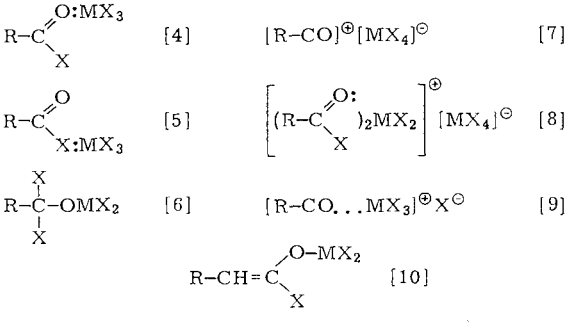
Structures of the Intermediate Complexes in Friedel-Crafts Acylations

By Bernard Chevrier and Raymond Weiss[*]

Addition compounds of Lewis acids MX_n and acyl halides R—COX occur as intermediates in Friedel-Crafts acylations. IR and NMR studies on these intermediates have indicated the probable existence of structural isomers. In X-ray structural analysis, it is possible to distinguish two forms, *i.e.* the molecular form, in which the compounds are present as donor-acceptor complexes $R—CXO \rightarrow MX_n$, and the ionic form, in which they can be formulated as oxocarbenium salts $[R—CO]^+[MX_{n+1}]^-$. The compounds of the donor-acceptor type $R—CXO \rightarrow MX_n$ are characterized by the formation of a coordinate oxygen-metal bond; the transfer of electrons from the oxygen to the metal of the acceptor is always due to a weak donor-acceptor interaction. The positive charge of the aryloxocarbenium ions is partly delocalized over the aromatic nucleus. The positive charge in alkyloxocarbenium ions, on the other hand, is essentially localized on the carbon atom of the carbonyl group, as is confirmed by electron density distribution calculations.

1. Introduction



The Lewis acids MX_n ($n = 3,5$) can form more or less stable addition compounds with molecules that contain one or more nucleophilic atoms.

The complexes of the type $MX_n \cdot R—COX$ are formed in the course of Friedel-Crafts acylations

$$Ar—H + R—COX \xrightarrow{MX_n} Ar—CO—R + HX$$

from the catalyst MX_n and the acyl halide R—COX[1]. The role of these intermediates suggests two possible reaction mechanisms: one is a substitution mechanism[2], in which a donor-acceptor complex acts as the acylating agent, and the other is an ionic mechanism[3], in which the kinetics of the reaction are controlled by the formation of oxocarbenium ions $[R—CO]^+$.

Several formulas have been proposed for the structure of these intermediates (Scheme 1). Spectroscopic studies (IR, NMR) and X-ray structural analyses have now led to a clear picture of the nature and the geometry of these addition compounds.

2. Spectroscopic Studies

2.1. IR Spectroscopy

IR spectroscopy has frequently been used during the past fifteen years for the study of the complexes of Lewis acids MX_n and acyl halides R—COX[11–25].

The vibrations of the carbonyl group lead to a strong band at about 1800 cm^{-1} in the spectra of the acyl halides R—COX. The most remarkable difference between the IR spectra of the acyl halides and their adducts $MX_n \cdot$R—COX is the displacement of this band. The *increase* in the frequency to 2200—2300 cm^{-1}, *i.e.* to the carbon-oxygen triple-bond range, is characteristic of the occurrence of oxocarbenium ions $[R—CO]^+$[11]; the *decrease* to 1550—1600 cm^{-1}, which is also observed when a ketone combines with a Lewis acid[26–28], is attributable to the formation of a coordinate bond between the oxygen atom and the metal atom of the electron acceptor: $R—CXO \rightarrow MX_n$.

Table 1 shows the characteristic vibration frequencies of selected complexes.

While IR spectroscopy is a great help in the classification of these complexes, it is not enough by itself to allow the definite assignment of the structure of an oxocarbenium salt or of a nonionic addition compound to the adduct. Bands at 2200—2300 cm^{-1} and at 1550 cm^{-1} very often occur together in the IR spectra (Table 1). *Cook*[15] found this situation in the investigation of mixtures of acetyl chloride and aluminum chloride, and assumed that a mixture of the ionic form and the molecular form is present. The idea that an equilibrium exists between the two forms has been generally accepted since that time. The position of this equilibrium

$$[R\text{–}CO]^{\oplus}[MX_{n+1}]^{\ominus} \rightleftharpoons R\text{–}C(=O\rightarrow MX_n)\text{–}X$$

depends on the complex under investigation as well as on the experimental conditions:

a) Acyl fluorides and metal fluorides give mainly ionic compounds[13, 23–25]. The affinity of the fluoride ion for the metal of the acceptor has been demonstrated by investigations on the protonation and dehydration of carboxylic acids by the mixtures BF_3/HF, SbF_5/HF and $SbF_5/SO_2/FSO_3H$[29–32]. The formation of stable anions BF_4^- or SbF_6^- in these reactions favors the displacement of the equilibrium toward the ionic form.

b) Dioxodicarbenium ions can be prepared from difluorides of dicarboxylic acids FOC—$(CH_2)_n$—COF only for $n \geq 3$. The dication cannot be formed from succinyl difluoride ($n=2$), since the distance between the charges is too small. Addition of the Lewis acid SbF_5 is reported to lead to the mixed addition compound $[SbF_5 \cdot FOC\text{—}(CH_2)_2\text{—}CO]^+[SbF_6]^-$[24].

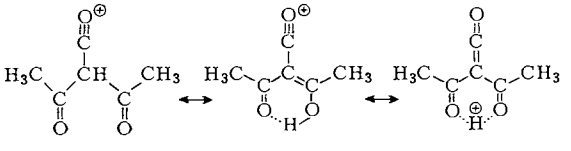
c) 2,6-Dimethylbenzoyl chloride and mesitoyl chloride, unlike benzoyl chloride, form addition compounds having ionic character with the acceptors $AlCl_3$ and $TiCl_4$[14, 20, 21]. This could be due to intramolecular steric hindrance, since the bulky methyl groups could favor the formation of a $C\equiv O^+$ bond in the complex. The molecule would thus become planar again, with the result that a conjugated system could develop.

d) The equilibrium can be displaced toward the ionic form or toward the molecular form by the use of suitable solvent. *Cook*[15] showed that the adduct of acetyl chloride and aluminum chloride predominantly dissociates into ions in a solvent having a high dielectric constant such as nitrobenzene ($\varepsilon = 36.1$), whereas only the molecular form is present in a solvent such as chloroform ($\varepsilon = 5.05$).

The formation of oxocarbenium ions is generally characterized by a single strong absorption band in the carbon-oxygen triple-bond region (2200—2300 cm^{-1}); however, two bands have been found in this region for some compounds, one at 2200 cm^{-1} and the other at 2300 cm^{-1} (Table 1). In the investigation of the complex $AlCl_3 \cdot CH_3COCl$ in the solid state at −15 °C, *Susz* and *Wuhrmann*[14] attributed the strong vibration at the higher frequency to the particle $[CH_3CO]^+$ but gave no assignment for the weak shoulder at 2200 cm^{-1}.

