accumulation of genetic information to $N_{total}\approx10^7$ base pairs, which later never increased very much, does not seem unrealistic. X-ray and electron microscopic studies indicate that chromosomes contain several DNA double strands coiled around one another to form a strand of about 100 Å in diameter (superhelix)[39]. It might even be that there are three strands involved and the postulated "three-strand mechanism" thus cannot be excluded as a possibility.

I am grateful to Dr. Jutta Peters for translating the paper, discussions, and advice regarding the literature.

Computer Model of the Formation of Self-Organizing Systems

By Horst-Dieter Försterling, Hans Kuhn, and Karl-Heinz Tews[*]

A model of a simple self-organizing system is investigated. Mechanisms that are important to a molecular-biological understanding of evolution are studied with the aid of the model.

1. Introduction

The behavior of simple self-organizing systems[1] is simulated below by a computer model. A system possessing a genetic apparatus is considered, and it is assumed that the formation of proteins is possible on the nucleic acid template. The course of the further evolution of such a system is investigated.

A protein formed by the system can react on the system in three ways. It can affect the average time τ_R that elapses between two successive replications, the average time τ_L after which the system is destroyed, or the probability W of the occurrence of an error in the replication (Fig. 1). The protein may either directly favor the replication process or protein synthesis (decrease in τ_R and W) or protect the system against destruction (increase in τ_L). However, τ_R, W, and τ_L can also be influenced indirectly. For example, the proteins formed may encapsulate the system and so

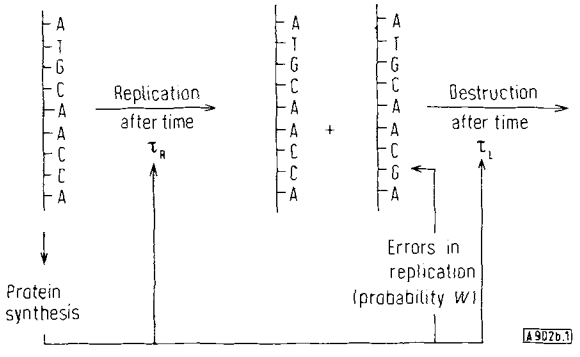

Fig. 1. Modification of τ_R, τ_L, and W by proteins. A = adenine, T = thymine, G = guanine, C = cytosine.

prevent important reactants from diffusing away, protect the system against external attacks, or facilitate the synthesis of a component that is important for the multiplication of the system. If such a facilitation is caused by a protein that has resulted over the generations from reading errors in the replication of the DNA, the system, once formed, has a selection advantage over systems with other base sequences. In the course of many generations, the accumulation of reading errors gradually leads to a change in the base sequences of the DNA strands and in the amino acid sequences of the corresponding proteins, and selection leads to forms with proteins whose amino acid sequence (real sequence) tends toward an optimum (ideal sequence).

If the probability W of an error occurring in the elementary step of the replication process is very low, it takes a very long time for a mutation to appear and for the system to approach the ideal sequence by selection of advantageous mutants. If W is relatively large, mutations occur very often, and the ideal sequence or a sequence very close to it may be very rapidly reached by chance; however, errors then occur so frequently in the course of further replication that the advantageous descendants cannot gain precedence over the numerous others in spite of their selection advantages. No convergence toward the ideal sequence therefore occurs. For the fastest possible selection, therefore, W must have an optimum value.

2. Computer Calculation

To make the mechanism of the selection of a protein easier to grasp, we first assume that W and τ_R are constant and only τ_L is influenced by the amino acid sequence. We shall consider a simple model with a DNA strand of only 9 bases, *i.e.* with the information for a protein consisting of three amino acids. Of the $4^9 = 6.3 \times 10^7$ possibilities of altering the four possible bases, one possibility, which we arbitrarily specify, will be assumed to lead to a protein that provides optimum protection of the system, *i.e.* that leads to the maximum τ_L (ideal sequence). The less the sequence actually present (real sequence) differs from the ideal sequence, the greater will τ_L be. We arbitrarily write:

$$\tau_L \sim r^{-F} \tag{1}$$

where F is the number of defects, *i.e.* of disagreements between the real sequence and the ideal sequence; r is the factor by which the chance of survival of an individual is increased by an advantageous mutation. We arbitrarily take $r = 1.5$. The greater F, the smaller is τ_L, and hence the earlier the individual must die.

We assume that the evolution begins with 50 identical DNA strands having a chance starting sequence; we allow the 50 individuals to replicate (error frequency $W = 1\%$, error positions randomly fixed) and then remove 50 individuals. Thus the total number of individuals remains constant. The removal is carried out randomly, but in such a way that relatively more individuals with a high τ_L survive than

Max-Planck-Institut für Biophysikalische Chemie
34 Göttingen-Nikolausberg, Postfach 968 (Germany)

with a low τ_L. This is followed by renewed replication and removal, and so on. The chance introduction of defects in the replication step and the chance removal of individuals are carried out in the computer by control of the further course by a random number before each step.

The sequences of the initially formed DNA strands will still be very different from the ideal sequence, since it is improbable for the correct possibility out of 4^9 to occur by chance. If an error in replication leads to better agreement with the ideal sequence, the mutated form will live longer and therefore replicate more often and thus multiply preferentially; if the opposite is the case, the error will lead to the death of the species. In this way the number of individuals that differ only slightly or not at all from the ideal sequence will steadily increase.

The ideal sequence is arbitrarily fixed. The chance sequence of the starting molecules is fixed by throw of dice. To take into account an important aspect of evolution, several ideal sequences are given, *i.e.* there is not just one sequence that corresponds to a particularly advantageous protein, but very many. Depending on the initial chance sequence, the evolving forms tend toward one ideal sequence or another. This shows that the initial random incidents are decisive to the course of evolution.

The result of such a computer calculation[2] is shown in Table 1 for the ideal sequences (A = adenine, C = cytosine, G = guanine, T = thymine)

G C A T T C T A A
A T G C A G G G T
A G T T C C G A G
T G G G A C C A C

and the initial chance sequence

C G T A T C G T C

Table 1. Selective matching of a system of 50 DNA strands (initial sequence C G T A T C G T C) to a protein with the ideal sequence A G T T C C G A G; frequency of errors in the replication $W = 1\%$ (*i.e.* out of the 450 bases of the 50 individuals, 4 to 5 are wrongly copied in the replication step); at the beginning (generation 0) all the DNA strands agree with the ideal sequence in 4 places ($F = 5$).

Generation	Number of examples with 0 sites of error	1	2	3	4	5	6	7	8	9
0						50				
10					4	42	4			
20				14	23	12	1			
30			5	45						
40		3	34	13						
50		14	36							
60		23	26	1						
70	1	33	15	1						
80	14	31	5							
90	41	8	1							
100	46	4								
110	47	3								
120	41	9								
130	49	1								

The computer heads for the third ideal sequence, for which F has the smallest value ($F = 5$).

Table 2 shows the result for the same ideal sequences when the initial chance sequence is

G C T A T G A A C

In this case the tendency is toward the first ideal sequence ($F = 5$).

Table 2. Selective matching of a system of 50 DNA strands (initial sequence G C T A T G A A C) to a protein with the ideal sequence G C A T T C T A A. Error frequency $W = 1\%$ as in Table 1.

Generation	Number of examples with 0 sites of error	1	2	3	4	5	6	7	8	9
0						50				
10				7	8	35				
20				40	10					
30			2	48						
40			27	23						
50			43	7						
60		2	45	3						
70		3	42	5						
80	4	22	21	3						
90	17	27	6							
100	34	15	1							
110	38	10	2							
120	48	2								
130	46	4								

It can be seen from the two tables how the matching to the ideal sequence in question gradually occurs in the course of 100 to 120 generations.

If the calculation for the first case (Table 1) is repeated with different values of W ($W = 0.25\%$ or $W = 4\%$), the results shown in Tables 3 and 4 are obtained. Whereas

Table 3. Selective matching of a system of 50 DNA strands as in Table 1, but with $W = 0.25\%$.

Generation	Number of examples with 0 sites of error	1	2	3	4	5	6	7	8	9
0						50				
50					47	3				
100				49	1					
150			49	1						
200		2	48							
250			46	4						
300		43	7							
350		48	2							
400		50								
450	44	6								
500	49	1								
550	50									

according to Table 1, 92% of the 50 DNA strands have the ideal sequence after 100 generations ($W = 1\%$), the matching is very much poorer with $W = 4\%$ (only 66% of the individuals have the ideal sequence after 100 generations, though the evolution is initially much faster than with $W = 1\%$); with $W = 0.25\%$ the evolution is very slow (not one individual has the ideal sequence after 100 generations), but practically 100% are ideally matched after a sufficiently long time (500 generations).

Table 4. Selective matching of a system of 50 DNA strands as in Table 1, but with $W = 4\%$.

Generation	Number of examples with sites of error								
	0	1	2	3	4	5	6	7	8	9
0						50				
10				11	29	6	3	1		
20		1	12	33	4					
30		6	34	9	1					
40	4	10	23	13

60	18	19	12	1						
70	15	25	10							
80	29	17	3	1						
90	30	13	7							
100	33	15	1	1						
110	28	20	2							
120	30	16	3	1						
130	28	16	5	1						

3. Estimation of the Optimum Mutation Frequency

The optimum value of W is estimated below for the model considered in Section 2.

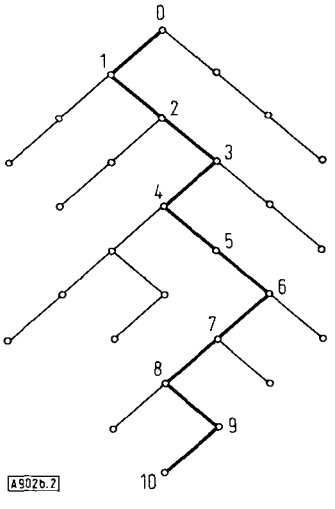

Fig. 2. Genealogical chain with $n = 10$ generations (continuous thick line). Replication occurs at each branching point (further branches have been omitted for clarity).

Let us consider genealogical chains of n generations (Fig. 2); let n be so large that there is an average of 1 replication error per chain. If N is the number of bases in the DNA ($N = 9$ in our model), then $N \times n \times W = 1$, *i.e.*

$$W = 1/(N \times n) \tag{2}$$

We shall first calculate n and start from the assumption that there are a individuals with identical base sequences at the start of the multiplication process ($a = 50$ in our model). The number of replication errors that occur in the course of n generations is therefore a; for F disagreements, the probability that one of these errors is advantageous is $F/(3N)$ [the replacement of one base by another leads to an advantageous mutation only if one of the bases that do not agree is changed (probability F/N) and if at the same time the correct base is inserted (probability 1/3)]. The number a' of advantageous errors is therefore

$$a' = aF/(3N) \tag{3}$$

In our model ($F = 5$, $N = 9$, $a = 50$), therefore

$$a' = 5 \times a/(3 \times 9) = 0.19a$$

i.e. only about 20% of all errors lead to advantageous mutants. We assume for simplicity that each of the a' errors that occur *on average* in the course of n generations occurs *precisely* after n generations. The a' advantageous mutants that are then suddenly present have an r-fold probability of survival over the other individuals ($r = 1.5$ in our model), so that they multiply more rapidly than any of the others. After n generations, therefore, there are a' individuals of the advantageous mutant that have been formed spontaneously, or out of

$$Z = a/a' = 3N/F \tag{4}$$

individuals in the population there is exactly one individual of the advantageous mutant. The ratio of the number of individuals of the advantageous mutant (m_v) to the number of other individuals (m) is therefore $m_v/m = a'/(a-a') = 1/(Z-1)$. After $n+1$ generations, the ratio m_v/m is greater by approximately the factor r (since each advantageous mutant has approximately an r-fold probability of survival over an unmutated individual), after $n+2$ generations it is greater by the factor r^2, and after $2n-1$ generations it is greater by the factor r^{n-1} (replication errors occur for the second time after exactly $2n$ generations). Thus the ratio m_v/m after $2n-1$ generations is

$$m_v/m = r^{n-1}/(Z-1)\,. \tag{5}$$

Before replication errors occur for the second time, the advantageous mutants must have practically entirely displaced all other individuals; we shall assume to have ten times as many individuals of the mutant than of the original form, *i.e.*

$$m_v/m = 10\,. \tag{6}$$

According to equations (5) and (6), $r^{n-1} = 10(Z-1)$ or

$$n = 1 + [1 + \log(Z-1)]/\log r\,. \tag{7}$$

According to equation (4), the selection becomes slower with decreasing F, and is slowest for $F = 1$. At this point, according to equation (4), $Z = 3N$; in the model investigated ($r = 1.5$, $N = 9$) this gives $n = 15$, and hence according to equation (2), $W = 0.8\%$.

In agreement with the computer result, the optimum value of W is about 1%; an advantageous mutant should have been formed after 15 generations, and should have been selected after 15 further generations. Since the initial chance sequence in the example considered differs in 5 places from the nearest ideal sequence, the selective matching should have occurred after approximately $5 \times 2 \times 15 = 150$ generations. This was in fact found (Tables 1 and 2).

For large values of Z and n, equation (7) changes into the simpler relation $n = \log Z/\log r$[11].

Note: In the above calculation the ratio m_v/m was assumed to increase in each generation by a factor r. This holds for $r-1 \ll 1$ and is only approximately true for larger values of r: In n generations we have a' individuals of the preferential mutant and $a-a'$ individuals of the normal form, and after replication $2a'$ and $2(a-a')$ individuals respectively. A total of a individuals must decay for the original number to be regained. Thus x and y being the

number of decays of individuals of the normal form and the mutant respectively, $x+y=a$. Since the probability of decay of an individual of the normal form is r times that for the mutant, $x/y=[(a-a')/a']\cdot r$. With these equations the relation

$$(m_v/m)_{n+1} = (m_v/m)_n \cdot f$$
$$f = [2a' + 2(a-a')r - a]/[2a' + 2(a-a')r - ar]$$

are obtained. In the case of $r-1 \ll 1$, we find $f=r$; in the case of the computer calculation ($r=1.5$; $a'=0.19a$) the value $f=1.38$ is obtained which is somewhat different from r.

The numerical calculations were carried out on the TR4 computer of the Zentrale Rechenanlage in Marburg. We are grateful to G. Lauer and T. Lichtenberg for their assistance.

COMMUNICATIONS

New Dihydroxyboryl-Substituted Polymers for Column-Chromatographic Separation of Ribonucleoside-Deoxyribonucleoside Mixtures[**]

By *Herbert Schott*[*]

Complex formation by boric acid with *cis*-glycol groups has been used for separation of mixtures of ribo- and deoxyribonucleic acid components by paper chromatography or electrophoresis[1]. This principle was later applied also to column chromatographic separation of these mixtures on boric acid carriers on an analytical scale[2].

However, for preparative separations dihydroxyboryl-substituted polymers ("boric acid gels"), which have been synthesized from polymerizable boric acid derivatives, seem more suitable than boric acid carriers since, unlike boric acid carriers, boric acid gels can in principle be synthesized with exclusion limits as high as desired and with notably larger contents of boric ester groups.

(1)

The synthesis of boric acid gels[3] has hitherto been demanding and it was not clear whether these gels are suitable for separation of nucleic acid components. We have worked out a simple method of preparing boric acid gels and have studied their efficiency for separation of ribonucleoside-deoxyribonucleoside mixtures. *m*-Aminobenzeneboric acid is treated with methacryloyl chloride to give a polymerizable boric acid derivative *(1)*. This monomer unit undergoes radical polymerization with tetramethylene dimethacrylate to afford a cross-linked boric acid gel. By varying the concentrations of the monomer and cross-linking agent the exclusion of the boric acid gels and the introduction of boric acid groups and thus the separatory capacity can be widely varied.

A maximum of *ca.* 200 mg of boric acid gel is required for separation of *ca.* 1 mg of a ribonucleoside-deoxyribonucleoside mixture. The elution profile (Fig. 1) of this separation

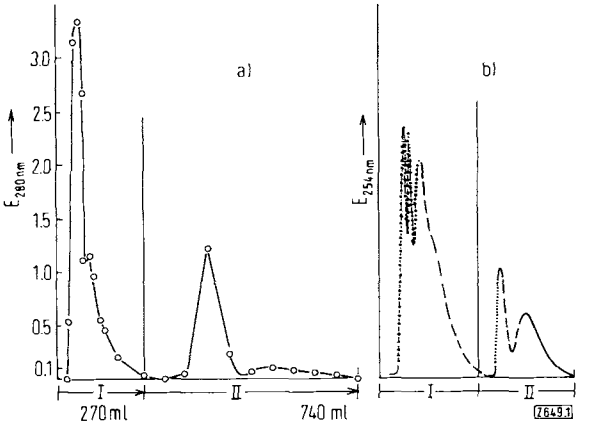

Fig. 1. Column chromatographic separation of a mixture of uridine, cytidine, guanosine, adenosine, and the analogous deoxyribonucleosides on a boric acid gel at 4 °C. Fraction I: 0.1% aqueous ammonia, pH 10.5; fraction II: H_2O, pH = 5.8. a) Elution profile measured at 280 nm; b) extinction of the fractions obtained, at 254 nm. (For details see text.)

shows not only that quantitative separation of ribonucleosides from deoxyribonucleosides occurs but also that both groups are presumably separated into purine and pyrimidine components.

Column chromatographic separations of ribonucleosides from deoxyribonucleosides has hitherto been carried out only in non-volatile salt buffers. With the boric acid gels described here separations are possible even in 0.1% aqueous ammonia; thus desalination of the nucleosides isolated becomes unnecessary, which makes preparative separation considerably easier.

Experimental:

Synthesis of the boric acid derivative *(1)*: Commercial bis(*m*-dihydroxyborylanilinium) sulfate (*m*-aminobenzeneboric acid hemisulfate) (1.5 g) is dissolved in water (20 ml), then neutralized with NaOH, and the solution is evaporated to dryness in a vacuum. The residue is dissolved in dioxane (50 ml), and undissolved Na_2SO_4 is filtered off. The clear solution is evaporated to *ca.* 5 ml in a vacuum, treated with anhydrous dioxane (40 ml) and anhydrous triethylamine (5 ml), and warmed briefly at 50 °C until an almost clear solution is formed. Methacryloyl chloride (5 ml) is added in one batch to the warm solution, which is then cooled in ice. Triethylammonium chloride soon separates and after 12 hours' storage at room temperature is filtered off. The clear yellow solution is concentrated in a vacuum to 3—5 ml and the resulting syrup is dissolved in dioxane/ethanol (1:1; 15 ml).

Polymerization: Tetramethylene dimethacrylate (3 ml) and α,α'-azoisobutyronitrile (0.5 g) are added to the preceding solution, which is then gently warmed and sealed in a glass ampoule. After 24 h at 55 °C a solid yellow block has been formed; this is ground, sieved, and then freed from portions that escaped cross-linking by extraction in a Kutscher-Steudel apparatus with commercial ethanol. After drying, there is thus obtained a pale yellow, hard polymer powder (5 g, 10 ml). Before being filled into the column the whole of the polymer powder is allowed to swell in 5% aqueous acetone for *ca.* 5 h; this affords 30 ml of gel suspension.

Chromatography: The separatory efficiency of the column was first tested with U/T, A/dA, and C/dC mixtures and then with the following mixture of all four ribonucleosides and deoxyribonucleosides: (a) deoxyribonucleosides: thymidine 60 mg, deoxyadenosine 44 mg, deoxyguanosine 25 mg, and deoxycytidine 63 mg, dissolved in 15 ml of water: $E_{280}=282$. (b) Ribonucleosides: uridine 60 mg, adenosine 41 mg, guanosine 16 mg, and cytidine 52 mg, dissolved in 15 ml of H_2O; $E_{280}=248$. 0.5 ml of the deoxyribonucleoside solution and 1.5 ml of the ribonucleoside solution were placed on a column (10/2 cm) filled with boric acid gel and were eluted at a rate of 68 ml/h first with 270 ml of 0.1% aqueous ammonia (pH = 10.5) and then with 900 ml of water (pH = 5.8). The elution profile measured at 280 nm is reproduced in Fig. 1a. As control, Fig. 1b shows the extinction of the individual fractions of the same run recorded automatically at 254 nm. Aliquot parts of the united fractions (I and II) were characterized by paper chromatography in the borate system[1]; fraction I contained only deoxyribonucleosides (142 OD_{280}-units) while the ribonucleosides (341 OD_{280}-units) were contained in fraction II. Elution of the ribonucleosides was greatly accelerated by lowering of the pH (*e.g.* H_2O, pH 5.8), since at lower pH the boric acid complex becomes unstable.

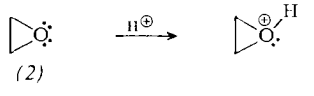
Effect of Protonation on Aziridine and Oxirane Bond Strengths[1]



By *Wolf-Dieter Stohrer* and *Roald Hoffmann*[*]

Cyclopropane bond strengths, indeed the very equilibrium structure of cyclopropanes, should be responsive to π-electron donor and acceptor substituents[2, 3]. We have now found that the C—C bonds in oxiranes and aziridines are strengthened upon protonation or other coordination of the heteroatom lone pair.

Thus in aziridine *(1)* the overlap population of the C—C bond increases on protonation from 0.648 to 0.666 in an extended Hückel calculation[4], and from 0.262 to 0.291 in an *ab initio* computation[5]. In oxirane *(2)* an effect of similar magnitude is found. The effect can be rationalized in terms of perturbation theory[6].

(1)

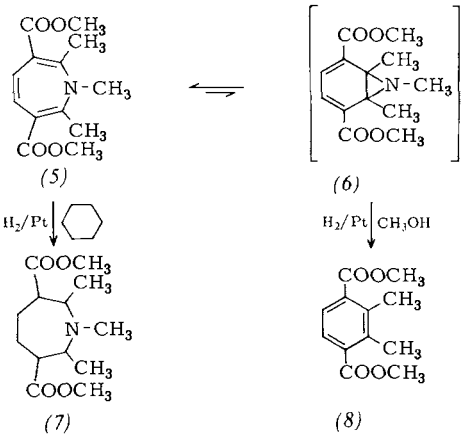
(2)

The *structural* evidence for the protonation effect is ambiguous. Several crystal structures of aziridinium salts[7] show no consistent shortening of the C—C bond. Compared with aziridine[8] itself, an aziridine-borane[9] and a trimer of dimethylaluminum aziridide[10] show barely significant C—C bond shortening.

The *thermodynamic* and *kinetic* evidence for a protonation effect is fragmentary, but, we believe, in accord with our calculation.

1. In the equilibrium *(3a)*⇌*(4a)* the bicyclic form is favored in more polar solvents[11-13].

(3) *(4)*



(a), X = O
(b), X = NR

The significance of this equilibrium in the first stages of the enzymatic formation of phenols[14], as well as in the general acid-catalyzed aromatization of oxepins[11, 13, 15a] should be noted.

2. Only some indirect observations have been made concerning the effect of protonation or coordination on the equilibrium *(3b)*⇌*(4b)*[16]. The substituted azepine *(5)* can be hydrogenated with H_2 over platinum in solution[17]. The resulting product depends on the nature of the solvent: *(7)* is formed in nonpolar cyclohexane while *(8)* is obtained in polar methanol, which is able to hydrogen-bond with the nitrogen. The different products may be explained by the assumption of *(6)* as an intermediate[13, 17], whose existence would be favored in the polar solvent. In the same way, one can understand the rapid aromatization of azepines to anilines under the influence of acids[13, 15, 18-20].

[**] Present address: Institut für Organische Chemie I der Universität 6 Frankfurt/Main, Robert-Mayer-Strasse 7—9 (Germany)

In this process, the formation of the bicyclic azanorcaradiene *(4b)* is proposed[13, 15, 18a, 19], whose existence in the equilibrium *(3b)*⇌*(4b)* would be favored by protonation[21].

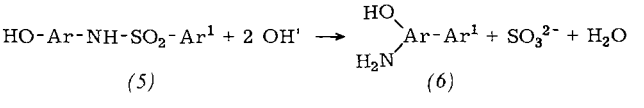
[21] In the case of the alkoxycarbonylazepines, it is not decisive for our arguments whether protonation occurs directly at nitrogen or—as suggested [18a, 15]—at the alkoxycarbonyl group; the electron pair on nitrogen will become involved in bonding in both cases: in the first case by the formation of a $^{+}N-H$ bond; in the second case by the formation of a $^{+}N=C$ bond.

Biaryls, Stilbenes, Benzo[*c*]cinnolines, and Dibenz[*c*,*mn*]acridines from Sulfonamides

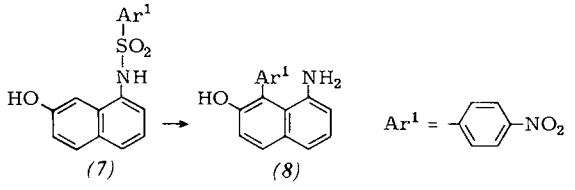


By *Eckart Waldau* and *Rolf Pütter*[*]

3'-Hydroxy-4-nitrobenzenesulfonanilide *(1)* reacts with alkali in water with formation of 3-amino-4-(4-nitrophenyl)phenol *(3)*.

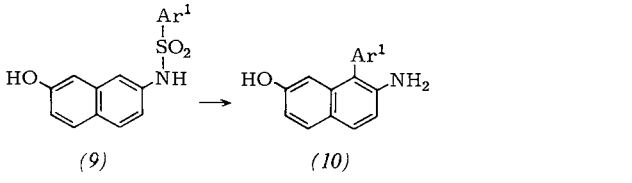
If the *para*-position to the hydroxyl group of compound *(1)* is substituted by a methyl group, the nitrophenyl group enters between the hydroxyl and the amino group to form *(4)*. In each reaction no more than one biaryl compound was isolated. The specificity strongly suggests an intramolecular reaction course.

This reaction has a field of general application:



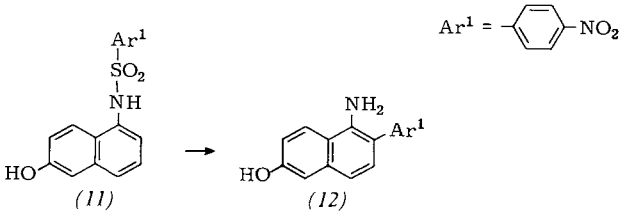
In order that it may take place the starting compound *(5)* must fulfil the following conditions:

1. In the aromatic group denoted Ar one *ortho*- or *peri*-position to the sulfonamide group, *i.e.* the position concerned in linkage to the other aromatic group Ar^1, must be unsubstituted *(7)*.



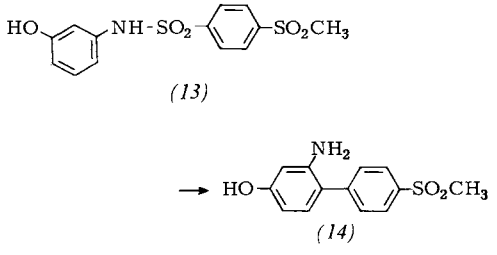
2. The hydroxyl group on Ar must enable electrophilic entry of Ar^1 to occur by virtue of its negativating effect.

[*] Dr. E. Waldau and Dr. R. Pütter
Bayer AG
509 Leverkusen (Germany)

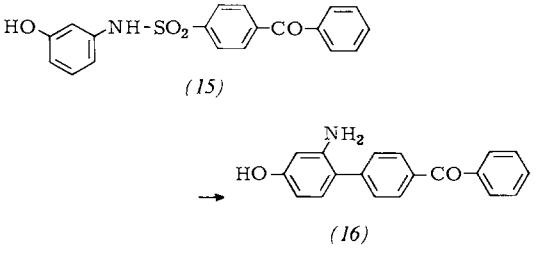


Thus its position decides the position at which linkage occurs, which can be *ortho* or *para* to this hydroxyl group. If Ar denotes a naphthalene derivative, then other positions must also be considered *(9)*, *(11)*.

(7) *(8)*

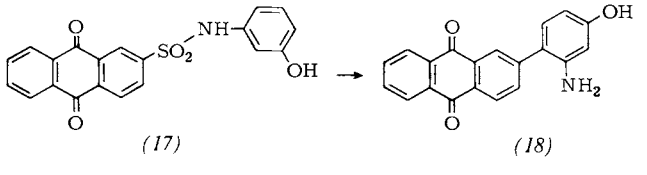


(9) *(10)*

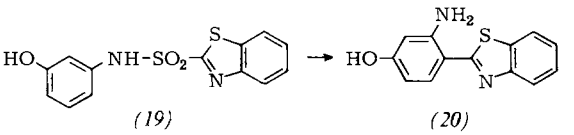


(11) *(12)*

3. During the reaction Ar^1 becomes bonded to Ar by the carbon atom carrying the sulfonamide group. This carbon atom must be rendered positive by Ar^1. The positivation can be effected by electron-withdrawing groups such as nitro, sulfonyl, or carbonyl in the *ortho*- or *para*-position *(13)*, *(15)*.

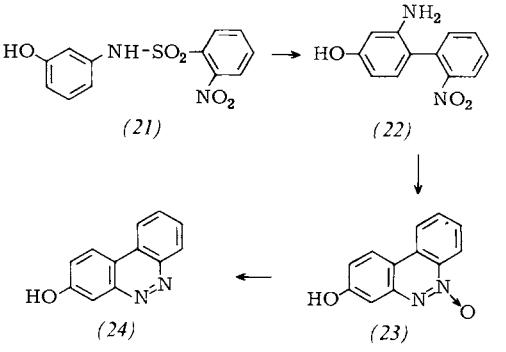


(13) *(14)*



(15) *(16)*

The carbonyl group that positivates the aromatic group Ar^1 may also be contained in a cyclic system *(17)*.

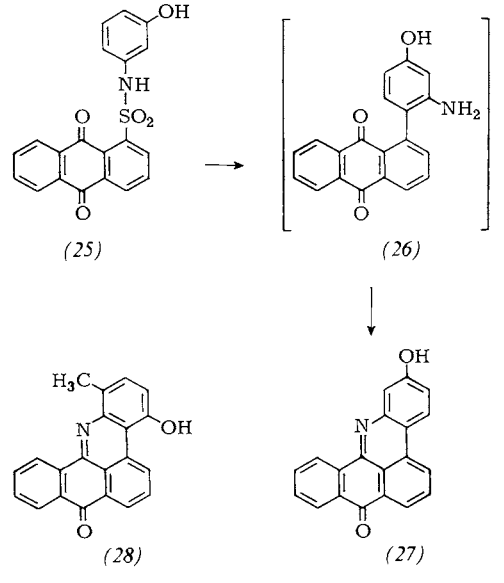


(17) *(18)*

Positivation also occurs if this carbon atom is a component of an aromatic heterocyclic ring *(19)*.

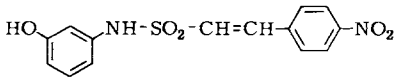
(19) *(20)*

In special cases further reaction may take place after formation of the biaryl. 3'-Hydroxy-2-nitrobenzenesulfonanilide *(21)* reacts with alkali in water at 250 °C to yield 3-hydroxybenzo[*c*]cinnoline *(24)*, *(22)* and *(23)* having been proved to be intermediates.



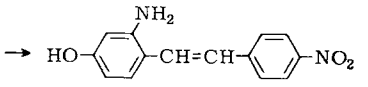
(21) *(22)* *(24)* *(23)*

Under the conditions chosen, reaction in dimethyl sulfoxide stops at the stage of 3-hydroxybenzo[*c*]cinnoline 6-*N*-oxide *(23)*, whereas in water *(23)* is reduced to *(24)* by the sulfite produced in the reaction. Because of its good yields (approximately 70%) this procedure provides a useful synthetic route to substituted benzo[*c*]cinnolines.



A subsequent reaction also occurs on treatment of 3'-hydroxyanthraquinone-1-sulfonanilide *(25)*; 2-hydroxy-8-*H*-dibenz[*c*,*mn*]acridin-8-one *(27)* is formed and the primary product *(26)* cannot be isolated.

If the *para*-position to the hydroxyl group of compound *(25)* is substituted by a methyl group, then 4-hydroxy-1-methyldibenz[*c*,*mn*]acridin-8-one *(28)* is obtained in a yield of 45%.



(25) *(26)* *(28)* *(27)*

Nitrostyrenesulfonamides *(29)*, as vinylogs of nitrobenzenesulfonamides, are also amenable to this reaction. Instead of biaryls one obtains stilbenes *(30)* with the *trans*-configuration.

(29)

(30)

General experimental procedure:

A sulfonamide of type *(5)* (0.1 mol) and potassium hydroxide (0.3 mol) are allowed to react in 2—3 liters of water or an organic solvent such as dimethyl sulfoxide or hexamethylphosphorotriamide under the conditions listed in Table 1. The crude product is precipitated by dilute mineral acid and filtered off. The pure products are obtained by recrystallization from alcohol or alcohol/water mixtures, if necessary with chromatography on alumina.

Table 1 gives a survey of the biaryls, benzocinnolines, dibenzacridines, and stilbenes synthesized. The yields were not optimized; they increase with decreasing concentration of the sulfonamide if the electron-withdrawing substituent can be reduced by the sulfite. Melting points are uncorrected. The structures of the products accord with elemental analyses and IR, NMR, and mass spectra.

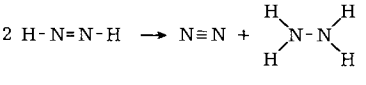
Isolation of Pure Diimine[1]



By *Nils Wiberg, Heinz Bachhuber,* and *Gerd Fischer*[*]

Unlike the organic azo compounds, which have considerable thermal (meta-)stability, their parent diimine, H—N=N—H[2], is extremely thermolabile[3]. Thus at room temperature it exists only as a reactive intermediate whose existence, founded in theory[4], can be recognized in the gas phase by mass spectroscopy[5–7] and in solution by reaction with double-bond systems[3]. It was concluded further from IR spectroscopic investigations that diimine must exist in the yellow or blue mixtures of compounds obtained on low-temperature photolysis of hydrogen azide in a foreign molecule matrix[8,9] or by quenching of the decomposition products of hydrazine[5,10,11] or hydrazoic acid[5,12] formed in an electric discharge at reduced pressure. Because of the heterogeneity of the product mixtures the infrared spectroscopic detection of diimine is inconclusive, being self-contradictory in detail in the various studies; the diimine was described as a yellow compound unstable above −150 °C.

In the thermolysis of alkali-metal tosylhydrazides *(1)*, which are readily accessible from tosylhydrazine and alkali-metal bis(trimethylsilyl)amides in benzene, we have found a process yielding diimine in isolable quantities.

The thermolysis of *(1)* must be carried out in a high vacuum ($<10^{-4}$ torr) in order largely to exclude subsequent disproportionation of the diimine by a reaction of higher order[3].

(As was proved by mass spectroscopy, diimine can be passed without loss at pressures of $<10^{-4}$ torr and room temperature through meter-long glass tubes.) Of especial preparative advantage is the fact that both *(1)* and the product Tos-M are involatile in the high vacuum.

As was found by mass spectroscopy, thermal decomposition of *(1)* gives nitrogen and hydrazine along with the diimine[13]. Apparently, when diimine is liberated from *(1)*, there are pressure conditions on the surface or in the interior of the crystals that lead to partial disproportionation of the diimine. The proportion of interfering "side reaction" in the total conversion decreases with decrease in the temperature of thermolysis and in the series *(1)*-Li > *(1)*-K > *(1)*-Na (Table 1).

Table 1. Formation of diimine on thermolysis of *(1)*.

	Optimal [a] thermolysis temp. (°C)	Proportion of diimine in the thermolysis gas (%) [b]
(1)-Li	80	40
(1)-Na	60	80
(1)-K	45	60

[a] Formation of about 1/10 mmol of diimine per h (cf. Experimental).
[b] Determined by mass spectroscopy.

After being passed through a tube cooled by dry ice, the gas mixture produced by thermolysis of *(1)* consists almost wholly of diimine and nitrogen[13]. If it is passed over a finger cooled to −196 °C (liquid nitrogen), the diimine is deposited as a brilliant yellow film. Diimine can thus be obtained in any desired amount, and its properties can be examined[14]. It can be sublimed off the cold finger at about −165 °C with partial decomposition *(ca.* $^1/_3$*)* (vapor pressure at −165 °C: *ca.* 10^{-6} torr)[15].

The mass spectrum (70 eV) of gaseous diimine contains, besides the molecular ions $N_2H_2^+$ (measured ionization potential 9.9 ± 0.3 eV; lit., 9.85 ± 0.1 eV[5]) and $N_2H_2^{2+}$, mainly ions with an intact nitrogen chain (HN_2^+, N_2^+), while ions with a cleaved nitrogen chain (H_2N^+, HN^+, N^+) appear with only low intensity.

Solid diimine decomposes very readily. Even brief irradiation by a flash at −196 °C or removal of the cooling medium suffices to introduce decoloration within a few seconds, release of nitrogen, and blistering of the deposit on the cold-finger. Nitrogen and hydrazine are the main compounds thus produced. As well as this *disproportionation* (around 90%) there is also *dimerization* of diimine to produce ammonium azide (cf.[16]) and—to a much smaller extent—*decomposition* of diimine to nitrogen and hydrogen or *cleavage* of diimine to nitrogen and ammonia.

Experimental:

For preparation of *(1)*, an alkali-metal bis(trimethylsilyl)-amide (alkali metal = lithium, sodium, or potassium)[17] (20 mmol) in anhydrous benzene (40 ml) is added dropwise over 2 h to a well stirred suspension of tosylhydrazine (20 mmol) in anhydrous benzene (250 ml) at room temperature. After reaction for 10 h, the finely crystalline *(1)* is filtered off and washed several times with anhydrous benzene (all operations with exclusion of water). The product is then dried in a high vacuum to a vapor pressure of $<10^{-6}$ torr.

The products formed on thermolysis of *(1)* are drawn by an efficient high-vacuum pump, first through a 1.6-m tube cooled to −78 °C and then through a double-walled vessel shielded from light and provided with a finger cooled to −196 °C. If *(1)* is heated just strongly enough for the pressure beyond the cold finger not to exceed 10^{-4} torr, then $^1/_{10}$ mmol of pure diimine is deposited on the cold finger per hour.

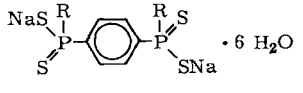
Coordination-Polymeric Metal Complexes as Stationary Phases in Gas Chromatography

By *Jürgen Delventhal, Helmut Keck*, and *Wilhelm Kuchen*[*]



We recently reported the preparation and selective adsorption properties of coordination-polymeric metal complexes[1] of type *(1)* derived from bifunctional dithiophosphinic acids, and also their use for separations by column chromatography. The results induced us to study the use of *(1)* as stationary phases in gas chromatography.

(1)

R = CH_3-O-C$_6$H$_4$- *(a)*, M = $Ni^{(II)}$ *(b)*, M = $Co^{(II)}$

For this purpose we applied the complexes *(1a)* and *(1b)* to Chromosorb (WAWDMCS 80—100 mesh) by the

(2), R = CH_3-O-C$_6$H$_4$-

following method: The Chromosorb was suspended in an aqueous solution of disodium *p*-phenylenebis(*p*-methoxyphenyldithiophosphinate) *(2)*, and the suspension was slowly evaporated to dryness in a rotary evaporator at *ca.* 40 °C and water-pump vacuum. The residue was treated with an aqueous-methanolic (1 : 1) solution of $NiCl_2 \cdot 6H_2O$ or $CoSO_4 \cdot 7H_2O$ and the mixture was again evaporated as described above. The proportions of the components are chosen so that a Chromosorb loaded with 4 wt.-% of metal complex results, assuming quantitative complex formation. This product is washed thoroughly with water and dried for 12 h at 100 °C. The pale green powder is filled into glass columns which are then heated for a further 12 h at 100 °C in a stream of helium. The relative retention volumes for the various Lewis bases shown in Table 1 were determined with these columns.

Table 1. Relative retention volumes of some Lewis bases in gas chromatography on Chromosorb containing *(1a)* or *(1b)*. Gas chromatograph: 5750 D Hewlett-Packard. Column length 1500 mm, internal diameter 1.5 mm. Carrier gas: 42 ml He/min, temp. 100 °C isothermal. Detector WLD (320 °C). Injection block: 250 °C. Paper movement: 2.5 cm/min. Bridge current: 150 mA. Standard: [a] diethylamine, [b] *N,N*-dimethylbenzylamine.

Lewis base	Chromosorb with 4 wt.-% of *(1a)*	*(1b)*
Pyridine	1.57 [a]	1.36 [a]
Tributylamine	3.02 [a]	2.66 [a]
N,N-Dimethylbenzylamine	2.77 [a]	1.94 [a]
N,N-Dimethyl-2-ethylhexylamine	2.07 [a]	1.69 [a]
2-(Dimethylamino)ethanol	1.62 [a]	1.41 [a]
Dimethylaniline	4.85 [a]	2.11 [a]
Dimethylcyclohexylamine	1.84 [a]	1.72 [a]
Triethylamine	0.54 [b]	0.46 [b]
Thiophene	0.49 [b]	0.54 [b]

We believe that the main advantage of the column packings described above is their thermal and chemical stability, for the retention volumes of the Lewis bases as well as the throughput of gas remained constant even after many hours of use.

1,3,5-Benzenetriyltris(1,5-diphenyl-3-verdazyl): A Radical Having a Nearly Degenerate Doublet-Quartet Ground State

By *Gerd Kothe, Franz A. Neugebauer*, and *Herbert Zimmermann*[*]

Organic radicals with three unpaired electrons (three-spin systems) have been known for only a few years. As was shown recently, the three-spin system *(1)*[1] has a quartet ground state with parallel spins of the radical electrons[2].

[*] Dr. Gerd Kothe and Prof. Dr. Herbert Zimmermann

The ESR spectrum of *(1)* can be interpreted quantitatively on the assumption that there is strong magnetic dipole coupling[2-4]. Similar magnetic properties are expected for the three-spin system *(2)* which was described recently by *Kuhn, Neugebauer,* and *Trischmann*[5,6].

(1) *(2)* *(3)*

However, previous measurements of the solid substance on the magnetic balance showed a paramagnetic susceptibility indicating three decoupled radical electrons[5,6]. Accordingly, *(2)* would be a true triradical and is to be considered as a three-fold monoradical without interaction between the radical electrons. The same paramagnetic susceptibility would, however, be obtained by finite interaction between the radical electrons if *(2)* consisted of a mixture of radicals in the doublet and the quartet state, in which the two radical species differed only slightly energetically and had the same occupancy of the corresponding electronic states. Unlike the situation for a quartet where the electron spins are parallel (↑ ↑ ↑), in the doublet the spins of two of the radical electrons compensate each other (↑ ↓ ↑) and the system then has the paramagnetic susceptibility χ_D of a monoradical. The limiting cases just discussed can be distinguished by ESR spectroscopy. We report here such investigations for *(2)*.

We have investigated the temperature- and concentration-dependence of the molar paramagnetic susceptibility χ of the radical *(2)* in dimethylformamide by quantitative ESR spectroscopy. The measuring set-up has been described previously[7]. The range of concentration was 6.7×10^{-5} to 2.7×10^{-4} mol/liter, and was limited by the solubility of the radical and the sensitivity of the apparatus. The temperature-dependence of χ was determined from $T = 230$ to $T = 340$ K[8].

The molar paramagnetic susceptibility χ/χ_D, referred to the susceptibility χ_D of a free monoradical as standard, was independent of the concentration or temperature within experimental error; it amounted to $\chi/\chi_D = 3$. This value accords with previous measurements of the solid substance on the magnetic balance and indicates either a triradical with decoupled radical electrons or a mixture of molecules with doublet and quartet ground states respectively. For a three-spin system with the quartet-doublet separation $J = E_{quartet} - E_{doublet}$ we have:

$$\chi/\chi_D = (1 + 5e^{-J/RT})/(1 + e^{-J/RT}) .$$

The expression accounts for the four doublet and four quartet spin functions in this system[9]. If the quartet-doublet separation in the temperature range studied is $|J| \ll RT$, then $\chi/\chi_D = 3$ and the quartet and doublet are nearly degenerate and equally occupied.

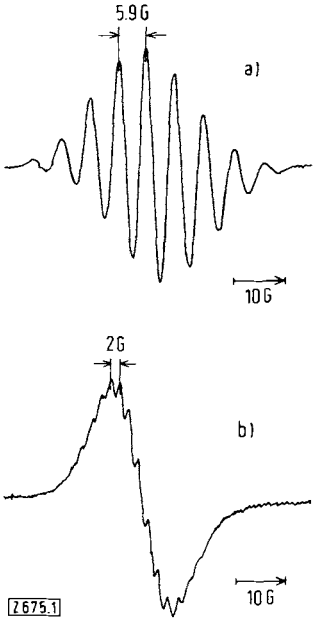

Fig. 1. ESR spectra in DMF at room temperature. a) 1,3,5-Triphenylverdazyl *(3)*. b) 1,3,5-Benzenetriyltris(1,5-diphenyl-3-verdazyl) *(2)*.

For a triradical without interaction an ESR spectrum would be expected that shows approximately the same hyperfine structure as the spectrum of the corresponding monoradical. As Figure 1 shows, the spectra of *(2)* and the monoradical *(3)* are completely different. Apparently *(2)* is not a triradical but is a doublet-quartet mixture in the sense discussed above. To demonstrate the quartet state we have studied the ESR spectrum of a solid glassy solution of the radical in DMF at 93 K (Figure 2); signals

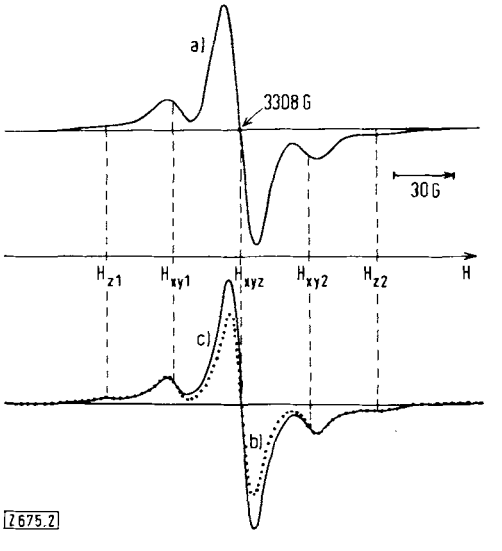

Fig. 2. ESR spectra of *(2)*. a) Experimental spectrum in DMF glass at 93 K. b) Calculated spectrum of the radical in the quartet state, zero field parameter $D' = 28.5$ G, half width of the Lorentz curve $B = 15$ G. c) Superposed spectra of the radical in the quartet and the doublet states, in the proportions 1 : 1, $D' = 28.5$ G, $B = 15$ G.

can be recognized in the $\Delta m = 1$ region which are characteristic of randomly oriented quartet radicals with threefold and higher-fold symmetry axes. They can be described by the spin Hamiltonian:

$$\mathcal{H} = g\beta\vec{H}\vec{S} + D(S_z^2 - \tfrac{1}{3}\vec{S}^2)$$

where g = the isotropic g tensor, β = the Bohr magneton, $\vec{H}$ = the external magnetic field, $\vec{S}$ = the total spin operator with the Cartesian component S_z in the direction of the main axis of rotation of the radical, and D = the zero field parameter.

The operator splits the degenerate quartet states. A first-order perturbation treatment yields the axial resonance field strengths at which the $\Delta m = 1$ transitions appear, as follows:

$$\left.\begin{aligned} H_{xy1} &= H_0 - D' \\ H_{xy2} &= H_0 + D' \end{aligned}\right\} \quad \vec{H} \perp \vec{z}$$

$$\left.\begin{aligned} H_{z1} &= H_0 - 2D' \\ H_{z2} &= H_0 + 2D' \end{aligned}\right\} \quad \vec{H} \parallel \vec{z}$$

$$H_{xyz} = H_0 \qquad \vec{H} \text{ at any orientation to } \vec{z}$$

where $H_0 = h\nu/(g\beta)$, $D' = D/(g\beta)$, ν = the frequency of the microwave field $\vec{H}_1 \perp \vec{H}$.

If the molecular axes $\vec{z}$ are oriented randomly to the direction of the external field $\vec{H}$, the ESR transitions are not limited to the axial resonance field strengths. The resulting ESR spectrum is then the sum of the spectra of the randomly distributed radicals.

If the line width is large or the zero field parameter small, the axial resonance field strengths can no longer be determined directly from the spectrum. In such cases the zero field parameter can be determined by spectral simulation and comparison with the experimental data. The ESR spectrum of *(2)* was calculated by a computer program[4]. For computing reasons a Lorentz curve was chosen as line form. The best agreement between the experimental and the calculated ESR spectrum was obtained with the zero field parameter $D' = 28.5$ G and a half width $B = 15$ G. The calculated spectrum and the corresponding axial resonance field strengths are reproduced in Figure 2. Comparison of Figures 2a and 2b shows the greater intensity of the central peak in the experimental spectrum. The difference is ascribed to the additional ESR absorption of the radical molecules in the doublet state. Superposing on the quartet spectrum a doublet spectrum with the same line form and half width yields the ESR spectrum shown in Figure 2c; in doing this, it was taken into account that the quartet and doublet states are nearly equally occupied and should occur in the ratio 1:1. The experimental and the calculated spectra now agree well. Thus it is shown that *(2)* is a radical with magnetic dipole coupling between the radical electrons, whose ground state is characterized by energetically very similar doublet and quartet states.

A Degenerate Rearrangement of *cis*-Bicyclo[6.1.0]nona-2,4,6-triene[1]

By *Frank Gerrit Klärner*[*]

The thermal behavior of the *cis*-bicyclo[6.1.0]nonatriene system has been very intensively studied. Thus far three types of rearrangement have been reported: the formation of dihydroindenes[2], of *cis*-bicyclo[5.2.0]nona-2,5,8-trienes[3-5], and of bicyclo[4.2.1]nona-2,4,7-trienes[6-9].

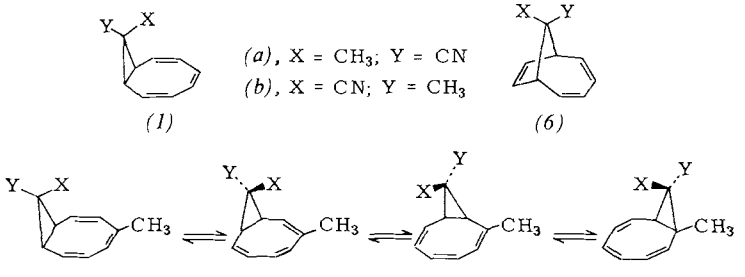
We have now discovered a novel type of rearrangement, which in the case studied precedes the competing processes and consists of a degenerate rearrangement of the system.

(1) *(1')*

For experimental detection of this rearrangement *(1)*→*(1')* it was necessary to label the eight-membered ring as well as to provide a substituent on carbon atom 9.

The 4,9-dimethyl-*cis*-bicyclo[6.1.0]nonatriene-9-carbonitriles *(2a)* and *(2b)* were synthesized as model compounds. Bromination of the separated diastereomers *(1a)* and *(1b)*[9], followed by dehydrohalogenation with 1,5-diazabicyclo[4.3.0]non-5-ene[10] and methylation with $Li[Cu(CH_3)_2]$[11] gave only *(2a)* (m.p. 43 °C) and *(2b)* (m.p. 60 °C), respectively[12].

The stereochemistry at C-9 of the epimers *(2a)* and *(2b)* is fixed by that of the starting materials *(1a)* and *(1b)*. That the vinylic methyl group is at position 4 follows from the ^{1}H-NMR spectra in the presence of the paramagnetic europium complex $Eu(DPM)_3$[13]. Under the influence of the europium complex the vinyl protons of *(2a)* and *(2b)* show the same splitting as the corresponding protons of the starting materials *(1a)* and *(1b)*. The intensities of the signals ascribed to the protons H-2, H-3, H-6, H-7 and to H-4 and H-5 in the spectra of *(1a)* and *(1b)* occur for *(2a)* and *(2b)* in the ratio of only 4:1, as expected.



Thermolysis of either *(2a)* or *(2b)* leads, even at 102.5 °C in benzene solution, to complete equilibration of the isomers *(2)* to *(5)* (identified by their ^{1}H-NMR spectra) in the proportions stated (determined by ^{1}H-NMR measurements).

The rate constants[11] $k_{2a\,3a}$ and $k_{2b\,3b} = 1.3 \times 10^{-4}$ and $1.0 \times 10^{-4}\,s^{-1}$, respectively, and hence the free energies of

[*] Dr. F.-G. Klärner
Abteilung für Chemie der Universität
4630 Bochum-Querenburg, Buscheystrasse (Germany)

activation $\Delta F^{+} = 28.8$ and 29.0 kcal/mol, respectively, were determined by following the course of the isomerization *(2)*→*(3)* (up to 10% conversion at 102.5 °C).

Migration of carbon atom 9 around the periphery of the eight-membered ring occurs with high stereospecificity. No *exo-endo*-isomerization of compounds *(2)* to *(5)* was observed under the conditions of the thermolysis, even after reaction for several days. The stereochemical integrity of

	(2)	(3)	(4)	(5)
(a):	35%	33%	21%	11%
(b):	34%	38%	24%	4%

C-9 remains preserved up to a temperature of 180 °C, where *(1)* rearranges to *(6)* (at 180.2 °C: $k_{1a\,6a} = 0.5 \times 10^{-5}\ s^{-1}$; $k_{1a\,6b} = 3.0 \times 10^{-5}\ s^{-1}$; $k_{1b\,6a} = 4.8 \times 10^{-5}\ s^{-1}$; $k_{1b\,6b} = 2.0 \times 10^{-5}\ s^{-1}$)[14]. From the rate constants for the rearrangements *(1)*→*(6)* and *(2)*→*(3)* one can extrapolate that the stereochemistry at C-9 is retained, even after 10^4 reaction steps.

The observed stereochemistry corresponds to inversion at carbon atom C-9 and fulfils the stereochemical requirements for an orbital symmetry controlled process[15]. For the concerted process of the degenerate rearrangement *(1)*→*(1')* all eight orbitals involved in the isomerization must overlap in the transition state. The transition state thus requires that at least seven carbon atoms (C-1 to C-7) become largely coplanar and should show greater conformational strain than the ground state. This geometry has conformation requirements similar to those of the homotropylium cation[16], so that resonance stabilization of the transition state may involve participation of a polar homotropylium structure.

Apart from the stereochemical results, the concerted nature of the rearrangement *(1)*→*(1')* is made plausible by the activation parameters. The difference in free energies of activation for cleavage of the cyclopropane bond (C-1)–(C-9) in the reactions *(1)*→*(1')* and *(1)*→*(6)* amounts to *ca.* 7 kcal/mol and thus suggests an aromatic transition state[17].

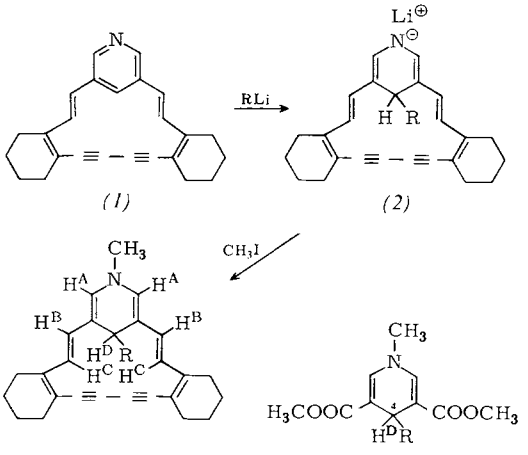
The Synthesis of Aromatic Bridged Didehydroaza[17]annulenes Bearing Alkyl Substituents Within the Cavity of the π-Electron Cloud[1][**]

By *Philip J. Beeby* and *Franz Sondheimer*[*]

We have recently reported the synthesis of the bridged pyridine *(1)*, and its conversion to aromatic methylene-bridged didehydroaza[17]annulenes [*e.g., (3a)*][1]. The pyridine *(1)* appeared to be a suitable precursor of aromatic didehydroaza[17]annulenes bearing substituents within the cavity of the π-electron cloud. We now report the achievement of this objective, the compounds synthesized [*(3b)—(3e)*] possessing alkyl groups as the substituents. Extensive work on related compounds bearing alkyl groups within the cavity of the π-electron cloud of aromatic bridged [14]annulene (15,16-dihydropyrene) derivatives has already been carried out by *Boekelheide et al.*[2]. The presently described synthesis has the advantage that the substituents are introduced essentially as the last step, making it simple to prepare the various substituted compounds.



Treatment of *(1)* in dimethoxyethane and tetrahydrofuran (1:1 v/v) with an excess of CH_3Li in ether at 0 °C under N_2 for 15 minutes led to the 1,4-addition product *(2)*, R = Me. Direct methylation with CH_3I (15 min at 0 °C, 15 min at 20 °C), isolation with ether, and rapid chromatography on Al_2O_3 afforded the methyl compound *(3b)*[3] as stable red crystals in 65% yield, m.p. *ca.* 230 °C (decomp.)[4]; λ_{max} ($CHCl_3$) *ca.* 341 sh (ε 43000), 353 (49500), *ca.* 374 sh (28000), 426 (8600), *ca.* 460 sh (7000), *ca.* 500 sh (3500), and *ca.* 536 sh nm (1200).

Similarly, using the appropriate alkyllithium compound, *(1)* was converted to the ethyl derivative *(3c)* [75%, m.p. *ca.* 230 °C (decomp.)], the *n*-propyl compound *(3d)* [85%, m.p. *ca.* 200 °C (decomp.)], and the *n*-butyl compound *(3e)* [70%, m.p. *ca.* 220 °C (decomp.)].

(4e), R = n-C_4H_9

6.39 (s, N—CH_3). These spectra show the compounds to be diatropic (see Ref. [1]), although the diamagnetic ring current is appreciably less than in *(3a)* [$\tau = 2.79$(s, H^A), 2.34 [d, $J = 16.0$ Hz, H^B), 7.29 (d, $J = 16.0$ Hz, H^C), and 6.30 (s, N—CH_3)]. The decreased ring current in *(3b)—(3e)* is presumably due to the greater deviation from planarity caused by the alkyl groups.

In order to have available models for comparison of the NMR resonances of the bridge substituents in *(3b)—(3e)*, the 4-alkyl diesters *(4b)—(4e)* were prepared. They were synthesized by treatment of dimethyl pyridine-3,5-dicarboxylate[1] with the appropriate Grignard reagent, followed by reaction of the resulting 1,4-dihydropyridine[5] with NaH in dimethoxyethane and finally with CH_3I [*(4b)*, m.p. 61—62 °C; *(4c)*, m.p. 134—135 °C; *(4d)*, m.p. 107—108 °C; *(4e)*, m.p. 59—60 °C]. The diesters *(4b)—(4e)* appear to be suitable models, since in the NMR spectrum of the unsubstituted diester *(4a)* (m.p. 132—134 °C, prepared by *N*-methylation of dimethyl pyridine-3,5-dicarboxylate[1], and subsequent reduction with sodium dithionite[5]) the 4-H protons ($\tau = 6.80$) resonate at essentially the same position as in *(5a)*[1] ($\tau = 6.85$)[6].

(5a), R = H
(5b), R = Alkyl

The chemical shifts of the bridge substituent protons in the NMR spectra of *(3b)—(3e)*, as well as those of the corresponding protons in *(4b)—(4e)* are given in Table 1. The differences in chemical shift on passing from the model to the corresponding aza[17]annulene are given in parentheses. As expected, this difference is most extreme in the case of H^D (*ca.* +3.25 ppm); it decreases as the proton is further removed from the mean plane, although it is still appreciable for the δ protons (*ca.* +0.3 ppm).

The Synthesis of Stereoisomeric Bisdehydrothia-[17]annulenes and Their Dioxides[1][**]

By *Richard H. McGirk* and *Franz Sondheimer*[*]

Heteroannulenes of the pyrrole type may be diatropic ("aromatic") if they are $(4n+1)$-membered, and paratropic ("anti-aromatic") if they are $(4n+3)$-membered, provided the heteroatom can contribute two π-electrons to the delocalized system[2]. The only known macrocyclic heteroannulenes of this type to show significant ring current effects contain bridging groups[1, 3], and it was of interest to prepare unbridged members[4] to discover whether similar effects could be observed.

Homologation of *(1)*[5] by conversion to the diethyl acetal, condensation with ethyl vinyl ether and hydrolysis[6] gave *(2)* (45%, m.p. 58—59 °C[7], isolated by chromatography on SiO_2). Wittig reaction of *(3)*[8] and 2 molar equivalents of *(2)* in dimethylformamide with ethanolic lithium ethoxide at 70 °C, followed by chromatography on SiO_2 and crystallization, led to *(4)* (15%, pale yellow; stereochemistry established by analysis of the NMR spectrum in C_6D_6). The mother liquors consisted of *(5)* and *(6)* (64%), which could not be separated. Oxidative coupling of *(4)* with cupric acetate in pyridine (2 h at 55 °C) yielded the didehydrothia[17]annulene *(7)* [13%, light orange, m.p. 157—159 °C (decomp.)]. Similar coupling of the mixture of *(5)* and *(6)* led to *(8)* (10%, light orange) and *(9)* [3.5%, yellow, m.p. 121—124 °C (decomp.)].

Table 1. Some ^{1}H-NMR parameters of compounds *(4)* and *(7)*—*(14)* in $CDCl_3$ at 100 MHz (τ; *J* values in Hz).

Compound	Olefinic H atoms	Allylic H atoms

(12) [a]	H^A, 4.35 (d, J = 15), H^B, 2.78 (dd, J = 5,15), H^C, H^D, 3.57 (m)	7.45—7.75 (m)
(13) [a]	H^A, 3.77 (d, J = 11), H^B, 3.50 (dd, J = 11), H^C, 2.20 (dd, J = 11,15), H^D, 3.72 (d, J = 15), $H^{A'}$, 2.46 (d, J = 15), $H^{B'}$, 3.06 (dd, J = 6,15), $H^{C'}$, 3.87 (dd, J = 6,15.5), $H^{D'}$, 1.69 (d, J = 15.5)	7.65—8.10 (m)
(14) [a]	H^A, 3.93 (d, J = 10.5), H^B, 3.28 (dd, J = 10.5), H^C, H^D, 2.73 (m)	7.55—7.85 (m)

[a] The assignments and conformations are based on decoupling experiments, nuclear Overhauser experiments, solvent shifts and/or NMR measurements in presence of Eu(fod)$_3$ [tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium(III)].

Oxidation of *(7)* with *m*-chloroperbenzoic acid in CH_2Cl_2 at −20 °C for 2 hours yielded the sulfoxide *(10)* (90%, orange-red), while oxidation at 20 °C for 4 hours gave the sulfone *(11)* (60%, red). Similar oxidation of *(8)* and *(9)* at 20 °C for 4 hours led to *(12)* (85%, pale yellow) and *(13)* (60%, light orange), respectively. The stereochemical assignments of the sulfones *(11)*, *(12)* and *(13)* were based on the NMR spectra (Table 1). For comparison, *(4)* was similarly oxidized to the sulfone *(14)* (50%, yellow).

The didehydrothia[17]annulenes *(7)*, *(8)* and *(9)* are potentially diatropic (18π-electrons), and the sulfones *(11)*, *(12)* and *(13)* paratropic (16π-electrons), provided they are reasonably coplanar. Examination of the NMR spectra of these compounds (Table 1) shows that two possess small ring currents: The sulfide *(8)* appears to be diatropic, since the inner H^B and H^D protons resonate at significantly higher field than in *(4)*, the closest available model [H^D, +1.97 ppm; H^B (in C_6D_6), +0.86 ppm]; there is a corresponding downfield shift of the allylic protons (−0.25 ppm) and of H^C (exact shift unknown), but not of H^A[9]. The sulfone *(11)* appears to be paratropic, since the inner H^C protons resonate at lower field (−2.79 ppm) than in the model *(14)*, while the outer protons resonate at higher field (H^A, +0.39; H^B, +0.37; H^D, +1.51; allyl protons, *ca.* +0.25 ppm). Comparison of the NMR spectra of *(10)* and *(11)* shows that the sulfoxide *(10)* is also paratropic.

[9] In fact, H^A in the NMR spectrum of *(8)* resonates at higher field than that in *(4)*. There is no obvious explanation for this observation, and similar effects of α-protons in cyclic unsaturated sulfides have been observed [*E. Vogel, R. Feldmann, H. Düwel, H. D. Cremer*, and *H. Günther*, Angew. Chem. *84*, 207 (1972); Angew. Chem. internat. Edit. *11*, 217 (1972)].

Conjugation in Aromatic Amines and Phosphanes[1]

By *Werner Schäfer* and *Armin Schweig*[*]

The differing conjugative interaction between the lone pair on a nitrogen(III) and that on a phosphorus(III) atom with an aromatic system has recently become the object of intensive research[2]. With the aid of the photoelectron (PE) spectra[3] of *N,N*-dimethylaniline[4] *(1)* and dimethylphenylphosphane *(2)* we have now been able to provide clear proof of the differing interactions in these compounds and to depict them directly in a manner that cannot be realized by any other technique.

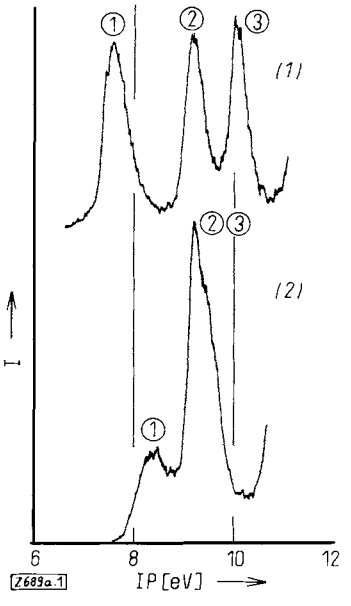

Fig. 1. Photoelectron spectra of *N,N*-dimethylaniline *(1)* and dimethylphenylphosphane *(2)*.

The PE spectra reproduced in Figure 1 show three almost equally intense resolved bands for *(1)* in the region of low ionization potentials at 7.6, 9.2, and 10.0 eV, and two bands of differing intensity for *(2)* at 8.4_5 and 9.2 eV. The ionization potentials (*IP*) of the lone pairs in trimethylamine *(3)* and trimethylphosphane *(4)* are 8.5[5] and 8.6 eV[6], respectively; the degenerate π orbital of benzene lies at 9.24 eV[4]. These data suggest that the band ① corresponding to the HOMO in the compounds *(1)* and *(2)* should be assigned to the lone pair. Depending upon the extent of conjugation, the antibonding interaction with the system should raise this orbital while the corresponding bonding linear combination should be stabilized by about the same amount (see Fig. 2).

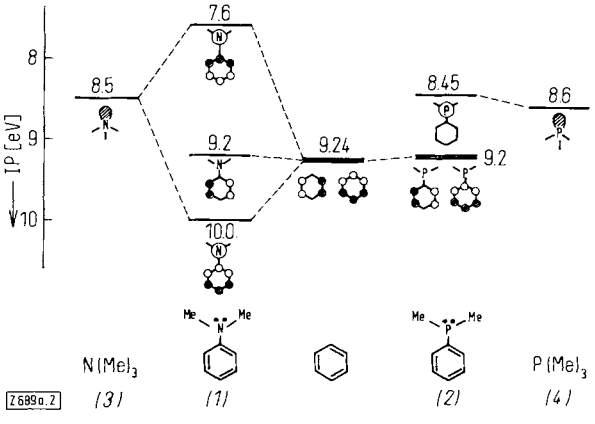

Fig. 2. Correlation diagram of the relevant highest occupied MOs of trimethylamine *(3)*, *N,N*-dimethylaniline *(1)*, benzene, dimethylphenylphosphane *(2)*, and trimethylphosphane *(4)*. The hatched (unhatched) circles in the six-membered ring indicate negative (positive) sings of the p_π-AOs on the respective atoms. The larger circles on the heteroatoms symbolize the lone pairs which are not oriented parallel to the p_π-AOs.

In the case of *(1)* the HOMO is destabilized by 0.9 eV by this antibonding interaction; the corresponding π orbital having a non-zero coefficient at the point of linkage is lowered by 0.76 eV as bonding combination (band ③). The π-MO having a node at the point of linkage stays at a constant *IP* of 9.2 eV (band ②). In the phosphane *(2)*, however, the HOMO is raised only slightly by 0.15 eV and the bands ② and ③ corresponding to the degenerate benzene π-MOs show no splitting.

The above results indicate, directly and unequivocally, that there are two practically uncoupled partial systems (the benzene system and the lone pair in the trialkylphosphane system) in dimethylphenylphosphane *(2)* in contrast to the situation in *N,N*-dimethylaniline *(1)*.

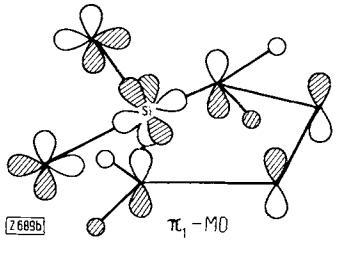
Photoelectron Spectroscopy and Transannular Interactions—The Question of Transannular d-π Interactions in 1-Sila- and 1-Germa-3-cyclopentenes[1]



By *Armin Schweig, Ulrich Weidner,* and *Georges Manuel*[*]

Unlike cyclopentene *(2)*, 1-sila-3-cyclopentene *(4)* and 1,1-dimethyl-1-germa-3-cyclopentene *(6)* have been shown by vibrational spectroscopy[2, 3] and theory[4] to have a planar ring. A transannular interaction[5] between the d-AOs on the Si atom and the π-MO of the ethylene system (d-π interaction) has been postulated to account for the planarity of *(4)*[3]. In the present communication we present evidence from photoelectron spectroscopy and quantum chemistry that definitely rules out any such interaction.

(1) *(2)* *(3)* *(4)* *(5)* *(6)*

In accord with model calculations[6] the two highest occupied π-MOs in *(5)*[7] can be regarded approximately as an antibonding (π_1: nodes over both Si—C ring bonds) and a bonding combination (π_2: no nodes over the Si—C ring bonds) of the H-C hyperconjugative antibonding π-MOs of *cis*-2-butene *(1)* on the one hand and the combination of the two extraannular Si—C MOs that is antisymmetric with regard to the molecular plane on the other hand. Alongside these two π-MOs we predict an antibonding (δ_1) and a bonding combination (δ_2) of the two ring Si—C MOs as further high-energy MOs.

PE measurements show the π_1-MO in *(1)* to lie at 9.33 eV and that in *(2)* at 9.18 eV[8]. Si—C ionization in tetramethylsilane Me_4Si occurs at 10.5 eV[9], and ionization of the σ- and π-Si—C combinations of correct symmetry for *(5)* is found to take place at 10.0, 10.6, and 11.0 eV in dimethyldivinylsilane $Me_2Si(CH{=}CH_2)_2$[10]. The comparison values form the basis for the MO assignment of the PE bands of *(5)* as shown in Figure 1[11]. The same assignments are also valid for the analogous germanium compound. The observed shift of the bands (0.3—0.5 eV)[12] of the second PE peak, which is essentially ascribable to Ge—C MOs, is in accord with such an assignment.

The above analysis shows the HOMOs of the systems *(2)* to *(6)* to contain the HOMO of *(1)* as one partial system

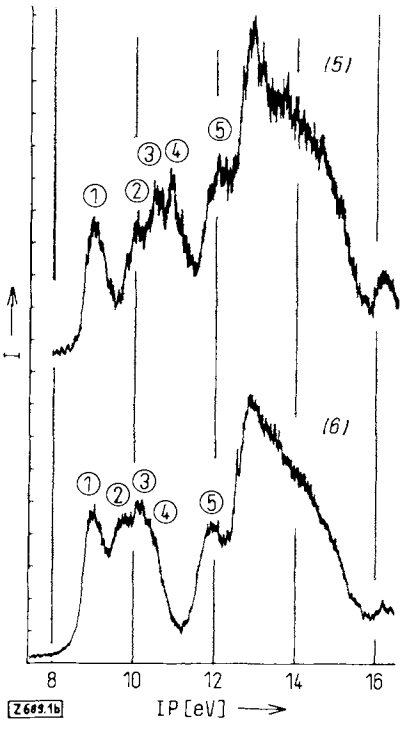


Fig. 1. Photoelectron spectra [15] of 1,1-dimethyl-1-sila-3-cyclopentene *(5)* and 1,1-dimethyl-1-germa-3-cyclopentene *(6)*. The vertical ionization potentials (in eV), relative corrected [16] intensities, and assignments of the bands 1 to 5 are: for *(5)*: ① 9.0/1/π_1; (②, ③, ④) (10.0/0.9, 10.5 1.0, 10.9/1.3)/(σ_1, π_2, σ_2) [11] ⑤ 12.0/?; – for *(6)*: ① 9.0/1/π_1; (②, ③, ④)/(9.7/1.0, 10.15/0.9, 10.4/0.9)/(σ_1, π_2, σ_2) [11]: ⑤ 12.0/?.

and a π-type MO of the groups $-CH_2-$, $-CMe_2-$, $-SiH_2-$, $-SiMe_2-$, or $-GeMe_2-$ as the other partial system. Hyperconjugative antibonding coupling of the two partial systems effects the following observed (PE) or calculated (MINDO/2) HOMO shifts relative to *(1)*: 0.15 eV (PE) for *(2)*; 0.25 eV (MINDO/2) for *(3)*; 0.33 eV (PE) for *(5)* and *(6)*. The small differences and the tendency shown by this series of values unequivocally rule out a significant symmetry-allowed and likewise antibonding transannular d-π interaction (see the representation of this MO). On the contrary, model calculations taking account of d-AOs indicate a HOMO stabilization in agreement with a previously developed d-AO bonding model[13]. This result clearly shows that the d-AO participation in the HOMO is effective in the $-SiMe_2-$ ($-GeMe_2-$) bonds (bonding) and not in a transannular fashion (antibonding).

Synthesis of Dineopentyl Phosphorothiocyanatidate: The First Compound with the >P(O)S—C≡N Structure

By *Andrzej Łopusiński* and *Jan Michalski*[*]

Phosphoroisothiocyanatidates >P(O)N=C=S are stable and relatively readily accessible compounds[1]. In contrast the isomeric thiocyanatidates >P(O)S—C≡N have not, as yet, been described and characterized[2]. Recently, we have investigated a variety of reactions in which formation of the latter structure is to be expected. In this communication we describe the first authentic representative of this interesting series of compounds.

$$[(CH_3)_3C\text{-}CH_2\text{-}O]_2\overset{\overset{O}{\|}}{P}\text{-}S\text{-}Cl \quad (1)$$

$$\downarrow \begin{matrix}+AgCN\\-AgCl\end{matrix}$$

$$[(CH_3)_3C\text{-}CH_2\text{-}O]_2\overset{\overset{O}{\|}}{P}\text{-}S\text{-}C{\equiv}N \quad (2)$$

$$\downarrow$$

$$[(CH_3)_3C\text{-}CH_2\text{-}O]_2\overset{\overset{O}{\|}}{P}\text{-}N{=}C{=}S \quad (3)$$

Bis(neopentyloxy)phosphinoylsulfenylchloride[4] reacts with an excess of silver cyanide in methylene chloride solution at −5 °C to give the dineopentyl phosphorothiocyanatidate *(2)*, which can be isolated by removal of silver chloride and solvent at −5 °C [IR (film): 2170 cm^{-1} (sharp band, medium intensity) ($\nu_{-S-C\equiv N}$); ^{31}P-NMR: $\delta = -10.8$ ppm (H_3PO_4 as external standard)].

[*] Dipl.-Chem. A. Łopusiński und Prof. Dr. J. Michalski
Polska Akademia Nauk, Centrum Badań Molekularnych i Makromolekularnych Lódź,
Przedzalniana 72 (Poland)

At room temperature *(2)* isomerizes to the isothiocyanatidate *(3)*[4] [IR: 2010 cm^{-1} (very strong, broad band, $\nu_{-N=C=S}$); ^{31}P-NMR: $\delta = +17.5$ ppm (H_3PO_4, external)], which can also be prepared by condensation of dineopentylphosphorochloridate *(4)* with thiocyanates[5].

Substituent Effects in 1,3-Dipolar Cycloadditions of Phenyl Azide

By *Reiner Sustmann* and *Heinrich Trill*[*]

In a model recently proposed[1, 2] for the effects of substituents in cycloadditions the separations of the highest occupied π-molecular orbitals (HOMOs) and the lowest unoccupied molecular orbitals (LUMOs) of the other system concerned provide a measure for the reactivity. This model is here placed on a quantitative foundation and tested experimentally for the example of cycloadditions of phenyl azide.

For 1,3-dipolar cycloaddition of an allyl anion 2nd order HMO perturbation theory[3, 4] provides equation (1) for the energy gain in bond formation between the centers 1 and 3 of the 1,3-dipole (A) and the atoms 1′ and 2′ of the olefin (O)[**]:

(A)

(O)

$$\Delta E = \frac{[(c_{Ho1}\cdot c_{Lu1} + c_{Ho2}\cdot c_{Lu3})\beta]^2}{E_{OHo} - E_{ALu}} + \frac{[(c_{Ho1}\, c_{Lu1'} + c_{Ho3}\, c_{Lu2'})\beta]^2}{E_{AHo} - E_{OLu}} \quad (1)$$

Simplifying, we now assume that the eigenvectors of the HOMOs and LUMOs in the numerator are independent of the 1,3-dipole and olefin concerned, *i.e.* the numerator is regarded as constant. This is valid for the contribution of a 1,3-dipole if its reactivity is studied with reference to a large number of olefins. Further, the contribution of the olefin should remain constant to a first approximation so

[*] Priv.-Doz. Dr. R. Sustmann und Dipl.-Chem. H. Trill

[**] In the subscripts Ho denotes HOMO and Lu denotes LUMO.

long as the π-MO considered as the HOMO is localized mainly in the reacting double bond. With these assumptions the expression for ΔE is only a function of the differences in orbital energies (eq. 2).

$$\Delta E = A\beta^2 \left[\frac{1}{E_{\mathrm{OHo}} - E_{\mathrm{ALu}}} + \frac{1}{E_{\mathrm{AHo}} - E_{\mathrm{OLu}}} \right]. \qquad (2)$$

The case where $E_{\mathrm{OHo}} - E_{\mathrm{ALu}} = E_{\mathrm{AHo}} - E_{\mathrm{OLu}} = D$ will be discussed in more detail. A substituent introduced into O may increase or decrease D. If for a given substituent one assumes the same shifts in orbital energies for HOMO and LUMO (this is the case in a first order perturbation calculation) and denotes an increase in orbital energy of the olefin by $-x$ and a decrease by $+x$, then we have:

$$\Delta E = A\beta^2 \left[\frac{1}{D+x} + \frac{1}{D-x} \right]. \qquad (3)$$

Figure 1 illustrates the pattern of this function, where the broken curve shows superposition of the two full branches which represent $1/(D+x)$ and $1/(D-x)$ separately.

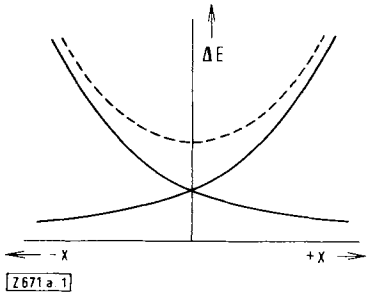

Fig. 1. Qualitative shape of the function (3). Broken line, total function; full lines, $1/(D+x)$ and $1/(D-x)$.

Three possibilities can be distinguished for the influence of substituents on the reaction rate, according to the relative positions of the frontier orbitals (Fig. 2). For case I the separation of HOMO (O) from LUMO (A) determines the reactivity, *i.e.* the first summand in equation (2) is dominant and the second can in a first approximation be neglected. In case III the situation is reversed; here it suffices to

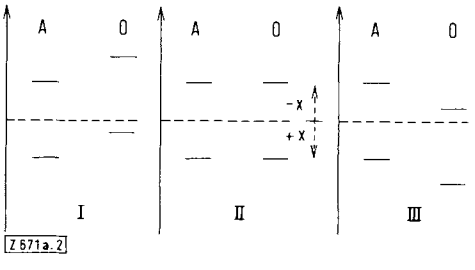

Fig. 2. Possible relative positions of frontier orbitals on cycloaddition of molecules A and O.

consider the second summand in equation (2) in order to determine the increase in reactivity caused by electron-attracting substituents in O. For type II, the separations of both HOMOs and LUMOs must be taken into account; it is always the separation that is reduced by substitution which becomes dominant. The character of a substituent is measured by its influence on the energy of HOMO and LUMO in ethylene. If the orbitals are lowered relative to ethylene, then the substituent is electron-attracting, and the reverse. This treatment takes into account the sum of inductive and mesomeric effects.

In 1,3-dipolar cycloadditions of phenyl azide[5] the reactivity is found to be increased both by electron-attracting and by electron-donating substituents, *i.e.* this system corresponds to type II of Figure 2. To prove the value of the model one must thus in principle know all the separations between HOMOs and LUMOs. However, since phenyl azide is a reactant throughout, its HOMO and LUMO energies give rise to a constant term in the calculation of the difference, and only the HOMOs and LUMOs of the olefins are needed for verification of the model. The energies of the HOMOs are determined from the photoelectron spectra of the olefins[6] or are taken from the literature[7]. The energies of the LUMOs are not known. Nevertheless, here one can use the fact that the energies of HOMOs and LUMOs are shifted in the same direction by any one substituent. So, in place of LUMO energies, the positions of the HOMOs of electron-poor olefins can be used as a measure for the decrease in the LUMO. It should thus be possible to confirm the model by plotting the ionization potentials of the highest occupied π-molecular orbitals against the logarithms of the rate constants for cycloadditions of phenyl azide to olefins. So far as Figure 1 is concerned this means following each rising branch of the hyperbola from the origin towards positive and negative x values instead of considering the superposition of the two stabilizations (broken curve).

Figure 3 shows the expected minimum in the region of the ionization potential of ethylene. That the correlation is sometimes only semiquantitative shows only that there are

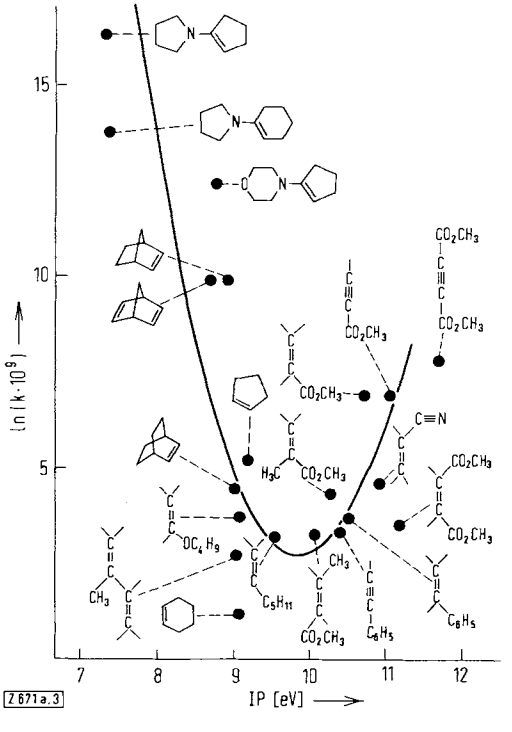

Fig. 3. Correlation of the logarithms of the rate constants for cycloaddition of phenyl azide with the ionization potentials of the highest occupied π-molecular orbitals of substitued olefins. Substituents denoted by bonds are hydrogen atoms.

also other factors affecting the rate of cycloadditions. The model considered here takes only electronic substituent effects into account. Steric influences, which are often very important for cycloadditions, cannot be incorporated in a model that uses only the properties of the isolated reactants as measure of the reactivity. Also electrostatic effects, which play a part in the interaction of polar reactants, do not enter into the correlation. It seems justified to interpret major deviations of individual olefins as a measure of the influence of non-electronic substituent effects. In this way it is possible to obtain an insight into the contribution of individual effects to the total substituent effect.

Substituent Effects in Diels-Alder Additions

By *Reiner Sustmann* and *Reinhard Schubert*[*]

Electronic substituent effects in cycloadditions can be interpreted by means of a model of the interaction of frontier orbitals[1–3] whose development goes back to *Fukui*[4, 5]. For the examples of Diels-Alder additions of maleic anhydride (MA) and of tetracyanoethylene (TCNE)[6, 7] to substituted butadienes it is shown that the qualitative reactivity model can be confirmed quantitatively by correlation of the separations of the highest occupied (HOMO) and the lowest unoccupied molecular orbitals (LUMO) with the logarithm of the rate constants for the cycloadditions. The reactions of these two dienophiles are "normal" Diels-Alder additions, in which the separations HOMO (diene)—LUMO(dienophile) determine the reactivity. The influence of the interaction HOMO(dienophile)—LUMO (diene) can thus be neglected in this work. The result of plotting the logarithms of the rate constants against the HOMO-LUMO separations is expected to be a hyperbola corresponding to one branch in Figure 1 of the preceding Communication[3].

The energies of the HOMOs of the diene skeleton of the substituted butadienes were determined by photoelectron spectroscopy[8]. The electron affinities of TCNE (1.7 eV) and MA (0.5 eV) were taken from the literature[9]. Figure 1 shows the result of the correlation. Even if the points do not all lie on the hyperbola drawn (because of the multiple approximations involved in the model this is not to be expected), expectation is still semiquantitatively fulfilled.

The deviations also allow recognition of other factors that are important for these cycloadditions. In both series, cyclopentadiene shows a reactivity that, measured by the energy of its HOMO is much too high. The fixed cisoid conformation and the short distance between the reacting centers caused by the clamping of positions 1 and 4 provide a simple explanation. If one assumes that the open-chain dienes exist to the extent of 1% or less in the cisoid form (this is so for unsubstituted butadiene[11]) and corrects the rate constants of cyclopentadiene, then this diene also moves

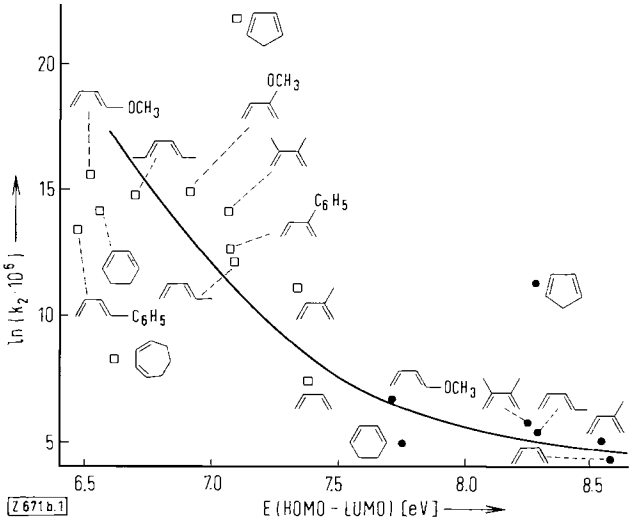

Fig. 1. Correlation of the rate constants of Diels-Alder additions of TCNE (□) and MA (●) to substituted butadienes. Open bonds in the formulas represent methyl groups.

to near the hyperbola drawn (a decrease of *ca.* 5 units on the logarithmic scale). Steric effects are also not taken into account in this model; deviations from the curve can also arise from this cause, as appears to be confirmed by the example of cycloheptadiene. As third factor, electrostatic interactions of polarized and unsymmetrical reactants may codetermine the reactivity, and can be responsible for deviations in some cases.

The kinetic data show that introducing a substituent into a diene has a greater effect on the rates of reactions of TCNE than on those of MA. This greater selectivity in spite of the greater reactivity follows naturally from the reactivity model. The smaller the HOMO-LUMO separation, the more a decrease in the separation caused by a substituent makes itself felt on the reactivity.

Single-Step Synthesis of 1,*n*-Dicarboxylic Diesters by Kolbe Electrolysis of Oxalic and Malonic Half Esters in the Presence of Olefins[**] [1]

By *Hans Schäfer* and *Rudolf Pistorius*[*]

Radicals of a great variety of structure are available by Kolbe electrolysis of carboxylates. Their preparative use has been almost exclusively for the preparation of dimers[2] whilst very little has been recorded on their addition to double bonds[3].

On electrolysis of ethyl hydrogen oxalate or methyl hydrogen malonate in the presence of mono- and di-olefins we have obtained the esters listed in Tables 1 and 2. The adducts were separated by gas chromatography and characterized by C, H analyses and NMR, IR, and mass spectrometry as well as by comparison with authentic samples.

The formation of the products can be explained in accordance with the annexed scheme (see over). The radicals *(3)* produced at the anode dimerize to *(1)* and/or add to the olefin (Ol), yielding *(4)*, which combines to give the dimer *(2)*, couples with *(1)* to give *(5)*, or to a small extent disproportionates to give *(6)* and *(7)*.

In experiments to date, dimers of type *(2)* are accessible in good yields from dienes and styrene, but the yields from

unconjugated monoenes are still unsatisfactory. The proportions of *(2)* : *(5)* (Table 1, expts. 1 and 2) and of the isomers *(2)* (Table 1, expt. 2) can be modified by varying the current density.

Electrolysis of methyl hydrogen malonate in the presence of styrene:

A solution of styrene (80 ml), methyl hydrogen malonate (30 g, 0.26 mol), and potassium methyl malonate (8 g, 51 mmol) was electrolyzed at 0 °C at a cylindrical platinum gauze anode (effective surface area 2.3 cm^3) with 0.6 A and a terminal voltage of 60 V to consumption of 0.336 F. Distillation of the crude product up to 40—135 °C/0.2 torr afforded 9.4 g, from which compounds *(8)* to *(10)* and *(12)* were separated by gas chromatography at 200 °C (column: 8 m, 10% of Apiezon M on Chromosorb P). The distillation residue (15.5 g) consisted to 93% of sublimable *(11)*.

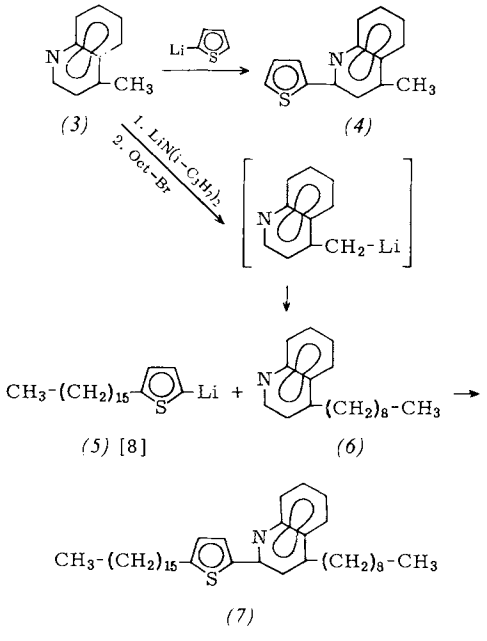
Linkage of Alkyl Groups through Arenofunctional Groups[1] [**]

By *Thomas Kauffmann* and *Annegret Woltermann*[*]

Alkyl groups are often linked through functional groups; some important types of such linkage are shown in Table 1. On the basis of the arenology principle[2] we have investigated the possibility of effecting corresponding linkages also through suitable hetarenes ("arenofunctional groups"[2]), and we have succeeded with types A, B, C, and E but surprisingly not with D.

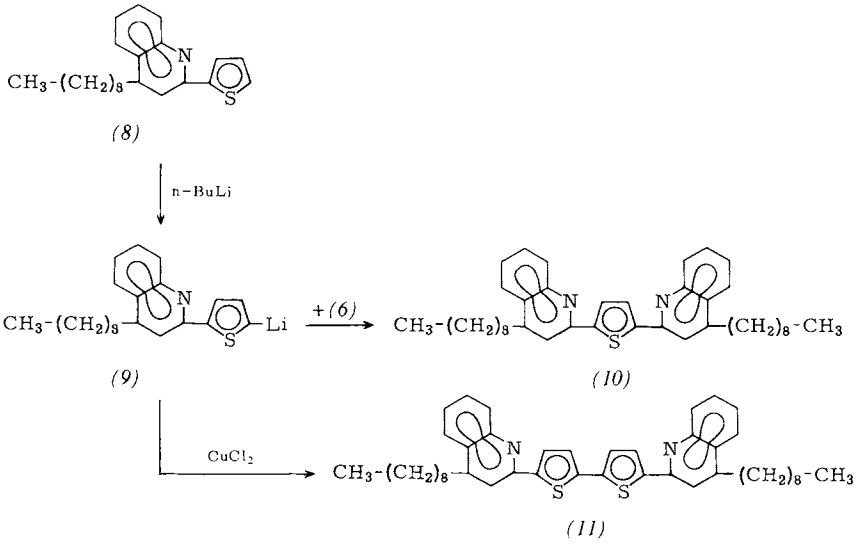
Type A (—Nu—El—): This type of linkage of alkyl groups by classical functional groups occurs readily. With arenofunctional groups, however, a difficulty arises: the slight reactivity of nucleophilic hetarenes[3] towards electrophilic hetarenes requires that they be first activated by lithiation. However, since just in those electrophilic alkylhetarenes that are readily accessible by synthesis the alkyl groups in the α-position are relatively acidic, an undesired transmetalation occurs easily, with subsequent aromatic substitution according to or analogous to the change *(1)* → *(2)* (in THF at −65 to +60 °C)[4], *i.e.* there is an "arenological Claisen reaction", as can be readily appreciated by comparing the two sets of following formulas [yield of *(2)*, *ca.* 80%; m.p. of *(2)*; 81 °C].

Table 1. Important types of linkage for alkyl groups (Nu = nucleophilic, El = electrophilic center).



Type	(—— = alkyl)	Through classical functional groups	Through arenofunctional groups
A	——Nu—El——	*e.g.* esters O ‖ ——O—C——	*e.g.* 
B	——El—Nu—El——	acid anhydrides O O ‖ ‖ ——C—O—C——	
C	——El—Nu—Nu—El——	diacyl peroxides O O ‖ ‖ ——C—O—O—C——	
D	——Nu—El—Nu—— ——Nu—El—Nu'——	carbonic acid esters/urethanes O ‖ ——O—C—X—— (X = O or NH)	 (X = S, O)
E	——Nu—Nu——	disulfides ——S—S——	

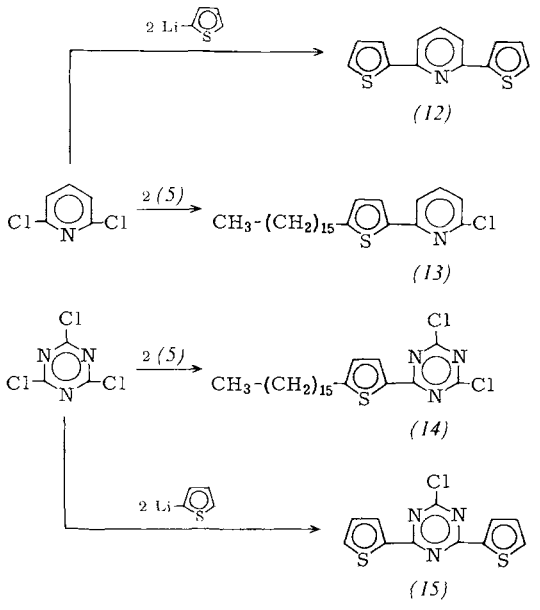
The bicyclic 10π-electron system of quinoline, with the relatively high double-bond character of its C—N bond, is suitable for linkages of this type, for its electrophilic activity



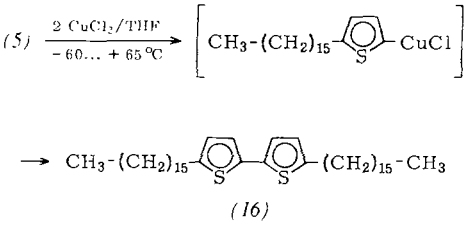
[*] Prof. Dr. Th. Kauffmann and A. Woltermann
Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie.

resembles that of a 2π-electron system such as >C=N— or >C=O more than that of the 6π-electron system of pyridine. Unlike *(1)* or 2-methylpyridine[5], 4-methylquinoline *(3)* reacts with 2-lithiothiophene to give *(4)* smoothly in ether/hexane (4 : 1) at 5 °C[6, 7]. Further, in THF at −60 °C it is lithiated by Li diisopropylamide almost quantitatively at the methyl group and can then be alkylated by alkyl halides to afford 4-alkylquinolines [synthesis of *(5)*: in THF at −60 °C]. These compounds can be linked to 2-hexadecylthiophene[8], as shown by the example *(5)* → *(7)* (in ether at 35 °C) [*(4)*: yield 36%, m.p. 120—121 °C[7]; *(6)*: yield 79% b.p. 158—159 °C/0.01 torr; *(7)*: yield 63%, m.p. 34 °C].



Types B and C (—El—Nu—El— and —El—Nu—Nu—El—): 4-Nonylquinoline *(6)* reacts with 2-lithiothiophene in ether/hexane (5 : 1) at 0—36 °C to give 58% of *(8)*, m.p. 43 °C. The lithium compound *(9)* obtained therefrom by *n*-BuLi in ether at 5 °C (yield >45%, proved by addition to benzophenone; m.p. of the alcohol obtained, 120—121 °C) was treated with 1 mol of 4-nonylquinoline



(in ether at 5 °C, after distillation of the ether in di-*n*-butyl ether at 120 °C). A surprisingly low yield (4%) of *(10)* (m.p. 70 °C, yellow) was thus obtained, together with unchanged starting material. However, the action of 2 mol of $CuCl_2$ on *(9)* (in ether at 5 °C after distillation of the ether in di-*n*-butyl ether at 140 °C) led to a 24% yield of *(11)*, yellow, m.p. 84—85 °C.

Type D (—Nu—El—Nu—): Since alkyl groups attached to *nucleophilic* hetarenes at the α-position are not acidic, the difficulty (transmetalation and secondary reaction) mentioned above need not be feared for this type. We attempted such a linkage by treating 2 mol of the 2-alkyl-5-lithiothiophene *(5)* with 2,6-dichloropyridine in ether at 35 °C and with 2,4,6-trichloro-*s*-triazine in ether/THF (2 : 1) at −25 °C. Unlike the analogous treatments with 2-lithiothiophene which gave *(12)* (yield 18%[9] or *(15)* (yield 52%, m.p. 147 °C[10]), this reaction stopped at the biaryl stage *(13)* (yield 28%, 46 °C) or *(14)* (yield 82%, m.p. 67—68 °C). The further reaction with *(5)*, which could not be forced under more severe conditions, is clearly hindered sterically by the long alkyl groups.

Type E (—Nu—Nu—): Except with thiols, oxidative coupling plays only a small role for compounds Alk—Nu—H (Nu = O, NH, or S) because of interfering side reactions and subsequent reactions. With the corresponding arenofunctional compounds such couplings become more important, since nucleophilic hetarenes mostly undergo satisfactory oxidative coupling through organocopper

compounds, and by the synthesis of *(16)* (yield 66%, m.p. 77 °C) we could show that long alkyl groups hardly hinder this type of coupling at all.

The compounds prepared, whose structural formulas are in accord with elemental analyses and spectra (MS, NMR, UV, IR), all melt sharply and usually in a favorable range; they are readily soluble in organic solvents and crystallize well. Working with such arenofunctional compounds is only little more difficult (chromatography in place of distillation) than with normal functional compounds.

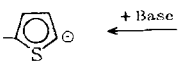
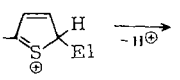
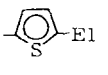
Protophanes by Oxidative Coupling of "Transposed Dithiols"[1][**]

By *Thomas Kauffmann, Jörg Jackisch, Annegret Woltermann*, and *Peter Röwemeier*[*]

According to the arenology principle[2,3] classical functional groups of organic chemistry such as —O—H, —S—H, —CO—X, —CS—X, *etc.*, can be regarded as the first members of homologous series whose higher members (6 or 10π-electrons, *etc.*) consist of "arenofunctional groups", *i.e.* nucleophilic or electrophilic hetaryl groups with suitable substituents (H or X[3]) (examples: Table 1). In their relevant properties[3], the higher members resemble the initial members that are poorer by one or more units of 4π-electrons (printed bold in Table 1), as shown by the comparison in Table 2. It seems reasonable, therefore, to "transpose"[4]







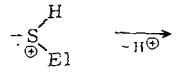


Table 1. Arenology principle for functional groups (examples) [6].

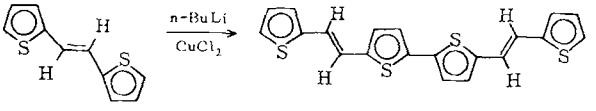
the important compound types containing functional groups into their higher π-electron analogs and to explore the scopes of the compounds thus obtained.—While the extreme importance of functional groups in organic chemistry renders the possibility of "pole reversal" in such groups[5] most valuable, the much broader possibility of modifying them whilst retaining the fundamental character of nucleophile and electrophile discussed here is certainly not less valuable.

Table 2. Comparison of functional groups/arenofunctional groups.

Deprotonatable, nucleophilic, and regenerative					
	+ Base		+ El⊕		
$-S^{\ominus}$	+ Base	−S−H	+ El⊕		−S−El

Transposing the dithioles *(1)* to the 6π-electron stage leads to α,ω-dithienylalkanes *(3)*. Since thienyl groups attached to an alkyl group[2], like thiol groups, are readily made to undergo oxidative coupling, we first coupled α,ω-dithienylalkanes in this way and thus obtained the first examples of the protophane type *(2)*, which, when Ar = nucleophilic hetarene, belongs to probably the most easily prepared types of protophanes.

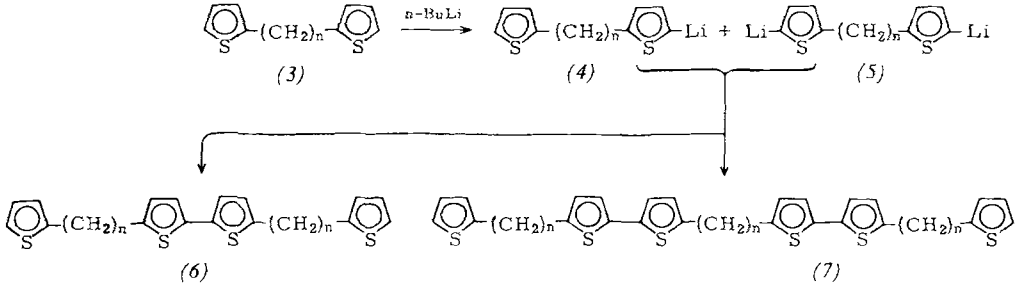


(1) *(2)*

In detail, the dithienylalkanes *(3)*, $n = 2$[7], $n = 6$[8], and $n = 9$ (Table 3) were treated with 1 mol of *n*-BuLi in THF at 0—5 °C and then with 3 mol of $CuCl_2$ at −65 °C. Since the mono- *(4)* and di-lithium compounds *(5)* are always obtained side by side on lithiation, the coupling always leads to a mixture of protophanes from which the tetranuclear *(6)* and the hexanuclear *(7)* product can be separated by extracting the solid reaction product (freed from solvent) with ethanol and benzene, respectively.

This is true also for the protophanes *(7)*, $n = 6$ and 9 (signals at $\tau = 7.8$ and 8.7).

Unlike the compounds *(3)*, *trans*-1,2-dithienylethylene *(8)*[10] is almost exclusively monolithiated (metalation yield *ca.* 80%) by 1 mol of *n*-BuLi in THF at 0—5 °C. Coupling with 3 mol of $CuCl_2$ at −65 °C therefore leads only to *(9)* [*trans,trans*: in KBr out-of-plane vibration at 950 cm^{-1}, as for *(8)*], along with resins.



(8) *(9)*

Table 3. New compounds prepared.

Compound	M.p. [°C] b.p. [°C/torr]	Yield [%]
(6), $n = 2$	108—109	32
(7), $n = 2$	145—146	7
(6), $n = 6$	68–70	40
(7), $n = 6$	107—109	7
(3), $n = 9$	185–189/0.5	63
(6), $n = 9$	47–48	33
(7), $n = 9$	77	6
(9)	216–217	28

The structures and configurations of the newly prepared compounds are in accord with elemental analyses and spectra (NMR, IR, UV, MS).

(3) *(4)* *(5)* *(6)* *(7)*

In the NMR spectrum (Varian T 60; $CDCl_3$; TMS) of *(7)*, $n = 2$, the signals of the aliphatic protons coincide to give a singlet at $\tau = 7.0$, as they do for *(6)*, $n = 2$. In this respect, therefore, there is no noticeable difference between the central aliphatic bridge and the peripheral bridges[9].

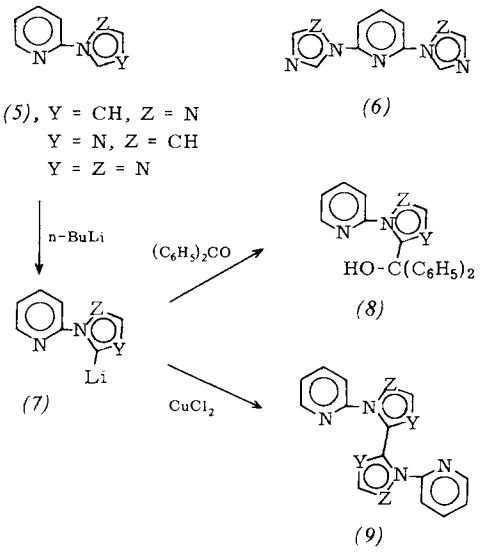
Synthesis and Properties of Azole-Pyridine Combinations: Problem of the Hydrolytic Cleavage of Hetarene Combinations[1] [**]



By *Thomas Kauffmann*, *Jochen Legler*, *Elisabeth Ludorff*, and *Heinz Fischer*[*]

The arenofunctional groups so far used (cf.[2]) have one considerable disadvantage compared with classical functional groups, namely, that the bond between the directly linked arenofunctional groups is not amenable to hydrolysis by normal means, so that it is necessary to seek heterocyclic groups that are more favorable in this respect.

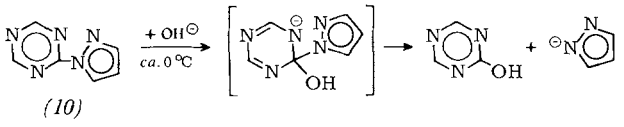
Azolides (*i.e. N*-acylazoles) are interesting in this connection[3]: replacing the amino group of *(1)* or *(2)* by azole groups containing two or more N atoms [*e.g.* compounds *(3)* and *(4)*] leads to a drastic increase in the susceptibility to hydrolysis.

Alk-CO-NH_2 *(1)*	H_2N-CO-NH_2 *(2)*
Alk-CO-azole *(3)*, Y = CH, Z = N; Y = N, Z = CH; Y = Z = N	azole-CO-azole *(4)*

The diarenes *(5)*, which can be considered as arenologs of the azolides *(3)*, have been described but not studied in detail[4]. For a test of their susceptibility to hydrolysis we have prepared these compounds, more simply than recorded in the literature, by treating 2-chloropyridine with the azoles at 190°C (autoclave, no solvent)[5]. Also, the hitherto unknown triarenes *(6)* (Table 1) have been synthesized analogously from 2,6-dichloropyridine.

All these compounds proved resistant to 2 N NaOH or 2 N HCl at 100°C. Even the strongly nucleophilic *n*-butyllithium did not cleave the internuclear C—N bond; the diarenes were lithiated by this reagent [in ether or ether/THF (1 : 1) at 20°C], giving *(7)*. This permitted synthesis of the colorless tetraarenes *(9)* by oxidative coupling of *(7)* with 2 mol of $CuCl_2$ (in ether/THF (1 : 1) at 0—50°C) as well as the preparation (in ether at 20°C) of the alcohols *(8)* (Table 1).

Table 1. Compounds synthesized.



Compound	M.p. [°C]	Yield [%]	Compound	M.p. [°C]	Yield [%]
(6), Z = CH	152	28	*(9)*, Y = CH, Z = N	136—137	21
(6), Z = N	217	21	*(9)*, Y = N, Z = CH	138	18
			(9), Y = Z = N	143	18
(8), Y = N, Z = CH	158	46	*(11)* (yellow)	235—237	82
(8), Y = Z = N	184	70	*(12)* (yellow)	270—273	25

The resistance of the diarenes *(5)* and the triarenes *(6)* to boiling sodium hydroxide solution and hydrochloric acid is at first sight surprising in view of the sensitivity of the corresponding azolides[3] to hydrolysis, but is ascribed by us to the inability of the pyridine system, unlike the carbonyl group, to add weak nucleophiles. This interpretation is favored by the fact that the known diarenes *(10)*[6], whose electrophilic group (*s*-triazine) is scarcely inferior to the carbonyl group in electrophilic activity, is cleaved by dilute sodium hydroxide solution at as low a temperature as *ca.* 0°C and indeed even by aniline at 20°C[6]. Since azolides usually react with nucleophiles by the AE

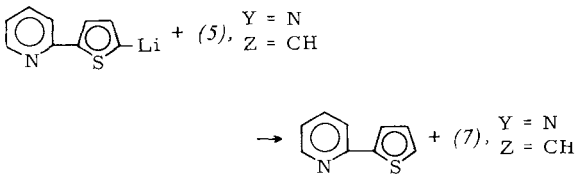
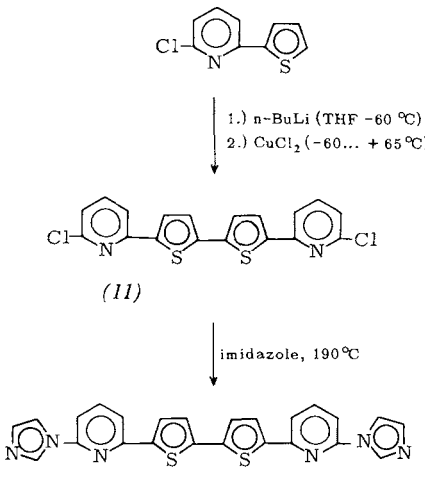
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie.



mechanism[3], this mechanism is also probable for the above cleavages[7].

Hetarene combinations that can be cleaved by hydrolysis will in general presumably be obtained if the azoles are linked, as in *(10)*, by a C—N bond to a strongly electrophilic hetarene.



(10)

That *n*-butyllithium neither adds to the diarenes *(5)* nor cleaves them may well be due to the relatively high acidity of *(5)*. This was indicated by transmetalation of *(5)*, Y = N, Z = CH, which occurs almost quantitatively within a few minutes in ether at 20 °C.

In our experience it is generally difficult to prepare oligoarenes containing more than four hetarene nuclei by means of organo-lithium and -copper compounds. It is therefore valuable that the autoclave reaction used for preparation of the di- and tri-arenes can also be applied to chain extension of tetraarenes *(11)*.

(11)

The structural formulas above are in accord with analytical values and spectra (MS, NMR, IR).

Long-Range Substituent Effects in Acylation of Thiophene-Pyridine Combinations

By *Thomas Kauffmann, Alfred Mitschker*, and *Hans-Joachim Streitberger*[*]

As a result of the mesomerism shown in the formula scheme the nucleophilicity of the terminal thiophene nucleus in the arene combinations *(1)* to *(4)*[2] would be expected to be lower than that of thiophene, and this has been confirmed by the results of acylation experiments.

When acylation in fact occurs—as expected, it takes place always in the α-position of the terminal thiophene ring —the yields (Table 1) are always distinctly lower than for unsubstituted thiophene.

(1), n = 0, X = H
(2), n = 0, X = Cl
(3), n = 1, X = H
(4), n = 1, X = Cl

(5)

Whereas there was no acylation of *(1)* or *(3)* by 1 mol each of acylating agent and Lewis acid ($SnCl_4$ or $TiCl_4$) under conditions that led to almost quantitative reaction of thiophene, it does result with the chloro derivatives *(2)* and *(4)* (Table 1). Further, with two mol each of acylating agent and Lewis acid results were, with one exception [benzoylation of *(4)*], better than for the non-chlorinated arene combinations (Table 1). In none of these cases was there any reaction other than monoacylation.

We interpret the easier electrophilic substitution at the α-position of the terminal thiophene nucleus due to a chlorine atom in the α-position of the pyridine nucleus in the following way: An electrophile (R—CO—Cl, $R—CO^+$, or MCl_4) present in the reaction mixture attacks primarily the pyridine nitrogen atom of the arene combinations *(1)* and *(3)*. Owing to the mesomerism *(6)* the positive charge thus induced in the aromatic system then makes it more difficult for electrophilic attack to occur on the terminal thiophene nucleus[4]. However, in the chloro compounds *(2)* and *(4)* the electron density on

Table 1. Acylation of thiophene and thiophene-pyridine combinations with 1 mol each of acylating agent and Lewis acid (in parentheses: with 2 mol each).

Reagents	Conditions	2-Acyl-thiophene	Yields and m.p.'s of the products (5), n = 0 X = H	(5), n = 0 X = Cl	(5), n = 1 X = H	(5), n = 1 X = Cl
CH_3COCl + $SnCl_4$	3 h in benzene, 20 °C (5 h in benzene, 80 °C) [a]	96 (98)%	0 (0)%	16 (45)%	0 (60)%	35 (77)%
			—	115—116 °C	178—179 °C	169—170 °C
C_6H_5COCl + $TiCl_4$	5 h in benzene, 80 °C	98 (98)%	0 (21)%	18 (48)%	< 1 (68)%	24 (62)%
			118—120 °C	128—130 °C	177—179 °C	204—206 °C

[a] Conditions for reaction with two mol each of acylating agent and catalyst.

the pyridine nitrogen is decreased by the −I effect of the chlorine to such an extent that electrophiles no longer add so readily to the pyridine nitrogen; and additionally the chlorine atom exerts steric hindrance.

(6)

(7)

This interpretation is supported by the fact that on titration in acetic anhydride with 0.1 N perchloric acid (added in glacial acetic acid) the chlorinated compounds *(2)* and *(4)* proved clearly less basic[5] than *(1)* and *(3)* and, correspondingly, unlike *(1)* and *(3)*, do not form picrates with ethanolic picric acid.

It is to be expected that such substituent effects will often play a role in reactions of substituted polyarenes consisting of nucleophilic and electrophilic hetarenes and will also be effective, though to a smaller degree, over more than three nuclei.

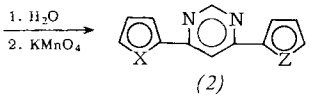
Triarenes of the Type Nucleophile-Electrophile-Nucleophile Containing Pyrimidine or *s*-Triazine as Central Nucleus[1][**]

By *Thomas Kauffmann, Patricia Bandi, Wolfgang Brinkwerth*, and *Bernhard Greving*[*]



Systems Nu—El—Nu composed of nucleophilic (Nu) and electrophilic (El) groups of the 2[p/π]-electron level[2] are important in organic chemistry both for syntheses (HO—CO—OH, H_2N—CO—NH_2, H_2N—CS—NH_2, H_2N—CNH—NH_2) and as linking member between carbon chains (low- and high-molecular carbonic acid esters and urethanes). On the basis of the arenology principle (cf. [2]) we are interested in systems Nu—El—Nu of the 6π-electron level. In particular, we envisage them as useful units in polyarene syntheses.

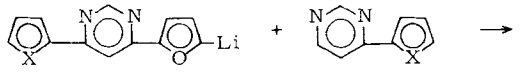
As first representative we were able to prepare 2,6-di-(2-thienyl)pyridine, but only in 18% yield in spite of systematic experiments[3]. The electrophilic activity of the pyridine nucleus of 2-chloro-6-(2-thienyl)pyridine, weakened by internuclear electron exchange, obviously does not suffice for smooth reaction with 2-lithiothiophene. More strongly electrophilic nuclei should thus be more suitable as central nucleus, and this has been confirmed.

By starting from the diarenes *(1)*, which are accessible from pyrimidine and 2-lithio-thiophene, -1-methylpyrrole [*(1)*, X = NCH_3; m.p. 74—75 °C], or -furan in 46, 35, and 53% yield[4,5], respectively, the pale yellow triarenes *(2a)—(2f)* (Table 1) could be obtained, in some cases in satisfactory yield, by the action of a molar amount of each lithium compound (in ether at −30 °C)[6].

(1), X = S [4]
X = NCH_3 [5]
X = O [4]

(2)

[*] Prof. Dr. Th. Kauffmann, P. Bandi, Dipl.-Chem. W. Brinkwerth, and B. Greving
Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie.

The yields stated were obtained when 1-methylpyrrole [for *(2d)*] or furan [for *(2e)* and *(2f)*] were first linked to pyrimidine, giving *(1)* as precursor. The reverse route of synthesis led to larger amounts of by-products, of which the yellow pentaarenes (of type Nu—El—Nu—El—Nu) rimidine nucleus according to *(1)* is surprisingly seen only in the shift of the H_d resonance to higher field. The shift in the H_e resonance in the opposite direction can be explained as van der Waals repulsion or as an anisotropy effect starting from the peripheral nuclei.

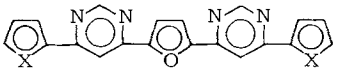


Table 1. Triarenes with pyrimidine as central nucleus.

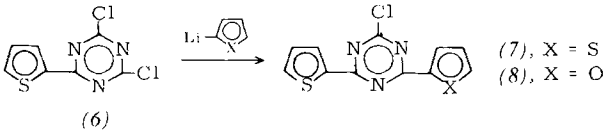
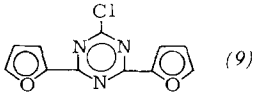
	X	Z	Yield [%]	M.p. [°C]		X	Z	Yield [%]	M.p. [°C]
(2a)	S	S	35	136—142	*(2d)*	NCH_3	S	48	106—106.5
(2b)	NCH_3	NCH_3	25	135—136	*(2e)*	O	S	20	95—98
(2c)	O	O	15	95—97	*(2f)*	O	NCH_3	12	84—85

(4) (m.p. 208—210 °C, 5%) and *(5)* (m.p. 172—174 °C, 4%) could be isolated in pure form; their structures still await confirmation by independent synthesis. A product of type *(3)* or a dihydro derivative thereof is assumed as intermediate in the formation of the pentaarenes.



(3)



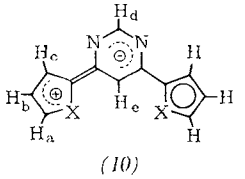
(4), X = S
(5), X = NCH_3

Combinations of *s*-triazine with two thiophene nuclei are also much more easily accessible than those with two furan nuclei. The diarene *(6)* was prepared in 84% yield from cyanuric chloride and 2-thienylmagnesium bromide in ether/THF (2 : 1) at 50—60 °C—it was previously prepared by a quite different route[7]—and, on treatment with 2-lithiothiophene [in ether/THF/*n*-hexane (2 : 1 : 1) at −20 °C] or with 2-lithiofuran [in ether/di-*n*-butyl ether/THF/*n*-hexane (4 : 2 : 1 : 2) at −25 °C] *(6)* afforded the pale yellow triarenes *(7)* (m.p. 147 °C, 59%) and *(8)* (m.p. 159 °C, 23%), respectively. Compound *(7)* can also be obtained from cyanuric chloride and 2 mol of 2-lithiothiophene [in ether/THF/*n*-hexane (4 : 3 : 2) at −15 °C, 52%]. The furan derivative *(9)* (m.p. 200—201 °C, 8%) was obtained analogously by using 1 mol (2 mol caused resinification) of 2-lithiofuran [in ether/THF (1 : 2) at −25 °C].

(6)

(7), X = S
(8), X = O

(9)



The NMR spectra (Table 2) of the triarenes prepared show the expected electron deficiency in the peripheral nuclei; pyrimidine and *s*-triazine nuclei exert approximately equal effects. The expected electron enrichment in the py-

In the mass spectra (70 eV, 300 mA, source 200 °C) of all the compounds prepared the base peak is the (M − 1) ion (if 1-methylpyrrole is a component) or the molecular ion.

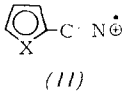


Table 2. Chemical shifts relative to thiophene, furan, or pyrimidine [ppm, $CDCl_3$, *ca.* 100 mg/ml, 20 °C; proton indices as in *(10)*].

Triarene	H_a	H_b	H_c	H_d	H_e
(2a)	−0.53	−0.10	−0.43	+0.21	−0.44
(2c)	−0.36	−0.38	−1.09	+0.20	−0.55
(7)	−0.59	−0.12	−1.17	—	—
(9)	−0.25	−0.27	−1.30	—	—

On fragmentation, the intranuclear bonds are broken preferentially; peaks indicating fission of internuclear bonds are weak or absent. The commonest fragment is always of type *(11)* [68—72% relative intensity for the triarenes *(7)* to *(9)*, 10—15% for the triarenes *(2)*, 8—10% for the pentaarenes].

(10)

(11)

The structural formulas ascribed accord with analytical results and spectra (MS, NMR, IR).

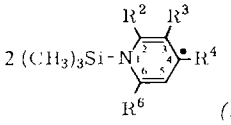
1,4-Dihydro-1-silylpyridyls—A New Class of Stable Radicals



By *Bernd Schroeder, Wilhelm P. Neumann*[*], *Jochen Hollaender*[**], and *Hans-Paul Becker*[***]

1,1',4,4'-Tetrahydro-1,1'-bis(trimethylsilyl)-4,4'-bipyridines *(1)* have been described recently[1]. In the same way or by use of $(CH_3)_3SiCl/Li$[1,2] we have prepared the compounds *(1a)* to *(1g)*.

(1)

(2)

(a), $R^2 = R^3 = R^4 = R^6 = H$
(b), $R^2 = CH_3$, $R^3 = R^4 = R^6 = H$
(c), $R^3 = CH_3$, $R^2 = R^4 = R^6 = H$
(d), $R^4 = CH_3$, $R^2 = R^3 = R^6 = H$
(e), $R^4 = CN$, $R^2 = R^3 = R^6 = H$
(f), $R^2 = R^6 = CH_3$, $R^3 = R^4 = H$
(g), $R^2 = R^4 = CH_3$, $R^3 = R^6 = H$

We now find that these compounds dissociate reversibly into very stable radicals *(2)* when heated with exclusion of air. Thus, for example, *(2a)* can be heated without decomposition in decalin for 3 h at 150 °C. Well resolved ESR spectra can be obtained above 70 °C (Table 1); these accord with expectations. For example, the simulated stick spectrum obtained for *(2a)* using the measured coupling constants agrees well with the recorded spectrum; of the 54 expected lines, the 46 most intense are readily found. Similarly for *(2b)* and *(2c)* one finds 67 and 98 of 192 respectively, and for *(2d)* 92 out of 108 expected lines.

The enthalpies ΔH for *(1)* $\rightleftharpoons$ 2 *(2)* could be calculated (Table 1) by following the intensity of a sharp ESR line; they are equivalent to the dissociation energies for *(1)*. Using literature values[3] we calculated the spin densities (Table 1); the high densities at C-2, C-4, and C-6, and the low densities on the nitrogen atom should be noted (cf. 1,4-dihydropyridyl[4]).

1,4-Dihydropyridyl is extremely unstable; its spectrum has been recorded only at −196 °C. Corresponding 1-alkyl derivatives could not be prepared[5]; however, derivatives with conjugating π-systems (*e. g.* CN, COOR, COR) in the 4-position are relatively stable[3,6]. The stability of *(2)* probably arises from the strong electron attraction of the silyl group. That the electron density on N is low, at least in compounds of type *(1)*, follows from the absence of a shift of the N-H and C-D bands in the IR spectra of pyrrole or $CDCl_3$ when mixed with *(1)* (solid or in CCl_4 solution).

When the known and the new stabilizing principles are combined, by reacting 4-cyanopyridine in benzene with $[(CH_3)_3Si]_2Hg$, the deep green solution that at once results contains radicals *(2e)* that are very sensitive to air but are otherwise stable. This radical apparently does not dimerize at all at room temperature, since temperature changes between 20 and 60 °C have no effect on the intensity of the ESR signal.

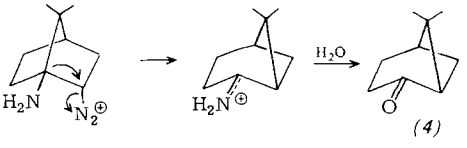
Concerted and Non-Concerted Deamination Reactions

By *Wolfgang Kirmse*[*]



Deamination reactions have been carried out in alcoholic alkaline solution by cleavage of nitrosoacylamines or sulfonylhydrazones in order to study the influence of strong nucleophiles on the decomposition of aliphatic diazonium ions.

For *intermolecular* substitutions it has been proved that the nucleophile participates in the removal of nitrogen from primary allylic diazonium ions *(1)*. For secondary allylic diazinium ions *(2)*, however, the product distribution is independent of the base; with the α-methylbenzylic diazonium ions *(3)* the amount of configurational inversion was not influenced by the concentration of alkoxide.

(3)

Concerted reactions were observed in the following cases of *intramolecular substitution* (= displacement of the diazonium nitrogen by the migrating alkyl group): with the *endo*-bornyl and norbornyl diazonium ions strong electron-donors in position 1 cause concerted rearrangement to the bicyclo[3.1.1]heptane series *(4)*.

(4)

By comparison of decomposition and deuterium exchange it was shown that bicyclo[*n*.1.0]alkane diazonium ions ($n = 3$ or 5) undergo preferentially a concerted ring fission to give cycloalkenyl cations. However, 2-phenylcyclopropane diazonium ions react by way of a phenylcyclopropyl cation as intermediate (identical product mixtures are formed from *cis/trans*-isomeric starting materials).

Concerted reactions can also be detected with aliphatic diazonium ions: the boundary between concerted and non-concerted decomposition is, however, shifted to more energetic carbonium ions in comparison with weaker leaving groups (halide or sulfonate).

Structural Aspects of Metal Ion-Ligand Interaction

By *Helmut Sigel*[*]

The problem of metal ion-ligand interaction with regard to the specificity of biochemical reactions can be resolved into three questions: (i) What factors determine the coordination tendency between ligand groups on the one hand and a certain metal ion on the other? [Or: Why is it that the "right" metal ion capable of activating an enzyme coordinates with that enzyme?]—(ii) How great is the coordination tendency of free (hydrated) coordination sites of a metal ion whose coordination sphere is already partially [as in an enzyme-metal ion complex] saturated by a ligand?—(iii) Does the first ligand coordinated to a metal ion exert any influence on the nature of the second ligand? [Or: Why does the "right" substrate coordinate with a certain enzyme-metal ion complex?]

Disregarding the "lock and key" concept[1] and the possiblity of forming distorted coordination spheres by binding of metal ions to proteins[2] the following essential points remain:

Regarding (i): In accord with *Pearson*'s rule— "hard acids prefer hard bases and soft acids soft bases" —Mg^{2+}, for example, preferentially coordinates with an R—O^- group, while Cu^+ definitely prefers R—S^-. Moreover, the coordination tendency of the metal ions of the Irving-Williams series towards N and O donors is known to vary. Thus, for instance, the ions Ba^{2+}, Sr^{2+}, Ca^{2+}, Mg^{2+}, and Mn^{2+} form relatively stable complexes with CH_3COO^-, and the ions Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} give more stable complexes with NH_3. The stability of the Fe^{2+} complex is about the same with both ligands. In both series, in accord with *Irving* and *Williams*, the Cu^{2+} complex is the most stable. A further important aspect is the pH dependence of most complexation reactions. Thus, for example, the competition between protons and metal ions to coordinate with NH_3 (and ligand groups derived therefrom) is very pronounced at pH 7, while it plays only a subordinate role in the case of imidazole, owing to its lower basicity, and is completely negligible in the case of acetate[3]. Correspondingly, *e.g.* Cu^{2+} coordinates preferentially to the glycinate-like group of L-dopa at pH < 8, while at pH > 8 preferential coordination to the pyrocatecholate-like group occurs. The "critical" pH value for Fe^{3+} is about 4.

Regarding (ii): Surprisingly, a ternary metal-ion complex consisting of an aromatic amine and a ligand having an O donor is frequently more stable than the binary complex —at least with Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+}. This means, that contrary to the general rule $K^{M}_{ML} > K^{ML}_{ML_2}$, positive values are obtained for[4]

$$\Delta \log K = \log K^{MA}_{MAB} - \log K^{M}_{MB}$$

in other words, the equilibrium

$$MA + MB \rightleftharpoons MAB + M$$

is shifted to the right.

[*] Priv.-Doz. Dr. Helmut Sigel
Institut für Anorganische Chemie der Universität
CH-4056 Basel, Spitalstrasse 51 (Switzerland)

Regarding (iii): If the first ligand coordinated is an aromatic amine, the binary complex of Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} possesses discriminating properties, *i. e.* a ligand having an O donor will be coordinated preferentially to a ligand with an N donor. This is mainly attributable to the π-acceptor qualities of the aromatic amine (*e.g.* of pyridine and imidazole groups) and only to a limited extent to the compensation of charge in the ternary complex[4]. Thus the equilibrium constant of the reaction

$$MA_2^{2+} + MB_2^{2-} \rightleftharpoons 2MAB$$

for the 2,2'-bipyridine-Cu^{2+}-pyrocatecholate system is 1.4×10^6 and only 450 for the ethylenediamine-Cu^{2+}-pyrocatecholate system, both constants being greater than the statistically predicted value of 4.

Additionally, with regard to biological systems the "kind of structure" of a ternary complex is important. For example, coordination of the nucleic bases is prevented in 2,2'-bipyridine-Cu^{2+}-nucleoside triphosphate complexes[5]. Such factors have an effect on the reactivity; *e.g.* the deprotonation of the amide group occurs at pH *ca.* 8 in 2,2'-bipyridine-Cu^{2+}-oligoglycine complexes whereas the same reaction takes place at pH 7 and 4, respectively in Cu^{2+}-glycinamide and Cu^{2+}-glycylglycine[6]. Similar effects are manifested in catalytic processes: 2,2'-bipyridine-Cu^{2+} is a more effective catalyst, as compared to Cu_{aq}^{2+}, both for the decarboxylation of acetonedicarboxylate and for the disproportionation of H_2O_2[3,4].

Malate-Lactate Transhydrogenase

By *S. H. George Allen*[*]

Malate-lactate transhydrogenase catalyzes the following reaction:

L-lactate + oxaloacetate $\rightleftharpoons$ pyruvate + L-malate

It has been purified and shown to be a single protein having a molecular weight of 70000. Spectroscopic and fluorescence analysis of the native enzyme reveal an absorbance band at 350 nm, and a fluorescence peak at 440 nm. Addition of L-malate or L-lactate causes an increase in these peaks while addition of either pyruvate or oxaloacetate to the enzyme eliminates them. Treatment of the native enzyme in 7M urea or 5M guanidinium chloride removes the prosthetic group which cannot be removed by other methods. The prosthetic group has been resolved from the apoenzyme by gel filtration. The isolated cofactor exhibited coenzyme activity with lactate dehydrogenase and is chromatographically identical with NADH. The apoenzyme is very insoluble and cannot be reactivated even in the presence of cofactor. This protein could be solubilized in 7M urea with 0.1% mercaptoethanol or by succinylation. Molecular weight determination of the apoenzyme by sedimentation and diffusion in the analytical ultracentrifuge gave a molecular weight of 40000. The equivalent weight per coenzyme binding site as measured by absorbance at 350 nm yields a value of 35000. Thus the transhydrogenase is similar in structure to the mitochondrial malate dehydrogenase and has the same equivalent weight per coenzyme binding site as lactate dehydrogenase which is a tetramer rather than a dimer.

Malate-lactate transhydrogenase reacts according to a modified "ping pong mechanism". The reaction can be shown to proceed in two separate steps. First by:

$$[2\text{-}^3H]\text{-L-lactate} + \text{E-NAD}^+ \rightarrow \text{pyruvate} + \text{E-}[^3H]\text{-NADH}$$

If this reaction is carried out using stoichiometric amounts of enzyme then equivalent amounts of pyruvate can be isolated by ultrafiltration, and if tritium labeled lactate is used then the radioactive enzyme can be isolated on a gel filtration column. If this radioactive enzyme is then incubated with oxaloacetate, and again subjected to gel filtration all the radioactivity is released from the enzyme and appears with the low molecular weight substances as labeled malate in the second step:

$$\text{oxaloacetate} + \text{E-}[^3H]\text{-NADH} + H^+ \rightarrow [^3H]\text{-L-malate} + \text{E·NAD}^+$$

The results of kinetic analysis at low substrate concentrations are in agreement with this mechanism. At higher substrate concentrations however substrate inhibition occurs and the kinetics become complex.

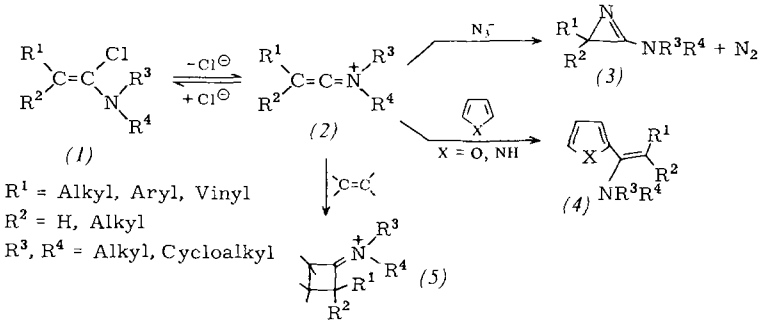
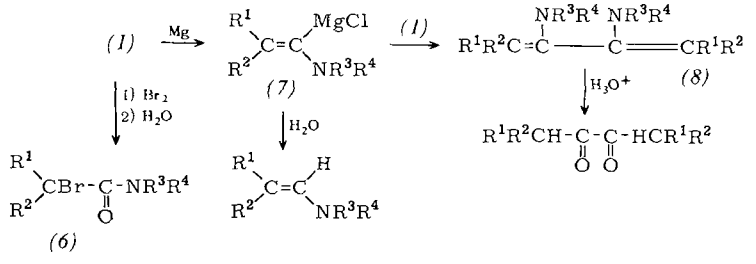
α-Chloroenamines: New Reagents for Organic Synthesis



By *Léon Ghosez*[*]

The presence of an electron donating group and a suitable leaving group on an sp^2 carbon atom is expected to confer a versatile chemical behavior to the unsaturated system. α-Chloroenamines *(1)* are interesting representatives of this class which can be readily obtained from tertiary amides and phosgene followed by elimination of HCl with triethylamine.

In contrast to ordinary vinyl halides they show a remarkably high reactivity toward nucleophilic reagents. The results are best explained by prior ionization to a keteneimmonium ion *(2)* followed by attack of the nucleophilic reagent. This behavior is illustrated by the reaction of α-chloroenamines with sodium azide which yields quantitatively aminoazirines *(3)*, a new class of cyclic amidines which show interesting properties.



[*] Prof. Dr. L. Ghosez
Laboratoire de Chimie Organique de Synthèse—U.C.L.
Naamsestraat, 96
B-3000 Louvain (Belgium)

Furthermore, alkylsubstituted α-chloroenamines react readily with electron-rich aromatics in electrophilic substitutions without the need of an acid catalyst. This reaction, called aminoalkenylation, allows for the specific and direct introduction of enamine functional groups on nucleophilic carbon centers *(4)*.

Keteneimmonium salts *(2)* cycloadd to various unsaturated substrates to give four-membered rings *(5)* in high yields. Even with ethylene the reaction takes place at room temperature with high yield. All additions are directio- and stereospecific.

Like enamines, α-chloroenamines *(1)* also react as nucleophiles at the β-carbon atom with various electrophilic reagents, *e. g.* Br_2, to yield compounds of type *(6)*.

Furthermore, with magnesium in boiling THF they form a new type of Grignard reagent *(7)* which can be hydrolyzed to enamines or coupled with *(1)* to give a new class of activated dienes *(8)*.

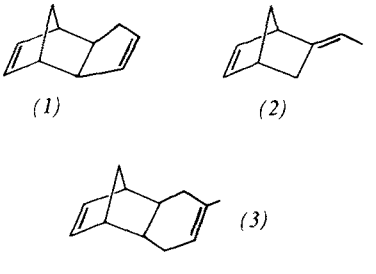
Synthesis of Ethylene-Olefin Copolymers by Means of Soluble Organometal Catalysts

By *Hans Schnecko*[*]



Besides the known ethylene-propylene copolymers and the terpolymers of these two monomers with small amounts of non-conjugated dienes (EPDM) it is possible also to prepare copolymers from ethylene and these dienes [especially bicyclic derivatives of norbornene such as dicyclopentadiene *(1)* and ethylidenenorbornene *(2)* or hexahydromethyl-1,4-methanonaphthalene *(3)*] in any desired molar ratio, and also terpolymers with diene contents appreciably higher than customary hitherto (*i.e.* up to > 60 wt.-%).

[*] Prof. Dr. H. Schnecko
Dunlop-Forschung
645 Hanau (Germany)

Combinations of the known vanadium halides with organoaluminum compounds are particularly suitable as catalyst systems. It is assumed that the active species are relatively short-lived soluble complexes of trivalent vanadium (half-life < 10 min, according to the aluminum compound used). Further, the activity of the catalyst is dependent on the amount and the nature of the diene.

The synthesis is best carried out in a closed system under slight excess pressure (< 5 atm). Addition of the reactants must be controlled. The molecular weight is regulated by H_2.

In ethylene-diene copolymers it was found that the polyethylene crystallinity decreases continuously with increase in the proportion of diene and that with 45—50 wt.-% of diene the polymers are amorphous. The modulus-temperature curves pass through a minimum at *ca.* 50—60 wt.-% of diene. Owing to the rigidity of the ethylene

comonomers the glass transition temperature T_G lies in the region of 0 °C, whereas with propylene as comonomer customary values of *ca.* −55 °C are found for T_G. Thus terpolymers starting from equimolar amounts of ethylene and propylene plus diene are characterized by appreciably lower softening ranges (*ca.* −45 °C), which, however, are shifted upwards again with increasing diene content; at > 30 wt.-% of diene the T_G values once more rise above 0 °C.

From IR spectra and measurement of oxygen uptake it can be shown that autoxidative cross-linking of the pro-

ducts readily occurs, this leading to insolubility. Polymers of this type can thus, for instance, be used as coatings, and pigmented or colorless lacquers with good properties can be obtained.

Lecture at Clausthal-Zellerfeld on June 2, 1972 [VB 350 IE]
German version: Angew. Chem. *84*, 902 (1972)

Chirooptical Properties of the Cystine Disulfide Bond

By *R. Schwyzer*[*]

In synthetic [2,7-cystine]gramicidin S the cyclodecapeptide is bridged by a disulfide group. NMR studies show that, as in gramicidin S, the peptide chain of the compound exists in the antiparallel β-conformation. Shielding effects indicate *P*-helical[1] chirality for the disulfide bridge. In molecular models the dihedral angle φ amounts to about 120°. According to theory[2] the *P*-helical arrangement, linked with $|90°| < |\varphi| < |180°|$, requires that the contribution of the longest-wavelength absorption band to the rotation should be negative, and we have confirmed this experimentally by measurement of the circular dichroism (λ_{min} = 271.5 nm, rotational strength $R = -12.3 \times 10^{-40}$ erg cm^3). In addition, the theoretically required second Cotton effect with the opposite sign can be clearly seen for this compound (λ_{max} = 230 nm, $R = +58.6 \times 10^{-40}$; measurement in ethanol).

[*] Prof. Dr. R. Schwyzer
Institut für Molekularbiologie und Biophysik der Eidgenössischen Technischen Hochschule
CH-8049 Zürich (Switzerland)

Theory further requires that disulfide bonds with $\varphi = \pm 90°$ absorb at *ca.* 250 nm, and also that when the arrangement of the disulfide bond is chiral none of the optical activity inherent in the disulfide bond should appear. This requirement seems to be satisfied with cyclo-L-cystine. According to ^{1}H- and ^{13}C-NMR measurements the molecule has a diketopiperazine ring in the chair form and a chiral disulfide bridge. In molecular models $\varphi = 90°$. In the ultraviolet spectrum, absorption is observed at 247 nm, but there is no long-wave Cotton effect. We assign a strong negative Cotton effect at 228 nm (CD in ethanol) to the n, π* transition of the peptide-carbonyl group. We interpret the sign and rotatory power ($R = 45.5 \times 10^{-40}$) of this band as indicating the existence of cyclo-L-cystine as the *P*-helical diastereomer, but this would require confirmation by other techniques.

These investigations support the theoretical treatment and confirm the quadrant rule: $0° < \varphi < 90°$, $180° < \varphi < 270°$: $R(+) \equiv P$-helical; $90° < \varphi < 180°$, $270° < \varphi < 360°$: $R(+) \equiv M$-helical. The chirality of the disulfide bond cannot be deduced from measurements of the circular dichroism (CD) and rotatory dispersion (ORD) alone without a knowledge also of the (approximate) dihedral angle.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The properties of collagen and gelatin in the solid state are reviewed in an article by *I. V. Yannas*. The structural unit of solid collagen in its various forms is the tropocollagen "molecule", a right-handed superhelix itself consisting of three left-handed protein helices connected by N—H···O bridges. Furthermore, these protein chains are apparently built up from two alternating types of subunits, one of which is rich and the other poor in imino acids (proline, hydroxyproline). Gelatin is the amorphous form of collagen. The report contains sufficient relative data, summarized and in some cases also interpreted, to form a basis for an adequate physico-chemical description of collagen and gelatin in the solid state. [Collagen and Gelatin in the Solid State. Rev. Macromol. Chem. *8*, 49—104 B (1972); 190 references]

[Rd 525 IE–G]

The labeling of receptor sites in biological material with photochemically generated reagents is the theme of a report by *J. R. Knowles*. This method aims to simulate the natural situation

receptor + ligand ⇌ [receptor·ligand]

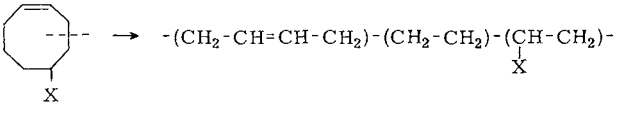
with a reagent that structurally resembles the ligand and interacts specifically with the receptor. In the reaction

[receptor·ligand] → [receptor – ligand]

the reagent should not behave specifically; it must be capable of insertion into C—H bonds. These conditions are fulfilled by photochemically generated carbenes and nitrenes. Examples of applications are the labeling of antidinitrophenyl- and anti-2-nitro-4-azidophenyl anti-

bodies. [Photogenerated Reagents for Biological Receptor-Site Labeling. Accounts Chem. Res. *5*, 155—160 (1972); 45 references]

[Rd 523 IE –L]



Carbenoids, carbenes, and nitrenes as polymerization initiators are described in a report by *M. Imoto* and *T. Nakaya*. The polymerizations of ethylene, methyl methacrylate, and vinyl monomers are described. Despite the same type of initiator being used, these polymerizations proceed partly by radical and partly by ionic mechanisms. The first two sections of the report constitute a review of the polymerizations of diazoalkanes and bisdiazo compounds. [Polymerization by Carbenoids, Carbenes, and Nitrenes. Rev. Macromol. Chem. *8*, 1—48 (1972); 64 references]

[Rd 524 IE –G]

Polymerizations of cycloolefins which proceed *via* ring opening are summarized in a report by *N. Calderon*. Processes of this type can be considered as reactions involving bond rearrangement since for each bond cleaved in the monomer there is formed a bond of similar type in the polymer. The analogy between these reactions and olefin metathesis

$$2R^1{-}CH{=}CH{-}R^2 \rightleftharpoons R^1{-}CH{=}CH{-}R^1 + R^2{-}CH{=}CH{-}R^2$$

is thus clear, and it is not by chance that the latter owes its discovery to efforts made in elucidating the mechanism of polymerization. Ring-opening polymerization of cycloolefins is the only process a available for preparation of copolymers exhibiting exact alternation:

[Ring-Opening Polymerization of Cycloolefins. Rev. Macromol. Chem. *8*, 105—159 (1972); 86 references]

[Rd 526 IE –G]

The thermodynamics of polymerization are outlined in a progress report by *H. Sawada*. The author limits this discussion to cationic reactions, *i.e.* to processes in which the growing polymer carries a positive charge. Ionic polymerizations can be divided into (i) the initial dissociation step, in which the active polymerization ion is formed, (ii) chain growth, the mechanisms of which resemble those of free-radical polymerization, (iii) growth termination, for example by loss of a proton, and (iv) transfer of charge to another molecule (usually a monomer). Data are given, on the basis of examples, regarding the magnitude of various thermodynamic parameters that are characteristic of these reaction steps. [Thermodynamics of Polymerization. Rev. Macromol. Chem. *8*, 161—187 (1972); 30 references]

[Rd 527 IE –G]

The electronic theory of cyclic $(pd)_\pi$-systems is dealt with in a review article by *G. Häfelinger*. The work is concerned with the question of what happens to the ground state of an aromatic π-electron system when p_π-orbitals are replaced by d-orbitals that can form π-bonds. Is an exceptional stabilization of the ground state, *i.e.* aromaticity, to be expected? This question is dealt with both theoretically and experimentally, in the latter case with regard to transition-metal chelates containing aliphatic 1,2-diimine ligands. It is found that in cyclic $(pd)_\pi$-systems a cyclic electron delocalization is possible, which could lead to enhanced stability. However, in not one case of such a system alone can it be proved that there is such an unusual stabilization of the ground state which could be looked upon as aromatic. [Theoretical Considerations for Cyclic $(pd)_\pi$-Systems. Fortschr. Chem. Forsch. *28*, 1—39 (1972); 129 References]

[Rd 531 IE –G]

Organic syntheses with transition metal complexes are reviewed by *J. Tsuji*. Many reactions of this type can be considered to proceed in three steps: formation of a σ-bond between the metal and hydrogen, carbon, oxygen, nitrogen, or halogen; insertion of groups with multiple bonds or of carbenes into this bond; and finally, detachment of the resulting molecule from the metal. The role of the metal in cyclization reactions is more complex, since, in this case, both π-bonding as well as σ-bonding to the metal are of importance. [Organic Synthesis by Means of Transition Metal Complexes. Fortschr. Chem. Forsch. *28*, 41—84 (1972); 173 References]

[Rd 532 IE –G]

The stereochemistry of double bonds, especially its determination by NMR spectroscopy, is the subject of a review by *G. J. Martin* and *M. L. Martin*. Double bonds of the type C=C, C=N, and N=N in organic compounds are dealt with, but not structural elements in which only partial double bond character occurs, as, for instance, in carboxamides of azoxy compounds. Various methods by which the configurations of double bonds can be determined NMR spectroscopically are described and values for chemical shifts and coupling constants are tabulated. [The Stereochemistry of Double Bonds. Prog. Nucl. Magn. Resonance Spectrosc. *8*, 163—259 (1972); 445 References]

[Rd 535 IE –G]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i.e.* provisionally published specifications as filed with the German Patent Office

Improved polyester fibers suitable for dyeing under high-temperature conditions are obtained by spinning polyesters with an oligomer content of less than 1.1%, preferably 0.3—0.8%, and a relative viscosity of 1.55—1.7. The oligomer content is reduced *e.g.* by extraction of the granulated polymer before spinning. The new polyester fibers exhibit a reduced tendency to give thread breaks during twisting, as well as less abrasion than conventional polyester fibers dyed under high-temperature conditions. [DOS 2000359; Glanzstoff AG, Wuppertal]

[PR 3 IE –A]

Crosslinked, carbon-loaded polyolefin textile fibers are produced by extrusion of substantially uncrosslinked mixtures of 20—80 wt.% of polyolefin, 80—20 wt.% of an electrically conducting carbon black, and 0.01 to 5 wt.% of an organic peroxide to form substantially uncrosslinked fibers, cooling the uncrosslinked fibers to temperatures below the melting point of the polyolefin, supporting the cooled fibers, and then passing the cooled fibers through an electromagnetic field having a frequency of between 8.9×10^2 and 1×10^{12} Hz. During the final phase, the temperature of the fibers is raised at least to the decomposition point of the peroxide, and at the same time at least to the melting point of the polymer. The polyolefin fibers have a tensile strength of at least 0.3 g/den and an elongation at break of at least 10%, so that they can be woven. [DOS 2123281; Beaunit Corp., New York]

[PR 6 IE -A]

New biologically active heptapeptides having the formula *(1)* are characterized by an action on the system's pressure

X—Trp—Ala—Val—Gly—His—Leu—Met—NH_2 *(1)*

X = H, carboxylic acid, amino acid, or dipeptide residue or protected derivatives or salts.

and a stimulatory action on the uterus, intestine, and gastric secretion, and they also increase the blood sugar level. They are prepared by known methods. [DOS 2137971; Societa Farmaceutici Italia, Milan]

[PR 11 IE -N]

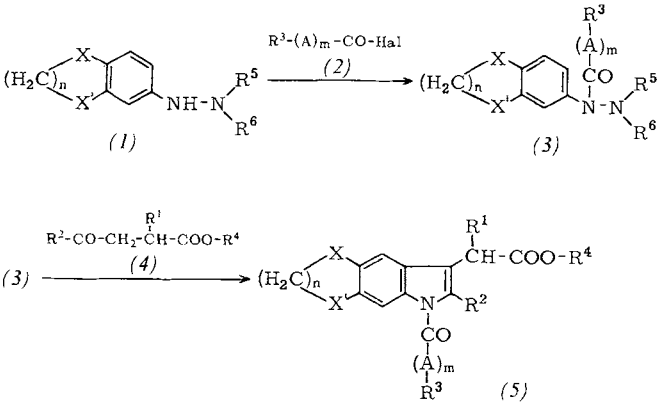
Insulin derivatives that cause only slight immunization and a method for their preparation are claimed. In these insulin derivatives (bovine and pig insulin), the terminal amino residue of the B chain (B_1, phenylalanine) is protected by an acyl residue or other blocking residue; the amino residue of the A chain (A_1, glycine) is either free or protected by an acyl residue or other blocking residue. Monosubstituted derivatives protected at B_1 are preferred. The protection can be readily achieved by known acylation processes, the content of acylating agent being kept low to obtain maximum yields of B_1-acylated insulin. [DOS 2023447; National Research Development Corp., London]

[PR 12 IE -N]

Monoacyl derivatives of insulin *(1)* **with improved physicochemical properties** are obtained as follows:

H—Gly—Ile— ..... (A-chain) ...
A—Phe—Val— ..... (B-chain) ... } *(1)*

A = alkanoyl, phenylalkanoyl, benzoyl, alkyloxycarbonyl, aralkyloxycarbonyl, aminoacyl.

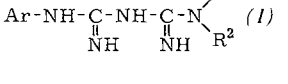


Insulin (preferably bovine and/or pig insulin) is treated with a mixture of an *N,N*-dialkylcarboxamide and an aqueous buffer solution (pH = 8.0—9.0) and an excess of *tert*-butyloxycarbonyl azide, and is then allowed to react with 2 to 4 equivalents of an activated ester of a carboxylic acid A—OH. The reaction product is then treated with a strong acid, *e.g.* trifluoroacetic acid. The new compounds, which are characterized *e.g.* by modified solubility coupled with full insulin activity, allow the production of preparations containing a component that dissolves more readily and one that dissolves less readily, so that a desired time-effect relationship can be produced. [DOS 2038121; Farbwerke Hoechst AG, Frankfurt/Main-Höchst]

[PR 14 IE -N]

A preparation containing L-3-(4-hydroxy-3-methoxyphenyl)-alanine and having an antiparkinsonian action is claimed. The active substance, which may also be present as a salt or hydrate, has a lower toxicity than L-dopa and a depot effect. By addition of one or more inhibitors of the peripheral decarboxylase, it is possible to reduce the quantity of active substance that must be administered. A process for the production of the preparation and a method for the treatment of parkinsonism are included in the idea of the invention. [DOS 2131616; F. Hoffmann-La Roche and Co. AG, Basel]

[PR 16 IE -N]



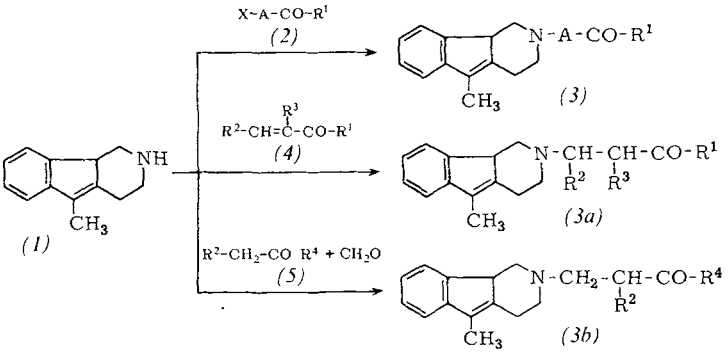
Antiphlogistic *N*-acyl-3-indolylacetic acid derivatives *(5)* are prepared by reaction of phenylhydrazine derivatives *(1)* with acyl halides *(2)* to form N^1-acyl compounds *(3)*, which are condensed with aliphatic keto acid derivatives *(4)*. The compounds *(5)* have antipyretic, analgesic, and antiphlogistic properties coupled with low toxicity. X, X' = —O—, —CH_2—; $m = 0, 1$; $n = 1,2$; A = substituted or unsubstituted saturated or unsaturated hydrocarbon residue

(up to C_5); R^1, R^2 = H, alkyl; R^3 = alkyl (C_{1-4}), cycloalkyl (C_{3-7}), unsubstituted or substituted aryl, monoalicyclic or polyalicyclic residue, heterocyclic residue; R^4 = H, alkyl (C_{1-4}), any cation; R^5, R^6 = H, protective group. [DOS 2142196; Sumitomo Chemical Co., Ltd., Osaka]

[PR 18 IE -N]

New biguanides *(1)* are prepared by condensation of an amine having the formula $ArNH_2$ or R^1R^2NH with a dicyanodiamide or an aryl derivative thereof. They have hypoglycemic and anorectic effects. Ar is a trifluoromethyl-

phenyl residue, which may be halogen-substituted. Possibilities for R^1 and R^2 are: R^1 and R^2 are H or a linear or branched alkyl residue containing 1—12 C atoms; R^1 is H, and R^2 is a cyclohexyl residue or a heterocyclic residue, which may be substituted with halogen atoms, lower alkyl residues, lower alkoxy residues, fluoroalkyl residues, tri-



haloalkyl residues, and/or nitro residues; R^1 and R^2 together with the nitrogen atom form a heterocycle. [DOS 1693036; Laboratories Laroche, Navarron]

[PR 19 IE -K]

The contraceptive reliability of the minipill can be improved by the daily administration of a combination of a progestagen and a progestin (ratio 10—30:1) instead of a gestagen. 17α-Ethynyltestosterone derivatives or 19-nortestosterone derivatives are regarded as progestins, and progesterone or retroprogesterone derivatives as progestagens. The dose of each component is lower than the dose of the same component that is required for reliable contraception when used alone as a minipill. [DOS 2146239; CIBA-Geigy AG, Basel]

[PR 27 IE -N]

1,3,4,9b-Tetrahydro-2*H*-indeno[1,2-*c*]pyridines *(3)* and their acid adducts are characterized by a pronounced inhibitory effect on open aggression in doses such that general depression of the central regulations is not yet detectable. They can be used for the treatment of hereditary or congenital disturbances of personality and for the prevention and treatment of mental illnesses. The compounds *(3)* can be obtained by reaction of the indenopyridines *(1)* with ketones *(2)* in the presence of an acid-binding agent. The compounds *(3a)* and *(3b)* can be obtained by reaction of *(1)* with the alkenes *(4)* in the presence of a base or by reaction of *(1)* with formaldehyde and the ketones *(5)* under the conditions of a Mannich reaction.

R^1 = lower alkyl, cycloalkyl, (substituted) aryl; A = alkylene (C_1—C_4)
X = acid residue of a reactive ester; R^2, R^3 = H, alkyl (C_1,C_2)
R^4 = lower *tert*-alkyl, (substituted) aryl.

[DOS 2046298; Sandoz AG, Basel]

[PR 26 IE -N]

BOOK REVIEWS

Biochemisches Praktikum (Manual of Practical Biochemistry). By *S. Heilenz, W. Höfner,* and *K. H. Neumann*. Bibliographisches Institut, Mannheim 1970. 1st Edit., 239 pp., 27 figures, bound, DM 8.90.

This laboratory course manual presents a collection of classical and modern methods of quantitative analysis for students of agricultural, forestry, and food sciences. It is intended to be covered in a two-semester course of 5 hours per week, and to provide students with a grasp of the possibilities for dealing quantitatively with their specific problems. The selection of methods is therefore almost entirely confined to the narrow field of fertilizer and plant ash analysis.

The first few sections, which are clearly based on direct practical experience, provide very exact and detailed introductions to the methods of gravimetric and volumetric analysis, flame photometry, and colorimetry. A few practical exercises are set in each case, but these are sometimes, as in the case of the colorimetric determination of Cu, highly colored by the circumstances of the particular application, or else the authors, as in the discussion of the further possibilities of spark spectroscopy or atomic absorption spectroscopy, have allowed their enthusiasm to carry them far beyond the bounds of a course manual. The presentation of the theoretical principles is readily comprehensible.

The chromatographic experiments are weak, the methods that are most important at present, such as gas chromatography, merely being reported. The radiochemical experiments are poorest of all. One receives the impression that these later parts of the book, which are treated unfeelingly, are too short, because of lack either of material or of time, and that they have been included mainly for show, though they constitute the most "biochemical" material of the entire course, since such an introduction becomes a handbook of practical biochemistry only if the biological aspect is not ignored. It is time for biochemists to resist the widespread misuse of their name. Where in this course is anything said about the living or surviving object? Only in the very briefly mentioned uptake of ^{32}P and ^{59}Fe in plant material. However, once the biochemist has overcome this disappointment and accepted the entire book as a slightly modified manual of practical analysis, it is a well-intentioned and well-produced book, from which the student and even the course supervisor can learn a great deal.

L. Jaenicke [NB 62 IE]

Foreign Compound Metabolism in Mammals. Vol. 1. Specialist Periodical Reports. Published by The Chemical Society, London, 1970. 1st Edit., iii, 455 pp., numerous figures and tables, bound £ 11.00.

The question of the metabolic fate of drugs, food additives, and pesticides has always been raised by biochemists and pharmacologists, but is also increasingly stirring the public conscience, following recent incidents that have shown the serious consequences, both for the individual

and for the community, that can result from the indiscriminate recommendation and use of such substances.

Toxicologists and clinical pharmacologists have the responsible task of investigating not only the mode of action but also the side reactions and breakdown of chemicals before they are placed on the market, and of pointing out possible dangers. In this work they make use of modern biochemical procedures and analytical methods, as well as their knowledge of biochemistry as a fundamental science. The information that has been acquired and collected here frequently allows *a priori* prediction of possible harmful effects and carcinogenic action, whether direct or *via* breakdown and transformation products. Nevertheless, there have been many surprises, which show the need for constant watchfulness, particularly since it is too easy to forget that extrapolations from one species of animal to another, or even to man, are unreliable, and that differences due to sex and condition exist even within the same species.

The present volume, which is the first of a series of progress reports on the metabolism of foreign compounds in mammals, deals with the absorption, distribution, and excretion of drugs, the kinetics of these processes, and the experimental labeling methods for the investigation of these pharmacodynamically important problems, as well as the transformations and transformation pathways of drugs in the mammalian organism as a function of age, sex, and state of development. It presents a modern and extremely topical survey of the pharmacological and other relevant literature of the 1960's. The publications, which were often widely scattered, have been collected, sorted, and above all presented critically and understandably from the chemist's point of view by several authors. The report does not mention the latest techniques of gas chromatography and mass spectrometry, which promise, individually and in combination, to become an important aid in the statics and dynamics of drug metabolism, or the bioactivation of drugs and inhibitors as an essential factor in their biological and therapeutic activity; however, the material presented is very carefully balanced in itself.

This work will be extremely useful to all clinical pharmacologists, toxicologists, and biochemists, as well as to interested chemists, as an up-to-date reference work. It also provides interesting reading, and goes into the principles and the development of the problems, so that it may provide the biologically less experienced chemist with new insights.

L. Jaenicke [NB 61 IE]

Radiochemie (Radiochemistry). By *W. Schulze*, Walter de Gruyter & Co., Berlin 1971. 1st Edit., 157 pp., 33 figures, stitched DM 7.80.

The book provides an introduction to the types of nuclear radiation, the interaction of radiation with matter, the measurement of radiation, working rules, and working methods of radiochemistry, as well as the preparation of radionuclides. Most radiochemical problems and some of the problems of nuclear chemistry are presented in a readily understandable fashion. The strength of the book lies in the concise manner in which the basic principles are presented. The text is well supported by tables and figures. The book is particularly suitable for chemistry students desiring an introduction to the field of radiochemistry, but will also be extremely useful to other scientists who wish to familiarize themselves with the fundamentals of radiochemistry. The subject index could have been somewhat more detailed; moreover, familiarization with the field would have been facilitated by a list of further reading.

Knut Bächmann [NB 63 IE]

Chemical Energetics. By *N. J. Selley*. Edward Arnold Ltd., London 1971. 1st Edit., ix, 209 pp., numerous tables, bound £ 3.20.

The author of this little book attempts to give an introduction to chemical thermodynamics, *e.g.* within the scope of a first course with exercises on general chemistry. The book contains many exercises (with solutions at the end of the book), fully worked examples, and instructions for practical experiments, as well as a (rather skimpy) subject index, a table of four-figure logarithms, and tables of atomic weights, bond energies, redox potentials, *etc.* It is therefore a textbook and a laboratory manual all in one.

The book is practically free from printing errors and is well laid out. Unfortunately, it has little pedagogical value and the writing is sloppy in places. It may be pardonable, when symbols like +ve (for "positive") or RMS (for "root mean square") are not explained anywhere in the book, since these are probably familiar to the English readers for whom the book was written. However, inadequacies stand out when definitions become ambiguous (*e.g.* on p. 9, $1\ \text{eV} = 1.6 \times 10^{-19}$ J is followed by 1 eV/mol $= 96487\ \text{J mol}^{-1}$) or when concepts are obscured (as *e.g.* van der Waals forces on p. 49). It almost seems to be a principle of the author to use a new concept first and to explain it later (*e.g.* the relation $\Delta G = -2.3\ RT \log K$ on p. 31 or the salt bridge on p. 36). Also awkward is the introduction of the entropy concept ($\Delta G = \Delta H - T \cdot$ something), and inept wording is too common to be overlooked (*e.g.* on p. 40 "... the sign of ΔS cannot be predicted, but is probably small..." or on p. 69 "As the efficiency of the harnessing of the work of reaction is made more efficient, the net gain of entropy is reduced", *etc.*). And that the reaction rate be proportional to $e^{-1/T}$ (p. 85) or that the kinetic energy be quantized (p. 59) can at best be described as misleading.

At most, therefore, the book has some value as a collection of exercises. However, in view of the outstanding books on chemical thermodynamics that already exist in German and in English, it cannot really be recommended to anyone.

Günther v. Bünau [NB 64 IE]

Organic Photochemical Syntheses. Vol. I. By *R. Srinivasan* and *T. D. Roberts*. Wiley-Interscience, New York—London 1971. 1st Edit., x, 108 pp., numerous figures and tables, bound £ 4.75.

The present volume, which is the first of a planned series, corresponds in style and layout to the well-tried pattern of "Organic Syntheses". A brief introduction to photochemical techniques, with mention of a number of safety precautions (17 pages), which is not intended to replace the study of more comprehensive systematic monographs (*e.g. A. Schönberg, G. O. Schenck,* and *O. A. Neumüller*: Preparative Organic Photochemistry. Springer, Berlin 1968), is followed in varied succession by 39 detailed procedures from 28 research groups, nearly all of which have been independently checked. This provides even the non-photochemist with easy access to 20 products containing four-membered rings and five products with three-

membered rings. The other examples deal with syntheses of products containing five-membered (three cases), six-membered (two cases), and eight-membered rings (one case), four isomerizations without ring formation in the end product, three oxidations, and one aromatic substitution.

The arrangement into structural formulas, authors, "Procedure", "Notes", "Methods of Preparation", and "Merits of the Preparation" in many cases enables the reader to find information that is not contained in the original publications. The concluding "References" cannot give complete coverage of the literature, which is unfortunate, since a complete collection of all the procedures published so far (*e.g.* including *H. M. Frey*, J. Chem. Soc. *1964*, 365, for the synthesis of quadricyclane) could be particularly useful to the non-photochemist, as the equipment listed in the examples in the volume may be unavailable in many cases.

It is to be hoped that further photochemists will be prepared to help with the later volumes, and that the selection of the examples will be based mainly on preparative considerations. "Organic Photochemical Syntheses" will then prove useful both in practical instruction and in research, and should be available in any library where these aspects are important.

Gerd Kaupp [NB 65 IE]

Polymer Networks—Structural and Mechanical Properties. By *A. J. Chompff* and *S. Newman*. Plenum Press, New York—London 1971. 1st Edit., xiv, 493 pp., numerous figures, bound $ 31.50.

The book contains 22 papers presented at a Symposium of the American Chemical Society in Chicago in September 1970 by distinguished scientists such as *P. J. Blatz*, *K. Dušek*, *M. Gordon*, *R. F. Landel*, *W. Prins*, and *M. L. Williams* on the subject of "Highly Crosslinked Polymer Networks". The discussions are appended to the papers.

The first ten papers are concerned with the network as a continuum. They deal with the kinetics of the crosslinking processes, the macrothermodynamics and the microstatic mechanics of networks, and the influence of the network structure and intermolecular forces on the glass transition temperature and the mechanical properties. The next twelve papers deal with the particularly important question of the inhomogeneities and heterogeneities of networks in a wide variety of forms. Four papers discuss the methods for the characterization of such networks by means of birefringence and light scattering. The importance of the microstructure to swelling and to the stress-strain behavior up to breakage is finally discussed in several papers.

The proceedings of the ACS Symposium do not have the character of a textbook with the integrated form of a monograph. Their main significance is the topicality of the various contributions. The book, a remarkable review of the most important developments in the field of crosslinked polymers, includes many results of recent research and provides an excellent supplement to former publications, *e.g.* to those by *Kuhn*, by *Treloar* and *Dušek*, and by *Prins*. Chemists, physicists and engineers with the necessary background find up-to-date information of research and development in the field of crosslinked polymers.

Dieter Heinze [NB 66 IE]

Organic Peroxides. Vol. 2. By *D. Swern*. Wiley-Interscience, New York—London 1971. 1st Edit., ix, 963 pp., numerous figures and tables, bound £ 19.00.

The new volume of *Swern's* work has followed the first[1] in a gratifyingly short time. Of the eight chapters in the volume, those by *Mair* and *Hall*: "Determination of organic peroxides by physical, chemical, and colorimetric methods" and by *Silbert*: "Physical properties of peroxides" deserve special mention because of their general interest, particularly since there were no similar modern reviews of these fields.

However, the other chapters (*Hiatt*: Hydroperoxides, *Sosnovsky* and *Rawlinson*: The chemistry of hydroperoxides in the presence of metal ions, *Sosnovsky*: Metal-ion catalyzed reactions of hydrogen peroxide and peroxydisulfate, *Davies*: Formation of organometallic peroxides by autoxidation, *Swern*: Organic peroxy acids as oxidizing agents. Epoxidation, and *Hiatt*: Acyl peroxides) are also valuable and exhaustive monographs on these fields, which are of great interest in part even to the inorganic chemist. Lavish use has been made of figures and tables throughout. An example is provided by a list of all expoxidations carried out since 1952, amounting to about 1600, arranged according to the peracid used. The total of almost 4000 references evaluated and the 32-page subject index also testify to the diligence of the authors and of the editor.

This work, which is practically free from errors and excellent in its presentation, is a necessity for any library. It is with keen anticipation that we look forward to the third and final volume.

Rudolf Criegee [NB 68 IE]

Crystal Chemistry and Semiconduction. By *J. P. Suchet*. Academic Press. New York—London 1971. 1st Edit., xvii, 380 pp., numerous figures, bound $ 22.—.

The book was written to provide scientists working on semiconductors in university polytechnics and in industry with a survey of the developments of the past 20 years and of the present research position in the difficult field of semiconducting binary compounds of the transition metals, the lanthanoids and the actinoids. The author is a chemist, and he can thus appreciate the great variety of the compounds investigated and their properties, and present the material in an orderly fashion.

The first 80 pages are spent in laying the theoretical foundations for the description of the bonding in crystals. In earlier years the author built up a classification that is partly his own, and this forms the basis of the book. The language is thus defined, and the reader is then in a position to translate a described situation into concepts with which he is familiar.

In the second part of the book (200 pages), the relationships between crystal structure, chemical bonding, and physical properties are discussed. The presentation intentionally avoids what the author, with some justification, calls the often "esoteric" tendencies of solid-state physicists. There are frequent hints of the author's own experience and of his familiarity with experimental work. The treatment of the compounds with IIIB, IVB, and VB elements is fairly short (45 pages); this is a reflection of the large amount of investigation that still remains to be carried out on these compounds. Considerable space (80 pages) is devoted to the oxides, while the chalcogenides occupy 50

pages. The topics discussed include the phase relations, the crystal structures, the electric, magnetic and sometimes also the optical properties. Conflicting experimental and theoretical results are considered critically. Observations for which no explanation has been found are also mentioned. The author expresses himself very briefly. He evidently places special value on complete coverage of the literature, since more than 1000 original publications to which the reader can and should refer are cited in this second part of the book.

The third part (60 pages) deals with some problems of major interest and with future applications, particularly with magnetic properties in their relation to electric and optical properties.

Comprehensive formula, author, and subject indexes enhance the value of the book.

The book has filled a need, since there had previously been no survey of the results obtained in this field. It can serve as an introduction for those with sufficient background knowledge, while it should stimulate experimental and theoretical workers to further research.

One disadvantage should not pass without mention. The captions to the figures, most of which have been taken from the literature, are frequently too brief, and the meanings of the symbols are often not explained.

Heinz Krebs [NB 69 IE]

The Alkaloids. Vol. 1. Specialist Periodical Reports. Published by The Chemical Society, London 1970. 1st Edit., xiii, 505 pp., numerous figures, bound £ 11.—.

The well-known series of reviews now examines another field of the chemistry of natural products, *i.e.* the chemistry of the alkaloids. The present book in every respect maintains the high standard set by earlier volumes (*e.g.* in the series: Amino Acids, Peptides, and Proteins). It covers works from the entire field of alkaloid chemistry in 1969 and in the first half of 1970; only publications on steroid alkaloids from the families *Solanum* and *Veratrum* have not been considered. The book also contains chapters on the biosynthesis of the indole alkaloids and also of the other alkaloids.

For the specialist, the volume is a valuable source of references (even to less readily accessible periodicals) and of detailed information. Chemists who are interested in natural products in general will also find this review very useful. The main directions that have been taken in recent years by the chemistry of the alkaloids are pointed out.

The volume reviewed here and the series that it introduces will be essential to all those who are concerned with natural products. It is to be hoped that the new publication will find many attentive readers.

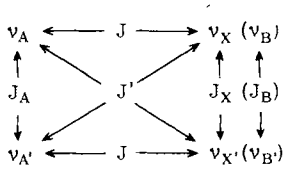
^{1}H-NMR Spectra of the AA'XX' and AA'BB' Type – Analysis and Classification[**]



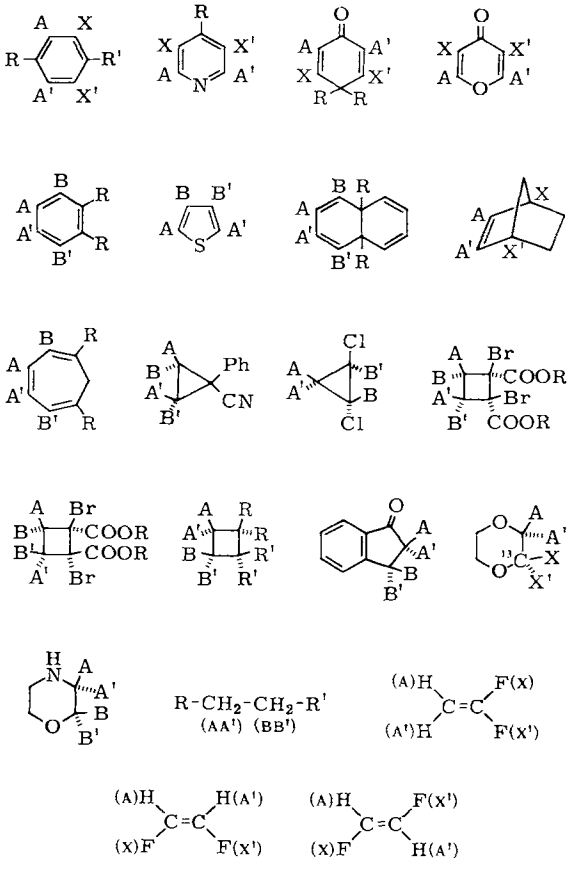
By Harald Günther[*]

It is shown how the secular determinant for the general four-spin case can be greatly simplified in the case of NMR spectra of the AA'XX' and AA'BB' type on the basis of molecular symmetry and with the aid of the so-called X approximation. The methods for the direct analysis of these spectra are presented, and the relations between the type of spectrum and the chemical structure are discussed in detail for selected examples. In an appendix, parallels are pointed out between the formalism of the Hückel MO theory and the calculation of the eigenvalues and eigenfunctions of nuclear spin systems.

1. Introduction

The theory of high resolution NMR spectra of nuclei with spin $^1/_2$ is now substantially complete, and numerous methods are available for the analysis of these spectra[2]. Analytical methods that are particularly important in practice are those that enable the desired information about the resonance frequencies and coupling constants of a spin system to be obtained directly from the observables, *i.e.* the line frequencies and intensities. However, the application of these *direct methods* is generally confined to spin systems with less than five nuclei, and a certain molecular symmetry is usually required.

Among the more complicated spectra for which direct analysis is possible are those of AA'XX' and AA'BB' spin systems. They are characterized by two resonance frequencies ν and four coupling constants J, *i.e.* the A and the X(B) nuclei are chemically, but not magnetically equivalent:



As can be seen from Table 1, these types of spectra are of wide occurrence for organic molecules; their analysis provides valuable information about the structure, configuration, and conformation of the compounds in question.

The mathematical formalism necessary for the *synthesis* of an NMR spectrum—*i.e.* the calculation of line frequencies and intensities from a set of resonance frequencies ν_i and coupling constants J_{ij}—also forms the basis of the HMO model[3], which rightly occupies an important place at present in chemical education. This parallel, which is almost trivial as far as the theory is concerned,

[*] Prof. Dr. H. Günther
Institut für Organische Chemie der Universität
5 Köln, Zülpicher Strasse 47 (Germany)

[**] This review supplements the earlier progress report in this journal by *Dischler*[1].

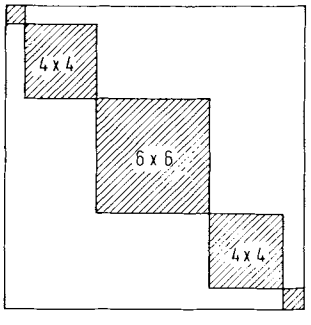
Table 1. Molecules with NMR spectra of the AA'XX' or AA'BB' types.

but which is only rarely recognized because of the still prevalent unfamiliarity with quantum-mechanical principles, will be shown in an appendix (Section 4). It will suffice for the present to point out that for the direct *analysis* of an NMR spectrum, *i.e.* the determination of the parameters ν_i and J_{ij} from the observed line frequencies, the mere reversal of the mathematical formalism mentioned, which at first seems the obvious course, is possible only in the two-spin case. In this case, the solution of the secular determinant[4] leads to quadratic equations, which can be explicitly solved. This leads to the well-known relations for the AB system[1]:

$$\delta\nu = \nu_A - \nu_B = \sqrt{(J_4 - J_1)(J_3 - J_2)} \quad (1)$$

$$|J| = J_4 - J_3 = J_2 - J_1 \quad (2)$$

All spin systems with more than two nuclei, on the other hand, have secular determinants of higher order, which generally no longer allow the derivation of similar equations. It is therefore an important object of the direct spectral analysis to simplify the secular determinant in such a way that it can be factorized into subdeterminants of the order two[5]. This can be achieved in favorable cases on the basis of the symmetry of the spin system or with the aid of the "X approximation"[6].



The significance of these principles will be illustrated below for AA'XX' and AA'BB' systems. By their application, the more complicated AA'XX' four-spin system may be regarded as a superposition of a_2 and ab subspectra—*i.e.* simple two-spin systems. On the one hand, a direct analysis is possible in this way, and on the other, the diversity of the experimental spectra can be systematically discussed, to a close approximation even for the AA'BB' case. For the derivation of a series of concepts that will be used in the next section, the reader is referred to the introductory article by *Dischler*[1] and to the appendix (Section 4).

2. Direct Analysis of AA'XX' and AA'BB' Systems

For the general four-spin case, the basis functions for the characterization of the spin states are, as usual, the products φ_k of the spin functions α and β, of which there is a total of 16 in the present case:

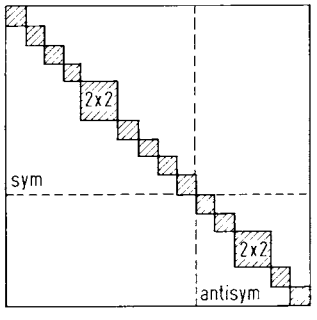
$m_T = +2$	$m_T = +1$	$m_T = 0$	$m_T = -1$	$m_T = -2$
(1) αααα	(2) βααα	(6) ββαα	(12) βββα	(16) ββββ
	(3) αβαα	(7) βαβα	(13) ββαβ	
	(4) ααβα	(8) βααβ	(14) βαββ	
	(5) αααβ	(9) αβαβ	(15) αβββ	
		(10) αββα		
		(11) ααββ		

The secular determinant that is derived on the basis of the variation method[3, 52] using eq. (A 2) and the Hamiltonian operator eq.(A6) is therefore of the order 16. Since only basis functions with the same total spin m_T mix with one another, it factorizes into subdeterminants of the order 1, 4, 6, 4, and 1:

(3)

For the AA'XX' system, much greater simplification results from the additional consideration of the symmetry and the application of the "X approximation".

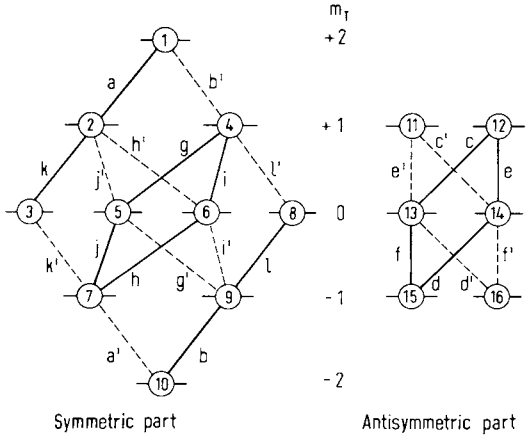
First, instead of using the usual product functions as the basis, it is possible to use the products of the symmetry functions s_{+1}, s_0, s_{-1} and a_0, such as are known for the A_2 system[2] (cf. Appendix), and which are valid here for the AA' and for the XX' nuclei. If the resulting basis functions are arranged according to the total spin $m_T(X)$ of the XX' group, one obtains Scheme 1. A similar result is obtained if the functions are arranged according to $m_T(A)$ instead of $m_T(X)$.