Cook[15], who obtained this complex in the liquid state by mixing the two components in the absence of solvent, found two strong bands at 2307 cm^{-1} and 2203 cm^{-1} and a very strong band at 1637 cm^{-1}. This last band was assigned by the author to the molecular compound, and the absorption at 2307 cm^{-1} to the free acetylium ion $[CH_3CO]^+$. *Cook* expresses the opinion that the band at 2203 cm^{-1} is due either to the complex ion $[CH_3CO \ldots AlCl_3]^+$ proposed by *Dilthey*[9] or again to an association of the acetylium and tetrachloroaluminate ions $[CH_3—\overset{+}{C}=O][Cl—AlCl_3]^-$.

In a later publication on the complex $GaCl_3 \cdot CH_3COCl$[16], *Cook* reversed the earlier assignment and attributed the band at 2200 cm^{-1} to the free acetylium ion and that at 2300 cm^{-1} to the complex ion $[CH_3CO \ldots AlCl_3]^+$. *Cook* deduced this new hypothesis from the analogy with the complexes $MX_n \cdot CH_3CN$ where the frequency of the C—N stretching vibration is higher in the complex than in the free nitrile[33–35].



Gates and *Steele*[36], on the other hand, on the basis of an IR and Raman study of the addition compound $SbCl_5 \cdot CH_3COCl$, reject the existence of a complex salt $[CH_3CO \ldots SbCl_5]^+Cl^-$ and assign the strong absorption at 2300 cm^{-1} to the carbonyl vibration of the free acetylium ion.

Cassimatis et al.[18,37] recently suggested the occurrence of two types of acetylium ion in the compounds $AlCl_3 \cdot CH_3COCl$ and $AlBr_3 \cdot CH_3COBr$. Type I, with a characteristic absorption at 2200 cm^{-1}, has the formula $CH_3—C\equiv O^+$, while type II, with the band at 2300 cm^{-1}, is a resonance hybrid between the three structures

$$CH_3—C\equiv\overset{\oplus}{O} \leftrightarrow CH_3—\overset{\oplus}{C}=O \leftrightarrow \overset{\oplus}{H}CH_2=C=O$$

with predominance of the hyperconjugated form.

Germain, Commeyras, and *Casadevall*[38] have isolated and characterized two crystalline tetrachloroaluminates. The one that causes the absorption at 2300 cm^{-1} contains the acetylium ion. The other, which absorbs strongly at 2200 cm^{-1}, contains the diacetylacetylium ion *(1)*, which is formed by reaction of the acetylium ion with acetyl chloride in a ratio of 1:2.

(1)

The contribution of the third resonance form, the ketene structure, is thought to be the cause of the decrease in the carbonyl frequency by about 100 cm^{-1} in relation to that of the acetylium ion. This effect also explains the frequency of 2190 cm^{-1} in the mesitoylium ion[14].

Mention should also be made of a publication by *Cassimatis* and *Susz*[17] on the adduct $TiCl_4 \cdot CH_3COCl$, which has no absorption in the CO triple-bond region. The authors assign the band at 1620 cm^{-1} to the carbonyl vibration, which is thought to be disturbed by the attachment of the acceptor $TiCl_4$ to the oxygen atom. They explain the occurrence of another strong absorption at 1760 cm^{-1} by the possibility of a dipole-dipole interaction[39], which could lead to a molecular compound $CH_3COCl \ldots TiCl_4$, or by the assumption of a weak dative bond between $TiCl_4$ and the chlorine atom of acetyl chloride, in which no ionization occurs. The authors rule out the existence of a compound of the type

$$CH_2=C(Cl)—O—AlCl_2$$

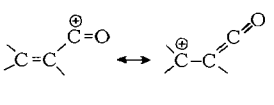
proposed by *Illari*[10]. While the value of 1620 cm^{-1} is acceptable for a CC double bond, 1760 cm^{-1} seems to them to be much too high for the frequency of a carbonyl vibration disturbed by a Lewis acid as strong as $TiCl_4$.

2.2. Nuclear Magnetic Resonance

Measurements of the nuclear magnetic resonance add to and extend the information provided by IR spectroscopy on the structure and behavior of the addition compounds under investigation in solution. The results are particularly informative, since it is in the dissolved state that these complexes function as intermediates in acylations.

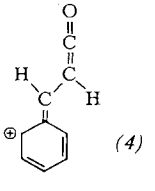
Olah et al. have made extensive use of this technique[12,19,23–25,32,40] for the investigation of the fluoride adducts dissolved in liquid sulfur dioxide or in anhydrous hydrogen fluoride. The resolution of the ^1H-NMR spectra is as good as that of the ^{19}F- or ^{13}C-NMR spectra; they exhibit a characteristic shift of the signals due to the protons α to the carbonyl group toward lower fields.

Two types of signals appear, and these are assigned to two particles having different structures[12]. The species with $\delta \approx -4.1$ ppm is the oxocarbenium ion $[R—CO]^+$, whose positive charge reduces the shielding by the electrons and so causes a strong chemical shift. The smaller chemical shift ($\delta \approx -2.9$ ppm) in the other particle points to stronger shielding in the strongly polarized coordination compound *(2)*. The spectra generally contain both signals, and again show that the two species occur together in solution[12,19].



$$R—\overset{\delta\oplus}{\underset{X}{C}}O \rightarrow \overset{\delta\ominus}{M}X_n \qquad (2)$$

Nuclear magnetic resonance also provides further information on the structure of the oxocarbenium ions.



From the study of the ^1H and ^{13}C resonances for solutions of the complexes $[CH_3CO]^+[SbF_6]^-$, $[CD_3CO]^+[SbF_6]^-$, and $[CH_3{}^{13}CO]^+[SbF_6]^-$ in SO_2 or HF[19], it can be concluded that the positive charge of the acetylium ion is mainly localized on the carbon atom of the carbonyl group:

$$CH_3—\overset{+}{C}=O$$

In the alkenyloxocarbenium ions, the chemical shift of the protons β to the carbonyl group is greater than that of the protons in the α position. This points to a contribution by the resonance structures *(3)*, and particularly in the case

(3)

(4)

of the cinnamoylium ion to a high contribution by the limiting form *(4)*[23], in which delocalization of the positive charge over the aromatic ring is possible.

From the NMR spectra of the phenyloxocarbenium ion and some of its *o*-, *m*-, and *p*-substituted derivatives, *Olah* and *Westerman*[41] concluded that considerable delocalization of the charge over the aromatic ring is to be expected.

3. X-Ray Structural Investigations

Recent X-ray structural analyses yield a clear picture of the structure and stereochemistry of the addition compounds under investigation in the solid state. These studies show the presence of either molecular donor-acceptor complexes of the type $R{-}CXO{\rightarrow}MX_n$ or adducts $[R{-}CO]^+[MX_{n+1}]^-$ having an ionic structure. No other species were detectable in the crystalline state.

3.1. Donor-Acceptor Addition Compounds (Molecular Form)

The crystal structures of the following molecular addition compounds have now been determined:

acceptor $AlCl_3$, donor propionyl chloride[42], benzoyl chloride[43], *o*-, *m*-, and *p*-toluoyl chloride[44];

acceptor $SbCl_5$, donor 1/2 succinyl dichloride[45], benzoyl chloride[46], *m*-toluoyl chloride[46], and *p*-toluoyl chloride[47].

The bonding between the acyl halide and the Lewis acid is brought about in these adducts by the oxygen atom, which shares a lone pair of electrons with the metal of the electron acceptor.

The formation of the coordinate metal-oxygen bond leads to a tetrahedral environment for the aluminum atom and an octahedral environment for the antimony atom (Fig. 1). The coordination polyhedra $AlCl_3O$ and $SbCl_5O$ are highly distorted because of intramolecular steric hindrance. In the first instance, the dissimilarity of the atoms of the coordination polyhedron causes the chlorine atoms to be displaced toward the oxygen atom (van der Waals radii: O = 1.40, Cl = 1.80 Å). Furthermore, the proximity of the acyl chloride group leads to an interaction with the chlorine atoms of the polyhedron, as a result of which the chlorine-metal-oxygen bond angles become unequal[42, 44–47].

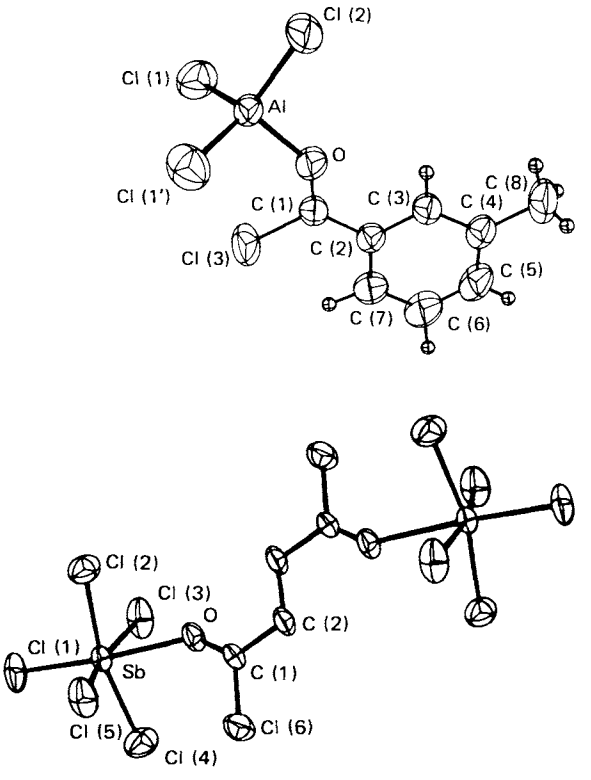


Fig. 1. Crystal structure of the molecular compounds $AlCl_3 \cdot 3\text{-}CH_3{-}C_6H_4COCl$ (top) and $2\,SbCl_5 \cdot ClOCCH_2CH_2COCl$ (bottom).

The deformation of the coordination polyhedra can be seen from Table 2, which shows the chlorine-metal-oxygen and chlorine-metal-chlorine bond angles. Comparison of these bond angles with those in compounds of hexacoordinate antimony $SbCl_5 \cdot POCl_3$, $SbCl_5 \cdot HCON(CH_3)_2$, and $SbCl_5 \cdot (CH_3)_3PO$[48, 49] shows particularly clearly that the displacement of the chlorine atom toward the oxygen atom increases with the length of the metal-oxygen bond.

The donor-acceptor interaction in these molecular addition compounds consists in the transfer of electrons from the oxygen of the acyl chloride to the metal of the Lewis acid. This transfer is limited, however, by the electron attraction of the chlorine atom in the acyl chloride, which is therefore only

Table 2. Length of the metal-oxygen bond and bond angles in the coordination polyhedra of the donor-acceptor complexes.

[a] Cl* denotes the chlorine atom situated opposite the oxygen atom in the $SbCl_5O$ coordination polyhedron.

a weak donor. The length of the coordinate bond Al—O between aluminum and oxygen is practically the same in all addition compounds of the Lewis acid $AlCl_3$, and is roughly the same as the bond length in inorganic compounds of tetracoordinate aluminum (1.80 Å)[50]. The antimony-oxygen bond Sb—O, on the other hand, varies over a wide range according to the nature of the donor (Table 2). The Sb—O distance of 2.253 Å in the compound $SbCl_5 \cdot 4\text{-}CH_3—C_6H_4COCl$ underlines the weak donor character of *p*-toluoyl chloride in comparison with trimethylphosphane oxide in the adduct $SbCl_5 \cdot (CH_3)_3PO$, in which the antimony-oxygen distance is only 1.94 Å[49]. In the compound $2SbCl_5 \cdot ClOCCH_2CH_2—COCl$, the extremely weak Sb—O bond with a length of 2.428 Å is due to the proximity of the two functional groups of the succinyl dichloride[45].

It must be emphasized that the M—O—C bond angle in all molecular addition compounds is much greater than the 120° that one would expect for sp^2 hybridization of the oxygen atom (Table 2). However, no correlation has been found between the size of this angle and the length of the metal-oxygen bond. This deviation of the angle has been ascribed to intramolecular steric hindrance or to the packing in the crystal[42, 44–47].

Finally, it should be noted that the lengths of the carbon-oxygen bonds are the same in all these addition compounds, as are the lengths of the carbon-chlorine bonds (Table 3).

Table 3. Lengths of the carbon-oxygen and carbon-chlorine bonds in the coordination polyhedra of the donor-acceptor complexes.

$AlCl_3 \cdot 2\text{-}CH_3—C_6H_4COCl$	1.235(6)	1.721(4)	[44]
$AlCl_3 \cdot 3\text{-}CH_3—C_6H_4COCl$	1.232(5)	1.710(5)	[44]
$AlCl_3 \cdot 4\text{-}CH_3—C_6H_4COCl$	1.235(3)	1.712(1)	[44]
$2SbCl_5 \cdot ClOCCH_2CH_2COCl$	1.211(12)	1.713(11)	[45]
$SbCl_5 \cdot C_6H_5COCl$	1.236(7)	1.712(5)	[46]
$SbCl_5 \cdot 3\text{-}CH_3—C_6H_4COCl$	1.211(6)	1.710(4)	[46]
$SbCl_5 \cdot 4\text{-}CH_3—C_6H_4COCl$	1.220(11)	1.726(9)	[47]

To a first approximation, therefore, these bonds seem to be independent of the nature of the donor (the acyl chloride) and of the nature of the acceptor (the Lewis acid). In other words, the donor-acceptor interaction is evident only in the metal-oxygen bond, and this interaction is very weak.