The result of this consideration is:

1. The separation of the basis functions into a symmetric and an antisymmetric set, between which transitions are forbidden by symmetry[2, 54].

	Symmetric product functions		
m_T			
+2	(1) $s_{+1}(A)\ s_{+1}(X)$		
+1	(2) $s_0\ (A)\ s_{+1}(X)$	(4) $s_{+1}(A)\ s_0(X)$	
0	(3) $s_{-1}(A)\ s_{+1}(X)$	(5) $s_0(A)\ s_0(X)$ (6) $a_0(A)\ a_0(X)$	(8) $s_{+1}(A)\ s_{-1}(X)$
−1		(7) $s_{-1}(A)\ s_0(X)$	(9) $s_0\ (A)\ s_{-1}(X)$
−2			(10) $s_{-1}(A)\ s_{-1}(X)$
$m_T(X)$	+1	0	−1
	Antisymmetric product functions		
m_T			
+1	(11) $a_0(A)\ s_{+1}(X)$	(12) $s_{+1}(A)\ a_0(X)$	
0		(13) $a_0(A)\ s_0(X)$ (14) $s_0(A)\ a_0(X)$	
−1		(15) $s_{-1}(A)\ a_0(X)$	(16) $a_0(A)\ s_{-1}(X)$
$m_T(X)$	+1	0	−1



Scheme 1. Products of the symmetry functions s_{+1}, s_0, a_0 and s_{-1} of the A_2 system (cf. Section 4). The symmetry of the products obeys the general rule that products of functions of like symmetry are symmetrical, while those of functions of unlike symmetry are antisymmetrical.

2. The extensive factorization of the secular determinant on the basis of the "X approximation", according to which states with different $m_T(X)$ (or $m_T(A)$) values do not mix[2, 6]. The corresponding offdiagonal elements are therefore zero. The secular determinant (3) thus simplifies to (4), and apart from twelve subdeterminants of the order 1, whose elements H_{kk} are already correct eigenvalues of the AA'XX' system, it now contains only two subdeterminants of the order 2:

(4)

The simplification resulting from this treatment becomes particularly clear when one arranges the functions of Scheme 1 or the eigenfunctions calculated in accordance with (4) in an energy level diagram. Considering the transitions possible on the basis of the selection rules[1, 2],

Scheme 2. Energy level diagram of the AA'XX' and AA'BB' systems.

the structures of simple systems of the A_2 and AB types (Scheme 2) are immediately recognized. The AA'XX' system is thus reduced in the AA' and XX' parts to two a_2 and two ab subsystems each, which can be analyzed directly. They are represented in Figure 1 for a typical example by the line pairs a, k, and b, l, and by the quartets c, d, e, f and g, h, i, j.

The quantitative treatment[6], which we shall not give here, provides proof that the subsystems mentioned are in fact spectra of the A_2 and AB type. Moreover, it also leads to the relations between the effective spectral parameters of the subsystems, the shift differences N and L and the coupling constants K and M as defined in Figure 1, and the data for the AA'XX' system:

$$N = J + J';\ L = J - J';\ K = J_A + J_X;\ M = J_A - J_X \tag{5}$$

With the aid of the expressions (1) and (2), the following equations are derived for the direct analysis of the AA'XX' system:

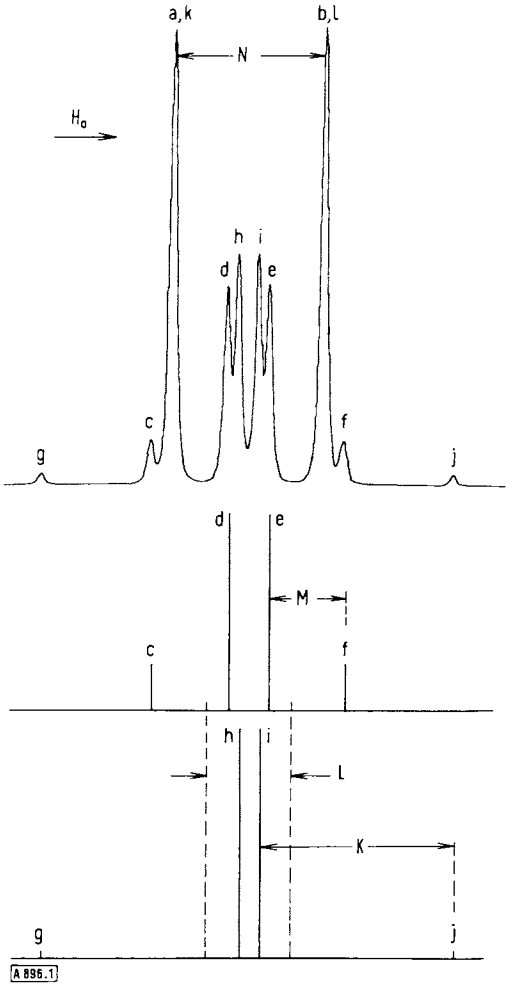
$$N = a - b \tag{6}$$

$$L = \sqrt{(c-f)(d-e)} = \sqrt{(g-j)(h-i)} \tag{7}$$

$$K = g - h = i - j \tag{8}$$

$$M = c - d = e - f \tag{9}$$

As expected, because of the "X approximation", $\delta\nu(AX)$ does not appear in these relations. The AA'XX' system is thus independent of the relative chemical shift between A and X nuclei. The spectrum is symmetrical with respect to $(\nu_A + \nu_X)/2$, and each half spectrum is symmetrical with respect to ν_A or ν_X. The analysis does not allow the assignment of the resonance frequencies that are determined directly as center of the AA'- and XX'-part, respectively, or of the coupling constants J and J' or J_A and J_X, since the spectrum is unaffected by an interchange of the nuclei within one group or of the A and X nuclei, *i.e.* it is independent of the relative signs of N and L as well as K and M. It is therefore necessary to make use of the empirical relations between coupling constants and chemical structure, which give a conclusive answer in practically every case. For the resonance frequencies, the necessary clue is often provided by an asymmetry of the spectrum due to long-range coupling. Since N may be differentiated from



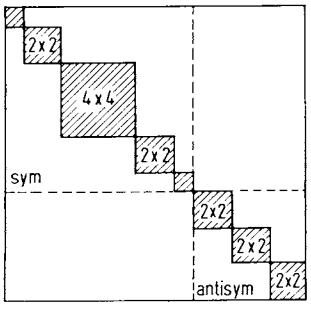


Fig. 1. Half-spectrum of an AA'XX' system ($J = 8.0$, $J' = 2.0$, $J_A = 9.0$, and $J_X = 4.0$ Hz) with antisymmetrical (c, d, e, f) and symmetrical (g, h, i, j) ab subspectra. Line designation after [9].

L, however, the relative signs of J and J' are obtained. For $|N| > |L|$, the signs are like, while for $|L| > |N|$ they are unlike. Equation (7) is decisive for the assignment of lines to the symmetrical and the antisymmetrical quartets, though the origin of the ab subspectra in the experimental spectrum may not be recognized. K and M cannot, therefore, be distinguished without further experiments (cf. Section 3.7), and the relative signs of J_A and J_X remain undetermined.

If we consider the AA'BB' system, the direct analysis is complicated by the fact that the spectrum now depends on the parameter $\delta\nu$(AB). The "X approximation" can no longer be applied, and the classification of the basis functions according to m_T(B) is lost. The secular determinant has the following form:

(10)

In the symmetrical part of the spectrum, therefore, the subdeterminant of order 4 prevents a simple solution. However, if one makes use of the theorem that the trace of the secular determinant is zero, *i.e.*

$$H_{44}+H_{55}+H_{66}+H_{77} = E_4+E_5+E_6+E_7$$

then equations can also be derived for the direct analysis of AA'BB' spectra[7–9]. These equations are given in Table 2. Further equations for special cases in which not all of the transitions are observed, as well as intensity relations[9, 10], are also known.

Table 2. Equations for the direct analysis of AA'BB' systems (after [9]). Line frequencies have to be measured with respect to the center of the spectrum at $(\nu_A+\nu_B)/2$.

$$\begin{aligned}
\delta\nu &= +\sqrt{4\,ab} \\
&= +\sqrt{2(ce+df)} \\
N &= a-b \\
K &= g+i+k-2a-l \\
&= 2b+k-h-j-l \\
&= b+g+k-a-h-l \\
&= b+i+k-a-j-l \\
M &= (ce-df)/\delta\nu \\
L &= +\sqrt{(c-e)^2-M^2} \\
&= +\sqrt{(d-f)^2-M^2}
\end{aligned}$$

An important difference between the AA'XX' system and the AA'BB' system is that in the latter case, the line groups a,k/b,l and c,d,e,f/g,h,i,j can no longer be regarded as a_2 or ab subsystems. The degeneracy of the line pairs a,k and b,l is lost, and the half-spectrum consists of twelve transitions. These are no longer symmetrical with respect to ν_A or ν_B, but the spectrum is still symmetrical with respect to the center $(\nu_A+\nu_B)/2$ (cf. *e.g.* Fig. 3). For very small $\delta\nu$(AB), the half-spectra may partly overlap, and the assignment of the lines will then be more difficult. The following distance relations still exist for the line groups of the symmetric and antisymmetric quartets

$$c-d=e-f \quad \text{and} \quad g-h=i-j.$$

Furthermore

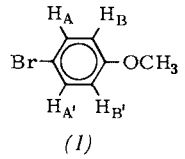
$$g-a=b-j \quad \text{and} \quad a-i=h-b.$$

The direct analysis here yields definite values for the parameters $\delta\nu$, N, L, K, and M, and in addition the relative signs of K and N. The relative signs of all the coupling constants are therefore obtainable. The assignments of the resonance frequencies and of the coupling constants J and J' on the one hand and J_A and J_B on the other, however, are still undetermined. The variety of the possible types of spectra and their relations to chemical structure are discussed in the next section.

3. Classification of Spectra of the AA'XX' and AA'BB' Types

The central problem of the direct analysis of AA'BB' spectra is to find the correct line assignment. Computers[11, 12] or experimental aids (cf. Section 3.7) may be used for this

purpose. However, it is important to recognize the relations between the expected coupling parameters, *i.e.* ultimately the chemical structure, and the type of spectrum. The reduction of the AA'XX' four-spin system to a_2 and ab subspectra allows the systematic discussion of these relations. With regard to proton resonance, however, it should be noted that the AA'XX' type is only approximately realized here, since the differences in the shifts are strictly speaking too small for the "X approximation" to be valid, that is fully acceptable only in the case of heteronuclear spin systems, such as ^1H, ^{13}C or ^1H, ^{19}F combinations. Nevertheless, the AA'XX' approximation is adequate here for a qualitative discussion, if it is realized that the AA'BB' treatment must always be used for accurate analysis in the case of homonuclear spin systems. Furthermore, efforts will always be made to check the line assignment derived by the calculation of a test spectrum using one of the relevant programs[11]. Misassignments may thus be avoided by a careful comparison of calculated frequencies and intensities with the experiment. In addition, an improvement of the parameters may be obtained in most cases by the application of an iterative computing process[11], since in this case all the experimental information is used likewise. In contrast, the direct analysis is based mainly on the lines a—f (cf. Table 2).



3.1. *p*-Disubstituted Benzenes of the Type XC_6H_4Y

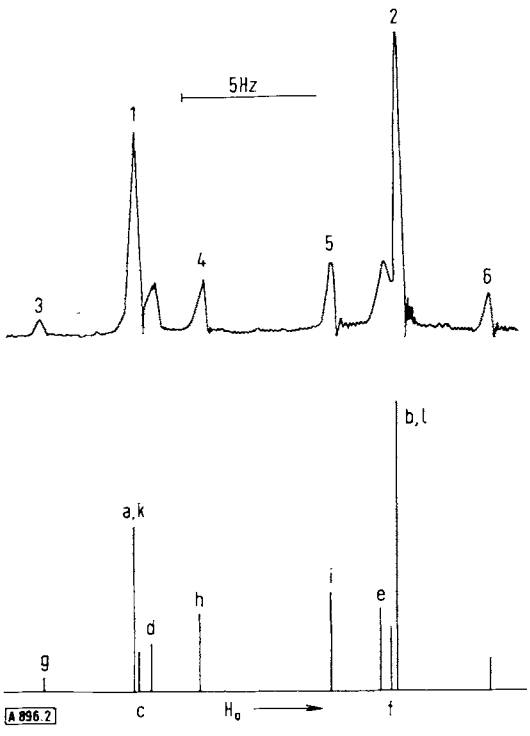
The typical appearance of the spectrum for this group of substances[13] and for a series of other compounds such as 4-pyrone[14, 15], 2,5-cyclohexadienones[16], and 4-substituted pyridines[17] is illustrated in Figure 2 by the spectrum of *p*-bromoanisole *(1)*[13]. It is easy to interpret if the coupling constants to be expected for the molecule, all of which are positive, are considered: Here $J \gg J'$, J_A, and J_B.

The parameter N then consists of the relatively large *ortho* coupling (J) and the smaller *para* coupling (J'). The two a_2 subspectra are thus separated by about 7—9 Hz, and can be immediately assigned to the strong lines 1 and 2. A value of about 5—7 Hz is then found for the parameter L. On the other hand, the effective coupling parameters K and M of the ab subsystem are very different in the present case, since the remaining two *meta* couplings (J_A and J_X) are similar in magnitude. M is therefore generally smaller than 1 Hz, whereas a magnitude of about 4—6 Hz is to be expected for K. The symmetrical ab quartet (g, h, i, j) is clearly visible, whereas only the inner lines (d, e) of the antisymmetric quartet can be recorded. The outer transitions (c, f) coincide with the a_2 subsystems, and the parameter M can therefore be determined only inaccurately. In the case of the 2,5-cyclohexadienones, on the other hand, the lines c and f can be satisfactorily measured[16].

3.2. *o*-Disubstituted Benzenes of the Type $C_6H_4X_2$

Here one finds spectra that differ considerably from the AA'XX' limit in the majority of cases, since the relative chemical shift is generally small. For the coupling parameters the relation $J, J_A \gg J', J_B$, that is $N \approx L$ and $K \approx M$, holds. The result is that the lines a,k and b,l are no longer

(1)



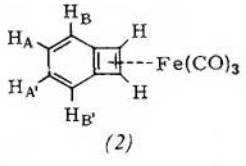


Fig. 2. Half-spectrum (AA' part) of the AA'BB' system of the aromatic protons in *p*-bromoanisole *(1)*: spectrometer frequency 60 MHz. The analysis gave $\delta\nu = 37.8$, $K = 5.6$, $L = 8.4$, $M = 0.5$, and $N = 9.0$ Hz (after [13]).

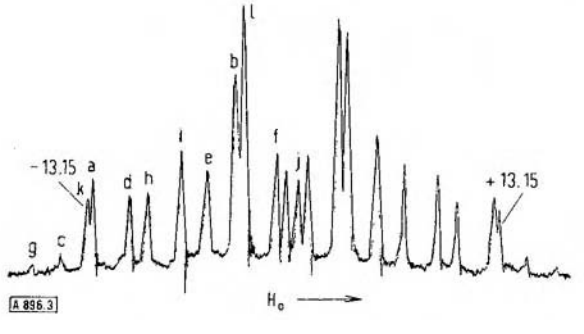
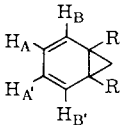
degenerate, and the A lines f and j are displaced in some cases past the center, *i.e.* into the B part. Moreover, the intensities of the lines c and g are greatly reduced. Figure 3 shows the spectrum of the six-membered ring protons in benzocyclobutadienetricarbonyliron *(2)*[18], as obtained with decoupling of the two four-membered ring protons.

(2)





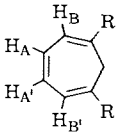


Fig. 3. AA'BB' system of the six-membered ring protons in benzocyclobutadienetricarbonyliron *(2)* with decoupling of the four-membered ring protons; spectrometer frequency 100 MHz. The analysis of the spectrum gave: $\delta\nu = 13.50$, $J = 8.61$, $J' = 0.69$, $J_A = 6.78$, and $J_B = 1.57$ Hz (after [18]).

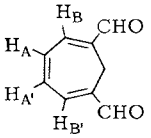
Similar systems are found for thiophene[15, 19] and for substituted cyclohexadienes[20]. It is relatively simple here to determine the parameter N, since the strong lines a and b can be easily located. This information proves to be an important aid in the assignment of structures for norcaradiene-cycloheptatriene isomers, since N values of 9—11 and 5—6 Hz are found for systems of the types *(3)* and *(4)*, respectively, because of the different positions of the double bonds.

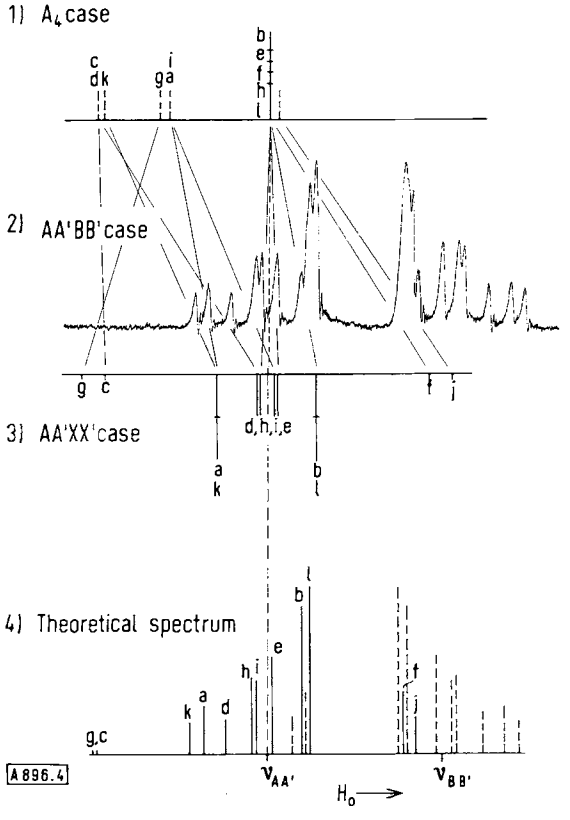


(3)

(4)

For strongly coupled spin systems, *i.e.* systems with small $\delta\nu$, according to *Dischler*, the assignment[9] is often possible by calculation of the A_4 and the AA'XX' limiting cases with estimated parameters and examination of the frequency changes of the various lines. Comparison of this interpolation between A_4 and AA'XX' systems with the experimental spectrum then shows the extent to which line superpositions occur or the regions in which lines of low intensity may be expected. This method was used, as shown in Figure 4, in the analysis of the four-spin system of the olefinic protons in cycloheptatriene-1,6-dialdehyde *(5)*[21], where, because of the large vicinal coupling $J_{3,4}$, the parameters K and M (12.27 and 10.93 Hz respectively) are much larger than the parameter L (5.31 Hz). One obtains $\delta\nu = 11.83$, $J_A = 11.60$, $J_B = 0.67$, $J = 6.03$, and $J' = 0.72$ Hz.

(5)



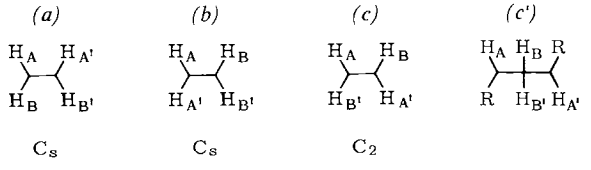


Fig. 4. AA'BB' system of the olefinic protons in cycloheptatriene-1,6-dialdehyde *(5)* with A_4 and AA'XX' limiting cases; spectrometer frequency 100 MHz (after [21]). The definite assignment h > i is possible here only on the basis of the iterative computer analysis.

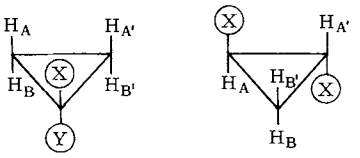
3.3. Substituted Cyclopropanes, Cyclobutanes, and Five-Membered Rings



Depending on substitution, a CH_2-CH_2 fragment is expected to give one of three types of AA'BB' systems, which differ in their coupling parameters because of differences in local symmetry (C_s or C_2):

Three-membered rings normally give spectra of type *(a)* and, in addition, those of type *(c')*. Thus for 1,1-disubstituted cyclopropanes [*(6)*, type *(a)*][22], the magnitudes of the *cis* coupling constants are similar, so that a large difference exists between the parameters K and M in the sense $|K| \gg |M|$. Because of the negative sign of the geminal spin-spin interaction, moreover, $|N| \ll |L|$. As is shown in Figure 5 for 1,2-bis-(1-cyanocyclopropyl)ethylene, therefore, the lines a and b are situated close together, as are the lines c and d as well as e and f. The outer lines of the symmetrical quartet (g, j) are difficult to locate, since g has a low intensity and j is displaced past the center.

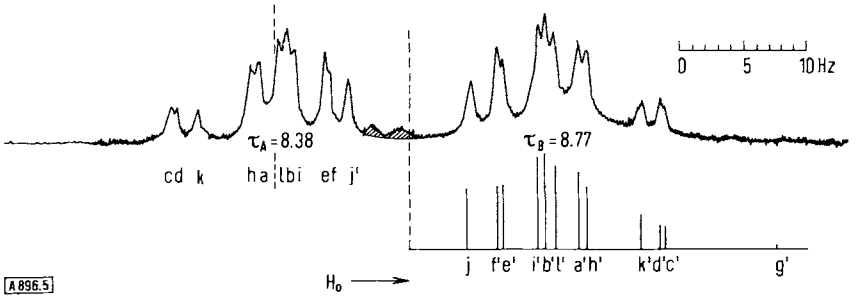
For the type *(c')* [*(7)*], in contrast with the case described above, $|K| \ll |M|$ and $|N| \gg |L|$[23, 24], so that an entirely different appearance is found. Finally, the type *(b)* is found for the ^{13}C satellite spectra of 1,1-disubstituted cyclopropanes with X = Y. In this case, $J_A = J_X$, *i.e.* $M = 0$. If K is also very large, the half-spectrum consists of five lines having an intensity ratio 2 : 1 : 2 : 1 : 2, as is found for the ^{13}C-satellites of the ^{19}F resonance of 1,1-dichloroperfluorocyclopropane[25].

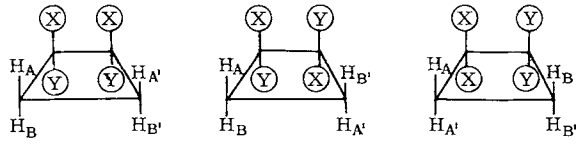
The symmetry in four-membered rings is again either C_s or C_2 [*(8)* or *(9)*], depending on the substitution type. However, the resulting spectra do not differ appreciably, and resemble the spectrum of *(6)*[26]. In the case *(8)*, the parameters N and L are found to be $^2J \pm {}^3J_{trans}$, and in case *(9)* $^2J \pm {}^3J_{cis}$; the corresponding expressions for K and M are $^3J_{cis} \pm {}^3J_{cis}$ and $^3J_{trans} \pm {}^3J_{trans}$, respectively. Another substitution type with C_s symmetry [*(10)*] leads to spectra of a type that has been discussed in detail for indanone *(11)*[27]. In this case $N = {}^3J_{cis} + {}^3J_{trans}$, $L = {}^3J_{cis} - {}^3J_{trans}$, $K = {}^2J_A + {}^2J_B$, and $M = {}^2J_A - {}^2J_B$. It was found for *(11)* that $\delta\nu = 33.04$, $K = -37.13$, $L = 5.12$, $M = 1.79$, and $N = 12.10$ Hz, so that only the lines h and i are measured for the symmetrical quartet, as shown in Figure 6.

(6) (7)

3.4. Larger Ring Systems

Because of the conformational mobility of ring systems with more than five members, some of the measured coupling parameters are time averages. If we consider the ethane fragment in morpholine in a Newman projection,





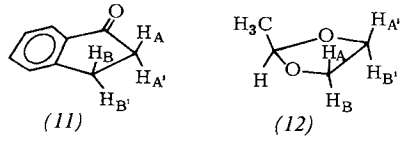


Fig. 5. 60 MHz AA'BB' spectrum of the three-membered ring protons in 1,2-bis(1-cyanocyclopropyl)-ethylene. The analysis gave: $\delta\nu = 39.1$, $J = -5.0$, $J' = 7.6$, $J_A = 9.6$, and $J_B = 9.2$ Hz (after [9]).

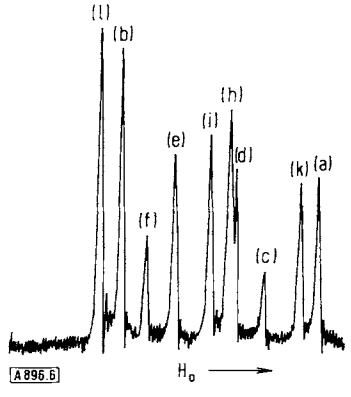
A type of spectrum that is similar to the type found for the disubstituted cyclopropane *(6)* is observed for 2-methyl-dioxolane *(12)*[28] and for ethylene sulfite[29]. In this case,

(8) (9) (10)

$J_A \approx J_B$, so that M is approximately zero. The AA'BB' half-spectrum generally consists of only ten lines, since the line pairs c,d and e,f may be resolved only under optimum conditions[2c].

(11) (12)



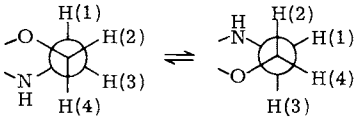


Fig. 6. Half-spectrum (BB' part) of the CH_2-CH_2 grouping in indanone *(11)*; spectrometer frequency 60 MHz (after [27]).

it is clear that the fast reversible ring inversion leads to a transition from the ABCD to the AA'XX' type of spectrum:

(13) *(14)*

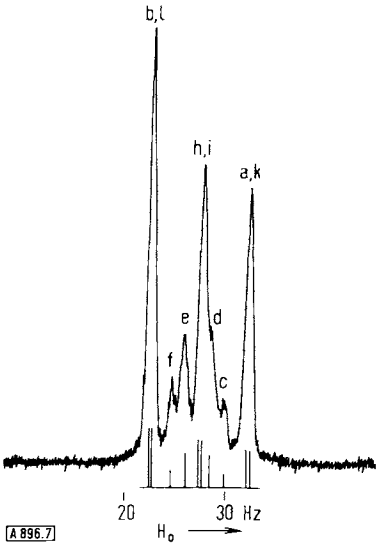
The protons H(1) and H(3) on the one hand and H(2) and H(4) on the other change their positions, so that effectively $\nu_1 = \nu_3 = \nu_A$ and $\nu_2 = \nu_4 = \nu_X$. For the coupling constants, in addition to the two geminal interactions $J_{1,3} = J_A$ and $J_{2,4} = J_X$, only two other constants are found on time average, *i.e.*

$$J = 1/2[J_{1,4}(13) + J_{1,4}(14)] = 1/2(J_{trans} + J_{gauche}) = 1/2[J_{2,3}(13) + J_{2,3}(14)] = 1/2(J_{gauche} + J_{trans}) \quad (11)$$

$$J' = 1/2[J_{1,2}(13) + J_{1,2}(14)] = 1/2(J'_{gauche} + J''_{gauche}) = 1/2[J_{3,4}(13) + J_{3,4}(14)] = 1/2(J''_{gauche} + J'_{gauche}) \quad (12)$$

The criteria for an AA'XX' system are thus satisfied. The appearance of the spectrum is again determined in this case by the large geminal coupling constants, which have values of about -10 to -12 Hz. As in the case of *(11)*, the parameter K is therefore very large and the parameter M, as the difference between two large values, is relatively small. Since $J > J'$, moreover, $N > L$. Of the ab subspectra, therefore, in the case of the symmetrical quartet only the inner lines h and i can be observed without difficulty (and may appear as a singlet), while the antisymmetrical quartet should approach an AX system[30]; in the case $M \approx 0$, it degenerates to a doublet. The parameter K frequently cannot be determined, so that only the difference (M) between the coupling constants J_A and J_X is obtainable (Fig. 7). Despite the fact that the coupling constants J and J' measured in these systems do not allow direct determination of the parameters J_{trans}, J_{gauche}, J'_{gauche}, and J''_{gauche} that are characteristic for the conformation, their ratio,

the so-called R-value ($= J/J'$), proves to be a useful source of information in this respect[58].



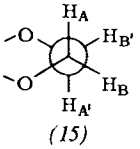


Fig. 7. Half-spectrum (BB' part) of the protons in morpholine, solution in benzene, at 60 MHz. The analysis gave: $\delta\nu = 54.3$, $N = 9.7$, $L = 3.6$, and $|M| = 1.5$ Hz (after [30]). The values found for the pure substance were: $\delta\nu = 81.0$, $J = 6.7$, $J' = 2.8$, $J_A = -12.2$, and $J_B = -11.1$ Hz [9]. At increased sensitivity it is also possible to measure line j [2b].

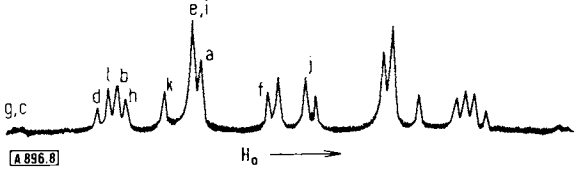
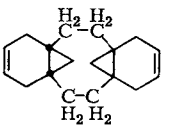
In symmetrical systems, such as 1,4-dioxane, fast ring inversion causes the spectrum to degenerate to the A_4 case, and the coupling parameters must be determined from the ^{13}C satellites, which give the desired AA'XX' system[31, 54]. The type of spectrum is the same as that of morpholine, except that because of the symmetry of the system (C_s, type *(b)* of the possibilities mentioned in Section 3.3), $M = 0$ and $J'_{gauche} = J''_{gauche}$.

(15)

On the other hand, an entirely different appearance is to be expected for a 1,4-dioxane *(15)* fixed in the chair form, since the CH_2-CH_2 fragment in this case has C_2 symmetry (type *(c)*), and $J = {}^2J$, $J' = {}^3J''_{gauche}$ (J_{ae}), $J_A = {}^3J_{trans}$ (J_{aa}), and $J_B = {}^3J_{gauche}$ (J_{ee}). Such a spectrum has been observed at -103 °C for the ethane fragment in [D_8]-cyclohexane[32] (Fig. 8). It is noteworthy here that because of the negative N value the transitions a and k lie closer to the center than b and l.





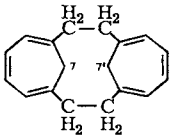


Fig. 8. AA'BB' system of the ethane fragment in [D_8]-cyclohexane at -103 °C with decoupling of the deuterons. The analysis gave: $\delta\nu = 28.76$, $J = -13.05$, $J' = 3.65$, $J_A = 13.12$, and $J_B = 2.96$ Hz (after [32]).

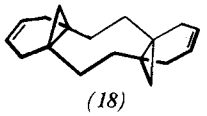


The connection between the type of spectrum of an ethane fragment and the dynamic behavior of the molecule in question is impressively demonstrated by the pair of compounds *(16)* and *(17)*[33]. For *(16)* one observes an AA'BB' system, whose analysis gives the following data: $J = {}^2J = -14.53$, $J' = {}^3J''_{gauche} = 2.21$, $J_A = {}^3J_{trans} = 10.61$, and $J_B = {}^3J_{gauche} = 5.58$ Hz.

(16)

(17)

(18)

The central eight-membered ring thus exists in a rigid chair conformation *(18)*. The compound *(17)*, on the other hand, gives an A_4 system for the ethane bridges between the cycloheptatriene fragments at room temperature. A fast consecutive inversion of the two cycloheptatriene rings must therefore be assumed for the molecule. As is shown by the experiments, it is only below -10 °C that this conformational transition becomes sufficiently slow on the NMR time scale to allow the observation of an AA'BB' system[*].

3.5. 1,2-Disubstituted Ethanes

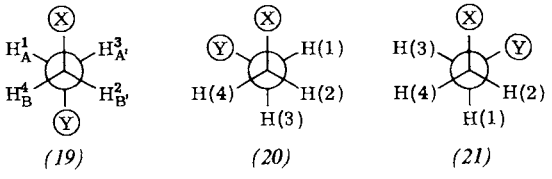
As is shown by the Newman projections *(19)*—*(21)*, in addition to the conformational equilibrium already discussed for morpholine [cf. *(13)* $\rightleftharpoons$ *(14)*], 1,2-disubstituted ethanes exhibit a third component, *i.e.* the *trans* form *(19)*. Since an AA'BB' system is to be expected for this conformation as well as for the equilibrium *(20)* $\rightleftharpoons$ *(21)*, the type of spectrum remains unchanged, but the average values are now:

$$J = p_t J_{1,4}(19) + (1 - p_t)\,[J_{1,4}(20) + J_{1,4}(21)]/2 \quad (13)$$

$$J' = p_t J_{1,2}(19) + (1 - p_t)\,[J_{1,2}(20) + J_{1,2}(21)]/2 \quad (14)$$

where p_t is the mole fraction of the *trans* conformation *(19)*. Moreover:

$$J_A = p_t J_{1,3}(19) + (1 - p_t) J_{1,3}(20) \quad (15)$$



$$J_B = p_t J_{2,4}(19) + (1 - p_t) J_{2,4}(20) \quad (16)$$

Against the four observables J, J', J_A, and J_B, therefore, including the mole fraction p_t, there are eleven unknowns, so that the analysis of the spectrum does not provide direct information regarding the conformation of the ethane in question. Under the simplifying assumption that only *two* different vicinal coupling constants—namely $^3J_{trans}$ and $^3J_{gauche}$—exist for a given compound, it is possible to deduce

[*] This dynamic process is also recognizable by changes in the spectrum of the methylene protons on C(7) and C(7'), which transforms from the A_2 to the AB type.

from equations (13) and (14) that the expression $3/2N + 1/2L$ is constant and independent of the conformational equilibrium[34].

Further, because ${}^3J_{trans} > {}^3J_{gauche}$ it follows that for $L > 0 p_t < 1/3$. In this case, the *gauche* conformers *(20)* and *(21)* are more stable than the *trans* conformer *(19)*. $L = 0$ and a spectrum of the A_2B_2-type (cf Section 3.8) is obtained for $E_{trans} = E_{gauche}$, whereas $L < 0$ means $p_t > 1/3$ and thus $E_{trans} < E_{gauche}$.

(19) *(20)* *(21)*

Of the various spectral parameters, K, as the sum of the geminal interactions, has the largest magnitude for the 1,2-disubstituted ethanes. Since L is small, the lines g and j are only rarely observed because of their low intensity. Various situations are found for the antisymmetric quartet (c, d, e, f). For $M \approx 0$, it degenerates to two lines (c+d and e+f), while for $M \gg L$, only one line (d+e) is found. The lines a, k, and b, l are generally well separated and strong, and since $N \gg L$, they flank the lines c, d, e, f, and h and i.

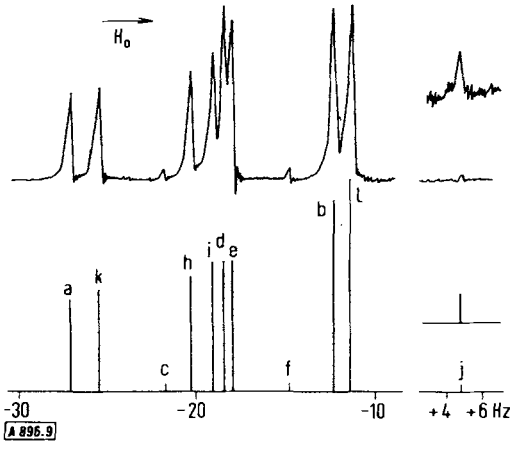


Fig. 9. Half-spectrum (AA' part) of the ethane protons in 1-phenyl-2-chloroethane; spectrometer frequency 60 MHz. The analysis gave: $\delta\nu = 36.54$, $J = 8.22$, $J' = 6.45$, $J_A = -10.66$, and $J_B = -13.84$ Hz (after [35]).

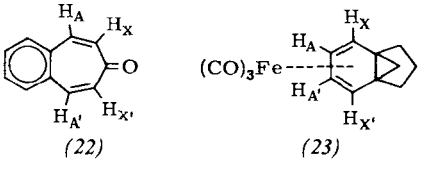
To illustrate the situation described, Figure 9 shows the spectrum of 1-phenyl-2-chloroethane[35]. Further examples have been described in detail[35, 36].

3.6. Deceptively Simple Spectra



The sensitivity and the resolution of the spectrometer determine whether all the theoretically expected transitions of a spin system can be measured experimentally. If there are weak or closely spaced lines, one often observes spectra whose appearance resembles that of a simpler type of spectrum because of the apparent deficiency of lines. The analysis of such "deceptively simple" spectra may then be incorrect.

A well-known case is the deceptively simple AA'XX' system of the protons in furan[13], whose half-spectrum degenerates to a triplet. Since $L \ll K$, the symmetrical ab subspectrum approaches the a_2 type. The lines of the antisymmetric quartet coincide on the one hand (d, e) with h, i, and on the other, (c, f) with a, k, and b, l. A triplet is also found for the ^{19}F resonance of *trans*-1,2-dichloroperfluorocyclopropane[25], where K and M are very much larger than L. In both cases, therefore, the spectrum is not of the A_2X_2-type and the conclusion $J = J'$ suggested by its appearance is incorrect.

On application of the rules derived in the AB case for deceptively simple spectra, *i. e.* in this case A_2-like systems with $\delta\nu \ll J$, to the ab subspectra of the AA'XX' case, one obtains[37]

$$\Delta > L^2/2M \quad \text{or} \quad > L^2/2K$$
$$i > L^2/2M^2 \quad \text{or} \quad > L^2/2K^2$$

where Δ (the half-width of the single line) characterizes the resolution and i (the smallest line intensity that is still measurable) the sensitivity of the spectrometer. The experimental aids therefore have the object of improving these instrument characteristics. In addition to the CAT storage instruments used for the detection of weak lines, a

(22) *(23)*

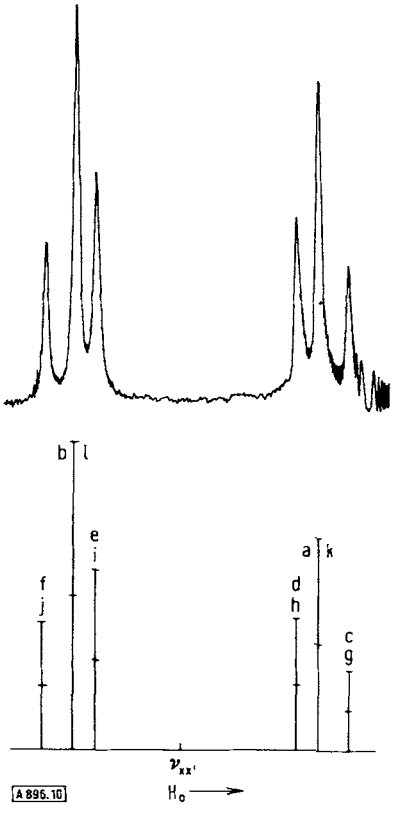


Fig. 10. 100 MHz half-spectrum (XX' part) of the seven-membered ring protons in 4,5-benzotropone *(22)* with decoupling of the aromatic protons. The analysis gave: $\delta\nu = 66.90$, $J = 12.64$, $J' = -0.11$, $J_A \leq 0.2$, and $J_X \approx 2.7$ Hz (after [21]).

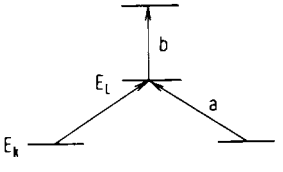
very promising method is now available in Fourier transform spectroscopy[38, 39], which also allows the improvement of the resolution[40].

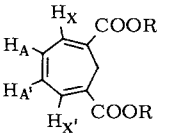


Another case of a deceptively simple four-spin system is found in the AA'XX' spectrum of the olefinic protons of 4,5-benzotropone *(22)*[21]. The coupling J_A here is very small, so that to within the accuracy of the measurements, $K = M$. Consequently, the two ab subspectra are degenerate, and only six lines are observed in the half-spectrum, which thus becomes similar to the X part of an ABX spectrum. According to the analysis, $|L| > |N|$, so that a negative sign results for J'. The limiting value for J_A can be estimated from the line width of the observed signals (Fig. 10). Deceptively simple six-line half-spectra of this type are also observed for a number of carbonylmetal complexes with cyclic diene ligands such as *(23)*[18, 41].

Finally, superposition of the inner quartet lines d, h and e, i can occur in the AA'XX' system for $K \approx M$ and $L < K, M$. The experimental half-spectrum then consists of eight transitions[42]. The olefinic protons of norbornene (Table 1) and similar unsaturated bicycles may give rise to such spectra, since in this case $J_X \ll J_A$.

3.7. Experimental Aids in Line Assignment

The line assignment for the direct analysis of AA'XX' or AA'BB' systems can be checked experimentally in many cases by spin tickling experiments[43, 44] or by the observation of double-quantum transitions[9, 15]. Reliable line assignment is often possible only with the aid of this additional information.



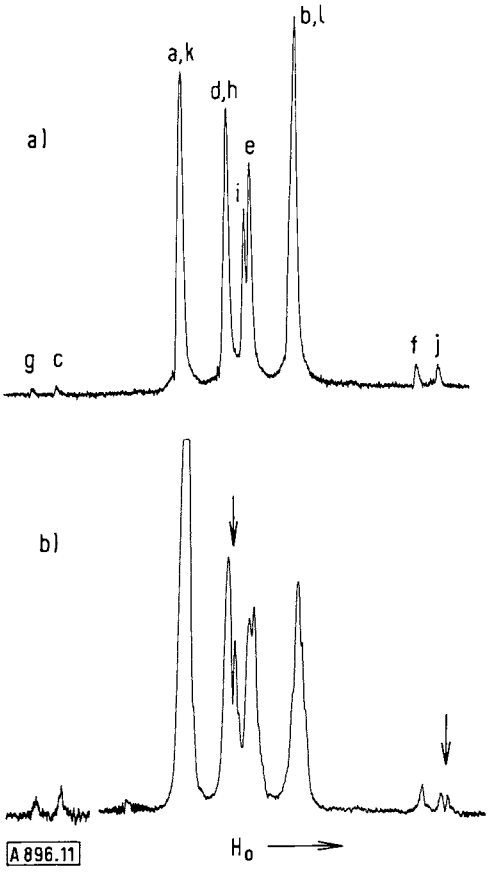
As is well known, in spin tickling experiments a transition $E_k \rightarrow E_l$ is irradiated with a second RF field of frequency ν_2 by selective double resonance; this leads to splitting of all lines that have an eigenvalue in common with the irradiated

transition. From the nature of the splitting (resolved or unresolved), moreover, it is possible to tell whether the line in question is regressively (a) or progressively (b) connected to the perturbed transition.

As can be seen from a glance at the energy level diagram of the AA'XX' and AA'BB' system (Scheme 2), spin tickling experiments should be useful here for distinguishing between symmetrical and antisymmetrical transitions and for the localization of subspectra. In this way it is possible even in the AA'XX' case to distinguish definitely between the line groups c, d, e, f and g, h, i, j, and hence between the parameters M and K. The relative signs of J_A and J_X are thus obtainable. Figure 11 illustrates such an experiment in the case of the cycloheptatriene-1,6-dicarboxylic ester *(24)*[21]. Irradiation was carried out in the XX' part at the line pair a', k'. In addition to the nuclear Overhauser effects[44] for the line pairs a, k and b, l due to the change in the Boltzmann distribution, one observes splitting of an inner and an outer line of the ab subspectra. The lines of the symmetrical quartet then flank those of the antisymmetrical quartet. Thus $K > M$, *i.e.* J_A and J_X have the same sign, which is positive in this case.

The nuclear Overhauser effect is often sufficient, with its characteristic intensity changes, to verify the line assignment[45]. Transitions of two or more quanta can be found at very high amplitudes of the observation field H_1, *i.e.* under saturation conditions for the one-quantum transi-

(24)



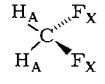


Fig. 11. Spin tickling experiment in the AA'XX' system of the olefinic protons of the cycloheptatriene-1,6-dicarboxylic ester *(24)*; spectrometer frequency 100 MHz. a) Single resonance spectrum (AA' part); b) double resonance spectrum (AA' part) with $\nu_2 = a'$, k' (after [21]). Result of the analysis: $J_A = 11.22$, $J_X = 0.82$, $J = 6.08$, $J' = 0.67$ Hz.

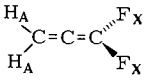
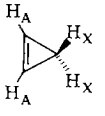
tions. They appear in the center of the ab subspectra and at $(\nu_A + \nu_B)/2$[9, 15]. In the case of AA'BB' spectra, whose appearance is influenced by the shift difference $\delta\nu$(AB), the recording of the spectrum at different field strength H_0 is often useful, since a superposition of lines may be detected in this way.

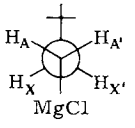


3.8. Magnetic Equivalence

The condition for the magnetic equivalence of the A and of the X or B nuclei in the AA'XX' or AA'BB' system is $J = J'$ and hence $L = 0$; one then obtains A_2X_2 or A_2B_2 spin systems.

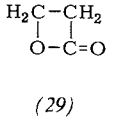


A_2X_2 systems, whose half-spectrum consists of a 1 : 2 : 1 triplet, are expected for symmetry reasons for difluoromethane *(25)*[46], 1,1-difluoroallene *(26)*, and cyclopropene *(27)*[47]. A transition AA'XX'→A_2X_2 is observed for 3,3-dimethylbutylmagnesium chloride *(28)*[48].

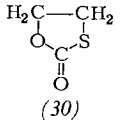


(25)

(26)

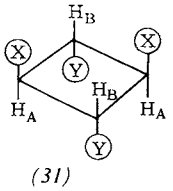


(27)

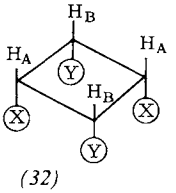


(28)

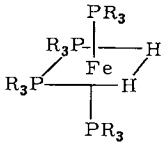
In this case, the fast inversion of the carbanion carbon at 32 °C leads to magnetic equivalence. In the calculation of the temperature-dependent line shape, the subspectral analysis was again found to be valuable. Under the condition that the parameter N remains constant, so that the line pairs a,k and b,l are unaffected by the dynamic process, it was possible to simulate the experimental spectra by the use of a simpler process ab→a_2 for the symmetrical and antisymmetrical quartets.



The theoretical A_2B_2 system has a half-spectrum of seven lines, and its line frequencies and intensities depend only on the ratio $J/\delta\nu$[2]. It is interesting to note that there does not at present seem to be any molecule for which this type of spectrum is obtained for protons. Earlier examples, such as propiolactone *(29)* or ethylene monothiocarbonate *(30)*, turned out to be deceptively simple AA'BB' systems[49, 50].



(29)



(30)

(31)

(32)

(33)

True A_2B_2 spectra should be expected on grounds of molecular symmetry (C_{2v}) for cyclobutanes of the type *(31)* or *(32)*, provided that the substituents do not induce excessively large shift differences, since an A_2X_2 spectrum would otherwise result. For the ^{31}P-NMR spectrum of the complex *(33)*, the molecular symmetry again leads to an A_2B_2 spectrum, which is indeed observed on decoupling of the protons[51].

Our own investigations cited in this review have been carried out in collaboration with Dr. W.-E. Bleck, Dr. D. Cremer, Dr. M. Görlitz, Dr. H.-H. Hinrichs, Dr. H. Klose, and Dr. R. Wenzl, to whom I am grateful for their enthusiastic cooperation. Thanks are also due to the Deutsche Forschungsgemeinschaft, to the Fonds der Chemischen Industrie, and to the Landesamt für Forschung of the State of Nordrhein-Westfalen for their support of our work.

4. Appendix

Ethylene and the A_2 System

The HMO treatment of the π system in ethylene starts with the approximation

$$\psi = c_1\phi_1 + c_2 > \phi_2 \qquad (A1)$$

as a linear combination of the orthonormalized $2p_z$ carbon atomic orbitals ϕ_1 and ϕ_2. According to a postulate of quantum mechanics, the energy of the system can be represented in such a case by the expression

$$E = \langle\psi|\mathscr{H}|\psi\rangle / \langle\psi|\psi\rangle \qquad (A2)$$

where $\mathscr{H}$ is the Hamiltonian operator, which has not been defined as yet, and where the Dirac notation is used for the integrals. The variation method[3, 52], with the abbreviations

$$\begin{aligned} \langle\phi_1|\mathscr{H}|\phi_1\rangle &\equiv H_{11} \quad \text{Coulomb integral} \\ \langle\phi_2|\mathscr{H}|\phi_2\rangle &\equiv H_{22} \\ \langle\phi_1|\mathscr{H}|\phi_2\rangle &\equiv H_{12} \quad \text{resonance integral} \\ \langle\phi_2|\mathscr{H}|\phi_1\rangle &\equiv H_{21} \end{aligned}$$

and the important approximation $\langle\phi_1|\phi_2\rangle = \langle\phi_2|\phi_1\rangle = 0$, *i. e.* neglect of the overlap integral, then gives the secular determinant

$$\begin{vmatrix} H_{11}-E & H_{12} \\ H_{21} & H_{22}-E \end{vmatrix} = 0 \qquad (A3)$$

whose solution, taking into account the identity $H_{12} = H_{21}$, leads to the eigenvalues E_1 and E_2 of the π system.

For the description of a spin system[53] of two nuclei (1) and (2) having the spin quantum number $I = {}^1/_2$, we use as the basis functions the products φ of the orthonormalized spin functions α and β, which are characterized by their total spin m_T as the sum of the magnetic quantum numbers m(i) of the individual nuclei i[54]:

$$\begin{aligned} \varphi_1 &= \alpha(1)\,\alpha(2) && m_T = +1 \\ \varphi_2 &= \alpha(1)\,\beta(2) \\ \varphi_3 &= \beta(1)\,\alpha(2) && m_T = 0 \\ \varphi_4 &= \beta(1)\,\beta(2) && m_T = -1 \end{aligned}$$

In the case of an A_2 system, both nuclei have the same Larmor frequency ν_A and are therefore indistinguishable. Thus for the case where an interaction exists between the nuclei, the states with total spin $m_T = 0$ cannot be satisfactorily characterized either by the product function φ_2 or by φ_3, both of which, unlike φ_1 and φ_4, presuppose the possibility of differentiation. We choose instead the linear combination

$$\psi = c_2'\varphi_2 + c_3'\varphi_3 \qquad (A4)$$

which expresses the fact that the two states "mix" with each other. With eq. (A2), the variation method then gives the determinant

$$\begin{vmatrix} H_{22}-E & H_{23} \\ H_{32} & H_{33}-E \end{vmatrix} = 0 \qquad (A5)$$

where

$$\langle\varphi_2|\mathscr{H}|\varphi_2\rangle \equiv H_{22}$$
$$\langle\varphi_3|\mathscr{H}|\varphi_3\rangle \equiv H_{33}$$
$$\langle\varphi_2|\mathscr{H}|\varphi_3\rangle \equiv H_{23}$$
$$\langle\varphi_3|\mathscr{H}|\varphi_2\rangle \equiv H_{32}$$

The solutions of the determinant (A5), taking into account the identity $H_{23} = H_{32}$, are the eigenvalues E_2 and E_3 of the A_2 system. It should be pointed out that neglect of the integrals $<\varphi_2|\varphi_3>$ and $<\varphi_3|\varphi_2>$, unlike neglect of the overlap integrals in the Hückel model, presents no problem here, since the spin functions naturally do not overlap, as there is no "bond" between the nuclear moments.

Definite results are obtained both for the eigenvalues E_1 and E_2 of the π system in ethylene and for the energies E_2 and E_3 of the A_2 system only if concrete values are inserted for the integrals H_{11}, H_{12}, *etc.* The HMO model avoids the difficulty of calculating these integrals by parametrization. The diagonal elements H_{kk} of the Hückel determinant are approximated by the Coulomb integral α, *i.e.* by the energy of an electron in an isolated $2p_z$ atomic orbital. The offdiagonal elements H_{kl} between adjacent centers k and l are given the adjustable value β of the resonance integral.

In NMR spectroscopy, the corresponding integrals are also not given explicitly. The phenomenological Hamiltonian operator (in Hz units)[2, 54]

$$\mathscr{H} = \sum_i \nu_i \, I_z(i) + \sum_{i<j} J_{ij} \, I(i) \, I(j) \qquad (A6)$$

on application to the spin functions, in this case gives expressions that contain the coupling constants J_{ij} in addition to the resonance frequencies ν_i. Neither of these parameters is an absolute energy quantity, since the resonance frequencies can be referred to any desired standard and the coupling constants are merely proportionality factors for the energy of the spin-spin interaction. The calculated energies are therefore relative; however, they are perfectly adequate for use in spectroscopy, where only energy differences are of interest.

For the application of the operator (A6) to the product functions φ_2 and φ_3, it is necessary to take into account the rules for the application of the nuclear spin operator $\boldsymbol{I}$ and its components $\boldsymbol{I}_x$, $\boldsymbol{I}_y$, and $\boldsymbol{I}_z$[55], as given in Table 3.

Table 3. Properties of the nuclear spin operators $\boldsymbol{I}_x$, $\boldsymbol{I}_y$, and $\boldsymbol{I}_z$.

$\boldsymbol{I}_x\alpha = \frac{1}{2}\beta$	$\boldsymbol{I}_y\alpha = i\frac{1}{2}\beta$	$\boldsymbol{I}_z\alpha = \frac{1}{2}\alpha$
$\boldsymbol{I}_x\beta = \frac{1}{2}\alpha$	$\boldsymbol{I}_y\beta = -i\frac{1}{2}\alpha$	$\boldsymbol{I}_z\beta = -\frac{1}{2}\beta$

On the basis of these relations, it is very easy to give the diagonal and offdiagonal elements of a determinant of the type (A5) in general form[56]. For the diagonal elements, we obtain

$$H_{kk} = \sum \nu_i \, m(i) + \frac{1}{4} \sum_{i<j} \sum J_{ij} \, T_{ij} \qquad (A7)$$

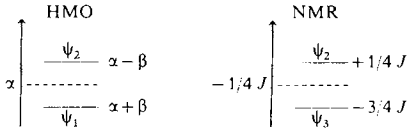
with $T_{ij} = +1$ if the nuclei i and j have parallel spins in the corresponding basis function φ_k, and $T_{ij} = -1$ if the nuclei i and j have antiparallel spins in the corresponding basis function φ_k.

The offdiagonal elements are given by

$$H_{kl} = \frac{1}{2} J_{ij} \, U_{ij} \quad \text{for} \quad i \neq j \qquad (A8)$$

where $U = 1$ if φ_k and φ_l differ only in the exchange of the spin functions of the pair of nuclei i,j (*e.g.* $\alpha\beta\alpha\beta$ and $\alpha\beta\beta\alpha$), and $U = 0$ in all other cases (*e.g.* $\alpha\beta\alpha\beta$ and $\beta\alpha\beta\alpha$).

According to this reasoning, the determinants (A3) and (A5) take the following form:



Hückel determinant

$$\begin{vmatrix} \alpha-E & \beta \\ \beta & \alpha-E \end{vmatrix} = 0 \qquad (A9)$$

NMR determinant

$$\begin{vmatrix} -1/4\,J-E & 1/2\,J \\ 1/2\,J & -1/4\,J-E \end{vmatrix} = 0 \qquad (A10)$$

Their solution leads to eigenvalue schemes in which the eigenstates are stabilized and destabilized in relation to the energy α or $-{}^1/_4 J$ by the amount β or ${}^1/_2 J$, respectively:

For the coefficients c_1 and c_2 on the one hand and c'_2 and c'_3 on the other of the linear combinations (A1) and (A4), which now have to be calculated, the determinants (A9) and (A10) yield the following equations on the basis of the variation method:

HMO	NMR
$c_1(\alpha-E)+c_2\beta=0$	$c'_2(-1/4\,J-E)+c'_3\,1/2\,J=0$
$c_1\beta+c_2(\alpha-E)=0$	$c'_2\,1/2\,J+c'_3(-1/4\,J-E)=0$

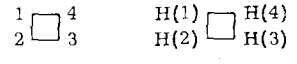
By insertion of the eigenvalues and using the relation $\sum_i c_i^2 = 1$, which is a consequence of the orthogonality of the basis functions ϕ_k or φ_k, one obtains $c_1 = c_2 = 1/\sqrt{2}$ or $c'_2 = -c'_3 = 1/\sqrt{2}$ for the more stable state, and $c_1 = -c_2 = 1/\sqrt{2}$ or $c'_2 = c'_3 = 1/\sqrt{2}$ for the state with the higher energy. The correct eigenfunctions are therefore:

HMO		NMR	
$\psi_1 = 1/\sqrt{2}\,(\phi_1+\phi_2)$	(A11)	$\psi_3 = 1/\sqrt{2}\,(\alpha\beta-\beta\alpha)$	(A13)
$\psi_2 = 1/\sqrt{2}\,(\phi_1-\phi_2)$	(A12)	$\psi_2 = 1/\sqrt{2}\,(\alpha\beta+\beta\alpha)$	(A14)

The eigenvalue scheme of the A_2 system is complete only when we also include the wave functions and eigenvalues of the states φ_1 and φ_4. The product functions $\alpha\alpha$ and $\beta\beta$ here are already eigenfunctions of the Hamiltonian operator $\mathscr{H}$; the eigenvalues E_1 and E_4 are calculated directly with the aid of the operator (A6) from the Schrödinger equation

$$\mathscr{H}\psi = E\psi \qquad (A15)$$

and are found to be $\nu_A + {}^1/_4\,J$ and $-\nu_A + {}^1/_4\,J$. In addition to the transition energies, which are found from the differences of the eigenvalues, the relative transition probabilities or intensities I of the individual lines are also of interest in NMR spectroscopy. They are calculated[2, 54] from



$$I = \langle\psi_k|\sum I_x(i)|\psi_l\rangle^2 \qquad \text{(A 16)}$$

as the square of the transition moment M. The complete result for the A_2 system is:

	eigenvalues	eigenfunctions	transitions	energies	intensities
(1)	$\nu_A + 1/4\,J$	s_{+1} $\alpha\alpha$	(2)→(1)	ν_A	1
(2)	$+1/4\,J$	s_0 $1/\sqrt{2}(\alpha\beta+\beta\alpha)$	(3)→(1)	$\nu_A + J$	0
(3)	$-3/4\,J$	a_0 $1/\sqrt{2}(\alpha\beta-\beta\alpha)$	(4)→(2)	ν_A	1
(4)	$-\nu_A + 1/4\,J$	s_{-1} $\beta\beta$	(4)→(3)	$\nu_A - J$	0

Thus transitions involving the eigenstate (3) are forbidden. This result can also be deduced from the symmetry behavior of the wave functions ψ_2 and ψ_3. ψ_3, as the only eigenfunction, is antisymmetric with respect to an interchange of the two nuclei. However, transitions between eigenstates with different symmetries are forbidden[2, 54]. The spectrum of the A_2 system thus consists of a single line at ν_A, *i.e.* the coupling between magnetically equivalent nuclei does not appear in the spectrum.

This brief comparison of the mathematical operations applied in the HMO theory and in calculation of NMR spectra shows clearly that the HMO formalism can be used without essential changes for the calculation of the eigenvalues and eigenfunctions for nuclei having the spin ${}^1/_2$. This similarity is not surprising in the end, since one is concerned with an eigenvalue problem in both cases[57]. For magentically equivalent nuclei, such as are present *e.g.* in a methyl group, the analogy is perceived even so far that, as in the A_2 system, the results for the corresponding π system, *i.e.* the cyclopropenylium ion can be taken over directly in this case. Differentiation is necessary for an A_4 group, owing to the different form of the Hamiltonian operator. Whereas in cyclobutadiene $\beta_{13} = \beta_{24} = 0$, it is also necessary in nuclear magnetic resonance to consider coupling *via* four bonds ($J_{1,3}$, $J_{2,4}$). Thus all the nondiagonal elements H_{kl} of

the secular determinant are different from zero in this case, and are not necessarily equal to one another. Finally, because of differences in the resonance frequencies, the diagonal elements H_{kk} also assume different values. However, there is no difficulty in simulating such a calculation with the aid of an HMO program, though this is undoubtedly only of didactic value.

Structure and Stereochemistry of the Transition States and Intermediates of Heterolytic Aromatic Substitutions[**]

By Paul Rys, Peter Skrabal, and Heinrich Zollinger[*]

Dedicated to the memory of Sir Christopher Ingold (1893–1970)

In the following progress report we discuss some current problems concerning the structure of the transition states and intermediates of heterolytic aromatic substitutions. This prompts us to present a critical analysis of the methods by which the existence of one or more intermediates may be clearly established. Energy relationships can provide information about the structure of the intermediate as long as the kinetics of the reaction are not disguised by diffusion. Investigations of the stereochemistry of the intermediates, which at present are not readily amenable to experiment, indicate that these intermediates, in contrast to the Wheland concept of symmetric σ-complexes, can participate in conformational equilibria.

1. Introduction

The classical investigations of *pre*-equilibria in electrophilic aromatic substitutions by *Ingold* and co-workers[1] have made available exact information concerning the nature of the species participating in the substitution. Stimulated by *Dewar*'s postulate[2] and fundamental studies by *Mulliken*[3], we speak today of π-[4] and σ-complexes as *intermediates* in heterolytic aromatic substitutions. However, further progress in understanding the mechanism of such reactions requires an exact determination of the structure of these intermediates. That the detection of one or the other type of complex cannot always be regarded unreservedly as unambiguous proof of its intermediacy, has only been recognized in the last few years.

We shall discuss these aspects for reactions of the S_E2 type for electrophilic, and of the addition-elimination type for nucleophilic substitutions.

2. Methods for Detecting Reaction Intermediates

Huisgen[5] has recently summarized available methods for the detection of intermediates. Therefore, we shall briefly consider only those methods which additionally allow the unambigous detection of *several* (consecutive) intermediates.

2.1. Detection of Quasi-Stationary Intermediates

Identification of a non-accumulating intermediate is based on *Bodenstein*'s early (1913) treatment in which the intermediate Z exists in a small, quasi-stationary concentration during the entire course of the reaction (steady-state kinetics: $d[Z]/dt \approx 0$)[6].

For *electrophilic* aromatic substitutions of this type, in which a proton leaves in the second step with the help of a base B [reaction (1)], this treatment leads to the kinetic relationship (2).

$$E^{\oplus} + Ar{-}H \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \overset{H}{\underset{E}{Ar^{\oplus}}} \xrightarrow[k_2]{+B} Ar{-}E + HB^{\oplus} \qquad (1)$$

$$\frac{d[Ar{-}E]}{dt} = [E^{\oplus}][Ar{-}H]\frac{k_1 k_2[B]}{k_{-1}+k_2[B]} \qquad (2)$$

The presence of a quasi-stationary intermediate is established if the observed rate constants show a non-linear dependence upon the base concentration [B] ($k_2[B] \approx k_{-1}$). If one finds a linear dependence on base concentration ($k_2[B] \ll k_{-1}$) then a concerted intermediate-free reaction path cannot be excluded on the basis of the formal kinetics.

These criteria also hold for those *nucleophilic* aromatic substitutions which give rise to a quasi-stationary inter-

[**] Expanded version of lectures given at Farbenfabriken Bayer AG in Leverkusen (January 14, 1971) and in the Società Chimica Italiana in Milan (March 3, 1971).

mediate. Their addition-elimination mechanism, as well as the existence of the intermediate, could be demonstrated for reactions of nitro-activated aryl halides with amines[7].

Rate-limiting proton extractions lead to a *kinetic hydrogen isotope effect* (k_H/k_D). This was found for the case of azo coupling reactions in 1955[8]. It is often incorrectly assumed that the isotope effect itself proves the existence of a quasi-stationary intermediate, and differentiates between a two-step and a concerted one-step mechanism. However, such proof can only come from a decrease in the numerical value of the isotope effect with increasing base concentration.

2.2. Identification of Intermediates in Reactions Involving Accumulating Adducts

In contrast to quasi-stationary intermediates, accumulating adducts can easily be detected and characterized by instrumental analysis.

If the spectrum (*e.g.* UV, NMR) of a reaction mixture is not the simple sum of the spectra of the individual reaction components, then adduct formation must have occurred. This is not necessarily a true reactive *intermediate* Z [eq. (3)], but can also be a *side-product* N [eq. (4)]. The two possibilities cannot be distinguished by kinetics if the main or side equilibrium is quickly established[9], a fact which is frequently overlooked in the study of reaction mechanisms.

$$C + D \underset{k_{-1}}{\overset{\text{fast } k_1}{\rightleftharpoons}} Z \xrightarrow[k_2]{\text{slow}} P + Q \qquad (3)$$

$$\begin{array}{l} C + D \xrightarrow[k_1]{\text{slow}} P + Q \\ \text{fast}\ \big\downarrow k_N \quad \big\uparrow k_{-N} \\ \quad N \end{array} \qquad (4)$$

In order to differentiate between (3) and (4) we shall now discuss an approximation method, which we call the "Method of Small Analogous Steps (Methode der kleinen Analogieschritte)": If the concentration of an adduct increases during a reaction, an attempt is made to progressively lower its concentration by slight changes in the reaction conditions or small changes in the structure of one of the reactants. Only if the Bodenstein equation (2) becomes valid (*i.e.* the intermediate becomes quasi-stationary) can the adduct be conclusively shown to be a reaction *intermediate*.

This method was used, for example, in studying the electrophilic substitution of 2-naphthol-6,8-disulfonic acid[10,11]. In those cases in which it does not succeed, other criteria must be employed[5]. Thus *Orvik* and *Bunnett*[12] were able to identify an accumulating adduct as an intermediate in the nucleophilic aromatic substitution of 2,4-dinitro-1-naphthyl ethyl ether. *Rys, Schmitz,* and *Zollinger*[13] found that during hydrolysis of cyanuric chloride an adduct accumulates that is involved in a side-equilibrium with a reactive intermediate. The side-equilibrium appears plausible since, as an acid-base equilibrium, it follows the Brønsted law of general acid-base catalysis, giving $\alpha + \beta = 1$ for the sum of the Brønsted coefficients. These observations support the previous mechanism postulated for the hydrolysis and alcoholysis of chlorotriazine reactive dyes[14].

2.3. Two and More Consecutive Intermediates

The same criteria as discussed in Sections 2.1 and 2.2 also hold for demonstrating the presence of two or more consecutive intermediates.

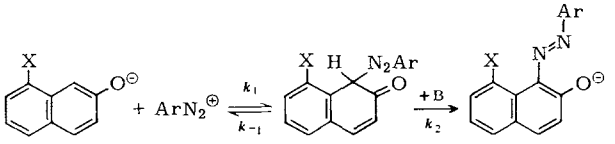
The presence of only quasi-stationary intermediates must result in a non-linear variation of the observed rate constants with the concentration of those reactants involved in the decomposition of the intermediates. The halogenation of polymethylbenzenes may be cited as an example[15].

On the other hand, if an accumulating intermediate is present in the reaction series, and the observed rate constant for its formation can be evaluated by the Bodenstein treatment (cf. Section 2.1), then the accumulating species must be preceded in the series by at least *one* quasi-stationary intermediate. This is the case, for example, in nucleophilic aromatic substitutions[12].

Proof of the existence of consecutive intermediates is of fundamental importance for the question of whether or not the sequence postulated[2] for aromatic substitutions actually occurs: reactants → first π-complex → σ-complex → second π-complex → products. Contrary to our previous view[10], the appearance of π-complexes under one set of conditions and σ-complexes when the reaction conditions are slightly altered[16] may be taken only as an indication, and not as proof, of a sequence of these two complexes in one and the same reaction. *Melander*[17] has already pointed out that intermediates may be by-passed, depending upon the reaction conditions[*].

3. Structural Information from Free Energy Relationships

H. C. Brown[19] has observed that the reaction rates of numerous electrophilic substitutions of benzene derivatives show linear free energy relationships (5) with the rate of solvolysis of substituted cumyl 2'-chlorides in water/acetone mixtures[20].



$$\log(k_x/k_0) = \rho\sigma_x^+ \qquad (5)$$

The substituent constants determined from the solvolysis kinetics are designated σ_X^+, while the reaction constants are designated ρ; by definition, $\rho = 1$ for solvolysis. *H. C. Brown* postulated that those electrophilic substitutions of benzene derivatives which are amenable to treatment by equation (5) go through a σ-complex-type, rate-limiting transition state.

An interesting extention of the Brown hypothesis is provided by the results of the azo coupling of 8-substituted 2-

[*] Currently under discussion is the question of whether or not the σ-(Meisenheimer-)complex formed during nucleophilic aromatic substitutions results from a radical anion as an *initial* (first) *intermediate* or if a parallel mechanism leads to one or more radical-type intermediates [18].

naphthol derivatives [reaction (6)][21]. These reactions are generally base catalyzed and proceed through a quasi-stationary intermediate. Therefore they follow the Bodenstein equation (2) in their kinetics. Position 8 of these 2-naphthol derivatives turns out to be a pseudo-*m*-position with respect to the reacting carbon atom, since $\log k_1$ is proportional to the m-σ_X^+ constants of the substituent X.

(6)

Remarkably, k_1—and thus also k_{-1}, from the principle of microscopic reversibility—is independent of the volume of the substituent X. However, since the steric effect of X is reflected in the ratio k_2/k_{-1}, it follows that the volume of the substituent X can only influence the second step (k_2). We will return to the conclusions derived from this observation in Section 4.

Since the rate of pyrolysis of substituted 1-phenylethyl acetates in the gas phase (300—400 °C)[22], the electrophilic substitution by diazonium ions in water[21], and the protonation equilibrium of benzene derivatives in hydrofluoric acid[23], as well as the solvolysis of cumyl derivatives in water/acetone mixtures, can be well correlated with the σ_X^+ values, these reactions are apparently all influenced by substituents in a similar manner.

Recently, *Olah*[24, 25] put forward a new postulate which extends *H. C. Brown*'s hypothesis. It says: Electrophilic substitutions of benzene derivatives have an "early" rate-limiting transition state on the potential energy surface of the reaction if the relative rates of reaction are proportional to the π-complex equilibrium constants of the respective benzene derivatives. The transition state in these cases has a structure similar to that of a π-complex. The relative rate constants of substitutions with "late" rate-determining transition states give a linear free energy relationship with the corresponding σ-complex equilibrium constants; the transition state therefore has a structure similar to that of a σ-complex.

On the one hand, *Olah* substantiates his hypothesis by citing the isomer ratios of reaction products from the Friedel-Crafts benzylation of toluene with ring-substituted benzyl chlorides[25]: The stronger the electron withdrawal of the substituents on the benzyl chlorides, the more electrophilic the carbonium ion pair formed with the catalyst, and the "earlier" the transition state along the reaction coordinate.

On the other hand, *Olah* compares the relative reactivities of methylated benzene derivatives for a series of electrophilic substitutions with the equilibrium constants of their σ- and π-complexes with hydrogen halides (cf. Table 1).

Table 1. Relative rates of electrophilic reactions of polymethylbenzenes and relative stabilities of their σ- and π-complexes (according to *Olah* [24]).

Compound	Relative rate of bromination [a]	Relative σ-complex stabilities [b]	Nitration product ratios [c]	Relative π-complex stabilities [d]
Benzene	1	1	1.00	1.00
Toluene	605	790	1.67	1.51
1,2-Xylene	5300	7900	1.75	1.81
1,3-Xylene	514000	1000000	1.65	2.06
1,4-Xylene	2500	3200	1.96	1.65
1,2,3-Trimethylbenzene	1670000	2000000		2.40
1,2,4-Trimethylbenzene	1520000	2000000		2.23
1,3,5-Trimethylbenzene	189000000	630000000	2.71	2.60
1,2,3,4-Tetramethylbenzene	11000000	20000000		2.68
1,2,3,5-Tetramethylbenzene	420000000	2000000000		2.74
1,2,4,5-Tetramethylbenzene	2830000	10000000		2.86
Pentamethylbenzene	810000000	2000000000		

[a] With Br_2/85% CH_3COOH [26].
[b] With HF/BF_3 [23].
[c] With $NO_2^{\oplus}BF_4^{\ominus}$/sulfolane [27].
[d] With HCl [28].

A very good correlation exists between the relative rates of bromination and the equilibrium constants for the addition of hydrogen fluoride, which represents[23] the formation of a σ-complex (benzenenium ion[29]). Moreover, according to *Olah*, the small substituent effect of the methyl groups on the rate of nitration of benzene derivatives with nitryl salts is further reflected in the π-complex equilibrium constants.

However, our interpretation of the data in Table 1 shows that only a part of *Olah*'s postulate can be confirmed: The relative rates of bromination and the nitration product ratios are plotted *versus* the σ- and π-basicity constants in Figures 1 and 2 respectively. One notices in Figure 1 the outstanding correlation of bromination rate with the σ-basicity constants[26]. However, only moderate correlation (Fig. 2) is found for the nitration product ratios from the competing reactions and the π-complex stabilities. We even see from Figure 3 that the nitration data are, "visually", essentially no more poorly correlated with σ-basicities! The product ratios from mixed-acid nitrations[30] give an even poorer correlation with π-complex stabilities than any of the nitrations with nitryl salt (Fig. 4).

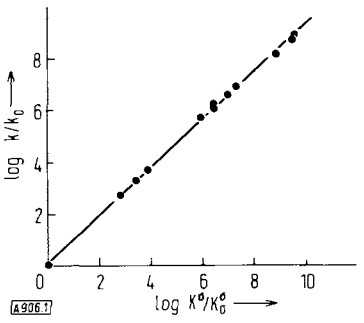


Fig. 1. Relative rate constants for the bromination of polymethylbenzenes [26] as a function of the relative σ-complex stabilities [23] (see Table 1). Correlation data: $r = 0.9988$, $a = 0.9398$, $b = 0.0804$.

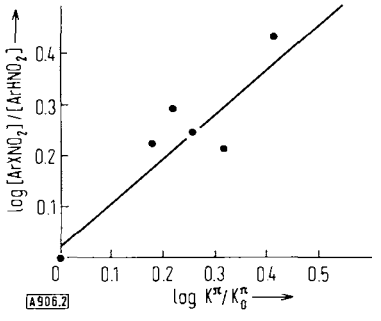

Fig. 2. Nitration product ratios of polymethylbenzenes ($NO_2^{\oplus}BF_4^{\ominus}$/sulfolane) [27] as a function of the relative π-complex stabilities [28] (see Table 1). Correlation data: $r = 0.9121$, $a = 0.9146$, $b = 0.0239$.

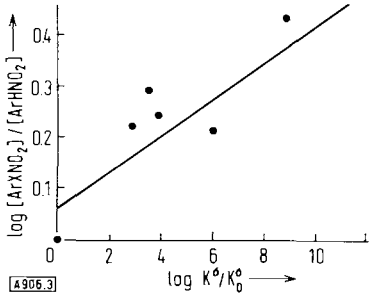

Fig. 3. Nitration product ratios of polymethylbenzenes ($NO_2^{\oplus}BF_4^{\ominus}$/sulfolane) [27] as a function of the relative σ-complex stabilities [23] (see Table 1). Correlation data: $r = 0.8820$, $a = 0.0415$, $b = 0.0610$.

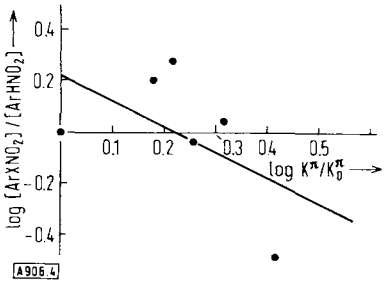

Fig. 4. Nitration product ratios of polymethylbenzenes (mixed acid/sulfolane) [30] as a function of the relative π-complex stabilities [28]. Correlation data: $r = -0.5493$, $a = -1.0284$, $b = 0.2326$.

The calculation of correlation coefficients shows this more clearly: Table 2 contains the results of a regression analysis of 18 electrophilic aromatic substitution reactions *versus* the σ^+ values of *Brown*[19]. With the exception of the nitrations and the destannylations the correlation coefficient lies between $r = -0.9988$ and -0.9807; the average is $\bar{r} = -0.9878$[31]. However, as Table 3 shows, the data from competitive nitrations also correlate poorly with the equilibrium constants of 15 different π-complexes[32] with polymethylbenzenes.

The good correlation coefficients obtained for the reactions in Table 2 leads us to believe that the transition states possess a *σ-complex-type structure*. In place of the solvolysis rate constants of cumyl chloride derivatives, the protonation equilibrium constants of polymethylbenzenes in HF (from *Mackor et al.*[23]) could just as well be used as a reference reaction for the bromination of polymethylbenzenes: The structures of the resulting benzenenium ions are supported by their NMR spectra[23].

The slope of the regression line (constant *a*, Table 2) is a measure of the "closeness" of the transition state to the σ-complex on the potential energy surface of a (three-dimensional) energy diagram: The smaller (more negative) the value of *a*, the more product-like (σ-complex-like) the transition state, in the sense of the Hammond postulate[49]. Bromination in aqueous acetic acid ($a = -13.14$) therefore proceeds through a transition state that lies energetically quite near the σ-complex. In contrast, the transition state for alkylation (Friedel-Crafts reactions) is *energetically* near the reactants since *a* is large (slightly negative); the transition state therefore lies "early" on the reaction coordinate. We conclude from the good correlation ($r = -0.9823$) obtained from the large number of points ($n = 11$) that the transition state is *structurally* similar to the *σ-complex*.

In contrast to this, *Olah*[24] would conclude—from the fact that toluene reacts only 6.0 times (ethylation) more quickly than benzene—that the transition state is "early" with a *π-complex-type* structure. However, in view of the good linear correlation with σ-complex stabilities, we cannot concur. Yet we agree in principle with the correlation between *positional* selectivity (*ortho/para* ratio) and "early"/"late" transition states which *Olah et al.* emphasize in their most recent papers[49a]. However, the criterion of positional selectivity has to be applied very carefully: *Myhre*[49b] demonstrated recently that *ortho* (but not *meta* or *para*) substitution products can be formed not only by the S_E2 mechanism (1), but also by a 1,2-rearrangement of a primary *ipso*-addition product[49c].

How can we understand the lack of correlation between *substrate* selectivity and nucleophilicity in fast electrophilic substitutions, *e.g.* nitrations? We would like to emphasize that the ratio of two (or more) products from competition reactions can only be calculated directly by the usual methods[50] (*i.e.* from the respective rate constants of the actual reaction steps) if the kinetics are not "disguised" by diffusion processes. *Wei*[51] has previously shown how often erroneous conclusions are drawn in this respect.

In general, two situations leading to diffusion effects can be differentiated: If the effective rate of a reaction is determined by the velocity of mixing of the reaction solutions, we speak, in agreement with *Ridd*[52, 53], of *mixing-con-*

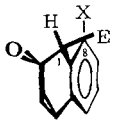
trolled reactions[*]. The observed reaction rate can also be influenced by the rate of formation of the encounter (collision) complex; we then call the reaction *encounter-controlled.*

In mixing-controlled reactions we are concerned with *macro*scopic, and in encounter-controlled, *micro*scopic diffusion effects. Both can largely disguise the observed kinetics of a reaction and thereby also the selectivity of competitive reactions. It is of value, on this account, to clearly distinguish the effects of diffusion on the different selectivities: While the positional selectivity is dependent mainly upon the probability of successful reaction in the encounter complex, and therefore not directly on diffusion effects, the substrate selectivity for diffusion-controlled reactions *is* disguised by such effects. This appears to be

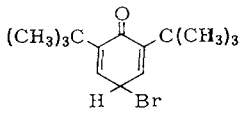
[*] The terms mixing or encounter *controlled* (generally: diffusion *controlled*) could be misleading in that only those reactions for which no reaction sites are present *along* the diffusion path are controlled exclusively by diffusion (*i. e.* have activation energies of 2.5 — 8.4 kJ/mol, [= 0.6—2 kcal/mol]). The measured reaction rate is then only proportional to the diffusion coefficients and independent of the reaction rate constants. A completely different situation arises however if *new* reaction sites are formed along the diffusion path. In the steady state the measured maximum rate is proportional to the root of the product of the diffusion coefficient and the rate constants of the chemical reaction. The measured activation energy will then be $(E_{aD} + E_{aR})/2$, where E_{aD} is the activation energy of diffusion (2.5—8.4 kJ/mol) and E_{aR} that of the chemical reaction (60—100 kJ/mol). It would be more reasonable to speak of diffusion-*disguised* reactions.

the case in electrophilic aromatic substitutions in polar aprotic solvents using preformed electrophilic reagents (especially nitryl salts). This occurs as well with nitrations of highly reactive aromatic compounds using the conventional nitration reagents (mixed acids): In a series of independent papers, it has been shown that such substitutions are so rapid that diffusion effects play a decisive role.



Although *Olah* and *Overchuk*[54] showed that the experiments of *Tolgyesi*[55] could not be taken as a definite proof of mixing effects, it was left to *Moodie, Schofield et al.*[56] to demonstrate that the reaction rate did not increase with increasing numbers of methyl groups for the nitration of methylated benzenes in sulfuric acid, as was initially expected. Rather, the reaction rates more often reach a limiting value, which is the rate of formation of the encounter complex between the nitryl ion and benzene derivatives. According to *Olah*'s postulate the rate limiting transition state should admittedly occur very "early" (*i. e. a* is slightly negative); however, current methods do not permit firm conclusions about the structure of these transition states. It is not surprising, therefore, that the correlation coefficient *r* of nitration with HNO_3 in H_2SO_4 (Table 2) is considerably lower than those of all other reactions. Furthermore, *Ridd et al.*[52, 53] were able to show that the product ratio for the nitration of bibenzyl *apparently* indicates that the second nitration (in the still unsubstituted phenyl ring) occurs faster than the introduction of the first nitro group.

A completely analogous result occurs with the nitration of durene—a result known since 1870[57]—where dinitrodurene is obtained almost exclusively (in nearly the 50% yield expected from theory) under conventional conditions, even at stoichiometric 1:1 reactant ratios. As we have recently been able to show in our laboratory[58], the ratio of mono- to dinitrodurene is dependent upon the mixing conditions as well as the concentration of starting material (at a stoichiometric ratio of 1:1). It could further be shown that the yield of mononitrodurene could be increased from a few percent to 83% by the introduction of small amounts of water. The theoretical examination of these results by *Rys*[59] clearly shows that we are dealing with a mixing-controlled process and that with two competing substrates the product ratio can only be of limited use in calculating the ratio of the actual rate constants.



4. Instrumental Analysis of Accumulating Adducts in Electrophilic and Nucleophilic Substitution Reactions

How can we understand the observations concerning reaction (6) (Section 3)? As opposed to k_1 and k_{-1} the reaction rate constant k_2, leading from the σ-complex to products, must depend upon the size of the substituent X in position 8[21] under the following conditions:

1. C-1—H and C-1—E bonds are *asymmetric* with respect to the plane of the benzene ring *(1)*. The electrophilic substituent E occurs in a pseudo-axial and the departing proton in a pseudo-equatorial position. The "swinging" of E into the plane of the original naphthalene nucleus occurs—synchronously with proton removal—only after the departing proton is attacked by the base in the rearomatization process. The steric effect of the substituent X is manifested only during this "swinging" of E into the nuclear plane.

(1)

(2)

2. A qualitatively similar picture also arises if the bonds in the 1-position are *symmetrically* disposed. The steric hindrance of the 2nd step is due to the "swinging" of the phenylazo residue from a *less* hindered position in the σ-complex into a sterically strained, planar aromatic system in the final product.

The asymmetric arrangement of substituents about the sp^3 C atom in the σ-complex[60] obtained from 2-naphthol-1-sulfonic acid and diazonium ions and in 4-bromo-2,6-di(*tert*-butyl)cyclohexa-2,5-dienone*(2)*[61] has been discussed elsewhere[*]. *Simon, Zollinger et al.* have proposed that the proton on the tetragonal C-1 atom of the σ-complex formed during the bromination of 2-naphthol-6,8-disulfonic acid adopts a pseudo-equatorial position[10]. Under similar conditions, iodination leads only to the π-complex[10].

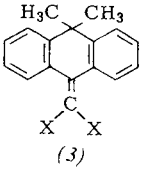
Our explanation for these two extreme cases is a gradual change in the steric interactions of the electrophiles with the substituent X in the substrate. On the one hand, reaction (6) giving a σ-complex has a rate constant k_1 which is independent of the volume of the substituent X. Only k_2 for the rearomatization is influenced by steric effects. On the other hand, the formation of the π-complex from 2-naphthol-6,8-disulfonic acid and iodine is the extreme case of a reaction type in which, as a consequence of the larger steric interaction, even the k_1 of the side attack of the electrophile is affected. In that case the steric hindrance to electrophilic attack is so large that only the π-complex is formed. Although only *slight*, the differences between structures 1 and 2 appear to be of fundamental importance in connection with investigations of reaction mechanisms and especially of accumulating intermediates.

Our proposal of an asymmetric σ-complex is contrary to *Wheland*'s concept of symmetrical σ-complexes[62]. The two fundamentally different arguments for the asymmetric cyclohexadienone-type σ-complex were a) the *non-planarity* of the cyclohexadienone part of the molecule and b) the *steric interactions* of the substituents. The non-planarity would necessarily be associated with an asymmetric disposition of substituents about the sp^3-hybridized C atom. Steric effects, however, could also cause the asymmetry in an otherwise *planar* intermediate.

We discuss below some examples of what is currently known about the structure of intermediates from heterolytic aromatic substitutions and what conclusions can be drawn from the known structures of model compounds.

[*] The question remains whether, after attack of the diazonium ion, the azo group in the σ-complex possesses the *cis* or *trans* configuration.

Cyclohexane is more planar than one would assume from Dreiding models. Its flattening is associated with an opening of the C—C—C angle from 109° 28′ to about 112°[63]. The introduction of just one double bond leads to a further, considerable flattening in cyclohexene. Hence, the substituents on atoms C-3 and C-6 are designated as *pseudo*-axial and -equatorial[64]. The six-membered ring in cyclohexadienones is formed from five trigonal and only one sp^3-hybridized C atom. How great is the tendency, therefore, of such molecules to be planar and thereby symmetrical with respect to the bonds to the sp^3 C atom?



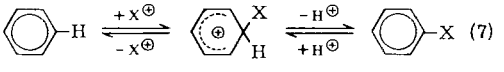
Dreiding models show that in 2,4-cyclohexadienone-type σ-complexes, the oxygen atom of the carbonyl group and the pseudo-equatorial substituent on C-6 occur in eclipsed positions. In order to bring two substituents in a saturated hydrocarbon into an eclipsed position about 12 kJ/mol (2.8 kcal/mol) is required. The opening of a C—C—C angle of about 5° requires only 2 kJ/mol and the energy barrier for twisting of a single bond attached to a C=O bond amounts to about 3.5 kJ/mol[65]. These numbers indicate that the conformations suggested by models are only approximately correct and that the real relationships in molecules can be considerably different.

The various possibilities for reactions of substituted 2,4- and 2,5-cyclohexadienones, and derivatives containing these chromophores, have been systematically studied[66]. However, very little is known about their conformations.

As research tools, NMR spectroscopy and X-ray structure analysis have much to offer. The latter naturally provides the most exact information concerning the spatial structure of molecules. Surprisingly, there appear to be no X-ray structures available for cyclohexadienone derivatives, although *p*-dienones form the chromophore of numerous natural products[*][**].

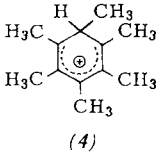
Systematic investigations of the PMR spectra of substituted cyclohexadienone derivatives do exist[68]: they show that, at room temperature, the dienones are at least statistically planar, since large activation energies for conformational changes can be ruled out. In order to differentiate between statistical and real planarity, it is necessary to examine the temperature dependence of the NMR spectra. Even if these investigations were to show that two separate conformations cannot be detected at low temperatures, it still would not prove that the molecules are planar. It might be possible that the activation energies of these conformational isomerizations are too small to permit freezing of the equilibria. However, if this were the case, then such equilibria should not be attributed any importance in reaction mechanistic considerations.

If there is a large steric interaction between substituents in cyclohexadienone derivatives, then the activation energy for conformational isomerization can be increased to such an extent that two conformers can be detected. In the PMR spectra of 9,10-dihydro-9,9-dimethyl-10-methyleneanthracene and derivatives *(3)* either one or two signals were found for both methyl groups in the position 9, depending upon temperature and substituent X[69].



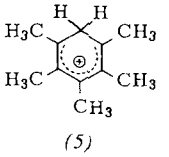
(3)

As a consequence of this observation, one can speak of a pseudo-axial and pseudo-equatorial methyl group. The authors therefore conclude that *(3)*, like 9,10-dihydroanthracene whose X-ray structure analysis is available[70], exists in the boat conformation. At room temperature, 10,10-dimethyl- and 10,10-diethylanthracenes appear to have equivalent substituents[71]. Likewise, a singlet was found for the methyl groups of 2-formyl-4,4-dimethyl-2,5-cyclohexadienone in the PMR spectrum[72]. In such work, low-temperature experiments should provide further help[73].



If one finds coupling of the nuclei of a substituent on an sp^3-hybridized C atom with nuclei of the ring, then it is, in principle, possible to deduce the conformation of the sp^3-hybridized C atom from the size of the coupling constants by the theory of spin-spin interactions. Under the constraint that the Karplus relation[74] cannot be precisely applied to dienone systems, a dihedral angle of 44° was calculated for *(2)*[61]. However, as long as these conclusions are not supported by results from known model compounds, they may not be considered as a structural proof. This is due to the large substituent effect on the coupling constants. Progress in this direction was made by *Colpa*, *McLean*, and *Mackor*[75, 76] who calculated the coupling constants in benzenenium ions.

Benzenenium ions (in general, arenenium ions)[29] can be considered as σ-complexes formed during electrophilic aromatic substitutions[77].



(7)

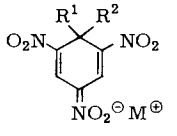
The PMR spectrum of hexamethylbenzenenium ion *(4)* shows a coupling of 2.0 Hz for the acidic protons with the *p*-methyl group. The analogous coupling constant of the CH_2-protons in pentamethylbenzenenium ion *(5)* amounts to 3.5 Hz[77].

(4)

(5)

Steric interaction between the $CHCH_3$-methyl group and both *o*-methyl groups in *(4)* is responsible for an asym-

[*] X-ray structures and HMO calculations of cyclohexadienone derivatives are in progress by Prof. *M. Simonetta*, University of Milan, at our suggestion. Recently, the X-ray analysis of 10-bromoanthrone which corresponds to the σ-complex of the bromination of 9-anthrole, was completed: 10-bromoanthrone has a boatlike middle ring, *i.e.* it is not planar [67]. Recent CNDO/2 calculations by *M. Simonetta* suggest that a pseudo-axial position of the attacking arylazo group in the σ-complex, concerning the azo coupling to 2-naphthol is probable.



[**] Note added in proof, Sept. 11, 1972: A recently published X-ray analysis of spiro[5,5]undeca-1,4-diene-3-one shows that the cyclohexadienone ring is planar (*H. Koyama* and *T. Irie*, J. Chem. Soc. Perkin II *1972*, 351).

metric conformation. The angle between the C—H bond and the plane of the rings is lowered from *ca.* 54° in *(5)* to *ca.* 35°, whereby the smaller coupling constant in *(4)* results[77].

In the range of −20 to +70°C, the PMR spectra of the 9-H$^{\oplus}$- and 10-H$^{\oplus}$-9-ethyl-10-methylanthracenenium ions, as well as those of the 10,10-dimethyl- and 10,10-diethyl-9-hydroxyanthracenenium ions, are independent of temperature[71]. From data in the literature[69, 70], we would consider the boat conformation, with a very small isomerization energy, as most probable. Isolable arenenium salts are probably too unstable for X-ray structure analysis[78].

Whereas there are no X-ray structure analyses for the above-mentioned σ-complexes of electrophilic aromatic substitutions, three such studies have been performed on the anionic σ-complexes of nucleophilic aromatic substitutions[79]. *Simonetta et al.*[80] and *Tanaka et al.*[81] have determined the crystal structures of *(6)* and *(7)*, respectively, while *Palenik* and *Messmer* have elucidated that of *(8)*[82].

Not only the picryl ether adducts of *(6)* and *(7)*, but also the 4-methoxy-5,7-dinitrobenzofurazan adduct *(8)*, possess

(6), $R^1 = R^2 = OC_2H_5$
(7), $R^1 = R^2 = OCH_3$

(8)

planar ring systems. The planar arrangement of five sp^2- and one sp^3-hybridized ring C atoms leads to an opening of the C—C—C angles of the trigonal C atoms from 120° up to as much as 127°. As expected, the planarity of these σ-complexes is associated with a symmetrical disposition of the substituents $R^1 = R^2$ about the tetragonal C atom. Only with this symmetrical arrangement are the steric interactions reduced to a minimum. The most interesting question can only be answered, however, by future structural analyses: What is the structure of Meisenheimer complexes substituted at the tetragonal C atom by $R^1 \neq R^2$?

The PMR spectra of Meisenheimer complexes in which R^1 differs from R^2 and in which R^1 is H have not, to our knowledge, been subjected to quantitative conformational analyses[83].

Both π- and *molecular*-complexes as adducts must be considered separately. Their existence as intermediates in heterolytic aromatic substitutions is experimentally uncertain, almost without exception[4, 10, 11, 36a]. We here refer the reader to the excellent summary by *Banthorpe*[4].

5. Prospects

The currently available X-ray structure analyses of Meisenheimer complexes confirm that as long as they carry two identical substituents on the tetragonal C atom these σ-complexes possess a planar ring and a symmetrical arrangement of the substituents. Future work will show which conformations are the most favorable for unequally substituted compounds.

Little is known so far about the conformations of cationic σ-complexes and cyclohexadienone-type intermediates. X-ray structures must not, however, be uncritically assumed for the molecular state in solution since intermolecular forces in crystals are able to influence conformations. It will be of great value, therefore, to use NMR spectroscopy along with kinetic experiments in order to obtain *kinetically* relevant information concerning the conformations of intermediates. The previously available results from NMR studies on arenenium ions and cyclohexadienone derivatives, however, allow the conclusion that it is safe to assume asymmetrical conformations for intermediates with large steric interactions. From refined MO calculations one should be able to obtain further information concerning the relative energies of planar and non-planar structures of σ-complex-type intermediates[67].

Helgstrand, as well as *Jakubetz* and *Schuster*[84], has ascertained by CNDO/2 methods that the π-complex of a proton with benzene ($C_6H_6 \ldots H^+$) is unsymmetrical and about 84 kJ/mol more stable than the σ-complex. Since these calculations only apply to the gas phase and neither solvation nor gegenion interactions are accounted for, they can hardly be considered valid for reaction in solution.

Apart from the above-mentioned structural (particularly conformational) problems, the question should also be studied whether several consecutive intermediates appear *at all* in heterolytic aromatic substitutions of the type discussed here, and if so when. The importance of mixing and encounter control—as apparent from the work of *Ridd*[52], *Schofield*[56, 85], and ourselves[58, 59]—must be considered in the interpretation of relative reactivities.

We would like to thank Professors G. A. Olah (Case Western Reserve University, Cleveland), J. H. Ridd (University College, London), and M. Simonetta (Università di Milano) for stimulating discussions and for making available unpublished work, Dipl.-Ing. Chem. F. Pfister (ETH) for the collection and evaluation of the data in Tables 2 and 3, as well as the Schweizerischer Nationalfonds zur Förderung der Wissenschaften for financial support of the research results included herein (Project No. 2.245.69).

Transcription of Genetic Information and Its Regulation by Protein Factors

By Wolfgang Rüger[*]

During transcription, genetic information is transferred from DNA to mRNA, the process being catalyzed by DNA-dependent RNA polymerase. Transcription comprises binding of the RNA polymerase to DNA, initiation, elongation, and termination. The interplay of the positive and negative control elements of these processes is illustrated for bacteria and bacteriophages.

1. Introduction

The genetic information of all life forms except RNA viruses is stored in DNA. This information, which determines the amino acid sequences of cellular or viral proteins, is not transmitted directly from the DNA to the protein-synthesizing ribosomes; instead, the base sequence of one of the two DNA strands, the reading or the codogenic strand, is transferred section by section and without errors to an intermediary molecule, messenger RNA (mRNA). mRNA is thus also a carrier of information. In each individual information section, only one of the two DNA strands carries the information which is therefore read off asymmetrically. Two groups of "translators", the transfer ribonucleic acids (tRNAs) and the aminoacyl-tRNA synthetases, then assign certain amino acids to certain mRNA base sequences on the ribosomes. The first step of information transfer (DNA→mRNA) is known as transcription since the genetic code is retained, while the second step (mRNA→protein) is termed translation.

The enzyme catalyzing the synthesis of all RNAs on the DNA is DNA-dependent RNA polymerase. The transcription of a genome is regulated by an interaction of this polymerase with positive and negative control elements, which are often proteins. Positive control elements permit transcription, while negative elements prevent it. Regulation ensures that only a fraction of all the possible transcription products is present in the cell at any one time, depending on the environmental conditions.

The following steps can be distinguished in the course of the transcription:

1. Binding of RNA polymerase to DNA.

2. Initiation: A series of events ultimately leading to formation of the first phosphodiester linkage.

3. Elongation: The elongation of the RNA chain by attachment of new nucleotides to the growing polynucleotide, whose sequence is complementary to the base sequence of the reading strand, as stipulated by the model of *Watson* and *Crick*. At the same time, the enzyme must move along the DNA strand, and the last nucleotide incorporated must be transposed from the hypothetical substrate site to the hypothetical product site of the enzyme (translocation), to allow the binding of new substrate molecules (Fig. 1).

4. Termination: The cesessation of RNA synthesis after transcription of a definite section of genetic information. This last step includes: (a) the recognition of a "termination signal" for the transcription of a genome section; (b) the release of the synthesized polynucleotide from the transcription complex comprising DNA, enzyme, triphosphates, and RNA; and (c) the separation of RNA polymerase from DNA.

RNA polymerase has been isolated from many organisms, but the *E. coli* enzyme has been the most extensively purified and studied[1-3].

2. DNA-Dependent RNA Polymerase

E. coli RNA polymerase consists of several subunits. In the presence of sodium dodecyl sulfate or urea these subunits can be separated electrophoretically in polyacrylamide gels, even without prior reductive cleavage of disulfide bridges. The enzyme is made up of one β′ (MW 165000), one β (MW 155000), and two α subunits (MW 40000)[4, 5], and in this arrangement it is known as core enzyme. A further subunit is the σ factor[6], a polypeptide (MW 95000) which is firmly associated with core enzyme, but is removed during transcription and can then associate with another core enzyme molecule[7]. This form of the polymerase ($\beta'\beta 2\alpha)\sigma$, is known as "holoenzyme". A small polypeptide chain ω (MW 9000) is also found, but it has not yet been established whether this protein is an enzyme component (possibly with a regulating action) or an impurity that cannot be removed during enzyme isolation.

The subunits can be separated preparatively by ultracentrifugation in sucrose gradients, in the presence of 3 mol/l of LiCl, or by electrophoresis on cellulose acetate blocks. They can reassociate to form the active enzyme. This technique[8, 9] made it possible to investigate the subunits separately and to gain information regarding their function.

The α-free complex ββ′ is very strongly bound to phosphate groups[4] and to DNA[8]. If holoenzyme is ultracentrifuged with an excess of DNA, only little protein remains in the supernatant. Since it contains only the polypeptides α and β, it probably comprises enzyme molecules without the β′ subunit and hence cannot be bound by the DNA. This observation, the comparatively high isoelectric point of the β′ subunit (between pH 8 and 9), and the reaction of the β′ enzyme with heparin, which can competitively displace the DNA from a DNA-enzyme complex, make the β′subunit the most likely candidate for binding the enzyme to DNA[10].

If the subunits of wild type polymerase are reassociated with subunits of mutant polymerases resistant to the antibiotics rifampicin[11] or streptolydigin[12], the resistance of the holoenzyme is altered only by replacement of the β subunit[9]. Since rifampicin inhibits initiation of RNA synthesis[13] and streptolydigin inhibits translocation[11, 14], it was concluded that the β subunit is involved both in initiation and in translocation. The β subunit also binds the α and σ polypeptides[10].

Nothing is known as yet about the function of the α subunit. It is likely that a certain steric arrangement is essential for optimum functioning of polymerase polypeptide chains. The two small α chains may be required for this arrangement.

The σ factor is involved in steps leading to the initiation of RNA synthesis. Its possible functions will be discussed later.

The ω-polypeptide chains have not yet been further characterized.

The RNA polymerases of other bacteria investigated have similar structures[15–17]. Though the enzyme was first found in rat liver nuclei[18], the RNA polymerases isolated from higher organisms have not yet been so well characterized because these enzymes are difficult to separate from the nucleoprotein of the cells and are rather unstable. The polymerases of higher organisms also consist of several subunits, but these differ from those of the bacterial enzymes in number and molecular weight distribution[19–21].

3. Transcription

3.1. Binding of RNA Polymerase to DNA

Binding of RNA polymerase to DNA is observed *in vitro* less than 15 s after addition of the polymerase to DNA[22]. It depends on ionic strength and pH, but does not require any bivalent cations (Mg^{2+}) or nucleoside triphosphates, and occurs even at 0 °C. At low ionic strengths ($\mu \leq 0.05$), the reaction is nonspecific and reversible. The DNA can be densely packed with polymerase molecules[22, 24], but bound enzyme may exchange with new enzyme molecules or else combine with freshly added DNA[25]. These reactions are observed both for single-stranded and double-stranded DNA. If the ionic strength is increased (μ between 0.1 and 0.2), the polymerase binds to double-stranded DNA at only a few points, probably indicating specific

binding[23]. Above 20 °C and in the presence of σ factor the enzyme-DNA complex no longer dissociates[10, 26], and was found to be resistant to the action of heparin and rifampicin[10, 27], even in the absence of nucleoside triphosphates.

Since free polymerase is immediately inactivated by heparin and rifampicin, the resistance of the complex suggests that the polymerase, once bound under these conditions, does not leave the DNA until initiation and synthesis of the RNA chain is complete. The binding sites must be located close to, or must be identical with, the start signals (promoters) for the transcription[28].

It has not yet been established whether the nonspecific binding of the polymerase to the DNA, observed *in vitro*, is only an artefact of the experiments, or whether it is a necessary intermediate reaction in the search for specific binding sites and in the formation of the stable initiation complex. Knowledge of the base sequence of these binding sites would contribute greatly to an understanding of transcription, and particularly of initiation.

Does the RNA polymerase recognize a sequence of bases, or are the promoters sites on the DNA with a particular secondary structure? The characteristic groups of the four bases, *i.e.* the N—1 and the C—6 positions in the case of the adenine-thymine pair and also the C—2 position in that of the guanine-cytosine pair, are not readily accessible to the enzyme, since either they lie inside the double helix (N—1) or the substituents are involved in hydrogen bonding[29]. Moreover, the stacking free energy of the bases[30] keeps the purine-pyrimidine assembly tightly closed. In addition, in the DNA of phage T4, α- or β-glucosyl residues attached to the 5-hydroxymethylcytosine protect the bases from the surroundings[31]. Therefore it is inconceivable that the enzyme can recognize promoter sites determined only by a characteristic base sequence without opening of the helix structure.

In double-stranded DNA, however, sequences of ten or more pyrimidines on one DNA strand face complementary purines on the other[32, 33]. Such regions have a secondary structure different from those with the average base composition[34]. If the RNA polymerase could recognize these regions as promoters[35], or if such regions were recognized by the polymerase as "pointers" to nearby promoters, a second problem would be simultaneously solved, *i.e.* the selection of the codogenic strand. The pyrimidine-rich strand is in fact the reading strand *in vitro*[36, 37].

Other suggestions have been made concerning the structure of promoter regions[38, 39]. However, this question can be answered unequivocally only if the promoter regions can be isolated and sequenced. Relevant experiments are currently being conducted in various laboratories[40].

3.2. Initiation of Transcription

The term "initiation" covers all reaction steps between binding of the polymerase near or in the promoter region and condensation of the first two ribonucleotide 5′-triphosphates to form a dinucleotide. An mRNA molecule synthesized by the RNA polymerase always starts with a purine. The 5′-triphosphate group of the first nucleotide is retained. The second nucleotide of an mRNA chain usually is a pyrimidine[42]. The reactions leading to the initiation remain to be fully clarified, but some idea of the course of events can be derived from the following observations.

Native T4-DNA is transcribed only by holoenzyme: the σ factor therefore is essential for RNA synthesis on this double-stranded DNA[6]. Since single-stranded DNA or a polymer of alternating adenyl and thymidyl residues[43, 44], or even double-stranded DNA with single-strand breaks[45], is readily transcribed by core enzyme, the enzyme in this configuration evidently requires single-stranded or partly single-stranded structures to avoid the reaction influenced by the σ factor in the initiation of transcription on double-stranded DNA.

For what reaction, therefore, is the σ factor responsible? In studies of diphosphate exchange[157], another reaction

$$\mathrm{pA + pppU \xrightarrow[\text{polymerization}]{} pApU + pp_i}$$
$$\mathrm{pApU + {}^{32}pp_i \xrightarrow[\text{phosphorolysis}]{} pA + {}^{32}pppU}$$

catalyzed by polymerase, it was shown that σ acts at some time before the completion of the first phosphodiester linkage[46], and thus has nothing to do with the actual synthesis of the polynucleotide chain. Hybridization experiments showed that only very specific DNA regions are transcribed in presence of σ factor[47, 48]. Therefore it is concluded that σ influences the selection of the promoters for the transcription of these specific DNA regions. Since σ is a fairly negatively charged polypeptide[5] which by itself has not much affinity for DNA it is unlikely that this polypeptide directly participates in the binding of the enzyme to DNA. Rather it is assumed to allosterically reduce the affinity of the core enzyme for all DNA regions except for the promoter[49], possibly by triggering a conformational change of the β′ polypeptide. Thus, σ would indirectly enable the enzyme to attach to promoter regions preferentially.

Initiation of RNA synthesis on a double-stranded DNA *in vitro* includes a temperature-sensitive process, which proceeds rapidly at 37 °C but slowly at 20 °C[50]. Since on the one hand binding of polymerase to DNA occurs in seconds and is not hindered by low temperatures, and on the other no temperature-induced retardation of the start of synthesis has been observed when the polymerase transcribes single-stranded DNA, the temperature-sensitive process can be interpreted as the local opening of the DNA double helix. This interpretation is supported by the observation that RNA synthesis is also retarded at 37 °C if the salt concentration is increased, since it is well known that the melting point of double-stranded DNA rises with increasing salt concentration. Local opening of the promoter region hence would be the reaction which is not necessary on single-stranded DNA, enabling also core enzyme to transcribe this template.

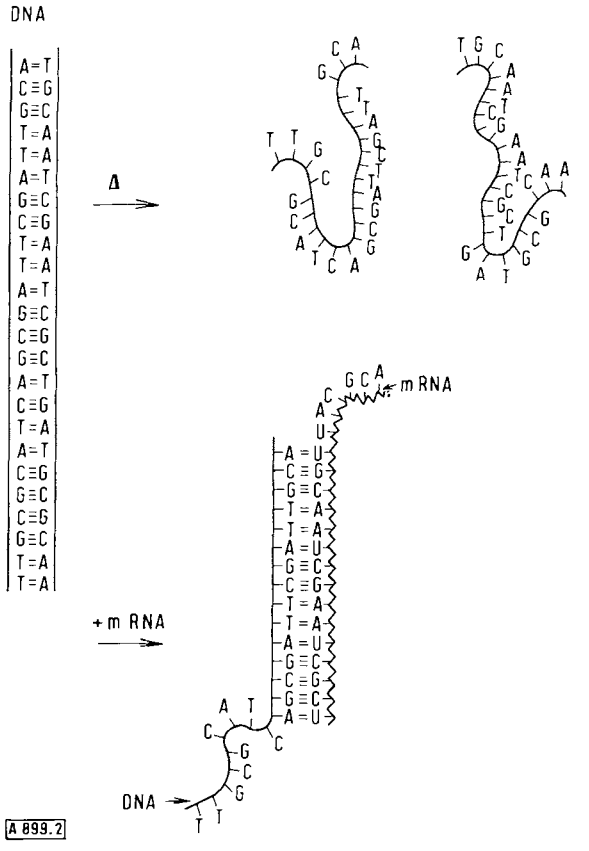

Fig. 2. The hybridization technique [41] is the most important method for identification of transcription products. Its principle is as follows. When double-stranded DNA is heated, the hydrogen bonds between the pairs of nucleotides are broken. The double-stranded molecule dissociates into two single strands. If this thermally denatured DNA is allowed to cool slowly, double-stranded DNA molecules are reformed. The re-aggregation of the single DNA strands can be prevented by fixation, *e.g.* on nitrocellulose membrane filters (DNA filters). If these DNA filters are incubated together with radioactively labeled mRNA, DNA-RNA hybrid molecules are formed provided that the mRNA was transcribed from the DNA species fixed on the filters. The extent of hybrid formation can be estimated from the radioactivity found on the filter. The hybrid molecule is stable. The reaction is extremely sensitive, and exhibits a high degree of specificity.

Thus there may be at least two reaction steps catalyzed by the σ factor in the course of initiation of mRNA synthesis: The effect of this factor on the selection of the promoters has been proved. This point is important to the regulation of transcription as will be shown later. It still remains unclear whether the factor functions in the opening of the promoter region. Possibly the heparin and rifampicin resistance of the enzyme bound to specific DNA regions, as mentioned in the preceding section, and the local opening of the promoter region are merely different aspects of the same reaction. Though it can be shown that the DNA double helix is opened in the course of transcription[51], it has not yet been possible to measure this process directly on a DNA-enzyme complex without nucleoside triphosphates; the disturbance of the DNA structure by the opening of the promoter may be insufficient without active transcription.

During or shortly after initiation, σ is released from the holoenzyme and can then initiate the synthesis of a new RNA chain together with another molecule of core enzyme[7]. This also appears to be the case *in vivo*, since no σ factor is found on careful isolation of a DNA and RNA polymerase complex in the process of transcription[52]. The factor is no longer required for polynucleotide elongation[53].

How is the σ factor released from the initiation complex? It is known that a short RNA chain, possibly of less than six nucleotides, must first be synthesized[54]. To explain this, it has been suggested that σ is attached to the enzyme close to the product binding site. During initiation, this site is brought into the proximity of the promoter region. If an RNA chain is now synthesized and incorporated into the transcription complex, the steric arrangement of the enzyme may consequently be changed, either purely mechanically or as a result of a new charge distribution, in such a way that σ is liberated.

The sequence of events leading from free polymerase and DNA, *via* the binding of the two components, to initiation is shown schematically in Figure 3[10].

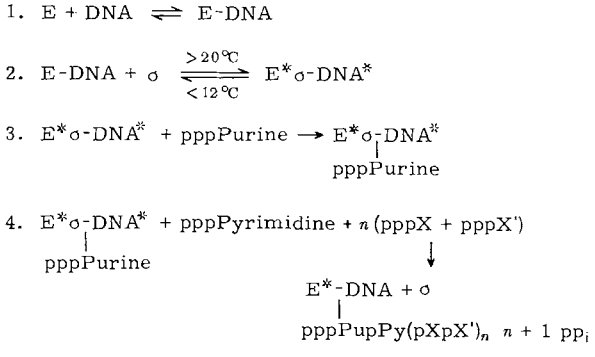

Fig. 3. Step 1: Primary binding, reversible; step 2: activated complex, reversible depending on temperature; step 3: initiation complex; step 4: initiation. Pu = purine, Py = pyrimidine, X, X' = any nucleobases, p = phosphate residue, pp_i = inorganic diphosphate, E = enzyme.

3.3. Elongation

As mentioned above, binding of polymerase to DNA is largely reversible. During or shortly after initiation, however, the transcription complex composed of DNA, enzyme, and nascent RNA becomes stable[55]. The completion of a single nucleotide linkage is sufficient to prevent the dissociation of the complex, even at salt concentrations which do not permit binding of free polymerase to DNA[56]. The finding that the addition of the two possible starting nucleotide 5'-triphosphates ATP and GTP is sufficient to bring about this stabilization in controversial[57]. With only a few exceptions[58], stabilization of the transcription complex prevents the liberation of incomplete RNA chains. This is essential for smooth and, with regard to the energy balance of the cells, economical transmission of the information *in vivo*.

In contrast, the transcription complex containing single-stranded DNA, cannot be stabilized, even at low salt concentrations. RNA synthesized *in vitro* on single-stranded DNA has a low molecular weight; the sedimentation constant is as low as 5S[59]. New RNA chains are continuously initiated[42], showing that transcription on single-stranded DNA probably does not correspond to the situation *in vivo*.

The rate of synthesis of mRNA chains on double-stranded DNA *in vitro* depends on the ionic strength, the substrate concentration, and the nature of the DNA. Average increases of 3—17 nucleotides per second and per RNA chain were found for T4-DNA at low ionic strengths ($\mu < 0.1$)[55, 60]. At higher ionic strengths ($\mu \approx 0.2$), 20—36 nucleotides are incorporated per second[60, 61]. This is close to the synthesis rate of 28 nucleotides per second found *in vivo*[62]. The higher ionic strengths in the *in vitro* experiments roughly correspond to the physiological conditions of growing cells[63]. Differences between the synthesis rates at lower and at higher ionic strengths are due to product inhibition[64, 65] in a manner yet to be clarified[66].

It has been considered in this connection whether the transcription rate might be influenced *in vivo* by the occupation of the nascent RNA with ribosomes and by a protein synthesis proceeding simultaneously with transcription[67]. Since the mRNA in the protein synthesis is translated in the 5′→3′ direction, coinciding with the direction of transcription[68], the ribosomes could occupy the mRNA even before completion of synthesis. The mRNA would thus be largely protected against enzymatic degradation by ribonuclease, and product inhibition would possibly also be prevented. However, a translation coupled with the transcription has not yet been proved to influence the rate of mRNA synthesis.

3.4. Termination

If the transcription complex is stabilized by active RNA synthesis, the question arises as to how RNA and enzyme are released after a section of information has been transcribed.

At higher ionic strengths, RNA synthesis stops by itself after a certain time. The transcription complex dissociates, polymerase and product are liberated, and the polymerase is again available for initiation[69]. It is not known whether these events require the recognition of certain DNA base sequences. Though the transcription products occurring under these conditions are larger (MW 2.2×10^6) than the corresponding mRNA formed *in vivo* (MW $0.2—1.1 \times 10^6$), the base at the 3′ end of the RNA product in most cases is uridine[66, 70]. Naturally occurring 5S and 23S RNA also end with a uridine nucleotide. Polyribonucleotide chains synthesized under these conditions carry genetic information, and can be used as mRNA for cell-free protein synthesis of, *e.g.*, active lysozyme[71, 72]. On the other hand, active lysozyme cannot be synthesized on mRNA transcribed under the same conditions from single-stranded DNA. This therefore contains the information only incompletely or not at all.

These results show that physiologically active RNA is synthesized *in vitro* on transcription at high ionic strengths and on double-stranded DNA. Consequently, the termination of transcription cannot be random under these conditions.

Another form of termination brought about by a protein factor was reported recently. This termination factor ϱ is isolated as a tetramer. Its polypeptide chains have a molecular weight of about 50000. mRNA synthesized *in vitro* in the presence of ϱ has a molecular weight similar to that of the corresponding mRNA formed *in vivo*[73].

The ϱ factor terminates mRNA synthesis at definite points even at high salt concentrations ($\mu \approx 0.2$)[74]. It is bound by RNA[75] and also by DNA[76, 77]. Since mRNA synthesized *in vitro* at high salt concentrations is not broken down into mRNA molecules of lower molecular weight by pure preparations of ϱ factor, it is unlikely that ϱ terminates the elongation of an mRNA chain by enzymatic cleavage at a termination signal coded on the mRNA. Its mode of action is therefore most simply explained as recognition of a specific DNA sequence as a termination signal. By binding to these positions, it could prevent the progress of the polymerase along the DNA molecule, and so terminate transcription. On the basis of other findings, however, more complicated hypotheses have also been developed[78]. For instance, it has been proposed that ϱ changes the conformation of a ternary complex comprising DNA, enzyme, and RNA, which could lead to the termination of transcription. Up to now it is unclear whether ϱ releases only the RNA from the transcription complex, or whether the polymerase is also released by ϱ action and consequently can initiate transcription of new RNA chains.

4. Regulation of Transcription in Bacteria

4.1. Reversible Regulation Processes

The bacterial cell can rapidly adapt its metabolism to suit the existing environmental conditions. For example, if the supply of available carbon sources changes, the cell synthesizes enzymes present only in small quantities or not at all which enable it to utilize the new energy sources. It will be shown below that such processes can be regulated at the level of transcription.

In 1961, *Jacob* und *Monod*[79] formulated a theory stating that the transcription of a group of structural genes forming a transcriptional unit (operon) is controlled by specific

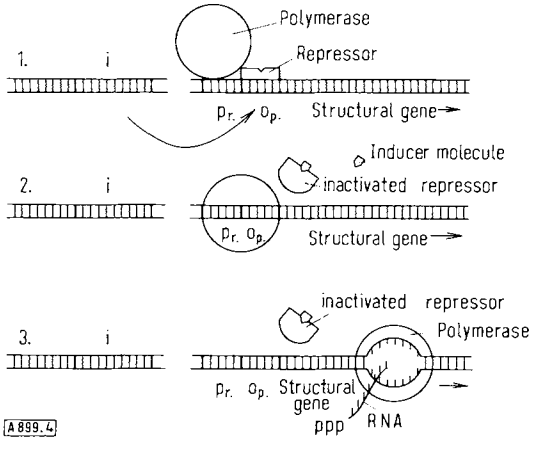

Fig. 4. Model for the transcription of a repressible operon. Left: "i" gene coding for the repressor. Pr. = promoter, Op. = operator. Step 1: repression; step 2: induction; step 3: transcription.

molecules, known as repressors. The repressors, which are readily diffusible products of the regulator genes, react with the operator, a DNA region of the operon, and thus block the transcription of the structural genes. The operator is situated proximally to the structural genes (Fig. 4). To induce the transcription of an operon blocked by the repressor, the corresponding repressor must be inactivated. This is achieved by specific metabolites, the inducers. These react with the repressors, which thus lose their affinity for the operator region, and the operon can be transcribed. This theory was developed to explain the regulation of the lactose *(lac)* operon and has proved entirely correct in genetic and biochemical experiments[80].

Experiments have shown that the promoter region is closely coupled with the operator[81, 82]. It has been possible to isolate three genetically defined repressors[83–85] which are all proteins capable of firm binding to the corresponding operator region of the DNA[86, 87].

The λ repressor, which represses the lytic development of λ bacteriophage *in vivo* and for which no low molecular weight inducer is known at present, was found also to prevent *in vitro* transcription of certain gene sections on the phage genome[88]. It binds strongly to DNA which is not chemically modified in the process. If the same DNA is first transcribed in presence of repressor and then deproteinated by phenol treatment and transcribed again without repressor, different RNA products are found. In the first case, the two operons which are under the control of the repressor in question are not transcribed; in the second case, these two operons are transcribed. If DNA with a mutation in the operator region is transcribed, the effect of the repressor on transcription is reduced; the repressor is totally inactive if the operator region in question has been genetically exchanged for that of a related phage (λimm^{434}).

Similar results were obtained with the isolated *lac* repressor. The transcription of the *lac* operon is subject not only to negative control by the repressor but also to positive control by another regulatory protein, the CRP factor [abbreviation for *c*yclic 3′:5′-adenosine monophosphate (cAMP) *r*eceptor *p*rotein][89]. In presence of cAMP, the CRP factor is attached to DNA. Both cAMP and CRP factor are necessary for the binding of RNA polymerase to *lac* promoter[90] and for asymmetric transcription[91] of the *lac* region. If *lac* repressor is added to this transcription system, the *lac* operon is not transcribed. However, if the *lac* repressor in this system is inactivated by addition of the inducer IPTG (abbreviation for *iso*propyl *thio*galactoside), *lac*-mRNA is synthesized.

The binding constants between the *lac* and the λ repressors and their operators are 2×10^{-11} and 7.3×10^{-12} mol/l respectively[92, 93], the binding constants between polymerase and promoter in both cases being 1×10^{-9} mol/l[94]. Though these values were determined at different temperatures and salt concentrations, and therefore are not strictly comparable, they nevertheless show that the polymerase can displace the repressor from its complex with DNA only when present in a 1000-fold excess. The experiments described above show that the binding of the repressor to the operator prevents transcription of an operon. The repressor therefore is a protein with a regulatory effect on transcription.

Another example of a protein factor auxiliary to transcription is ψ_r[*]. Though polymerase effectively transcribes the DNA of most phages, little RNA is synthesized *in vitro* on *E. coli* DNA. In rapidly growing *E. coli* cells, the content of ribosomal RNA (rRNA) increases up to 40% of the total cellular RNA[95, 96], though only 0.2—0.4% of the total *E. coli* genome codes for rRNA[95, 97]. This disparity suggested that some special mechanism exists for the transcription of these genes. Since rRNA is not synthesized in measurable quantities *in vitro*, there may be an "effector" that causes the preferential transcription of the rRNA genes.

A protein factor ψ_r that stimulates the synthesis of rRNA *in vitro* together with the holoenzyme has in fact been isolated from cell extracts of *E. coli*[98]. In presence of ψ_r, 30% of all RNA synthesized was ribosomal RNA. However, it has yet to be proved that ψ_r stimulates only the synthesis of rRNA, and thus controls the transcription of a specific class of genes. The activity of the ψ_r factor is inhibited by guanosine 5′-diphosphate 3′-diphosphate (ppGpp)[99], which accumulates in the cells under certain restrictive growth conditions[100] and which also negatively influences transcription by *E. coli* polymerase[101].

Both negative control by the repressor and positive control by protein factors such as ψ_r enable the cell to react rapidly and reversibly at the level of transcription to changes in its environment. These two systems are no exceptions. Several inducible catabolic enzyme systems that are regulated in a similar way to the *lac* operon have now been reported and genetically defined, and further protein factors that also have a stimulating effect on RNA synthesis, such as the M factor[102], have also been found and partly characterized; however, these will not be discussed further here.

4.2. Irreversible Regulation Processes

Not only reversible changes in metabolism, but also changes that are irreversible to the cell are regulated at the level of transcription. An example is the sporulation of *Bac. subtilis*.

RNA molecules different from those found in the vegetative phase occur in the sporulation phase of this organism[103]. The sporulating cells lack several enzymes found in the vegetative cells, and *vice versa*[104, 105].

The following genetic observations suggested that there must be a connection between RNA polymerase and sporulation.

1. Rifampicin-resistant mutants of *Bac. subtilis* are frequently found to include some which, in a single mutation

[*] During the printing of this paper some controversy arose concerning the ψ_r factor. Attempts to repeat the experiments were unsuccessful. Careful analysis of the RNA transcribed in presence of this factor yielded no evidence for preferential transcription of rRNA [158]. The function of ψ_r therefore remains to be clarified.

step, acquire rifampicin resistance and simultaneously lose the ability to form normal spores[106].

2. If cells of *Bac. subtilis* in the early sporulation phase are infected with the virulent phage φe, the sporulating cells, unlike the vegetative cells, can no longer transcribe the phage genes. The phage genome is incorporated into the spore. Transcription of phage DNA and multiplication begin only on germination of the spore. However, some sporulation-negative mutants can multiply the phage also at a time when proteins characteristic of the sporulation phase are present[107].

According to its electrophoretic behavior, the RNA polymerase isolated from vegetative cells of *Bac. subtilis* is similar to the RNA polymerase of *E. coli*. Therefore the corresponding designations were used for its subunits. Like the *E. coli* RNA polymerase, it is composed of a β′ and a β subunit (MW 155000 and 120000 respectively), two identical α units (MW 45000), and a σ factor (MW 57000)[108–110]. φe DNA is transcribed *in vitro* by the holoenzyme from vegetative cells, but not by core enzyme. On the other hand, transcription of φe DNA cannot be achieved with polymerase from sporulating cells, even when σ factor isolated from vegetative cells is added[111].

Comparison of the two *Bac. subtilis* enzymes revealed that the β subunit has a lower molecular weight in the polymerase from sporulating cells[108]. It remains to be clarified whether the change in molecular weight is due to modification, *e.g.* proteolytic cleavage, or whether a new β-polypeptide is synthesized in the early sporulation phase subsequently replacing the β unit from the enzyme of the vegetative form. Since σ factor of this enzyme is necessary for transcription of φe DNA, the change in the β subunit could prevent further synthesis of "vegetative mRNA".

In the case of *E. coli* polymerase the β subunit is responsible for the rifampicin resistance and the binding of σ. Application of these findings to RNA polymerases from vegetative and from sporulating cells of *Bac. subtilis* affords an explanation of the differences in transcription behavior. The enzyme of sporulating cells with the modified β-polypeptide might not be able to bind the "vegetative σ factor", which specifically initiates the "vegetative operons". The relationship pointed out between rifampicin resistance and sporulation could then be explained by assuming that the β subunit rendered resistant to rifampicin by mutation can no longer be exchanged for or converted into a sporulation-specific subunit. Experiments are being carried out to establish whether the change in the β subunit is sufficient by itself to change the initiation specificity of the polymerase from sporulating cells, or whether a new σ factor that forms a sporulation-specific holoenzyme with the modified core enzyme also occurs.

5. Regulation of Transcription in Bacteriophage Development

5.1. Phage T 4

T4 is one of the largest and most complex bacteriophages. Its DNA is double-stranded, and its molecular weight is *ca.* 1.1×10^8. It carries about 70 genes, the functions of a number of which are known[112, 113].

If *E. coli* bacteria are infected with T4, the multiplication of the phage proceeds in an ordered sequence of syntheses until the host bacteria lyse and the T4 progeny are liberated. This multiplication cycle takes about 20 minutes. Immediately upon infection synthesis of "early" proteins is started. They are responsible for "switching off" mRNA and protein synthesis of the host bacterium and for phage-specific DNA synthesis[114–116]. About 5 minutes after infection replication of phage DNA begins. At this stage mainly coat proteins, *i.e.* "late" proteins[117], are found. At the same time, synthesis of early proteins levels off, and can no longer be detected approximately 10 minutes after infection[118].

As in the case of the proteins, a distinction is made between early mRNA before, and late mRNA after the start of DNA replication. 98% of the early mRNA is read from the "l strand" of the DNA, while 80% of the late mRNA is copied from the "r strand"[119] [*]. Both the early and the late mRNA can be divided into at least two subclasses, *i.e.* the pre-early and the early mRNA[**] on the one hand, and the quasi-late and the late mRNA on the other[120].

How do the four classes of mRNA differ? The synthesis of the pre-early mRNA even occurs when the bacteria are infected in the presence of chloramphenicol, *i.e.* independently of phage-specific protein synthesis[121]. The appearance of the early mRNA two minutes after infection and of the two other classes of mRNA, on the other hand, depends on the phage-specific protein synthesis. Quasi-late mRNA is a class that appears in small quantities shortly before the start of DNA replication. Late mRNA is synthesized only when DNA replication has already started[122] and when the gene product of phage gene 55 is present[123]. The gene product of gene 33 stimulates the synthesis of late mRNA[124].

The sequential appearance of clearly distinguishable classes of mRNA parallel to the appearance of different classes of proteins suggested that the multiplication of T4 is regulated mainly at the level of transcription. How is this regulation effected? In presence of σ, *E. coli* polymerase synthesizes only pre-early mRNA[125]. This explains why this mRNA is synthesized even without phage-specific protein synthesis. Immediately after infection, the *E. coli* enzyme with *E. coli* σ factor transcribes a series of genes. The σ factor acts here as a positive control element, which allows the RNA polymerase to transcribe selectively a certain part of the T4 genome.

How are the other parts of the phage genome transcribed? Throughout phage development, the RNA polymerase remains sensitive to rifampicin[126]. Therefore it is assumed that at least that part of the polymerase which is responsible for the rifampicin phenotype of the enzyme participates in transcription of all types of T4-mRNA. In contrast,

[*] The l strand by definition is the strand transcribed counterclockwise relative to the circular genetic map of T4; the r strand is transcribed clockwise.

[**] Two nomenclatures are commonly used in the literature for the classes of T4 – mRNA. The simpler nomenclature has been chosen here, though some authors cited prefer the other.

transcription of the mRNAs which appear later depends on phage-specific protein synthesis, thus leading to the conclusion that at least one of the components responsible for transcription of this group of mRNAs must be coded for on the phage genome. Corresponding to the σ factor, selectively controlling the transcription of the pre-early mRNA, there could exist phage-coded protein factors altering the initiation specificity of polymerase for the synthesis of other classes of mRNA.

Such a protein factor σ^{T4} has in fact been isolated from T4-infected cells[127]. It stimulates core enzyme to transcribe the DNA of T4 and of two closely related phages, a mRNA class occurring *in vivo* between 1.75 and 2.5 min after infection[128].

What causes the core enzyme to exchange factor σ for σ^{T4}? Conceivably, σ factors no longer "wanted" for further transcription are inactivated, either by interaction with an "anti-σ" activity[129] or by structural modification. Some time after infection, the σ protein can no longer be found[130]. Moreover, a modification of the core enzyme could also lead to a decrease in its affinity for σ in favor of σ^{T4}. In fact soon after infection a change is observed in the electrophoretic behavior of the α chain[131], which depends on the phage-specific protein synthesis[132]. Roughly half of the α chains are affected within two minutes after infection, and the change is complete after four minutes. The change, however, is not due to a *de novo* synthesis and mutual exchange of the two α chains but rather to a modification of the α-polypeptide of the host polymerase. This includes the covalent bonding of a 5'-adenylate residue, presumably 5'-adenosine monophosphate[133].

In the course of the infection cycle changes can be observed also in the other enzyme subunits. Distinct differences are found in the fingerprints of the peptides obtained on trypsin digestion of the polymerase subunits from uninfected and from T4-infected cells. It can be deduced from these differences that the enzyme subunits are modified in the course of the infection cycle by the addition of newly sythesized peptide material[10]. In the β' unit, this modification occurs between 10 and 15 minutes after infection. It depends on the synthesis of late mRNA[134] and is therefore undoubtedly effected by a late protein.

However, the appearance of a phage-specific factor and the modification of the host enzyme are not the only model that could explain the regulation of the synthesis of early mRNA.

The genes for the early mRNA are interspersed between the genes for the pre-early mRNA[135]. Since both classes of mRNA are copied from the same DNA strand[119], the transition from synthesis of pre-early to early mRNA can be explained as follows[135]. Both classes of mRNA are coded for on the same transcription unit. The synthesis of the "pre-early" mRNA is initiated by the host polymerase. The ρ factor then terminates the transcription of this mRNA at certain points. It has been suggested that the pre-early mRNA also carries the information for the synthesis of an antitermination factor[136]. This inactivates ρ. Polymerization beginning transfer at this time in the infection cycle would still start at the pre-early promoters but because of inactivation of ρ would now also synthesize early mRNA. This "reading through" is observed *in vitro* if the ρ factor is absent from the transcription system[135] and also occurs *in vivo*, since early mRNA is found on long mRNA molecules that were initiated immediately after infection, *i.e.* at a time when pre-early promoters were recognized exclusively[137]. Transcription could terminate by itself without further termination factors, as is observed *in vitro* at high salt concentrations. The two models for the regulation of synthesis of early mRNA are not mutually exclusive, and experimental observations indicate that both views are correct.

There may be still other classes of early mRNA, which cannot be resolved by methods used so far. For example mRNAs could exist that are transcribed only together with pre-early mRNA after the termination factor has been inactivated, as could mRNAs that have their own promoters and are initiated in presence of modified core enzyme and σ^{T4}. The transcription of the first class would reach an optimum during a short period after infection, until the core enzyme is modified and σ is no longer functioning; the other class would then be transcribed for a longer time, until it is relieved by the appearance of the quasi-late and late mRNAs.

Late mRNA is generally synthesized only if the replication of DNA takes place at the same time, *i.e.* transcription of late mRNA does not occur from the parental DNA, and the DNA must in some way be "competent" for the transcription of the late mRNA. What constitutes this competence? On the basis of several experimental findings[138], it is assumed that single-strand breaks in the DNA are necessary in order to allow transcription of the late mRNA. It is known that such breaks occur in DNA that has just been replicated[139]. It is also conceivable that an endonuclease cleaves the DNA at specific points. Since the late mRNA is mainly transcribed from the "r strand" of the DNA, the single-strand breaks would have to be asymmetrically distributed on the two DNA strands.

Late mRNA is synthesized only in presence of gene 55 product[140]. What is the function of this product in the synthesis of the late mRNA?

1. It could be a protein factor that enables a further modified core enzyme to recognize certain single-strand breaks in the DNA and to initiate synthesis of late mRNA. A new protein factor appearing 18 minutes after infection of *E. coli* bacteria with T4 has recently been identified[134]. Together with core enzyme, it stimulates "r strand"-specific transcription. No connection has so far been found between this factor and gene 55 product. Work is in progress on further characterization of this factor.

2. Gene 55 product could react directly with DNA. By binding to DNA regions with single-strand breaks, initiation points could be provided for synthesis of late mRNA. This view is in agreement with the observation that modification of core enzyme leads to an increased affinity for single-stranded DNA[141]. It is unlikely that gene 55 product itself causes single-strand breaks in DNA and so makes it competent for the transcription of late mRNA[138].

3. It has not yet been ruled out that gene 55 product is a new polymerase coded on the phage genome, with entirely new initiation properties specially for synthesis of late mRNA.

As mentioned earlier, polymerase remains sensitive to rifampicin throughout the infection cycle, and it was therefore concluded that at least one subunit is involved in the synthesis of all T4-mRNA. However, it is conceivable that the host polymerase must remain active throughout the infection cycle and continuously transcribe some DNA regions specific for early mRNA in order to maintain the synthesis of the late mRNA classes by the phage-specific polymerase[142]. It will be shown in the next section that synthesis of a new polymerase is in fact used for regulation of phage development.

5.2. Phages T7 and T3

The *E. coli* phages T7 and T3 number among the smaller T phages. They are closely related and their DNA is double-stranded. The molecular weight of T7-DNA is about 2.5×10^7[143]. In the case of T7, 19 essential genes have so far been genetically localized[144, 145]. The products of a series of these genes are known[146].

On T7 infection, the host DNA is broken down[144]; six to seven minutes after infection at 30 °C only phage-specific mRNA is found. The "switch-off" of host RNA synthesis is probably controlled by an early phage-specific protein[37]. In contrast to transcription of T4-DNA, all T7-mRNA is transcribed from the "r strand" *in vivo* and transcription of late mRNA is independent of the DNA replication. Late and early mRNAs are distinguished according to whether phage-specific protein synthesis is necessary for their transcription[147, 148].

On the basis of an average molecular weight of 50000 per polypeptide, it may be estimated that the phage genome can carry the information for at most 26 genes. In view of this small number, it was thought feasible to identify each of the T7 proteins individually, and hence, since the genome is also well characterized genetically, to obtain an insight into the regulation of the development of this phage. Both the phage-specific proteins and their mRNAs were resolved into separate bands by radioactive labeling, polyacrylamide electrophoresis, and subsequent autoradiography. On attempting to assign individual protein or mRNA bands to each of the T7 genes by infection with phage mutants that cannot synthesize a gene product under very specific growth conditions (conditionally lethal mutants) it was found that gene no. 1 exerts a special regulatory role in transcription of the phage genome. When *E. coli* bacteria were infected under restrictive growth conditions with phages having such a mutation in gene no. 1, only three of twelve known T7-mRNA bands[147] and only three of 25 known protein bands were found[148]. Upon infection with phage mutants exhibiting a mutation in any other gene, at most one band was absent in each case.

On the basis of a number of other experimental observations and the knowledge of the role of σ in the *E. coli*-T4 system, it was assumed at first that gene 1 product was a new σ factor that changes the initiation specificity of the host polymerase in favor of the promoters for transcription of late mRNA[149]. In the attempt to isolate this T7-specific protein component complexed with the host enzyme, it was found that the T7 component itself was a new polymerase[142]. Unlike the *E. coli* enzyme, it consists of only one polypeptide chain having a molecular weight of 107000. It transcribes T7-DNA asymmetrically and is responsible for the transcription of late mRNA. A polymerase having a similar molecular weight (110000) was also isolated from T3-infected cells[150, 151]. Both the T3 and T7 polymerase exhibit high DNA specificity. Apart from T3-DNA, T7 polymerase transcribes only T7-DNA, while T3 enzyme transcribes only T3-DNA, and no T7-DNA. Neither of these polymerases is inhibited either by rifampicin or by streptolydigin. Higher salt concentrations, which stimulate the transcription by *E. coli* polymerase, inhibit T3 and T7 polymerases.

Following the discovery of T7 and T3 polymerases, a new model can be developed for the positive control of transcription of these phage genomes.

A small quantity of the infecting DNA is first transcribed by the *E. coli* polymerase. In the case of T3-DNA, three types of mRNA molecules are found *in vitro* at high salt concentrations and in presence of the termination factor ρ[74]; these RNAs are all copied from the "r strand". The resulting transcription products correspond to early *in vivo* T7 or T3 mRNA. The translation of these messengers results in the synthesis of three early proteins, *i.e.* the polymerase and two others whose function is not yet known. The newly synthesized T7 polymerase recognizes the promoters for transcription of the remaining DNA regions, and then takes over the synthesis of the late mRNA. In this system, therefore, there must be at least two types of promoters[152]. In this connection, it is necessary to point out the following:

1. The "r strands" of T7 and T3 contain pyrimidine-rich (cytosine-rich) regions[153]; no such regions are found in the "l strand".

2. The *E. coli* polymerase, in addition to a series of DNA molecules of other organisms, also transcribes the small d(A—T) copolymer very satisfactorily, whereas dGdC is hardly transcribed at all[1]. Apart from their own DNAs, the T7 and T3 polymerase transcribe only dGdC, but not the d(A—T) copolymer[142, 150].

Ten minutes after infection of *E. coli* cells with T7, synthesis of gene 1 protein stops[148]. The phage thus evidently also carries the information for a protein that exerts a negative control on transcription. It is not yet known how this control is exerted. One of several possibilities would be the modification of one or more subunits of *E. coli* polymerase by one of the late proteins.

6. Closing Remarks

Out of a number of systems that are particularly suitable for the study of regulation, a few have been selected to illustrate the possibilities for the regulation of transcription of certain sections of the genetic information. By no means all of the existing data on this topic have been presented. Thus two other extensively studied systems have been

omitted. These are the regulation of phage λ transcription (this has already been reviewed[38, 154]) and the regulation of transcription of the *Bac. subtilis* phage SPO1, which seems at present to be as complicated as that of T4, but has not yet been as thoroughly investigated[155, 156].

It was shown that in both uninfected and infected bacterial cells, there are several possibilities for switching the transcription of certain groups of genes on or off. "Switching on" can take place:

1. by the change in the initiation specificity of the enzyme caused by modification of the subunits and/or by synthesis of new protein factors such as σ and ψ_r;

2. by the synthesis of an antitermination factor, which enables the polymerase to transcribe new gene groups beyond certain "stop signals"; and

3. by the synthesis of a new polymerase with a different initiation specificity.

These three possibilities are not mutually exclusive, but may operate together, since several classes of mRNA occur in some cases.

The "switching off" of the transcription of gene groups can occur:

1. by modification of enzyme subunits, as a result of which certain promoters are no longer recognized; and

2. by the synthesis of repressors that can be bound to DNA in the neighborhood of individual promoters and can thus prevent transcription of the corresponding gene section.

The proteins taking part in the regulation of transcription can be inhibited in some cases by low molecular weight substances, such as the ψ_r factor by ppGpp or the *lac* repressor by lactose. This enables the cell to react rapidly and reversibly to changes in environmental conditions.

Though the regulation even of simple systems is not yet fully understood, the existing data show that the cell functions can be very effectively regulated at the level of transcription by a balanced cooperation of positive and negative control elements.

This article covers the literature published up to June 1971. I am grateful to Prof. Dr. U. Winkler for encouragement and continued interest in this work, as well as to all those who have assisted in the preparation of the manuscript. I also thank Mrs. A. Hörling for typing the manuscript and Mrs. B. Benninghoven for preparing the drawings. This work was supported by the Deutsche Forschungsgemeinschaft.

Cooperative Conformational Changes in Globular Proteins

By Fritz M. Pohl[*]

In globular proteins, the complicated steric arrangement of the polypeptide chain is determined by several interdependent cooperative interactions. These macromolecules are capable of reacting to changes in the environmental conditions such as temperature and pressure or the concentration of a wide range of compounds by changing their conformation and hence their biological and chemical properties. They are thus suitable for regulation processes or information storage in solution with a wide range of time constants. Environmental effects of this kind can be followed and explained in part at the molecular level by investigation of the time-dependent reversible unfolding of a number of proteins that can be described to a good approximation by a strongly cooperative "all-or-none" transition between two states.

1. Introduction

Proteins are among the most complicated of all organic molecules, and also among the most fascinating[1]. Together with the "linear" macromolecules, the nucleic acids, which serve in particular for the storage and transfer of genetic information, the "two-dimensional" membranes, which serve also as boundaries and partitions for the separation of compartments, and water with its special properties as a solvent[2-5], they are responsible for numerous structures and processes in biology. As enzymes, the proteins have the function of accelerating chemical reactions and considerably increasing their specificity. Proteins are important molecules for regulation processes in the cell, without which it would be impossible for the many reactions to proceed in an orderly manner under changing environmental conditions[6, 7].

The large number of natural proteins is understandable from their chemical structure. A very large number of possible sequences can be produced by linking together 20 different amino acids to form polypeptide chains of 100—500 members in most cases. Weak interactions such as hydrogen bonds, "hydrophobic" bonds, van der Waals interactions, and "ionic bonds" occur between the members of the same chain and also between the chain and other small and large molecules[8-10]. These interactions influence one another and lead to the cooperative stabilization of certain steric arrangements. Cooperative effects of this type are familiar for small molecules in the form of phase transitions such as melting and evaporation.

Many biological and biochemical properties of the proteins are associated with one particular three-dimensional arrangement of functional groups, which is often referred to as the "native" form. If this arrangement or "conformation" is changed, the corresponding properties of the proteins are also changed. It is thus possible to build up molecular control and switching circuits in which changes in the environment are reflected in changes in the macromolecular conformation, often intensified by cooperativity[11], as for example in a non-linear response to changes in the concentration of small molecules.

The environmental influences can be best summarized by equation (1)[12]. In this equation, ΔG_p^0 is the change in the free energy of a protein upon a change in temperature of ΔT, in pressure of ΔP, or in the mole fraction of the i-th type of particle of ΔM_i (effects due to a change in electric field $\Delta\mathfrak{E}$ are not taken into account):

$$\Delta G_p^0 = \sum_i \mu_i \Delta M_i - S\Delta T + V\Delta P \qquad (1)$$

(μ_i are the chemical potentials, S is the entropy of the system, V is the volume). Eq. (1) can be illustrated by the impressions of the senses, such as smell and taste (ΔM_i), heat and cold (ΔT), and sound and touch perceptions (ΔP). In all these cases, a change in the conformation of certain "receptor" proteins, *i.e.* ΔG_p^0, is very probably important to the initiation of the stimulus.

In addition to an accurate determination of the native conformation itself, questions of special interest include the extent, the rate, and the reason for the conformational change of a protein on variation of the environment. Apart from general observations on the conformation of globular proteins, problems of conformational changes connected with eq. (1) are discussed here with respect to a particular example, *i.e.* the kinetics of the reversible unfolding of certain mutually "related" proteins[13].

The conformation of a protein is the steric arrangement of the polypeptide chain, which consists of 1000—10000 atoms in many cases. The conformers can be converted into one another by rotation about covalent bonds[14]. A conformational change is a change in which no chemical bonds (with the exception of hydrogen bonds) are altered and the torsion angles θ about the bonds are the essential variables. Figure 1 shows part of a peptide chain with the designations of the principal torsion angles.

Strictly speaking, this definition rules out any change in the bond lengths b and bond angles α. This is justifiable to a first approximation for the general steric arrangement of the main and side chains[15, 16]. Thus for an energy consumption of kT, the relative position of a C^α atom, for

[*] Priv.-Doz. Dr. F. M. Pohl
Max-Planck-Institut für Biophysikalische Chemie
34 Göttingen-Nikolausberg (Germany)

example, changes by ± 0.04 Å on variation of b, by ± 0.15 Å on variation of α, but by ± 1 Å on variation of θ. This naturally does not mean that such changes in b or α cannot be of particular importance, *e.g.* in enzymatic catalysis.

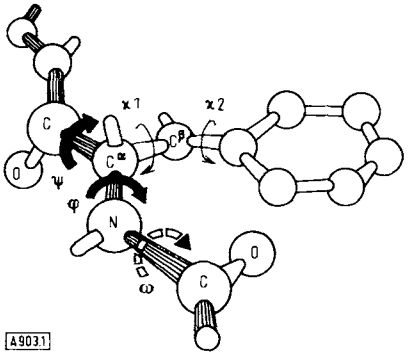

Fig. 1. Schematic representation of part of a polypeptide chain, with designation of the torsion angles about bonds of the main chain (ϕ, ψ, ω) and of the side chains of phenylalanine ($\chi 1$, $\chi 2$) [14].

This "geometric" definition, which is oriented in particular toward the requirements of the X-ray structure analysis of protein crystals, does not give any lower limit for conformational changes. In this progress report, a change will be referred to as a conformational change only if the torsion angle changes by at least 30°.

The determination of changes in certain torsion angles in solution is still rather hopeless for macromolecules, despite the progress that has been made *e.g.* for cyclic oligopeptides[17]. In many cases, an indication of conformational changes in macromolecules is the observation that reaction steps are independent of the protein concentration or that such steps are necessary for the quantitative explanation of the reaction scheme[18-20].

Reversible conformational changes may involve the rotation of a single side chain or they may involve the collapse of the entire steric structure. It is therefore often necessary to use very different methods for their measurement. (Conformational changes in which protein properties such as absorption or fluorescence of aromatic side chains are altered can fairly easily be followed *directly*.) For processes involving a large part of a protein molecule, at least a rough classification seems justifiable:

1. The change *e.g.* in the activity is due to a change from the native to a "flexible" conformation ($A \rightleftharpoons F$), the investigation of which is possible practically only in solution. Readily measurable changes *e.g.* in the hydrodynamic and thermodynamic properties occur here. An example that has been intensively studied is the glyceraldehyde-3-P dehydrogenase (GAPDH) from yeast[20-22]. However, this group also includes processes such as reversible denaturation (by extreme temperatures and pH values or by a change of solvent), which can be best compared with transitions between a solid and a liquid phase of the macromolecule.

2. The change is due to the transition from a "relaxed" to a "locked" or "strained" conformation, *i.e.* both have solid-like properties and can be investigated by X-ray analysis in the crystal. An example is the transition from the arterial form of hemoglobin into the venous form ($A \rightleftharpoons V$) on release of oxygen[23], which can be compared with transitions between two solid phases.

2. Conformation of Globular Proteins

2.1. Anatomy of Proteins

Two methods complement each other excellently in the determination of the static three-dimensional arrangement of the polypeptide chain:

1. The determination of the electron density distribution with atomic resolution by X-ray diffraction in protein crystals[24-26]. (The distribution of nuclei (mainly hydrogen) can now also be determined by neutron diffraction[27].)

2. The determination of the amino acid sequence by chemical methods[28-30].

By means of the two methods together, it is possible to construct models of globular proteins in which the nature and the steric positions of a few thousand atoms are given. The rapid progress in this field is indicated in Figure 2.

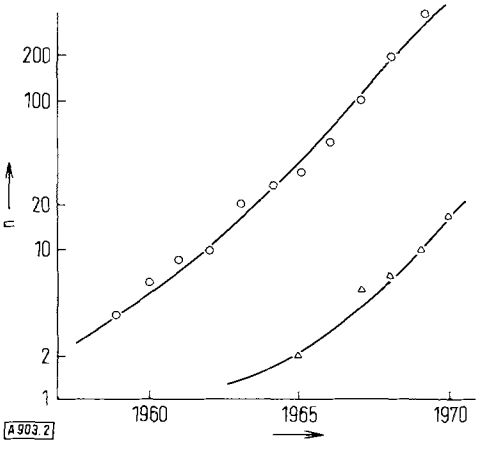

Fig. 2. Number n of globular proteins whose primary structure (—o—o—) [30] and whose three-dimensional crystal structure with an atomic resolution of better than 3.5 Å (—△—△—) have been determined in recent years [25, 26]. The rapid progress is impressively shown even by the logarithmic plot.

No simple "geometric" structural principles can be deduced from the structures obtained. Even the description of the secondary structure, *i.e.* the arrangement of small regions of the main chain, by α (helix) and β (pleated sheet) structures is only a relatively rough approximation; considerable deviations occur from the geometry observed for polyamino acids. An example of the complicated structure of two related enzymes is illustrated in Figure 3, where only the course of the peptide chain is shown[31-33]. This great similarity of the conformations, though only 39% of the amino acids are homologous, is also found in other members of this family of proteins, chymotrypsinogen A[34] and trypsin[35].

Different crystal forms of the same protein, such as α- and γ-chymotrypsin[36] or subtilisin novo and subtilisin

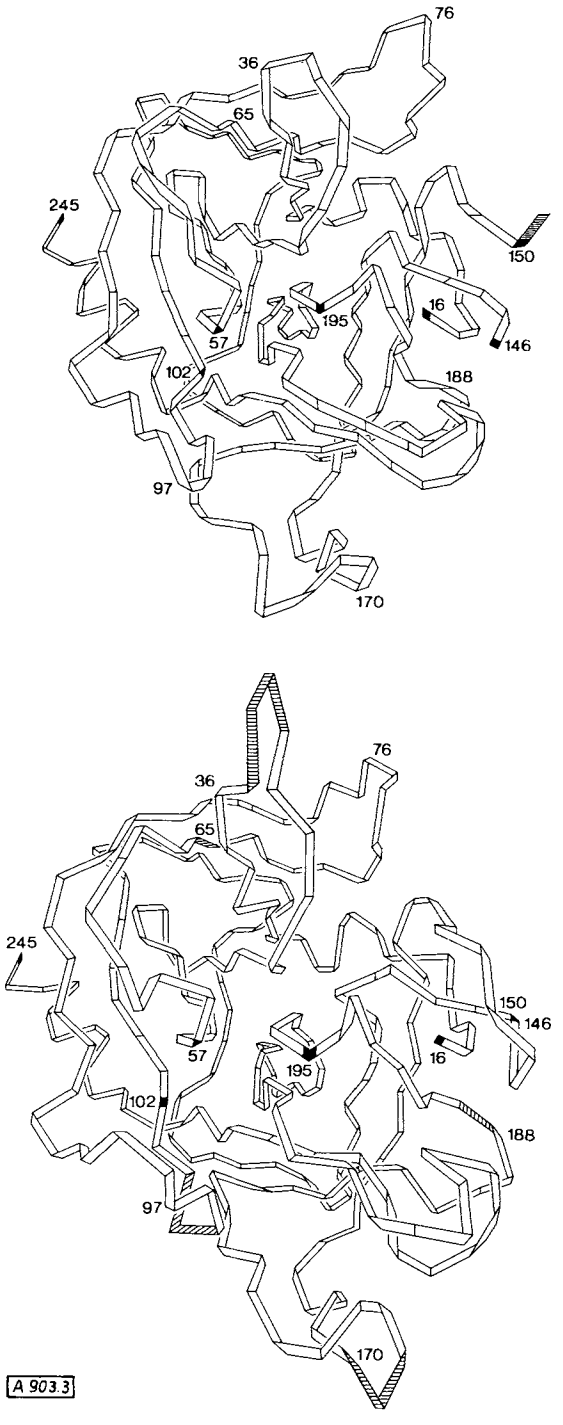

Fig. 3. Conformation of the polypeptide chain of α-chymotrypsin (top) and of elastase (bottom), two related proteins, as found from X-ray diffraction on protein crystals. The band, which is bent at each C^{α} atom, represents the main chain (after [33]). Though the two enzymes differ in a number of amino acids, a very similar steric folding is found.

BPN[37, 38] also show only minor differences in conformation. However, small differences in conformation even within the same crystal can be observed for the two proteins constituting the dimers of α-chymotrypsin or insulin[31, 39]. Great similarities, such as have already been found between myoglobin and hemoglobin, suggest that the influence of the exchange of amino acids on the conformation of proteins of various species can be predicted relatively accurately if the fundamental structure is known.

It is interesting to correlate the conformation of dissolved proteins with the conformation in the crystal. Observations so far indicate that under comparable conditions, the two conformations probably often differ only in the mobility of some side chains at the surface of the molecule.

An "energetic" structural principle is confirmed at least as a very good approximation by all X-ray structure analyses. The polar side chains are nearly all in contact with the aqueous solution, while mainly apolar or hydrophobic side chains are arranged in the interior[8, 40]. The magnitude of such interactions with water can be estimated from the solubility of amino acids in water and in organic solvents respectively[41]. The change in free energy when amino acids are transferred from ethanol into water (ΔG_t^0)[42, 43] is shown in Figure 4 as a function[71] of their volume[44].

The dangers of the simple application of these numerical values to changes in conformation lie in the fact that it is not entirely certain whether and to what extent the free energy is additive for macromolecules. Models for liquid mixtures suggest *e.g.* a higher than linear dependence on the relative volume[45]. Moreover, it has not been established how well a thermodynamic description of the interior of the protein as a liquid organic or oily phase fits the facts. The results of X-ray diffraction are more easily reconciled with a "solid" phase and very dense packing of the amino acids[49, 43]. Furthermore, the ΔG_t^0 values for the transfer

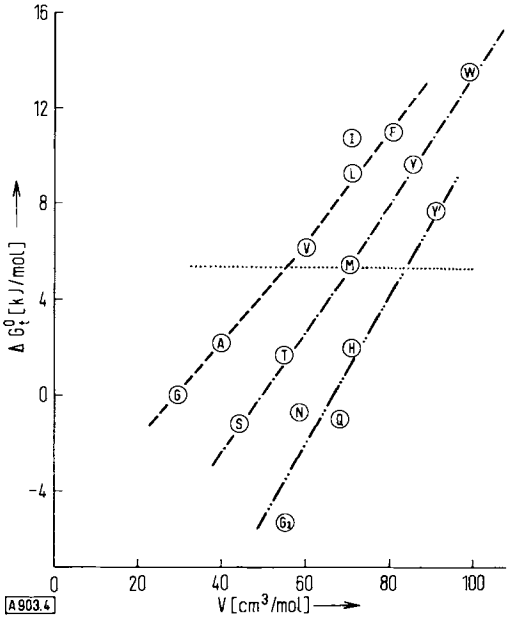

Fig. 4. Change in free energy ΔG_t^0 for the transfer of several amino acids from water into ethanol at 25 °C [42, 43], plotted as a function [71] of the molecular volume [44]. The curves connect amino acids whose side chains contain no polar atoms (– – –), one polar atom (–.–.–), or two polar atoms (–..–..–) such as nitrogen or oxygen. ΔG_t^0 was deduced from the solubility [43]; the value for glycine was taken as zero. If the solubility difference of the peptide group as found from the difference between glycine and diglycine is also taken into account, the dotted line roughly represents the zero line for the transfer of a peptide. The parts of the polypeptide chain that have side chains above this dotted line will prefer a nonaqueous environment, while the remainder will prefer contact with water. The amino acids are denoted in accordance with the one-letter code [30]: A (alanine), F (phenylalanine), G (glycine), G_2 (diglycine), H (histidine), I (isoleucine), L (leucine), M (methionine), N (asparagine), Q (glutamine), S (serine), T (threonine), V (valine), W (tryptophan), Y (tyrosine), and Y' (dihydroxytyrosine).

of peptide groups are difficult to estimate, and are indicated in Figure 4 only very approximately. However, these values and data on the influence of solvent mixtures on the thermodynamics of conformational changes may allow at least a rough estimation of the number of additional amino acids that come into contact with the solution[41,46].

This example of a "hydrophobicity scale" shows that though the behavior of small molecules is relatively well known, additional problems arise in the application of the data to proteins, and quantitative conclusions can therefore be drawn only with reservations. The same is true of stabilization by hydrogen bonds or electrostatic interactions[47,48].

In this connection, it should be pointed out that practically no systematic investigations on the packing properties of "irregular" polymers have been reported. The minimum free space required in the interior of a polypeptide is unknown. On the other hand, the rules for the tight packing of polypeptide chains are particularly important to the understanding of the conformation of globular proteins[49] since relatively large amounts of energy must be supplied to produce an "empty" volume in water.

Another difficulty in the deduction of thermodynamic stabilities of proteins from the crystal structure is that too little is known, at least with the required accuracy, about the height of the barriers to rotation about individual bonds in polypeptide chains[15]. Values for several thousand bonds have to be added together and this also presents a difficult problem. A possible simplification by consideration of the distribution of the various conformations observed in proteins themselves is discussed in Section 2.2.

2.2. Conformational Analysis

The numerous conformations that have been established experimentally (Fig. 2) allow the derivation of additional information. The most probable conformations around certain bonds can be determined by the use of all the corresponding data found for many proteins at high resolution for the construction of "empirical protein energy maps"[50]. Though peculiarities of a particular protein are lost by this averaging procedure, the underlying "conformation patterns" become very clear.

To illustrate this with an example, Figure 5 shows the distribution of the conformations of aromatic side chains found in eleven proteins for the torsion about the C^{α}—C^{β} bond, which is described by the torsion angle $\chi 1$ (Fig. 1). A logarithmic plot was chosen, from which a kind of conformation energy $E_{\chi 1}$ can be derived which, apart from a constant Q, is given by

$$E_{\chi 1} = -RT(\ln q_{\chi 1} + \ln Q) \qquad (2)$$

The relative density of experimental values $q_{\chi 1}$ from as many proteins as possible is equal to the number $n_{\chi 1}$ of conformations observed in the range of angles $\chi 1 \pm \Delta\chi 1$, divided by the total number of observed values N. Figure 5 shows the conformations of $N = 230$ aromatic side chains given for intervals of $\pm 10°$[50]. The curve shown is obtained by superposition of two harmonic functions

$$E_{\chi 1} = \frac{E_1}{2} \times \sin(\chi 1) + \frac{E_3}{2} \times \cos(3\chi 1) \qquad (3)$$

where E_3, the three-fold barrier to rotation about the C^{α}—C^{β} bond, is 8.6 kJ/mol. This is comparable with the values found by very different methods for small molecules[51]. The other contribution to the conformation energy, $E_1 = -5.4$ kJ/mol, represents the interaction between the peptide chain and the aromatic ring. The relative populations of the three conformations I, II, and III are given in Table 1. This distribution is practically the same for the side chains of phenylalanine, tyrosine, histidine, and tryptophan, and agrees well with the values found from NMR measurements on model molecules[52].

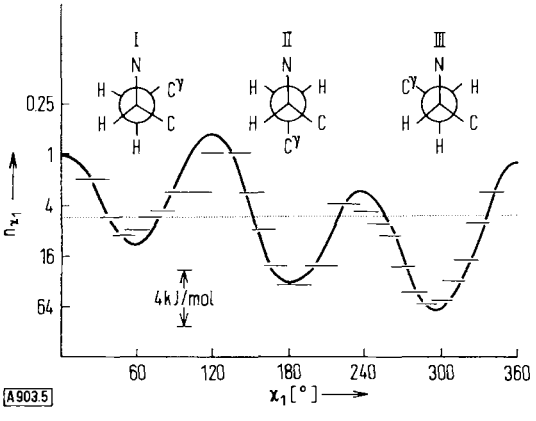

Fig. 5. Distribution of the conformations of 230 aromatic side chains as found for eleven proteins by X-ray structure analysis with a resolution of 2.8 Å or better [50]; the conformations I, II, and III, which differ in torsion about the C^{α}—C^{β} bond, are shown as Newman projections. The observed number of conformations $n_{\chi 1}$ per 20° of the torsion angle $\chi 1$ (short dashes) is shown in a logarithmic plot to facilitate comparison with the conformation energies in accordance with eq. (2). The continuous curve is the superposition of two harmonic functions in accordance with eq. (3).

An advantage of the method outlined here is that important information can be obtained relatively easily from the immense volume of data on the X-ray structure analysis of proteins. This is naturally not restricted to rotation about a single bond. When sufficient data are available, correla-

Table 1. Relative abundances of the three conformers I, II, and III (Fig. 5), which differ in rotation about the C^{α}—C^{β} bond, in the side chains of aromatic amino acids. For comparison, data found from NMR spectroscopy for the tripeptide Gly-Phe-Gly in D_2O are also given [52]. The data for the side chains (see Fig. 5) were obtained from conformations observed in the crystal structure of eleven different proteins [50].

Side chains of	Number of observations	Population		
	N	p_{I}	p_{II}	p_{III}
Histidine	53	0.09	0.36	0.55
Tryptophan	34	0.15	0.35	0.50
Tyrosine	65	0.11	0.29	0.60
Phenylalanine	78	0.09	0.37	0.54
Total:	230	0.11	0.34	0.55
Gly-Phe-Gly [52]		0.14	0.34	0.52

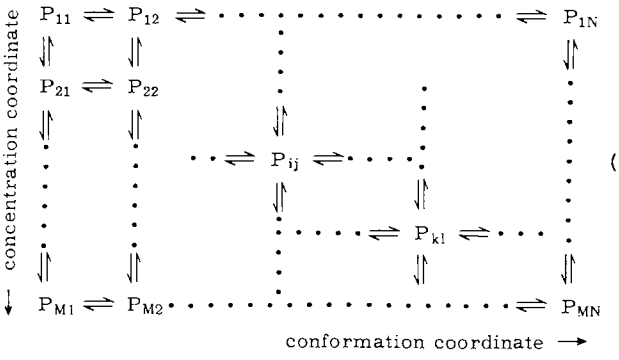
tions in two and more variables can be established; these should be of considerable value in the prediction of unknown conformations, and should contribute to the molecular explanation of conformational changes. Empirical distributions of this type can also be compared with calculations of the conformation energy[16, 53, 54].

3. Reversible Conformational Changes

3.1. Theoretical Considerations

An extensive literature exists on the theory of cooperative structural changes of linear polymers, such as helix-coil transitions of polypeptides; this literature deals both with the statistical mechanics and thermodynamics of such systems and with their kinetics[55-57]. The "linear Ising model", in which interactions with nearest neighbors are taken into account, has proved particularly useful.

Numerical calculations have been carried out on a simple three-dimensional Ising model for cooperative transitions of globular proteins[58]. However, a complicating factor here is that the state of an element in the three-dimensional network of the interactions not only depends on the state of the nearest neighbors in the chain or in space, but may also be influenced by the state of relatively remote parts of the macromolecule. An example is provided by the changes in the positions of a number of groups in chymotrypsinogen A as a result of the breakage of the peptide chain in positions remote from these groups on activation[59].



The folding of proteins can also be regarded as analogous to the nucleation and condensation phenomena in phase transitions[61-63].

However, the most serious problems are due to the fact that a large number of parameters must be known before a moderately realistic quantitative description on the molecular level is possible. Moreover, relatively few conformational changes have so far been experimentally studied so systematically as to allow a decision in favor of one of several models[60].

If one disregards "small" conformational changes, such as the reorientation of a single side chain, for which the description normally used for small molecules is adequate, a large number of elementary steps such as opening and closing of hydrogen bonds and simultaneous rotation about one or more bonds must always be expected in cooperative changes. This can be represented in a greatly simplified form by a general conformation coordinate

$$P_1 \rightleftharpoons P_2 \rightleftharpoons \ldots P_i \ldots \rightleftharpoons P_N \qquad (4)$$

where the P_i each denote a different conformation. Even if it is assumed that each of the n amino acids can exist in only two conformations, there will be $N = 2^n$ possible states; however, these will be occupied with very different weights. Since the conformational changes take place in solution and not in a vacuum, the influence of other molecules must also be taken into account[64, 65]. This is achieved with the aid of a general concentration coordinate. The two coordinates can be combined to give (5):

(5)

The states within a column differ in the number and positions of "bound" water molecules, cations, anions, *etc.* The relative concentrations of the states and their dependence on external variables are important to the description of such a system. A relaxation spectrum is generally to be

$$\phi(t) = \sum_i \beta_i \exp(-t/\tau_i) \qquad (6)$$

expected for the kinetics if a small sudden disturbance of the equilibrium occurs, *i.e.* a superposition of exponential functions with different time constants τ_i and amplitudes β_i should be observed if the various states are present in comparable concentrations[56].

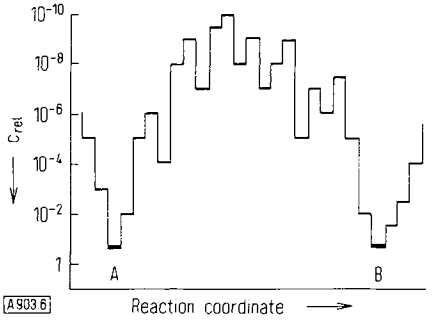


Fig. 6. Schematic representation of a concentration distribution (relative concentration C_{rel} in arbitrary units) of the distinguishable conformations of a protein as expected if *e.g.* unfolding at the melting point T_m can be described as an "all-or-none" process. The states A and B may each represent a collection of somewhat different conformations, which cannot be distinguished experimentally [79].

A significant simplification results if only two states P_{ij} and P_{kl} can be detected, as indicated schematically in Figure 6. If the concentrations of intermediate states and their variation with time can be disregarded, we have an "all-or-none" process, which is described by two overall or steady state rate constants:

$$A \underset{\bar{k}}{\overset{\vec{k}}{\rightleftharpoons}} B \qquad (7)$$

Information on the individual intermediate states is largely lost here. However, the simplification also allows a closed solution of extensive systems of kinetic differential equations, since under steady-state conditions, the change in the concentration of intermediate states as a function of time is zero; the overall rate constants $\vec{k}$ and $\bar{k}$ are then obtained by straightforward calculations.

3.2. Model Systems

Investigations have so far been carried out in solution only for relatively few cooperative conformational changes in proteins that are fully reversible, *i.e.* in which the initial state is restored after a disturbance and in which a parameter that directly characterizes the conformation of the protein is followed. Measurements are often hindered by the low concentrations, which are around $10^{-4}-10^{-6}$ mol/l in many cases. It is sometimes also difficult to distinguish clearly between changes in the conformation itself and in the bonding of small molecules.

As was mentioned earlier, the cooperative effects are particularly important. Unfortunately, there are no macromolecules with simple structures that exhibit *three-dimensional* folding similar to that shown by globular proteins, so that it is necessary at present to investigate natural proteins. To observe these cooperative effects within a molecule, there should be no aggregation between the molecules which might mask intramolecular processes. The main problem is that, in many proteins consisting of subunits[65, 66], cooperative unfolding is often not fully reversible[67]; thermodynamic and kinetic data are then only of limited validity.

The acid denaturation of some intensively studied proteins such as chymotrypsinogen, trypsin, ribonuclease, and lysozyme is at present the simplest model system for the investigation of cooperative and reversible conformational changes in globular proteins, in which many biologically interesting phenomena can also be simulated. This reaction, which is also known as transition I, can be best described as a transition from a compact to a more mobile conformation, which, however, involves only parts of the protein and apparently does not lead to a completely random coil conformation[9].

There are a series of excellent reviews on this transition, which deal in particular with the equilibrium properties[9, 68, 69]. As a typical example, Figure 7 shows the transition of chymotrypsinogen A in acidic solution as a function of temperature[70, 71]. The change in the tryptophan absorption of the protein was measured here after equilibrium had been reached at various temperatures.

When the solution is cooled, the original values are restored; the transition curve can be transversed repeatedly with no deviation from the original curve, *i.e.* the transition is fully reversible. (In the case of α-chymotrypsin, the enzymatic properties are also fully restored if the refolding takes place in acidic solution, but only partially in neutral solution[71].)

Several properties of the native form A, which exists at low temperatures, change into those of the unfolded form B within a range of about 15 °C. The transition may also be regarded as a melting process within the macromolecule[79]. The temperature in the middle of the transition is also referred to as the melting temperature T_m.

The transition can be initiated by various experimental methods; changes in the temperature, pH, or the pressure [eq. (1)][70-73] reflect "environmental changes". Spectroscopic detection of the conformational change is advantageous *e.g.* in kinetic measurements down to the nanosecond range. The most important of the methods used so far to follow the equilibrium of transition I, in addition to the measurement of UV and IR absorption, optical rotation, fluorescence, and NMR spectra[68-74], include measurements of viscosity, sedimentation behavior, specific volume[75], specific heat[76], solubility[77], and tritium exchange[78].

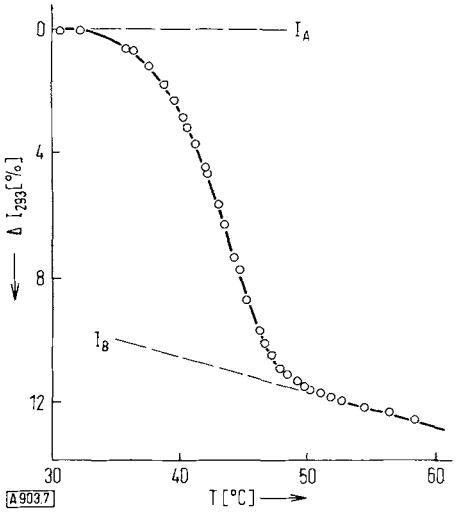

Fig. 7. Equilibrium curve of the transition I of chymotrypsinogen A at pH = 2.0 as a function of the temperature. The percentage decrease in the tryptophan absorption at 293 nm (I_{293}) was measured after equilibrium had been reached. I_A and I_B (---) are the values for forms A and B in the transition region extrapolated from the optical behavior at low and at high temperatures respectively.

One question is whether this transition can be described as an "all-or-none" process between two macroscopic conformations of the protein, *i.e.* whether half of the molecules are in the form A and the other half in the form B at the temperature T_m, or whether at T_m *e.g.* half of each individual molecule is changed, and very many different conformations are present in measurable concentrations, as is expected for the helix-coil transition of long polypeptides[80]. It is difficult to answer this question on the basis of equilibrium measurements. Important tests are[79]:

1. A two-state model may be assumed if several parameters change by the same relative amount when an external variable is changed. The methods mentioned above should therefore give the same equilibrium constant K [eq. (7)] under comparable conditions. Extremely high accuracy of measurement is often necessary for such a comparison; this criterion is satisfied *e.g.* by isosbestic points in the protein spectra in the transition region.

2. Another test is the agreement of the enthalpy found by calorimetric measurement with that calculated from the van't Hoff equation. This test has satisfactorily confirmed a two-state model in acidic solution for the three proteins investigated so far, *i.e.* chymotrypsinogen[76], ribonuclease A[81], and lysozyme[82].

3. A further test, which can also be applied to very small quantities of substance, is the examination of the kinetic behavior after a rapid perturbation of the equilibrium.

4. Kinetics of Reversible Folding

Kinetic measurements, in addition to the information on the thermodynamics of the system, also provide information on its behavior as a function of time. This is particularly important for biological phenomena, with their strong time dependence. Even intermediate states with very short lifetimes can be detected, and it may thus become easier to decide between several possible reaction mechanisms.

4.1. Methods

As a result of the development of kinetic methods, the variation of the conformation with time after a sudden or periodic disturbance of an external parameter in equation (1) can be followed over many orders of magnitude[83-85]. For very fast reactions, rapid mixing of solutions in stop-flow apparatus (ΔM_i) and relaxation methods, *e.g.* temperature jump (ΔT) and pressure jump (ΔP) methods, are particularly important, as well as ultrasonic and nuclear magnetic resonance measurements.

To follow the kinetics of the transition I (Fig. 7), one need only vary the temperature rapidly enough and follow the establishment of a new equilibrium, *e.g.* on the basis of the change in absorption. This is a relatively slow process, in the second to minute region. A very simple temperature jump method has proved to be very suitable for this purpose[70].

In this method, the solution to be investigated is placed in a thermostatically controllable microcell, which allows a fast temperature equilibration (half time $\approx$ 1s) between the thermostat liquid and the solution. The solution can be subjected to positive and negative temperature jumps of any size by the alternate passage of the liquids from two thermostats at different temperatures through the thermostat jacket of the cell with the aid of magnetic valves. The variation of the absorption, fluorescence, optical rotation, *etc.* with time is then recorded.

4.2. Kinetic Criteria for an "All-or-None" Process

For a multi-stage reaction system of type (5) which must certainly be the case for the unfolding of a protein, a relaxation spectrum in accordance with (6) will be expected for a small disturbance of the equilibrium. Such a relaxation spectrum has been observed in the denaturation of high molecular weight DNA[86, 71]. If the measurable concentration distributions before and after the disturbance correspond roughly to those indicated in Figure 5, very stringent conditions must be satisfied for the kinetics (see Fig. 8)[13, 87].

1. The establishment of the new equilibrium as a function of time after a sudden disturbance follows a simple exponential function, which gives a straight line in a semi-logarithmic plot (Fig. 8a); the relaxation time or time constant τ can be determined from the slope of this line. (Changes such as those responsible for the change in the density of the solution after a sudden temperature change or the change in the bonding of small molecules, must be considered separately.)

2. The rexalation time is independent of the parameter followed, *e.g.* absorption at various wavelengths, solubility, *etc.*

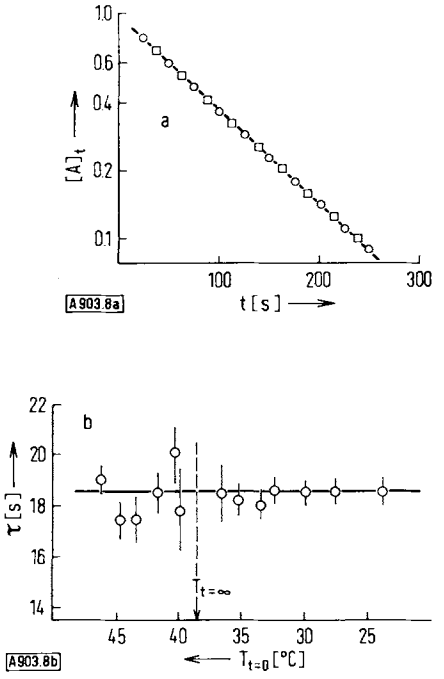

Fig. 8. "All-or-none" transition of trypsin at pH = 1.8 [87, 13]. The relaxation time τ is independent of the protein concentration ($10^{-7}-10^{-5}$ mol/l). a) Change in the optical rotation at 315 nm (— o — o —) and in the absorption at 293 nm (— □ — □ —), divided by the total change between $t=0$ and $t=\infty$, as a function of time. (Temperature jump from the transition region at 39 °C to 20.0 °C.) b) Lack of dependence of the relaxation time τ on the initial state (temperature at time zero, $T_{t=0}$) and on the magnitude of the disturbance. The final temperature is constant at 38.4 °C. The varying error limits are due to the different amplitudes of the relaxation curves.

3. The time constant τ depends only on the final state reached after the disturbance, and not on the initial state (Fig. 8b), as is to be expected from the equation[88]

$$[A]_t = ([A]_{t=0} - [A]_{t=\infty})\, e^{-t/\tau} + [A]_{t=\infty} \qquad (8)$$

which describes the change in the concentration of A as a function of time after a sudden disturbance.

If these criteria are satisfied, as in the transition I discussed here, it is justifiable to describe the conformational change in the approximation of an "all-or-none" process. (With very sensitive kinetic methods, it is also possible to detect fast preceding equilibria, though these usually account for only a few percent of the total change[70, 108].) The overall rate constants for the folding $\vec{k}$ and for the unfolding $\overleftarrow{k}$ can be determined. The equilibrium constant K can be deduced *e.g.* in accordance with eq. (9)

$$K = [A]_{t=\infty}/(1-[A]_{t=\infty}) = \vec{k}/\overleftarrow{k} \qquad (9)$$

from the relative amplitude $[A]_{t=0} - [A]_{t=\infty}$, which also contains all the thermodynamic information. Together with the definition of the relaxation time

$$\tau^{-1} = \vec{k} + \overleftarrow{k} \qquad (10)$$

two equations for the determination of the two unknowns $\vec{k}$ and $\overleftarrow{k}$ are given.

These two overall rate constants can be regarded, according to the theory of the activated state[89], as "quasi-thermodynamic quantities" the zero of the free energy of activation ($\Delta\vec{G}$ or $\Delta\overleftarrow{G}$) being taken as $RT \ln (kT/h)$ (where k is Boltzmann's constant and h is Planck's constant). For the unfolding, this leads to

$$\vec{k} = (kT/h) \times \exp(-\Delta\vec{G}/RT) = (kT/h) \times \exp(-\Delta\vec{H}/RT + \Delta\vec{S}/R) \quad (11)$$

with $\Delta\vec{H}$ as the enthalpy and $\Delta\vec{S}$ as the entropy of activation. $\Delta\vec{H}$ can be obtained from the Arrhenius equation or the first derivative of $\Delta\vec{G}$ with respect to the temperature.

$$\Delta\vec{H} = RT^2 \frac{\mathrm{d} \ln \vec{k}}{\mathrm{d}T} - RT \quad (12)$$

If $\Delta\vec{H}$ itself is temperature-dependent, it is also possible to define a specific heat of activation.

$$\Delta\vec{C} = \mathrm{d}\vec{H}/\mathrm{d}T \quad (13)$$

Similar equations are found for $\overleftarrow{k}$; the connection with the usual thermodynamic functions in the case of the equilibrium is provided by eq. (9) and the expression for the free energy ΔG^0:

$$\Delta G^0 = -RT \ln K \quad (14)$$

4.3. Temperature Dependence

The relaxation time as a function of temperature for the transition I of chymotrypsinogen A, a typical example, is shown in Figure 9[93]. (The corresponding dependence of the overall rate constants is also given.) It can be seen that below the transition temperature, the reciprocal relaxation time τ^{-1} becomes equal to the rate constant for folding $\vec{k}$; at high temperatures, τ^{-1} becomes equal to $\overleftarrow{k}$. The experimental values found some 20 years ago by *Eisenberg* and *Schwert*[77] are also plotted. Instead of the tryptophan absorption, these authors used the solubility of the protein in a precipitation buffer as the parameter. The good agreement, among other things, supports the proposed course of the transition.

A striking feature in comparison with conventional chemical reactions in this temperature and time range is the high positive activation energy for unfolding ($\Delta\vec{H}$) and the strong temperature dependence of $\Delta\overleftarrow{H}$ for folding, with negative values at high temperatures (Fig. 10). Both observations indicate that several elementary steps are necessary for this conformational change[103, 108]. A similar temperature dependence is observed in the denaturing of other heterogeneous biopolymers such as DNA and collagen[90, 91], as well as in phase transitions[63]. The transition I can thus be placed in the larger group of problems of cooperative processes involving nucleation.

An important result is that high positive, but also zero or negative, temperature coefficients are found for the kinetics

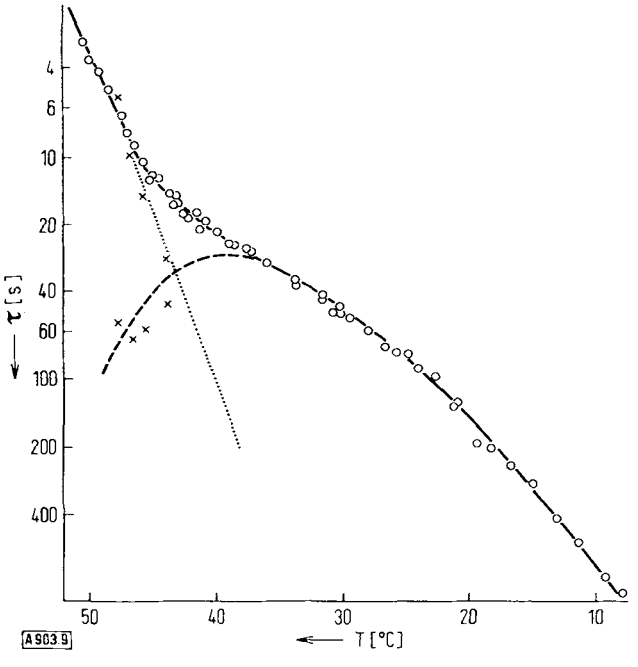

Fig. 9. Relaxation time τ (--o--o--) for the transition I of chymotrypsinogen A at pH = 2.0 as a function of the final temperature, determined by following the change in the tryptophan absorption of the protein as a function of time [70, 71]. In the transition region, the overall rate constants for unfolding $\vec{k}$ (. . . .) and folding $\overleftarrow{k}$ (– – –) are given. The values + and × were obtained by *Eisenberg* and *Schwert* [77] by following the change in the solubility of the protein as a function of time.

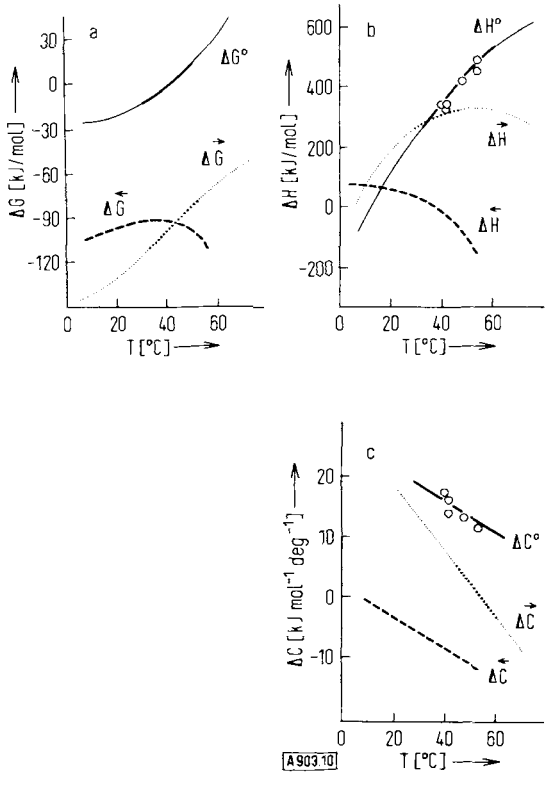

Fig. 10. Temperature dependence of the thermodynamic and kinetic parameters for the transition I from chymotrypsinogen A. a) Free energy, b) enthalpy, c) specific heat. The thin lines indicate the extrapolation of the experimental data when the change in the specific heat ΔC is described by a linear dependence on temperature. (—o—o—) denotes data from calorimetric measurements [76] and (——) the equilibrium data determined by optical measurements. The kinetic quantities for unfolding (....) and for folding (– – –) are given. (An error of ±0.1 °C in the measurement of the temperature and of 5% in the rate constants over a temperature range of 10 °C gives an uncertainty of about ±4 kJ mol^{-1} deg^{-1} for ΔC.)

in such conformational changes of proteins. The negative activation energy of $\Delta\vec{H}$ at high temperatures can be attributed to the fact that several steps are necessary for the nucleation, which for its part determines the rate of the folding. With falling temperature, instead of the formation of a nucleus, the further folding of the polypeptide chain may be rate-determining.

Another explanation is that falling temperatures lead to the formation of more and more "false" nuclei, which must be reopened before a successful nucleus is formed. Both can lead to $\Delta\vec{H} < 0$ at high temperatures. The interaction of apolar groups with water, as expressed in the form of the concentration coordinate [see (5)] and the associated contributions to the free energy, may be very important in this respect. Hydrophobic interactions of this type can be responsible for the temperature dependence of the activation energy, since these involve fast pre-equilibria, which enter into the overall rate constants.

Figure 10 shows the currently accepted temperature dependences of the thermodynamic and kinetic functions, a linear temperature dependence being assumed for the variation of the specific heat. (The accuracy of measurement is not sufficient to allow a definite decision as to whether and how ΔC depends on the temperature.) The corresponding functions for the enthalpy and the free energy are then found by integration. If the curves for $\vec{k}$ and $\overleftarrow{k}$ intersect at low temperatures, a cold transition may also be observed[92, 93].

The considerable change in the specific heat was pointed out in particular by *Brandts*[92]. Corresponding results for a series of protein reactions are summarized in Table 2.

Table 2. The change in the specific heat at constant pressure, ΔC^0, for several protein reactions.

Reaction	ΔC^0 [kJ mol^{-1} deg^{-1}]	Ref.
Chymotrypsinogen A:		
solvation	10	[76]
transition I, pH = 2.0, A → B	14	[76]
Ribonuclease A: transition I, pH = 2.8	8.2	[81]
S-protein + S-peptide → RNase S	2.9	[112]
GAPDH (yeast) → holoenzyme + NAD	2.2	[22]
α-Chymotrypsin: dimer → monomer	2.8	[113]

(Calorimetric measurements on small molecules, both apolar and polar, show that their interaction with water leads to changes in the specific heat[5].)

4.4. pH Dependence

Not only does the transition I exhibit a strong and complicated temperature dependence, but the pH dependence also reflects the cooperativity of the transition. Thus for the proteins investigated so far, the rate constant for unfolding $\vec{k}$ increases with the second to third power of the H_3O^+ activity (Fig. 11). Protons influence the native form A as "negative" effectors, since they destabilize this form with increasing concentration[93]. The rate constant for folding $\overleftarrow{k}$, on the other hand, changes only slightly; it decreases somewhat. Much more complicated molecules may act as cooperative effectors (E)[6] on proteins built up from subunits, and may *e.g.* stabilize the native form, as in the stabilization of GAPDH from yeast by NAD at high temperatures and pH values[19].

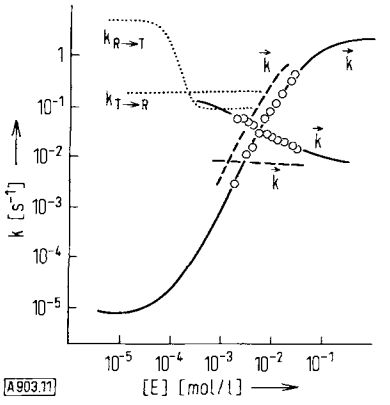

Fig. 11. Rate constants for the conformational change as a function of the effector concentration [E]. (—o—o—) $\vec{k}$ and $\overleftarrow{k}$ for chymotrypsinogen A with H_3O^+ as the effector. Additional measurements in urea solutions were used for the extrapolation [71, 95]. (----) $\vec{k}$ and $\overleftarrow{k}$ after chemical modification (removal of the negative charge) of 13 of the 16 carboxyl groups of chymotrypsinogen A [97, 71]. There are only minor changes in the pH dependence of $\vec{k}$, which is evidence for the stabilization of the form A by special "trigger groups". (....) As a comparison, the kinetics of an "allosteric transition" in an enzyme consisting of four identical subunits, *i.e.* the GAPDH from yeast with NAD as the effector molecule (after [19]).

The dependence of the overall rate constants $\overleftarrow{k}$, $\vec{k}$ of the conformational change can be described in both cases by a very similar reaction scheme. Thus for trypsin with two such peculiar binding sites we have[87]

$$\begin{array}{ccccc} 2H & + A_0 & \rightleftharpoons & B_0 & + 2H \\ K_a \downuparrows & & & \downuparrows K_b & \\ H & + A_1 & \rightleftharpoons & B_1 & + H \\ K_a \downuparrows & & & \downuparrows K_b & \\ & A_2 & \rightleftharpoons & B_2 & \end{array}$$

The concentration dependence of τ is found in a closed form in the case of simplifying and well satisfied assumptions[83]. The assumptions are:

1. The binding of the effector is fast in comparison with the conformational change (a bimolecular rate constant of about 10^{10} l mol^{-1}s^{-1} can be expected for protonation reactions[96]).

2. The change in the concentration of free effector following the disturbance of the equilibrium and the change in the conformation can be disregarded.

3. Within the forms A and B, all n binding sites have equal binding constants for the particular effector; however, the values for the two forms are different ($pK_a \neq pK_b$)[6, 87, 92].

From the values of $\vec{k}$ and $\overleftarrow{k}$, *e.g.* for the measured pH dependence in the case of chymotrypsinogen or α-chymotrypsin, it is found, on the assumption of an "all-or-none" process, that three binding sites for protons with a dissociation constant $K_a = 0.05$ mol/l considerably stabilize the native form A in the unprotonated form, by a factor of about 100—1000 per binding site. The constants K_b (pK values of 3.5—4.5) found for these binding sites in state B are

close to the values expected for carboxyl groups in water and are accordingly smaller by a factor of 100—1000.

A possible explanation for this effect of protons on the conformation is that ionic bonds are formed between certain carboxyl groups and ammonium groups, *e.g.* of lysine, which stabilize the form A[93]. Up to five such ionic bonds are present in crystalline α-chymotrypsin, two being completely shielded from the solution[113].

An experimental confirmation of such "trigger groups" is the observation that the pH dependence of the transition I is not appreciably influenced by removal of the negative charge of 13 of the 16 carboxyl groups in chymotrypsinogen A by chemical modification (Fig. 11)[97, 71]. This is to be expected if the electrostatic repulsion of the positive net charge of the protein in water contributes only slightly to the destabilization of the form A. For such a general electrostatic effect, a monotic dependence of the rate constants on the ionic strength would be expected, which is not observed (Fig. 12a). Ionic bonds of this nature explain also the very low pK value found for carboxyl groups in form A. The proximity of a positive charge causes a considerable pK shift even in small molecules[98].

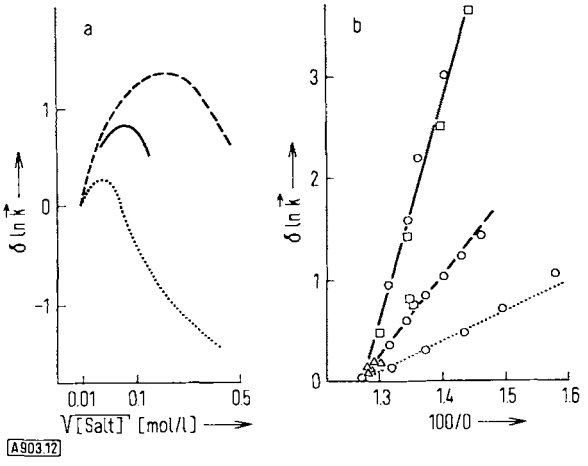

Fig. 12. Influence of monovalent ions (a) and small molecules (b) on the rate constant for unfolding $\vec{k}$ in 8×10^{-3} M HCl for (——) chymotrypsinogen A, (– – – –) trypsin, and (. . . .) ribonuclease [13, 93]. $\delta \ln \vec{k}$ represents the ratio of the rate constant in the corresponding solvent mixture to that in 8×10^{-3} M HCl. a) Change on addition of salts such as NaCl, corrected for the secondary salt effect; b) change in solvent mixtures at 30 °C, plotted against the reciprocal of the macroscopic dielectric constant D of the mixture [93]. (—□—□—) up to 15 vol.% dioxane, (—○—○—) up to 25% ethanol, and (—△—△—) up to 25% ethylene glycol.

4.5. Salt Effects

The unfolding reaction depends in a complicated manner on the salt concentration. A maximum is found for $\vec{k}$, indicating two factors with opposing effects (Fig. 12a). An explanation for the salt dependence of $\vec{k}$ is that the ionic bonds (and hence form A) are destabilized at low ionic strengths by binding of counterions, whereas at higher salt concentrations the electrostatic shielding of the net charge of the protein predominates and $\vec{k}$ decreases[93]. However, such reasoning, which is familiar and justified for small molecules, is not always permissible for proteins[94]. At very high salt concentrations, destabilization of the native form may also occur because the ions change the structure of water[99, 5].

4.6. Variation of Solvent

Slight differences in the transition I are observed when it takes place in heavy water instead of in water (see Table 3). The difference in behavior in H_2O and D_2O found for complicated biological systems[100] may be partly due to the same causes; a possible explanation is provided by small changes in the structure and thermodynamic properties of water upon deuteration[101].

The use of solvent mixtures makes it possible to vary the dielectric constant, the viscosity, *etc.* continuously. The thermodynamic properties of small molecules in these mixtures can be compared with those of the macromolecules[92].

Figure 12b shows experimental values for $\vec{k}$ in several solvent mixtures. A plot of the relative free energy of activation $\delta\vec{G}$ against the reciprocal of the dielectric constant D gives a surprisingly good linear relationship, such as one could expect for electrostatic interactions. No such simple relationships are found for the folding, however, particularly at low temperatures[87]. $\delta\vec{G}$ depends in a very similar manner on the solvent composition and the temperature as does the solubility of apolar molecules[102]. This may be regarded as evidence of the additional interactions of apolar groups with water in the form B[92, 93].

4.7. Change in Covalent Structure of Proteins

Quantitative data on the influence of chemical modifications or the exchange of amino acids on the stability of proteins are important, in particular because of their industrial and medicinal use. The recent successes in the chemical synthesis of proteins offer the possibility of systematically investigating the influence of an amino acid exchange[104]. Another, less systematic method is the comparison of families of proteins or proteins of mutants or of different species.

4.7.1. Exchange of Several Amino Acids

An example is the family of serine proteinases such as chymotrypsinogen A and B, trypsin, and elastase, where parts of the amino acid sequence agree with each other. [Their crystal structure is also very similar (Fig. 3).] The stability and the kinetics of the transition I in acidic solution are also very similar for these proteins (Fig. 13 and Table 3).

4.7.2. Chemical Modifications

Several chemical reactions allow a more or less selective, mild, and specific modification of the side chains of proteins[105]. A modification of carboxyl groups and its influence on the pH dependence has already been mentioned (Fig. 11).

Another example is the modification of the active site of α-chymotrypsin by a diisopropylphosphoryl (DIP-CT) or an anthraniloyl group (AN-CT), these groups being covalently bonded to the active center. There are differences in stability, which are mainly due to a lower unfolding rate (Table 3). With the aid of the fluorescent AN group, however, it is also possible to follow the transfer of energy from tryptophan side chains to the chromophore. This energy

transfer is very sensitive to distance[106], so that distance measurements can be carried out within the protein molecule during the unfolding or folding. Kinetic results obtained in this way agree with the behavior expected for an "all-or-none" process[71].

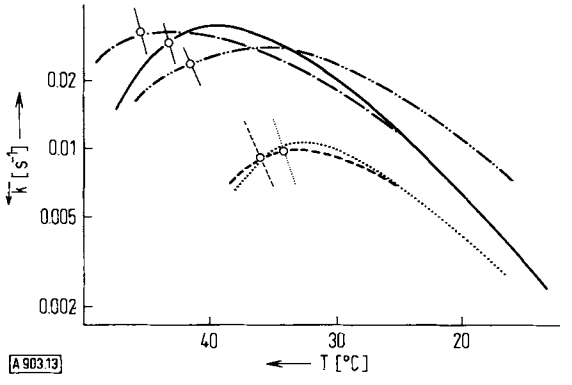

Fig. 13. Rate constant for folding ($\vec{k}$) for several members of a family of proteins at pH = 2.0 as a function of the temperature [13, 93] after a change in the covalent structure. Exchange of several amino acids: (——) chymotrypsinogen A, (—·—·—) chymotrypsinogen B, and (—··—··—) trypsin; specific breakage of the polypeptide chain of chymotrypsinogen A; once: (– – –) gives δ-chymotrypsin, twice: (.....) α-chymotrypsin. The circles show the middle of the transition (T_m), where $\vec{k}$ is equal to $\overleftarrow{k}$. The short lines indicate the dependence of the rate constant for unfolding ($\overleftarrow{k}$).

The introduction of covalently bonded "reporter groups" also offers the possibility of measuring conformational changes in systems in which other parameters are difficult to follow optically[107].

Table 3. Kinetic parameters for folding (←) and unfolding (→) in the transition I for several proteins in 0.01 M HCl at 30 °C [13].

Protein	$-\ln \overleftarrow{k}$ [s^{-1}]	$-\ln \vec{k}$ [s^{-1}]	$\Delta\vec{H}$ [kJ mol]	$\Delta\overleftarrow{H}$ [kJ mol]	$\Delta\vec{C}$ [kJ mol^{-1} deg^{-1}]
Chrymotrypsinogen A	11.1	3.90	340	70	6
δ-Chymotrypsin	6.8	4.88	230	33	12
α-Chymotrypsin	6.8	4.88	350	33	12
AN-Chymotrypsin [a]	6.8	5.10	320	25	14
DIP-Chymotrypsin [b]	7.5	5.30	330	42	10
Chymotrypsinogen B	10.8	4.05	370	80	8
Trypsin	8.4	3.77	280	50	14
Trypsin (D_2O)	8.2	3.44	190	50	14
Ribonuclease A	6.0	3.5	280	20	5

[a] AN = anthraniloyl.
[b] DIP = disopropylphoryl.

4.7.3. Cleavage of Peptide Chains

If the polypeptide chain in globular proteins is broken, their stability decreases in the cases investigated so far. In the enzymatic activation of chymotrypsinogen A to δ and α-chymotrypsin, the peptide chain is broken once and twice respectively. The first break also leads to the most important changes in the crystal structure[37]. This is also reflected in the kinetics of the transition I. The order of the reaction does not change; the reaction remains intramolecular, since the parts of the chain are still joined by disulfide bridges (Fig. 13 and Table 3).

5. Closing Remarks

With the transition I of some "simple" globular proteins as an example, the influence of "environmental changes" (pH, temperature, *etc.*) or of a change in the covalent structure of the protein on the thermodynamics and kinetics of cooperative conformational changes in proteins can be relatively easily investigated and described. This is greatly facilitated by the fact that this reversible partial unfolding can be represented to a very good approximation by an "all-or-none" process between two macroscopic states of the protein. This approximation is less satisfying in other reversible folding reactions[109, 110], so that generalizations are not possible, and are not really to be expected for such complicated systems depending on many parameters. However, reversible transitions of this type are suitable for use as models of "molecular switches".

In contrast to the cooperative transitions of linear homopolymers, for which the thermodynamics and kinetics can be described quantitatively on a molecular basis, we are still far from achieving this aim in the case of globular proteins. Even the knowledge of the crystal structure, *e.g.* of a family of proteins (Fig. 3), does not lead to satisfactory correlations with the observed thermodynamics and kinetics of cooperative transitions in solution.

Because of the many kinds of interactions in the three-dimensional folding of the polymer chain, the time constants for various transitions can vary by many orders of magnitude, and may be very appreciably increased or decreased by small external changes due to cooperative effects. It is not only fast conformational changes that are important to biological regulation processes[111]. It is conceivable that even processes such as the differentiation of cells, the phenomenon of a biological "clock" or the storage of information in the memory may in part be due to cooperative conformational changes with time constants of seconds – years. A time constant of one year corresponds to a difference in the free energy of activation of about – 35 kJ/mol in relation to the values given in Table 3, *i.e.* a quantity of energy that is compensated *e.g.* by the transfer of three tryptophan side chains from water into an organic phase (Fig. 4) or by rupture of about three ionic bonds (Fig. 11). Such slow conformational changes, on which very little investigation has been carried out so far, can probably be brought about within a single protein molecule, because of the specific three-dimensional interaction between the parts of the chain.

In biologically important processes, however, coupling with further reactions and interactions with other macromolecules is also to be expected, and the cooperativity and the specificity of responses to changes in the environment can be considerably increased in this way.

This work was partly supported by an EMBO long-term fellowship during a period spent in the Molecular Enzymology Laboratory (University of Bristol). I am very grateful to all those who have made information available to me before publication.

Crystal Chemistry of Complex Carbides and Related Compounds

By Hans Nowotny[*]

Numerous metal carbides can be discussed in a rather uniform way by means of structural features, mainly characterized by the mode of linking of octahedral and occasionally trigonal prismatic [M_6C] groups (M = transition element). From this point of view perovskite carbides ($M_3M'C$, M' = another transition or A-group element) and derivatives, β-Mn carbides ($M_3M'_2C$), κ-carbides, carbides with V_3AsC- and Cr_2AlC type structures and derivatives, η-carbides ($M_3M'_3C$) and carbides having the filled Mn_5Si_3 type structure will be treated. The high stability of these complex carbides is due to the strong bonding M—C and additional bonding of M—M' atoms forming an ordered parent lattice. Besides the interstitial principle of filling of lattice holes (by isolated carbon atoms), substitution with A-group elements may also take place. Thus in borocarbides extended structural elements occur.

1. Introduction

The review deals mainly with the structural aspects of some metallic carbides which occur in ternary systems of the type: two transition elements—carbon and transition element—A group element—carbon. The term complex carbide is arbitrarily introduced and stands for a double or higher carbide of intermediate character. There are more reasons than just classification for contrasting complex carbides with pseudoternary or pseudoquaternary compounds having their origin in binary carbides or nitrides such as (Ti,V)C_{1-x} or (Zr,Ta)(C,N) solid solutions. The latter carbonitride is found, for example, to be a constituent in cobalt based superalloys. Considering the compounds such as (Mo, Re)C or (W, Re)C having NaCl type structure[1], it is very likely, but not proven, that rhenium is able to stabilize the high-temperature modifications MoC_{1-x} and WC_{1-x} at much lower temperatures. Some kind of ordering may however occur in such solid solutions. Thus metal-metal short range order in carbides was found by analyzing the diffuse X-ray scattering[2]. Solid solutions of (Hf, Ta)C or (Nb, Mo)C_{1-x} apparently exhibit discontinuities of the electronic state[3], and clustering is indicated by miscibility gaps which have been detected at low temperatures for cubic carbide solid solutions such as TiC-HfC or VC-TaC[4]. In addition, ordering of carbon (and void) sites can be envisaged as is well known particularly for a number of subcarbides[5], carbohydrides *etc.*

Another peculiar case is encountered with the chromium-iron substitution in Fe_3C; chromium enters the lattice only in the eightfold position, thus a partial ordering of the metal atoms takes place[6]. The same seems to occur with $Cr_{21}W_2C_6$ within the solid solution (Cr, W)$_{23}C_6$, as one can assume from the numerous borides such as $Ni_{21}Hf_2B_6$ displaying metal ordering[7]. There are multicomponent carbides such as $Nb_3(Ni, Fe, Cr)_3C$, reported as a dispersion phase in stainless steels, which obviously derives from the η-carbide[*] Nb_3Ni_3C, and also phases such as $Nb_3Cr_{1-2}Al_{2-1}C$ which have been shown to exist only as a quaternary compound[8].

Relatively few true quaternary (and higher) carbides have been characterized so far. A number of metal carbides which correspond to intermediate carbides, develop from binary or ternary intermetallic compounds by uptake of carbon, *e. g.* $Nd_3InC_{0.7}$ or (Cr, W, Fe)$_{18}C$[9]. An interesting case involves the complete miscibility between rhenium metal and W_2C observed by *Kuz'ma et al.*[10] and confirmed by *Fackelman et al.*[11].

[*] Prof. Dr. H. Nowotny
Institut für Physikalische Chemie der Universität
A-1090 Wien IX, Währingerstrasse 42 (Austria)

[*] η-carbides, first detected as constituents in high speed steels by *A. Westgren* and *G. Phragmén*, Jernkontorets Ann. *111*, 525 (1927), are of formula $M_{2-3}M'_{4-3}C$ or $(M,M')_6C$, occasionally occurring with less carbon. They are characterized by a cubic cell with lattice parameters around 11 Å.

2. The Carbon Positions in Carbides

The determination of the carbon positions in metal carbides is usually accomplished by neutron diffraction; but difference Fourier synthesis can also be applied—as has been demonstrated by *Cromer et al.*[12] for $UMoC_2$ and by *Jeitschko et al.*[13] for Ti_3SiC_2. The carbon position within the perovskite carbide lattice is fairly well established for the compound Ti_3AlC[14]; however, it would seem to be desirable to investigate other perovskite carbides, particularly those containing heavier metal atoms, by neutron diffraction. The same is true for β-Mn carbides and κ carbides[*]. The precise carbon position for some of the H-phases[**] such as Cr_2AlC and V_2PC[15] can unambiguously be determined by X-ray experiments. In addition, neutron diffraction studies have confirmed the carbon positions in Nb_2SnC[16]. Similarly, the carbon positions in $Mo_{\sim 5}Si_3C_{0.6}$[17] with partially filled Mn_5Si_3 type structure and in the η-carbide W_6Fe_6C[18] have been determined by neutron diffraction.

Carbides, particularly transition element carbides, belong in a wider sense to interstitial compounds as defined by *Hägg*[19] and, more recently, by *Goldschmidt*[9]. The latter named author was aware of the formal character of geometrical conditions while discussing the size of interstitial atoms and proposed the term "inverse" interstitials for compounds such as MoS_2 where the metal atoms are inserted in a hexagonal close packed structure of sulfur atoms. Since very little information is available about the size and state of the interstitial atoms within metallic compounds, various concepts may be useful as guidelines.

It is obvious, therefore, that drastic structural changes can be expected depending on the metal-nonmetal ratio. Thus in the metal-rich boride Ni_3B[20] (having Fe_3C type structure) isolated boron atoms are present, while in the boron-rich boride YB_{66}[21] the metal atoms are inserted in a framework built up by boron atoms. A few examples of the following types of complex carbides will be discussed: (i) metal-rich carbides which reveal the usual interstitial concept (Section 3) and (ii) metal carbides which are characterized mainly by a substitutional mode between nonmetal and carbon (Section 4). Extended building elements are formed in borocarbides (Section 5).

Finally, it should be mentioned that minute amounts of other nonmetal elements (N, O, H *etc.*) are sometimes able to stabilize carbide structures, which either do not exist or cannot be prepared in the absence of these impurities.

3. Complex Carbides Consisting of $[M_6C]$ Groups

The strong tendency for ordering of the carbon atoms, as is clearly demonstrated for subcarbides or other carbides such as V_8C_7, does not support the assumption that carbon atoms because of their small size are just neutral particles filling the voids in a parent lattice. A more appropriate description is therefore based on the structural elements with the predominating octahedral and trigonal prismatic groups $[M_6C]$. The same building elements have also been found in a large class of complex carbides and, to some extent, in analogous transition element nitrides, some oxides, and some borides.

The occurrence and structural data of a number of representative compounds have recently been reviewed[22,23]. A few more complex carbides have been detected in the meantime, but a systematic inspection still reveals many gaps as far as analogous carbides and nitrides are concerned. Because of the high stability of many binary carbides of transition elements, the complex carbides are usually formed only at relatively low temperatures. In fact most of the complex carbides are formed by peritectic reactions *e.g.*:

$$TiC + (Ti,Si,C)_{liq.} \rightarrow Ti_3SiC_2$$

The variety of complex carbides is governed by the mode of linking of the structural elements; thus a few typical features always emerge[24].

1. The $[M_6C]$ groups can be linked by corners, by edges or by faces.

2. The transition element octahedra can be partially or completely filled.

3. An ordered metal parent lattice occurs, which occasionally exists as a binary compound.

4. The M—C distances are always relatively short compared to those in binary carbides.

5. There are no indications of bonding between the A-group element and carbon.

These features apply to a great many carbides (perovskite carbides[*], β-Mn carbides, κ-carbides, η-carbides), no matter whether the second metal is another transition element or an A-group element. However, H-phases have been observed only with A-group elements and the same is true for the partially filled Mn_5Si_3- and filled Re_3B-phases. As expected, the number of compounds with a more complicated structure type is smaller than those with simple crystal structure types.

3.1. Perovskite Carbides and Related Compounds ($M_3M'C$)

More than eighty such carbides have been reported so far; the perovskite type structure is the most regular structure of the complex carbides. A great many representatives contain transition elements of group III B and VIII such as in Sc_3AlC[25] or $Fe_3GeC_{0.45}$[26]. M components may also stem from group IV B and VII B such as in Ti_3AlC and Mn_3ZnC. One can add group VI B by considering the phase $(Cr, Pt)_3PtC_x$[27], while M components of group V B have been observed only in perovskite nitrides and oxides.

[*] β-Mn carbides display an arrangement of metal atoms corresponding to that of the manganese atoms in β-Mn (20 atoms per unit cell). Intermetallic compounds having β-Mn type structure are called π-phases. The term Kappa-carbides stems from the corresponding W—Co—C system, which is basic to the cemented carbides (hard metals); it was first investigated by *P. Rautala* and *J. T. Norton*; Plansee Proc. *1952*, 303.

[**] H-phase stands for hexagonal carbides or nitrides of formula M_2XC or M_2XN (M = transition element, X = A group metametal).

[*] The crystal structure of the perovskite carbides ($M_3M'C$) corresponds to an antitype of perovskite ($CaTiO_3$).

The chromium platinum carbide obviously leads to another branch of perovskite carbides such as VRu_3C or $ThRu_3C_{1-x}$ ($x = 0-0.1$), which were recently discovered by *Holleck*[28].

The perovskite carbide Fe_3CuC detected as a constituent in copper-containing cast iron[29] fits in the series $Fe_3\{Cu, Zn, Ga, Ge\}C$; nevertheless, the existence of Fe_3CuC appears remarkable in view of the low chemical affinity between Fe and Cu on the one hand, and Cu and C, on the other.

Rare earth perovskite carbides (except ytterbium) containing Al, In, Tl, Sn and Pb display a regularity inasfar as the lattice parameters increase proportionally with increasing radius of the trivalent rare earth ion[30]; this is in agreement with the behavior of the corresponding silicides and germanides[31]. Rare earth perovskite carbides containing gallium behave differently because of partial substitution of the metal atoms, *e.g.* $Nd_3(Nd, Ga)C_{0.2-0.8}$. It is not very likely that the so-called perovskite condition for ionic compounds can be applied to the corresponding carbides. As was pointed out by *Stadelmaier*[23] there are no satisfactory models available to explain the stability and occurrence of the perovskite carbides. With regard to the high metal-carbon ratio the interstitial concept may still constitute a first approach. Extending the radii criterion r_C/r_M to *ca.* 0.65 (nonmetal/transition metal) embraces all perovskite carbides. The problem at hand is closely related to the carbon solubility in γ-iron (austenite), where, however, the metal:carbon ratio is higher ($Fe_3FeC_{0.4}$). Substitution of the corner atom (M′) by a larger one (as *e.g.* in Fe_3CuC), obviously favors the condition for entry of a carbon atom into the octahedral void. In this way adjustment of the size of the two kinds of metal atoms (M and M′), that is the relative expansion and contraction, is responsible for the stability, as has been suggested by *Rosen* and *Sprang*[25]. Strong contraction —in order to meet the most favorable packing—can be observed for A group elements such as Mg, while small transition element atoms such as iron increase in average size; on the other hand, large atoms, *e.g.* of the lanthanum series, decrease in size because of the A group element. The arrangement of the metal atoms in the parent lattice (Cu_3Au type structure) provides another stabilizing factor in addition to the strong M—C bonding within the octahedral group $[M_6C]$. From the present data, including magnetic measurements mainly obtained on perovskite nitrides, no conclusive statements can be made on the role of electron concentration or type of electron transfer. The previously assumed electron transfer from the nonmetal atom to the transition element d-band is questionable. Measurements of the atomic scattering factor of nitrogen in the series Mn_3MnN—Mn_3GaN indicate the existence of uncharged nitrogen atoms; by no means is the donor role of the nonmetal supported[32].

3.1.1 Carbides of Filled-up U_3Si Type

Mn_3GeC_{1-x}, which has been described as a perovskite carbide[33], also occurs in a slightly modified arrangement, as was found by *Boller*[34]. Fig. 1 reveals the close relationship between these structures. The main difference consists of a slight twisting of the linked $[M_6C]$ octahedra along the *c*-axis. Thus the cell dimensions *c′* and *a′* correspond to 2*c* (perovskite) and $a/\sqrt{2}$ (perovskite) respectively. The short Mn—C distances (1.94 and 2.02 Å) are once again indicative of a strong interaction within the $[M_6C]$ group. Most likely, in Mn_3GeC there is only partial filling with carbon since the corresponding nitride has a somewhat larger cell volume. Complex nitrides are usually smaller than the analogous complex carbides—as is also the case for binary transition element carbides and nitrides.

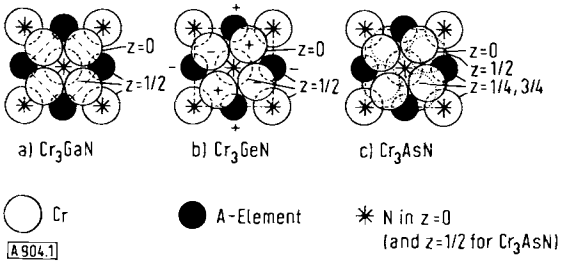

Fig. 1. Crystal structures of a) perovskite nitride (carbide), b) Cr_3GeN, and c) filled U_3Si viewed along [001] (*c* axis).

Another perovskite derivative was recently observed for Cr_3GeN[35], but no carbide having this arrangement has been found so far. The deformation of the octahedral group $[M_6N]$ generates a similarity to the white tin coordination. In the above mentioned series (Fig. 1a—1c) the coordination number of the Group A element (Ga, Ge, As) decreases from 12 to 10 to 8.

3.2. β-Manganese Carbides ($M_3M'_2C$)

From the standpoint of interstitial alloys this class of complex carbides having the filled β-Mn type structure belongs to the so-called π-phases described by *Goldschmidt*[9]. The partial lattice $\{M_3C\}$ consists—as is the case in the perovskite carbides—of a linking of fairly regular octahedral $[M_6C]$ groups by corners. Deviations in the carbon filling and in the ordering of the parent metal lattice $M_3M'_2$ also occur. The participating transition elements are mainly from group V B and VI B while a variety of the M′ components is observed (VII B to III A) if the analogous nitrides are also taken into consideration. As is shown in Table 1, the transition element as well as the A group element can be substituted, *e. g.* $(Mo,Cr)_3Al_2C$ or $Nb_3(Au,Ga)_2C$. The latter carbide, however, seems to be a quaternary compound. As constituents in high alloyed steels[36], the β-Mn carbides exhibit a manganese-like allotropy. Thus in the Fe—Cr—W—C system the χ-phase having an α-Mn type structure with respect to the metal positions transforms to β-Mn type structure on heating. The same mode of transformation was recently found within the Co—Cr—W—C system by *Ettmayer*[37]. There is no explanation available for the stability of the β-Mn carbide type. This is also true for the β-manganese type structure itself if there is a nonmetal-free β-Mn. As the interstices possess a nonvariant fourfold position, any filling with small nonmetal atoms appears to exert a stabilizing effect, since transition element-carbon bonds can be formed. It is interesting to note that Mo_3Al_2C compares

with $RbAg_4I_5$, where the Rb ions correspond to the carbon positions, while the metal parent lattice Mo_3Al_2 has the same arrangement as the iodine anion lattice. The small silver ions are randomly distributed over 72 positions and can thus be compared with the free electrons in the complex carbide.

Table 1. Complex carbides having filled β-Mn type structure.

Phase	Remarks
$Nb_3(Au,Ga)_2C_x$	amount of carbon unknown
Nb_3Al_2C	
Ta_3Al_2C	
Mo_3Re_2C	
W_3Re_2C	metal ordering likely
W-Fe-C	metal atoms disordered [39]
W-Mn-Fe-C	possibly derived from W-Fe-C
$Cr_9W_2Fe_{10}C$	partially filled [38]
Mo_3Al_2C	homogeneous range (Mo-Al)
$MoCr_3Al_2C$	solid solutions derived from Mo_3Al_2C
$(Mo,V)_3Al_2C$	
$(Mo,Mn)_3Al_2C$	

3.3. κ-Carbides and -Borides

According to the arrangement proposed by *Schönberg*[40] the $[M_6C]$ octahedra are linked by corners in such a way that trigonal metal prisms are formed between them. Although a number of ternary and quaternary κ-carbides have been detected, the amount of carbon and consequently the degree of filling is still uncertain. Besides the filling of the metal octahedra, it has been assumed that carbon atoms are also accommodated in the trigonal metal prisms, but unusually large metal-carbon distances result. As has been recognized from the formation of complex carbides in ternary and quaternary systems, aluminum is considered to be a suitable M′ component for stabilizing (Table 2). Since the lattice parameters of the Al-containing carbides are higher than those for the ternary carbides, it is very likely that aluminum atoms also occupy an additional crystallographic position; metal icosahedra are formed and complete resemblance of the parent lattice of the κ-carbides to the arrangement of Mn_3Al_{10} or Mn_3Al_9Si[41]. results. In addition to the metal atoms having the same positions within the same space groups, it is found that the atomic parameters are nearly the same. A characteristic feature of the κ-carbide phases is the c/a ratio equal to unity. The existence of the complex carbide Mo—Cu—Al—C indicates a lower degree of filling by carbon atoms inasfar as only strong Mo—C bonds can be expected. Nevertheless, the filling, or eventual filling, of the trigonal metal prism by carbon atoms must be regarded as a first step in the mixing of octahedral and trigonal prismatic $[M_6C]$ groups.

Very recently κ-borides have also been observed in the Hf—Mo(W)—B systems[42]. As can be seen from Table 2, the c/a ratio is once again approximately equal to one, and the atomic parameters for the metal atoms differ only slightly. A ternary phase in the above named systems was first reported by *Harmon*[43] and designated as a φ-phase in the region 50 at % of Hf, 20 at % Mo(W) and 30 at % B. A more detailed investigation confirmed the existence of ternary borides, the composition however was found to be less boron-rich and a formula Hf_9Mo_4B was adopted. In the case of the κ-boride one can rule out filling of the octahedra because of the short hafnium-octahedral void distance. On the other hand the filling of the trigonal prismatic void meets perfectly with the space requirements. In addition, further occupation by boron atoms is possible which leads, as in aluminum-containing κ-carbides, to completion of the metal icosahedron; in other words these boron atoms behave metal-like, as is already known for some other boron-containing intermetallics, such as $CeCo_3B_2$.

Table 2. κ-carbides and borides.

Phase	c/a	Phase	c/a	Phase	c/a
W-Mn-C	1.000	Mo-Mn-Al-C	0.999	Hf_9Mo_4B	0.99_1
$W_{9-10}Co_3C_4$	1.000	Mo-Fe-Al-C	1.000	$(Hf,W)_{13}B$	0.98_8
$W_{16}Ni_3C_6$	1.000	Mo-Ni-Al-C	0.995		
W-Mn-Al-C	0.986	$Mo_{12}Cu_3Al_{11}C_6$	0.989		

3.4. Carbides with V_3AsC Type Structure (Filled Re_3B Type)

It is a well established rule that a larger radius ratio nonmetal: metal shifts the octahedral environment to the trigonal prismatic groups. In some way this is a continuation of the building principle mentioned in Section 3.3.; thus a structural type of complex carbides has been detected, which equally combines octahedral and trigonal prismatic $[M_6C]$ groups[44,45]. The following complex carbides can be treated in the same way as above because the octahedral voids are filled by carbon (or nitrogen). The ordered parent lattice corresponds to the Re_3B type structure (or anti-$PuBr_3$ type), in which the boron atoms fill the voids of the trigonal metal prism (Fig. 2). As has

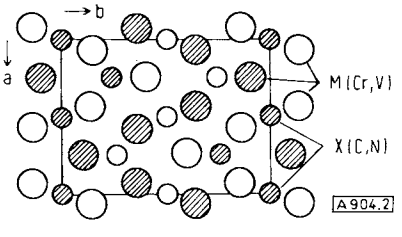

Fig. 2. Crystal structure of the filled Re_3B type. Small nonmetal atoms fill the M_6 octahedra.

already been shown there is no significant difference between a second participating transition element and an A group element in the complex carbides as fas as the structural features are concerned. Similarly, carbon may act like other non-metals or A group elements. As a result, the larger nonmetal or A group element must occupy the interstices of the trigonal prism in compliance with the larger ratio of radii nonmetal/transition metal. Thus V_3PC, for example, can topochemically be built up from the structural elements V_2C (octahedra) and VP (trigonal prisms). Conversely, for VCr_2C_2 a metal ordering is expected in which the vanadium atoms preferentially form the octahedral and the small chromium atoms the trigonal prismatic groups. In fact VCr_2C_2 is a perfect intermediate

between the cubic carbide (V, Cr)C_{1-x} and Cr_3C_2. The former represents the octahedral portion, while the latter consists of trigonal prisms.

Table 3. Lattice parameters of complex carbides and nitrides with filled Re_3B type structure.

Phase	a [Å]	b [Å]	c [Å]
V_3GaN	2.95_0	10.30	7.93_1
V_3GeN	3.01	10.30	7.79_3
V_3GeC	3.04_7	10.14	7.88_4
V_3PN	3.101	9.840	7.419
V_3PC	3.119	9.758	7.531
V_3AsN	3.130	10.18	7.590
V_3AsC	3.128	10.14	7.699
VCr_2C_2	2.870	9.30	6.99
$Cr_3(B,C)C$	2.870	9.260	6.982
Cr_3GeC	2.89_9	10.33_9	7.72_4
$Cr_3C(C,N)$	2.843	9.25_5	6.95_2
Cr_3PN	3.047	9.833	7.224
Cr_3PC	3.054	9.704	7.299
$Cr_3As(C,N)$ [a]	3.057	10.21	7.470

[a] Previously described as carbide.

In contrast to VCr_2C_2, the complex carbide VTa_2C_2 has, according to *Rudy*[46], a metal layer structure with the sequence $(hhc)_3$[*]. In the case of Cr_7BC_4[47] or $Cr_3(B,C)C$ and $Cr_3C_{1.4}N_{0.6}$[48] or $Cr_3C(C,N)$ carbon atoms occupy, at least partially, both kinds of voids. One must assume that the smaller nitrogen atoms enter only the octahedral sites. In Table 3 complex carbides and nitrides having the filled Re_3B type structure have been listed. The ratio $a/\sqrt{bc}$ increases with the A group number indicating less interaction between these atoms if the A group element is getting more electronegative. A similar behavior has been observed for H-phases, as is shown below (cf. Section 3.5).

3.4.1. The Compound V_4P_2C

The ternary system vanadium-phosphorus-carbon is distinguished by the occurrence of several complex carbides: V_5P_3C (filled Mn_5Si_3-type), V_3PC (see Section 3.4.), V_2PC (H-phase), and V_4P_2C recently detected by *Boller*[49]. The carbide V_4P_2C (Fig. 3) also combines the building elements

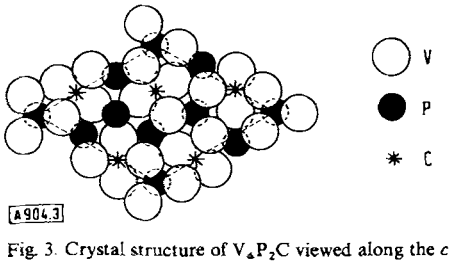

Fig. 3. Crystal structure of V_4P_2C viewed along the *c* axis.

of octahedra and trigonal prisms (parallel and perpendicular to the *c*-axis). As for V_3PC, the phosphorus atoms are filling the prisms, carbon the octahedral voids. Moreover, an irregular body-centered cube of metal atoms appears which is a common structural element in borides, silicides and phosphides[50].

[*] h signifies hexagonal close packed layer sequence 1212...; c a cubic close packed layer sequence 123123...; thus $(hhc)_3$ consists of nine layers of mixed type.

3.5. Complex Carbides Having the Cr_2AlC Type Structure (H-phases) and Related Structures

Almost seventy H-phases (mostly carbides) have been described. The crystal structure of the H-phase compares to that of the perovskite carbide in the same way as hexagonal close packing compares to cubic close packing. There is, however, no binary compound known which corresponds to the metallic parent lattice M_2M', *i. e.* a hexagonal close packed array with a superstructure $c' = 3c$ according to the sequence $M_AM_BM'_AM_BM_AM'_B$. Table 4, the major part of which is taken from the thesis work by *Jeitschko*[51], clearly shows the distinct dependency of the $c/3a$ ratio on the nature of the M' component. Thus, one can speak of a more metallic branch having a high $c/3a$ ratio and a less metallic (ionic) branch with a low $c/3a$ ratio, as is exemplified by the series: $V_2GaC(1.45_7) \rightarrow V_2GeC(1.36_1) \rightarrow V_2AsC(1.21_8) \rightarrow Ti_2SC(1.16_2)$.

Kudielka[52], who discovered the very first H-phase, namely Ti_2SC as a constituent in steels, pointed out that Hf_2SC is very likely a quaternary phase containing some iron. Deviations from the composition $M_2M'C$ are relatively rare, but nevertheless they do occur, *i.e.* incomplete filling of the transition element octahedra which are linked by edges. Some other H-phases, such as Ti_2PbC, also deviate from the ideal ratio $M/M' = 2$. In other words there is some partial Ti/Pb substitution corresponding to a lead defect. Ta_2GaC on the other hand exhibits a distortion which may be connected with stacking faults indicating derivative structure types (see the following Section).

With respect to the six layer type structure of $(hhh)_2$ there is a close relationship in cell dimensions with the MoC_{1-x}-phase[53], occasionally formulated as Mo_3C_2[46] and having a sequence $(cch)_2$, particularly if it is referred to the metallic branch of H-phases. Even more pronounced, however, is the relationship to the TiP type structure. Substituting two phosphorus atoms in Ti_4P_4 by two carbon atoms leads to the H-phase arrangement (Fig. 4). This represents another way of looking at the building elements of the H-phases—particularly for the less metallic branch. It clearly results from the analogy that both structural elements, the octahedral group $[M_6C]$ and a trigonal prismatic group $[M_6M']$ are building blocks in the H-phase. Thus the arrangements develop stepwise from the κ carbides to the filled-up Re_3B types and further to the H-phases. From the above mentioned series it can be seen that the ordered close packing of the metallic parent lattice (small *a*-axis) will be more and more replaced by the trigonal prismatic structural element (large *a*-axis). Consequently there is an M'—M' contact for the metallic branch such as V_2AlC or V_2GaC while no such contact can be assumed for phosphorus-, arsenic- or sulfur-containing H-phases. From this point of view H-phases are just another example of the topochemical mode of generation by two essential building groups, one characteristic of the large class of NaCl type structures (octahedra) and one characteristic of the NiAs type structures (trigonal prism). This is best demonstrated with V_2PC which is a sum of VC (octahedra)

+VP (trigonal prism). It is therefore not surprising that the H-phase parent lattice is an anti-type of MoS_2 which represents a stacking variant of the well known CdI_2 type structure.

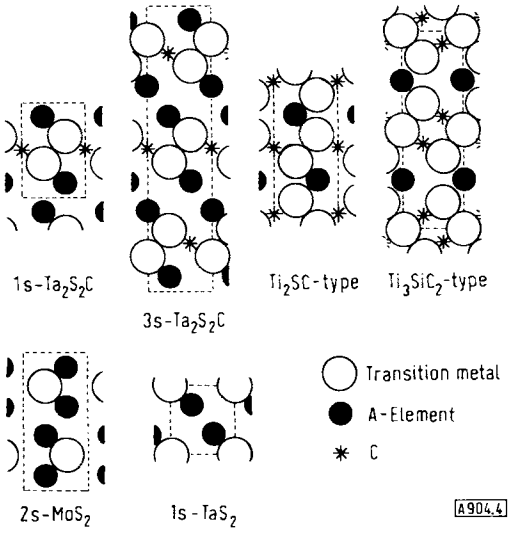

Fig. 4. Comparison of the different complex carbide layer structures [(11$\bar{2}$0) plane of hexagonal cell]. Ti_2SC (= Ti_2P_2 if * = •); 1 s-, 2 s-, 3 s- indicates the number of layers along the hexagonal axis.

Table 4. Complex carbides (H-phases).

Compound	$c/3a$	Compound	$c/3a$
Sc_2InC	—	V_2AlC	1.500
Ti_2CdC	1.550	V_2GaC	1.457
Ti_2AlC	1.490	V_2GeC	1.361
Ti_2GaC	1.448	V_2PC	1.182
Ti_2InC	1.400	V_2AsC	1.218
Ti_2TlC	1.476	Nb_2AlC	1.486
Ti_2GeC	1.400	$Nb_{1.2}Zr_{0.8}AlC$	1.497
Ti_2SnC	1.444	Nb_2GaC	1.443
Ti_2PbC	1.434	Nb_2InC	1.510
Ti_2SC	1.162	Nb_2SnC	1.414
Zr_2InC	1.486	Nb_2PC	1.172
Zr_2TlC	1.467	Nb_2AsC	1.196
Zr_2SnC	1.454	Nb_2SC	1.166
Zr_2PbC	1.445	$Nb_2SC_{0.4}$	1.168
Zr_2SC	1.190	Ta_2AlC	1.500
Hf_2InC	1.487	Ta_2GaC	1.458
Hf_2TlC	1.469	Cr_2AlC	1.495
Hf_2SnC	1.448	Cr_2GaC	1.458
Hf_2PbC	1.437	Cr_2GeC	1.365
Hf_2SC	1.190	Mo_2GaC	1.457
$Ti_{0.8}V_{1.2}SC$	1.142		

The transition element can partially be replaced by another transition element such as $(Nb,Zr)_2AlC$, however nothing is known about an M′/M′ substitution or replacement of carbon, *e.g.* by nitrogen, although a large number of H-phase nitrides also exists.

3.5.1. The Ti_3SiC_2 Structure

A ternary phase first reported by *Brukl*[54] was shown to be structurally closely related to the H-phase[55] (see Fig. 4). The Ti_3SiC_2 phase can be regarded as an intermediate between the H-phase and the cubic monocarbide arrangement. A double layer of $[Ti_6C]$ groups perpendicular to the hexagonal axis is present instead of the one $[Ti_6C]$ layer in the H-phase. The sequence of the parent lattice corresponds to the $(hhhc)_2$ scheme. In this context it is interesting to note that the ratio of the respective c-axes for the isotypic Ti_3GeC_2[56] and the H-phase Ti_2GeC is precisely 4/3 due to the additional TiC layer. This can again be expressed by a topochemical reaction according to: $Ti_2GeC + TiC = Ti_3GeC_2$. Because of the strongly bonded double layer of $[Ti_6C]$ groups, the lamellar character of Ti_3SiC_2 is very much pronounced. Only very recently *Nickl*[57] reported on stacking faults in titanium silicocarbides, thus indicating that an intergrowth of TiC layers and H-phase layers occurs.

3.5.2. Ta_2S_2C Type Structures

Similar layer arrangements have also recently been found in tantalum sulfocarbides[58] which exhibit a mechano-chemical transformation mode. The building elements consist of $[Ta_6C]$ layers and the well known transition element disulfide layer group. Ta_2S_2C (formed by sintering the powder components at 1200°C) behaves like a solid lubricant. Powdering the sintered mass in a mortar leads to platelet-like particles having a distinct texture. The crystal structure of the mechanically treated carbide (1 s-Ta_2S_2C) was found—ignoring the somewhat different c/a ratio—to be isotypic with the valence compound Ce_2O_2S. Annealing of 1 s-Ta_2S_2C at 1250°C (70 h) yields the initial 3 s-Ta_2S_2C state, which exhibits a more complex stacking corresponding to the arrangement of another valence compound, namely Bi_2Te_2S (tetradymite). Fig. 4 demonstrates the relationship of the hexagonal structure types. As can be seen in the (11$\bar{2}$0) plane, which lies perpendicular to the hexagonal layers (of metal, A group element (sulfur) and carbon atoms), 3 s-Ta_2S_2C consists of a sum of TaC layers and TaS_2 layers (1 s-TaS_2), while 1 s-Ta_2S_2C can be generated out of TaC layers and TaS_2 layers corresponding to the 2 s-MoS_2 type structure. The sequences of the layers along the c axis can be expressed as follows:

3s-Ta_2S_2C	-M-C-M-X-X-M-C-M-X-X-M-C-M-X-X-
Ti_3SiC_2	-M-C-M-C-M-X-M-C-M-C-M-X-
H-Phase	-M-C-M-X-M-C-M-X-
1s-Ta_2S_2C	-M-C-M-X-X-

M (transition metal), X (A group element), C (carbon)

As seen from the viewpoint of inverse interstitial compounds one has to mention that 3 s-Ta_2S_2C is an antitype structure of the complex carbide VTa_2C_2 mentioned in Section 3.4. inasfar as the partial lattice $[S_2C]$ and $[Ta_2V]$ on the one hand and $[Ta_2]$ and $[C_2]$ on the other perfectly correspond. Similarly, the H-phase is an antitype of alkali metal-niobium disulfide.

The partial filling of the metal octahedra in VTa_2C_2 is explained, as in the case of Mo_3C_2, by assuming that the carbon atoms repel each other if they come too close.

The complex compounds UBC[59] and Mo_2BC[60] consist of $[M_6C]$ or $[M_5BC]$ octahedra and $[M_6B]$ trigonal prisms; here the distinct boron-boron interaction (zigzag boron chains) is already noticeable.

3.6. Complex Carbides of the Filled Ti_2Ni Type (η-Carbides) and Filled Mn_5Si_3 Type

These complex carbides are characterized by $[M_6C]$ octahedra linked by planes. The first group, the so-called η-carbides, is of great interest from a practical point of view and has already been described in detail by *Stadelmaier*[23].

The filled or partially filled Mn_5Si_3 type structure reveals, in a particular way, the interstitial character inasfar as compounds with larger transition element atoms may also accommodate boron, germanium, and even metal atoms in the octahedral voids. Similarly to perovskite carbides there are many binary $M_5M'_3$ compounds which are able to take up carbon. In the case of rare earth silicides having this composition it has recently been shown that carbon can continuously be dissolved up to Ln_5Si_3C (Ln ≙ lanthanoid)[61]. For some of the intermediate complex carbides (Table 5) the amount of the stabilizing carbon has not been determined. Extended or complete solid solutions between such carbides also exist, *e.g.* $V_5(Si,Ge)_3C_x$. Furthermore, solid solutions occur between these carbides and the analogous binary compounds, *e.g.* $Mo_5Si_3C_x$ and Ti_5Si_3.

Table 5. Complex carbides of the filled Mn_5Si_3 type.

Phase	a[Å]	c[Å]	c/a	Remarks
$Zr_5Si_3C_x (x \simeq 0.2)$	7.91	5.58	0.705

$W_5Si_3C_x$	7.19	4.85	0.675	contains Cr

4. Complex Carbides Characterized by A Group Element—Carbon Substitution

Only A group elements larger than carbon are to be considered—that is to say no carbonitrides or carbohydrides, even though $Cr_3C(C,N)$ represents such an intermediate compound. On comparing this carbonitride with $Cr_3AsC_{0.75}N_{0.25}$ it is seen that carbon substitutes arsenic in a formal way, at least for the larger portion, while the other part plays the role of an interstitial atom. To some extent TiP (H-phase array) can also be regarded as a P/C substitution type.

4.1. Carbon in Cr-P and Cr-As Phases

A carbon-stabilized chromium phosphide of formula $Cr_6P_{2.6}C_{0.4}$ having Fe_2P type structure was recently detected[62]. As one can see from the change of the lattice parameters within the homogeneous region (Table 6), carbon obviously acts more in a substitutional phosphorus-carbon mode. This is also supported by the behavior of the isotypic compound $Cr_6As_{3-x}C_x$, which, however, develops from the high temperature phase Cr_2As[63]. It was shown from single crystal data that the electronic density at the arsenic positions is lower than expected for full occupation according to $Cr_6As_{2.8}$. These findings are, furthermore, in agreement with the short Cr—As distances and the relatively high density calculated for Cr_2As. Carbon dissolves up to $Cr_6As_{2.2}C_{0.8}$ (1000 °C, quenched). As is seen from Fig. 5 the volume increases only slightly from low

Table 6. Complex carbides based on partial substitution.

Compound	Type	a[Å]	c[Å]	c/a
$Cr_6P_{2.55}C_{0.45}$	Fe_2P	6.136	3.227	0.526
$Cr_6P_{2.75}C_{0.25}$		6.117	3.242	0.530
$Cr_6As_{2.2}C_{0.8}$	Fe_2P(ordered)	6.302	3.402	0.540

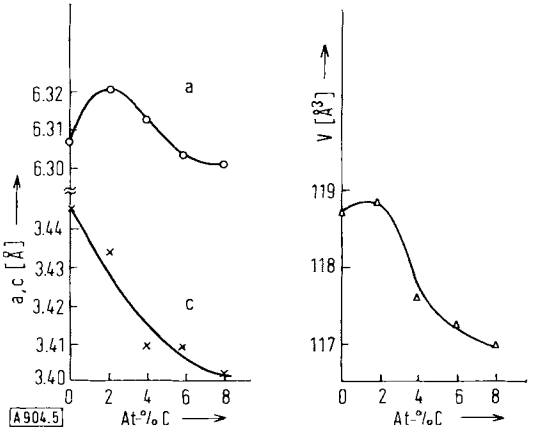

Fig. 5. Lattice parameters of $Cr_6As_{3-x}C_x$ as a function of the amount of carbon.

carbon concentrations, but then decreases because of a carbon/arsenic substitution. One can assume that take-up of carbon proceeds in a partially ordered way as is the case for Ni_6Si_2B (ordered Fe_2P type structure[64]); however, the ideal composition will not be reached. The behavior of carbon is also similar to that of boron in Cr_5PB_2[63].

5. Borocarbides of Transition Elements

The ease of replaceability between carbon and boron has been known for a long time regarding the solid solution $Fe_3(B,C)$; but more characteristic in this respect is the intermediate phase $Fe_{23}(B,C)_6$, discovered by *Carroll et al.*[65]. However, in contrast to the borocarbides already mentioned (UBC, Cr_7BC_4, Mo_2BC) the structural element of $Fe_{23}(B,C)_6$ (τ-phase) differs inasfar as the metal atoms form quadratic antiprisms whose voids are occupied by the non-metal atoms. The changing of the building elements (increase in coordination number) corresponds to the limit of the ratio of nonmetal-metal radii as proposed by *Hägg*[19] for the interstitial phases. No boro-

carbides of the transition elements of group IVB and VB appear to exist; this fact can be explained by the high stability of the corresponding monocarbides and diborides. There are obviously no borocarbides of tungsten or manganese either, although the latter case has not, as yet, been completely studied. On the other hand, there is a series of borocarbides of the transition elements of group III B (lanthanum and actinium series). As already mentioned, in UBC the carbon is octahedrally surrounded by five metal atoms and one boron atom; however, one can view the structural elements in a different way because of the occurrence of boron-boron chains. As is demonstrated in Fig. 6a the nonmetal atoms form a so-called branched chain.

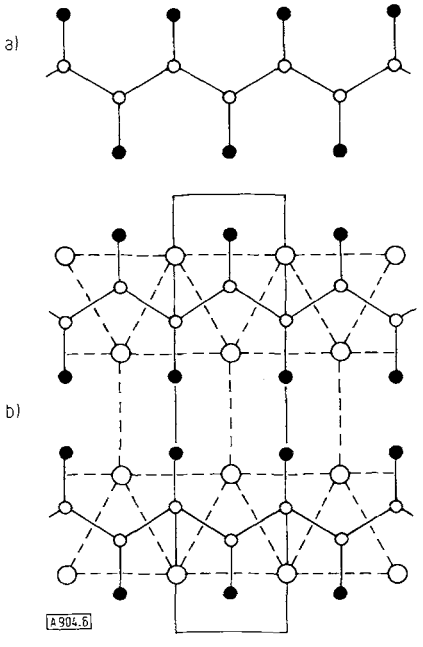

Fig. 6. a) Branched boron-carbon chain in UBC; b) Crystal structure of YBC.

While UBC seems to be the only ternary compound in this system, several borocarbides of thorium are known to exist[66], but no conclusive data are however available as yet. The compound of approximate composition ThB_2C is related to the AlB_2 type structure; thus, two-dimensional networks consisting of boron and carbon atoms were assumed. A complete structural characterization of ScB_2C_2 was later carried out by *Smith et al.*[67]. These authors found a two-dimensional boron-carbon network built up from 5- and 7-membered rings (Fig. 7a). The metal layers above and below can be regarded as a deformed hexagonal pack. Numerous borocarbides of elements of the lanthanum series have been reported by *Smith et al.*[68]; among these compounds GdB_2C_2 and analogous borocarbides were shown to exist which crystallize with a tetragonal unit cell; hence a two-dimensional boron-carbon network (4- and 8-membered rings) is likely to be present. According to these findings the compounds previously reported as lanthanoid borides of formula $LnB_x (x = 3-4)$[69] have now been identified as LnB_2C_2 compounds. A similar assumption has already been made by *Binder*[70].

5.1. Yttrium Borocarbides[71]

A detailed investigation of the ternary system yttrium-boron-carbon reveals the existence of the borocarbides YB_2C_2, YB_2C, YBC and $YB_{0.5}C$. The composition of the latter is not quite certain.

YB_2C_2: This borocarbide is obviously of the same structure type as LnB_2C_2. If it is assumed that no random distribution of boron and carbon atoms occurs, then the c-axis of the tetragonal cell must be doubled. Fig. 7b shows the arrangement of the atoms; the nonmetal network is built up of 4- and 8-membered rings; the cell parameters (a and $c/2$) in Table 7 correspond to those previously proposed for "YB_2C"[70]. There is no doubt that the same borocarbide is involved in both cases.

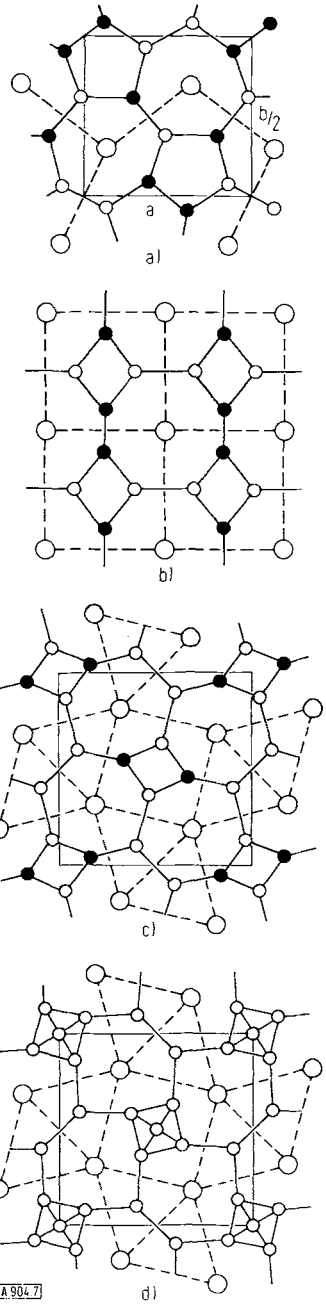

Fig. 7. a) Boron-carbon network in ScB_2C_2 (according to Ref. [67]). b) Boron-carbon network in YB_2C_2 (turned above and below by 90°); c) Boron-carbon network in YB_2C (turned above and below by 90°); d) Crystal structure of YB_4 (according to *C. E. Lundin*, in *F. H. Spedding* and *A. H. Daane*: The Rare Earths Wiley, New York, 1961).

YB_2C: The crystal structure has been proposed on the basis of single crystal patterns. From Fig. 7c one can recognize a close similarity to the architecture of YB_4 (Fig. 7d): Leaving out two boron atoms and substituting two further boron atoms by two carbon atoms yields YB_2C, which is a topochemical sum of the building elements of YB_2 (diboride type structure) and YB_2C_2. The arrangement of the metal atoms in the layer is well known from the U_3Si_2 type structure. The nonmetal atoms are again linked to a two-dimensional network (may be slightly puckered) consisting of 4- and 7-membered rings. Lattice parameters and atomic distances are given in Table 7.

Table 7. Yttrium borocarbides (lattice parameters and distances in Å).

	YB_2C_2	YB_2C	YBC
a	3.79_6	6.76_9	3.38_8
b	—	—	13.69_3
c	7.12_4	7.430	3.62_7
space group	D_{2d}^2–$P\bar{4}2c$	D_{4h}^{13}–$P4_2/mbc$	D_{2h}^{19}–Cmmm
Y–Y	3.68	3.60	3.71
B–B	1.76	1.75	1.98
C–C	1.28	—	—
B–C	1.62	1.64	1.65
Y–B	2.75	2.73	2.70
Y–C	2.68	2.55	2.55

YBC: By means of single crystal data the arrangement shown in Fig. 6 can be proposed. A close relationship to UBC occurs inasfar as branched boron-boron zigzag chains constitute the predominant structural element. As usual the boron atoms are accommodated in voids of a trigonal prism, however the surrounding of the carbon atoms differs. The fifth metal atom is missing and because of the large carbon-carbon distance no interaction takes place. Easy gliding of YBC crystals in the (010) plane is in agreement with the layer-like structure. Cell dimensions and interatomic distances are given in Table 7. The atomic parameters of boron and carbon, and therefore the atomic distances Y—B, Y—C, B—B, B—C and C—C, are a first approximation. No difference Fourier synthesis has, as yet, been carried out.

6. Discussion

6.1. Isolated Carbon Atoms

The concept of interstitial compounds applies in a similar way to the metal rich complex carbides. The dominant feature can be seen in the structural group $[M_6C]$ which mainly occurs as octahedra, but, sometimes, also as trigonal prisms. Thus, more complicated parent lattices than the simple cubic and hexagonal close packing must be envisaged. As seen from the viewpoint of critical radii ratio r_C/r_M there is a stepwise transition to metastable carbides and further to structural groups $[M_8C]$ consisting of square antiprisms; this occurs particularly frequently in the case of metal rich borides. Prediction on the basis of the radii criterion does not mean, however, that the size of the atoms in the carbide corresponds to the atomic radius in the elemental state. So far we have no unambiguous information about the electron transfer or the shape of the so-called atomic spheres in the carbides. At best, only the atomic distances and the coordination are precisely determined; consequently, in a first approach speculations about covalent radii (neutral state) and ionic radii (polar state) do not allow any discrimination. The large class of complex carbides reveals in a uniform way the strong bonding between transition metal atoms and carbon atoms, the M—C distances always being somewhat shorter than in the corresponding binary carbide, while the A group element atoms obviously do not form bonds with carbon. On the other hand transition element—A group element bondings contribute to the stabilization of complex carbides in addition to the M—M-bonds.

6.2. Carbon-Carbon and Carbon-Nonmetal Aggregates

A smaller amount of metal favors the nonmetal aggregation *per se* as is well known for borides and silicides. While these compounds display all kind of aggregates X_n (X = nonmetal), namely: X_2, X_3, X_4, X-chains, branched chains, double chains, nets *etc.*, the aggregation mode for carbides is much less pronounced. Carbon pair formation has been observed in dicarbides such as CaC_2 *etc.*; other examples are sesquicarbides such as Pu_2C_3 or $Sc_{15}C_{19}$. C_3-aggregates are, so far, only known for B_4C. No carbon-chain formation takes place in metal carbides; it was earlier assumed to occur in Cr_3C_2, but could not be confirmed by neutron diffraction studies. Nevertheless the carbon atoms in Cr_3C_2 come relatively close together which also might be a hint that no "CrC" can exist. In this context, carbon-carbon aggregation is indicative of competition between carbide formation and metal-graphite decomposition. As is immediately seen from the decreasing stability of carbides with increasing group number Ti → Ni, this parallels the decreasing atomic size of the metal and increasing carbon:metal radii ratio. All attempts to prepare graphite compounds of transition metals have so far failed; however, alkali metal and alkaline earth metal graphite compounds have been known for some time. It is of interest to note that borocarbides fill this gap by formation of branched chains or two-dimensional networks. There is no doubt that, here, metal-nonmetal covalent bonds between the nonmetal atoms play a significant role in the stabilization of such metal carbides.

In conclusion one may ask whether cage-like carbides can be formed analogous to those of the borides and silicides (clathrates).

Reactions of Enamines with *N*-Dichloromethylene--*N*,*N*-dimethylammonium Chloride[1]

By *Heinz Günter Viehe, Thérèse van Vyve,* and *Zdenek Janousek*[*]

The highly electrophilic salt *(1)* reacts with enamines *(2)* containing β-hydrogens to give the amide chlorides *(3)*, some examples of which are given in Table 1. Thus *(1)* behaves analogously to phosgene—which produces β-(chlorocarbonyl)enamines *(4)* with *(2)*[2]—and to Vilsmeier reagents[3].

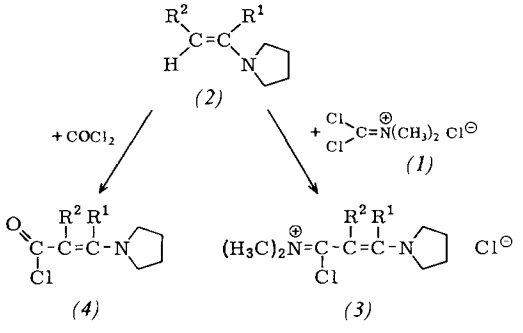

Table 1. Properties of a few compounds of type *(3)*.

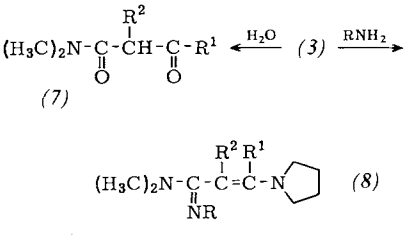
	R^1	R^2	Yield (%)	UV in CH_2Cl_2 (nm)
(3a)	$-(CH_2)_4-$		95	389
(3b)	$-(CH_2)_3-$		90	370
(3c)	H	C_6H_5	92	366
(3d)	$(CH_2)_2$-*o*-C_6H_4-		96	387

Table 2. Properties of a few compounds of type *(7)*. [R^1 and R^2 for *(a)* and *(c)* as in Table 1.]

Cpd.	Yield (%)	B.p. (°C/torr)	IR (cm^{-1})	NMR($CDCl_3$, TMS—O) δ(ppm)
(7a)	60	115–120/0.2	1710, 1640	3.6(1H/m), 2.8(6H/s, 1.6–2.6(8H/br.)
(7c)	92	130/0.1	1730, 1640	10.0(1H/d), 7.4(5H/m), 4.5(1 H/d). 2.9, 3.0(6 H/2s)

Compounds *(3)* react like *(4)* with dinucleophiles such as hydrazine and amidines to give aminopyrazoles *(5)* and *(5a)* or aminopyrimidines *(6)* respectively.



or yellow oil, which in some cases crystallizes (Table 1). Hydrolysis of *(3)* with water yields the corresponding β-ketoamide *(4)*. The enaminoamidines *(8)* are formed by aminolysis in ether.

Table 3. Properties of a few compounds of type *(8)*, $R^1 + R^2 = -(CH_2)_4-$.

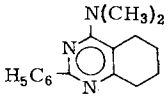
R	Yield (%)	B.p. (°C/torr)	NMR($CDCl_3$, TMS = 0) δ(ppm)
H	60	180/1	7.6(1H/s), 2.8(6H/s), 2.4–1.4(16H/br.)
CH_3	65	140/2	2.8(9H/d), 2.4–1.4(14H/m), 3.2(2H/m)
C_6H_5	65	160/0.05	6.8–7.2(5H/m), 3.2(2H/m), 3.0(6H/s), 2.4–1.4(14 H/m)

Hydrolysis of *(3)* affords tertiary β-ketoamides *(7)* (Table 2); aminolysis of *(3)* gives enaminoamidines *(8)* (Table 3).

Synthesis of (3):

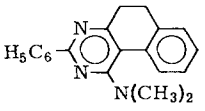
1 mole of enamine *(2)* in CH_2Cl_2 solution is added dropwise at 20 °C to a stirred suspension of *(1)* (1 mole) in the same solvent. Stirring is then continued at room temperature until *(1)* is completely dissolved. About two thirds of the solvent are distilled off and an excess of dry ether is added, whereupon the product *(3)* separates as an orange

Cyclization of (3a) with hydrazine:



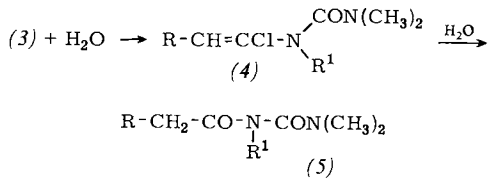
A solution of *(3a)* (9.34 g) in CH_2Cl_2 (50 ml) is added dropwise to a stirred solution of hydrazine dihydrochloride

[*] Prof. Dr. H. G. Viehe, Dipl. Chem. Th. van Vyve, and Dr. Z. Janousek
Laboratoire de Chimie Organique
96, Naamsestraat, B-3000 Louvain (Belgium)

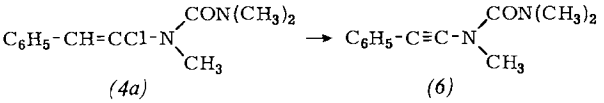


(2.33 g) in CH_2Cl_2 (100 ml). The mixture is boiled under reflux for 5 hours then cooled to 0°C and treated with 15 ml of concentrated KOH. The organic layer is separated, dried over solid K_2CO_3, filtered, and finally evaporated. 3.4 g (60%) of a mixture of *(5)* and *(5a)* is obtained.

Reaction of phenylhydrazine with *(3)* gave analogously a 56% yield of a mixture of isomers *(5)* and *(5a)* in a ratio of about 1:1 (determined by gas chromatography).



Cyclization of *(3a)* and of *(3d)* with benzamidine gave the pyrimidines *(6a)* and *(6d)* in 37 and 30% yield, respectively.



(6a)

(6d)

Compounds *(3)* are generally yellowish stable salts (Table 1) which on hydrolysis first form the *N*-(1-chloroalkenyl)ureas *(4)* and then the *N*-acylureas *(5)*, whereas with hydrogen sulfide the analogous dithio compounds are formed. Compounds *(4)* are of particular interest as starting materials for the hitherto unknown ethynylureas *(6)*. They are formed from *(4)* by treatment with potassium *tert*-butoxide in anhydrous THF. *(6)*, $R = C_6H_5$, is a colorless stable and

(4a) *(6)*

Table 1. Properties of a few compounds of type *(3)*.

	R	R'	Yield (%)	M.p. (°C)	NMR ($CDCl_3$, TMS—O) δ(ppm)
(3a)	C_6H_5	CH_3	97	82–5	3.74(9H/s), 7.47 and 7.80(6H/2mult.)
(3b)	Cl	CH_3	85	154	3.76(3H/s), 3.78(6H/s), 8.11(1H/s)
(3c)	$-(CH_2)_4-$		86	liq.	6.23(1H/t), 4.16(2H/t), 3.78(6H/s), 1.7–2.6(6H/br.)
(3d)	H	CH_3	90	liq.	3.80(6H/s), 3.89(3H/s), 5.90(1H/d), 6.41(1H/d)

The structures of all the new compounds were confirmed IR, NMR, and mass spectrometrically.

Reaction of Secondary Acetamides with *N*-Dichloromethylene-*N*,*N*-dimethylammonium Chloride[1]

By *Zdenek Janousek, Juliette Collard,* and *Heinz Günter Viehe*[*]

Secondary acetamides of the general formula *(1)* react with phosgeneimmonium chloride similarly as with phosgene itself[2], to give a new class of chloroformamidinium salts *(3)*.

(3)

[*] Dr. Z. Janousek, Miss J. Collard, and Prof. H. G. Viehe
Laboratoire de Chimie Organique, Université de Louvain
96, Naamsestraat, B-3000 Louvain (Belgium)

distillable liquid. Its chemical behavior is similar to that of the recently described *N*-alkynylamides[3].

Synthesis of compounds (3):

1 mole of the acetamide *(1)* and 2 moles of *(2)* are boiled under reflux in chloroform for 30—60 min. The solvent is then evaporated and the residue is washed with anhydrous ether to remove the dimethylcarbamoyl chloride formed as a by-product.

Hydrolysis of (3a) to (4a):

2.5 g of *(3a)* (8.54 mmoles) is added to 10 ml of a stirred suspension of $NaHCO_3$ in water, the resulting mixture being kept about neutral during the addition. After about 5 minutes the mixture is extracted with methylene chloride and the extract is dried over potassium carbonate, filtered, and finally evaporated. Yield: 1.8 g (88.5%) of *(1)*, $R = C_6H_5$, $R^1 = CH_3$.

Hydrolysis of (3a) to (5a):

A solution of *(3a)* [from 10 g (67 mmoles) of *(1a)*] in chloroform (40 ml) is treated with 10 ml of water and an excess of $NaHCO_3$ for a period of 2 hours. The organic layer is separated off and then dried over K_2CO_3. Fractional distillation affords 10.1 g (71%) of *(5a)*, b.p. 135°C/0.2 torr.

Dehydrochlorination of (4a) to (6):

A solution of potassium *tert*-butoxide (0.176 g, 1.55 mmoles) in anhydrous THF (5 ml) is added to a stirred solution of 0.37 g (1.55 mmoles) of *(4a)* in THF (2.5 ml) at room temperature. After 10 minutes, 10 ml of anhydrous ether is added and stirring is continued for 30 minutes. The pre-

cipitate is filtered off and the filtrate is evaporated to remove solvent; the oily residue is distilled at 140 °C/0.4 torr [yield of *(6)*: 0.20 g (64%); colorless stable oil].

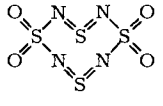
Synthesis of the First Oxide of Tetrasulfur Tetranitride



By *Herbert W. Roesky* and *Olaf Petersen*[*]

We reported recently the synthesis of $S_3N_3O_3Cl$, the *S,S,S'*-trioxide of a six-membered sulfur-nitrogen ring[1]. We have now succeeded in isolating the first oxide of the S_4N_4 ring.

N,N'-Bis(trimethylsilyl)sulfur diimide *(1)*[2] reacts with the anhydride of fluorosulfuric acid with cleavage of trimethylfluorosilane and trimethylsilyl fluorosulfate to give $S_4N_4O_4$ *(2)*.

$$2\ (CH_3)_3Si\text{-}N{=}S{=}N\text{-}Si(CH_3)_3 + 2\ FSO_2\text{-}O\text{-}SO_2F \longrightarrow$$

(1)

$$+ 2\ (CH_3)_3SiF + 2\ (CH_3)_3SiOSO_2F$$

(2)

(2) is a yellow solid which sublimes at 80—90 °C under oil-pump vacuum. Decomposition point: 115 to 120 °C. The compound is not formed on reaction of *(1)* with SO_2Cl_2. In the presence of moisture it decomposes with loss of SO_2 and turns brown in color. The given structure follows from complete elemental analysis and the MS and IR data.

The mass spectrum contains the molecular ion at $m/e = 248$ with a relative intensity of only 0.1%. This is accompanied by the following characteristic ions: $m/e = 216$, $S_4N_4O_2$ (16%); 184, S_4N_4 (1%); 170, $S_3N_3O_2$ (13%); 138, S_3N_3 (1%); 124, S_3N_2 (4%); 110, S_3N (1.5%); 92, S_2N_2 (8%); 78, S_2N (14%); 64, SO_2 (17%); 48, SO (16%); 46, NS (100%); 32, S (9%); 28, N_2 (17%).

In the IR spectrum absorptions occur at (cm^{-1}): 1420 (s), 1400 (s), 1328 (vs), 1280 (w), 1218 (m), 1202 (m), 1175 (s), 1137 (vs), 1115 (vs), 1072 (w), 1018 (w), 980 (w), 895 (w), 850 (w), 830 (w), 715 (s), and 704 (s). The bands at 1420 and 1400 cm^{-1} are assigned to asymmetric S=O stretching vibrations.

6 Frankfurt, Robert-Mayer-Strasse 7–9 (Germany)

Experimental:

To a solution of *(1)* (0.1 mol) in CCl_4 (200 ml) in a 500-ml two-necked flask fitted with dropping funnel is added dropwise over 3h a solution of $F_2S_2O_5$ (0.1 mol) in CCl_4 (100 ml). The mixture is then boiled under reflux for 4h and the solvent and volatile products subsequently removed by evaporation and condensation into a trap under vacuum. The residue remaining in the flask is sublimed under oil-pump vacuum. Four sublimations are required for complete purification of the product. Yield 2.5 g (5%).

Side-Chain Alkylation of Toluene with Ethylene[1]

By *Ernst Oltay*, *Johannes M. L. Penninger*, and *Hendrik Maatman*[*]

In the presence of metallic Na or K as a catalyst, with or without promoter, the three hydrogen atoms of the methyl group in toluene can be stepwise alkylated with ethylene, the most highly alkylated product formed being 3-ethyl-3-phenylpentane[2–4]. In the presence of butyl-Li and a di-tertiary amine, toluene reacts with ethylene to give a straight-chain homologous series[5, 6].

We have found that toluene reacts with ethylene in the absence of a catalyst even at as low a temperature as ≈ 400 °C and a pressure of 50 atm to give alkylbenzenes having straight alkyl chains (for instance, *n*-propylbenzene and *n*-pentylbenzene). The reaction proceeds *via* free radicals.

Compounds yielding benzyl radicals catalyze the reaction. Thus the conversion of toluene and the selectivity of the side-chain alkylation to give straight-chain alkylbenzenes are favored by addition of benzyl chloride and benzyl bromide (Table 1).

All compounds were isolated by preparative gas chromatography and identified by NMR, IR, and MS, as well as by their gas-chromatographic retention times. The new reaction is of general applicability.

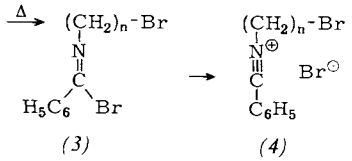
The Mechanism of the Bischler-Napieralski Reaction[1]

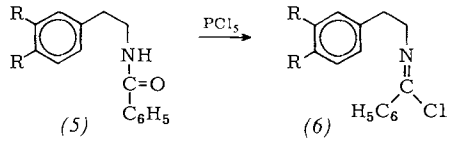


By *Gábor Fodor, J. Gal*, and *B. A. Phillips*[*]

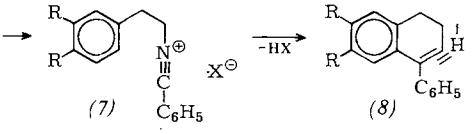
The fragmentation of cyclic benzamides of type *(1)* upon the action of phosphorus pentabromide[2] leads to α, ω-dibromoalkanes and benzonitrile. Our recent studies have revealed that the first step of this reaction is in fact the formation of the α-bromoiminium tribromide *(2a)* which can be isolated[3] in more than 90% yield. Reduction of this compound with an olefin (*e.g.* cyclohexene) results in the quantitative formation of the monobromide *(2b)*[4]. Mild heating of *(2b)* gave the *N*-(ω-bromoalkyl)imidoyl bromide (with $n = 5$) which was also synthesized *via* its hydrobromide from *N*-(5-bromoamyl)benzamide and carbonyl bromide[4] (or phosphorus pentabromide) followed by reduction of Br_3^- to Br^-, and mild heating.

(1)

(2a), X = $Br_3^{\ominus}$
(2b), X = $Br^{\ominus}$



(3) *(4)*



Imidoyl bromides—unlike imidoyl chlorides[5]—have not been previously known in pure form. We have found that imidoyl bromides equilibrate with nitrilium bromides *(4)* and hence are the intermediates which occur after the bromoiminium bromide in the degradation of the amide *(1)*[6].

[*] Prof. Dr. G. Fodor, Dr. J. Gal, and B. A. Phillips
Department of Chemistry, West Virginia University
Morgantown, West Virginia 26506 (USA)

However, if unlike in the amide degradation there is an internal nucleophile present, it should react with the carbon of the nitrilium group. This is the case in the Bischler-Napieralski ring closure reaction of *N*-acyl-2-arylethylamines *(5)* under the influence of P_2O_5, $POCl_3$ or $ZnCl_2$ to give the 3,4-dihydroisoquinolines *(8)*. To prove this we have converted *N*-[2-(3,4-dimethoxyphenyl)-ethyl]benzamide *(5a)* at room temperature with phosphorus pentachloride in CCl_4 into the crystalline hydrochloride of the benzimidoyl chloride *(6a)* (80% yield). This salt loses hydrogen chloride slowly at room temperature (more rapidly at 85 °C) and gives quantitatively the cyclized product, *i.e.* 6,7-dimethoxy-1-phenyl-3,4-dihydroisoquinoline hydrochloride *(8a)*.

(5) *(6)*

(7) *(8)*

(a), R = CH_3O
(b), R = H

The reaction can be followed with NMR using $CDCl_3$ as solvent: *(6a)* shows a singlet at 3.82 ppm for the six methoxy protons which is converted to two singlets at 3.80 and 4.09 ppm as the cyclization to *(8a)* proceeds. The aromatic region is also informative in that the original peak at 6.82 ppm integrating for three protons changes to two singlets at 6.94 and 7.13 ppm which integrate for one proton each.

Addition of a Lewis acid ($ZnCl_2$, $SnCl_4$, *etc.*) enhanced the rate of cyclization. This could be explained through a push-pull displacement of chlorine from the imide carbon in *(6)* by the nucleophilic arene carbon, synchronously with attack of the Lewis acid upon the chloride ion. Alternatively, one can suppose intermediary formation of the nitrilium ion *(7a)*, which could then react very fast[7] with the aromatic carbon.

In order to slow down the cyclization, and detect the nitrilium ion, *N*-(2-phenylethyl)benzamide *(5b)* was converted into the crystalline imidoyl chloride hydrochloride[8] and then into the base *(6b)*, which was distilled at 132 °C/0.045 torr. If stannic chloride is added to a solution of *(6b)* in a NMR tube, the triplet at 4.02 ppm of the methylene adjacent to nitrogen disappears and a new CH_2 triplet appears at 4.68 ppm, indicating nitrilium ion *(7b)* formation. Upon standing at 25 °C this triplet is slowly (faster upon heating) displaced to 4.20 ppm, which is the chemical shift of the methylene protons at C-3 in the hydrochloride of the 3,4-dihydroisoquinoline *(8b)*. Moreover, the *N*-(2-phenylethyl)benzonitrilium ion could also be trapped as the crystalline hexafluoroantimonate. It reacts subsequently in solution to give the dihydroisoquinolinium hexafluoroantimonate.

N-(2-Phenylethyl)benzonitrilium complexes have previously been obtained from a metal halide complex of the nitrile and 2-phenylethyl chloride[9], reminiscent of the Ritter reaction[10]. The product was also cyclized into the

isoquinoline[9]; previously, however, nitrilium salts have not been trapped, let alone suggested as intermediates in the Bischler-type cyclization reaction. The results of our investigation explain why certain phenylethylamines gave under forcing conditions, but in absence of an appropriate Lewis acid, a nitrile besides an olefin[11]. Actually, these were von Braun products arising from decomposition of the imidoyl chloride at relatively high temperatures. This failure of the Bischler cyclization is partly due to the weak nucleophilicity of the aromatic *ortho* carbon, as well as to the inability of phosphorus oxychloride to form a stable complex anion.

Nitrilium ions, however, cannot be formed as intermediates, in the cyclization of *N*-alkyl-*N*-(2-phenylethyl)-amides *via* chloroiminium chloride, to the quaternary isoquinolinium salt. In this case the nucleophilic displacement of the chlorine atom is the only reasonable pathway.

The knowledge of this mechanism now enables us to carry out the Bischler-Napieralski reaction in high yields—at 20—80 °C depending on substituents in the arene, instead of refluxing with $POCl_3$ in high-boiling solvents. The two-step process of isolating the imidoyl chloride and cyclizing the nitrilium salt nevertheless gives an appreciable improvement in yields even in the case of "unactivated" aromatic rings. Therefore, we think that the long list[12] of amides which have failed to undergo dihydroisoquinoline ring closure will be appreciably shortened when using this improved technique.

We feel that the system

imidoyl halide$\rightleftharpoons$nitrilium salt

can make smooth ring closure possible in other fields, *e.g.* in the synthesis of 4-quinolones from 2-amino-*N*-aryl-acrylamides, or of complex fused heterocycles. Furthermore, correlation of the mechanism of the von Pechmann and von Braun amide degradations with the Bischler-Napieralski and the Ritter reactions will probably lead to a better understanding and improvement of the Vilsmeier aldehyde and the Hoesch ketone syntheses when generating nitrilium salts as reactive intermediates.

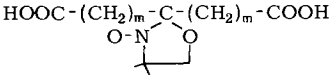
Folding of Fatty Acid Chains in Liquid Crystalline Bilayers

By *Hugo Limacher* and *Joachim Seelig*[*][**]



Spin label studies have shown that several types of motion can occur in lipid bilayers: exchange of molecules between the half-layers[1], lateral diffusion of molecules within the half-layers[2], rigid body rotation of hydrocarbon chains around their long molecular axes[3–5], the rapid isomerization of carbon-carbon bonds between *trans* and *gauche* conformations[4–7].

Here we wish to compare two different methods, both employing spin labels, for measuring the energy difference, E_σ, between *trans* and *gauche* conformations of hydrocarbon chains in bilayers. In our model both the intramolecular bond rotation potential and interactions between adjacent hydrocarbon chains contribute to E_σ. Since the *intra*molecular bond rotation potential is known from several sources (*e.g.* studies of macromolecules in solution[8]), it is possible to extract information about the *inter*molecular interactions in bilayers from measurements of E_σ.

(1), n = 2-12

In our first approach, which has been described previously[4, 6], we measured the order parameter S_3 for spin labeled stearic acids *(1)* in two different liquid crystalline bilayers. The carboxyl group of the spin label is fixed at the lipid-water interface and the order parameter decreases continuously as the label group is translated along the chain towards the center of the bilayer. A plot of log S_3 *versus* the distance of the label group from the bilayer surface yields straight lines in the central part of the bilayers. The slope of the plot measures the chain flexibility in the liquid crystalline phase. Applying a linear Ising model to these data, one can easily obtain values for E_σ[6]. The composition of the liquid crystalline bilayers[9] and the corresponding results for E_σ are listed in Table 1 (fourth row). A more direct way of measuring E_σ results on use of spin labels of type *(2)*[10]. The chain length is selected to be nearly the same as the thickness of the bilayer[10]. An

(2), m = 6, 7

equilibrium then exists between folded (B) and extended configurations (A) of the hydrocarbon chains, as illustrated in Figure 1. In the folded form B both carboxyl groups

[*] Dipl.-Phys. H. Limacher and Priv.-Doz. Dr. J. Seelig [***]
Biozentrum, Universität Basel
Klingelbergstrasse 70, CH-4056 Basel (Switzerland)

[**] We are much indebted to Dr. *C. J. Scandella* for critically reading the manuscript and for making valuable comments.

[***] To whom correspondence should be addressed.

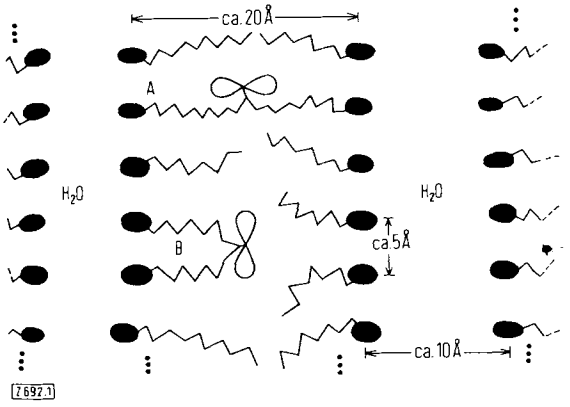


Fig. 1. Schematic diagram of the spin label orientation within the bilayer.

are on the same side of the bilayer, whereas in the extended form A the polar groups are on opposite sides of the bilayer. In homogeneously oriented samples of liquid crystals the EPR signals arising from the two different configurations are well resolved[10], so that the relative concentrations of A and B can be obtained directly from the resonance spectra. From these concentrations one can evaluate the equilibrium constant K of the transition $A \rightleftarrows B$. We have measured the temperature dependence of this equilibrium constant for two labels of type *(2)* in the liquid crystalline bilayers mentioned above. Increasing temperature shifts the equilibrium towards the folded

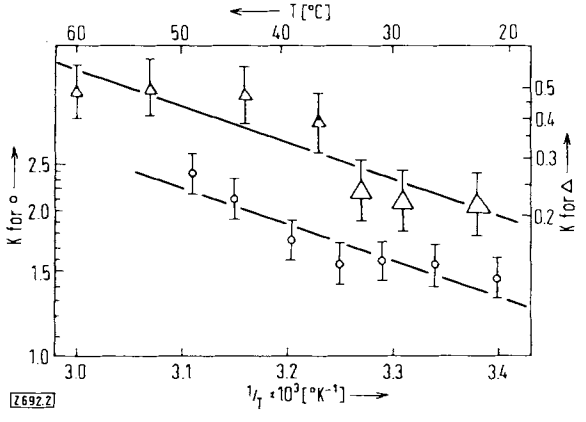

Fig. 2. Temperature dependence of the equilibrium constant K on a logarithmic scale. – ○, spin label *(2)*, $m = 6$; △, spin label *(2)*, $m = 7$.

configuration (Fig. 2). The slope of the straight line affords the reaction enthalpy ΔH (Table 1, first row). In the notation of the rotational isomeric model[8] the transition from the extended to the folded configuration can be written as

$$t\,t\,t\,t\,t\,t\,t \rightarrow t\,g\,g\,t\,g\,g\,t$$

(t and g denote the *trans* and *gauche* rotational states, respectively. All *gauche* conformations must exhibit the same angular rotation, *i.e.* either $+120°$ or $-120°$). The equilibrium constant K can be expressed in terms of the statistical probabilities p of the two configurations. One can easily show, using the linear Ising model, that

$$K = p_{tggtggt}/p_{ttttttt} = \sigma^4 \qquad (1)$$

where

$$\sigma = \exp(-E_\sigma/RT)\,. \qquad (2)$$

To a first approximation E_σ can be assumed to be temperature independent. Then

$$(\partial \ln K/\partial T) = \Delta H/RT^2 = 4(\partial \ln \sigma/\partial T) = 4E_\sigma/RT^2 \qquad (3)$$

and

$$E_\sigma = \Delta H/4\,. \qquad (4)$$

The third row in Table 1 lists the values of E_σ calculated from ΔH using eq. (4). These values are in good agreement with the values of E_σ obtained by our first method. Subtracting the internal rotation potential[8] $E_{rot} \approx 500$—700 cal mol^{-1} from E_σ yields the intermolecular energy contribution ΔW to the flexibility of the fatty acid chains (Table 1, fifth row).

ΔW can be interpreted as the energy required per CH_2 unit to overcome at least partially the van der Waals attraction between parallel chain segments. For monomolecular layers of stearic acid with a perfectly parallel arrangement of the hydrocarbon chains an interaction energy of -470 cal mol^{-1} per CH_2 unit has been calculated[11]. The melting behavior of polyethylene can be described reasonably well with an interaction energy of -680 cal mol^{-1} per CH_2 unit[12]. Our experimental results for liquid crystalline bilayers are consistent with these atomistic calculations.

The entropy ΔS of the folding process can also be determined from K and ΔH. The positive ΔS values (Table 1, second row) show that the transition from the extended to the folded form substantially increases the disorder of the system.

Table 1. Thermodynamic parameters for folding of fatty acids in liquid crystalline bilayers.

	Label *(2)*, $m = 6$, in sodium caprylate 35 wt.-% caprylic acid 35 wt.-% water 30 wt.-%	Label *(2)*, $m = 7$, in sodium caprylate 28 wt.-% decanol 42 wt.-% water 30 wt.-%
ΔH [cal mol^{-1}]	3230	5190
ΔS [e.u.] at 25 °C	*ca.* 11.6	*ca.* 14.5
E_σ [cal mol^{-1}]	810	1290
E_σ [cal mol^{-1}] determined with label *(1)*	820	1200
ΔW [cal mol^{-1}]	100–300	500–700

It seems that spin labels of type *(2)* might be used as rulers to measure the thickness of bilayer membranes, including biological membranes with bilayer structure. A label long enough to pass easily through the bilayer will be in the extended form, while a label too short to span the bilayer will be in the folded form. Only spin labels whose length is comparable with the bilayer thickness will exhibit resonance spectra representing both configurations.

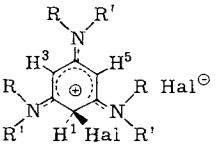
σ-Complexes in Halogenation of Aminobenzenes—Isolation and Secondary Reactions[1]

By *Peter Menzel* and *Franz Effenberger*[*]

σ-Complex intermediates in electrophilic aromatic substitution have so far been established only for protonation and alkylation[2, 2a]. Due to exceptional mesomeric stabilization, they can be isolated in the case of protonation and alkylation of 1,3,5-tripyrrolidinobenzene[3a, b].

The primary isotope effect found in bromination of 1,3,5-tri-*tert*-butylbenzene[4] and the observation that bromination of *N*,*N*-dialkylanilines is reversible even below 100 °C[5] clearly indicate long-lived halo σ-complex intermediates in these cases. Steric factors are held responsible for the additional stabilization in the first instance, electronic influences in the second example. The intermediate identified NMR-spectroscopically for the bromination of 2-hydroxynaphthalene-6,8-disulfonic acid, however, is no σ-complex but rather the tautomeric quinonoid form[6]; corresponding quinonoid intermediates have been isolated from the bromination of sterically hindered phenols[7].

If bromine is added to tris(dialkylamino)benzenes *(1)* in dry chloroform at −60 °C, deep-red colored solutions are formed from which the dark-red σ-complexes may be precipitated by addition of ether. While *(2a)* and *(2b)* are stable for some time at ambient temperature, *(2c)* and *(2d)* rearrange to give the *N*-protonated aminobromobenzenes *(3c)* and *(3d)* respectively. When the aminobenzenes *(1)* are chlorinated with sulfuryl chloride or chlorine under like conditions, *(2e)* is obtained in crystalline form; *(2f)*



(1a)-(1d) *(2a)-(2f)*

(3c), (3d)

	R	R'	Hal
(a)	—$(CH_2)_4$—		Br
(b)	CH_3	CH_3	Br
(c)	—$(CH_2)_5$—		Br
(d)	—$(CH_2)_2$—O—$(CH_2)_2$—		Br
(e)	—$(CH_2)_4$—		Cl
(f)	CH_3	CH_3	Cl

can be detected by NMR spectroscopy but may be isolated only with the less nucleophilic tetrafluoroborate as gegenion. By anion exchange with $AgBF_4$, all the halides *(2a)* to *(2f)* are converted to the tetrafluoroborates, which, as expected, are more stable, and thus better suited for further investigations. The structure of the σ-complexes *(2)* has been unequivocally established both by chemical reactions and spectroscopically; some characteristic NMR and UV data are given in Table 1.

Table 1. ^{1}H-NMR and UV-spectroscopic data of halogen σ-complexes *(2a)* to *(2f)*.

	^{1}H-NMR data [a] H^1	$H^{3,5}$	UV absorption bands (in $CHCl_3$) λ_{max} [nm] (ε)

[b] UV spectrum of the tetrafluoroborate.

The σ-complexes formed as intermediates in normal arene halogenation suffer immediate deprotonation. Since we isolate the σ-complexes *(2)* in crystalline form, the secondary reactions can be directed along different routes. Deprotonation to give the halobenzenes *(4)* is the course taken with strong bases while highly nucleophilic or reducing agents cleave off a halogen cation thus re-forming *(1)*. Tertiary amines produce the biphenyls *(5)* from *(2a)* and *(2b)*, most likely *via* radical intermediates. These biphenyls are also formed when *(1)* is treated with iodine or iodine chloride under the reaction conditions described. From

7000 Stuttgart 1, Azenbergstr. 14—18 (Germany)

the reaction of *(2)* with carboxylate ions, quinone iminium salts *(6)* are isolated besides *(1)*. We have ascertained that these compounds do not arise from interaction with atmo-

spheric oxygen. However, as to whether highly reactive cyclohexadienylium dications are precursors for the formation of *(6)* or whether the σ-complexes *(2)* are oxidized to *(6)* by carbonic acid hypohalites that are formed as intermediates, has yet to be investigated.

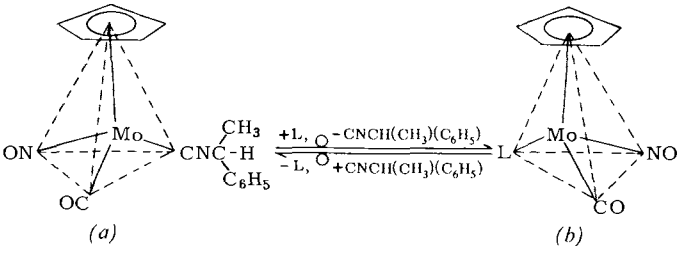
Walden Inversion at an Asymmetric Molybdenum Atom[1]

By *Henri Brunner* and *Marta Lappus*[*]



The isocyanide ligand in the molybdenum complex *(3)* can be replaced by nucleophiles. We have shown that these reactions occur with inversion of configuration at the asymmetric Mo atom.

On reaction of *(1)* with the optically active isocyanide *(2)*[2], $[\alpha]_{589}^{25} = +40°$ (pure liquid), in the molar ratio 1:1, the diastereoisomeric replacement products *(3a)*, $[\alpha]_{589}^{25} = +275°$, and *(3b)* $[\alpha]_{589}^{25} = -365°$, are formed,

and they can be separated by fractional crystallization from benzene/pentane. The rotations given are reached after 20 recrystallizations. *(3a)* and *(3b)* are configurationally stable in the solid state and in benzene solution (up to +50 °C)[3].

If the isocyanide *(2)* is added to a 10^{-2} M solution of *(3a)* in benzene in the molar ratio 1:1, the rotation falls to values near 0° within about 2 h at room temperature. This loss of optical activity is to be ascribed to back-side attack by *(2)* on the complex *(3a)*. It results in an equilibrium between *(3a)* and *(3b)* that, like *(2)*, shows only very low optical rotation.

$C_5H_5MO(CO)(NO)L$	*(3a), (3b)*	*(4a), (4b)*	*(5a), (5b)*
L	$(+)_{589}$-CNCH(CH$_3$)(C$_6$H$_5$)	CNC$_6$H$_{11}$	P(C$_2$H$_5$)$_3$

If the more nucleophilic cyclohexyl isocyanide is used, the decrease of rotation is complete in only about 1.5 h under similar conditions. If in this case a three-fold excess of cyclohexyl isocyanide is used and the reaction is stopped after about 10 min, chromatographic working up gives a mixture in which *(4b)* predominates but which also contains *(4a)* and, according to ^{1}H-NMR analyses, 10 to 20% of *(3a)*, *(3b)*.

Table 1. Specific rotations of *(3a)*, *(4b)* [a] and *(5b)* in benzene solution (*ca.* 10^{-3} M solution).

	(3a)	*(4b)* [a]	*(5b)*
$[\alpha]_{589}^{25}$ (°)	+220	−37	−205
$[\alpha]_{579}^{25}$ (°)	+270	−44	−235
$[\alpha]_{546}^{25}$ (°)	+350	−60	−215
$[\alpha]_{436}^{25}$ (°)	−330	− 8	+190
$[\alpha]_{365}^{25}$ (°)	−475	+27	+615

[*] Prof. Dr. H. Brunner and Dipl.-Chem. M. Lappus
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

The opposite signs of the rotatory values of the comparable isocyanide complexes *(3a)* and *(4b)* (Table 1) prove the inversion of configuration on reaction of *(3a)* with CNC_6H_{11} as our investigations up to now have shown that small changes on the ligands do not influence the optical rotations and CD spectra of these compounds appreciably.

Treatment of *(3a)* with $P(C_2H_5)_3$ in benzene for 2h at room temperature gives the complex *(5b)*, which can be isolated in 50% yield by chromatography on Al_2O_3. Table 1 contains the rotatory values at different wave lengths. The CD spectra of *(3a)* and *(5b)* are opposite to each other. In this case also, the nucleophile probably attacks the complex at the back-side, thus replacing the isocyanide ligand with Walden inversion.

(5b) is configurationally stable in solution, but racemizes slowly in the presence of $P(C_2H_5)_3$. This racemization is also to be ascribed to rear attack by the nucleophile on the complex; it occurs considerably more slowly than the reaction of *(3a)* with $P(C_2H_5)_3$. Since however this reaction cannot be wholly excluded it leads to reduction in the optical purity of *(5b)*, although to a considerably smaller extent than during reaction of *(3a)* with cyclohexyl isocyanide.

Photoelectron Spectroscopy and Conjugation—Direct Proof of the Unusual Sequence of the Two Highest Occupied π-Molecular Orbitals in the Phosphorin (Phosphabenzene) and the Arsenin (Arsabenzene) System[1]

By *Werner Schäfer, Armin Schweig, Friedrich Bickelhaupt*, and *Hans Vermeer*[*]

In 1970 we found[2] by approximate quantum chemical calculations[3] for phosphorin *(3)* the unusual sequence of the two highest occupied π-molecular orbitals: $b_1(\pi)$ as HOMO ("highest occupied MO") before $a_2(\pi)$ (*i.e.* π-MO with non-zero coefficient on the heteroatom energy-richer than the π-MO with the node; cf. representation of the two MO's), this contrasting with the situation for pyridine *(2)*. In two later papers[4, 5] we were able, by comparative photoelectron (PE) spectroscopic studies on 2,4,6-tri-*tert*-butylpyridine *(6)*[6], 2,4,6-tri-*tert*-butylphosphorin *(7)*[6] and 2,4,6-tri-*tert*-butyl-1,1-dimethoxyphosphorin *(9)*[7], to render this hitherto unique heterocyclic MO sequence very probable. We now record here, on the basis of PE spectra of 9-phenylanthracene *(10)*, 9-phenylacridine *(11)*, 10-phenyldibenzo[*b*,*e*]phosphorin (10-phenyl-9-phosphaanthracene) *(12)*[8] and 10-phenyldibenzo[*b*,*e*]arsenin (10-phenyl-9-arsaanthracene) *(13)*[9], an unambiguous proof of the correctness of the sequence proposed for the phosphorin *(3)*[10, 11] and we extend our considerations and conclusions to the arsenin *(4)*[10, 11].

The six-membered ring systems *(1)* to *(9)* suffer from two main disadvantages for proof of reversal in the MO sequence on changing from the azabenzenes *(2)* and *(6)* to the phospha- and arsa-benzenes *(3)*, *(4)* and *(7)* to *(9)*: 1. The two initial MO's $e_{1g}(\pi)$ in *(1)* and $e''(\pi)$ in *(5)* are degenerate, and 2. lacking experience with the new types of system, we do not know *a priori* how the orbital energies of the MO's $b_1(\pi)$ and $a_2(\pi)$ alter under the influence of the phosphorus and arsenic ring atoms in the phospha- and arsa-benzenes (the position is different with azabenzenes, where the effect of aza replacement is known from long experience).

These difficulties (which permit only circumstantial evidence) can be avoided (and a direct proof made possible) if one can find a non-degenerate MO of a benzenoid hydrocarbon that fulfills the following conditions: 1. It must be known from the symmetry and topology that this MO has a non-zero coefficient in one specific atom; 2. the sign of the coefficients on the two neighboring atoms must be the same as on the specified atom (these two conditions make

[*] Prof. Dr. A. Schweig and Dipl.-Chem. W. Schäfer
Fachbereich Physikalische Chemie der Universität

this MO related to the "$b_1(\pi)$ MO" of benzene); 3. the aza, phospha, and arsa homologs can be obtained from the selected hydrocarbon by replacement of this specific atom; 4. it must be possible to observe the chosen test MO experimentally in the hydrocarbon and in the derived heterocycles separately from all the other MO's and without a change in the sequence.

These four conditions are fulfilled in an ideal manner by the $b_{2g}(\pi)$ HOMO of the anthracene derivatives *(10)* to *(13)*[12, 13] (cf. the representation of this MO). Comparing the HOMO ionization potentials (IP) of compounds *(10)* to *(13)* with the IP values that, from previous work[2, 4, 5], are probable for the $b_1(\pi)$ MO's [$e_{1g}(\pi)$ in *(1)* and $e''(\pi)$ in *(5)*] of compounds *(1)* to *(4)* or *(5)* to *(7)* thus shows sequence reversal if the behavior is similar and absence of reversal if behavior is different.

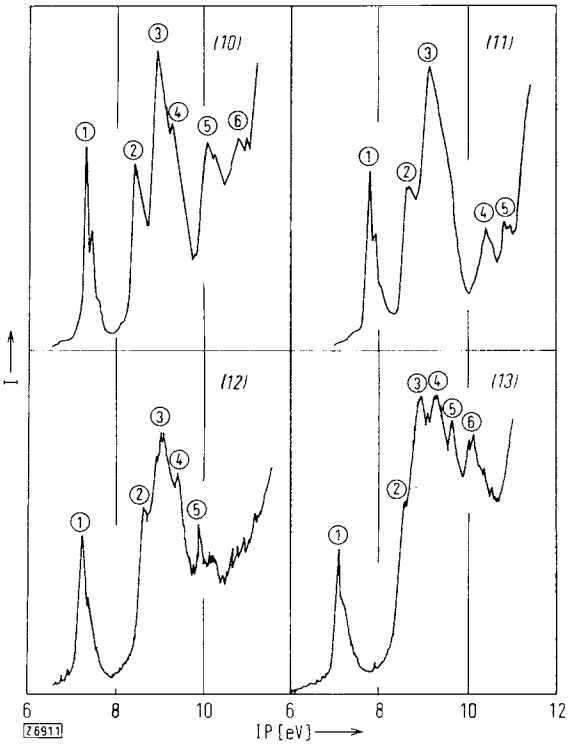

Fig. 1. Photoelectron spectra [18] for 9-phenylanthracene *(10)*, 9-phenylacridine *(11)*, 10-phenyl-9-phosphaanthracene *(12)* and 10-phenyl-9-arsaanthracene *(13)*. The vertical ionization potentials (in eV) are: for *(10)*, ① 7.25, ② 8.45, ③ 9.00, ④ 9.25, ⑤ 10.05, ⑥ 10.80; for *(11)*, ① 7.80, ② 8.65, ③ 9.15, ④ 10.40, ⑤ 10.85; for *(12)*, ① 7.25, ② 8.65, ③ 9.00, ④ 9.30, ⑤ 9.90; for *(13)*, ① 7.05, ② 8.60, ③ 8.95, ④ 9.25, ⑤ 9.70, ⑥ 10.10 [19].

Figure 1 shows the PE spectra of *(10)* to *(13)*. In Figure 2 the IP values of the probable $b_1(\pi)$ MO's [$e_{1g}(\pi)$ in *(1)* and $e''(\pi)$ in *(5)*] of *(1)* to *(4)* (9.24[14], 10.5[15], 9.1[16], and 8.7[16] eV) on the one hand and of *(5)* to *(7)* (8.15, 9.3[4] and 8.0[4] eV) on the other are plotted against the HOMO IP's of *(10)* to *(13)* (7.25, 7.80, 7.25 and 7.05 eV). There is very good correspondence in both cases, and the two straight lines are strictly parallel[17]. These results provide the first direct and unambiguous proof that the hitherto unique MO sequence — π-MO with non-zero coefficient on the hetero atom [$b_1(\pi)$] higher in energy than the π-MO with its node on the hetero atom [$b_1(\pi)$] — does in fact exist in the phosphorin and in the arsenin system.

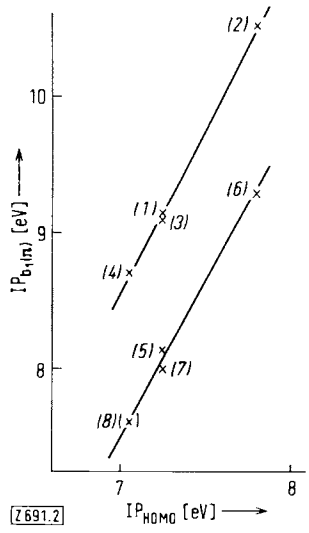

Fig. 2. Correlation between the ionization potentials of the $b_1(\pi)$ MO's [e_{1g} for *(1)* and e'' for *(5)*] probable from previous work [2, 4, 5] in the six-membered ring systems *(1)* and *(8)* (ordinates) and the HOMO ionization potentials of the anthracene systems *(10)* to *(13)* (abscissae).

[11] Meanwhile an *ab initio* calculation has been made on *(3)* by *D. T. Clark* and the compounds *(3)* and *(4)* have been measured by *E. Heilbronner*; the unpublished results [16] of these two investigations provide a welcome confirmation of our previous findings.
[12] We have proved that the phenyl group in 9-phenylanthracene *(10)* does not influence the results of our work. For anthracene we have measured the vertical ionization potentials (in eV) for the first four PE bands as: ① 7.40, ② 8.55, ③ 9.15 and ④ 10.30. The phenyl group lowers the HOMO IP inappreciably, by 0.15 eV. Very recently the IPs of anthracene were also measured by *H. D. Eland*, Int. J. Mass Spectrom. Ion Phys. *9*, 214 (1972) and *P. A. Clark, F. Brogli*, and *E. Heilbronner*, Helv. Chim. Acta *55*, 1416 (1972). The values found by these authors are in very good agreement with those measured by us.
[13] The anthracene derivatives have a further considerable advantage over the benzene derivatives: comparing the HOMO photoelectron bands of *(10)* and its hetero homologs *(11)* to *(13)* proves clearly that bands ① in *(11)* to *(13)* cannot arise by ionization of the free electron pair on the hetero atoms. Such a direct proof is not possible for the series of six-membered rings.
[14] *A. D. Baker, D. P. May*, and *D. W. Turner*, J. Chem. Soc. *B 1968*, 22; *D. W. Turner, C. Baker, A. D. Baker*, and *C. R. Brundle*: Molecular Photoelectron Spectroscopy. Wiley-Interscience, London 1970.

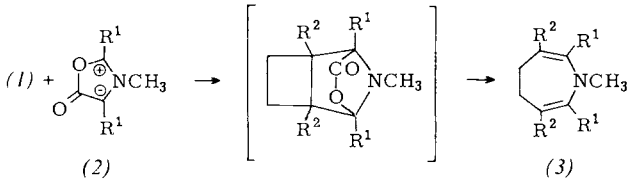
[16] *E. Heibronner*, personal communication.
[17] From Fig. 2 we expect an HOMO IP of 7.5 to 7.6 eV for the arsenin *(8)* that has not yet been synthesized.
[18] The He-I (584 Å) photoelectron spectra were measured with a PS-16 spectrometer from Perkin-Elmer Ltd., Beaconsfield, England.
[19] Our investigations of the higher PE bands not discussed here will be reported later.

A General Synthetic Route to Seven-membered Heterocycles from Cyclobutenes and 1,3-Dipoles

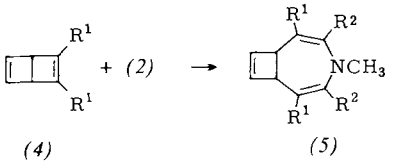


By *Hans-Dieter Martin* and *Mirko Hekman*[*]

Addition of diazomethane to the cyclobutenes *(1)* and subsequent fission of the internal σ-bond of the adduct affords seven-membered heterocycles according to the scheme ④ + ③ → ⑦[**][1].

(1)

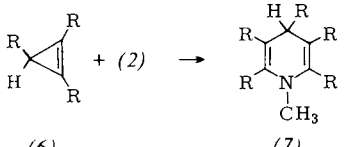
We report here on the reaction of cyclobutenes *(1)* with the mesoionic oxazolone *(2)*[2], which leads to dihydroazepines *(3)* [*(3)*: NMR (CCl_4): δ=2.32 (3 H, S), 2.86



(2) *(3)*

$R^1 = C_6H_5$, $R^2 = CO_2CH_3$

(4 H, S), 3.22 (6 H, S), 7.33 ppm (10 H, M).—UV in CH_3CN: $\lambda_{max}(\varepsilon)$=241 (17400), 307 nm (9100).—M.p. 120°C].



The still more reactive Dewar-benzene derivative *(4)*[3] adds one molar equivalent of *(2)*, yielding the bicyclic, thermally not very stable 4-azabicyclo[5.2.0]nonatriene *(5)*. Systems of this type have hitherto been accessible only by addition of nitrenes to cyclooctatetraene[4]. [*(5)*: NMR ($CDCl_3$): δ=2.32 (3 H, S), 3.30 (6 H, S), 4.30 (2 H, S), 6.32 (2 H, S), 7.40 ppm (10 H, M).—UV in CH_3CN: $\lambda_{max}(\varepsilon)$=233 (17400), 313 nm (10000).—Mass spectrum: M^+ at m/e=401.]

(4) *(5)*

$R^1 = CO_2CH_3$, $R^2 = C_6H_5$

The appreciably more strained cycloadducts from cyclopropenes undergo relatively ready ring opening to six-membered heterocycles[1]. Triphenylcyclopropene *(6)* and *(2)* give a 63% yield of dihydro-1-methylpentaphenylpyridine *(7)* [NMR ($CDCl_3$): δ=2.56 (3 H, S), 4.42 (1 H, S),

(6) R = C_6H_5 *(7)*

[*] Dr. H.-D. Martin and Dipl. Chem. M. Hekman
Organisch-chemisches Institut der Universität
78 Freiburg, Albertstrasse 21 (Germany)

[**] ⑦ means the number of ring atoms contributed by each of the reactants and the ultimate size of the ring formed.

6.90—7.80 ppm (25 H, M).—UV in CH_3CN: $\lambda_{max}(\varepsilon)$= 222 (sh, 30400), 268 (14700), 345 nm (sh, 6300).—M.p. 209 C].

Experimental for synthesis of (5):

Compound *(4)* (1 g, 5.1 mmol) in benzene (50 ml) is warmed at 35 C and *(2)* (2.5 g, 10 mmol) is added portionwise with stirring during 20 min. Stirring is continued for 10 min after cessation of gas evolution and the excess of *(2)* is then filtered off. The filtrate is concentrated in a rotatory evaporator. Methanol (about 40 ml) is added to the concentrated solution. Crystallization begins in about 5 min and is completed by storage for a day at −15 C. Recrystallization from methanol affords white crystals which, being thermally unstable, melt between 132 and 136 C. Yield: 20% (400 mg).

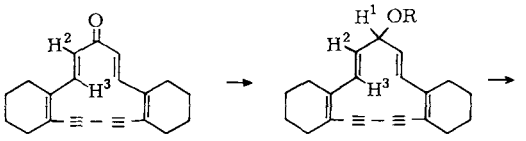
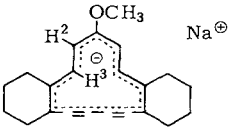
The Synthesis of the 1-Methoxy-4,5:10,11-bis-(tetramethylene)-6,8-didehydro[13]annulenyl Anion, an Aromatic 13-Membered Carbocyclic System[1]

By *Eugene LeGoff* and *Franz Sondheimer*[*]



(4n+1)-Membered conjugated carbocyclic anions contain (4n+2) π-electrons, and are therefore expected to be aromatic (diatropic)[2]. The properties of the known 5-, 9- and 17-membered ring anions are in agreement with this prediction[2, 3], but it has previously not been possible to prepare an example of a 13-membered ring system. We now report the synthesis of a didehydro[13]annulenyl anion, which, as expected, proved to be strongly diatropic.

Reduction of 4,5:10,11-bis(tetramethylene)-6,8-didehydro[13]annulenone *(1)*[4] in ether with ethanolic $NaBH_4$ for 2 h at room temperature, followed by chromatography on silicic acid, gave 80% of the alcohol *(2)* as pale yellow crystals, which decomposed on attempted melting point determination. [m/e = 290.—UV (in ether): $\lambda_{max}(\varepsilon)$ = 257 (13100), *ca.* 300 sh (5500), 321 (7400), 335 nm (7200).—IR (in $CHCl_3$): 3600 w, 3425 m (OH), 2200 m (C≡C), 1715 w, 1640 w, 1580 m (C=C), 975 s cm^{-1} (*trans* C=C).—NMR: see Table 1.]



Methylation of *(2)* in ether with MeI and Ag_2O for 15 hours at room temperature led to 90% of the ether *(3)*, an unstable pale yellow oil. [m/e = 304.—UV (in ether): $\lambda_{max}(\varepsilon)$ = 257 (12700), *ca.* 300 sh (5300), 320 (7100), 335 nm (6900).—IR (in CCl_4): 2205 m (C≡C), 1730 m, 1630 w, 1585 w (C=C), 975 s cm^{-1} (*trans* C=C).—NMR: see Table 1.]

OCH_3	—	—	6.57 s	5.87 s

[a] This assignment was confirmed by the addition of tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium(III) [Eu(fod)$_3$].
[b] The lower limit of this band cannot be determined accurately due to the overlap of the solvent band.

Abstraction of H^1 from *(3)* by addition of a solution of dimsyl sodium in DMSO (prepared from NaH and DMSO)[5] at room temperature afforded a deep red solution of the sodium salt *(4)*. [UV (in DMSO): λ_{max} (ε) = 348 sh (8200), *ca.* 440 sh (6000), *ca.* 500 sh nm (4400)[6], with absorption >700 nm.]

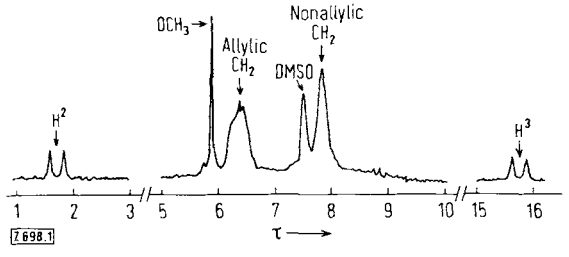

Fig. 1. ^{1}H-NMR spectrum of *(4)* in [D_6]-DMSO at 60 MHz.

The NMR spectrum of *(4)* [Table 1, Figure 1] was obtained by treatment of *(3)* with [D_5]-dimsyl sodium in [D_6]-DMSO (from NaH and [D_6]-DMSO)[7]. The very high field resonance of the inner olefinic protons and the low field resonances of the outer olefinic, allylic and nonallylic protons clearly demonstrate *(4)* to be strongly diatropic. This is also shown by the relatively low field resonance of the methoxyl protons (cf. anisole: $\tau = 6.22$). It is clear that the downfield shift of the outer protons due to the diamagnetic ring current far outweighs the small upfield shift to be expected of the negative charge. The diatropic (4n + 2) π-electron system *(4)* presumably contains a reasonably coplanar carbon skeleton, unlike the related 4n systems *(1)* and protonated *(1)*, which are not appreciably paratropic[4].

Sequence of Orbitals in Sulfones and Sulfodiimides[1]

By *Bahman Solouki*[*], *Hans Bock*[*], and *Rolf Appel*[**]

Compared with dialkyl sulfoxides R_2SO[2] the number of "sulfur valence electrons" in dialkyl sulfones R_2SO_2 is raised to a total of 12. The 3d atomic orbitals of sulfur must therefore be included in any description of the σ- and π-bonds[3,4] ($d_{SO}^{R_2SO} = 1.47$ Å, $d_{SO}^{R_2SO_2} = 1.45$ Å[3]). Combination of four oxygen 2p, two σ-bonding, and two sulfur 3d orbitals allows construction of the qualitative MO diagram in Figure 1.

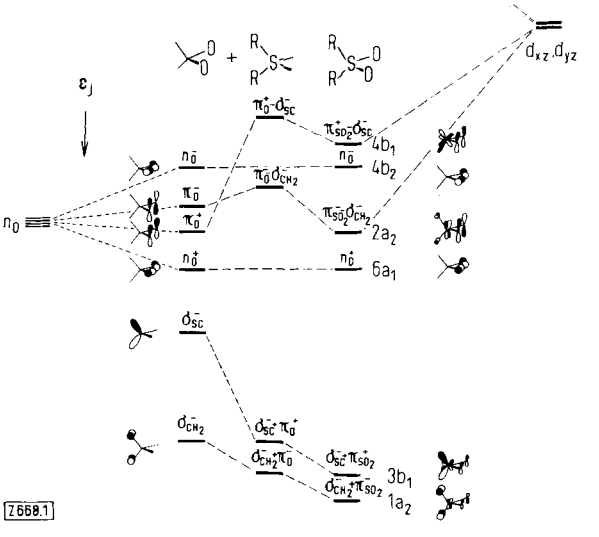

Fig. 1. Qualitative MO diagram for dialkyl sulfones.

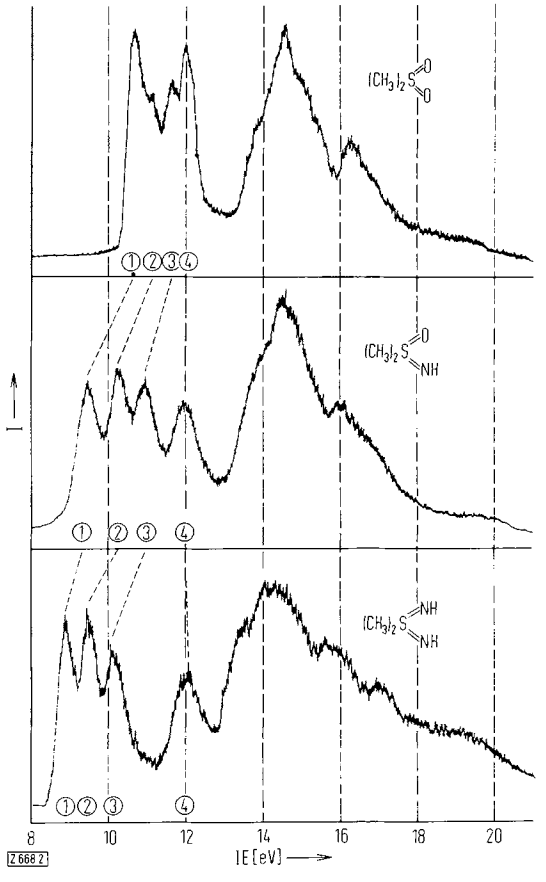
[*] Prof. Dr. H. Bock and Dipl.-Chem. B. Solouki
Chemische Institute der Universität
6 Frankfurt 70, Ludwig-Rehn-Str. 14 (Germany)
[**] Prof. Dr. R. Appel
Anorganisch-chemisches Institut der Universität
53 Bonn, Meckenheimer Allee 168 (Germany)

The qualitatively derived sequence of the four highest occupied molecular orbitals, which can also be reproduced by CNDO/2 calculations[5], is substantiated by comparison of the ionization potentials determined by photoelectron spectroscopy for isoelectronic series of compounds and by the additional "transannular π-interaction" in an unsaturated five-membered ring sulfone.

In the photoelectron (PE) spectra of the isoelectronic series $(CH_3)_2SX_2$ (X = O→NH) the first four bands exhibit varying shifts towards lower ionization potentials (Fig. 2 and Table 1).



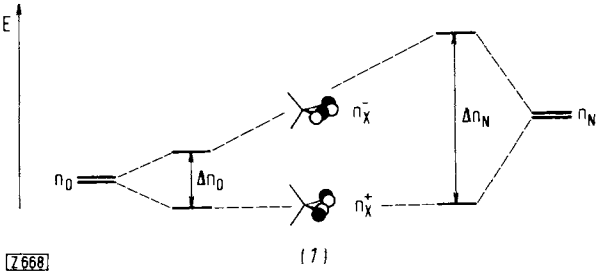


Fig. 2. PE spectra of dimethyl sulfone, dimethylsulfonimide, and dimethylsulfodiimide.

Table 1. Vertical ionization potentials IE_n (eV) of dimethyl sulfone and derivatives.

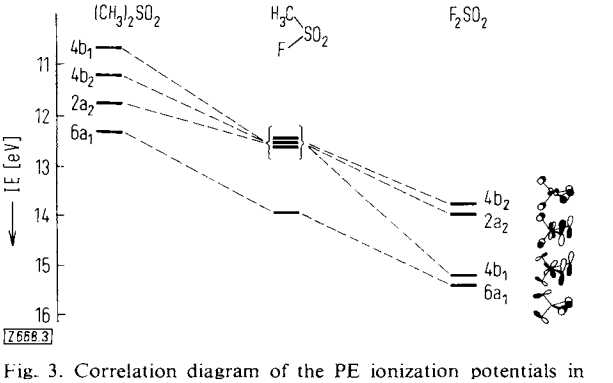
Cpd.	IE_1	IE_2	IE_3	IE_4	IE_5
$(CH_3)_2SO_2$	10.65	11.18	11.65	12.0	
$(CH_3)_2S(NH)O$	9.5	10.29	10.94	12.0	
$(CH_3)_2S(NH)_2$	8.87	9.4	10.0	12.06	
$(CH_3)FSO_2$	12.53	12.53	12.53	13.91	15.57
F_2SO_2	13.75	13.92	15.16	15.29	16.68
$(CH_3)ClSO_2$	11.6	11.94	12.36	12.6	13.32
Cl_2SO_2	12.41	12.41	13.17	13.67	14.06
2,5-Dihydrothiophene 1,1-dioxide	10.44	10.66	11.25	11.63	11.99

The differences in the PE spectra on replacement of oxygen by an NH group can be discussed in terms of the qualitative MO diagram (Fig. 1) with the aid of *Koopmanns'* theorem[6]. In so doing attention must be paid to structural modifications in the molecular skeleton such as the increased π-bond length ($d_{SO} = 1.45$ Å, $d_{SN} = 1.53$ Å[7]) and the widened angle XSX ($\sphericalangle$ OSO = 117.9°, $\sphericalangle$ NSN = 122.2°[7]) which suggest an enhanced spatial interaction between the nitrogen lone pairs. If n_N lies above n_O according to *(1)* and if the splitting Δn_N is greater than Δn_O then n_X^- should be raised more than n_X^+. A comparison of the

(1)

PE ionization potentials (Table 1), shows that IE_4 remains roughly constant and IE_2 decreases additively as expected from Figure 1 with decreasing energy of the center of gravity of the electron pair orbitals. The qualitative MO diagram thus suggests assignment of PE band 4 to the MO $6a_1$ and the PE band 2 to the MO $4b_2$. The splitting of the bands 1 and 3, again for a constant center of gravity, is greatest in the unsymmetrical dimethylsulfonimide, and can be rationalized according to the CNDO/2 calculations in terms of a larger N contribution to the higher MO $4b_1$ and a larger O contribution to the MO $2a_2$.

The qualitative orbital sequence for dimethyl sulfone (Fig. 1) is also in accord with the substituent effects in the isoelectronic series X_2SO_2 (X = CH_3→F or CH_3→Cl). Thus the replacement of methyl groups by fluorine (Fig. 3) should lead to a lowering of all orbitals by the "perfluoro effect"[6]. The $4b_1$ orbital should be lowered particularly drastically since no antibonding σ_{sc}^- contribution has to be considered in this case (Fig. 1). In contrast, the orbitals $4b_2$ and $2a_2$ should exhibit less pronounced lowering owing to the more effective antibonding admixture of fluorine orbitals. These arguments are confirmed by *ab initio*[4] and CNDO/2 calculations[5] for F_2SO_2 and explain the correlation diagram of the PE ionization potentials (Fig. 3 and Table 1).



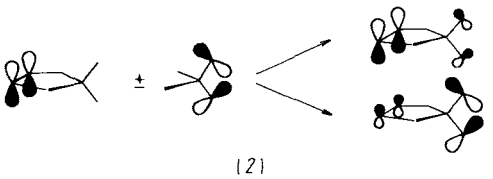


Fig. 3. Correlation diagram of the PE ionization potentials in the isoelectronic series $(CH_3)_2SO_2 \rightarrow F_2SO_2$.

As a final argument in favor of the derived dialkyl sulfone MO scheme (Fig. 1) we would like to cite the transannular interaction in 2,5-dihydrothiophene 1,1-

dioxide. The occupied π_{CC} orbital is of b_2 symmetry (group C_{2v}) and can therefore mix only with the $4b_2$ orbital of the sulfone group according to *(2)*. The first PE band of the five-membered ring sulfone (Table 1: IE_1) is to be assigned to the π level on the basis of the

[2]

observed vibrational fine structure ($1200 \pm 100\,cm^{-1} \triangleq \tilde{\nu}_2$ and $560 \pm 100\,cm^{-1} \triangleq \tilde{\nu}_3$). Comparison of the ionization potentials IE_{n+1} of the unsaturated five-membered ring (Table 1) shows that, as expected, equal contributions are found for $n = 1,3,4$. The small lowering for $n = 2$ suggests that the second highest occupied molecular orbital in dialkyl sulfones does have b_2 symmetry.

Synthesis of Isocyanides from *N*-Monosubstituted Formamides, Phosphanes, and Azodicarboxylic Acid Derivatives

By *Barbro Beijer, Ernst von Hinrichs*, and *Ivar Ugi*[*]

The mechanism proposed[1] for the reaction of phthalimide with alcohols, triphenylphosphane *(1)*, and diethyl azodicarboxylate *(2)* induced us to investigate whether the

combination of *(1)* and *(2)* was suitable for removal of water from *N*-monosubstituted formamides *(3)* and thus for the synthesis of isocyanides *(4)*. An isocyanide synthesis of this type would have the advantage over all others[2] of occurring without addition of a base, which would be of interest for the several isocyanides that racemize or decompose in the presence of bases[2]. The results of such reactions are collected in Table 1.

Table 1. Preparation of isocyanides from *N*-monosubstituted formamides *(3)* with *(1)* and *(2)*.

(4), R =	Yield (%)
Methyl	0
tert-Butyl	0
Cyclohexyl	39
Phenyl	38
Benzyl	25
p-Nitrophenyl	0
2,6-Dimethylphenyl	53
2,4,6-Trimethylphenyl	58
$-CH_2-CO_2CH_3$	0
$-CH(CH_3)-CO_2CH_3$	0
$-CH[CH(CH_3)_2]-CO_2CH_3$	0

The yields are about the same whether *(2)* or dimethyl azodicarboxylate is used, but *N*-phenylazodicarboximide gives yields that are about 10% lower. If *(1)* is replaced by tri-*n*-butylphosphane in the synthesis of cyclohexyl isocyanide, the yield amounts to 30%, but no isocyanide is formed when trimethyl phosphite, hexamethylphosphorotriamide, or 2-methoxy-3-methyl-1,3,2-oxazaphospholidine is employed[3].

Example:

Triphenylphosphane (524 mg, 2 mmol) *(1)* is dissolved in anhydrous tetrahydrofuran (THF) (5 ml) under N_2 and is treated at 20 °C under N_2 with diethyl azodicarboxylate *(2)* (174 mg, 2 mmol) in anhydrous THF (5 ml). Finally, *N*-cyclohexylformamide *(3)*, R = cyclo-C_6H_{11} (254 mg, 2 mmol) in anhydrous THF (2 ml). After being kept for 24 h at 20 °C the mixture is worked up, giving 39% (85 mg) of *(4)*, R = cyclo-C_6H_{11}. If *(1)* and *(2)* are used in 100% excess, the yield is 70%.

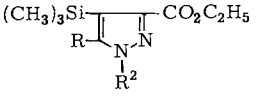
N. D. Zelinsky Institute for Organic Chemistry, Academy of Sciences of the USSR
Moscow, B-334, Leninsky Prospekt 47 (USSR)

Dropwise addition of a solution of *(2)*, $R^1 = CH_3$, in an equal volume of *(1)* in the presence of 6×10^{-4} mol $CuSO_4$/mol *(2)* at 100—110 °C to an excess of *(1)* [total molar ratio *(1)* : *(2)* = 6 : 1 to 10 : 1] leads—depending on the nature of R in *(1)*—to formation of the 2-substituted 3-trimethylsilyl-2-cyclopropene-1-carboxylates *(3)* [yields and properties, see Table 1].

$$R\text{-}C{\equiv}C\text{-}Si(CH_3)_3 + N_2CH\text{-}CO_2R^1$$
(1) *(2)*

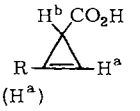


(3)

Table 1. Properties of the cyclopropenecarboxylates *(3)*, $R^1 = CH_3$.

R	Yield (%)	B.p. (°C/torr)	d_4^{20}	n_D^{20}	IR (cm^{-1}) $\nu_{C=C}$
$(CH_3)_3Si$[4]	5—8	85—87/10	0.9020	1.4500	1900
$(CH_3)_3C$[4]	10	76.5—77.0/8	0.8892	1.4435	1820
CH_3	54	67—69/10	0.9280	1.4460	1830
n-C_5H_{11}	50	118/15	0.9074	1.4490	1820
n-C_8H_{17}	35	151—151.5/7	0.8901	1.4538	1830

On the other hand, reaction of *(1)*, $R = (CH_3)_3Si$ with the ethyl ester *(2)*, $R^1 = C_2H_5$, under the same conditions, gives the pyrazoles *(4a)* and *(4b)* in about 60% yield [*(4a)*: m. p. 138.5 °C, from $CH_3OH/n\text{-}C_7H_{16}$ (5:1)[1]; *(4b)*: m. p. 70.8—70.9 °C, from $CH_3OH/n\text{-}C_7H_{16}$ (5:1)[2]].



(4a), R = $(CH_3)_3Si$, R^2 = H
(4b), R = $(CH_3)_3Si$, R^2 = $CH_2\text{-}CO_2C_2H_5$
(4c), R = $(CH_3)_3C$, R^2 = $CH_2\text{-}CO_2C_2H_5$

Similarly, reaction of *(2)*, $R^1 = C_2H_5$, with an excess of *(1)*, $R = (CH_3)_3C$, affords the pyrazole *(4c)* [m.p. 73—74 °C, from C_2H_5OH[3], yield: 5%] and small amounts of *(3)*, $R = (CH_3)_3C$, $R^1 = C_2H_5$.

The difference in behavior between *(2)*, $R^1 = CH_3$, and *(2)*, $R^1 = C_2H_5$, may be due to the lower thermal stability of the methyl ester, which favors the formation of methoxycarbonylcarbene and, consequently, of *(3)*.

The action of dilute aqueous or aqueous-alcoholic solutions of NaOH, KOH, Na_2CO_3, K_2CO_3 or other bases at 20 °C or higher temperatures on *(3)* leads successively to hydrolytic cleavage of the trimethylsilyl group and hydrolysis of the ester group with quantitative formation of the free carboxylic acids *(5)* [Table 2]. These, particularly when R = H, are converted at temperatures above 50 °C into polymeric products that are only sparingly soluble in organic solvents.

A New Route to Triple-Decker Sandwich Compounds[1]

By *Albrecht Salzer* and *Helmut Werner*[*]

We recently reported the synthesis of tris (η-cyclopentadienyl)dinickel cation[2]—the first representative of a new class of metal π-complexes—which was assumed to have a "triple-decker sandwich structure"[3]. Reaction *(1)* proceeds almost quantitatively.

$$2\ Ni(C_5H_5)_2 + R^{\oplus}X^{\ominus} \longrightarrow [Ni_2(C_5H_5)_3]^{\oplus}X^{\ominus} + C_5H_5R \qquad (1)$$
$R = C(C_6H_5)_3, C_7H_7$; $X = BF_4, PF_6$

Attempts to prepare the complexes *(2b)* and *(2c)* by reaction of substituted bis(η-cyclopentadienyl)nickel compounds such as *(1b)* and *(1c)* with $R^{\oplus}X^{\ominus}$ gave unsatisfactory results. The products were either oils that proved difficult to handle or still contained considerable amounts of the reagent $R^{\oplus}X^{\ominus}$ which was exceptionally difficult to remove.

We therefore sought a new route to the cations of *(2a)* to *(2c)*, returning to our previously voiced opinion regarding

[*] Prof. Dr. H. Werner and A. Salzer

Table 2. Properties of the cyclopropenecarboxylic acids *(5)*.

R	M.p. (°C)	IR (cm^{-1}) $\nu_{C=C}$	$\nu_{C=O}$	NMR (CCl_4) δ (ppm) H^a	H^b
H[4]	147—148 (from C_6H_6/C_2H_5OH)	—	—	—	—
CH_3	42.5—43.0 (from hexane)	1820	1690	6.23	2.00
$(CH_3)_3C$[4]	41.5 (from C_6H_6)	1790	1700	6.08	2.06
n-C_5H_{11} [a]	oil	1815	1690	6.02	2.00
n-C_8H_{17} [b]	oil	1805	1690	6.02	2.00

[a] $n_D^{20} = 1.4610$; $d_4^{20} = 0.9783$.
[b] $n_D^{20} = 1.4676$; $d_4^{20} = 0.9596$.

the mechanism of the reaction between *(1a)* and carbo cations[2, 5]. Accordingly, a primary one-electron transfer and subsequent radical addition, or direct attack by $R^{\oplus}$ on *(1a)*, is assumed to yield a diene(dienyl)nickel cation $[Ni(C_5H_5)(C_5H_5R)]^{\oplus}$ which undergoes an ion-molecule reaction with an additional molecule of *(1a)* to give *(2a)*. If this were the case one could expect a *proton* to react with the sandwich complex *(1)* in an analogous fashion to $R^{\oplus}$.

We have now actually succeeded in preparing good yields of the compounds *(2a)* – *(2c)* by reaction of *(1a)* – *(1c)* with 50% aqueous HBF_4 in propionic anhydride as solvent[6].

(1) *(2)*

(a), R = H
(b), R = CH_3
(c), R = *tert.*-C_4H_9

(2b) is obtained as a blackish violet microcrystalline powder, and *(2c)* as platelets having a metallic sheen. The properties of *(2b)* and *(2c)* closely resemble those of *(2a)*: the compounds dissolve without decomposition only in nitromethane, are insoluble in nonpolar solvents, and react with water, ethanol, or acetonitrile to give *(1b)* and *(1c)* respectively. In the solid state *(2b)* and *(2c)* are only slightly sensitive to air and are stable for weeks in a nitrogen atmosphere.

Like that of *(2a)*[2], the NMR spectra of *(2b)* and *(2c)* exhibit separate signals for the protons of the two outer rings and the inner ring[7]. Whereas the eight protons of the two outer rings give a sharp singlet, the signals of the four protons of the inner ring are split into a multiplet, weakly in *(2b)* and more strongly in *(2c)* (Fig. 1).

It is noticeable (see Table 1) that the signals of the ring protons of *(2b)* are shifted 0.1 ppm *upfield* compared to *(2a)*. In the case of *(2c)* the signal of the outer rings is unchanged compared to *(2a)* while those of the inner ring are shifted 0.15 ppm *downfield*. *Nesmeyanov et al.* have recently also reported similar differential effects of the methyl and the *tert*-butyl group on the chemical shifts of the ring protons of substituted ferrocenes and substituted cobaltocenium salts[8].

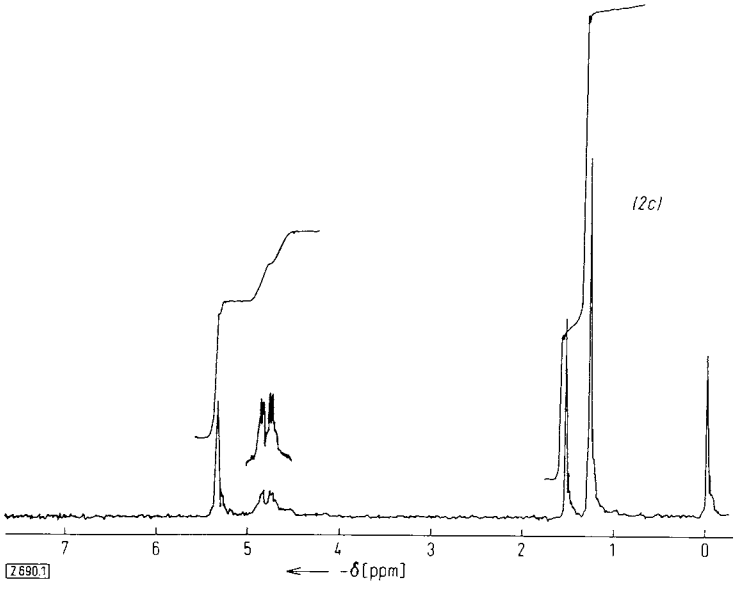

Fig. 1. ^{1}H-NMR spectrum of *(2c)* in CD_3NO_2.

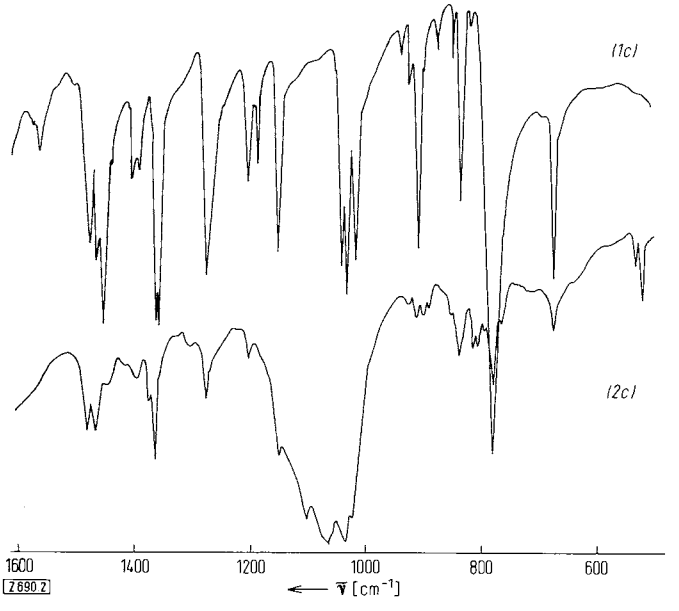
Table 1. ^{1}H-NMR data for the compounds *(2a)*, *(2b)*, and *(2c)* [solvent: CD_3NO_2; TMS as internal standard; chemical shifts in ppm].

Compound	δ	
(2a)	4.7	(5 H, s)
	5.4	(10 H, s)
(2b)	2.0	(6 H, s)
	2.2	(3 H, s)
	4.6	(4 H, m)
	5.3	(8 H, s)
(2c)	1.8	(18 H, s)
	2.05	(9 H, s)
	4.85	(4 H, m)
	5.4	(8 H, s)

IR measurements indicate a pronounced resemblance between the spectra of compounds *(1)* and those of the cations of *(2)*, thus supporting the proposed triple-decker sandwich structure.



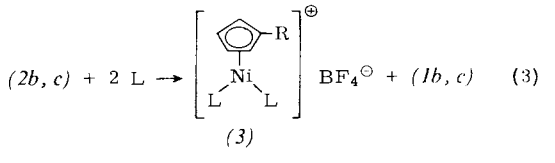


Fig. 2. IR spectra of *(1c)* and *(2c)* in KBr.

Like *(2a)*[9], *(2b)* and *(2c)* readily react with Lewis bases, losing their upper deck and forming cationic monocyclopentadienylnickel compounds *(3)*. The reactions according to eq. (3) proceed quantitatively.

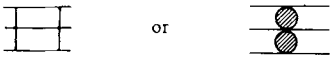
(3)

(3)

L = $P(C_6H_5)_3$, $P(OCH_3)_3$, $P(OC_6H_5)_3$;
2 L = Norbornadiene

Preparation, properties, and reactions of the new η-cyclopentadienyl(diolefin)nickel complexes will be reported in detail elsewhere.

Tris(η-methylcyclopentadienyl)dinickel tetrafluoroborate (2b)



A 50% aqueous solution of HBF_4 (0.4 ml) is added very slowly with exclusion of air to a solution of *(1b)* (650 mg, 3 mmol) in propionic anhydride (5 ml). After brief mixing the resulting dark brown solution is carefully added dropwise to vigorously stirred diethyl ether (75 ml). The blackish violet, finely crystalline precipitate is isolated by filtration through a G 3 frit and washed several times with ether. Vacuum drying affords 620 mg of *(2b)* (93% yield based on *(1b)*).

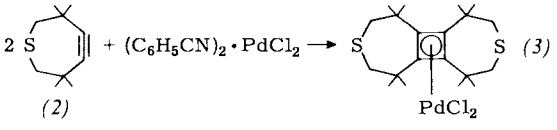
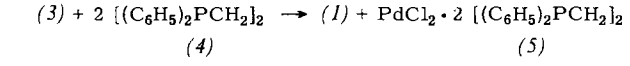
Synthesis of a Cyclobutadiene Stabilized by Steric Effects[**]

By *Horst Kimling* and *Adolph Krebs*[*]



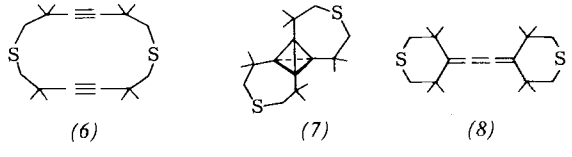
In our investigations of the stabilization of strained cyclic compounds by large substituents we have isolated a compound to which we assign the cyclobutadiene structure *(1)* on the basis of its mode of formation, its reactions and its spectroscopic data; the substituents on the four-membered ring correspond to four *tert*-butyl groups if the two S bridges are neglected.

Starting material for the synthesis of *(1)* was the 3,3,6,6-tetramethyl-1-thiacycloheptyne *(2)*[1], treatment of which with $(C_6H_5CN)_2PdCl_2$ in tetrahydrofuran (24 hours' boiling under reflux) afforded the yellow cyclobutadiene complex *(3)* (80%). Elemental analyses and spectroscopic data (Table 1) prove the structure *(3)*.



(1a) *(1b)*

A suspension of *(3)* in chloroform or methylene dichloride reacts with ethylenebis(diphenylphosphane) *(4)* completely within 1 h at 45 °C under N_2, yielding the $PdCl_2$-phosphane complex *(5)* as a white precipitate. Evaporation of the solvent from the supernatant solution and recrystallization of the residue from chloroform affords transparent yellowish crystals of *(1)*.



(2) *(3)*

(4) *(5)*

The most intense signal in the mass spectrum of *(1)* is that of the molecular ion at $m/e = 336$, as was confirmed by low-voltage spectra; fragmentation occurs similarly to that of *(3)* and *(10)*. The ^{1}H-NMR spectrum with only two sharp signals indicates a highly symmetrical structure. The occurrence of C=C double bonds is shown by a ^{13}C-NMR signal in the olefinic region and by a Raman band at 1590 cm^{-1}; the diacetylene *(6)* and tetrahedrane *(7)* formulas are thus eliminated as alternatives. The cumulene structure *(8)* also cannot be brought into accord with the ^{13}C-NMR and UV spectra: the two central C atoms of the butatriene chain should appear in the ^{13}C-NMR spectrum of *(8)* at $\delta = -200$ to -220 ppm (relative to TMS), similarly to the central C atom of allene[2]; and the UV spectrum of *(1)* shows only a maximum at 227 nm with an extinction decreasing very slowly to the visible region, whereas tetraalkylbutatrienes show maxima at considerably longer wavelengths[3].

(6) *(7)* *(8)*

(1) is very sensitive towards oxygen with which it affords, amongst other, unidentified, products, a colorless compound to which we assign the structure of the furan *(9)* on the basis of its spectroscopic data (Table 1).

The cyclobutadiene structure of *(1)* is supported by the reaction with nickel dibromide: this gives the deep violet cyclobutadiene complex *(10)* (10%), that can also be prepared from *(2)* and nickel dibromide. *(10)* was characterized by elemental analysis and spectra (Table 1); its UV spectrum is in good agreement with that of the tetramethylcyclobutadiene-nickel dichloride complex[4]. With dimethyl acetylenedicarboxylate, *(1)* gives a 1:1 adduct, whose spectroscopic data accord with structure *(11)* or *(12)* (Table 1).

X-ray analysis is in progress for unambiguous proof of structure *(1)* and decision between *(1a)* and *(1b)*.

1,3-Oxazolidine-2-thiones from Alkyl Isothiocyanates and Carbonyl Compounds

By *Dieter Hoppe*[*]

1,3-Oxazolidine-2-thiones *(6)* are of interest because some of the naturally occurring members[1] show antithyroid activity. They are obtained in good yield, by bond formation between C-4 and C-5[2], on treatment of alkyl isothiocyanates (mustard oils) *(1)* with bases (potassium *tert*-butoxide or sodium hydride in tetrahydrofuran) and carbonyl compounds *(3)*. The decisive intermediate is the α-metalated alkyl isothiocyanate *(2)*, which adds to the carbonyl compound, giving the anion of the 2-hydroxyalkyl isothiocyanate *(4)*. Cyclization to the anion *(5)* and protonation by glacial acetic acid affords the oxazolidine-2-thione *(6)* (Table 1).

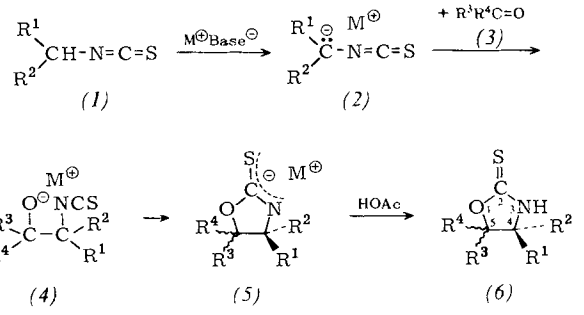

Table 1. 1,3-Oxazolidine-2-thiones *(6)* synthesized.

(6)	R^1	R^2	R^3	R^4	Base [a]	*trans*/*cis*	Yield (%)

Organisch-Chemisches Institut der Universität
34 Göttingen, Windausweg 2 (Germany)

If the isothiocyanate *(1)* does not possess a further group stabilizing the anion *(2)* and stronger nucleophilic bases such as butyllithium or Grignard reagents are used, then attack on the isothiocyanate group predominates, affording thioamides[3]. Diastereomeric oxazolidine-2-thiones *(6)*, $R^1 \neq R^2$ and $R^3 \neq R^4$, are readily separable by chromatography on silica gel or, for *(6f)* and *(6h)*, even by crystallization: *cis-(6f)* (m.p. 104°C) is obtained in 58% yield by crystallizing the crude product from tetrachloromethane. Evaporation of the mother liquor and crystallization of the residue by ether/petroleum ether yields 22% *trans-(6f)* (m.p. 112°C). The compounds *(6)* were identified by IR-, NMR-, and mass spectra and afforded satisfactory CH-analyses. Characteristic IR absorptions are found between 3100 and 3200 cm^{-1} (NH proton) and near 1500 cm^{-1} (thiocarbamate).

Experimental:

a) With potassium *tert*-butoxide: A solution of the alkyl isothiocyanate *(1)* (0.040 mol) and the carbonyl compound *(3)* (0.040 mol) in anhydrous tetrahydrofuran (THF) is added dropwise with stirrring to potassium *tert*-butoxide (0.042 mol) in THF (30 ml) at −60 to −50°C (nitrogen atmosphere). The mixture is stirred for a further 15 min at this temperature, allowed to warm to 0°C, and then poured into a solution of glacial acetic acid (3.0 g) in THF (10 ml). The solvent is distilled off in a vacuum (bath temperature max. 40°C), and the residue is taken up in dichloromethane (100 ml) and treated with water (30 ml). The organic phase is separated, shaken with water (30 ml), and dried over sodium sulfate. On evaporation of the solvent the oxazolidinethione *(6)* remains as a yellow to brown viscous oil. It is purified by crystallization from carbon tetrachloride or chloroform or by chromatography on silica gel with chloroform/ethyl acetate.

b) With sodium hydride: Procedure is as in a), but with sodium hydride (0.044 mol), one-tenth of the solution of *(1)* and *(3)* being added dropwise at 10°C. If hydrogen evolution does not occur, the temperature is raised slowly to a maximum of 35°C. As soon as reaction begins, the remainder of the solution is added dropwise, the whole is stirred for 15 min, then the mixture is cooled to 10°C and worked up as described above.

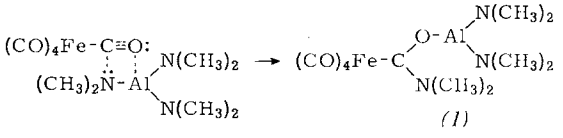
[Bis(dimethylamino)aluminoxy]dimethylamino-carbene as a Complex Ligand[**]



By *Wolfgang Petz* and *Günter Schmid*[*]

During investigations of the behavior of carbonylmetal complexes towards elements of the third main group[1, 2] we have studied the reaction of pentacarbonyliron with dimeric tris(dimethylamino)alane. Whereas some alanes form addition or cluster compounds with octacarbonyldicobalt[2], we observed in this case the surprising formation of a carbene complex:

$$2\,Fe(CO)_5 + \{[(CH_3)N_2]_3Al\}_2 \rightarrow \{(CO)_4FeC[N(CH_3)_2]OAl[N(CH_3)_2]_2\}_2$$
(1)

This complex, whose composition corresponds to the results of elemental analysis, is obtained in almost quantitative yield as yellow crystals that are extremely sensitive to air. Its dimeric nature follows from the ^{1}H-NMR spectrum and is to be ascribed to bridge building by the dimethylamino groups attached to the aluminum.

The unexpected formation of a carbene complex can be interpreted as due to nucleophilic attack by one amino group of the alane on a carbonyl-carbon atom of $Fe(CO)_5$.

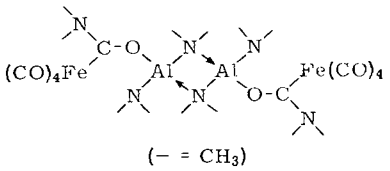
(1)

An Al—O bond is presumably formed at the same time as the Al—N bond is broken. Many examples are known of reactions that are caused by nucleophilic attack of amines on the C atom of carbonyl groups[3–6].

In Table 1 are collected the proton signals of *(1)*, the $C_{carbene}N(CH_3)_2$ group of the comparable carbene complex $(CO)_4FeC[N(CH_3)_2]C_6H_5$ *(2)* and dimeric tris(dimethylamino)alane *(3)*.

Table 1. ^{1}H-NMR signals of $\{(CO)_4FeC[N(CH_3)_2]OAl[N(CH_3)_2]_2\}_2$ *(1)*, $(CO)_4FeC[N(CH_3)_2]C_6H_5$ *(2)* and $\{Al[N(CH_3)_2]_3\}_2$ *(3)* (τ values referred to TMS as internal standard; relative intensities in parentheses).

	$C_{carbene}N(CH_3)_2$	Terminal $AlN(CH_3)_2$	Bridging $AlN(CH_3)_2$	Solvent
(1)	6.37(1), 6.88(1)	7.22(2)	7.33(2)	CH_2Cl_2
(2)	5.96(1), 6.78(1)	—	—	[D_6]Acetone
	(trans) *(cis)*			
(3)	—	7.26(2)	7.63(1)	Benzene



The Table shows clearly that the proton signals of *(1)* can be derived formally by combining the corresponding signals of *(2)* and *(3)*. The two signals found for $CN(CH_3)_2$ of *(1)* and *(2)* can be ascribed to the *cis*- and *trans*-*N*-methyl groups[7]. The terminal and bridging amino groups bound to the Al of *(1)* can be distinguished, as already found in the case of *(3)*, the proton signals of the bridging $N(CH_3)_2$ groups appearing at higher field[8]. If a monomeric structure had been assumed for *(1)* only one kind of $AlN(CH_3)_2$ proton would have been observed. Thus the annexed structure is suggested for *(1)*.

The IR spectrum also accords with this structure. If trigonal-bipyramidal surroundings are assumed for the iron, three ν(CO) vibrations are to be expected for the carbene ligand in the axial position (C_{3v}), and these were found at 2031 (m), 1949 (vs) and 1912 (vs) (measurements in THF

[*] Prof. Dr. G. Schmid and Dr. W. Petz
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *J. Pebler* for measuring the Mössbauer spectrum and for contributions to the discussions.

solution); if the carbene ligand had been in the equatorial position it should lead to four ν(CO) vibrations. The large separation of the two $(CO)_4Fe$ groups prevents coupling, so that, as far as CO vibrations are concerned, the molecule behaves as a monomeric substance of type $(CO)_4FeL$.

(– = CH_3)

We assign a band at 1512 cm^{-1} of medium intensity provisionally to the C—O—Al vibration. The relatively high position of this frequency may be connected with the four-fold coordination of the aluminum, which could lead to a relatively large C=O double bond character. The remainder of the IR spectrum is dominated mainly by the amino groups.

The trigonal-bipyramidal arrangement of the ligands attached to the iron in *(1)*, as indicated by the number of ν(CO) vibrations, is confirmed by the Mössbauer spectrum: The isomeric shift (IS) is at +0.154 mm s^{-1} [referred to $Na_2Fe(CN)_5NO \cdot 2H_2O$], and the quadrupole splitting amounts to 1.96 mm s^{-1}. The compound thus fits well into the series of trigonal-bipyramidal iron(0) complexes; for comparison: $Fe(CO)_5$: IS = +0.160, QS = 2.57[9]; $(CO)_4FeP(C_6H_5)_3$: IS = +0.135, QS = 2.42 mm s^{-1}[10]. Six-fold coordinated iron(0) complexes show appreciably smaller quadrupole splittings, *e.g.* $Fe_2(CO)_9$: IS = +0.360, QS = 0.54 mm s^{-1}[10].

Experimental:

A solution of *(3)* (5.32 g, 16.8 mmol) in benzene/pentane (1:1; 150 ml) is cooled to 0 °C with rigorous exclusion of air and then mixed by stirring with $Fe(CO)_5$ (6.59 g, 33.6 mmol). Lemon-yellow crystals of *(1)* separate from the orange-red solution after *ca.* 3—5 min. The whole is stirred at 0 °C in the dark for a further 30 min and the precipitate is collected, washed twice with pentane, and dried in a vacuum. A further amount of *(1)* separates if the mother liquor is kept in a refrigerator. The united precipitates are recrystallized from tetrahydrofuran. Yield: 10 g, 84%.

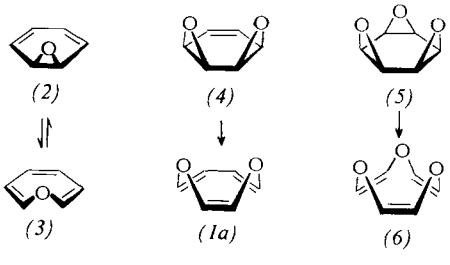
1,4-Dioxocin

By *Emanuel Vogel, Hans-Josef Altenbach*, and *Dieter Cremer*[*]

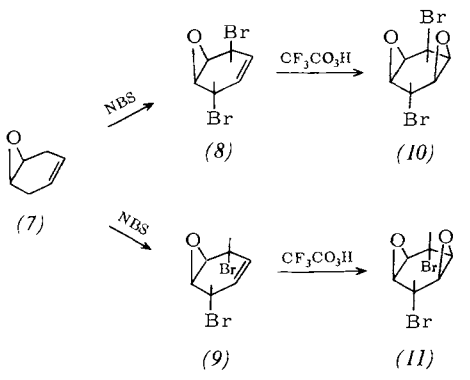


Dedicated to Professor R. Criegee in Honor of his 70th Birthday

The existence and aromaticity of the cyclooctatetraene dianion[1] has stimulated many attempts in recent years to synthesize the 10π-heterocycles *(1a)—(1c)*, the 1,4-diheterocins (1,4-dihetero[8]annulenes[2]), which are isoelectronic with that dianion. Although these investigations have led to the preparation of some non-aromatic benzo derivatives of the 1,4-diheterocins[3], no one has yet succeeded in obtaining the parent compounds[4].

(1a), X = O
(1b), X = NH
(1c), X = S

Our interest in such 10π-heterocycles, and especially in 1,4-dioxocin *(1a)*, arose naturally from further development of experiments begun some time ago on the synthesis and valence isomerizations of arene oxides[5, 6]. While benzene monoxide *(2)* exists at room temperature in rapid, energetically balanced equilibrium with oxepin *(3)*[5], it is to be expected that the hitherto unknown *syn*-benzene dioxide *(4)* would fairly readily undergo an orbital-symmetry allowed $[_\pi 2_s + _\sigma 2_s + _\sigma 2_s]$-cycloreversion (retro-Diels-Alder reaction) to 1,4-dioxocin *(1a)*. Finally, the also still hypothetical *syn*-benzene trioxide *(5)* can be anticipated to experience a $[_\sigma 2_s + _\sigma 2_s + _\sigma 2_s]$-cycloreversion (retro-homo-Diels-Alder reaction) to yield the interesting heterocycle *all-cis*-1,4,7-trioxonin *(6)*[7, 8].



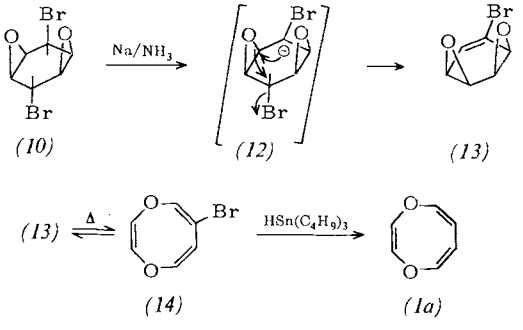
(2) *(4)* *(5)*
(3) *(1a)* *(6)*

We are now able to report the synthesis of the 1,4-dioxocin *(1a)* by way of a thermal *syn*-benzene dioxide valence isomerization.

The starting point of the route to *(1a)* is the monoepoxide of 1,4-cyclohexadiene *(7)*[9]. If *(7)* is treated in boiling carbon tetrachloride with *N*-bromosuccinimide (NBS) (molar ratio 1:2), a mixture of bromination products is formed from which it is possible to isolate, by fractional crystallization from ether/methylene chloride (1:1), *trans*-3,6-dibromo-4,5-epoxycyclohexene *(8)* [m. p. 117 °C; yield 18%; NMR ($CDCl_3$): broad multiplets at τ = 4.25 (2 olefinic protons), 4.95 and 5.10 (2 CHBr protons) as well as 6.09 and 6.30 ppm (2 epoxidic protons)] together with

[*] Prof. Dr. E. Vogel, Dipl.-Chem. H.-J. Altenbach, and Dipl.-Chem. D. Cremer
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

one of the two *cis*-3,6-dibromo isomers, very probably the *cis*-3,6-dibromo-*anti*-4,5-epoxycyclohexene *(9)* [m. p. 97 °C; yield 5%; NMR ($CDCl_3$): narrow multiplets at $\tau = 4.17$ (2 olefinic protons), 5.12 (2 CHBr protons) and 6.28 ppm (2 epoxidic protons)].



(7) *(8)* *(10)* *(9)* *(11)*

The configurations assigned to these epoxy dibromides follow from comparison of their NMR spectra. For the compound of m. p. 117 °C the epoxy and CHBr protons each give rise to different chemical shifts, from which the presence of *(8)* can be concluded, whereas for the isomer of m. p. 97 °C, in accord with the symmetry of a configuration containing the Br atoms in *cis*-relationship, these types of protons each give rise to a narrow multiplet. The configuration *(9)* for the isomer of m. p. 97 °C can be deduced from the NMR finding[10] that with cyclohexene epoxides having *syn*- and *anti*-substituents (OH or OAc groups) respectively next to the epoxide ring the resonances of the epoxide protons always occur at the higher field strength if an *anti*-relationship of the substituents obtains. Finally, the occurrence of *(9)* is supported by the argument that formation of this epoxy dibromide rather than its *syn-cis*-3,6-dibromo isomer should be favored on steric grounds[11].

The epoxy dibromides *(8)* and *(9)* could be epoxidized by trifluoroperacetic acid—but not by other peracids—in Na_2HPO_4-buffered methylene chloride solution, whereby each afforded a sterically homogeneous diepoxy dibromide in almost quantitative yield. The diepoxy dibromide formed from *(9)* must have structure *(11)* since its NMR spectrum [($CDCl_3$): narrow multiplets at $\tau = 5.13$ (2 CHBr protons) and 6.44 ppm (4 epoxidic protons)] shows the four epoxidic protons to be equivalent. The *syn*-stereospecificity of the epoxidation of *(9)* is apparently due to the tendency of the pre-existing epoxide function to stabilize the transition state of the reaction by hydrogen-bridge formation[12]. For the diepoxy dibromide derived from *(8)*, assignment of configuration from the NMR spectrum [($CDCl_3$): triplets at $\tau = 5.15$ and 5.31 (2 CHBr protons) as well as multiplets at $\tau = 6.27$ and 6.49 ppm (4 epoxidic protons)] is problematical, but *syn*-arrangement of the two epoxide rings in accord with structure *(10)* can be regarded as certain also for this compound both by analogy and as a result of its subsequent reactions[11].

The diepoxy dibromide *(10)* undergoes a remarkable rearrangement when treated with 1 g-atom of sodium per mol of *(10)* in liquid ammonia at −78 °C: by elimination of one mol of hydrogen bromide, presumably by way of the anionic intermediate *(12)*, this affords 1-bromo-*syn*-benzene dioxide *(13)*, m. p. 73 °C (dec), in 63% yield [NMR ($CDCl_3$): doublet of doublets at $\tau = 3.21$ (1 olefinic proton) and multiplet at $\tau = 6.41$ ppm (4 epoxidic protons). The *syn*-configuration of this benzene dioxide follows with considerable certainty from the relatively small activation energy of 28.5 kcal/mol ($A = 3.8 \times 10^{13}$) for thermal rearrangement of the compound in carbon tetrachloride to achieve equilibrium with 6-bromo-1,4-dioxocin *(14)* [composition at 77 °C (in CCl_4), 35% of *(13)* and 65% of *(14)* (activation parameters of the reverse reaction: $E_a = 25.6$ kcal/mol and $A = 3.2 \times 10^{12}$)]. The equilibrium can be set up from both sides. Isolation of *(14)* [b. p. 35 °C/0.5 torr; NMR (CCl_4): singlet at $\tau = 3.15$ (H-5), AB system at $\tau = 4.06$ and 4.20 with $J = 4.2$ Hz (H-2, H-3), and a further AB system at $\tau = 3.72$ and 4.63 ppm with $J = 7.5$ Hz (H-7, H-8)] was achieved by careful distillation below the isomerization temperature. *(14)* can be converted readily into the 1,4-dioxocin *(1a)*, a colorless liquid of b. p. 39 °C/14 torr, $n_D^{20} = 1.5215$, in 32% yield by reductive elimination of the bromine atom by means of tri-*n*-butyltin hydride at room temperature.

(10) *(12)* *(13)* *(13)* *(14)* *(1a)*

The 1,4-dioxocin *(1a)* is unambiguously shown to be an olefinic compound both by its spectra and by its chemical behavior. In accord with the structure assumed, the NMR spectrum (100 MHz, CCl_4) of this compound only consists of a singlet at $\tau = 4.0$ (H-2, H-3) and an AA'XX' system at $\tau_A = 3.41$ and $\tau_X = 4.88$ ppm (H-5, H-8, and H-6, H-7, respectively). Analysis of the AA'XX' system showed that the protons of the diene portion of the molecule have the following coupling constants: $J_{5,6} = 8.00$ $J_{5,7} = -0.17$, $J_{5,8} = 0.76$, and $J_{6,7} = 9.22$ Hz. In view of the absorption of all the protons in the olefinic region the fact that the vicinal couplings J_{AX} and $J_{XX'}$ are of the same order of magnitude is certainly not an expression of any considerable bonding equalization in *(1a)*[3b] but may be ascribed to the different influences of the oxygen atoms on the two couplings[13] as well as to a coplanar arrangement of the conjugated double bonds[14]. The NMR spectrum does not permit any statement about the favored conformation of the whole molecule.

The shape of the UV spectrum of *(1a)* [λ_{max} (in cyclohexane) = 238 ($\varepsilon = 7400$) and 285 nm (320, shoulder)] shows a relation to that of 1,3,6-cyclooctatriene[16].

Chemically, the olefinic nature of the 1,4-dioxocin is manifested particularly in the tendency of the compound to polymerize on standing for even a short time. The new heterocycle is also readily hydrogenated over palladium/charcoal, yielding a compound [95%; b. p. 149 °C: NMR (CCl_4): multiplets at $\tau = 6.22$ (4 protons) and 8.27 (4 protons) and a singlet at $\tau = 6.43$ ppm (4 protons)] considered to be 1,4-dioxacyclooctane, as well as a further, unidentified hydrogenation product (5%).

The experience with *(14)* indicates that a thermal equilibrium between the 1,4-dioxocin *(1a)* and the valence-isomeric *syn*-benzene dioxide *(4)* might be established above *ca.* 60 °C, but this could not as yet be realized experimentally. If such an equilibrium exists, the amount of the *syn*-benzene dioxide component in CCl_4 solution below 100 °C is certainly less than 5% (NMR limit of detection). The same follows from the thermal and spectroscopic properties of *syn*-benzene dioxide *(4)* which has meanwhile been synthesized by an independent route[17].

Valence Tautomerism of 1,4-Dioxocin with *syn*-Benzene Dioxide[**]

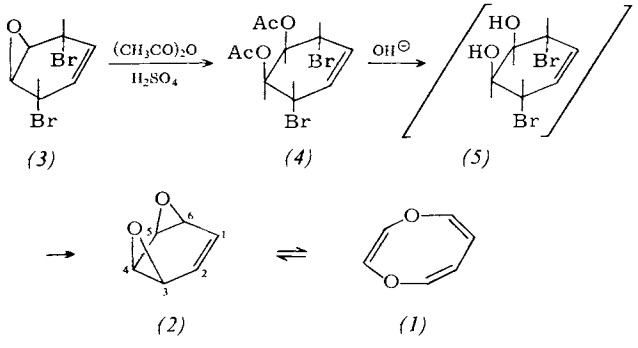
By *Hans-Josef Altenbach* and *Emanuel Vogel*[*]

Oxepin and its valence tautomer, benzene oxide, exist in rapid equilibration at room temperature, the two components being present in comparable amounts[1]. In the conversion of oxepin into benzene oxide the removal of a C=C double bond and the formation of an epoxide-C—C bond must thus be energetically in approximate balance[2]. This finding implies the at first sight surprising possibility that 1,4-dioxocin *(1)* and *all-cis*-1,4,7-trioxonin might also be in equilibrium with detectable amounts of their benzene oxide-type valence tautomers, *i.e. syn*-benzene dioxide *(2)* and *syn*-benzene trioxide[3], respectively, for the isomerization of the two oxaannulenes also involves loss of a double bond and gain of an epoxide ring. We provide below proof of existence of valence tautomerism, mobile above *ca.* 50 °C, between 1,4-dioxocin and *syn*-benzene dioxide[4, 5].

(1) *(2)*

In benzene (but not in CCl_4) at 50—80 °C, the 1,4-dioxocin *(1)* described in the preceding communication[4] undergoes slight isomerization, that can be followed readily by NMR spectroscopy (Figs. 1a and 1b) and whose amount is not notably increased by continued heating. The isomerization product is homogeneous and can be isolated as a crystalline compound of m. p. 93 °C (from ether/pentane) after removal of the relatively volatile *(1)* by distillation in a vacuum. Spectral comparison and a mixed melting point determination proved the identity of this isomer with *syn*-benzene dioxide *(2)* obtained by an independent synthesis.

Availability of *cis*-3,6-dibromo-*anti*-4,5-epoxycyclohexene *(3)*[4, 6] encouraged us to attempt the preparation of *syn*-benzene dioxide in a conventional manner by way of benzene bis(bromohydrins), *e.g. (5)*, having a configuration suitable for a double epoxide ring closure.



If it were possible to open the epoxide ring of *(3)* in a *cis* fashion with formation of *(5)* or an ester of *(5)*, this would place in our hands a benzene bis(bromohydrin) that should yield *(2)* under the influence of bases.

Treatment of *(3)* with acetic anhydride and sulfuric acid at room temperature—a procedure that could be considered the most likely to lead to *cis*-opening of the epoxide ring (formation of a diacetate)[7]—gave a homogeneous diacetate of m. p. 98 °C in 90% yield. This product is, however, clearly not the expected *(4)* since its NMR spectrum showed the presence of two different acetyl groups; it seems probable that it is the *trans*-diacetate corresponding to *(4)*. Neglecting the structural and configurational un-

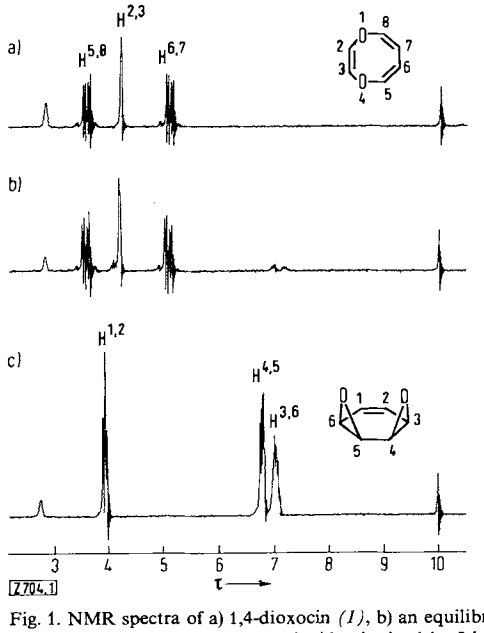
[**] *Note added in proof* (September 22, 1972): *anti*-Benzene dioxide, the only still unknown oxide of benzene, has now also been synthesized [m. p. 58—59 °C; NMR ($CDCl_3$): triplet at $\tau = 3.9$ and multiplets at $\tau = 6.2$ and 6.9]. The compound is formed from *trans*-3,6-dibromo-4,5-epoxycyclohexene by reaction with acetic anhydride/sulfuric acid and treatment of the diacetate (m. p. 101 °C) thus obtained with sodium hydroxide in ether.

certainty[8] of the compound of m. p. 98 °C we treated it at room temperature with methanolic potassium hydroxide; there was formed, in 60% yield, a non-phenolic

substance of m. p. 93 °C having the molecular formula $C_6H_6O_2$ and identified by means of its NMR and IR spectra as one of the stereoisomeric benzene dioxides.

Its NMR spectrum (100 MHz, $CDCl_3$) shows a triplet at $\tau = 3.53$ (H^1, H^2) and multiplets at $\tau = 6.29$ (H^4, H^5) and 6.61 (H^3, H^6). Assignment to the epoxide protons, according to which the multiplet at higher field refers to the allylic protons H^3 and H^6, was based on double resonance experiments, as follows. Irradiation at $\tau = 6.61$ reduces the other two signals each to a singlet, while irradiation at $\tau = 6.29$ only converts the multiplet at 6.61 into a triplet. On irradiation at $\tau = 3.53$ the multiplet at higher field is simplified in such a way that together with the multiplet at lower field it now forms an AA'BB' system; analysis of the AA'BB' system affords the following coupling constants for the epoxide protons: $J_{3,4} = 3.52$, $J_{3,5} = 0.43$, $J_{4,5} = 2.83$, and $J_{3,6} = 0.01$ Hz[9]. The NMR-spectrum in C_6D_6 is reproduced in Fig. 1c.

The IR spectrum shows two relatively strong bands in the region 750 to 950 cm^{-1} where numerous epoxides absorb. There is no UV absorption above 220 nm.