3.2. Oxocarbenium Salts (Ionic Form)

In this type of addition compound, the ion X^- formed on ionization of the acyl chloride R—COX provides the electron pair to complete the electron complement in the metal of the acceptor.

These compounds are salts, in which the ions $[MX_{n+1}]^-$ and $[R—CO]^+$ can be detected. The cations $[R—CO]^+$ were originally named oxocarbonium ions, but since true carbonium ions containing pentacoordinate carbon have been found[50a], they should be referred to as oxocarbenium ions. As was shown by NMR studies, the positive charge of the ion $[CH_3CO]^+$ is essentially localized on the carbon atom of the carbonyl group. According to *Olah*[41], the most appropriate name is acylium ion, since this covers all three resonance forms of the cation $[R—CO]^+$:

$$R—C\equiv\overset{\oplus}{O} \leftrightarrow R—\overset{\oplus}{C}=O \leftrightarrow \overset{\oplus}{R}=C=O$$

The geometry of the following alkyloxocarbenium and aryloxocarbenium ions has been established by X-ray structural investigations: the methyloxocarbenium ion in the compounds $[CH_3CO]^+[SbF_6]^-$[51], $[CH_3CO]^+[SbCl_6]^-$[52], and $[CH_3CO]^+[AlCl_4]^-$[52], the ethyloxocarbenium ion in $[C_2H_5CO]^+[GaCl_4]^-$[53], the isopropyloxocarbenium ion in $[(CH_3)_2CHCO]^+[SbCl_6]^-$[53], the 2-tolyloxocarbenium ion in $[2\text{-}CH_3—C_6H_4CO]^+[SbCl_6]^-$[54], and the 4-tolyloxocarbenium ion in $[4\text{-}CH_3—C_6H_4CO]^+[SbCl_6]^-$[47].

It was shown by an X-ray crystallographic study that the complexes of antimony pentachloride and 2,6-dimethylbenzoyl

Table 4. Geometry of the oxocarbenium ions.

Cation	Anion	C(1)—O [Å]	C(1)—C(2) [Å]	∢O—C(1)—C(2) [°]	Ref.
$[CH_3CO]^+$	$[SbF_6]^-$	1.108(15)	1.385(16)	177.20(1.60)	[51]
	$[SbCl_6]^-$	1.109(30)	1.452(24)	180.00	[52]
	$[AlCl_4]^-$	[a]	[a]	179.79(0.54)	[52]
$[(C_2H_5CO]^+$	$[GaCl_4]^-$	1.099(20)	1.435(24)	177.45(1.35)	[53]
$[(CH_3)_2CHCO]^+$	$[SbCl_6]^-$	1.116(10)	1.439(12)	175.72(0.48)	[53]
$[2\text{-}CH_3—C_6H_4CO]^+$	$[SbCl_6]^-$	1.111(13)	1.387(14)	178.69(0.77)	[54]
$[4\text{-}CH_3—C_6H_4CO]^+$	$[SbCl_6]^-$	1.097(9)	1.396(10)	179.39(0.55)	[47]

[a] Owing to the random distribution of the $[CH_3CO]^+$ cations in the unit cell the individual C(1)—O and C(1)—C(2) distances cannot be determined from the X-ray data. However, the distance between the atoms O and C(2) (2.56 Å) approaches that in the salt $[CH_3CO]^+[SbCl_6]^-$: 1.109 + 1.452 = 2.561 Å.

chloride or mesitoyl chloride (2,4,6-trimethylbenzoyl chloride) in the solid state are oxocarbenium salts. However, it has not been possible to establish the precise geometry of the cations in these complexes, since the two ions are not oriented regularly in the unit cell[55].

The principal data on the structure of these oxocarbenium ions are shown in Table 4. We have used the following designations: C(1) for the carbon atom of the carbonyl group and C(2) for the carbon atom α to this group. Figure 2 shows the structure of the ionic compounds $[CH_3CO]^+[SbCl_6]^-$ and $[(CH_3)_2CHCO]^+[SbCl_6]^-$.

The average C(1)—C(2) bond length in the alkyloxocarbenium ion is 1.43 Å. One would expect a much greater distance between two carbon atoms where one is sp^3 hybridized and the other sp hybridized; for example, the CN bond in acetonitrile CH_3CN[57], which is isoelectronic with the acetylium ion $[CH_3CO]^+$, has a length of 1.458 Å. Comparable results have also been obtained for the C(1)—C(2) bond lengths in aryloxocarbenium ions. The bonds in the 2-tolyloxocarbenium and 4-tolyloxocarbenium ions [1.387(14) and 1.396(10) Å] are only slightly shorter than the distance between an sp^2 hybridized and an sp hybridized carbon atom in benzonitrile

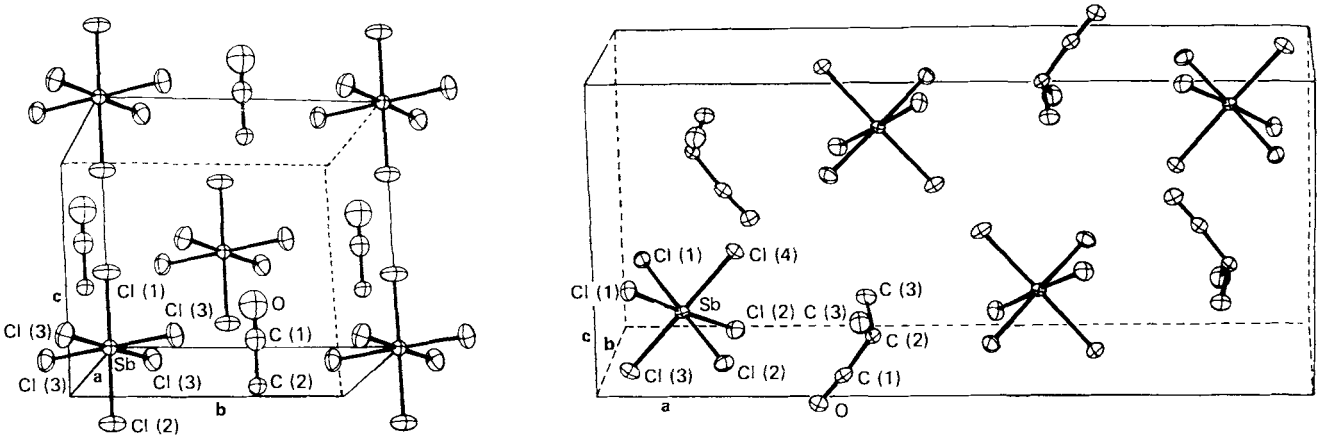

Fig. 2. Crystal structure of the ionic compounds $[CH_3CO]^+[SbCl_6]^-$ (left) and $[(CH_3)_2CHCO]^+[SbCl_6]^-$ (right).