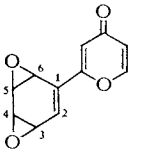


Fig. 1. NMR spectra of a) 1,4-dioxocin *(1)*, b) an equilibrium mixture of 1,4-dioxocin and *syn*-benzene dioxide obtained by 8 hours' heating of *(1)* in C_6D_6 at 70 °C, and c) *syn*-benzene dioxide *(2)* in C_6D_6 (60 MHz, TMS as internal standard).

The *syn*-configuration of this benzene dioxide follows from the chemical finding that catalytic hydrogenation of the compound over Pd/C in ethyl acetate affords the known *cis*-1,2:3,4-diepoxycyclohexane[10].

In the crystalline state *syn*-benzene dioxide *(2)* is stable for some time at room temperature. However, as expected from the thermal behavior of 1,4-dioxocin, *(2)* rearranges in solution, relatively rapidly above 50 °C, until equilibrium is reached with its valence tautomer containing an eight-membered ring. At 60 °C in benzene, the relative amounts of *(2)* and *(1)* are 5:95, independently of from which side equilibrium is approached. Kinetic evaluation, by NMR spectroscopy, of the valence tautomerism between *syn*-benzene dioxide and 1,4-dioxocin gave, for the forward reaction *(2)* → *(1)* $E_a = 27.0$ kcal/mol and $A = 7.1 \times 10^{13}$ and for the back reaction *(1)* → *(2)* $E_a = 25.4$ kcal/mol and $A = 3.2 \times 10^{11}$.

Since soon after their synthesis[1] arene oxides were recognized as metabolites of aromatic compounds[11], and have even been connected with carcinogenesis[12], it is hardly remarkable that nature can also produce arene dioxides. Recently *Borders, Shu,* and *Lancaster*[13] isolated, as a metabolite from an unspecified type of fungus, an antibiotic whose structure was determined by spectroscopic and chemical investigation as *(6)* which contains a benzene dioxide ring system. The *anti*-configuration

(6)

proposed by these authors for the two epoxide rings was based solely on the relatively low $J_{4,5}$ coupling constant of 2.8 Hz (dihedral angle between the appropriate protons in the *syn*- and *anti*-configuration = 0° and 50°, respectively). Since, according to the analysis given above, the corresponding protons in *(2)* also have an unusually low coupling constant (2.83 Hz)[14], the question whether the benzene dioxide moiety of *(6)* has the *syn*- or the *anti*-configuration seems to us to be still open.

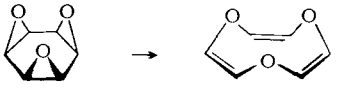
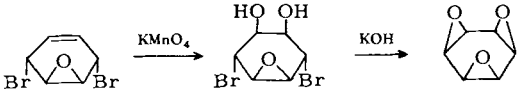
[12] *P. L. Grover, P. Sims, E. Huberman, H. Marquardt, T. Kuroki*, and *C. Heidelberger*, Proc. Nat. Acad. Sci. USA, *68*, 1098 (1971).



[13] *D. B. Borders, P. Shu*, and *J. E. Lancaster*, J. Amer. Chem. Soc. *94*, 2540 (1972).

[14] As shown by *K. Tori, T. Komeno*, and *T. Nakagawa* [J. Org. Chem. *29*, 1136 (1964)], in the 1,2-epoxycyclohexane system the value of $J_{vicinal}$ between an epoxide proton and a proton on the neighboring carbon atom is appreciably smaller for dihedral angles of 0° to *ca.* 50° than would be expected from the Karplus equation. These authors cite the electronegativity of the oxygen atom as the cause of this deviation. In the light of this, the coupling of 2.83 Hz found for $J_{4,5}$ in *(2)* seems reasonable.

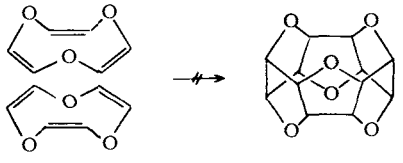
Valence Isomerization of *syn*-Benzene Trioxide to *cis,cis,cis*-1,4,7-Trioxacyclononatriene; *anti*-Benzene Trioxide[**]



By *Emanuel Vogel, Hans-Josef Altenbach*, and *Claus-Dieter Sommerfeld*[*]

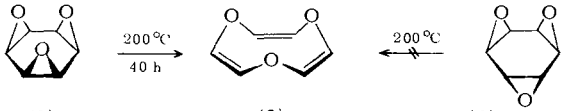
Simple consideration of energetics[1] indicates that *syn*-benzene dioxide and *syn*-benzene trioxide *(1)*—by analogy with the valence tautomerism between benzene oxide and oxepin[2]—would be in equilibrium with comparable or at least detectable amounts of their monocyclic valence tautomers, *i.e.* 1,4-dioxocin and *cis,cis,cis*-1,4,7-trioxacyclononatriene *(2)*, respectively. We have already reported[1] that valence tautomerism does exist between *syn*-benzene dioxide and 1,4-dioxocin, becoming mobile only above 50 °C, and that the benzene oxide component can just be identified both chemically and spectroscopically. We have now succeeded in realising the thermal valence isomerization of the *syn*-benzene trioxide to *cis,cis,cis*-1,4,7-trioxacyclononatriene, but have so far found no evidence of reversibility of this rearrangement.

(1) *(2)*



After our experience with the systems named above it seemed to us that a synthetic approach to the *syn*-benzene trioxide-*cis,cis,cis*-1,4,7-trioxacyclononatriene system was most likely to be realizable from the benzene oxide side. The obvious epoxidation of *syn*-benzene dioxide *(8)* by trifluoroperacetic acid, where there was the possibility that both stereoisomeric benzene trioxides might be obtained, gave in fact the *anti*-isomer with high stereoselectivity (see below). Our attempts to prepare *(1)* therefore concentrated on dehydrohalogenation, by bases, of benzene monoxide bis(bromohydrins) and benzene tris(bromohydrins) having configurations suitable, respectively, for a double and a treble epoxide ring-closure.

(3) *(4)* *(1)*



When treated with potassium permanganate in ethanol/water, the known *cis*-3,6-dibromo-*anti*-4,5-epoxycyclohexene *(3)*[3] afforded a homogeneous *cis*-glycol (m. p. 69 °C; yield 60%), which must have structure *(4)* since hydroxylation on the side remote from the bromine atoms is sterically favored. In agreement with this assumed configuration, *(4)* can be converted by treatment with methanolic potassium hydroxide at room temperature into the desired *syn*-benzene trioxide *(1)* (yield 35—40%); this melts at 242 °C (long needles from acetonitrile), which is remarkably high for a compound of this structure.

The NMR spectrum (CD_3CN) of *(1)* shows only one sharp signal at $\tau = 6.62$, corresponding to the symmetry and the epoxide structure of the compound (Fig. 1a). In the IR spectrum it is indicative that there are fewer bands than in that for the *anti*-isomer *(6)*.

(2) *(5)*

The high melting point of *(1)* at first caused us to speculate whether we had the dimer *(5)* derived from *(2)* rather than the trioxide, for this would also have been in accord with the NMR spectrum. This speculation, moreover, was entertained by the experiments of *Woodward, Fukunaga*, and *Kelley*[4] to dimerize triquinacene[5] to dodecahedrane. However, the molecular weight determined by mass spectrometry and osmometry proved the formula $C_6H_6O_3$.

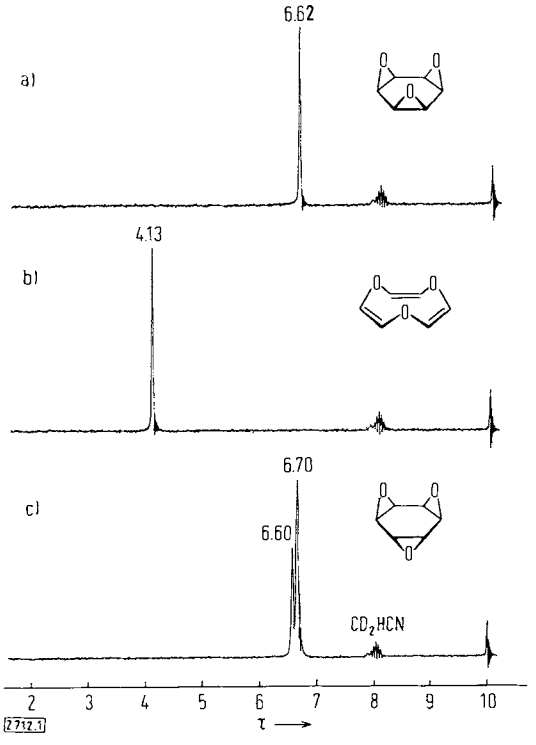
(1) *(2)* *(6)*

The orbital-symmetry allowed $[_\sigma 2_s + _\sigma 2_s + _\sigma 2_s]$ cycloreversion[6] of *syn*-benzene trioxide *(1)* to *cis,cis,cis*-1,4,7-trioxacyclononatriene *(2)* occurs only on heating to 200 °C (40 h) in acetonitrile (quartz ampoule) (yield 70% on 80% reaction). For preparative purposes it is preferable, because of the shorter reaction time, to carry out the isomerization in the gas phase (Pyrex tube) at 400 to 500 °C (yield 75—80%). *(2)* is obtained as a relatively stable, colorless compound

[*] Prof. Dr. E. Vogel, Dipl.-Chem. H.-J. Altenbach, and C.-D. Sommerfeld
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

[**] The first report of our syntheses of *syn*- and *anti*-benzene trioxide *(1)* and *(6)* was made by *E. Vogel* at a seminar in Freiburg arranged by Professor *H. Prinzbach* on July 11, 1972. The synthetic methods, melting points and NMR spectra of the two compounds were included in a previous paper [1] received on July 28, 1972.

of b. p. 90 °C. In agreement with the postulated structure, the NMR spectrum (CD_3CN) consists of a singlet at $\tau = 4.13$ (Fig. 1b), and in the IR spectrum (in substance) a C=C stretching band occurs at 1650 cm^{-1}. The UV spectrum (cyclohexane) shows end absorption that finally vanishes only at *ca.* 290 nm (ε between 240 and 290 nm: 260→0).



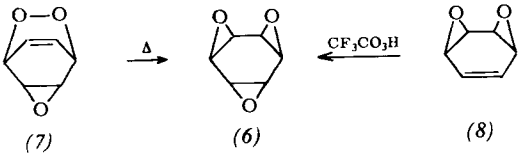


Fig. 1. NMR spectra of a) *syn*-benzene trioxide *(1)*, b) *cis,cis,cis*-1,4,7-trioxacyclononatriene *(2)* and c) *anti*-benzene trioxide *(6)* in CD_3CN (60 MHz; TMS as internal standard).

The *anti*-benzene trioxide was included in the present investigation to obtain a comparison of its thermal stability with that of its *syn*-isomer, in view of the interest in cycloreversions of *syn-anti*-isomers of bis- and tris-homobenzene compounds[7]. According to the *Woodward-Hoffmann* rules[6], *(6)* should also be susceptible to symmetry-allowed cycloreversion to give *(2)*, although in this case it would be a $[_\sigma 2_s + _\sigma 2_a + _\sigma 2_a]$ process, which for steric reasons would certainly require a relatively high activation energy. *(6)* should therefore be considerably more stable than *(1)* if there were no interference by side reactions.

(7) *(6)* *(8)*

anti-Benzene trioxide *(6)*[8] can be obtained by thermolysis of the *endo*-peroxide *(7)*[9] that in turn is formed on methylene blue-sensitized photooxygenation of benzene oxide-oxepin in acetone[10, 11]. The peroxide is not isolated in this process; instead, after the irradiation, the solution is boiled under reflux for 3 h, which causes the rearrangement. *(1)* is not obtained by this reaction, which permits the conclusion that addition of singlet oxygen to benzene monoxide affords *(7)* with high stereoselectivity. Working up by chromatography on silica gel with methylene dichloride as eluant yields *(6)* as a crystalline substance of m. p. 88 °C (needles from ether/pentane; yield 11%). *(6)* is also obtained, in 10% yield, by epoxidation of *(8)* with trifluoroperacetic acid.

Structural proof for *(6)* rests mainly on the NMR spectrum (CD_3CN), in which two narrow multiplets appear, at $\tau = 6.60$ and 6.70 (Fig. 1c).

(6) is very stable thermally, as expected; heating for several hours at 200 °C, and even gas-phase pyrolysis at 400 to 500 °C [as described for *(1)*], do not change the compound.

As crown ethers, compounds *(1)*, *(2)*, and the hydrogenation product of the latter, 1,4,7-trioxacyclononane, may be expected to yield interesting metal complexes[12], and investigations of this aspect are in progress.

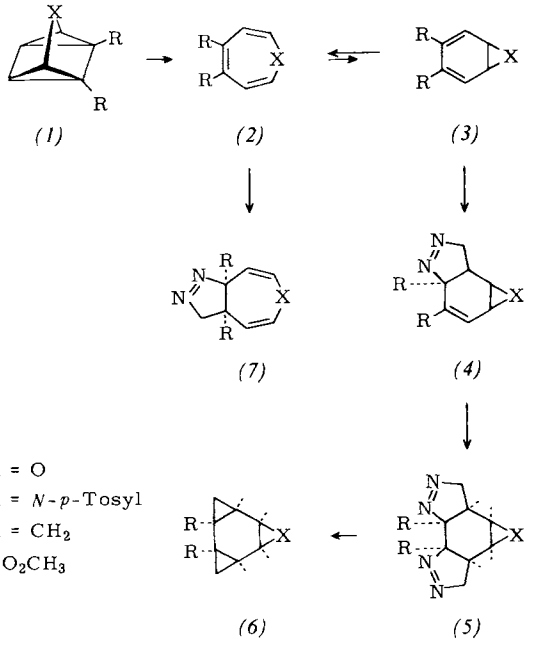
trans-σ-Bis- and -Tris-homobenzene Derivatives; Synthesis of Cycloheptatriene-3,4-dicarboxylic Acid Derivatives[**]



By *Horst Prinzbach* and *Reinhard Schwesinger*[*]

The first unbridged *cis*-σ-trishomobenzene derivatives *(6a)* and *(6b)* were synthesized by the reaction sequence *(1)* → *(2)* → *(3)* → *(4)* → *(5)* → *(6)*[1]. Here the methoxy-

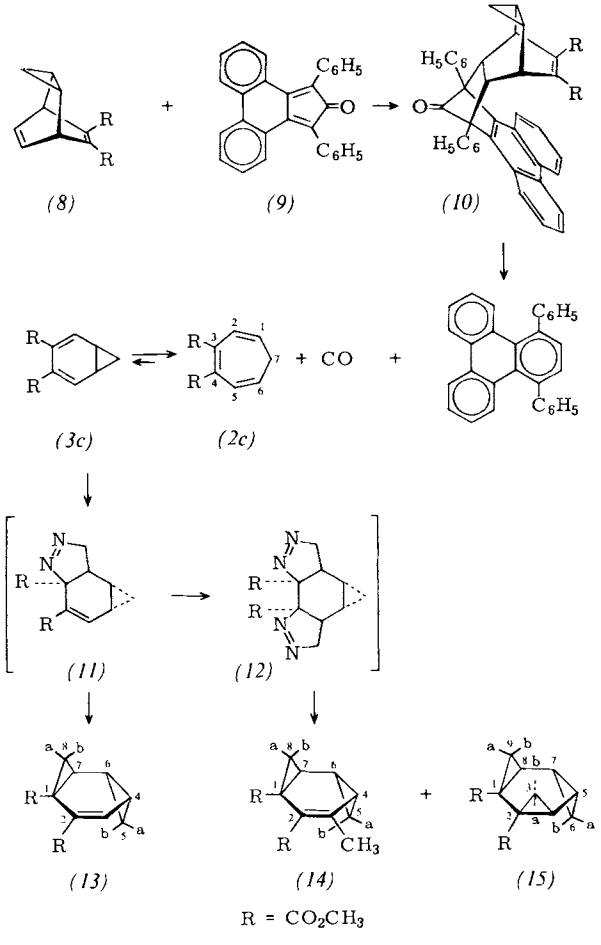
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

carbonyl substituents have a decisive influence; they act favorably on the addition of diazomethane to the bicyclic components *(3a)* and *(3b)* of the equilibrium mixture to give *(4a)* and *(4b)* which is in general disfavored thermodynamically[2] in comparison with the addition to *(2a)* and *(2b)* which gives *(7a)* and *(7b)*.

(a), X = O
(b), X = *N*-*p*-Tosyl
(c), X = CH_2
R = CO_2CH_3

The utility of this procedure for preparation of carbocyclic trishomobenzene compounds has been studied for the example *(2c)*⇌*(3c)*. Particular attention was paid to whether the notably high *cis*-selectivity was preserved in the stages *(3)*→*(4)* and *(4)*→*(5)* when X = CH_2.

In contrast to *(2a)*⇌*(3a)* and *(2b)*⇌*(3b)*, the system *(2c)*⇌*(3c)* could not be prepared by thermolysis of the tetracycle *(1c)*[3]. We have now obtained *(2c)*⇌*(3c)* in 60% yield by thermal fission of the adduct *(10)* obtained from the homobarrelene diester *(8)*[4] and the cyclopentadienone *(9)*[5]. According to ^{1}H-NMR measurements so far made on *(2c)* and its anhydride *(2d)* the proportion of the bicyclic valence tautomer in the equilibrium mixture at −120 °C is below the limit of detection by this method[6].



On reaction of *(2c)* with an excess (*ca.* 4 equivalents) of diazomethane in ether, which was stopped after 5 days, a complex mixture of pyrazolines is formed that, according to NMR analysis, contained about 20% of the dipyrazoline compound *(12)* which, however, could not be separated in spite of many modifications of the conditions. The crude mixture was therefore photolyzed directly, chromatographed and treated with permanganate, and the products separated, with much loss, by thin-layer and gas chromatography; the *trans*-σ-bis- *(13)* and *(14)* and *trans*-σ-trishomobenzene derivatives *(15)* were isolated in *ca.* 2% yield. Unlike the *cis*-compounds, they are thermally very stable and up to *ca.* 250 °C do not undergo the 2σ→2π or 3σ→3π isomerizations which, as synchronous reactions, are symmetry-allowed but sterically unfavorable (*cis,trans,trans*-geometry in the products). Thus, as judged

[f] Anhydride of *(2c)*.

by the formation of *(11)* and *(12)*, the norcaradiene diester *(3c)* which is not directly detectable can be trapped by diazomethane in the carbocyclic system *(2c)* $\rightleftharpoons$ *(3c)*. However, it appears that addition of CH_2N_2 to *(3c)* and to *(11)* occurs, even if not exclusively, in a manner with high selectivity *trans* to the cyclopropane ring. The *cis*-selectivity found for *(3a)*, *(3b)*, *(4a)*, and *(4b)* must consequently be ascribed to a *cis*-directing effect of the hetero ring members[7]. Carbocyclic *cis*-σ-trishomobenzene derivatives thus seem to be inaccessible by the *(1)* → *(6)* route[8]. The structures of the new compounds have been proved by subsequent reactions, elemental analyses and spectroscopic data (Table 1). The coupling constants determined

for *(13)*, *(14)*, and *(15)* accord particularly well with values obtained for model compounds.

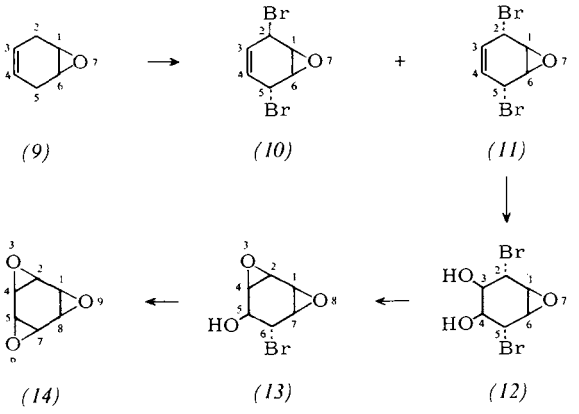
cis-Trioxatris-σ-homobenzene (*cis*-"Benzene Trioxide")[**]

By *Reinhard Schwesinger* and *Horst Prinzbach*[*]

The preparation of *cis*-monohetero-bis- and -tris-homobenzene derivatives, *(1)* and *(3)*, respectively, has been reported several times[1]. These systems are not of the least preparative importance because of the σ→π isomerization to *(2)* and *(4)*, respectively.

We have extended these studies to the σ/π-bis- and -tris-homobenzene compounds *(5)* to *(8)* with, respectively, two and three three-membered hetero rings in which the hetero atoms may be the same or different[2].



We have succeeded in synthesizing the particularly attractive *cis*-trioxatris-σ-homobenzene (*cis*-"benzene trioxide"; 3,6,9-trioxatetracyclo[6.1.0.$0^{2,4}$.$0^{5,7}$]nonane by the reaction sequence *(9)*→*(11)*→*(12)*→*(13)*→*(14)*[3]. The *cis*- and *trans*-dibromides obtained on allylic halogenation (CCl_4; *N*-bromosuccinimide + azodiisobutyronitrile) of *(9)*[5] can be separated by crystallization [isolated yields: *ca.* 25% of *(10)*, 20% of *(11)*]. As expected, *cis*-hydroxylation of *(11)* by potassium permanganate to yield *(12)* is much faster than that of *(10)*. Epoxide formation by sodium glycolate is almost quantitative, and larger or smaller amounts of the intermediate *(13)* can be isolated along with *(14)* according to the experimental conditions. The trioxide *(14)* crystallizes in colorless columns from

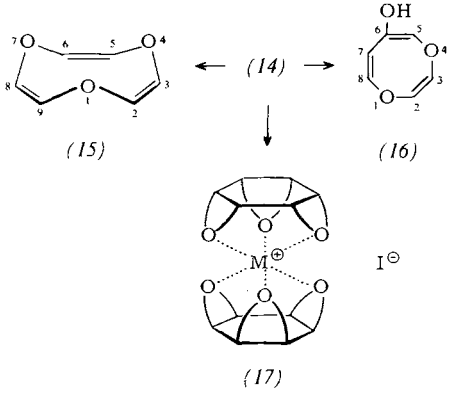
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



acetone, has a very high melting point [240 °C (dec)], and is thermally very stable. In solution in hexamethylphosphoric triamide or benzonitrile, there is no $3\sigma \rightarrow 3\pi$ conversion into 1,4,7-trioxonin *(15)* before decomposition sets in at *ca.* 220 °C.

(9) *(10)* *(11)*

(14) *(13)* *(12)*

The hitherto unknown heterocycle *(15)* [NMR (CCl_4; 30 °C): singlet at $\tau = 4.3$; temperature-independent between +20 and −85 °C] can, however, be obtained on a preparative scale in 80% yield by gas-phase pyrolysis at 400 °C[6]. The stability of *(14)* provides an impressive confirmation of the effect of the oxygen as a ring member in stabilizing the σ-structures, as already found for the analogs *(1)* and *(3)*. We have temporarily assigned the 1,4-dioxocin-6-ol structure *(16)* [NMR ($CDCl_3$; 30 °C): $\tau = 4.8$ (1 H; $J = 7.5$; 2.0 Hz); 5.7 (1 H, $J = 7.5$; 2.5 Hz); 6.1—6.6 (3 H; M); 6.6 to 6.8 (1 H; M)] to the product selectively formed from *(14)* by acid catalysis (CF_3CO_2H) at 30 °C[7]. Because of its geometrical properties the crown ether *(14)* seemed to us predestined for complex formation with metal ions[8]. In fact more or less stable complexes were obtained with a number of metal salts: for example, with KI in acetone, *(14)* affords a crystalline 2:1 complex as colorless needles that decompose from 180 °C to a brown melt (not the starting materials) (molecular weight: =418.2; Calc.: C 34.46; H 2.89; Found: C 34.26; H 3.08; IR (KI): 3226, 1376, 1280, 1238, 1099, 1071, 999, 896, 843, 746 cm^{-1}]; a structure with octahedral coordination to the central atom [*e.g. (17)* with $M^+ = K^+$] seems likely[9].

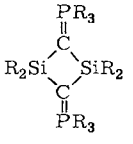
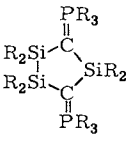
Silicon as a Carbanion Substituent in Ylides[**]

By *Hubert Schmidbaur*[*]

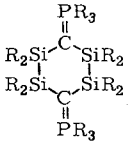


From numerous recent publications[1] it appears that silicon atoms as substituents can stabilize an ylide group very considerably. The consequence is a much diminished basicity or nucleophilicity of silylated ylides. Investigations of silyl ylides of phosphorus, arsenic, and sulfur containing various ligands on the silicon atom have shown that this "silicon effect" is founded in the properties of the silicon itself and is not caused by inductive, mesomeric, or steric effects of the ligands.

Possible explanations are concerned with a d-orbital-π-interaction or an altered charge distribution in the σ-skeleton. Photoelectron spectra and mass-spectroscopic determination of ionization potentials[2] do not provide unambiguous differentiation since the data for the free ylides and their silyl derivatives show hardly any stepwise progression.



Extension of the substituents to *disilanyl* groups, which would potentially permit a *(d-d)*π-interaction, did not lead to appreciable further stabilization; on the contrary, considerable steric hindrance occurred, which made syntheses much more difficult. Investigations were made, not only with open-chain mono- and di-silanyl ylides, but also especially with cyclic ylides *(1)*—*(4)*, in which the steric



(1)

(2)

(3)

(4)

factors would be largely eliminated. The tendency for formation of the latter and their stability were surprisingly high.

Among the reactions of silyl ylides, *trans-* and *de*-silylation processes are particularly important. The former permit simple introduction of other substituents, including functional ones, such as $SiCl_3$, $SiHCl_2$, $Si(CH_3)Cl_2$, $Si(CH_3)_2Cl$, $Ge(CH_3)_3$, $Sn(CH_3)_3$, PCl_2, and $As(CH_3)_2$ groups. Desilylation leads to salt-free pure ylides whose preparation by other routes is often difficult or impossible. Addition of reagents such as HF, CH_3OH, or CH_3SH *in situ* in connection with desilylations has led to the first syntheses of pentacoordinated tetraorganofluoro-, -alkoxy-, and -mercaptophosphoranes (R_4PF, R_4POR, and R_4PSR)[3]. By use of an excess of the reagent, products of the type $R_4PF \cdot HF$, $R_4POR' \cdot R'OH$, *etc.*, are obtained, in which the anions contain strong hydrogen bonds.

Crystalline Transition-Metal Complexes with Strongly Anisotropic Physical Properties

By *H. J. Keller*[*]

Square coordination compounds of the transition metals, which crystallize in columnar stacks, *i.e.* with formation of infinite linear metal chains, exhibit strongly anisotropic physical properties in the solid state. Among these solid substances there are a few representatives—such as Magnus salt or the glyoximato complexes of the d^8-ions Ni(II), Pd(II), and Pt(II)—with only weak intermolecular interactions along the metal chain, which can, however, be enhanced in various ways:

a) By oxidation of $[Pt(NH_3)_4]$ $[PtCl_4]$ or bis(benzildioximato)palladium(II) an originally fully occupied d_{z^2} band (valence band) can become partly emptied (conduction band). This results in the partly oxidized complexes having a metallic luster and increased electrical conductivity.

b) By coordination of d^8 metal ions with ligands which make an overlapping of the energetically higher and empty $d_{x^2-y^2}$ band with the fully occupied d_{z^2} band possible. Among these may be mentioned the isonotriles in complexes of the type $PtCl_2(CNR)_2$ (R = phenyl, *p*-toluyl, naphthyl, *etc.*). A half-occupied conduction band results, which explains the one-dimensional metallic properties of these compounds.

c) By use of d^7 central metal ions, *e.g.* cobalt(II). α-Modifications of diiodotetrakis(arylisonitrile)cobalt(II) exhibit, depending on the type of isonitrile, greatly reduced magnetic moments (one-dimensional antiferromagnetic behavior) and remarkable metallic surface luster.

Since lattice defects hinder metallic dc conductivity, for the identification of strong one-dimensional interactions in such compounds, resort must be made to either optical methods, ESR investigations of doped single crystals, or NMR investigations of the central metal ion.

Compounds of this type are—as suggested by *W. A. Little*—suitable as high-temperature superconductors. For this purpose it is necessary to link the one-dimensional metallic chain with easily polarizable organic groups. Hence, in the synthesis of columnar complexes of platinum(II), iridium(I), rhodium(I) or (II), and cobalt(II) with one-dimensional metallic properties readily variable organic molecules (glyoximes or isonitriles) were chosen as ligands in order to verify *Little's* model experimentally.

Reviews

Abstracts of selected progress reports and review articles

The polymerization of *N*-vinylcarbazole with metal salts is reviewed by *M. Biswas* and *D. Chakravarty*. Depending on their nature, metal salts can either convert *N*-vinylcarbazole *(1)* into a radical cation *(2)*, in which the positive charge

(1)

(2)

subsequently migrates to the vinyl double bond thus initiating polymerization, or they can attack the vinyl double bond directly and there generate a cationic, polymerization-active center. While the mode of action of oxidizing metal salts regarding the formation of *(2)* is well known, the way in which compounds of the BF_3 type (aprotic acids) initiate the polymerization of *(1)* is still unclear. [Polymerization of *N*-Vinylcarbazoles. Rev. Macromol. Chem. *8*, 189—208 (1972); 40 References]

[Rd 528 IE—G]

Polymer compatibility is the subject of a report by *Sonja Krause*. By compatibility is understood the miscibility of homopolymers and of random copolymers in the amorphous, non-crystalline state. The review is divided, in effect, into two parts, the first of which gives detailed experimental data on the miscibility of polymer pairs including that in the literature up to March 1971 under the heading "polymer compatibility". The second part deals with the theory of miscibility of polymers and a step-by-step account is given of how one can predict the miscibility of two particular polymers. [Polymer Compatibility. Rev. Macromol. Chem. *8*, 251—314 (1972); 135 References]

[Rd 530 IE—G]

Transition-metal complexes of olefins and acetylenes are dealt with by *L. D. Pettit* and *D. S. Barnes* in a review which is mainly devoted to the stability, structures, and bond characteristics of these compounds. Both σ- as well as π-complexes of the metals silver, copper, platinum, palladium, and rhodium are discussed and thermodynamic data and results of X-ray or neutron diffraction analysis are quoted. [The Stability and Structures of Olefin and Acetylene Complexes of Transition Metals. Fortschr. Chem. Forsch. *28*, 85—139 (1972); 153 References]

[Rd 533 IE—G]

Ring ligand substitution reactions of aromatic-metal complexes form the theme of a progress report by *H. Werner*. Reactions of this type, for instance

$$Ni(C_5H_5)_2 + 4KCN \rightarrow K_2[Ni(CN)_4] + 2KC_5H_5$$

often require a relatively high activation energy, so they are generally not so characteristic of the complexes of the type C_nH_n—M. However, they form an important part of the chemistry of aromatic-metal complexes, which has earned attention not only from the preparative point of view but also from the point of view of bond theory and reaction kinetics. Substitution reactions of complexes of the type C_5H_5—M and C_6H_6—M are discussed. Cyclobutadiene complexes are also dealt with; the analogous reactions of C_7H_7—M and C_8H_8—M are, as yet, unknown. [Fortschr. Chem. Forsch. *28*, 141—181 (1972); 166 References]

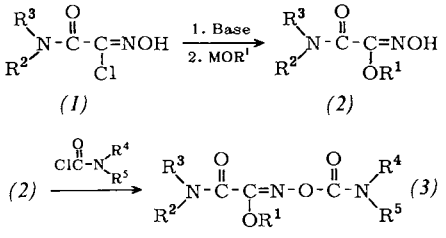
[Rd 534 IE—G]

Enzymes containing molybdenum are the subject of a review by *R. C. Bray* and *J. C. Swann*. The dynamics of reactions catalyzed by enzymes of this group are described extensively using xanthine oxidase from cow's milk as an example. The role of molybdenum in other oxidases as well as in reductases, dehydrogenases, and nitrogenases is outlined. [Molybdenum-Containing Enzymes. Structure and Bonding *11*, 107—144 (1972); 115 references]

[Rd 543 IE—H]

The occurrence of iron in living nature is reviewed by *J. B. Neilands*. Iron compounds found in microorganisms, in plants, and in animals are specified and, if known, their physiological role and mode of action are explained. The present state of knowledge suggests that the primordial type of iron complexation was with sulfur; coordination with sulfur and nitrogen, sulfur and oxygen, and exclusively with oxygen developed stepwise. [Evolution of Biological Iron Binding Centers. Structure and Bonding *11*, 145—170 (1972); 112 references]

[Rd 544 IE—H]



The synthesis of hydroxy-deuterated alcohols, R-OD, is summarized by *L. Verbit* in an article giving procedures for large-scale preparations of substances having high isotopic purities. D_2O is mostly used as deuterium source. Sufficient methods are available to permit deuteration of almost any desired hydroxyl group: Simple exchange reactions and hydrolysis of alkoxides, trialkyl borates, dialkyl carbonates, dialkyl sulfites, silicone derivatives, carboxylates, ortho esters, and ketals. Countercurrent exchange in the gaseous phase between D_2O and alcohols having b.p. < 200 °C (isotopic purity > 98%) appears of special interest. [The Synthesis of Alcohols-OD. Synthesis *1972*, 254—258; 38 references]

Nucleinsäuren (Nucleic acids). By *D. Beyersmann*. Chemische Taschenbücher Band 16 (Chemical Pocketbooks Vol. 16). Verlag Chemie GmbH, Weinheim/Bergstr. 1971. 1st edit., viii, 192 pp., numerous figs, and tables, bound, DM 24.—.

This book is the latest in the "Chemical Pocketbooks" series, which have already won a name for themselves by their good presentations of interesting specialist topics; it deals with the topical subject of nucleic acids in six chapters.

A discussion on nomenclature, the fundamental monomer building blocks, and the chemistry of the high-molecular nucleic acids is followed by a detailed exposition on the molecular weight and conformation of these compounds. The remaining four chapters include the essential facts on the biosynthesis of nucleotides and a comprehensive treatment of the metabolism of nucleic acids, tables helping to present the wealth of information in a clear and easily comprehensible manner. After the role of nucleic acids in the transmission of genetic information has been clearly shown and a number of regulation mechanisms have been discussed, the last chapter indicates some possible ways of attacking the problems of the metabolism and function of the nucleic acids.

The author has succeeded in presenting the most important aspects of this very extensive field in a clear, detailed, and attractive manner. The reader is familiarized with the current position on the chemical and biochemical viewpoints on the nucleic acids, and can go into the subject more deeply by means of the literature references (there could have been more of these in one or two chapters). The book is recommended to anyone requiring information on nucleic acids.

Herbert Schott [NB 71 IE]

Kunststoff-Handbuch (Plastics Handbook). Vol. 11. Polyacetals, Epoxy Resins, Polymers Containing Fluorine, Silicones, *etc.*, Production, Properties, Processing, and Use. Edited by *R. Vieweg*, *M. Reiher* and *H. Scheurlen*. Carl Hanser Verlag, München, 1971, 1st ed., xxii, 616 pp., 362 figures, 176 tables, bound DM 220.—.

Volume 11, the latest volume of the collective work[1], deals with plastics that do not fit into the rigorous classification of the earlier volumes. The polyacetals, epoxy resins, polymers containing fluorine, and silicones are discussed in detail, while polyvinylalcohols, polyvinylacetals, polyvinyl ethers, polyvinylpyrrolidone, and poly-*N*-vinylcarbazole are described relatively briefly. The first group of products mentioned above, like the major plastics described in earlier volumes (polyethylene, polyvinyl chloride, polystyrene, *etc.*), are discussed in sections dealing with production, properties, processing, and use, after an introduction presenting a historical survey and some economic data.

The sections on epoxy resins and polymers containing fluorine are particularly successful. A rather more comprehensive discussion would have been justified in the chapter on polyvinyl acetals, polyvinyl ethers, *etc.* Lacquer raw materials should also find a place in a plastics handbook. It is a pity that the book contains no contributions on high-temperature plastics, such as diphenyl oxides, polyimides, and poly-*p*-xylylenes, though sufficient literature for such contributions has existed for a number of years. The polysulfones should also belong to this volume.

Nevertheless, the book provides users and processors with a good, concise source of quickly retrievable information on polyacetals, epoxy resins, *etc.* Since the relevant literature is abundantly cited, chemists and applications technologists who wish to delve deeper into the subject can do so with the aid of this book. The volume can be wholeheartedly recommended to all who wish to obtain fairly detailed information on the plastics mentioned in the title.

Otto Horn [NB 72 IE]

Römpps Chemie Lexikon (Römpp's Chemical Lexicon). By *O.-A. Neumüller*. Franck'sche Verlagshandlung, W. Keller & Co., Stuttgart, 1972, 7th ed., vol. 1; xiv, 734 pp., numerous figs., bound, DM 110.—.

Twenty-five years have elapsed since the first edition of this work appeared. The first volume of the seventh edition is now out, covering the entries from A to C. The new editor is *O.-A. Neumüller*, who took over when *E. Ühlein* died.

On thumbing through the new first volume, one first notices that it is now the pages and not the columns that are numbered, the head words stand out, and the material must have been subjected to very careful editing and proofreading. The number of entries has not yet been specified, but comparison with the sixth edition[1] points to a roughly 10% increase in volume. Almost all the entries have been revised or rewritten; in particular those coming under organic chemistry, physical chemistry, biochemistry, and nuclear chemistry have been extended. This amplification has not been entirely successful in the case of named reactions, because some of them are still missing. The key words are also given in English and French, and, as mentioned in the Preface, they will be listed alphabetically at the end of the last volume. However, this list is likely to be incomplete, because the terms are not always given after the head words. Compounds are named according to IUPAC rules. One or more sources of supply are usually specified for each substance, which will certainly be found most useful. The literature references have been increased in number and are now fully up to date. The listing of tradenames in entries on drugs has been mostly abandoned.

This volume deserves a good reception, as do the further volumes of Römpps Chemie Lexikon, which are to be published at intervals of six months.

Transition Metal Carbides and Nitrides. By *L. E. Toth*, Academic Press New York—London 1971. 1st ed., xiii, 279 pp., numerous figures and tables, bound $ 16.50.

The carbides and the nitrides of groups 4 to 6 of the periodic system have found steadily growing importance in research

[1] Cf. Angew. Chem. Internat. Edit. *9*, 817 (1970).

and in industry because of their high melting points (up to 4100 °C), their very low creep rates at high temperatures and their particularly good wear resistance, as well as other favorable thermal and electrical properties. Whereas the tungsten-based hard metals have been of world-wide importance for many years, it is only during the past few years that in particular the carbides of titanium, zirconium, and tantalum, as well as their nitrides, have come into industrial use. Thus, because of their low tendency to wear, thin coatings of titanium carbide and titanium nitride with lower-melting metals lead to a considerable improvement in the service life of cutting metals, and solid solutions of the carbides and nitrides of titanium have yielded valuable materials for special uses in electrical engineering. For the further development of these carbide and nitride materials, however, a thorough knowledge of their crystal-chemical, thermodynamic, and electrical properties as well as of their superconductivity will be necessary in order to improve above all their mechanical properties.

The fundamental knowledge about the properties of these substances is presented comprehensively in this book, which therefore offers the investigator in this field valuable support, in connection both with the preparation of these materials and with their possible uses.

W. Dawihl [NB 80 IE]

The Periodic System of Chemical Elements. By *J. van Spronsen*. Elsevier Publ. Comp., Amsterdam-London-New York 1969. 1st ed., xv, 368 pp., numerous figures and tables, bound Dfl. 50.—.

For more than ten years now *van Spronsen* has been intermittently publishing interesting material on the history and prehistory of the periodic system of chemical elements, and the profession was aware that a larger work from his pen was to be published in 1969, 100 years after *Dimitri Ivanovich Mendeleev's* publication. The hopes and expectations of a new standard work on the history of chemistry were fulfilled, and it was surprising how much additional material the author had to relate.

By dividing the book into two parts (Part I: General Aspects pp. 7 to 211; Part II: Specific Aspects, pp. 213—355, followed by a personal index and a subject index), he has managed to present this material without overwhelming the reader with details, since the first part gives a systematic survey, into which everything else fits automatically because of the cross references in the second part. Moreover, because of the great scientific importance of the search for a system of elements and the construction of the periodic system, the book also constitutes a history of the chemistry of the past 200 years, and in particular a history of ideas and problems.

Not surprisingly to a science historian, it emerged that the idea of a "natural" system of the chemical elements was already very old, and that the stimulus by no means always arose exclusively from chemistry or was chemically oriented from the outset. There was a series of affinity tables in the 18th century, which are not discussed in any detail by *van Spronsen* (but cf. *A. M. Duncan*: Some theoretical aspects of eighteenth-century Tables of Affinity I. Annals of Science *18*, 177—194 (1962)), but comprehensive tables of a "natural" system were possible only after the acceptance of *Lavoisier's* antiphlogistic chemistry; the first appeared soon after this (*Döbereiner's* triads, *Berzelius's* electrochemical system, *etc.*). A periodic system was possible only after terms such as atom and atomic weight had been clarified at the Chemist's Conference at Karlsruhe in 1860. A whole series of such systems immediately appeared, and the well-known systems of *Lothar Meyer* (1864/1870) and *Mendeleev* (1869) were by no means the first; *A. E. Béguyer de Chancourtois* (1862), *J. A. R. Newlands* (1863), *W. Odling* (1864), and *G. D. Hinrichs* (1867) had preceded them in part. However, the various workers knew little or nothing about one another, and *van Spronsen* rightly states (p. 135): "It should be clearly understood that Mendeleev's work was so brilliant precisely because he knew nothing of the studies of his contemporaries... If he had known of them, Mendeleev's work could only be considered as a useful summary and continuation of that of his predecessors". (It was only on the presentation of his results to the meeting of the Russian Chemical Society in March 1869 that *Olding's* work was brought to his notice.)

On the basis of *van Spronsen's* definition of the periodic system (p. 338: "The periodic system of elements is a sequence of all [known] elements arranged according to increasing atomic weight in which the elements with analogous properties are arranged in the same group or column"), all six investigators mentioned above should be referred to as "discoverers", and this is confirmed by the many other attempts that were subsequently made to find an arrangement. (The author lists and discusses them with their reasons and their consequences up to and including 1949; *E. G. Mazur* [Types of graphic representation of the Periodic System of Chemical Elements, 1957] carried them on up to 1955, but mainly only bibliographically.)

The book is a goldmine for those who are interested in the history of chemistry, and contains an abundance of interesting information and ideas from the recent history of chemistry, which would offer stimulation and orientation even to the non-historically minded chemist.

New Reactions with Cyanic Esters

By Ernst Grigat[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

The reactions of cyanic esters with acylating agents and the reactions of the resulting *N*-acyliminocarbonic ester halides are surveyed, and syntheses of heterocycles with cyanic esters and their reaction products are then reported.

1. Introduction

Since the appearance of the review "Synthesis and Reactions of Cyanic Esters" in 1967[1,2], the chemistry of these esters has expanded further. In addition to the preparation methods, the basic reaction types that had been investigated until then were described, *viz.*:

A) Nucleophilic reactants H—X add under mild conditions to the nitrile group of ArO—C≡N to form derivatives of iminocarbonic esters ArO—C(=NH)X.

B) Under more forcing conditions, these decompose into ArOH and N≡C—X, *i.e.* esters of cyanic acid can be used to transfer a nitrile group to nucleophilic reactants.

C) C—C bonds are formed by addition of compounds having a nucleophilic C atom to the nitrile group of the cyanates.

D) The readiness with which esters of cyanic acid add water and hydrogen sulfide can be used for the intramolecular and intermolecular elimination of organically bonded H_2O and H_2S.

E) The tendency to trimerize, even with the inclusion of nitrile groups from other sources, offers possibilities for the direct synthesis of *s*-triazine derivatives.

F) As very reactive dipolarophiles, cyanic esters enter into 1,3-dipolar cycloadditions under mild conditions.

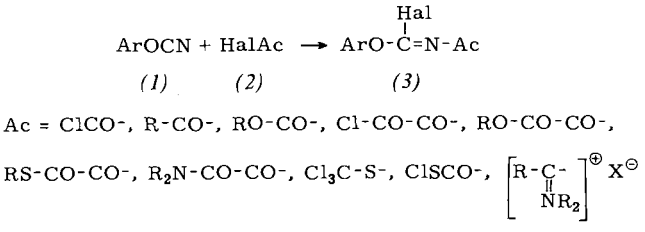
G) Ring closure to form benzoxazinones occurs on reaction of aryl cyanates having carboxylic ester functions *ortho* to the OCN group with nucleophiles.

H) The addition of electrophiles to the —O—C≡N group occurs only in a few special cases

In the meantime, extensions have been found mainly in two areas:

1. With acid chlorides in the widest sense, cyanic esters are smoothly acylated to form *N*-acyliminocarbonic ester halides[3]. These new classes of extremely reactive compounds open up many synthetic possibilities, particularly in the fields of heterocycles and carbonic acid derivatives. This work is discussed in the first part of the present article.

2. Syntheses of heterocycles are not confined to reaction types E), F), and G). With suitable reactants, reaction types A) to D) can also be used for direct syntheses of heterocycles. Hitherto unpublished syntheses of this type form the subject of the second part of the article.

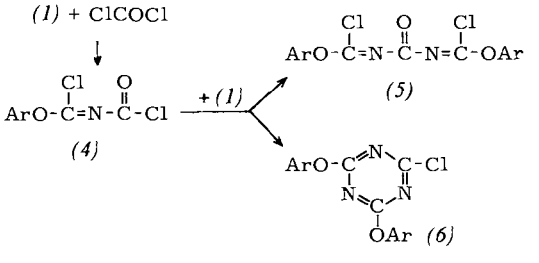


[*] Dr. E. Grigat
Present address:
Bayer AG, PU Forschung 2
4047 Dormagen (Germany)

New individual results obtained by reactions of types A) to G) are not reported here. Where possible, they are incorporated into the tables at the end of the article.

1. Reaction of Cyanic Esters with Acylating Agents

1.1. Reaction with Acid Halides

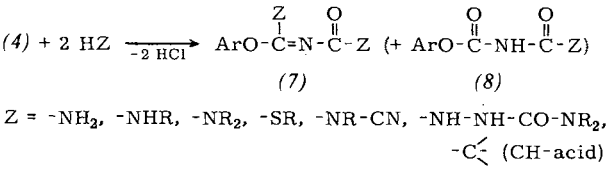


Since cyanic esters *(1)* had proved to be very inert toward electrophilic reagents[1, 2, 4], it was surprising to find that they can be *N*-acylated under very mild conditions in some cases, and in good yields, with various types of acyl halides *(2)*[3]. The resulting *N*-acyliminocarbonic ester halides *(3)* are surprisingly stable, but extremely reactive.

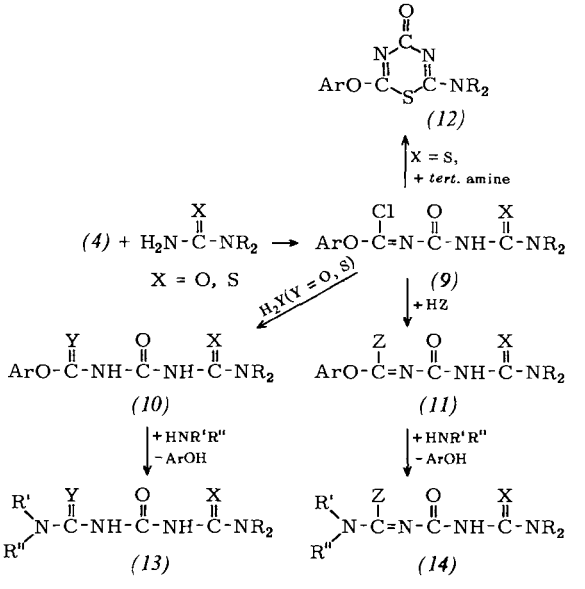
The versatility of these previously undescribed classes of substances for further syntheses is illustrated below.

1.1.1. Addition of Phosgene to Cyanic Esters

When equimolar quantities of phosgene and *(1)* are mixed in an inert solvent, reaction to form *(4)* takes place even at 0 °C without addition of a catalyst. The reaction products are formed in good yields and can be distilled[5].



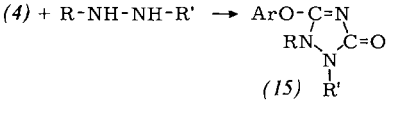
Further reaction with an excess of cyanate *(1)* leads to two products, which are formed in various proportions. In the case of R = α-naphthyl, *(5)* predominates, whereas *(6)* predominates for R = C_6H_5 or 4-CH_3—C_6H_4.



Further reactions:

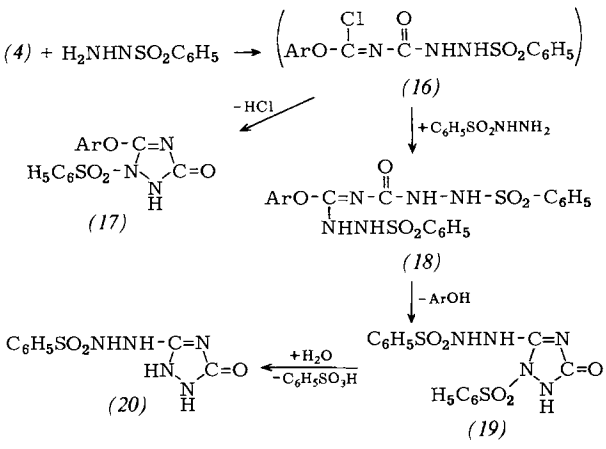
On hydrolysis, *(4)* decomposes into ArOCO—NH_2, HCl, and CO_2; ArO—CS—NH_2 is isolated after reaction with H_2S, and ArO—CO—NH—CO—OAlk on alcoholysis. Strong nucleophiles immediately substitute both Cl atoms to form *(7)*[6], a C—C bond being formed if the group Z exhibits C—H acidity. If moisture is present during the reaction, *(8)* is observed as a by-product.

With less nucleophilic reagents, it is possible to make use of the difference in the reactivities of the two Cl atoms in *(4)*. Thus with ureas or thioureas, reaction initially occurs only with the Cl atom adjacent to the CO group,

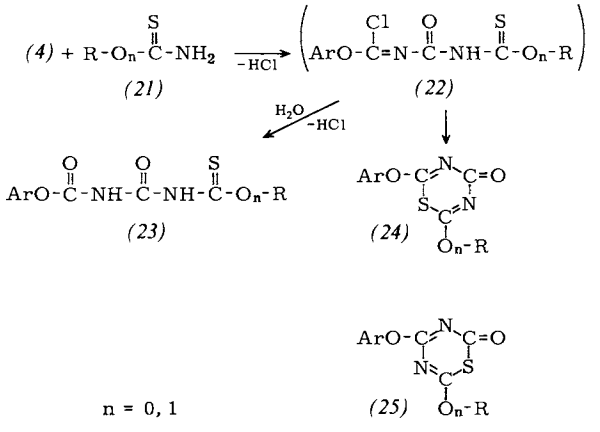


with formation of *(9)*[7]. This intermediate product, which can be isolated, can then be hydrolyzed in a second step to *(10)*[8], reacted with other nucleophilic reactants to form *(11)*, or cyclized intramolecularly to form *(12)*[9].

The exchangeability of the aryloxy residue in *(10)* and *(11)* against amines, hydrazines, semicarbazides, *etc.* offers possibilities for the synthesis of compounds of the types *(13)* and *(14)*.

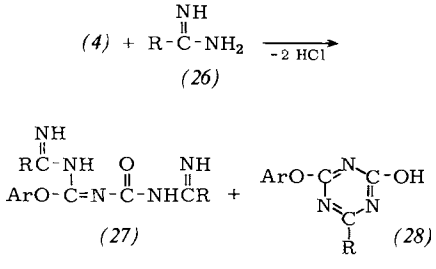


Direct ring closure reactions of *(4)* can also be carried out with suitable reactants. Examples of the formation of five-membered heterocycles are the reactions of *(4)* with hydrazine and its derivatives. Whereas reaction with hydrazines themselves lead exclusively to the triazolones *(15)*[10], sulfonohydrazides lead to a whole range of

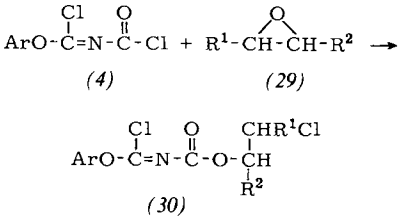


substances *(16)* to *(20)*, which, with the exception of *(16)*, have all been isolated and identified.

Examples of the formation of six-membered heterocycles are the reactions of *(4)* with amides or thiocarboxylic or thiocarbamic acids *(21)* to form thiadiazinones *(24)*[11].

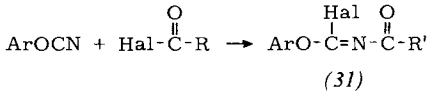


Whereas reaction at room temperature leads only to *(22)*, whose hydrolysis product *(23)* can be isolated by working up with water, ring closure to form *(24)* occurs at moderately higher temperatures (40 to 80°C).



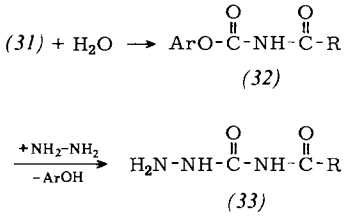
The isomeric thiadiazinone *(25)* has been isolated as a by-product in one case (R = 4-H_3C—C_6H_4—).

Amidines *(26)* add less uniformly to *(4)* than thioamides or thiocarbamates. The compounds *(27)* and *(28)* are both formed; the less basic trichloroacetamidine gives mainly *(27)* (with R = Cl_3C), while more of *(28)* (with R = C_6H_5) is formed with benzamidine.



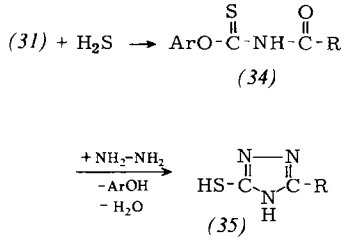
A smooth route to *(28)* (also with R = CCl_3) without formation of *(27)* as a by-product involves the addition compounds of *(4)* with epoxides. Like the α-chloroalkylidenecarbamoyl chlorides[12], the *N*-chlorocarbonyliminocarbonic ester halides *(4)* add to epoxides *(29)* in such a way that the oxirane ring is opened. The epoxide

molecule is formally inserted between the CO group and the Cl atom of the —CO—Cl grouping, and the alkoxycarbonyliminocarbonic ester chlorides *(30)* are formed[13]. They belong to the same class of substances as the products of the addition of carbonic ester halides to ArOCN. Their further reactions are described in Section 1.1.3. It will merely be mentioned here that *(30)* cyclizes smoothly with amidines *(26)* to form *(28)*, with elimination of HCl and HO—CHR^2—CHR^1—Cl.

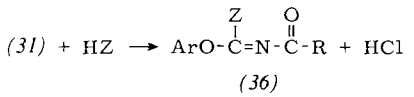


1.1.2. Addition of Halides of Carboxylic Acids to Cyanic Esters

Higher temperatures are required for the reaction of carboxylic acid halides with cyanic esters than for the addition of phosgene. The undiluted components are heated to temperatures of up to 200 °C (depending on the acyl chloride), and the very stable *N*-acyliminocarbonic ester halides *(31)*, which are formed in good yields, are purified by vacuum distillation[3,14].



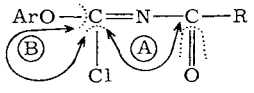
Further reactions:



Hydrolysis leads to *N*-acylated carbamates *(32)*[15]. Of the reactions of these products (exchange of ArO for nucleophiles), only that with hydrazine will be mentioned, since this provides a simple route to the acylsemicarbazides *(33)* with a free hydrazino group and an acylated amino group[16].

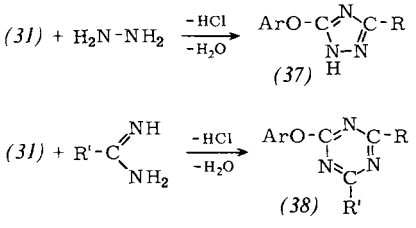
The reaction of H_2S or H_2S donors (R—CS—NH_2; H_2N—CS—NH_2) yields *N*-acylthiocarbamates *(34)*[17]. However, further reaction of these products with hydrazine leads not to the acylthiosemicarbazides analogous with *(33)* but directly to the mercaptotriazoles *(35)* with cyclization. No similar spontaneous ring closure has been observed with *(33)*.

The halogen atom in *(31)* is easily exchanged for other nucleophiles. Compounds of the type *(36)* are formed[18].



(36)

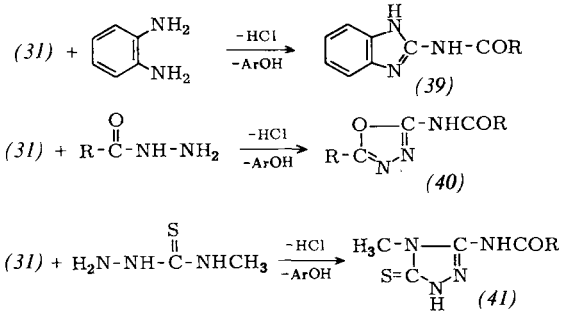
Z = $-NH_2$, $-NHR$, $-NR_2$, $-SR$, $-OR$, $-NHNR-CO-NH_2$, $-C\langle$ (CH-acid)



Direct syntheses of heterocycles with *(31)* are possible by two types of reactions:

Type A: Substitution of the halogen atom, followed by ring closure to the carbonyl group of the *N*-acyl residue, with removal of water.

Type B: Substitution of the halogen atom, followed by ring closure to the same C atom, with removal of the ArO residue and retention of the *N*-acyl grouping.

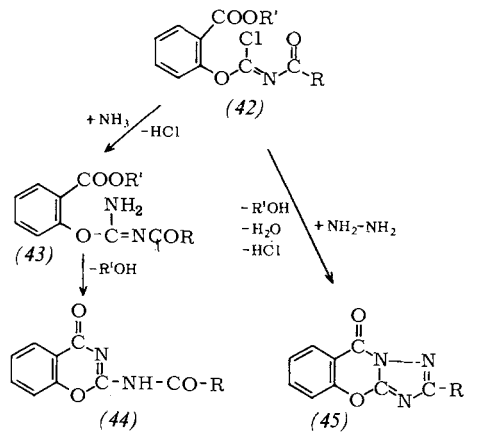


An example of a five-membered ring synthesis of type A is the reaction of *(31)* with hydrazine to form the triazole *(37)*[19], while an example of a six-membered ring synthesis is the reaction with amidines to form the *s*-triazines *(38)*[20].

(37)

(38)

As examples of type B, *(31)* reacts with *o*-phenylenediamine to form 2-(*N*-acylamino)benzimidazoles *(39)*, with acylhydrazides to form the oxadiazoles *(40)*[21], and with thiosemicarbazides to form the triazoles *(41)*[22].



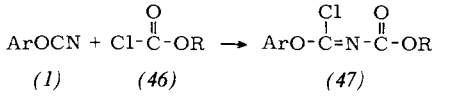
(39)

(40)

(41)

N-Acyliminocarbonic ester halides having a carboxylic ester function in the *ortho* position *(42)*, like the cyanic esters from which they are derived, also exhibit special cyclization reactions. The reaction with NH_3 leads *via (43)* to the 2-acylaminobenzoxazinones *(44)*[23], while the reaction with hydrazine leads directly to the triazolobenzoxazinones *(45)*[24].

(42)



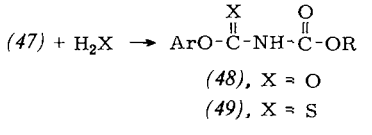
(43)

(44)

(45)

1.1.3. Addition of Carbonic Ester Halides to Cyanic Esters

Carbonic ester halides *(46)* can also add to cyanic esters *(1)* in good yields to give the *N*-aryloxy- or alkyloxycarbonyliminocarbonic ester halides *(47)*[25].

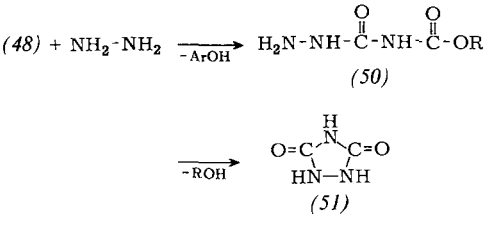


(1) *(46)* *(47)*

A limitation is that *alkyl* carbonate halides *(46)* with R = lower alkyl decompose in the presence of ArOCN into CO_2 and RCl.

Reference should again be made to the possibility of synthesizing some substances of the class *(47)* from the addition compound *(4)* with epoxides (cf. Section 1.1.1).

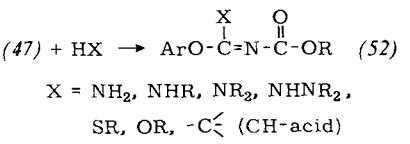
Further reactions:



Hydrolysis and reaction with H_2S (or H_2S donors such as R—CS—NH_2, H_2N—CS—NH_2) lead to the products *(48)* and *(49)* respectively[17].

(48), X = O

(49), X = S

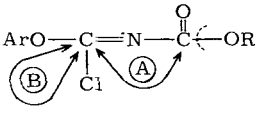


The replaceability of the aryloxy residue in the hydrolysis product *(48)* by nucleophiles is again illustrated by the reaction with hydrazine. Unlike in the same reaction with *(37)*, the ring closure product *(51)* is formed here by further reaction (particularly in the case of R = aryl), as well as *(50)*[16].

(50)

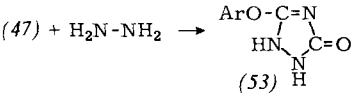
(51)

The reaction of *(47)* with nucleophiles (HX) leads, with elimination of HCl, to the compounds *(52)*[18].



(47) + HX → ArO-C(X)=N-C(=O)-OR *(52)*

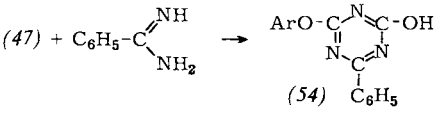
X = NH_2, NHR, NR_2, $NHNR_2$, SR, OR, -C< (CH-acid)



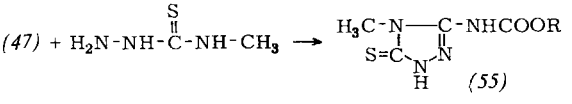
In the case of *(47)*, the direct synthesis of heterocycles is again possible by two types of reactions:

Type A: Substitution of the halogen atom, followed by ring closure to the aryloxycarbonyl group, with elimination of ROH.

Type B: Substitution of the halogen atom, followed by ring closure to the same C atom with removal of the ArO residue and retention of the *N*-alkyloxycarbonyl or *N*-aryloxycarbonyl grouping [strictly analogous to *(31)*].

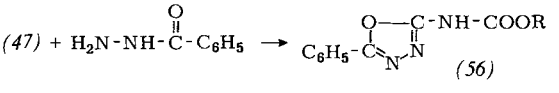


Five-membered ring synthesis of type A[26]:



(47) + H_2N-NH_2 → ArO-C(=N)-HN-N(H)-C=O *(53)*

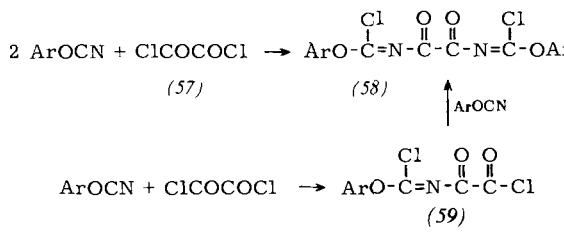
Six-membered ring synthesis of type A:



(47) + C_6H_5-C(=NH)-NH_2 → ArO-C(=N)-N=C-OH *(54)* C_6H_5

Heterocycle syntheses of type B[21,22]:

(47) + H_2N-NH-C(=S)-NH-CH_3 → H_3C-N(-C=S)-C(=N)-NHCOOR



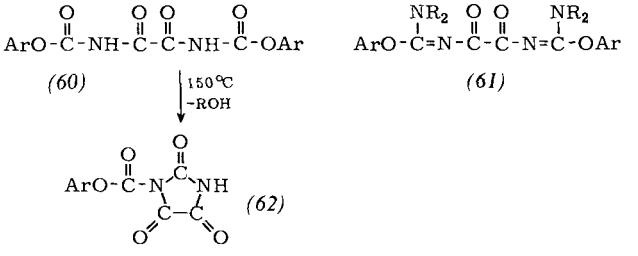
(47) + H_2N-NH-C(=O)-C_6H_5 → O—C(=N)-NH-COOR, C_6H_5 *(56)*

1.1.4. Addition of Oxalyl Chloride to Cyanic Esters

Oxalyl chloride *(57)* can be converted into two products with cyanic esters[3].

With 0.5 mole of *(57)* per mole of ArOCN, only the 2:1 addition product *(58)* is formed[27], whereas with an excess of *(57)* (2.5 moles) with respect to ArOCN only the 1:1 addition product *(59)* is formed[28]. An advantageous point here is that if the correct molar ratios are used, each of the two products can be prepared in good yields without contamination by the other.

As expected, *(59)* can be converted into *(58)* by reaction with further ArOCN, and it is thus possible to synthesize unsymmetrical compounds *(58)*[29].

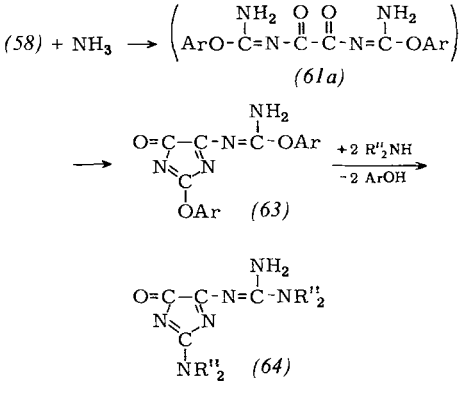


2 ArOCN + ClCOCOCl → ArO-C(Cl)=N-C(=O)-C(=O)-N=C(Cl)-OAr *(58)* (*(57)*)

(58) + ArOCN → ArO-C(Cl)=N-C(=O)-C(=O)-N=C(Cl)-OAr *(59)*

Some reactions with (58):

Hydrolysis and reaction with secondary amines lead to the products *(60)* and *(61)* respectively[30].



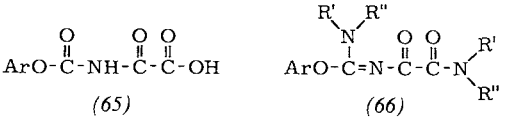
ArO-C(=O)-NH-C(=O)-C(=O)-NH-C(=O)-OAr *(60)*

(60) —150°C, -ROH→ *(62)*

ArO-C(=O)-N(-C(=O)-C(=O)-)-NH *(62)*

$(NR_2)_2$-C=N-C(=O)-C(=O)-N=C-OAr *(61)*

When heated, *(60)* cyclizes with elimination of phenol to form *(62)*. On reaction with NH_3, instead of *(61a)*, its cyclized further reaction product *(63)* is formed immediately; both ArO groups in this product can be replaced *e.g.* by amine [to form *(64)*][30].

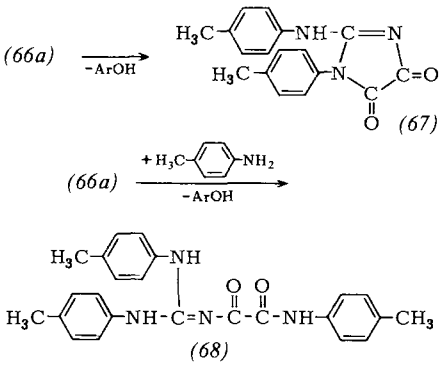


(58) + NH_3 → $(NH_2)_2$-C=N-C(=O)-C(=O)-N=C-OAr *(61a)*

(61a) → *(63)* (+2 R''_2NH, -2 ArOH)

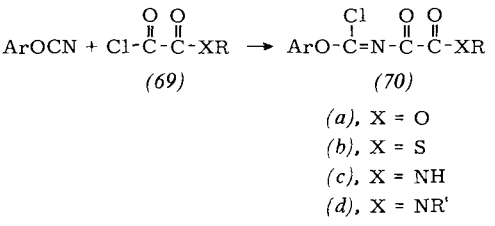
(63) → *(64)* (+2 R''_2NH, -2 ArOH)

Some reactions with (59):



Hydrolysis and reaction with amines lead to the products *(65)* and *(66)* respectively[30,31].

ArO-C(=O)-NH-C(=O)-C(=O)-OH *(65)*

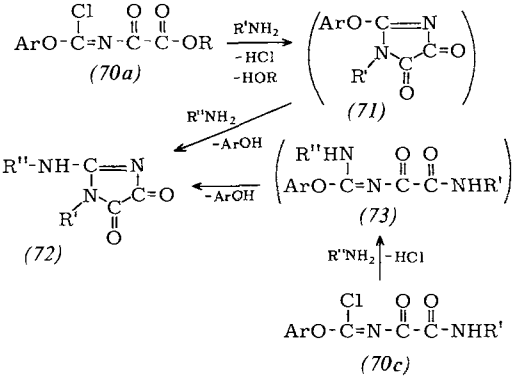


ArO-C(=N-C(=O)-C(=O)-N(R')R'')-C=N *(66)*

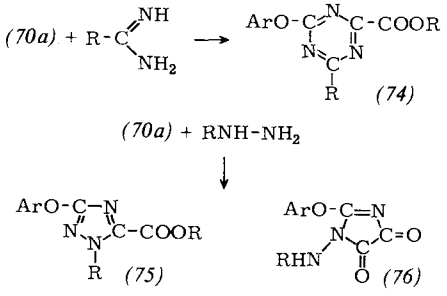
Here we have another example of a follow-on reaction that proceeds immediately: With primary amines (*e.g. p*-toluidine), in addition to *(66a)* [=*(66)* with R′=H, R″=4-CH_3—C_6H_4—], products are also formed in which the ArO residue is immediately displaced, either by cyclization to form *(67)* or by exchange with a further mole of amine to form *(68)*[30].

1.1.5. Addition of Oxalic Ester Chlorides, Oxalic Thioester Chlorides, and Oxalic Amide Chlorides to Cyanic Esters

The addition of *(69)* to ArOCN proceeds smoothly when the components are admixed in an inert solvent at temperatures of up to 40 °C[32].



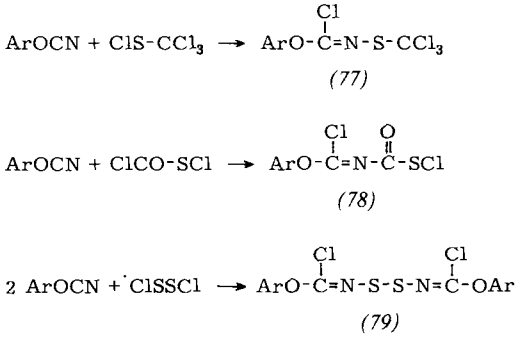
The halogen atom in *(70)*, as in the analogous compounds *(4)*, *(31)*, *(47)*, *(58)*, and *(59)*, is readily hydrolyzed, thiolyzed, and replaced by nucleophiles (amines, hydrazines, mercaptans, thiophenols, CH-acid compounds such as malodinitrile, *etc.*)[33]. Special mention will be made here only of a few direct ring closure reactions:



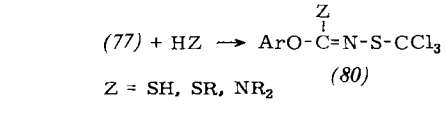
The imidazolinediones *(72)* are formed

a) from *(70a)* by replacement of the Cl with primary amine, cyclization with elimination of the ester alcohol ROH and displacement of the ArO residue by a further mole of amine [*(71)* not isolable, so R′=R″ in every case];

b) from *(70c)* by substitution of the halogen with amine followed by cyclization with removal of ArOH (in this case R′≠R″ is possible).

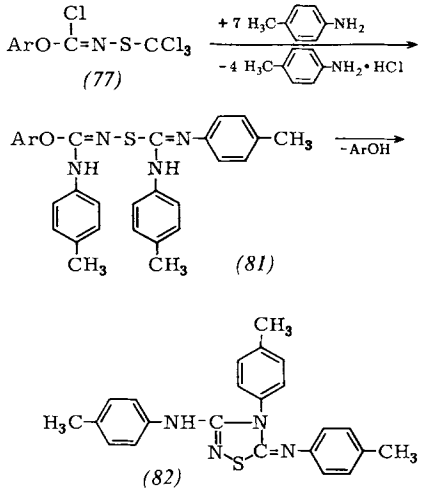


Amidines react with *(70a)* to give only the *s*-triazinecarboxylic esters *(74)*[20], whereas with hydrazines *(70a)* is converted in moderate yields partly with elimination of HCl and H_2O into the triazolecarboxylic acids *(75)*, and partly with elimination of HCl and ROH into the *N*-aminoimidazoledione derivatives *(76)*.



1.1.6. Addition of Sulfenyl Halide Derivatives to Cyanic Esters[34-36]

ClCO—SCl does not add to the OCN group *via* the sulfenyl chloride grouping [to form *(78)*][37], but it is mentioned here because of its similarity to the other compounds. The three classes of compounds *(77)* to *(79)* are formed in very good yields when the components are heated in inert solvents to temperatures of 30 to 80 °C. The compounds *(77)* can generally be distilled under vacuum, whereas *(78)* and *(79)* decompose on distillation. When they are oily they are subjected to further reaction as crude products; the crystalline products *(78)* and *(79)* can be purified by recrystallization. The storage life of both classes of substances is limited as they slowly decompose on standing.



Reactions with (77)[37]:

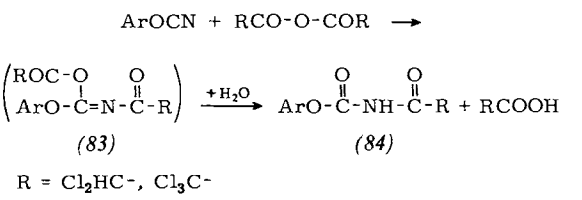
The —S—CCl_3 residue is removed on hydrolysis. The carbamate ArO—CO—NH_2 is obtained. On the other hand, the molecular structure remains intact on replacement of the imidoyl chloride halogen by a number of other nucleophiles [to form *(80)*]:

With primary aromatic amine (*p*-toluidine), even the CCl_3 halogens are replaced. The reaction leads in good yields

to *(81)*, which cyclizes even on slight heating in solution to form the thiadiazole derivative *(82)*.

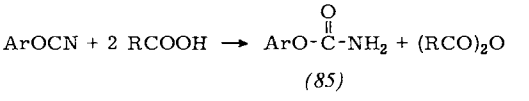
Two comments are in place with regard to Sections 1.1.1 to 1.1.6:

1. The foregoing summary is intended to give a general picture of the possible reactions of cyanic esters with acyl halides and of the wide uses of the resulting products, particularly for the synthesis of heterocycles. For this reason it included neither all the acylating agents that have been added to cyanic esters nor all the further reactions of the various *N*-acylation products.



2. Disubstituted cyanamides can be *N*-acylated in the same way as the cyanic esters. The classes of substances analogous to the compounds *(31)*[38], *(47)*[39], *(59)*[40], *(70)*[41], *(77)*[42], and *(78)* with the R_2N residue instead of ArO have been obtained in good yields. The description of the further reactions of these *N*-acyliminocarbonic amide chlorides would take as much space as the above. It will therefore merely by pointed out that in nearly every instance the reactions proceed in the same manner as in the case of the Ar—O analog, including the observed heterocycle syntheses. As far as possible the reaction products are included in the tables at the end.

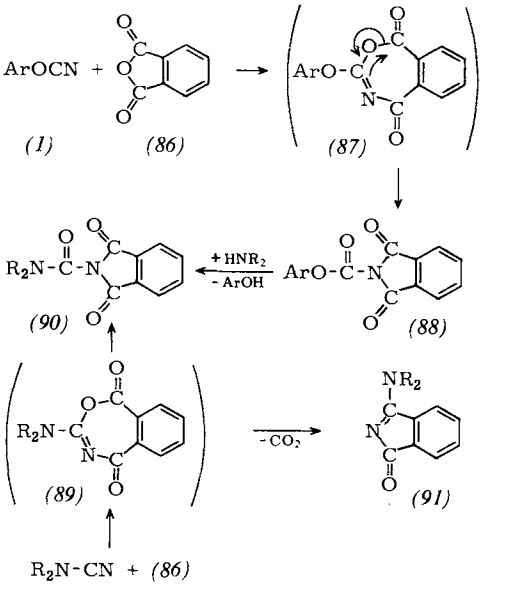
The *N*-acylation of the thiocyanic esters is more difficult, but has been achieved in some cases ($ClCOCH_3$, ClCOCOCl).



1.2. Reaction with Acid Anhydrides

1.2.1. Anhydrides of Unsubstituted Aliphatic or Aromatic Monocarboxylic Acids

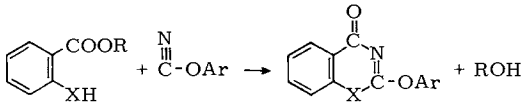
Cyanic esters do not react with these compounds[43]. On the other hand, anhydrides of particularly acidic carboxylic acids (Cl_2HC—COOH; CCl_3COOH) add in the same way as the acyl chlorides to the nitrile group of the cyanic esters. It was not possible to obtain the primary adducts *(83)* in the pure state, since they are strong acylating agents, and as such they immediately acylate traces of water to form the carboxylic acid and decompose on distillation. The *N*-acylated carbamates *(84)* were isolated in good yields.



With cyanic esters, the carboxylic acids formed are converted back into their anhydride with simultaneous carbamate formation *(85)*[43].

1.2.2. Anhydrides of Aromatic and Cycloaliphatic *o*-Dicarboxylic Acids

These compounds react directly with cyanic esters to form cyclic *N*-aryloxycarbonyldicarboximides. The reaction probably again proceeds *via* a primary *N*-acylation of the —O—C≡N group. The intermediate *(87)*, which cannot be isolated, is stabilized by intramolecular transacylation to form *(88)*[44,45]. Evidence pointing to the seven-membered ring as an intermediate is the isolation of the by-product *(91)* in the reaction of cyanamides with *(86)* to form *(90)*, which proceeds in an exactly analogous manner[46]. The formation of *(91)* is easily explained by elimination of CO_2 from *(89)*. *(88)* can react with amine, with displacement of the ArO residue, to form *(90)*.

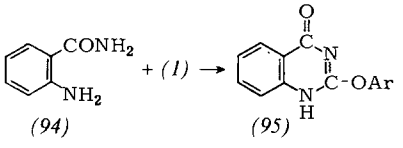


2. Further Heterocycle Syntheses with Cyanic Esters

2.1. *o*-Bifunctional Benzene Derivatives as Reactants

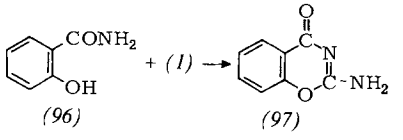
2.1.1. Aromatic *o*-Hydroxy-, *o*-Mercapto-, and *o*-Aminocarboxylic Acid Derivatives

As was reported earlier[47], the reactions of *o*-hydroxy-, *o*-mercapto-, and *o*-aminocarboxylic *esters (92)* with



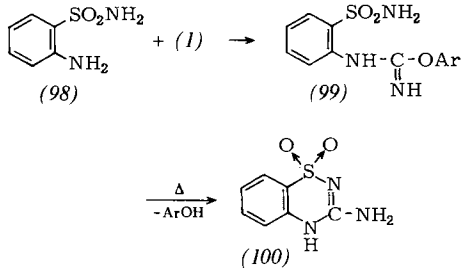
cyanic esters proceed in the same manner with elimination of the ester alcohol to form the 2-aryloxy-4*H*-1,3-benzoxazinones, -benzothiazinones, and -quinazolones *(93)*.

(92) *(1)* *(93)*



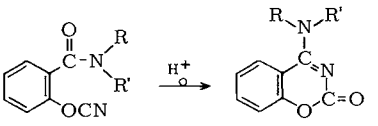
X = O, S, NH

The amides, on the other hand, react differently. Only anthranilamide *(94)* reacts in the same way as the esters, with loss of NH_3 to form the 2-aryloxyquinazolone *(95)*.



(94) *(95)*

In the case of salicylamide *(96)*, on the other hand, ring closure takes place with loss of the aryloxy residue and incorporation of the amide NH_2 group into the ring. The product is *(97)*.

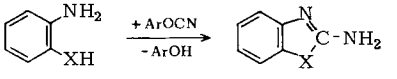


(96) *(97)*

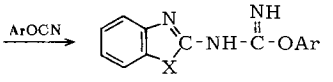
Similar behavior is observed for *o*-aminobenzenesulfonamide *(98)*, which forms the amino heterocycle *(100)* *via* the isolable primary addition product *(99)*[48]. In both cases the cyanic ester functions only as a C≡N group donor.

(98) *(99)* *(100)*

Mention should also be made of the rearrangement of the salicylamide cyanates *(101)*, derived from secondary amines in nonaqueous solvents under the catalytic influence of protons and Lewis acids, which leads to the 4-amino-1,3-benzoxazin-2-ones *(102)*[49].

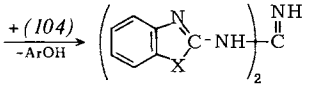


R, R' ≠ H



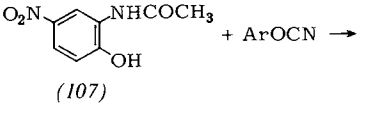
(101) *(102)*

2.1.2. *o*-Hydroxy-, *o*-Mercapto-, and *o*-Aminoanilines

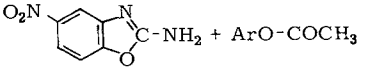


The aminoheterocycles *(104)* are obtained from *(103)* and ArOCN in an exhothermic reaction even at room temperature. *(105)* and *(106)* sometimes occur as further reaction products. As in the formation of *(97)* and *(100)*, the cyanic esters function here as CN group donors (cf. Introduction, basic reaction type B). The transferred cyano group is incorporated in such a way that it is found in the $\geq C-NH_2$ grouping of the ring closure product. If the group $\geq C-NH_2$ is lacking for the formation of a heterocycle, the use of cyanic esters for its introduction can generally be recommended (cf. Section 2.1.3.).

(103), X = O, S, NH *(104)*



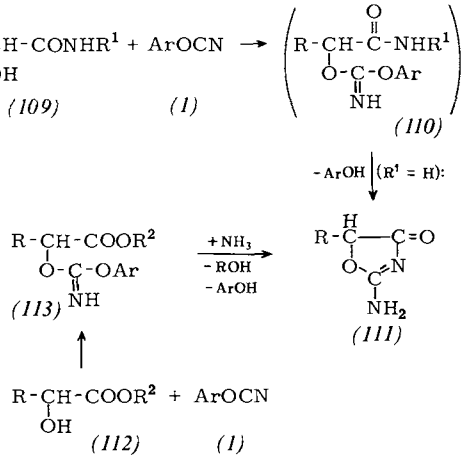
(105)



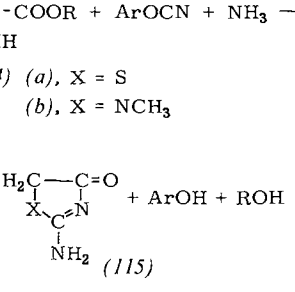
(106)

The influence of acylation of the NH_2 group on the course of the reaction has been investigated for *(107)*. The *N*-acyl group does not prevent the ring closure to form *(108)*; it is eliminated. In anhydrous media it acylates the liberated phenol.

(107)



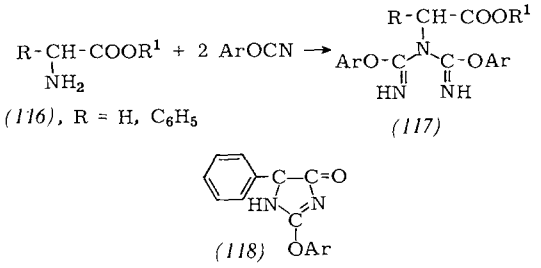
(108)



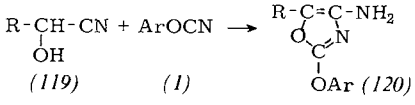
2.2. Aliphatic Carboxylic Acid Derivatives with a Functional Group in the α-Position as Reactants

2.2.1. α-Hydroxy-, α-Mercapto-, and α-Aminocarboxylic Esters and Amides

At room temperature, mandelamide *(109)*, $R=C_6H_5$, $R^1=H$, reacts immediately with cyanic esters in the presence of NaOH to form the aminooxazolone *(111)*, $R=C_6H_5$[50]. The reaction probably proceeds *via* the unisolated intermediate *(110)*, since the addition of cyanate to carboxamides under such mild conditions has not so far been observed in any other case. With *N*-ethylmandelamide *(109)*, $R=C_6H_5$, $R^1=C_2H_5$, the final product of the reaction is *(110)*, $R=C_6H_5$, $R^1=C_2H_5$. It was not possible to force a ring closure.

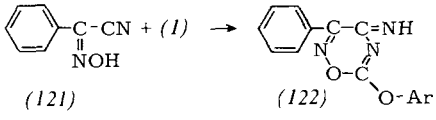


(111) is also formed in good yields when the reaction solution from the ester *(112)* and *(1)* is poured into ammonia water[50]. With mercaptoacetic esters *(114a)*, cyanic esters, and ammonia, on the other hand, the corresponding thiazole *(115a)* is formed only in very low yield.



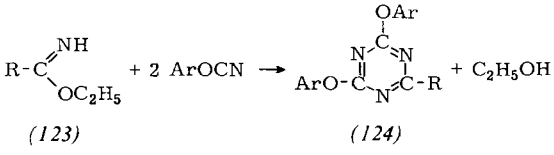
When subjected to the same procedure α-(methylamino)-acetic esters *(114b)* also undergo ring closure in satisfactory yields to give *(115b)*.

On the other hand, the NH_2 group in α-aminocarboxylic esters *(116)* behaves as a primary amine and immediately adds 2 moles of cyanate to form *(117)*. In the case of $R=C_6H_5$, *(118)* was also isolated with alcohol as the solvent.

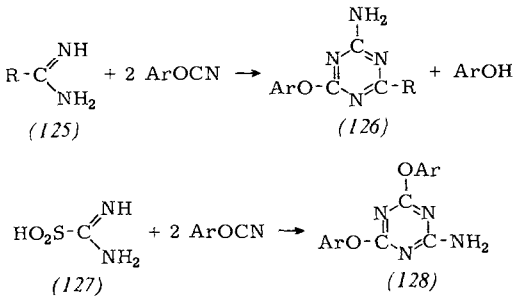


2.2.2. α-Hydroxybenzonitrile and α-Hydroxyiminobenzonitrile

Mandelonitrile *(119)* and cyanic esters *(1)* react directly in the presence of triethylamine to form the aminooxazole *(120)*, a surprisingly unstable compound, which rapidly yellows and decomposes even after immediate purification by recrystallization.



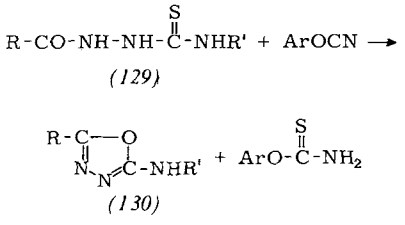
α-Hydroxyiminobenzonitrile *(121)* and *(1)*, again in the presence of triethylamine, react quantitatively to give the oxadiazine derivative *(122)*, which slowly decomposes on standing.



2.3. Iminocarboxylic Acid Derivatives and Reactants

Imino ethers *(123)* react immediately with 2 moles of ArOCN *(1)*, in all mixing ratios, to give the *s*-triazines *(124)*. Both molecules of *(1)* are incorporated, while the C_2H_5O group of the imino ether is removed[51].

In the reaction of the amidines *(125)* to form *(126)*, on the other hand, 1 mole of ArOCN is incorporated, while the second mole merely transfers its CN group[52]. An exception is the special "amidine" *(127)*, which loses its SO_2H group on ring closure to form *(128)*.



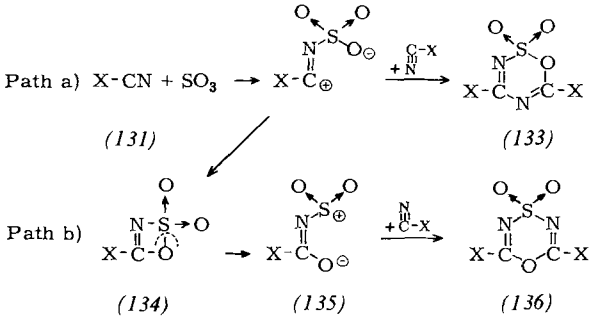
(125) (126)

(127) (128)

2.4. Ring Closure by Removal of H_2S with ArOCN

Cyanic esters function only as H_2S acceptors in the reaction with *N*-acylthiosemicarbazides *(129)*. After the removal of H_2S, the residual molecule is stabilized by ring closure to form the aminooxadiazole *(130)*[53].

(129)



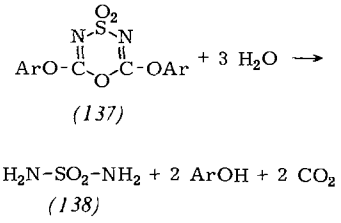
(130)

2.5. Ring Closure by 1,4-Dipolar Cycloaddition

The possibilities of using cyanic esters as dipolarophiles in 1,3-dipolar cycloadditions have already been exhaustively described[1, 2a].

An example showing the ability of cyanic esters to react as in a 1,4-dipolar cycloaddition is the reaction with SO_3. The dipole is first formed by addition of SO_3 to 1 mole of ArOCN, and it then reacts with a second mole of ArOCN as the dipolarophile. There are two possibilities for the structure of the final product:

In the reaction of benzonitrile *(131)*, X=C_6H_5, with SO_3, the unsymmetrical oxathiadiazine *(133)* is formed by path a)[54], whereas cyanogen chloride *(131)*, X=Cl, and SO_3 react by path b), which was formulated by *Huisgen*, to give the symmetrical isomer *(136)*[55].



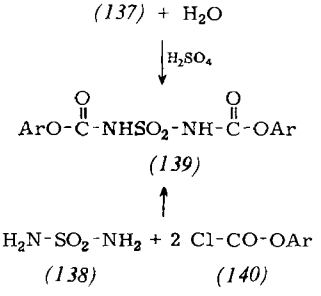
(131) (133)

(134) (135) (136)

The following findings[57] confirm that the reaction of cyanic esters with SO_3 proceeds *via* path b) and leads to the symmetrical compounds *(137)*, X=ArO[56]:

a) In the reaction of cyanamides *(131)*, X=NR_2, with SO_3[58], both isomers *(133)* and *(136)* were formed in one case [X=$N(CH_3)_2$][59]. It was thus possible to assign the products to the alternative structures (substance giving fewer IR bands has the symmetrical structure). An oxathiadiazine obtained on replacement of the two ArO residues in the product from ArOCN and SO_3 by —$N(CH_3)_2$ was identical with the symmetrical one *(136)*, X=$N(CH_3)_2$, of the two cyanamide reaction products.

b) Mild alkaline hydrolysis (milk of lime, 40 °C) led quantitatively to *(138)*.

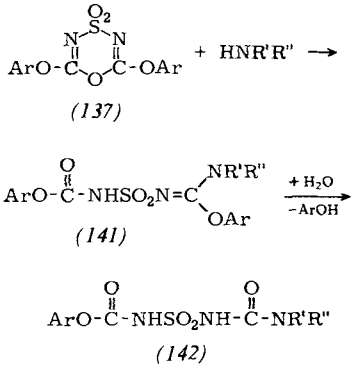


(137)

$H_2N-SO_2-NH_2$ + 2 ArOH + 2 CO_2

(138)

c) Acid hydrolysis (96% H_2SO_4) leads to *(139)*, the structure of which was verified by independent synthesis from *(138)* and *(140)*.

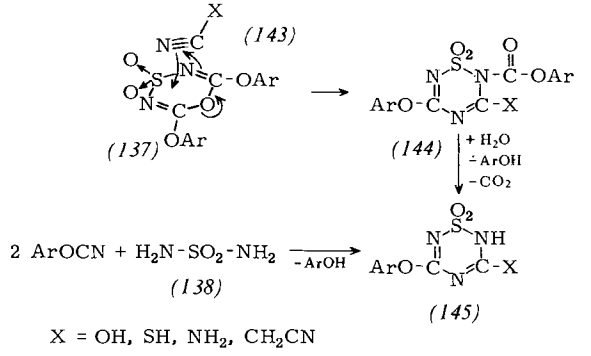


(138) (140)

(139)

Further reactions with (137):

Replacement of the aryloxy groups by —$N(CH_3)_2$ with retention of the ring structure in the reaction of *(137)* with dimethylamine [cf. a) above] is an exception. Amines generally add to one of the C atoms in *(137)*, and ring cleavage occurs to give *(141)*[60], which can be hydrolyzed to *(142)*. One of the aryloxy residues of *(141)* is exchanged against a second mole of amine only at higher temperatures.

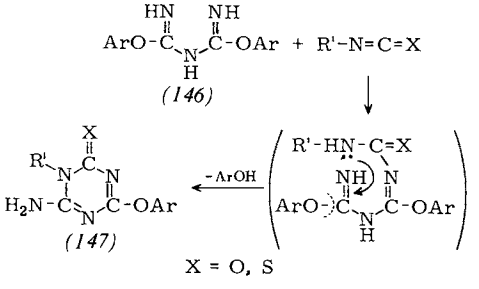


(137)

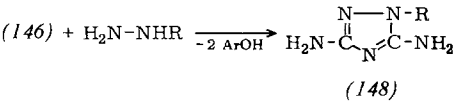
(141)

(142)

Compounds *(143)*, X=OH, SH, NH_2, CH_2CN, containing a nitrile group react in the form of their alkali metal salts with *(137)* in very good yields even at room temperature. They are formally inserted between C and N of the oxathiadiazine ring, in such a way that a new thiatriazine system *(144)* is formed on ring cleavage[59]. With X=OH, NH_2, and CH_2CN the reaction stops at compound *(144)*, while with X=SH the hydrolysis product *(145)* is formed immediately[59]. Another route to *(145)* with X=NH_2 is the reaction of ArOCN with sulfodiamide *(138)*[61].



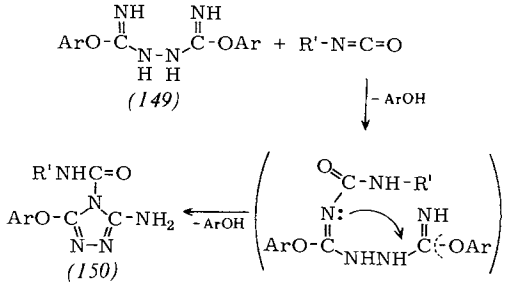
2.6. Heterocycle Syntheses with Further Reaction Products of Cyanic Esters



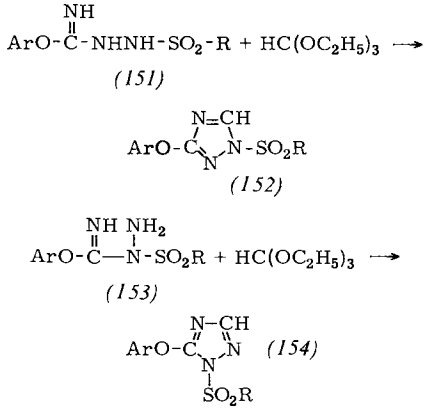
A number of heterocycle syntheses that became available through further reaction products from cyanic ester chemistry will be mentioned in conclusion.

2.6.1. From the 2:1 Addition Product *(146)* of ArOCN with NH_3

Even at room temperature the *s*-triazine derivatives *(147)* are formed directly in an exothermic reaction from *(146)* and isocyanates or isothiocyanates[62,63]



With hydrazines, again at room temperature, both ArO residues are exchanged to form *(148)*.



2.6.2. From the 2:1 Addition Product *(149)* of ArOCN with NH_2—NH_2

The triazoles *(150)* are obtained from the components only at temperatures above 100 °C. The yields are good[64].

2.6.3. From the Addition Products *(151)* and *(153)* of ArOCN with Sulfonohydrazide[65]

When *(151)* or *(153)* is heated in boiling ethyl orthoformate, the triazole *(152)* or *(154)* is formed. The yields are best if the alcohol formed is distilled off during the reaction[66].

2.6.4. From the Addition Product *(155)* of ArOCN with Cyanamide

As in most iminocarboxylic acid derivatives (cf. Section 2.6.1), the aryloxy residue in *(155)* can be replaced by nucleophiles. Stirring with hydrazines at room temperature leads smoothly to the cyanoaminoguanidines *(156)*, which cyclize to form *(157)*, in some cases on prolonged standing (R=H) and in others when heated (R=alkyl, aryl).

Reactions of Electron-Rich Olefins with Proton-Active Compounds

By Jürgen Hocker and Rudolf Merten[*]

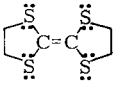
Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

Proton-active substances react with certain electron-rich olefins with cleavage of the central C=C double bond to give compounds that can be formally regarded as insertion products of nucleophilic carbenes. If they satisfy certain structural conditions, they isomerize with β elimination to give open-chain compounds. Both CH-acidic compounds and compounds containing NH or OH groups can undergo this reaction. The mechanisms are discussed, and the importance of the intermediate products to biochemistry (thiamine, tetrahydrofolic acid) is indicated.

1. Introduction

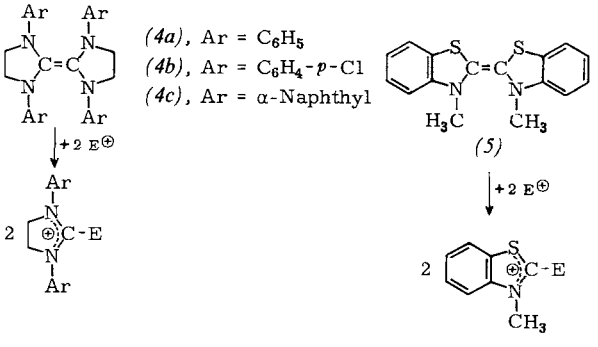
The reactivity of the central C=C double bond in tetracyanoethylene *(1)* is determined by the influence of the four electron-attracting groups. The electron-poor double bond exhibits strongly electrophilic character[1,2].

Olefins *(2)* with four electron-donating substituents, on the other hand, react as strong nucleophiles. These compounds are referred to as *electron-rich olefins*[**][3-6].



(1) *(2)*

A, B = NR_2, OR, SR.



A and B not both SR

The ability of the substituents A and B to supply electrons increases in the order SR < OR < NR_2. Whereas tetraaminoethylenes are very reactive, strongly nucleophilic compounds, tetramercaptoethylenes exhibit only weak reactivity toward electrophiles. For example, they dissolve in concentrated sulfuric acid and are reprecipitated unchanged on dilution[8]. An extended Hückel calculation shows that the charge density on the sulfur in *(3)* is greater than that on the olefinic C atom. Electrophiles are therefore directed to the sulfur and not to the double bond; the chemical behavior of the tetramercaptoethylenes does not agree with that of an electron-rich olefin.

(3)

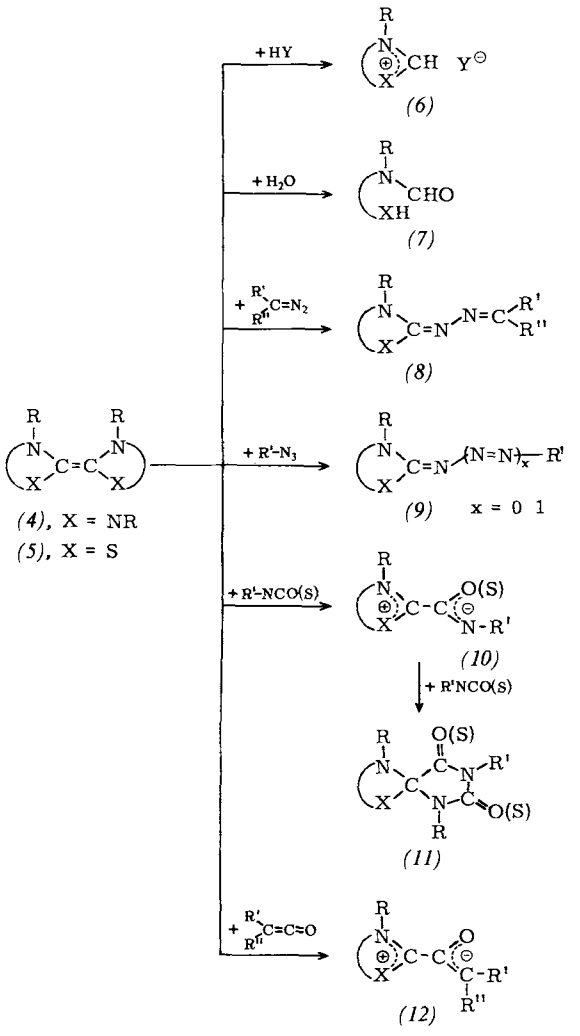
Electron-rich olefins of the type *(4)* or *(5)* react with electrophiles ($E^{\oplus}$) preferentially with cleavage of the central C=C double bond. The obvious assumption that the olefins dissociate[9,10] into two resonance-stabilized carbenes was not confirmed by crossover experiments[11,12].

(4a), Ar = C_6H_5
(4b), Ar = C_6H_4-*p*-Cl
(4c), Ar = α-Naphthyl

(5)

Nevertheless, electron-rich olefins represent a source of nucleophilic carbenes[*][11,13].

Characteristic reactions of the olefins of types *(4)* and *(5)* with electrophiles that proceed *via* cleavage of the molecule are those with mineral acids to form the azoli(ni)um salts *(6)*[6,13-15], hydrolysis to form *N*-formyl compounds *(7)*[6,16], reactions with diazo compounds to form azines *(8)*[17-20], with azides to form monoaza and/or triaza compounds *(9)*[12,21,22], with iso(thio, seleno)cyanates to form stable dipoles *(10)* or (thio, seleno)hydantoin derivatives *(11)*[22-26], and the reaction of *(4a)* with ketenes, which also gives stable dipoles *(12)*[19,27,28].



Reactions of olefins of types *(4)* and *(5)* with proton-active compounds are discussed in detail below. The products nearly always contain one "carbene" half of the original ethylene molecule. They are formally products of the insertion[**] of a nucleophilic carbene into an XH bond, possibly with formation of a new C—C, C—N, or C—O bond in addition to a new CH bond.

[*] Dr. J. Hocker and Dr. R. Merten
Wissenschaftliches Hauptlaboratorium der
Bayer AG
509 Leverkusen-Bayerwerk (Germany)

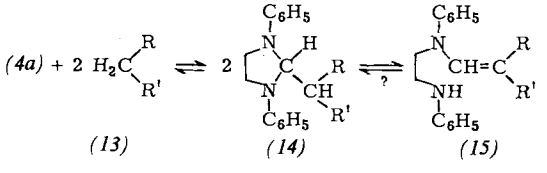
[**] The term "electron-rich olefins" is sometimes also applied to ketene (thio)acetals or aminals, in which the π-electron density of the C=C double bond is also greater than 1.0 [7].

[*] The occurrence of *free* nucleophilic carbenes has not yet been definitely established.

[**] The expression "insertion product" carries no implications regarding the mechanism of the reaction.

2. Reactions with Formation of a New C—C Bond

2.1. With Aliphatic CH-Acidic Compounds (Table 1)



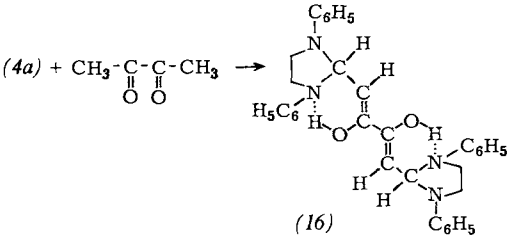
The first reactions of an electron-rich olefin, *i.e.* 1,1',3,3'-tetraphenyl-2,2'-biimidazolidinylidene *(4a)* with CH-acidic compounds *(13)* were described by *H.-W. Wanzlick*. Two types of products can be formed in these reactions:

1. a primary product *(14)*, which may be thought of as resulting from the insertion of a nucleophilic carbene into an activated CH bond, and, in some cases,

2. a further reaction product *(15)*, which is formed from *(14)* by β elimination.

(4a) does not react with α-picoline and valeronitrile at 180 °C[30].

The rate of the reaction of *(4a)* with *(13)* increases with the acidity of the proton-active compound. If a mixture of



(13) *(14)* *(15)*

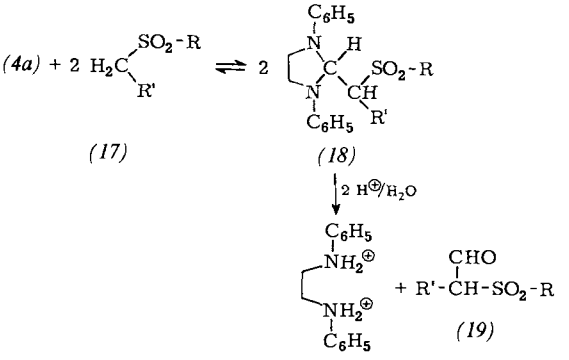
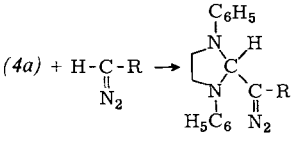
(m) 5,6-Benzomorpholin-3-one	70	—	[31]



benzyl cyanide *(13h)* and ethyl phenylacetate *(13g)* is allowed to act on *(4a)*, only the benzyl cyanide reacts[30], in agreement with known acidity series.

Biacetyl, which has two activated methyl groups, reacts *via* both to give a yellow compound *(16)*. Spectroscopic data indicate the presence of a double enol chelate. An isolable red-violet complex is obtained with iron(III) chloride[31].

(16)

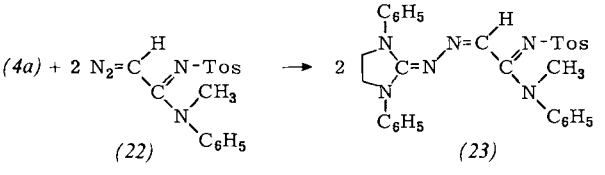


The 2-substituted imidazolidines *(18a)* to *(18f)* were obtained exclusively on reaction of SO_2-activated methylene compounds *(17a)* to *(17f)* with *(4a)*[32]. This reaction can be used for the synthesis of α-sulfonyl aldehydes *(19)*, since acidic hydrolysis of the aminals *(18)* leads to the carbonyl compounds from which they are derived[32].

(17) *(18)* *(19)*

(17)	R	R'
(a)	CH_3	H
(b)	n-C_4H_9	H
(c)	C_6H_5	H
(d)	$C_6H_4CH_3$-(*p*)	H
(e)	C_6H_4Cl-(*p*)	H
(f)	R + R' = —$(CH_2)_3$—	

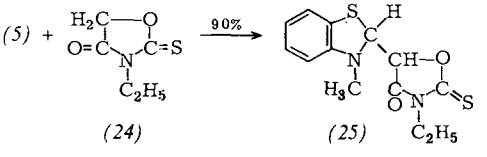
Diazo compounds *(20)*[33-35] containing mobile diazomethyl hydrogen also give 2-substituted imidazolidines *(21)* on reaction with *(4a)*[19]. Ring cleavage with β



(20) *(21)*

(a), R = $COOC_2H_5$
(b), R = $COOC_4H_9$-*(t)*
(c), R = $CON(C_2H_5)_2$

(d), R = CON⟨ ⟩

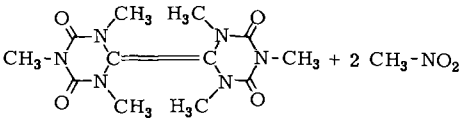


(e), R = $CO—C_6H_5$
(f), R = $PO(C_6H_5)_2$
(g), R = $C_6H_4NO_2$-*(p)*

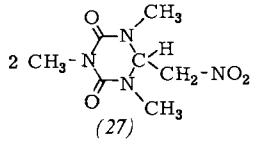
elimination is ruled out here for structural reasons. Diazo compounds having an immobile diazomethyl proton react in the same way as the disubstituted diazomethanes to give azines[17-20]. An example is the compound *(22)*, in which the acidity of the diazomethyl proton is insufficient for the formation of a diazoaminal *(21)* because of the weak activating effect of the amidine group. Electrophilic attack of the terminal N atom on the double bond of *(4a)* followed by cleavage of the molecule yields the azine *(23)*[19].

(22) *(23)*

Very few reactions of other electron-rich olefins with CH-acidic compounds involving cleavage of the molecule and formation of a new C—C bond have been investigated. The use of *(5)* instead of *(4a)* should merely lead to a change in the reaction rate, but apart from the reaction of *(5)* with 3-ethyl-2-thioxooxazolidin-4-one *(24)* to form



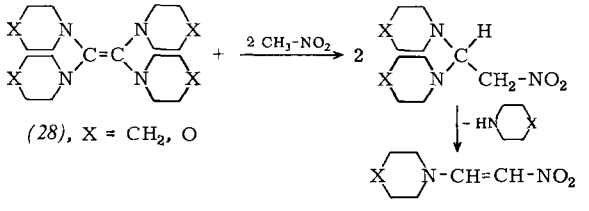
(24) *(25)*



(25)[13], no reactions of this olefin with CH-acidic compounds are known.

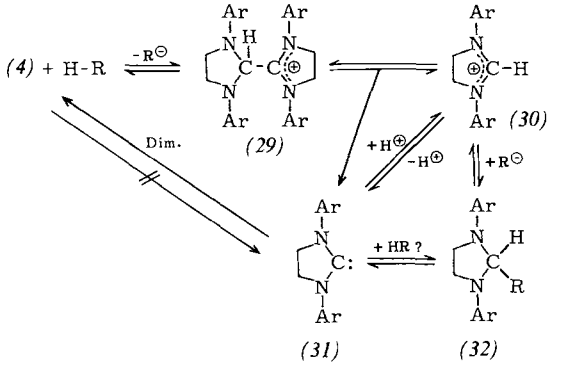
1,1',3,3',5,5'-Hexamethyl-6,6'-bi-(1,3,5-triazinylidene)-2,2',4,4'-tetraone *(26)* reacts with nitromethane to give a "CH insertion product" *(27)*[15].

The unbridged electron-rich olefins tetramorpholinoethylene and tetrapiperidinoethylene *(28)* react with nitromethane with elimination of morpholine or piperidine in a



(26)

(27)

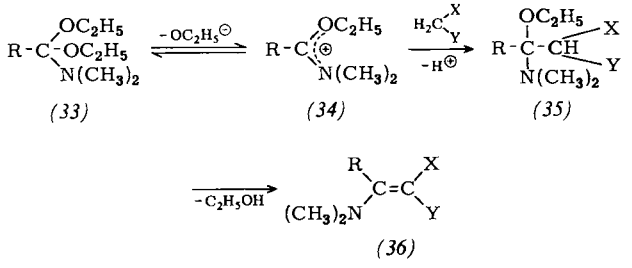


reaction sequence analogous to *(13)*→*(14)*→*(15)* to give enamines[35a].

(28), X = CH_2, O

2.1.1. Mechanistic Considerations

The CH acidity of the proton-active compounds and the fact that electron-rich olefins are strong π bases justify the assumption that the reactions are initiated by protonation of the electron-rich double bond of *(4)* to form *(29)*. Decomposition of *(29)* affords the imidazolinium cation *(30)* and a nucleophilic carbene *(31)*[11]. Direct addition of the anion R^- to *(29)*, as detected by *Hoffmann* and

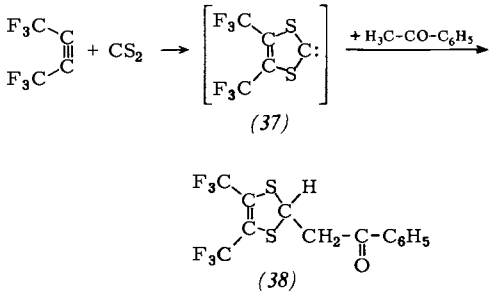


(29) *(30)* *(31)* *(32)*

Gehlhaus[36] in the reaction of tetramethoxyethylene with malodinitrile, has not been observed in the reactions of *(4)*. The cation *(30)* now attacks R^- or RH electrophilically and gives *(32)*. This step is plausible in view of the reactions of azoli(ni)um salts with bases in the presence of CH-acidic compounds, which also yield CH insertion products. For example, 3-methylbenzothiazolium iodide reacts with *(24)* in the presence of Na methoxide to give *(25)* in 71% yield[13].

The mechanism is also supported by the reactions of the amide acetals *(33)*[37] with CH-acidic compounds, which probably proceed *via* carbonium ions *(34)*. The dissociation *(33)*⇌*(34)* is very fast even at −50 °C, as is shown by NMR studies on exchange experiments with *N,N*-dimethyl-

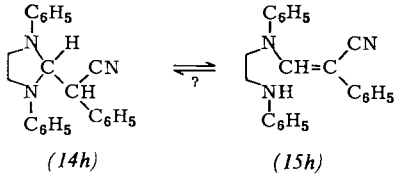
formamide dimethyl acetal[38,39]. The aminomethylene compound *(36)* is obtained with elimination of 2 moles of ethanol.



(33) *(34)* *(35)* *(36)*

The nucleophilic carbene *(31)* formed as an intermediate in the reaction *(29)*⇌*(30)* can react in two ways:

1. Dimerization to give the starting olefin *(4)*. This step is irreversible, as is shown by crossover experiments[11,12]. The olefin can take part in the reaction again.



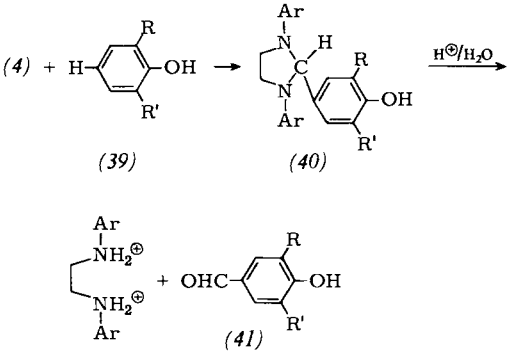
2. Protonation to give the imidazolinium cation *(30)*. This step is reversible, as was shown by H-D exchange experiments on the C-2 atom of imidazoli(ni)um or thiazolium salts[40–49]. *Hartzler*[50] was able to show in the reaction of the dithiocarbene[*] *(37)* with acetophenone to form *(38)* that a carbene formed as an intermediate reacts directly with a CH-acidic compound to give the CH insertion product.

(37) *(38)*

The overall reaction *(4)*⇌*(32)* is reversible, as was shown by *Wanzlick*[30]. Thus when *(14a)* is heated at 130 °C and 14 torr, it is converted back into the starting olefin *(4a)*.

In the reaction of an active methyl or methylene compound with *(4a)*, two products, *(14)* and *(15)*, are possible. The reaction of *e.g. (13h)* with *(4a)* leads to a colorless substance *(14h)*, whose IR spectrum contains no NH absorption[30]. Under certain conditions, however, *(15h)* can be detected as well as *(14h)* in the NMR spectrum[31].

(14h) *(15h)*

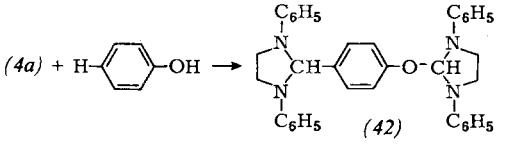


[*] It should be noted, however, that dithiocarbenes react mainly electrophilically [51]. For the reaction of dithiolium salts or dithiocarbenes with CH-acidic compounds, cf. also [52]. For the reaction of an intermediate diaminocarbene with a CH-acidic compound, cf. [26].

This product appears to result from a ring-chain tautomerism, which has not yet been investigated in detail.

The reaction of 4-nitrophenylacetonitrile with *(4a)* leads to a 70% yield of *(15i)*, which shows no tendency to undergo ring closure either in the crystalline state or in solution[31].

2.2. With Aromatic Compounds



Only preliminary studies have so far been carried out on the reactions of electron-rich olefins with phenols, the examples studied being *(4a)* and *(4b)*. *o,o'*-Disubstituted phenols *(39)* give the compound *(40)* in good yields[31]. These products are cyclic aminals, and they can be hydrolyzed with hydrochloric acid to give high yields of *p*-hydroxybenzaldehydes *(41)*[31]. The introduction of formyl groups with the aid of *Wanzlick*'s olefin *(4)* is thus possible not only for aliphatic CH-acidic compounds (cf. α-sulfonyl aldehydes, Section 2.1) but also for activated aromatic compounds.

(39) *(40)* *(41)*

(40)	Ar	R	R'

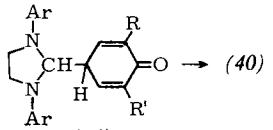
The reaction of unsubstituted phenol and *(4a)* yields a 1:1 adduct, which probably has the structure *(42)*:

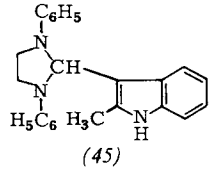


(42)

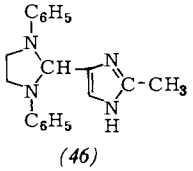
The *mechanism* differs only in the further reaction from that of the reactions of aliphatic CH-acidic compounds with electron-rich olefins. The first step is probably again the protonation of the electron-rich double bond of the olefin to give *(29)* by the proton of the hydroxyl group. *(29)* decomposes into the imidazolinium cation *(30)* and a nucleophilic carbene *(31)*, which can either dimerize to give the starting olefin or can take part in the reaction as

such. The cation *(30)* reacts first with the phenoxide anion[*], probably at the point of highest electron density[**], *i.e.* the oxygen, with reversible formation of the "OH insertion product" *(43)* (cf. Section 4.2), which reacts further *via (44)* to give the thermodynamically more stable ring-substituted product *(40)*.

(30) *(43)*



(44)



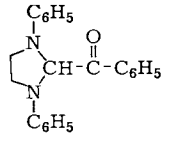
When 2,6-disubstituted phenol *(39c)* deuterated in the hydroxyl group is allowed to react with *(4a)*, a product *(40c)* deuterated in position 2 of the imidazolidine ring should be expected according to this mechanism. However, the deuterium content actually found[31] in position 2 is only about 60%; this is probably due to a fast H-D exchange between the phenol group of the *(40c)* formed and the imidazolinium cation *(30)*.

No reaction with *(4a)* was achieved either with phenetole [no possibility of protonation of the electron-rich double bond of *(4a)*] or with 2,4-di-*tert*-butyl-4-methylphenol (no possibility of electrophilic substitution on the aromatic ring)[31].

Heterocycles containing NH can also form "insertion products" under certain conditions. *(4a)* reacts with 2-methyl-2,3-dihydroindole to form an "NH insertion product" *(59d)* (cf. Section 3.1). The "CH insertion product" *(45)* is obtained, on the other hand, with 2-methylindole[31]. 2,3-Dimethylindole is inert toward *(4a)* under the usual reaction conditions (up to 70 hours in boiling toluene).

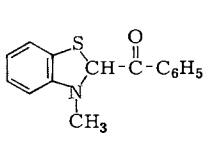
(45)

(46)



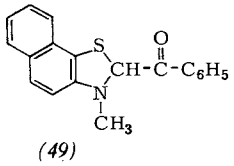
2-Methylimidazole also gives a "CH insertion product" *(46)*, whereas 1-methylimidazole and 1,2-dimethylimidazole do not react with *(4a)*[31]. It follows that in addition to an NH proton [for protonation of the double bond in *(4a)*], another active center must also be present (for the electrophilic substitution). The reaction mechanism is probably analogous to that of phenols.

[*] For the reaction of a dithiocarbene with phenols, cf. [50].

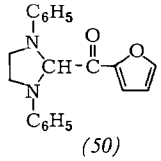


[**] It is possible that *(30)* attacks the *para* position of the phenoxide anion directly in the case of phenols with strong steric hindrance, such as *(39c)*, with formation of *(44)*.

2.3. With Aldehydes

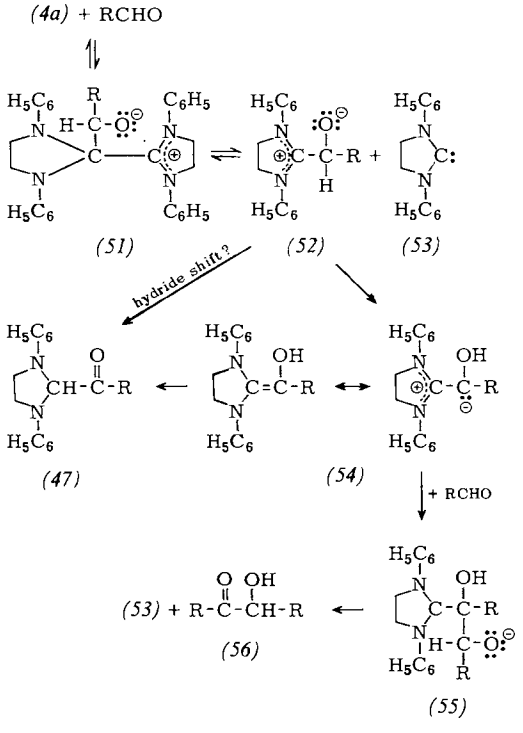


Though aldehydes are not proton-active compounds, their reactions with electron-rich olefins will be discussed here, since the products can also be regarded as "CH insertion products". Benzaldehyde reacts with *(4a)*[6, 9, 53], *(5)*[13, 53], and 3,3'-dimethyl-2,2'-bi(naphtho[2,1-*d*]thiazolinylidene)[53] to give the products *(47)* to *(49)*; furfural reacts with *(4a)* to form the analogous compound *(50)*[6, 29]. Benzoin and furoin are obtained as by-products, *i.e.* the electron-rich olefin or nucleophilic carbene formed *in situ* can replace the cyanide ion[54] in the benzoin condensation.



(47)

(48)

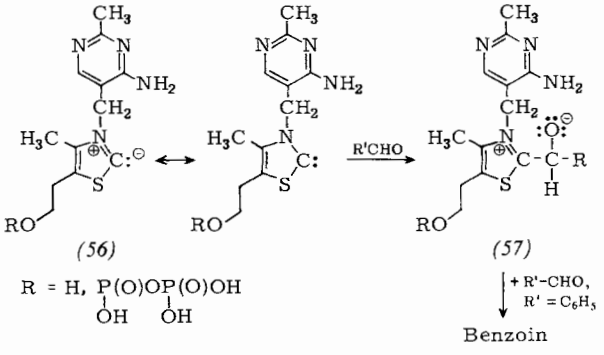


(49)

(50)

Protonation of the double bond of the electron-rich olefin can be ruled out as the initial step of this reaction, since the aldehyde proton possesses no acidity. The electrophilic

(51) *(52)* *(53)* *(47)* *(54)* *(56)* *(55)*



carbonyl carbon atom of the aldehyde probably attacks the electron-rich double bond with formation of *(51)*. A diaminocarbene *(53)* is eliminated to form *(52)*, which either

1. gives the acylimidazolidine *(47)* by a proton shift and ketonization of the enol form *(54)*[*] or

2. reacts by addition of a second aldehyde molecule to form *(55)*, which gives the acyloin *(56)* by proton migration and removal of the carbene *(53)*. The carbene *(53)* can either attack an aldehyde molecule nucleophilically on the carbonyl carbon atom to form *(52)* or can dimerize to form the starting olefin and thus undergo renewed reaction.

This mechanism of acyloin formation is similar to the classical Lapworth mechanism[54].

The carbene-catalyzed acyloin formation seems important in biochemistry. *Breslow*[55] showed in 1958 that a thiazolium zwitterion *(56)* (the limiting resonance form of a nucleophilic carbene) is responsible for the thiamine-catalyzed acyloin formation and for the formation of "active aldehydes" *(57)*. The reactions of the thiamine

zwitterion (thiamine carbene) *(56)* formed *in situ* with aldehydes[56, 57] and α-keto aldehydes[58–62], which lead to C-2-acylated thiamines, hydroxyalkyl(aryl)thiamines, or acyloins has been thoroughly investigated. Benzaldehyde is actually used as a carbene detector[63] in the reactions with 4,5-diphenyldithiolium salts. Neither the 4,5-diphenyldithiolium ion nor the carbene dimer (tetramercaptoethylene) can react with benzaldehyde, which reacts exclusively with the dithiocarbene to form 2-acyl-4,5-diphenyldithiols.

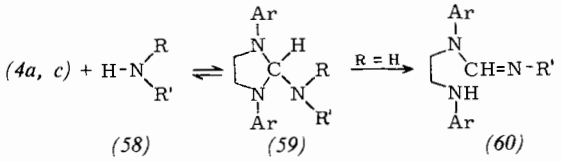
3. Reactions with Formation of a New C—N Bond

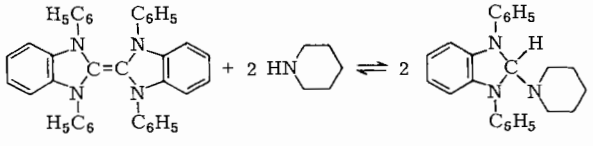
3.1. With Primary and Secondary Amines and Hydrazines (Table 2)

Aliphatic, aromatic, and heterocyclic amines react with the electron-rich olefins *(4a)* and *(4c)* with initial formation of extremely readily hydrolyzed "NH insertion products" *(59)*, which can be isolated in the case of the secondary amines, but isomerize to the aminoamidines *(60)* in the cases of primary amines and hydrazines[64].

[*] A hydride shift *(52)*→*(47)*, cf. [13, 50, 63] seems unlikely in comparison with a keto-enol tautomerism. For the formation of an enol acetate, cf. [62].

The reaction rate increases in the order aliphatic < araliphatic < aromatic amines.





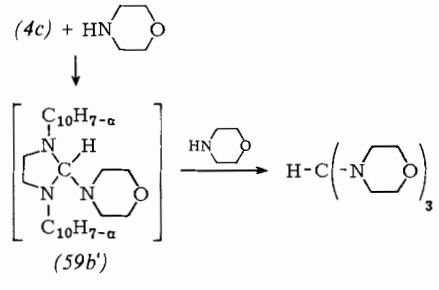


Table 2. Products *(59)* and *(60)* of the reaction of *(4a)* and *(4c)* with amines and hydrazines, respectively [64].

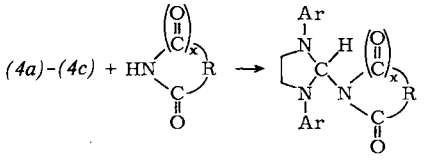
[a] Contrary to our earlier belief [19], the compound exists in the open-chain form *(60)*.



conditions for ring cleavage are satisfied. This behavior may be due to carboxamide resonance.

Carbohydrazides *(58i)* and *(58k)*, sulfonamides *(58l)* to *(58n)*, and phosphoramides or phosphonamides *(58o)* to *(58r)*, on the other hand, react *via (59)* with ring cleavage to give *(60)* (see Table 3).

Whereas the imidazolidine structure *(14)* was isolable in some cases as well as the open structure *(15)* after the reactions of active methyl and methylene compounds with *(4a)* (cf. Table 1), the reaction with compounds containing NH_2 groups leads exclusively to products having the formula *(59)* or *(60)*. The presence of a mixture of isomers has not so far been detected.

3.3. With Lactams and Imides

The tetraaminoethylenes *(4a)* to *(4c)* also react with lactams *(63)* and imides *(64)* with cleavage of the molecule

(4a)-(4c) + HN(C=O)$_x$R(C=O) → N(Ar)C(=NH)N(Ar)C(=O)$_x$R

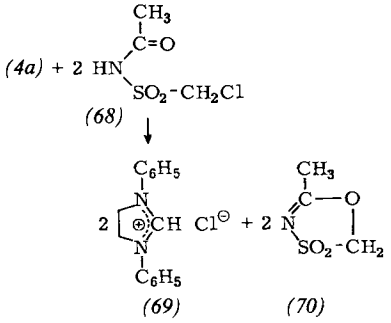
to form "NH insertion products" *(65a)* to *(65m)*. The compounds *(65a)* to *(65m)* are more resistant to hydrolysis than *(59a)* to *(59e)*.

3.4. With Strongly Acidic NH Compounds[66]

If the acidity of the NH compounds is increased by the introduction of two strongly electron-attracting groups, the reaction with *(4)* leads to the imidazolinium salts *(67)* because of the low nucleophilic strength of the amidate anion. Whereas amines activated by two carbonyl groups, such as phthalimide *(64a)*, give "NH insertion products", amines that are activated by one SO_2 group and one CO group, such as *(66a)* to *(66e)* form the salts *(67a)* to *(67f)* with *(4a)* to *(4c)*[*]. Similarly, the extremely acidic amines *(66f)* to *(66h)*, which are activated by two SO_2 groups, and the SO_2-PO activated amines *(66i)* to *(66l)* give the imidazolinium salts *(67g)* to *(67m)* and *(67n)* to *(67p)* respectively. These reactions are acid-base reactions between the strong π bases *(4a)* to *(4c)* and the strong NH acids *(66a)* to *(66l)*.



(4a)-(4c) + 2 HN(SO$_2$-R^1)R^2 → 2 [Ar-N-CH-N-Ar]$^{\oplus}$ [N(SO$_2$-R^1)R^2]$^{\ominus}$

(a)	*(k)*	*(o)*	$C_6H_4NO_2$-(*m*)	$PO[N(C_2H_5)_2]_2$
(a)	*(l)*	*(p)*	C_6H_5	$PO(NHC_6H_5)_2$

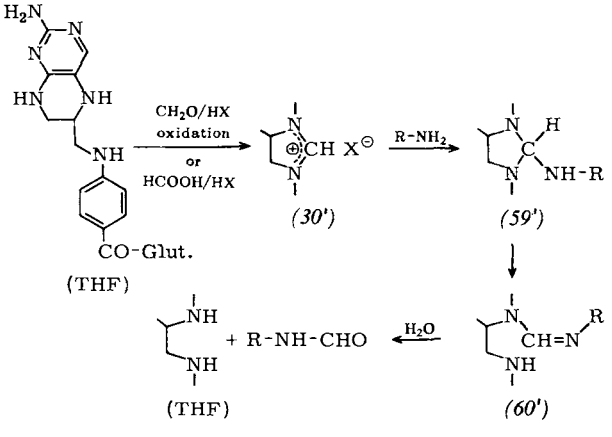
On the other hand, the *N*-acylated chloromethanesulfonamide *(68)* reacts with *(4a)* with elimination of HCl to

(4a) + 2 HN(C(=O)CH$_3$)SO$_2$-CH$_2$Cl → *(68)*

2 [C$_6$H$_5$-N-CH-N-C$_6$H$_5$]$^{\oplus}$ Cl$^{\ominus}$ + 2 N(C(=O)CH$_3$)SO$_2$-CH$_2$

(69) *(70)*

[*] The compounds ethyl 2-diazo-2-[*N*-(1,3-diphenyl-2-imidazolidinyl)-*N*-(*p*-toluenesulfonyl)aminocarbonyl]acetate and 2-diazo-*N*-(1,3-diphenyl-2-imidazolidinyl)-*N*-(*p*-toluenesulfonyl)acetoacetamide, which are described in [19], also occur in the form of the imidazolinium salts, as is shown by the spectroscopic data.



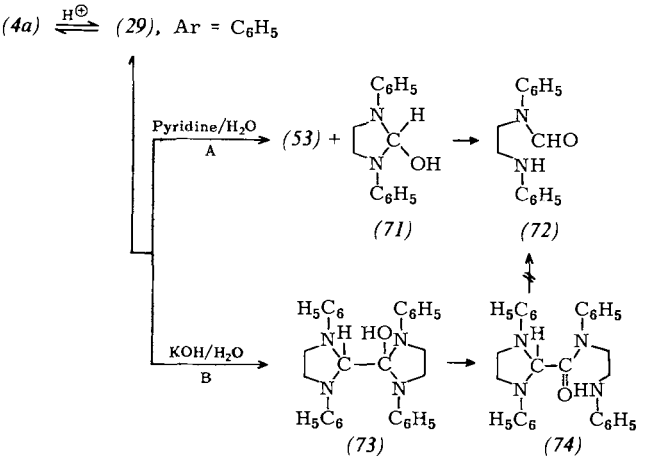
give 5-methyl-1,3,4-oxathiazoline 3,3-dioxide *(70)* together with 1,3-diphenylimidazolinium chloride *(69)* in a yield of more than 90%[31][*].

3.5. Mechanistic Considerations

For the mechanism of the formation of the "NH insertion products" *(59)* and *(60)* cf.[64]. The initial step, *i.e.* the proton transfer from the nitrogen of the amino compound to the nucleophilic double bond of the electron-rich olefin, is followed by cleavage of the molecule into an imidazolinium cation *(30)* and a nucleophilic carbene *(31)*.

In the case of the strongly acidic NH compounds *(66)*, the reaction stops at this stage, and one obtains the imidazolinium amidates *(67)*. In the case of more weakly acidic NH compounds, the mechanism is probably similar to that of the reactions with CH-acidic compounds[**] (cf. Section 2.1).

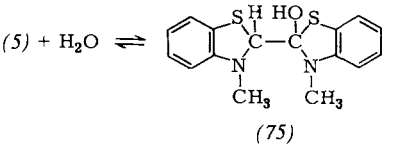
Tetrahydrofolic acid (THF) is important as a cofactor for the biochemical transfer of formaldehyde and formic acid to amines[80]. Formylation of the THF and cyclization yields an imidazolinium cation *(30')* similar to *(30)*, which then reacts with amines to give formimino-THF with formation of an "NH insertion product" *(59')* and ring cleavage to form *(60')* (in the case of primary amines)[81]. Since the hydrolysis of the aminoamidines *(60)* can be carried out in such a way that the *N*-formyl compound of *(58)* is formed in addition to dianilinoethane[31], the hydrolysis of *(60')* to form THF and the *N*-formyl compound also seems plausible. *(4a)* and the imidazolinium cation *(30)*, which can be easily obtained from it, can thus serve as model substances for the biochemical formaldehyde transfer reaction[81].



[*] For the preparation of aromatically substituted 1,3,4-oxathiazoline 3,3-dioxides from *N*-acylated chloromethanesulfonamides and bases, cf. [67, 68].

[**] The ability of the azolium and dithiolium salts, when used as such, to react with amines to form "NH insertion products" is shown by the reactions of *N*-methylbenzothiazolium salts with piperidine [13] and diethylamine [14], and of dithiolium salts with piperidine, benzylamine, dibenzylamine, ethylamine, and NH_3 [63, 69] and from the detailed investigations on the reactions of thiamine with bases [70—73], in which an intramolecular "NH insertion product" (free thiamine base) was obtained among other products [74—76]. The reactions of the aminal esters [77] and amide acetals [78, 79] with amines and amides to form amidines probably also proceed *via* a cation similar to the ion *(30)* [38].

4. Reactions with Formation of a New C—O Bond

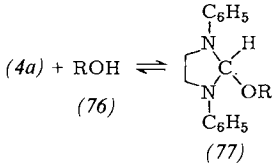


4.1. Hydrolysis of *(4a)* and *(5)*

On hydrolysis of *(4a)*, two different products are formed, depending on the reaction conditions. Hydrolysis in pyridine/water leads with molecular cleavage to *N*-formyl-*N*,*N'*-diphenylethylenediamine *(72)*, whereas hydrolysis with aqueous potassium hydroxide solution leads, with retention of the original C—C bond, to *(74)*[6, 16].

The hydrolysis is probably initiated by the addition of a proton to the nucleophilic double bond of the electron-rich olefin to form *(29)*. At low concentrations of hydroxide ions (path A), *(29)* is split into a carbene *(53)* and an imidazolinium cation *(30)*, Ar=C_6H_5, which adds a hydroxide ion to give *(71)*. Compound *(71)* rearranges with β elimination to form *(72)*. The alkaline hydrolysis of the imidazolinium cation *(30)*, Ar=C_6H_5, is plausible in view of the hydrolysis of azoli(ni)um salts[83].

At high concentrations of hydroxide ions (path B), the cation *(29)* adds a hydroxide ion to form *(73)*, which undergoes ring cleavage to give *(74)*. It has been shown that *(74)* does not change into *(72)* under the reaction conditions[16]. On hydrolysis of *(5)*, the reaction appears to stop at compound *(75)* [addition of water to the double bond][*][13]. Ring cleavage to give a compound corresponding to *(74)* has not been observed.



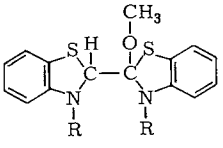
4.2. Reactions with Alcohols

Little is known about the reactions of electron-rich olefins with alcoholic or phenolic OH groups with cleavage of the molecule and formation of a new C—O bond. *(4a)*

[*] Structure *(75)* appears more plausible from a mechanistic viewpoint than a structure suggested in [14, 82].

reacts with the alcohols *(76a)* to *(76d)* in good yields to give the readily hydrolyzed cyclic aminal esters *(77a)* to *(77d)*[84].

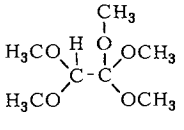
(4a) + ROH ⇌ *(76)* → *(77)*



(a), R = CH_3
(b), R = CH_2-C_6H_5
(c), R = $CH(C_6H_5)_2$
(d), R = $CH(CH_2)_5$

The reaction of tetrakis(dimethylamino)ethylene with methanol leads with cleavage of the molecule and replacement of dimethylamino groups by ethoxy groups to dimethoxy(dimethylamino)methane, dimethylamine, and, with retention of the central C—C bond, 1,2-bis(dimethylamino)-1,1,2-trimethoxymethane as the main products[85]. For the reaction of a phenol with formation of an "OH insertion product", cf. Section 2.2.

The mechanism is probably similar to the hydrolysis mechanism by path A, *i.e.* proton transfer from the OH group to the double bond of *(4a)* to give the cation *(29)*, Ar=C_6H_5, which decomposes into the imidazolinium ion *(30)*, Ar=C_6H_5, and a nucleophilic carbene *(53)*. The reaction of *(30)*[*] with alcohol yields *(77)*.



The reaction *(4a)*⇌*(77)* is reversible. *(77a)* loses methanol when heated in xylene, with regeneration of *(4a)*[84].

A reaction by path B is observed for *(5)* and for tetramethoxyethylene. An addition to the double bond leads to the compounds *(78)*[13,90] and *(79)*[91] respectively.

(78)

(a), R = CH_3
(b), R = C_2H_5

(79)

5. Closing Remarks

The reactivity of the electron-rich olefins *(4)* and *(5)* with proton-active compounds can be attributed in the majority of cases to the reactivities of the fragments formed by cleavage of the protonated olefin [*e.g. (29)*], *i.e.* to the azoli(ni)um ion [*e.g. (30)*] and the nucleophilic carbene [*e.g. (31)*]. Since the nucleophilic carbene formed *in situ* can probably dimerize to give the starting olefin or can be protonated by the proton-active compound to form the azoli(ni)um ion, while the azoli(ni)um ion exists in equilibrium with the carbene in the presence of bases [cf. the base-catalyzed H-D exchange of azoli(ni)um salts, which can proceed only *via* a carbene, Section 2.1], it does not seem possible to distinguish the reactions of the azoli(ni)um ion and of the carbene in these cases. The same product is obtained from both[*].

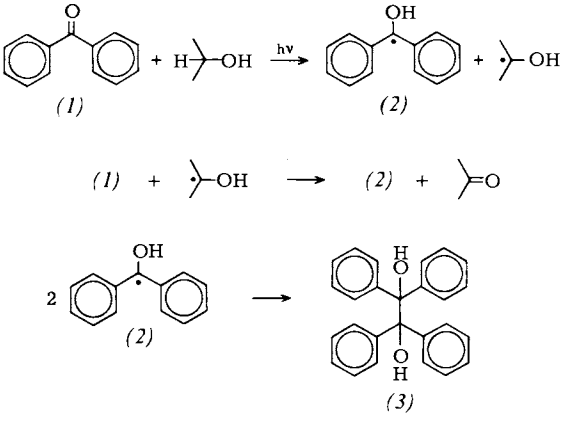
Aromatic Keto Compounds as Initiators in Photopolymerizations

By H.-G. Heine, H.-J. Rosenkranz, and H. Rudolph[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday



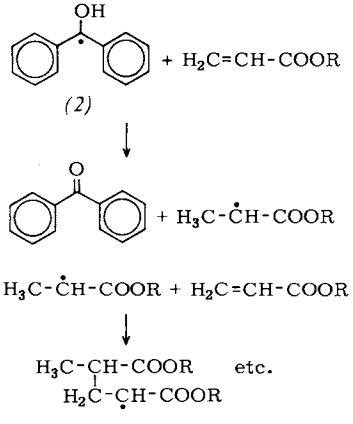
The present article deals with the primary photochemical reactions of carbonyl compounds commonly used as photoinitiators. It is shown that radical formation results mainly from three processes, *i.e.* hydrogen abstraction, β-cleavage, and α-cleavage. The difference in the suitability of the radicals for chain initiation is discussed.

Introduction

Photopolymerizations are initiated by radical formation through the action of light on light-sensitive compounds (photoinitiators) added to the vinyl monomers. Compounds of many classes can be used for this initiation[1]; the most important of these are carbonyl compounds with UV absorptions in the range between 300 and 400 nm. The known compounds of this type that are suitable for practical use and the reactions of these compounds that lead to the initiation of a polymerization chain form the subject of the present article.

1. Chain Initiation by Hydrogen Abstraction

The photoreduction of benzophenone *(1)* to benzopinacol *(3)* is probably one of the best-known light-induced reactions. There have been numerous attempts to make use



of the ability of benzophenone to form free radicals by hydrogen abstraction in the excited triplet state for the initiation of vinyl polymerizations[2]. However, these attempts have led to conflicting results. Thus in the common acrylic or methacrylic esters, such as methyl, ethyl, or *n*-butyl acrylate or methacrylate, benzophenone has only a very weak initiator action, if any. On the other hand, if benzophenone is exposed to light in a mixture of these esters with a solvent containing ether groups (diethyl ether, tetrahydrofuran, polyethylene glycol, or methyl glycol acetate), polymerization begins after a very short time[3]. Benzophenone has an equally good initiator action even without solvents in esters of acrylic acid with an alcohol containing ether groups, such as diethylene glycol diacrylate. Very slow polymerization is observed, on the other hand, when benzophenone and alkyl acrylates are exposed to light in isopropanol.

This observation is surprising at first, since kinetic measurements indicate that hydrogen abstraction occurs at almost equal rates on exposure of benzophenone to light in ethers and in isopropanol[4], and the quantum yield of the photoreduction in isopropanol is almost 1. According to investigations by *Elad*[5], however, the free radicals formed from ethers have a strong tendency to add to double bonds. Though a corresponding addition of semipinacol radicals has occasionally also been observed[6], ether radicals add preferentially when present together with semipinacol radicals[7].

The difference in the initiator action of benzophenone in the presence of isopropanol and ethers corresponds to the variation in the ease of addition of the free radicals formed by hydrogen abstraction from the solvent. The role of the semibenzopinacol radicals *(2)* invariably formed in photoinitiation with benzophenone, which, according to *Braun*[8], also initiate polymerizations by hydrogen transfer, appears to be of minor importance according to these findings.

As mentioned previously, the initiation of polymerization by hydrogen abstraction is effected by triplet-excited

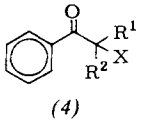
Wissenschaftliches Hauptlaboratorium der Bayer AG
415 Krefeld-Uerdingen (Germany)

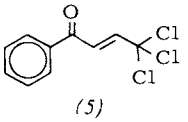


benzophenone ($E_T = 68.5$ kcal/mol[9]). It is therefore not surprising that benzophenone is practically inactive in polymerizable mixtures containing styrene ($E_T = 61$ kcal/mol[10]), *e.g.* in solutions of unsaturated polyesters in styrene[11], even if the unsaturated polyester contains groups suitable for hydrogen abstraction, *e.g.* by incorporation of oxaalkyldiols. In this case, exposure to light results in quenching of the triplet-excited benzophenone by styrene without any chemical reaction.

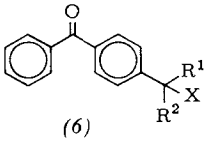
In some cases, however, an energy transfer of this type is the basis of the initiation of a polymerization chain, as in the benzophenone-sensitized system maleic anhydride/cyclohexene[12]. This initiation mechanism is of no practical importance, since it leads only to oligomeric products.

Many other, mainly aromatic carbonyl compounds and α-diketones behave photochemically in the same way as benzophenone[13], and are fundamentally capable of initiating polymerizations by hydrogen abstraction[14]. However, these compounds are less important, either because of a less favorable UV absorption or because of a lower quantum yield in the primary step. Only a few quinones, *e.g.* anthraquinone derivatives, exhibit good initiator activity[15]. These compounds have a long-wave absorption, which allows excitation even with daylight. They are used as initiators in copying systems involving crosslinking by photopolymerization (dry-resist foils for the production of printed circuits).

2. Chain Initiation by β-Cleavage



Another type of initiation is exhibited by aromatic α-haloketones *(4)* which are frequently mentioned in the literature[16] as photoinitiators. In addition to phenacyl chloride and bromide, which are possibly the best-known representatives, this group of compounds includes desyl chloride and practically all phenyl ketones with one or more halogen atoms in the α-position.



(4)

X = Cl, Br
$R^1 = R^2$ = Cl, Br, H, Alkyl, Phenyl
$R^1 \neq R^2$ = Cl, Br, H, Alkyl, Phenyl

It is not surprising that ω-trichlorocrotonophenone *(5)*[17] and halogenated *p*-alkylbenzophenones *(6)*[18] are also good photoinitiators. These vinylogous and phenylogous α-haloketones react in the same way as the compounds of type *(4)* on exposure to light, with homolysis of a

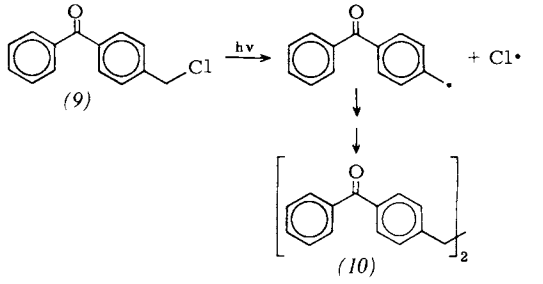
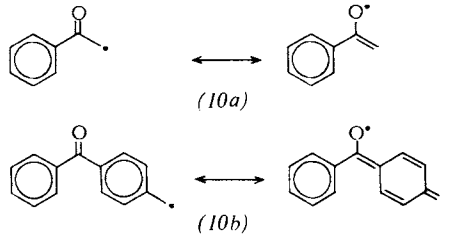
$R^1 \neq R^2$ = Cl, Br, H, Alkyl



C—halogen bond. This cleavage has been described in the literature for the formation of bidesyl *(8)* by photolysis of desyl chloride *(7)*[19].

(7)

(8)



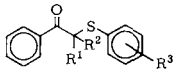
We have investigated photoinitiation by *p*-halomethylbenzophenones. After exposure of *p*-chloromethylbenzophenone *(9)* to light in benzene, we were able to isolate the dimer *(10)* as a secondary product of the phenylogous β-cleavage[20].

(9)

(10)

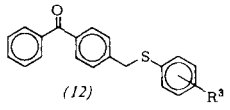
The photolysis of this group of initiators evidently yields two radicals of differing reactivity, *i.e.* halogen and phenacyl radicals or their vinylogs and phenylogs. The pronounced tendency of halogen radicals to add to double bonds and thus to initiate polymerization processes is well known[21], and there can be little doubt that chlorine or bromine radicals liberated when these initiators are exposed to light are of primary importance in chain initiation. The resonance stabilization of the phenacyl radical *(10a)* and to an even greater extent of the *p*-benzoylbenzyl radical *(10b)* probably explains a reduced tendency for these radicals to add to unsaturated systems.

(10a)



(10b)

The chloromethylated benzophenones, as very effective initiators, are used in the photopolymerization of acrylic acid derivatives. Moreover, bromomethylated benzophenones are suitable for the light-induced curing of unsaturated polyester resin-styrene mixtures. The cleavage



into radicals is evidently faster in this case than the quenching of the excited benzophenone chromophore by styrene[18].

As well as the haloketones, the ketosulfides *(11)* and *(12)*, which are obtainable by reaction of these compounds with thiophenols, can also be used as photoinitiators[22] (Table 1). They react in the same way as the

Table 1. Reactivity of the keto sulfides *(11)* and *(12)* in the light-induced curing of unsaturated polyesters [*].

(11)

(12)

	R^1	R^2	R^3	Bleeding time of paraffin (min)	Hardness (min)

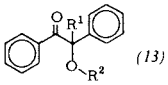
[*] The polymerization experiments were carried out with a solution of an unsaturated polyester (Roskydal W 13, Farbenfabriken Bayer, solids content 54 wt. % in styrene) containing 0.1 wt. % of paraffin (m.p. 52—53°C) in the form of a 10% (w/w) solution in toluene. 2 wt. % of photoinitiator was added to this mixture. Coated films 500 µm thick were exposed to a fluorescent tube (Osram L 40 W/70-1) at a distance of 5 cm, and the time taken for the paraffin to bleed out was determined. The exposure time required for complete hardening was taken as the time when the coating could no longer be marked with a rounded pencil lead of hardness 6 H.



haloketones on exposure to light, with β-cleavage, which is not suppressed by triplet quenchers such as 1,3-cyclohexadiene or piperylene. The thiyl radicals formed are probably mainly responsible for the initiation of polymerization; addition reactions of thiyl radicals to double bonds are generally known, and are used in preparative chemistry[23]. The equally well-known reversibility of these reactions, which partly forms the basis of the action of thiols as regulators in thermal polymerization processes, is probably the reason for the unsatisfactory quality of some polymers prepared with photoinitiators listed in Table 1.

3. Initiation of Polymerization by α-Cleavage

Benzoin and its derivatives are extremely important as photoinitiators. They are currently used in unsaturated polyester resin varnishes, in compositions for the production of acrylate-based printing plates, and in printing inks that are dried by UV light. Benzoin was first claimed for light-induced polymerization in 1945[24], but it was more than ten years before a polymerization process initiated by benzoin ethers was used in practice[25]. This was the process introduced by DuPont under the name Dycryl for the production of plastic printing plates for relief printing and dry offset.

A further ten years passed before the light-induced copolymerization of unsaturated polyesters with styrene in the presence of benzoin ethers as initiators was developed into an industrially used vanishing and coating process[26]. As the importance of this process grew, a more thorough knowledge of the classes of substances that could be used became desirable. We have therefore synthesized a large number of benzoin derivatives *(13)*, a selection of which is shown in Table 2[27].

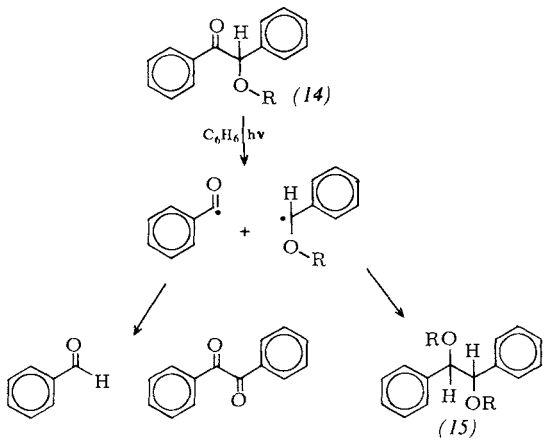
[a] See footnote [*] to Table 1.



It can be seen that benzoin alkyl ethers and α-alkylated benzoins are particularly reactive. Benzoin itself has only a relatively low reactivity in the system investigated. Among the initiators listed, however, only those that exhibit high reactivity without impairing the storage life of the resin are suitable for practical use. This condition is satisfactorily fulfilled only by benzoin ethers of secondary alcohols and by the α-substituted benzoin and their ethers. Some of these compounds were used for investigations on the photochemical behavior of this class of substances as well as on the initiation process.

The photochemical decomposition of benzoin has been known for a long time[28]. The cleavage into benzoyl and hydroxybenzyl radicals[30] as postulated by *De Mayo*[29] seems plausible also in the light of studies on deoxybenzoins[31].

It seemed obvious that α-cleavage must also be the primary photochemical process in photopolymerizations initiated by benzoin alkyl ethers. When benzoin ethers *(14)* are exposed to light, benzaldehyde and benzil can in fact be isolated as reaction products of the benzoyl radical, and the dimerization product *(15)* as a reaction product of the alkoxybenzyl radical[32].

In the presence of oxygen, the initially formed radicals are completely captured with formation of benzoic acid

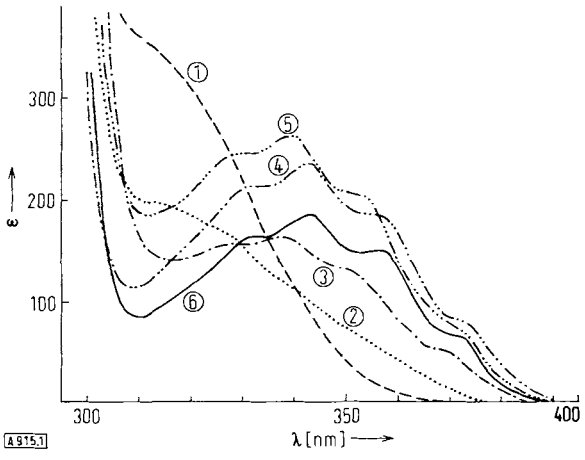
and esters of benzoic acid, respectively. As is shown by quenching experiments with naphthalene or piperylene, α-cleavage of the benzoin ethers cannot be quenched in

benzene. Even with piperylene as the solvent, no inhibition is observed. α-Cleavage is evidently faster than the transfer of energy to the triplet quenchers piperylene ($E_T = 59$ kcal/mol)[33] and naphthalene ($E_T = 61$ kcal/mol)[9], the rate of which is practically diffusion-controlled (5×10^9 liter/mol·s in benzene). α-Cleavage thus competes with intersystem crossing, whose rate for acetophenone has been estimated to be $10^{10} s^{-1}$[34], and therefore probably takes place from an excited singlet state. The solvent dependence of the long-wave UV maximum ($\lambda_{max} = 330$ nm in ethanol; 345 nm in cyclohexane) indicates that this is an (n→π*) state.

This could be one of the reasons for the difference in the reactivities of the benzoin derivatives listed in Table 2, since, as was mentioned earlier, styrene like piperylene has a strong quenching action on (n→π*) triplet excited phenyl ketones[9]. The photoreactions of some of the benzoin derivatives that are not very effective as photoinitiators in this system take place preferentially from an excited triplet state. For example, the photolysis of benzoin acetate in benzene is suppressed by piperylene (1 M)[35]. Quenching experiments also indicate that benzoin, which is relatively inactive in unsaturated polyester/styrene mixtures, undergoes the α-cleavage mainly from a triplet state. α-Alkylated benzoins and in particular their ethers, which have a very good initiator action (Table 2), again react preferentially from the excited singlet state[32], which suggests that the rate of formation of free radicals is increased for these compounds by the higher degree of substitution on the α-C atom. They also have a more favorable UV spectrum than benzoin for excitation with conventional UV lamps (Fig. 1).

The difference in the behavior of the benzoin derivatives listed in Table 2, and particularly the pronounced differences between benzoin alkyl ethers and benzoin esters, could be explained by the stabilizing effect of the α-hetero atom on the radicals being formed. However, kinetic studies on the photochemical α-cleavage of some phenyl ketones show that the transition state of the free-radical formation lies on the reaction coordinate at a very early stage[36]; at this stage, the free-radical character is not yet very highly developed, and radical-stabilizing substituents could thus have little effect on the rate of α-cleavage. An explanation that seems much more plausible is one involving polar effects, such as have recently been discussed by *Rüchardt* for thermal free-radical reactions[37].

Whereas it was possible to establish the facts presented above by kinetic and analytical studies, it is relatively difficult to determine the subsequent steps of the photoinitiation of free-radical polymerizations by benzoin derivatives.



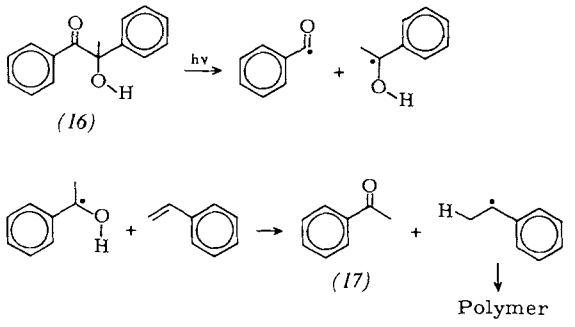


Fig. 1. UV spectra of some benzoin derivatives in benzene. 1, Benzoin 2, α-methylbenzoin; 3, α-hydroxymethylbenzoin; 4, benzoin isopropyl ether; 5, benzoin phenyl ether; 6, α-methylbenzoin methyl ether.

The addition of acyl radicals generated thermally or by irradiation to unsaturated compounds has been described in numerous reports[38]; that of benzoyl radicals to maleic esters was also observed by *Patrick*[39]. The corresponding reaction of acyl radicals with styrene is described as exothermic[40]. Chain initiation by the benzoyl radical formed on photolysis of the benzoin derivatives is therefore quite conceivable.

On the other hand, the behavior of the second fragment, *i.e.* the substituted benzyl radical, is less uniform in the presence of unsaturated compounds. Our experiments have shown that benzyl ether radicals from the photolysis of benzoin alkyl ethers dimerize even in the presence of piperylene and styrene, while the formation of benzaldehyde and benzil from the benzoyl radicals is suppressed in the presence of small quantities of these unsaturated compounds by addition to the double bonds[32]. These observations indicate that α-alkoxybenzyl radicals have less tendency to add to unsaturated compounds.

Another possible mode of reaction of the substituted benzyl radicals is the fragmentation postulated by *Braun* for semibenzopinacol radicals *(2)*[8]. The secondary radical similarly formed from semibenzopinacol ether radicals is thought to be responsible for the actual chain initiation in various thermally initiated free-radical polymerizations[41]. A mode of reaction that agrees with this mechanism has been observed in photopolymerizations initiated by benzoin derivatives only for benzoin and its α-substituted derivatives. Thus α-methylbenzoin *(16)* gives the

expected carbonyl compound acetophenone *(17)* on exposure to light in styrene.

The most effective benzoin-based photoinitiators, *i.e.* the benzoin alkyl ethers and the α-alkylbenzoin ethers, evidently do not undergo fragmentations of this type in the presence of unsaturated compounds. Thus the expected carbonyl compounds were not detected when benzoin isopropyl ether or α-methylbenzoin methyl ether was exposed to light[42].

However, since only very low concentrations are used in photoinitiation with these compounds (1 to 2% based on the unsaturated polyester) and the mobility of the free radicals formed is very quickly restricted by the rapid gelling of the system, it may be assumed that the dimerization observed on exposure to light in solution does not take place during the photoinitiation of unsaturated polyesters. It is more likely that the benzyl ether radicals ultimately also add to double bonds in the same way as thermally produced alkoxybenzyl radicals add to maleic anhydride[43], and thus initiate polymerization chains, or that they react with growing free-radical chains to cause chain termination. This is probably the explanation of *Mochel*'s report[44] of the incorporation of radioactivity into the polymethyl methacrylate obtained by photoinitiation with [methyl-^{14}C]-benzoin methyl ether.

In our view, the difference in the reactivities of the benzoyl and substituted benzyl radicals is essential to the suitability of many benzoin derivatives for photoinitiation. Only in this way, apparently, is it certain (and this also applies to the other types of initiators mentioned here) that a chain growth initiated by an initiator radical is not prematurely terminated by combination with another chain initiated at the same time in its immediate vicinity or with a reactive second radical.

Structure Determinations of Nitrogen Compounds with the Aid of NQR, NMR, and ESCA Spectroscopy

By Hans G. Fitzky, Detlef Wendisch, and Reimer Holm[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

Since it is often necessary or desirable to determine the structures of compounds containing nitrogen directly *via* the nitrogen atoms, the nuclear quadrupole resonance (NQR) and the nuclear magnetic resonance (NMR) as well as the photoelectron and the Auger-electron spectroscopy (ESCA) of nitrogen are becoming increasingly important. A comparative review of these three methods on the basis of measurement effect, information obtainable, applications, and limitations forms the subject of this article.

Introduction

Three new fields of the spectroscopy of nitrogen compounds, which have not yet been extensively used, are the ^{14}N nuclear quadrupole resonance[1], the ^{14}N and ^{15}N nuclear magnetic resonance[2], and the photoelectron spectroscopy of nitrogen[3]. Though these methods have been in practical use for a number of years, their wide application has been prevented mainly by experimental difficulties. In recent years there have been reports of some important technical improvements, which should lead to an increase in the capabilities of these methods and hence also to their wider use. On the other hand, an assessment of the methods with regard to their capabilities is possible on the basis of existing knowledge.

The usual methods of nuclear magnetic resonance and IR and mass spectroscopy often do not yield conclusive answers in the determination of the structures of nitrogen compounds. Thus in mass spectroscopy, compounds that are difficult to volatilize sometimes suffer pyrolysis. Moreover, difficulties in interpretation often arise in the formation of zwitterions from salt-like nitrogen compounds or *N*-oxides. In IR analyses, it is difficult to distinguish between C=N and C=C bonds or between nitro and nitroso groups; it is also difficult to detect azo groupings and tertiary amines. The structures of molecules containing several nitrogen atoms, such as substituted polynuclear heterocycles, often cannot be determined by conventional NMR spectroscopy; the ^{1}H resonance of compounds containing nitrogen is always negatively influenced by the nuclear quadrupole moment of the ^{14}N nucleus. It is therefore often necessary or desirable to determine the structures of compounds containing nitrogen directly *via* the nitrogen atoms.

1. Nuclear Quadrupole Resonance

Since its introduction by *Dehmelt* and *Krüger*[4,5] in 1950, nuclear quadrupole resonance spectroscopy has been increasingly used for the investigation of chemical bonds in crystalline solids. Primarily through the work of *Townes* and *Dailey*[6], it was possible to use the spectroscopic data to establish the electron structure of the chemical bond. The method is applicable to compounds of 130 isotopes whose nuclear spin is greater than 1/2. Nuclear quadrupole resonance thus complements nuclear magnetic resonance, since it can be used for the detection of the very nuclei whose measurement with the aid of nuclear magnetic resonance is impossible because of excessive line broadening due to quadrupole coupling.

Apart from the investigations on halogen compounds, which have been the main subject of studies carried out so far, spectra of ^{14}N were also recorded. Investigations on a large number of nitrogen compounds have shown that not only are answers provided for problems of bonding theory, but the method can also be applied to structural analysis as carried out recently in the nuclear quadrupole resonance of chlorine[7,8].

1.1. Principles of ^{14}N Nuclear Quadrupole Resonance

1.1.1. The Nuclear Quadrupole

Nuclei having a nuclear spin greater than 1/2 have a nuclear charge distribution in the form of an ellipsoid of rotation, and consequently possess a nuclear quadrupole moment, whose magnitude and sign depend on the nature and magnitude of the ellipticity (Fig. 1). The nucleus ^{14}N

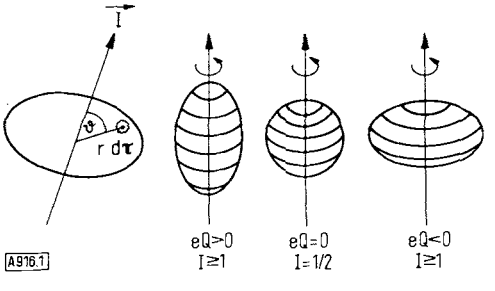

Fig. 1. Electric nuclear quadrupole moment. Definition of the scalar electric quadrupole moment:
$eQ = \int \varrho r^2 (3\cos^2\vartheta - 1) d\tau$.
e = nuclear charge, I = nuclear spin quantum number.

[*] Dr. H. G. Fitzky, Dr. D. Wendisch, and Dr. R. Holm
Ingenieur-Bereich Angewandte Physik, Bayer AG
509 Leverkusen-Bayerwerk (Germany)

(content in the natural nitrogen isotope mixture: 99.635%) has the nuclear spin I = 1 and the relatively small quadrupole moment $eQ = +0.016 \times 10^{-24}\,cm^2$. The nuclear quadrupole can assume positions that differ in energy in relation to the direction of the nuclear spin moment I in the inhomogeneous internal electric field of the molecule. The energies are determined by the magnitude of the quadrupole moment eQ and the field inhomogeneity at the position of the nucleus q, the possible orientations of the nucleus, *i.e.* the number of terms, being determined by the spin quantum number I. The field gradient provides the chemical information. Its magnitude is determined exclusively by the bonding electrons in incomplete shells, mainly p electrons. Complete shells and s electrons make no contribution, because of their spherically symmetrical density distribution. The influence of the d electrons is weaker than that of the p electrons by a factor of about 10.

1.1.2. The Nuclear Quadrupole in an Axially Symmetrical Field Gradient

If the field gradient at the position of the nucleus is characterized by the second derivatives of the electrostatic potential, one obtains the Laplace equation

$$\frac{d^2V}{dx^2} + \frac{d^2V}{dy^2} + \frac{d^2V}{dz^2} = \sigma$$

with the gradients

$$q_x = \frac{d^2V}{dx^2}, \quad q_y = \frac{d^2V}{dy^2}, \quad q_z = \frac{d^2V}{dz^2}$$

If the field gradient is axially symmetrical, *e.g.* about the z axis joining the nuclei, then $q_x = q_y$ and $q_z = -2q_x = -2q_y$.

The classical equation for the energy of the quadrupole nucleus in an axially symmetrical field (Fig. 2)

$$E = (1/8)e^2 q_z Q(3\cos^2\varphi - 1)$$

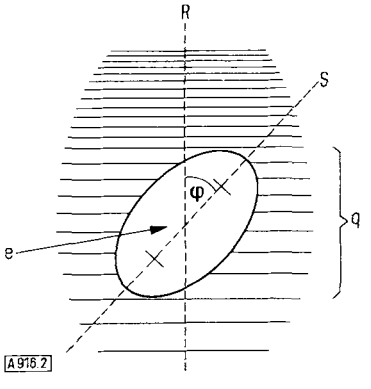

Fig. 2. Nuclear quadrupole in an inhomogeneous electric field. Q = quadrupole moment, e = charge of the proton, q = average value of the field gradient at the position of the nucleus, R = direction of the field gradient (also quantization axis), S = spin axis (+Q).

leads, with quantization of the angle φ, to the quantum-mechanical energy

$$E_m = (1/4)e^2 q_z Q \frac{3m^2 - I(I+1)}{I(2I-1)}$$

where $m = I, I-1, \ldots -I$.

For ^{14}N, with I = 1, axial symmetry gives a transition (Fig. 3) having the frequency $\nu = (3/4)e^2 q_z Q$ corresponding to $\Delta m = \pm 1$.

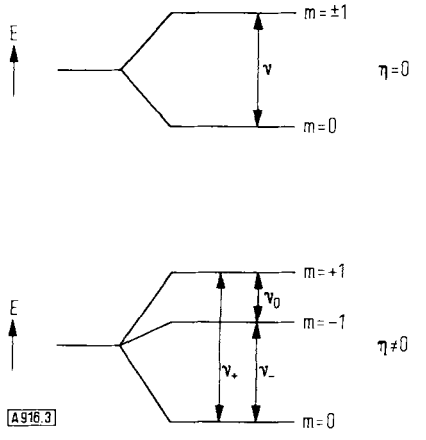

Fig. 3. Energy level diagram of the ^{14}N quadrupole nucleus in axially symmetrical (top) and non-axially symmetrical field gradients (bottom).

1.1.3. The Nuclear Quadrupole in an Asymmetric Field Gradient

In the presence of a non-axially symmetrical field, *i.e.* for $q_x \neq q_y$, the m degeneracy of the term is eliminated, so that further transitions occur. If the degree of asymmetry is characterized by the parameter

$$\eta = \frac{q_x - q_y}{q_z} \quad \text{with} \quad 1 > \eta > 0,$$

the three possible transitions of the ^{14}N nucleus are found to be

$$\nu_+ = (3/4)e^2 q_z Q(1 + \eta/3)$$
$$\nu_- = (3/4)e^2 q_z Q(1 - \eta/3)$$
$$\nu_0 = \nu_+ - \nu_-$$

1.1.4. Field Gradient and Chemical Shift

The resonance frequencies are proportional to the field gradients at the position of the nucleus q, which is predominantly determined by the p electrons of the valence shell. An approximate calculation of q is possible by the method of *Townes* and *Dailey*[1,6]. The influence of the p electrons is represented by the equation

$$q = N_x q_x + N_y q_y + N_z q_z$$

in which the numbers N of p_x, p_y, and p_z electrons are taken into account. For a full P shell, with

$N_x = N_y = N_z = 2$
$q_x = 0$; it follows that
$q_z = -2q_x = -2q_y$

Substitution in the above equation gives the basic equation of *Townes* and *Dailey*:

$$q = q_z[N_z - (1/2)(N_x + N_y)]$$

In the case of one unpaired p electron, the field gradient has a maximum (*e.g.* $N_x = N_y = 2$, $N_z = 1$, chlorine atom). This gives a maximum resonance frequency of *e.g.* $(1/2)e^2q_{at}Q = 54.87$ MHz for chlorine. The other extreme is reached in the chloride ion, with the completely filled P shell and extremely low resonance frequencies. The ionic character of a bond very strongly influences the position of the resonance frequency. In singly coordinated compounds, the three main factors affecting the chemical shift can be taken into account relatively easily as follows.

The ionic character i of a bond, which is characterized *e.g.* by the difference in electronegativity between the bonded atoms[9], secondly the degree of s hybridization s, which leads to a decrease in the field gradient because of the spherical symmetry of the s electrons, and thirdly the multiple bond character π, which influences the magnitude and the symmetry of the field gradient, can be represented as follows:

$$e^2q_zQ/(e^2q_{at}Q) = (1 - i)(1 - s) - \pi$$

The multiple bond component (conjugation effect) due to p_π bonding is found to be

$$\pi = \frac{2}{3} \cdot \frac{e^2q_zQ}{e^2q_{at}Q}\eta$$

1.2. Possibility of Use for Structural Analysis

The very frequent predominance of the ionic contribution in chlorine compounds facilitates the construction of shift tables (named by analogy with usage in NMR) as an aid in structural analysis[10-13]. Similar classifications are based on the electronic properties of atoms and groupings, which are described by the Hammett σ constant and the Taft σ parameter (inductive effects)[1].

Two difficulties arise in the use of these methods for the construction of a shift table for nitrogen compounds. Firstly, for the nitrogen atom, because of its ^4S ground state, $e^2q_{at}Q = 0$, so that a value of about 8.4 MHz must be assumed for an unpaired p electron[1, 14], and secondly, the multiple coordination of the bonded atoms leads to difficulties in establishing the principal axes of the field gradients, which make a general representation difficult. However, the method of *Townes* and *Dailey* can again be used here[14], and it is found that within certain classes of substances the concept of the relation between the chemical shift and the electronic properties of the atoms and groupings can be applied here in the same way as for the chlorine compounds (Table 1).

Table 1. NQR shifts and electronegativity.

^{14}N-Resonance		^{35}Cl-Resonance	
Compound	Resonance frequency (MHz)	Compound	Resonance frequency (MHz)
NC—CN	4.269	NC—CCl_3	41.46
Cl_3C—CN	4.052	Cl_3C—CCl_3	40.67
Cl—CN	3.219 [a]	Cl—CCl_3	40.60
H—CN	4.018	H—CCl_3	38.28
C_6H_5—CN	3.885	C_6H_5—CCl_3	38.70
CH_2=CH—CN	3.800	CH_2=CH—CCl_3	38.30
C_2H_5—CN	3.775	C_2H_5—CCl_3	–
CH_3—CN	3.737	CH_3—CCl_3	37.94

[a] Because of a high conjugation component, which is expressed in the structure Cl^+=C=N^- and leads to an excessively high π-electron density on the N, Cl—CN lies at a very low frequency.

A more comprehensive shift table is shown in Figure 4, which is based on an empirical evaluation of the available resonance frequencies of ^{14}N compounds. The shift range is much smaller than for the chlorine resonance, but because of the smaller line width of 0.3 to 1 kHz, the ratio

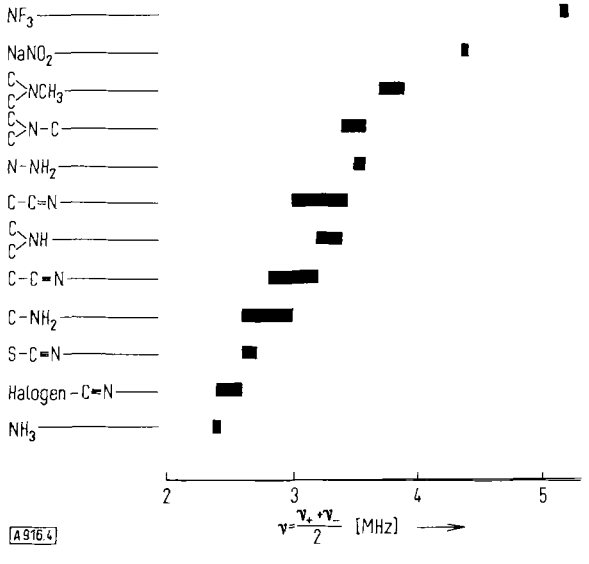

Fig. 4. Correlation of position of the ^{14}N-NQR resonance and type of structure.

of the shift range to the line width is roughly the same for ^{14}N as for chlorine. The electronegativity of the bonding partner, as in the case of chlorine, influences the position of the ^{14}N resonance most strongly, *e.g.* in the series NF_3, $N(CH_3)_3$, NH_3. The monotonic increase in shift in the series C≡N, C=N, and C—N is also typical. A significant analytical advantage over IR spectroscopy is the possibility of recognizing C···N in the presence of C=C. The differences between primary amines of the type C—NH_2 and N—NH_2 are also remarkable.

Table 2. New *N*-chlorine resonances.

Compound	^{35}Cl-Resonance frequency (MHz)
N,N'-Dichloroazodicarboxamidine	45.550
Trichloroisocyanuric acid	46.430
N,2,3,4,4,5,5,6,6-Nonachloro-2-cyclohexeneimine	48.275
N-Chlorotrichloroacetoimide chloride	49.083
	48.707
N-Chloroisocyanide dichloride	49.205 (2 lines)

The question whether a Cl—N or a C—Cl bond is present can be easily settled with the aid of the chlorine nuclear quadrupole resonance, since the chlorine resonance for N—Cl bonds is situated above 43.8 MHz, whereas the maximum frequency for C—Cl bonds is 41.5 MHz. To supplement the data known earlier[1], Table 2 gives further *N*-chlorine resonances[15].

Additional information on the symmetry of the molecule is provided by the spectra in the form of two transitions, whose frequency difference is proportional to the asymmetry of the field gradient. Symmetrically tricoordinate nitrogen as in hexamethylenetetramine gives only one transition, as do monocoordinate —C≡N compounds with vanishingly small π-bond components[16]. In general, the position and number of lines and the distance between them will be used in the assignment of structures to new substances. Doubling of the number of lines may be due to crystal field effects depending on the arrangement of two molecules per unit cell. For a reliable analysis, it is always essential to find at least the $\nu_{\pm}$ transitions; where the unit cell contains several molecules, it is advisable, for reliable pairing of the $\nu_{\pm}$ transitions, to determine also the difference frequencies ν_0, though these lie at very low frequencies and have very weak line intensities.

1.3. Experimental for the Nitrogen Resonance

1.3.1. Nuclear Quadrupole Resonance Spectrometer

Transitions between the energy levels of the nuclear quadrupole (Fig. 3) are induced by the magnetic coupling of the nuclear spin with the magnetic high frequency field[17]. A spectrometer therefore consists essentially of a slow-drive variable high-frequency generator, which produces a high-frequency magnetic field of variable frequency and intensity, into which the substance to be investigated is introduced. Quadrupole nuclei with relatively long spin-lattice relaxation times, such as ^{14}N, require low high-frequency power, which cannot be satisfactorily produced with the superregenerative oscillator used for the chlorine resonance. The system used almost exclusively so far for the detection of the nitrogen resonance is the marginal oscillator[18-21], an oscillator detector system in which the oscillator swings constantly, but the amplitude depends sensitively on the damping of the frequency-determining oscillator circuit because of nuclear quadrupole resonance absorption. The marginal oscillator is usually frequency-modulated with a bisymmetric rectangular voltage for better marking of the resonance absorption, the frequency deviation chosen being roughly equal to half of the line width. The first derivative of the line shape is obtained with phase-sensitive rectification of the nuclear resonance signal, or the second derivative on adjustment of the lock-in rectifier to twice the modulation frequency (Fig. 5).

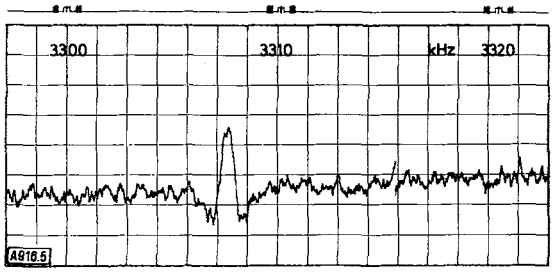

Fig. 5. Part of a ^{14}N nuclear quadrupole resonance spectrum (10 g of hexamethylenetetramine at 300 K); range covered with one instrument setting: 60 kHz at 3300 kHz. Recording time: 50 minutes.

The time taken to record a long spectrum is much greater for the nitrogen resonance than for the chlorine resonance, since, because of the lower line intensities, higher time constants of the detector are required and the marginal oscillator, unlike the superregenerative oscillator, requires manual resetting of the marginality and intensity at frequency intervals of 100 to 300 kHz to maintain maximum detection sensitivity. The usual recording rates are between 10 and 30 Hz/s. The frequency range between 0.5 and 5 MHz can be covered with about 4 interchangeable oscillator inductances. Electronic counters are used for accurate frequency measurement. Accurate frequency marks may be superimposed on the spectra for calibration (edge marks in Fig. 5).

1.3.2. Execution of the Measurements

The quantities of material used for the measurement are 5 to 50 g; the purity should be 98 to 100%. Sufficiently intense spectra are obtainable only with well crystallized compounds. Liquids must accordingly be cooled, usually to 77 °K (liquid nitrogen). Since the electric field of the crystal influences the position of the lines, frequencies are usually given for 77 °K to make the data comparable. Frequency tables for analytical purposes have been given in various publications[22-25].

In addition to impurities incorporated into the crystal, thermally induced mechanical stresses also lead to pro-

nounced broadening of the lines, which may hinder detection. The measurement is often hindered by piezoelectric resonances, particularly at 77 °K, which lead to the appearance of numerous "false" resonances[26].

The spectrum used for the structural analysis must contain one line ($\eta = 0$) or three lines ($\eta \neq 0$) per nitrogen nucleus, with appropriate multiplication where there are several molecules per unit cell. No superposition of lines is to be expected, owing to the low line width and the large shift range.

2. Nuclear Magnetic Resonance

Nuclear magnetic resonance has been used in the past mainly as proton resonance spectroscopy for the determination of the structures of compounds containing nitrogen. In some cases, however, this indirect information was insufficient, or even unobtainable, so that it was often desirable or necessary to use the nitrogen itself.

2.1. Principles and Experimental for the Nitrogen Resonance

The two naturally occurring isotopes of nitrogen, ^{14}N (natural abundance 99.635%) and ^{15}N (natural abundance 0.365%), have a spin that differs from zero, and can therefore be detected in principle in NMR experiments. The nucleus ^{14}N has the spin $I = 1$, and hence has a quadrupole moment (see Section 1). Its low magnetic moment ($\mu = 0.40357$ nuclear magnetons) causes an extremely low sensitivity, which is only 1.01×10^{-3} of that of the ^{1}H nucleus for a constant magnetic field. ^{15}N, with $I = (-)1/2$, also has only an extremely low relative sensitivity (1.04×10^{-3}).

In the case of ^{14}N, the line broadening caused by the quadrupole moment and the very low relative sensitivity lead to experimental difficulties; the difficulties encountered with ^{15}N are due to its low natural abundance and an extremely low sensitivity. Some of the difficulties can be overcome by the use of materials enriched in ^{15}N for the measurements[27]; this is an expensive process, and cannot be carried out in every case.

Increases in the signal/noise ratio in the ^{14}N spectra have been achieved by the use of the INDOR (internuclear double resonance) technique[28]. *Baldeschwieler* and *Randall*[29] described a double resonance technique for the measurement of the ^{14}N shifts that is particularly suitable for compounds in which nitrogen is bonded directly to hydrogen. The ^{1}H spectrum of the compound is observed and the ^{14}N nucleus is simultaneously irradiated with its resonance frequency by means of a variable-frequency oscillator; spin decoupling has been achieved when the fine structure of the NH proton signal disappears. The ^{14}N shifts are finally determined by measurement of the frequency differences that are necessary for decoupling in the various compounds. This process becomes more effective when a high-field spectrometer is used, *e.g.* a commercially obtainable 220 MHz spectrometer designed in such a way that the acceptance of the ^{14}N frequency of 15.89 MHz is possible[30-31]. However, the accuracy of the Baldeschwieler-Randall method for the determination of ^{14}N shifts is limited at very short ^{14}N relaxation times and where proton exchange processes occur.

The recording of nitrogen resonance spectra has recently been facilitated by:

improvement of the sensitivity of the spectrometers,
improved methods of spectrum accumulation,
refined double resonance techniques,
execution of the measurements as pulse experiments with subsequent Fourier transformation.

2.2. Chemical Shifts

Changes in the paramagnetic term of the Ramsay equation for the shielding constant[32] are regarded as the main reason for the large differences in the chemical shifts of compounds containing nitrogen. The simple shielding theory of *Karplus* and *Pople*[33], which takes into account only the paramagnetic contribution σ_p to the shielding constant, satisfactorily explains the chemical shifts of some linear triatomic molecules and ions[34]. Changes in the ionic character of the nitrogen atom influence the orbital angular momentum, on which the magnitude of the paramagnetic term depends[35]. For an inert gas configuration the orbital angular momentum is zero, and the paramagnetic term has a very small value. This case is found for the nitrogen atom in the ammonium ion. With increasing electronegativity of an atom or group bonded directly to the nitrogen, the ionic character of the nitrogen decreases and the paramagnetic contribution to the shielding increases, so that shifts of the N signals to lower fields are finally observed. The electronegativity is a very important factor in saturated nitrogen compounds, whereas the paramagnetic term becomes dominant in aromatic and conjugated compounds. For some systems it was found that charge-transfer interactions and hyperconjugation also have an influence. The large variations of the line widths of ^{14}N signals depend both on the hybridization and steric factors and on the symmetry and charge distribution. Figure 6 shows a survey of typical ^{14}N shifts for some classes of compounds.

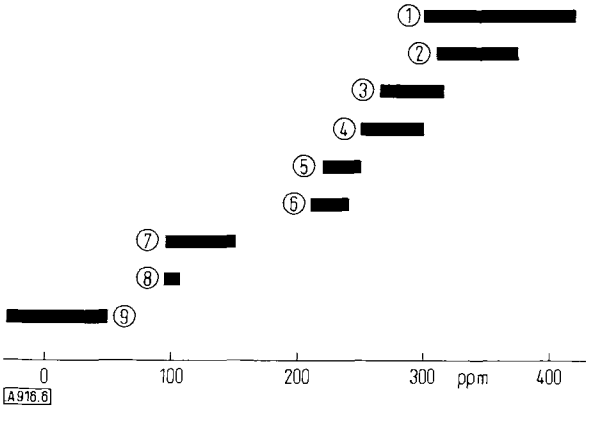

Fig. 6. Positions of the ^{14}N-NMR resonances (based on NO_3^-) of: (1) ammonium compounds, (2) amines, (3) vinylogous amides, (4) amides, (5) pyrroles, (6) thioamides, (7) cyanides, (8) thiocyanates, (9) nitro compounds.

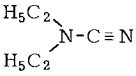
The chemical shifts of the ^{14}N and ^{15}N signals are based on different reference substances, a situation analogous to that in the early stages of proton resonance. Thus ^{14}N shifts have been referred to the NO_2^- ion[36], the NO_3^- ion[37] (as an external standard), and the NH_4^+ ion[38]. Nitromethane has been used as an internal standard[39,40]. For ^{15}N shifts, *Roberts et al.* used liquid $^{15}NH_3$ as an external standard[27,41]. The resonance position of the $^{15}NH_4^+$ ion has been used by other workers as the reference value[42-44]. Efforts are being made at present to construct a unified table for ^{14}N and ^{15}N signal shifts[30,31]. *Becker* has proposed the use of tetramethylammonium iodide as an internal standard, and in this case positive ppm values should be used in the direction of increasing frequency[31].

2.3. Coupling Constants

The observation of coupling constants of ^{14}N with other nuclei is impossible in most cases because of the quadrupole moment. The observation of couplings becomes possible only with a highly symmetrical field gradient at the nitrogen nucleus, since the symmetry leads to a sufficiently large increase in the spin-lattice relaxation time T_1. These difficulties do not arise for ^{15}N. The coupling constants can be determined unequivocally by measurements on materials enriched in ^{15}N. Table 3 shows a survey of some ^{15}N—H coupling constants.

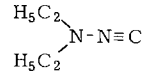
Table 3. Examples of ^{15}N—H couplings from measurements on substances enriched in ^{15}N.

Compound	Coupling Constants (Hz)	Ref.
Diphenylurea	$J_{^{15}N-H} = 89.7 \pm 0.1$	[45]
Diphenylthiourea	$J_{^{15}N-H} = 89.8 \pm 0.2$	[45]
Benzylidenemethylamine	$J_{^{15}N-C-H} = 0.6$	[27]
N-Methylphthalimide	$J_{^{15}N-C-H} = 1.4$	[27]
N,N-Dimethyl-*N'*-phenylformamidine	$J_{^{15}N=C-H} = 2.4 \pm 0.1$	[45]
Benzylideneaniline	$J_{^{15}N=C-H} = 3.8 \pm 0.1$	[45]
Formamide	$J_{^{15}N-C-H} = 19.0$	[46]
N,N-Dimethylformamide	$J_{^{15}N-C-H} = 15.6$	[47]
Pyridine	$J_{^{15}N-C-H\alpha} = -10.76$	[48]
	$J_{^{15}N-C-H\beta} = -1.53$	
	$J_{^{15}N-C-H\gamma} = \pm 0.21$	



Roberts et al. have interpreted the ^{15}N—H couplings in the sense of the Fermi contact term of the coupling mechanism[27]. Except in a few cases (high anisotropy of the electron distribution on the nitrogen atom), a quantitative correlation is possible between the s character of ^{15}N—H bonds and the ^{15}N—H coupling constants. Values between 88 and 94 Hz correspond to a partial s bond character of 31 to 34%[27].

2.4. Examples of Applications



Some examples of the application of the nitrogen resonance are given below.

Cyanamides and Carbodiimides

By recording the ^{14}N spectrum of diethylcyanamide[49], it was possible to show that the molecule has a nitrile structure *(1)* and not an isocyanide structure *(2)*. The ^{14}N spectrum of this compound has two signals at +149

(1)

(2)

and +285 ppm (referred to the absorption line of NO_3^- in an NH_4NO_3 solution). The higher-field signal was assigned to the N atom of the amino type on the basis of its shift[36]. Since methyl isocyanide has a ^{14}N shift of +240 ppm, the diethylcyanamide signal at +149 ppm cannot be attributed to an isocyanide nitrogen.

The ^{14}N spectrum of *N,N'*-dicyclohexylcarbodiimide contains only one signal at +240 ppm (referred to NO_3^-), which can be reconciled with a symmetrical structure *(3)*[49].

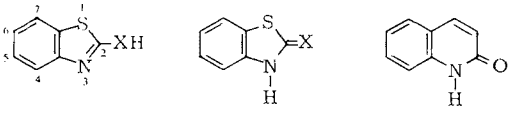
(3)

The ^{14}N nuclear resonance allows a distinction between the isomeric fulminate, cyanate, and isocyanate compounds. This is of interest in view of the frequently observed isomerization fulminate→cyanate or isocyanate[50] and nitrile oxide→isocyanate[51]. Thiocyanato and isothiocyanato complexes can also be distinguished[52].

The ^{14}N resonance has been successfully used for the study of transition metal complexes with ligands containing nitrogen[52-55]. Table 4 contains a survey of the ^{14}N shifts of some complexes of this type[55]. Where there is a direct metal-nitrogen bond, the ^{14}N signal of the complex

Table 4. ^{14}N shifts of some transition metal complexes with ligands containing nitrogen [55].

Complex	$\delta_{^{14}N}$ [a] (ppm)	Geometry
$Ru(NH_3)_6Cl_2$	+316	octahedral
$Rh(NH_3)_6Cl_3$	+295	octahedral
$Co(NH_3)_6Cl_3$	+286	octahedral
H_2RuCl_5NO	−107	octahedral
$Co(CO)_3NO$	−149	tetrahedral
$Fe(CO)_2NO_2$	−167	tetrahedral
$Na_2Pd(NO_2)_4$	−134	planar
$Na_3Co(NO_2)_6$	−135	octahedral
$Na_2Pt(NO_2)_4$	−136	planar
$K_2Ni(CN)_4$	− 46	planar
$K_2Pd(CN)_4$	− 33	planar
$K_2Pt(CN)_4$	− 20	planar
$K_2Zn(CN)_4$	− 35	tetrahedral
$K_2Cd(CN)_4$	− 45	tetrahedral
$Na_4Os(CN)_6$	− 31	octahedral
$Na_3Co(CN)_6$	− 34	octahedral
$NaAu(CN)_2$	− 16	linear
$Hg(CN)_2$	− 40	linear



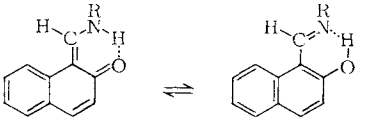
[a] Referred to the ^{14}N signal of acetonitrile; reference values: $\delta_{^{14}N}$ for $NaNO_2 = -385$ ppm, $\delta_{^{14}N}$ for $KCN = -5$ ppm.

occurs at a higher field than that of the free ligand, since the lone pair of electrons on the nitrogen in the complex contributes only slightly to the negative or paramagnetic term of the Ramsay equation. Shifts to lower fields are observed if there is no direct metal-nitrogen bond. Pseudohalogen-metal compounds with ligands containing nitrogen have also been investigated with the aid of the ^{14}N resonance[56].

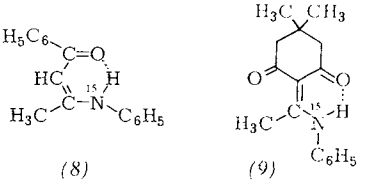
The kinetics of the NH_3 exchange between nickel-ammine complexes and ammonia in aqueous and in nonaqueous solutions has also been successfully studied with the aid of the ^{14}N resonance[57].

Heterocycles Containing Nitrogen

The ^{14}N nuclear resonance was very useful for differentiating between tautomeric structures in heterocycles containing nitrogen. Mention should be made here of investigations on 2-substituted benzothiazoles[58], which can exist in the tautomeric forms *(4)* and *(5)*. The derivatives substituted in position 4 and 6 give chemical shifts as expected for aromatic compounds such as pyridine or isoquinoline. However, the 2-amino and 2-methylamino compounds absorb in the region of 310 to 320 ppm, so that these exist in the amino form *(4)* rather than in the imino form *(5)*. 2-Hydroxybenzothiazole and 2-mercaptobenzothiazole give ^{14}N shifts that indicate the presence of a nitrogen of the thiazoline type *(5)*. Similar behavior is observed for 2- and 8-hydroxyquinolines, in which only the isomers substituted in position 2 can exist in the oxo form *(6)*[59]. 8-Hydroxyquinolines again exhibit an absorption in a region to be expected for a ring nitrogen, as in quinoline, whereas the resonances at higher fields must be attributed to the isomers substituted in position 2. The observation of the ^{14}N—H coupling is further evidence that these isomers exist exclusively in the oxo form.



(4) *(5)* *(6)*



X = O, S, NH, NCH_3

An example of a combination of the nitrogen resonance with other NMR spectroscopic studies is the ^{13}C, ^{14}N, and ^{1}H measurements on *m-/p*-substituted *N*-methylpyridinium iodides[60]. A distinct dependence of the chemical shifts on the nature of the substituent was found for all three nuclei. The resonances occur at higher fields with increasing π-electron density. In the case of the ^{14}N shielding it was possible to attribute this to the change in the paramagnetic shielding term, whereas the neighbor anisotropy was held to be responsible in the cases of ^{13}C and ^{1}H. This explanation is based on the observation that the calculated C and H charge densities showed no significant changes within the series in question. Excellent correlations between the shifts and the Hammett substituent constants were obtained by the use of σ^+ values for the substituents that act as donors. A similar substituent dependence was found for the direct ^{13}C—H methyl coupling constants, whose magnitude increases with decreasing charge density on the nitrogen[60].

The observation of ^{15}N coupling constants can be a particularly sensitive method for the study of isomerism and valence-tautomerism phenomena. In the case of ^{15}N—H coupling, this is most easily accomplished by measurement of the proton resonance of material enriched in ^{15}N. If for instance a fast intramolecular proton exchange occurs between two positions in a system, *e.g.* between oxygen and nitrogen, the ^{15}N—H coupling is a good measure of the residence time of the proton on the nitrogen. This method has been used for the investigation of the keto-enol equilibrium (as a function of temperature and solvent) in various Schiff bases derived from anilides, aldehydes, and ketones[61-64]. For example, the low value of 33 Hz for $J_{^{15}N-H}$ in 1-([^{15}N]-phenyliminomethyl)-2-naphthol has been explained by the assumption that this compound exists predominantly in the enolimine form *(7b)*, since much higher values were found for typical keto amine structures *(8)* [$J_{^{15}N-H}$ = 89.2 Hz] and *(9)* [$J_{^{15}N-H}$ = 84.7 Hz].

(7a) *(7b)*

(8) *(9)*

Of the many ^{15}N—H studies that have been carried out, only a few will be mentioned here:

cis-trans isomerism in formanilide[47]; investigations on cytosine derivatives[65]; structural investigations on the phenyldiazonium ion[66]; *syn-anti* isomerism in oximes[67]; studies on configuration in *N*-nitrosamines[68]; *N*-nitrosohydrazides[69], *N*-nitrosohydroxylamines[70], and alkyl nitrites[71].

The nitrogen resonance should also be important in the future for analysis. For example, a method was recently described in which the amino function (primary, secondary, and tertiary) of organic compounds is characterized on the basis of the ^{14}N shifts of the protonated amines[72]. The method has been used in the meantime in the investigation of the thermal degradation of polyamides[73].

3. Photoelectron and Auger-Electron Spectroscopy (ESCA)

Electron spectroscopy may be defined as the measurement of the kinetic energy distribution of electrons emitted by a sample on irradiation with UV light, X-rays, or electrons. Only the special case of excitation with X-rays

will be considered here. This method was introduced by *K. Siegbahn*, who called it ESCA (electron spectroscopy for chemical analysis)[74-76]. It is applicable to all elements, and in principle allows the study of bonding effects on all participating atoms.

Excitation with UV light is not atom-specific. Auger lines have so far been used only in surface analysis for the detection of the element nitrogen, and no further chemical information was deduced from them. In the ESCA spectrum, the N 1s photoelectron line is much more intense than the Auger lines. Since the results are easier to interpret and the escape depth of the electrons is larger for the N 1s line because of the higher kinetic energy, the Auger lines are disregarded in the following discussion.

3.1. Principles and Experimental

An electron spectrometer consists essentially of the following parts: specimen chamber, X-ray tube, energy analyzer, and detector system. When X-rays fall on the substance, photoelectrons are emitted, and their kinetic energy is measured with the aid of the energy analyzer.

The use of electron spectrometers expanded rapidly when easy-to-operate instruments with electrostatic energy analyzers became commercially available. A decisive step toward an increase in resolution was achieved by retarding the electrons and carrying out the energy analysis at low kinetic energies[77]. The sensitivity was considerably increased by imaging the sample on the entry slit of the analyzer. A channeltron (open secondary-electron multiplier) is normally used as the electron detector.

In view of the necessary mean free path of the electrons, a vacuum of at least 10^{-5} torr must be maintained. The method is therefore applicable primarily to solids having a sufficiently low vapor pressure (with cooling if necessary). With a suitable specimen chamber, however, gases can also be investigated by differential pumping[75].

Photoelectron spectroscopy is based on the Einstein equation

$$E_{kin} = h\nu - E_I$$

where E_{kin} is the kinetic energy of the photoelectron, $h\nu$ is the energy of the incident X-ray quantum, and E_I is the ionization energy (in our case that of the N 1s level). Since the ionization energy of the N 1s level is about 400 eV, the expected positions of the photoelectron lines on excitation with Al-K_α (1487 eV) and with Mg-K_α X-rays (1254 eV) are roughly 1085 and 850 eV respectively.

It is important for the investigation of solids that the energy losses of the emitted electrons during their passage through the material are not continuous but quantized (excitation of plasmons)[78,79]. Electrons that have suffered no energy loss contribute to a sharp line, which is separated by at least one minimum from a tail on the low kinetic energy side due to inelastically scattered electrons.

As the mean free path for electron-electron scattering is about 30 Å for kinetic energies of 1000 eV only those electrons originating in the uppermost monolayers can contribute to the lines. It must therefore always be remembered that ESCA is a method of surface analysis, and that the information comes from a surface layer with a thickness of only about 30 Å[80]. This has the advantage on the one hand that very small quantities of material are necessary; 5 to 10 monolayers uniformly distributed on the specimen holder (about 0.5 cm^2) are sufficient for an analysis (this corresponds to about 10^{-8} g). The uniform distribution over a fairly large area is necessary for intensity reasons because of the small layer thickness that contributes to the signal. On the other hand, the possibility of special surface effects (*e.g.* oxidation) must be taken into account. The purity of the substance is of no importance. Mixtures can also be investigated.

ESCA is a statistical method of measurement. Within the stability range of the instrument, therefore, the detection limit is a question of time. If the N content is greater than 1%, the time required to record the N 1s spectrum is 1/2 to 1 h.

3.2. "Chemical Shift"

ESCA can contribute to the determination of the structures of organic and inorganic molecules since the accuracy of measurement is sufficient for the detection of shifts of the N 1s level under the influence of the neighboring atoms. The shifts arise as follows: Partial withdrawal of electrons causes the remaining electrons to become more tightly bound to the nucleus; this results in a higher ionization energy and hence in a lower kinetic energy of the photoelectrons. A partial negative charge on the atom has the opposite effect. One thus obtains information about the electron density in the vicinity of the nucleus, from which one can deduce *e.g.* the oxidation state, valency, *etc.*

It must be stressed, however, that one should not expect too much. It can be seen from Figures 9 and 10 that the ratio of the maximum shift to the observed line width is only of the order of 10; in other words, the sharpness of separation is not very high. The following difficulties must be taken into account in particular for solids. The shift expected for a free ion is partly compensated by the Madelung potential. The line width is always greater than for gases. It consists (apart from apparatus effects, which are normally negligible) of the width of the incident X-ray line and the width of the N 1s level investigated. Too little is known about the latter at present (broadening due to band structure, lifetime of the excited state) to enable us to decide whether the sharpness of separation is generally improved by an order of magnitude by the use of an X-ray monochromator[81] (decrease in the width of the X-ray line from about 1 eV to about 0.1 eV). On changing from Al-K_α (half width 1 eV) to Mg-K_α (half width 0.8 eV), we have not always obtained a correspondingly higher resolution[*]. On the basis of the line width, the chemical shift can be measured with an accuracy of

[*] Recently we had the opportunity to carry out measurements on a spectrometer with X-ray monochromator. In some cases we could obtain line widths of 0.8 eV for the N 1s lines.

± 0.2 eV, However, if the position of a line of substance A is to be compared with that of a line of substance B, the question of suitable calibration of the spectra arises, particularly if different spectrometers were used; on the one hand electrostatic charging in insulating specimens due to the emission of electrons leads to a shift of the spectra, and on the other the work function of the spectrometer material, which can be uncertain by up to 1 eV due to surface coatings, enters into all measurements on solids. Ionization by the X-rays (in spectrometers without a monochromator, mainly of the high-energy tail of the bremsstrahlung) opposes charging and at least a rather uniform charge distribution is reached on the surface of the specimen. The contamination with carbon (*e.g.* adsorbed pump oil) that is always present on the surface of the substance or a standard mixed with the substance and investigated at the same time may be used as a reference. *Bremser*[82] suggested the use of LiF as a standard of this type; in most of the work published so far the results were referred to the C 1s level of hydrocarbons[74] ($E_I = 284.0$ eV) or, particularly in studies on nitrogen compounds, to the N 1s level of KNO_3[83] ($E_I = 407.0$ eV).

Nearly all these difficulties disappear in measurements on gases. Only in such measurements, therefore, does one find satisfactory agreement between measured and calculated ionization energies and a linear correlation between the shift and the calculated charge of the atom[84] (Fig. 7).

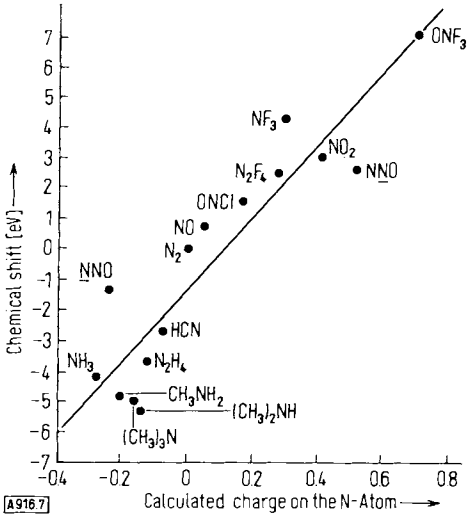


Fig. 7. Correlation of shift values with calculated charge on the N atom (gaseous compounds, reference: N_2) [84].

One may expect the use of an X-ray monochromator here to lead to a distinct improvement of the resolution as soon as the intensity problem has been solved (*e.g.* by suitable detectors and by the use of high-output X-ray tubes)[81].

3.3. Examples

Figure 8 shows the N 1s ionization energies of some classes of nitrogen compounds, arranged in order of decreasing electron density on the N atom (standard: KNO_3 = 407.0 eV). It can be seen that *e.g.* nitro groups or *N*-oxides differ markedly from trivalent nitrogen in N—H or N—C bonds. Figure 9 shows, as an example, the spectrum of 7-nitrobenzothiazole *N*-oxide. The line at the lowest kinetic energy (highest ionization energy) is due to the nitrogen in the nitro group (lowest electron density). Clearly separated from this are the line of the *N*-oxide and a third line, whose intensity increased with the duration of the exposure to X-rays, while that of the *N*-oxide line decreased. This is explained by the removal of oxygen as a result of the exposure to X-rays. Radiation damage of this type is occasionally observed for sensitive bonds[85].

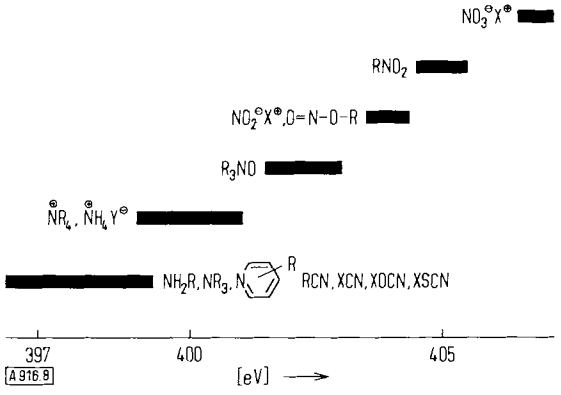

Fig. 8. N 1s ionization energies of various types of structure.

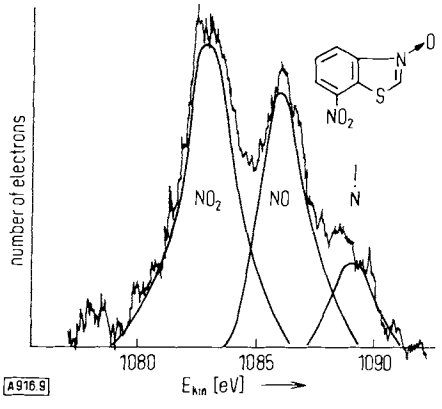

Fig. 9. N 1s photoelectron spectrum of 7-nitrobenzothiazole *N*-oxide. The band indicated by the exclamation point arises during irradiation (Al-K_α) as a result of removal of oxygen.

Another typical example is the N 1s spectrum of *N*-(2-pyridyl)-*p*-nitrobenzenesulfonamide[3,76], which has three lines. The line at the lowest kinetic energy is again due to the nitrogen in the nitro group, and that at the highest kinetic energy to the pyridine nitrogen. On the other hand, the ionization energy of the amino nitrogen in 4-amino-4'-nitroazobenzene[3] differs only slightly from that of the azo nitrogen, so that a somewhat broadened unsymmetrical line appears in the region of the trivalent nitrogen signal. 4-Aminobenzenesulfonamide[3] gives only one sharp N 1s line, from which it follows that the ionization energies and hence the electron densities are the same for the amino and sulfonamide nitrogen atoms. Conversely, the two lines separated by 4 eV in the spectrum of $Na_2N_2O_3$[86] point to the presence of two dissimilar nitrogen atoms in the $N_2O_3^{2-}$ ion.

A rough assignment of the ionization energies is also possible for complexes, *e. g.* for *trans*-$[CO(NH_2—CH_2—CH_2—NH_2)_2(NO_2)_2]NO_3$[86]. However, the deduction of bonding details from the spectra requires careful calibration and the measurement of a sufficiently large number of reference substances. Thus *Hendrickson*, *Hollander*, and *Jolly*[86] showed that the ionization energies for NH_3 ligands in Co(III) Rh(III), Ir(III), and Cr(III) complexes correspond to those of the ammonium ion in NH_4NO_3. On the other hand, the ionization energies for $NaNO_2$ and coordinated NO_2 are approximately equal. The same authors found that the CN line for metal nitrosyl cyanides remains constant, whereas the NO line is displaced; this points to the possibility of charge transfer by back-bonding from the metal.

There is practically no overlap between the quaternary *N*-compound region and other signal regions (Fig. 8). *Jack* and *Hercules*[83] have shown by very careful measurements that the N 1s ionization energy for tetraalkylammonium compounds is comparable with that of corresponding pyridines, but greater than for analogous polynuclear aromatic compounds. To determine the effects of substituents on the ring, the effects of the anions and of the Madelung potential were also taken into account within the groups of pyridinium and tetraalkylammonium salts.

Since the chemical shift depends on the electron density on the N atom, ESCA is very suitable for the detection of polar structures such as occur *e.g.* in azides and amine imides (cf. Fig. 10). The difference in the ionization energies in the amine imide is a direct measure of the localization of the charges on the individual N atoms. The N 1s ionization energy of the corresponding hydrazide lies exactly between the two values for the amine imide. The same is true in general for the detection of charge separations in mesoionic compounds[87]. If, for example, in the corresponding salt one charge is taken over by another ion, the difference in the ionization energies reduces to the difference between the partly positive and the neutral N atom[88].

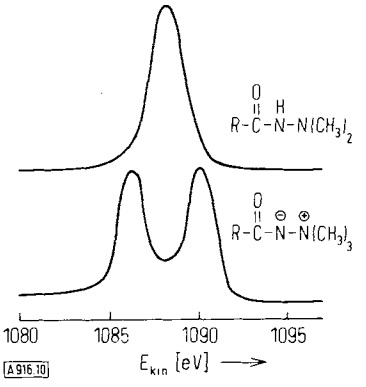

Fig. 10. N 1s photoelectron spectra of a hydrazide and of an amine imide.

The intensity of the N 1s line is a measure of the number of N atoms in the surface layer measured. With the aid of calibration measurements, the N content of a sample can be determined with an accuracy of a few percent with no extra outlay. Since the interaction with the X-ray quantum is essentially an atomic property, matrix effects are generally small. At most they manifest themselves in an effect on the escape depth of the electrons. This means that when several lines appear because of different bonding states, the intensity of each line corresponds to the number of N atoms in the state in question.

It should be mentioned in passing that the shifts are carefully investigated not only for structural determinations. In surface analysis with ESCA (*e.g.* in the study of catalysts), they form the basis for the identification of compounds[85, 89].

Table 5. Comparative survey of the methods described.

Method	Data, parameters measured	Data for structure determination	Shift range/ line-width	Amount of substance required	Purity of sample	Aggregate state	Recording time
^{14}N-NQR	line frequencies, chemical shifts	size and symmetry of the field gradients, ionic bond character, s-hybridization, multi-bonding components	*ca.* 5000	5—10 g	99—100%; good crystallizability	crystalline, powdered (if necessary, cooling to 77 K)	1—10 h per line
^{14}N-NMR	chemical shifts, line widths, coupling constants with other nuclei	bond character, electronegativity, hyperconjugation, steric factors	8 to 400	0.1—1 g	analysis of mixtures also possible	liquid or in solution	minutes to hours
^{15}N-NMR	chemical shifts, coupling constants with other nuclei	bond character, electronegativity, hyperconjugation, steric factors	*ca.* 5000	0.1—1 g	analysis of mixtures also possible	liquid or in solution	longer than with ^{14}N
ESCA	ionization energy of the N 1s level	electronic density in the neighborhood of the nucleus, partial charge (oxidation state, valency)	*ca.* 10	1 molecular layer per 0.5 cm^2 $\hat{=}10^{-8}$ g	analysis of mixtures also possible	solid (gaseous)	0.5—1 h

4. Comparison of the Methods

Table 5 shows a comparison of the three methods described. Only the data that are relevant to the spectroscopic determination of structures are included. The table is intended to facilitate the selection of an appropriate method or combination of methods in the light of the particular problem in hand and the nature of the material under investigation. If the substance to be examined is sufficiently pure and crystallizable, for example, nuclear quadrupole resonance is probably the method of choice as regards expense. Nuclear magnetic resonance is growing in importance for smaller samples, though these must be liquid or in solution. Whether the ^{14}N or the ^{15}N resonance should be examined is a question of the expense that can be tolerated, the ^{15}N resonance being preferable in cases of doubt because of the favorable shift range/line width ratio of the ^{15}N resonance. Since this ratio is very unfavorable in the ESCA method, this method is suitable only for the fast determination of rough structural information. It should be pointed out, however, that the requirements with regard to quantity and purity of the material are the lowest.

In principle, the three methods provide all the necessary structural information about the nitrogen. However, the outlay can be considerably reduced if information is already indirectly available through the other atoms bonded to the nitrogen. Indirect information of this type is obtainable by the usual spectroscopic methods or *e.g.* from the ^{35}Cl nuclear quadrupole resonance for N—Cl bonds (see Table 2) or the O 1s ESCA spectrum for N—O bonds.

Growth Processes due to Reactions in Swellable Cellular Matrixes

By Kuno Wagner and M. Dahm[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

In matrix reactions in swellable cellular matrixes, the solids formed are oriented in space and arranged in the form of cells in strong three-dimensional growth processes. Open-cell, flexible, elastic polyurethanes have a particularly good matrix action. The principle is of general validity, and can be realized with a wide variety of matrixes and reaction types. The dimensional changes, which are always symmetrical, are largely determined by the chemical constitution of the matrix, segment structure, degree of crosslinking, and solvation and hydration behavior. One-component reactions having high rates give sigmoid growth curves and exhibit parallels with growth curves of plant cell walls containing cellulose.

1. Introduction

The development of cellular plastics led at an early date to the application of chemical and physical after-treatments to cellular substrates. Since nearly all high polymers can be converted into cellular materials by appropriate techniques, the number of patents and new patent applications on the modification of existing foams with impregnants, fillers[1], polymers, *etc.* is very large. An example is the preservation of the cavity volume with stiffening of the cell webs by after-treatment and additional crosslinking of the foams with polyisocyanate solutions[2].

One-component and multicomponent reactions on cellular substrates, whose course is reminiscent of plant growth in the phase of non-cell division in elongational growth, form the subject of the present article. We found that cellular substrates (foams)[4] prepared in particular by the diisocyanate polyaddition method[3] are excellent matrixes, with which it is surprisingly easy to produce cellular arrangements of material with formation of new structured spaces. The growth phenomena and dimensional changes observed in the course of these investigations were found in the ion-catalyzed polymerization of formaldehyde[5], and led to an examination of the principles of these phenomena. This work resulted in the recognition of a generally valid principle of the cellular arrangement of matter, which can be applied to any organic cellular substrate and can be realized with any type of reaction from organic or inorganic chemistry. Cell growth and cell expansions are the most important features of the reactions discussed here. The principles of the process have been described, from the standpoint of applications, in the patent literature[5, 6].

Figure 1 shows a Stereoscan photograph of an open-cell, elastic polyurethane matrix, and is intended to provide an introductory indication of the site of the processes discussed here, which consist in the synthesis of organic or inorganic materials in the cell webs, in which the cell webs are greatly extended and these extensions are irreversibly fixed by the solids formed (often with multiple folding of the cell webs). Only then does the surface of the cell webs increasingly become the reaction site. From this moment on, the open-cell character of the substrate can, if desired, be reduced until the cells are completely closed.

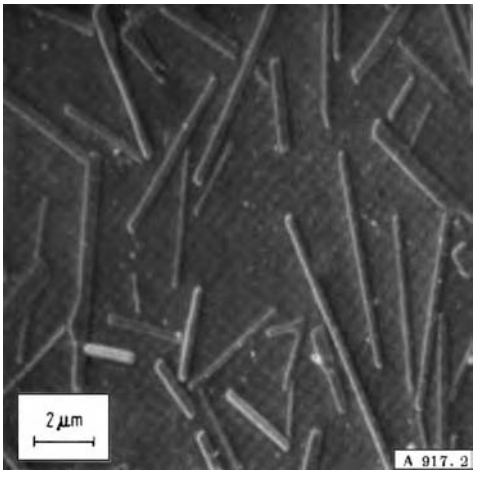

Fig. 2. Formation of polyoxymethylene crystallites on the surface of a cell web during slow growth of the matrix. 3.5 wt.% of polyoxymethylene. Stereoscan photograph.

2. Polymerization of Formaldehyde in Cellular Polyurethanes

We shall first describe the experiment that drew attention to the possibility of preparing homogeneous cellular arrangements of matter in an open-cell, elastic polyurethane matrix.

When gaseous formaldehyde is allowed to act on completely or partly open-cell polyurethane substrates in the presence of catalytic quantities of the tin(II) salt of 2-ethylcaproic acid, polyoxymethylene *(1)* is formed. The polymerizing formaldehyde adapts itself to the existing cell

$$n\ CH_2O\ (\text{gaseous}) \xrightarrow{Sn^{II}} \sim O\text{-}CH_2\text{-}O\text{-}(CH_2O)_{n-2}\text{-}CH_2\text{-}O\sim \quad (1)$$

structure and causes strong three-dimensional extension of the cells. The irreversibly fixed volume extension in extreme cases amounts to about 324% of the starting volume; during this process the material remains completely open-celled. The polyoxymethylenes formed are stabilized at one end to an extent of about 60% by chain termination reactions with NH groups of the matrix, while at the other end they still have hemiacetal groupings, *i.e.* thermally less stable groups. The nitrogen content is the same at all points of the new foam, which has a polyoxymethylene content of about 93 wt.%. Only when the quantity of spatially ordered polyoxymethylene exceeds 93 wt.% does filling of the cell begin, and the growth process comes to a stop.

With the aid of Stereoscan photographs, it is possible to discern the phenomena shown in Figures 2 and 3 in the microscopic and submicroscopic range during the arrangement of the polyoxymethylene in the form of cells. The processes on the cell webs are particularly easy to follow in the period of fast, macroscopically easily measurable growth of the matrix (see Section 7) (Figs. 4 and 5). During the period in which the growth of the matrix is gradually

Fig. 7. Folding in part of a cell web and subdivision of primary cellular spaces. Stereoscan photograph shortly before the start of cell filling. Quantity of polyoxymethylene fixed: 88 wt.%.

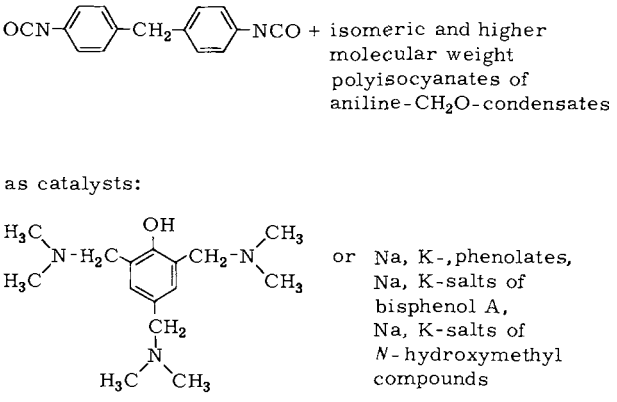
declining, it is possible to discern the cell structures before filling of the cells begins (Fig. 6). An interesting observation at this stage is the subdivision of primary cellular spaces by folding processes (Fig. 7). Figures 8 and 9 illustrate the extension and folding processes for a small section of a cell web. Both figures clearly show the swelling of the marginal zones of the cell webs, which begins toward the end of the growth period. These cell webs now consist chemically of about 88 wt.% of polyoxymethylene and 12 wt.% of polyurethane, about 60 wt.% of the polyoxymethylene being chemically bonded *via* the NH groups of the matrix. It is instructive to compare the cell webs of the matrix before the start of the reaction (Fig. 1) with the rapidly growing and folding cell webs (Fig. 3) at the same magnification. The multiple folding of the cell webs in the period of rapid growth increases the inner surface of the matrix. Macroscopically, the matrix changes symmetrically in all dimensions, *i.e.* any surfaces and edges always undergo parallel displacements.

Optimum cell extension is achieved when at least one of the reactants is used in the form of a gas or mist. This procedure also allows good control of the evolution and dissipation of the heat of reaction. In principle, however, the swelling and its irreversible fixation can also be achieved

a) with a liquid or gaseous compound that condenses in the foam, with stiffening by reaction with itself,

b) with a liquid, gaseous, or molten compound, with stiffening by reaction with a second compound,

c) with several liquid or gaseous compounds or compounds that crystallize out, with stiffening by reaction of these compounds with one another,



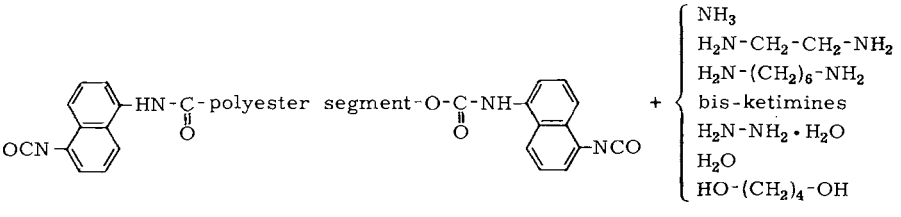
d) with reaction intermediates (oligomers) that have a swelling action and become stiff,

e) with inert organic solvents, with stiffening of the swollen structure by reactive compounds with or without a swelling action.

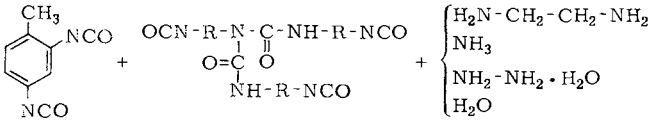
3. Diisocyanate Polyaddition and Diisocyanate Polymerization in Cellular Polyurethanes

It will now be shown with the aid of selected examples that swelling and irreversible fixation of the resulting structure and volume expansion can be achieved by a wide range of reaction types. In view of the economic importance of polyisocyanate chemistry, the emphasis in this section is placed on isocyanate reactions and connections with the chemistry of monomers that can be polymerized by free-radical or ionic mechanisms.

Reaction type:



Open-cell, rigid polyisocyanurate foams are formed. Fixed volume increase: 80 to 100%, density 35 to 60 kg/m^3. Foams in which the matrix used accounts for a surprisingly small fraction of the whole can be prepared.



Modifications are possible in this type of reaction with various polyisocyanates, diols, diamines, and masked polyamines, such as polyketimines and poly-Schiff bases. The swelling of the matrix is initiated by the reactant together with perchloroethylene, acetone, or ethyl acetate. The reaction can be initiated by catalysts fixed in the matrix.

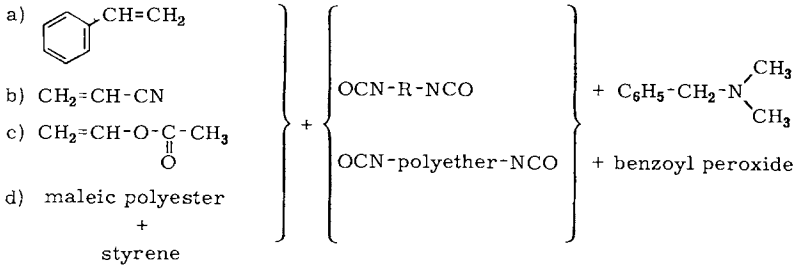
Combination foams having particularly high strengths and elasticities are obtained by application of the elastomer synthesis principle (preparation of Vulkollan)[7] to the following matrix reactions:

Reaction type:

Reaction type:

Highly crosslinked, rigid polybiuret polyureas are formed. Fixed volume increase: 100 to 120%, density 30 to 50 kg/m^3.

Another example is the rapid polymerization of isocyanurates in polyurethane matrixes swollen with isocyanates and ethyl acetate.

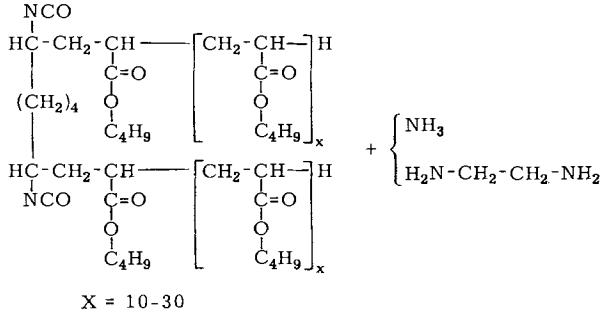


Polyurethane elastomers (soft and hard Vulkollan) are formed in the matrix[8]. Fixed volume increase: 0 to 25%. The preferred reactants here are 1,5-naphthylene diisocyanate, 4,4'-diisocyanatodiphenylmethane, or hexamethylene diisocyanate and chain extenders such as H_2O, ethylenediamine, or NH_3 introduced in the gaseous state.

4. Coupled NCO Polyadditions, NCO Polymerizations, and Vinyl Polymerizations in Cellular Polyurethanes[8]

Tertiary bases such as dimethylbenzylamine are able to accelerate peroxide-initiated vinyl polymerizations or to

cause them to proceed at lower temperatures. The large quantities of heat that are liberated in isocyanate polyadditions and polymerizations can be used to initiate free-radical vinyl polymerizations.

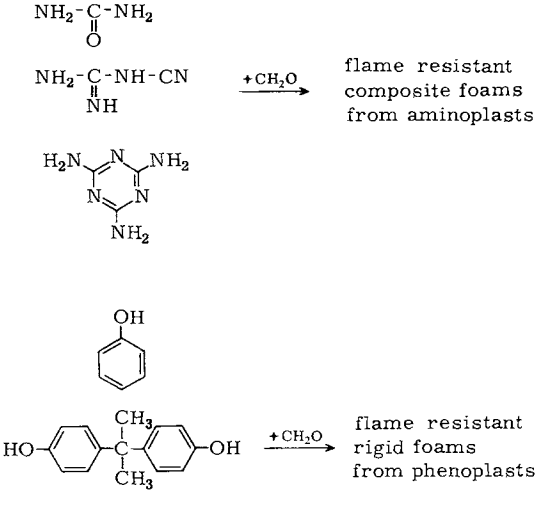


Reaction type:

Elasticized polystyrene foams are formed. Fixed volume increase: 200%. A large number of polyisocyanates and vinyl compounds having a swelling action are also available for this type of reaction. Styrene and maleic acid polyesters are particularly interesting.

Matrix reactions of gaseous ammonia with polyisocyanate telomers[8] based on aliphatic, cycloaliphatic, and araliphatic polyisocyanates[9] containing *e.g.* high contents of grafted butyl acrylate or styrene lead to combination foams with surprising combustion behavior.

Reaction type:



Open-cell, self-extinguishing, light-fast rigid foams are formed. Fixed volume increase: 100%, density: 35 kg/m^3. Contents of only about 28% of butyl acrylate telomers are sufficient, after conversion into polyureas, to make the foam self-extinguishing. The products are light-fast, since the original matrix is completely covered. Similarly, self-extinguishing composite foams can also be prepared from polyisocyanates grafted with large quantities of polystyrene or with polyvinyl acetate. The small extent of surface burning of these foams and the small amount of smoke gas evolved are striking, as is the fact that the effects that can be obtained are distinctly superior to those obtained with vinyl chloride telomers. The thermoplasticity and a certain ratio of the content of vinyl polymer to that of bound urea are more important to these properties than the chlorine content due to the polyvinyl chloride incorporated.

The type of reaction described has some advantages over the free-radical matrix polymerization of unsaturated compounds. Polymerizations of styrene, vinyl acetate, and vinyl chloride proceed slowly and are sensitive to oxygen. The styrene-maleic anhydride polymerization is an interesting matrix reaction because of its rapidity, as is the polymerization of unsaturated polyesters of maleic acid with styrene. Composite foams with high vinyl acetate, vinyl chloride, or acrylate contents can also be obtained in a fast reaction *via* NCO telomers and their reaction with amines.

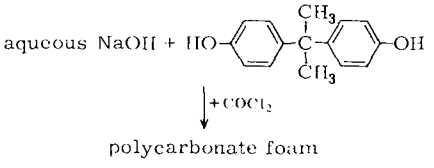
5. Variation of the Matrix

Substrates with optimum swellability are obtained[10] by the incorporation of segments having maximum solubility in the reactants used or in solutions of the reactants. For example, cellular polyurethanes having a high polyethylene oxide content are strongly to extremely strongly swellable in aqueous solutions. The use of these substances for matrix reactions allows condensation reactions of carbonyl compounds with substances that can form aminoplasts or phenoplasts[11].

The irreversibly fixed volume increase is 150%. The strong swelling of polyurethane foams in aqueous phenol or in phenol-bisphenol A mixtures is surprising. Volume increases of 200% can be achieved by formaldehyde condensation, and up to 300% with incorporated polyacetal seg-

ments. The products are used as soil improvers for the storage of water and plant nutrient salts as well as bactericidal, herbicidal, and fungicidal agents.

5.1. Matrix Reactions with Aggressive Gases



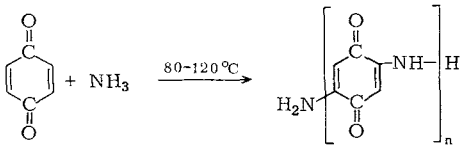
With a suitable procedure, aggressive gaseous components such as phosgene can also be used without discoloration and damage to the matrix and to the resulting composite foam[11].

swelling-components for the matrix:

$$(C_2H_5)_3N + H_2N\text{-}(CH_2)_6\text{-}NH_2 \xrightarrow{+\,COCl_2}$$

open-cell polyurea foam

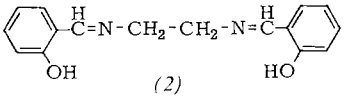
swelling-components for the matrix:



polycarbonate foam

Remarkably soft cellular materials with good feel are obtained with about 40 wt.% of polycarbonates. This is due to the formation of short-chain polycarbonate segments, which react *via* chlorocarbonyl groups with NH groups of the matrix and act as built-in plasticizers.

Dicyanates[11] and diepoxides[11], compounds that can undergo fast Diels-Alder reactions[11], and solutions or latices of high molecular weight substances that can undergo precipitation reactions with crosslinking can also be used for matrix reactions.

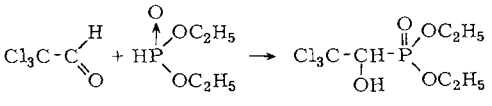


5.2. Heat-Resistant Foams

The extremely high reactivity of benzoquinone or tetrachlorobenzoquinone with ammonia, aromatic polyamines, or polyketimines[11] allows the preparation of graphite-like composite foams, with a volume increase of about 95%.

The matrix component, which corresponds to about 30 wt.%, can be burned off in air. The resulting product is an open-cell foam that is resistant to high temperatures and has a graphite-like luster. Such products, which are obtainable by matrix reactions from quinone, phenoplast, aminoplast, polyacrylonitrile, and polystyrene chemistry, can be used *e.g.* as supports for catalysts.

Matrix reactions leading to a cellular arrangement of ion exchangers, redox systems (quinone-hydroquinone segments) or complexing agents, *e.g.* of the type *(2)*, are also of interest. Reactions of this type may be coupled with the



(2)

fixation of cell-filling solids, *e.g.* using cationic or anionic polyurethane dispersions as impregnants and adhesion promoters[12].

5.3. Cellular Arrangement of Low Molecular Weight Organic Substances in Polyurethane Matrixes

Reactions leading to crystalline, low molecular weight substances can also proceed with strong growth phenomena and dimensional changes if one reactant has a swelling action on the matrix. Thus numerous bactericidal, herbicidal, and insecticidal substances can be arranged in the form of cells. In the case of the matrix reaction volume increases of about 130% can be irreversibly fixed[13].

6. Inorganic Matrix Reactions

The dust-free cellular arrangement of aluminum oxide, titanium oxide, polymeric silica, or asbestos-like, fibrous high polymers is possible by the use of matrixes that are strongly swollen in water, *i.e.* of polyurethanes having high contents of polyethylene oxide or polyacetal. An interesting matrix reaction in this connection is the charging of the substrate with water-soluble sodium silicates followed by gassing with carbon dioxide or phosgene and ammonia, since this method allows a very uniform production of free silica, which condenses in the matrix to form rings, chain molecules, and sheet structures. For the completely dust-free arrangement of the macromolecular silica, the simultaneous use of water-dispersible latices, particularly of anionic polyurethane dispersions[12], as adhesion promoters can be recommended.

7. Sigmoid Growth Curves in Matrix Reactions

A number of matrix reactions that proceed rapidly, *e.g.* reactions of formaldehyde, lead to dimensional changes that are always symmetrical but vary with time. A plot of the linear growth of a cellular polyurethane matrix at a

constant CH_2O gas pressure of 760 mm as a function of time gives a sigmoid growth curve (Fig. 10)[5].

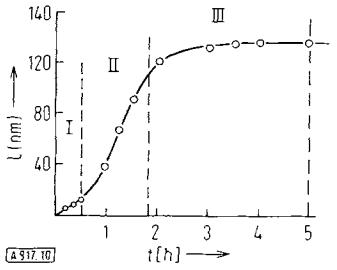


Fig. 10. Linear (L) growth of a cellular polyurethane matrix as a function of time in the formation of polyoxymethylene. Dimensions at $t = 0$: 20 cm × 7 cm × 0.5 cm.

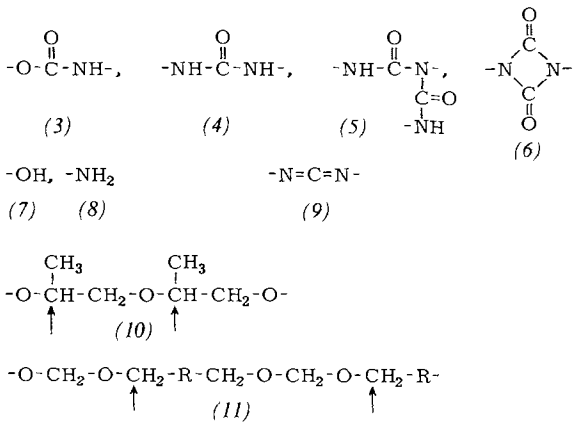
This shape of curve arises as follows[13]. The slow start of growth (I) is due to diffusion of the formaldehyde into the cell webs of the matrix and the slow start of the polymerization of formaldehyde after an "equilibrium concentration" of formaldehyde has been reached in the matrix. This concentration is around 0.9 wt.% of formaldehyde. The fast polymerization of formaldehyde begins slightly above this concentration, the swelling being irreversibly fixed. Rapid growth is recorded in this phase (II). When the growing matrix reaches a polyoxymethylene content of about 60 wt.%, the swelling slows down considerably. The growth slowly declines (III).



8. Matrix Reactions as Analytical Aids

To give some idea of the possibilities for the separation of substances, let us first divide the matrix reactions described into two groups. Group 1 comprises reactions in which the solids formed do not react with active centers of the matrix. Group 2 comprises reactions in which the matrix, *via* its active centers, enters into reactions with crosslinked or uncrosslinked solids formed (condensations, polyadditions, polymerizations, grafting).

Group 1 includes the crystallization of sugars, amino acids, etc., *i.e.* of nutrients for biological reactions, in the matrix. These nutrients, possibly together with gelatins, can be fixed over a large area without dusting, and can be easily exposed to oxygen or kept under anaerobic conditions.

On subsequent dissolution of such mixtures of solids out of the matrix, the smaller molecules accumulate in the matrix. By the choice of extracting agents that have a strong or moderate swelling action, one can achieve separation effects[13] that probably lead in many cases to results similar to those obtained in gel chromatography.

Solids formed by reactions of Group 2, which are not themselves crosslinked, and which are covalently bonded to the matrix, must have reacted with one or more of the groups *(3)* to *(11)* of the substrate *e.g.* in polycondensations, polyadditions, polymerizations, or grafting reactions. The arrows in *(10)* and *(11)* indicate points where groups can be grafted by free-radical transfer.

By dissolving out the unbound part of the material, it is possible to obtain information *e.g.* about the extent to which the active sites of the matrix have reacted, graft yields, molecular weights of the substances fixed to the matrix, *etc.* The question of the possibility of grafting the matrix with a vinyl monomer can also be clarified.

9. Closing Remarks

The described principle for the cellular arrangement of matter is generally valid and by no means necessitates the use of crosslinked matrixes. For uncrosslinked matrixes one uses reactants and solvents that are "poor solvents", and the collapse and dissolution of the cellular matrix can thus be avoided. In many cases, particularly in polyurethane, polypeptide, polyamide, and cellulose chemistry, groups and segments that tend to form hydrogen bonds can assume the role of crosslinking sites (physical crosslinking). Matrixes of this type behave as highly crosslinked systems in swelling processes with moderately solvating reactants.

The use of microporous films or membranes as cellular matrixes also leads to dimensional changes that can be irreversibly fixed. Specific modification of the properties of membranes is possible in this way, interest here being centered on microporous films and membranes of anionic and cationic polyurethane ionomers. Swellable nonwoven fabrics made from natural and synthetic materials can also be used as matrixes.

We are grateful to Professor Holtschmidt and Professor Ley for their support of this work, to Drs. Piechota, Patzelt, von Gyzicki, and Rothermel for discussions on questions of applications, to Herr Horacek for processing studies, to Dr. Hentze for the measurements of heats of swelling and of reaction, and to Dr. Holm for the Stereoscan photographs.

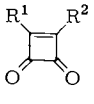
The Chemistry of Phenylcyclobutenediones

By Walter Ried and Arthur H. Schmidt[*]



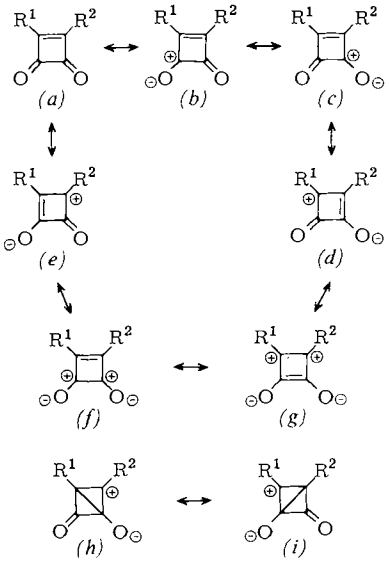
Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

Phenylcyclobutenediones are easily obtainable and very stable. Depending on the nature of the substituent R in position 3, they may be formally regarded as vinylogous carboxylic acid derivatives (R = halogen, OCH_3, OH, SH) or as α,β-unsaturated diketo compounds (R = H, alkyl, aryl). Their behavior in reactions justifies this approach. Ring contraction, ring expansion, and ring cleavage reactions are described.

1. Introduction

Investigations on cyclobutenedione *(1)*, which has been known in the unsubstituted form for only a short time[1], have been concerned with three characteristic derivatives:

1. phenylcyclobutenedione *(2)*,
2. benzocyclobutenedione *(3)*,
3. squaric acid *(4)*.



(1), $R^1 = R^2 = H$
(2), $R^1 = C_6H_5$, $R^2 = H$
(3), $R^1 + R^2 = -CH=CH-CH=CH-$
(4), $R^1 = R^2 = OH$
(5), $R^1 = R^2 = C_6H_5$
(6), $R^1 = O^{\ominus}$, $R^2 = H$

Since reviews on syntheses and reactions of squaric acid[2, 3] and of benzocyclobutenedione[4, 5] have recently been published, our attention will be focused here on the phenylcyclobutenediones[6].

2. Stability of Cyclobutenediones

Simple LCAO-MO calculations indicate that cyclobutenedione *(1)* should have a delocalization energy of 1.24 β[7].

Depending on the substituents in positions 3 and 4, this value increases to 3.68 β for phenylcyclobutenedione *(2)* and to 6.03 β for 3,4-diphenylcyclobutenedione *(5)*. The ground state of the cyclobutenediones can accordingly be described by the resonance structures *(a)* to *(g)*.

If the formulas *(h)* and *(i)* are also taken into account, further stabilization should result from electronic cross-ring interaction between the orbitals of the carbon atoms in the 1,3 and 2,4 positions. The delocalization energy of cyclobutenedione *(1)* then increases from 1.24 β to 1.99 β[8].

[*] Prof. Dr. W. Ried and Dr. A. H. Schmidt [**]

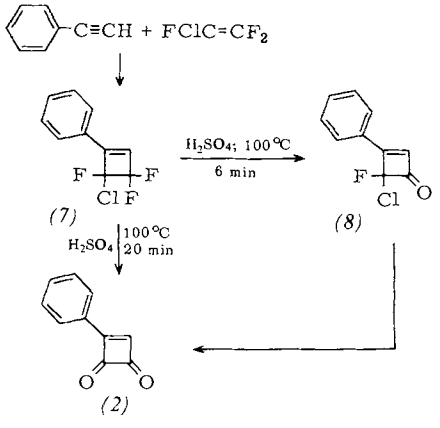
[**] Present address: Department of Chemistry, Columbia University New York, N. Y. 10027 (USA)



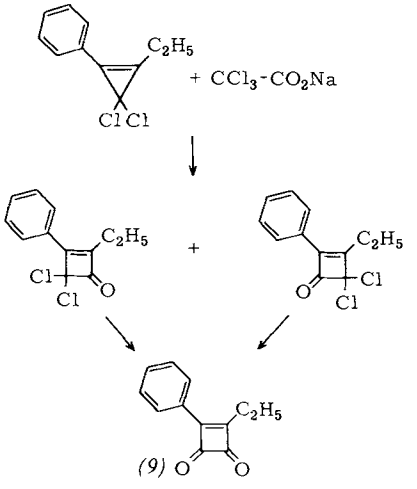
and that of dioxocyclobutenolate *(6)*[9] from 6.11 β to 6.94 β[7].

Since all data on the ring strain of the cyclobutenediones is associated with great uncertainty, the values for their resonance energy can be given only very approximately. Thus a value of between 31 and 60 kcal/mole has been suggested for phenylcyclobutenedione *(2)*[7].

3. Synthesis of Simple Phenylcyclobutenediones

3.1. Phenylcyclobutenedione

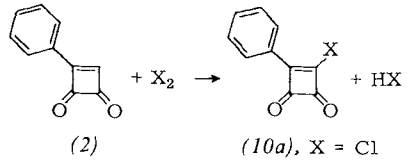
The first cyclobutenedione, *i.e.* phenylcyclobutenedione *(2)*, was prepared by *J. D. Roberts et al.*[7, 10] by cycloaddition of chlorotrifluoroethylene to phenylacetylene and hydrolysis of the resulting 4-chloro-3,3,4-trifluoro-1-phenylcyclobutene *(7)* with sulfuric acid (reaction temperature: 100 °C; contact time: 20 minutes). Phenylcyclobutenedione *(2)* is obtained by this method in the form of yellow crystals in a yield of 86%.



When *(7)* is hydrolyzed for a short time (6 minutes) with sulfuric acid, 4-chloro-4-fluoro-3-phenylcyclobutenone *(8)* can be intercepted. The action of sulfuric acid on *(8)* then leads to *(2)*[7].

Other methods for the preparation of *(2)* are based on the same synthetic scheme. Thus cycloaddition of a perhalogenated ethylene[11] to phenylacetylene leads to tetrahalogenated phenylcyclobutenes, which are subjected to acid hydrolysis either immediately[7] or after conversion into dihalogenated phenylcyclobutenones[7, 12] or into substituted phenylcyclobutenes[13].

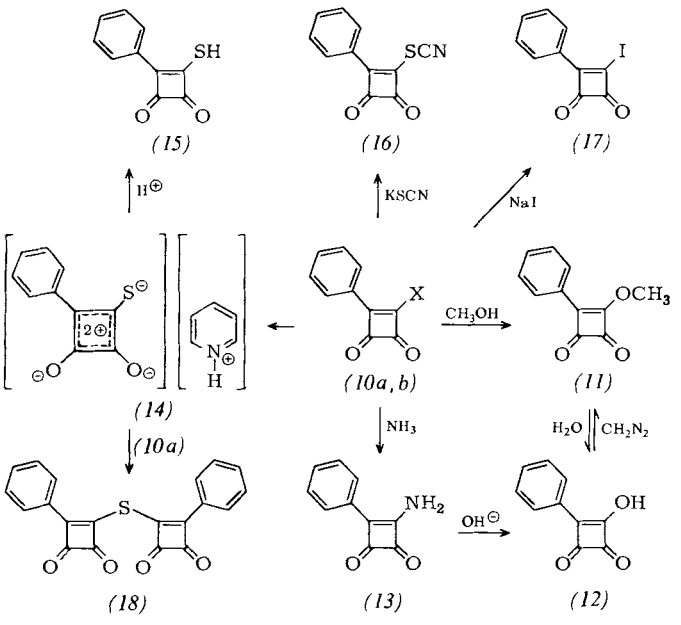
Cyclobutenediones substituted on the phenyl ring [3,3'-(1,4-phenylene)dicyclobutene-1,2-dione[14], 4-nitrophenylcyclobutenedione, 4-methoxyphenylcyclobutenedione[15]] and cyclohexenylcyclobutenedione[16] have also been prepared on the basis of the synthesis of *(2)*. The reaction of cyclohexenylcyclobutenedione with an equimolar quantity of bromine results in the aromatization of the cyclohexenyl residue, so that small quantities of *(2)* are formed in addition to unidentified products[16].



Other phenylcyclobutenediones were obtained in the same way as *(2)* by acid hydrolysis of dihalogenated phenylcyclobutenones and tetrahalogenated phenylcyclobutenes. Phenylcyclobutenediones can also be obtained by substitution reactions of *(2)* and its derivatives. As is shown by the synthesis of 3-ethyl-4-phenylcyclobutenedione *(9)*, dihalogenated phenylcyclobutenones can be obtained in moderate yields by the action of excess sodium trichloroacetate on dihalocyclopropenes or acetylenes[17, 18].

Tetrahalogenated arylcyclobutenes can be prepared by the reaction of perfluorocyclobutene or 1,2-dichlorotetrafluorocyclobutene with aryllithium[19, 20] or aryl Grignard compounds[20, 21]. Tetrafluoro-1,2-diphenylcyclobutene obtained in this way was used for the synthesis of 3,4-diphenylcyclobutenedione *(5)*[22].

3.2. Derivatives of Phenylcyclobutenedione



A striking property of phenylcyclobutenedione *(2)* is the ease with which it can be halogenated in glacial acetic acid. The chloro and bromo derivatives *(10a)* and *(10b)* are formed with elimination of hydrogen halide.

(2) *(10a)*, X = Cl
(10b), X = Br

No corresponding reaction has been observed in CCl_4. This suggests that the solvent takes part in the reaction. Since all attempts to intercept intermediates have been unsuccessful, it is not possible to decide whether the halogen is introduced by an addition-elimination step or by direct electrophilic attack[7].

(10a) and *(10b)* are characterized by high reactivity. Their reactions with methanol, water, and ammonia yield the derivatives *(11)*, *(12)*, and *(13)* respectively.

The action of an acetone solution of NaI on bromophenylcyclobutenedione *(10b)* leads to the iodine compound *(17)*[7]. We obtained the thiocyanato derivative *(16)* in a similar manner[23]. The synthesis of the thiol *(15)* was achieved only recently[24]. The path followed leads *via* the pyridinium salt *(14)*, from which *(15)* can be liberated with acids. The reaction of *(14)* with *(10a)* yields the sulfide *(18)*.

4. Physical Properties

4.1. Solubility

The phenylcyclobutenediones *(2)*, *(10a)*, *(10b)*, *(11)*, *(17)*, *(16)*, *(15)*, *(12)*, and *(13)* show a pronounced lightening in color in this order. Whereas *(2)*, *(10a)*, and *(10b)* are deep yellow, *(12)* and *(13)* form white crystals. The compounds *(2)*, *(10a)*, *(10b)*, and *(17)* dissolve readily in the common organic solvents, and *(12)* is also readily soluble in water. The thiol *(15)* and the thiocyanate *(16)* are moderately soluble, whereas *(13)* is practically insoluble in organic solvents. However, *(13)* can be satisfactorily dissolved with concentrated sulfuric acid or boiling glacial acetic acid.

4.2. Acidity

As a vinylogous carboxylic acid, *(12)* is unusually acidic. Its pK_a value is 0.37[7], which is higher than the values for picric acid (0.71[25]) and for squaric acid *(4)*[26,27]. Table 1 shows the pK_a values of some hydroxycyclobutenediones.

Table 1. pK_a values of some hydroxycyclobutenediones.

	pK_a	Ref.
(12)	0.37 ± 0.04	[7]
(2), $R^1 = p\text{-}CH_3OC_6H_4$, $R^2 = OH$	2.05	[20]
(2), $R^1 = CH_3$, $R^2 = OH$	0.69 ± 0.03	[28]
(4)	1; 2.2	[26]
	1.5; 2.93	[20]

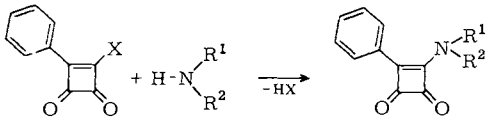
4.3. Spectra

A reliable analytical detection of the phenylcyclobutenediones is possible with the aid of their IR spectra. The two carbonyl groups give strong absorptions in the region between 1800 and 1740 cm^{-1}, which are characteristic of the stretching vibrations of carbonyl functions in four-membered ring systems. The conjugated C=C double bond absorbs at about 1600 cm^{-1}, while the C=C vibrations of the phenyl ring appear in the region between 1550 and 1450 cm^{-1}. The CH deformation vibrations of the monosubstituted phenyl residue, as expected, are found at 740 and 690 cm^{-1}.

The ^{1}H-NMR spectrum of *(2)* contains the following signals[29]: $\delta = 7.3$ to 7.6 ppm (3 H; M), $\delta = 7.8$ to 7.9 ppm (2 H; M), $\delta = 9.45$ ppm (1 H; S). The position of the signal for the olefinic four-membered ring proton corresponds to that of an aldehyde proton[30]. The ^{1}H-NMR spectra of other phenylcyclobutenediones have been described by *J. E. Thorpe*[31].

The UV spectra of the phenylcyclobutenediones in ethanol show a broad absorption band with a maximum in the region of 280 to 330 nm. In apolar solvents (isooctane), the absorption band splits into a principal band and a small secondary band or shoulder. The phenylcyclobutenediones have no absorption in the visible region; the yellow color of *(2)*, *(10a)*, *(10b)*, and *(11)* is explained by the strong spread of the principal UV band into the visible region[7].

5. Reactions of the Phenylcyclobutenediones

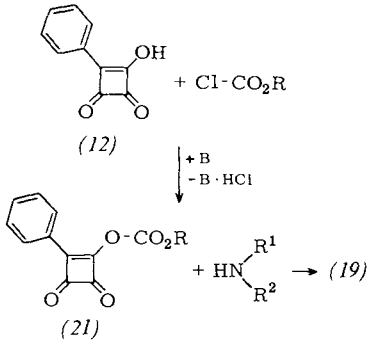


Whereas *(10)*, *(11)*, and *(13)*, as vinylogous carboxylic acid derivatives, react mainly with substitution, *(2)* and *(12)* exhibit great versatility in their reactions. In addition to the reaction of *(2)* with halogens, which was mentioned above, additions of nucleophiles and condensations have also been observed. The products may be stable and isolable, or they may react further with expansion, cleavage, or contraction of the four-membered ring.

5.1. Substitution Reactions

5.1.1. With Amines and Hydrazines

The reaction of *(10a)* and *(10b)* with aliphatic[32] and aromatic amines[33] leads smoothly to the vinylogous amides *(19)* (Method a).

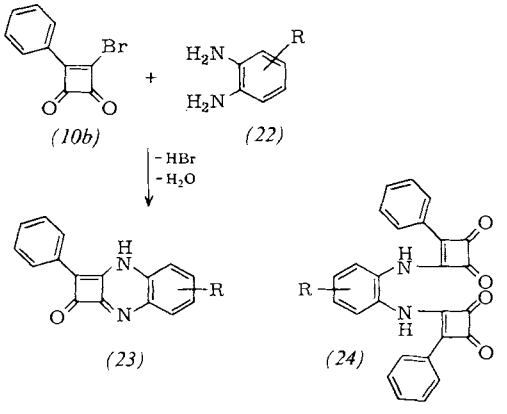


(11) reacts similarly with amines[31,34]. Its reaction with hydrazines also allows the synthesis of vinylogous hydrazides *(20)*[35] (Method b). The "mixed anhydrides" *(21)*,

(10a), X = Cl
(10b), X = Br
(11), X = OCH_3

(19)
(20), $R^1 = NR^3R^4$

which are obtainable from *(12)* and alkyl esters of chlorocarbonic acid, can also be used for the preparation of *(19)*[36] (Method c). Their use not only allows the reaction to be carried out under extremely mild condition but also



(12)

(21)

offers great flexibility with regard to the nucleophile[36]. Some amides *(19)* and hydrazides *(20)* prepared by various methods are listed in Table 2.

Table 2. Examples of amides *(19)* and hydrazides *(20)*.

R^1	R^2	M. p. (°C)	Yield (%)	Method	Ref.
H	H	282–283 (dec.)	82	a	[7]
CH_3	H	267–269	100	a	[32]

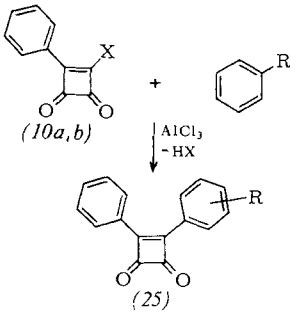
(10b) *(22)*



(23) *(24)*

The reaction of the halophenylcyclobutenediones *(10)* with amines was also extended to *o*-phenylenediamines *(22)*. The products were cyclobuta[*b*]quinoxalines *(23)*[37]. It was possible to show that the most strongly basic amino group of the component *(22)* always attacks position 3 of the bromo compound *(10b)*, and the position of the substituent R in the quinoxalines *(23)* is fixed in this way. Only with symmetrical *o*-phenylenediamines were compounds of the type *(24)* formed as by-products.

For the reaction of the phenylcyclobutenediones *(10)* to *(12)* with aziridine, see Ref. [32, 38].

5.1.2. With Aromatic Compounds

An elegant method for the preparation of arylphenylcyclobutenediones *(25)* is based on the reaction of *(10)* with aromatic compounds in the presence of molar quantities of aluminum chloride[2, 39].

(10a,b) *(25)*

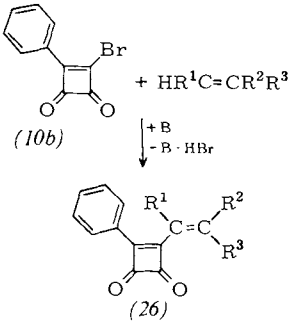
The reaction conditions are the same as for a Friedel-Crafts acylation with acyl halides. As can be seen from Table 3, wide variation of the aromatic component is possible. The reaction can also be carried out with heterocycles that possess aromatic character, such as thiophene.

Table 3. Arylphenylcyclobutenediones *(25)*.

R	M. p. (°C)	Yield (%)
H	98	65
4-CH_3	138.5	48
2,4-$(CH_3)_2$	127	54
4-F	168	67.5
4-Cl	157	67
4-Br	152	32
4-OCH_3	144	77
4-$N(CH_3)_2$	177	5

5.1.3. With Electron-Rich Olefins

The logical extension of the reactions described in Sections 5.1.1 and 5.1.2 to electron-rich olefins (enamines, ketene aminals, ketene acetals) leads in the presence of an equimolar quantity of triethylamine to the phenylcyclobutenediones *(26)*[40] (Table 4).



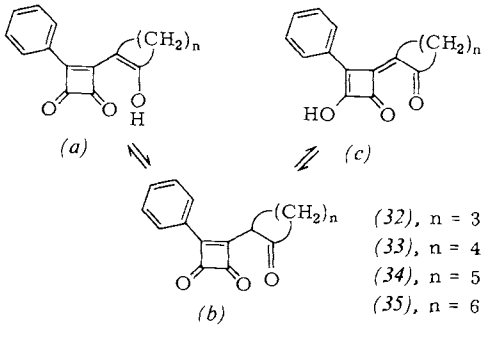


Table 4. Phenylcyclobutenediones of the type *(26)*.

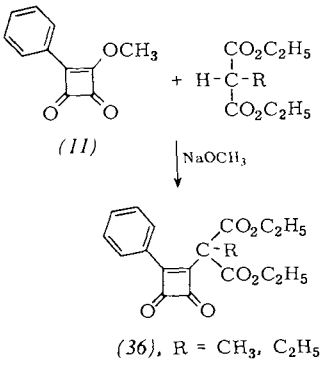
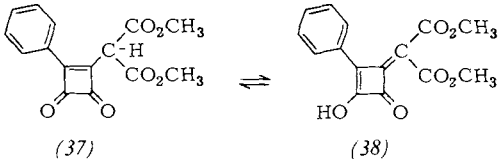
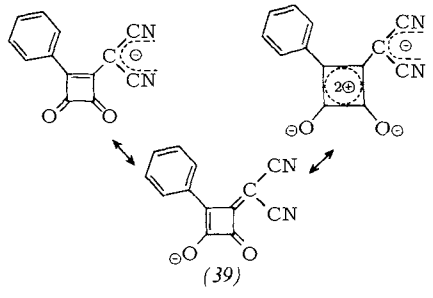
	R¹	R²	R³	M. p. (°C)	Yield (%)
(27)	C_6H_5	Piperidyl	H	212–213	47
(28)		$-(CH_2)_3-$	Morpholino	160–162 (dec.)	65
(29)		$-(CH_2)_4-$	Morpholino	136–138	56
(30)		$-(CH_2)_5-$	Morpholino	146–148	65
(31)		$-(CH_2)_6-$	Morpholino	167–168	46



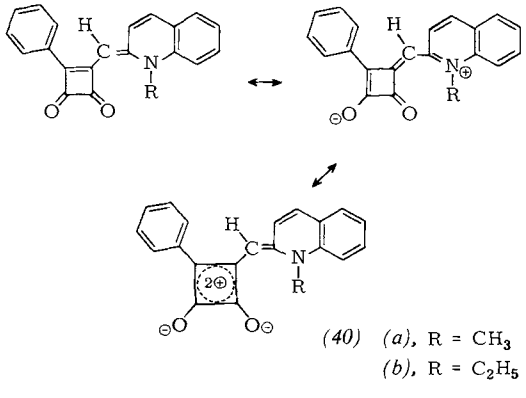
The configuration of the phenylcyclobutenediones of the type *(27)* has been established by NMR spectroscopy. The cyclobutenyl and the piperidyl residues were found to be *trans* to each other[40].



The compounds *(28)* to *(31)* can be readily hydrolyzed with hydrochloric acid to *(32)* to *(35)*. The equilibrium between the forms *(a)* to *(c)* favors the form *(a)* in *(32)* ($n=3$), while the keto form *(b)* is favored in *(33)* to *(35)* ($n=4$—6). The occurrence of the cyclobutenol *(c)* has not been observed in any case.

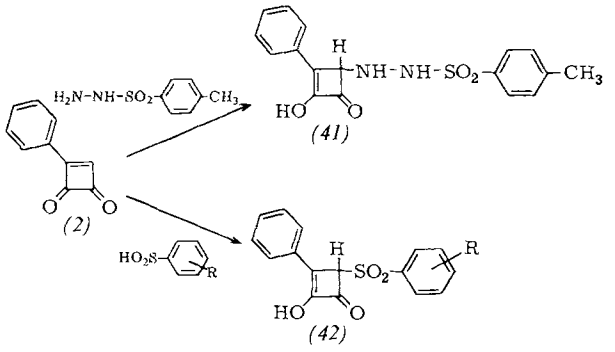


5.1.4. With Carbanions



The reactions of methoxyphenylcyclobutenedione *(11)* with active-methylene compounds in the presence of alkalis are particularly interesting[41]. Whereas *(11)* reacts with substituted malonic esters to form the 3-alkyl-4-phenylcyclobutenediones *(36)*, we obtained the hydroxyphenylcyclobutenone *(38)* with diethyl malonate; this result points to a displacement of the equilibrium between the phenylcyclobutenedione *(37)* and its enol form *(38)* in favor of the latter. Under the same conditions, the reaction with malonodinitrile leads to the anion *(39)*.

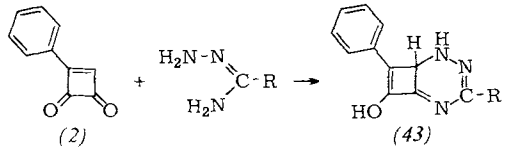
We obtained compounds having a similar mesomeric four-membered ring system in the reaction of *(11)* with quinaldinium iodides.



The strong contribution of limiting resonance structures to the ground state of the compounds *(40a)* and *(40b)* can be deduced from their properties. Unlike the phenylcyclobutenediones *(36)*, they are practically insoluble in the common organic solvents. They are also characterized by deep colors and unusually high decomposition points, and are closely related to the dyes synthesized from diethyl squarate and pyridinium, quinolinium, and benzothiazo-

lium iodides[42], though the latter have similar substituents in positions 3 and 4.

5.2. Addition Reactions



5.2.1. With Tosylhydrazine and Sulfinic Acids

The possibility of additions to phenylcyclobutenedione *(2)* with formation of cyclobutenols is illustrated by the reaction with tosylhydrazine. Instead of tosylhydrazone, the addition product *(41)* was isolated[43].

Phenylcyclobutenedione *(2)* reacts in a similar way with arenesulfinic acids with formation of 4-arenesulfonylcyclobutenols *(42)*[44] and parallels the aldehydes[45] and quinones[46] in its behavior.

The reaction of phenylcyclobutenedione *(2)* with amidrazones includes a condensation step and addition to the four-membered ring system[43].

5.2.2. With Aromatic Compounds

Aromatic compounds add readily to phenylcyclobutenedione *(2)* in the presence of an equimolar quantity of aluminum chloride. It may be assumed that the complex *(44)*, which is a strong electrophile, is formed as an intermediate[47].

Some 3,4-diaryl-2-hydroxy-2-cyclobuten-1-ones *(45)* are listed in Table 5.

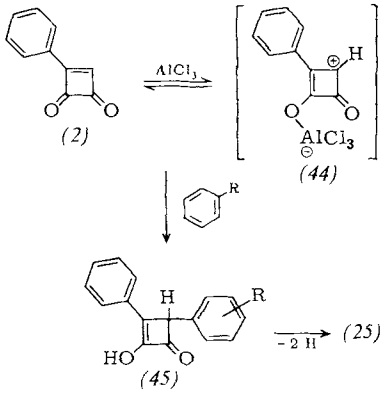


Table 5. 3-Aryl-4-phenyl-2-hydroxy-2-cyclobuten-1-ones *(45)*.

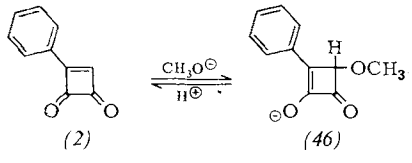


R	M. p. (°C)	Yield (%)
H	198	95
4-CH_3	188	85
2.4-$(CH_3)_2$	191	91
4-F	163	85
4-Cl	172	89
4-Br	175	61
4-OCH_3	198	80
4-$N(CH_3)_2$	220	74

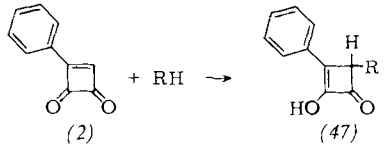
The nucleophilic strength of the aromatic compound is important to the reaction conditions. Weakly nucleophilic aromatic compounds (benzene, halobenzene) are added at boiling point in the absence of solvents, while more strongly nucleophilic aromatic compounds (methoxybenzene) add at lower temperatures in 1,2-dichloroethane. Dialkylanilines can react even in boiling glacial acetic acid[33]. Active-methylene compounds of the malonic acid type have been added to *(2)* in the presence of an equimolar quantity of aluminum chloride[48].

The diarylhydroxycyclobutenones *(45)* can be oxidized with chlorine, bromine or *N*-bromosuccinimide in high yields to form arylphenylcyclobutenediones *(25)*[47], whose preparation by a Friedel-Crafts reaction was described in Section 5.1.2.

5.2.3. With Carbanions

On addition of an equimolar quantity of sodium methoxide to a methanolic solution of phenylcyclobutenedione *(2)*, the equilibrium *(2)* ⇌ *(46)* is established[49].

On the basis of this observation, alkylhydroxyphenylcyclobutenones *(47)* have been obtained from *(2)* and carbanions after the fashion of a Michael addition[48] (see Table 6).



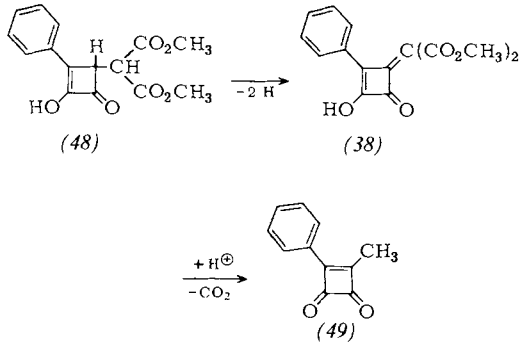


Table 6. Alkylhydroxyphenylcyclobutenones *(47)*.

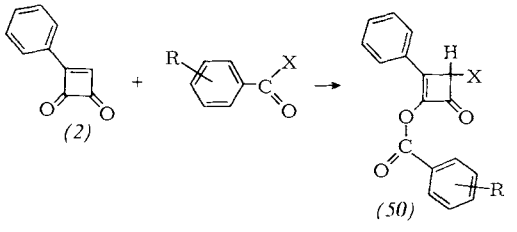
R	M. p. (°C)	Yield (%)
$C(CO_2C_2H_5)_2CH_2C_6H_5$	174	38
$C(CO_2C_2H_5)_2C_2H_5$	127	30
$C(CO_2CH_3)_2H$	149	54

The hydroxycyclobutenones *(47)* are comparable to the compounds *(45)* in their properties and reactivity. Surprisingly, however, the hydroxycyclobutenone system is retained on oxidation of *(48)*; the product formed is 2-



[bis(methoxycarbonyl)methylene]-4-hydroxycyclobutenone *(38)*[41] (see Section 5.1.4), whose hydrolysis and decarboxylation leads to 3-methyl-4-phenylcyclobutenedione *(49)*[50].

(48) *(38)* *(49)*

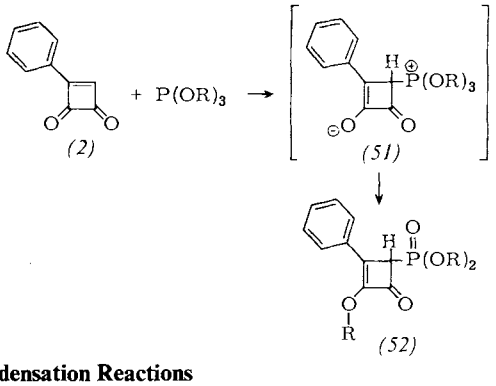
5.2.4. With Aroyl Halides

The action of aroyl halides on phenylcyclobutenedione *(2)* results in aroylation of the carbonyl group adjacent to the phenyl residue to form the 2-aroyloxy-4-halo-3-phenyl-2-cyclobuten-1-ones *(50)*[51], whose constitution has been demonstrated chemically and spectroscopically as follows:

(2) *(50)*

a) When sulfuric acid is allowed to act for a short time on *(50)*, X = Cl, R = H, *(2)* is formed again, *i. e.* the compound contains a four-membered ring.

b) The bands at 1775 cm^{-1} (with a shoulder at 1800 cm^{-1}) and 1625 cm^{-1} in the IR spectrum of *(50)*, X = Cl, R = H, can be interpreted as the C=O and C=C stretching vibrations of a cyclobutenone system. The UV spectrum (λ_{max} = 294 nm; ε_{max} = 24895 in acetonitrile) also points to a cyclobutenone.



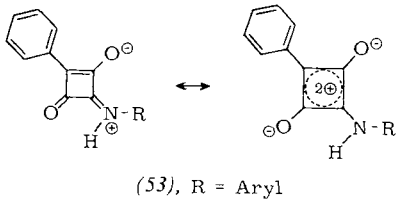
c) The ^{1}H-NMR spectrum of *(50)*, X = Cl, R = H, shows a multiplet at δ = 7.4 to 8.3 (10 H) and a singlet at δ = 5.6 (1 H). The position of the singlet is characteristic of an "allyl proton" in the cyclobutenone system[52, 53].

The nature of the halogen X in the aroyl halides determines how the reaction proceeds. Whereas no reaction takes place with benzoyl bromide and aroyl chlorides, the reaction with benzoyl iodide is complete after a short time. However, aroyl chlorides and aroyl bromides also add smoothly to *(2)* in the presence of Lewis acids[54].

The cyclobutenones *(50)*, which are in the form of white to yellowish-white crystals after recrystallization, are photochromic[55]. The reaction of 3,4-diphenylcyclobutenedione *(5)* with benzoyl bromide in the presence of catalytic quantities of zinc chloride[56] or with thionyl chloride in dimethylformamide[57] leads to 2,2-dihalo-3,4-diphenylcyclobutenones.

5.2.5. With Trialkyl Phosphite

De Selms[58] showed that trialkyl phosphites also add to phenylcyclobutenediones *(2)*. An alkyl group is transferred to the polarized carbonyl group of the hypothetical intermediate *(51)*, and the cyclobutenones *(52)* are formed.



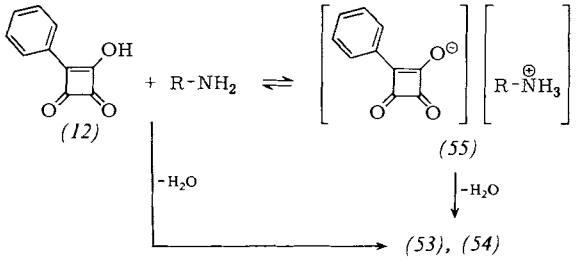
(2) *(51)* *(52)*

5.3. Condensation Reactions

The products formed on reaction of phenylcyclobutenediones with reagents for carbonyl groups have not been extensively studied. Whereas 3,4-diphenylcyclobutenedione *(5)* reacts with tosylhydrazine to give a mixture of mono- and ditosylhydrazones[22], the reaction with 2,4-dinitrophenylhydrazine leads exclusively to the monocondensation product. Monocondensation products are also formed on reaction of *(2)* with 2,4-dinitrophenylhydrazine and with hydroxylamine[7]. There are no reports of investigations on which of the two carbonyl groups of the cyclobutenedione system is attacked or whether a mixture of isomers is formed. Moreover, the occurrence of open-chain products cannot be definitely ruled out[4].

5.3.1. Condensation Reactions of 3-Hydroxy-4-phenylcyclobutenedione

3-Hydroxy-4-phenylcyclobutenedione *(12)* undergoes condensation with primary amines to give derivatives of 2-imonio-3-oxo-4-phenylcyclobuten-1-olate[34, 59] (Table 7), which are similar to the intramolecular salts obtained from squaric acid and amines[42, 60].



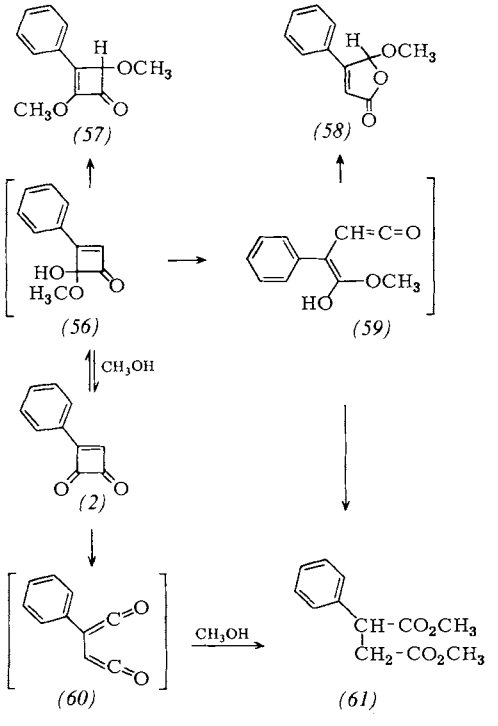
(53), R = Aryl
(54), R = Alkyl

Table 7. Condensation products *(53)* from *(12)* and aromatic amines, and *(54)* from *(12)* and aliphatic amines.

R	M. p. (°C)	Yield (%)
Phenyl	275	72
3-Bromophenyl	280	83
4-Bromophenyl	284	80
3-Nitrophenyl	273	78
4-Aminophenyl	320	72
1-Naphthyl	276	80
2-Naphthyl	262	61
n-Butyl	197—198	89
Benzyl	239—240	64
Cyclohexyl	211—213	65

The compounds *(53)* form yellow to orange-yellow crystals, which are only slightly soluble in solvents of low polarity, but readily soluble in DMF, DMSO, and nitrobenzene. Their decomposition points indicate a high polarity. On the other hand, the compounds *(54)* are yellowish-white and readily soluble. The phenyl residue on the nitrogen atom must thus be responsible for the difference in the properties of the cyclobutenolates.

The reaction of *(12)* with amines under mild conditions leads to the ammonium salts *(55)*, whose stability increases with increasing basicity of the amine. At higher temperatures, the salts *(55)* readily lose water and form the cyclobutenolates *(53)* or *(54)*[59].

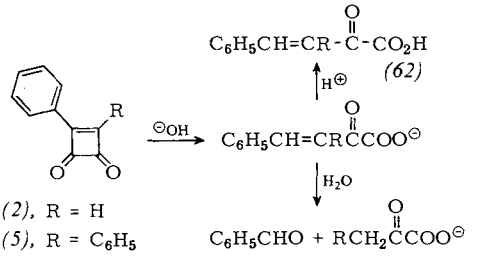


5.4. Ring Cleavage Reactions

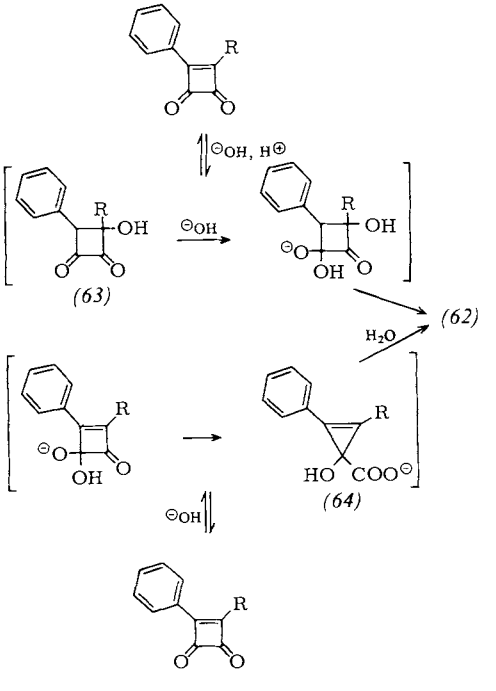
5.4.1. With Alcohols

When phenylcyclobutenedione *(2)* is heated in neutral or acidified methanol, three products are formed, the yields of these products being strongly dependent on the reaction conditions, particularly the temperature. They are dimethyl phenylsuccinate *(61)*, 5-methoxy-4-phenyl-2,5-dihydrofuran-2-one *(58)*, and 2,4-dimethoxy-3-phenylcyclobutenone *(57)*[61].

If the temperature is kept below 135 °C, the main product is *(57)*. By acid catalysis, its yield can be increased to a maximum of 49%.



At higher temperatures (150 °C) *(61)* predominates (64%), while *(58)* is formed in a yield of 8%. 4-Hydroxy-4-methoxy-3-phenylcyclobutenone *(56)* existing in equilibrium with phenylcyclobutenedione *(2)* in methanol solution has been postulated as the precursor of the compounds *(57)*, *(58)*, and *(61)*.

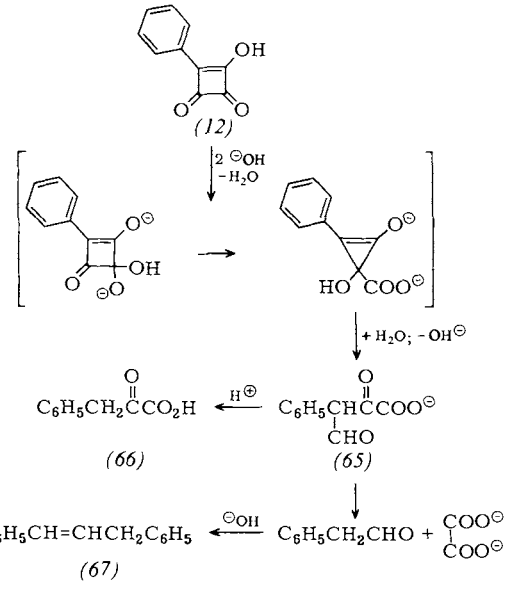


Another path for the formation of *(61)* is offered by the thermal ring cleavage of *(2)* to give the diketene *(60)* and the addition of the latter to methanol. The cleavage of 3,4-diphenylcyclobutenedione *(5)* in ethanol presumably also proceeds *via* a diketene. It leads to a mixture of the meso form and the racemate of diethyl diphenylsuccinate[22].

5.4.2. With Alkalis

Phenylcyclobutenedione *(2)* undergoes ring cleavage when heated in methanolic alkali solution. Benzylidenepyruvic acid *(62)*, R = H, was found as a primary decomposition product. Under the conditions indicated, however, *(62)*, R = H, decomposes mainly into benzaldehyde and pyruvic acid in a reversed aldol reaction[49].

The action of methanolic sodium hydroxide solution on diphenylcyclobutenedione *(5)* similarly yields benzaldehyde and benzylidenephenylpyruvic acid *(62)*, R = C_6H_5, which was isolated as 2,3-diphenyltetrahydrofuran-4,5-dione[62].

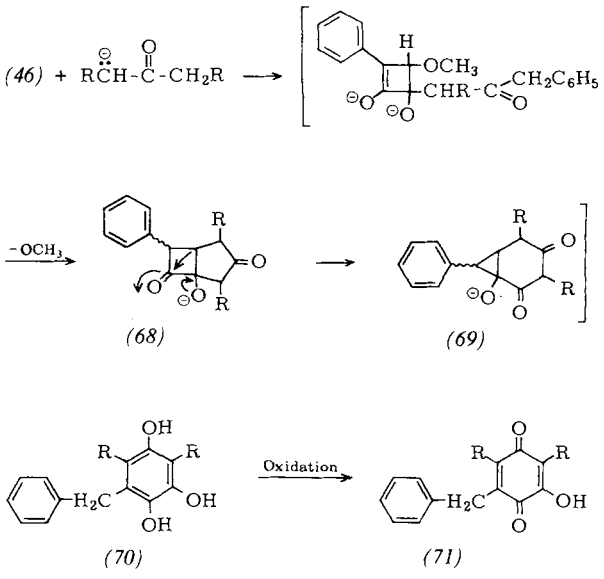


Two mechanisms have been proposed for the alkaline ring cleavage of the phenylcyclobutenediones *(2)* and *(5)*:

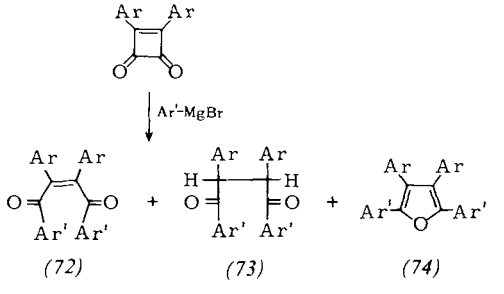
1. Addition of a hydroxide ion to the double bond of the cyclobutenedione system followed by uptake of a proton leads to the hydroxycyclobutanedione *(63)*, which is converted into *(62)* by the action of further alkali after the manner of a ring cleavage-elimination reaction[62].

2. Addition of a hydroxide ion to one of the two carbonyl groups of the cyclobutenedione yields a cyclobutenone, which rearranges to give the hydroxyphenylcyclopropenecarboxylic acid *(64)*, and this finally undergoes ring cleavage to form *(62)*[49].

A similar mechanism is thought to occur in the alkaline ring cleavage of hydroxyphenylcyclobutenedione *(12)*, which yields phenylpyruvic acid *(66)*, 1,3-diphenylpropene *(67)*, and oxalic acid[49].



The assumption of 3-formylpyruvic acid *(65)* as the first ring cleavage product[49] was recently confirmed by its isolation[37b].

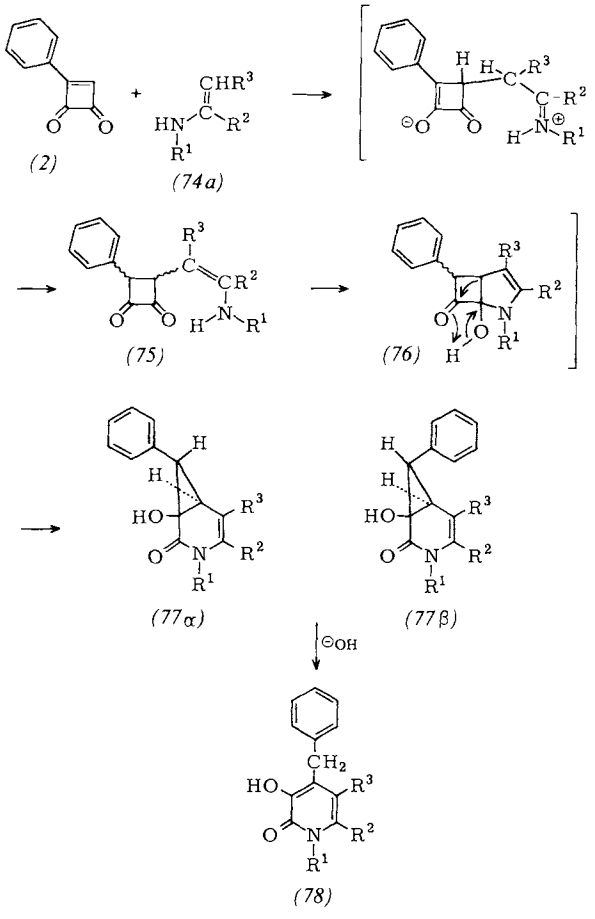


5.4.3. With Carbanions

The reaction of phenylcyclobutenedione *(2)* with dibenzyl ketone in methanolic alkali can be interpreted by a mechanism similar to that proposed by *Roberts* for the alkaline decomposition of 2-hydroxy-3-phenyl-2-cyclobuten-1-one[49]. The reaction leads to 1,2,4-trihydroxy-3,5-diphenyl-6-benzylbenzene *(70)*, which can be oxidized with air to the *p*-quinone *(71)* and isolated in this form[63]. Contraction of the four-membered ring in the bicyclic compound *(68)* and rearrangement of the resulting cyclopropanol system *(69)* are accepted as characteristic reaction steps.

The action of arylmagnesium bromides on diarylcyclobutenediones yields a mixture of the products *(72)* to *(74)*, in which the *cis*-diaroylstilbenes *(72)* form the principal component[64].

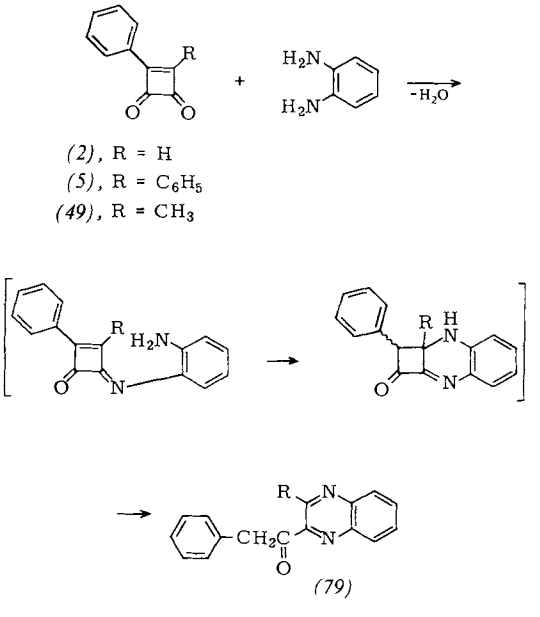
Phenylcyclobutenedione *(2)* reacts with phenyllithium at 0 °C and even at −90 °C to form complicated mixtures of products, which have not yet been investigated[65].



5.4.4. With Enamines

The reaction course described in Section 5.4.3 is supported by the reaction of *(2)* with enamines. The products are azabicyclo[4.1.0]heptenes *(77)*[66], which rearrange smoothly in alkaline media to give the 3-hydroxypyridones *(78)*[67].

It may be assumed that the bicyclic compound *(76)* heteroanalogous to *(68)* is formed *via* the cyclobutane-1,2-dione stage *(75)*; ring contraction then leads to *(77)*. Similar ring contractions have been known in the cyclobutane-1,2-dione series for some time[68]. Behavior of this type has been assumed since 1958 for 2-hydroxy-3-phenyl-2-cyclobuten-1-one[49]. Diarylhydroxycyclobutenones *(45)* also undergo ring contraction under the action of amines and hydrazines to give 2,3-diaryl-1-hydroxycyclopropane-1-carboxamides and -carbohydrazides[69].

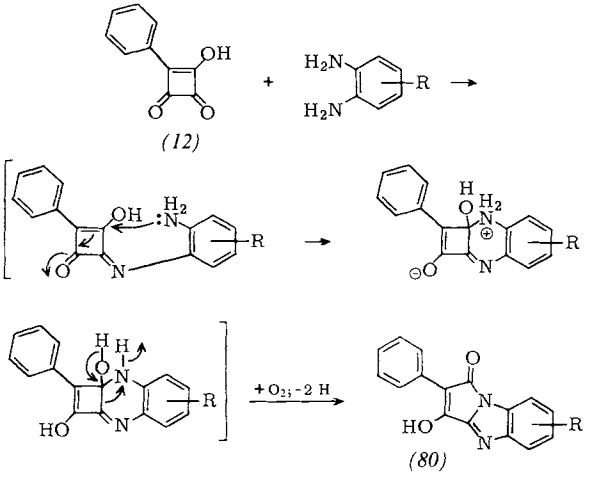


Whereas a bicycloheptene *(77)* having the configuration α was isolated on reaction of *(2)* with ethyl 3-aminocrotonate *(74a)*, $R^1=H$, $R^2=CH_3$, $R^3=CO_2C_2H_5$, the reaction with ethyl *N*-phenyl-3-aminocrotonate *(74a)*, $R^1=C_6H_5$, yields a product having the configuration β. Compounds having the β configuration (65%) and the α configuration (2%) were obtained from a reaction mixture with ethyl *N*-methyl-3-aminocrotonate *(74a)*, $R^1=CH_3$.

(2) (74a) (75) (76) (77α) (77β) (78)

5.4.5. With *o*-Phenylenediamine

Benzocyclobutenedione *(3)*[70] and 1,2-cyclobutanedione[71,68b,c] react with *o*-phenylenediamine to form cyclobuta[*b*]quinoxalines. Phenylcyclobutenedione *(2)*, on the other hand, behaves in an entirely unexpected manner. On fusion of a mixture of *(2)* and *o*-phenylenediamine, *J. D. Roberts et al.*[7] observed the formation of 2-phenylacetylquinoxaline *(79)*, R = H. Diphenylcyclobutenedione *(5)*[62] and methylphenylcyclobutenedione *(49)*[50] react in the same way.



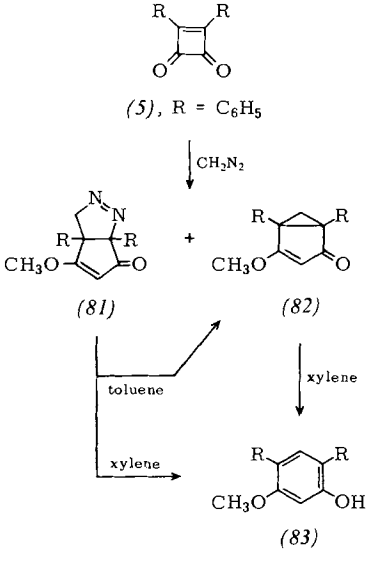
(2), R = H
(5), R = C_6H_5
(49), R = CH_3

(79)

5.5. Reactions with Ring Expansion

5.5.1. With *o*-Phenylenediamine

A new type of reaction has been found in the reaction of *o*-phenylenediamine with hydroxyphenylcyclobutenedione *(12)*. With glacial acetic acid as the solvent and in the presence of atomospheric oxygen, the cyclobutenedione system undergoes ring expansion to give the pyrrolobenzimidazole *(80)*[72,73].

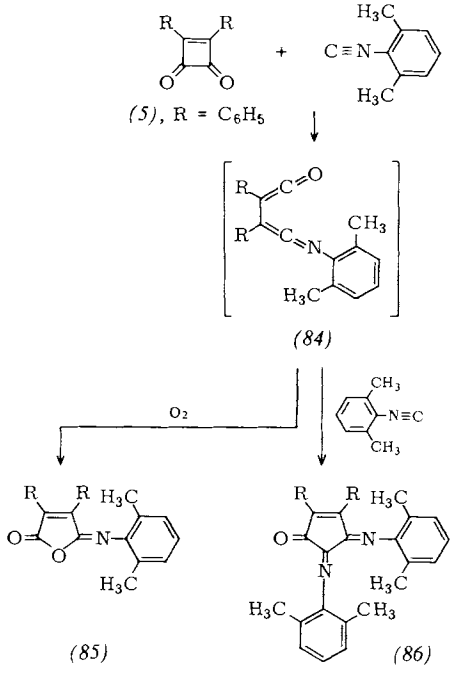


(12) *(80)*

The special position of hydroxyphenylcyclobutenedione *(12)* among the phenylcyclobutenediones, which was observed earlier in the alkaline decomposition, is thus confirmed by its behavior in acids.

5.5.2. With Diazomethane

The action of excess diazomethane on diphenylcyclobutenedione *(5)* leads to cyclopentapyrazole *(81)* and bicyclo[3.1.0]hexenone *(82)* in approximately equal yields.

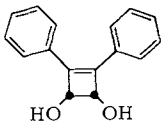


(5), R = C_6H_5
(81) *(82)* *(83)*

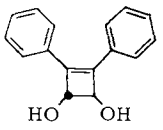
When heated in toluene, *(81)* loses N_2 to form *(82)*, which rearranges into 4'-hydroxy-6'-methoxy-*m*-terphenyl *(83)* when heated for 12 hours in xylene[74].

In view of the immediate formation of *(81)* and *(82)* when the reactants are brought together and the behavior of cyclopentadienone[75] and 2,4,5-triphenyl-4-cyclopentene-1,3-dione[76] towards diazomethane, it is possible to rule out a cyclopentenedione as an intermediate. We believe that the first step is a 1,3-dipolar addition of diazomethane to the double bond of the cyclobutenedione, and that a CH_2 group is only then inserted between the carbonyl groups. The reaction is completed by enolization and methylation.

5.5.3. With Isocyanides



Obata and *Takizawa* found that when diphenylcyclobutenedione *(5)* is heated with 2,6-dimethylphenyl isocyanide, carbon monoxide is eliminated with formation of 4,5-bis-(2,6-dimethylphenylimino)-2,3-diphenylcyclopenten-1-one *(86)* and 5-(2,6-dimethylphenylimino)-3,4-diphenyl-2,5-dihydrofuran-2-one *(85)*[77]. These authors assume that the phenyliminoethyleneketene *(84)* is formed as an intermediate, and reacts with further isocyanide to form *(86)* and with atmospheric oxygen to form *(85)*. Insertion of the isocyanide into the four-membered ring system is ruled out. The authors detected a compound of the type *(84)* on photolysis of *(5)* or its imine derivative[78].

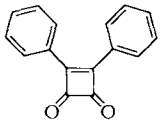


6. Various

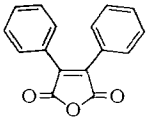
6.1. Reduction

Phenylcyclobutenedione *(2)* is extremely resistant to reducing agents. Attempted catalytic hydrogenations were unsuccessful, since *(2)* or a product formed in small quantities acts as a catalytic poison. Heating with catechol in toluene also failed to cause any perceptible change. Polarographic studies show that the reduction of *(2)* is irreversible and pH-dependent. Under the drastic conditions of the Clemmensen reduction, *(2)* is converted into phenylcyclobutane[7]. The reduction of diphenylcyclobutenedione *(5)* with lithium aluminum hydride yields a mixture of 23% of *cis*-3,4-diphenylcyclobutene-1,2-diol *(87)* and 3% of the *trans* compound *(88)*[79].

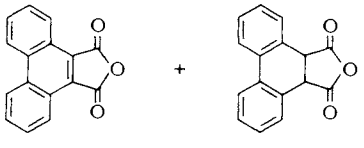
(87)



(88)



6.2. Oxidation



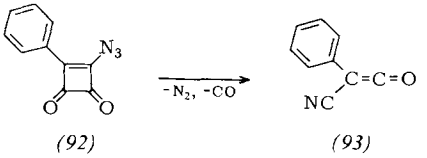
The oxidation of phenylcyclobutenedione *(2)*[7] and of the diphenyl compound *(5)*[22] with permanganate leads to benzoic acid. The action of hydrogen peroxide on *(2)* or *(5)* results in ring expansion after the manner of a Baeyer-Villiger reaction, with formation of substituted maleic anhydrides[7,22].

6.3. Photolysis

The photooxidation of *(5)* in benzene or acetonitrile yields a mixture of phenanthrene-9,10-dicarboxylic anhydride *(89)* and its dihydro derivative *(90)*.

(5)

(91)



(89) *(90)*

The same products are obtained by the action of light on diphenylmaleic anhydride *(91)*, which is postulated as an intermediate[80]. The photolysis of phenylcyclobutenedione *(2)* in methanol at 60 °C leads in a fast reaction to dimethyl phenylsuccinate *(61)* and a substance whose structure is unknown[61,81].

6.4. Phenylcyanoketene

The action of sodium azide on a solution of halophenylcyclobutenedione *(10a)* or *(10b)* in acetonitrile[82] or

(92) *(93)*

acetone[83] leads to immediate evolution of gas. It must be assumed that the azide *(92)* formed as an intermediate decomposes with liberation of CO and N_2. This leads to phenylcyanoketene *(93)*, which has been intercepted with OH compounds.

We are grateful to the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the Hermann-Schlosser-Stiftung, and Farbwerke Hoechst AG for their support of our investigations on this topic. W. R. is grateful to the co-workers mentioned in the references for their assistance. A. H. S. is grateful to the Stiftung Stipendien-Fonds des Verbandes der Chemischen Industrie for a Liebig scholarship.

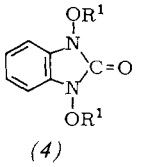
COMMUNICATIONS

Reaction of Benzofuroxan with Formaldehyde

By *Florin Seng* and *Kurt Ley*[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday



Reaction of formaldehyde *(2)* with benzofuroxan *(1)* in the presence of alkali proceeds exothermally to give the hitherto unknown 1,3-dihydroxybenzimidazolin-2-ones *(3)*.

(1) *(2)* *(3)*

(3), R =	Dec. pt. [°C]	Color	Yield [%]
H	227	pale yellow	91
Cl	206	brownish red	65
CH_3	209	yellow	80
CH_3O	153	yellow	62
COOH	260	yellow	76
H_2NCO	220	yellowish brown	67

Reduction of *(3)* by sodium dithionite leads to benzimidazolinones. Numerous reactions can be effected at the hydroxyl groups (alkylation, acetylation, addition of isocyanates and acrylonitrile). Compounds of type *(4)* are thus obtained.

(4)

(a), $R^1 = CH_3$; m.p. 99 °C
(b), $R^1 = COCH_3$; m.p. 91 °C
(c), $R^1 = CONHC_6H_5$; m.p. 183 °C
(d), $R^1 = CH_2CH_2CN$; m.p. 192 °C.

Oxidation of *(3)* with PbO_2 or irradiation in tetrahydrofuran yields a radical with the following splitting parameters $a_N = 5.96$ G; $a_{H_{2,3}} = 0.92$ G; $a_{H_{1,4}} = 2.76$ G; $(= 3 \times a_{H_{2,3}})$; $a_{H_{OH}} = 0.18$ G: $a_{N'} = 0.92$ G $(= a_{H_{2,3}})$

1,3-Dihydroxybenzimidazolin-2-one (3), R = H:

Benzofuroxan (136 g, 1 mol) is suspended in methanol (500 ml) and water (500 ml) and treated with 30% aqueous formaldehyde (100 g, 1 mol). Then a solution of potassium hydroxide (114 g, 2 mol) in water (100 ml) and methanol (100 ml) is added dropwise, the temperature being kept at 40–50 °C by cooling. After the main reaction the solution is stirred for 1 h. The deep red solution is then treated with water (1 l) and acidified with 10% hydrochloric acid. Pale yellow crystals of *(3)*, R = H, then separate (150 g, 91%), which after recrystallization from water melt at 227 °C with violent decomposition. If the solution is acidified with acetic acid, the colorless monopotassium salt (decomp. 204 °C) is obtained.

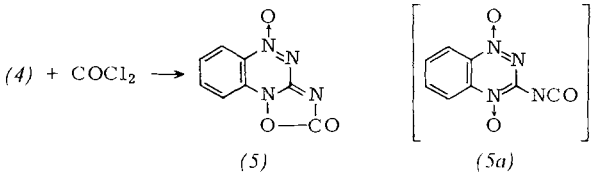
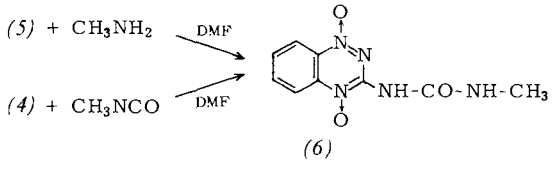
Simple Synthesis of 3-Amino-1,2,4-benzotriazine 1,4-Dioxide

By *Florin Seng* and *Kurt Ley*[*]



Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

Disodiocyanamide *(2)* adds exothermally to benzofuroxan *(1)* with formation of the sodium salt *(3)*, which on acidification is transformed into 3-amino-1,2,4-benzotriazine 1,4-dioxide *(4)*.



[*] Prof. Dr. K. Ley and Dr. F. Seng
Wissenschaftliches Hauptlaboratorium der Farbenfabriken
Bayer AG
509 Leverkusen-Bayerwerk (Germany)

Treating *(4)* with phosgene in toluene at 90 °C gives *(5)*, which behaves like the isocyanate *(5a)* towards nucleophiles.

The structure of *(5)* is proved by its reaction with methylamine to give the urea *(6)* that is also obtained from *(4)* and methyl isocyanate.

3-Amino-1,2,4-benzotriazine 1,4-dioxide (4):

Benzofuroxan (136 g, 1 mol) is suspended in methanol (400 ml) and water (400 ml) and treated with disodiocyanamide (172 g, 2 mol). The temperature rises to 50—60 °C and the solution becomes bluish-violet. After 10 min a further portion of disodiocyanamide (86 g, 1 mol) is added, and 15 min later *(3)* separates as a bluish-violet precipitate. This is filtered off and dissolved in water, the solution is filtered and the filtrate is acidified with acetic acid. *(4)* (144 g, 81%) then separates as reddish-yellow crystals that melt with decomposition at 220 °C (Ref. [1], 220 °C).

Reaction of (4) with phosgene:

(4) (35.6 g, 0.2 mol) is suspended in toluene (200 ml). A vigorous stream of phosgene is passed into this suspension at 90 °C. After 4 h, filtration gives *(5)* as yellowish-brown crystals (34 g, 84%), which after recrystallization from acetonitrile melt at 262 °C with decomposition.

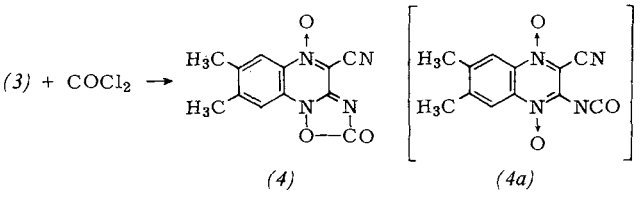
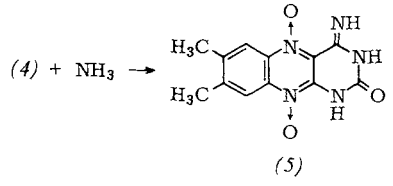
A New Synthesis of Lumichrome

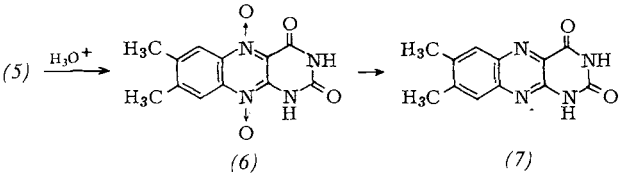


By *Florin Seng* and *Kurt Ley*[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday



Benzofuroxans add malonodinitrile *(2)* in the presence of bases, yielding 2-amino-3-cyanoquinoxaline 1,4-dioxides[1,2]. This type of synthesis provides a very simple route to lumichrome[3].



5,6-Dimethylbenzofuroxan *(1)*[4] is converted by *(2)* into the dioxide *(3)*. Intramolecular ring closure of *(3)* with phosgene in chlorobenzene at 90 °C leads to 4-cyano-7,8-dimethyl-2-oxo-1,2,4-oxadiazolo[2,3-*a*]quinoxaline 5-oxide *(4)*, which behaves like the isocyanate *(4a)* on treatment with nucleophiles.

Thus reaction with ammonia leads to the iminobenzopteridine 5,10-dioxide *(5)* by addition and simultaneous ring closure involving the nitrile group.

Acid hydrolysis of *(5)* to give *(6)*, and reduction of the latter, afford lumichrome *(7)* in high yield.

The structures of the new compounds *(3)* to *(6)* were proved by analysis and spectroscopy.

2-Amino-3-cyano-6,7-dimethylquinoxaline 1,4-dioxide (3):

5,6-Dimethylbenzofuroxan *(1)* (164 g, 1 mol) and malonodinitrile (70 g, 1.05 mol) are dissolved in dimethylformamide

[*] Prof. Dr. K. Ley and Dr. F. Seng
Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG
509 Leverkusen-Bayerwerk (Germany)

(750 ml), and triethylamine (25 g, 0.25 mol) is added dropwise over 30 min. The temperature is kept at 25—30 °C by cooling in ice. After 1.5 h the precipitate is filtered off, affording *(3)* (160 g, 70%) as golden-red crystals, which after recrystallization from dimethylformamide melt at 253 °C with decomposition.

4-Cyano-7,8-dimethyl-2-oxo-1,2,4-oxadiazolo[2,3-a]-quinoxaline 5-oxide (4):

(3) (230 g, 1 mol) is suspended in chlorobenzene (2 l), and a vigorous stream of phosgene is passed through the suspension at 80—90 °C, whereupon the color changes from red to yellow. The reaction is complete when addition of a sample of the yellow precipitate to water no longer produces a red color. On filtration, yellow crystals of *(4)* (239 g, 93%) are obtained, which after recrystallization from DMSO melt at 228 °C with decomposition.

4-Imino-7,8-dimethylbenzopteridine 5,10-dioxide (5):

(4) (25.6 g, 0.1 mol) is suspended in dimethylformamide (150 ml) and treated with concentrated ammonia solution (20 g). After 8 h, filtration affords yellowish-brown crystals of *(5)* (25 g, 92%), which after recrystallization from dimethylformamide melt at 360 °C with decomposition.

7,8-Dimethylbenzopteridine 5,10-dioxide (6):

(5) (27.3 g, 0.1 mol) is stirred in 20% sulfuric acid (300 ml) for 8 h at 80 °C. Filtration then affords yellow crystals of *(6)* (21.5 g, 77%).

7,8-Dimethylbenzopteridine (7), lumichrome:

(6) (27.4 g, 0.1 mol) is suspended in methanol (200 ml) and treated at 70 °C dropwise with a solution of sodium dithionite (60 g) in water (210 ml). After 5 h the mixture is cooled and filtered. The precipitate isolated is stirred with water, thus affording lumichrome *(7)* as yellow crystals that, after recrystallization from glacial acetic acid, melt with decomposition at 354 °C (Ref. [3], 360 °C).

N-Carbonylureas from Azomethines and *N*-Chlorocarbonyl Isocyanate

By *Hermann Hagemann* and *Kurt Ley*[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

Although it is known that carboxamides[1], carbamidic esters[2], and carbamidamides[3] are converted by oxalyl chloride or phosgene into the corresponding isocyanates, the analogous reaction with ureas has not previously been recorded. We have now prepared isocyanates of type *(3)* (water-clear distillable liquids) by a simple method, namely addition of *N*-chlorocarbonyl isocyanate *(2)*[4] to Schiff bases *(1)*.

$$\mathrm{Ar\text{-}CH{=}N\text{-}R} + \mathrm{Cl\text{-}CO\text{-}NCO} \longrightarrow \mathrm{Ar\text{-}\underset{\displaystyle Cl}{\underset{|}{CH}}\text{-}\overset{\displaystyle C{=}O}{\overset{|}{N}}\text{-}R}$$

(1) *(2)* *(3)*

(3)	Ar	R	B.p. [°C/torr]	Yield [%]
(a)	C_6H_5	CH_3	112/0.05	66
(b)	C_6H_5	$i\text{-}C_3H_7$	115/0.15	65
(c)	C_6H_5	Cyclohexyl	142/0.07	15
(d)	C_6H_5	C_6H_5	152/0.1	70
(e)	$p\text{-Cl—}C_6H_4$	CH_3	115/0.1	86

In *(3)* the basic character of the amide nitrogen is weakened by the neighboring chlorine atom, which would be expected to contribute significantly to the stability of such *N*-carbonylureas. The reactivity towards acylatable compounds is comparable with that of alkoxycarbonyl isocyanates[2].

The structures of the compounds obtained are proved by their IR spectra [stretching vibrations at 1700 cm^{-1} (C=O) and 2242 cm^{-1} (N=C=O)], NMR spectra, results of elemental analysis, and chemical reactions.

Experimental:

N-Chlorocarbonyl isocyanate *(2)* (105.5 g, 1 mol) in chlorobenzene (250 ml) is treated dropwise over 45 min at 15—30 °C with the Schiff base (119 g, 1 mol) from benzaldehyde and methylamine. The whole is stirred at *ca.* 25 °C for 3 h, then the chlorobenzene is removed at water-pump pressure and the residue is distilled at oil-pump vacuum. This affords *(3a)* (148 g, 66%) as a colorless oil of b.p. 112 °C/0.05 torr.

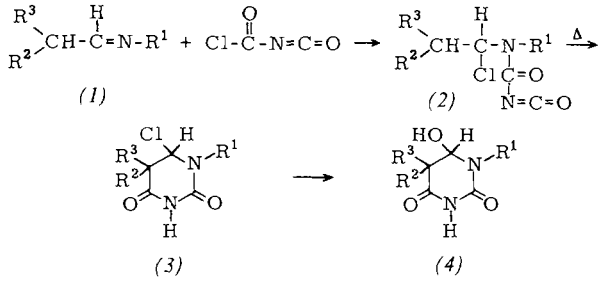
Cyclization of Azomethines by *N*-Chlorocarbonyl Isocyanate



By *Hermann Hagemann* and *Kurt Ley*[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

Schiff bases from aromatic aldehydes add *N*-chlorocarbonyl isocyanate[2] with retention of the isocyanate group[1]. The products, of type *(2)*, are formed also on treatment of azomethines *(1)* with *N*-chlorocarbonyl isocyanate.

509 Leverkusen (Germany)

(1) (2) (3) (4)

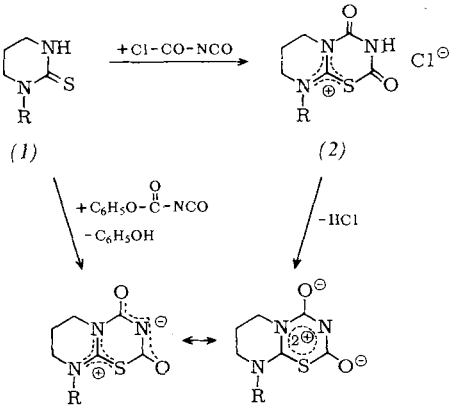
within wide limits[1]. Only little is known about six-membered representatives of this class of compound[2]. We obtained *(3)*, a derivative of imidodicarboxylic acid, by treatment of *N*-chlorocarbonyl isocyanate[3] with trisubstituted thioureas *(1)* and dehydrochlorination of the salt-like compounds *(2)* first formed.

Reservations may be made about the aromatic character of *(3)*, as for the five-membered mesoionic aromatic compounds of type *(4)*[4,1]. The photoelectron spectra[5] of *(3)*

	R^1	R^2	R^3	*(3)*, m.p. [°C]	*(3)*, yield [%]	*(4)*, m.p. [°C]	*(4)*, yield [%]
(a)	cyclohexyl	CH_3	CH_3	198	92	213	92
(b)	cyclohexyl	$-CH_2-CH=CH-(CH_2)_2-$		211	91	213	98
(c)	CH_3	CH_3	CH_3	205—207	57	180	66
(d)	CH_3	$-CH_2-CH=CH-(CH_2)_2-$		190	44	192	60
(e)	benzyl	CH_3	CH_3	86—88	70	204	39
(f)	i-C_3H_7	CH_3	CH_3	161—163	78	203	92

The reaction of derivatives of disubstituted acetaldehyde does not stop at the isocyanates *(2)*, but on gentle warming (*ca.* 90 °C) a rapid cyclization occurs, yielding 6-chloropyrimidine-2,4-diones *(3)*.

Like the open-chain analogs[3], these heterocycles are readily substituted by nucleophiles at carbon atom 6: heating with water or aqueous ethanol leads smoothly to *(4)*.



The structures of the products are proved by IR and NMR spectra and the results of elemental analysis.

Experimental:

A solution of the aldimine (153 g, 1 mol) from isobutyraldehyde and cyclohexylamine in chlorobenzene (600 ml) is added dropwise at 20—30 °C (cooling) to a solution of *N*-chlorocarbonyl isocyanate (105.5 g, 1 mol) in chlorobenzene (200 ml). The mixture is kept at room temperature for 2 h, then stirred for a further hour with gradual warming to 90 °C. Most of the product then separates. After cooling, compound *(3a)* is obtained as colorless crystals (190 g), melting at 198 °C. A further crop (47 g) of *(3a)* can be isolated from the mother liquor.

(3f) (100 g, 0.46 mol) is recrystallized from water (500 ml). This affords the dihydrobarbiturate *(4f)* (84 g, 92%) melting at 203 °C.

Six-Membered Mesoionic "Aromatic" Compounds

By *Hermann Hagemann* and *Kurt Ley*[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

The position and nature of the hetero atoms in five-membered mesoionic compounds of sydnone type can be varied

[*] Dr. H. Hagemann and Prof. Dr. K. Ley
Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG
509 Leverkusen-Bayerwerk (Germany)

152—155 °C, which is recyclized to *(3a)* by phosgene in the presence of a tertiary amine. 3,4-Dichloroaniline reacts with *(3a)* even at *ca.* 20 °C, giving the monothiotriuret *(6a)*, m.p. 163 °C. *(3a)* can be prepared from *(1a)* and phenoxycarbonyl isocyanate in boiling toluene even in absence of a tertiary base.

Experimental:

A solution of *(1a)* (11.6 g, 0.1 mol) in methylene chloride (40 ml) is added, with cooling, to one of *N*-chlorocarbonyl isocyanate (10.5 g, 0.1 mol) in methylene chloride (60 ml). The white precipitate of *(2a)* that is immediately formed is filtered off and dried. M. p. 222 °C. Yield 19.5 g (95%).

A solution of *(2a)* (22.15 g, 0.1 mol) in water (50 ml) is added dropwise with cooling, to one of *N,N*-dimethylaniline (12.1 g, 0.1 mol) in methanol (50 ml). The white precipitate is filtered off and washed with water, giving 70% (13 g) of *(3a)*, m.p. 210—211 °C.

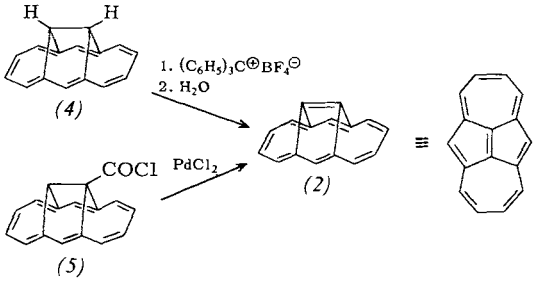
Dicyclohepta[*cd,gh*]pentalene—A New Pyrene Isomer[**]

By *Henning Reel* and *Emanuel Vogel*[*]

Dedicated to Professor Otto Bayer on the occasion of his 70th birthday

HMO calculations[1] on the three non-alternant pyrene isomers consisting only of five- and seven-membered rings dicyclopenta[*ef,kl*]heptalene *(1)*, dicyclohepta-[*cd,gh*]pentalene *(2)*, and pentaleno[2,1,6-*def*]heptalene *(3)* which, like pyrene, have Kekulé structures with a peripheral 14π Hückel system and a central double bond yield the relatively high resonance energies (R_E) of 6.05 β, 6.03 β, and 5.95 β respectively (pyrene: $R_E = 6.51$ β). Accordingly, compound *(1)* which has very recently been synthesized by two independent routes[2] and the longer known 9-methyl derivative of *(3)*[3] are thermodynamically

(1) *(2)* *(3)*



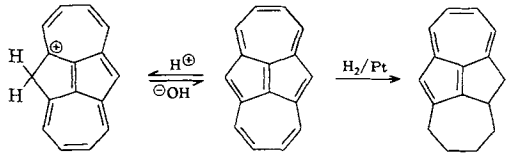
[*] Dr. H. Reel and Prof. Dr. E. Vogel
Institut für Organische Chemie der Universität
5 Köln 1, Zülpicher Strasse 47 (Germany)

[**] To facilitate comparison, the numbering chosen for *(2)* corresponds to that of bridged [14]annulenes having an anthracene perimeter.

stable hydrocarbons deserving the designation aromatic. The hitherto elusive pyrene isomer *(2)*—which has long been the goal of synthetic efforts[4] and the subject of quantum mechanical calculations[1,4-8]—has now been prepared in our laboratory.

Dicyclohepta[*cd,gh*]pentalene *(2)* attracted our interest since it is to be regarded as the parent of the bridged [14]annulenes possessing an anthracene perimeter: 1,6;8,13-ethanediylidene[14]annulene *(4)*[9], 1,6;8,13-propanediylidene[14]annulene[10], 1,6;8,13-butanediylidene-[14]annulene[11] *etc.*[8,12].

As can be readily seen, this series of [14]annulenes is derived from the above Kekulé structure of *(2)* by replacement of its formal central double bond by the >CH—$(CH_2)_n$—CH< grouping with $n = 0,1,2$, *etc.* The recently described 1,6;8,13-ethanediylidene[14]annulene *(4)*[9] thus represents the *cis*-15,16-dihydro derivative of *(2)*. This relationship prompted experimental efforts to convert *(4)* into *(2)* by dehydrogenation.



Contrary to expectation, dehydrogenation of *(4)* by the usual methods ran into difficulties; either no reaction took place (with noble metal catalysts in boiling decalin!) or decomposition occurred (with 2,3-dichloro-5,6-dicyanobenzoquinone). The desired transformation eventually became possible when we observed that a bridge hydrogen is abstracted as hydride ion when *(4)* is treated with triphenylmethyl tetrafluoroborate in acetonitrile (at *ca.* 50 °C). Treatment of the resulting stable carbenium ion, *i.e.* protonated *(2)*, with water effects deprotonation to give *(2)* [yield 70% based on *(4)*][13]. The interesting question whether the aforementioned carbenium ion intermediate is the primary product of hydride abstraction [*(2)* protonated in position 15] or the hydride-shift product *(6)*[4] is still open since the poor solubility of the ion has so far hampered NMR studies.

The hydrocarbon *(2)* was subsequently found to be more readily accessible by degradation of 1,6;8,13-ethanediylidene[14]annulene-15-carboxylic acid[9] than by the two-step dehydrogenation of *(4) viz.* a) by heating the acyl chloride *(5)* with palladium chloride in decalin to 170—180 °C (yield 25%) and b) by reaction of *(5)* with sodium azide in acetone/water and subsequent heating of the resulting carbonyl azide in ethanol (yield 50%)[14]. Compound *(2)* is relatively stable towards air and crystallizes from cyclohexane (yellowish-brown solution) as greenish black needles of m.p. 141—142 °C (partial decomposition).

The NMR spectrum of the pyrene isomer *(2)* (0.35 mol in CS_2/TMS) consists only of an AA'BB' system at $\tau_A = 1.34$ (H^2,H^5,H^9,H^{12}) and $\tau_B = 1.92$ (H^3,H^4,H^{10},H^{11}) with the coupling constants $J_{2,3} = 9.91$ Hz, $J_{2,4} = 0.44$ Hz, $J_{2,5} = 0.80$ Hz, and $J_{3,4} = 10.23$ Hz, and a singlet at $\tau = 1.94$ (H^7,H^{14})[15]. The shape and coupling constants of the spectrum thus correspond to those of the spectra

of the bridged [14]annulenes derived from *(2)*. The pronouncedly downfield position of the proton resonances can be rationalized by assuming an important contribution by the Kekulé structures with a peripheral 14π system—as inferred from the theoretically determined bond orders in *(2)*[4]. An alternative interpretation of the observed chemical shifts derives from ring-current calculations by *Jung*[6], which predict diamagnetic ring currents in the five- and seven-membered rings of *(2)* and of the isomers *(1)* and *(3)*. Support for the conclusions drawn from the NMR spectrum and MO calculations regarding the π-electron structure of *(2)* should come from an X-ray structural analysis of the hydrocarbon that is currently in progress[16].

The absorption bands of the UV spectrum of *(2)* [(in cyclohexane): $\lambda_{max}=235$ ($\varepsilon=27000$, sh), 284 (181300), 296 (33750 sh), 310 (26500), 321 (6950, sh), 363 (6200, sh), 367 (8700), 374 (4750, sh), 383 (6780), 387 (12200), 427 (720, sh), and 486 nm (4660)] are in satisfactory agreement with the values calculated by a simplified Pariser-Parr-Pople method[5].

(6) *(2)* *(7)*

The prediction, based on HMO calculations[4], that electrophiles will preferentially attack *(2)* in position 7 (or 14) has meanwhile been confirmed for protonation. *(2)* dissolves in trifluoroacetic acid or in 50% sulfuric acid to form the stable carbenium ion *(6)* [NMR spectrum (in CF_3COOH): complex multiplet at $\tau=0.52-1.58$ (9H) and singlet at 4.30 (2H)], from which the hydrocarbon can be regenerated, albeit with some losses, by addition of dilute sodium hydroxide solution at 0°C.

By analogy with the catalytic hydrogenation of the 9-methyl derivative of *(3)*[3], treatment of *(2)* with Pt/H_2 in ethanol yields an azulene derivative (together with other hydrogenation products); the compound designated structure *(7)* has so far become available in only very small quantities so that its characterization has been limited to UV and mass spectrometry.

Unusual Oxidation States of Metalloporphyrins: Octaethylporphinatosilver(III) Perchlorate[**]

By *Karl Kadish, Donald G. Davis*, and *Jürgen H. Fuhrhop*[*]

During a comprehensive survey of the redox potentials of some 30 different metalloporphyrin compounds certain anomalies were noticed which indicated the formation of some unusual oxidation states of the central metal ion. It has been shown that for the case of a simple derivative, such as tetraphenylporphinatozinc(II) or the corresponding etioporphyrin compound, the porphyrin ring can be oxidized in two successive, reversible, one-electron steps[1-3] (yielding π cation radicals and dications) and reduced in two successive, reversible, one-electron steps[4-6] (yielding π anion radicals and dianions). In several metalloporphyrins, such as those involving Mn, Co, and Fe, the central metal ion itself may undergo an oxidation state change $M^{II} \rightleftarrows M^{III}$. The decision as to whether a given reaction is that of the ring or the metal ion can often be made on the basis of visible and/or ESR spectra[1, 3, 5, 6].

Another criterion for differentiating between metal and ring reactions is provided by electrochemical potentials. During a cyclic voltammetric study[7] we observed that the absolute redox potentials of ring oxidations and reductions fall into well defined patterns: the numerical difference between the half-wave potential ($E_{\frac{1}{2}}$) for the first ring oxidation (in butyronitrile) and the first ring reduction (in dimethyl sulfoxide) remained constant at $E_{\frac{1}{2}ox}-E_{\frac{1}{2}red}=2.25\pm0.15$ V, regardless of the charge on the central metal ion. This was true for the M^{2+} ions of Mg, Ca, Cu, Ni, Pd,

Zn, Cd; the M^{3+} ions of Al, Ga, In, Tl, Sc, Cr, and Fe; and the M^{4+} ions of Si, Sn, Ge, Ti, and V. Intermediate changes in the metal oxidation state appeared to have little effect on the observed value of 2.25 V. The only exceptions were Mn and Mo, which is probably due to an interaction of metal d orbitals with the porphyrin $e_g(\pi)$ orbitals. Further correlations also indicated that the difference between the first and second ring oxidation ($\Delta E_{\frac{1}{2}\,ox}$) was 0.29 ± 0.05 V, while that between the first and second ring reduction ($\Delta E_{\frac{1}{2}\,red}$) was 0.42 ± 0.05 V. These values agree well with the average values of 0.30 and 0.44 V, respectively, from the data available for a number of tetraphenylporphyrin-metal chelates[2, 5].

Constancy of these ΔE values over a wide range of central metal ions is a good indication that the electron transfers involve the porphyrin ring and not the metal. Conversely, apparent deviations can be regarded as an indication that the reaction possibly involves an originally unsuspected change in metal oxidation state. Visible and ESR spectroscopy can then be used to fully elucidate the situation.

For example, the $\Delta E_{\frac{1}{2}\,ox}$ for octaethylporphinatoiron(III) is 0.24 V and thus agrees well with the value expected for two consecutive ligand oxidations. This finding appears not to support the contention that the oxidation of porphyrin-Fe^{III} compounds produces Fe^{IV} complexes[8]. However, the difference between the first reduction at -1.33 V and the closest oxidation at -0.24 V is much smaller than the 2.25 V expected, and one can reasonably postulate that the latter process involves an $Fe^{III} \rightleftarrows Fe^{II}$ transition; this reaction is well confirmed and generally accepted in the literature. Assignment of the first ring reduction to the reaction at -1.33 V yields a resonable value for $E_{\frac{1}{2}\,ox} - E_{\frac{1}{2}\,red}$ of 2.33 V. In a similar manner the $\Delta E_{\frac{1}{2}\,ox} = 0.28$ V for octaethylporphinatomanganese(III) fits for two consecutive ligand oxidations but the closest reduction at -0.42 V is "too oxidizing" for a ring reduction and can be regarded as the known $Mn^{III} \rightarrow Mn^{II}$ transition.

The case of octaethylporphinatosilver(II) *(1)* is of special interest. It is well established[9] that when silver is inserted into the porphyrin ring it is simultaneously oxidized to Ag^{2+}. The $\Delta E_{\frac{1}{2}\,red}$ of 0.55 V is in fair agreement with two ring reductions, but the oxidation which occurs at 0.44 V is only 1.73 V more oxidizing than the first ring reduction — far less than our observed 2.25 V. We therefore assign the oxidation at 0.44 V to the formation of an octaethylporphinatosilver(III) complex *(2)*, an assignment which has not been previously reported.

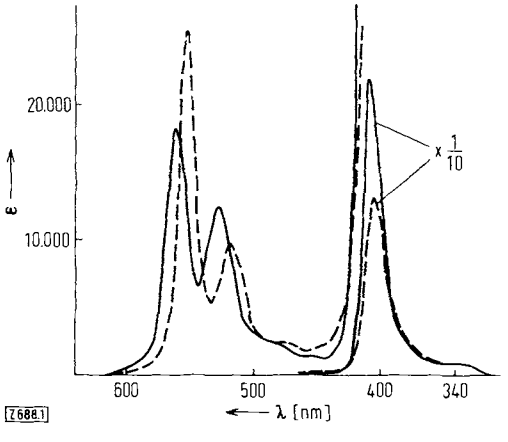

Fig. 1. The spectra of octaethylporphinatosilver(II) *(1)* (——) and octaethylporphinatosilver(III) perchlorate (– – –) in chloroform/methanol.

(1) is paramagnetic and has similar properties to the analogous copper complex, but on oxidation, either electrochemically or chemically, it does not yield a porphyrin cation radical as the latter does[1, 3]. Oxidation of *(1)* with $Fe(ClO_4)_3$ in chloroform/methanol solution produces the spectral changes shown in Figure 1. The new spectrum is typical for metalloporphyrins with no single electron in the ligand orbitals. The Ag^{II} complex *(1)* also yields a typical ESR spectra (nine lines with a $g_{\parallel}$ of 2.1060 and a $g_{\perp}$ of 2.0304 in acetone solution)[10]. This spectrum disappears on oxidation with Fe^{III} salts. Octaethylporphinatosilver(III) perchlorate *(2)* was also obtained in crystalline form and magnetic measurements on a Gouy balance confirmed it to be diamagnetic as would be expected for a d^8 square-pyramidal complex. Elemental analyses of *(1)* and *(2)* were satisfactory. To our knowledge the only other complexes of Ag^{III} reported are guanidine derivatives[11, 12] obtained by oxidation with persulfates. No oxidation potentials have been reported. The porphyrin-like square planar arrangement of four nitrogens is also probable in these systems and can explain the extraordinary stabilization of d^8 ions in these two ligand fields. Another interesting fact is that *(2)* is unusually hard to oxidize further. The complex is stable up to 1.4 V and remains unoxidized after treatment with *N*-bromosuccinimide. A second oxidation step reported by *Stanienda* and *Biebl*[12] at 0.9 V could not be confirmed by us.

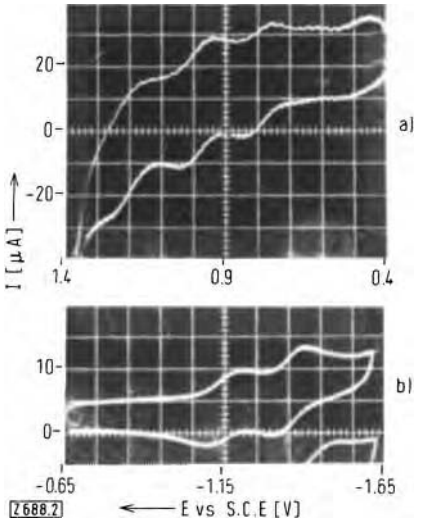

Fig. 2. Cyclic voltammogram of a) the oxidation of octaethylporphinatochromium(III) hydroxide *(3)* in butyronitrile (scan rate 1.54 V/s, 0.1 M $[Bu_4N]ClO_4$ as electrolyte) and b) the reduction of *(3)* in dimethyl sulfoxide (scan rate 0.60 V/s, 0.1 M $[Bu_4N]ClO_4$ as electrolyte).

Another case to be considered is that of octaethylporphinatochromium(III) hydroxide *(3)*. A typical set of cyclic voltammograms is shown in Fig. 2; five sets of peaks may be seen with $E_{\frac{1}{2}}$'s at 1.22, 0.99, 0.79, -1.14, and -1.35 V. A comparison of these potentials with the redox patterns found for normal porphyrins suggests that the two most oxidizing steps at 1.22 and 0.99 V can be assigned to ring oxidations since $\Delta E_{\frac{1}{2}\,ox}$ is close to the expected 0.29 ± 0.05 V. In addition, since there is another one-electron oxidation between the starting material *(3)* and the standard ring oxidation at 0.79 V, it is concluded that the Cr^{IV} complex is being produced. Unfortunately our initial attempts to produce pure solutions of this complex for the purpose of recording visible and ESR spectra were unsuccessful, owing

to instability of the complex at longer than polarographic time spans. Although reports on this oxidation state are rare (*e.g.*[14]) it has been invoked to explain the properties of hydroxy-bridged dimeric complexes of Cr^{III}[13]. The reaction at −1.14 V is believed to be the reduction of *(3)* to the Cr^{II} complex, with the second reduction at −1.35 V being attributed to the ring. Either of the values of −1.14 or −1.35 V satisfies the criterion of $E_{\frac{1}{2}\,ox} - E_{\frac{1}{2}\,red} = 2.25 \pm 0.15$ V. However the $\Delta E_{\frac{1}{2}\,red}$ of all octaethylporphyrin chelates is about 0.42 V. In the case at hand this difference would be only 0.21 V if the first reduction were that of the ring. The existence of a stable Cr^{II} complex[15] supports a $Cr^{III} \rightarrow Cr^{II}$ transition.

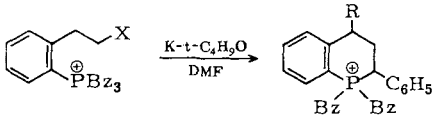
1,1-Dibenzyl-2-phenyl-1-phosphanaphthalene

By *Gottfried Märkl* and *Karl-Heinz Heier*[*]

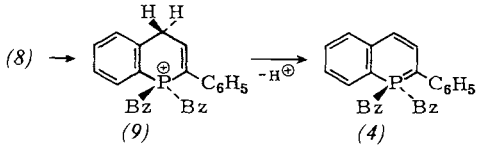
1,1-Disubstituted phosphabenzenes *(1)* have been prepared by total synthesis[1], from pyrylium salts[2], and from phosphabenzene *(2)* by radical or ionic additions to the heteroatom[3].



(1) *(2)* *(3)*

The question of the bonding relations in these systems with a formal $3d\pi - 2p\pi$ double bond has been discussed by *Mason*[4], *Fukui*[5], and *Vilceanu*[6]; *Schweig*'s assumption[7] of a delocalized π-electron system for *(1)* agrees with the results of ^{1}H-NMR spectroscopy[8] and of X-ray structure analysis[9].

These facts made it of interest to enquire whether the mesomerism of the benzene ring in 1,1-disubstituted phosphanaphthalenes *(3)* would prevent conjugation in the heterocycle and thus destabilize the system or whether the π-electron systems of both "halves" of the molecule would participate in naphthalene mesomerism.



A successful synthesis of 1,1-dibenzyl-2-phenyl-1-phosphanaphthalene *(4)* has provided us with the first crystalline derivative of *(3)*[10].

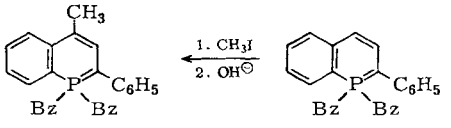
Tribenzylphosphane[11] was arylated by *o*-bromophenylethyl methyl ether in methanol in presence of anhydrous $NiBr_2$[12], yielding the quaternary salt *(5)* in 60% yield (perchlorate, m.p. 121—123 °C). The bromide *(6)* (m.p. 136—137 °C) obtained by fission of this ether with HBr in glacial acetic acid (78% yield) cyclized on treatment with K-*tert*-butoxide in DMF by intramolecular *C*-alkylation[13] of the intermediate alkylidenephosphane, thus giving 1,1-dibenzyltetrahydro-2-phenylphosphonianaphthalene perchlorate *(7)* (80% yield) as colorless needles, m.p. 160—161 °C [^{1}H-NMR spectrum ($CDCl_3$): benzyl-CH_2: τ = 6.02 (d, 2H); 6.34 (d, 2H); $^2J_{P-H} = 13.5$ Hz].

(5), X = OCH_3 *(7)*, R = H
(6), X = Br *(8)*, R = Br

The 4-bromo derivative *(8)* prepared from *(7)* by *N*-bromosuccinimide (yield 77%; m.p. 180—181 °C) was dehydrobrominated when heated in 100% H_3PO_4 and simultaneously isomerized to the perchlorate of *(9)* [yield 96%; m.p. 151—152 °C; ^{1}H-NMR spectrum ($CDCl_3$): benzyl-CH_2: τ = 5.66 (m, 4H); H_γ: τ = 6.81 (m, 2H)].

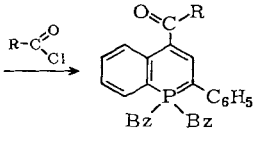
(9) *(4)*

Deprotonation of *(9)* by dilute sodium hydroxide solution gave 1,1-dibenzyl-2-phenyl-1-phosphanaphthalene *(4)* which was moderately stable in solution and very stable in the solid state [yield 80%; shiny red leaflets, m.p. 123 °C (from ethanol/ethyl acetate).—IR spectrum (KBr): characteristic double band at 1285 cm^{-1} and 1295 cm^{-1}[14]. —UV spectrum (CH_3CN): λ_{max} (ε) = 470 (7400), 420 sh (4000), 310 nm (5600).—Mass spectrum: *m/e* = 404, rel. intensity 65% (M); 313, 100% (M − C_7H_7); 91, 54% (C_7H_7)].



An increase in the π-electron density at positions 2, 4, and 6 (ylide character) of 1,1-disubstituted phosphabenzenes has been observed experimentally[8] and confirmed by *Schweig* by CNDO/2 calculations[7], which leads one to expect nucleophilic reactivity for *(4)* at positions 2 and 4. In agreement with this, *(4)* undergoes smooth alkylation and acylation:

With methyl iodide, *(4)* forms a phosphonium salt, deprotonation of which by aqueous NaOH gives 1,1-dibenzyl-4-methyl-2-phenyl-1-phosphanaphthalene *(10)* [yield 50%; carmine-red crystals (from ethanol/ethyl acetate), m.p. 109—111 °C.—UV spectrum: λ_{max} = 480

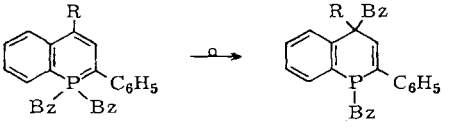


[*] Prof. Dr. G. Märkl and Dipl.-Chem. K.-H. Heier
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

nm (ε = 8000).—Mass spectrum: $m/e = 418$, rel. intensity 33% (M); 327, 100% ($M - C_7H_7$); 91, 94% (C_7H_7)].

Treating *(4)* with benzoyl chloride leads directly to 4-benzoyl-1,1-dibenzyl-2-phenyl-1-phosphanaphthalene *(11)*. The phosphonium salt first formed is immediately deprotonated by the more strongly basic *(4)* (transylidation).—*(11)*: yield 68%; shiny yellow needles, m. p.

(10) *(4)*



(11), R = C_6H_5
(12), R = OC_2H_5

186—188 °C (from ethanol/ethyl acetate).—IR spectrum (KBr): $\nu_{C=O} = 1500$ cm^{-1} (for comparison: for $(C_6H_5)_3P{=}CH{-}CO{-}C_6H_5$ $\nu_{C=O}$ is at 1527 cm^{-1} [15]); characteristic double band at 1270 and 1290 cm^{-1} [14].—^{1}H-NMR spectrum ($CDCl_3$): benzyl-CH_2: $\tau = 6.21$ (m, 4H) (ABX spectrum).—UV spectrum (ethanol): λ_{max} (ε) = 395 (26000); 275 nm (8200, sh).—Mass spectrum: $m/e = 508$, rel. intensity 68% (M); 417, 44% ($M - C_7H_7$); 91, 100% (C_7H_7).

(4) also reacts with ethyl chloroformate. The yellow ethyl 1,1-dibenzyl-2-phenyl-1-phosphanaphthalene-4-carboxylate *(12)* has not yet been obtained crystalline.—*(12)*: IR spectrum (KBr): $\nu_{C=O} = 1640$ cm^{-1}.—UV spectrum (ethanol): λ_{max} (ε) = 415 (10400); 375 (9500); 312 (10900).—Mass spectrum: $m/e = 476$, rel. intensity 40% (M), 385, 49% ($M - C_7H_7$); 91, 100% (C_7H_7).

Thermolysis of the 1,1-dibenzylphosphanaphthalenes proceeded in a surprising manner. Whereas 1,2-dibenzyldihydro-2,4,6-triphenylphosphabenzene rearranges at 180 °C to the 1,1-dibenzyl compound, which in turn decomposes to 2,4,6-triphenylphosphabenzene and bibenzyl at 220 °C [8], the 1,1-dibenzylphosphanaphthalenes *(4)* and *(10)* rearrange at 230—250 °C with migration of the benzyl group to position 4, yielding the 1,4-dibenzyl-1,4-dihydrophosphanaphthalenes *(13)* and *(14)*, respectively.—*(13)*: m.p. 126—128 °C, pale yellow crystals.—

(4), R = H
(10), R = CH_3

(13), R = H
(14), R = CH_3

UV spectrum (ethanol): λ_{max} (ε) = 265 (6500); 220 nm (48000, sh).—Mass spectrum: $m/e = 404$, rel. intensity 19% (M); 91, 100% (C_7H_7).—*(14)*: m. p. 131—134 °C, colorless crystals.—UV spectrum (ethanol): λ_{max} (ε) = 268 (5200); 215 nm (38000, sh).—Mass spectrum: $m/e = 418$, rel. intensity 50% (M); 91, 100% (C_7H_7).

Unlike the phosphabenzenes, 1,4-dihydrophosphanaphthalenes, as tertiary phosphanes, are clearly favored energetically over the phosphanaphthalenes with ter- or quinque-valent phosphorus.

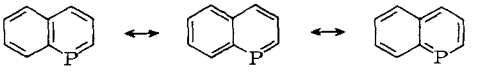
2-Phenyl-1-phosphanaphthalene

By *Gottfried Märkl* and *Karl-Heinz Heier* [*]



According to the results of spectroscopy [1], X-ray structure analysis [2], and CNDO/2 calculations [3], there exist in the phosphabenzoles *(1)* Hückel-aromatic systems with a π-electron density distribution differing from that in the pyridine system. As a result of the reactivity at positions 9

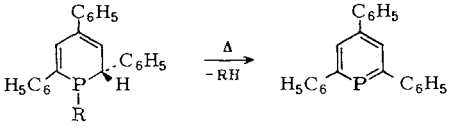
(1)

(3)

(2)

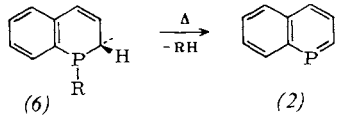
and 10 arising from the π-electron density distribution in anthracene itself, the dibenzannelated phospha compound 9-phosphaanthracene *(3)* [4] is less stable and cannot be isolated in the solid state; only the 10-phenyl derivative [5] is relatively stable, owing to reduction of the reactivity by steric shielding.

There arise the questions whether the decreasing stability would be observable also with the singly benzannelated



[*] Prof. Dr. G. Märkl and Dipl.-Chem. K.-H. Heier
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)

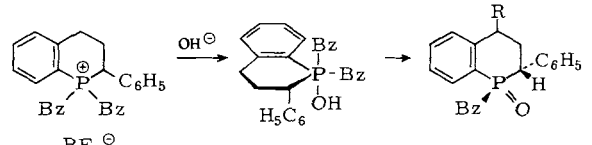
phosphabenzenes, the phosphanaphthalenes *(2)*, whether bond fixation with support for the Kekulé structure by benzene mesomerism would result, or whether a delocalized 10π electron system incorporating the P=C $3p\pi-2p\pi$ double bond would be formed.



We now report the first synthesis of a phosphanaphthalene not carrying a substituent on the P atom, namely 2-phenyl-1-phosphanaphthalene *(4)*. Since we also describe 1,1-dibenzyl-2-phenyl-1-phosphanaphthalene[6] we can compare phosphanaphthalenes with tri- and quinquevalent phosphorus.

Unlike 1,1-dibenzyl-2,4,6-triphenylphosphabenzene which decomposes smoothly at 220°C to 2,4,6-triphenylphosphabenzene and bibenzyl, the benzyl groups at position 1 acting as protecting groups, the 1,1-dibenzyl-1-phosphanaphthalenes isomerize to 1,4-dihydrophosphanaphthalenes with migration of a benzyl group[6].

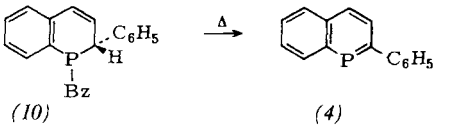
1-Alkyl-1,2-dihydro-2,4,6-triphenylphosphabenzenes *(5)* also undergo smooth thermal cleavage to the phosphabenzenes[7] [*(5a)* at 220°C, *(5b)* at 120°C]. 1-Alkyl-1,2-dihydrophosphanaphthalenes *(6)* should yield phosphanaphthalenes *(2)* analogously on thermolysis.



(5a), R = $CH_2C_6H_5$
(5b), R = $C(CH_3)_3$

(6) *(2)*

For the preparation of 1-benzyl-1,2-dihydro-2-phenylphosphanaphthalene, 1,1-dibenzyltetrahydro-2-phenylphosphonianaphthalene tetrafluoroborate *(7)* was hydrolyzed by alkali. Since in the pentacoordinated transition state of the hydrolysis[8] the diequatorial attachment of the ring to phosphorus is favored, the degradation proceeds smoothly, yielding 1-benzyltetrahydro-2-phenylphosphanaphthalene 1-oxide *(8)* [m.p. 209—211°C; yield 100%; mass spectrum: $m/e=332$ (M)].



(7)

(8), R = H
(9), R = Br

Bromination of the oxide *(8)* by *N*-bromosuccinimide to give the 4-bromotetrahydrophosphanaphthalene 1-oxide *(9)* is effected in 50% yield[9]. The product crystallizes with 1 mol of ethanol [M.p. 120—122°C; mass spectrum: $m/e=410$ ($^{79}Br-M$); 412 ($^{81}Br-M$); 330, rel. intensity 100% (M−HBr)].

On dehydrobromination of *(9)* by LiBr in DMF at 150°C 1-benzyl-1,2-dihydrophosphanaphthalene 1-oxide is formed in 42% yield[9] (m.p. 143—144°C) and its reduction by trichlorosilane in boiling benzene smoothly affords the free phosphane *(10)*.

The 1-benzyl-2-phenyl-1,2-dihydrophosphanaphthalene *(10)* was heated at 260—300°C without purification. The pale yellow oil that distills off through an upright air-condenser soon crystallizes, yielding 2-phenyl-1-phosphanaphthalene *(4)* as shiny, pale yellow leaflets, m.p. 101—102°C (from ethanol), that are stable in air.—

(10) *(4)*

Mass spectrum: $m/e=222$, rel. intensity 100% (M); 189, 19% (M−PH_2); 178, 14% (M−HCP); 110, 18% ($C_6H_5PH_2$).—The ^{1}H-NMR spectrum (Fig. 1), with a

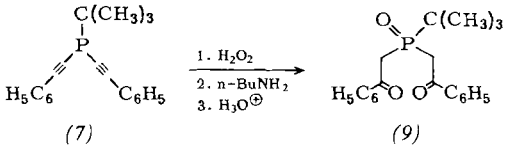
2,6-Diphenyl-1-aza-4-phosphabenzene

By *Gottfried Märkl* and *Dieter Matthes*[*]

Our knowledge of six-membered aromatic phosphorus heterocycles containing trivalent phosphorus with coordination number 2 was until recently confined to the phosphabenzene system *(1)*[1].

It was not previously possible to prove that —P=N— or —P=P— double bonds to trivalent phosphorus could exist either as isolated double bonds or in systems stabilized by mesomerism[2]; fundamentally, however, there is no argument against the existence of six-membered phosphaheteroaromatic compounds containing heteroatoms of the fifth main group in positions 4 or 3,5 of the phosphabenzene ring.



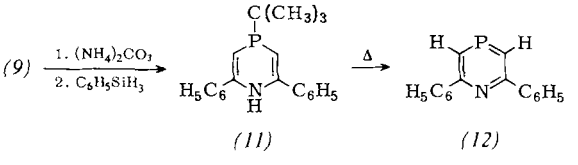
(1) *(5)* R *(2)*, X = As *(3)*, X = N *(4)* *(6)* R

The fact that diarsaanthracene *(2)* (as a 1,4-diarsabenzene derivative[3]) and azaarsaanthracene *(3)* (as a 1-aza-4-arsabenzene derivative[4]) occur as non-aromatic dimers[5] could be ascribable to destabilization of these systems by the dibenzannelation.

A basis for our envisaged preparation of 1-aza-4-phosphabenzenes *(4)* was offered by the synthesis[6] of 3,5-disubstituted 4-phenyl-1-aza-4-phosphacyclohexa-2,5-diene 4-oxides. It should be possible to extend the principle of thermolysis of 1,2-dihydrophosphabenzenes *(5)* to phosphabenzenes[7] to cover the aza system *(6)* if there were suitable leaving groups R[—$CH_2C_6H_5$ or —$C(CH_3)_3$] on the phosphorus.

For the synthesis of 4-*tert*-butyl-1,4-dihydro-2,6-diphenyl-1-aza-4-phosphabenzene *(11)*, *tert*-butylbis(phenylethynyl)phosphane *(7)* (obtained from *tert*-butyldichlorophosphane and C_6H_5—C≡C—MgBr, yield 75%; m.p. 84 °C; $\nu_{C\equiv C} = 2160\ cm^{-1}$) was converted into its oxide *(8)* (yield 98%; m.p. 82 °C; $\nu_{C\equiv C} = 2180\ cm^{-1}$, $\nu_{P=O} = 1230\ cm^{-1}$), whose *n*-butylamine adduct was hydrolyzed to the diketone *(9)* by *Aguiar*'s method[6].

(9): yield 56%, m.p. 108 °C (from ether/light petroleum; $\nu_{C=O} = 1665\ cm^{-1}$.—^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: τ = 1.85—2.8 (10 H, m); —CH_2—: τ = 6.2 (4 H, d), $^2J_{P-H} = 7$ Hz; *tert*-butyl: τ = 8.71 (9 H, d), $^3J_{P-H} = 8$ Hz.



(7) *(9)*

The diketone *(9)* reacts with $(NH_4)_2CO_3$ during 24 h in a bomb-tube at 100 °C, giving a 65% yield of 4-*tert*-butyl-2,6-diphenyl-1-aza-4-phosphacyclohexa-2,5-diene 4-oxide *(10)*.

(10): m.p. 360—362 °C (from ethanol/water), $\nu_{NH} = 3250\ cm^{-1}$ (w), $\nu_{C=C} = 1620\ cm^{-1}$ (s).—^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: τ = 2.87 (10 H, s); vinyl-H: τ = 4.7 (2 H, dd), $^2J_{P-H} = 4$ Hz, $^4J_{NH-H} = 1$ Hz; *tert*-butyl: τ = 9.03 (9 H, d), $^3J_{P-H} = 10$ Hz; NH: τ = 1.73.

Phenylsilane reduces the oxide in boiling toluene during 72 h to the free dihydroazaphosphorin *(11)*.

(11) *(12)*

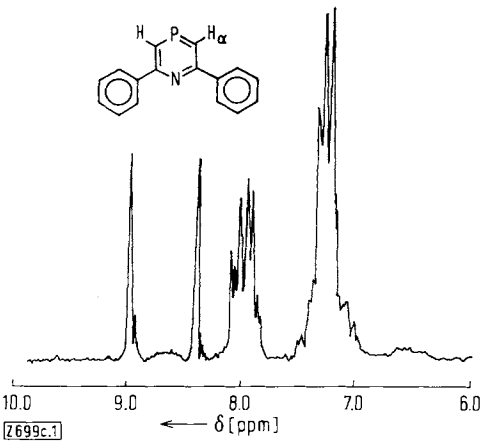
(11): yield 74%; m.p. 258—261 °C (dec); $\nu_{C=C} = 1620\ cm^{-1}$ (s).—Mass spectrum: *m/e* = 307, rel. intensity 13.5% (M); 250, 100% (M − C_4H_9); 219, 5.4% (M − C_4H_9P).—^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: τ = 2.6 (10 H, s); vinyl-H: τ = 4.92 (2 H, dd), $^2J_{P-H} = 7$ Hz, $^4J_{NH-H} = 1$ Hz; *tert*-butyl: τ = 8.8 (9 H, d), $^3J_{P-H} = 10$ Hz.

Methiodide of *(11)*: yield 68%, m.p. 229—230 °C.—^{1}H-NMR spectrum ($CDCl_3$): CH_3: τ = 8.04 (d), $^2J_{P-H} = 6.5$ Hz.

As expected, the azaphosphorin *(11)* was cleaved smoothly and quantitatively at 260—280 °C, 2,6-diphenyl-1-aza-4-phosphabenzene *(12)* distilling off *in vacuo* as a pale yellow, viscous oil.

(12): mass spectrum: *m/e* = 249, rel. intensity 100% (M), 172, 23% (M − C_6H_5); 146, 19% (M − C_6H_5CN); 102, 27% (C_6H_5—C≡C).—^{1}H-NMR spectrum (Fig. 1): phenyl-H: τ = 1.84—3.0 (m); H_α: τ = 1.34 (d), $^2J_{P-H} = 18$ Hz.—The position of the signal of the H_α ring protons of *(12)* corresponds to the position of the signals of the α-protons in the phosphabenzenes *(e.g.* τ = 1.2 for 3,4,6-triphenylphosphabenzene, $^2J_{P-H} = 38$ Hz[8]), but the P—H coupling is distinctly smaller. This shows *(12)* to be a heteroaromatic compound, an assumption that is supported by the ^{31}P-

[*] Prof. Dr. G. Märkl and D. Matthes
Fachbereich Chemie der Universität
84 Regensburg, Universitätsstrasse 31 (Germany)



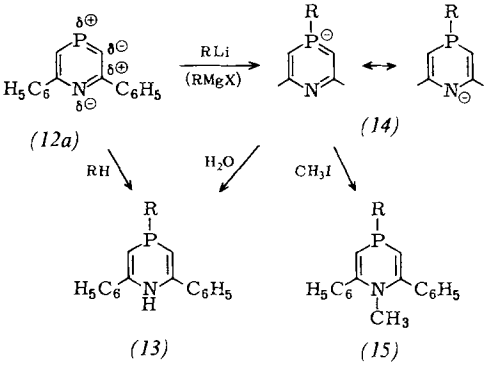


Fig. 1. ^{1}H-NMR spectrum of 2,6-diphenyl-1-aza-4-phosphabenzene *(12)*.

NMR spectrum: $\delta = -245.4$ ppm (t), $^2J_{H-P} = 18$ Hz (H_3PO_4 as external standard). The signal lies at even lower field than that for 2,4,6-triphenylphosphabenzene [$\delta = -178$ ppm (m)].

The chemistry of *(12)* is surprising and clearly shows the influence of aza substitution. The phosphabenzene ring system exhibits no nucleophilic character but is, instead, markedly electrophilic[9]. This reactivity of trivalent phosphorus of coordination number 2 is considerably enhanced by the nitrogen at position 4 [the π-electron density distribution indicated in *(12a)* is in agreement with CNDO/2 calculations[10] for the phosphorin system]. The compound *(12)* reacts with organometallic compounds (RLi and RMgX) and, unlike phosphabenzene, also with weak nucleophiles such as alcohols, phenols, thiols, and amines with addition of the nucleophile to phosphorus.

(13a), $R = OC_2H_5$, yield 78%; m.p. 117—120 °C.

Mass spectrum: $m/e = 295$, rel. intensity 11.4% (M); 249, 100% ($M - C_2H_5OH$) [= M(12)]; 250, 50% [M(12)+H]; 248, 89% [M(12)−H].

^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: $\tau = 2.2$—2.6, (10H, m); —OCH_2—: $\tau = 6.25$ (q), 6.44 (q) (2H), $^3J_{P-H} = 3.5$ Hz, $^3J_{H-H} = 3.5$ Hz; —CH_3: $\tau = 8.67$ (t), 8.71 (t) (3H), $^3J_{H-H} = 3.5$ Hz; vinyl-H: $\tau = 4.32$ (dd), $^2J_{P-H} = 4$ Hz, $J_{NH-H} = 1$ Hz; $\tau = 4.12$ (d), $^2J_{P-H} = 19$ Hz (2H); there are probably some equatorially and some axially attached ethoxy groups on the phosphorus.

(13b), $R = -OC_6H_5$, yield 64%; m.p. 197—199 °C.

Mass spectrum: M does not appear; $m/e = 266$, rel. intensity 2.1% ($M - C_6H_5$); 249, 100% ($M - C_6H_5OH$) [= M(12)]; 248, 60% [M(12)−H].

^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: $\tau = 3.32$—3.95 (15H, m); vinyl-H: $\tau = 5.6$ (2H, dd), $^2J_{P-H} = 4$ Hz, $J_{NH-H} = 1$ Hz.

(13c), $R = -SCH(CH_3)_2$, yield 59%; m.p. 263—265 °C (oxide).

^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: $\tau = 2.3$—2.78 (10H, m): vinyl-H: $\tau = 4.5$ (2H, dd), $^2J_{P-H} = 2.5$ Hz, $J_{NH-H} = 1$ Hz; S—CH: $\tau = 6.95$ (1 H, 2 septets), $^3J_{H-H} = 3$ Hz, $^3J_{P-H} = 1$ Hz; CH_3: $\tau = 8.68$ (6 H, d).

Reaction of *(12)* with organometallic compounds affords first the mesomeric anions *(14)*, whose hydrolysis gives the dihydroazaphosphorins *(13)* and whose alkylation gives the *N*-alkyl derivatives *(15)*.

tert-Butyl-MgCl affords the dihydro compound *(11)* in 72% yield.

In the reaction with phenyllithium the compound *(13d)* with $R = C_6H_5$ is formed in 58% yield as pale yellow needles, m.p. 145—146 °C.—Mass spectrum: $m/e = 327$, rel. intensity 100% (M); 328, 24% (M+H); 326, 6% (M−H); 250, 64% ($M - C_6H_5$); 219, 48% ($M - PC_6H_5$).—^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: $\tau = 1.8$—2.8 (15H, m); vinyl-H: $\tau = 4.68$ (2H, dd), $^2J_{P-H} = 7$ Hz, $^4J_{NH-H} = 1$ Hz.

After treatment of a solution of *(14)*, $R = C_6H_5$, with methyl iodide, the *N*-methyl derivative *(15)*, $R = C_6H_5$, can be isolated in 42% yield as colorless needles, m.p. 194—196 °C.—^{1}H-NMR spectrum ($CDCl_3$): phenyl-H: $\tau = 2.32$—2.72 (15H, m); vinyl-H: $\tau = 3.63$ (2H, s); N—CH_3: $\tau = 6.32$ (3H, s).

Preparation and Structure of the Fluoro Complex $Rb[Mo_2O_2F_9]$

By *Arndt Beuter* and *Wolfgang Sawodny*[*]

It has been concluded several times[1-3] from ^{19}F-NMR data that dimeric fluoro complexes of the formula $[M_2O_2F_9]^-$ should exist (M = Mo or W), but it has not previously been possible to isolate such compounds. In attempts to prepare the complex $[MoOF_5]^-$ we obtained by-products in varying amounts. One of these was obtained pure after treatment of RbF with $MoOF_4$ in liquid SO_2.

[*] Dipl.-Chem. A. Beuter and Prof. Dr. W. Sawodny
Abteilung für Anorganische Chemie der Universität
79 Ulm, Oberer Eselsberg (Germany)

Analytical results and vibrational spectra showed it to be $Rb[Mo_2O_2F_9]$.

It was found that the dimeric fluoro complex $[Mo_2O_2F_9]^-$ was formed as the main product by all the methods tried by us for preparation of $[MoOF_5]^-$ (treatment of moist CsF with MoF_6 in IF_5 or SO_2, reaction of $Cs_2[MoO_2F_4]$ with MoF_6 in SO_2, and reaction of K_2MoO_4 with anhydrous HF). On the other hand, the analogous tungsten complex $[W_2O_2F_9]^-$ could be detected as an impurity in $Cs[WOF_5]$ and $Cs[WF_6]$ by means of vibrational spectroscopy [ν_{WO} at 1032 (s) and 1047 (vw) cm^{-1}] but has not yet been isolated in a pure state[4].

Although the vibrational spectra of $Rb[Mo_2O_2F_9]$ cannot yet be fully assigned (Table 1), some conclusions about the structure of the $[Mo_2O_2F_9]^-$ ion can be drawn from them. The MoO stretching vibrations lying above 1000

Table 1. IR and Raman spectra of $Rb[Mo_2O_2F_9]$ [a].

IR [cm^{-1}]	Raman [cm^{-1}]	Assignment
1033 w	1033 m	ν_{MoO}sym.
1022 s		ν_{MoO}asym.

284 s		
270 m		

[a] The IR spectra were determined for a Nujol suspension on a grating spectrograph of Perkin-Elmer 325 type, and the Raman spectrum for the crystal powder in a glass capillary with the Coderg apparatus PH1 with excitation by the blue (4880 Å) and the green (5140 Å) line of an Ar/Kr mixture gas laser.

cm^{-1} (*i.e.* very high) show that the O atoms must be terminal, *i.e.* that there is no Mo—O—Mo bridge, and that there is not more than one oxygen atom on each Mo atom[5]. Besides the stretching frequencies of the terminal F atoms (579—689 cm^{-1}) an IR band appears at 422 cm^{-1} which, from its position, cannot be assigned to these stretching vibrations or to bending modes; it can be plausibly interpreted as an asymmetric Mo—F—Mo bridge vibration. The deformation vibrations (from 321 cm^{-1} downwards) are incomplete and cannot yet be assigned. In all the spectra, bands of various intensities between 900 and 1000 cm^{-1} are probably to be attributed to products of hydrolysis of this substance, which is very sensitive to moisture.

Assuming the coordination number 6 for the metal atom, we therefore consider the structure to be $OF_4Mo—F—MoF_4O$. The intensity ratio of 1:8 in the ^{19}F-NMR spectrum[1-3] makes it probable that the MoO bonds are in *trans*-position to the F bridge. Whether the bridge is bent or linear, and whether the equatorial F atoms of the two octahedra, linked at corners, are eclipsed or not, cannot by yet determined.

Experimental:

$MoOF_4$ (10 mmol) is stirred with RbF (3 mmol) in liquid SO_2 under N_2 for 2 h at −20 to −30 °C in a Pyrex glass apparatus. All the vessels and substances must have been well dried. After only a short time the very finely crystalline product separates. After the SO_2 and excess of $MoOF_4$ have been pumped off with gradual warming to 100 °C, the product $Rb[Mo_2O_2F_9]$ is obtained as a fine, pale bluish-grey powder. It is extremely sensitive to hydrolysis, which causes intense blue coloration. Presumably the pale blue color of our samples is due to slight hydrolysis, *i.e.* quite pure $Rb[Mo_2O_2F_9]$ should be white. In the reaction described, $Rb[Mo_2O_2F_9]$ is the sole product independently of the relative amounts of starting materials.