The arrangement of the oxygen atom and the carbon atoms C(1) and C(2) is linear in all oxocarbenium ions. A slight deviation is found only in the isopropyloxocarbenium ion, where the angle O—C(1)—C(2) is 175.72(0.48)°; this is probably due to crystal lattice forces[53]. The packing in the crystal should also be such that the aryloxocarbenium ions are not strictly planar. It is in fact found that the oxygen atom and the carbon atom C(1) lie appreciably outside the central plane in the 2-tolyloxocarbenium and 4-tolyloxocarbenium ions[47,54].

An important point is the length of the carbon-oxygen bond, which is the same in all these oxocarbenium ions (Table 4). This bond thus appears to be independent of the residue R. The average bond length of 1.11 ± 0.01 Å is smaller than in most aldehydes or ketones, but similar to the bond length in carbon monoxide (1.128 Å). This points to a partial triple-bond character[56].

The structural analyses do not indicate any weakening of the C(1)—C(2) bond, which one should expect if the polarity of this bond was increased by the inductive effect of methyl groups on the carbon atom C(2). The C—C bond lengths, which were measured by *le Carpentier* and *Weiss*[52,53] in the methyl-, ethyl-, and isopropyloxocarbenium ions, do indeed agree within the limits of error. However, chemical findings point to weakening of this bond with increasing substitution on the carbon atom α to the carbonyl group. Thus the ion $[(CH_3)_2CHCO]^+$ is reported to be partly dissociated at room temperature, and the ion $[(CH_3)_3CCO]^+$ to be almost completely dissociated[19]:

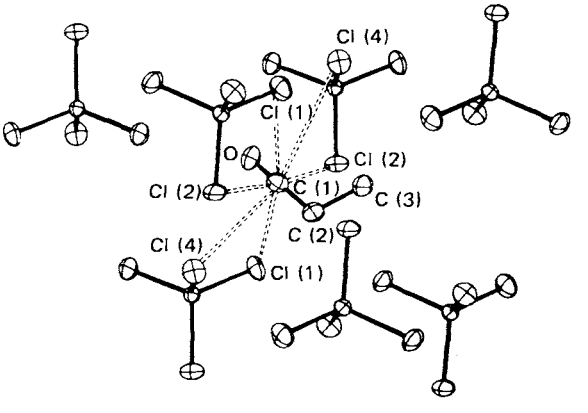
$$[R{-}CO]^{\oplus} = R^{\oplus} + CO$$

(1.419 Å)[58]. It can be concluded from these results as a whole that the value of 1.385(16) Å given by *Boer*[51] for the acetylium ion is too small.

The oxocarbenium ions can be described by the following series of resonance structures, which are given here for the methyloxocarbenium ion:

$$\underset{(a)}{CH_3{-}C{\equiv}\overset{\oplus}{O}} \leftrightarrow \underset{(b)}{CH_3{-}\overset{\oplus}{C}{=}O} \leftrightarrow \underset{(c)}{\overset{\oplus}{H}CH_2{=}C{=}O}$$

If one considers the environment of the oxocarbenium ions, one finds that the shortest distances to the anions $[MX_{n+1}]^-$ always occur between the carbon atom C(1) of the carbonyl group and the halogen atoms of the adjacent anions. As an example, Figure 3 shows the environment of the ethyloxo-



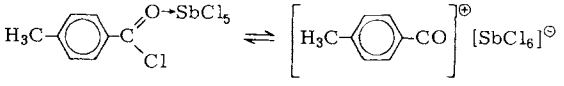


Fig. 3. Environment of the ethyloxocarbenium ion in the complex $[C_2H_5CO]^+[GaCl_4]^-$.

carbenium ion in the complex $[C_2H_5CO]^+[GaCl_4]^-$. The unusually short C(1)...Cl distances have been attributed to a decrease in the covalent radius of the C(1) atom as a result of its positive charge. Apart from this shorter distance, the arrangement of the ions in the lattice gives no evidence of any association of anions and oxocarbenium ions. Above all, the halogen atoms show no affinity for the oxygen atoms of the oxocarbenium ion, since the O...X distances in every case are greater than the sum of the van der Waals radii of these atoms. It therefore seems justifiable, in the description of the oxocarbenium ions, to place particular weight on the resonance structure *(b)* in which the positive charge is essentially localized on the carbon atom of the carbonyl group. It should be remembered in this connection that a positive partial charge was found on this carbon atom by NMR studies[19].

3.3. Coexistence of the Ionic and Molecular Forms

The vibrational spectra and the NMR spectra have shown that the two possible structures, *i.e.* the ionic and the molecular form, can exist together in solution for the same addition compound. Which of the two forms predominates depends on the solvent. A polar solvent with a high dielectric constant (ε) increases the concentration of the ionic form at the expense of the molecular form[15].

The influence of the solvent on the structure of the complex formed is particularly clear in the case of the addition compound of antimony pentachloride and *p*-toluoyl chloride. Thus *Chevrier, le Carpentier,* and *Weiss*[47] isolated two crystalline modifications. Rhombic crystals of the modification A were obtained from carbon tetrachloride, an apolar solvent ($\varepsilon = 2.2$), while the monoclinic modification B crystallizes from chloroform, a polar solvent ($\varepsilon = 5.05$). The crystal structures show conclusively that the modification A corresponds to the complex in its molecular form $4\text{-}CH_3—C_6H_4CClO \rightarrow SbCl_5$ and the modification B to the oxocarbenium salt $[4\text{-}CH_3—C_6H_4CO]^+[SbCl_6]^-$. Figure 4 shows the two structures in which this addition compound can exist in the solid state. It must be emphasized that the salt B can be obtained from a solution of the molecular form A in $CHCl_3$, and that conversely, the molecular form A can be isolated from a solution of the ionic form B in CCl_4. This result confirms that the two structures exist in equilibrium with each other in solution.

This equilibrium in solution must be expected for all addition compounds $MX_n \cdot R—COX$; the results of spectroscopic measurements cannot therefore be compared directly with the information obtained from X-ray diffraction, since the equilibrium may be displaced by recrystallization, with the result that the compound that is more stable in the solid state is isolated. It can often be seen even from the IR spectra of the solids that the ionic form and the molecular form are present together. This may be due to interactions between the complex and the support material, or the equilibrium may be displaced when part of the complex temporarily changes its state of aggregation. Thus according to their crystal structure, the adducts $AlCl_3 \cdot C_2H_5COCl$ and $AlCl_3 \cdot 2\text{-}CH_3—C_6H_4COCl$ are exclusively donor-acceptor complexes[42,44]; on the other hand, a predominantly ionic structure can be deduced from their IR spectra[15,42].

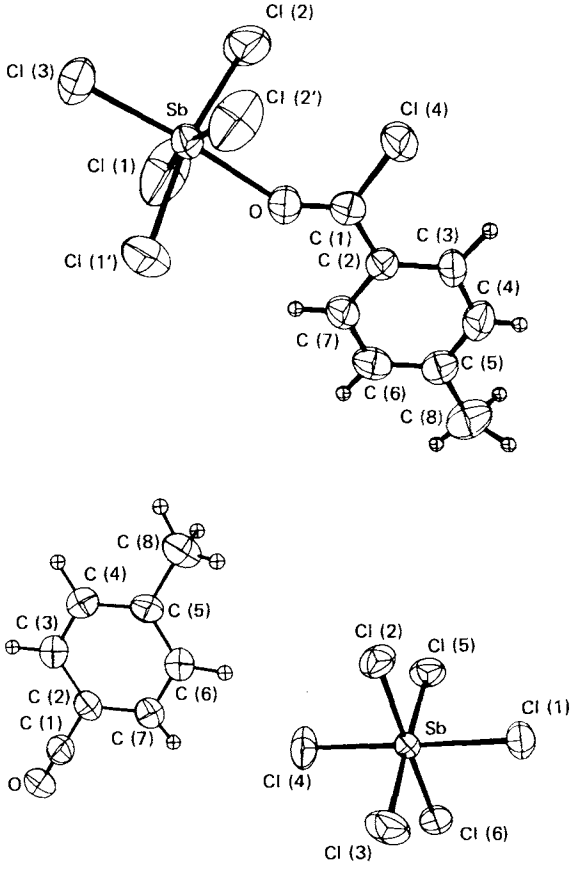

Fig. 4. The two isomeric structures of the complex $SbCl_5 \cdot 4\text{-}CH_3—C_6H_4COCl$: the molecular form (top) and the ionic form (bottom).

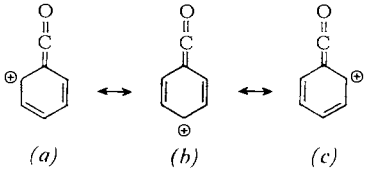

4. Electron Distribution in the Oxocarbenium Ions

Boer[51] has carried out an MO calculation of the electronic configuration of the $[CH_3CO]^+$ ion. He found a positive charge of +1.18e according to *Mulliken* for the carbon atom C(1) of the carbonyl group. The calculated charges for the other atoms are −0.35e for the oxygen atom, −0.11e for the carbon atom C(2) of the methyl group, and +0.07e for each of the hydrogen atoms. This last value in particular agrees well with that calculated for the hydrogen atoms in ethane, and leads to the assumption that the contribution of hyperconjugated forms in the methyloxocarbenium ion is probably negligible.

Rees, Veillard, and *Weiss*[59] recently compared the electron density distributions of the methyloxocarbenium ion $[CH_3CO]^+$ and of the isopropyloxocarbenium ion $[(CH_3)_2CHCO]^+$ with that of acetonitrile by a series of *ab-initio* calculations by the LCAO-MO-SCF method. Their results confirm that the positive charge in these oxocarbenium ions is essentially localized on the $p\pi$ orbitals of the carbon atom C(1) of the carbonyl group. Nevertheless, the total charge on the carbon C(1) (+0.60e) in the methyloxocarbenium ion is smaller than that calculated by *Boer* (+1.18e); however, it is offset in its immediate vicinity by a strong negative

charge of −0.58e on the carbon atom C(2). The ionic character of the bond C(1)—C(2) is even more pronounced in the isopropyloxocarbenium ion, in which the positive charge of the atom C(1) is higher (+0.73e); the charge on the atom C(2), on the other hand, is only slightly affected (−0.60e), though one would expect an inductive effect due to the methyl group. Optimization of the bond length C(1)—C(2) gave the value 1.45 Å, which is in excellent agreement with the value found experimentally for the ion $[CH_3CO]^+$ by *le Carpentier* and *Weiss*[52]. It should also be emphasized that the C(1)—C(2) bond in the methyloxocarbenium and isopropyloxocarbenium ions has no π-bond character, and that the optimization of the position of the hydrogen atoms in the $[CH_3CO]^+$ ion has led to the usual geometry of the methyl group. In other words, the contribution of the limiting resonance form *(c)* can be safely disregarded in the alkyloxocarbenium ions.

In aryloxocarbenium ions, on the contrary, the participation of resonance forms of this type is favored by the phenyl group, which allows much easier displacement of the positive charge than the methyl group.

(a) *(b)* *(c)*

Nucleophilic substituents in the *o* and *p* positions should help to stabilize this limiting form. This has in fact been observed for the 2-tolyloxocarbenium and 4-tolyloxocarbenium ions[47,54]. The C—C bonds lengths in these two ions, which are shown in Figure 5, support this assumption.

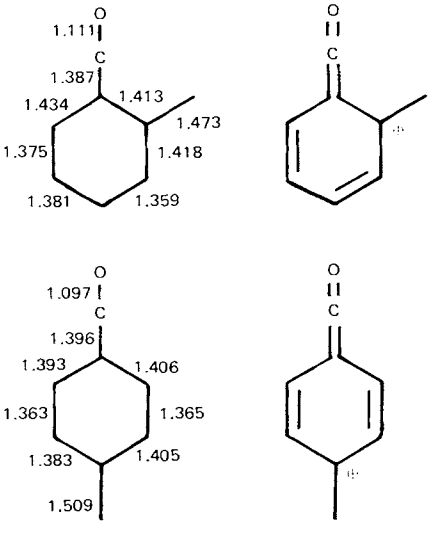

Fig. 5. Contribution of limiting resonance forms to the structure of aryloxocarbenium ions.

Recent investigations confirm the foregoing results. On the one hand the interpretation of the ^{13}C resonance in the phenyloxocarbenium ion and in some *o*-, *m*-, and *p*-substituted derivatives justifies the inclusion of the resonance structure *(c)*[41]. On the other hand, ESCA measurements have shown[60] that the difference between the energies of the 1s electrons of carbon atoms C(1) and C(2) is smaller in the aryloxocarbenium ions than in the alkyloxocarbenium ions. This can be attributed to the delocalization of the charge over the aromatic nucleus of the aryloxocarbenium ions.

Biochemistry of Natural Proteinase Inhibitors

By Harald Tschesche[*]

The natural inhibitors of proteolytic enzymes are proteins. These inhibitors associate reversibly with the enzymes to form stoichiometric protein-protein complexes, in which substrate-analogous association at the active center of the enzyme results in competitive inhibition of all catalytic functions. The very widespread occurrence of inhibitors in the animal and plant kingdoms underlines their biological importance in the intermediate metabolism, which can be understood as an extension of the possibilities for temporary and local limitations of enzyme activities. Existing knowledge includes a series of covalent structures, detailed kinetic data on the reversible protein-protein interaction, the processes involved in inactivation, and chemical methods for the modification of these proteins. Early X-ray structural data for an inhibitor and its enzyme complex provide an insight into the molecular structure of the latter and the interactions involved in the association to form the complex.