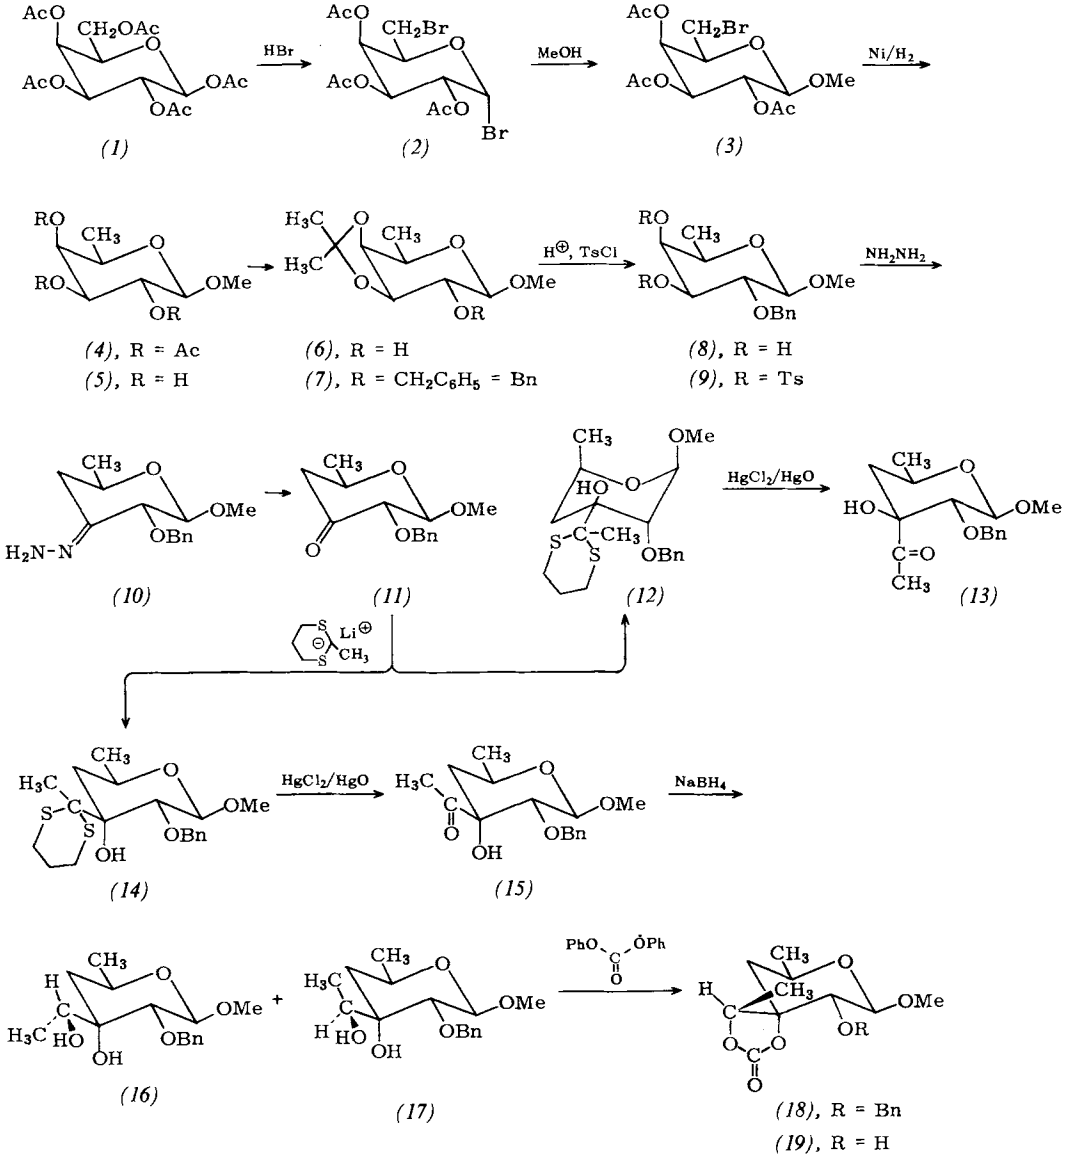
Total Synthesis of D-Aldgarose[1]

By *Hans Paulsen* and *Hartmut Redlich*[*]

Aldgamycin E, a neutral macrolide antibiotic from *Streptomyces lavendulae*, contains besides mycinose a further sugar component, called aldgarose[2, 3], which is a complex branched monosaccharide, the stereochemistry of whose sidechain has not previously been elucidated. We have now succeeded in introducing the desired sidechain[5] by *Seebach*'s procedure[4] of adding 1,3-dithiane anions to carbonyl compounds, and we have thus synthesized the four possible isomeric methyl β-D-aldgarosides. Comparing the physical and spectroscopic data with results from the natural product has made it possible to assign the configuration of the latter unambiguously.

The starting material for this synthesis was D-galactose pentaacetate *(1)*, which with HBr afforded the dibromo compound *(2)*, and this was at once converted into the methyl glycoside *(3)*, m.p. 93 °C, $[\alpha]_D^{20} = -5.3°$, in 72% yield. Hydrogenation of *(3)* gave *(4)*[6], from which methyl β-D-fucoside *(5)* was obtained by hydrolysis. Reaction of *(5)* with acetone dimethyl ketal yields the 3,4-acetal *(6)* selectively (a syrup, $[\alpha]_D^{20} = +24.5°$, yield quantitative), which was converted into the 2-benzyl ether *(7)* (a syrup, $[\alpha]_D^{20} = +39.8°$, yield quantitative). The acetal group of *(7)* was removed by acid, yielding *(8)* (a syrup, $[\alpha]_D^{20} = +10.0°$, yield quantitative), whose ditosylate *(9)* (m.p. 165 °C, $[\alpha]_D^{20} = +35.0°$) was then prepared in 75% yield. In a process developed by us[7] 1,2-*cis*-di-*O*-tosylpyranoses can be converted by hydrazine into deoxyketoses, the axial *O*-tosyl group being converted into a deoxy, and the equatorial *O*-tosyl group into a keto, group. This reaction can be effected with *(9)*, whereby the 3-ulose hydrazone *(10)* is formed and this is at once cleaved by salicylaldehyde into the free 3-ulose *(11)* (an oil, $[\alpha]_D^{20} = -64.0°$, yield 65%).

The 3-ulose *(11)* can be treated with 2-lithio-2-methyl-1,3-dithiane[4] in THF at −70 °C, whereupon the dithiane



[*] Prof. Dr. H. Paulsen and Dipl.-Chem. H. Redlich
Institut für Organische Chemie und Biochemie der Universität
2 Hamburg 13, Papendamm 6 (Germany)

sugars *(14)* and *(12)* are obtained in a molar ratio of 3 : 2 (syrups, $[\alpha]_D^{20} = -7.4°$ and $+2.1°$, respectively, total yield 80%). The 2-methyl-1,3-dithiane sidechain behaves sterically as a *tert*-butyl group; therefore, *(14)* and *(12)* assume conformations in which the sidechain is equatorial, with the result that *(12)* assumes a reversed chair form. This finding is important because, with the chair form proved, the configuration at the branch point can be determined for both isomers by complete NMR analysis, and this would not be possible in any other simple way. Desulfuration of *(14)* by $HgCl_2/HgO$ affords ketone *(15)* (m.p. 107 °C, $[\alpha]_D^{20} = -0.8°$, yield 37%), and that of *(12)* affords the ketone *(13)* (m.p. 73 °C, $[\alpha]_D^{20} = -8.6°$, yield 21%). The side chain of *(13)* is not so sterically demanding, so that here the normal $^4C_1$ conformation with an axial acetyl group is once more assumed.

β-D-aldgarosides, of which the compound *(19)* (m.p. 178—180 °C, $[\alpha]_D^{20} = -43.5°$) proved identical in ^{1}H-NMR spectrum, melting point and optical rotation with the aldgaroside B described in the literature[2].

The configuration of the sidechain at C-7 is assigned from the following findings: In *(18)* and the carbonate from *(16)* a methyl group and a proton, respectively, are attached to C-7 of the sidechain in a 1,3-quasiaxial position relative to the *O*-benzyl group at C-2. In both cases the corresponding NMR signals are found to be shifted to lower field, whence the assignment can be made by the rules due to *Lemieux*[8] and *Zürcher*[9].

For the alcohol *(16)*, the *gauche* conformation shown in *(16)* should be favored, according to the views of *Lemieux*[10], and *ab initio* calculations by *Jeffrey* and *Pople*[11] and by

The ketones *(13)* and *(15)* each give two alcohols on reduction with $NaBH_4$; the alcohols *(16)* and *(17)* are formed from *(15)*. The two pairs of alcohols can be separated, and all four alcohols were converted into their respective 3,7-carbonates by diphenyl carbonate; in this way, *(17)* gave *(18)* (m.p. 181 °C, $[\alpha]_D^{20} = -14.9°$, yield 70%). Removal of the benzyl group by hydrogenolysis from each of the four carbonates afforded the four isomeric methyl

Wolfe et al.[12]. No preference can be recognized for either of the two possible *gauche* conformations of alcohol *(17)*. If, on these assumptions, one estimates the optical rotations, using the empirical standard values given by *Lemieux*[13] for all the asymmetric conformational elements, one finds that *(17)* should have a more negative optical rotation than *(16)*; the values found are *(17)*, $[M]_D^{20} = -109°$, and *(16)*, $[M]_D^{20} = -57.5°$. The two methods lead

to the same conclusion, namely that the configuration is (*S*) at C-7 of *(19)*.

A Catalyzed Asymmetric Synthesis

By *Borislav Bogdanović, Biserka Henc, Burkhard Meister, Horst Pauling*, and *Günther Wilke*[*]

Few asymmetric syntheses proceeding under catalytic conditions have been reported. High optical purity has been obtained only in hydrogenation using optically active catalysts in which the chiral centers are formed as a result of C—H bond formation[1].

During our studies[2] on the influence of phosphanes upon the oligomerization of olefins by π-allylnickel halide-Lewis acid systems we have developed catalysts which are able to convert 1,3-cyclooctadiene *(1)* and ethylene *(2)* into 3-vinylcyclooctene *(3)* having an optical purity of up to 70%.

(1) *(2)* *(3)*

The catalysts *(4)* were prepared, for example, in methylene chloride or chlorobenzene from π-allylnickel chloride, ethylaluminum sesquichloride and an optically active phosphane (molar ratio 1:2.5:1.2) in which the groups R on the phosphorus atom are chiral. Ethylene is led into a mixture of the catalyst solution and 1,3-cyclooctadiene.

The greatest optical induction was obtained with phosphanes containing very bulky, optically active groups R and by carrying out the catalysis at the lowest possible temperature. The high activity of the catalysts allows the reaction to be carried out even at temperatures around −75 °C, so that the maximum effect is obtained from the small differences in the free activation enthalpy for the reaction of the intermediate diastereoisomers formed from the catalyst and the substrate. The $\Delta\Delta H^{\neq}$ are about 1.1 kcal/mol to which the entropy and enthalpy terms contribute the following values at the temperatures stated: $T\Delta\Delta S^{\neq}$ 0 °C −0.82, −40 °C −0.70, −75 °C −0.59 kcal/mol; and $\Delta\Delta G^{\neq}$ 0 °C 0.28, −40 °C 0.40, −75 °C 0.51 kcal/mol. These values should be treated only as estimates of the orders of magnitude.

(+)-3-Methyl-1-pentene *(5)* [Ref. [3]: $[\alpha]_D^{22} = +36.95°$] with a maximum optical purity of 64% is a by-product formed by the trimerization of ethylene. Table 1 shows the relation of the optical yield to the nature of the phosphane (chlorobenzene and 0 °C being chosen as standard conditions for these comparisons).

Table 1. Relation of optical yield to the nature of the phosphane.

[**] Now Continental Gummi Werke AG., Hannover.
[***] Now Hoffmann La Roche, Basel (Switzerland).

The values obtained for the optical purities of *(3)* and *(5)* show that the catalysts are to some extent substrate-specific since the order of increasing optical purity found for *(3)* differs widely from that for *(5)*. When (−)-dimenthylmethylphosphane is used as catalyst the optical purity

of *(3)* increases with decreasing temperature: 0 °C 23.5%; −40 °C 41.5%; −75 °C 53% (in CH_2Cl_2).

The greatest optical purity for *(3)* (70%) is already obtained with (−)-dimenthylmethylphosphane at 0 °C with a Ni : P ratio of 1 : 3.8, so that in this case it is the effect of phosphane excess which is most important. It is possible that a second molecule of the inducing phosphane bonds to the Ni atom.

The absolute configuration and the rotation of optically pure 3-vinylcyclooctene were determined in three ways:

1. Degradation to (−)-3-methylnonene and correlation with the known (+)-(*S*)-3-methylnonane[6].

2. Conversion into 2- and 3-ethylcyclooctanol and gas-chromatographic analysis of the diastereoisomeric lactic esters[7].

3. A seven-stage synthesis with separation of the intermediate racemic 3-cyclooctenylacetic acid as its quinine salt.

(−)-(*S*)-3-Vinylcyclooctene with $[\alpha]_D^{22.8} = -162.3°$ was obtained by the third method. The optical yields determined by the three methods agreed within the experimental errors.

To the best of our knowledge, the codimerization of 1,3-cyclooctene and ethylene to give optically active 3-vinylcyclooctene as described here is the first case of an asymmetric synthesis, proceeding catalytically, in which the chiral centers are generated in high optical purity as a result of C—C bond formation. The phosphanes listed are new.

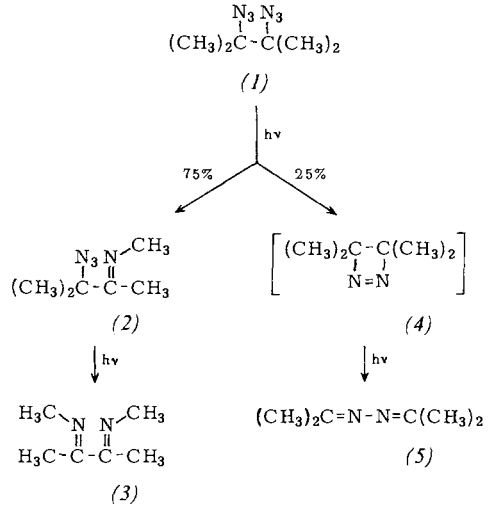
Photolysis of 2,3-Diazido-2,3-dimethylbutane



By *Paul Margaretha* and *Sonja Solar*[*]

There is no report in the literature about the photochemical behavior of vicinal diazides, though there are some about geminal diazides. We describe here the photolysis of the ditertiary[1] vicinal diazide *(1)*.

[*] Dr. P. Margaretha and Dr. S. Solar
Max-Planck-Institut für Kohlenforschung
Abteilung Strahlenchemie
433 Mülheim/Ruhr, Stiftstrasse 34—36 (Germany)

The main reaction takes the expected course: the Schiff bases *(2)* and *(3)* are formed in two successive steps by migration of methyl groups and elimination of nitrogen[2].

Remarkably, however, there is formation of acetone azine *(5)*, which can be understood by assuming elimination of nitrogen and simultaneous formation of a new N—N bond, whereby the 1,2-diazetine *(4)* is formed as an intermediate. In fact we were unable to detect *(4)* spectroscopically, but this may perhaps be ascribed to the instability of this compound under the experimental conditions.

Experimental:

Irradiations were carried out in pentane solutions at room temperature in a Pyrex glass apparatus with a HPK-125 W lamp (Philips).

Preparation of *(1)*: 2-Azido-1,1,3-trimethylpropyl nitrate[3] (0.1 mol; b.p. 47 °C/0.05 torr) and NaN_3 (0.2 mol) were heated in 90% ethanol (200 ml) for 10 min at 100 °C. Water (2 liters) was then added, the mixture was extracted with pentane, and the organic phase was dried and freed from solvent. Distillation (b.p. 26—27 °C/0.05 torr) and recrystallization from pentane at −40 °C afforded *(1)*, m.p. −10 °C, in 20% yield. NMR[4] ($CDCl_3$): $\delta = 1.33$ ppm; IR (CCl_4): 2085, 1265 cm^{-1}; UV (C_6H_{14}): $\lambda_{max} = 284$ nm, $\varepsilon = 43$.

(2) was isolated by gas chromatography after 2 hours' irradiation. NMR ($CDCl_3$): $\delta = 3.10$ (3), 1.82 (3), 1.37 (6) ppm; IR (CCl_4): 2090, 1665 cm^{-1}.

(3) and *(5)* were identified by means of NMR and IR spectra, and by gas-chromatographic comparison with authentic samples.

Protection of Adenosine 5′-Triphosphate toward Hydrolysis by the Formation of a Mixed-Ligand Metal Ion Complex[**]

By *David H. Buisson* and *Helmut Sigel*[*]

It is well known that metal ions of the 3d-series enhance the rate of hydrolysis of adenosine 5′-triphosphate (ATP) considerably[1, 2]. Cu^{2+}, in fact, was shown to be one of the most effective catalysts[1] and to form—within the mentioned series—the most stable binary complex with ATP[3]. We have now investigated the tendency for hydrolysis of ATP within a ternary complex.

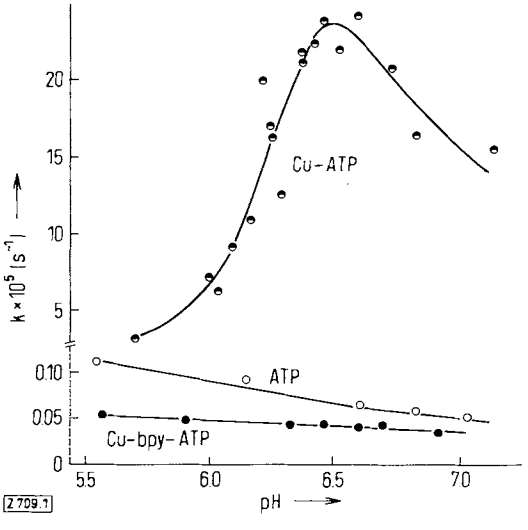
Studies of mixed-ligand complexes revealed that those which contain an aromatic amine and a second ligand with O as donor atoms are especially stable[4, 5]. This is also true for 2,2′-bipyridyl(bpy)-Cu^{2+}-phosphate complexes[6]. Indeed, these ternary complexes are even more stable than the corresponding binary ones. Hence, equilibrium (a)

$$Cu(ATP)^{2-} + Cu(bpy)^{2+} \rightleftharpoons Cu(bpy)(ATP)^{2-} + Cu^{2+} \qquad (a)$$

is shifted towards the right. (Equilibrium constant:

$$\Delta \log K = \log K^{Cu(bpy)}_{Cu(bpy)(ATP)} - \log K^{Cu}_{Cu(ATP)} = 6.91 - 6.38 = 0.53^{[6]}).$$

This fact stimulated us to study the rate of the hydrolysis of ATP in the mixed-ligand complex, Cu(bpy) $(ATP)^{2-}$ [probable structure cf. *(1)*] and compare it with the corresponding rates for $Cu(ATP)^{2-}$ and free ATP. The results are shown in Figure 1, where the first order rate constant *(k)* is plotted against pH. Obviously, the hydrolysis of ATP in the ternary complex is insignificant compared with that of the binary complex. Moreover, even free ATP is somewhat more sensitive toward hydrolysis



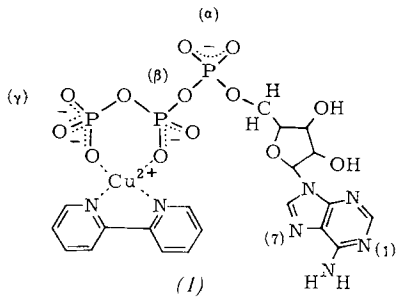


Fig. 1. Hydrolysis of ATP in dependence on pH, characterized as the first order rate constant. (The increasing concentration of phosphate was measured with molybdenum-reagent [8].) The reagent concentrations were each 10^{-3} M. In the pH range shown the binary complex, $Cu(ATP)^{2-}$, and the ternary complex, Cu(bpy) $(ATP)^{2-}$, are formed to more than 93% and 95%, respectively (computed with the constants given in Ref. [6]).

(1)

than is ATP in the mixed-ligand complex. This demonstrates unequivocally that ATP is protected toward hydrolysis by the formation of the ternary complex, Cu(bpy)$(ATP)^{2-}$. This result is of interest with regard to biological systems, *e.g.* the transport of hydrolysis-sensitive phosphates.

The different behavior in the hydrolysis of these binary and ternary complexes can be rationalized as follows: As Cu^{2+} prefers a square-planar coordination sphere in aqueous solution, only two positions are left in $Cu(bpy)^{2+}$ for the coordination of ATP, namely by two of its phosphate groups. Hence, in the mixed-ligand complex, Cu(bpy) $(ATP)^{2-}$, the adenine moiety, *i.e.* N(7), is unable to participate in further complex formation[6] [cf. *(1)*]. In contrast it does so in the binary complex, $Cu(ATP)^{2-}$, by forming a macrochelate—which is obviously crucial for hydrolysis—with the β- and γ-phosphate groups and N(7)[1, 7].

In other cases $Cu(bpy)^{2+}$ is a better catalyst than Cu^{2+}_{aq}, *e.g.*, in the decarboxylation of acetonedicarboxylate[9] and the disproportionation of H_2O_2[10]. However, in these cases, the substrate coordinates identically in the binary and ternary complexes.

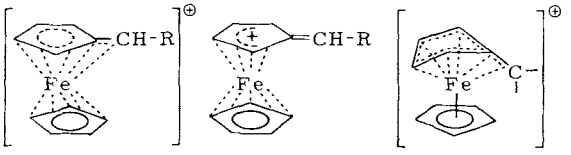
Structure and Properties of α,α-Diferrocenylmethylium Ion

By *S. Lupan*, *M. Kapon*, *Michael Cais*, and *Frank H. Herbstein*[*]



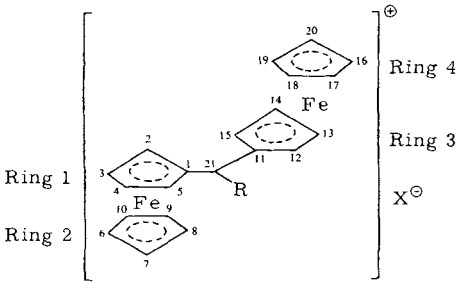
The origin of the unusual stabilization of carbenium ions adjacent to metallocenes has been a matter of vigorous debate for over a decade[1]. Three distinct models have been

[*] S. Lupan, M. Kapon, Prof. Dr. M. Cais, and Prof. Dr. F. H. Herbstein
Department of Chemistry, Israel Institute of Technology,
Haifa (Israel)

suggested[1] as appropriate for explaining the special stability of α-ferrocenylcarbenium ions:

(a) Interaction of the central metal atom with the π-electron system of the fulvene part with a concomitant shift of the metal towards the exocyclic carbon atom *(1)*[2, 3];

(b) Little or no interaction between the metal and the exocyclic carbon, stabilization being due to significant contribution of the resonance form *(2)*. The latter is said to



(1) *(2)* *(3)*

result from weakening of the bond between metal and carbon at the substituted position on the cyclopentadienyl ring[4];

(c) Distortion and bending of bonds in the substituted ring so as to bring the exocyclic carbon nearer the metal atom *(3)*[1].

Recently, iterative extended Hückel calculations[5] generated a structure supporting some of the features shown in *(3)*. Weakening of the bond ring-exocyclic carbon is said[5] to be caused by interaction of the filled non-bonding $3d_{z^2}$-orbital of iron with the empty π* orbital of the fulvene moiety, thus facilitating bending of the bond in question.

In view of our experience with the synthesis of α-ferrocenylcarbenium salts[1, 6] we have undertaken the preparation of a derivative suitable for X-ray structure analysis. Of the carbenium ions prepared for this purpose, *(4a)* —*(4j)*[7], the compound of choice was α,α-diferrocenylmethylium

(4)	R	X

tetrafluoroborate *(4a)*. It could be recrystallized and recovered unchanged from a number of solvents, including even methanol, and was found to be stable on prolonged exposure to air.

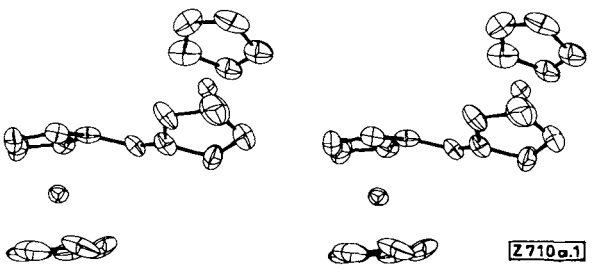

Fig. 1. Structure of α,α-diferrocenylmethylium ion (stereoscopic drawing prepared with *C. K. Johnson*'s ORTEP program).

An ORTEP diagram of the structure of α,α-diferrocenylmethylium ion is shown in Figure 1[8]. The principal results from the diffraction study are:

1. The carbenium ion is in the *transoid* conformation, and the angle ring center—Fe—ring center is 132.9°. The conformation of the carbenium ion is rather similar to that of diferrocenyl ketone[9]. However, the latter has an exact diad axis through the carbonyl group whereas the carbenium ion symmetry is C_1-1.

2. The rings in both ferrocenyl moieties are planar (maximum displacements 0.03 Å) and almost parallel (angles between the pairs of rings are 3.1° and 7.1° respectively). Mean distances between ring planes are 3.31 Å in both ferrocenyl moieties (3.32 Å in ferrocene); mean C—C distances in the rings are 1.41 and 1.43 Å (range 1.39 to 1.50), and 1.42 and 1.44 Å (range 1.34—1.52), while the mean Fe—C (ring) distances are 2.05 and 2.06 Å (range 2.02 to 2.15), also close to the values in ferrocene (2.03 to 2.06). The mean bond angle in the rings is 108° (range 102 to 115°). In one ferrocenyl moiety (rings 1/2) the twist away from the eclipsed conformation is 11.1°, while the second ferrocenyl moiety is fully eclipsed.

3. As previously predicted[1, 5], the exocyclic carbon atom has been found to deviate from the planes of the two cyclopentadienyl rings to which it is attached (19.9° toward the iron atom of ring 1/2, and 17.7° away from the iron atom of rings 3/4). The exocyclic carbon is displaced 0.5 Å below (*i.e.* towards Fe) the plane of ring 2 and 0.4 Å (in the same direction) below the plane of ring 3. As a result of the above features, the exocyclic carbon atom is closer to the Fe atom of rings 1/2 (2.71 Å) than to the other Fe atom (2.85 Å)[10]; nevertheless, the distances found are not indicative of strong *direct* interaction between the metal atoms and the methine carbon atom. The angle C(1)—C(21)—C(11) around the exocyclic carbon atom is 131(3)°, which is significantly larger than the value of 120° appropriate to symmetrical sp^2 hybridization. Increase of this angle reduces the steric hindrance between H-2 and H-5.

The special stability of α-ferrocenylcarbenium ions is, of course, also evinced in solution and hence it was of interest to study their NMR spectrum[3] over a range of temperatures. The ^{1}H-NMR spectrum of *(4a)* at 18 °C (CD_2Cl_2) consists of a sharp singlet at δ = 4.57 ppm (C_5H_5-ring protons), a triplet at δ = 5.00 ppm (H-2, H-5; H-12, H-15), and another triplet at δ = 5.61 ppm (H-3, H-4; H-13, H-14). The NMR spectrum of the deuterated derivative *(4d)* indicates that the methine proton absorption (H-21) is hidden under the triplet due to H-2 and H-5. The apparent pairwise magnetic equivalence of protons in the substituted rings of *(4)* (H-2, H-5 and H-3, H-4) is in sharp contrast to the experi-

mentally observable chemical shift non-equivalence of all four protons in the ferrocenylphenylmethylium ion[1b, 3, 12]. The NMR spectra in Figure 2 show that the rings in *(4a)*

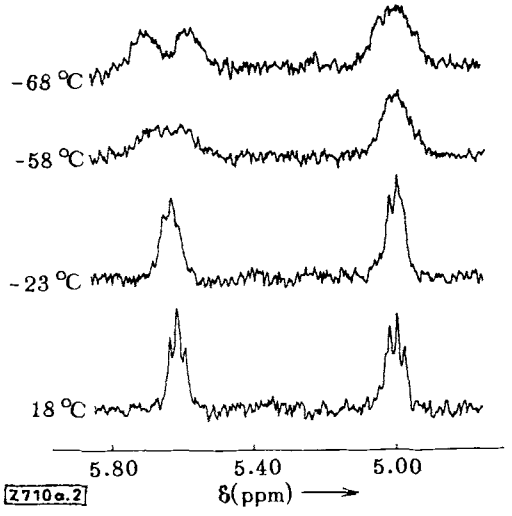

Fig. 2. Temperature dependence of ^{1}H-NMR spectrum of α,α-diferrocenylmethylium fluoroborate in the δ range of 4.8—5.8 ppm (recorded on a Bruker HFX-90 instrument with CH_3CN as internal standard).

can flip rapidly about the bond to the exocyclic carbon atom. Coalescence occurs at −66°C and rotation is apparently stopped at −70°C when protons H-3, H-4 (and H-13, H-14) show absorptions at δ = 5.55 and 5.68 ppm (Δν = 13 Hz). The absorption which corresponds to protons H-2, H-5 (and H-12, H-15) broadens on lowering the temperature but separation does not occur even at −100°C[13].

Similarly, the NMR spectrum of the phenyl derivative *(4j)*, which at 28°C shows absorptions at δ = 5.02 (H-2, H-5, H-12, H-15) and 5.85 ppm (H-3, H-4, H-13, H-14), coalesces at −30°C. At −45°C when rotation is apparently stopped, the spectrum exhibits absorptions for all four protons with H-2, H-5 (and H-12, H-15), absorptions appearing at δ = 4.44 and 5.53 ppm and those of H-3, H-4 (and H-13, H-14) at δ = 5.65 and 5.87 ppm[14]. In connection with the above results, it is noteworthy that measurements[16] of the Fe-$2p_{3/2}$ ionization energies by the ESCA method indicate that in *(4a)* the two Fe atoms appear to exhibit the same charge density.

The present results enable us to eliminate some of the structural models which have been proposed to account for the special stability of α-ferrocenylcarbenium ions. Unfortunately our results cannot in themselves provide an explanation for this special stability.

[6] *M. Cais* and *A. Eisenstadt*, J. Org. Chem. *30*, 1148 (1965).
[7] The perchlorate analog of *(4a)* was first reported by *C. Jutz*, Tetrahedron Lett. *1959*, 1.
[8] Crystals of *(4a)* are monoclinic, $P2_1/a$, with $a = 15.96$ (2), $b = 12.75$ (1), $c = 9.36$ (2) Å, $\beta = 90°38$ (5)', and four formula weights per cell (here and elsewhere in this paper numbers in parentheses are the estimated standard deviations in the least significant digits). Intensities of 2720 reflections (layer lines *h0l* to *h8l*; 228 reflections had zero intensity) were measured on a Stoe semi-automatic Weissenberg diffractometer, using graphite-monochromatized Mo-Kα radiation. Appropriate geometrical and absorption corrections were applied; poor crystal quality prevented high accuracy in intensity measurements. The structure was solved by Patterson methods and refined by a combination of Fourier and least-squares methods. At the present stage of refinement $R = 0.12$; all non-hydrogen atoms were given anisotropic temperature factors, while two positions were found for the fluoroborate ion, with occupancies of $^2/_3$ and $^1/_3$ respectively. Hydrogen atoms were not found in the difference synthesis computed at this stage.
[9] *J. Trotter* and *A. C. Macdonald*, Acta Cryst. *21*, 359 (1966).
[10] Our results are very similar to those recently reported [11] for bis(tricarbonylcyclobutadienyliron) phenylcarbonium fluoroborate, which has a *transoid* conformation, with one Fe atom closer (2.85 Å) to the exocyclic carbon than the other (2.94 Å).
[11] *R. E. Davis, H. D. Simpson, N. Grice*, and *R. Pettit*, J. Amer. Chem. Soc. *93*, 6688 (1971).
[12] *M. Hisatome* and *K. Yamakawa*, Tetrahedron *27*, 2101 (1971).
[13] This effect might be due to one or both of the following factors: (a) accidental identity (or near-identity) of the chemical shifts of H-2, H-5 leading to $b_{1/2} > \Delta\nu$; (b) the superposition of the absorption band of the methine proton, H-21, on the absorptions due to H-2, H-5.
[14] Use of approximate equations to determine coalescence temperature rotation rates and the Eyring equation [15] produced the following values for the free enthalpy of activation: $\Delta G^{\neq}$ *(4a)* ≈ 11.1 kcal/mol; $\Delta G^{\neq}$ *(4j)* ≈ 12.7 kcal/mol. We wish to thank Dr. *H. Gilboa* for help in the measurement of low temperature spectra.

Reaction of Ferrocenylmethylium Ions with Nitrosobenzene

By *P. Ashkenazi* and *Michael Cais*[*]

The special behavior of ferrocenylmethylium ions[11] in various chemical reactions has led to the postulate that these ions are capable of reacting either as diamagnetic species *(1)* or as biradical cations *(2)*[2, 3]. We now report results of the reaction between ferrocenylphenylmethylium tetrafluoroborate and nitrosobenzene, which resemble results of spin-trapping experiments[4] and as such may lend support to the formulation *(1)* ⇌ *(2)*.

Addition of nitrosobenzene to a solution of ferrocenylphenylmethylium tetrafluoroborate in dichloromethane yielded a nitroxide radical which exhibited the typical triplet in the ESR spectrum (Fig. 1a). A simulated ESR spectrum (Figure 1b) gave a good fit with the following hyperfine splitting constants: $a_N = 10.90$ G; $a_H = 2.70$ G; $a_{H(o,p)} = 2.95$ G; $a_{Hm} = 1.00$ G[5]. The nitroxide is stable and decay of its spectrum was not noticeable during the ESR measurements. Ethyldiisopropylamine, which is known not to enter into nucleophilic reactions[3, 6] produces a color change (from violet to brown) as well as a highly enhanced ESR nitroxide signal when added to the carbenium ion/nitrosobenzene mixture. This effect may be due to the amine reducing the nitroxide cation *(3)* to the electrically neutral species *(5)* and thereby removing the line-broadening effect of the ferricenium species on the ESR signal of *(5)*. (We have observed that ferricenium

[*] P. Ashkenazi and Prof. Dr. M. Cais
Department of Chemistry, Israel Institute of Technology
Haifa (Israel)

tetrafluoroborate is quantitatively reduced to ferrocene by ethyldiisopropylamine.) Presumably the signal enhancement could also arise from an increase in the concentration of *(5)* as a result of the amine also reducing[7b]

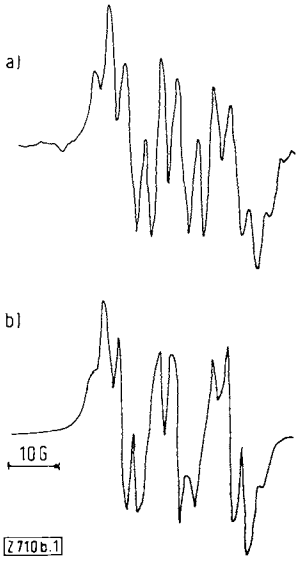

Fig. 1. (a) The ESR spectrum of nitroxide *(5)* and (b) the simulated spectrum with hyperfine splitting constants given in text. (Spectrum taken with Varian model V 4502-10 A instrument.)

the diamagnetic cation *(4)*[8]. In order to dispel suspicions that the nitroxides might not have any of the structures proposed but rather be due to some non-metal containing artifact of the system, the reaction mixture comprising the nitroxide(s) was treated with $LiAlH_4$ to yield the amine *(6)* which was shown to be identical with an authentic sample[9]. Furthermore, oxidation of the amine *(6)* with 3-chloroperoxybenzoic acid[11] gave rise to the same nitroxide *(5)* as demonstrated by an ESR spectrum identical to that obtained in our "spin-trapping" experiments.

Analogous experiments with a large variety of organometallic cations[12] gave similar results[13]. Hopefully, these may also help elucidate the stabilization mechanism operating in ferrocenylmethylium ions.

Partial Charge on the Iron in the Diferrocenylmethylium Ion

By *Rolf Gleiter, Rolf Seeger, Herbert Binder, Ekkehard Fluck*, and *Michael Cais*[*]

The unusual thermodynamic stability[1] of ferrocenylmethylium ions has been explained either by metal participation *(1)*[1,2] or by conjugation of the 2p orbital of the methylene group with the π-system of the five-membered ring *(2)*[1,3]. A "bent" structure *(3)* was predicted by an iterative Extended-Hückel calculation[4]. Very recent X-ray

Haifa (Israel)

crystal structure investigations[5] have confirmed this. As a result of this calculation the Mulliken charge on the iron was only 0.2 charge units more positive than that in ferrocene in spite of the appreciable interaction between the metal and the fulvene moiety.

To learn more about the relative partial charge on the iron in a ferrocenylmethylium ion, we have measured the ionization energy of the Fe-$2p_{3/2}$ level[*] of ferrocene *(4)*, 1,1'-dibenzoylferrocene *(5)*, and diferrocenylmethylium tetrafluoroborate *(6)* as well as that of ferrocinium tetrafluoroborate *(7)*, by the ESCA method[6]. (The measurements were carried out with an A.E.I. ES-100 photoelectron spectrometer. The samples were irradiated with the Al-$K\alpha_{1,2}$ line (1486.6 eV). The relative positions of the bands refer to the C-1s line, for which an energy of 286.6 eV has been taken.)

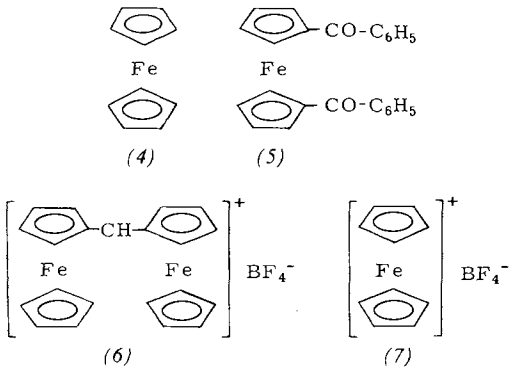

Table 1 shows the vertical ionization potentials found for the Fe-$2p_{3/2}$ bands. The ionization potentials of *(5)* and *(6)* are very similar, differing by only 0.5 eV from that for *(4)* but by about 1.3 eV from that for *(7)*. The results can be best explained as due to a similar partial charge on the iron in *(5)* and *(6)*, which differs markedly from the partial charge on the iron in *(7)*. A similar trend is shown by the isomeric shifts[12] listed in Table 2; these decrease from *(4)* to *(7)* and show similar values for *(4)*, *(5)*, and *(6)*.

Table 1 also lists the half-widths of the Fe-$2p_{3/2}$ signals. Calculations of the UHF type require that an exchange interaction between unpaired valence electrons (*e.g.* in Fe^{3+}) and inner electrons of the same spin should lead to line broadening or to splitting of the observed bands[7]. In some cases this was observed[8]. The same trend was found for the half-width of the Fe-$2p_{3/2}$ line as for the ionization potentials: similar values for *(4)*, *(5)*, and *(6)* that differ considerably from that for *(7)*. The relatively large half-width of the signal for *(6)* may be ascribed partly to the fact that the iron atoms in *(6)* are different[**]; a difference in the electron populations of *(6)* and *(4)*[9] could also be considered as explanation.

Table 1. Bond energies E_b and line widths for Fe-$2p_{3/2}$.

Compound	E_b (eV)	Line width (eV)
(4)	709.0	1.7
(5)	709.5	1.8
(6)	709.6	2.1
(7)	710.8	3.3

[*] The Fe-$2p_{3/2}$ level was chosen because its use led to the best signal-to-noise ratio and to the best resolution.

[**] Whereas the difference between the two iron atoms in *(6)* is too small to be detected by the ESCA method or by Mössbauer spectroscopy, two different iron atoms can be demonstrated by these methods in diferrocene picrate [8, 10].

The Mössbauer data[10, 11] given in Table 2 permit comparison of the half-widths of the Fe-$2p_{3/2}$ bands with the quadrupole splittings. The latter arise by interaction of the Fe nucleus in the excited state with an electric field gradient[12]. On the other hand, unpaired electrons, which are the cause of this electric field gradient, give rise to line broadening of the ionization bands[13]. There should thus be a relation between the two sets of values, and this was observed by *Cowan et al.*[8].

Table 2. Isomeric shifts and quadrupole splittings at 25 °C.

Compound	Isomeric shift [mm/s]	Quadrupole splitting [mm/s]
(4)	0.714 ± 0.005	2.396 ± 0.020
(5)	0.702 ± 0.005	2.185 ± 0.020
(6)	0.692 ± 0.005	2.100 ± 0.020
(7)	0.658 ± 0.010	0.609 ± 0.020

In Fig. 1 the quadrupole splitting is plotted against the half-width of the Fe-$2p_{3/2}$ bands. It is evident from the graph that the line width rises with increasing numbers of unpaired 3d electrons. The quadrupole splitting, however, is very small when, as in *(7)*, the 3d level is only half occupied, since in this case the electron shell around the Fe nucleus has almost spherical symmetry.

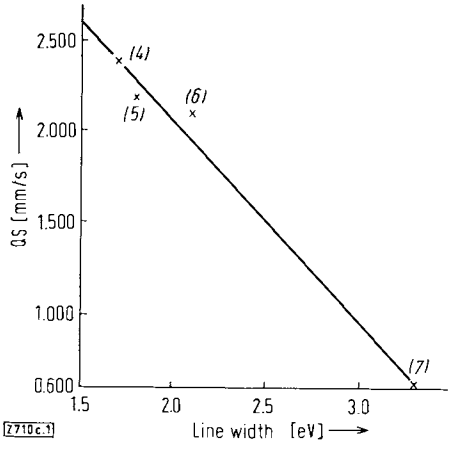

Fig. 1. Correlation between the measured quadrupole splitting (QS) and the line width of the Fe-$2p_{3/2}$ bands of ferrocene *(4)*, 1,1'-dibenzoylferrocene *(5)*, diferrocenylmethylium tetrafluoroborate *(6)*, and ferrocinium tetrafluoroborate *(7)*.

From our results it appears that the two iron atoms in *(6)* have approximately the same charge and that this does not differ appreciably from that in ferrocene. It is in accord with our results to assume a positive charge on the iron in all the compounds studied.

Synthesis of Non-Enolizable β-Diketones by Acid-Catalyzed Intramolecular Claisen Condensation

By *Hans Gerlach* and *Werner Müller*[*]

According to the literature[1], synthesis of β-diketones by Claisen condensation appears to be possible only when the product can form an enol and can be stabilized as the enolate or boron fluoride complex. For example, bicyclo-[2.2.2]octane-2,6-dione cannot be obtained by base-catalyzed condensation of methyl 3-oxo-1-cyclohexaneacetate[2]; the diketone is obtained, and then in small yield, only when 3-oxo-1-cyclohexaneacetic acid is passed over manganese(II) oxide heated at 340 °C[2]. In diterpene syntheses important intermediates of analogous structure have been prepared by aldol condensation of keto aldehydes and subsequent oxidation[3].

[*] Dr. H. Gerlach and Dipl.-Chem. W. Müller
Laboratorium für organische Chemie der ETH
CH-8006 Zürich, Universitätsstrasse 6/8 (Switzerland)

We have found that 3-oxo-1-cyclohexaneacetic acid, dissolved in glacial acetic acid, is converted into bicyclo-[2.2.2]octane-2,6-dione *(1)* in 75% yield on reaction with polyphosphoric acid. Under the same conditions spiro-[4.4]nonane-1,6-dione *(2)* is obtained in 81% yield from 2-oxo-1-cyclopentanebutyric acid. Yields are smaller if acetic acid is omitted from the reaction mixture, and glacial acetic acid cannot be replaced by acetic anhydride.

The reaction can be considered to take the following course: the polyphosphoric acid and the oxo acid form a mixed anhydride which can decompose to give the acyl cation; at the same time, enol formation by protonation of the keto-carbonyl group is catalyzed; the resulting enol then reacts with the activated carboxyl group.

The cyclization of the oxo acid to the bicyclo[2.2.2]octane-2,6-dione is an acid-catalyzed intramolecular Claisen condensation, a type of reaction hardly ever used so far for the synthesis of non-enolizable β-diketones. The only example known to us is the cyclization of a gibberone precursor[4]. However, the latter reaction also occurs by heating to 180 °C on sublimation; this is so also for conversion of α-campholonic acid into 6-oxocamphor[5]. In contrast, the β-diketones *(1)* and *(2)* are not formed in detectable amount when the corresponding oxo carboxylic acids are heated.

Experimental:

Bicyclo[2.2.2]octane-2,6-dione *(1)*:

A solution of 3-oxo-1-cyclohexaneacetic acid[2] (10 g) in glacial acetic acid (180 g) is treated with polyphosphoric acid (100 g)[6] and heated at 100 °C for 7 h. For hydrolysis the mixture is poured on ice/water and extracted with benzene, and the benzene solution is washed with sodium hydrogen carbonate solution, dried and evaporated. Sublimation of the residue at 110 °C/0.05 torr and recrystallization from hexane/benzene (9:1) gives colorless crystals (6.6 g, 75%), m.p. 188—190 °C[7]; IR (CCl_4): 1720 and 1745 cm^{-1}; UV (cyclohexane): $\varepsilon_{max} = 75$ (330 nm), 100 (320 nm) and 100 (300 nm); 100 MHz ^{1}H-NMR (CCl_4): $\delta = 1.77$—2.00 (2 H), 2.00—2.25 (2 H), 2.33—2.40 (4 H), 2.62 (m, 1 H), 3.00 (t, $J = 2.5$, 1 H). Mass spectrum: M^+ at $m/e = 138$.

Spiro[4.4]nonane-1,6-dione *(2)*:

Analogously, heating 2-oxo-1-cyclopentanebutyric acid[8] (50.30 g), polyphosphoric acid (170 g) and glacial acetic acid (340 g) for 4 h at 100 °C, followed by hydrolysis, extraction with benzene and distillation of the crude product affords 37.35 g (81%) of the dione, b.p. 91—92 °C/9 torr, m.p. 38—40 °C; IR, ^{1}H-NMR and mass spectra agree with the spectra of a sample prepared by the method of Ref. [9].

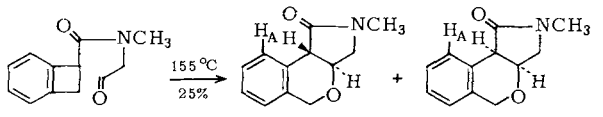
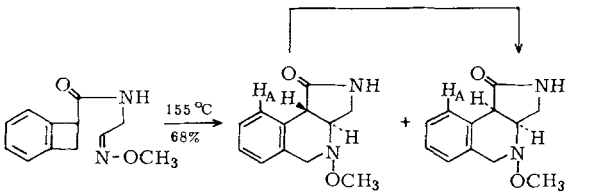
Intramolecular Cycloadditions of C,O and C,N Multiple Bonds to *ortho*-Quinodimethanes[1]

By *Wolfgang Oppolzer*[*]



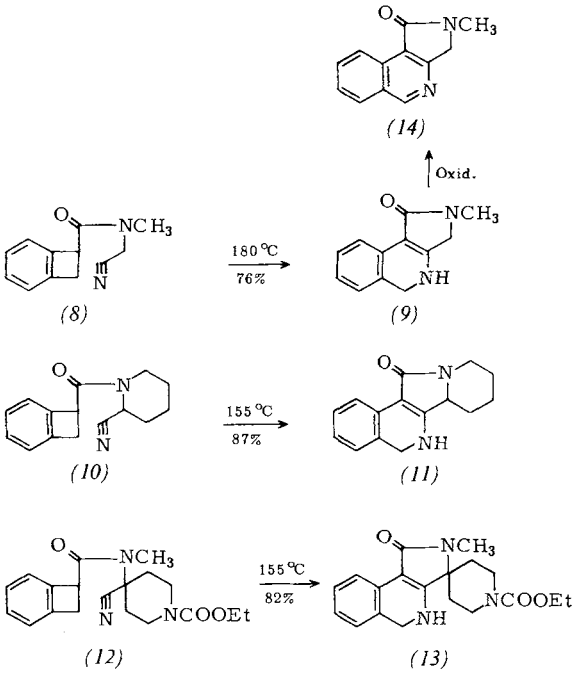
Recently the smooth intramolecular cycloadditions of even nonactivated olefins and acetylenes to *o*-quinodimethanes *(1a)*[2], have been described. This communication deals with the analogous reactions of weakly dienophilic carbonyl compounds, azomethines and nitriles *(1b)*[3].



(1)

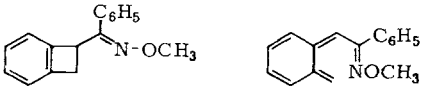
(a), Y = C
(b), Y = O, N

When a 1% solution of the aldehyde *(2)*[4] was heated in boiling bromobenzene under argon for 23 h a mixture of the stereoisomeric benzopyranopyrroles *(3)* (m. p. 134 to 135 °C; NMR: δ_{H_A} = 8.1 ppm) and *(4)* (m. p. 218—219 °C; NMR: δ_{H_A} = 7.64 ppm) resulted in 25% yield.



(2) *(3)* *(4)*

(5) *(6)* *(7)*



Similarly the oxime ether *(5)*[6] rearranged in boiling bromobenzene to the stereoisomers *(6)* (m. p. 124—126 °C; NMR: δ_{H_A} = 8.1 ppm) and *(7)* (m. p. 231—232 °C; NMR: δ_{H_A} = 7.65 ppm), in this case with a much better yield. After addition of a catalytic amount of *p*-toluenesulfonic acid, the *trans*-lactam *(6)* epimerized in boiling bromobenzene to the *cis*-lactam *(7)*. This sequence thus opens an efficient, stereo-controlled access to *cis*-pyrrolo[3,4-*c*]isoquinolines.

Surprisingly, even nitriles can add intramolecularly to *o*-quinodimethanes under similiar conditions. Thus the thermolysis of the nitriles[8] *(8)*, *(10)* and *(12)* gave a high yield of the dihydroquinolines *(9)*, *(11)* and *(13)*, which could be readily oxidized to the corresponding isoquinolines (*e. g. (9)* → *(14)*).

(14) *(8)* *(9)* *(10)* *(11)* *(12)* *(13)*

On thermolysis in boiling bromobenzene the oxime ether *(15)*[11] gave a low yield of 3-phenylisoquinoline[12]. This transformation obviously involves an electrocyclic reaction of the intermediate *o*-quinodimethane *(16)* similiar to the cyclizations recently described by *Schmid*[13] and *Kametani*[14].

(15) *(16)*

The new compounds described here were characterized by elemental analyses or high-resolution mass spectra as well as by IR, UV and NMR spectra ($CDCl_3$).

cis-2,3,3a,4,5,9b-Hexahydro-4-methoxy-1H-pyrrolo[3,4-c]-isoquinolin-1-one (7):

A solution of the oxime ether *(5)*[6] (99 g) in bromobenzene (2.5 liters) is refluxed for 20 h under argon atmosphere. The product *(7)* (57.2 g), which crystallizes from the cooled solution, is collected, washed with pentane and dried. The mother liquor (from which the isomer *(6)* can be isolated by chromatography) is refluxed for 14 h with *p*-toluenesulfonic acid (0.5 g) and evaporated. The residue is then purified by chromatography (silica gel) and crystallized (ether/pentane) to give a further 10.0 g of the product *(7)* (total yield 68%).

2,3,4,5-Tetrahydro-2-methyl-1H-pyrrolo[3,4-c]isoquinolin-1-one (9):

A solution of the nitrile *(8)*[8] (46 g) in toluene (460 ml) is transferred into a steel autoclave, flushed carefully with argon and then heated at 180 °C for 16 h. Evaporation of the reaction mixture and crystallization from dichloromethane affords the product *(9)* (35.2 g, 76%).

2,3-Dihydro-2-methyl-1H-pyrrolo[3,4-c]isoquinolin-1-one (14):

Oxygen is passed for 2 h through a solution of the compound *(9)* (12.5 g) in ethanol (500 ml) containing $FeCl_3$

[*] Dr. W. Oppolzer

[3] Carbonyl compounds, azomethines and nitriles in general act as weak dienophiles, except for some derivatives that are activated by electron-withdrawing substituents: *J. Hamer*: 1,4-Cycloaddition Reactions, Academic Press, New York 1967, p. 97, 128, 205; *J.-M. Biehler*, *J. Perchais*, and *J.-P. Fleury*, Bull. Soc. Chim. Fr. *1971*, 2711; *M. F. Ansell* and *A. A. Charalambides*, J. C. S. Chem. Comm. *1972*, 739; *D. vor der Brück*, *R. Bühler*, and *H. Plieninger*, Tetrahedron *28*, 791 (1972).

[4] The oily aldehyde *(2)* was obtained by the following reaction sequence: a) acylation of (methylamino)acetaldehyde dimethylacetal by benzocyclobutene-1-carbonyl chloride [5] and 3 equiv. of pyridine in dichloromethane; b) cleavage of the acetal by 1 N $HClO_4$ in dioxane/water (1.5:1) for 6 h at 25 °C.

[5] *J. A. Skorcz* and *J. E. Robertson*, J. Med. Chem. *8*, 255 (1965).

[6] The oxime ether *(5)* (m. p. 92—94 °C) was prepared by reaction of the N-formylmethyl-benzocyclobutene-1-carboxamide (cf. Ref. [4]) with 1 equiv. methoxyamine-hydrochloride in pyridine in the presence of an excess of molecular sieves, 2 h, 25 °C.

[7] After heating a 2% solution of methyl benzocyclobutene-1-carboxylate in acetonitrile for 16 h at 200°, only dimethyl *trans*-5,6,11,12-tetrahydrodibenzo[*a*,*e*]cyclooctene-5,6-dicarboxylate (m. p. 154 to 156 °C) could be isolated. This shows how strongly the course of the reaction depends on the steric proximity of the nitrile group and the *o*-quinodimethane moiety.

[8] The nitriles *(8)* (m. p. 70—72 °C), *(10)* (mixture of diastereoisomers, m. p. 90—110 °C) and *(12)* (m. p. 138—140 °C) were obtained by treating benzocyclobutene-1-carbonyl chloride [5] with (methylamino)acetonitrile, 2-piperidenecarbonitrile [9], or ethyl 4-cyano-4-(methylamino)-1-piperidinecarboxylate [10] respectively, in the presence of 3 equiv. of pyridine in dichloromethane for 1 h at −15 °C.

The Influence of Haloalkanes on the ^{13}C-NMR spectra of *n*-Alkanes

By *Gerhard Bergmann* and *Joachim Dahm*[*]

In contrast to the extensive study of solvent effects in ^{1}H-NMR spectroscopy, little has hitherto been reported about such effects on ^{13}C-NMR spectra[1–6]. The observed effects have mostly been interpreted as due to hydrogen bonds[2,4] or the polar reaction field[3]. However, more recent results[5,6] with the apolar, isotropic tetramethylsilane indicate that other factors, perhaps van der Waals forces, also have a marked influence on the chemical shifts of ^{13}C signals.

We have measured the solvent-dependence of all the ^{13}C-NMR signals of a series of linear alkanes for infinite dilution in the halomethanes CH_2Cl_2, CCl_4, CH_2Br_2 and CH_3I. The changes of the chemical shifts $\Delta\sigma$ in halomethanes, referred to the shift at infinite dilution in cyclohexane, are listed in Table 1, from which the following facts can be recognized.

Table 1. ^{13}C solvent shifts $\Delta\sigma$ (ppm) [a].

Solvent	*n*-Alkane	Position of ^{13}C					
		1	2	3	4	5	6–8
CH_2Cl_2	C_5H_{12}	−0.46	−0.19	−0.11			
	C_8H_{18}	−0.46	−0.19	−0.12	−0.12		
	$C_{10}H_{22}$	−0.47	−0.19	−0.12	−0.16	−0.14	
	$C_{15}H_{32}$	−0.44	−0.19	−0.14	−0.13	−0.13	−0.13
CCl_4	C_5H_{12}	−0.87	−0.25	−0.18			
	C_8H_{18}	−0.85	−0.24	−0.18	−0.20		
	$C_{10}H_{22}$	−0.87	−0.24	−0.18	−0.20	−0.20	
	$C_{15}H_{32}$	−0.89	−0.25	−0.19	−0.21	−0.20	−0.20
CH_2Br_2	C_5H_{12}	−1.48	−0.63	−0.43			
	C_8H_{18}	−1.47	−0.63	−0.46	−0.47		
	$C_{10}H_{22}$	−1.46	−0.63	−0.44	−0.46	−0.46	
	$C_{15}H_{32}$	−1.45	−0.62	−0.46	−0.49	−0.48	−0.49
CH_3I	C_5H_{12}	−1.59	−0.80	−0.54			
	C_8H_{18}	−1.58	−0.80	−0.60	−0.64		
	$C_{10}H_{22}$	−1.59	−0.80	−0.58	−0.62	−0.63	
	$C_{15}H_{32}$	−1.60	−0.79	−0.60	−0.64	−0.62	−0.63

[a] Resonance frequencies ν for infinite dilution in haloalkanes minus ν for infinite dilution in cyclohexane and susceptibility correction; negative values towards lower field. Infinite dilution shifts were extrapolated from measurements at six different concentrations with a least squares parabola. Assignment of the signals by *Grant* and *Paul*'s method [8]; the assignment for C-5 to C-8 of *n*-pentadecane is uncertain; this has, however, no influence on the interpretation because of the almost equal solvent shifts of these signals.

1. With cyclohexane as reference solvent, all the haloalkanes studied shift the signals to lower field. A systematic relation exists between the shift of the ^{13}C signal and the position of the C atom: the methyl group is the most sensitive to solvent effects. Within any one alkane, $|\Delta\sigma|$ decreases rapidly with increase in the distance from the end of the chain and reaches, beginning with C-4, an approximately

[*] Prof. Dr. G. Bergmann and Dipl.-Chem. J. Dahm
Lehrstuhl für Analytische Chemie der Universität
463 Bochum-Querenburg, Buscheystr. NC 4/72 (Germany)

constant value for the methylene groups in the middle of the chain. The differences in sensitivity of the individual C atoms depends on the solvent.

2. The sensitivity to solvent influence does not decrease monotonically within one alkane but shows a feebly marked minimum at C-3.

3. The solvent shift of the signals of corresponding C atoms in different alkanes shows no recognizable relation to the length of the chain but only slight unsystematic variations (mean 0.03 ppm).

4. With the exception of CH_2Br_2a should have good linear correlation ($r^2 = 0.99$) exists between the $\Delta\sigma$ value of the methyl group of the alkanes and the McRae term[7] of the solvent $(n^2-1)/(2n^2+2)$. The correlation is poorer ($r^2 = 0.92$ and 0.93 respectively) for C-2 and C-3. Because of the slight polarity of alkanes the polar reaction field has no appreciable influence. Correspondingly there is no recognizable dependence on $(\varepsilon-1)/(2\varepsilon+n_0^2)$[3].

CONFERENCE REPORTS

Properties of Molecules in Electric Fields

By *Armin Schweig*[*]

Molecules are composed primarily of electrically charged particles. Electric fields therefore play an important role in chemistry. Thus a polar dye molecule in solution gives rise to an electric dipole (reaction field) by orientation of the solvent molecules. Electronic absorption bands of the dye molecule can experience very powerful shifts and changes in intensity under the influence of the solvent- and temperature-dependent reaction field (solvatochromism and thermochromism).

A theory for calculating the solvatochromism of polar dyes which extends beyond the qualitative explanation due to *Förster* is developed. This theory poses the problem of calculating molecular dipole moments and polarizabilities in electronic ground and excited states. The solution of this problem afforded a method (*Kuhn* and *Schweig* 1964)[1] providing an exceptional stimulus to the calculation of quantities of second and higher order (polarizabilities[2], susceptibilities[3], shielding[3] and coupling[4] constants, hyperpolarizabilities[5]).

An extension of the theory has lead to the first theoretical treatments of quadrupole moments and quadrupole polarizabilities[6] of large molecules. Calculations of quadrupole moments including all valence electrons[7] show that the π-electron clouds obtained by this method do not extend far enough in a direction perpendicular to the molecular plane. A discussion of the quadrupole moments for molecules containing third-row elements suggests that an admixture of d orbitals becomes essential, in agreement with chemical intuition, whenever they can superimpose a bonding bridge on an antibonding orbital between two atoms[8]. The calculated quadrupole moments thus prove to be a new and highly sensitive probe for p-d bonding effects.

A study of intermolecular interaction on the basis of the calculated multipole moments and multipole polarizabilities furnished two noteworthy results[9]: in contrast to a view that previously found wide general acceptance, the interaction of π systems is not determined by dispersional interaction but by quadrupole-quadrupole interaction. An interaction of this kind suggests that the most favorable electrostatic arrangement of two π systems is achieved when the molecular plane of one system is twisted through 90° relative to the other one so that the π-electron cloud of one system is directed towards the nuclei of the other system. This finding offers a possible explanation of the mutual arrangement of molecules in hydrocarbon dimers and the arrangement of hydrocarbon molecules in the crystalline state.

Short-lived Molecules as Ligands in Coordination Compounds

By *Günter Schmid*[*]

Short-lived molecules that cannot be isolated under normal conditions often appear as ligands in coordination compounds. Carbene, cyclobutadiene and thiocarbonyl complexes may be cited as examples, in which the unstable molecules CR^1R^2, C_4H_4 and CS are stabilized by coordination to the metal atoms.

Our attempts to stabilize the lower oxidation states of main group elements in this way have led to compounds of boron, aluminum and silicon. Borylenes of the type BNR_2 exist as ligands in carbonyliron derivatives $(CO)_4FeBNR_2$ ($R=CH_3$ or C_2H_5) that are derived from pentacarbonyliron, a CO group being replaced by BNR_2. Aluminum(I) in the form of the unstable $AlN(CH_3)_2$ replaces a carbonyl group of $(CO)_4FeBr_2$ and thus forms the dimeric $\{(CO)_3[(CH_3)_2NAl]FeBr_2\}_2$ that is bridged by the amino groups. Finally silylenes SiX_2 (X = Cl, Br or I) are fixed in platinum complexes of composition $[(C_6H_5)_3P]_2Pt(SiX_2)_2$ (X = Cl or Br) or $[(CO)_5WSiI_2]_2$ where SiI_2 occurs in place of a CO group in hexacarbonyltungsten. The dimeric character of the compound is probably due to Si—I→Si bridges which lead to better coordinative saturation of the silicon atom, whereby the formal oxidation state 2 is retained. Similar bond relations appear to exist in the dimeric aluminum(I) compound $\{(CO)_3[(CH_3)_2NAl]FeBr_2\}_2$, where the dimethylamino groups act as bridging ligands between the aluminum atoms without changing the univalent character of the Al atoms.

The Al—N bonds readily become involved in insertion reactions, as reactions with CO_2 and CO show.

The bond relations in the B^I, Al^I and Si^{II} complexes are marked by the efforts of the main-group elements to achieve electronic saturation. This can occur by backbonding from the metal atoms but the extent of this backbonding is not known. On the other hand, the ligands NR_2, Cl, Br and I can also reduce the electron deficiency of the elements boron, aluminum and silicon by π-bond contributions. In the dimeric compounds $\{(CO)_3[(CH_3)_2NAl]FeBr_2\}_2$ and $[(CO)_5WSiI_2]_2$ the increase in the coordination number of aluminum and silicon is clearly more important than intramolecular saturation by π-bond contributions.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The vibrational spectroscopy of polymers is the theme of a review by *F. J. Boeris* and *J. L. Koenig*. IR spectroscopy is of use not only for the identification of polymers but also for the determination of crystallinity, conformation, terminal groups, branching, cross-linking, hydrogen bonding, and folding in polymers. In the case of copolymers it can also be used for the determination of composition and distribution of monomers. Owing to the progress made in spectroscopical methods both Raman spectroscopy and the investigation of the inelastic scattering of neutrons play an important role in polymer research. In this review the authors first deal with the theory of vibration spectroscopy and then describe its application to eight types of polymers. [Vibrational Spectroscopy of Polymers. Rev. Macromol. Chem. *8*, 209—249 (1972); 113 References]

[Rd 529 IE—G]

Hydride complexes, in which hydrogen is bonded to a transition metal and other stabilizing ligands are present as separate molecules or ionic species, are reviewed by *H. D. Kaez* and *R. B. Saillant*. The syntheses of transition metal hydrides can be divided into five groups: direct hydrogenation (1); reduction of metal halide complexes (2); H transfer from the solvent or from a group coordinated to the metal (3); hydrolysis of metal complex anions in water or acid (4); and protonation of metal complexes (5).

$$FeI_2 + Co + H_2 + PF_3 \rightarrow HCo(PF_3)_3 \quad (1)$$

$$HIrCl_2(AsEt_2Ph)_3 + LiAlH_4 \rightarrow mer\text{-}H_3Ir(AsEt_2Ph)_3 \quad (2)$$

$$OsCl_3L_3 + N_2H_4 \cdot H_2O + C_2H_5OH \rightarrow HOsCl_2L_3 \quad (3)$$
$$L = Pn\text{-}Bu_2Ph$$

$$Ir_4(CO)_{12} \xrightarrow{H^{\ominus}} HIr_4(CO)_{11}^{\ominus} \xrightarrow{H^{\oplus}} H_2Ir_4(CO)_{11} \quad (4)$$

$$HIr(CO)L_3 + HCl \rightarrow [H_2IrCOL_2]^{\oplus}Cl^{\ominus} \quad (5)$$
$$L = PPh_3$$

The authors discuss the properties and reactions of transition metal hydrides, *e.g.* reactions with halogens, mercury (II) halides, and halohydrocarbons, addition to unsaturated compounds, as well as participation in olefin isomerizations, hydrogenation, and hydroformylation. [Hydride Complexes of the Transition Metals. Chem. Rev. *72*, 231-281 (1972); 395 references]

[Rd 536 IE—M]

Poly(tertiary phosphanes) and their metal complexes are summarized by *R. B. King*. Tertiary phosphanes play an important role as ligands in coordination chemistry. A new method of synthesis consists in the addition of a P-H bond to the double bond of a vinylphosphane in the presence of a basic catalyst such as phenyl-Li:

$$C_6H_5PH_2 + 2(C_6H_5)_2P{-}CH{=}CH_2 \rightarrow C_6H_5P[CH_2{-}CH_2{-}P(C_6H_5)_2]_2$$
$$2(C_6H_5)_2PH + C_6H_5P(CH{=}CH_2)_2 \rightarrow \underset{(1)}{}$$
$$PH_3 + 3(C_6H_5)_2P{-}CH{=}CH_2 \rightarrow P[CH_2{-}CH_2{-}P(C_6H_5)_2]_3$$

Mixed arsane-phosphane compounds can also be prepared by this technique. Moreover, it also proves possible to synthesize P^{III} and As^{III} derivatives by addition of P-H and As-H bonds, *e.g.* to vinyl isocyanide. The reaction yields azaphospholines or the analogous arsenic compounds. The new compounds of type *(1)* react with transition metals to give numerous new complexes in which they act as mono-, bi-, and/or tridentate ligands. The coordination chemistry of poly(tertiary phosphanes) opens up new possibilities in fields of practical importance (nitrogen fixation, fuel cell technology, homogeneous hydrogenation, catalysts for new processes). [Some Recent Studies on Poly(tertiary phosphines) and Their Metal Complexes. Accounts Chem. Res. *5*, 177—185 (1972); 32 references]

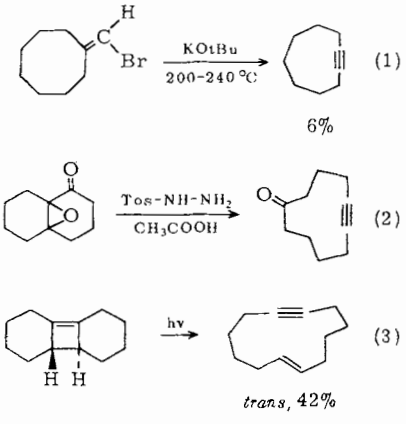
[Rd 537 IE—M]

The reduction of organic compounds by alkoxyhydridoaluminates *(1)* forms the subject of a review by *J. Málek* and *M. Černý*. Introduction of alkoxy groups into $LiAlH_4$, $NaAlH_4$, and AlH_3 alters the bulk and thus modifies the reducing properties of the hydrides. A survey of methods available for production of *(1)* is followed by a discussion of their reactions, particularly the selective reduction of functional groups in the presence of other reducible groups,

$$R{-}COOC_6H_5 + \underset{(1a)}{LiAlH(OtBu)_3} \xrightarrow[0\,^\circ C]{THF} R{-}CHO + LiAl(OC_6H_5)(OtBu)_3$$
$$R{-}COCl + (1a) \xrightarrow[-70 \text{ to } -80\,^\circ C]{THF} R{-}CHO + LiCl + Al(OtBu)_3$$

e.g. the partial reduction of esters, carbonyl halides, amides, and nitriles to aldehydes, especial interest pertaining to the partial reduction of aromatic and aliphatic nitriles with $LiAlH(OC_2H_5)_3$. The compound $LiAlH(OCH_3)_3$ reduces bicyclic alcohols such as camphor, norcamphor, isopinocamphor, and fenchone to the thermodynamically less stable of the two possible alcohols in a high degree of optical purity. Hydrogenolyses with *(1)* are compared with those of the simple hydridoaluminates. The paper contains preparative examples. [Reduction of Organic Compounds by Alkoxyaluminohydrides. Synthesis *1972*, 217—234; 177 references]

[Rd 538 IE—M]



The chemistry of vitamin B_{12} enzymes is reviewed by *J. M. Wood* and *D. G. Brown*. Methyl- and hydrogen-transferring enzymes are amply treated. Magnetic resonance methods are recommended as promising methods for the study of these enzymes: ESR for Co(II) corrinoids and for "spin-labeled" derivatives, NMR (^1H, ^{13}C, ^{19}F) for the evaluation of electronic effects of the ligands coordinated with the Co atom and for conformational studies, *e.g.* of the dimethylbenzimidazole group. [The Chemistry of Vitamin B_{12}-Enzymes. Structure and Bonding *11*, 47—105 (1972); 146 references]

[Rd 542 IE—H]

Possible interactions of transition metal complexes with biological macromolecules are depicted by *A. J. Thomson*, *R. J. P. Williams*, and *S. Reslova*. The anti-tumor activity of *cis*-$Pt(NH_3)_2Cl_2$ and some related compounds is the starting point of the article. Two-thirds of the paper are concerned with the chemistry relevant to this subject (thermodynamic and kinetic stability, oxidation states, spectroscopic properties, photochemical behavior, while the rest considers the interaction of metal complexes with amino acids, proteins, and nucleotides. The review concludes with a discussion of the possible modes of biological action of complexes. [The Chemistry of Complexes Related to *cis*-$Pt(NH_3)_2Cl_2$. An Anti-Tumour Drug. Structure and Bonding *11*, 1—46 (1972); 90 references]

[Rd 541 IE—H]

The synthesis of stable, isolable cycloalkynes having 7- to 12-membered rings including carbocycles having additional unsaturated groups or aromatic rings and cycloalkynes with heteroatoms in the ring, is reviewed by *H. Meier*. In the case of cyclic acetylenes one has to expect valence isomerizations (transannular π-electron interactions), isomerization to allenes and other dimers, particularly when syntheses are carried out in the presence of strong bases. The most important synthetic routes are the elimination reactions of types (1) to (3). Dehalogenations and dehydrohalogenations of 8-, 9-, and 10-membered rings generally give poor yields. The photolysis of bistosylhydrazones

and the thermolysis of polymethylenecyclopropenones represent fairly new methods. [Synthesewege zu Cycloalkinen mittlerer Ringgrösse. Synthesis *1972*, 235—253; 124 references]

[Rd 539 IE—M]

Patents

Easily extrudable plastic mixtures based on polyvinyl chloride suitable for the production of transparent bottles and having a Fikentscher *K* number of 58 to 67, measured in dichloroethane, are obtained by polymerization of vinyl chloride under a partial pressure that is always below the saturation vapor pressure of the monomer at the polymerization temperature, in the presence of polyethylene having 0.2 to 4 double bonds and/or 5—30 methyl groups per 1000 C atoms and a melt index of 0.3 to 40, followed by mixing of 0.1 to 5 parts by weight of this product, which consists of graft polymers of vinyl chloride with polyethylene and unchanged polyethylene, with 100 parts by weight of polyvinyl chloride. The total quantity of polyethylene in the mixture is at most 2.5 wt.%, based on polyvinyl chloride.

0.5 to 20 wt.% of reinforcing agent, *e.g.* graft polymers of polybutadiene or butadiene-styrene copolymers with methyl methacrylate and styrene or methyl methacrylate and acrylonitrile or methyl methacrylate, styrene, and acrylonitrile or methyl methacrylate, styrene, and ethyl methacrylate, may be added to improve the impact strength. Good results are also obtained if instead of polyethylene and polyvinyl chloride, the corresponding copolymers of ethylene and 0.4 to 6 mole % of other α-olefins or of more than 80 wt.% of vinyl chloride are used. [DOS 2138875; Solvay & Cie., Brussels]

[PR 29 IE—C]

Imidazoisoquinolinediones *(3)* can be obtained in a smooth reaction and in good yields by reaction of halides of phthalic acid *(1)* with imidazoles *(2)* in the presence of a polar solvent and a base. The dielectric constant of the solvent should be at least 4.8, and the parity constant of the base should be at most 8.7. The diones *(3)*, some of which are

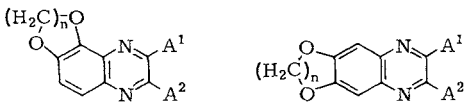
Phenols substituted with benzothiazylthioalkyl groups *(1)* are used as stabilizers for natural and synthetic rubber.

(1)

R denotes alkyl, cycloalkyl, alkylcycloalkyl, or aralkyl; the ring A may be substituted with alkyl, alkylamino, or alkoxy and chlorine. The compounds are obtained from *(2)* and *(3)* at 60 to 120°C (molar ratio roughly 2:1).

(2) *(3)*



(1) has good antiozonant and antioxidant properties, and is non-staining. [DOS 1694446, Imperial Chemical Industries, Ltd., London]

[PR 35 IE—E]

Foamed thermoplastic resins are obtained by extrusion of a thermoplastic resin that contains a volatile blowing agent and orthoboric acid as a nucleating agent, the extrusion conditions being such that the orthoboric acid decomposes with formation of nucleation sites for the cell formation. Orthoboric acid may also be used in combination with known nucleating agents, which have undesirable side effects when used alone. Aliphatic hydrocarbons, lower alkyl halides, acetone, and inorganic gases may be used as blowing agents. The foamed resins have a fine, uniform cell size. [DOS 1694649; Monsanto Chemicals Ltd., London]

[PR 41 IE—E]

The quinoxalines *(1)* can be used as hydrogen carriers in photographic processes, particularly as bleaching catalysts in the silver bleaching process for the production of color photographs.

(1a) n = 1, 2 *(1b)*

A^1, A^2 = alkyl (C_1-C_5), at most bicyclic (substituted) aryl, five- or six-membered heterocycle containing N, O, or S.

The ring containing O is linked to the quinoxaline grouping in the 5,6 *(1a)* or the 6,7 position *(1b)*. The new bleaching catalysts *(1)* give uniform bleaching of all three dye layers of a multilayer material. Catalysts known in the past have very different effects on azo dyes having different constitutions. The compounds *(1)* have favorable redox potentials and good solubility and activity properties, and they give good gradation. Bleach coupling between the individual layers containing the dyes is also largely suppressed. [DOS 2144298; CIBA-Geigy AG, Basel]

BOOK REVIEWS

Adsorption of Organic Compounds on Electrodes. By *B. B. Damaskin, O. A. Petrii,* and *V. V. Batrakov.* Plenum Press, New York—London 1972. 1st Edit., xvi, 499 pp., numerous figures, bound $ 40.50.

The present book is an English translation of a 1968 Russian edition revised by the authors for this purpose. It presents a hitherto lacking, comprehensive description of the entire field of the adsorption of organic substances on liquid and solid metals, written by members of the Flumkin school, whose mark it clearly bears. The first part describes the methods for the investigation of adsorption on liquid metals, mainly mercury, and the numerous results that have been obtained by these methods, including the hypotheses and theories derived from them. Chapter 3 in particular provides an insight into the controversy about the choice of the electrode potential or the electrode charge as the more appropriate independent variable, a decision being made here in favor of the electrode potential.

The second part deals with the methods and results for solid metals; a distinction is drawn between metals with high and with low hydrogen overvoltages. The metals of the iron group and those of the platinum group are treated separately. All problems in which the adsorption of organic substances plays a part, including those of practical importance, are discussed: additives in the deposition of metals, inhibitors in corrosion, fuel cells. To allow a better understanding of the processes involved in the adsorption, the kinetics of the actual electrode process are considered to some extent.

The book is worth reading for theoretical and practical workers in the fields of electrochemistry and physical chemistry, and because of the unusually large number of references it is a mine of information. An effort is made to show to whom or to which research group the priority belongs for given results or lines of investigation.

This abundance of references may actually be confusing to the beginner, since a number of conclusions are clearly understandable only when one knows the cited works in some detail. This is true in particular where *e.g.* in the case of alternating current measuring bridges (p. 16), Russian textbooks and handbooks are cited, whereas references to more easily accessible literature would have been preferable in the translation.

The numerous tables are very useful, particularly those giving values for the point of zero charge of the metals, which are otherwise widely scattered in the literature.

Horst Binder [NB 67 IE]

Anstrichstoffe und ähnliche Beschichtungsstoffe, Pigmente (Paints and Similar Coating Materials, Pigments). Issued by the Deutscher Normenausschuss. Beuth-Vertrieb GmbH, Berlin-Köln-Frankfurt 1971. 1st ed., 392 pp., numerous figures, stitched DM 54.—.

The publication of this pocket book is very welcome to the practical worker. Whereas it was formerly necessary to acquire individual standards in his field of interest, which were difficult to keep together, he now has available a neat collection of the relevant standards.

The collection has been carefully prepared, and a quick examination gives some idea of the numerous matters in the field of paints and pigments for which standardization has been necessary. A glance at the appended list of standards and draft standards that have not been reproduced shows how many more matters in daily work are covered only by draft standards, so that even now it is necessary to express the wish for a new edition as soon as a sufficiently large number of the drafts dealt with by the committees have become preliminary standards or standards.

Some readers will no doubt regret that complete standards for certain fringe areas have not been reproduced, but the inclusion of these standards would probably have made the book too large, to the inconvenience of other users.

The existence of a standard does not mean the end of the matter, as is shown *e.g.* in the field of definitions by an article that appeared in the journal "Farbe + Lack" in February 1972, in which the definition of a pigment as laid down in a standard was critically examined and found to be in need of modification.

The present book is arranged in numerical order, and contains an index arranged according to field as well as an alphabetic subject index.

It contains the standards on terminology and abbreviations, binders, solvents, driers, softeners, pigments and fillers, paints and similar coating materials, and color. The very wide field of pigments and fillers is broken down into general test methods, white pigments, colored pigments, luminous pigments, carbon blacks, and fillers.

The aquisition (and the frequent use) of this pocket book can be strongly recommended to all practical workers.

Heinz Rechmann [NB 78 IE]

Atomic and Molecular Radiation Physics. By *L. Christophorou*. John Wiley & Sons Ltd., New York—London 1971. 1st ed., x, 672 pp., numerous figures and tables, bound £ 10.50.

The book deals with the processes in the eV to keV range that occur on interaction of electrons, ions, and photons with individual atoms and molecules. Processes in liquids and solids are merely touched upon. It should be stressed that triatomic and polyatomic molecules are included in the discussion. The physical principles are presented clearly before the description of the experimental methods and the results obtained by these methods. Practically all the results mentioned are supported by references; this enhances the value of the book, since original papers up to and including 1969 are covered.

The book is divided into nine chapters. The first two deal with the deceleration and the resulting total ionization during the passage of ionizing radiation through matter. The next six chapters form the main part of the book, and deal with the processes that are brought about in or on atoms and molecules by photons, electrons, and ions: photophysical processes; elastic scattering of slow electrons; inelastic scattering of electrons; negative ions; electron detachment from negative ions and electron affinities of atoms and molecules; interactions between heavy neutral and charged particles. In the concluding chapter on biophotophysics and bioelectronics, reference is made to the importance of the physical understanding of molecular processes to biological problems, with the development of cancer as an example. The appendix contains ionization potentials of atoms, molecules, and radicals, some physical constants and conversion factors, and the periodic table and the table of radioactive isotopes. An author index and subject index are included. The book can be recommended to anyone who wishes a general picture of the present position of knowledge on the interactions of photons, electrons, and ions with free atoms and molecules in the low-energy range.

Hans Steidl [NB 82 IE]

***In Vitro* Methods in Cell-Mediated Immunity.** Ed. by *B. R. Bloom* and *P. R. Glade*. Academic Press, New York—London 1971, 1st edit., xxiv, 578 pp., numerous figs, bound, $ 14.00.

At a conference held in April 1969 at Brook Lodge on "Mediators of Cellular Immunology" it became apparent how greatly the clarification of the mechanisms of cellular immunity depended upon suitable *in-vitro* methods. These in their turn became the subject of a symposium held at the New York University, Bellevue Medical Center, New York, on May 28-29, 1970. The present book is an edited version of the discussions at this meeting, supplemented by an extensive section on the methods used.

The topics discussed are the characterization of the currently known supposed mediators of cellular immunity by simple chemical and physical parameters and their differentiation from one another (some short summary tables on this are given at the end of the book), the appropriate *in-vitro* systems, which are described by several of the participants and subsequently freely discussed and criticized, the correlation with *in-vivo* phenomena, and starting points for the development of new experimental systems.

The second part of the book consists of a clearly arranged description of 37 experimental *in-vitro* systems, by means of which the following phenomena may be studied: cell migration (particularly macrophage migration and related effects on macrophages), cytotoxicity of lymphocytes, lymphocyte transformation, inhibition of cell growth, chemotaxis, production of skin-reactive factor and of interferon, transference of delayed type of skin reactivity by transfer factor, and intracellular virus multiplication. A guide to the cultivation of human lymphocytes in long-term cultures is also given.

One great advantage of this book is that the methods represented are not merely described but are also discussed in an extremely lively fashion. It is true that this makes it difficult to obtain a good allover view, but this disadvantage is far outweighed by the wealth of suggestions and critical objections arising from the discussions. The extensive practical section which derives from the contributions of well-known scientists, in many cases the originators of the systems in question, is impressive in the clarity of its arrangement and in the precision and detail of its descriptions.

The book is highly recommended to all immunologists and immunological chemists active in this field.

Günter Sommer [NB 79 IE]

Organisch-chemisches Praktikum (Practical Organic Chemistry). By *G. Kempter*. Vieweg Verlag, Braunschweig 1971. 1st edit. 203 pp., 85 figs., bound, DM 9.80.

This is a brief practical manual produced by the author and a group of associates for students who are taking chemistry as a subsidiary subject. An introduction to instrument technology is followed by expositions on safety and fire precautions and on general methods (melting point, sublimation, distillation, rectification, and chromatographic methods). The organic experiments which follow are arranged by type of reaction. Each set of operating instructions is preceded by a brief theoretical introduction. Access to the literature is simplified for the student by a short introductory chapter. The book ends with sections on qualitative analysis and on ultraviolet and infrared spectroscopy. Each chapter is accompanied by test questions and practical exercises.

An attractive feature of the book is its compact and precise presentation, together with the clarity of the figures and formulas. The experiments to be carried out are simple, in accordance with the level of experience of the intended readership. In the reviewer's opinion the theoretical introductions are too short, for in many cases they do no more than show the student the concept he will need to study more thoroughly in a textbook. In addition, the brevity of the entries sometimes leads to the risk of making false statements due to excessive simplification (*e.g.* p. 74, nucleophilic substitution by $^{\ominus}NO_2$; p. 97, 1st section on poly-

merization, *etc.*). In general, one misses references to further literature; even in a book for beginners they should not really be left out. It is also a pity that the chapters on analytical methods and spectroscopy are separated from the preparations. If these chapters could have been integrated into the preparative sections the student would have had a much greater motivation for learning these techniques, *i.e.* he would learn the method in relation to its use on "his own preparation".

One minor point: it is to be hoped that the extremely good section on safety and fire precautions (p. 70) will not be spoilt in the next edition by the comment "All pranks, larks, and squabbles at the laboratory bench are absolutely forbidden."

For students whose main subject is something other than chemistry (teachers, physicists, pharmaceutical chemists), this brief practical manual can be recommended, if used in conjunction with a good textbook. For chemistry students the level is too low, even for the early organic practicals. Medical students will probably find the lack of medical applications a drawback.

Jürgen Sauer [NB 81 IE]

Organotin Compounds Vol. 1. By *A. K. Sawyer*. Marcel Dekker Inc., New York 1971, 1st ed., xiv, 252 pp., numerous tables, bound, $ 30.00.

The chemistry of organotin compounds, which has been advancing in leaps and bounds, is to be covered in three volumes, comprising fourteen survey articles by leading authors. Ten articles will deal with the main groups of compounds, arranged in the classical way as Sn—X compounds where X is *e.g.* hydrogen, halogen, oxygen, sulfur, or nitrogen. The other four chapters will be about technical applications, biological effects, tin-containing polymers, and analysis. However, the reviewer would have preferred to find in a reasonably comprehensive treatise a more detailed account in the form of some general chapters about theory, thermochemistry, bond lengths, and bond energies, structural chemistry, reaction mechanisms, and comparison with other organometallic compounds. It is to be hoped, however, that the separate chapters will contain some data on these aspects as well.

Volume 1 contains three survey articles, with literature up to the middle of 1968. The way the material is treated reflects the approach of the author in each case. The first article, by *E. J. Kupchik*, on 72 pages and with 316 references, is about organotin hydrides, and it discusses the results of relevant work in a rigid pattern. Mechanisms are mentioned only occasionally, as are also the ways of using these compounds, which can be deduced from the mechanisms. The author often refrains from criticism and reports some partly or fully invalid results without comments (*e.g.* Eq (7) or at the top of p. 35, with conflicting results in the middle of the same page). Comments and an explanation of the causes (*e.g.* competition between two mechanisms) would have been desirable in places.

The second article, in which *G. P. Van der Kelen, E. V. Van den Berghe*, and *L. Verdonck* discuss organotin halides (excluding organotin pseudohalides) on 70 pages, with 567 references, is a thorough account of the essentials with special emphasis on structure and spectroscopy, which are the authors' fields.

The third article is about organotin compounds, containing the Sn—O bond (Part I—alkoxides, oxides, and related compounds; 99 pages, with 347 references). It is written by *A. J. Bloodworth* and *A. G. Davies*, who are leading authors in this field and who have given a complete and critical account, including some unpublished results. The tables for compounds giving the recommended methods of preparation, are very extensive. The correlations are explained clearly, and the mechanisms and their useful applications are not omitted either. It is altogether an excellent and useful article.

This work is not a textbook but a collection of competent review articles, such as appear elsewhere as well (*e.g.* Advances in Organometallic Chemistry and Organometallic Chemistry Reviews). This is why the book will be found useful by those working in this field. Volume 2 has been published recently. It is hoped that volume 3 will be available soon because it will carry the cumulative index.

W. P. Neumann [NB 85 IE]

The Nitrile Oxides. Organische Chemie in Einzeldarstellungen, Vol. 13, By *Ch. Grundmann* and *P. Grünanger*. Springer Verlag, Berlin-Heidelberg-New York 1971. 1st ed., ix, 242 pp., numerous figures and tables, bound DM 98.—.

Until about 20 years ago the nitrile oxides were a little-known and only sporadically investigated class of compounds. They have recently become the subject of growing interest. Some recently published reviews made no effort to present a complete survey, and the publication of a comprehensive monograph thus seemed justified.

The authors have divided the book into nine chapters. The introduction contains, *inter alia*, a historical outline most of which is devoted to the 200 year odyssey of the structure of fulminic acid. The physical properties and the methods for the preparation of nitrile oxides and their rearrangement into isocyanates, their reduction to nitriles, and their polymerization reactions are then discussed. The fifth and longest section describes the numerous 1,3-dipolar cycloadditions. The representative examples are well chosen, and are explained only in so far as is necessary for understanding. A complete list of all cycloadducts in the form of tables is presented in the ninth chapter. In the sixth section, reactions leading to open-chain products are discussed under 1,3-additions. Finally, two short chapters deal with further reactions and with physiological properties and practical uses of nitrile oxides.

The widely scattered and in part poorly accessible literature has been carefully collected and arranged; a strikingly large proportion of the publications appeared during the past ten years. The shortness of the book facilitates reading. It is well worth the price both to those interested in synthesis and to those whose interest is mechanistic. The authors' personal involvement can be seen in occasional critical comments.

This is a successful attempt to present the latest position in the chemistry of nitrile oxides, and fills a gap in the chemical literature.

Manfred Christl [NB 76 IE]

Zement, Herstellung und Eigenschaften (Manufacture and Properties of Cement) by *F. Keil*. Springer-Verlag, Berlin-Heidelberg—New York, 1971. 1st ed., viii, 439 pp., 96 figs., bound, DM 88.—.

Most books on cement deal with the physical chemistry of the manufacture and hardening of cement either in a simple and readily understandable manner for technologists or comprehensively for scientists. *Keil's* aim seems to have been to do both. Though he says in the Preface that he has omitted many details, the table of contents and about 900 references indicate that he has succeeded in giving the fullest possible account of present-day knowledge of cement.

The first of the five chapters deals with the various types of cement and their uses, besides explaining how to make mortar and concrete. The second chapter, which is about the chemistry of cement clinker, gives a concise description of the reactions during the burning of cement clinker, the properties of the clinker phases and the hydraulic additives, as well as the products of the hydration of cement and the processes involved in hardening. This is followed by an account of the methods of investigation. The next two chapters discuss the physical characteristics (structures, strength, volume changes of hardened cement paste and concrete, and the influence of temperature on setting) and natural and technological effects (weathering and its significance for the formation of the raw materials and in connection with the chemical attack of concrete; corrosion and its prevention in steel reinforcing elements). The last chapter describes the technology of cement manufacture with particular emphasis on kiln processes and the topical question of emission and immission.

In just under 400 pages the author gives a complete picture of the physical chemistry and the technology of cement and the main properties of mortar and concrete. This book therefore enables students and technologists who prefer a clear and concise account to acquire an up-to-date knowledge of cement. The scientist will find this book interesting mostly because it is based on the literature and so it gives an excellent brief and objective account of all the main results, including the most recent ones. It will be an indispensable reference work for all those who are involved in the research and development of cement.

F. W. Locher [NB 84 IE]

Physical Chemistry—An Advanced Treatise. Vol. I. By *H. Eyring, D. Henderson*, and *W. Jost*. Academic Press, New York—London, 1971. 1st ed., xxii, 659 pp., bound, £ 13.—.

This volume, which is the first of a work that is expected to run to 11 volumes and of which a series of single volumes have appeared during the past few years[1], deals with the thermodynamic principles in twelve sections written by nine authors. This division into sections guarantees that each section provides a good foundation and at the same time takes the latest research results into account in its approach.

A wide range of applications, such as interfacial thermodynamics, treatment of several simultaneous equilibria, thermodynamics of extreme pressures and temperatures, irreversible thermodynamics, and thermodynamics in external fields are therefore discussed. A fundamental section deals with the Second Law from the Caratheodory standpoint; however, other fundamental questions such as the problem of the unattainability of absolute zero and the formalism of negative temperatures are also discussed.

In view of this diversity, it is not surprising that some matters that are important to the applications receive rather too little attention. These include the thermodynamic phenomena in gravitational fields, which play a role in meteorology and even in the theory of the constitution of the stars. Certain areas of thermodynamics, on the other hand, are dealt with more than once by different authors. It is often too much to expect the editor to eliminate overlapping of this nature; moreover, a section becomes too difficult to read if it is necessary to refer too often to other sections.

The presentation naturally differs from section to section, but it is always sufficiently clear to enable the reader to follow the course of developments without too much difficulty. The main advantage of the presentation lies in the fact that the reader is brought abreast with present-day research, and an extensive bibliography makes it easy to find further information where the book lacks space for detailed discussions. The work can therefore be wholeheartedly recommended to all those who are interested in gaining a more thorough knowledge of thermodynamics, particularly for their own research work.

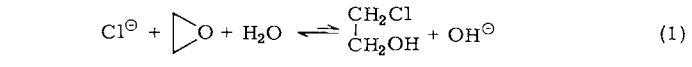
Pages 1041–1110

International Edition in English

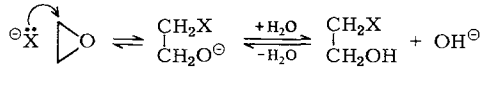


Basic Behavior of Epoxides in the Presence of Halide Ions[1]

By J. Buddrus[*]

Epoxides behave as bases in the presence of catalytic quantities of halide ions. They convert halogenated hydrocarbons into olefins, suitable phosphonium salts into ylides, and haloforms into dihalocarbenes. Kinetic studies with the aid of IR and NMR spectroscopy show that the species that functions as the proton acceptor is neither the epoxide ion nor the halide ion, but the 2-haloethoxide ion.

1. Introduction[2a–2c]

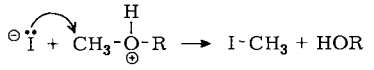


Brønsted et al. observed in 1929 that an aqueous solution of KCl has an alkaline reaction after the addition of an epoxide[2d]. The weakly basic chloride ion enters into a covalent bond and liberates the equivalent quantity of the stronger base OH^-. Eq. (1) is an equilibrium reaction[3a, 3b]. The reverse reaction is the well-known epoxide formation from 2-haloalcohols and hydroxide ions.

(1)

The equilibrium is displaced well to the side of the epoxide. Thus the equilibrium constant for ethylene oxide and sodium chloride at 20 °C is 3.2×10^{-4}, *i. e.* an equimolar solution of ethylene oxide and NaCl contains the components of the left-hand and of the right-hand sides of eq. (1) in contents of 98% and 2% respectively[**].

The forward reaction and the reverse reaction both proceed *via* the same intermediate (principle of microscopic reversibility[3b]). The intermediate (2-haloethoxide) can be intercepted by electrophilic compounds such as acrylonitrile[4], and can also be observed by measurement of conductivity and heat of mixing[5]. Among the halide ions, the iodide ion reacts fastest[2d], in agreement with the increase in nucleophilic character in the order $Cl^- < Br^- < I^-$ in protonic solvents[6].

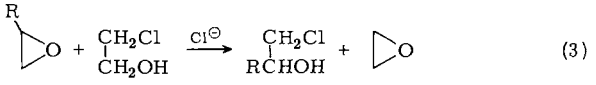


The fact that epoxides undergo ring cleavage so readily is evidently connected with their ring strain, since halide ions do not cleave cyclic ethers with larger rings or open-chain ethers. Additional protonation or other complex formation on the oxygen is necessary to weaken the C—O bond to

[*] Priv.-Doz. Dr. J. Buddrus
Fachbereich Synthetische und Analytische Chemie
Technische Universität, Berlin (Germany) and
Institut für Spektrochemie und angewandte Spektroskopie
46 Dortmund, Bunsen-Kirchhoff-Strasse 11 (Germany)
(present address)

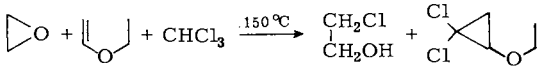
[**] *Brønsted*'s observation can be easily demonstrated in a small-scale experiment. 1 g of KI is dissolved in 10 ml of water, and a few drops of phenolphthalein solution are added. 1 ml of ethylene oxide [alternatives: propylene oxide; epichlorohydrin (chloromethyloxirane)] is also dissolved (or suspended) in 10 ml of water, and phenolphthalein is added to the solution. The two colorless solutions are combined. After a few seconds, the solution is turned deep red by the hydroxide ions produced.

such a degree that it can be broken by the attack of a halide ion[7,8] ["ether cleavage", eq. (2)].



(2)

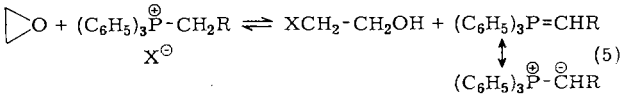
2. Rediscovery of the Basic Behavior



The uptake of a proton in accordance with eq. (1) should not be confined to water, but should also extend to other compounds containing mobile hydrogen (alcohols, C—H acid compounds).

However, only isolated experiments have been carried out in this direction. Thus the dehydrohalogenation of β-haloalcohols by epoxides in the presence of halide ions has been described [eq. (3)][9].

(3)

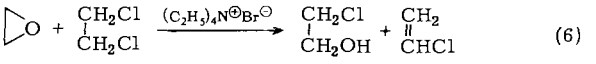


The basic behavior of the halide ion/epoxide system was rediscovered by accident. Attempts made by the author to add the three-membered ring of the epoxide to a double bond to obtain tetrahydrofuran derivatives were unsuccessful[10]. The reaction (4) took place instead in the "solvent" chloroform[11,12]. In this reaction, ethylene oxide eliminates

(4)

hydrogen chloride from chloroform and is converted into 2-chloroethanol. Quaternary ammonium halide, whose activating effect on epoxides has been described[13], was used as the catalyst.

In another experiment, a quaternary phosphonium halide was tried as the catalyst. Ethylene oxide was again found to be a base, but this time toward the "catalyst" [eq. (5)][14].

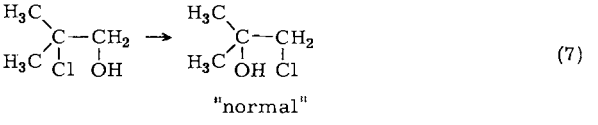


(5)

We shall first discuss the 1,2-elimination of hydrogen halide from haloalkanes, a reaction that we have also investigated kinetically. The deprotonation of phosphonium salts and the 1,1-elimination will then be discussed mainly from the preparative standpoint.

3. 1,2-Elimination from Haloalkanes[15-17]

Epoxides eliminate hydrogen halide from reactive haloalkanes, *e.g.* in accordance with eq. (6). The reaction proceeds only in the presence of catalytic quantities of a halide such as tetraethylammonium halide. The lower the



(6)

C—H acidity of the haloalkane, the higher is the reaction temperature (Table 1). Simple haloalkanes such as isopropyl bromide, *n*-butyl bromide, and cyclohexyl chloride do not react.

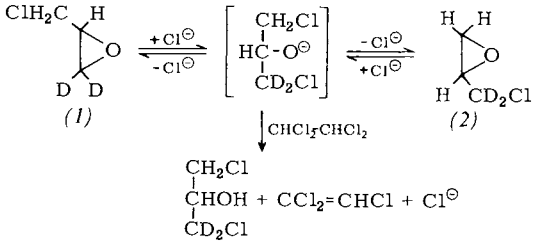
Table 1. Conversion of some haloalkanes into olefins by ethylene oxide in the presence of $(C_2H_5)_4N^{\oplus}Br^{\ominus}$.

Haloalkane	*T* [°C]	Olefin	Yield [%]
$CHCl_2$—$CHCl_2$	80	$CHCl{=}CCl_2$	92
CH_2Br—CH_2Br	150	$CH_2{=}CHBr$	63
CH_2Cl—CH_2Cl	150	$CH_2{=}CHCl$	61
$(CH_3)_3CCl$	150	$(CH_3)_2C{=}CH_2$	54
trans-1,2-Dibromocyclohexane	150	1-Bromocyclohexene	21

Alkyl-substituted epoxides give two isomeric alcohols in reaction (6), the isomer with terminal halogen ("normal isomer") predominating. However, the ratio of the normal isomer to the other isomer provides no information about the course of the dehydrohalogenation, for two reasons. Firstly, ring cleavages of epoxides both in acidic and in alkaline solution lead mainly to the normal isomer[18-24]. Secondly, at least at 150 °C, the ratio is controlled thermodynamically and not kinetically, as is shown by the following isomerization effected by isobutylene oxide and chloride ions at 150 °C [reaction (7)][15,9,25].

(7)

The base in the epoxide/halide ion system could be:



a) the halide ion (with subsequent transfer of hydrogen halide to the epoxide ring). *Winstein, Parker et al.*[26] showed that tetrabutylammonium chloride in acetone converts tosylates and (more slowly) haloalkanes into alkenes

b) the epoxide ring (with subsequent ring cleavage of the protonated epoxide by halide ions). *Searles* and *Tamres* detected hydrogen bonds between epoxides and alcohols[27]

c) the 2-haloethoxide ion. As was pointed out earlier, this intermediate has been detected indirectly in water. Hydrogen bonds presumably contribute appreciably to the formation and stability of the ion, since cleavage of the epoxide ring occurs only very slowly, if at all, in aprotic solvents. Thus ethylene oxide reacts with diethylamine in methanol to give *N*,*N*-diethylaminoethanol; in the absence of methanol, no reaction occurs[2c]. Styrene oxide and

benzylamine react 100 times as rapidly in methanol as in acetonitrile[19].

Investigations were first carried out to establish whether halides could cleave the epoxide ring in *aprotic* media. If tetrabutylammonium chloride is allowed to react with deuterated epichlorohydrin *(1)*, a 1:1 equilibrium *(1)*⇌*(2)* is slowly established, as is shown by ^{1}H-NMR spectroscopic investigation.

As is to be expected, the isomerization is first order with respect to the epoxide and with respect to the chloride. The rate constant k_i at 43.5 °C is 4.6×10^{-3} l.mol^{-1}.min^{-1}.

If 1,1,2,2-tetrachloroethane is now added to this solution, the isomerization is suppressed (as long as tetrachloroethane is still present), and dehydrohalogenation to form trichloroethylene occurs instead. IR spectroscopic investigation of the ethylene formation shows the same order with respect to the epoxide and to the salt. Tetrachloroethane is not involved in the rate-determining step, and its deuterated form exhibits no appreciable kinetic isotope effect: $k_H/k_D = 1.2$. The rate constant k_d at 43.5 °C, however, is 10.65×10^{-3} l.mol^{-1}.min^{-1}; it is roughly *double* k_i. This doubling can be readily explained by the occurrence of the alkoxide as an intermediate. Each successful nucleophilic attack by the chloride on *(1)* leads to alkoxide formation, and hence to (fast) dehydrohalogenation, but only every *second* intermediate molecule is converted into *(2)* (1:1 equilibrium).

If, on the other hand, a relatively inert haloalkane such as 1,2-dichloroethane is added, a different kinetic picture is found, though the mechanism does not change. The dehydrohalogenation is now by far the slowest step. In addition to the epoxide and the salt, 1,2-dichloroethane also appears with an order of one in the rate equation for the vinyl chloride formation. Therefore an appreciable kinetic isotope effect is observed: $k_H/k_D = 40$ at 43.5 °C. Furthermore, a kinetic analysis reveals that out of 50 alkoxide ions $(CH_2Cl)_2CHO^-$ formed, 49 revert to epichlorohydrin and chloride "without having done anything", while only one undergoes further reaction with 1,2-dichloroethane (c = 1 mol/l)[15]. The isomerization (with the rate constant k_i) is fast in comparison with this process, and is practically complete before appreciable quantities of vinyl chloride have been formed.

These experiments show that the epoxide ring is opened by chloride ions even in aprotic media, and that the *alkoxide* formed is the actual base.

Electron-attracting residues on the epoxide ring accelerate the ring cleavage:

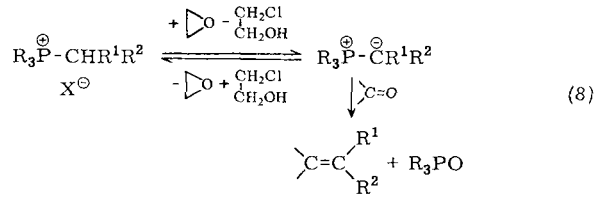
$$C_2H_5 < CH_3 < H < CH_2Cl < CCl_3 < CF_3$$

This increase is in agreement with a nucleophilic ring cleavage of the epoxide. ρ^*, the reaction constant of the Taft equation, is +0.86. The influence of substituents is thus small. No differences were observed in the reactivity of free chloride and of ion-pair chloride in the solvent (and reactant) epichlorohydrin (dielectric constant 22) and at salt concentrations of 0.01 to 0.15 mol/l, presumably because the chloride ion is surrounded by the reactant epichlorohydrin in both cases.

4. Deprotonation of Phosphonium Salts[14]

As was mentioned earlier, epoxides deprotonate phosphonium salts [eq. (5)]. This was surprising, since strong bases[28] such as alkoxides or organometallic compounds had previously been used in most cases for deprotonation. The preparative possibilities of the deprotonation and of the Wittig reaction will be discussed first, and this will be followed by studies on the mechanism of the deprotonation.

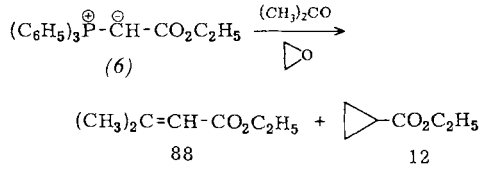
Epoxides react with alkyltriphenylphosphonium halides[29] having a CH group α to the phosphorus to form phosphonium ylides and 2-haloalcohols [eq. (5)]. The halide required is itself the reactant in this case. Phosphonium *tetrafluoroborates* accordingly do not react, since the BF_4^- ion cannot form a covalent bond with the epoxide. This dependence on the anion is unknown for conventional bases.



The reaction in accordance with eq. (5) is reversible[30]. Thus $(C_6H_5)_3P^+—CH_2—C_6H_5\ Cl^-$ reacts with ethylene oxide to a smaller extent to form the ylide (recognizable by the red color) and 2-chloroethanol, while the ylide and 2-chloroethanol react instantaneously to give the salt and ethylene oxide. The position of the equilibrium, as expected, depends on the C—H acidity of the phosphonium ion. C—H-acidic cations of the type *(3)* (pK_a 4—11[31a]) are almost completely converted into chloroform by excess epoxide at room temperature, those of the type *(4)* ($pK_a > 11$[31b]) are only partly deprotonated, and those of the type *(5)* are no longer deprotonated at room temperature, but only at higher temperatures.

$(C_6H_5)_3\overset{\oplus}{P}—CH_2—COR$ *(3)* $(C_6H_5)_3\overset{\oplus}{P}—CH_2—Aryl$ *(4)* $(C_6H_5)_3\overset{\oplus}{P}—Alkyl$ *(5)*

Irreversible reactions may be superimposed on the equilibrium. Thus ylides react with excess epoxide to form cyclopropane compounds, among other things[32-36]. However, these (side) reactions proceed slowly and at relatively high temperatures. Only in exceptional cases do they interfere with the faster reaction between the ylide present in equilibrium and carbonyl compounds.

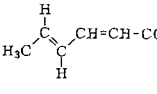


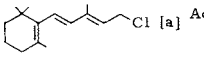
4.1. Reaction of the Ylides with Carbonyl Compounds

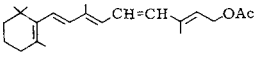
The ylides present in equilibrium in accordance with eq. (5) can be intercepted with carbonyl compounds. The irreversible reaction sequence (8) then occurs instead of the equilibrium (5). Excess epoxide does not interfere.

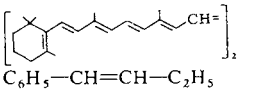
(8)

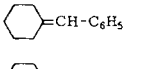
There is one exception: ethylene oxide successfully competes with inert ketones such as acetone for the ylide only in the case of the weakly nucleophilic ylide *(6)*.

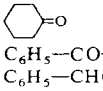


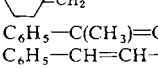


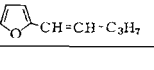












The Wittig olefination of carbonyl compounds proceeds surprisingly easily in this way (Table 2). The phosphonium salt (examples 6—8, 10, 13—15) or its precursors, *i. e.* triphenylphosphane and halogen compound (examples 1—5, 9, 11, 12) are dissolved in an aprotic solvent, excess epoxide (usually ethylene oxide) and carbonyl compound are added, and the mixture is heated if necessary (sealed tube or autoclave). The reaction temperature depends mainly on the acidity of the phosphonium salt, and also on the reactivity of the ylide formed *in situ* toward the carbonyl compound. Salts having cations of the type *(3)* are deprotonated by ethylene oxide even at room temperature (examples 1—6), and those with cations of the type *(4)* are deprotonated between room temperature and 90 °C (examples 7—10). Ethylene oxide surprisingly also removes the proton from the salts having low C—H acidities [cations of the type *(5)*], but only at 150 °C (examples 11—15). Resonance-stabilized ylides, as expected, give mainly *trans*-olefins; unstabilized ylides give mixtures of *cis* and *trans* olefins, in which the *cis* isomer usually predominates somewhat (examples 9, 13, 15).

The advantage of ethylene oxide over the bases normally used in the Wittig reaction, such as alkoxide and organolithium compounds, is that the reaction is easier to carry out[37] (no separate preparation of ylide). α,β-Unsaturated esters can be prepared particularly easily. Moreover, the reaction medium is not basic; the typical side reactions brought about by bases are thus avoided. Whereas furfural reacts with butylidenetriphenylphosphorane to give mainly disproportionation products of the aldehyde[38,39], the reaction with ethylene oxide and triphenylbutylphosphonium bromide leads to the desired olefin, 2-(1-pentenyl)-furan (example 15). One disadvantage is that weakly C—H-acidic salts with cations of the type *(5)* are deprotonated to the ylides only at 150 °C. The equilibrium concentration of the ylides is very low here; aldehydes are still olefinated surprisingly well (examples 13—15), whereas the olefination of ketones is poorer (examples 11, 12).

4.2. Kinetic Investigation of the Deprotonation of Phosphonium Salts with Epoxides[40]

The C—H-acidic salts with cations of the type *(3)* react rapidly (half lives under the conditions chosen here between one minute and a few hours) and practically com-

Table 2. Examples of the reaction
$(C_6H_5)_3P$ + halogen compound + ethylene oxide + carbonyl compound → $(C_6H_5)_3P{=}O$ + olefin + Hal-CH_2—CH_2—OH

[a] Used as the triphenylphosphonium salt.

pletely with excess epoxides to form ylides. They are therefore particularly suitable for quantitative investigations. The progress of the reaction can be followed by IR spectroscopy based on the decrease in the intensity of the carbonyl band in the cation (region: 1680—1735 cm^{-1}, depending on the substituent R) and the increase in the intensity of the carbonyl band of the ylide formed (1500—1600 cm^{-1}).

The investigastions carried out so far indicate that the deprotonation proceeds by two mechanisms. More weakly acidic (C—H acidic) phosphonium salts ($pK_a \geq 8.8$) are deprotonated by the 2-haloethoxide ion (or its derivatives). They include phosphonium salts such as $R_3P^+—CH_3\ X^-$, $R_3P^+—CH_2—C_6H_5\ X^-$, and $R_3P^+—CH_2—CO_2R'\ X^-$ (here and below, $R=C_6H_5$). More strongly acidic phosphonium salts ($pK_a < 8.8$), however, are presumably deprotonated by their *own anion*, and not by the relatively slowly formed alkoxide. These include $R_3P^+—CH_2—CO—CH_3\ X^-$ and $R_3P^+—CH_2—CO—C_6H_5\ X^-$.

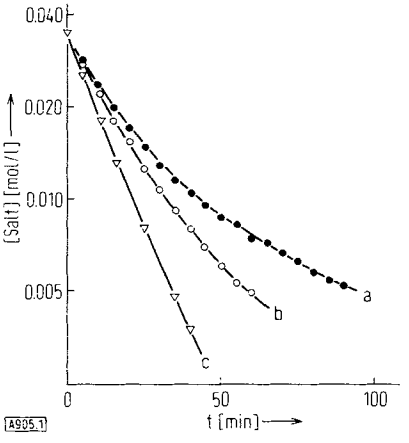
The reaction kinetics of the more weakly acidic salts will be discussed first. The deprotonation of $R_3P^+—CH_2—C_6H_5\ Cl^-$ in epichlorohydrin as the reactant and solvent is first order with respect to the salt (and first order with respect to the epichlorohydrin, as is shown by a separate measurement in acetonitrile). Simultaneously, benzaldehyde is added to react with the ylide formed. The rate constant of the deprotonation at 43.5 °C is $k_p = 9.8 \times 10^{-3}$ $l.mol^{-1}.min^{-1}$. It agrees with the constant of the 1,2-dehydrohalogenation of 1,1,2,2-tetrachloroethane by epichlorohydrin (see Section 3), $k_d = 10.65 \times 10^{-3}$ $l.mol^{-1}.min^{-1}$, again at 43.5 °C. In both cases, the alkoxide

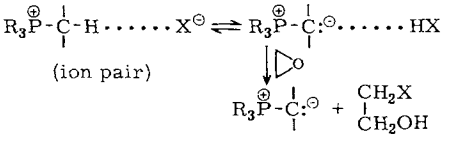
is formed in the slow step, and quickly reacts further, with the phosphonium ion in one case and with tetrachloroethane in the other. Here again, the deuterated compound ($R_3P^+—CD_2—C_6H_5\ Cl^-$) exhibits no kinetic isotope effect ($k_H/k_D = 1.0$). Electron-attracting residues on the epoxide ring accelerate the reaction, while electron-repelling residues retard it.

Strongly C—H-acidic phosphonium salts are deprotonated in accordance with a divergent rate equation:

$$-\frac{d[salt]}{dt} = k \cdot [epoxide]\,[salt]\,(1-\alpha)$$

This equation evidently contains the quantity of *associated* salt (ion pair) ([salt] = salt concentration according to quantities weighed out; α = degree of dissociation). This assumption is confirmed by the influence of foreign salts having the same anion on the reaction rate. The foreign halide has no effect in chloroform, since the phosphonium salt is associated in any case, as is shown by conductivity measurements. In acetonitrile, the foreign halide causes practically complete association ($\alpha = 0$) of the partly dissociated phosphonium halide[41, 42] ($K_{diss} \approx 10^{-2}$) in accordance with the law of mass action, and thus leads to a first order rate equation with respect to the salt (see Fig. 1).





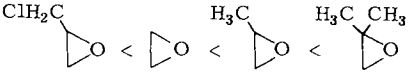


Fig. 1: Decrease in the concentration of $(C_6H_5)_3P^+—CH_2—COCH_3Br^-$ at 34.9 °C in acetonitrile ($K_{Diss} = 2 \times 10^{-2}$) a) without foreign salt, as well as in the presence of b) 0.0175 mol/l and c) 0.070 mol/l of $(n\text{-}C_4H_9)_4N^+Br^-$. [Ethylene oxide] = 4.13 mol/l (118-fold excess).

The rate constants for the deprotonation k_p increase with increasing pK_a value, and are up to 100 times as great as the rate constant of the dehydrohalogenation k_d. This rules out the alkoxide mechanism. The following course is suggested. The halide in the ion pair reversibly deprotonates the phosphonium salt, with formation of an ylide-hydrogen halide complex. Evidence of hydrogen bonding (in ion pairs) has been found by other authors in IR and NMR spectroscopic studies on phosphonium salts[43, 44]. The complex is finally converted by the epoxide into the ylide[*].

The kinetic isotope effect in this case is between 1.3 and 1.7. Effects as small as this are to be expected for the equilibrium[45] and the subsequent step[46]. Substituents on the epoxide ring have an opposite influence on the rate of ring opening in this case. Electron-repelling substituents *accelerate* the process:

This sequence is expected for *proton*-catalyzed ring cleavage[47–49].

[*] Also in accordance with the rate is the assumption of a reversible deprotonation by the epoxide itself, followed by an opening of the protonated epoxide by the ion-pair halide.

It has been shown by *Schiemenz et al.*[39] that one can make use of the basicity of the anion itself, particularly that of the fluoride ion, for the deprotonation of phosphonium salts, and the Wittig reaction, in some cases at least, can thus be carried out without an auxiliary base.

5. Deprotonation of Haloforms

Epoxides deprotonate haloforms in the presence of a catalytic quantity of a halide [reaction (9)].

$$X^{\ominus} + \triangleright O + CHX_3 \rightleftharpoons \begin{matrix} CH_2X \\ | \\ CH_2OH \end{matrix} + [CX_3^{\ominus}] \qquad (9)$$

The trihalomethyl anion formed is intercepted by electrophilic double bonds (Section 5.1) or by carbonyl compounds (Section 5.2). Its decomposition into dihalocarbene and

$$[CH_3^{\ominus}] \rightleftharpoons [CX_2] + X^{\ominus}$$

halide[50a, 50b] can be detected by addition to nucleophilic double bonds (Section 5.3)[50c], and can be used preparatively[11, 12].

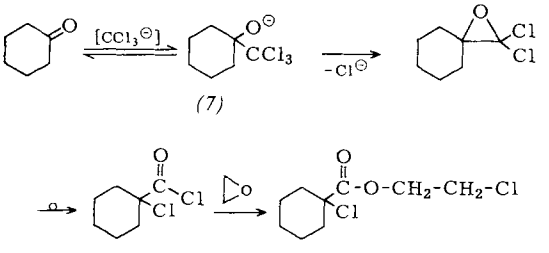
Halides that are soluble in organic solvents, such as quaternary ammonium or phosphonium halides, are used as catalysts. Alkali metal halides may also be used, if cryptates are added as solubilizing agents[50d].

Our kinetic investigations on the primary step of the deprotonation are not yet complete[40].

5.1. Addition of the Trihalomethyl Anion to Polarized Double Bonds[51a]

The trihalomethyl anion formed in accordance with eq. (9) attacks the α position of α,β-unsaturated esters and nitriles[51b]. Subsequent proton uptake from the haloform leads to the final product, so that the overall process is represented by (10). The ethylene oxide and the halide ion have a purely catalytic function here, *i. e.* the production of the nucleophile CX_3^-.

$$CHCl_3 + CH_2{=}CH{-}CN \xrightarrow[(C_2H_5)_4N^{\oplus}Br^{\ominus}]{\triangleright O} CCl_3{-}CH_2{-}CH_2{-}CN \qquad (10)$$

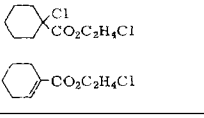


Enol esters react in accordance with eq. (11). The trihalomethyl residue becomes attached to the α position of the

$$CHBr_3 + \overset{\delta\ominus}{C}H_2{=}\overset{\delta\oplus}{C}H{-}O{-}CO{-}CH_3 \xrightarrow[(C_2H_5)_4N^{\oplus}Br^{\ominus}]{\triangleright O} CH_3{-}\underset{\displaystyle CBr_3}{\underset{|}{C}}H{-}O{-}CO{-}CH_3 \qquad (11)$$

enol ester[52], corresponding to the polarity of the latter, as was found earlier by *De Selms* and *Lin* in the reaction with sodium trichloroacetate[53]. Nucleophilic additions to the double bond of vinyl acetate have evidently not been observed before[53].

5.2. Addition of the Trihalomethyl Anion to Carbonyl Compounds[54]



It is well known that haloforms react with carbonyl compounds in the presence of bases to give α-trihalomethyl alcohols *via* compounds of the type *(7)*[55]. The reaction proceeds further in the presence of ethylene oxide and

(7)

$(C_2H_5)_4N^+ Br^-$. Esters of α-halocarboxylic acids are formed between 50 and 150°C (Table 3). It is assumed that *(7)* first reacts by an S_Ni mechanism to give the dichloroepoxide, which isomerizes to the chloride of the α-chlorocarboxylic acid. Similar isomerizations are known[56]. The α-chloro acid chloride reacts with further ethylene oxide to form the ester[57]. Two observations support this assumption. On the one hand, the reaction can also be carried out with the alcohol corresponding to *(7)*, and on the other, 1,1,1-trichloro-2-methyl-2-propanol can be saponified with potassium hydroxide solution to give α-chloroisobutyric acid[58].

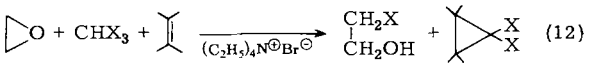


Table 3. Conversion of aldehydes and ketones into α-halocarboxylic esters with haloforms and ethylene oxide.

Carbonyl cpd.	Haloform	Final product	Yield [%]
$(CH_3)_2CH{-}CHO$	$CHCl_3$	$(CH_3)_2CH{-}CHCl{-}CO_2C_2H_4Cl$	48
$(CH_3)_2CH{-}CHO$	$CHBr_3$	$(CH_3)_2CH{-}CHBr{-}CO_2C_2H_4Br$	45
$(CH_3)_2CO$	$CHCl_3$	$(CH_3)_2CCl{-}CO_2C_2H_4Cl$	24

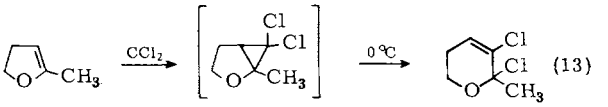
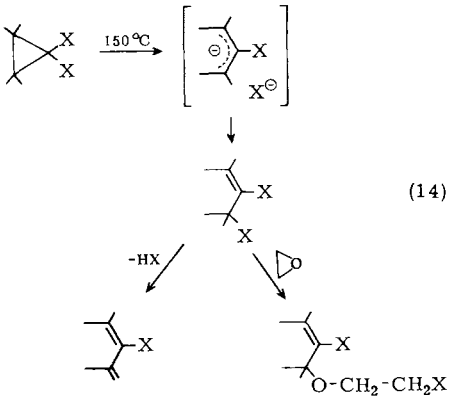
	$CHCl_3$		28[a]

[a] Total yield; ratio of cyclohexane to cyclohexene compound = 1:3.



5.3. Addition of Dihalocarbenes to Olefins

The reaction proceeds in accordance with eq. (12). It is easy to carry out. Equimolar quantities of olefin and



(12)

haloform are heated with excess ethylene oxide in the presence of catalytic quantities of tetraalkylammonium halide for 5 hours at 150 °C in a sealed tube or autoclave, and the dihalocyclopropanes are distilled from the crude reaction mixture. If dihalocyclopropane and 2-haloethanol have about the same boiling point, the alcohol is removed by extraction with water. As is usual in the formation of dihalocyclopropanes[59], the addition proceeds stereospecifically, despite the high reaction temperature. *cis*-2-Butene gives *cis*-1,1-dichloro-2,3-dimethylcyclopropane, while *trans*-2-butene gives the corresponding *trans* compound. Dibromo-, dichloro-, chlorofluoro-, and even difluorocarbene can be produced in this way and converted into dihalocyclopropanes[60, 61] (Table 4). Methylene chloride does not react.

(13)

On the other hand, ring cleavage frequently occurs when ethylene oxide/halide is used, since the reaction temperature is higher in this case (150 °C). This behavior is observed in reactions with highly alkylated olefins, strained olefins, and enol ethers.

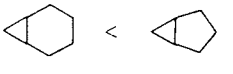
(14)

Table 4. Dihalocyclopropanes [a] from ethylene oxide, haloform, and olefins; catalyst: $(C_2H_5)_4N^+Br^-$.

Olefin	Haloform	Cyclopropane	Yield [%]
$CH_2=CH_2$	$CHCl_3$	1,1-Dichlorocyclopropane	8
$CH_3-CH=CH_2$	$CHCl_3$	1,1-Dichloro-2-methylcyclopropane	26
$(CH_3)_2C=CH_2$	$CHCl_3$	1,1-Dichloro-2,2-dimethylcyclopropane	72
cis-2-Butene	$CHCl_3$	*cis*-1,1-Dichloro-2,3-dimethylcyclopropane	50
trans-2-Butene	$CHCl_3$	*trans*-1,1-Dichloro-2,3-dimethylcyclopropane	84
$CH_2Cl-C(CH_3)=CH_2$	$CHCl_3$	1,1-Dichloro-2-chlormethyl-2-methylcyclopropane	36
$CH_2=CH-CH=CH_2$	$CHCl_3$	1,1-Dichloro-2-vinylcyclopropane	61
Cyclohexene	$CHCl_3$	7,7-Dichloronorcarane	78
$(CH_3)_2C=CH_2$	$CHBr_3$	1,1-Dibromo-2,2-dimethylcyclopropane [b]	45
Cyclohexene	$CHBr_3$	7,7-Dibromonorcarane [b]	45
$(CH_3)_2C=CH_2$	$CHCl_2F$	1-Chloro-1-fluoro-2,2-dimethylcyclopropane	39
Cyclohexene	$CHCl_2F$	7-Chloro-7-fluoronorcarane	45
$(CH_3)_2C=CH_2$	$CHClF_2$	1,1-Difluoro-2,2-dimethylcyclopropane	13
Cyclohexene	$CHClF_2$	7,7-Difluoronorcarane	29

[a] Selection; for further examples see [60—62].
[b] Also ring cleavage products [61].

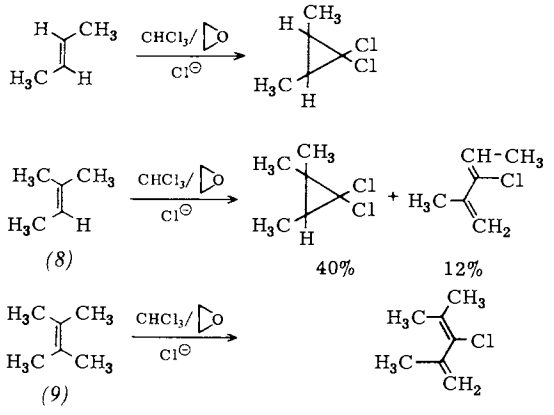
When ethylene oxide, chloroform, and ammonium salt are heated in the absence of an olefin, the greater part of the starting compounds is recovered on distillation. Tris-(2-chloroethyl) orthoformate is formed in 7.5% yield, presumably by attack of CCl_2 on ethylene oxide or 2-chloroethanol.



5.4. Addition of Dihalocarbenes to Highly Alkylated Olefins, Strained Olefins, and Enol Ethers

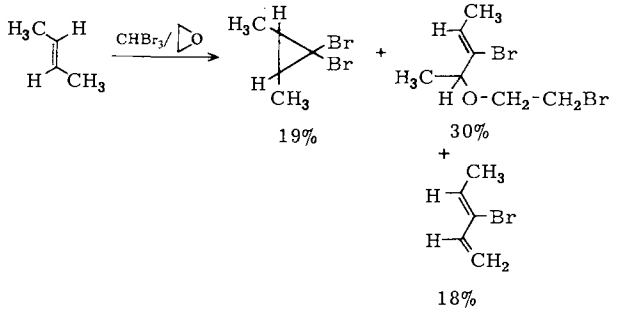
The discovery by *Doering* and *Hoffmann*[63] that dihalocarbenes can be produced from haloforms and strong bases and reacted with olefins to form dihalocyclopropanes led to a very rapid development in the field of carbene production. The dihalocyclopropanes prepared from dihalocarbenes were found to be stable under the reaction conditions (−80 to +80 °C). Ring cleavage was observed only occasionally, *e. g.* after reaction (13)[64, 65].

The cyclopropane compound is first formed from olefin, haloform, and ethylene oxide. This isomerizes *via* an ionic transition state[66] to give a dihalo compound, which either loses hydrogen halide to form a diene or reacts with excess ethylene oxide to give an allyl ether [reaction (14)][67].



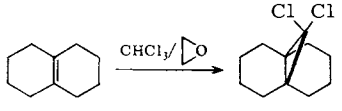
The following substituents (or arrangements) favor the isomerization[68]:

$$Br > Cl \gg F$$
$$2RO > RO \approx 4CH_3 > 3CH_3 > 2CH_3$$

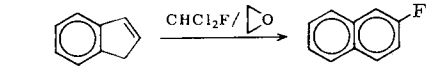


This can be illustrated by some examples. *trans*-2-Butene with chloroform/ethylene oxide gives only the cyclopropane compound, whereas 2-methyl-2-butene *(8)* gives both

the cyclopropane compound and the diene[69], and 2,3-dimethyl-2-butene *(9)* gives only the diene[1, 69].

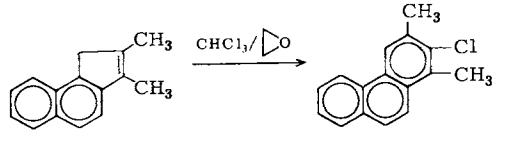


With bromoform/ethylene oxide, even *trans*-2-butene gives open-chain compounds[61].



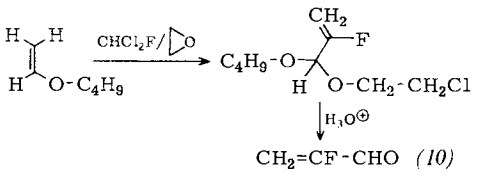
Finally, 1-hexene, as a monosubstituted olefin, gives only the cyclopropane compound both with chloroform and with bromoform.

If the environment of the cyclopropanes prevents the formation of a double bond in the transition state (Bredt's rule), even tetraalkylated cyclopropanes are stable [reaction (15)][1].

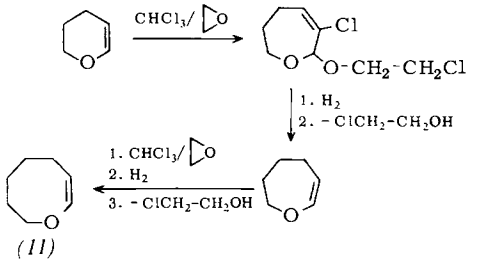


(15)

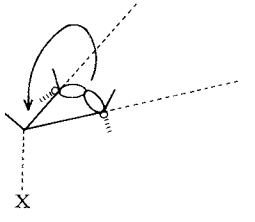
Compounds containing the cyclopentene skeleton (cyclopentene, cyclopentadiene, indene) also give isomerization products [reactions (16) and (17)]. Indenes can be smoothly converted into naphthalenes in this way[1, 11, 70–72].



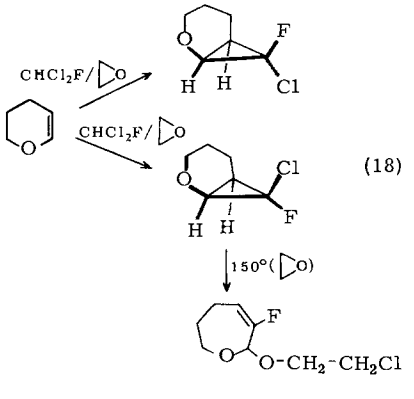
(16)



(17)

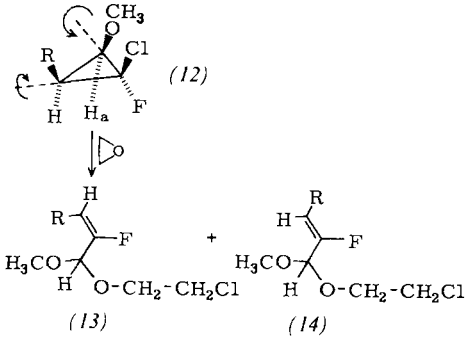


Enol ethers are extended by one C atom, with formation of unsaturated acetals[12, 73]. Let us pick out a few of the many reactions. Vinyl *n*-butyl ether is converted with dichlorofluoromethane and ethylene oxide into the acetal, and this is then converted into α-fluoroacrolein *(10)*[74], which was prepared for the first time.



Here again, only the chlorine atom migrates, since the heterolysis of the C—Cl bond is easier than that of the C—F bond[75]. Cyclic enol ethers react similarly with ring expansion. Dihydropyran can be converted in this way into its next higher homologs, *e.g.* into 5,6,7,8-tetrahydro-4*H*-oxocin *(11)*[76], which was also unknown until then.

The thermal cleavage of the dihalocyclopropanes formed *in situ* is strictly stereospecific. The cyclopropane bond opens disrotatorily and synchronously displaces the leaving groups by backside attack (comparable with an S_N2 substitution)[77, 78].



In the reaction of dihydropyran with $CHCl_2F$/ethylene oxide, the two isomeric cyclopropanes are formed first, and the *endo*-chloro isomer then undergoes cleavage [reaction (18)]. The *exo*-chloro isomer[79a] is stable, since

(18)

ring cleavage with C—Cl heterolysis would lead to a *trans* double bond in the seven-membered ring[79b]. Accordingly, the all-*cis* compound *(12)* ($R = n\text{-}C_3H_7$; $J_{F,H_a} = 12$ Hz[79a]) gives the *cis* olefin *(13)* when heated with ethylene oxide[79c]. The *trans* isomer *(14)*, which is obtained in a smaller quantity (*trans* : *cis* = 25 : 75), is evidently formed only after the stereospecific cleavage by partial *cis/trans* equilibration[79d] of the α-chloro ether formed as an intermediate.

(12)

(13) *(14)*

The reaction of aromatic compounds[1,80,81] or acetylenes[82] with haloforms/ethylene oxide again leads not to cyclopropanes or cyclopropenes but to their isomerization products.

5.5. Carbene Production with Ethylene Oxide and Halide Ions—an Alternative

The production and reaction of dihalocarbenes with ethylene oxide/halide ions require a relatively high temperature (150 °C). This is associated with a number of disadvantages and advantages. The disadvantage lies in the control of the reaction; because of the low boiling point of ethylene oxide, the reaction must be carried out in a sealed vessel. The advantage lies in the fact that instead of the initially formed dihalocyclopropanes, their ring cleavage products are obtained in many cases. In this way, suitable open-chain olefins undergo chain lengthening and cyclic olefins undergo ring expansion by one C atom. This reaction thus proves to be an alternative to the methods known until now[50c,65] for the generation of dihalocarbenes and their reaction with olefins, where the reaction temperature lies between −80 and +80 °C, and the stable dihalocyclopropanes themselves are obtained.

6. Closing Remarks

Finally, the basicity of the β-haloalkoxide ion will be compared with that of the halide ion.

Winstein, Parker, et al. investigated the behavior of halides in aprotic solvents (*e.g.* $(n\text{-}C_4H_9)_4NCl$ in acetone)[26,83] and found them to be "strong carbon nucleophiles, but very weak hydrogen bases". Nevertheless, this basicity is sufficient to eliminate hydrogen halide from reactive alkyl halides. The HX formed is trapped by addition of 2,6-lutidine (which does not influence the rate of reaction). This process presumably also takes place in the system halide/epoxide, the epoxide taking on the role of the lutidine. However, it can only be of secondary importance since, according to previous kinetic investigations, the rate equation is first order in epoxide and zero order in some haloalkanes.

It must be assumed, therefore, that the nucleophilic opening of the epoxide ring by the halide ion (to yield a strong oxygen base) proceeds much more rapidly than uptake of a proton by the halide ion.

The author is grateful to the Deutsche Forschungsgemeinschaft for its support of this work.

Industrial Application of the Semiconductor Properties of Dyes[**]

By Hans Meier, Wolfgang Albrecht, and Ulrich Tschirwitz[*]

Effects of industrial interest have been detected in investigations on the dark conductivity and photoconductivity of dyes. For example, it was found that organic dyes can be used in the same way as inorganic photoconductors in vidicon television pickup tubes for the reproduction of images. Among other things, pointers were obtained to the formation of rectifying and photoelectrically sensitive pn junctions, to relatively high thermoelectromotive forces of doped and polymeric dyes, to the possibility of use in reprography, and to a high catalytic activity connected with the conductivity, which is already being utilized in fuel cells.

1. Introduction

Though the semiconductor properties of organic compounds have been under investigation for a number of years (cf. reviews in[1-4]), the question of an industrial use of this new class of semiconductors is still in the discussion stage. On the one hand, the dark conductivity and the photoconductivity of organic compounds has long been regarded merely as a side effect, so that the search for a practical use did not seem very promising. On the other hand, too much hope was placed on attempts to produce organic semiconductor components for industrial use with compounds that were unsuitable. The superiority of inorganic materials then started to lead to a certain amount of pessimism; however, there appears to be no justification for this when one considers the decades that have gone into the development of inorganic semiconductors.

What can be said about the present position in the industrial application of the semiconductor properties of organic dyes and about future development possibilities?

2. Conduction Mechanism of Dark Conductivity and Photoconductivity

Since the discussion of the above question is closely linked to the mechanism of the dark conductivity and photoconductivity of dyes, some prefatory remarks on the conduction mechanism are appropriate.

The conductivity of organic dyes, like that of inorganic semiconductors, is attributed to electrons and defect electrons (holes). Three processes act together to produce the dark currents and the stationary photoelectric currents:

1. *Generation process:* For dyes with a difference of less than 2 eV between the ground state and the excited state, it may be assumed that, as in the case of inorganic intrinsic semiconductors, charge carriers are formed by thermal transfer of an electron from the ground state to the excited state, since measurements of the temperature dependence of the dark conductivity $\sigma\,[\Omega^{-1}\,\mathrm{cm}^{-1}]$, which follows eq. (1)

$$\sigma = \sigma_0 \exp(-\Delta E/2kT) \tag{1}$$

lead for many dyes to a thermal activation energy ΔE that agrees with the optical excitation energy found from the first absorption maximum[5]. The possibility of the formation of charge carriers by an optical excitation process of corresponding energy can also be seen from the agreement of the photoconduction and absorption spectra and of the thermal activation energy ΔE with the optical activation energy (ΔE_{opt}) deduced from the long-wave limit of the photoconductivity; for Cu-phthalocyanine (phthalocyaninatocopper(II)) for example, $\Delta E = 1.7$ and $\Delta E_{opt} = 1.63$ eV, or for indigo $\Delta E = 1.75$ and $\Delta E_{opt} = 1.79$ eV. In addition, particularly where the difference between the electronic excitation levels is greater than 2 eV, one may expect thermal excitation of defect centers (impurities, adsorbed gases, incorrectly placed counterions in the case of ionic dyes) and injection of electrons or defect electrons from the electrodes at high voltages, which leads to space charge limited currents

$$I \sim U^n (n > 1) \tag{2}$$

(I = current intensity [A], U = voltage [V]). It is also possible, particularly on excitation with high light intensities (laser light), that a detectable concentration of secondary charge carriers will be produced from excitons (by ionization of defect centers[6, 7], by annihilation processes[8, 9]).

2. *Transport of charge carriers:* As in the case of inorganic semiconductors, many organic solids may be assumed to have energy bands that arise from the discrete energy levels of the molecules by electronic interaction and allow quasi-free transport of electrons and defect electrons[10]. On the one hand this is confirmed by quantum-mechanical calculations of the energy eigenvalues belonging to the wave functions of an excess electron or defect electron of the organic solid, which give band widths of the order of kT or 10^{-2} eV[11, 12], *e.g.* 0.47 kT for metal-free phthalocyanine[13]. These band widths are characteristic of the narrow band type that explains the transport of electronic charge carriers[14], as is also shown by the mobilities of 0.1 to 10 $\mathrm{cm}^2\,\mathrm{V}^{-1}\,\mathrm{s}^{-1}$ derived with the aid of approximations and by the free paths corresponding to several lattice constants (18—80 Å for metal-free phthalocyanine[13]). On the other hand, the band model is confirmed for dyes and aromatic hydrocarbons by experimental observations. These include

[*] Prof. Dr. H. Meier, Dr. W. Albrecht, and Dr. U. Tschirwitz
Staatliches Forschungsinstitut für Geochemie
86 Bamberg, Postfach 4041 (Germany)

[**] Presented in part as a lecture to the 4th International Color Symposium in Lindau on April 11, 1971.

the electron and defect electron mobilities of 0.1 to more than $100\,cm^2\,V^{-1}\,s^{-1}$ deduced from measurements of transient currents[15], Hall effect[16, 17], thermal EMF[18], and space charge limited currents[19]; a decrease in mobility with rising temperature, which is characteristic of energy band conduction[15, 20]; the observation of an anomalous Hall effect characteristic of narrow-band conductors[14, 21]; and the detection of a charge carrier transport influenced by multiple capture in traps and quantitatively described by the energy band theory (Shockley-Read model[22])[23].

3. *Recombination of the charge carriers:* Two processes lead to recombination. One is the direct recombination of the electrons and defect electrons, which occurs in particular at high concentrations of charge carriers, and the other is the recombination *via* defect centers (recombination centers), which capture electrons or defect electrons in the first step and allow them to recombine in the second step with the defect electrons of the valence band or with electrons of the conduction band. Since the parameters of the recombination centers depend considerably on structural effects and on the chemical purity, the recombination rate and hence the lifetime τ can vary within wide limits (up to a factor of 10^{10}) in different samples of a compound.

The essential point is that the conductivity of organic dyes is determined by the interplay of the elementary processes discussed here; cf.[14]. The generation of the charge carriers is determined in the unilluminated system by the thermal activation energy ΔE and in the illuminated system by the primary quantum yield η (=number of excited charge carriers per absorbed photon). The band width and the concentration and energy of traps or defect centers are important parameters to the transport of electrons and defect electrons, which is expressed by the mobility $\mu\,[cm^2\,V^{-1}\,s^{-1}]$. On the other hand, the recombination process fixes the lifetime and hence the steady-state concentration of the charge carriers.

These processes are generally contained in the equations for the dark conductivity

$$\sigma_D = e\,(n\mu_n + p\mu_p) \tag{3}$$

and for the photoconductivity

$$\sigma_{phot} = e\,(\Delta n\mu_n + \Delta p\mu_p) \tag{4}$$

n and p are the concentrations of electrons and of defect electrons respectively in the unilluminated solid, μ_n and μ_p are the mobilities of the electrons and defect electrons, and Δn and Δp are the steady-state electron and defect electron concentrations on illumination. Δn and Δp are given by

$$\Delta n = g\tau_n; \quad \Delta p = g\tau_p \tag{5}$$

where the generation rate g (=number of charge carriers formed per cm^3 and per second) takes into account the primary quantum yield, and the lifetimes of the electrons (τ_n) and defect electrons (τ_p) take into account the concentration of defect centers (N_r) and their capture cross section (s) as follows:

$$\tau = \frac{1}{N_r \times v \times s} \tag{6}$$

(thermal velocity $v \approx 10^7$ cm/s). It can be seen from eq. (6) that changes in the defect center concentrations, which are of the order of $N_r = 10^{12}$—$10^{18}\ cm^{-3}$, the capture cross sections ranging from $s = 10^{-12}$ to $10^{-20}\ cm^2$, can strongly influence the photoconductivity [eq. (4)] *via* eq. (5).

It should be pointed out that if the concentrations and mobilities of the electrons and defect electrons are equal, one speaks of intrinsic conduction. The predominant migration of electrons in the conduction band is referred to as n conduction, and the predominance of (positive) defect electrons (or holes) as p conduction (cf. Fig. 1).

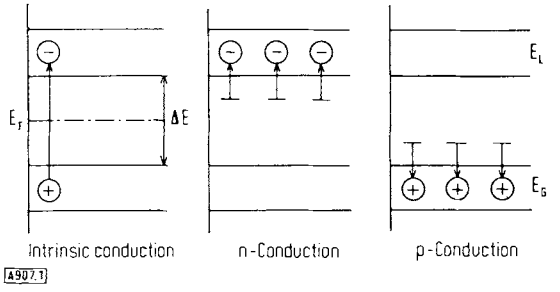

Fig. 1. Diagram of intrinsic conduction, n conduction, and p conduction. E_F = Fermi level; E_L = conduction band; E_G = valence band.

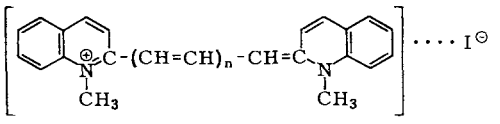
3. Possibility of Influencing the Conduction Behavior through Structure



In the examination of a possible industrial application, the most important factors are the attainable orders of magnitude of the dark conductivity and of the photoconductivity.

3.1. Dark Conductivity

Organic dyes generally have only a low dark conductivity, of the order of 10^{-10} to $10^{-14}\ [\Omega^{-1}\,cm^{-1}]$, since only a few charge carriers can be excited thermally because of the relatively broad forbidden zone between the ground state band and the conduction band. However, a high conductivity is desirable for some application problems, *e.g.* for the production of thermoelectric components or rectifiers. This can be achieved in dyes, as in other organic solids, by two methods:

1. By increasing the number of delocalizable π electrons. This is possible for the following reasons. On the one hand the activation energy of the dark conduction, as the intramolecular excitation energy of the π electrons, decreases with increasing number of delocalizable π electrons[2, 24] in agreement with the electron gas theory. On the other hand the conductivity within a given semiconductor type increases with decreasing activation

energy[25,26]. These relationships are illustrated in Table 1 for polymethine dyes *(1a)*—*(1c)* that absorb at long wavelengths.

(1a), n = 1; *(1b)*, n = 2; *(1c)*, n = 3

Table 1. Relation between number of π electrons N, thermal activation energy ΔE, and dark conductivity σ_D of polymethine dyes (after [27]).

Dye	Structure	N	λ_{max} [nm]	ΔE [eV]	σ_D [Ω^{-1} cm^{-1}]
Trimethinecyanine	*(1a)*	8	605	1.8	2×10^{-13}
Pentamethinecyanine	*(1b)*	10	710	1.4—1.87	10^{-11}—10^{-9}
Heptamethinecyanine	*(1c)*	12	817	0.7—0.98	10^{-9}—10^{-7}

More highly polymeric dyes, such as the polymeric phthalocyanines, also become more conducting as the degree of polymerization increases. Thus a Cu-phthalocyanine consisting of five units, in contrast with the monomer (ΔE = 1.7 eV[2]), has an activation energy of 0.12—0.26 eV[28], the dark conductivity increasing from 10^{-14} to 0.3 Ω^{-1} cm^{-1}.

2. Another possibility for increasing the conductivity is offered by doping with special doping agents such as *o*-chloranil, tetracyanoethylene, or tetracyanoquinodimethane[26,29,30]. The conductivity increases very rapidly with the concentration of the doping agent. For example, according to eq. (7)

$$\sigma_D = a \times C^{\beta} \tag{7}$$

(C = concentration of the doping agent; a = constant), a β value of 5.3 is found on doping of phthalocyanine with

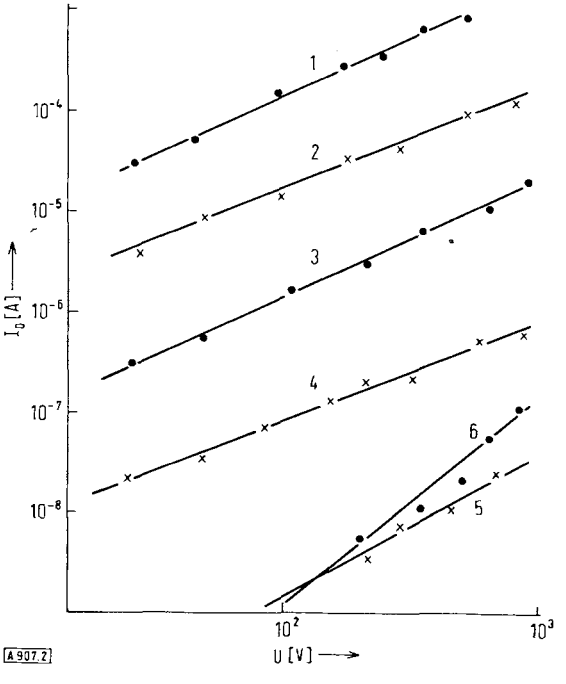


Fig. 2. Dependence of the dark conductivity on doping; plot: $\log I_D = n \log U$.
1, iodine; 2, tetracyanoethylene; 3, *o*-chloranil; 4, tetracyanoquinodimethane; 5, *p*-bromanil; 6, *p*-chloranil.

o-chloranil[26]. Figure 2 shows the increase in conductivity that can be achieved by variation of the doping agent.

By means of the above methods, the dark conductivity of p-conducting dyes can be displaced to the order of magnitude of the conductivity of inorganic materials.

3.2. Photoconductivity

Under the influence of traps and recombination centers the photoelectric current of organic dyes can become very small, particularly when unsuitable measuring arrangements are used (*e.g.* with an excessively large distance between the electrodes). This can be understood with the aid of eq. (8),

$$I_{phot} = \eta g' \times v \times e\tau\mu(E/L) \tag{8}$$

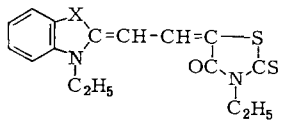
(g' = quanta absorbed per cm^3 per second), which expresses the relationship between the photoelectric current of a sample (v = volume of sample, L = distance between electrodes, E = field strength) and the lifetime τ and mobility μ of the charge carriers. A change in the defect concentration affecting the lifetime τ [according to eq. (6)] and the decrease in mobility μ caused by temporary capture in traps must, according to eq. (8), reduce the photoelectric current. I_{phot} can be increased by an increase in the field strength and a decrease in the distance between the electrodes. Above all, however, it is important that the photoconductivity can be reproducibly varied and the quantum yield G [which can be deduced from eq. (8)] increased through the elementary processes discussed in Section 2, *i.e.* by modification of η, μ, and τ.

$$G = \frac{\text{number of detectable charge carriers}}{\text{number of photons absorbed}} = \frac{I_{phot}/e}{g'v} \tag{9}$$

$$\text{or } G = \eta \times \tau \times \mu \times \frac{E}{L} = \eta \times \frac{\tau}{T} \tag{10}$$

$$\text{where } T = \frac{L}{\mu E} \tag{11}$$

(T = transit time of the charge carriers from one electrode to the other).



This increase in G can be achieved as follows:

1. By addition of doping agents. It can be seen from Table 2 that the photoconductivity of dyes can be increased by several orders of magnitude by doping.

The quantum yield G can even assume values >1 with suitable doping agents[31]. Figure 3 shows how strongly the photoconductivity can be influenced, as had already been described by *Hoegl*[29] in connection with an electrophotographic application of organic semiconductors, for phthalocyanine doped with *o*-chloranil.

For the doping mechanism cf.[15,26,30].

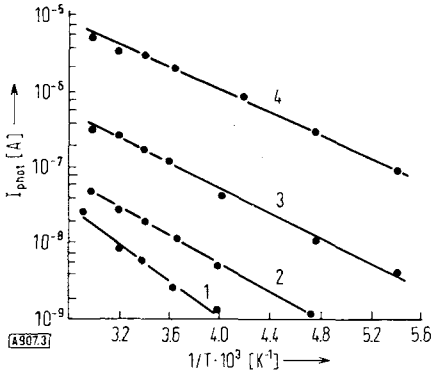
2. By specific synthesis. As in the case of the dark conductivity, relationships exist between the photoconductivity and the chemical structure that suggest the possibility of synthesizing good dye photoconductors. These structural relationships include (cf. review in[14]):

(2), X = S
(3), X = O

Table 2. Change in the photoconductivity of dyes on doping.

Dye	Doping agent	$\frac{I_{phot}\text{ (doped)}}{I_{phot}\text{ (undoped)}}$	Ref.
(2)	*o*-Chloranil	60	[31]
	Iodine	1.7×10^3	
(3)	*p*-Chloranil	6	[31]
	o-Chloranil	150	
Phthalocyanine	Tetracyanoethylene	400	[26, 32]
	o-Chloranil	10^4	[26, 32]

a) In the triphenylmethane dyes, a proportionality between the degree of methylation of the amino groups and the photoconductivity and a decrease in sensitivity on replacement of a methyl group by other substituents[1].



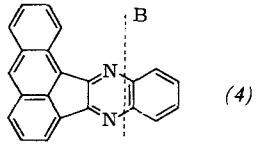


Fig. 3. Dependence of the photoconductivity on doping; plot: $\log I_{phot} = f(1/T)$.
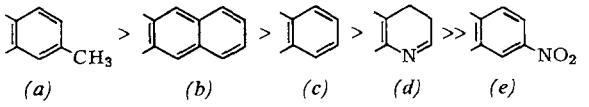
1, Phthalocyanine, undoped; 2, *o*-CA/Phth. $= 1.26\times10^{-2}$; 3, *o*-CA/Phth. $= 1.89\times10^{-2}$; 4, *o*-CA/Phth. $= 3.15\times10^{-2}$ (*o*-CA = *o*-chloranil).



b) In cyanines and merocyanines, an increase in the photoconductivity with the number of methine groups, *i.e.* with lengthening of the conjugated chain[24, 33].

c) On modification of part B of aceanthraquinoxaline *(4)*

(4)

a variation of the action of substituents on the photoconductivity in the order[34]:

(a) *(b)* *(c)* *(d)* *(e)*

It can be concluded from this gradation that the photoconductivity is closely connected with the number and the degree of delocalization of the π electrons. An increase in the number of aromatic rings or methyl substitution increases the photoelectric sensitivity, whereas electron-accepting substituents decrease it.

This structural dependence is further illustrated in Table 3 by some I_{phot}/I_D values.

Table 3. Dependence of the photoconductivity of pyrazines on structure (after [34]).

Part B of *(4)*	I_{phot}/I_{dark}
(a)	7×10^5
(b)	7.2×10^4
(c)	2.6×10^4
(e)	4×10^2

The influence of the structure is particularly clear from Figure 4, which shows the dependence of the photoelectric current on the voltage for the case of two pyrazines *(4)* that differ by a methyl group. This example shows clearly that systematic studies can be very important for the clarification of relationships between structure and photoconductivity in the search for dye photoconductors suitable for practical use.

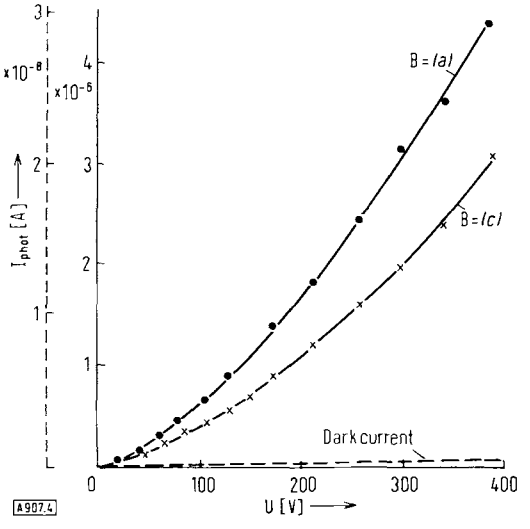


Fig. 4. Dependence of the photoconductivity on the structure for aceanthraquinoxaline *(4)*.

4. Possible Applications of the Dark Conductivity

What possible applications are presented by the conductivity of unilluminated organic dyes?

4.1. Rectifiers

Some dyes are p or n conductors in the unilluminated state, particularly in the doped form. This is confirmed by measurements of the Hall effect[35, 36] or of the thermal EMF[37]; in agreement with the rules for extrinsic semiconductors, moreover, the Fermi levels are close to the

energy bands, *e.g.* close to the ground state band for phthalocyanine doped with tetracyanoethylene, which is p conducting (cf. Fig. 5).

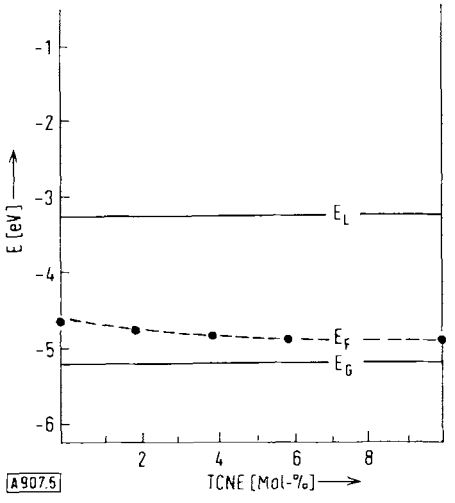

Fig. 5. Position of the Fermi level E_F in phthalocyanine doped with tetracyanoethylene (TCNE).

The use of organic dyes for the production of rectifiers therefore seems attractive. There are two possibilities:

a) The formation of pn rectifiers by contact between n- and p-conducting systems, an example being layers of p-conducting Cu-phthalocyanine and n-conducting ClIn-chlorophthalocyanine pressed together[38].

b) The formation of peak rectifiers, which are realized *e.g.* in arrangements consisting of Ag/phthalocyanine/Al point contact and prove, with a ratio of forward current to reverse current of 3000:1, to be suitable for the rectification of alternating currents up to 10^4 Hz[39]; cf. Figure 6.

4.2. Thermoelectric Components

The observation of a thermoelectromotive force that is high in comparison with that of inorganic semiconductors, and which can reach an order of magnitude of almost 3 mV/degree for organic semiconductors[40] also suggests a possible use. Under the influence of a temperature gradient, charge carriers can diffuse from the warm region to the cold; on the other hand, cooling at one electrode and warming at the other may be expected on passage of a current. The practical possibility of using such an arrangement as a thermoelectric generator or electrothermal cooling element is favored:

a) by a high differential thermoelectromotive force Q,

b) by a high conductivity σ,

c) by a low thermal conductivity κ.

Table 4 shows the quality factors or thermoelectric effectivities G_T

$$G_T = \frac{\sigma \times Q^2}{\kappa} \quad [\text{deg}^{-1}] \tag{12}$$

of some systems.

Table 4. Thermoelectric effectivities G_T of various systems.

System	σ [Ω^{-1} cm^{-1}]	Q [μV/deg]	κ [W/cm·deg]	G_T [deg^{-1}]	Ref.
Cooling system				6×10^{-3}	[41]
Bi_2Te_3	1000	200	1.6×10^{-2}	2×10^{-3}	[41]
Pyromellitonitrile		−150	5×10^{-3}	10^{-12}—10^{-8}	[42]
Phthalocyanine (doped)	10^{-7}	1000	5×10^{-3}	10^{-10}	[40]
Cu-polyphthalocyanine	0.3	3100	5×10^{-3}	5×10^{-4}	[43]

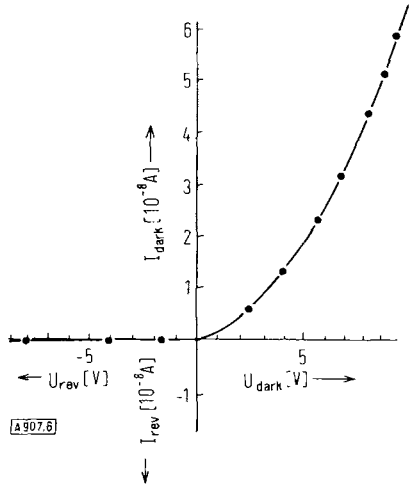

Fig. 6. Rectifier effect in the system Ag/phthalocyanine solid solution/Al point contact (after [39]).

Though pure phthalocyanines give a thermal EMF of up to 2 mV/degree, the quality factor G_T is very low because of the low conductivity. However, the conductivity can be

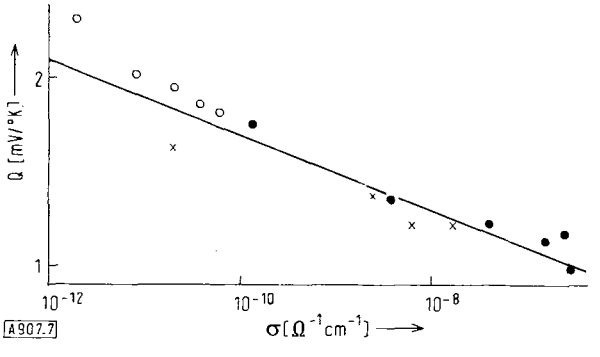

Fig. 7. Relation between thermoelectromotive force Q and conductivity σ; plot: $Q = C - (k/e \log e) \log \sigma$.
●: iodine/phthalocyanine; × = TCNE/phthalocyanine; ○: *o*-chloranil/poly-*N*-vinylcarbazole.

increased by polymerization or doping (cf. Section 3) without an excessive decrease in the thermoelectromotive force. This is demonstrated in Figure 7 for the case of doped systems.

It can be seen from Figure 7 that when the conductivity is increased to $10^{-7}\,\Omega^{-1}\,cm^{-1}$, thermoelectromotive forces of up to 1 mV/degree are still obtained. It will be necessary to look for systems having even higher conductivities, since a Peltier refrigerator, for example, becomes competitive in its power consumption only above a thermoelectric effectivity of $G_T = 6 \times 10^{-3}\,deg^{-1}$. In the example of poly-Cu-phthalocyanine[43], the quality factor should already have a remarkably favorable value of about $5 \times 10^{-4}\,deg^{-1}$.

4.3. Gas Detectors

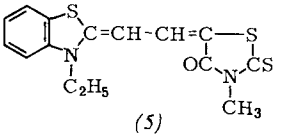
Changes in the dark conductivity (and in the photoconductivity) of organic layers are observed on absorption and desorption of gases[1, 44, 45]. Besides oxygen and hydrogen, other gases also have characteristic reversible effects on the conductivity. As can be seen from Table 5, the conductivity changes of certain systems, *e.g.* of β-carotene[46–48], range over six orders of magnitude, depending on the type of gas.

Table 5. Dependence of the dark conductivity of β-carotene on the nature of an absorbed gas (after [48]).

Gas	$\sigma_{gas}/\sigma_{vacuum}$
NO	2
Butanol	7
Methyl acetate	10
Oxygen	10^2
SO_2	10^3
Acetone	10^4
Ethanol	10^5
NH_3	10^5
Methanol	10^6
NO_2	10^6

As in the case of ZnO[49, 50], it seems feasible to utilize this effect for the detection of gases. According to *Rosenberg*[51], odorous substances have been qualitatively separated with an instrument containing β-carotene.

4.4. Electrets



Since the electronic charge carriers injected into organic solids from ohmic contacts[14] can build up a stable space charge by combination with deep traps, some dyes assume the properties of electrets in the dark on application of an electric field. According to *Euler et al.*[52], this effect can be used for the storage of electrical energy. Thus with nigrosine paste (using silver electrodes), a storage of 1.5 mAh/cm³ and, at a mean voltage of 0.9 V with a discharge time of about 11 min, a volumetric storage capacity of 1.3 mWh/cm³ were measured. The corresponding capacity of a lead starter accumulator is 11 mAh/cm³ or 15 mWh/cm³.

5. Possible Applications of the Photoconductivity

The photoelectric sensitivity also offers possibilities for the practical use of organic dyes.

5.1. Photoresistance Cells

It is possible to use organic dyes in photoresistance cells, which are designed as surface cells (electric field normal to the direction of the light) or sandwich cells (electric field parallel to the direction of the light)[1, 2]. This possibility is supported in particular by the fact that the characteristics (dependence on intensity, voltage, *etc.*) largely agree with those of the photoconductivity of inorganic photoconductors. Moreover, the high quantum yields found for some dyes ($G > 1$) and the photoelectric current/dark current ratio of up to 7×10^4 (cf. Section 3) also suggest that a systematic examination of this possibility would be worth-

(5)

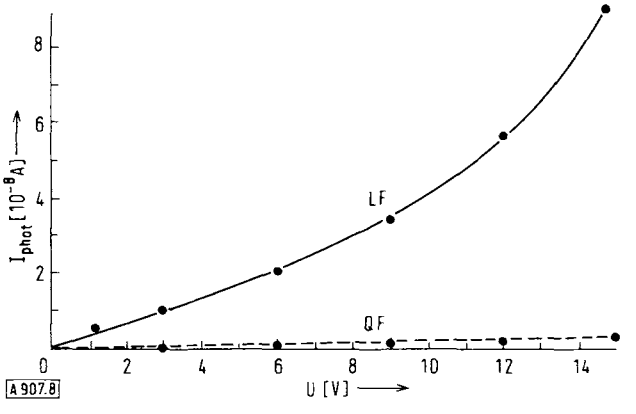


Fig. 8. Influence of the cell arrangement (LF and QF: longitudinal and transverse field cells respectively) on the magnitude of the photoelectric current of the merocyanine dye FX 79 *(5)*.

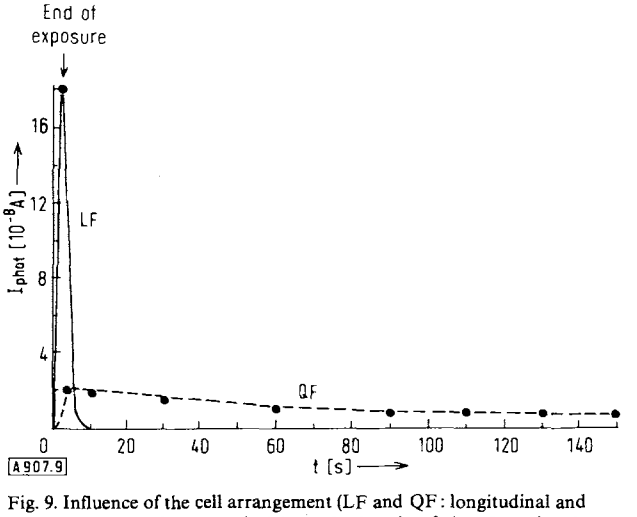

Fig. 9. Influence of the cell arrangement (LF and QF: longitudinal and transverse field cells respectively) on the inertia of the photoelectric current of malachite green; plot: $I_{phot} = f$ (exposure time).

while. With merocyanine dyes it was even possible to construct photoresistance cells that gave photoelectric currents of up to 10^{-4} A with an external voltage of 100 V and a light intensity of 1 mW/cm^2[1]. It is important for measuring cells of this type that the distance between the electrodes be as small as possible. On the one hand, a short distance between the electrodes can compensate for a low mobility and a short charge-carrier lifetime due to high defect concentrations in accordance with eq. (8) (cf. Fig. 8). On the other hand, the effect of the traps in delaying the start and the decay of the photoelectric current can be largely eliminated[14], as is shown by a comparison of the photoelectric currents measured for malachite green in the longitudinal and transverse field arrangements (Fig. 9).

5.2. Photoelectric Cells

The photoelectric sensitivity in conjunction with n and p conduction allows the production of photoelectric cells that give photoelectric currents and photoelectric voltages with no applied EMF[1, 53, 54]. The essential arrangement here is the combination of an n-conducting dye such as malachite green or Rhodamine B with a p-conducting dye, which may be *e.g.* a phthalocyanine or a merocyanine[55]. The directional and intensity dependence of the photoelectric current (cf. Fig. 10) show that the photovoltaic effect is due to a p-n junction between the compounds in contact.

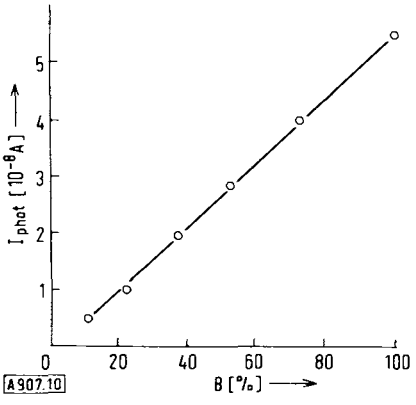

Fig. 10. I_{phot} = f(irradiation intensity B); system: malachite green (n) + merocyanine FX 79 (p) *(5)* (λ = 6200 Å, 100% corresponds to 3.7×10^{15} quanta/cm^{2}s; cell dimensions: distance between electrodes approx. 10^{-4} cm, illuminated area 1 cm^2).

An organic component can therefore also be replaced by an inorganic photoconductor of the corresponding conduction type (*e.g.* Rhodamine B (n) by CdS (n)[15, 24, 56, 57]). Table 6 shows the outputs obtained so far for some organic pn photoelectric cells.

Since the photoelectric currents and no-load voltages can be increased by doping, and there is evidence of the formation of pn junctions in homogeneous bodies[62], an improvement on the outputs N_{max} obtained so far seems possible. It should also be mentioned that dyes can be used in two-layer photocondensers (consisting *e.g.* of phthalocyanine and a ferroelectric ceramic), which are very sensitive to light and have a response time of 10^{-4} to 10^{-3} s[63].

5.3. Spectrally Sensitive Detectors

In addition to the photoelectric effects due to a pn boundary layer or to a difference in the mobilities of the charge carriers (Dember effect), the photovoltaic effects due to metal/semiconductor or metal/gas/semiconductor interfaces could possibly also be of practical importance. The photoelectric currents of these systems reach an order of magnitude of only about 10^{-10} A/cm^2, but they are characterized by the dependence of their direction on the wavelength. For example, the measurements in Figure 11 for Orthochrome T[64] and β-carotene[65] show that the photoelectric currents and voltages change their sign on transition from short to long wavelengths. The approximate wavelength of the light falling on the dye can therefore be read off simply from the direction of the photoelectric current.

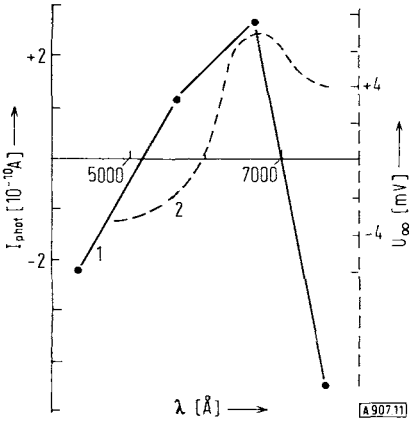

Fig. 11. Dependence of photoconductivity on wavelength.
1: Orthochrome T; I_{phot} = f(λ) [64].
2: β-Carotene; U_∞ = f(λ) [65].
Exposure conditions: curve 1: 10^3 μW/cm^2; curve 2: 3.9×10^{15} quanta/cm^{2}s.

It would be important to increase the sensitivity of the photoelectric effect.

Table 6. Outputs N_{max} of organic pn photoelectric cells.

System n	p	U_∞ [mV]	I_0 [A]	N_{max} [W]	Ref.
Malachite green	Phthalocyanine	100	10^{-8}	10^{-9}	
CdS	Phthalocyanine	300	10^{-8}	3×10^{-9}	
Triphenylmethane dyes	Phthaleins	100	0.5×10^{-9}	6×10^{-10}	[58]
Tetramethyl-*p*-phenylenediamine	Mg-Phthalocyanine	200		3×10^{-12}	[59, 60]
Ion exchange membrane with thionine/ascorbic acid		15	1.6×10^{-6}	2×10^{-8}	[61]

5.4. Use in Vidicon Television Pickup Tubes

Because of the photoelectric sensitivity and the frequently high I_{phot}/I_D ratio, organic dyes of various classes can be used as targets in vidicon television pickup tubes for image reproduction[66]. In principle, the dye is arranged in these camera tubes as in a longitudinal field cell (cf. Fig. 12). In the vidicon, however, one electrode is replaced by an electron beam, which brings the dye layer to the potential of the beam system cathode by scanning. Since the transparent electrode carrying the dye is slightly charged, light falling on the dye produces a photoelectric current, which can be measured in a galvanometer and recorded on the television screen.

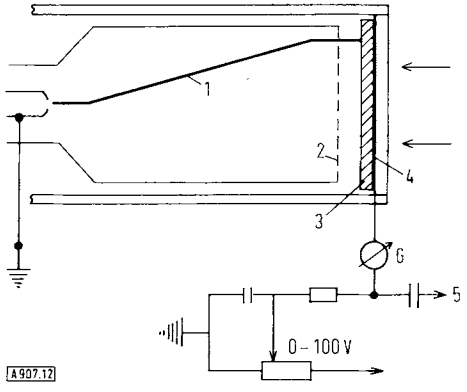

Fig. 12. Diagram of the vidicon measuring tube (for details see [66]). 1, Scanning beam (emerging from the beam system cathode with a potential $V=0$ volt); 2, gauze; 3, dye layer; 4, transparent electrode (potential up to about +30 volt); 5, amplifier; G, galvanometer.

Some characteristics of the organic vidicon are:

a) A sensitivity of about 10—100 μA/lm (or 100 nA/lx) which extends to the order of magnitude of inorganic vidicons.

b) A variation of the photoelectric current with voltage, irradiation intensity, and beam current corresponding to that of inorganic targets. Figure 13 shows this agreement for the intensity dependence of the vidicon photoelectric currents of phthalocyanine and of Sb_2S_3.

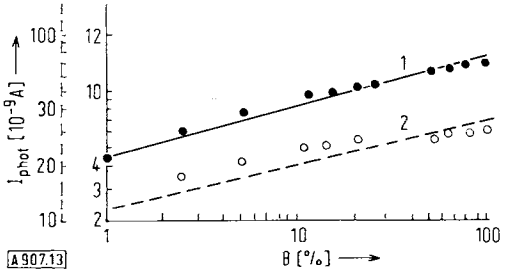

Fig. 13. Photoelectric currents of Sb_2S_3 and phthalocyanine in the vidicon arrangement; plot: $\log I_{phot} = f(\log \text{irradiation intensity})$. 1, Sb_2S_3; 2, phthalocyanine ($\lambda = 5500$ Å).

c) The fundamental possibility of reproducing several colors with a single target containing photoconductor points that absorb differently.

d) Appreciable storage in the case of layers that are rich in traps. It should be the aim of further systematic studies to test as many dyes as possible for use in television image reproduction. The results are of interest *e.g.* for color television, for medicinally important IR vidicons[1, 67], and for the production of storage vidicons[*].

5.5. Use in Reprography

There is a real chance for the use of organic photoconductors on an industrial scale in the near future in the reproduction methods based on photoelectric and electrostatic processes (cf. review in[14]).

Even in the general electrophotographic processes (cf.[1, 14, 68–70]) organic systems offer advantages over inorganic photoconductors. For example, the sensitivity of polyvinylanthracene is higher than that of sensitized ZnO materials by a factor of 1.7[71]. Compounds having a dye structure are also important. Thus the utilizability of photoconducting polymers with a phthalocyanine structure that are easily applied to a substrate has been established[72], and the feasibility of using photoconducting leuco bases of triarylmethane dyes as components of transparent electrophotographic recording materials, which allow *e.g.* the electrophotographic production of microfilms, has been described[73].

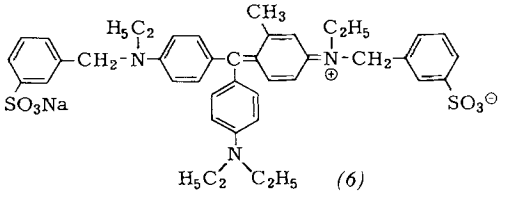
Above all, the development of new reproduction processes based on the electrophotographic principle is made possible by organic photoconductor systems (cf.[14]). Dyes play an important role here, not only as spectral sensitizers of the organic photoconductor[29, 74, 75]. Photoelectric effects of the dye can also be utilized directly. Examples that could be mentioned include:

a) the use of the memory effect observed *e.g.* for dyes after exposure to light (persistent photoconductivity[76, 77]), by means of which several copies of equal quality can be obtained from one original after exposure to light without a corona discharge[78];

b) the use of the photoelectric sensitivity of dyes of the triphenodioxazine class[79], of metal-free phthalocyanine (α form), azo pigments, *etc.*[80] in a polychromatic photoelectrophoretic image reproduction process.

6. Connections with Industrial Processes

6.1. Questions of Lightfastness



In the discussion of the application of photoconduction measurements to the lightfastness testing of dyes (cf.[81]), it must be noted that the photoconductivity is not due to intermolecular or intramolecular bleaching processes. Only the start of the photochemical decomposition of the dye is recorded, since it is associated with a decrease in conductivity. For example, it was found for the triphenylmethane dyes used as standards in the ISO lightfastness

[*] We are grateful to AEG-Telefunken, Ulm, and particularly to Dr. *A. Bogenschütz*, for valuable technical support.

test method[81] that the conductivity decreases with the photochemically induced transition of the dyes into the leuco form[82]. It is not yet known to what extent negative photoelectric effects[83] of colored fibers can be correlated with their lightfastness[84, 85]. However, the relation found for the ISO standards between lightfastness and the thermal activation energy of the photoconductivity (ΔE_{phot}) determined from eq. (13)

$$\sigma_{phot} = \sigma'_0 \exp(-\Delta E_{phot}/kT) \tag{13}$$

could be of importance for lightfastness measurements[82]. According to this relation, ΔE_{phot} increases with the lightfastness for the standard dyes CI Acid Blue 104, 109, and 83 (see Table 7, and, for interpretation[81]).

(6)

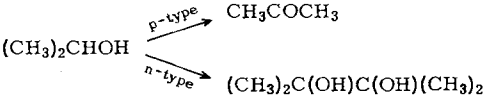
Table 7. Relation between ΔE_{phot} and time t_B until the start of bleaching (after [82]).

Dye	t_B [min]	ΔE_{phot} [eV]
CI Acid Blue 104 *(6)*	9	0.39
CI Acid Blue 109	25	0.48
CI Acid Blue 83	60	0.58

However, only structurally similar dyes can be used for such comparisons.

6.2. Spectral Sensitization

In the case of an electron transfer mechanism for the spectral sensitization of the photographic process and the photoconduction of inorganic semiconductors[1, 24, 86–88], a relationship can obviously be assumed between the electric behavior of a dye and its sensitizing effect. According to a modified mechanism[24, 27, 89], the spectral sensitization is regarded as a type of pn or nn' photoelectric effect, in which two effects act together. One of these effects is the build-up of a space charge in the unilluminated state in the interfacial zone between the dye and the semiconductor as a result of an electron transfer leading to the balancing out of different chemical potentials of the electrons. The second is a separation under the action of the space charge field of the electrons and defect electrons formed in the dye on exposure to light.



Photovoltaic effects in model arrangements of sensitized systems are in agreement with this mechanism[24]. However, it is not yet certain how far these findings can be utilized for the production of particularly effective sensitizing dyes.

6.3. Catalytic Effect

It can be concluded from various experiments that a correlation exists between electrical and catalytic data for organic solids if the catalytically active substances to be compared are very similar in their specific chemical and structural properties[14, 90, 91]. Thus in the oxidation of acetaldehyde ethylene acetal to ethylene glycol monoacetate with Fe-M polyphthalocyanines (M: V, Cr, Cu, *etc.*) as catalysts, a linear relation exists between catalytic activity K_a and the thermal activation energy of the dark conductivity ΔE_{therm}[92]:

$$K_a \sim \frac{1}{\Delta E_{therm}} \tag{14}$$

Mention should also be made of the increase in the catalytic activity of Cu-phthalocyanine samples for the decomposition of H_2O_2 with increasing conductivity and decreasing activation energy[93], and of the observed increase in the catalytic activity, *e.g.* in the oxidation of cumene in the presence of Cu-phthalocyanine, on transition from the monomer to the polymer[94]. The catalytic activity is also related to the type of conduction. For example, the decomposition of HCOOH is catalyzed more strongly by n-conducting poly-Cu-phthalocyanine than by p-conducting Cu-phthalocyanine[95]. *Inoue et al.*[96] found, moreover, that dye photoconductors of the p type (eosin, fluorescein, acridine, *etc.*) catalyze the photooxidation of isopropyl alcohol with O_2 to acetone, while semiconductors of the n type (Crystal Violet, Rhodamine, *etc.*) are either inactive or cause pinacol formation.

This reaction shows an important characteristic of organic catalysts, *i.e.* their high selectivity.

The relations between structure, conductivity, and catalytic activity are of interest particularly in connection with the use of organic dyes for the reduction of oxygen in fuel cells. Since *Jasinski*'s discovery[97, 98] that Co-phthalocyanine can be used for the reduction of oxygen in fuel cell cathodes instead of the usual platinum, which is uneconomical because of its high price, several investigations have been concerned with this question[99, 100–103]. *Jahnke*[103] was able to show that the catalytic reduction of oxygen in H_2SO_4 depends on the nature of the central atom and particularly on the degree of polymerization. This last finding (cf. also[99]) probably suggests a relationship similar to that between the conductivity and the catalytic activity of the phthalocyanines. It should be stressed that poly-Fe-phthalocyanines exhibit a higher activity than platinum metal alloys in sulfuric acid-methanol cells[103]. The stability of the phthalocyanine catalysts is probably not yet ideal, but the results obtained so far should allow

an optimistic prognosis regarding the possibility of using fuel cells with high-conductivity dye catalysts, which could be used *e. g.* in heart pacemakers[104].

We are grateful to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for their support of this work.

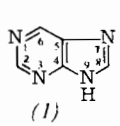
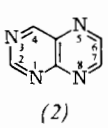
Biochemistry of the Pteridines

By Heinz Rembold and William L. Gyure[*]



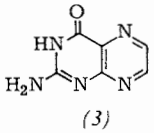
Biochemical information about the ubiquitous pteridines has become generally available only within the last fifteen years. This delay can be traced to the chemical lability of these compounds and their small concentrations in organisms. New methods of isolation and isotopic techniques have provided data on the biosynthesis, anabolism, and catabolism of this class of compounds. Hydrogenated pteridines are recognized today as cofactors for various mixed function oxygenases and are involved in cellular electron transport. Further unknown catalytic functions for pteridines in cellular metabolism are indicated by their physiological activity, negative redox potentials, and histoautoradiographic data.

1. Introduction

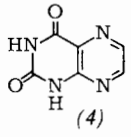


At the end of the last century *Hopkins* reported on a crystalline pigment which he had extracted from the wings of a butterfly[1]. This finding formed the basis for later investigations by *Wieland* and his co-workers who succeeded in isolating first a yellow[2] and then a white pigment[3]. After much experimental difficulty *Purrmann* was finally able in 1940 to determine the structure of these natural pigments, which were named xanthopterin *(35)* and leucopterin *(37)*. At the same time he also elucidated the structure of a related pigment called isoxanthopterin *(38)*[4].

For the bicyclic ring system of these new butterfly pigments *Wieland* chose the name "pteridine" while the designation "pterin" was originally used as a general term for all insect pigments. Today pyrazino[2,3-*d*]pyrimidine is called pteridine *(2)*. The naturally occurring pteridines are commonly called pterins when they are derivatives of the parent compound 2-amino-4-oxodihydropteridine *(3)* and lumazines when they are derivatives of 2,4-dioxotetrahydropteridine *(4)*.



As a simple approach pteridines *(2)* may be considered related to the purines *(1)* to which they bear a structural resemblance. Both classes of compounds have many properties in common such as low solubility at neutral pH values, well defined ultraviolet absorption spectra, ability to form chelates with metal ions, and the property of forming precipitates with mercury and silver salts. In addition to the purine-like properties, fully oxidized, or



(1)

(2)

(3)

(4)

aromatic, pteridines exhibit strong blue to red fluorescence when irradiated with ultraviolet light. This fact aids their purification from sources containing only trace amounts of these compounds.

Reviews of the chemistry of the pteridines are available[5, 6]. One property of pteridines is especially important from a biochemical standpoint and that is their ability to form dihydro and tetrahydro derivatives. These reduced forms are very reactive and not only can they serve as specific reductants but they can also participate in electron transport reactions. It is precisely because these reduced forms are so reactive that working with them is difficult. The aromatic structures are already photolabile while the reduced forms are even more photolabile and subject to oxidative degradations. As an example of this lability,

reduced biopterin and neopterin can respectively lose their dihydroxypropyl and trihydroxypropyl side chains simply upon heating in neutral aqueous solution in the presence of air[7].

2. Isolation

The naturally occurring pteridines are found throughout the plant and animal kingdoms. Several reviews discuss the pteridines found especially in insects[8], in microbes[9], and in amphibia and fish[10]. Normally pteridines are found in only trace amounts in biological material. Biopterin *(6b)* occurs, for example, in concentrations of less than 10 mg/kg and other pteridines are often present in even lower amounts. In Table 1 the results of an analysis of honeybees clearly illustrates this general fact.

Pierid butterflies, utilized in *Wieland's* original studies, contain relatively high concentrations of pterins. Along with other compounds, xanthopterin *(35)*, isoxanthopterin *(38)*, and leucopterin *(37)* serve these insects as pigments. However, disregarding a few exceptions among fish and amphibians, pteridines generally occur in very small concentrations. Examination of the values in Table 1 shows that many pteridines must be enriched 10^9 fold in order to reach an analytically pure state.

A variety of methods are available for the isolation of these compounds from natural sources; the choice of which to use depends upon the solubility and lability of the pteridine in question (Table 2). Relatively soluble pteridines such as the 6-polyhydroxyalkyl derivatives [biopterin *(6b)*, neopterin *(6a)*, sepiapterin *(7b)*, *etc.*] can be isolated from trichloroacetic acid extracts. These extracts are free of most protein and peptide materials and labile hydrogenated pteridines are stabilized under the acidic conditions. Acid extraction however cannot be used in a quantitative sense for such acid-insoluble pteridines and lumazines as isoxanthopterin, leucopterin, and 7-hydroxylumazine. Often pteridines occur in association with other molecules such as protein, peptides, and nucleic acids[13, 14]. In order to isolate these complexed pteridines and to solubilize the acid-insoluble pteridines, basic solvents are useful and when used in conjunction with an alkaline precipitation

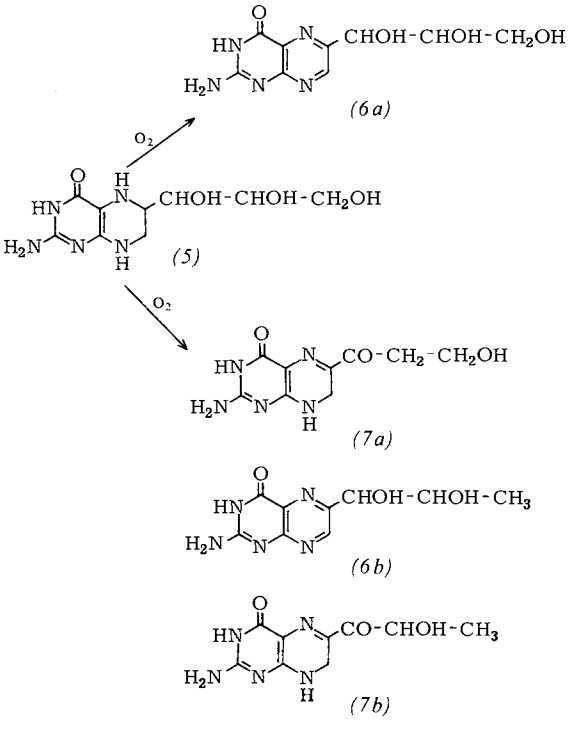

Table 1. The pteridines listed as occurring in the honeybee [11, 12], *Apis mellifica* L., are given in micrograms per animal. The average weight of a bee is 150–200 mg.

Pteridine	Pupa	Flight bee
Biopterin *(6b)*	0.2	0.2
Neopterin *(6a)*	0.015	0.005
7-Hydroxylumazine *(30)*	0.25	0.4
Isoxanthopterin *(38)*	0.009	0.23
Pterin *(3)*	0.02	0
6-Pterincarboxylic acid	0.013	0.01
6-Isoxanthopterincarboxylic acid	0	0.004

Table 2. Procedures for isolating and identifying pteridines from biological material.

1. Extraction

Type of pteridine	Extraction medium	Protein and peptide removal
acid-soluble pteridines	water or 5% trichloroacetic acid	trichloroacetic acid [17]
alkaline-soluble pteridines	2 N NH_4OH	$Al_2(SO_4)_3/Ba(OH)_2$ [15]
labile reduced pteridines	water or 5% trichloroacetic acid	trichloroacetic acid [18] or sephadex [19]
	2 N NH_4OH with mercaptoethanol	$Al_2(SO_4)_3/Ba(OH)_2$ [15]

2. Purification

Column chromatography (Dowex 1 and 50 [17], phosphocellulose [17], ecteola cellulose [17], cellulose [20], Florisil [9]); paper chromatography [21]; thin layer chromatography [22]; paper electrophoresis [23]; electrophoresis on cellulose acetate [24]; isoelectric focusing [25]

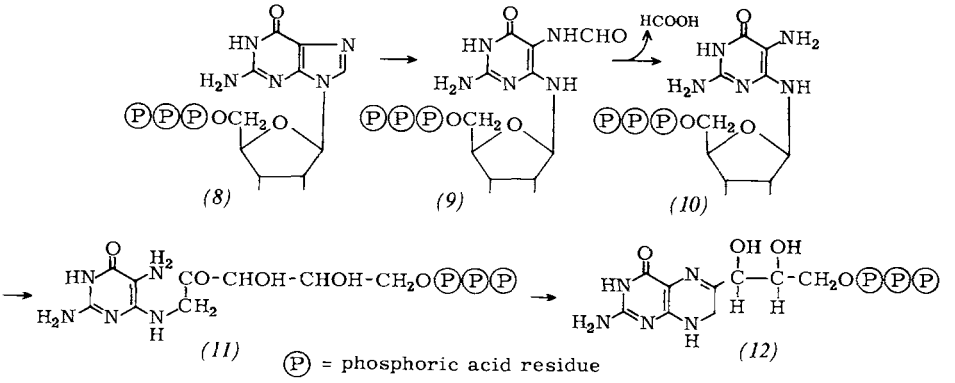
3. Identification

UV absorption spectra; fluorescence emission spectra; chromatographic behavior; *Crithidia* growth tests [26]; color tests [15, 27]; enzyme tests [28]; gas chromatography [29, 30]

4. Quantitative determinations

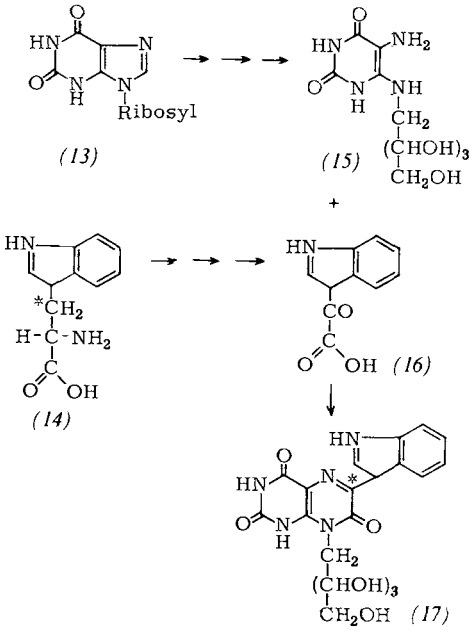
UV extinction coefficient; measurement of fluorescence on paper [31] or in solution [32]; *Crithidia* growth [26]; isotopic dilution [18]; color tests [15, 27]; enzyme tests [28]; gas chromatography [29, 30]

method give quantitative results[15]. Alkaline extraction methods necessitate precautions, such as the addition of mercaptoethanol to the solvent, to prevent the degradation of the labile reduced pteridines.



Depending on the conditions used the structure of the reduced pteridines can be changed during isolation. As an example, tetrahydroneopterin *(5)* can be adsorbed on a column of phosphocellulose and eluted with dilute formic acid in the presence of mercaptoethanol. After evaporation, renewed chromatography of the eluate on the same column yields two bands upon elution with water. Structural analysis[16] showed that tetrahydroneopterin is oxidized in the process producing neopterin *(6a)* and a yellow pterin 6-(3-hydroxypropionyl)-7,8-dihydropterin *(7a)*. When the original tetrahydroneopterin is chromatographed in the absence of mercaptoethanol, the dihydropterin is formed on the column.

Once the pteridines have been extracted, they can be purified, identified, and assayed by the methods in Table 2. Nuclear magnetic resonance, mass spectroscopy, and elemental analysis are additional methods which aid in identification; however they are of limited value due to the low solubility and volatility of most pteridines. After preparation of trimethylsilyl derivatives even very polar pteridines are volatile enough to be separated by gas chromatography and identified by mass spectral fragmentation[29, 30].



3. Metabolism

3.1. Biosynthesis of the Pteridine Ring

Because of structural similarities purines and pyrimidines were early considered as potential starting materials for pteridine biosynthesis. Numerous studies indicated that purines are utilized for pteridine ring formation in bacteria, fungi, amphibia, and insects[33]. Direct proof of this conversion has been offered by *Brown et al.*[34] who have isolated the enzyme GTP-cyclohydrolase from *Escherichia coli*. This enzyme catalyzes the conversion of guanosine-5'-triphosphate *(8)* into D-*erythro*-7,8-dihydroneopterin-3'-triphosphate *(12)*. *Shiota* has isolated a similar enzyme from *Lactobacillus plantarum*.

Many reports tend to support this set of reactions and these have been discussed by *Shiota*[33] and by *Brown*[34] in their reviews on the biosynthesis of folic acid. Recent data however cautions against accepting the Brown-Shiota pathway as the sole mode of pteridine synthesis. A cyclic dihydroneopterin phosphate has been found by *Cone* and *Guroff*[102] to be the end product of GTP conversion in *Comamonas*. In addition *Forrest*[9] rightly discusses the possibility of alternate pathways for pteridine biosynthesis, such as from a pyrazine compound. Another possibility has been put forward by *Takeda*[35] in his studies on the formation of indolyl- and hydroxyphenylpteridines by *Achromobacter petrophilum*. Although GTP *(8)* and xanthine derivatives *(13)* were utilized by the microbe for the formation of the pteridines, radioactivity was incorporated into the ring system when [3-^{14}C]tryptophan was added to the culture medium. *Takeda* discusses the following biosynthetic route to *(17)*[*]:

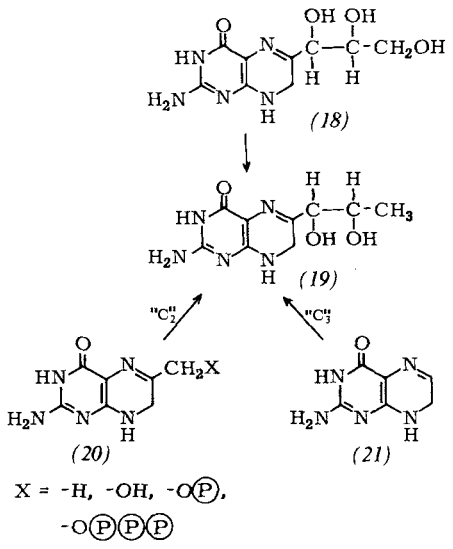
Data on pterin biosynthesis in the rat is also difficult to resolve utilizing the Brown-Shiota scheme. In studies on possible precursors in the rat, *Remboldet al.* have established that biopterin excretion per day is constant at about 30 µg even when several generations are fed on a biopterin free diet[36]. This indicates biopterin formation in a mammal which is incapable of forming folic acid. When purine precursors, such as formate and glycine, or possible pteridine

[*] *Note added in proof* (October 12, 1972): 6-(3-Indolyl)-7-oxo-8-(1-D-ribityl)lumazine *(17)* has also been isolated from a culture of *Pseudomonas ovalis*[113]. This fact shows that *Takeda*'s scheme of pteridine biosynthesis may also occur in *Pseudomonas*.

precursors, such as adenine, guanine, guanosine, guanylic acid, or GTP, were injected or fed to rats only trace amounts were converted to biopterin. The formation of biopterin was somewhat increased when nucleic acid synthesis was inhibited by injection of actinomycin D and the accompanying flow of purine precursors into nucleic acid biosynthesis was decreased[37]. The injection of radioactive neopterin *(6a)* or radioactive tetrahydroneopterin *(5)* did not result in incorporation of label into the biopterin excreted over the next four days[38]. *Fukushima*[39] described a very low incorporation of radioactivity into biopterin by tadpoles of *Rana catesbeiana* after injection of dihydroneopterin or its triphosphate derivative. These results in the rat and tadpole make it difficult to postulate the involvement of neopterin or one of its derivatives as an intermediate in biopterin synthesis.

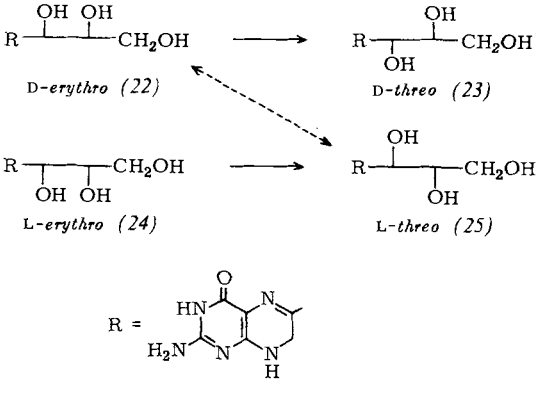
3.2. Anabolism

Once the pteridine ring has been formed by an organism a considerable number of subsequent reactions must occur in order to account for the great diversity of naturally occurring pteridines. The first results in the clarification of the metabolic steps are now beginning to appear. Table 3 is a summary of the investigated enzymes and their reactions.



In spite of the great effort expended the direct relationship between neopterin *(6a)* and the other pteridines found in nature is not yet clear, the intermediates in folic acid biosynthesis being excluded. This is remarkable since neopterin is the parent and first pteridine formed according to the Brown-Shiota scheme. The unknown relation between neopterin and biopterin *(6b)* has already been mentioned. In this connection recent work by *Dayman* and *Guroff*[111] has shown the presence of a neopterin cyclic phosphate phosphodiesterase in *E. coli*, in *Comamonas*, and in the rat. This enzyme catalyzes the hydrolysis of neopterin cyclic phosphate to neopterin phosphate. *Guroff*[102] suggests that in this hydrolysis the neopterin side chain is inverted from the D-*erythro* to the L-*threo* configuration. Such a coupled reaction, *i.e.* hydrolysis and inversion, can explain why neither D-*erythro*-neopterin nor its non-cyclic phosphate derivative can be converted to biopterin.

Even more fundamental and still debated is the origin of the carbon chain on C-6 of the pteridine ring. Three hypotheses have been advanced concerning the chain[33]. The first one states that it is formed by a simple rearrangement of the intact neopterin side chain in which the hydroxyl groups are enzymatically epimerized. This hypothesis is the basis for *Guroff*'s suggestion as described above. This statement assumes that 7,8-dihydroneopterin *(18)*, or one of its phosphate derivatives, is the parent compound for the whole series of 6-(polyhydroxyalkyl)pteridines, including biopterin. The second hypothesis states that 6-substituted pteridines arise by an addition of carbon units to a 6-methylpteridine *(20)*. This statement assumes nothing about the origin of the 6-methylpteridine nor of the carbon units attached to it. According to the third hypothesis carbon units are attached directly to the pteridine ring *(21)*—in the case of biopterin a three-carbon unit is attached. These three suggestions are illustrated for the formation of 7,8-dihydrobiopterin *(19)*.

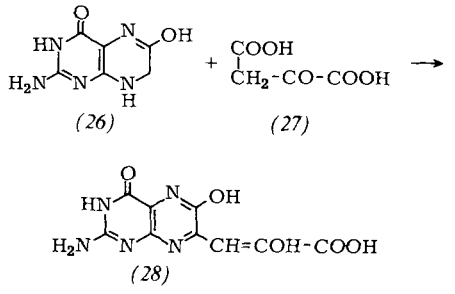


From the available data there is much that could be said for and against each hypothesis and it may well be that each plays its own role depending on the particular pteridine.

Table 3. Summary of enzymes involved in pteridine metabolism.

Type of reaction	Enzyme (source)	Substrate	Product
Biosynthesis	GTP cyclohydrolase [41, 102] *(E. coli, Comamonas sp.)*	GTP	dihydroneopterin triphosphate and cyclic phosphate
	dihydroneopterin-triphosphate synthetase [48] *(L. plantarum)*	GTP	dihydroneopterin triphosphate
Anabolism folic acid formation	dihydroneopterin aldolase [49] *(E. coli)*	dihydroneopterin	6-hydroxymethyl-dihydropterin
	hydroxymethyldihydropteridine pyrophosphorylase [50, 51] *(E. coli, L. plantarum)*	6-hydroxymethyl-dihydropterin	6-hydroxymethyl-dihydropterin pyrophosphate
	dihydropteroate synthetase [52] (pea seedlings)	6-hydroxymethyldi-hydropterin	6-hydroxymethyl-dihydropterin pyrophosphate
	dihydropteroate synthetase *(E. coli* [50], *L. plantarum* [51], pea seedlings [52])	6-hydroxymethyl-dihydropterin pyrophosphate	dihydropteroate
erythropterin synthesis	erythropterin synthetase [32] *(Oncopeltus fasciatus)*	dihydroxanthopterin	erythropterin
biopterin and sepiapterin synthesis	sepiapterin reductase [54, 98] (rat liver, horse liver)	sepiapterin	dihydrobiopterin
	dihydrofolate reductase [108]	sepiapterin, dihydrobiopterin	reduced sepiapterin, tetrahydrobiopterin
	dihydropterin reductase [73, 114] (sheep liver, rat liver)	quinonoid dihydrobiopterin	tetrahydrobiopterin
neopterin synthesis	neopterin cyclic phosphate phosphodiesterase [111] *(Comamonas)*	neopterin cyclic phosphate	neopterin phosphate

According to the Brown-Shiota scheme D-*erythro*-neopterin is the parent compound formed in *E. coli*[40, 41]. L-*threo*-Neopterin is however found in various organisms and indeed it is the chief pteridine found in *E. coli* itself[42]. *Brown*[43] has reported on neopterin epimerase activity found in this bacterium. His preliminary results, which ought to be further tested, indicate an alteration of the optical configuration of the intact dihydroneopterin side chain.



This scheme is based on the assumption of the validity of the first hypothesis on the origin of the side chain.

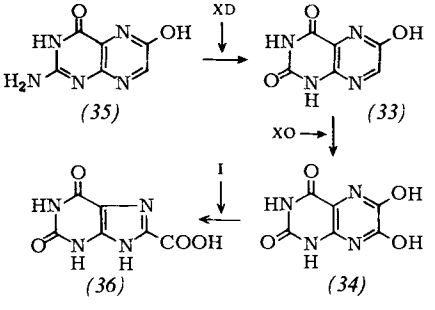
The characteristics of the four optical isomers of neopterin[44] and of biopterin[45] are listed in Table 4. Conveniently the *erythro* and *threo* isomers can be chromatographically separated from one another, while further determination of an unknown isomer by the *Crithidia* test is only applicable to the *erythro* series. In the case of the *threo* series optical rotations must be measured, a necessity not always met for the natural *threo* isomers listed in the literature. Because of the similarities of the isomers, all four optical forms should be tested for their cofactor activity in enzymatic reactions.

Table 4. Characteristics of the four optical isomers of neopterin [44] and biopterin [45]. R_f values measured in isopropanol/5% boric acid solution (4:1).

	R_f values	*Crithidia* half optimal growth concentration (ng/ml medium)	$[\alpha]_D^{25}$ [°]
Neopterin *(6a)*			
D-*erythro*	0.21	10	+45±3
L-*erythro*	0.21	0.03	−44±3
D-*threo*	0.12	10	−92±3
L-*threo*	0.12	2	+97±3
Biopterin *(6b)*			
D-*erythro*	0.30	0.7	+61
L-*erythro*	0.30	0.006	−62
D-*threo*	0.26	0.5	−94
L-*threo*	0.26	0.2	+95

The direct addition of a complete carbon chain to position 7 of the pteridine ring is illustrated by the synthesis of erythropterin. In the butterflies *Colias eurytheme* and *Colias croceus* xanthopterin *(35)* and, even better, dihydroxanthopterin *(26)* are directly incorporated into erythropterin *(28)*[46, 47]. With xanthopterin as a cosubstrate, *Forrest*[32] found that in the eggs of *Oncopeltus fasciatus* oxaloacetic acid *(27)* is utilized for the formation of the erythropterin side chain.

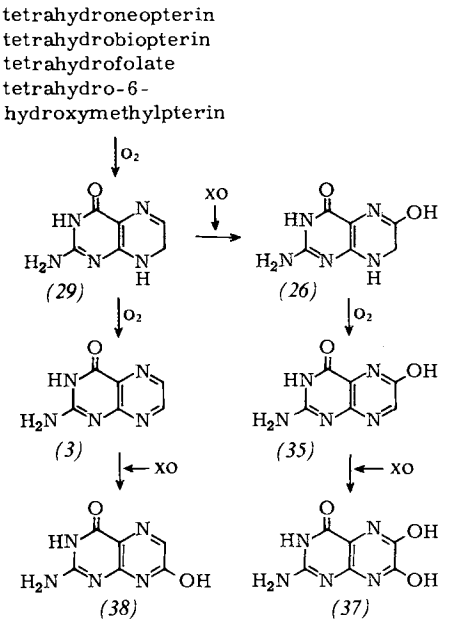
3.3. Catabolism



The degradation of pteridines is now better understood than any other part of their biochemistry. In a series of studies *Rembold et al.* have shown that tetrahydrobiopterin

(42) and tetrahydroneopterin *(22)* are degraded similarly *in vitro* by rat liver homogenates and *in vivo* after intraperitoneal injection into the rat[7, 55, 56]. The main pathway leading to the formation of simple lumazines is shown in the formula scheme.

After the polyhydroxyalkyl chain is oxidatively cleaved in a non-enzymatic reaction to form an aldehyde, the remaining 7,8-dihydropterin *(29)* is used as a substrate in either of two enzyme-catalyzed reactions. The pterin can be oxidized to dihydroxanthopterin *(26)* by xanthine oxidase[57] or it can serve as a substrate for the highly specific enzyme pterin deaminase. In the last case, which is illustrated in the above scheme, either 7,8-dihydrolumazine *(31)* or lumazine *(4)* is formed, depending on the state of oxidation of the substrate of the deaminase. The products in both cases serve as further substrates for xanthine oxidase and the end result is the formation of either 6,7-dihydroxylumazine *(34)* or 7-hydroxylumazine *(30)*.



Levy and *McNutt*[58, 59] examined the degradation of pteridines by the organism *Alcaligenes faecalis* and found that starting with the simple pteridines isoxanthopterin *(38)* and xanthopterin *(35)* a series of deaminations and oxidations yielded the same lumazine derivatives as noted in the studies conducted with rats. However, *Alcaligenes* was able to proceed one step further and convert the 6,7-dihydroxylumazine *(34)* into its isomer xanthine-8-carboxylic acid *(36)*, *i.e.* the pteridine ring was converted into a purine ring.

XD = xanthopterin deaminase
XO = xanthine oxidase
I = isomerase

Ring-hydroxylated pterins are formed in a manner completely analogous to the reactions in the lumazine series[56]. Depending upon the presence or absence of the different pteridine deaminases, the catabolism of pteridines results in either simple pterins or simple lumazines. Pterin *(3)* and lumazine *(4)* undergo the same reaction in the presence of xanthine oxidase: both pteridines are hydroxylated at C-7[60, 61]. The 7,8-dihydro derivatives however are attacked at C-6[57].

Forrest et al.[62] found that pterin *(3)* occurs in the ry^2 mutant of *Drosophila melanogaster* which lacks xanthine oxidase while the wild strain has isoxanthopterin *(38)* in its place. After injection of radioactive pterin into pupae of the butterfly *Colias croceus*, *Descimon*[64] showed that radioactive isoxanthopterin was accumulated while injection of tetrahydropterin led to accumulation of labeled isoxanthopterin *(38)*, xanthopterin *(35)*, and leucopterin *(37)*. *Harmsen*[65] raised pupae of the butterfly *Mylothris chloris* at different oxygen partial pressures and showed that reducing conditions favored the formation of xanthopterin *(35)* and other 6-substituted pterins in the adult while high oxygen partial pressure favored the formation of pterins oxidized at position 7. *Dustmann*[63] found 6-hydroxylumazine *(33)* and 6,7-dihydroxylumazine *(34)* in drone honeybees while *Rembold* and *Buschmann*[12]

XO = xanthine oxidase

found that worker bees accumulated 7-hydroxylumazine (see Table 1). Drone honeybees apparently utilize 7,8-dihydrolumazine while worker bees use lumazine to form their end products.

The question arises whether the simple oxidized pterins and lumazines are in general further degraded by organisms or represent true terminal catabolites. This problem was studied by *Gyure* and *Corrigan*[15] in several species of insects. In the case of the silkworm *Bombyx mori*, homogenates deaminated isoxanthopterin *(38)* by a highly specific deaminase. The product, 7-hydroxylumazine *(30)*, was not further metabolized. When synthetic 6-hydroxylumazine was added to the homogenates, 6,7-dihydroxylumazine *(34)* was formed by the catalytic action of xanthine oxidase. The 6,7-dihydroxylumazine was not further catabolized by the homogenates.

The same results were obtained with the cockroach *Periplaneta americana* and the silkworms *Hyalophora cecropia* and *Rothschildia orizaba*. When the cockroach *Brysotria fumigata* and the firebug *Pyrrochoris apterus* were studied they were found to perform the same or similar reactions; however they possessed pterin deaminase activity similar to that found in rat tissues. In all these insects 7-hydroxylumazine was formed but not further catabolized. Since 7-hydroxylumazine is naturally found in *Bombyx mori*, *Hyalophora cecropia*, *Rothschildia orizaba*, and *Pyrrochoris apterus* it is most probably a terminal catabolite in these organisms.

Homogenates prepared from the relatively pteridine-rich butterflies *Pieris rapae* and *Colias eurytheme* did not degrade

isoxanthopterin, leucopterin, 7-hydroxylumazine, or 6,7-dihydroxylumazine. Since pterin deaminase activity was not observed, isoxanthopterin and leucopterin appear to be the terminal catabolites in these two insects. These data show that among the organisms studied only the bacterium *Alcaligenes* was capable of fully degrading the pteridine ring while the rat and the insects described end their catabolism at the stage of simple pteridines and lumazines.

The properties of the pteridine deaminases listed in Table 5 are very similar to one another with the exception of sepiapterin deaminase. Comparison with the properties of guanine deaminase (guanase) indicates that there are similarities here too. Guanase has the same pH optimum,

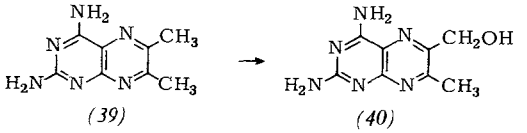


Table 5. Comparison of the characteristics of different pteridine deaminases.

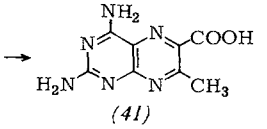
Characteristic	*A. faecalis* pterin deaminase [66]	Rat liver pterin deaminase [55]	*P. americana* isoxanthopterin deaminase [15]	*B. mori* isoxanthopterin deaminase [15]	*B. mori* sepiapterin deaminase [53, 67]
pH optimum	6.3—6.7	6.5	6.6	6.6	8.0
Stability	unstable at pH 7 and 0 °C; stable at pH 9 and 0 °C	unstable at pH 6.5 and 4 °C; activity decreases 50% in 5 days	unstable at pH 7 and 0 °C	unstable at pH 7 and 0 °C; activity decreases 50% in 7 days	stable
K_M		3×10^{-5} mol/l		1.2×10^{-5} mol/l	5.9×10^{-4} mol/l
Specificity	pterin and all 6-substituted derivatives	tetrahydropterin >pterin >iso-xanthopterin	isoxanthopterin	isoxanthopterin	sepiapterin and isosepia-pterin
Inhibitors	*p*-chloromercuri-benzoate, NaF	KCN, lumazine, azaguanine	KCN, KF, xanthopterin, azaguanine	KCN, KF, xanthopterin, guanine	pterin biopterin, xanthopterin

it catalyzes an irreversible deamination reaction, and it is also inhibited by xanthopterin[15]. These similarities may point to a common mechanism of action.



In contrast to these enzymes, sepiapterin deaminase from *Bombyx mori* has very different properties. However it must be noted that its substrate is a 7,8-dihydropterin while the other deaminases utilize the oxidized, or aromatic pteridines. Exceptions are the pterin deaminases from rat liver[55] and *Drosophila melanogaster*[15] which can catalyze the deamination of both aromatic and reduced pterins. The substrate specificity of the deaminases for the pteridines alone is in marked contrast to xanthine oxidase which catalyzes oxidations of both purines and pteridines. Guanase and uricase from bacteria, fungi, insects, and mammalian sources utilize no pteridine as substrate; conversely no purine acts as substrate for the pterin deaminases[15].

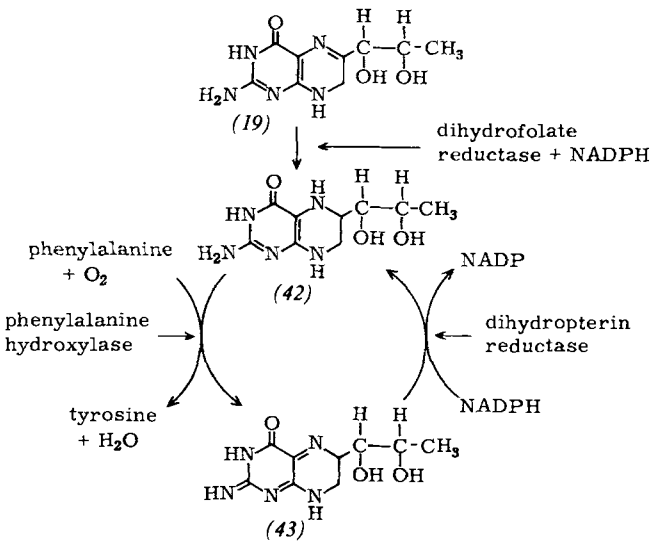
Numerous synthetic pteridines possess diuretic action. In investigations with the diuretic 2,4-diamino-6,7-dimethyl-

(39)

(40)

(41)

pteridine *(39)* *Eder* and *Rembold*[68, 69] noted that, after intraperitoneal injection into the rat, this pteridine was quickly detoxified by catabolism to the 6-hydroxymethyl *(40)* and the 6-carboxylic acid derivative *(41)*.



The first oxidation product *(40)* has only weak diuretic action while the second *(41)* is pharmacologically inactive. The enzymatic reaction is another example of the importance of position 6 of the pteridine ring. This position is attacked in preference to position 7. Such an importance can also be seen in the fact that biopterin is a growth factor for *Crithidia fasciculata* while the isomer of biopterin bearing the side chain in position 7 is completely without activity[70].

4. Cofactor Functions

Reduced pterins play a functional role in nature by acting as cofactors in a number of oxygenase reactions. *Kaufman*[71] was the first to show this when he reported that reduced biopterin serves as the natural cofactor in the hydroxylation of phenylalanine[103]. The reduced pterin in its inactive 7,8-dihydro form *(19)* is converted into the tetrahydro form *(42)* and after releasing two reducing equivalents it is converted to a quinonoid-dihydro form *(43)*[72]. The tetrahydropterin structure is regenerated from the quinonoid form by the action of an NADPH-dependent dihydropterin reductase.

The pteridine in this hydroxylation reaction has been shown to be specific since other reductants, such as ascorbate, glutathione, ferrous ions, *etc.*, are incapable of replacing the reduced pterin. The pterin functions catalytically, *i.e.* when a regenerating system is present a small amount of tetrahydrobiopterin will serve to catalyze the oxidation of greater amounts of substrate. Reduced biopterin has also been shown to be consumed stoichiometrically in the reaction and this utilization is substrate and enzyme dependent[73]. Further studies by *Osanai* and *Rembold*[74] have demonstrated that of the four isomers of biopterin the L-*erythro*-tetrahydrobiopterin isomer is by far the best cofactor in the rat liver system.

A reduced pteridine also functions as a cofactor for *Pseudomonas* phenylalanine hydroxylase[75]. The structure of the natural cofactor in this system has not yet been identi-

fied but it is known that *Pseudomonas* can accomplish the *de novo* synthesis of the pteridine ring and the necessary cofactor for the reaction[76]. When pteridines are extracted from this organism L-*threo*-neopterin occurs in the greatest amount followed by 6-pterincarboxylic acid, pterin, and xanthopterin. No biopterin was observed. Since reduced neopterin functions as well as tetrahydrobiopterin in the *Pseudomonas* system it may represent the natural cofactor.

Tyrosine hydroxylase has been highly purified from bovine adrenal medulla[77]. Tetrahydrobiopterin also seems to be the natural cofactor for this enzyme[110]. In all other oxygenase systems in which reduced pteridines have been suggested as cofactors the natural cofactor has not been identified or proved to be a pteridine. However, at least one of these other systems has been shown to utilize reduced pteridines specifically, catalytically, and also stoichiometrically. This system is the rat liver enzyme preparation which catalyzes the conversion of long chain alkyl ethers of glycerol to fatty acids and glycerol[78].

Other less well characterized reactions nevertheless showing considerable dependence on reduced pteridines are listed in Table 6. More studies are necessary to validate these

Table 6. Enzyme reactions reported to involve pteridine cofactors.

Enzyme	Reaction	Ref.
Tryptophan 5-hydroxylase	tryptophan to 5-hydroxytryptophan	[84, 115]
Cinnamic acid hydroxylase	cinnamic acid to *p*-cumaric acid	[85]
Anthranilic acid hydroxylase	anthranilic acid to hydroxyanthranilic acid	[86]
Progesterone 17-hydroxylase	progesterone to 17-hydroxyprogesterone	[87]
Proline hydroxylase	proline to hydroxyproline	[88]
Prostaglandin synthetase	prostaglandin biosynthesis	[89]
Pseudomonas alcohol dehydrogenase	ethanol to acetaldehyde	[90]

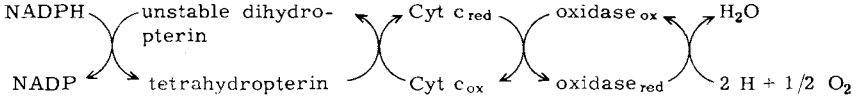
reported pteridine-dependent reactions, especially since it has been shown that reduced pteridines can stimulate an enzyme-catalyzed reaction by protecting the enzyme from inactivation[79].

Because reduced pteridines are active reagents in their own right, it is not surprising that recent reports have demonstrated that in the presence of Fe^{2+} tetrahydropterins in molar excess can act as non-specific hydroxylation agents for aromatic amino acids[80, 81, 112]. With these pteridine characteristics in mind the reactions in Table 6 should be restudied. Nevertheless it is significant that when *Rembold* and *Hanser* injected labeled biopterin and neopterin into bee pupae[82] and into the rat[37] radioactivity was found in cells of high metabolic activity such as bee cuticle at the time of sclerotization, bee fat body, rat liver, and the peripheral ganglion sheath of the rat central nervous system. These are exactly the locations required of cofactors for tyrosine hydroxylase, phenylalanine hydroxylase, and the alkyl ether hydroxylase. Similar findings have been reported by *Kokolis* and *Ziegler*[83] who noted that high concentrations of tetrahydrobiopterin *(42)* were localized in regenerating portions of the tails of *Triturus cristatus*.

5. Hydrogenated Pterins in Cellular Electron Transport

Recent studies, especially those on redox potentials, point to the probable importance of pteridines in cellular electron transport[91]. The polarographic halfwave potentials of the aromatic pteridines are similar to those of the pyridine nucleotides[92]. The standard halfwave potential of 6,7-dimethyltetrahydropterin is +150 mV[93], which is similar to those of the cytochromes (Table 7). EPR measurements show the possibility that this tetrahydropterin can form a cationic radical under physiological conditions[94].

Table 7. Standard redox potentials E_0' of components of the respiratory chain compared with 6,7-dimethyltetrahydropterin (DMTH).



Compound	E_0' [V]
Cytochrome a/a_3	+0.29
Cytochrome c	+0.25
Cytochrome c_1	+0.23
DMTH	+0.15
Cytochrome b	+0.04
Flavoproteins	−0.05

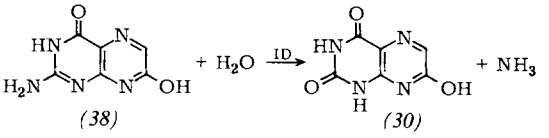
These findings, although not conclusive, support the hypothesis of *Fuller* and *Nugent*[95] that pteridines are primary electron receptors in photosynthesis. According to these authors, a trihydropteridine radical is the electron receptor in the photosynthetic light reaction, and a tetrahydropteridine is thereby formed which then reduces ferredoxin. The hypothesis is not supported by the fact that the standard potential for tetrahydropterins is +0.15 V while for ferredoxin it is −0.42 V. From these potentials a reverse sequence of electron flow, *i.e.*, the reduction of an oxidized pterin by a reduced ferredexin, would be the expected reaction. Further studies will help to solve this question.

The occurrence of pteridines in chloroplasts has not been clearly demonstrated. It is possible that the few simple pteridines isolated from plants are decomposition products

of folic acid or riboflavin. The function of pteridines in mitochondria is much clearer. By isotopic dilution methods a significant amount of tetrahydrobiopterin *(42)* has been detected in these organelles[18]. Reduced pteridines in physiological concentrations stimulate mitochondrial respiration and the utilization of oxygen has been found to be linearly proportional to the amount of tetrahydropteridine present. At a concentration of reduced pterin which is five times higher than the physiological concentration the linearity of the oxygen utilization levels to a plateau.

Low temperature difference spectra show the reduction of the respiratory chain at the cytochrome c and a/a_3 sites. Cytochrome c_1 is not reduced even though its redox potential makes it appear a likely candidate (Table 7). It is noteworthy that respiration is not coupled to ATP production in the presence of tetrahydropterins. Obviously the electrons must flow from the tetrahydropteridine, *via* cytochrome c, directly to cytochrome oxidase[91]. A soluble electron transport system can be formed (Scheme 1).

Scheme 1.



For an optimal oxidation of the reduced pyridine nucleotide, NADPH, every component of the system is essential. Tetrahydropterin can also be non-enzymatically regenerated in the system by NADPH probably from an unstable radical. The system can reduce more material than the amount of component tetrahydropterin and is limited only by the NADPH concentration. Therefore tetrahydropterin has a distinct catalytic effect in the system[16, 96]. The exact significance of tetrahydrobiopterin *(42)* and similar pteridines in cellular electron transport will have to be clarified in further studies.

6. Physiological Aspects

Once pteridines have been synthesized by an organism they can be utilized *in situ* or they can be transported to other tissues to be used directly or stored for later needs. The mechanisms of pteridine transport and storage are not yet well understood but investigations by *Gyurè*[15] on pteridines in the silkworm *Bombyx mori* give an insight into the general physiological process in insects. The results of the study will therefore be given in detail.

7-Hydroxylumazine *(30)* occurs in *Bombyx* eggs in very small amounts, its presence presumably arising from the maternal tissues. At the time of hatching the enzyme isoxanthopterin deaminase becomes active. This enzyme in *Bombyx* has been shown to be responsible for catalyzing the synthesis of 7-hydroxylumazine *(30)* from isoxanthopterin *(38)*.

Parallel to the deaminase activity, 7-hydroxylumazine is found throughout larval development, especially localized in the integument. *Tsujita* and *Sakurai*[97] have shown that in *Bombyx* larvae pteridines and purines are bound to specific proteins and are localized in integument pteridine granules. There are specific binding proteins for uric acid, sepiapterin *(7b)*, and isoxanthopterin *(38)*. It is not yet

ID = isoxanthopterin deaminase

known if such proteins exist also for deaminated sepiapterin and for 7-hydroxylumazine which are the other two pteridines found in *Bombyx*. Presumably there is either a specific carrier protein for 7-hydroxylumazine or the carrier for isoxanthopterin serves also to bind 7-hydroxylumazine. Because isoxanthopterin deaminase is mainly found in larval integument, it is clear that 7-hydroxylumazine is produced and stored in this tissue.

At the beginning of the spinning phase, which occurs at the start of metamorphosis from larval to pupal form, the integument loses its creamy white color. It now becomes clear due to the breakdown of the membrane of the pteridine granules which in turn releases purines and pteridines to the cytoplasm and insect hemolymph. That the poorly soluble 7-hydroxylumazine can be so suddenly accommodated and transported by the hemolymph is probably an indication that it is again complexed to a protein.

As *Bombyx* pupal tissues form, the concentration of hemolymph 7-hydroxylumazine rapidly decreases, a portion being excreted while the rest is stored in the fat body. New 7-hydroxylumazine is not formed in the fat body and the observable lumazine in this organ represents a transported and stored compound. This can be deduced from observations on the behavior of isoxanthopterin deaminase. This enzyme disappears from *Bombyx* at the time of the breakdown of larval pteridine granules and at no time does it ever occur in the fat body. 7-Hydroxylumazine is stored in the fat body only during the first half of pupal development; during the second half it collects in the meconium. After emergence of the moth a great part of the lumazine is excreted while the rest remains attached to the meconial sac membranes. In the last few days of imaginal development, newly forming female wings and integument abruptly start fresh synthesis of 7-hydroxylumazine. This is accompanied by an equally abrupt appearance of isoxanthopterin deaminase activity in the same tissues. This effect is not observed in male silk moths, probably for genetic reasons.

Similar findings to those in *Bombyx* have been reported for other insects, fish, and amphibia. *Hama*[101] has des-

cribed the pteridine granules in various fish, reptiles, and amphibia. *Obika*[99] isolated pterinosomes from lower vertebrates and found that about 60% of all pteridines were bound to cell particles. Isoxanthopterin deaminase and 7-hydroxylumazine display the same localization patterns in the wild silkmoths *Hyalophora cecropia* and *Rothschildia orizaba* as found in *Bombyx mori*[115]. *Hanser* and *Rembold*[82,100] found that after injection of labeled biopterin into bee pupae radioactivity was located in the meconial sac membranes.

Worthy of further mention are the studies of *Harmsen* on the cabbage butterfly, *Pieris brassicae*[101]. During the larval and early pupal stages much the same results as found in *Bombyx mori* were observed. However, at the time of the development of adult tissues in the pupae, pteridines were noted to be synthesized in relatively large amounts. In this regard Pierids differ from other lepidoptera. For example, in this species the isoxanthopterin concentration in the adults is thirty times that found in *Bombyx*. *Ziegler* and *Harmsen*[8] assumed that the large amounts of pteridines in *Pieris brassicae* adult wings arise in part from *de novo* synthesis in the wings and in part by transport from the fat body. The results of studies by *Watt*[46] with the butterfly *Colias eurytheme* support this assumption. He found that incubation of isolated developing wings of this butterfly with labeled guanine precursors led to formation of radioactive wing pteridines. On the other hand *Descimon*[47] has found that synthetic 6-hydroxymethylpterin injected into *Colias croceus* pupae could be recovered from the adult wings. Since this pteridine does not normally occur in *Colias* wings it must have been transported from the site of injection and stored in the developing wings. *Lafont*[109] has noted that, after injection of radioactive isoxanthopterin into *Pieris brassicae* pupae, this pteridine could be observed first in the pupal fat body and later during adult development in the wings, meconial sac, and eggs. These findings indicate that butterfly wings have separate but parallel capacities for pteridine synthesis and storage.

7. Conclusion

From the reported findings it appears that purines are generally utilized as biochemical precursors of the pteridine ring. A specific GTP-cyclohydrolase has been purified from a microorganism but even in this case there is uncertainty about the enzymatic reaction mechanism. The first tangible product of the purine-pteridine conversion in *Escherichia coli*[41] is D-*erythro*-7,8-dihydroneopterin triphosphate *(12)*; in *Comamonas* on the other hand it is a cyclic D-*erythro*-7,8-dihydroneopterin 2',3'-monophosphate[102]. However, the example of the indolyl derivative *(17)* shows that the Brown-Shiota scheme of purine-pteridine conversion is not universal, even for microorganisms.

Even greater reservations are held with regard to application of the scheme to higher organisms which appear able to synthesize the pteridine ring *de novo*. No enzyme of pteridine biosynthesis has been purified in such a case. However, one can predict that in view of the anabolic enzymes already described in Table 3, biosynthetic enzymes will be soon reported.

In contrast, pteridine catabolism is much clearer especially since the functions of xanthine oxidase and specific pterin deaminases are now known. Yet to be answered is the question whether the pteridine side chain is non-enzymatically split in an organism or whether there is a specific enzyme which performs this task and which thus can control the concentration of pteridine cofactors.

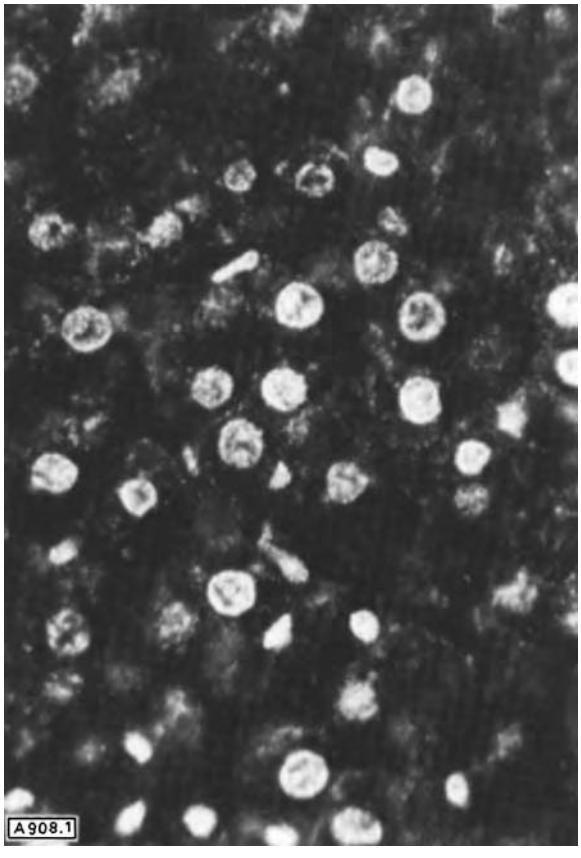


Fig. 1. Histoautoradiography of liver slices from a rat injected 24 hours earlier with [2-^{14}C]tetrahydrobiopterin. The bright shining spots which occur in the nucleus show the location of radioactivity in the cells. (Photograph by Dr. *G. Hanser*.)

Pteridines have not been found to be materials for the formation of high molecular weight substances, and their primary function appears to be much more that of redox catalysts which are coupled by specific reactions to the hydrogen potential of the pyridine nucleotides. In the case of the synthesis of the precursors of adrenaline (tyrosine, DOPA) and of serotonin (5-hydroxytryptophan) the cofactor importance of pteridines is already apparent and one can expect that this will apply to the other enzymes listed in Table 6.

The discovery that mitochondrial respiration is activated by tetrahydropterins in physiological concentrations throws up a number of questions concerning the importance of pteridines in cellular electron transport. Because of their very small concentration in the cell, pteridines must be limited to very special regulatory steps. On the other hand, it is remarkable how ubiquitous the 6-(polyhydroxyalkyl)-

pteridines are in nature. The autoradiographic data of Figure 1 show how pteridines are concentrated in the nucleus of rat cells.

Their physiological behavior shows also that pteridines do not generally play the role of metabolic end products as formerly thought. It is therefore necessary to further study the findings of protein-pteridine[97] and pteridine-flavin complexes[104] and of energy-dependent selective biopterin transport[105]. Pteridine binding to DNA[106] molecules may be the mechanism by which these substances can function as regulators. Also of regulatory importance may be the observations on the remarkable difference between the pteridine patterns in the ant *Formica polyctena*[107].

Thermally Reversible Photoisomerizations[**]

By Gerhard Quinkert[*]

Dedicated to Professor Vladimir Prelog

This article consists of a programmatic part and a pragmatic one. The programmatic aspects are the establishment of photochemistry, in the broadest definition of its scope, as a developing field directed toward the elucidation of photobiological phenomena, and an appeal for the wide development of the hitherto neglected dimension of electronically excited states. The pragmatic part is the detailed description of the photochemistry of linearly conjugated cyclohexadienones as an example of a thermally reversible photoisomerization system. The logical use of methods for obtaining information about the formal kinetics of light-induced reactions and for the identification of short-lived transients by low-temperature spectroscopy is of value to both parts.

1. The Developing Field of Photochemistry

As far as semantics are concerned all the processes participating in the formation and deactivation of electronically excited molecules are liberally treated as topics of photochemical interest. The purist's desire to speak generally of photoprocesses and to distinguish photophysical events from photochemical ones—intelligible at first sight—is opposed by the consequences of an obscure division of the field; such a subdivision is questionable from the standpoint of development of that part of science which, in the region of molecular dimensions, deals with interaction between light and matter and whose most challenging problems lie above all in the complex[***] systems of biology. With the broadest possible definition of its scope, photochemistry is a wide field aimed at the unravelling of photobiological phenomena selected through the processes of evolution[****].

Adaptation to and further development by existing terrestrial light conditions are characteristic of the various phases of evolution, which have been labeled chemical, biochemical, and biological[7] without regard for separative effects, in order to emphasize growing complexity. Photosynthesis, photomorphogenesis, and phototropism are the principal phenomena by which plant organisms have adapted themselves to the environmental condition of light, while the dominant comparable phenomenon in animal organisms is vision. The photoprocesses of the light-absorbing receptors are substantially unknown apart from the visual pigments[8]. Why is this so?

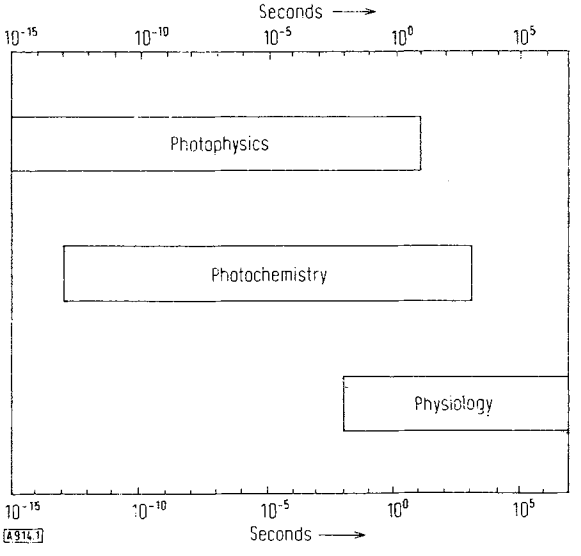

Fig. 1. Time ra[illegible]id schematized composition of the interdisciplinary complex of photobiology; cf. [9].

[**] 5th essay on light-induced reactions; based on a lecture to the General Meeting of the Gesellschaft Deutscher Chemiker on September 14, 1971, in Karlsruhe. The 4th essay was ref. [35].

[***] From the largely indistinct clamour of voices expressing uneasiness over the present structure and role of chemistry there rises a clear call for a revision of the structure of chemistry and a turning towards complex problems; see [1–3].

[****] A guide to photobiological problems are *e.g.* the monographs of [4–6].

First there is the enormous span in the train of events that should belong to different regions according to a scheme that is still in use (see Fig. 1). The photophysical region in any case embraces the series of processes that are associated with light phenomena; for organic molecules of normal size the absorption occurs in approximately 10^{-15} seconds, and the decay time of the emission of phosphorescence is occasionally as long as a few seconds. The area of radiationless deactivation extends from almost 10^{-12} seconds for vibrational relaxations to a few seconds for slow intercombinations; it is normally regarded as a physical domain, but can also be advantageously included in the field of interest of chemical dynamics[*].

Where photoproducts are formed from electronically and vibrationally excited states, these have an average lifetime of about 10^{-13} second. In light-induced reactions kinetically unstable transients with a considerable diversity of half-lives, extending from the nanosecond range well into the minute range, frequently occur under normal conditions. The time span of the light-induced physiological processes also covers several orders of magnitude. Whereas the eyes of bees, for example, can detect up to 200 oscillations per second[12], flower formation is measured 10^6 to 10^7 seconds after photoperiodic induction[13]. The solution of photobiological problems thus requires the experimental treatment of processes that can extend over more than 20 orders of magnitude on the time scale! The "convoy principle", suitably applied, is valid for the disentanglement of interdisciplinary complexes. One can scarcely avoid the impression that chemists have not so far made the contribution that is necessary for the elucidation of photobiological phenomena.

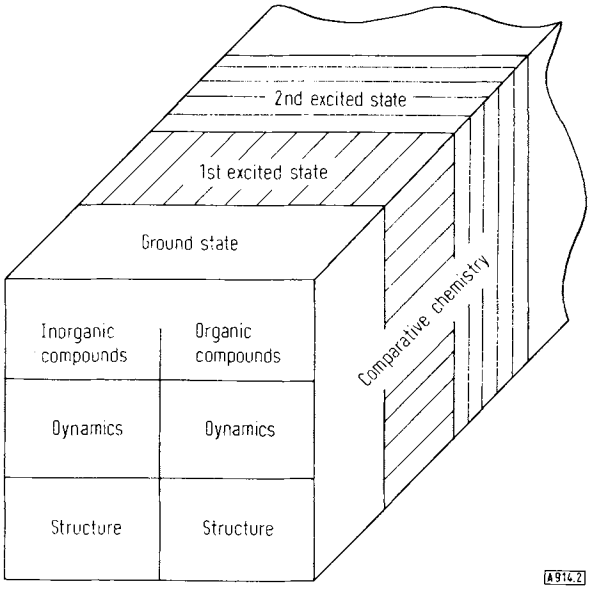

Fig. 2. Structure-oriented classification of chemistry, including electronically excited states.

[*] If conformational changes of molecules in their electronic ground state, such as occur *e.g.* by rotation about bonds and inversion at centers (including the accompanying changes in bond lengths) are the concern of chemical dynamics, this is also true of conformational changes in electronically excited molecules during radiationless deactivation. For a discussion of the geometry of electronically excited molecules see [10, 11].

This omission becomes understandable when one considers (see Fig. 2) that the structure-oriented part in the chemical education of scientists is still directed almost exclusively toward inorganic and organic compounds in their electronic ground state. Questions concerning the structure and chemical dynamics of compounds in their various electronically excited states are hardly considered in this connection. The reason for this is obvious: Electronically excited compounds are so short-lived that they have not been regarded consciously enough in the past as independent species with structures and reactivities of their own. Their study was a domain of spectroscopists, who did not use the conventional terminology of chemistry. Nowadays the need for development and cultivation of a "comparative chemistry"[14] (see Fig. 2) appears not only to exist but also to be largely feasible because of the disappearing linguistic differences.

With the growing familiarity at least with the qualitative principles of *Mulliken*'s molecular orbital method[15], which is largely due to the successes of the Hückel rule[16] and the Woodward-Hoffmann rules[17], there has also been an increase in the general ability to use intelligibly the terms of group theory. This has led to the removal of a barrier that formerly prevented a broad development of the neglected dimension of electronically excited states. Another impetus to that expansion has been provided by the dramatic development of experimental methods for the study of reactions not long ago considered to be immeasurably fast[18, 19], and hence for the reliable detection of short-lived transients. With the aid of information from flash spectroscopy[20, 21], electron emission spectroscopy[22–25], ESR spectroscopy[26], and NMR emission spectroscopy (CIDNP)[27], what were necessarily speculations of photochemistry in the past can now be turned into questions to be answered experimentally.

2. The Model of Thermally Reversible Photoisomerizations

The extremely numerous photobiological problems cannot be reduced to a common denominator as far as structure is concerned. They naturally all begin with the absorption of light by a chromophoric system. The photoprocesses of the electronically excited pigments, as was mentioned earlier, are inadequately known in almost all cases.

It may be useful at this stage to devise models for structure systems with similar reaction behavior. Their study not only furthers our knowledge of structure-photoreactivity relationships but also allows the continuous testing of promising experimental methods. A suitable model in our view is provided by thermally reversible photoisomerization systems[*].

[*] These include some of the photochromic systems. They have been suggested as systems for temporary storage of information ("memory models") [28], as systems for the temporary storage of energy [29], as subjects for practice in handling of transients [30], and for use in reproduction processes [31]; see [32] and further literature cited there.

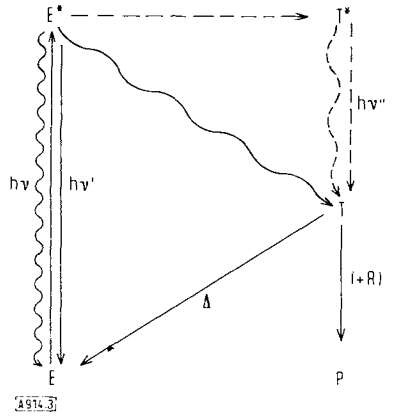

Fig. 3. Scheme of a thermally reversible photoisomerization system with transients that can be trapped (by R) (for the sake of completeness the broken lines show the adiabatic isomerization course).

A reactant E is converted *via* the electronically excited compound E* into an isomeric transient T, which is very short-lived (kinetically very unstable) under normal conditions since it is converted back into the original reactant E and/or reacts further to form the isolable product P. P is either isomeric with T, and hence also with E, or (*e.g.* after reaction of T with R) is not isomeric with T (see Fig. 3).

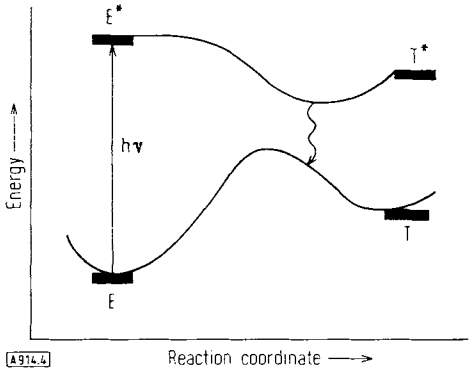

Fig. 4. Scheme of a diabatic photoisomerization.

Unlike in thermal isomerizations, which normally proceed exclusively on the lowest energy surface, *i.e.* adiabatically (see Fig. 4), it is possible in photoisomerizations, and is even the rule in condensed phase, for the electronically excited compound to pass from a higher energy surface to the lowest one even before the electronically excited transient T* has been reached; in other words, the photoisomerization can proceed diabatically from E *via* E* to T[33][*].

Whether isomer T accumulates under normal conditions and with suppression of formation of P or whether the intact reactant E is regenerated will depend on the height of the threshold on the lowest energy surface. In the latter case seemingly no chemical reaction will have occurred; one might lower the temperature in order to try to conserve transient T.

Quite apart from the fact that it may become possible in this way to prepare reactive compounds that are otherwise obtainable only with difficulty if at all, the manifestation of latent thermo-reversible photoisomerization systems is worth the effort for still another reason: The energy taken up by a compound E on absorption of light is used to synthesize the chemically different species E* (see Fig. 3) and thereupon partitions between radiationless and/or radiative deactivation paths leading either back to reactant E or on to product P. The quantum yield of photochemically produced P as well as the quantum yield of E regenerated with emission of light can be determined experimentally. The deficit by which this sum is smaller than the amount of energy originally taken up is accounted for by radiationless deactivation of E* leading back to E. This radiationless deactivation obtained by subtraction branches into one route from E* to E directly and another one from E* to E *via* T[*].

3. Structural and Kinetic Analysis in Real Model Cases

Understanding a thermally reversible photoisomerization requires a structure-oriented analysis of the product and transient involved as well as a kinetic analysis of the reaction course. Since the investigation of product P can be carried out in the usual manner, no explicit comment is needed. Special low-temperature techniques[14,39] have been developed for the analysis of the reactive transient T; details of these methods will be omitted here in favor of results obtained by these techniques. A brief discussion of the type of analysis of the reaction course, however, seems appropriate.

Light-induced reactions are generally so complex that the concept of reaction order becomes meaningless. According to *Mauser*[40], an extremely useful differentiation of photoreactions, which is admittedly based on formal kinetics, is possible by the following procedure: A diagram of extinction differences (ED diagram) is obtained by plotting differences in absorption intensity at specified wavelengths observed at various intervals during a light-induced reaction that can be followed electronic spectroscopically against each other in rectangular coordinates. This contains either a family of straight lines passing through the origin (see Fig. 5), in which case it is known as a linear ED diagram, or a family of curves arising from the origin, in which case the ED diagram is designated as nonlinear (see Fig. 6).

Linear ED diagrams belong to spectroscopically simple photoreactions. They are observed if *e.g.* the premise of

[*] Adiabatic types in which the chemical reaction occurs after the deactivation of the electronically excited reactant and those in which the chemical reaction occurs before the deactivation of the electronically excited product are discussed in [33, 34] and in [23, 33, 34] respectively.

[*] We referred earlier to the matter of differentiation for radiationless deactivations [35]. *Lamola, Hammond,* and *Mallory* [36] and *Phillips, Lemaire, Burton,* and *Noyes* [37] also regard isomerizations as a possibly widely occurring mechanism of radiationless transitions (see also [38]). The proposal to distinguish between "physical" and "chemical" deactivation may for a time provide a stimulus to experiment, but it readily gives the impression of two essentially different deactivation phenomena.

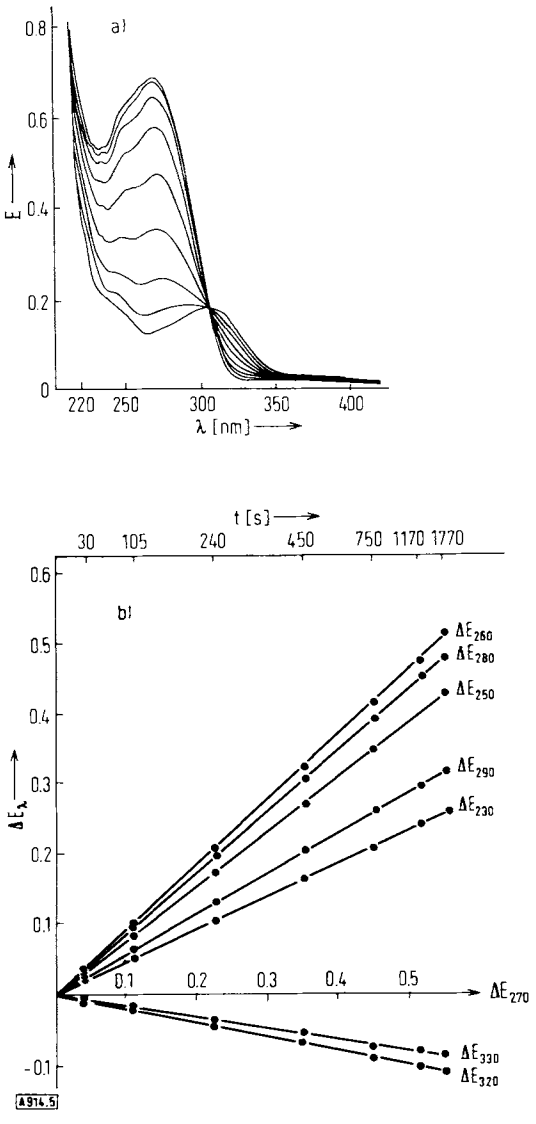

Fig. 5. The absorption spectra recorded at various times during a photochemical reaction (family of curves a) and the corresponding linear ED diagram (b).

the steady-state approximation[41] is fulfilled; *i.e.* if apart from reactant and product no further participant in its time-dependent change of concentration can be determined spectroscopically; if a reaction is accompanied by its reversed process or if parallel reactions of the same order occur.

Non-linear ED diagrams are due to spectroscopically complex photoreactions. The latter consequently are differentiated by the number of spectroscopically detectable partial reactions. Diagrams of quotients of extinction differences (EDQ diagrams) conveniently serve to distinguish between complex photoreactions[40]. In order to obtain these diagrams quotients $\Delta E_1/\Delta E_2$ and $\Delta E_3/\Delta E_2$ found after various reaction times are plotted against each other in rectangular coordinates. A resulting straight line signifies a linear EDQ diagram (see Fig. 6) which indicates the participation of two different partial reactions each of which can be recognized spectroscopically. If a curve arises, *i.e.* if one obtains a non-linear EDQ diagram, there are more than two spectroscopically detectable partial reactions.

Mention was made earlier of flash spectroscopy[20,21], which, with the aid of laser light, is preparing the way for an advance into the picosecond range and hence well into the range of molecular dynamics[42,43]. This technique can be used for the detection and identification of electronically excited species and of transients in their electronic ground state, as well as for the kinetic study of their decay processes[*].

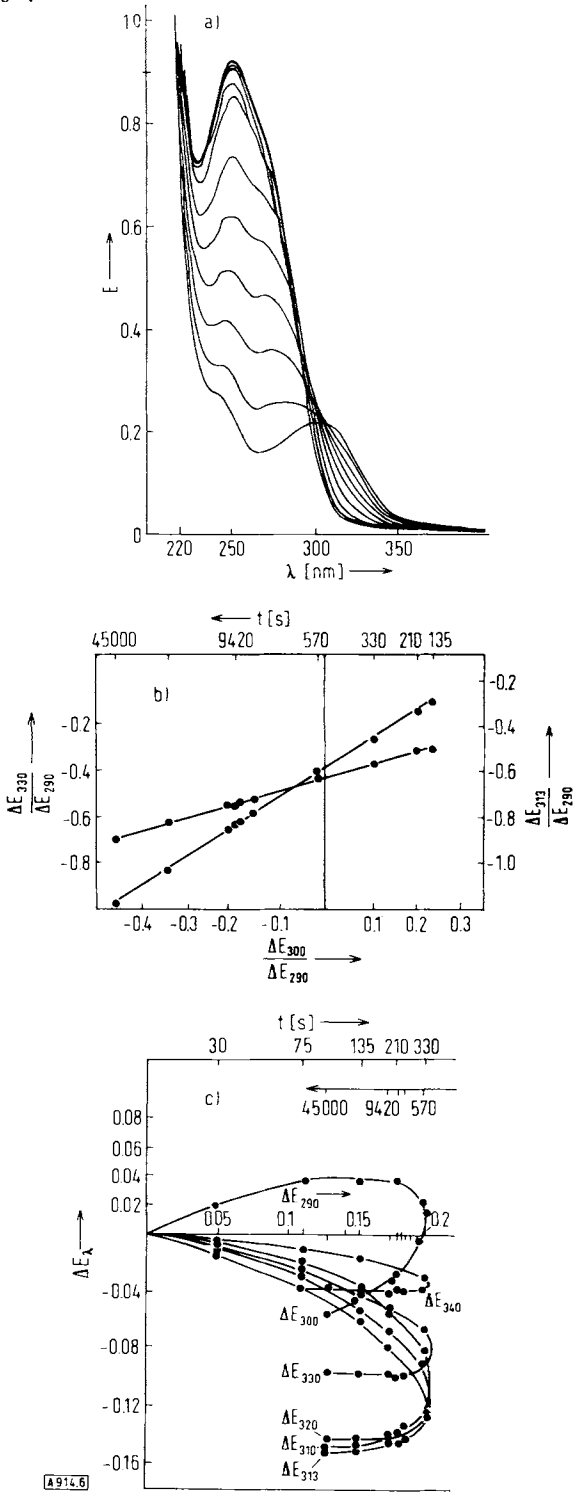

Fig. 6. The absorption spectra recorded at various times during a photochemical reaction (family of curves a), the corresponding non-linear ED diagram (c), and the corresponding linear EDQ diagram (b).

[*] In the following discussion of the chemistry of electronically excited cyclohexa-2,4-dienones, flash-spectroscopic studies, which have just begun, are not mentioned.

4. Thermally Reversible Light-Induced *cyclo/seco* Isomerization of Linearly Conjugated Cyclohexadienones to Dienylketenes

4.1. Introduction

When reference was made unspecifically in the past to cyclohexadienones on account of their photoreactivity, the compounds referred to were usually of the cross-conjugated type (C) (see Fig. 7). The careless manner in which these compounds were talked about arises from the extensive history of cyclohexa-2,5-dienones and is due to the role they have played in the renaissance of "organic photochemistry".

C L

A914.7

Fig. 7. The structurally isomeric cyclohexadienones: the cross-conjugated (C) cyclohexa-2,5-dienone and the linearly conjugated (L) cyclohexa-2,4-dienone.

Reports on the action of light on santonin date back to 1830[44]. The first investigations on the photoproducts of this sesquiterpene, which were completed toward the end of the 1950's[45-47], not only revealed their structure, but also considerably increased the confidence of chemists that with the aid of a sufficiently large number of cases of a reactant/product relationship it would be possible to find the underlying rules for light-induced reactions, just as had previously been accomplished in the investigation of reactions that do not require light.

The progress that has been achieved in the past 15 years can be seen in the growing use of photoreactions for specific structural transformations[*]. The photochemistry of linearly conjugated cyclohexadienones (L) (see Fig. 7), which was completely undeveloped at the beginning of this period, has caught up with the photochemistry of cross-conjugated cyclohexadienones as far as the variety of phenomena and the transparency of their interpretation are concerned.

4.2. Activation by Light Absorption, Deactivation by Competing Quenching Processes

The first question of general importance for an understanding of a light-induced reaction concerns the nature of the electronically excited reactant. For the sake of the discussion it may be assumed that the incident light has such a wavelength that the absorbing molecule passes—within about 10^{-15} seconds—from the ground state to the second excited singlet state. (see Fig. 8). Since only the relatively intense spin-allowed absorption (1) is considered here, the ground state of the molecule is, of course, also a singlet state (normal case for the compounds encountered in organic chemistry).

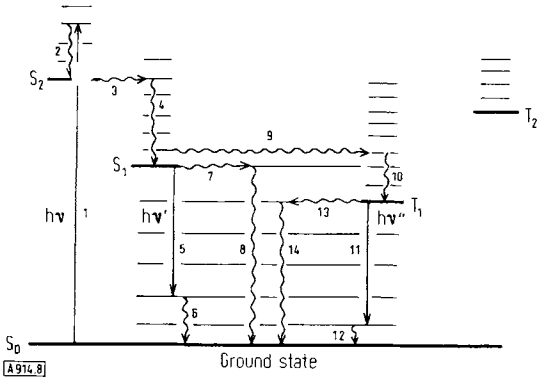

Fig. 8. Extended Jablonski diagram with radiationless transitions (wavy arrows) and transitions associated with radiation (straight arrows) between singlet (S) and triplet (T) states, such as is typical of organic compounds; for explanation of numbers see text.

Since the nuclear coordinates of a molecule, of course, do not change in the time interval mentioned (Franck-Condon principle), and since the various electronic states generally have different equilibrium conformations[10, 11], it is plausible that a higher vibrational level of the corresponding electronically excited state is reached in the general case. A chemical reaction can occur from this vibronic state if it is fast enough. Otherwise, or additionally, a Boltzmann energy distribution occurs over the vibrational levels (and the rotational levels, which are not considered here) of the first excited singlet state. This takes place by vibrational relaxation (Fig. 8, 2 and 4) and by an isoenergetic transition between two electronic states having the same multiplicity (3), which is known as an internal conversion[*].

The ground state and/or the triplet state can be reached from the zeroth vibrational level of the lowest excited singlet state. The initial state is restored by a combination of fluorescence emission (5) and vibrational relaxation (6) or of internal conversion (7) and vibrational relaxation (8). The triplet state is reached by a sequence of vibrational relaxation (10) and intersystem crossing (9), an isoenergetic transition between two electronic states with different multiplicities. If the molecule whose energy has been enriched by light absorption fails to enter into a chemical reaction from the singlet ladder, it often has a further opportunity to do so from the triplet sequence. If at this stage it does not use the routes of phosphorescence emission (11) and vibrational relaxation (12) or of radiationless deactivation (to be regarded in this case as a sequence of intersystem crossing (13) and vibrational relaxation (14)) leading back to the ground state, the triplet state can be quenched by a chemical reaction.

[*] The most outstanding example is the light-induced cycloisomerization of a *seco*-corrinoid metal complex to the *trans*-corrin complex in *Eschenmoser*'s corrin synthesis [48], which involves a hydrogen shift and proceeds extremely stereoselectively.

[*] The nature of the resulting photoproduct and the quantum yield in which it is formed may depend on the stage of the sequence of singlet or of triplet electronic or vibrational levels from which the reaction takes place [34, 49].

By analogy with the scheme of an extended Jablonski diagram (see Fig. 8)[*], therefore, for every compound undergoing a photochemical reaction there arises the fundamental question whether the decisive structural change takes place from an excited singlet state or from the relevant triplet state. Molecules in the two excited states differ in structure and reactivity from one another and from molecules in the ground state. It is therefore necessary, but by no means sufficient, to know the multiplicity.

4.3. π^*,π and π^*,n Excited States of Linearly Conjugated Cyclohexadienones

With the aid of the formal partial MO scheme (see Fig. 9) one attains a deeper understanding of the properties of an electronically excited linearly conjugated cyclohexa-2,4-dienone.

Figure 9 shows the π_3 and π_4^* MOs of the conjugated six-center system, which are occupied by electrons or unoccupied, respectively, in the ground state, as well as the orthogonal p orbital of the carbonyl oxygen atom, with the so-called nonbonding n electrons, which are in reality delocalized to a considerable degree[**].

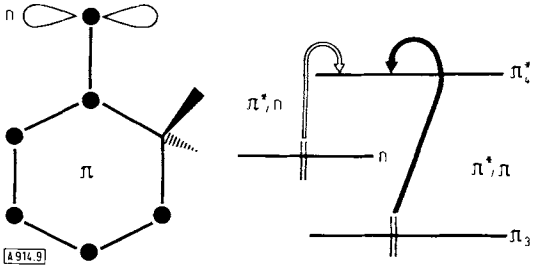

Fig. 9. Partial formal MO scheme of linearly conjugated cyclohexadienones with the two highest occupied MOs and the lowest unoccupied MO in the electronic ground state.

Electronic transitions not requiring much energy take place from the relatively high n and π_3 MOs to the lowest antibonding π_4^* MO. The π^*,n absorption[***] takes place in the gas phase at relatively long wavelengths; it is symmetry forbidden, and is consequently not very strong. On the other hand, the π^*,π absorption[***] which requires more energy under these conditions, is symmetry allowed, and is more intense by about two orders of magnitude. How do the absorption spectra appear in a concrete case?

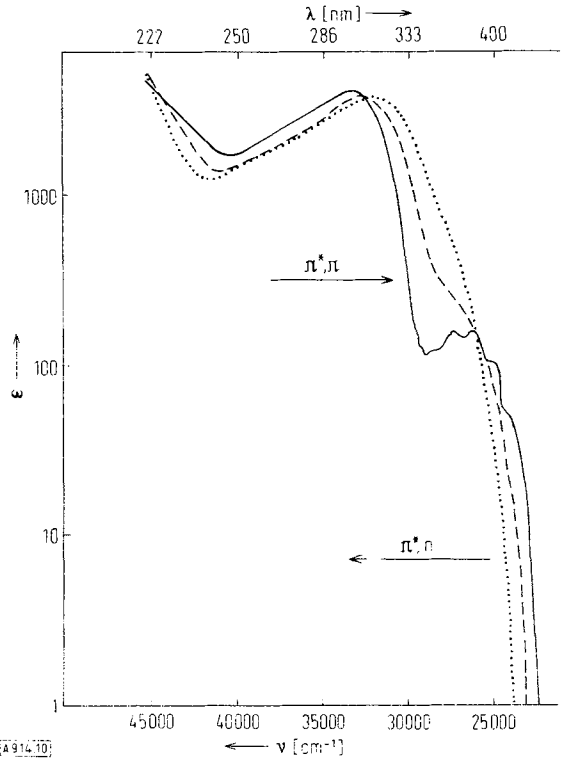

Fig. 10. Electronic absorption spectra of 6-phenyl-6-methylcyclohexa-2,4-dienone at room temperature in methylcyclohexane (———), ethanol (- - - -), and trifluoroethanol (·····).

Figure 10 shows the electronic spectra of 6-phenyl-6-methyl-cyclohexa-2,4-dienone in several solvents at room temperature. In the curve recorded in methylcyclohexane, two relatively long-wave absorption regions can clearly be distinguished. That at higher wavelengths is due to the π^*,n transition, as is shown not only by its energy but also by its low intensity and the characteristic vibrational fine structure. The relatively intense absorption region at lower wavelengths corresponds to the π^*,π transition.

This assignment is supported by the direction of the band shift observed when alcoholic solvents are used. On replacement of the weakly polar hydrocarbon by a strongly polar alcohol, which also acts as a proton donor in systems allowing hydrogen bonding, one observes the disappearance of the fine structure and a red shift of the π^*,π absorption region, as well as a blue shift of the π^*,n absorption region; these shifts may be sufficiently large to cause the two regions to coincide. A glance at a state diagram[*] (see Fig. 11) may help in the understanding of this solvent effect and in the consideration of its consequences.

If these opposing effects are so strong that they lead to leveling of the excited states, or possibly even to a reversal of their hierarchic order, the following question arises. Does the chemical reaction take place from the lowest

[*] The diagram contains no details concerning the various routes to or from electronically excited molecules [50]. In particular, "chemical quenching processes", which do not lead back to the reactant, are entirely absent. Similarly, biphotonic processes [51] and the direct interaction with other molecules (of the same or of a different kind) in spectral transitions [52], in the formation of electronically excited complexes [51, 53, 54], and in the transfer of electronic energy [55] have not been taken into account.

[**] The highest σMO of a ketone that is occupied by electrons in the electronic ground state corresponds to a mixture in which the main contribution is from the p orbital of the oxygen, with contributions from skeletal σ orbitals that are by no means negligible [56]. This delocalization is shown both by *ab initio* calculations [57] and by experimentally determined ionization potentials [58], and has already been taken into account in the interpretation of the photochemistry of formaldehyde [59, 60]; see also [61].

[***] For the discussion of the electronic spectra of organic compounds see [62, 63].

[*] Concerning the dependence of electronic spectra on the nature of the solvent used, see [52].

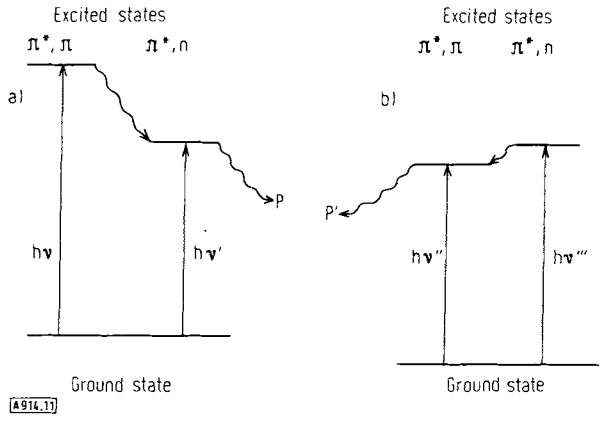

Fig. 11. State diagrams illustrating a medium-induced perturbation of the hierarchy of electronically excited states: a) unperturbed in the gas phase and in weakly polar saturated hydrocarbons; b) strongly perturbed, in alcoholic solvents.

excited state[*], irrespective of which excited state was initially reached on absorption of light, or do the nature and/or quantum yield of the photoproduct depend on the electronically and possibly on the vibrationally excited state that is reached directly on excitation by light? In the latter case irradiation conditions and medium effects would be product-determining variables, while in the former case the wavelength of the light that interacts with the dienone chromophore has no product-determining effect. In addition to knowing the multiplicity (singlet or triplet), therefore, one has to know the electronic configuration (π^*,n or π^*,π) of the initial spectroscopic state and of the photoreactive excited state, which are usually different.

4.4. Photoisomerization of Linearly Conjugated Cyclohexadienones to Dienylketenes

Under conditions favoring the π^*,n state as the lowest excited state, a linearly conjugated cyclohexa-2,4-dienone is converted into the derivative of a hexadienoic acid in the presence of a protonic nucleophile HX[64-66]. As indicated in our model (see Fig. 3), the reaction may be regarded as a primary photoisomerization of the *cyclo*-isomeric reactant to the *seco*-isomeric dienylketene. The transient undergoes

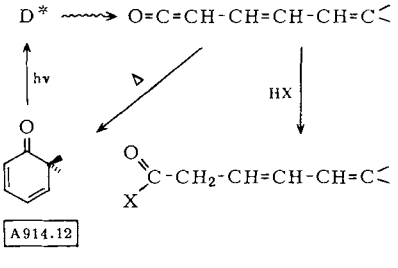

Fig. 12. Thermally reversible photoisomerization of a linearly conjugated cyclohexadienone to a dienylketene, which can in principle be trapped. Concrete example of the abstract scheme in Fig. 3.

[*] When we refer here to the lowest excited state, we are concerned, for the moment, only with the electronic configuration and not with the multiplicity.

secondary reaction with HX and/or recyclizes to form the original dienone (see Fig. 12).

Checking this proposed reaction course requires answering the following questions. What precisely is the isolable reaction product? Its constitution is in doubt, since 1,4 and/or 1,6 additions may occur alongside or instead of the 1,2 addition of a protonic nucleophile to a hypothetical dienylketene as outlined in the scheme (Fig. 12). Even if the constitution indicated proved to be correct, the stereochemistry and ultimately the conformation[*] would still remain to be determined. Stereoisomers are possible with respect to the disubstituted CC double bond, and also with respect to the trisubstituted CC double bond if the substituents at the terminal C atom are different.

Does the postulated transient actually occur? If so, it is necessary to determine its complexity, the stereochemistry of the individual components, and their thermal and/or light-induced recyclization to the original reactant. If these details were known, the uncertainty surrounding the stereoselectivity of the postulated *cyclo/seco* isomerization would disappear[**]. Finally, the multiplicity (singlet or triplet) and the postulated π^*,n electronic configuration of the photoreactive excited state must be determined.

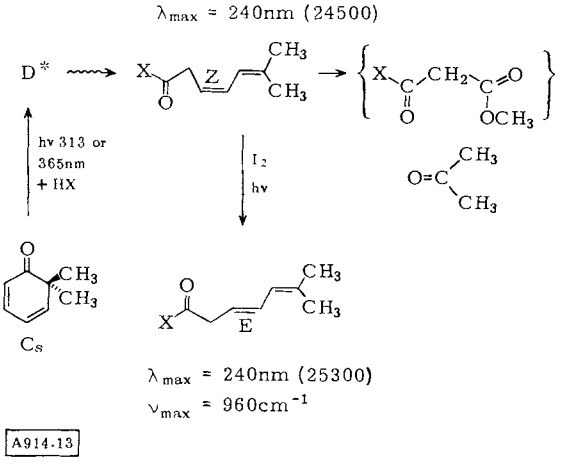

Fig. 13. Information on the constitution and stereochemistry of the irradiation product obtained from 6,6-dimethylcyclohexa-2,4-dienone at room temperature and in the presence of a protonic nucleophile HX.

The first subject to be investigated was 6,6-dimethylcyclohexa-2,4-dienone, which belongs to the symmetry point group C_s. This compound was irradiated in ether solution and in the presence of cyclohexylamine as a protonic nucleophile. Irrespective of whether 365 nm or 313 nm light is used one and the same product is obtained in practically quantitative yield. The ozonolysis products confirm the constitution indicated (see Fig. 13). The 3*Z*

[*] Stereochemical usage is so diverse (see [67]) that it is always necessary to define the term "conformation". In this article the conformation of a molecule denotes the arrangement of its atoms in space in terms of bond lengths, bond angles, and dihedral angles. Stereoisomerism with respect to a CC double bond is specified according to IUPAC Rule E 2.21 [67].

[**] As far as we know, only three articles have expressed an opinion on this point. The findings were interpreted in two cases [68, 69] as indicating extreme stereoselectivity, and in the third case [70] as indicating partial selectivity.

arrangement is deduced from the absence of the IR band at 960 cm^{-1} that is characteristic of 1,2-disubstituted ethylene derivatives having the *E* orientation, and which is observed on the other hand for the iodine isomerization product. UV data given for both stereoisomers indicate that these are of no value for a reliable stereochemical assignment. If one of the two methyl groups is replaced by a different substituent one obtains a more promising source of information.

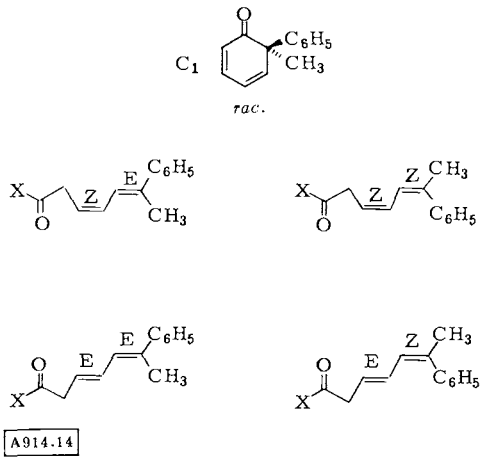

Fig. 14. 6-Phenyl-6-methylcyclohexa-2,4-dienone and the complete set of possible stereoisomers of derivatives of 6-phenylhepta-3,5-dienoic acid; $X = C_6H_{11}NH$.

6-Phenyl-6-methylcyclohexa-2,4-dienone is chiral; consequently, the stereochemistry of potential ring cleavage products with respect to both the CC double bonds is uncertain *a priori*. The complete set of stereoisomers of the constitution to be expected by analogy is shown in Figure 14. To ensure an unequivocal reaction and product

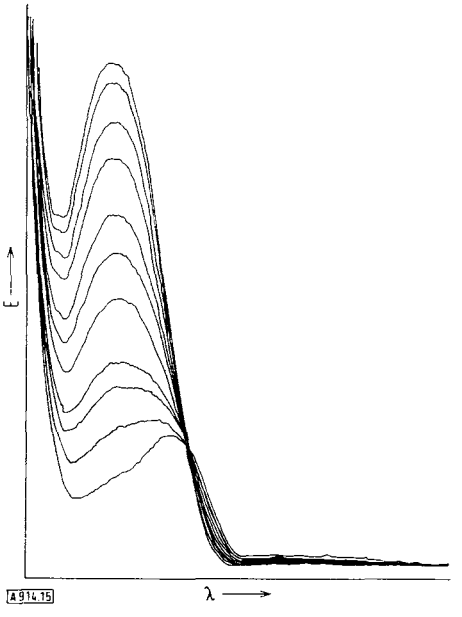

Fig. 15. The electronic absorption spectra recorded at various times for the UV irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone with 365 nm light at room temperature in the presence of cyclohexylamine in ether (isosbestic point at 306.5 nm, $\varepsilon = 3700$).

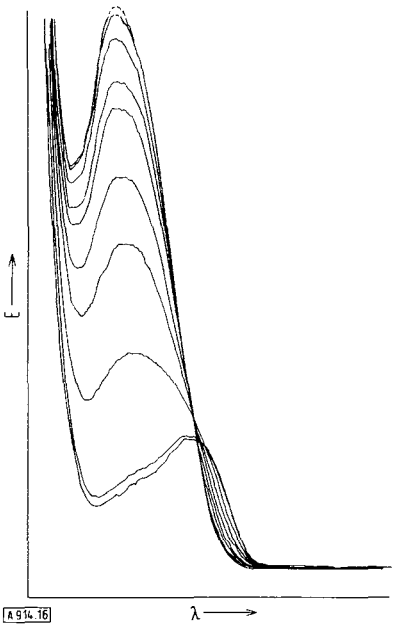

Fig. 16. The electronic absorption spectra recorded at various times for the UV irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone with 313 nm light at room temperature in the presence of cyclohexylamine in ether.

analysis for the UV irradiation in the presence of cyclohexylamine, all the stereoisomeric cyclohexylamides ($X = C_6H_{11}NH$ in Fig. 14) were synthesized by conventional methods and their stereochemistry was determined[71, 72]. Before considering the identity of the photo-

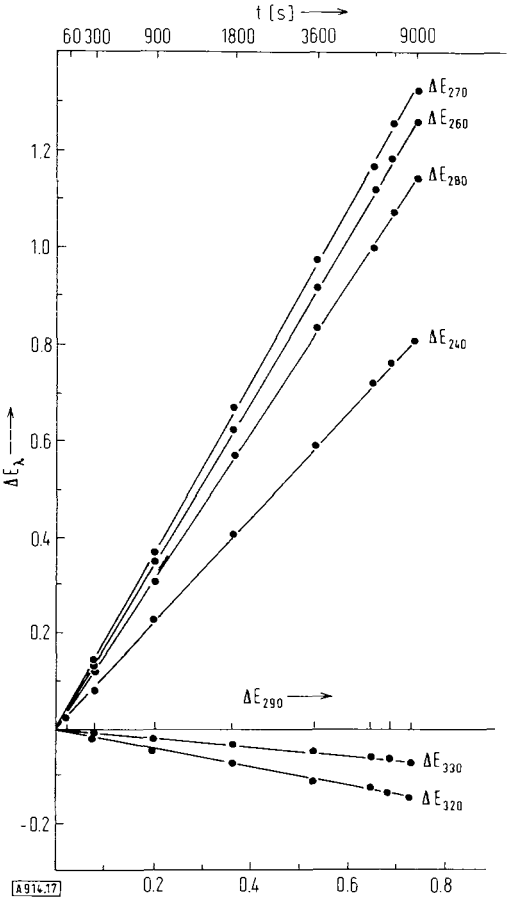

Fig 17. Linear ED diagram for the family of curves in Fig 15.

product from 6-phenyl-6-methylcyclohexa-2,4-dienone, we shall first discuss spectroscopic information on the kinetics of the light-induced ring cleavage.

When a solution of 6-phenyl-6-methylcyclohexa-2,4-dienone in methylcyclohexane/isopentane to which cyclohexylamine has been added[70] is irradiated with 365 nm light, one obtains a family of curves (Fig. 15) that intersect at an isosbestic point having the indicated characteristics. The picture changes when 313 nm light is used instead; no isosbestic point is now found (Fig. 16). The difference between the two figures may not be very impressive; it becomes more distinct and instructive when one makes use of the ED and EDQ diagrams mentioned earlier (see Figs. 5 and 6).

The family of curves having an isosbestic point (Fig. 15) is associated with the linear ED diagram of Figure 17. Irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone with 365 nm light in the presence of cyclohexylamine thus leads to a spectroscopically simple photoreaction. The conditions of the steady state are satisfied; apart from reactant and product, no other reaction participant can be detected spectroscopically.

The nonlinear ED diagram of Figure 18 was found for the irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone with 313 nm light in the presence of cyclohexylamine, and corresponds to the family of curves with no isosbestic point (Fig. 16). Since this is a spectroscopically complex photoreaction, the number of spectroscopically detectable

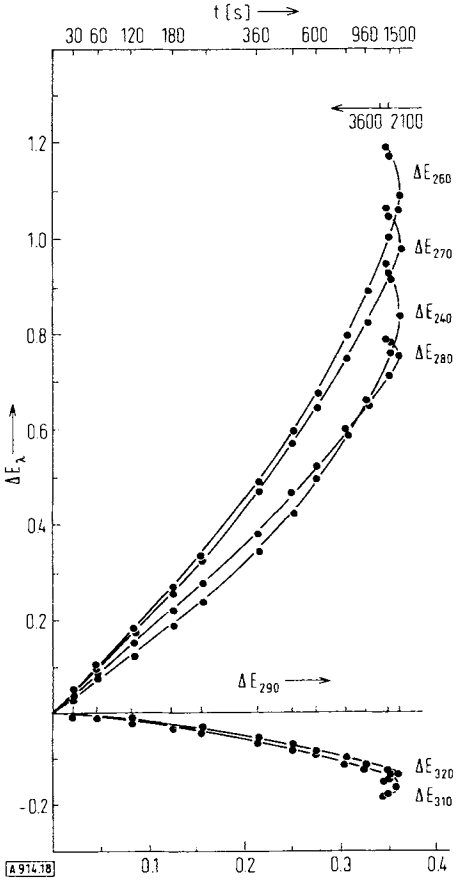

Fig. 18. Nonlinear ED diagram for the family of curves in Fig. 16.

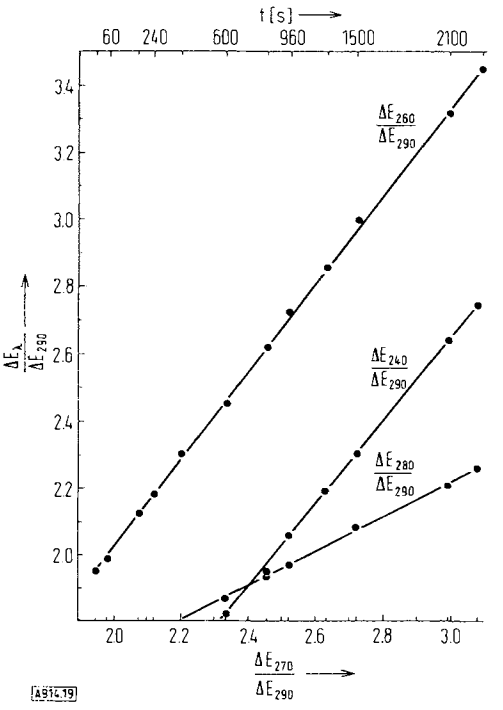

Fig. 19. Linear EDQ diagram for the family of curves in Fig. 16.

reaction steps remains to be established. The linear EDQ diagram in Figure 19 shows that two different reaction steps can now be detected spectroscopically. The result of the reaction analysis is supplemented by that of the product analysis.

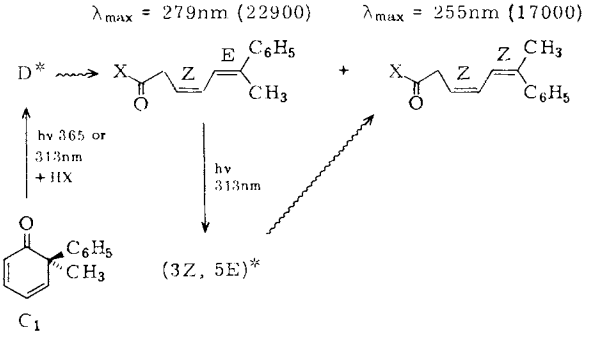

Fig. 20. Information on the constitution, stereochemistry, and wavelength dependence of the irradiation product obtained from 6-phenyl-6-methylcyclohexa-2,4-dienone at room temperature and in the presence of protonic nucleophiles.

Irradiation of the 2,4-dienone in question with 365 nm light[70] leads, by a reaction that has been shown to be spectroscopically simple, to a mixed product; among its components, the stereoisomers with *Z* orientation of the 3,4 double bond occur in a ratio of 1:1.8 (see Fig. 20). Irradiation with 313 nm light, on the other hand, leads in a spectroscopically complex reaction to a single product with 3*Z*, 5*Z* arrangement of the CC double bonds. It seems reasonable to assume that in the product, which is primarily binary in both cases, the component that absorbs at longer wavelengths is converted by secondary photoiso-

merization into the component that absorbs at shorter wavelengths by 313 nm light, but not by 365 nm light. This assumption can be confirmed by separate investigations on the two stereoisomers.

What do we know about the dienylketene transient? Under normal conditions it cannot be detected by UV, IR, or NMR spectroscopy in any of the cases investigated, even in the absence of protonic nucleophiles. However, this negative result simply means that the dienylketene is not present in measurable concentrations, a fact that could well be explained by the assumed ability to recyclize (see Fig. 12). If the ring opening of linearly conjugated cyclohexadienones still takes place at low temperatures, low-temperature photolysis offers prospects for the conservation of the potential transient, and low-temperature spectroscopy for its detection and identification.

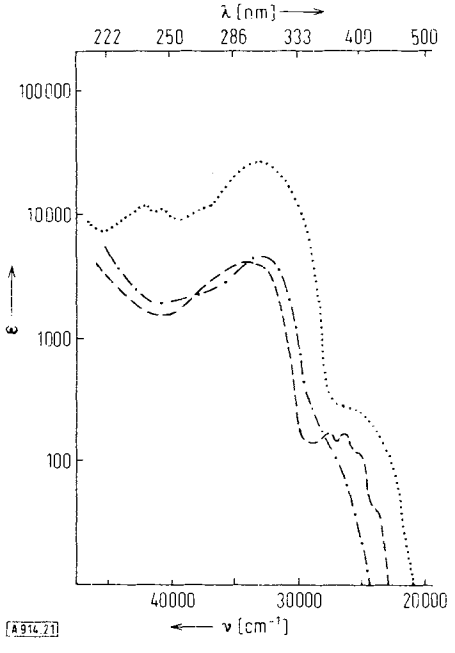

Fig. 21. Detection of the formation of a photoproduct from 6-phenyl-6-methylcyclohexa-2,4-dienone at −189 °C in methylcyclohexane/isopentane (1 : 4) with 365 nm light by low-temperature electronic spectroscopy. (– – –) spectrum of the reactant at room temperature; (–·–·–) spectrum of the reactant at −189 °C; (·····) spectrum of the photoproduct at −189 °C.

Figure 21 shows the electronic absorption spectrum of 6-phenyl-6-methylcyclohexa-2,4-dienone in methylcyclohexane/isopentane at −189 °C, as well as the room-temperature spectrum. A comparison of the spectra shows that lowering the temperature in the low-polarity medium is equivalent in its effect to the use of ethanol instead of saturated hydrocarbons at room temperature (see Fig. 10)[*].

Exposure of the glass specimen to 365 nm light[74] causes a spectroscopically detectable reaction, at the end of which the third absorption curve in Figure 21 is found.

[*] It is know [73] that lowering the temperature leads to an increase in the density and in the dispersion forces of the system (red shift) and to a decrease in the Boltzmann distribution of higher vibrational levels (blue shift).

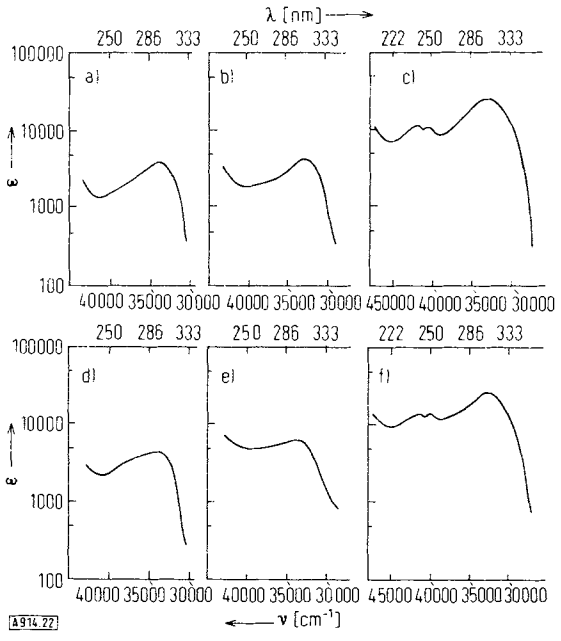

Fig 22. Detection of the thermally induced regeneration of 6-phenyl-6-methylcyclohexa-2,4-dienone from the corresponding photoproduct (which is kinetically stable at −189 °C) in methylcyclohexane/isopentane (1 : 4) by electronic spectroscopy; for explanation of the partial spectra see text.

Figure 22 shows parts of the spectra (a) at room temperature, (b) at −189 °C, and (c) after irradiation at −189 °C. If the irradiation product is then warmed to room temperature one obtains d, and subsequent recooling to −189 °C leads to curve e, which changes into curve f on renewed irradiation of the sample. This indicates formation of a photoproduct that is kinetically stable at low temperature, but reverts almost quantitatively[*] into the original reactant at room temperature.

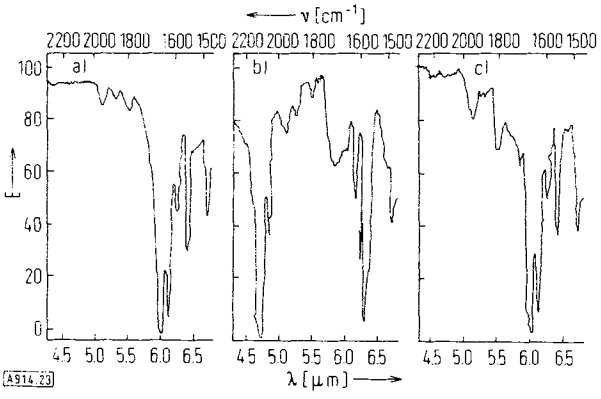

Fig. 23. Detection of the ketenic nature and of the thermally reversible formation of the photoproduct by low-temperature IR spectroscopy; for explanation of the partial spectra see text.

Following the reaction by low-temperature IR spectroscopy[74] indicates that the photoproduct is a ketene. The partial room-temperature IR spectrum of 6-phenyl-6-methylcyclohexa-2,4-dienone in chloroform shows the

[*] Comparison of extinctions shows 92% reversion to the original reactant.

absorption of the conjugated unsaturated carbonyl system (Fig. 23a). After cooling to −63 °C and exposure to light from which wavelengths below 340 nm have been filtered one obtains the partial spectrum b. The carbonyl band has at least largely disappeared, and a new absorption characteristic of the ketene group appears at 2120 cm^{-1}. The initial situation is substantially restored (c) if the irradiated sample is warmed to room temperature.

After the observation that a *seco*-isomeric dienylketene is related to the *cyclo*-isomeric cyclohexa-2,4-dienone by thermally reversible photoisomerization[*], it should be remembered that two ring cleavage products are formed together on irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone with 365 nm light in the presence of a protonic nucleophile (see Fig. 20). The simplest interpretation would of course be that these two components of the product have two stereoisomeric dienylketenes as precursors. The spectra discussed so far give no information on this point; however, such information is provided by the NMR spectra recorded at about −60 °C in deuteriochloroform[74].

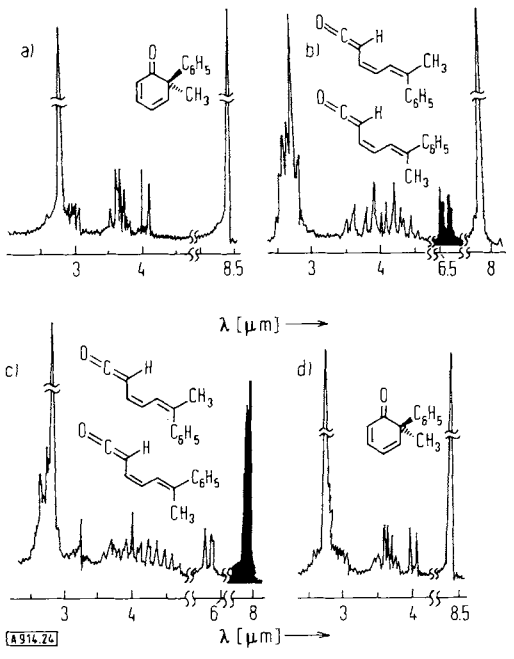

Fig. 24. Detection of the existence and of the thermally induced *seco/cyclo* isomerization of two stereoisomeric dienylketenes as photoproducts from 6-phenyl-6-methylcyclohexa-2,4-dienone by low-temperature NMR spectroscopy; for explanation of the partial spectra see text.

In addition to the proton resonance signals of the reactant at room temperature (a), Figure 24 shows the absorption of the photoproduct obtained at a low temperature (b). The two overlapping doublets[**] observed in the aldoketene proton region constitute evidence in favor of a mixture of two stereoisomers. On the other hand, the presence of only one methyl proton singlet contradicts the above conclusion, unless this singlet occurs by accidental coincidence of two signals. Justification of the latter assumption is provided by the spectrum obtained in the presence of 25% of deuteriobenzene (c). While the two doublets of the aldoketene protons have now moved closer together, the methyl proton signal is clearly split. In this case too, the initial spectrum is restored when the irradiated solution is warmed to room temperature (d).

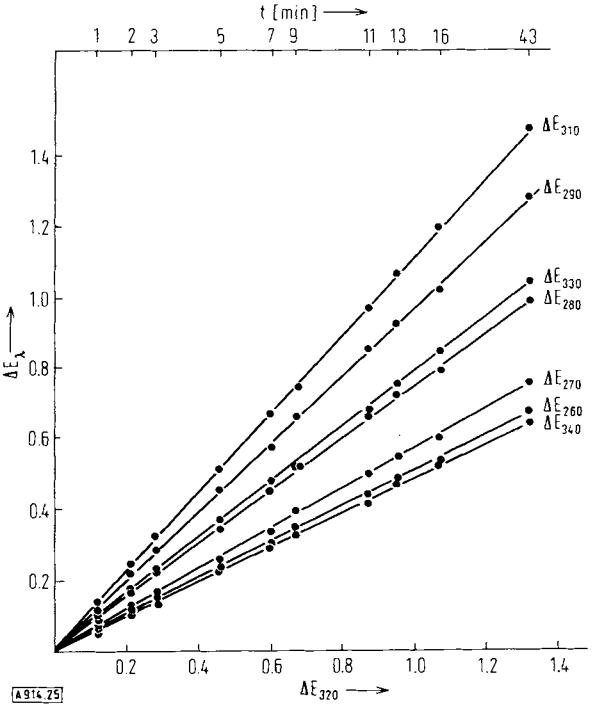

Fig. 25. Linear ED diagram corresponding to the conditions of the low-temperature NMR spectroscopic measurements (see Fig. 24).

The linear ED diagram (see Fig. 25) corresponding to the conditions of the low-temperature NMR measurements rules out the possibility that the binary transient was formed by subsequent photoisomerization of a single original dienylketene.

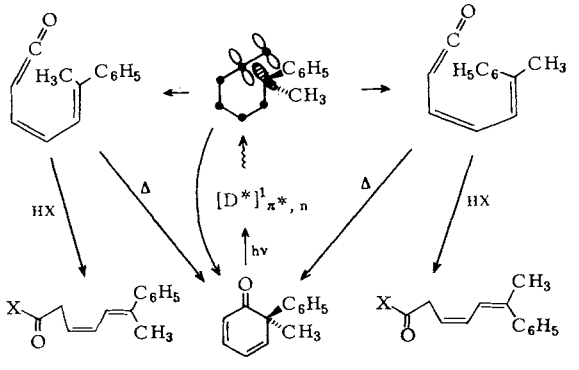

Fig. 26. Interpretation of the results of the structure-oriented product and transient analysis and of the formal kinetic analysis of the reaction course for the UV irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone.

[*] Following our report that we had detected the thermally reversible photoisomerization of linearly conjugated cyclohexadienones to dienylketenes by low-temperature UV and IR spectroscopy [75], similar investigations were reported from other laboratories: for UV spectroscopic studies see [69, 76], and for IR studies see [76—79].

[**] One doublet is shown *e.g.* by the stereochemically less complex dienylketene from 6,6-dimethylcyclohexa-2,4-dienone. A report on NMR spectra of aldoketenes at −80 °C was recently published [80]. For a discussion of the NMR spectra of cyclohexa-2,4-dienones see [81].

The pieces of information obtained fit together to give the model case of a thermally reversible photoisomerization system (see Fig. 26). In the presence of cyclohexylamine, 6-phenyl-6-methylcyclohexa-2,4-dienone is converted by 365 nm light in a partly stereoselective reaction into a mixture of two stereoisomeric amides. These are derived from the two corresponding dienylketenes, which are formed side by side during ring cleavage.

Since the components of the transient undergo unimolecular recyclization to the reactant[*] and/or bimolecular reaction to form the acid derivatives, the product composition is expected to be influenced by the nucleophilic strength and by the concentration of the addend HX[83]. Complete suppression of thermal recyclization of the two dienylketenes requires adequate nucleophilicity and corresponding minimum concentration of HX.

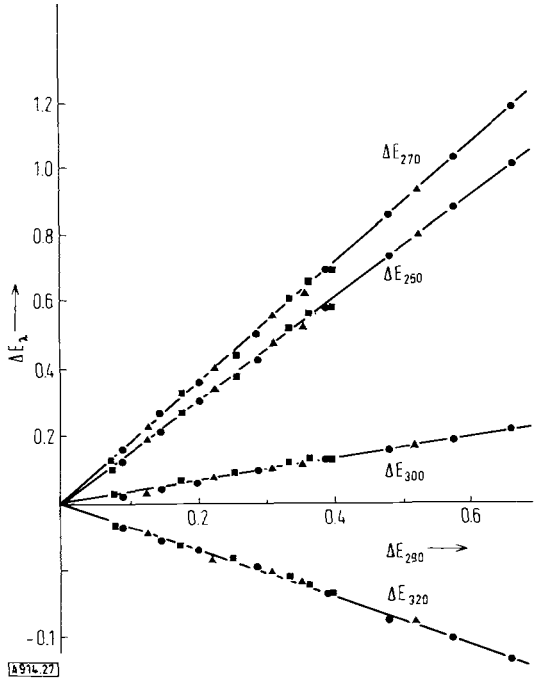

Fig. 27. Linear ED diagram with concentration-invariant lines for the irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone in ether/isopentane (1:1) containing cyclohexylamine at 25 °C with 365 nm light. Cyclohexylamine content: 0.0730 mol/l; • 0.135 mol/l; 0.173 mol/l.

The linear ED diagram of the light-induced amide formation in ether/isopentane at 25 °C (see Fig. 27) shows that the experimental points obtained at various concentrations and for a given wavelength lie on the same straight line in the concentration range indicated. Since the components of the reaction product differ in their absorption at the various wavelengths (see Fig. 20), failure of the straight lines to vary with concentration of HX means that the product composition is independent of this concentration. In the present case, therefore, the concentration exceeds the critical limit, which is specific for each nucleophile, and above which every dienylketene molecule is converted into the amide.

With the much weaker nucleophile ethanol, the slope of the straight lines varies with the nucleophile concentration in the same concentration range as in the previous case (see Fig. 28). The gas-chromatographic study confirms that the relative weights of the ester components in the reaction product are partly determined by the ethanol concentration.

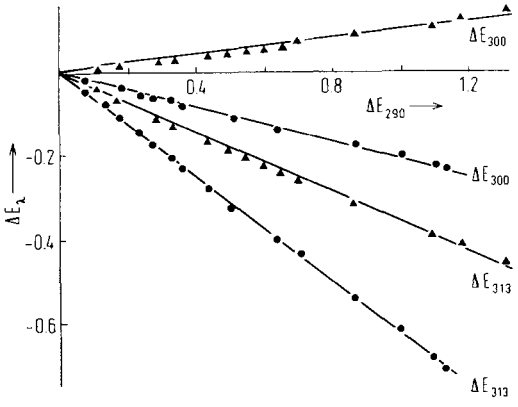

Fig. 28. Linear ED diagram with concentration-dependent lines for the irradiation of 6-phenyl-6-methylcyclohexa-2,4-dienone in ether/isopentane (1:1) containing ethanol at 25 °C with 365 nm light. Ethanol content: ▲ 0.0805 mol/l; • 0.171 mol/l.

Under conditions ensuring conversion of every transient molecule into the acid derivative, the quantum yield, both for 365 nm and for 313 nm light (!), reaches a maximum value of 0.55[83]. This value is reached at relatively low concentrations with cyclohexylamine, but only at very high concentrations with ethanol. What happens to the other 45% of the energy absorbed, which is not available for ring cleavage in any circumstances?

Since the electronically excited dienone does not emit either at room temperature or at the boiling point of nitrogen[84], the only possible explanation for the deficit is radiationless deactivation. This might, in part, be accounted for in a structurally reasonable manner, the electronically excited ketone undergoing a so-called α-cleavage[*] and the resulting bifunctional species being converted partly into the dienylketenes and partly back into the dienone. An optically active reactant, the racemization of which could provide the answer, was hitherto unavailable. The existence of the bifunctional species would in any case be consistent with the fact that the two stereoisomeric dienylketenes occur together.

What are the electronic configuration and the multiplicity of the photoreactive state of the light-induced *cyclo/seco* isomerization? Does it possess π*,n character, as assumed, and is it singlet and/or triplet in nature? The absence of any emission[84] rules out a source of information that

[*] The half-life for the dienylketene corresponding to 6-phenyl-6-methylcyclohexa-2,4-dienone is 95 min at −15.4 °C; for further data see [74]. Alkyl substituents of the dienone chromophore decrease the half-life of the corresponding dienylketenes while substituents with n or π electrons at C-6 increase it [82] (see also [76]).

[*] π*,n-Excited ketones in which at least one of the two C atoms adjacent to the carbonyl chromophore carries four ligands generally undergo homolysis of the bond between the C atom specified and that of the carbonyl group; see also "Norrish type I cleavage" *e.g.* in [85]. Concerning the problem of "biradicals" see [86—89].

would otherwise be important. The photochemical formation of the acid derivative cannot be sensitized by triplet-excited benzophenone (or by derivatives of benzophenone)[90][*], and piperylene, a common ketone triplet quencher[94–96], has practically no effect on the quantum yield[83]; the former observation provides no clear-cut answer to the questions raised, but the second definitely rules out the participation of relatively long-lived dienone triplets.

Finally, the fact that the molecular environment affects not only the shape of the electronic absorption spectra of the cyclohexa-2,4-dienones (see Section 4.3), but also the nature of the resulting photoproduct (see Section 5), can be used as a pointer to the electronic configuration of the photoreactive state involved. In a medium favoring the spectroscopic π^*,n excited state energetically over the π^*,π excited state, the light-induced *cyclo/seco* isomerization discussed leads, irrespective of the wavelength of the incident light (365 or 313 nm), to the dienylketene transient. On the other hand, under conditions that decrease the difference between the spectroscopic excited states, or even reverse their order, a reaction type that has not yet been mentioned occurs. This is the photoisomerization of linearly conjugated cyclohexadienones to bicyclo[3.1.0]hexenones (see Fig. 29)[79, 97–104][**].

Though a correlation of spectroscopic properties of the reactant with the nature of the photoproduct is problematic, since the spectroscopic excited states reached on absorption are not necessarily the same as the product-determining photoreactive excited states, the characteristics of the reactions occurring indicate a specific electronic configuration of the photoreactive state in question. As was mentioned earlier, α cleavage is characteristic of π^*,n excited ketones with at least one α-C atom having a coordination number of 4; the intramolecular cycloaddition to form bicyclo[3.1.0]hexenones is typical of π^*,π excited linearly conjugated cyclohexadienones[***].

5. Photoisomerization of Linearly Conjugated Cyclohexadienones to Bicyclo[3.1.0]hexenones

Hart et al.[97–104] gave a powerful boost to the chemistry of electronically excited cyclohexa-2,4-dienones with their observation that, under certain conditions, bicyclo[3.1.0]-hexenones are photoproducts of linearly conjugated cyclohexadienones. The explanation[107] that the direct photoisomerization takes place from the π^*,π excited reactant (see Fig. 29) raises the question of the conditions under which the photoreactive π^*,π excited state can be reached. The solvent dependence of the absorption spectra (see Section 4.3) suggests the use of an alcoholic solvent; experience shows that trifluoroethanol should be particularly suitable as a polar solvent, while silica gel should prove useful as a polar adsorbent[*][107].

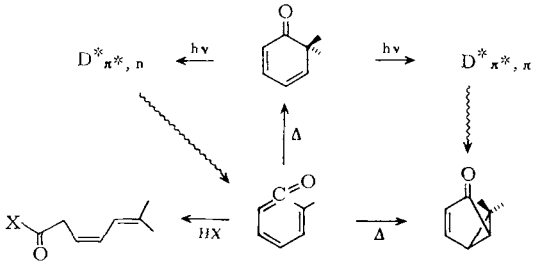

Fig. 29. The different paths of the photoisomerization of linearly conjugated cyclohexadienones. Elaboration of the scheme in Fig. 12.

The effectiveness of these perturbing factors on the relative positions of the π^*,π and π^*,n excited states (see Fig. 11) requires that in the unperturbed case (in the gas phase or in weakly polar hydrocarbons) the two excited states are not so far apart as to rule out the necessary regrouping. The difference between the π^*,π and π^*,n absorption regions depends on the substitution of the dienone chromophore. Figure 30 shows the electronic spectra of three linearly conjugated cyclohexadienones, measured in *n*-heptane at room temperature. The bathochromic shift

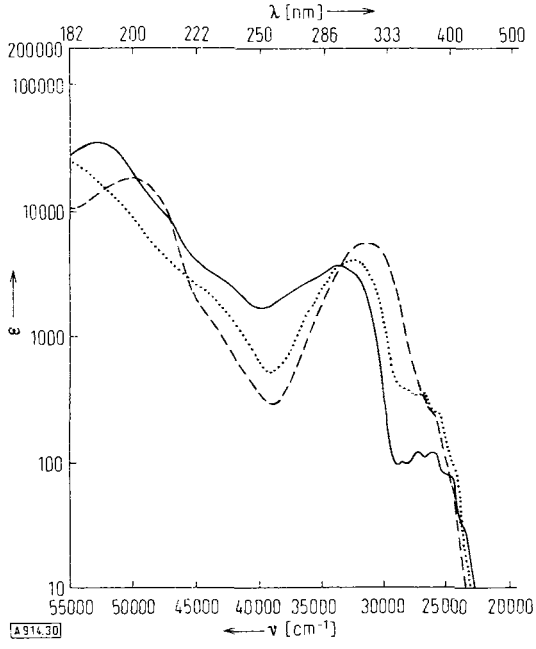

Fig. 30. Electronic absorption spectra of several cyclohexa-2,4-dienones at room temperature in *n*-heptane; 6-phenyl-6-methylcyclohexa-2,4-dienone (———); 6-acetoxy-2,4,6-trimethylcyclohexa-2,4-dienone (·····), 2,3,4,5,6,6-hexamethylcyclohexa-2,4-dienone (– – –).

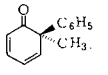
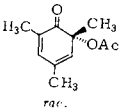
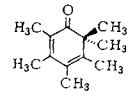
[*] For a discussion of sensitized photoreactions see [91–93].







[**] Detailed investigations (see Section 5) show that bicyclo[3.1.0]-hexenones are formed directly from π^*,π-excited cyclohexa-2,4-dienones, and under certain conditions they are also formed from dienylketenes by intramolecular cycloaddition. Both isomerizations of the *seco* isomer, *i.e.* the recyclization to the linearly conjugated cyclohexadienone are symmetry allowed as one-step reactions in the electronic ground state.

[***] This is shown by linearly conjugated methylenecyclohexadienes, where π^*,n excitation is of course impossible; these compounds photoisomerize stereospecifically to form conjugated methylenebicyclo[3.1.0]hexene derivatives [105, 106].

[*] Concerning the spectroscopy and photochemistry of adsorbed organic compounds see [108].

Table 1. Summary of conditions and products of the photoreactions of cyclohexa-2,4-dienones.
Reaction conditions:
1. Irradiation at room temperature without (additional) protonic nucleophile
2. Irradiation at room temperature with (additional) protonic nucleophile
3. Low-temperature spectroscopic information on the transient obtained at low temperatures
4. Spectroscopic or gas-chromatographic information on the photoproduct obtained by irradiation at low temperatures followed by warming to room temperature.

Photoproducts:
A: Cyclohexa-2,4-dienone
B: Bicyclo[3.1.0]hexenone
C: Cyclohexa-2,5-dienone
D: Dienylketene
E: Ester of carboxylic acid
F: *N*-Cyclohexylamide of carboxylic acid.

Cyclohexa-2,4-dienone	Photoproduct obtained under particular reaction conditions Φ = quantum yield	Medium
 *rac.*	1. A; Φ = 0.014 [a] 2. (Cyclohexylamine): two F [70], Φ = 0.58 (365 nm, 25 °C) [b] 3. Two D [74] 4. A (92%); see Figs. 22–24	MCl [c] or EI [d]

	1. Three E; Φ = 0.21 (methanol; 313 nm; 25 °C) [109] 2. (Cyclohexylamine) = two F [h]; Φ = 0.53 (365 nm; 20 °C) [109] 3. Two D [109] 4. A + three E [109]	CH_3OH, C_2H_5OH or EPA [f]
	1. A + B + C [109]; Φ = 0.32 (313 nm; 20 °C); Φ = 0.32 (365 nm; 20 °C) [109] 2. (Cyclohexylamine): A + B + two F + C [109]; Φ = 0.42 (313 nm; 20 °C); Φ = 0.40 (365 nm; 20 °C) [109] 3. Two D + B + C [109] 4. A + B + C [109]	CF_3CH_2OH
	1. A [109], Φ = 0.007 (EI [d]; 365 nm; 25 °C) [a] 2. (Cyclohexylamine): F [79] 3. D [79, 82] 4. A + E [79, 82]	MCl [c] or EI [d]
	1. A + B [79, 109]; Φ = 0.41 (ethanol; 313 nm; 25 °C) [109]	CH_3OH or C_2H_5OH

[a] Slow, irreversible degradation of the reactant.
[b] 0.77 mol/l of cyclohexylamine.
[c] Methylcyclohexane/isopentane = 4:1.
[d] Ether/isopentane = 1:1.
[e] The quantum yield, which is described as independent of the wavelength [34], is slightly influenced by the energy of the incident light.
[f] Ether/isopentane/ethanol = 5:5:2.
[g] On prolonged exposure to light in the absence of protonic nucleophiles, or in the presence of protonic nucleophiles whose concentration and/or nucleophilic strength are too low to allow complete trapping of the dienylketene transients, phenols are formed [64]. Another possible reaction of electronically excited cyclohexa-2,4-dienones, which was observed *e.g.* for 1,1-disubstituted 2(1*H*)-naphthalenones, is cycloaddition to give dimeric cyclobutane derivatives [66].
[h] The two stereoisomeric *N*-cyclohexylamides are formed with an extremely unequal weight distribution [109].

of the π^*,π absorption region due to methyl substituents and the resulting shift of the π^*,π excited state toward the π^*,n state are clearly to be seen. Table 1 shows the effect of varying conditions on the photoproducts from these three cyclohexa-2,4-dienones[109, 110].

6-Phenyl-6-methylcyclohexa-2,4-dienone does not give the corresponding stereoisomeric bicyclo[3.1.0]hexenones under any of these conditions. 6-Acetoxy-2,4,6-trimethylcyclohexa-2,4-dienone photoisomerizes either to dienylketenes (for detection by low-temperature spectroscopy see[35]) and their further reaction products (original reactant or acid derivative; see footnote [g] in the Table) or directly to the corresponding bicyclo[3.1.0]hexenone derivatives. Under nearly all the conditions indicated, 2,3,4,5,6,6-hexamethylcyclohexa-2,4-dienone gives the bicyclo[3.1.0]hexenone, irrespective of whether the dienylketene occurs as an intermediate or not (for detection of the transient by low-temperature spectroscopy see Figs. 31 and 32, and[79]).

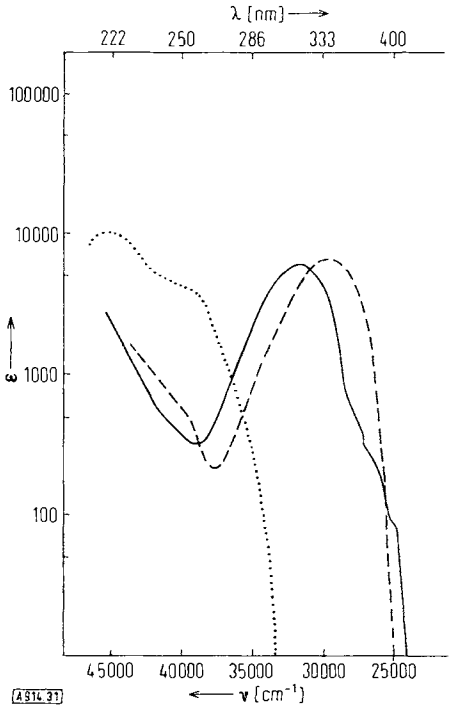

Fig. 31. Detection of the formation of a photoproduct from 2,3,4,5,6,6-hexamethylcyclohexa-2,4-dienone at −189 °C in methylcyclohexane/isopentane (1:4) with 365 nm light by low-temperature electronic spectroscopy. (———) spectrum of the reactant at room temperature, (– – –) spectrum of the reactant at −189 °C, (·····) spectrum of the photoproduct.

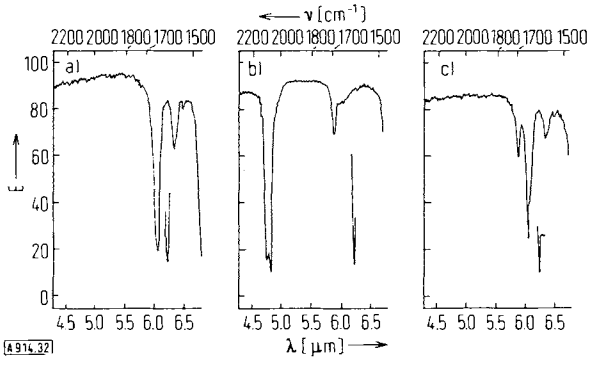

Fig. 32. Detection of the ketenic nature of the photoproduct from 2,3,4,5,6,6-hexamethylcyclohexa-2,4-dienone (which is kinetically unstable at room temperature) by low-temperature IR spectroscopy. a) Partial spectrum of the reactant at room temperature in paraffin; b) after irradiation with light of wavelengths >340 nm at −155 °C; c) after subsequent warming to room temperature.

Since bicyclo[3.1.0]hexenones can be formed directly from π^*,π excited cyclohexa-2,4-dienones and/or from π^*,n excited cyclohexa-2,4-dienones *via* intermediate dienylketenes (see Fig. 29), the nature of the product isolated is not a reliable guide to its mode of formation. However, a definite answer to the question whether dienylketenes occur as short-lived transients in the photoisomerization of linearly conjugated cyclohexadienones can be obtained by low-temperature spectroscopy.

I am indebted to Prof. Dr. H. H. Perkampus, Dr. B. Bronstert, P. Michaelis, Dr. G. Prescher, Dr. D. Egert, Dr. M. Hintzmann, Dr. P. Jürges, A. Syldatk, K. Schmieder, Dr. U. Krüger, and H. Appelt for suggestions and active assistance. The investigations were generously supported by Farbwerke Hoechst AG, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie and assisted by research grants from the State of Lower Saxony. B. B., D. E., P. J., and K. Sch. were temporarily stipendiaries of Schering AG. I am very grateful to the institutions mentioned.

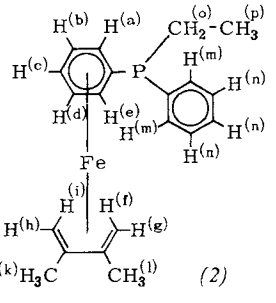
[(η-Phenyl)phenylethylphosphane](η-2,3-dimethylbutadiene)iron(0), A Phosphane Complex without Coordinated Phosphorus

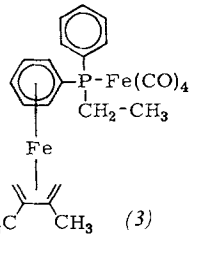
By *Ernst Koerner von Gustorf, Ingrid Fischler, Johannes Leitich,* and *Herbert Dreeskamp*[*]

In our systematic studies of the photochemistry of transition metal π-complexes[1,2] we have now turned our attention to complexes of molecular nitrogen. We have turned to an observation by *Sacco et al.*, who report that solid $[(C_6H_5)_2PC_2H_5]_3FeH_2N_2$ *(1)*[3] loses H_2 reversibly in sunlight and is converted[4] into



$HFe[C_6H_4P(C_6H_5)C_2H_5][N_2][C_2H_5P(C_6H_5)_2]_2$

Solid *(1)* exhibits strong photochromism: In daylight it changes color from yellow-orange to brown within a few minutes. After a few days in the dark, it shows its original color again. According to remission measurements this process is about six times faster under 60 at of N_2 than under argon. Therefore, it can be assumed to involve primary loss of N_2 rather than that of H_2. If this is so then the coordinatively unsaturated intermediate ought, as a derivative of iron hydride, to be capable of hydrogenating unsaturated hydrocarbons[5]. We have therefore irradiated solutions of *(1)* in benzene in the presence of methyl acrylate or 2,3-dimethylbutadiene. In the former case 60 to 65% propionate, 40 to 35% H_2, and the theoretical amount of N_2 are formed, in the latter 40 to 50% 2,3-dimethyl-2-butene, 60—50% H_2, and, once again, a quantitative amount of N_2. We consider these findings as evidence that electronic excitation of *(1)* in the region of the absorption maximum at 24600 cm^{-1} leads, with primary loss of N_2, to formation of $[(C_6H_5)_2PC_2H_5]_3FeH_2$, which acts as hydrogenating agent.



On working up the products of the photoreaction of *(1)* with 2,3-dimethylbutadiene we were able to isolate an orange colored substance *(2)*, m.p. 43—46 °C, in yields of about 50%. According to elemental analysis and molecular weight determination the composition of *(2)* is $C_6H_{10}Fe[(C_6H_5)_2PC_2H_5]$. The mass spectrum shows the molecular ion (M) and fragment ions corresponding to $(M-C_6H_{10})$, $(M-C_6H_{10}-C_2H_4)$, and $(C_6H_5)_2PC_2H_5$. The ^{1}H-NMR spectrum[6] shows an intact, coordinated[2] 2,3-dimethylbutadiene system in an asymmetric environment: τ = 7.94 ppm (CH_3^k), 7.97 (CH_3^l), 8.63 (H^g), 8.71 (H^h), 10.63 (H^f), 10.68 (H^i); $J_{i,h}$ = 1.1 Hz; $J_{f,g}$ = 0.9 Hz; J_{allyl} can be estimated to be about 0.3 Hz. Of the aromatic protons of the coordinated $(C_6H_5)_2PC_2H_5$ only five are to be found (as two multiplets) in the same region as in the free phosphane[7]: τ = 2.32 ppm (H^m) and 2.85 (H^n). The remaining aromatic protons appear much further upfield: τ = 4.52 ppm (H^a), 4.87 (H^e), 5.33 (H^c), 5.68 (H^b), 5.84 (H^d)[8]. The protons of the ethyl group in *(2)* appear at τ = 7.85 ppm (H^o) and 8.77 (H^p) [$J_{o,p}$ = 7.6 Hz; $J_{o,P}$ = 0; $J_{p,P}$ = 17 Hz]. The chemical shifts show that a phenyl group of the phosphane is coordinated to the iron; according to the coupling constants this ring functions as a 6-electron donor. A stable 1,3-diene-arene-iron(0) complex must therefore be present for which there are several analogs, *e.g.* 1,3-cyclohexadiene-benzene-iron(0)[9] and butadiene-toluene-iron(0)[10], in which the aromatic protons appear at τ = 5.13 ppm (in C_6D_6) and τ = 4.8 ppm (in CD_3COCD_3). Our observation that a phenyl ring and not the phosphorus participates in the coordination of an aryl substituted phosphane must be ascribed to the high tendency of formation of diene-arene-Fe(0) complexes.

Further evidence that the phosphorus in *(2)* is not coordinated is provided by the following facts: The chemical shift[11] of ^{31}P in *(2)* with δ = 12.5 ppm is very similar to that in $(C_6H_5)_2PC_2H_5$ (12.0 ppm). As expected[12], on the other hand, we have found that δ = −66.3 ppm for $[(C_6H_5)_2PC_2H_5]Fe(CO)_4$ prepared photochemically from $Fe(CO)_5$. The values $J_{o,P} \approx 0$ and $J_{p,P}$ = 17 Hz for *(2)* are in complete agreement with those found for $(C_6H_5)_2PC_2H_5$[7], whereas the values for $[(C_6H_5)_2PC_2H_5]Fe(CO)_4$ are 9.5 and 19 Hz.

We have also been able to coordinate $Fe(CO)_4$ to the phosphorus of *(2)* to give the complex *(3)* by photochemical reaction with $Fe(CO)_5$; *(3)* [m.p. ≈ 60 °C (decomp.); ν_{CO} (in KBr): 2055, 1978, and 1940 cm^{-1}] was characterized by elemental analysis and its mass spectrum [*m/e* = 520 (M); 492 (M − CO); 436 (M − 3CO); 352 (M − $Fe(CO)_4$)]. ^{31}P in *(3)* is observed at δ = −69.3 ppm.

(2)

(3)

Coordination at an aromatic ring in bis(diphenylarsino)-methane and tri(*o*-tolyl)phosphane can also be achieved with Cr, Mo, and W[13].

Procedure for preparation of (2):

A solution of *(1)* (5.6 mmol) in benzene (100 ml) and 2,3-dimethylbutadiene (10 ml) was irradiated under argon in an immersion apparatus (filter, λ > 370 nm) at 20 °C with a high-pressure mercury-vapor lamp (Philips HPK 125 W) until evolution of gas was complete (*ca.* 90 min). After evaporation of the solvent from the reaction mixture, the liberated phosphane was removed by molecular

433 Mülheim/Ruhr, Stiftstrasse 34—36 (Germany)

distillation under high vacuum at room temperature (time required *ca.* 48 h). Double recrystallization of the residue from pentane afforded *(2)* in 50 to 55% yield (based on *(1)*).

For conversion of *(2)* into *(3)* a solution of *(2)* (2.3 mmol) and $Fe(CO)_5$ (3 ml) in ether (50 ml) was irradiated at −40 °C until evolution of 1 mol CO/mol *(2)*. After evaporation of the ether and addition of pentane (10 ml) *(3)* precipitates almost quantitatively.

Aliphatic 1,2,3-Triketones by Ozonolysis of Dialkyl-1,4-benzoquinones[**]

By *Gottfried Schill, Enno Logemann*, and *Clemens Zürcher*[*]

The ozonolysis of 1,4-benzoquinone and its derivatives is not uniform[1–4]. 1,2,3-Tricarbonyl compounds, which ought to be formed by ozonolytic cleavage of the two double bonds of the quinonoid nucleus have been isolated in only one case: *Bernatek*[3] obtained small yields of mesoxaldialdehyde by ozonolysis of unsubstituted 1,4-benzoquinone.

We have found that ozonolysis of 3,5-didodecyl-2,6-dihydroxy-1,4-benzoquinone *(1)*, 3,5-didodecyl-2-hydroxy-1,4-benzoquinone *(2)*, and 2,6-didodecyl-1,4-benzoquinone *(3)*, in ethyl acetate/methanol (10:1) below 0 °C followed by reduction of the ozonide with dimethyl sulfide[5] leads to heptacosa-13,14,15-trione *(4)*. Repeated recrystallization of the crude product from petroleum ether

(60—70 °C) or CCl_4, or chromatography on silica gel with benzene/glacial acetic acid (8:2) afforded yellow crystals of *(4)* (m. p. 71.5 to 73 °C). The structure of *(4)* was confirmed by elemental analysis, IR and NMR spectra. The molecular ion occurs at $m/e = 422$. The base peak at $m/e = 197$ is assigned to the fragment $C_{12}H_{25}$—CO. Addition of water[6] to a solution of *(4)* in acetone afforded the colorless hydrate.

The triketone *(4)* could be reduced to the triol by treatment with sodium borohydride and converted *via* the bromides into *n*-heptacosane (m. p. 58.5 to 60.0 °C; Ref. [8]: 59.5 °C). Aliphatic 1,2,3-triketones were previously prepared from 1,3-diketones[6, 7].

degradation reaction with retention of the catenane structure to give the compounds *(5)* and *(6)*.

3,5-Dialkyl-2-hydroxy-1,4-benzoquinones can be converted by ozonolysis into 1,2,3-triketones[2]. In a similar fashion we have ozonized the catenane *(2)* in ethyl acetate at −40 °C in the presence of tetracyanoethylene[3]. Without isolation the tetraketone *(3)* was reduced with sodium borohydride to the tetraol *(4)*. The crude product *(4)* was treated at room temperature with hydrogen bromide in glacial acetic acid to give a mixture of the bromides and acetates. After hydrogenation of the mixture over Raney nickel the *O*-acetyl groups were saponified. The above treatment of *(4)*, *i.e.* reaction with hydrogen bromide, catalytic reduction, and hydrolysis, was carried out four times in order to ensure complete replacement of the hydroxyl groups by hydrogen. The catenane *(5)* was isolated in pure form [yield 24% based on *(1)*; m. p. 149.5 to 150.5 °C (one recrystallization from ethanol/methanol)] from the reaction mixture by chromatography on a silical-gel column with *n*-butyl acetate; its composition and structure were confirmed by elemental analysis, and NMR, IR, and mass spectra.

Hydrolysis of the *N*-acetyl group with hydrochloric acid in dioxane or with sulfuric acid in acetic acid afforded the catenane *(6)*, which was separated from small amounts of unreacted *(5)* by preparative thin-layer chromatography on silica gel with *n*-butyl acetate. One recrystallization from benzene/ethanol or *n*-butyl acetate provided colorless plates, having m. p. 191 to 194 °C (after previous sintering).

Compounds *(5)* and *(6)* are the first catenanes to be obtained in crystalline form from solution.

The mass spectrum of *(6)* shows the peak for the molecular ion at $m/e = 757$ (intensity 53%). The region from $m/e = 755$ to $m/e = 395$ is practically free of peaks (no peak with intensity greater than 0.2% of that of the base peak). A signal appears at $m/e = 392.4372$ (calc. 392.4382; intensity 1.6%) which originates from the 28-membered polymethylene ring of the catenane. The base peak at $m/e = 366.4085$ (calc. 366.4100) corresponds to the (M + 1)-ion of the aza-macrocycle of the catenane *(6)*. We explain its occurrence as resulting from hydrogen transfer within the catenane[4].

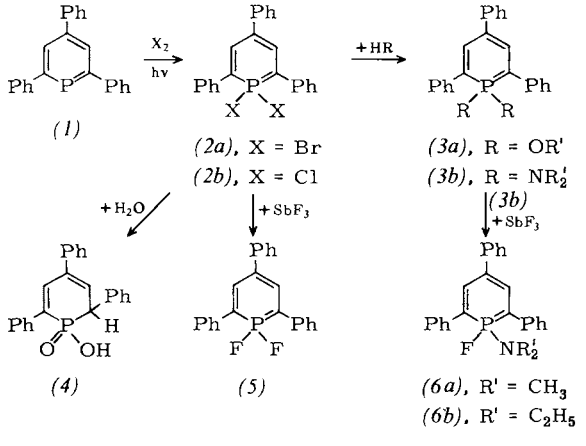
1,1-Dihalo-λ^5-phosphorins

By *Hartmut Kanter* and *Karl Dimroth*[*]



λ^3-Phosphorins bearing substituents in positions 2, 4, and 6 are readily oxidized to the radical cation[1]. Nucleophiles and radicals add to the phosphorus atom to give 1,1-disubstituted λ^5-phosphorins *(3)*[2]. According to *Mach*, prolonged action of an excess of bromine or chlorine on 2,4,6-tri-*tert*-butyl-λ^3-phosphorin leads to higher oxidation products[3].

We have now found that the dibromides and dichlorides, *(2a)* and *(2b)* respectively, can be synthesized by reaction of 2,4,6-triphenyl-λ^3-phosphorin with 1 mol. equiv. of bromine or chlorine in the presence of light. Whereas the dibromide *(2a)*, which is very readily soluble in all common inert solvents, has been obtained as a solid but not in crystalline form, the dichloride *(2b)* could be isolated as a yellow crystalline, analytically pure substance. Both compounds were characterized by their ^{1}H-NMR spectra (see below). They can also be prepared without the aid of light, *(2a)* from *(1)* with pyridinium perbromide, and *(2b)* from *(1)* with phosphorus pentachloride.

The high reactivities of the dihalides *(2a)* and *(2b)* open up numerous synthetic possibilities. Reaction of *(2a)* with alcohols or amines affords 1,1-dialkoxy- or bis(dialkyl-

355 Marburg, Lahnberge (Germany)

amino)-2,4,6-triphenyl-λ^5-phosphorins, which have already been obtained by another route[2]; reaction with water yields the likewise known cyclic phosphinic acids *(4)*[4]. Treatment with antimony trifluoride furnishes the 1,1-difluoro compound *(5)* as a yellow crystalline, chemically highly stable compound. Particular interest attaches to its ^{1}H-, ^{19}F-, and ^{31}P-NMR data (see below) on account of the bonding in the λ^5-phosphorin series.

We prepared the 1-dialkylamino-1-fluoro compounds *(6a)* and *(6b)* by nucleophilic displacement[5] from the bis(dialkylamino)-λ^5-phosphorins of type *(3b)* with antimony trifluoride.

1,1-Dibromo-2,4,6-triphenyl-λ^5-phosphorin (2a)

A solution of Br_2 (1 mmol) in CCl_4 (20 ml) is added dropwise over one hour to an irradiated (mercury arc lamp) solution of *(1)* (1 mmol) in anhydrous CCl_4 (25 ml) under a nitrogen atmosphere; irradiation is continued for another hour and the solvent then removed *in vacuo*, leaving a brown powder as residue (crude yield quantitative). ^{1}H-NMR in C_6D_6 (TMS internal standard): δ = 7.0–7.8 ppm (m/15 H); 7.47 ppm (d/2 H, J_{P-H} = 48 Hz). Treatment with alcohols immediately affords the strongly fluorescent 1,1-dialkoxy-2,4,6-triphenyl-λ^5-phosphorins *(3a)* (R' = = CH_3 or C_2H_5) in more than 50% yield.

1,1-Dichloro-2,4,6-triphenyl-λ^5-phosphorin (2b)

A stirred mixture of compound *(1)* (6 mmol) and PCl_5 (8 mmol) in CCl_4 (125 ml) is irradiated for 25 min with a mercury arc lamp. The residue left on evaporation of solvent gives analytically pure *(2b)* on recrystallization from a small volume of acetonitrile. Yield at least 55%, m.p. 100–103 °C. ^{1}H-NMR in C_6D_6 (TMS internal standard): δ = 7.1–7.8 ppm (m/15H); 7.6 ppm (d/2H; J_{P-H} = 50 Hz); ^{31}P-NMR in C_6D_6 (H_3PO_4 external reference): $\delta = -17.00$ ppm (t, $J_{P-H} = 50$ Hz).

1,1-Difluoro-2,4,6-triphenyl-λ^5-phosphorin (5)

Compound *(5)* results from *(2a)* or *(2b)* on 12 hours' stirring with an excess of SbF_3 in CCl_4 and evaporation of solvent. The residue is taken up in light petroleum (60 to 70 °C)/acetone (3 : 1), filtered over a silica gel column (activity 4), and concentrated; yellow crystals, m.p. 129—131 °C, analytically pure, 50—60% yield. ^{1}H-NMR in C_6D_6 (TMS internal standard): δ = 7.0—7.6 ppm (m/15H); 7.68 ppm (2t/2H, J_{P-H} = 46 Hz; J_{F-H} = 8 Hz); ^{19}F-NMR in C_6D_6 ($CFCl_3$ internal standard): $\delta = +47.02$ ppm (2t, J_{F-H}=8Hz; J_{P-F}=1040Hz); ^{31}P-NMR in C_6D_6 (H_3PO_4 external reference): $\delta = -73.0$ ppm (3t, J_{P-F}=1040Hz; J_{P-H}=46Hz).

1-Diethylamino-1-fluoro-2,4,6-triphenyl-λ^5-phosphorin (6b)

(6b) is obtained by 3 hours' refluxing of 1,1-bis(diethylamino)-2,4,6-triphenyl-λ^5-phosphorin (1 mmol) in anhydrous acetonitrile (40 ml) with SbF_3 (1.5 mmol) and trifluoroacetic acid (1.2 mmol) under N_2; yield 74%, m.p. 158—159 °C. The compound is also formed with BF_3-ether in the presence of nucleophiles. ^{1}H-NMR in C_6D_6 (TMS internal standard): δ=7.9 ppm (2d/2H; J_{P-H}= 37Hz; J_{F-H}=6Hz); 7.0—7.5 ppm (m/15H); 2.64 ppm (2q/4H, J_{H-H}=7Hz; J_{P-H}=11Hz) 0.47 ppm (t/6H; J_{H-H}= 7 Hz); ^{19}F-NMR in C_6D_6 ($CFCl_3$ internal standard): $\delta = +29.3$ ppm (J_{P-F} = 1020 Hz).

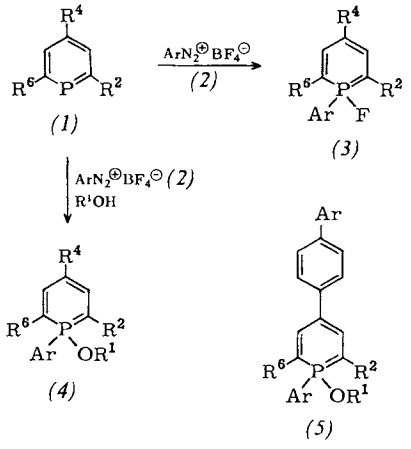
Reactions of λ^3-Phosphorins with Arenediazonium Salts to Give λ^5-Phosphorins



By *Ortwin Schaffer* and *Karl Dimroth*[*]

The ease of oxidation of 2,4,6-trisubstituted λ^3-phosphorins *(1)* to the radical cation[1] and the product's ability to add nucleophiles[2] and radicals[3] at the phosphorus prompted us to study their behavior towards arenediazonium tetrafluoroborates *(2)* in nonaqueous solution. Reaction proceeds surprisingly smoothly in dimethoxyethane with liberation of N_2 to give 1-aryl-1-fluoro-2,4,6-trisubstituted λ^5-phosphorins *(3)*. If the reaction is carried out in the presence of alcohols then 1-alkoxy-1-aryl-2,4,6-trisubstituted λ^5-phosphorins *(4)* result (see Table 1). The radical cation of λ^3-phosphorin can readily be detected by ESR spectroscopy. It is probably the first intermediate, formed by oxidation of λ^3-phosphorin by the arenediazonium ion and then giving 1,1-addition products with the aryl radical and the nucleophile (alcohol or $F^\ominus$ ion from the $BF_4^\ominus$ ion). The new synthesis is highly adaptable.

In the presence of an excess of 2-methyl-4-nitrobenzenediazonium tetrafluoroborate, λ^3-phosphorins bearing a phenyl group in position 4 also give small amounts (yields up to 5%) of doubly arylated λ^5-phosphorins *(5)*; they were also formed with evolution of nitrogen from *(4)* and the diazonium salt *(2)*, thus establishing the intermediacy of *(4)*. The course of the reaction resembles the

[a] Analytically pure substance, yield not optimized.
[b] Cyclohexyloxy.
[c] 2-Methyl-4-nitrophenyl.
[d] 2'-Methyl-4'-nitro-4-biphenylyl.

in place of the readily polarizable and oxidizable iodide. The composition of the new compounds was confirmed by elemental analyses and spectroscopic data. 1-Methoxy-1,2,4,6-tetraphenyl-λ^5-phosphorin has already been prepared by *Märkl et al.*[4] from 2,4,6-triphenylpyrylium tetrafluoroborate with phenylphosphane and methanol.

Compounds *(3a)* and *(3b)* appear to be of special interest since they number among the first 1-fluoro-λ^5-phosphorins[5]. For instance, *(3a)* gave the following NMR data in C_6D_6: ^{1}H-NMR (TMS internal standard): besides the multiplet of aromatic protons a quartet at $\delta = 8.01$ ppm (2H, $J_{H-P}=33$ Hz; $J_{F-H}=6$ Hz). ^{19}F-NMR ($CFCl_3$ internal standard): $\delta=25.6$ ppm (sextet, $J_{F-P}=1115$ Hz; $J_{F-H}=5.5$ Hz); ^{31}P-NMR (85% H_3PO_4 external reference): $\delta=48.98$ ppm (2m, $J_{F-P}=1113$ Hz).

1-Aryl-1-fluoro-2,4,6-trisubstituted λ^5-phosphorins (3)

Compound *(1)* (1 mmol) is dissolved in dry dimethoxyethane (20 ml). *(2)* (1 mmol) is then added portionwise to the stirred and cooled reaction mixture. The deeply colored fluoro-λ^5-phosphorins *(3)* formed with evolution of N_2 can be isolated by preparative layer chromatography with benzene/light petroleum (1 : 1) on silica gel, and recrystallized from methanol or ethanol.

Tetranitrosylchromium $[Cr(NO)_4]$[**]

By *Max Herberhold* and *Abbas Razavi*[*]

Attempts to prepare the binary nitrosylmetal compound, $Cr(NO)_4$, have so far failed[1]. This mononuclear complex is the last missing member in the isoelectronic series of uncharged, tetracoordinated carbonyl-nitrosyl complexes, the so-called pseudo-carbonylnickel series:

$$Ni(CO)_4 \quad Co(CO)_3NO \quad Fe(CO)_2(NO)_2 \quad Mn(CO)(NO)_3 \quad Cr(NO)_4$$

We have found that $Cr(NO)_4$ is formed when a slow stream of NO is drawn through an irradiated solution of $Cr(CO)_6$ in a hydrocarbon solvent (*n*-pentane, *n*-hexadecane, benzene). The reaction can be followed by IR spectroscopic measurement of the decrease in intensity of the C≡O stretching vibration of $Cr(CO)_6$ (mode F_{1u}, 1986 cm^{-1} in *n*-pentane). According to the IR spectra, the unknown

[*] Doz. Dr. M. Herberhold and Dipl.-Chem. A. Razavi

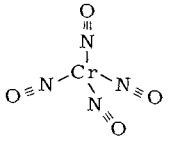
Technischen Universität
8 München 2, Arcisstrasse 21 (Germany)

[**] These investigations were supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



compound $Cr(CO)_3(NO)_2$, which could conceivably occur as an intermediate of the photoinduced nitrosylation, is *not* formed in noticeable amounts; furthermore, recarbonylation of the dissolved $Cr(NO)_4$ by CO gas cannot be achieved under the reaction conditions.

$Cr(NO)_4$ dissolves in hydrocarbons to give intense reddish brown solutions, which absorb over the whole range of the visible spectrum. In *n*-hexane solution, absorption maxima were recorded at $\approx$750 nm ($\log\varepsilon\approx1.85$), $\approx$555 ($\approx$2.80), 458 (3.29), and $\approx$290 (3.61); a further maximum occurs below 220 nm ($\log\varepsilon>4.7$).

Formulation of the new complex as "$Cr(NO)_4$" is supported by the following facts:

1. Satisfactory elemental analyses (Cr, N) have been obtained, even though the air-sensitivity and high volatility of the compound present considerable problems.—2. The complex is diamagnetic (^{1}H-NMR).—3. The highest peak in the mass spectrum corresponds to $m/e=172$, as would be expected for $Cr(NO)_4^+$; in addition, the mass spectrum contains peaks for all the fragments expected to occur by successive loss of NO ligands: $Cr(NO_3)^+$ (142), $Cr(NO)_2^+$ (112), $Cr(NO)^+$ (82), Cr^+ (52). All these fragment ions show the characteristic isotopic pattern of chromium.—4. The IR spectrum in the range 4000 to 800 cm^{-1} contains only one strong absorption (1721 cm^{-1} in *n*-pentane), which can be assigned to the asymmetric N≡O stretching vibration (mode F_2) in a tetrahedral complex[2]. Two additional bands appear at 650 and 496 cm^{-1} (in Nujol)[3].

We assume, on the basis of these finding, that the reddish brown complex of the composition $Cr(NO)_4$ is isoelectronic and isostructural with the colorless complex $Ni(CO)_4$. A tetrahedral molecule of this type possesses only four IR-active fundamentals, which belong to the triply degenerate representation F_2[2]; three bands ($\nu(N\equiv O)_{as}$, $\nu(Cr—NO)_{as}$, and $\delta(Cr—N—O)_{as}$) appear in our IR spectra, the fourth ($\delta(ON—Cr—NO)_{as}$) should lie below 100 cm^{-1}. The two vibrations $\nu(Cr—NO)_{as}$ and $\delta(Cr—N—O)_{as}$ are presumably strongly coupled, and the corresponding bands at 650 and 496 cm^{-1} ought to be considered as absorptions of mixed character. The comparatively high frequencies of these absorptions indicate a strong Cr→NO back bonding; similar IR frequencies (646 and 556 cm^{-1})[4] have been reported for the tetrahedral ion $[Fe(CO)_4]^{2-}$ (cf. Ref. [5]), which is again isoelectronic with the pseudocarbonylnickel series.

It is tempting to extrapolate the valence force constants $k(N\equiv O)$ of the carbonyl-nitrosyl complexes[6] $Co(CO)_3NO$ (14.6 mdyn/Å), $Fe(CO)_2(NO)_2$ (14.1), and $Mn(CO)(NO)_3$ (13.7) and to predict a $k(N\equiv O)$ value of *ca.* 13.2 mdyn/Å for $Cr(NO)_4$. However, just how problematic such an extrapolation can be is indicated by a comparison of the valence force constants $k(C\equiv O)$ of the same compounds: extrapolation of the $k(C\equiv O)$ values from the series $Mn(CO)(NO)_3$ (17.6 mdyn/Å), $Fe(CO)_2(NO)_2$ (17.1) and $Co(CO)_3NO$ (16.5) yields for the end member $Ni(CO)_4$ a value of *ca.* 15.9 mdyn/Å, which deviates considerably from the value of 17.4 mdyn/Å found experimentally[6].

From purely formalistic considerations the central metal in $Cr(NO)_4$ can be assigned an oxidation state of −IV if—as is usual—the nitrosyl ligand is considered as a NO^+ cation. Actually, the effective charge on the chromium should deviate very little from zero because of strong backbonding. In any case, $Cr(NO)_4$ is an interesting counterpart to the paramagnetic, tetracoordinated Cr^{+IV} complexes (such as *e.g.* $Cr[CH_2C(CH_3)_3]_4$[7], Cr[1-norbornyl]$_4$[8], $Cr[CH_2Si(CH_3)_3]_4$[9], $Cr(OR)_4$ (R = *tert*-alkyl[10,11] or $Si(C_2H_5)_3$[11]), and $Cr(NR_2)_4$ (NR_2 = dialkylamido)[12], to which a tetrahedral or pseudotetrahedral structure has also been ascribed. It can be assumed that a whole series of complexes of the general type $Cr(NO)_nL_{(4-n)}$ exists ($n=0$—4; L = univalent, anionic ligand without β hydrogen atoms, *e.g.* neopentyl, *tert*-alkyl, trialkylsilylmethyl, *tert*-alkoxy or dialkylamido). Of this series, both the end members ($Cr(NO)_4$ and CrL_4) and the mononitrosylchromium(III) complexes $Cr(NO)L_3$ (L = *e.g.* $N[CH(CH_3)_2]_2$, $N[Si(CH_3)_3]_2$, $OCH(CH_3)_2$, $OC(CH_3)_3$) are already known[13]; according to an X-ray structure analysis $Cr(NO)[N(Si(CH_3)_3)_2]_3$ has a pseudotetrahedral structure with a linear CrNO group[14].

The synthesis of transition metal-nitrosyl complexes by photoinduced nitrosylation of carbonylmetal compounds can be applied to other systems. Thus $Mn_2(CO)_{10}$ is converted stepwise into red $Mn(CO)_4NO$, green $Mn(CO)(NO)_3$, and finally into a new nitrosylmangenese complex, which is green and very volatile ($\nu(N\equiv O)$ 1666 cm^{-1} in tetrahydrofuran). Similarly, the know complexes $Fe(CO)_2(NO)_2$ and $(\pi\text{-}C_5H_5)V(CO)(NO)_2$[15] are formed when solutions of $Fe(CO)_5$ and $(\pi\text{-}C_5H_5)V(CO)_4$, respectively, are irradiated in solution and simultaneously treated with gaseous NO.

Experimental:

A stream of purified NO is passed through a solution of $Cr(CO)_6$ (220 mg; 1 mmol) in *n*-pentane (300 ml) which is irradiated with a high-pressure mercury arc (Hanovia L-450 W) until the strong IR absorption of $Cr(CO)_6$ has completely disappeared (*ca.* 2 hours). The intense reddish brown solution is filtered in a nitrogen atmosphere and evaporated at normal pressure to about 30 ml; the remaining solvent is removed in a high vacuum at −78 °C. The extremely volatile complex, $Cr(NO)_4$, can be isolated as a brownish black solid (m. p. 38—39 °C in a nitrogen-filled capillary) and purified by multiple sublimation at low temperature: final yield *ca.* 50% (80—90 mg).

Reaction of ClF_5 with OF_2: Preparation and Properties of Chlorine Oxide Trifluoride and the Existence of Chlorine Oxide Pentafluoride[1]

By *Klaus Züchner* and *Oskar Glemser*[*]

Irradiation of a gaseous mixture of ClF_5 and OF_2 in a quartz flask leads to formation of white crystalline $[ClOF_2]_2^+[SiF_6]^{2-}$, which melts under its own vapor pressure at 50.5 °C and dissociates into $ClOF_3$ and SiF_4, both of which can be detected in the gaseous phase by IR and mass spectrometry. Subsequent cooling leads to reformation of $[ClOF_2]_2^+[SiF_6]^{2-}$, which is also formed from $ClOF_3$ and SiF_4 at room temperature.

Chlorine oxide trifluoride $ClOF_3$ *(1)*, which was recently prepared *via* another route[2][**], was characterized by elemental analysis, mass, IR, Raman, and ^{19}F-NMR spectra[**]. Mass spectrum (rel. intensity in %): $^{37}ClOF_2^+$ (30), $^{35}ClOF_2^+$ (100); $^{37}ClF_2^+$ (0.8), $^{35}ClF_2^+$ (2.8); $^{37}ClOF^+$ (25.6), $^{35}ClOF^+$ (78.9); $^{37}ClO_2^+$ (1.1), $^{35}ClO_2^+$ (2.2); $^{37}ClF^+$ (2.6), $^{35}ClF^+$ (7.8); $^{37}ClO^+$ (11.1), $^{35}ClO^+$ (32.8); $H^{37}Cl^+$ (0.6), $^{37}Cl^+$ (2.8), $H^{35}Cl^+$ (2.4), $^{35}Cl^+$ (8.9); HF^+ (2.8), F^+ (2.2); O^+ (1.5).—^{19}F-NMR ($CFCl_3$ as external standard): $\delta_{ClF} - 253$ ppm. The vibration spectra are given in Table 1 along with a tentative assignment of the bands assuming C_s symmetry for the molecule. We are of the opinion that our assignment of the bands is more probable than that by *Bougon et al.* assuming C_{3v} symmetry.

We have studied the reactions of *(1)* both with Lewis acids and with Lewis bases. Reaction with AsF_5, SbF_5, and SiF_4 affords the white salts $[ClOF_2]^+[AsF_6]^-$, $[ClOF_2]^+[Sb_2F_{11}]^-$, and $[ClOF_2]_2^+[SiF_6]^{2-}$, the first two of which can also be prepared from $[ClOF_2]_2^+[SiF_6]^{2-}$ by reaction with AsF_5 and SbF_5 respectively at room temperature with removal of SiF_4. The Raman spectra of the salts containing the $[ClOF_2]^+$ ion are in complete agreement with those given in the literature[3]. The hexafluoroarsenate and the new hexafluorosilicate may be quoted as examples. Raman spectrum [cm^{-1}] of $[ClOF_2]^+$: $[ClOF_2]^+[AsF_6]^-$ (values in brackets: cf. Ref. [3]): ν_1 1335 (1332), ν_1 1325 (1321); ν_2 763 (760); ν_3 513 (511); ν_4 410 (408); ν_5 747 (725); ν_6 not observed. $[ClOF_2]_2^+[SiF_6]^{2-}$: ν_1 1333, ν_1 1324; ν_2 728; ν_3 521; ν_4 428; ν_5 not observed; ν_6 383.

Reaction of *(1)* with fluoride ion as Lewis base leads to formation of the hitherto unknown oxotetrafluorochlorate ion $[ClOF_4]^-$:

$$ClOF_3 + CsF \xrightarrow{20\,^\circ C} Cs^+[ClOF_4]^-$$

The bands in the Raman spectrum [cm^{-1}] of the $[ClOF_4]^-$ ion were assigned, by analogy with the assignment of the bands in the Raman spectrum of $XeOF_4$[4], as follows: ν_1 1202 (w); ν_2 455 (vs); ν_3 410 (s); ν_4 349 (vs); ν_5 – ; ν_6 285 (m); ν_7 – ; ν_8 – ; ν_9 204 (w).

If the photochemical reaction of ClF_5 and OF_2 is carried out in a nickel vessel fitted with sapphire window the principal product is $ClOF_3$ *(1)*; small amounts of $ClOF_5$ *(2)* are also formed, but this could not be isolated in pure form. The mass spectrum (negative ions!) of the reaction product contains the fragments $^{37}ClOF_4^-$, $^{35}ClOF_4^-$, $^{37}ClOF_3^-$, and $^{35}ClOF_3^-$, which can originate only from *(2)*, since the spectrum of pure *(1)* does not contain

these ions. Mass spectrum (rel. intensity in %): $^{37}ClOF_4^-$ (0.6), $^{35}ClOF_4^-$ (1.8); $^{37}ClF_4^-$ (1.0), $^{35}ClF_4^-$ (2.9); $^{37}ClOF_3^-$ (1.1), $^{35}ClOF_3^-$ (3.3); $^{37}ClF_3^-$ (8.7), $^{35}ClF_3^-$ (28.3); $^{37}ClOF_2^-$ (32.6), $^{35}ClOF_2^-$ (100.0); $^{37}ClO_3^-$ (15.2), $^{35}ClO_3^-$ (50.0); $^{37}ClF_2^-$ (28.3), $^{35}ClF_2^-$ (95.7); $^{37}ClOF^-$ (8.7), $^{35}ClOF^-$ (23.9); $^{37}ClF^-$ (3.3), $^{35}ClF^-$ (11.9); $^{37}ClO^-$ (0.7), $^{35}ClO^-$ (2.2); F_2^- (52.2); $^{37}Cl^-$ (56.5); $^{35}Cl^-$ (193.5); F^- (>100); O^- (>100).

The recording of the ^{19}F-NMR spectrum was difficult, since inexplicable exchange effects led to extensive line broadening that could not be resolved in the spectrometer. The best spectrum at room temperature showed a broad signal at −146 ppm ($CFCl_3$, external; halfwidth 180 Hz), which broadened with decreasing temperature and had almost disappeared at −30 °C (Fig. 1). At −76 °C a new

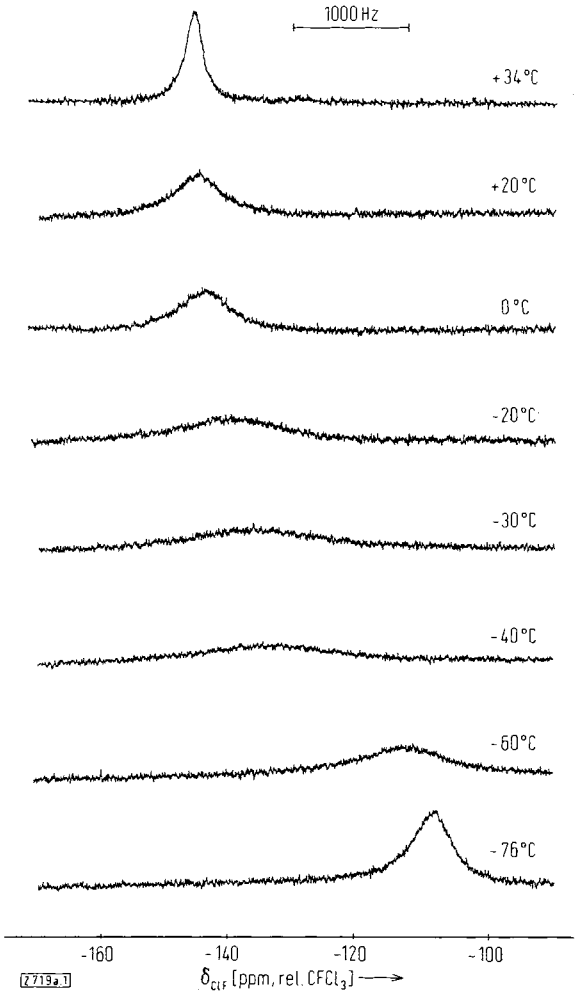

Fig. 1. ^{19}F-NMR spectrum of $ClOF_5$ *(2)* at various temperatures.

signal appeared at −103 ppm (halfwidth 480 Hz). The sample still contained ClF_5, which was identified by a sharp doublet at −256 ppm[5]. We assume that the ligand exchange processes in $ClOF_5$ at −76 °C are so slow that the variously bound F atoms can be differentiated. If the molecule is assumed to have a tetragonal bipyramidal structure, then the signal at −103 ppm can be ascribed to the four equivalent equatorially disposed F atoms. The signal of the axial F atoms could not be observed since the very broad lines due to nuclear quadrupole interactions are spread over a fourfold greater base line with only 1/4 of the area. At room temperature reorientation of structure takes place rapidly, all F atoms becoming equivalent and giving rise to just one signal at −146 ppm.

Experimental:

A 1:1 mixture of ClF_5[6] and OF_2[6] (500 torr) is irradiated in a 3 l quartz flask for 48 hours with a high-pressure mercury vapor lamp. The reaction product is condensed in a quartz trap and purified by evaporation in a high vacuum at −78 °C to free it from unused ClF_5 and OF_2 and other volatile reaction products. In the trap there remained white crystalline $[ClOF_2]_2^+[SiF_6]^{2-}$

The same procedure is adopted when using a nickel flask (3 l), the products, in this case, being condensed in a KEL-F trap.

Our high-resolution spectrum of pure ClF_5 shows the chemical shift for the chlorine isotopes. $\delta^{35}ClF_4 = -260.35$ ppm ($CFCl_3$, external); $\delta^{37}ClF_4 - \delta^{35}ClF_4 = 0.076$ ppm; $^2J_{FF}(^{37}ClF_4-F) = {}^2J_{FF}(^{35}ClF-F) = 134.2 \pm 0.2$ Hz.

[6] We thank Dr. *Massone*, Kalichemie AG Hannover, for supplying the ClF_5 and OF_2.

Oxohalocyclothiazenes[1]

By *Teh-Pei Lin, Uwe Klingebiel*, and *Oskar Glemser*[*]

Thermal cleavage of $ClSO_2—N{=}PCl_3$ in a vacuum leads to formation of 1,3,5-trioxo-1,3,5-trichloro-1λ⁶,3λ⁶,-5λ⁶,2,4,6-trithiatriazene (trioxotrichlorocyclotrithiazene, "trimeric sulfanuric chloride") $[—N{=}S(O)Cl—]_3$[2]. In the mass spectrum of the products of this reaction there occur also fragments such as $N_5S_5O_5Cl_4^+$ (450), $N_5S_5O_5Cl_3^+$ (415), and $N_4S_4O_3Cl_4^+$ along with corresponding Cl isotope distribution. They cannot, however, be unequivocally ascribed to the larger rings $[NSOCl]_5$ and $[NSOCl]_4$. The completely fluorinated eight-membered ring $[NSOF]_4$ was prepared by thermolysis of $Hg(NSOF_2)_2$. The mass spectrum shows a fragmentation analogous to that of $[NSOF]_3$.

Fluorination of $[NSOCl]_3$ with SbF_3 (1:1.2) at 110 °C and 200 torr for 24 hours affords $[NSOF]_3$ in about 80% yield, whereas the yields obtained previously with other fluorinating agents[3] were much lower. Partially fluorinated products are also formed, usually in yields of about 10%.

$$[NSOCl]_3 + SbF_3 \xrightarrow[-SbCl_3]{110\,°C/200\,torr} [(NSOCl)_2(NSOF)]$$
$$[(NSOCl)(NSOF)_2], [NSOF]_3$$

The fluorinated products are first evaporated in a vacuum (oil-pump) and the $[NSOF]_3$ is subsequently separated

[*] Prof. Dr. O. Glemser, Dipl.-Chem. T.-P. Lin, and Dr. U. Klingebiel
Anorganisch-chemisches Institut der Universität
34 Göttingen, Hospitalstrasse 8—9 (Germany)

from partially fluorinated compounds by distillation at 12 torr. $[(NSOCl)_2(NSOF)]$ and $[(NSOCl)(NSOF)_2]$ are isolated by further distillation in a spinning band column. The *cis-trans* isomers of $[NSOF]_3$ were separated gas-chromatographically and their physical properties were determined. These were in complete agreement with those reported in the literature[3].

The colorless compounds $[(NSOCl)_2(NSOF)]$, b. p. 105 to 110 °C/20 torr, and $[(NSOCl)(NSOF)_2]$, b. p. 168 to 175 °C/760 torr, each occur in three isomeric forms, which are completely separable by analytical gas-chromatography and which can be characterized by the ^{19}F-NMR spectrum.

Trioxodichlorofluorocyclotrithiazene $[(NSOCl)_2(NSOF)]$: Mass spectrum (rel. intensity in %): $N_3S_3O_3FCl_2^+$ (1), $N_3S_3O_3FCl^+$ (7), $N_3S_3O_3F^+$ (21), $NS_2O_2^+$ (1), $NSOCl^+$ (2), $SOCl^+$ (37), SOF^+ (100), NSO^+ (9), SO^+ (43). IR [cm^{-1}]: 1350 (vs), 1205 (w), 1133 (vs), 837 (s), 768 (vs), 691 (m), 557 (vs), and 512 (vs). ^{19}F-NMR ($CFCl_3$, external): δ_{SF} *(cis-cis)* −59 ppm; δ_{SF} *(cis-trans)* −64.8 ppm; δ_{SF} *(trans-cis)* −67.2 ppm[5].

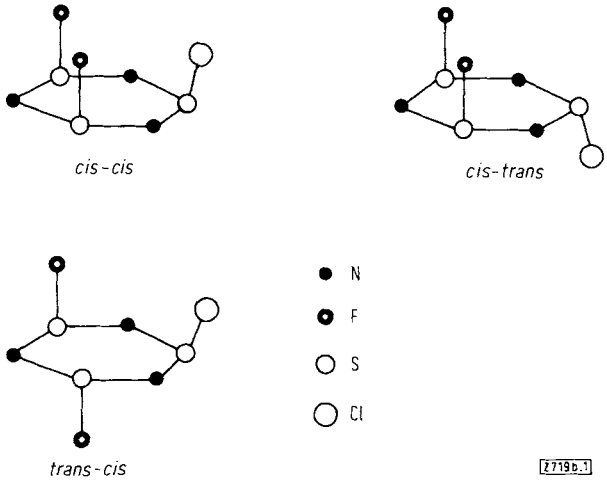

Fig. 1. Isomers of $[(NSOCl)(NSOF)_2]$: simplified models assuming a planar ring, cf. the structure of $[NSOCl]_3$ [4].

Trioxochlorodifluorocyclotrithiazene $[(NSOCl)(NSOF)_2]$ (Fig. 1): Mass spectrum (rel. intensity in %): $N_3S_3O_3F_2Cl^+$ (1), $N_3S_3O_3FCl^+$ (4), $N_3S_3O_3F_2^+$ (100), $SOCl^+$ (4), SOF^+ (98), NSF^+ (1), SF^+ (1), SO^+ (20). IR [cm^{-1}]: 1358 (vs), 1215 (s), 1140 (vs), 840 (s), 775 (vs), 695 (s), 565 (vs), 515 (vs). ^{19}F-NMR ($CFCl_3$, external): δ_{SF} *(cis-cis)* −56.4 ppm; δ_{SF} *(cis-trans)* −66.3 ppm; δ_{SF} *(trans-cis)* [AB spectrum]: δ_{SF_A} −64.0, δ_{SF_B} −71.7 ppm: $J_{F_AF_B}$ 22.0 Hz.

Preparative separation of the isomers is in progress.

Relation between Structure and Proton Donor Strength of Octahedrally Coordinated Tris(3,5-di-isopropylsalicylato)-aluminum(III), -gallium(III), and -indium(III)

By *H. F. Eicke*, *V. Arnold*, and *F. L'Eplattenier*[*]

The surprisingly high proton donor strength of tris(3,5-di-isopropylsalicylato)aluminum(III) $[Al(dips)_3]$[1] in apolar media of very low dielectric constant made it desirable to investigate the structure of this compound. We have found it to have the structure shown in Figure 1.

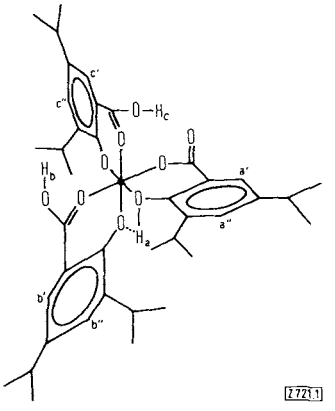

Fig. 1. Structure postulated for tris(3,5-diisopropylsalicylato)aluminum(III).

The 100 MHz NMR spectrum of the CCl_4 solution showed three separate proton signals in the 10—11 ppm region (Table 1 and Fig. 2). Exchange measurements with D_2O showed the protons to exchange at differing rates.

Table 1. Positions of the NMR signals (10—11 ppm) of 3,5-diisopropylsalicylic acid (Hdips) and some of its chelates (100 MHz, CCl_4, δ values).

Cpd.	H_a	H_b	H_c
Hdips	10.42	—	—
$Al(dips)_3$	10.83	10.44	10.25
$Ga(dips)_3$	10.62	10.5	10.05
$In(dips)_3$	—	10.4	—

The signals in the 10—11 ppm region can arise in this case only from hydrogen atoms of COOH and/or OH groups; phenolic protons, however, can be found in this region only if they occur in a hydrogen bridge. Signals of carboxylic protons always lie above 9 ppm.

In principle these conditions can be fulfilled by four types of structures, namely chelate structures with (i) three carboxylic protons, (ii) three phenolic protons contained in H-bridges, (iii) one carboxylic and two bridged phenolic protons, and (iv) two carboxylic and one bridged phenolic proton.

To decide between these four possibilities $Al(dips)_3$ was methylated stepwise by diazomethane. Only two groups

[*] Dr. H. F. Eicke and V. Arnold
Institut für Physikalische Chemie der Universität
CH-4056 Basel, Klingelbergstrasse 80 (Switzerland)
Dr. F. L'Eplattenier
Ciba-Geigy AG, Basel (Switzerland)

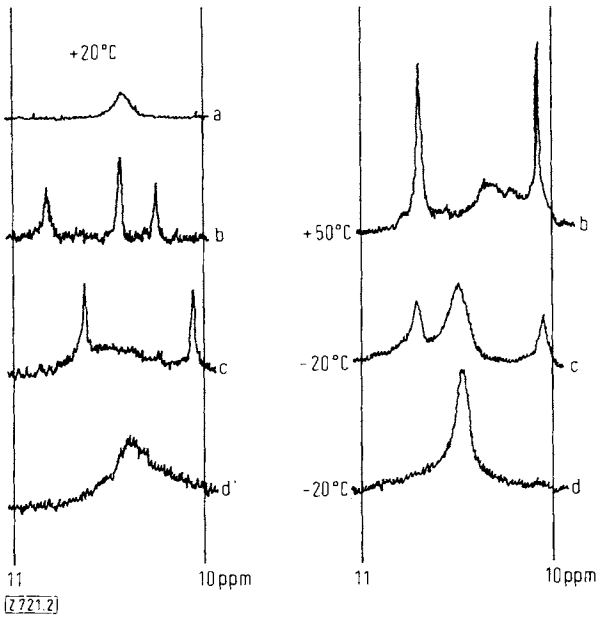

Fig. 2. Temperature-dependence of the 100 MHz NMR spectrum of (a) 3,5-diisopropylsalicylic acid (Hdips), (b) tris(3,5-diisopropylsalicylato)aluminum(III) [Al(dips)$_3$], (c) tris(3,5-diisopropylsalicylato)-gallium(III) [Ga(dips)$_3$], and (d) tris(3,5-diisopropylsalicylato)indium(III) [In(dips)$_3$].

could be methylated in this way. The relative rates of methylation corresponded to those of H/D exchange. IR spectroscopic study of Al(dips)$_3$ showed the C=O stretching vibration of free diisopropylsalicylic acid at 1662 cm^{-1} (see, *e.g.*, Refs. [2 and 3]); this band is shifted to 1683 cm^{-1} by methylation, as is typical of methyl ester formation[4].

On the basis of these NMR and IR results the existence of limiting structure iv appears the most probable (see Fig. 1). This structure explains very simply the chemical shift of the protons of the aromatic ring [indicated by ′ and ″] in the region 7—8 ppm for the two-fold methylated chelates (Table 2).

Table 2. Positions of the NMR signals (7—8 ppm) of 3,5-diisopropylsalicylic acid (Hdips) and some of its dimethylated chelates (100 MHz, CCl_4, δ values).

Cpd.	$H_{a'}$	$H_{a''}$	$H_{b'}$	$H_{b''}$	$H_{c'}$	$H_{c''}$
Hdips	7.59	7.26	—	—	—	—
Dimethylated Al(dips)$_3$	7.82	7.45	7.58	7.25	7.25	7.00
Dimethylated Ga(dips)$_3$	7.87	7.46	7.53	7.19	7.22	7.00
Dimethylated In(dips)$_3$	7.76	7.55	7.55	7.18	7.18	7.03

The difficulty in methylating the phenolic group engaged in intramolecular hydrogen bridging also indicates stability of that bridge, as is to be expected from structure iv. These facts are also in line with the relative rates of H/D exchange, since the intramolecularly bridged proton was completely exchanged only after 48 hours. Activation of the carboxylic proton (H_b) by this hydrogen bridge confers the character of free 3,5-diisopropylsalicylic acid (Hdips)) on ligand (b), as can be seen from the NMR spectrum. This proton should thus have the greatest reactivity (and thus the greatest rate of H/D exchange).

Analogous studies of other elements of group 3B appeared interesting for comparison with the above results. The NMR spectrum of the gallium compound at 20 °C (Fig. 2) in the 10—11 ppm region, unlike that of the aluminum compound, shows marked broadening of the middle proton signal (H_b, Table 1); with Ga(dips)$_3$, cooling to −20 °C results in a considerable decrease in the half-width of the middle band. It is interesting that this spectral region for the aluminum compound at +50 °C is similar to that of the gallium compound at +20 °C. The sign of the chemical shift of the ring protons in tris(3,5-diisopropylsalicylato)-gallium(III) corresponds to that of the δ_H values for the aluminum compound.