1. Introduction

As early as the turn of the century, the occurrence of "antienzymes" was held responsible for the anti-trypsin activity of serum[1, 2] and for the resistance of nematodes to the digestive enzymes of their host organisms[3]. During the 1930's and 1940's *Kunitz* pioneered the isolation of the natural tissue trypsin inhibitor from bovine pancreas[4] and the inhibitor from soybeans[5, 6]. He demonstrated their protein nature, crystallized the proteins and their trypsin complexes[4], and started investigations on the stoichiometry of the enzyme-inhibitor association[4, 7]. Since then, with the aid of modern ion-exchange methods and affinity chromatography, many proteinase inhibitors have been concentrated and/or isolated from a variety of animal and plant tissues and characterized.

General interest in this field was stimulated less by the improved methods of protein chemistry than by the increased knowledge of the physiological, pharmacological, and food-technological significance of proteinases and their functions in normal and pathological processes in human and animal organisms. The function of proteolytic enzymes is by no means confined to the utilization of food protein, but plays a decisive part in the mobilization of tissue proteins, the activation of proenzymes, and the liberation of pharmacologically very active polypeptides such as the kinins (bradykinin, angiotensin, *etc.*) and peptide hormones (insulin *etc.*). Proteolytic enzymes also play a part in the control of blood coagulation and fibrinolysis and in inflammatory processes, immunobiological processes, and the fertilization process.

The naturally occurring inhibitors (*i.e.* inhibitors having a protein nature as opposed to low molecular weight, synthetic inactivators), as natural antagonists of proteinases, can intervene selectively in the multifarious occurrences of specific proteolytic processes in the organism.

The recognized molecular and biological principles for natural inhibitors of the endopeptide serine proteases, *i.e.* peptidyl peptide hydrolases, will be discussed in the present article. For many details, the reader is referred to the literature (on pharmacological[8, 9], food-physiological[10–12], molecular[13–24], and kinetic aspects[18–24]).

The discussion will not include inhibitors formed by immunobiological reactions and based on antigen-antibody interactions; bacterial peptide inhibitors from Penicillium[25] and Streptomyces species[26], the inactivating pepsinogen fragment[27], and inhibitors that are not proteins, such as the acidic polysaccharide heparin[28] and amino acid polycondensates[29], will also be excluded.

2. Occurrence

Proteinase inhibitors are of widespread occurrence in the animal and plant kingdoms. They have been isolated from seeds of Leguminosae (soybeans[5, 6], lima beans[8, 30], and other

beans[8,12]) and grains (wheat[8,12,31] and rye[31]), as well as *e.g.* from potatoes[8,12,32], beets[8], nuts[8,12,33,74], corn[8,12,33], and peas[208]. However, their occurrence is not confined to the seeds[12,34]. They have recently also been isolated from bacteria (*Streptomyces albogriseolus*[224] and *Neurospora crassa*[225]).

A striking analogy with the plant seeds is the occurrence of proteinase inhibitors in the food protein (albumen) of many eggs in the animal kingdom. Thus proteinase inhibitors have been found as ovoinhibitors (with approx. 10% of carbohydrates) or as ovomucoids (with approx. 25% of carbohydrates) in the whites of the eggs of hens[8,17] and other birds[17,35] and in the secretion of the albumin glands of snails[36,37] and other molluscs[38].

The animal inhibitors, whose natural occurrence has been investigated in much greater detail, are found both in tissue and in secretions of organs. Thus the trypsin-kallikrein®[*] inhibitor from bovine organs (Kunitz inhibitor or kallikrein inactivator[39]) has been found exclusively as an intracellular component in the parotid gland, liver, lung[8,39], and pancreas[4]. The secretory trypsin inhibitor (Kazal inhibitor[40]), which, unlike the trypsin-kallikrein inhibitor, probably occurs in all mammals[8,41], is also formed in the pancreas, but is extruded with the proenzymes in the juice of the gland[41,42]. Many of the animal inhibitors are secretory proteins, such as the trypsin inhibitor of mammalian pancreas[41-45], of blood plasma[8,46] and seminal plasma[8,47,48,187], of milk and colostrum[13,15,16,50,77,179], of the submandibular glands[8,202], and of snails' slime[49].

Despite their different physiological functions, it is quite possible for tissue inhibitors and secretory inhibitors to be genetically related, as has been found for the trypsin-kallikrein inhibitor (Kunitz inhibitor) from bovine organs (58 amino acids, carbohydrate-free; cf. Figs. 5a, 6a, 11), the bovine colostrum inhibitor (67 amino acids with carbohydrate present; Fig. 5b)[50], and isoinhibitor K from snails (*Helix pomatia*, 58 amino acids, carbohydrate-free; Fig. 5c)[214,215], all of which have homologous structures.

The molecular weights of plant and animal inhibitors are mainly in the range from 5000 to 25000, but, as in the case of the inhibitors of human blood plasma, which belong to the group of α-globulins, they may also be of the order of 54000 (α_1-antitrypsin), 69000 (α_1-antichymotrypsin), and up to 160000 (inter-α-trypsin inhibitor), and in exceptional cases considerably higher (725000 for α_2-macroglobulin)[46,226].

3. General Properties

3.1. Assay of Inhibitors

Activities and concentrations of proteinase inhibitors are nowadays determined mainly by means of their complex formation with the enzymes, the decrease in the hydrolysis of natural or synthetic substrates being measured by enzyme-kinetic methods[51]. The methods are extremely sensitive, and allow the fast determination of microgram quantities of inhibitors. Sufficient preincubation of the enzyme and the inhibitor to enable the inhibition equilibrium to be reached is necessary for accurate determinations. When specific enzyme substrates are used, inhibitor concentrations can be determined even in crude tissue extracts, provided that the association constant of the enzyme and the inhibitor is high ($K_{ass} \approx 10^6$—10^7 l/mol) or the exact enzyme concentration is known. The difficulty that very pure enzymes are necessary for accurate determinations by kinetic methods can be overcome by the use of the "active site" titration reagents of *Chase* and *Shaw*[53] and *Kezdy* and *Kaiser*[52], since only active enzyme molecules are then determined. For reliable values of the specific inhibition activity, the measurements should be carried out at about 50% inhibition of the enzyme, provided that the inhibition proceeds stoichiometrically at least up to this range.

In addition to the enzymatic methods, methods based on the changes in physico-chemical parameters on complex formation have also been developed (for a survey see Ref.[19]).

3.2. Special Isolation Methods

Proteinase inhibitors, particularly the many low molecular weight proteins, are mostly extremely resistant to denaturation by acids and by heat. These remarkable properties were utilized by *Kunitz*[4] for the precipitation and separation of accompanying proteins during purification. In particular, they allow the dissociation of enzyme-inhibitor complexes with irreversible inactivation and precipitation of the proteinase. This also offers the possibility of separating inhibitors *via* their enzyme-inhibitor complexes, which are then decomposed. Both the free inhibitors and their complexes can be purified by molecular sieve filtration on gels, since the association constants are generally so high that the complexes migrate undissociated in neutral solution under the conditions of a gel exclusion chromatography, whereas at low pH values or in urea solutions they can be separated from the enzymes on the column.