In(dips)$_3$ at room temperature gives a broad band between 10 and 11 ppm which becomes appreciably narrower at −20 °C (center of gravity of the band: 10.46 ppm). The slight resolution of the ring proton signals in the 7—8 ppm region indicates increasing equalization of the ligands. In this connection it was particularly important that the three carboxylic protons could be titrated, a finding that indicates the above-designated structure i. As the ionic radius increases from aluminum to indium [$r(Al^{3+})=0.51$ Å, $r(Ga^{3+})=0.62$ Å, and $r(In^{3+})=0.81$ Å] the existence of the H-bridge observed in Al(dips)$_3$ becomes less probable. The metal chelate can then be stabilized only by participation of the central metal atom in the conjugation of the chelate ring[5].

The position of the C=O band in the IR spectrum of Ga(dips)$_3$ and In(dips)$_3$ is exactly the same as for Al(dips)$_3$, as is the shift of the C=O frequency on methylation.

Experimental

3,5-Diisopropylsalicylic acid (3.33 g, 0.015 mol) was dissolved in methanol (25 ml) and added to the metal(III) chloride or nitrate (0.005 mol) in methanol (25 ml). The mixture was treated with 0.1 M methanolic $NaOCH_3$ solution (150 ml) and stirred for 30 min. The solvent was then evaporated in a vacuum and the residual product was dissolved in benzene (100 ml). The resulting solution was cooled to 0 °C to facilitate complete crystallization of the NaCl or $NaNO_3$. The precipitate was separated and the solution was evaporated in a vacuum. To free the resulting metal chelate from benzene it was redissolved in diethyl ether, then freed from solvent in a vacuum and finally dried in a high vacuum.

elements[1,2] we have been able to synthesize a mercury compound $Hg[P(CF_3)_2]_2$ that is suitable for introduction of $(CF_3)_2E$-groups.

Processes analogous to the preparation of the nitrogen compound $Hg[N(CF_3)_2]_2$[3] are here excluded because in the phosphorus case the starting material does not exist. Indications of the desired compound were obtained particularly from the reaction of $Hg[Si(CH_3)_3]_2$ with $(CF_3)_2PH$[2] in which formation of (trimethylsilyl)bis(trifluoromethyl)phosphane $(CH_3)_3SiP(CF_3)_2$ had to be explained as due to decomposition of the intermediate $(CH_3)_3SiHgP(CF_3)_2$. Also an unstable intermediate compound $(CF_3)_2PHgI$ was postulated for the reaction of $(CF_3)_2PI$ with mercury[4] or mercurous iodide[2].

The interesting new compound $Hg[P(CF_3)_2]_2$ *(1)* was formed on treatment of divinylmercury with bis(trifluoromethyl)phosphane in an all-glass apparatus for 16 days at room temperature, the yield being about 60%:

$$Hg[CH{=}CH_2]_2 + 2\,HP(CF_3)_2 \rightarrow \underset{(1)}{Hg[P(CF_3)_2]_2} + 2\,CH_2{=}CH_2$$

The ethylene liberated was determined quantitatively and identified by molecular weight determination and its IR spectrum.

(1) was also obtained, in about 10% yield, by the analogous reaction of dimethylmercury with $HP(CF_3)_2$. However, this reaction is extremely slow (reaction time: 2 years at 20 °C). Fractional condensation in a high vacuum (receiver at 0 °C) affords compound *(1)* in a purity not exceeding 90% and further purification is prevented by the too small differences between the boiling points of this product and its impurities. The compound inflames at once on contact with air; it was identified as follows by reactions in sealed NMR tubes:

a) *(1)* decomposes when heated, with formation of mercury and $P_2(CF_3)_4$.

b) Treatment of *(1)* with hydrogen iodide leads to HgI_2 and $HP(CF_3)_2$:

$$\underset{(1)}{Hg[P(CF_3)_2]_2} + 2\,HI \rightarrow HgI_2 + 2\,HP(CF_3)_2$$

c) Cleavage of the Hg—P bond by iodosilane affords HgI_2 and $H_3SiP(CF_3)_2$.

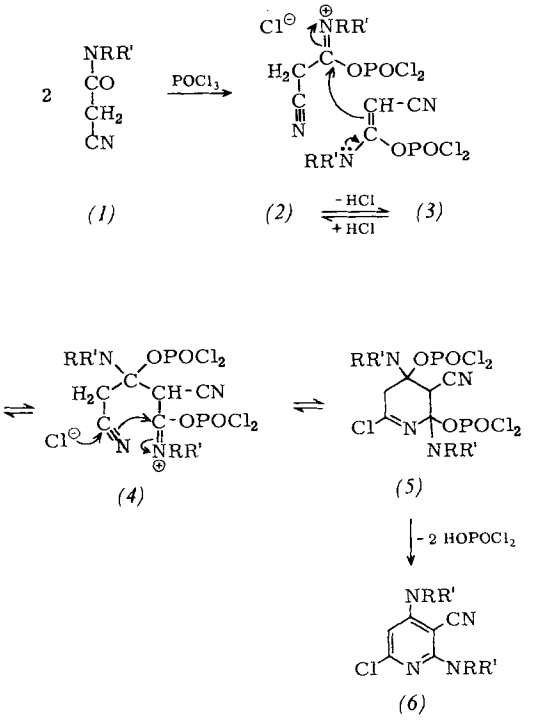
d) On reaction of *(1)* with an excess of bis(trifluoromethyl)-arsane the $P(CF_3)_2$ groups are replaced by $As(CF_3)_2$ groups:

$$\underset{(1)}{Hg[P(CF_3)_2]_2} + 2\,HAs(CF_3)_2 \rightarrow \underset{(2)}{Hg[As(CF_3)_2]_2} + 2\,HP(CF_3)_2$$

(2) is thermally less stable than *(1)* and decomposes to mercury and $As_2(CF_3)_4$.

The following data were obtained for compounds *(1)* and *(2)* by ^{19}F-NMR measurements (solvent TMS, CCl_3F as external standard): *(1)* $\Phi_F = 37.1$ ppm; $^2J_{PF} = 58$ Hz, $J_{^{13}CF} = 322$ Hz, $J_{FF'} = 7.9$ Hz; *(2)* $\Phi_F = 32.8$ ppm.

The use of $Hg[E(CF_3)_2]_2$ (E = P or As) as reagent for introduction of $(CF_3)_2E$-groups is currently under examination with further examples[**].



Received: September 18, 1972 [Z 722 IE]
German version: Angew. Chem. *84*, 1153 (1972)

[**] Note added in proof (26. Oct. 72): Further investigations have shown that *(1)* is also formed on reaction of $Hg(CN)_2$ or $Hg(SCH_3)_2$ with $HP(CF_3)_2$, the reaction rate decreasing in the order $Hg(CN)_2 > Hg(CH{=}CH_2)_2 > Hg(SCH_3)_2 > Hg(CH_3)_2$.

The Synthesis of Tetrasubstituted Pyridines from *N,N*-Dialkylcyanoacetamides[1]

By *A. L Cossey, R. L N. Harris, J. L Huppatz,* and *J. N. Phillips*[*]

We wish to report a novel pyridine synthesis based on the reaction between *N,N*-dialkylcyanoacetamides *(1)* and phosphorus oxide trichloride. Thus, when *(1a)* and phosphorus oxide trichloride were heated together at 100 °C a reaction occurred and HCl was evolved. The product

Scheme 1

isolated was a pale yellow crystalline solid, m.p. 108 to 109 °C, whose analysis and mass spectrum indicated that it had the structure *(6a)*[2]. The NMR spectrum ($CDCl_3$) of *(6a)* showed that it contained two dissimilar *N,N*-dimethyl groups ($\delta = 3.13$ and 3.18 ppm, each 6 H/s) and a

single aromatic proton ($\delta = 6.00$, s). The IR spectrum indicated the presence of a conjugated nitrile group. A close examination of the high resolution mass spectrum revealed an $M - CH_3N$ peak, which is characteristic for 2-(*N,N*-dimethylamino)pyridines[3]. In the NMR spectrum of the product of catalytic hydrogenation, m.p. 57—58 °C, two aromatic protons appeared as an AB quartet ($\delta = 6.0$ and 7.82 ppm, $J = 6$ Hz), implying that the chlorine was originally present in a position adjacent to the aromatic proton in the original product.

The substitution pattern in *(6a)* could not be deduced absolutely by spectral means but follows from a consideration of the possible mode of formation of the compound (Scheme 1). This was confirmed in later investigations[4].

Eilingsfeld et al.[5] postulated a similar reaction course for the reaction of simple substituted acetamides in the presence of phosphorus oxide trichloride to give substituted acetoacetamides. The reaction in Scheme 1 is therefore reminiscent of the conversion of malonodinitrile *via* its dimer into 2,4-diamino-5-bromo-4-cyanopyridine on treatment with HBr[6].

The reaction was found to be general for a number of *N,N*-disubstituted cyanoacetamides, representative examples of which are given in Table 1.

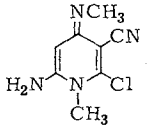
The Synthesis of *N*-Alkylpyridinium Salts from *N*-Alkylcyanoacetamides[1]

By *A. L. Cossey, R. L. N. Harris, J. L. Huppatz*, and *J. N. Phillips*[*]

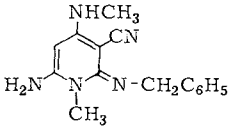
N,N-Dialkylcyanoacetamides react in the presence of phosphorus oxide trichloride to give pyridine derivatives[2]. We now describe an extension of this reaction in which *N*-alkylpyridinium salts can be synthesized.

When *N*-methylcyanoacetamide *(1a)* and phosphorus oxide trichloride were heated together in chloroform a yellow precipitate rapidly crystallized out. On isolation the product proved to be a water soluble salt whose analysis indicated the structure *(7a)*. The NMR spectrum (D_6-DMSO) showed signals at $\delta = 2.87$ (3H, doublet collapsing to a singlet on deuteration, $NH-CH_3$), 3.73 ($s/\geqslant N-CH_3$), and 6.00 ppm (s/aromatic H). The presence of a broad variable absorption in the region $\delta = 4.0—7.0$ indicated the presence of other exchangeable protons. The IR spectrum indicated the presence of a conjugated nitrile group and there was strong absorption in the C=N region. The mass spectrum showed a molecular ion for the free base at *m/e* 196 (with Cl = 35).



Scheme 1

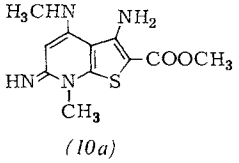
We believe that the pyridinium salt is formed as shown in Scheme 1. The compound *(4)* may cyclize to the pyridine derivative (route A)[2] or be converted, *via* the intermediates



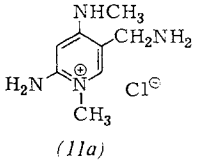
[*] Dr. R. L. N. Harris, Dr. J. L. Huppatz, Dr. J. N. Phillips, and A. L. Cossey
CSIRO, Division of Plant Industry
Canberra, A.C.T. 2601 (Australia)

(5) and *(6)* (route B), into the pyridinium salt *(7)*. It appears that this latter route (a prospect not available with *N,N*-substituted cyanoacetamides) must be favored when it can occur, since in the many examples studied, *N*-alkylcyanoacetamides on treatment with phosphorus oxide trichloride gave only *N*-alkylpyridinium salts of type *(7)*, usually in yields exceeding 80%.

The chemical properties of the salt *(7a)* further substantiated the structure proposed. The free base was readily obtained and on the basis of its NMR spectrum was assigned the 1,4-dihydropyridine structure *(8a)* (in D_6-DMSO both $N-CH_3$ signals appear as singlets at $\delta = 2.6$ and 5.52 ppm). The halogen is readily replaced by nucleophiles; for example, reaction with benzylamine leads to compound *(9a)*, whose 1,2-dihydropyridine structure follows from NMR evidence [in D_6-DMSO one of the $N-CH_3$ groups was observed to be coupled to an exchangeable proton (doublet at $\delta = 2.72$ ppm, collapsing to a singlet on deuteration; α-benzyl protons give a singlet at $\delta = 4.87$ ppm]. The formation of benzyliminopyridines eliminates possible structures in which the chlorine occupies a position *meta* to the ring nitrogen.



(8a)



(9a)

Reaction of *(7a)* with methyl thioglycollate results in rapid formation of the fused thieno[2,3-*b*]pyridine *(10a)*. This indicates that the active chlorine in *(7a)* must be adjacent to the nitrile group. Similarly reaction with hydrazine gave the pyrazolo[4,5-*b*]pyridine. Finally, catalytic hydrogenation of *(7a)* gave the pyridinium salt *(11a)*, whose NMR spectrum in D_2O (two singlets for the ring protons at $\delta = 6.02$ and 7.73 ppm) clearly eliminates possible structures for *(7a)* in which the chlorine substituent is adjacent to an unsubstituted position.

(10a)

(11a)

Several examples of compounds of type *(7)* are given in Table 1.

Table 1. *N*-Alkylpyridinium salts *(7)* from *N*-alkylcyanoacetamides *(1)* and $POCl_3$.

Cpd.	R	Yield [%]	M.p. [°C]
(7a)	CH_3	80	>250
(7b)	n-C_4H_9	86	230—231
(7c)	n-C_8H_{17}	75	233—234

6-Amino-2-chloro-3-cyano-1-methyl-4-methylamino-pyridinium chloride (7a)

(1a) (9.8 g, 0.1 mol) was dissolved in chloroform (50 ml) and $POCl_3$ (15.3 g, 0.1 mol) added. The reaction mixture was warmed on a steam bath under reflux for 2 h during which time the product crystallized. It was collected and recrystallized from methanol to give a pale yellow solid m.p. >250°C (9.4 g, 80%).—Higher homologs of *(7a)* are soluble in chloroform; they are isolated by removal of the solvent *in vacuo* and treatment of the residue with cold methanol.

Synthesis of Pentasubstituted Pyridines from *C*-Alkyl-*N,N*-dialkylcyanoacetamides[1]

By *A. L. Cossey, R. L. N. Harris, J. L. Huppatz,* and *J. N. Phillips*[*]

Pyridines are obtained by a one-step synthesis from *N,N*-dialkylcyanoacetamides by reaction with phosphorus oxide trichloride[2]. We now describe an extension of this synthesis leading to pentasubstituted pyridines.

When *C*-methyl or *C*-ethyl-*N,N*-dialkylcyanoacetamides are heated with phosphorus oxide trichloride no pyridines are formed, presumably because the irreversible aromatization step, which would involve alkyl elimination or rearrangement, is energetically less favorable. Inclusion of a suitable substrate, however, allows a mixed condensation to occur; for example, the cyanoacetamide *(1a)* and *N,N*-dimethylphenylacetamide *(2)* react in $POCl_3$ (100°C, 2 h) to give the pentasubstituted pyridine *(3a)* as the only isolable product in 16% yield[3]. Further examples are given in Table 1.

(1) *(2)* *(3)*

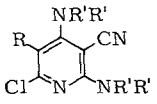

Table 1. Pyridines *(3)* from the reaction of *C*-alkyl-*N,N*-dialkylcyanoacetamides *(1)*, *N,N*-dimethylphenylacetamide *(2)* and $POCl_3$.

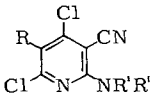
Cpd.	R	R′	R′	Yield [%]	M.p. [°C]
(3a)	CH_3	CH_3	CH_3	16	119—120
(3b)	C_2H_5	CH_3	CH_3	17	73— 74
(3c)	CH_3	$-(CH_2)_4-$		35	110—111
(3d)	C_2H_5	$-(CH_2)_4-$		40	84— 85



When the compounds *(1)* are substituted at the methylene group by *i*-propyl or benzyl, however, two molecules react with $POCl_3$ with elimination of the *iso*-propyl or benzyl group. For example, *(1f)* reacts in $POCl_3$ (100°C, 2 h) to give a mixture of the two pyridines *(4f)* and *(5f)* (total yield 54%), which can be separated by careful chromatography on silica gel. When the reaction time is extended to 16 hours, the pyridine *(5f)* is the only product isolated

5-Ethyl-6-chloro-2-(N,N-dimethylamino)-3-phenyl-4-pyrrolidinopyridine (3d)

Compounds *(1d)*[4] (3.3 g, 0.02 mol), *(2)*[5] (3.3 g, 0.02 mol), and $POCl_3$ (7.5 g, 0.042 mol) are mixed and heated on a steam bath under a reflux condenser protected from moisture for two hours. The orange reaction mixture is cooled, cautiously poured into ice-water and rendered alkaline with sodium hydroxide solution. The crude product is extracted with chloroform (3 × 50 ml) and the combined extracts are washed once with water and dried (Na_2SO_4). After evaporation of the solvent the remaining dark red, viscous oil (6.3 g) is chromatographed on a silica-gel column (30 × 4 cm) using chloroform-petroleum ether (b.p. 40—60 °C) (1 : 1) as eluent. The first fractions eluted from the column afford a pale yellow oil (2.6 g, 40%) which subsequently solidifies and can be recrystallized from aqueous ethanol (as colourless plates, m.p. 84—85 °C).

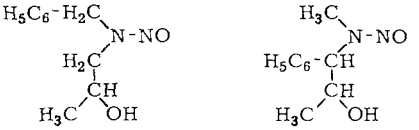
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

actions with electrophiles that involved C—C linkage[1]. We drew the somewhat premature conclusion that this provided a general method *(1)* → *(2)* for chain-extension at the α-C atom of secondary amines.

(1) *(2)*

(3) *(4)*



(5), E = COOH
(6), E = C_6H_5-CH_2
(7), E = CH_3-CH(OH)
(8), E = $(C_6H_5)_2C(OH)$

We can now report that the reaction has wide applicability, as shown by H/Li exchange *(3)* → *(4)* on a variety of nitrosamines and subsequent reaction with CO_2, benzyl bromide, acetaldehyde, or benzophenone to give products of types *(5)* to *(8)* (Table 1).

The following should be emphasized:

1. The methylnitrosamines *(3)* may have R = ethyl, isopropyl, *tert*-butyl, benzyl, or phenyl (Table 1, Nos. 1—6).

2. Metalation of ethylmethyl- and isopropylmethyl-nitrosamine occurs selectively at the CH_3 group, but that of benzylmethylnitrosamine is not specific [see *(9a)* and *(9b)* from acetaldehyde].

(9a) *(9b)*

3. Both secondary[2] and tertiary hydrogen of *(3)* can also be replaced electrophilically (Nos. 5, 7, 8).

4. Five- (Nos. 9 and 10), six- (Nos. 11—13), and seven-membered (No. 14) cyclic nitrosamines react in good yield independently of the ring size.

The danger of working with the carcinogenic nitrosamines can be minimized by removing the nitroso group after the reaction without previous workup, as described in the following experimental procedure.

Isopropylphenethylamine from isopropylmethylnitrosamine:

Isopropylmethylnitrosamine (33.0 mmol, 3.06 ml) is added rapidly to a solution of lithium diisopropylamide (34.5 mmol) [from the amine and butyllithium in THF (100 ml)] at −78 °C and is treated 10 min later with benzyl bromide (35 mmol, 4.1 ml). After 3 h the cooling bath is removed and the solvent distilled off. The residue is dissolved in 7% HBr-glacial acetic acid (65 ml) and set aside at room temperature for 30 min, whereafter the amine is isolated by adding the whole cautiously and with cooling to aqueous sodium hydroxide solution covered with a layer of ether and finally precipitating the hydrochloride [m.p. 162.5 to 165.5 °C (168—169 °C[4]), yield 4.79 g, 79%] by passing gaseous hydrogen chloride into the ethereal phase previously separated from the aqueous layer.

Reaction of Metalated Nitrosamines with Nitriles. A New Method for Preparation of *v*-Triazoles[**]

By *Dieter Seebach* and *Dieter Enders*[*]

Treatment of metalated nitrosamines[1] with nitriles leads to 40—70% yields of *v*-triazoles[2]. 1-Methyl-4-phenyl-1,2,3-triazole *(1a)*, m.p. 122 °C (123 °C[3]) is obtained from benzonitrile and metalated dimethylnitrosamine in this way. Varying the nitrile components afforded the corresponding *p*-tolyl *(1b)* (m.p. 134 °C) and β-naphthyl derivative *(1c)* (m.p. 180 °C); the triazoles *(2a)* (m.p. 43.5 °C), *(2b)* (m.p. 96.4 °C), and *(3)* (m.p. 156 °C) are formed by reaction of benzonitrile with metalated isopropylmethylnitrosamine, *tert*-butylmethylnitrosamine, and 1-nitrosopyrrolidine, respectively. The NMR spectra of compounds *(1)* and *(2)* include a characteristic signal for the proton at position 5 at δ = 7.5—7.9 ppm; *(3)* shows CH_2 multiplets at δ = 2.95, 3.12, and 4.36 ppm.

(1a), R = C_6H_5
(1b), R = *p*-CH_3-C_6H_4

(2b), R = *tert*-C_4H_9

(3)

Since a great variety of nitrosamines can be metalated[1] this method makes di- and trisubstituted triazoles generally accessible and these are interesting as precursors of azirines[4]; enolizable nitriles are not amenable to the reaction described here[5]. Studies on the mechanism of the reaction and on photolysis and thermolysis of the products are in progress.

1-Methyl-4-phenyl-1,2,3-triazole (1a)

Pure dimethylnitrosamine (1.62 ml, 22 mmol) is added with stirring to a solution of lithium diisopropylamide (23 mmol) in anhydrous THF (70 ml) (from 3.22 ml of diisopropylamine and 14.2 ml of *n*-butyllithium; 1.6 M in *n*-hexane) at −78 °C and the mixture is treated 10 min later with benzonitrile (1.03 ml, 10 mmol). After being kept for 10 h at the temperature of Dry Ice, the mixture is treated with a solution of glacial acetic acid (1.32 ml, 23 mmol) in THF (5 ml). Working up with methylene dichloride affords a crystalline crude product that, recrystallized from CCl_4 or ligroin, forms colorless needles, m.p. 122 °C (yield 1.15 g, 72%).

Model Reactions for Synthesis of Pharmacologically Active Polymers by Way of Monomeric and Polymeric Reactive Esters[**]

By *Hans-Georg Batz*, *Giselher Franzmann*, and *Helmut Ringsdorf*[*]

Pharmacologically active polymers have aroused increasing interest in recent years[1]. These polymers may act as drugs themselves or only after release of lower-molecular species. The problem is to effect linkage[2] of the drug with monomers and polymers under mild conditions to ensure complete retention of the biological activity and exclusion of side reactions.

(1) - (3) *(4) - (6)* *(7) - (9)*

We have examined reactive esters, of the type known in peptide chemistry[3], for their suitability as precursors of pharmacologically active polymers. By treating unsaturated acid chlorides or anhydrides, esters or isocyanates with *N*-hydroxy compounds and chloro- or nitro-phenols[4] we have prepared the reactive unsaturated esters *(1)* to *(9)* shown in Table 1.

The monomers *(1)*, *(2)*, *(7)*, and *(8)* are resistant to hydrolysis; they react at 0 °C in neutral or weakly alkaline water/dioxane solution with amines, giving amides in yields of up to 80%. The monomers *(4)* and *(5)* react at room temperature with alcohols as well as with amines and are hydrolyzable. Compounds *(3)*, *(6)*, and *(9)* were subjected to reaction only as polymers since the monomers lose acetaldehyde relatively easily[5].

All the monomers were subjected to radical polymerization. The homopolymers of *(1)*—*(4)* and *(6)* are soluble in dimethyl sulfoxide, and the other polymers dissolve also in other polar solvents, *e.g.* tetrahydrofuran and methylene dichloride. Copolymers that dissolve in water or organic solvents were prepared by copolymerization of the monomers *(1)*—*(9)* with 1-vinylpyrrolidone, methacrylamide, acrylamide, or styrene.

Like the monomers, the polymers of active esters react readily with nucleophilic reagents. This makes possible to effect reaction of pharmacologically active compounds

Table 2. Model reactions for synthesis of pharmacologically active polymers [22 °C, in methylene dichloride, polymer 0.4 mol/l (monomer units), cyclohexylamine 0.8 mol/l].

[**] Part 3 of Pharmacologically active polymers.—Part 2: *H. Ringsdorf, A. G. Heisler, F. H. Müller, E. H. Graul*, and *W. Ruther*, Biol. Aspects Rad. Protect. *1971*, 138.

with polymers without racemization or side reactions. Table 2 shows the model reactions effected with cyclohexylamine and ammonia. Methyl polyacrylate and polymethacrylate do not react under the stated conditions.

The polymers prepared from *(4)*—*(6)* and containing benzotriazole are hydrolyzed in aqueous sodium carbonate solution even at room temperature. If polymeric *(4)*—*(6)* undergoes partial reaction with the model compounds and is then hydrolyzed, polymers are obtained containing carboxyl groups [from poly-*(4)* and poly-*(5)*] or amino groups [from poly-*(6)*]. Neutral polymers are obtained by treatment of the residual active ester groups with an excess of amine or ammonia.

N-Hydroxysuccinimide methacrylate (2)[6]

Triethylamine (0.5 mol) and methacryloyl chloride (0.5 mol), each in 150 ml of CH_2Cl_2, are added dropwise with stirring and ice cooling to *N*-hydroxysuccinimide (0.5 mol) in anhydrous methylene dichloride (200 ml). After 6 hours' stirring at room temperature the precipitated triethylammonium chloride is removed and the filtrate is shaken with, successively, water, a little saturated sodium hydrogen carbonate solution, and again water, dried and evaporated. The residue is recrystallized from ethyl acetate/light petroleum; yield 70 g (77%).

Polymerization

The ester *(2)* (0.1 mol) is kept in anhydrous tetrahydrofuran (200 ml) containing 0.5 mol-% of azodiisobutyronitrile for 8 h at 60 °C. The precipitated polymer is filtered off, digested with tetrahydrofuran, filtered off again, and dried; yield 15 g, 81%.

Reaction with amines: poly-N-acryloylcyclohexylamine

Poly-1-acryloyloxybenzotriazole [poly-*(4)*] (1.89 g, 0.01 mol) is mixed with cyclohexylamine (2.26 ml, 0.02 mol) in methylene dichloride (25 ml). The solution becomes homogeneous after *ca.* 1 min. After 1 day the product is precipitated by ether and reprecipitated from methanol/water. The poly-1-acryloyloxycyclohexylamine was characterized by elemental analyis and its IR and NMR spectra. The conversion amounted to 100%.

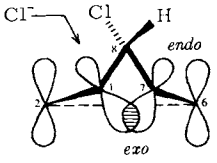
The Primary Step in the Halogenation of Cyclooctatetraene

By *Rolf Huisgen* and *Johann Gasteiger*[*]

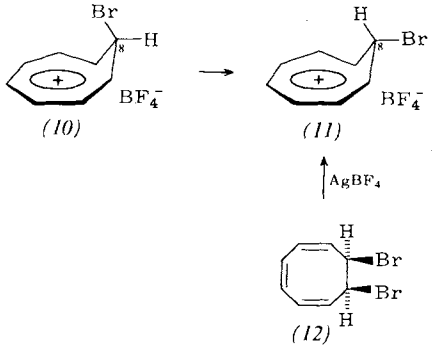
The dichloride *(5)* of cyclooctatetraene, isolated by *Reppe, Schlichting, Klager*, and *Toepel*[1], and the corresponding dibromide are the result of a multi-stage reaction sequence that is analogous for chlorination and bromination. We have obtained the dichlorides *(3)* to *(5)* in crystalline form and have elucidated their thermodynamic and kinetic interrelationships[2]. Halogenation of *(1)* is unusually rapid and affords the *cis*-dichloride *(4)* exclusively.

The *endo*-8-chlorohomotropylium chloride *(2)* presumed to be the primary product provided the key to the understanding of the fast rate of chlorination and of the anomalous course leading to the *cis*-compound. The fluorosulfonate *(2)* (FSO_3^- in place of Cl^-) combines with a chloride ion to give the *cis*-dichloride *(4)*, whereas the *exo*-8-chlorohomotropylium salt *(6)* and Cl^- afford the *trans*-dichloride *(3)*[3]. Our attempts to demonstrate the primary *endo*-chlorination *(1)* → *(2)* were not at first entirely successful. Chlorination of *(1)* at −90 °C in the presence of antimony pentachloride afforded mixtures of *endo*- and *exo*-8-chlorohomotropylium hexachloroantimonate[3]; the disturbing formation of *(6)* was ascribed to the subsequent reaction *(4)* + $SbCl_5$ → *(6)*, which occurred quantitatively in a separate experiment[4].



In our search for a chlorinating agent that would stop the reaction of *(1)* reliably at the homotropylium stage *(2)*, we have found that antimony pentachloride itself plays a unique double role as Cl^+ donor and strong Lewis acid. When 2 equivalents of $SbCl_5$ react with *(1)* in methylene chloride at −60 °C the crystalline *endo*-salt *(8)* separates

[*] Prof. R. Huisgen and Dr. J. Gasteiger
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)



in 94% yield (correct CH analyses); *(8)* was shown by its NMR spectrum to be free from the isomer *(6)*. The conversion *(7)*→*(8)* is a rapid subsequent reaction, as was shown by reaction of *(1)* with 1.2 equivalents of $SbCl_5$ in SO_2 at −55 °C to form *(8)* in 60% yield; 40% of compound *(1)* remained unchanged. The almost complete conversion *(1)*→*(8)* on use of 2 equivalents of $SbCl_5$ provides the missing link for the unusual halogenation mechanism.

The solution of *(8)* in SO_2 reacts quantitatively at −50 °C with 1.1 equivalents of tetramethylammonium chloride to give NMR-pure *cis*-dichloride *(4)*. The two steps, *(1)*→*(8)*, and *(8)*→*(4)*, thus proceed with high stereoselectivity.

(9)

Whilst the cause of the exclusive *endo* attack by chlorine on *(1)* is not yet clear, the model *(9)* for compound *(2)* indicates the reason for the nucleophilic *endo* attack in step *(2)*→*(4)*. The model shows C-atoms 1 and 7 to be moved out of the plane of the trigonal C-atoms 2 to 6[5]. This motion destroys the parallelism of the π orbitals of the homoaromatic ion. The σ-overlap of the orbitals of C-1 and C-7 shown in *(9)* causes an increase in electron density below the ring plane. The electron deficiency in the upper lobes results in increased electrophilicity on the *endo* side.

(10) *(11)* *(12)*

The complex of *(1)* and silver tetrafluoroborate, on reaction with one equivalent of bromide in ethylene dichloride at −35 °C, affords a precipitate of *(10)* and AgBr; the crystalline *endo*-8-bromo-homotropylium fluoroborate *(10)* was obtained with more than 97% stereoselectivity. In the NMR spectrum (SO_2, −40 °C, 60 MHz) the strongly deshielded 8-H appears as a triplet at τ = 2.70 ppm, whereas the homoaromatic 1-H and 7-H give a triplet ($J_{1,2} = J_{1,8} = 6.9$ Hz) at τ = 3.77 ppm.

The *endo*-bromo compound *(10)* isomerizes to the *exo* form *(11)* in SO_2 solution at 20 °C, presumably by ring inversion. The same *exo*-bromo fluoroborate *(11)* is formed on treatment of the *cis*-dibromide *(12)* with $AgBF_4$ at −60 °C. *(11)* gave a correct CH analysis and showed in the NMR spectrum (SO_2, −40 °C) the *endo*-8-H as a triplet at τ = 8.76 ppm. The high Δτ = 6 ppm of the *endo*-8-H in *(11)* and the *exo*-8-H in *(10)* is characteristic for homotropylium salts[4, 6].

Hendecacesium Trioxide, $Cs_{11}O_3$[**]

By *Arndt Simon* and *Edgar Westerbeck*[*]

Metal-rich oxides (suboxides) of cesium entered the literature long ago as Cs_7O, Cs_4O, Cs_7O_2, and Cs_3O[1], but few investigations of these compounds have been reported[2, 3] although the unusual stoichiometry leads one to expect interesting bonding relations. Further, there have been references[4] to the possible technical importance of alkali-metal suboxides: The cesium layers evaporated on to superficially oxidized silver or on to Cs_2O layers in current photocathodes are found experimentally[5] to react on subsequent heating ('forming') with suboxide formation, so that chemical causes can effect the altered photoeffects (spectral shift, sensitivity) of such composite cathodes.

Recent studies[4, 6, 7] have shown that the suboxides of rubidium and cesium belong to a structurally homogeneous type that is designated by the concept 'complex metal'[6]. The suboxide hitherto formulated as Cs_2O_3 has, according to the results of thermoanalytical and X-ray measurements the formula $Cs_{11}O_3$ and shows a close structural relation to the compounds Cs_7O, Rb_6O and Rb_9O_2 which have been studied in more detail.

$Cs_{11}O_3$ forms permanganate-colored crystalline needles that are extremely sensitive to air and melt incongruently at 52 °C. Phase width could not be detected. In the presence of an excess of cesium, millimeterlong single crystals can be grown in a capillary which enable the structure to be determined[8]. The compound crystallizes monoclinically, space group $Pc(C_s^2)$, with $Z = 4$, $a_0 = 17.610$, $b_0 = 9.218$, $c_0 = 24.047$ Å, $\beta = 100.24°$, $d_{exp} = 2.61$, $d_{calc} = 2.610\ g \cdot cm^{-3}$. The lattice parameters were obtained from modified[9] Guinier photographs of poly- and single-crystalline samples.—The structural model is based on 1386 independent *h0l* to *h3l* reflections ('Pailred' diffractometer; corrected for absorption, anisotropically refined; $R = 0.09$, $R' = 0.11$). Figure 1 shows the projection of the atom

[**] Part 5 of Alkali-metal Suboxides. This work was supported by the Deutsche Forschungsgemeinschaft.— Part 4: [5].

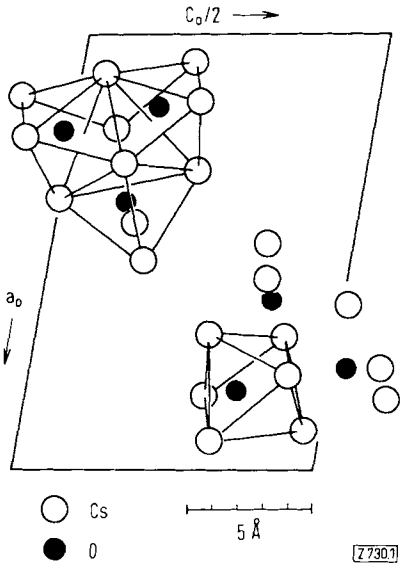

Fig. 1. Half unit cell of the crystal structure of $Cs_{11}O_3$, projection of the atomic centers of gravity along [010].

centers of gravity in $Cs_{11}O_3$ along [010]. The striking feature of this structure is the exclusive occurrence of discrete $[Cs_{11}O_3]$ groups in which the oxygen atoms are in quasitrigonal arrangement. Each oxygen is surrounded by a distorted octahedron of cesium atoms. The $[Cs_{11}O_3]$ unit results from face sharing of coordination octahedra in the manner of a polynuclear metallo complex.

Units of this geometry were first found in Cs_7O[4], in which they are surrounded by purely metallic, close-packed structural regions. Thus there is a close relation between $Cs_{11}O_3$ and $[Cs_{11}O_3]Cs_{10}=Cs_7O$, completely analogous to the relation between Rb_9O_2 and $[Rb_9O_2]Rb_3=Rb_6O$[6, 7]. $Cs_{11}O_3$ is the structural analog of Rb_9O_2.

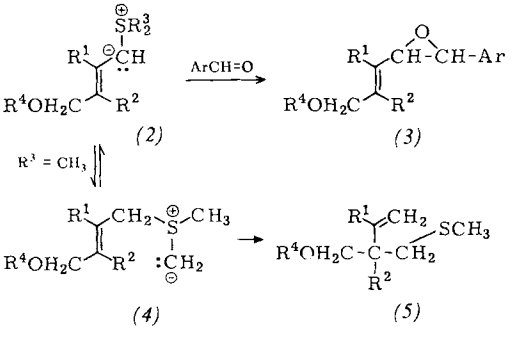
CONFERENCE REPORTS

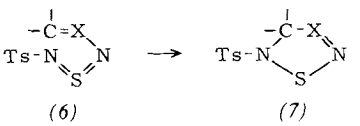
Two Unusual Sulfur Groups: Butadienylsulfonium Salts and Sulfur Diimides

By *Günter Kresze*[*]



1. *trans*-1,3-Butadienylsulfonium salts such as *(1)* are best prepared by reaction of *trans*-1,4-dihalo-2-butenes with dialkyl sulfides and treatment of the resulting 1,4-bis(dialkylsulfonio)-2-butene dihalides with sodium methoxide.

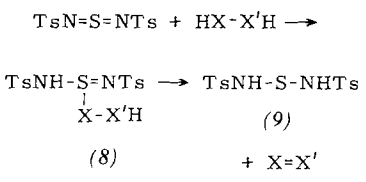
Thermolysis of the butadienylsulfonium salts *(1)* provides a useful synthesis of *trans*-1-(alkylthio)butadienes. Nucleophilic addition of alkoxides gives as intermediates sulfonium ylides *(2)*, which with aromatic aldehydes afford 3-(3-alkoxy-1-propenyl)-2-aryloxiranes *(3)* and moreover (in the case of the dimethylsulfonium compounds, $R^3=CH_3$) are in equilibrium with alkylsulfonium methylides *(4)* whose sigmatropic rearrangement leads to 3-butenyl sulfides *(5)*.



(1)

2. Sulfur diimides RN=S=NR also display ylide-like character in some reactions: α,β-Unsaturated NSN compounds of type *(6)*, derived from primary vinylamines, hydrazones, or hydrazine derivatives usually occur only as intermediates; they cyclize to *(7)* in reactions corresponding to *(4)* → *(5)*.

(2) *(3)* *(4)* *(5)*



(6) *(7)*

Sulfur bis(tosylimide) not only undergoes the usual additions (*e.g.* of alcohols or secondary amines) to one S=N

[*] Prof. Dr. G. Kresze
Organisch-Chemisches Laboratorium der Technischen Universität
8 München, Arcisstrasse 21 (Germany)

bond but also, in a series of cases, can act as dehydrogenating agent, with formation of bis(tosylamino)sulfane *(9)*. For example, reaction in aprotic media afforded azobenzenes from hydrazobenzene, quinones from hydroquinones, benzylidenemalonic esters from benzylmalonic esters, diphenyl sulfide from thiophenol, and naphthalene from 1,2- or 1,4-dihydronaphthalene. The first step in these dehydrogenations is to be formulated as an addition [in some case an ene reaction], and the second [because of the ylide character of the S=N bond in the adduct *(8)*] is considered as elimination of a sulfonium salt or, in some cases, as 1,5-H shift.

Lecture at Mainz on June 29, 1972 [VB 352 IE]

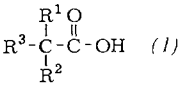
ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

Isotope separation by electrical migration in molten salts forms the theme of a report by *V. N. Lyubimov*. An introductory review of the underlying theoretical principles of the process is followed by an account of the application of this method to the separation of stable isotopes. Fused salts are used since here the mass effect is greater than in aqueous solutions. The author describes apparatus, methods of measurement, and experimental conditions, both for laboratory-scale investigations and for plant-scale production. The report contains a comprehensive table of experimental results for 20 elements. In connection with this work the following topics are also dealt with: Determination of ionic mobilities in molten salts, the structure of molten salts, and the mechanism of ionic migration in an electric field. [Separation of Isotopes by Electrical Migration and Determination of Ionic Mobilities in Molten Salts. Russ. Chem. Rev. *41*, 222—249 (1972); 31 references]

[Rd 587 IE –Q]



Analytical methods screening of drugs and narcotics are discussed by *M. Riedmann*. The rather expensive methods of mass spectrometry, nuclear magnetic resonance, spectrofluorimetry, and IR and UV spectrometry are not necessary for rapid testing of drugs. Thin-layer and, particularly, gas chromatography are quite suitable since they provide reliable results within a few minutes, which is of decisive importance in cases of acute poisoning and when dealing with a large number of samples (doping control at sports meetings!). Because of its high selectivity, an N-sensitive flame ionization detector is used for the detection of doping agents and drugs such as opiates, phenylalkylamines, indole alkaloids, benzilic acid esters, barbiturates, methadon, and lysergides. If the result is positive, then identification of the doping agent is confirmed by the gas chromatographic retention time. UV spectroscopy and thin-layer and gas chromatography are used for the analysis of cannabis products such as hashish and marijuana. The author also deals with the identification of opium alkaloids and barbiturates and with the importance of testing for drug misuse. [Analytische Methoden des Nachweises von Drogen und Giftstoffen. Naturwissenschaften *59*, 306–310 (1972); 19 references]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Film-forming polymer masses that are suitable for use as a resin base for hair-fixing preparations because of their solubility and film-forming properties consist of vinyl acetate, crotonic acid, and at least one vinyl ester of an α-branched, saturated, aliphatic monocarboxylic acid containing 5—10 carbon atoms in the carboxylic acid unit, which has the general formula *(1)*, where R^1 and R^2 denote alkyl and R^3 denotes hydrogen, alkyl, or aryl. The terpolymer consists of about 7 to 89% of vinyl acetate, about 6 to

(1)

13% of crotonic acid, and about 5 to 80% of vinyl ester, based on the total weight, and exhibits good solubility both in the typical organic solvents for use in hair sprays and in the typical aqueous solvent systems used for wave setting preparations. The terpolymer is also very compatible with the typical hydrocarbon propellants used for hair sprays. [DOS 1745208; National Starch and Chemical Corp., New York]

[PR 36 IE—E]

Nitration and Aromatic Reactivity. By *J. G. Hoggett, R. B. Moodie, J. R. Penton,* and *K. Schofield.* Cambridge University Press, London 1971. 1st edit., xii, 246 pp., £ 5.—.

Of the aromatic substitution reactions, nitration has been studied with particular thoroughness. It is not only of central importance in preparative organic chemistry, but has also played a decisive part in molding the development and progress of theoretical chemistry. Full account is taken of this in the present book. The authors have succeeded in exemplary fashion in giving the reader a closer look at the current problems in physical organic chemistry, using nitration as an example. They show their deep knowledge of the subject in their discussion of the relationship between structure, reactivity, and selectivity of electrophilic nitration reagents, in relation to nucleophilic substrates. Even more praiseworthy is the exposition (the need for which has been felt for a long time) on mixing and encounter controlled reactions and their disguising effect on the selectivity of chemical processes.

The contents of the book are arranged as follows:

1. Introduction; 2. Nitrating systems: A. mineral acids; 3. Nitrating systems: B. inert organic solvents; 4. Nitrating systems: C. miscellaneous (nitration with nitrogen pentoxide, nitration *via* nitrosation, nitration with nitronium salts in organic solvents); 5. Nitrating systems: D. benzoyl nitrate and systems formed from nitric acid and acetic anhydride; 6. The process of substitution. The remaining four chapters are devoted to the topic of nitration and aromatic reactivity: 7. Theoretical background; 8. Nitration of bases; 9. Nitration of monocyclic compounds; 10. Nitration of bicyclic and polycyclic compounds.

The book has author, subject, and compounds indexes and gives an impressive survey of the literature up to 1970. It can be recommended without reservations to any chemist of modern outlook.

Paul Rys [NB 88 IE]

Handbuch der Analytischen Chemie (Handbook of Analytical Chemistry). Part 3, Vol IIIa. Quantitative Analysis, Aluminium. By *W. Fresenius* and *G. Jander*, revised by *H. Bensch.* Springer-Verlag, Heidelberg—Berlin—New York, 1972. 2nd Edit., xix, 716 pp., 47 figs., bound DM 198.—.

With the appearance of the present edition, this well tried handbook has been expanded by a further important chapter. The author, who is a recognized specialist in the field of the analysis of aluminum, must be congratulated on his splendidly comprehensive contribution (no less than 2521 references!).

In addition to the two main sections on determination techniques (550 pp.) and separation techniques (80 pp.), the book contains an introduction to the principles of the chemistry of the aluminum ion in aqueous systems and a short section on special techniques, which consist essentially of techniques for the determination of aluminum metal, *e. g.* in metal powders or dross, and the determination of aluminum oxide in aluminum and its alloys and in iron and steel.

The chapter on determination techniques is subdivided into gravimetric, titrimetric, photometric, fluorometric, nephelometric, polarographic, spectrochemical and radiochemicals methods, and deals not only with the usual methods but also with a large number of other possibilities. The chapter on separation methods is subdivided into techniques involving precipitation of aluminum itself, separation by precipitation of the accompanying elements, by masking the aluminum or by complex formation, extraction techniques, separation by electrolysis on a mercury cathode, chromatographic techniques, and separation by evaporation in a current of hydrogen chloride or chlorine.

The material is concisely presented and contains a large number of clearly formulated operating procedures, useful notes being given wherever possible to indicate their accuracy, the possibility of interference, and the range of application. This is a genuine treasure house and no analytical laboratory should be without it.

Günther Kraft [NB 99 IE]

Diffusion Data. By *F. Wöhlbier.* Trans Tech Publications, Clausthal 1971. 1st edit., 269 pp., bound, $ 44.—.

"Diffusion Data" is a review of experimental results in the field of migration phenomena in crystalline and amorphous solids, and also in liquids that are solid at normal temperatures. Despite the brevity of the individual items it is comprehensive, and the results appear only a short time after their initial publication. Apart from work on diffusion as such, there are reports on the isotope effect in diffusion, on thermo- and electrotransport, ionic conductivity, permeation of gases, experimental methods for determining these effects, *etc.* Consideration is given to atomic transport processes in crystal lattices, along grain boundaries or dislocations, on surfaces and interfaces, and in thin films. The data are arranged in alphabetical order of the matrix substance concerned for each material grouping, *e.g.* metals and their alloys, semiconductors oxides, halides, organic crystals, *etc.* In conjunction with the author, subject, and subject field indexes, this breakdown enables the reader rapidly to find the information he wants. The bibliography is also broken down by material groupings.

The brief discussion on each article contains not only the actual experimental data, which are often advantageously supplemented by graphical presentations, but also information on the experimental method and the material used and the author's interpretation of the transport mechanisms, anomalies, *etc.* involved.

Vol. 5, No. 1 (1971) has an Appendix consisting of a complete author, subject, and subject field index to the first four volumes, which makes the present edition a miniature work of reference in its own right. For anyone requiring information on current results and experimental techniques in the field of migration phenomena, "Diffusion Data" offers the best possible method at present available for obtaining such information quickly, conveniently, and reliably.

Christian Herzig [NB 83 IE]

1000 Fragen aus der Chemie (1000 Questions from Chemistry) By *W. Geissler* and *T. Reinholz*. J. F. Lehmanns Verlag, München 1971. 1st ed., v, 210 pp., numerous figures, bound DM 16.—.

About 170 questions on general chemistry, 230 on inorganic and analytical chemistry, and 600 on organic chemistry are given, with short answers, in about 200 pages. According to the preface, the questions are largely authentic examination questions from the medical courses of West German universities. In the reviewer's opinion, however, a number of the questions are rather irrelevant to the budding physician. In view of the tightening-up of the syllabus that is necessitated by the new Education Act, there will be an increasing need in the future for the subject matter of courses to be closely concerned with medicine.

The collection of questions will probably be of little interest to the medical student in the foreseeable future. This is the more regrettable in that the authors have taken a great deal of trouble in the preparation of the book, which they undoubtedly also intended to be of assistance to medical students. (However, the authors cannot be held responsible for the selection of the examination material.) This criticism in no way limits the usefulness of the book to the other groups for whom it is intended. This collection of questions will be a significant and reasonably priced aid to teaching candidates and first-semester chemistry students, and can be recommended with a clear conscience.

Klaus Beyermann [NB 77 IE]

Absorption Spectra in the Ultraviolet and Visible Region. Vol. XV. Edited by *L. Láng*. Academic Press, New York—London 1971. 1st Edit., 408 pp., numerous tables and spectra. Ring-bound, $ 27.50.

The present 15th volume contains almost 200 spectra of a wide variety of compounds (aromatic, heterocyclic, organometallic compounds, *etc.*). The spectra are reproduced as $\log \varepsilon/m\mu$ diagrams on loose A 5 sheets. The reverse of each sheet, in addition to the name of the substance, the molecular formula, the molecular weight, and the melting point, carries information about the instrument with which the spectrum was recorded and data on the solvent, the concentration, the light path, and (in tabulated form) a number of recorded values [wavelength ($m\mu$) and $\log I_0/I$]. The sheets are held together in a ring binder. A clear list of contents contains a substance index, an author index, and a formula index.

Like the entire series, the volume is a collection of spectra that will be useful to any chemist

Egon Fahr [NB 98 IE]

Malting and Brewing Science. By *J. S. Hough, D. E. Briggs,* and *R. Stevens* Chapman & Hall Ltd., London, 1971, 678 pp., about 250 figs., £ 10.—.

As the authors state, this book has been written to provide a suitable textbook for students of brewing sciene in Birmingham. Since a single book obviously cannot cover all the aspects of this subject, the emphasis here is on the scientific side rather than on analytical methods or the use of equipment.

The main topics, treated in 22 chapters, including the biochemistry and technology of malting and drying barley; brewing water; the chemistry and biochemistry of mashing; brewing sugars and sirups; the chemistry of wort preparations and hop extraction; the biology and metabolism of brewers' yeasts; the growth of yeast and the fermentation of beer; and the treatment and quality of beer.

This book gives a detailed account of the field from the British standpoint. It contains about 300 structural formulas and metabolic schemes, 250 illustrations of equipment, and some 1000 references. Unfortunately, the Continental contribution to modern brewing technology is hardly represented and it might have been better perhaps to include some authors who have a command of French, Czech, and German, so as to arrive at a more complete and balanced picture of the field—as has been done in "Barley and Malt" and "The Chemistry and Biology of Yeasts", edited by *A. H. Cook*, which were written by 29 authors.

Anton Piendl [NB 86 IE]

Water and Water Pollution. Vol. 1. Ed. by *L. L. Ciaccio*. Marcel Dekker, Inc., New York 1971. 1st edit., xix, 449 pp., numerous figs., bound $ 27.50.

The editor has succeeded in getting some of the leading American experts in water chemistry for this four-volume handbook. The first volume takes as a starting point the chemical, physical, and biological characteristics of water, and goes on to apply a blend of practical experience and theoretical fundamentals to specific situations such as estuaries and rivers, the influence of pollution on the aquatic ecosystem, and the utilization of water during excessive rainfall or ground water enrichment.

The current position as regards the evaluation of waste waters and their chemical, physical, and biological purification is illustrated.

Although on many points the book concerns itself specifically with the water industry in the USA—which differs in many respects from its West German counterpart—this first volume is still of direct value in the way in which it successfully combines theory and practice. The systematic layout and the extremely careful way in which the bibliographies to the individual chapters have been compiled make this book easy to use. It can be used as a working tool by the student and practising specialist alike. It is also clearly enough written to act as a chemical textbook for civil engineers. It is to be hoped that the remaining three volumes will soon make their appearance.

Wilhelm Husmann [NB 87 IE]

Techniques of Chemistry. Edited by *A. Weissberger*. Vol. 2. **Organic Solvents, Physical Properties and Methods of Purification.** By *J. A. Riddick* and *W. B. Bunger*. Wiley-Interscience, New York–London 1970. 3rd Edit., xiii, 1041 pp., numerous tables, bound £ 11.75.

Our increasing understanding of the influence exerted by solvents on chemical reactions, equilibria, and absorption spectra has led not only to more objective criteria for the selection of suitable solvents but has also resulted in a marked increase in the number of solvents available. While

the first edition of the present handbook[*] described 160 solvents and thereby covered the whole known field, the present, third edition reports the physical properties and methods of purification of 354 solvents.

After a brief classification of organic solvents with regard to their chemical constitution, which is used in the arrangement of the 354 solvents (Chapter 1, 18 pages), Chapter 2 (42 pages) gives a thorough discussion of the tabulated physical constants, the methods by which they are determined, and the criteria for their selection from the literature. Chapter 3 (491 pages) contains in tabular form an overall summary of all the constants characteristic of a solvent. Here are the physical constants needed for identification and checking of purity (melting and boiling points, refractive index, density, *etc.*), and also those required in physicochemical measurements (*e.g.* cryoscopic and ebullioscopic constants). All in all, some 45 individual items of information are provided for each solvent, including literature references to UV, IR, NMR, and mass spectra of the solvent in question, and the Beilstein reference. I found the seven following tables particularly useful; here all the solvents are arranged by increasing boiling point, melting point, and dipole moment, and also by increasing density, ebullioscopic and cryoscopic constants, and dielectric constant. In Chapter 4 (20 pages) there is a brief discussion of the concept of purity of a substance and criteria of purity, together with an enumeration of the general methods used for the determination of water in organic solvents, and for its removal. Finally, in Chapter 5 (306 pages) there is a detailed summary of the general and specific purification methods for all the solvents tabulated in Chapter 3, together with notes on their handling and storage (toxicity, flashpoint, explosion limits). A distinction is made in the methods of purification according to the purpose to which the purified solvent is to be put. This extensive work is concluded by a bibliography of over 5300 references, which covers the literature up to 1968 (Chapter 6, 132 pages), and by a subject index.

The authors have succeeded in taking the almost unmanageably great mass of material on the constants and methods used in the selection and purification of solvents, and assembling it critically in a readily comprehensible form. All the same, certain hopes remain unrealized. There are no data on deuterated solvents, and only a few on the solvent mixtures (ligroin, petroleum ether) commonly used in laboratory practice. A note on the empirical parameter of the solvent polarity would have been useful. Solvents with high dielectric constants dissociate well, but are not necessarily ionizing solvents, as is maintained on p. 57. The ionizing capabilities of a solvent are determined by factors other than the dielectric constant.

In conclusion, it may be said that the present book is a highly successful and considerably extended revision of its well-known predecessor. The assessment of the reviewer of the first edition may be repeated without reservation: "The book should represent an extremely useful source of information for anyone concerned with solvents"[*]

SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
PR = Patent abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ABSOLUTE CONFIGURATION, of a 1,2-disubstituted ferrocene derivative with two different chiral substituents (SC) 138 [G.E. *84*, 164 (1972)]
Determination in (+)-pentahelicene (SC) 296 [G.E. *84*, 293 (1972)]

Absorption spectra, of tetragonal fluorides from the first transition metal series (LA) 64

Acetamide, syn-Planar conformation of oxalic acid: crystal structure of the oxalic acid-~ complex (SC) 514 [G.E. *84*, 536 (1972)]
Reaction of secondary ~-s with N-dichloromethylene-N,N-dimethylammonium chloride (SC) 917 [G.E. *84*, 993 (1972)]

Acetonitrile, Reaction with cyclohexanone (SC) 722 [G.E. *84*, 797 (1972)]

Acetylcholinesterase, Reactivation of phosphorylated ~ - dependence upon activator acidity (SC) 307 [G.E. *84*, 354 (1972)]

Acetylenes, Metal-olefin and -acetylene bonding in complexes (FP) 596 [G.E. *84*, 649 (1972)]
2-Cyclopropene-1-carboxylic acids from trimethylsilyl-~ (SC) 929 [G.E. *84*, 946 (1972)]
Transition-metal complexes of olefins and ~ (LA) 945
Chemistry of ~ (Book Review) 344

Acids, Transition states as ~ and bases (LA) 546
Solid ~ and bases (Book Review) 649

Acoustical holography, Advances in (FP) 279 [G.E. *84*, 280 (1972)]

Acridinium betaines, Novel method for synthesis (SC) 59 [G.E. *84*, 65 (1972)]

N-Acylaminopyrrolidinone, New ~ derivatives (PR) 1036

Acylating agents, Trifluoromethanesulfonic-carboxylic anhydrides, highly active ~ (SC) 299 [G.E. *84*, 294 (1972)]

Acylation, Catalytic Friedel-Crafts ~ of aromatic compounds (SC) 300 [G.E. *84*, 295 (1972)]

Acyloxylation, One-step substitutive ~ at carbon (LA) 446

(1-Adamantyl)-α-peroxylactone, Synthesis, kinetics, and luminescence (SC) 540 [G.E. *84*, 590 (1972)]

Adenosines, Simple new synthesis of N^6-substituted ~ and 2-amino-~ (SC) 304 [G.E. *84*, 347 (1972)]

Adenosine 3',5'-cyclophosphate, New analogs (SC) 713 [G.E. *84*, 711 (1972)]

Adenosine 3',5'-monophosphate, Mode of action of hormones (FP) 7 [G.E. *84*, 41 (1972)]

Adenosine 5'-triphosphate, Protection of ~ toward hydrolysis by the formation of a mixed-ligand metal ion complex (SC) 1025 [G.E. *84*, 1103 (1972)]

Adsorbents, Structure of porous ~ (FP) 267 [G.E. *84*, 331 (1972)]
Coordination-polymeric metal complexes of bifunctional dithiophosphinic acids and their use as ~ in chromatography (SC) 435 [G.E. *84*, 485 (1972)]

Adsorption, Photochemical and spectroscopic properties of organic molecules in the adsorbed state (LA) 156
~ and colloidal properties of radioactive elements (LA) 156
~ of organic compounds on electrodes (Book Review) 1037

Alanine, Preparation containing L-3-(4-hydroxy-3-methoxyphenyl)-~ and having antiparkinsonian action (PR) 856

Alcohols, Synthesis of hydroxy-deuterated ~ (LA) 945

Aldgarose (SC) 1021 [G.E. *84*, 1100 (1972)]

Alkali metal complexes, Formation in solution (LA) 545

Alkaloids, The ~ (Book Review) 860

n-Alkanes, The influence of haloalkanes on the ^{13}C-NMR spectra of ~ (SC) 1032 [G.E. *84*, 1101 (1972)]

Alkenes, Stereochemistry of cycloaddition of 1,3-diphenyl-2-azaallyllithium to ~ at 0 °C (SC) 290 [G.E. *84*, 261 (1972)]
Oxidation with mercury(II) salts (LA) 245

Alkylation, Anodic oxidation of trihexylmethoxyborate in presence of butadiene (SC) 48 [G.E. *84*, 32 (1972)]
Side-chain ~ of toluene with ethylene (SC) 918 [G.E. *84*, 947 (1972)]

Allenes, Reaction with a $L_2Ni(0)$ system (SC) 136 [G.E. *84*, 120 (1972)]
Dimerization of optically active 1,3-diphenylallene (CR) 322 [G.E. *84*, 304 (1972)]

Allyl anion, Ring opening of a cyclopropyl anion and cycloaddition of ~ (SC) 724 [G.E. *84*, 768 (1972)]

Aluminates, The reduction of organic compounds by alkoxyhydrido~ (LA) 1035

Aluminum complexes, Relation between structure and proton donor strength of octahedrally coordinated tris(3,5-diisopropylsalicylato)-~ (III), -gallium(III) and -indium(III) (SC) 1096 [G.E. *84*, 1151 (1972)]

Aluminum compounds, 2,3:3,4:4,2-Tri-μ-carbonyl-2,2,3,3,4,4-hexacarbonyl-1-aluminotricobalt: Preparation and spectroscopic findings (SC) 535 [G.E. *84*, 587 (1972)]
[Bis(dimethylamino)aluminoxy]dimethylaminocarbene as a complex ligand (SC) 934 [G.E. *84*, 997 (1972)]

Amalgam electrodes, Electrochemical measurements with ~ (LA) 447

Amination, Simple ~ of aromatic hydroxy-nitrogen heterocycles (SC) 305 [G.E. *84*, 348 (1972)]

Amine oxides, Photochemistry of aromatic ~ (CR) 240 [G.E. *84*, 220 (1972)]

Amines, C—C-Bond formation in the α-position to nitrogen in secondary ~. Lithiodimethylnitrosamine (SC) 310 [G.E. *84*, 350 (1972)]
Conjugation in aromatic ~ and phosphanes (SC) 836 [G.E. *84*, 898 (1972)]

Amino acid antagonists, Mode of action of ~ of biological origin (LA) 343

Amino acids, Analysis on the picomole scale (SC) 227 [G.E. *84*, 255 (1972)]
Simple method for the synthesis of some boc-~ (SC) 289 [G.E. *84*, 259 (1972)]
Rapid method for determination of optical purity (SC) 529 [G.E. *84*, 586 (1972)]
Rearrangement and polymerization mechanisms of DTE-~ and 2-thioxo-5-oxazolidones (CR) 337 [G.E. *84*, 360 (1972)]
Aromatic ~ in the metabolism of higher plants (LA) 244

2-Aminoadenosines, Simple new synthesis of N^6-substituted adenosines and ~ (SC) 304 [G.E. *84*, 347 (1972)]

Aminobenzenes, σ-Complexes in halogenation of ~ - isolation and secondary reactions (SC) 922 [G.E. *84*, 954 (1972)]

Aminoethanesulfonyl derivatives, New ~ (PR) 946

Aminopentalenecarbonitriles, a group of stable pentalenes (SC) 50 [G.E. *84*, 61 (1972)]

Ammonolysis, Neighboring group effects in ~ of acetic esters of polynuclear phenolic compounds (CR) 335 [G.E. *84*, 357 (1972)]

Analysis, Chemical ~ in extractive metallurgy (Book Review) 649

Analytical chemistry, Handbuch der Analytischen Chemie (Book Review) 1108

Analytical reagents, Use of radioisotopically labeled ~ (LA) 65

Annulenes, Simple synthesis and NMR spectroscopic behavior of 1,2-dihalo[18]-annulene (SC) 51 [G.E. *84*, 36 (1972)]
Bridged hetero[11]-~ (SC) 217 [G.E. *84*, 207 (1972)]
2-Hydroxy-4,9-methano[11]annulenone, a 10π-electron analog of tropolone (SC) 218 [G.E. *84*, 208 (1972)]
Oxa[17]-~ (SC) 424 [G.E. *84*, 472 (1972)]
Aza[17]-~ (SC) 426 [G.E. *84*, 474 (1972)]
Synthesis of aromatic bridged didehydroaza[17]-~ bearing alkyl substituents within the cavity of the π-electron cloud (SC) 833 [G.E. *84*, 896 (1972)]
Synthesis of stereoisomeric bisdehydrothia[17]-~ and their dioxides (SC) 834 [G.E. *84*, 897 (1972)]
Synthesis of 1-meth oxy-4,5:10,11-bis(tetramethylene)-6,8-didehydro[13]annulenyl anion, an aromatic 13-membered carbocyclic system (SC) 926 [G.E. *84*, 996 (1972)]
The ~ (LA) 546

Anorectics, N-Thienylalkyl-β-phenyl-ethylamines (LA) 736

Ansamycins (LA) 448

Anthracene, [2+4]- and [4+4]-Photoaddition to cyclopentadiene (SC) 718 [G.E. *84*, 718 (1972)]

Antibiotics, Chemistry and biochemistry of branched-chain sugars (FP) 159 [G.E. *84*, 192 (1972)]
Ansamycins (LA) 448

Antibody-complement interaction, Investigation with lipid model membranes (LA) 448

Anti-inflammatory agents, Perspectives in nonsteroidal ~ (FP) 460 [G.E. *84*, 512 (1972)]
4-(2-Benzoxazolyl)phenylacetic acids, alcohols, esters, and amides (LA) 736

Antiparkinsonian action, Preparation containing L-3-(4-hydroxy-3-methoxyphenyl)alanine and having ~ (PR) 856

Aquo complexes, Kinetic data on water exchange between ~ and solvent water (LA) 157

Archeology, Study of prehistoric metallurgy (FP) 620 [G.E. *84*, 668 (1972)]

Arenology principle, Linkage of alkyl groups through arenofunctional groups (SC) 842 [G.E. *84*, 824 (1972)]
Protophanes by oxidative coupling of "transposed dithiols" (SC) 844 [G.E. *84*, 826 (1972)]
Synthesis and properties of azole-pyridine combinations: problem of the hydrolytic cleavage of hetarene combinations (SC) 846 [G.E. *84*, 828 (1972)]

Aromatic, An alternative approach to the nomenclature of cyclic conjugated polyolefins, together with some observations on the use of the term "~" (FP) 404 [G.E. *84*, 447 (1972)]

Aromatic compounds, Synchronous six-electron cyclization of hexatriene systems as a new synthetic principle for preparation of ~ and hetero-~ (SC) 315 [G.E. *84*, 299 (1972)]

Aromatic substitutions, Structure and stereochemistry of the transition states and intermediates of heterolytic ~ (FP) 874 [G.E. *84*, 921 (1972)]

Aromatization of cyclohexylideneacetonitrile (SC) 723 [G.E. *84*, 767 (1972)]

Arsabenzenes, General synthesis of arylsubstituted ~ (SC) 441 [G.E. *84*, 440 (1972)]
Photoelectron spectroscopy and conjugation – direct proof of the unusual sequence of the two highest occupied π-molecular orbitals in the phosphorin (phosphabenzene) and the arsenin (arsabenzene) system (SC) 924 [G.E. *84*, 993 (1972)]

Arsanes, Stereochemistry of the halocarbonyl-phosphanes and ~ of molybdenum and tungsten (LA) 64

Arsenic compounds, $CH_3AsS_2N_2$, a five-membered arsenic-sulfur-nitrogen ring (SC) 529 [G.E. *84*, 585 (1972)]

Arsenides, $Ge_{38}P_8I_8$ and $Ge_{38}As_8I_8$, a new class of compounds with clathrate structure (SC) 43 [G.E. *84*, 30 (1972)]

Arsenin, X-ray structure analysis of 2,3,6-triphenyl-~ (SC) 630 [G.E. *84*, 679 (1972)]
Photoelectron spectroscopy and conjugation—direct proof of the unusual sequence of the two highest occupied π-molecular orbitals in the phosphorin (phosphabenzene) and the ~ (arsabenzene) system (SC) 924 [G.E. *84*, 993 (1972)]

Arsoles, Cleavage of 1-aryl-~ by alkali metals (SC) 439 [G.E. *84*, 483 (1972)]
Unusual substitution in an arsole ring (SC) 441 [G.E. *84*, 439 (1972)]

1-Arylarsoles, Cleavage by alkali metals (SC) 439 [G.E. *84*, 483 (1972)]

Asymmetric synthesis, A catalyzed ~ synthesis (SC) 1023 [G.E. *84*, 1070 (1972)]

Atoms, How are metal ~ formed in flames? (LA) 64

Autoradiography, Autoradiographie (Book Review) 68

Autoxidation, Kinetics of ~ of hydrocarbons in the liquid phase (LA) 64

2-Azaallyllithium, Stereochemistry of cycloaddition of 1,3-diphenyl-~ lithium to alkenes at 0°C (SC) 290 [G.E. *84*, 261 (1972)]
Ring opening of N-lithio-2,3(cis)-diphenylaziridine to 1,3(cis, trans)-diphenyl-~ and its rearrangement to the trans, trans-form (SC) 291 [G.E. *84*, 262 (1972)]

Aza[17]annulenes (SC) 426 [G.E. *84*, 474 (1972)]
Synthesis of aromatic bridged didehydro-~ bearing alkyl substituents within the cavity of the π-electron cloud (SC) 833 [G.E. *84*, 896 (1972)]

2-Aza-1,3-butadienes, Addition of phosphanes and phosphites to trifluoromethyl-substituted ~ (SC) 319 [G.E. *84*, 258 (1972)]

1-Aza-4-phosphabenzene, 2,6-Diphenyl-~ (SC) 1019 [G.E. *84*, 1069 (1972)]

3-Aza-2,4-trans-hexadiene, Structure of 2:1 cycloaddition product of diazomethane and 1,1,1-trifluoro-2-trifluoromethyl-~ (SC) 223 [G.E. *84*, 212 (1972)]

Aziridine, 2-Cyano-~ (SC) 151 [G.E. *84*, 108 (1972)]
Ring opening of N-lithio-2,3(cis)-diphenyl-~ to 1,3(cis,trans)-diphenyl-2-azaallyllithium and its rearrangement to the trans, trans-form (SC) 291 [G.E. *84*, 262 (1972)]
Effect of protonation on ~ and oxirane bond strengths (SC) 825 [G.E. *84*, 820 (1972)]

Azo compounds, Structurally isomeric metal chelates of unsymmetrical o,o′-dihydroxy-~ (SC) 312 [G.E. *84*, 351 (1972)]

Azodicarboxylic acid, Synthesis of isocyanides from N-monosubstituted formamides, phosphanes, and ~ derivatives (SC) 929 [G.E. *84*, 957 (1972)]

Azodicarboxylic imide, 1,4-Cycloaddition of azodicarboxylic phenylimide (4-phenyl-1,2,4-triazoline-3,5-dione) to cyclooctatetraene and its halogen derivatives (SC) 715 [G.E. *84*, 765 (1972)]

Azole, Synthesis and properties of ~-pyridine combinations: problem of the hydrolytic cleavage of hetarene combinations (SC) 846 [G.E. *84*, 828 (1972)]

Azomethines, N-Carbonylureas from ~ and N-chlorocarbonyl isocyanate (SC) 1011 [G.E. *84*, 1062 (1972)]
Cyclization of ~ by N-chlorocarbonyl isocyanate (SC) 1011 [G. E. *84*, 1063 (1972)]

Azulene, New routes to the ~ system (SC) 135 [G.E. *84*, 117 (1972)]

BACTERIA, Formation, structure, and function of the flagella of ~ (CR) 334 [G.E. *84*, 357 (1972)]

Bactericides, Fungicidal and bactericidal 4,5-dicyano-2-sulfonylimido-1,3-dithiacyclopentenes (PR) 946

Bacteriostatic fibers, Polymer based synthetic fibers with antibacterial properties (LA) 734

Barrelene, Bridgehead reactivities of trishomo-~ and trishomobullvalene (SC) 56 [G.E. *84*, 63 (1972)]

Bases, Basic behavior of epoxides in the presence of halide ions (FP) 1041 [G.E. *84*, 1157 (1972)]
Transition states as acids and ~ (LA) 546
Solid acids and ~ (Book Review) 649

Benzaldehyde, Photoisomerization of 2-[2-(N-ethoxycarbonyl-N-allylamino)ethyl]-~ (SC) 728 [G.E. *84*, 712 (1972)]

Benzene oxides, 1,4-Dioxocin (SC) 935 [G.E. *84*, 983 (1972)]
Valence tautomerism of 1,4-dioxocin with syn-benzene dioxide (SC) 937 [G.E. *84*, 985 (1972)]
Valence isomerization of syn-benzene trioxide to cis, cis, cis-1,4,7-trioxacyclononatriene; anti-benzene trioxide (SC) 939 [G.E. *84*, 986 (1972)]
trans-σ-Bis- and -tris-homobenzene derivatives; synthesis of cycloheptatriene-3,4-dicarboxylic acid derivatives (SC) 940 [G.E. *84*, 988 (1972)]
cis-Trioxatris-σ-homobenzene (cis-"benzene trioxide") (SC) 942 [G.E. *84*, 990 (1972)]

Benzenes, Ionization potentials of substituted ~ (SC) 525 [G.E. *84*, 544 (1972)]

Benzimidazolin-2-ones, Reaction of benzofuroxan with formaldehyde (SC) 1009 [G.E. *84*, 1060 (1972)]

Benzo[c]cinnolines, biaryls, stilbenes, and dibenz[c,mn]acridines from sulfonamides (SC) 826 [G.E. *84*, 822 (1972)]

Benzocyclopropene, X-ray structure analysis of a ~ derivative (SC) 422 [G.E. *84*, 434 (1972)]

Benzofuroxan, Reaction of ~ with formaldehyde (SC) 1009 [G.E. *84*, 1060 (1972)]

6,7-Benzomorphans, New racemic and optically active 2-cyclobutylmethyl-5-phenyl-~ (LA) 735

1,4-Benzoquinones, Aliphatic 1,2,3-triketones by ozonolysis of dialkyl-1,4-benzoquinones (SC) 1089 [G.E. *84*, 1144 (1972)]

p-Benzoquinones, Flash-vacuum thermolysis (CR) 333 [G.E. *84*, 314 (1972)]

Benzothiazylthioalkyl groups, Phenols substituted with ~ (PR) 1036

1-Benzothiepins, Synthesis of stable ~ (SC) 423 [G.E. *84*, 477 (1972)]

1,2,4-Benzotriazine 1,4-dioxide, Simple synthesis of 3-amino-~ (SC) 1900 [G.E. *84*, 1061 (1972)]

Benzoxazinones,4-(Dialkylamino)quinolines and 3,3-disubstituted 4(3H)-quinolones from 4H-3,1-~ and ynamines (SC) 720 [G.E. *84*, 716 (1972)]

Benzoxazole, 4-(2-Benzoxazolyl)phenylacetic acids, alcohols, esters, and amides (LA) 736

Benzyl cyanide, Aromatization of cyclohexylideneacetonitrile (SC) 723 [G.E. *84*, 767 (1972)]

Biallenyl, Cyclopropanation products (SC) 234 [G.E. *84*, 263 (1972)]

Biaryls, stilbenes, benzo[c]cinnolines, and dibenz[c,mn]acridines from sulfonamides (SC) 826 [G.E. *84*, 822 (1972)]

Bicycloheptafulvene, Methylenenorbornadiene, a ~ (SC) 512 [G.E. *84*, 533 (1972)]

Bicyclo[4.1.0]hept-1-ene, Bridged methylenecyclopropanes as test cases for Bredt's rule: 2,5,5,7,7-pentamethyl-~ (SC) 52 [G.E. *84*, 62 (1972)]

Bicyclo[4.2.1]nonane series, Reductive fragmentation of 3,3-dihalotricyclo[4.2.1.$0^{2,4}$]-non-2-yl acetates: a new route to the ~ (SC) 641 [G.E. *84*, 643 (1972)]

cis-Bicyclo[6.1.0]nona-2,4,6-triene, Degenerate rearrangement (SC) 832 [G.E. *84*, 892 (1972)]

Bicyclo[4.4.1]octane, Synthesis of 7,7-dimethyl-~-3-one by pinacolic rearrangement (SC) 640 [G.E. *84*, 642 (1972)]

Bilayers, Folding of fatty acid chains in liquid crystalline ~ (SC) 920 [G.E. *84*, 950 (1972)]

Biguanides, New ~ (PR) 856

Biochemical mechanisms, Exploration by tritium labeling (LA) 734

Biochemistry, Biochemisches Praktikum (Book Review) 857

Biography, The avenue of years — a memoir of Sir James Irvine (Book Review) 648

Biology, Die biologische Zukunft des Menschen (Book Review) 550

Biomembranes, Structural principles (FP) 551 [G.E. *84*, 597 (1972)]

Biopolymers, Kinetics of cooperative conformational transitions of linear ~ (FP) 568 [G.E. *84*, 615 (1972)]

Biphenylene, A squaric diamidine and an aza analog of ~ (SC) 433 [G.E. *84*, 481 (1972)]

7,7-Bis(alkylthio)norcaranes, Solvolysis of ~. A new method of homologation (SC) 49 [G.E. *84*, 50 (1972)]

Bischler-Napieralski reaction, Mechanism (SC) 919 [G.E. *84*, 947 (1972)]

Bishomoquinone, Synthesis and X-ray structure analysis of anti-1-bromotricyclo-[5.1.0.$0^{3,5}$]octane-2,6-dione (anti-1-bromo-~ (SC) 236 [G.E. *84*, 170 (1972)]

Block polymers, High-impact plastics formed by two phases. Adjustment of the degree of dispersion and of the interfacial adhesion by ~ (CR) 339 [G.E. *84*, 362 (1972)]

Blood coagulation, Molecular deficiencies in humans (LA) 446

Bond, Thermochemistry of the chemical ~ (LA) 545

Bonding, X-ray spectroscopic investigation of chemical ~ in solids (FP) 34 [G.E. *84*, 51 (1972)]
Metal-olefin and -acetylene ~ in complexes (FP) 596 [G.E. *84*, 649 (1972)]
Application of magnetic resonance methods in the elucidation of ~ in transition metal compounds (LA) 245
Current views of ~ in carbonylmetal compounds (LA) 545
~ in inorganic pseudohalides (LA) 545

Bond strengths, Effect of protonation on aziridine and oxirane ~ (SC) 825 [G.E. *84*, 820 (1972)]

9-Boraanthracene, Preparation of 9-phenyl-~ anion (SC) 53 [G.E. *84*, 28 (1972)]

Boranes, Organic syntheses via free-radical displacement reactions (FP) 692 [G.E. *84*, 702 (1972)]

Borates, Anodic oxidation of trihexylmethoxyborate in presence of butadiene (SC) 48 [G.E. *84*, 32 (1972)]

Boron compounds, Structure of $(CH_3OBC_5H_5)_2Co$, a derivative of the aromatic hydridoborinate anion (SC) 42 [G.E. *84*, 29 (1972)]

Bredt's rule, Bridged methylenecyclopropanes as test cases for ~: 2,5,5,7,7-pentamethylbicyclo[4.1.0]-hept-1-ene (SC) 52 [G.E. *84*, 62 (1972)]

Brewing science, Malting and ~ (Book Review) 1109

Bullvalene, Bridgehead reactivities of trishomobarrelene and trishomo-~ (SC) 56 [G.E. *84*, 63 (1972)]

Butadiene, Chemical syntheses with metal atoms: preparation of bis (~)iron complexes and ~-tetracarbonylchromium (SC) 532 [G.E. *84*, 547 (1972)]

3-Butenyl Grignard reagents, Rearrangement: anionic or radical? (SC) 542 [G.E. *84*, 531 (1972)]

CALCULATIONS, Insights into small ring carbocations provided by MO ~ (CR) 330 [G.E. *84*, 316 (1972)]

Camptothecin, Biogenetically oriented total synthesis of ~ and 7-chloro-~ (SC) 289 [G.E. *84*, 265 (1972)]

Carbanions, Silicon as a carbanion substituent in ylides (CR) 944 [G.E. *84*, 957 (1972)]

Carbene complexes, Unusual ^{13}C chemical shifts of transition metal-~ (SC) 141 [G.E. *84*, 155 (1972)]
Transition metal-~ as π-ligands — [ethoxy-(2,6-dimethoxyphenyl)carbenetetracarbonyliron(0)]tricarbonyliron(0) (SC) 238 [G.E. *84*, 214 (1972)]
Dimethylphosphane(phenylmethoxy)-methylenepentacarbonylchromium(0) — a route from ~ to ylide complexes (SC) 643 [G.E. *84*, 679 (1972)]
Demonstration of isomers and intramolecular isomerization of ~ of chromium (SC) 644 [G.E. *84*, 682 (1972)]

Carbene reactions, Carbonyl ylides and dichlorooxiranes in ~ (CR) 326 [G.E. *84*, 307 (1972)]

Carbene rearrangements, Cycloheptatrienylidene: structure and role in carbene-~ (CR) 325 [G.E. *84*, 306 (1972)]

Carbenes, DTA studies on formation of dehydrobenzene and dichlorocarbene from haloorganolithium compounds (SC) 507 [G.E. *84*, 527 (1972)]
[Bis(dimethylamine)aluminoxy]dimethylaminocarbene as a complex ligand (SC) 934 [G.E. *84*, 997 (1972)]
Carbenoids, ~, and nitrenes as polymerization initiators (LA) 855

Carbenoids, Chemistry of ~ and other thermolabile organolithium compounds (FP) 473 [G.E. *84*, 557 (1972)]
Organomercury ~ for the synthesis of cyclopropane derivatives (SC) 231 [G.E. *84*, 160 (1972)]
~, carbenes, and nitrenes as polymerization initiators (LA) 855
Carbides, Crystal chemistry of complex ~ and related compounds (FP) 906 [G.E. *84*, 973 (1972)]
Transition metal ~ and nitrides (Book Review) 947

Carbocations, Insights into small ring ~ provided by MO calculations (CR) 330 [G.E. *84*, 316 (1972)]

Carbocycles, Synthesis of five-membered ~ by [1,3]-anionic cycloaddition (SC) 292 [G.E. *84*, 292 (1972)]

Carbodiimidium compounds as reagents in organic chemistry (SC) 229 [G.E. *84*, 158 (1972)]

Carbohydrase, Enzymic synthesis of homogeneous stereoregular polymers (CR) 645 [G.E. *84*, 644 (1972)]

Carbohydrate esters, Rearrangements with anhydrous hydrofluoric acid (CR) 241 [G.E. *84*, 221 (1972)]

Carbohydrates, Chemistry and biochemistry of branched-chain sugars (FP) 159 [G.E. *84*, 192 (1972)]
Synthesis and pulse Fourier transform ^{13}C-NMR spectra of brached-chain ~ (SC) 148 [G.E. *84*, 111 (1972)]
Synthesis of branched ~ with aldehyde side chains. – Simple synthesis of L-streptose and D-hamamelose (SC) 149 [G.E. *84*, 112 (1972)]
Complex shift reagent for ^{13}C-NMR studies on ~ (SC) 539 [G.E. *84*, 589 (1972)]
Aldgarose (SC) 1021 [G.E. *84*, 1100 (1972)]

Carbon, Preparation, properties, and applications of vitreous ~ (LA) 66

Carbonate, Methyl hydrogen ~ (SC) 534 [G.E. *84*, 549 (1972)]

Carbon disulfide, Conversion of cyclic nitrones to thiolactams by reaction with ~ (SC) 47 [G.E. *84*, 34 (1972)]

Carbonic anhydrase, Metal ion function in ~ (FP) 408 [G.E. *84*, 461 (1972)]

Carbon monoxide, Catalytic deoxygenation of aromatic nitro compounds by ~ in presence of diphenylacetylene (SC) 634 [G.E. *84*, 641 (1972)]

Carbonyl compounds, 1-Formylamino-1-arylsulfonyl alkenes from α-metalated isocyanomethyl aryl sulfones and ~; conversion of a carbonyl compound into the next higher carboxylic acid (SC) 311 [G.E. *84*, 289 (1972)]
1,3-Oxazolidine-2-thiones from alkyl isothiocyanates and ~ (SC) 933 [G.E. *84*, 956 (1972)]

Carbonylmetal compounds, Current views of bonding (LA) 545

Carbonyl olefination, Ketene thioacetals by "Peterson-~" with metalated formyl trimethylsilyl thioacetals (SC) 443 [G.E. *84*, 476 (1972)]

N-Carbonylureas from azomethines and N-chlorocarbonyl isocyanate (SC) 1011 [G.E. *84*, 1062 (1972)]

Carbonyl ylides and dichlorooxiranes in carbene reactions (CR) 326 [G.E. *84*, 307 (1972)]

Carboxylic acid, 1-Formylamino-1-arylsulfonyl alkenes from α-metalated isocyanomethyl aryl sulfones and carbonyl compounds; conversion of a carbonyl compound into the next higher ~ (SC) 311 [G.E. *84*, 289 (1972)]

Carboxylic anhydrides, Trifluoromethanesulfonic-~, highly active acylating agents (SC) 299 [G.E. *84*, 294 (1972)]

Carbylamine reaction, Phase transfer catalysis in the Hofmann ~ (SC) 530 [G.E. *84*, 587 (1972)]

Carrier, Novel ~ for solid phase synthesis of oligomers (SC) 713 [G.E. *84*, 712 (1972)]

Carrier-bound biologically active substances and their applications (FP) 249 [G.E. *84*, 319 (1972)]

Catalysis, Phase transfer ~ in the Hofmann carbylamine reaction (SC) 530 [G.E. *84*, 587 (1972)]
~ by phthalocyanine complexes (CR) 239 [G.E. *84*, 219 (1972)]

Catalysts, Carrier-bound biologically active substances and their applications (FP) 249 [G.E. *84*, 319 (1972)]

Catalytic hydrogenation, Practical ~. Techniques and applications (Book Review) 649

β-Diketone chelates, Structures and bonding properties (LA) 64
Isomerization of metal ~ (LA) 65

Dimerization, Cathodic ~ (FP) 760 [G.E. *84*, 798 (1972)]

6,6-Dimethylfulvene, Dye-sensitized photooxygenation of ~; a new 1,2-dioxolane rearrangement (CR) 330 [G.E. *84*, 311 (1972)]

Diols, Polycondensation of diethyl phosphite with aliphatic ~ (CR) 341 [G.E. *84*, 363 (1972)]

1,4-Dioxocin (SC) 935 [G.E. *84*, 983 (1972)]
Valence tautomerism with syn-benzene dioxide (SC) 937 [G.E. *84*, 985 (1972)]

1,2-Dioxolane rearrangement, Dye-sensitized photooxygenation of 6,6-dimethylfulvene; a new ~ (CR) 330 [G.E. *84*, 311 (1972)]

1,3-Diphenylallene, Dimerization of optically active ~ (CR) 322 [G.E. *84*, 304 (1972)]

1,3-Dipoles, General synthetic route to seven-membered heterocycles from cyclobutenes and ~ (SC) 926 [G.E. *84*, 995 (1972)]

Diradicals, Electronic properties (FP) 92 [G.E. *84*, 86 (1972)]

Displacement reactions, Organic syntheses via free-radical ~ (FP) 692 [G.E. *84*, 702 (1972)]

Disulfides, Chirooptical properties of the cystine disulfide bond (CR) 854 [G.E. *84*, 902 (1972)]

Disulfur monoxide, Chemistry of ~ (LA) 244

1,3-Dithiacyclopentenes, Fungicidal and bactericidal 4,5-dicyano-2-sulfonylimido-~ (PR) 946

Dithiazepine, New principle for preparation of bicyclic ~ systems (SC) 511 [G.E. *84*, 535 (1972)]

Dithiophosphinic acids, Coordination-polymeric metal complexes of bifunctional ~ and their use as adsorbents in chromatography (SC) 435 [G.E. *84*, 485 (1972)]

Double bond, Reactivity of ~ in higher olefins depending upon position and geometrical configuration (CR) 62 [G.E. *84*, 37 (1972)]
Reactions of ~-s activated by methoxy groups (CR) 324 [G.E. *84*, 306 (1972)]
Stereochemistry of ~-s (LA) 855

Drugs, Analytical methods of detection of ~ and poisons (LA) 1107

Dyes, Industrial application of the semiconductor properties of ~ (FP) 1051 [G.E. *84*, 1077 (1972)]
The chemistry of synthetic ~ (Book Review) 547, 737
Leitfaden der Farbstoffchemie (Book Review) 246

Dyotropic rearrangements, a new class of orbital-symmetry controlled reactions. Type I. (SC) 129 [G.E. *84*, 161 (1972)]
~, a new class of orbital-symmetry controlled reactions. Type II. (SC) 130 [G.E. *84*, 163 (1972)]

ELECTRIC fields, Properties of molecules in ~ (CR) 1033 [G.E. *84*, 1074 (1972)]

Electrochemistry, Cathodic dimerization (FP) 760 [G.E. *84*, 798 (1972)]
Anodic oxidation of trihexylmethoxyborate in presence of butadiene (SC) 48 [G.E. *84*, 32 (1972)]
Single-step synthesis of 1,n-dicarboxylic diesters by Kolbe electrolysis of oxalic and malonic half esters in the presence of olefins (SC) 841 [G.E. *84*, 893 (1972)]
Modern ~ (Book Review) 67,

Electrodes, Electrochemical measurements with amalgam ~ (LA) 447
Adsorption of organic compounds on ~ (Book Review) 1037

Electronic states, Three isomerization routes originating from different ~ of a linearly-conjugated cyclohexadienone (SC) 637 [G.E. *84*, 638 (1972)]

Electronic theory of cyclic $(pd)_\pi$-systems (LA) 855

"Electron lone pairs" in organic sulfides and disulfides (SC) 150 [G.E. *84*, 119 (1972)]

Electron-rich olefins, Reactions with proton-active compounds (FP) 964 [G.E. *84*, 1022 (1972)]

Electron spectroscopy for chemical analysis: ESCA (FP) 83 [G.E. *84*, 144 (1972)]

Electron transfer reactions, Cation radicals in ~ (LA) 734

Electron transport, Energy coupling and ~ (CR) 544 [G.E. *84*, 553 (1972)]

Electrophilic substitution, Model reactions for ~ of aromatic compounds (CR) 61 [G.E. *84*, 37 (1972)]
Unusual aromatic ~ (LA) 65

Eliminations, The syn and anti steric course in bimolecular olefin-forming ~ (FP) 200 [G.E. *84*, 177 (1972)]

Enamines, Reactions with N-dichloromethylene-N,N-dimethylammonium chloride (SC) 916 [G.E. *84*, 991 (1972)]

Energetics, Chemical ~ (Book Review) 858

Energy coupling and electron transport (CR) 544 [G.E. *84*, 553 (1972)]

Enone lactones, Synthesis and photochemical behavior (CR) 327 [G.E. *84*, 308 (1972)]

Enzymes, Carrier-bound biologically active substances and their applications (FP) 249 [G.E. *84*, 319 (1972)]
Enzymatic hydroxylations with molecular oxygen (FP) 701 [G.E. *84*, 689 (1972)]
Enzymic synthesis of homogeneous stereoregular polymers (CR) 645 [G.E. *84*, 644 (1972)]
~ containing molybdenum (LA) 945

Epoxides, Basic behavior in presence of halide ions (FP) 1041 [G.E. *84*, 1173 (1972)]

7,8-cis-Epoxy-2-methyloctadecane, Novel total synthesis of the sex attractant of Porthetria dispar (~) (SC) 60 [G.E. *84*, 67 (1972)]

Erythrinanes, Rearrangements of spirolactams with synthetic cis- and trans-~ as example (CR) 240 [G.E. *84*, 220 (1972)]

ESR spectroscopy, ESR measurements for the 2,2',6,6'-tetrachloro derivative of Chichibabin's hydrocarbon (SC) 531 [G.E. *84*, 546 (1972)]
1,3,5-Benzenetriyltris(1,5-diphenyl-3-verdazyl): A radical having a nearly degenerate doublet-quartet ground state (SC) 830 [G.E. *84*, 890 (1972)]
~ as a method of conformational analysis (CR) 242 [G.E. *84*, 223 (1972)]

Ester migrations, Sigmatropic [1,5]-~ (SC) 513 [G.E. *84*, 534 (1972)]

Esters, Model reactions for synthesis of pharmacologically active polymers by way of monomeric and polymeric reactive ~ (SC) 1103 [G.E. *84*, 1189 (1972)]

Ethylene, Side-chain alkylation of toluene with ~ (SC) 918 [G.E. *84*, 947 (1972)]

Ethylene-olefin copolymers, Synthesis by means of soluble organometal catalysts (CR) 853 [G.E. *84*, 902 (1972)]

Evolution, Self-organization of molecular systems and ~ of the genetic apparatus (FP) 798 [G.E. *84*, 838 (1972)]
Computer model of the formation of self-organizing systems (FP) 821 [G.E. *84*, 862 (1972)]

FATTY acid chains, Folding in liquid crystalline bilayers (SC) 920 [G.E. *84*, 950 (1972)]

Fatty acid synthetase, Genetic organization of the ~ complex of yeast (CR) 154 [G.E. *84*, 124 (1972)]

Favorskii rearrangement, Cyclopropanones and the ~. An unexpectedly large secondary isotope effect (CR) 329 [G.E. *84*, 311 (1972)]

Fenton's reagent, Free-radical alkylation with sulfoxides and ~ (CR) 241 [G.E. *84*, 222 (1972)]

Ferredoxins, X-ray photoelectron spectroscopy of iron-containing proteins – Valency of iron in ~ (SC) 232 [G.E. *84*, 156 (1972)]

Ferrocene, Absolute configuration of a 1,2-disubstituted ~ derivative with two different chiral substituents (SC) 138 [G.E. *84*, 164 (1972)]
Structure and properties of α,α-diferrocenylmethylium ion (SC) 1025 [G.E. *84*, 1104 (1972)]
Reaction of ferrocenylmethylium ions with nitrosobenzene (SC) 1027 [G.E. *84*, 1106 (1972)]
Partial charge on the iron in the diferrocenylmethylium ion (SC) 1028 [G.E. *84*, 1107 (1972)]

Ferrocenylmethylium ions, Reaction with nitrosobenzene (SC) 1027 [G.E. *84*, 1106 (1972)]

Fiber chemistry, Essential ~ (Book Review) 647

Fibers, Polycrystalline inorganic ~ – production, properties, applications (FP) 751 [G.E. *84*, 866 (1972)]
Polymer based synthetic ~ with antibacterial properties (LA) 734
A new composite fiber (LA) 735
Crosslinked, carbon-loaded polyolefin textile ~ (PR) 856
Improved polyester ~ suitable for dyeing under high-temperature conditions (PR) 855

Flagella, Formation, structure, and function of ~ of bacteria (CR) 334 [G.E. *84*, 357 (1972)]

Flames, How are metal atoms formed in ~? (LA) 64

Flame spectroscopy, Analytical ~ – selected topics (Book Review) 547

Flash-vacuum thermolysis of p-benzoquinones (CR) 333 [G.E. *84*, 314 (1972)]

Flavor research principles and techniques (Book Review) 650

Fluorides, Preparation of non-noble metals (Li, Ca, Sr, Ba, Am, Cf) by reduction of their oxides and ~ with hydrogen (SC) 515 [G.E. *84*, 537 (1972)]
Absorption spectra of tetragonal ~ from the first transition metal series (LA) 64

Fluorinated β-sultones (FP) 583 [G.E. *84*, 623 (1972)]

Fluorine compounds, 1-Cyclopentadienyldifluorophosphane: a new fluxional molecule (SC) 644 [G.E. *84*, 683 (1972)]
4-(Difluorooxophosphoranyl)-1λ⁴,3,5,2,-4,6-trithiatriazine (SC) 642 [G.E. *84*, 684 (1972)]

Fluoro complexes, Preparation and structure of $Rb[Mo_2O_2F_9]$ 1020 [G.E. *84*, 1099 (1972)]

Fluorophosphoranes, Tetraorgano-~ (SC) 144 [G.E. *84*, 165 (1972)]

Fluxional molecule, 1-Cyclopentadienyldifluorophosphane: a new ~ (SC) 640 [G.E. *84*, 683 (1972)]

Folding of fatty acid chains in liquid crystalline bilayers (SC) 920 [G.E. *84*, 950 (1972)]

Force constants, Calculation of vibrational frequencies and ~ (LA) 66

Formaldehyde, Reaction with benzofuroxan (SC) 1009 [G.E. *84*, 1060 (1972)]

Formamides, Synthesis of isocyanides from N-monosubstituted ~, phosphanes and azodicarboxylic acid derivatives (SC) 929 [G.E. *84*, 957 (1972)]

Formimidates, New 1-carbamoyl-N-carbamoyloxy-~ (PR) 946

α-Formylamino-β-hydroxy-acid esters, Ethyl ~(β-substituted N-formylserine esters) from ethyl 2-oxazoline-4-carboxylates (SC) 432 [G.E. *84*, 435 (1972)]

N-Formylserine esters, Ethyl α-formylamino-β-hydroxy-acid esters (β-substituted ~) from ethyl 2-oxazoline-4-carboxylates (SC) 432 [G.E. *84*, 435 (1972)]

Fragmentation, Reductive ~ of 3,3-dihalotricyclo[4.2.1.$0^{2,4}$]non-2-yl acetates: a new route to the bicyclo[4.2.1]nonane series (SC) 641 [G.E. *84*, 643 (1972)]

Friedel-Crafts acylation, Catalytic ~ of aromatic compounds (SC) 300 [G.E. *84*, 295 (1972)]

Fries rearrangement, Photo-~ (LA) 65

Fulvalenes, Sesqui-~ from dihydro-~ (SC) 133 [G.E. *84*, 115 (1972)]
Vinylogous fulvalene: synthesis and electrocyclic reaction (SC) 296 [G.E. *84*, 297 (1972)]

Fulvenes, Vinylogous hepta-~ from vinylogous ~ (SC) 131 [G.E. *84*, 113 (1972)]

Fungicides, Fungicidal and bactericidal 4,5-dicyano-2-sulfonylimido-1,3-dithiacyclopentenes (PR) 946

GALLIUM complexes, Relation between structure and proton donor strength of octahedrally coordinated tris(3,5-diisopropylsalicylato)-aluminum(III), -gallium(III), and -indium(III) (SC) 1096 [G.E. *84*, 1151 (1972)]

Gas chromatography, Data processing in ~ (FP) 366 [G.E. *84*, 390 (1972)]

Gelatin, Properties of collagen and ~ in the solid state (LA) 854

Gel permeation chromatography, Errors in the determination of narrow and broad molecular weight distributions by ~ and their possible elimination (CR) 334 [G.E. *84*, 356 (1972)]

Genetic information, Transcription of ~ and its regulation by protein factors (FP) 883 [G.E. *84*, 961 (1972)]

Genetics, Genetic aspects of hemoglobin synthesis (FP) 576 [G.E. *84*, 649 (1972)]

Geochemistry, Organic ~ (LA) 446

1-Germa-3-cyclopentenes, Photoelectron spectroscopy and transannular interactions – the question of transannular d-π interactions in 1-sila-3-cyclopentenes and ~ (SC) 837 [G.E. *84*, 899 (1972)]

Germanium compounds, $Ge_{38}P_8I_8$ and $Ge_{38}As_8I_8$, a new class of compounds with clathrate structure (SC) 43 [G.E. *84*, 30 (1972)]
Publications on organo-~ (LA) 733
The organic compounds of germanium (Book Review) 652

Glow discharges, Organic syntheses in the plasma of ~ and their preparative application (FP) 781 [G.E. *84*, 876 (1972)]

Glutaronitriles, Simple synthesis of substituted ~ (SC) 723 [G.E. *84*, 767 (1972)]

Gold complexes, Trimeric 1-(cyclohexylimino)methoxymethylgold(I), a new type of organometallic compound (SC) 429 [G.E. *84*, 482 (1972)]

Graft reactions on SiO_2 surfaces (CR) 337 [G.E. *84*, 359 (1972)]

Gramicidin S, Chirooptical properties of the cystine disulfides bond (CR) 854 [G.E. *84*, 902 (1972)]

Grignard reagents, Rearrangement of 3-butenyl ~: anionic or radical? (SC) 542 [G.E. *84*, 531 (1972)]

Growth processes due to reactions in swellable cellular matrixes (FP) 990 [G.E. *84*, 1001 (1972)]

Guanidine, Alkylamino-~ derivatives (LA) 735

HAIR sprays, Film-forming polymer masses (PR) 1107

Halide ions, Basic behavior of epoxides in presence of ~ (FP) 1041 [G.E. *84*, 1173 (1972)]

Haloalkanes, Influence on ^{13}C-NMR spectra of n-alkanes (SC) 1032 [G.E. *84*, 1101 (1972)]

Halogenation, σ-Complexes in ~ of aminobenzenes – isolation and secondary reactions (SC) 922 [G.E. *84*, 954 (1972)]
Primary step in ~ of cyclooctatetraene (SC) 1104 [G.E. *84*, 1187 (1972)]

Halogen cations and interhalogen cations (LA) 447

Halogen compounds, Vibrational spectra of octahedral hexa-~ (LA) 447
Base-catalyzed halogen dance (LA) 734

Halomalonaldehydes, Preparation and reactions (CR) 62 [G.E. *84*, 68 (1972)]

D-Hamamelose, Synthesis of branched carbohydrates with aldehyde side-chains. – Simple synthesis of L-streptose and ~ (SC) 149 [G.E. *84*, 112 (1972)]

Handbook, of chemistry and physics (Book Review) 449
Römpps Chemie Lexikon (Book Review) 947
Handbuch der Analytischen Chemie (Book Review) 1108

Heme, Biosynthesis of ~ and vitamin B_{12} from [α,γ-$^{14}C_2$]-uroporphyrinogen-III (SC) 421 [G.E. *84*, 433 (1972)]

Hemoglobin, Genetic aspects of ~ synthesis (FP) 576 [G.E. *84*, 649 (1972)]

Heptafulvenes, Vinylogous ~ from vinylogous fulvenes (SC) 131 [G.E. *84*, 113 (1972)]

Herbicides, S-Benzyl-N,N-di-sec-butylthiocarbamate (PR) 946

Hetero[11]annulenes, Bridged ~ (SC) 217 [G.E. *84*, 207 (1972)]

Heterocycles, New reactions with cyanic esters (FP) 949 [G.E. *84*, 1008 (1972)]
A general synthetic route to seven-membered ~ from cyclobutenes and 1,3-dipoles (SC) 926 [G.E. *84*, 995 (1972)]
Use of polyphosphoric acid for the synthesis of polymeric aromatic ~ by cyclopolycondensation reactions (LA) 244

Heterocyclic systems, Conformational analysis in ~: recent results and applications (FP) 739 [G.E. *84*, 779 (1972)]

Hexafluoro complexes, Electronic spectra (LA) 65

Hexatriene, Synchronous six-electron cyclization of ~ systems as a new synthetic principle for preparation of aromatic and heteromatic compounds (SC) 315 [G.E. *84*, 299 (1972)]

High-impact plastics formed by two phases. Adjustment of the degree of dispersion and of the interfacial adhesion by block polymers (CR) 339 [G.E. *84*, 362 (1972)]

High pressure properties, and their dependence on molecular structure (CR) 645 [G.E. *84*, 686 (1972)]

Histones, Structure and function of chromosomal nucleo-~ (FP) 496 [G.E. *84*, 451 (1972)]

History, Study of prehistoric metallurgy (FP) 620 [G.E. *84*, 668 (1972)]

Holography, Advances in acoustical ~ (FP) 279 [G.E. *84*, 280 (1972)]

Homobenzene, trans-σ-Bis- and -tris-~derivatives; synthesis of cycloheptatriene-3,4-dicarboxylic acid derivatives (SC) 940 [G.E. *84*, 988 (1972)]
cis-Trioxatris-σ-~ (cis-"benzene trioxide") (SC) 942 [G.E. *84*, 990 (1972)]

Homologation, Solvolysis of 7,7-bis(alkylthio)norcaranes. New method of ~ (SC) 49 [G.E. *84*, 50 (1972)]

Homopolymerization, Determination of kinetic constants of ~ by measurement of copolymerizations (CR) 341 [G.E. *84*, 363 (1972)]

Homotropilidene, Kinetics of the ~ valence tautomerism (SC) 517 [G.E. *84*, 539 (1972)]

Hormones, Mode of action (FP) 7 [G.E. *84*, 41 (1972)]
Arthropod molting ~ of plant origin (LA) 546

Hydrazines, Spirophosphoranes from acyl-~ and phosphorus compounds (SC) 306 [G.E. *84*, 349 (1972)]

Hydride complexes (LA) 1034

Hydrocarbons, Photoelectron spectra of benzenoid ~ $C_{18}H_{12}$ (SC) 538 [G.E. *84*, 551 (1972)]
Kinetics of autoxidation of ~ in the liquid phase (LA) 64
Rearrangements of $(CH)_n$ compounds (LA) 733

Hydrofluoric acid, Rearrangements of carbohydrate esters with anhydrous ~ (CR) 241 [G.E. *84*, 221 (1972)]

Hydroformylation, New aspects of the ~ reaction (CR) 155 [G.E. *84*, 172 (1972)]

Hydrogenation, Practical catalytic ~ .Techniques and applications (Book Review) 649

Hydrogen carriers, Quinoxalines as ~ (PR) 1037

Hydrogen cyanide chemistry: synthesis of diiminosuccinonitrile (CR) 153 [G.E. *84*, 173 (1972)]

Hydroxylations, Enzymatic ~ with molecular oxygen (FP) 701 [G.E. *84*, 689 (1972)]

Hypoiodite reaction (LA) 245

IMIDAZOISOQUINOLINEDIONES (PR) 1036

Immunity, In vitro methods in cell-mediated ~ (Book Review) 1038

Immunochemistry, Einführung in die Immunchemie und Immunologie (Book Review) 650

Immunology, Einführung in die Immunchemie und Immunologie (Book Review) 650

Indene, 1-Diazo-~ and spiro[~-1,7'-norcaradiene] (SC) 44 [G.E. *84*, 31 (1972)]

2H-Indeno[1,2-c]pyridines, 1,3,4,9b-Tetrahydro-~ (PR) 857

Indium complexes, Relation between structure and proton donor strength of octahedrally coordinated tris(3,5-diisopropylsalicylato)-aluminum(III), -gallium(III) and -indium(III) (SC) 1096 [G.E. *84*, 1151 (1972)]

3-Indolylacetic acid, Antiphlogistic N-acyl-~ derivatives (PR) 856

Infrared rotatory dispersion (IRD) (SC) 226 [G.E. *84*, 218 (1972)]

Infrared spectra of pseudo-halide complexes (LA) 65

Inorganic chemistry, Experimentelle Einführung in die Anorganische Chemie (Book Review) 71
Chemie 1, Anorganisch (Book Review) 737

Inorganic fibers, Polycrystalline ~ - production, properties, applications (FP) 751 [G.E. *84*, 866 (1972)]

Insulin, Influence of N-acylation on the three-dimensional structure and the properties of ~ (CR) 335 [G.E. *84*, 358 (1972)]
~ derivatives that cause only slight immunization (PR) *856*
Monoacyl derivatives of ~ with improved physicochemical properties (PR) 856

Insertion reactions, MO calculations on ~ of vinyl cations (SC) 635 [G.E. *84*, 680 (1972)]

Interelectronic repulsion, Assessment of the ~ parameter (LA) 66

Interhalogen cations, Halogen cations and ~ (LA) 447

Intermolecular interactions: van der Waals molecules (FP) 486 [G.E. *84*, 570 (1972)]

Invertebrates, Toxins from marine ~ (LA) 244

Iodine compounds, $Ge_{38}P_8I_8$ and $Ge_{38}As_8I_8$, a new class of compounds with clathrate structure (SC) 43 [G.E. *84*, 30 (1972)]

Ion binding by synthetic macrocyclic compounds (LA) 343

Ionization, Effect of polar substituents on ~ of organic acids (LA) 447

Ionization energies, Geometry and π-~ of alkyl-substituted triketones (SC) 220 [G.E. *84*, 210 (1972)]

Ionization potentials of substituted benzenes (SC) 525 [G.E. *84*, 544 (1972)]

Ion pair solvation complexes, Structure (FP) 112 [G.E. *84*, 127 (1972)]

Iron, Gmelin-Durrer: Metallurgie des Eisens (Book Review) 246, 256

Iron complexes, Cationic γ-oxo-isocyano complexes of iron, ruthenium, and osmium (SC) 527 [G.E. *84*, 584 (1972)]
Chemical syntheses with metal atoms: preparation of bis(butadiene)-~ and butadienetetracarbonylchromium (SC) 532 [G.E. *84*, 547 (1972)]
Dimethylene(2-propenylidene)methanetricarbonyliron (SC) 637 [G.E. *84*, 684 (1972)]
[(η-Phenyl)phenylethylphosphane] (η-2,3-dimethylbutadiene)iron(0), a phosphane complex without coordinated phosphorus (SC) 1088 [G.E. *84*, 1143 (1972)]
Physical chemistry of iron(II) complexes with ligands containing the structural element N=C-C=N (LA) 66

Iron compounds, X-ray photoelectron spectroscopy of iron-containing proteins - Valency of iron in ferredoxins (SC) 232 [G.E. *84*, 156 (1972)]
Transition metal carbene complexes as π-ligands - [ethoxy-(2,6-dimethoxyphenyl)carbenetetracarbonyliron(0)]tricarbonyliron(0) (SC) 238 [G.E. *84*, 214 (1972)]
Tetracarbonyl(π-vinyl alcohol)iron (SC) 520 [G.E. *84*, 581 (1972)]
Occurrence of iron in living nature (LA) 945

β-Isocyanatocrotonate, Reversible isomerization in β-isocyanatocrotonic esters (SC) 128 [G.E. *84*, 107 (1972)]

Isocyanides, Cycloaddition to 4,5-dihydro-1,3,5-oxazaphosph(V)oles (SC) 47 [G.E. *84*, 35 (1972)]
Synthesis from N-monosubstituted formamides, phosphanes, and azodicarboxylic acid derivatives (SC) 929 [G.E. *84*, 957 (1972)]
Polymerization (LA) 733

α-Isocyanoalkanoates, Ethyl γ-cyano-~ from α-metalated ethyl isocyano-acetates or -propionates and acrylonitriles (SC) 429 [G.E. *84*, 478 [1972)]

Isoelectric focusing: present and future state of a new method (CR) 445

Isomerization, Thermally reversible photo-~-s (FP) 1072 [G.E. *84*, 1157 (1972)]
Reversible ~ in β-isocyanatocrotonic esters (SC) 128 [G.E. *84*, 107 (1972)]
Three ~ routes originating from different electronic states of a linearly-conjugated cyclohexadienone (SC) 637 [G.E. *84*, 638 (1972)]
Demonstrations of isomers and intramolecular ~ of carbene complexes of chromium (SC) 644 [G.E. *84*, 682 (1972)]
~ of metal β-diketone chelates (LA) 65

Isonitrile chemistry (Book Review) 71

7-Isopropylidenenorbornadiene (SC) 54 [G.E. *84*, 65 (1972)]

Isothiocyanates, 1,3-Oxazolidine-2-thiones from alkyl ~ and carbonyl compounds (SC) 933 [G.E. *84*, 956 (1972)]

Isotope effects, Metal ~ on metal-ligand vibrations (FP) 666 [G.E. *84*, 755 (1972)]
Cyclopropanones and the Favorskii rearrangement. An unexpectedly large secondary isotope effect (CR) 329 [G.E. *84*, 311 (1972)]

Isotopes, Use of radioisotopically labeled analytical reagents (LA) 65

Isotope separation by electrical migration in molten salts (LA) 1107

KETENE, Thermal formation of 1-propenyl-~ from 2,4-pentadienal (SC) 288 [G.E. *84*, 345 (1972)]

Ketene thioacetals by "Peterson carbonyl olefination" with metalated formyl trimethylsilyl thioacetals (SC) 443 [G.E. *84*, 476 (1972)]

Keto compounds, Aromatic ~ as initiators in photopolymerizations (FP) 974 [G.E. *84*, 1032 (1972)]

Ketones, Synthesis of the lithium enolate of (S)-(+)-sec-butyl methyl ketone and formation of chiral 1,3-di-~ by acylation (SC) 127 [G.E. *84*, 107 (1972)]

Geometry and n-ionization energies of alkyl-substituted tri-~ (SC) 220 [G.E. *84*, 210 (1972)]
Synthesis of non-enolizable β-di-~ by acid-catalyzed intramolecular Claisen condensation (SC) 1030 [G.E. *84*, 1110 (1972)]
Aliphatic 1,2,3-tri-~ by ozonolysis of dialkyl-1,4-benzoquinones (SC) 1089 [G.E. *84*, 1144 (1972)]
Photochemistry of α-dicarbonyl compounds (LA) 155
Metal complexes of thio-β-di-~ (LA) *157*

Kinetics, Application of computers to MO theory and chemical ~ (FP) 393 [G.E. *84*, 418 (1972)]
~ of cooperative conformational transitions of linear biopolymers (FP) 568 [G.E. *84*, 615 (1972)]
~ of the homotropilidene valence tautomerism (SC) 517 [G.E. *84*, 539 (1972)]
Studies of reaction ~ in the solid state: first and second order reaction constants (CR) 445

LABORATORY manual, Kleines Chemisches Praktikum (Book Review) 246

Lactone rings, Cyclopolymerization with intramolecular formation of ~ (CR) 339 [G.E. *84*, 362 (1972)]

Lactones, Synthesis and photochemical behavior of enone ~ (CR) 327 [G.E. *84*, 308 (1972)]

Lead, Gmelins Handbuch der anorganischen Chemie (Book Review) 548

Ligands, Structural aspects of metal ion-ligand interaction (CR) 851 [G.E. *84*, 833 (1972)]
Short-lived molecules as ~ in coordination compounds (CR) 1034 [G.E. *84*, 1111 (1972)]

Liquid crystals, Optical properties of cholesteric ~(CR) 731 [G.E. *84*, 720 (1972)]

Lithiodimethylnitrosamine, C—C-Bond formation in the α-position to nitrogen in secondary amines. ~ (SC) 301 [G.E. *84*, 350 (1972)]

Lithium compounds, Chemistry of carbenoids and other thermolabile organo-~ (FP) 473 [G.E. *84*, 557 (1972)]
Stereochemistry of the cycloaddition of 1,3-diphenyl-2-azaallyllithium to alkenes at 0 °C (SC) 290 [G.E. *84*, 261 (1972)]
Ring-opening of N-lithio-2,3(cis)-diphenylaziridine to 1,3(cis, trans)-diphenyl-2-azaallyllithium and its rearrangement to the trans, trans-form (SC) 291 [G.E. *84*, 262 (1972)]
DTA studies on formation of dehydrobenzene and dichlorocarbene from haloorgano-~ (SC) 507 [G.E. *84*, 527 (1972)]

Lumichrome, New synthesis (SC) 1010 [G.E. *84*, 1061 (1972)]

Luminescence, (1-Adamantyl)-α-peroxylactone: synthesis, kinetics, and ~ (SC) 540 [G.E. *84*, 590 (1972)]

MACROCYCLIC compounds, Ion binding by synthetic ~ (LA) 343

Macromolecular Colloquium (CR) 334 [G.E. *84*, 356 (1972)]

Macromolecules, New aspects of the structure of randomly branched ~ (CR) 63 [G.E. *84*, 69 (1972)]
Possible interactions of transition metal complexes with biological ~ (LA) 1035

Magnetic properties, Theory of ~ of polynuclear transition metal compounds (LA) 545

Magnetic resonance methods in elucidation of bonding properties of transition metal compounds (LA) 245

Malate-lactate transhydrogenase (CR) 852 [G.E. *84*, 901 (1972)]

Maleic anhydride, Anionic polymerization with tertiary phosphanes (CR) 342 [G.E. *84*, 364 (1972)]

Malonaldehydes, Preparation and reactions (CR) 62 [G.E. *84*, 68 (1972)]

Malonates, Single-step synthesis of 1,n-dicarboxylic diesters by Kolbe electrolysis of oxalic and malonic half esters in the presence of olefins (SC) 841 [G.E. *84*, 893 (1972)]

Malting and brewing science (Book Review) 1109

Management, Quantitative ~ in R & D (Book Review) 648

Manganese compounds, Reversible N_2 fixation by dicarbonyl-π-cyclopentadienyl-(tetrahydrofuran)manganese(I) (SC) 534 [G.E. *84*, 549 (1972)]
Chemistry of the higher oxidation states of ~ (LA) 733

Manganese-porphyrin complexes, Literature on ~ (LA) 447

Mannich bases, Dehydro N-~ (SC) 144 [G.E. *84*, 109 (1972)]

Marketing, Der Absatz in der Chemischen Industrie (Book Review) 158

Mass spectrometry, Computer-aided analysis of organic mass spectra (FP) 357 [G.E. *84*, 381 (1972)]
Decomposition of organometallic complexes in the mass spectrometer (FP) 653 [G.E. *84*, 725 (1972)]
~ of heterocyclic compounds (Book Review) 648

Matrix reactions, Growth processes due to reactions in swellable cellular matrixes (FP) 990 [G.E. *84*, 1001 (1972)]

Membranes, Structural principles of bio-~ (FP) 551 [G.E. *84*, 597 (1972)]
Comparative studies of the topography of the ~ of mitochondria and chloroplasts (CR) 153 [G.E. *84*, 123 (1972)]
Investigations of the antibody-complement interaction with lipid model ~ (LA) 448
Investigation of protein conformation in chemically unchanged, functionally and enzymatically active bio-~ by measurement of optical rotation and UV- and visual light absorption (LA) 448

Mercury carbenoids, Organo-~ for synthesis of cyclopropane derivatives (SC) 231 [G.E. *84*, 160 (1972)]

Mercury complexes, Preparation and some properties of di[bis(trifluoromethyl)phosphido]mercury $Hg[P(CF_3)_2]_2$ (SC) 1097 [G.E. *84*, 1153 (1972)]

Mercury compounds, Chemistry of phenyl-(trihalomethyl)-~ (LA) 448

Mercury(II) salts, Oxidation of alkenes with ~ (LA) 245

Mesityl group as a ring current probe in transition metal 1,2-diimine chelates (SC) 725 [G.E. *84*, 769 (1972)]

Mesoionic compounds, Six-membered mesoionic "aromatic" compounds (SC) 1012 [G.E. *84*, 1063 (1972)]

Metabolism, Energy ~ in mitochondria (FP) 792 [G.E. *84*, 792 (1972)]
Foreign compound ~ in mammals (Book Review) 857

[2.2]Metacyclophanes, Stereochemistry (FP) 73 [G.E. *84*, 75 (1972)]

Metalation at primary, secondary, and tertiary carbon atoms in open-chain and cyclic nitrosamines (SC) *1101* [G.E. *84*, 1186 (1972)]

Metal atoms, How are ~ formed in flames? (LA) 64

Metal complexes, Metal ion function in carbonic anhydrase (FP) 408 [G.E. *84*, 461 (1972)]
Coordination-polymeric metal complexes of bifunctional dithiophosphinic acids and their use as adsorbents in chromatography (SC) 435 [G.E. *84*, 485 (1972)]

Metal-ligand vibrations, Metal isotope effects on ~ (FP) 666 [G.E. *84*, 755 (1972)]

Metalloporphyrins, Coordination chemistry (LA) 64

Metallurgy, Study of prehistoric ~ (FP) 620 [G.E. *84*, 668 (1972)]
Chemical analysis in extractive ~ (Book Review) 649

Metal-olefin complexes, Chemie der Metall-Olefin-Komplexe (Book Review) 68

Metals, Preparation of non-noble ~ (Li, Ca, Sr, Ba, Am, Cf) by reduction of their oxides and fluorides with hydrogen (SC) 515 [G.E. *84*, 537 (1972)]

Metal surfaces, Properties of clean ~ and reactions thereon (LA) 64

Metathetic reactions of olefins (LA) 646

4,9-Methano[11]annulenone, 2-Hydroxy-~, a 10 π-electron analog of tropolone (SC) 218 [G.E. *84*, 208 (1972)]

Methanol, Reaction with phenyl radicals (SC) 45 [G.E. *84*, 33 (1972)]

Methoxy groups, Reactions of double bonds activated by ~ (SR) 324 [G.E. *84*, 306 (1972)]

Methylenecyclopropane, Bridged ~-s as test cases for Brendt's rule: 2,5,5,7,7-pentamethylbicyclo[4.1.0]hept-1-ene (SC) 52 [G.E. *84*, 62 (1972)]
Cyclodimerization of ~ on a Ni(0) catalyst (SC) 309 [G.E. *84*, 352 (1972)]
Cyclodimerization of heated ~ (SC) 433 [G.E. *84*, 483 (1972)]

Methylenenorbornadiene, a bicycloheptafulvene (SC) 512 [G.E. *84*, 533 (1972)]

Methyl hydrogen carbonate (SC) 534 [G.E. *84*, 549 (1972)]

Methyl methacrylate copolymers, Structural investigations on polymethyl methacrylate and ~ in solution (CR) 341 [G.E. *84*, 365 (1972)]

Meyer-Schuster rearrangement and Rupe rearrangement (LA) 156

Milk proteins, Chemistry and molecular biology (Book Review) 345

Mineralogy and chemistry (CR) 342 [G.E. *84*, 267 (1972)]

Mitochondria, Energy metabolism in ~ (FP) 792 [G.E. *84*, 792 (1972)]
Comparative studies of the topography of the membranes of ~ and chloroplasts (CR) 153 [G.E. *84*, 123 (1972)]

Molecular biology, Introduction to ~ (Book Review) 549

π-Molecular orbitals, Unusual sequence of the two highest occupied ~ in the phosphorin system (SC) 631 [G.E. *84*, 636 (1972)]

Molecular structure, High-pressure properties and their dependence on ~ (CR) 645 [G.E. *84*, 686 (1972)]

Molecular weight distributions, Errors in the determination of narrow and broad ~ by gel permeation chromatography and their possible elimination (CR) 334 [G.E. *84*, 356 (1972)]
The analysis of narrow ~ as an aid to the kinetic investigation of ionic polymerization processes (CR) 340 [G.E. *84*, 362 (1972)]

Molybdenum complexes, Optically active tungsten complexes and ~ with tetragonal-pyramidal configuration (SC) 418 [G.E. *84*, 442 (1972)]

Molybdenum compounds, Coordination compounds with silicon-molybdenum and silicon-tungsten bonds (SC) 516 [G.E. *84*, 538 (1972)]
Walden inversion at an asymmetric molybdenum atom (SC) 923 [G.E. *84*, 955 (1972)]
Preparation and structure of the fluoro complex $Rb[Mo_2O_2F_9]$ (SC) 1020 [G.E. *84*, 1099 (1972)]
Stereochemistry of halocarbonylphosphanes and arsanes of molybdenum and tungsten (LA) 64
Enzymes containing molybdenum (LA) 945

Monobromocyclopropanes, New direct synthesis (CR) 326 [G.E. *84*, 308 (1972)]

Mössbauer measurements on neptunium-(VII) compounds (SC) 57 [G.E. *84*, 26 (1972)]

MO theory, Application of computers to ~ and chemical kinetics (FP) 393 [G.E. *84*, 418 (1972)]

NATURAL products, New directions of the chemistry of ~ (LA) 156

Neighboring group effects in ammonolysis of acetic esters of polynuclear phenolic compounds (CR) 335 [G.E. *84*, 357 (1972)]

Nematic liquids with positive dielectric anisotropy (SC) 633 [G.E. *84*, 636 (1972)]

Neopentane, Equivalent orbital method of interpreting photoelectron spectra: ~ (SC) 221 [G.E. *84*, 168 (1972)]

Neptunium(VII) compounds, Mössbauer measurements on ~ (SC) 57 [G.E. *84*, 26 (1972)]

Nickel catalyst, Cyclodimerization of methylenecyclopropane on a Ni(0) catalyst (SC) 309 [G.E. *84*, 352 (1972)]

Nickel complexes, Reaction of a $L_2Ni(0)$ system with allenes (SC) 136 [G.E. *84*, 120 (1972)]
Molecular structure of a bridged cis-bis-(π-allyl)nickel system (SC) 137 [G.E. *84*, 121 (1972)]

Nickel compounds, New route to triple-decker sandwich compounds (SC) 930 [G.E. *84*, 949 (1972)]
Spectra and structural properties of complex tetracyanides of platinum, palladium, and nickel (LA) 545

Nitrate groups, Structure of coordinated ~ (LA) 244

Nitration and aromatic reactivity (Book Review) 1108

Nitrenes, Carbenoids, carbenes, and ~ as polymerization initiators (LA) 855

Nitrides, Transition metal carbides and ~ (Book Review) 947

Nitrile oxides, The ~ (Book Review) 1039

Nitriles, Aminopentalenecarbo-~, a group of stable pentalenes (SC) 50 [G.E. *84*, 61 (1972)]
Reaction of metalated nitrosamines with ~. A new method for preparation of v-triazoles (SC) 1102 [G.E. *84*, 1187 (1972)]

Nitro compounds, Catalytic deoxygenation of aromatic ~ by carbon monoxide in the presence of diphenylacetylene (SC) 634 [G.E. *84*, 641 (1972)]

Nitrogen, Reactions and compounds with molecular ~ (CR) 243 [G.E. *84*, 267 (1972)]

Nitrogen compounds, Structure determinations of ~ with the aid of NQR, NMR, and ESCA spectroscopy (FP) 979 [G.E. *84*, 1037 (1972)]
$CH_3AsS_2N_2$, a five-membered arsenic-sulfur-nitrogen ring (SC) 529 [G.E. *84*, 585 (1972)]
Some new redox polymers containing nitrogen (CR) 338 [G.E. *84*, 360 (1972)]
UV spectroscopic properties of simple compounds having N—N and N—O bonds (LA) 244

Nitrogen fixation, Reversible ~ by dicarbonyl-π-cyclopentadienyl(tetrahydrofuran)-manganese(I) (SC) 534 [G.E. *84*, 549 (1972)]

Nitrogen heterocycles, Simple amination of aromatic hydroxy-~ (SC) 305 [G.E. *84*, 348 (1972)]

Nitrones, Conversion of cyclic ~ into thiolactams by reaction with carbon disulfide (SC) 47 [G.E. *84*, 34 (1972)]

Nitrosamine, C—C-Bond formation in the α-position to nitrogen in secondary amines. Lithiodimethyl-~ (SC) 301 [G.E. *84*, 350 (1972)]
Metalation at primary, secondary, and tertiary carbon atoms in open-chain and cyclic ~ (SC) 1101 [G.E. *84*, 1186 (1972)]
Reaction of metalated ~-s with nitriles. A new method for preparation of v-triazoles (SC) 1102 [G.E. *84*, 1187 (1972)]

Nitrosobenzene, Reaction of ferrocenylmethylium ions with ~ (SC) 1027 [G.E. *84*, 1106 (1972)]

NMR spectroscopy, Use of a computer in ~ (FP) 375 [G.E. *84*, 400 (1972)]
Nuclear magnetic resonance in solid-state chemistry (FP) 607 [G.E. *84*, 498 (1972)]
Shift reagents in ~ (FP) 675 [G.E. *84*, 737 (1972)]
^{1}H-NMR spectra of the AA'XX' and AA'BB' type – analysis and classification (FP) 861 [G.E. *84*, 907 (1972)]
Unusual ^{13}C chemical shifts of transition metal-carbene complexes (SC) 141 [G.E. *84*, 155 (1972)]
Synthesis and pulse Fourier transform ^{13}C-NMR spectra of branched-chain carbohydrates (SC) 148 [G.E. *84*, 111 (1972)]
Complex shift reagent for ^{13}C-NMR studies on carbohydrates (SC) 539 [G.E. *84*, 589 (1972)]

The mesityl group as a ring current probe in transition metal 1,2-diimine chelates (SC) 725 [G.E. *84*, 769 (1972)]
Influence of haloalkanes on the C-NMR spectra of n-alkanes (SC) 1032 [G.E. *84*, 1101 (1972)]

Noble gas compounds, Radiochemical investigations on ~ (CR) 61 [G.E. *83*, 986 (1971)]

Nomenclature, An alternative approach to the ~ of cyclic conjugated polyolefins, together with some observations on the use of the term "aromatic" (FP) 404 [G.E. *84*, 447 (1972)]

Norbornadiene, 7-Isopropylidene-~ (SC) 54 [G.E. *84*, 65 (1972)]
Methylene-~, a bicycloheptafulvene (SC) 512 [G.E. *84*, 533 (1972)]

1-Norbornene, Does ~ exist? (SC) 518 [G.E. *84*, 540 (1972)]

Norcaradienes, Photofragmentation of spiropyrazoles. – Stable ~ and spiroheptatrienes (SC) 224 [G.E. *84*, 215 (1972)]

Norcaranes, Solvolysis of 7,7-bis(alkylthio)-~. New method of homologation (SC) 49 [G.E. *84*, 50 (1972)]

Nucleic acid, Chemical synthesis of polynucleotides (FP) 451 [G.E. *84*, 489 (1972)]
Melting of d(T-A)oligomers (LA) 66
Interaction of protons and metal ions with ribo-~, deoxyribo-~ (LA) 66
Nucleinsäuren (Book Review) 947

Nucleohistones, Structure and function of chromosomal ~ (FP) 496 [G.E. *84*, 451 (1972)]

Nucleosides, New dihydroxyboryl-substituted polymers for column-chromatographic separation of ribonucleoside-deoxyribonucleoside mixtures (SC) 824 [G.E. *84*, 819 (1972)]

OLEFINATION, Ketene thioacetals by "Peterson carbonyl ~" with metalated formyl trimethylsilyl thioacetals (SC) 443 [G.E. *84*, 476 (1972)]

Olefin formation, The syn and anti steric course in bimolecular olefin-forming eliminations (FP) 200 [G.E. *84*, 177 (1972)]

Olefins, Metal-olefin and -acetylene bonding in complexes (FP) 596 [G.E. *84*, 649 (1972)]
Reactions of electron-rich ~ with proton-active compounds (FP) 964 [G.E. *84*, 1022 (1972)]
Anodic oxidation of trihexylmethoxyborate in presence of butadiene (SC) 48 [G.E. *84*, 32 (1972)]
Single-step synthesis of 1,n-dicarboxylic diesters by Kolbe electrolysis of oxalic and malonic half esters in presence of ~ (SC) 841 [G.E. *84*, 893 (1972)]
Reactivity of the double bond in higher ~ depending upon position and geometrical configuration (CR) 62 [G.E. *84*, 37 (1972)]
Transition-metal π-complexes with activated ~ (CR) 730 [G.E. *84*, 773 (1972)]
Metathetic reactions of ~ (LA) 646
Transition-metal complexes of ~ and acetylenes (LA) 945

Oligodeoxynucleotides, Synthesis of ~ with 5'-terminal phosphate groups (SC) 717 [G.E. *84*, 710 (1972)]

Oligonucleotides, Novel carrier for solid phase synthesis of oligomers (SC) 713 [G.E. *84*, 712 (1972)]

Optical purity, Rapid method for determination of ~ of amino acids (SC) 529 [G.E. *84*, 586 (1972)]

Optimization, Einführung in die Optimierung (Book Review) 346

Orbitals, Sequence of ~ in sulfones and sulfodiimides (SC) 927 [G.E. *84*, 944 (1972)]

Organic chemistry, Organische Chemie (Book Review) 157
Allgemeine Organische Chemie (Book Review) 649
Organisch-chemisches Praktikum (Book Review) 1038

Organic solvents, Techniques of chemistry (Book Review) 1109

Organic syntheses, Survey of ~ (Book Review) 70

Osmium complexes, Cationic γ-oxo-isocyano complexes of iron, ruthenium, and osmium (SC) 527 [G.E. *84*, 584 (1972)]

Oxa[17]annulenes (SC) 424 [G.E. *84*, 472 (1972)]

Oxalates, Single-step synthesis of 1,n-dicarboxylic diesters by Kolbe electrolysis of oxalic and malonic half esters in the presence of olefins (SC) 841 [G.E. *84*, 893 (1972)]

Oxalic acid, syn-Planar conformation of ~: crystal structure of the ~-acetamide complex (SC) 514 [G.E. *84*, 536 (1972)]

1,3,5-Oxazaphosph(V)oles; Cycloaddition of isocyanides to 4,5-dihydro-~ (SC) 47 [G.E. *84*, 35 (1972)]

4H-1,3-Oxazines, Simple synthesis of 2-substituted 2-oxazolines and 5,6-dihydro-~ (SC) 287 [G.E. *84*, 343 (1972)]

1,3-Oxazolidine-2-thiones from alkyl isothiocyanates and carbonyl compounds (SC) 933 [G.E. *84*, 956 (1972)]

5-Oxazolidones, Rearrangement and polymerization mechanisms of DTE-amino acids and 2-thioxo-~ (CR) 337 [G.E. *84*, 360 (1972)]

2-Oxazoline-4-carboxylates, Ethyl α-formylamino-β-hydroxy-acid esters (β-substituted *N*-formylserine esters) from ethyl ~ (SC) 432 [G.E. *84*, 435 (1972)]

Oxazolines, Simple synthesis of 2-substituted 2-~ and 5,6-dihydro-4H-1,3-oxazines (SC) 287 [G.E. *84*, 343 (1972)]
Survey of the chemistry of ~ (LA) 156

Oxidation states, Unusual ~ of metalloporphyrins; octaethylporphinatosilver-(III)perchlorate (SC) 1014 [G.E. *84*, 1072 (1972)]
Chemistry of the higher ~of manganese compounds (LA) 733

Oxidative coupling, Protophanes by ~ of "transposed dithiols" (SC) 844 [G.E. *84*, 826 (1972)]

Oxides, Preparation of non-noble metals (Li, Ca, Sr, Ba, Am, Cf) by reduction of their ~ and fluorides with hydrogen (SC) 515 [G.E. *84*, 537 (1972)]

Oxirane, Effect of protonation on aziridine and ~ bond strengths (SC) 825 [G.E. *84*, 820 (1972)]

2-Oxyallyl systems, Cycloadditions and rearrangements (CR) 324 [G.E. *84*, 305 (1972)]

Oxygen, Enzymatic hydroxylations with molecular ~ (FP) 701 [G.E. *84*, 689 (1972)]
Polarographic reduction of ~ in the presence of phthalocyanine complexes (SC) 140 [G.E. *84*, 154 (1972)]
Spatial requirements of pyridine N-oxide ~ (SC) 727 [G.E. *84*, 770 (1972)]

Oxygenation, Photochemical ~ of 2,4,6-tri-tert-butyl-λ^3-phosphorin and 2,4,6-tri-tert-butyl-1,1-dimethoxy-λ^5-phosphorin (SC) 506 [G.E. *84*, 526 (1972)]

Ozonolysis, Aliphatic 1,2,3-triketones by ~ of dialkyl-1,4-benzoquinones (SC) 1089 [G.E. *84*, 1144 (1972)]
Ozonolytic degradation of a catenane (SC) 1089 [G.E. *84*, 1144 (1972)]

PAINTS, Anstrichstoffe und ähnliche Beschichtungsstoffe, Pigmente (Book Review) 1037

Palladium compounds, Spectra and structural properties of complex tetracyanides of platinum, palladium, and nickel (LA) 545

[2.2]Paracyclophanes, Simple synthesis (SC) 419 [G.E. *84*, 471 (1972)]

Paramagnetic anisotropy (LA) 155

Pentaacetylene, Preparation of pure triacetylene, tetraacetylene, and ~ and investigation of their electronic spectra (SC) 438 [G.E. *84*, 483 (1972)]

2,4-Pentadienal, Thermal formation of 1-propenylketene from ~ (SC) 288 [G.E. *84*, 345 (1972)]

Pentafluoroorthoselenic acid (SC) 630 [G.E. *84*, 715 (1972)]

(+)-Pentahelicene, Determination of absolute configuration (SC) 296 [G.E. *84*, 293 (1972)]

Pentalenes, Aminopentalenecarbonitriles, a group of stable ~ (SC) 50 [G.E. *84*, 61 (1972)]

Peptides, New biologically active hepta-~ (PR) 856
Synthetic ~ (Book Review) 647

Peptide synthesis, Side-reactions arising on formation of cyclodipeptides in solid-phase ~ (SC) 293 [G.E. *84*, 290 (1972)]
Solid-phase ~ on an inorganic matrix having organic groups on the surface (SC) 314 [G.E. *84*, 266 (1972)]

Peroxides, Organic ~ (Book Review) 859

Pesticides, New 1-carbamoyl-N-carbamoyloxyformimidates (PR) 946

Petroleum, Die Verarbeitung des Erdöls (Book Review) 736

Phanes, Stereochemistry of [2.2]metacyclo-~ (FP) 73 [G.E. *84*, 75 (1972)]

Pharmaceutical chemistry, Lehrbuch der Pharmazeutischen Chemie (Book Review) 345

Phase transitions in polymers (CR) 334 [G.E. *84*, 356 (1972)]

Phenolic compounds, Neighboring group effects in the ammonolysis of acetic esters of polynuclear ~ (CR) 335 [G.E. *84*, 357 (1972)]

Phenols substituted with benzothiazylthioalkyl groups (PR) 1036

Phenyl azide, Substituent effects in 1,3-dipolar cycloadditions of ~ (SC) 838 [G.E. *84*, 887 (1972)]

9-Phenyl-9-boraanthracene, Preparation of ~ anion (SC) 53 [G.E. *84*, 28 (1972)]

Phenylcyclobutenediones, Chemistry (FP) 997 [G.E. *84*, 1048 (1972)]

Phenyldiimine in the reduction of diazonium salts by sodium tetrahydridoborate (SC) 45 [G.E. *84*, 33 (1972)]

Phenyl radicals, Reaction with methanol (SC) 45 [G.E. *84*, 33 (1972)]

Phosphabenzene, Photoelectron spectroscopy and conjugation – direct proof of the unusual sequence of the two highest occupied π-molecular orbitals in the phosphorin (~) and the arsenin (arsabenzene) system (SC) 924 [G.E. *84*, 993 (1972)]

1-Phosphanaphthalene, 1,1-Dibenzyl-2-phenyl-~ (SC) 1016 [G.E. *84*, 1066 (1972)]

2-Phenyl-~ (SC) 1017 [G.E. *84*, 1067 (1972)]

Phosphanes, Addition of ~ and phosphites to trifluoromethyl-substituted 2-aza-1,3-butadienes (SC) 319 [G.E. *84*, 258 (1972)]
1-Cyclopentadienyldifluorophosphane: a new fluxional molecule (SC) 640 [G.E. *84*, 683 (1972)]
Conjugation in aromatic amines and ~ (SC) 836 [G.E. *84*, 898 (1972)]
Synthesis of isocyanides from N-monosubstituted formamides, ~, and azodicarboxylic acid derivatives (SC) 929 [G.E. *84*, 957 (1972)]
[(η-Phenyl)phenylethylphosphane] (η-2,3-dimethylbutadiene)iron(0), a phosphane complex without coordinated phosphorus (SC) 1088 [G.E. *84*, 1143 (1972)]
Anionic polymerization of maleic anhydride with tertiary ~ (CR) 342 [G.E. *84*, 364 (1972)]
Stereochemistry of the halocarbonyl-~ and arsanes of molybdenum and tungsten (LA) 64
Poly(tertiary ~) and their metal complexes (LA) 1034

Phosphides, $Ge_{38}P_8I_8$ and $Ge_{38}As_8I_8$, a new class of compounds with clathrate structure (SC) 43 [G.E. *84*, 30 (1972)]

Phosphites, Addition of phosphanes and ~ to trifluoromethyl-substituted 2-aza-1,3-butadienes (SC) 319 [G.E. *84*, 258 (1972)]
Polycondensation of diethyl phosphite with aliphatic diols (CR) 341 [G.E. *84*, 363 (1972)]

Phosphoranes, Tetraorganofluoro-~ (SC) 144 [G.E. *84*, 165 (1972)]
Tetramethyl(methoxy)-~and related compounds (SC) 145 [G.E. *84*, 166 (1972)]
Formation of macrocyclic polyolefins on autoxidation of bifunctional alkylene-~ (SC) 508 [G.E. *84*, 528 (1972)]
4-(Difluorooxophosphoranyl)-1λ^4,3,5,2,-4,6-trithiatriazine (SC) 642 [G.E. *84*, 684 (1972)]

Phosphorin, Photochemical oxygenation of 2,4,6-tri-tert-butyl-λ^3-~ and 2,4,6-tri-tert-butyl-1,1-dimethoxy-λ^5-~ (SC) 506 [G.E. *84*, 526 (1972)]
Unusual sequence of the two highest occupied π-molecular orbitals in the ~ system (SC) 631 [G.E. *84*, 636 (1972)]
Photoelectron spectroscopy and conjugation – direct proof of the unusual sequence of the two highest occupied π-molecular orbitals in the ~ (phosphabenzene) and the arsenin (arsabenzene) system (SC) 924 [G.E. *84*, 993 (1972)]
1,1-Dihalo-λ^5-~-s (SC) 1090 [G.E. *84*, 1145 (1972)]
Reactions of λ^3-~-s with arene-diazonium salts to give λ^5-~-s (SC) 1091 [G.E. *84*, 1146 (1972)]

Phosphorothiocyanatidate, Synthesis of dineopentyl ~ : the first compound with the P(O)S—C≡N structure (SC) 838 [G.E. *84*, 896 (1972)]

Phosphorus compounds, Spirophosphoranes from acylhydrazines and ~ (SC) 306 [G.E. *84*, 349 (1972)]
Structure and mechanisms of formation of a novel phosphorus-containing heterocycle; P—Cl bond length and ^{35}Cl-NQR frequency (SC) 510 [G.E. *84*, 530 (1972)]
1,3,3,5,5-Pentachloro-1λ^4,2,4,6,3λ^5,5λ^5-thiatriazadiphosphorine (SC) 642 [G.E. *84*, 685 (1972)]
Preparation and some properties of di-[bis(trifluoromethyl)phosphido] mercury $Hg[P(CF_3)_2]_2$ (SC) 1097 [G.E. *84*, 1153 (1972)]

Photoadditions, Cyclovinylogous [2π→2σ]- ~ (SC) 313 [G.E. *84*, 259 (1972)]
[2+4]- and [4+4]-Photoaddition of cyclopentadiene to anthracene (SC) 718 [G.E. *84*, 718 (1972)]

Photochemistry, of dimethyl 1,2-dihydrocyclobutabenzene-1,2-diylidenediacetate (SC) 216 [G.E. *84*, 206 (1972)]
Light-induced [2+4]-cyclodimerization in the crystalline state (SC) 434 [G.E. *84*, 479 (1972)]
Photochemical oxygenation of 2,4,6-tri-tert-butyl-λ³-phosphorin and 2,4,6-tri-tert-butyl-1,1-dimethoxy-λ⁵-phosphorin (SC) 506 [G.E. *84*, 526 (1972)]
Photoprocesses of phenyl-substituted tetrahydropentalenes (SC) 719 [G.E. *84*, 719 (1972)]
~ of aromatic amine oxides (CR) 240 [G.E. *84*, 220 (1972)]
Synthesis and photochemical behavior of enone lactones (CR) 327 [G.E. *84*, 308 (1972)]
~ of α-dicarbonyl compounds (LA) 155
Photochemical and spectroscopic properties of organic molecules in the adsorbed state (LA) 156
Photochemical reactions of solid coordination compounds (LA) 157
Organic photochemical syntheses (Book Review) 858

Photoelectron spectroscopy, Equivalent orbital method of interpreting photoelectron spectra: neopentane (SC) 221 [G.E. *84*, 168 (1972)]
X-ray ~ of iron-containing proteins – Valency of iron in ferredoxins (SC) 232 [G.E. *84*, 156 (1972)]
Photoelectron spectra of unsaturated systems containing cyclopropane and cyclobutane rings (SC) 524 [G.E. *84*, 543 (1972)]
Ionization potentials of substituted benzenes (SC) 525 [G.E. *84*, 544 (1972)]
Evidence for conjugation through a saturated silicon atom (SC) 536 [G.E. *84*, 550 (1972)]
Estimation of spiro-interaction (spiroconjugation) in tetravinylsilane (SC) 537 [G.E. *84*, 551 (1972)]
Photoelectron spectra of benzenoid hydrocarbons $C_{18}H_{12}$ (SC) 538 [G.E. *84*, 551 (1972)]
Conjugation in aromatic amines and phosphanes (SC) 836 [G.E. *84*, 898 (1972)]
~and transannular interactions – question of transannular d-π interactions in 1-sila- and 1-germa-3-cyclopentenes (SC) 837 [G.E. *84*, 899 (1972)]
~ and conjugation – direct proof of the unusual sequence of the two highest occupied π-molecular orbitals in the phosphorin (phosphabenzene) and the arsenin (arsabenzene) system (SC) 924 [G.E. *84*, 993 (1972)]

Photofragmentation of spiropyrazoles. – Stable norcaradienes and spiroheptatrienes (SC) 224 [G.E. *84*, 215 (1972)]

Photo-Fries rearrangement (LA) 65

Photoisomerization, Thermally reversible ~-s (FP) 1072 [G.E. *84*, 1157 (1972)]

~ of 2-[2-(N-ethoxycarbonyl-N-allylamino)-ethyl]benzaldehyde (SC) 728 [G.E. *84*, 712 (1972)]

Photolysis of 2,3-diazido-2,3-dimethylbutane (SC) 1024 [G.E. *84*, 1102 (1972)]

Photooxidation of 3,4-diethyl-2,5-dimethylpyrrole (SC) 215 [G.E. *84*, 216 (1972)]

Photooxygenation, Dye-sensitized ~ of 6,6-dimethylfulvene: a new 1,2-dioxolane rearrangement (CR) 330 [G.E. *84*, 311 (1972)]

Photopolymerizations, Aromatic keto-compounds as initiators in ~ (FP) 974 [G.E. *84*, 1032 (1972)]

Photoreactions of cyclobutanones in solution (CR) 331 [G.E. *84*, 312 (1972)]

Photosensitized reactions, Complications in ~ (LA) 156

Phthalocyanine complexes, Polarographic reduction of oxygen in the presence of ~ (SC) 140 [G.E. *84*, 154 (1972)]
Catalysis by ~ (CR) 239 [G.E. *84*, 219 (1972)]

Physical chemistry, Physikalische Chemie in Experimenten – Ein Praktikum (Book Review) 651
~ – an advanced treatise (Book Review) 1040

Pigments, Anstrichstoffe und ähnliche Beschichtungsstoffe, Pigmente (Book Review) 1037

Pinacolic rearrangement, Synthesis of 7,7-dimethylbicyclo[4.1.1]octan-3-one by ~ (SC) 640 [G.E. *84*, 642 (1972)]

2,5-Piperazinedione, X-ray structural analysis of N,N'-dimethyl-3,6-epitetrathio-~ (SC) 632 [G.E. *84*, 640 (1972)]

Plant protection, Chemical ~ – past, present, and future (FP) 260 [G.E. *84*, 271 (1972)]
Chemie der Pflanzenschutz- und Schädlingsbekämpfungsmittel (Book Review) 71

Plasma, Organic syntheses in the ~ of glow discharges and their preparative application (FP) 781 [G.E. *84*, 876 (1972)]

Plastics Foamed thermoplastic resins (PR) 1036
Stabilisierung und Alterung von Plastwerkstoffen (Book Review) 449

Plastics Handbook, Kunststoff-Handbuch (Book Review) 947

Platinum(IV) complexes, Substitution reactions (LA) 447

Platinum compounds, Spectra and structural properties of complex tetracyanides of platinum, palladium, and nickel (LA) 545

Poisons, Analytical methods of detection of drugs and ~ (LA) 1107

Polarography, Polarographic reduction of oxygen in the presence of phthalocyanine complexes (SC) 140 [G.E. *84*, 154 (1972)]

Polyamide, Development of a new type of ~ (CR) 63 [G.E. *84*, 69 (1972)]

Poly-1-butene, Polymorphic transformations II to I in ~ (CR) 337 [G.E. *84*, 359 (1972)]

Polycarbonate fibers, Crystalline ~ (LA) 734

Polycations of Group VI (LA) 446

Polychlorobiphenyls, Occurrence and environmental significance (LA) 245

Polycyclic molecules, Reactions of highly strained ~ promoted by transition metal complexes (CR) 323 [G.E. *84*, 304 (1972)]

Polyester fibers, Improved ~ suitable for dyeing under high-temperature conditions (PR) 855

Polyethers, Macrocyclic ~ and their complexes (FP) 16 [G.E. *84*, 16 (1972)]

Polyethylene, Deformation (LA) 646

Polyimides, Solid, non-tacky ~ (LA) 735

Polymer compatibility (LA) 945

Polymer emulsions, Aqueous graft and or block copolymer emulsions (LA) 735

Polymeric Wittig reagents (SC) 298 [G.E. *84*, 296 (1972)]

Polymerization, Aromatic keto-compounds as initiators in photo-~ (FP) 974 [G.E. *84*, 1032 (1972)]
Analysis of narrow molecular weight distributions as an aid to the kinetic investigation of ionic ~ processes (CR) 340 [G.E. *84*, 362 (1972)]
~ of vinyl- and related compounds in the presence of sulfur compounds (LA) 245
~ of isocyanides (LA) 733
Thermodynamics of ~ (LA) 855
~ of cycloolefins (LA) 855
~ of N-vinylcarbazole with metal salts (LA) 945

Polymerization initiators, Carbenoids, carbenes, and nitrenes as ~ (LA) 855

Polymer networks – Structural and mechanical properties (Book Review) 859

Polymers, Kinetics of cooperative conformational transitions of linear bio-~ (FP) 568 [G.E. *84*, 615 (1972)]
New dihydroxyboryl-substituted ~ for column-chromatographic separation of ribonucleoside-deoxyribonucleoside mixtures (SC) 824 [G.E. *84*, 819 (1972)]
Model reactions for synthesis of pharmacologically active ~ by way of monomeric and polymeric reactive esters (SC) 1103 [G.E. *84*, 1189 (1972)]
Phase transitions in ~ (CR) 334 [G.E. *84*, 356 (1972)]
Mixtures of ~ having different tacticities with a melting point maximum (CR) 335 [G.E. *84*, 357 (1972)]
Turbidimetric titration of ~ (CR) 336 [G.E. *84*, 358 (1972)]
Use of ~ with enzyme-analogous structures for the resolution of racemates (CR) 341 [G.E. *84*, 364 (1972)]
Enzymic synthesis of homogeneous stereoregular ~ (CR) 645 [G.E. *84*, 644 (1972)]
Compositions containing block ~ of vinyl chloride (LA) 735
Vibrational spectroscopy (LA) 1034
Branched amide-imide-ester ~ for non-hygroscopic electrical insulating varnishes with unlimited storage life (PR) 946
Film-forming polymer masses (PR) 1107

Polymethyl methacrylate, Chemical reactions on ~ (CR) 339 [G.E. *84*, 361 (1972)]
Structural investigations on ~ and methyl methacrylate copolymers in solution (CR) 341 [G.E. *84*, 365 (1972)]

Polynucleotides, Chemical synthesis (FP) 451 [G.E. *84*, 489 (1972)]
Possibilities and limits of the enzymatic synthesis of ~ (CR) 336 [G.E. *84*, 359 (1972)]

Polyolefin fibers, Crosslinked, carbon-loaded ~ (PR) 856

Polyolefins, An alternative approach to the nomenclature of cyclic conjugated ~, together with some observations on the use of the term "aromatic" (FP) 404 [G.E. *84*, 447 (1972)]
Formation of macrocyclic ~ on autoxidation of bifunctional alkylenephosphoranes (SC) 508 [G.E. *84*, 528 (1972)]

Polyphenylenes, High molecular ~ (LA) 343

Polyphosphoric acid, Use for the synthesis of polymeric aromatic heterocycles by

cyclopolycondensation reactions (LA) 244

Polypropylene, Shear-induced crystallization (CR) 338 [G.E. *84*, 360 (1972)]

Polyurethanes, Growth processes due to reactions in swellable cellular matrixes (FP) 990 [G.E. *84*, 1001 (1972)]

Polyvinyl chloride, Easily extrudable plastic mixtures based on ~ suitable for the production of transparent bottles (PR) 1036

Porphyrin complexes, Literature on manganese-~ (LA) 447

Porphyrins, Unusual oxidation states of metallo-~: octaethylporphinatosilver-(III)perchlorate (SC) 1014 [G.E. *84*, 1072 (1972)]

Coordination chemistry of metallo-~ (LA) 64

Porous adsorbents, Structure (FP) 267 [G.E. *84*, 331 (1972)]

Positron, Chemistry of the ~ and of positronium (FP) 179 [G.E. *84*, 234 (1972)]

Positronium, Chemistry of the positron and of ~ (FP) 179 [G.E. *84*, 234 (1972)]

1-Propenylketene, Thermal formation from 2,4-pentadienal (SC) 288 [G.E. *84*, 345 (1972)]

Protein chemistry, Physical principles and techniques of ~, Part B (Book Review) 547

Proteins, Transcription of genetic information and its regulation by protein factors (FP) 883 [G.E. *84*, 961 (1972)]
Cooperative conformational changes in globular ~ (FP) 894 [G.E. *84*, 931 (1972)]
Investigation of protein conformation in chemically unchanged, functionally and enzymatically active biomembranes by measurement of optical rotation and UV- and visual light-absorption (LA) 448
Milk ~, Chemistry and molecular biology (Book Review) 345
Struktur und Funktion der Proteine (Book Review) 651

Protophanes by oxidative coupling of "transposed dithiols" (SC) 844 [G.E. *84*, 826 (1972)]

Protonation, Effect on aziridine and oxirane bond strengths (SC) 825 [G.E. *84*, 820 (1972)]

Proton transfer, Studies of intramolecular ~ to cysteine and related compounds by relaxation kinetics (SC) 428 [G.E. *84*, 430 (1972)]

Pseudohalides, Bonding properties of inorganic ~ (LA) 545
Infrared spectra of pseudohalide complexes (LA) 65

Pteridines, Biochemistry (FP) 1061 [G.E. *84*, 1088 (1972)]

Pyrene, Dicyclohepta[cd,gh]pentalene – a new ~ isomer (SC) 1013 [G.E. *84*, 1064 (1972)]

Pyridine, Synthesis and properties of azole-~ combinations: problem of the hydrolytic cleavage of hetarene combinations (SC) 846 [G.E. *84*, 828 (1972)]
Long-range substituent effects in acylation of thiophene-~ combinations (SC) 847 [G.E. *84*, 829 (1972)]
Synthesis of tetrasubstituted ~-s from N,N-dialkylcyanoacetamide (SC) 1098 [G.E. *84*, 1183 (1972)]
Synthesis of pentasubstituted ~-s from C-alkyl-N,N-dialkylcyanoacetamides (SC) 1100 [G.E. *84*, 1185 (1972)]
Chemistry of dihydro-~-s (LA) 732

Pyridine N-oxide, Spatial requirements of ~ oxygen (SC) 727 [G.E. *84*, 770 (1972)]

Pyridinium salts, Synthesis of N-alkyl-~ salts from N-alkylcyanoacetamides (SC) 1099 [G.E. *84*, 1184 (1972)]

Pyrido[2,3-d]pyrimidine-4(3H)-ones, 2-Amino-~ (PR) 946

Pyridyls, 1,4-Dihydro-1-silyl-~ – A new class of stable radicals (SC) 850 [G.E. *84*, 894 (1972)]

Pyrimidine, Triarenes of the type nucleophile-electrophile-nucleophile containing ~ or s-triazine as central nucleus (SC) 848 [G.E. *84*, 830 (1972)]

Pyrrole, Photooxidation of 3,4-diethyl-2,5-dimethyl-~ (SC) 215 [G.E. *84*, 216 (1972)]

Pyrrolidinone, New N-acylamino-~ derivatives (PR) 1036

QUESTIONS, 1000 Fragen aus der Chemie (Book Review) 1109

Quinodimethanes, Intramolecular cycloadditions of C,O and C,N multiple bonds to ortho-~ (SC) 1031 [G.E. *84*, 1108 (1972)]

Quinolines, 4-(Dialkylamino)-~ and 3,3-disubstituted 4(3H)-quinolones from 4H-3,1-benzoxazinones and ynamines (SC) 720 [G.E. *84*, 716 (1972)]

Quinone, Synthesis and X-ray structure analysis of anti-1-bromotricyclo[5.1.0.-$0^{3,5}$]octane-2,6-dione (anti-1-bromobis-homo-~) (SC) 236 [G.E. *84*, 170 (1972)]

Quinoxalines as hydrogen carriers (PR) 1037

RACEMATES, Use of polymers with enzyme-analogous structures for the resolution of ~ (CR) 341 [G.E. *84*, 364 (1972)]

Radiation physics, Atomic and molecular ~ (Book Review) 1038

Radicals, Electronic properties of di-~ (FP) 92 [G.E. *84*, 86 (1972)]
Organic syntheses via free-radical displacement reactions (FP) 692 [G.E. *84*, 702 (1972)]
A stable aromatic diradical with strong dipolar electronic interaction (SC) 303 [G.E. *84*, 353 (1972)]
1,3,5-Benzenetriyltris(1,5-diphenyl-3-verdazyl): A radical having a nearly degenerate doublet-quartet ground state (SC) 830 [G.E. *84*, 890 (1972)]
1,4-Dihydro-1-silylpyridyls – A new class of stable ~ (SC) 850 [G.E. *84*, 894 (1972)]
Free-radical alkylation with sulfoxides and Fenton's reagent (CR) 241 [G.E. *84*, 222 (1972)]
Some properties of a three-membered cyclic diradical intermediate (CR) 320 [G.E. *84*, 314 (1972)]
Cations and ~ from cyclopropanone adducts (CR) 321 [G.E. *84*, 303 (1972)]

Radioactive elements, Adsorption and colloidal properties of ~ (LA) 156

Radioactive nuclides, Messung radioaktiver Nuklide (Book Review) 69

Radiochemistry, Radiochemie (Book Review) 858

Reaction constants, Studies of reaction kinetics in the solid state: first and second order ~ (CR) 445

Rearrangement, Oxidative ~ of C-sulfonylthioformamides (SC) 295 [G.E. *84*, 293 (1972)]
Electron-impact induced ~-s in dibenzoazastannines (SC) 521 [G.E. *84*, 542 (1972)]
~ of 3-butenyl Grignard reagents: anionic or radical? (SC) 542 [G.E. *84*, 531 (1972)]
Degenerate ~ of cis-bicyclo[6.1.0]nona-2,4,6-triene (SC) 832 [G.E. *84*, 892 (1972)]
~-s of spirolactams with synthetic cis- and trans-erythrinanes as example (CR) 240 [G.E. *84*, 220 (1972)]
~-s of carbohydrate esters with anhydrous hydrofluoric acid (CR) 241 [G.E. *84*, 221 (1972)]
Cycloadditions and ~-s of 2-oxyallyl systems (CR) 324 [G.E. *84*, 305 (1972)]
Catalysis of strained σ-bond ~-s by silver ion (CR) 328 [G.E. *84*, 310 (1972)]
~-s of $(CH)_n$ compounds (LA) 733
Base-catalyzed halogen dance (LA) 734

Receptor sites, Labeling of ~ (LA) 854

Redox polymers, Some new ~ containing nitrogen (CR) 338 [G.E. *84*, 360 (1972)]

Reduction of organic compounds by alkoxyhydridoaluminates (LA) 1035

Reductive fragmentation of 3,3-dihalotricyclo[4.2.1.$0^{2,4}$]non-2-yl acetates: a new route to the bicyclo[4.2.1]nonane series (SC) 641 [G.E. *84*, 643 (1972)]

Repulsion, Assessment of the interelectronic ~ parameter (LA) 66
Influence of non-bonded H atom ~-s (LA) 66

Ring contractions, Cyclobutane ~ not involving carbonium ions (LA) 447

Ring opening of a cyclopropyl anion and cycloaddition of the allyl anion (SC) 724 [G.E. *84*, 768 (1972)]

Rotaxanes, catenanes, ~, and knots (Book Review) 248

Rubidium compounds, Preparation and structure of the fluoro complex Rb-$[Mo_2O_2F_9]$ 1020 [G.E. *84*, 1099 (1972)]

Rupe rearrangement and Meyer-Schuster rearrangement (LA) 156

Ruthenium complexes, Cationic γ-oxo-isocyano complexes of iron, ruthenium, and osmium (SC) 527 [G.E. *84*, 584 (1972)]

SANDWICH compounds, New route to triple-decker ~ (SC) 930 [G.E. *84*, 949 (1972)]

Scandium compounds, Coordination chemistry (LA) 245

Schiff bases, Structure of metal complexes of some quadridentate ~ (LA) 733

Selenate, Xenon bis(pentafluoroortho-~) and xenon fluoride pentafluoroortho-~ (SC) 723 [G.E. *84*, 715 (1972)]

Selenic acid, Pentafluoroortho-~ (SC) 630 [G.E. *84*, 715 (1972)]

Self-organization, of molecular systems and evolution of the genetic apparatus (FP) 798 [G.E. *84*, 838 (1972)]
Computer model of the formation of self-organizing systems (FP) 821 [G.E. *84*, 862 (1972)]

Semiconduction, Crystal chemistry and ~ (Book Review) 859

Semiconductors, Industrial application of the semiconductor properties of dyes (FP) 1051 [G.E. *84*, 1077 (1972)]

Sesquifulvalenes from dihydrofulvalenes (SC) 133 [G.E. *84*, 115 (1972)]

Sex attractant, Novel total synthesis of the ~ of Porthetria dispar (7,8-cis-epoxy-2-methyloctadecane) (SC) 60 [G.E. *84*, 67 (1972)]

Shift reagents, in NMR spectroscopy (FP) 675 [G.E. *84*, 737 (1972)]
Complex shift reagent for ^{13}C-NMR studies on carbohydrates (SC) 539 [G.E. *84*, 589 (1972)]

Signal transducers: Terra incognita of molecular biology (FP) 1 [G.E. *84*, 1 (1972)]

1-Sila-3-cyclopentenes, Photoelectron spectroscopy and transannular interactions – the question of transannular d-π interactions in ~ and 1-germa-3-cyclopentenes (SC) 837 [G.E. *84*, 899 (1972)]

Silane, Nature of the "silicon β-effect" in allyltrimethyl-~ (SC) 146 [G.E. *84*, 167 (1972)]

Silicon compounds, Coordination compounds with silicon-molybdenum and silicon-tungsten bonds (SC) 516 [G.E. *84*, 538 (1972)]
Evidence for conjugation through a saturated silicon atom (SC) 536 [G.E. *84*, 550 (1972)]
Estimation of spiro-interaction (spiroconjugation) in tetravinylsilane (SC) 537 [G.E. *84*, 551 (1972)]
Silicon as a carbanion substituent in ylides (CR) 944 [G.E. *84*, 957 (1972)]

Silicon dioxide, Graft reactions on ~ surfaces (CR) 337 [G.E. *84*, 359 (1972)]

Silicon β-effect, Nature of the "~" in allyltrimethylsilane (SC) 146 [G.E. *84*, 167 (1972)]

Silicon-nitrogen compounds, Two crystal structures of cyclic ~ with different disorder (SC) 58 [G.E. *84*, 27 (1972)]

Silver, Gmelins Handbuch der anorganischen Chemie (Book Review) 69

Silver compounds, Unusual oxidation states of metalloporphyrins: octaethylporphinatosilver(III) perchlorate (SC) 1014 [G.E. *84*, 1072 (1972)]

Silver ion, Catalysis of strained σ-bond rearrangements by ~ (CR) 328 [G.E. *84*, 310 (1972)]

1-Silylpyridyls, 1,4-Dihydro-~ – A new class of stable radicals (SC) 850 [G.E. *84*, 894 (1972)]

Single crystals, Chemical reactions on ~ of copolymers (CR) 340 [G.E. *84*, 363 (1972)]

Small ring carbocations, Insights into ~ provided by MO calculations (CR) 330 [G.E. *84*, 316 (1972)]

Small ring compounds, Bicyclic and tricyclic ~ (CR) 332 [G.E. *84*, 313 (1972)]

Small rings, International symposium on the chemistry of ~ (CR) 320 [G.E. *84*, 303 (1972)]

Solid compounds, Vibration-spectroscopic studies on ~ (FP) 26 [G.E. *84*, 8 (1972)]

Solid phase synthesis, Novel carrier for ~ of oligomers (SC) 713 [G.E. *84*, 712 (1972)]

Solid state, Mechanisms of reactions in the ~ (FP) 173 [G.E. *84*, 227 (1972)]
Nuclear magnetic resonance in ~ chemistry (FP) 607 [G.E. *84*, 498 (1972)]

Solvation complexes, Structure of ion pair ~ (FP) 112 [G.E. *84*, 127 (1972)]

Solvent molecules, How many ~ are nearest neighbors to a metal ion in solution? (LA) 65

Solvents, The chemistry of nonaqueous ~ (Book Review) 546

Spectroscopic methods, Spektroskopische Methoden in der organischen Chemie (Book Review) 650

Spectroscopy, Vibration-spectroscopic studies on solid compounds (FP) 26 [G.E. *84*, 8 (1972)]
X-ray spectroscopic investigation of chemical bonding in solids (FP) 34 [G.E. *84*, 51 (1972)]
Metal isotope effects on metal-ligand vibrations (FP) 666 [G.E. *84*, 755 (1972)]
Structure determinations of nitrogen compounds with the aid of NQR, NMR, and ESCA ~ (FP) 979 [G.E. *84*, 1037 (1972)]
Photochemical and spectroscopic properties of organic molecules in the adsorbed state (LA) 156

Spiroconjugation, Estimation of spiro- interaction (~) in tetravinylsilane (SC) 537 [G.E. *84*, 551 (1972)]

Spirodiene rearrangement (LA) 446

Spiroheptatrienes, Photofragmentation of spiropyrazoles. – Stable norcaradienes and ~ (SC) 224 [G.E. *84*, 215 (1972)]

Spiroheptatrienes by [1+2]-cycloaddition (SC) 225 [G.E. *84*, 215 (1972)]

Spiro[indene-1,7'-norcaradiene], 1-Diazoindene and ~ (SC) 44 [G.E. *84*, 31 (1972)]

Spiroisoindolines (LA) 735

Spirolactams, Rearrangements of ~ with synthetic cis- and trans-erythrinanes as example (CR) 240 [G.E. *84*, 220 (1972)]

Spirophosphoranes from acylhydrazines and phosphorus compounds (SC) 306 [G.E. *84*, 349 (1972)]

Spiropyrazoles, Photofragmentation of ~. – Stable norcaradienes and spiroheptatrienes (SC) 224 [G.E. *84*, 215 (1972)]

Squaric 1,3-diamides, New routes to ~ (SC) 431 [G.E. *84*, 480 (1972)]

Squaric diamidine, A ~ and an aza analog of biphenylene (SC) 433 [G.E. *84*, 481 (1972)]

Stability constants, Methods for calculation of ~ of metal complexes in solution (LA) 65

Steric effects, Influence of non-bonded H atom repulsions (LA) 66

Stereochemistry, Spatial requirements of pyridine N-oxide oxygen (SC) 727 [G.E. *84*, 770 (1972)]
~ of double bonds (LA) 855

Stilbenes, Biaryls, ~, benzo[c]cinnolines, and *dibenz[c,mn]*acridines from sulfonamides (SC) 826 [G.E. *84*, 822 (1972)]

L-Streptose, Synthesis of branched carbohydrates with aldehyde side-chains. – Simple synthesis of ~ and D-hamamelose (SC) 149 [G.E. *84*, 112 (1972)]

Structure determinations of nitrogen compounds with the aid of NQR, NMR, and ESCA spectroscopy (FP) 979 [G.E. *84*, 1037 (1972)]

Substituent effects, in 1,3-dipolar cycloadditions of phenyl azide (SC) 838 [G.E. *84*, 887 (1972)]
~ in Diels-Alder additions (SC) 840 [G.E. *84*, 888 (1972)]
Long-range ~ in acylation of thiophene-pyridine combinations (SC) 847 [G.E. *84*, 829 (1972)]

Substitutions, Structure and stereochemistry of the transition states and intermediates of heterolytic aromatic ~ (FP) 874 [G.E. *84*, 921 (1972)]
Ring ligand ~ of aromatic-metal complexes (LA) 945

Succinonitrile, Hydrogen cyanide chemistry: synthesis of diimino-~ (CR) 153 [G.E. *84*, 173 (1972)]

Sugars, Chemistry and biochemistry of branched-chain ~ (FP) 159 [G.E. *84*, 192 (1972)]

Sulfenyl halides, Oxidation, reduction, and addition reactions of ~ (LA) 244
Substitution and cyclization reactions (LA) 344

Sulfides, "Electron lone pairs" in organic ~ and disulfides (SC) 150 [G.E. *84*, 119 (1972)]

Sulfodiimides, Sequence of orbitals in sulfones and ~ (SC) 927 [G.E. *84*, 944 (1972)]

Sulfonamides, Biaryls, stilbenes, benzo[c]-cinnolines, and dibenz[c,mn]acridines from ~ (SC) 826 [G.E. *84*, 822 (1972)]

Sulfones, 1-Formylamino-1-arylsulfonyl alkenes from α-metalated isocyanomethyl aryl ~ and carbonyl compounds; conversion of a carbonyl compound into the next higher carboxylic acid (SC) 311 [G.E. *84*, 289 (1972)]
Sequence of orbitals in ~ and sulfodiimides (SC) 927 [G.E. *84*, 944 (1972)]

Sulfonium salts, Two unusual sulfur groups: Butadienyl-~ and sulfur diimides (CR) 1106 [G.E. *84*, 1154 (1972)]

C-Sulfonylthioformamides, Oxidative rearrangement (SC) 295 [G.E. *84*, 293 (1972)]

Sulfoxides, The "sulfoxide bond" (SC) 436 [G.E. *84*, 436 (1972)]
Free-radical alkylation with ~ and Fenton's reagent (CR) 241 [G.E. *84*, 222 (1972)]

Sulfur, Function in living organisms (LA) 157

Sulfur compounds, Preparation of cyclooctasulfur oxide, S_8O (SC) 302 [G.E. *84*, 344 (1972)]
$CH_3AsS_2N_2$, a five-membered arsenic-sulfur-nitrogen ring (SC) 529 [G.E. *84*, 585 (1972)]
X-ray structural analysis of N,N'-dimethyl-3,6-epitetrathio-2,5-piperazinedione (SC) 632 [G.E. *84*, 640 (1972)]
Synthesis of the first oxide of tetrasulfur tetranitride (SC) 918 [G.E. *84*, 946 (1972)]
Polymerization of vinyl- and related compounds in the presence of ~ (LA) 245
Recent developments in the synthetic organic chemistry of sulfur (LA) 732

Sulfur diimides, Two unusual sulfur groups: Butadienylsulfonium salts and ~ (CR) 1106 [G.E. *84*, 1154 (1972)]

Sulfur dioxide, Recent developments in the synthesis of organic compounds in liquid ~ (LA) 343

β-Sultones, Fluorinated ~ (FP) 583 [G.E. *84*, 623 (1972)]

Surfaces, Properties of clean metal ~ and reactions thereon (LA) 64
Physical ~ (Book Review) 549

Synthetic problems, Computer-assisted analysis of complex ~ (LA) 446

TACTICITIES, Mixtures of polymers having different ~ with a melting point maximum (CR) 335 [G.E. *84*, 357 (1972)]

Tetraacetylene, Preparation of pure triacetylene, ~, and pentaacetylene and investigation of their electronic spectra (SC) 438 [G.E. *84*, 483 (1972)]

Tetracyanoethylene, 1,4-Cycloaddition to methoxy- and phenoxy-cyclooctatetraene (SC) 716 [G.E. *84*, 766 (1972)]
Cycloaddition with cyclopropylethylenes (CR) 328 [G.E. *84*, 309 (1972)]

Tetracyclononane, cis,trans-Tetracyclo[6.1.-0.0^{2,4}.0^{5,7}]nonane, "trans-trishomobenzene" (SC) 310 [G.E. *84*, 346 (1972)]

Tetrahydropentalenes, Photoprocesses of phenyl-substituted ~ (SC) 719 [G.E. *84*, 719 (1972)]

Tetrasulfur tetranitride, Synthesis of the first oxide of ~ (SC) 918 [G.E. *84*, 946 (1972)]

Textbook, Lehrbuch der analytischen und präparativen anorganischen Chemie (Book Review) 547

Thermochemistry of the chemical bond (LA) 545

Thermolysis, Flach-vacuum ~ of p-benzoquinones (CR) 333 [G.E. *84*, 314 (1972)]

Thia[17]annulenes, Synthesis of stereoisomeric bisdehydro-~ and their dioxides (SC) 834 [G.E. *84*, 897 (1972)]

Thiatriazadiphosphorine, 1,3,3,5,5-Pentachloro-1λ^4,2,4,6,3λ^5,5λ^5-~ (SC) 642 [G.E. *84*, 685 (1972)]

N-Thienylalkyl-β-phenylethylamines, Anorectic ~ (LA) 736

Thiocarbamate, S-Benzyl N,N-di-sec-butyl-~ (PR) 946

Thioformamides, Oxidative rearrangement of C-sulfonyl-~ (SC) 295 [G.E. *84*, 293 (1972)]

Thioketones, Metal complexes of thio-β-diketones (LA) 157

Thiolactams, Conversion of cyclic nitrones into ~ by reaction with carbon disulfide (SC) 47 [G.E. *84*, 34 (1972)]

Thiophene, Long-range substituent effects in acylation of ~-pyridine combinations (SC) 847 [G.E. *84*, 829 (1972)]

Tin, Gmelins Handbuch der anorganischen Chemie (Book Review) 69

Tin compounds, Electron-impact induced rearrangements in dibenzoazastannines (SC) 521 [G.E. *84*, 542 (1972)]
Organotin compounds (Book Review) 1039

Titanium compounds, Bis(π-cyclopentadienyl)(1,2,3-triphenyltriphosphanato-P^1,P^3)-titanium and -zirconium (SC) 527 [G.E. *84*, 582 (1972)]

Titration, Titrationen in nichtwässrigen Medien (Book Review) 344

Toluene, Side-chain alkylation of ~ with ethylene (SC) 918 [G.E. *84*, 947 (1972)]

Toxins from marine invertebrates (LA) 244

Transannular interactions, Photoelectron spectroscopy and ~ – the question of transannular d-π interactions in 1-sila- and 1-germa-3-cyclopentenes (SC) 837 [G.E. *84*, 899 (1972)]

Transition metal compounds, Application of magnetic resonance methods in the elucidation of bonding properties of ~ (LA) 245
Theory of the magnetic properties of polynuclear ~ (LA) 545

Transition states as acids and bases (LA) 546

Triacetylene, Preparation of pure ~, tetraacetylene, and pentaacetylene and investigation of their electronic spectra (SC) 438 [G.E. *84*, 483 (1972)]

Triarenes of the type nucleophile-electrophile-nucleophile containing pyrimidine or s-triazine as central nucleus (SC) 848 [G.E. *84*, 830 (1972)]

s-Triazine, Triarenes of the type nucleophile-electrophile-nucleophile containing pyrimidine or ~ as central nucleus (SC) 848 [G.E. *84*, 830 (1972)]

v-Triazoles, Reaction of metalated nitrosamines with nitriles. New method for preparation of ~ (SC) 1102 [G.E. *84*, 1187 (1972)]

Tricyclo[5.1.0.0^{3,5}]octane-2,6-dione, Synthesis and X-ray structure analysis of anti-1-bromo-~ (anti-1-bromobishomoquinone) (SC) 236 [G.E. *84*, 170 (1972)]

Trifluoromethanesulfonic-carboxylic anhydrides, highly active acylating agents (SC) 299 [G.E. *84*, 294 (1972)]

Triketones, Geometry and n-ionization energies of alkyl-substituted ~ (SC) 220 [G.E. *84*, 210 (1972)]

1,4,7-Trioxacyclononatriene, Valence isomerization of syn-benzene trioxide to cis, cis,cis-~; anti-benzene trioxide (SC) 939 [G.E. *84*, 986 (1972)]

Trishomobarrelene, Bridgehead reactivities of ~ and trishomobullvalene (SC) 56 [G.E. *84*, 63 (1972)]

trans-Trishomobenzene, cis,trans-Tetracyclo[6.1.0.0^{2,4}.0^{5,7}]nonane, "~" (SC) 310 [G.E. *84*, 346 (1972)]

Trishomobullvalene, Bridgehead reactivities of trishomobarrelene and ~ (SC) 56 [G.E. *84*, 63 (1972)]

Trithiatriazine, 4-(Difluorooxophosphoranyl)-1λ^4,3,5,2,4,6-~ (SC) 642 [G.E. *84*, 684 (1972)]

Tritium labeling, Exploration of biochemical mechanisms by ~ (LA) 734

Tropolone, 2-Hydroxy-4,9-methano[11]annulenone, a 10π-electron analog of ~ (SC) 218 [G.E. *84*, 208 (1972)]

Tungsten complexes, Optically active molybdenum complexes and ~ with tetragonal-pyramidal configuration (SC) 418 [G.E. *84*, 442 (1972)]

Tungsten compounds, Coordination compounds with silicon-molybdenum and silicon-tungsten bonds (SC) 516 [G.E. *84*, 538 (1972)]
Stereochemistry of the halocarbonylphosphanes and arsanes of molybdenum and tungsten (LA) 64

Turbidimetric titration of polymers (CR) 336 [G.E. *84*, 358 (1972)]

UMBELLIFERAE, Structural studies on constituents of ~ (CR) 239 [G.E. *84*, 219 (1972)]

Uroporphyrin III, Total synthesis of [α,γ-$^{14}C_2$]-~ (SC) 420 [G.E. *84*, 432 (1972)]

Uroporphyrinogen III, Biosynthesis of heme and vitamin B_{12} from [α,γ-$^{14}C_2$]-~ (SC) 421 [G.E. *84*, 433 (1972)]

UV spectroscopy, UV spectroscopic properties of simple compounds having N-N and N-O bonds (LA) 244

VALENCE tautomerism, Kinetics of the homotropilidene ~ (SC) 517 [G.E. *84*, 539 (1972)]

Vanadium compounds, Gmelins Handbuch der anorganischen Chemie (Book Review) 449

van der Waals molecules, Intermolecular interactions: ~ (FP) 486 [G.E. *84*, 570 (1972)]

Vibrational frequencies, Calculation of ~ and force constants (LA) 66

Vibrational spectroscopy of polymers (LA) 1034

N-Vinylcarbazole, Polymerization of ~ with metal salts (LA) 945

Vinyl cations, MO calculations on the insertion reactions of ~ (SC) 635 [G.E. *84*, 680 (1972)]
Formation and detection of ~ (CR) 544 [G.E. *84*, 592 (1972)]
Solvolysis of 1-cyclobutenyl nonafluorobutanesulfonate (SC) 714 [G.E. *84*, 714 (1972)]

Vinyl compounds, Polymerization of ~ and related compounds in presence of sulfur compounds (LA) 245

Vinyl chloride, Compositions containing block polymers of ~ (LA) 735

Vinylcyclopropanes, Reactions of strained C—C single bonds with transition metals–influence of geometrical factors on the reactivity of complex-bound vinylcyclopropane systems (SC) 522 [G.E. *84*, 583 (1972)]

Vinylogous fulvalene: synthesis and electrocyclic reaction (SC) 296 [G.E. *84*, 297 (1972)]

Vitamin B_{12}, Biosynthesis of heme and ~ from [α,γ-$^{14}C_2$]-uroporphyrinogen III (SC) 421 [G.E. *84*, 433 (1972)]

Vitamin B_{12} enzymes, Chemistry (LA) 1035

WALDEN inversion at an asymmetric molybdenum atom (SC) 923 [G.E. *84*, 955 (1972)]

Water, Kinetic data on ~ exchange between aquo complexes and solvent ~ (LA) 157
~ and ~ pollution (Book Review) 1109

Wittig reagents, Polymeric ~ (SC) 298 [G.E. *84*, 296 (1972)]

XENON compounds, Xenon bis(pentafluoroorthoselenate) and xenon fluoride pentafluoroorthoselenate (SC) 723 [G.E. *84*, 715 (1972)]

X-ray analysis, Automated X-ray structure determination as an analytical method (FP) 387 [G.E. *84*, 412 (1972)]
~ of a benzocyclopropene derivative (SC) 422 [G.E. *84*, 434 (1972)]
~ of 2,3,6-triphenylarsenin (SC) 630 [G.E. *84*, 679 (1972)]
~ of N,N'-dimethyl-3,6-epitetrathio-2,5-piperazinedione (SC) 632 [G.E. *84*, 640 (1972)]

X-ray spectroscopy, X-ray spectroscopic investigation of chemical bonding in solids (FP) 34 [G.E. *84*, 51 (1972)]

YLIDE complexes, Dimethylphosphane-(phenylmethoxy)methylenepentacarbonylchromium(0) – a route from carbene complexes to ~ (SC) 643 [G.E. *84*, 679 (1972)]

Ylides, Silicon as a carbanion substituent in ~ (CR) 944 [G.E. *84*, 957 (1972)]

Ynamines, 4-(Dialkylamino)quinolines and 3,3-disubstituted 4(3H)-quinolones from 4H-3,1-benzoxazinones and ~ (SC) 720 [G.E. *84*, 716 (1972)]

ZIEGLER-Natta catalysts, Characterization of the intermittently polymerization-active species of soluble ~ (CR) 336 [G.E. *84*, 359 (1972)]

Zirconium compounds, Bis(π-cyclopentadienyl)(1,2,3-triphenyltriphosphana to-P^1,P^3)-titanium and -zirconium (SC) 527 [G.E. *84*, 582 (1972)]