The stability of the complex of the enzyme and the inhibitor makes affinity chromatography using resin-bound enzymes[54-59] an almost ideal purification method in the isolation of inhibitors[55]. With tissue and plant extracts that had undergone little preliminary purification, and even with organ fluids themselves as starting materials, *Fritz*, *Hochstrasser*, and *Werle* for the first time isolated a series of proteinase inhibitors from pancreas[43,55], corn and rye[56,60], seminal vesicles[55,57], and human sperm plasma[61]. Several inhibitors with different specificities can also be separated on suitable enzyme resin columns[57]. There is nothing to prevent the repeated use of the enzyme resins; in our laboratory, trypsin resins have been repeatedly used for isolation purposes over a period of a year. Subsequent purification of the preparations by ion-exchange chromatography is essential in most cases, since many extracts, particularly from plant materials, contain several inhibitors[8] or isoinhibitors[38,62,63]. Moreover, partial proteolysis of the "reactive site"[64] and (as in the case of the temporary inhibitors of the mammalian pancreas) modification by proteolytic cleavage of further peptide linkages[65,66] may be brought about by the active enzyme during the isolation process. The isolation of inhibitors by "classical" methods of protein chemistry in the presence of chemical enzyme inactivators such as diisopropyl fluorophosphate (DFP), benzamidine, or sulfonyl fluoride avoids these dangers and has been successfully used in particular in the isolation of pancreatic inhibitors directly from the pancreatic secretion by *Greene et al.*[42,44,45].

[*] Kallikrein is a registered trade mark of Bayer AG, Leverkusen. The name approved by the enzyme commission is kininogen (EC 3.4.21.8).

4. Inhibitory Behavior

4.1. Nature of the Inhibition

The inhibition of the esterolytic and proteolytic activities of the endopeptidases results from substrate-analogous attachment of the inhibitors to the active center of the enzyme. The competitive (or pseudocompetitive) character of the inhibition of enzymes by protein inhibitors, synthetic inhibitors, and specific substrates has been satisfactorily demonstrated[60-70].

Non-competitive inhibition has occasionally been deduced from Lineweaver-Burk diagrams. This type of inhibition occurs if $1/K_m$ for the substrate is very much smaller than K_{ass}[71] or if the dissociation of the enzyme-inhibitor complex (after the usual preincubation) is so slow that equilibrium is not reached within the period of the measurements[19].

4.2. Course of the Inhibition with Time

Whereas the majority of low molecular weight inhibitors, such as those from Ascaris[20, 21, 72], bovine organs[8, 13-21, 24], sea anemones[62], snails[63], leeches[73] or cuttle-fish or from plants such as soybeans[5, 6, 18-21] and lima beans[8, 30], nuts[33, 74], corn[33], potatoes[8, 12, 32] *etc.* cause permanent inhibition (Fig. 1a) of the proteolytic activity, the inhibition due to some inhibitors is effective only for a limited time. This phenomenon, which was first observed by *Gorini* and *Audrain*[75] for ovomucoid from hens' egg-white, was also found by *Laskowski Sr.* and *Wu*[76] for the secretory bovine inhibitor (Kazal inhibitor) and referred to as "temporary inhibition" (Fig. 1b). The reasons for this difference in behavior lie in the difference in the stabilities of the inhibitors (which are themselves proteins) toward proteolytic degradation by the proteinases initially inhibited by them[64, 65, 75-78]. In the case of the temporarily acting secretory pancreatic inhibitors of mammals, this special property could be of physiological significance (see Section 11).

In addition to permanent and temporary inhibition, a "progressive inhibition" has also been observed[46], particularly for the inhibitors of (human) blood plasma. Slow-acting and immediate-acting "antiplasmins" and "antithrombins" are found among the high molecular weight proteinase inhibitors of the α_1- and α_2-globulin fractions. Whereas the $C\bar{1}$ inactivator (MW 104000) and α_2-macroglobulin (MW 725000) inhibit plasmin immediately, the inactivation by α_1-antitrypsin is a slow, time-dependent reaction (Fig. 1c)[46]. However, α_1-antitrypsin and $C\bar{1}$ inactivator (and α_2-macroglobulin) also act as progressive inhibitors toward kallikrein[79, 80]. The inactivation rate increases with rising temperature, suggesting that this behavior could be due to a conformational change of the inhibitor molecule. Similar observations have been made for the inhibition of thrombin by α_2-macroglobulin and antithrombin III[46].

4.3. Association Constants K_{ass}

The constants for the association of the enzyme (E) and the inhibitor (I) to form the complex (C) in accordance with the simplified equation (see Section 6.1) $E + I \rightleftarrows C$ are relatively

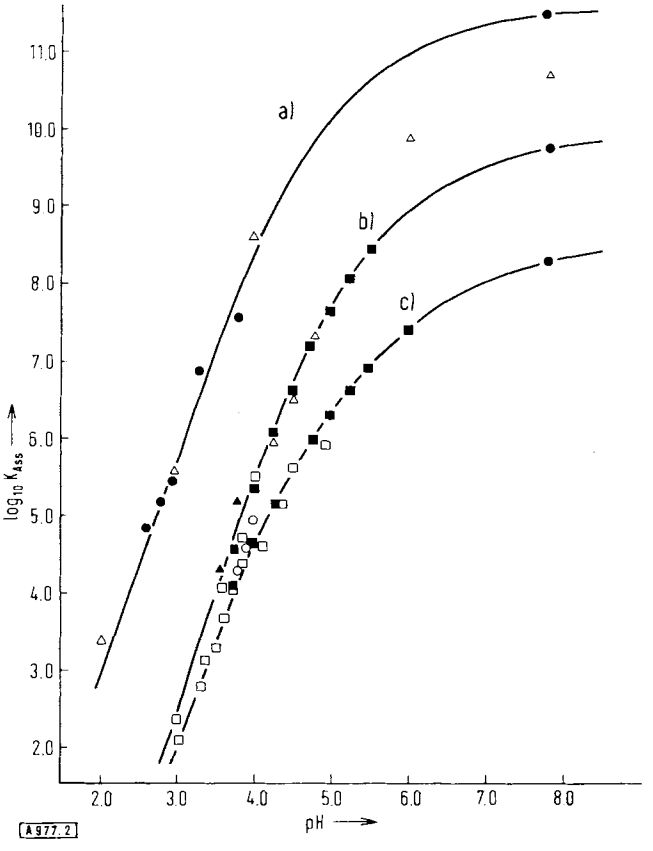

Fig. 2. pH dependence of the association constants K_{ass} for the association of bovine trypsin with a) the trypsin-kallikrein inhibitor (Kunitz inhibitor), b) the soybean inhibitor (Kunitz), c) hen ovomucoid, as found by the following measurement methods: ■ potentiometric, □ light scattering, △ gel chromatography, ▲ sedimentation, ● enzymatic residual activity, ○ fluorescence [19].

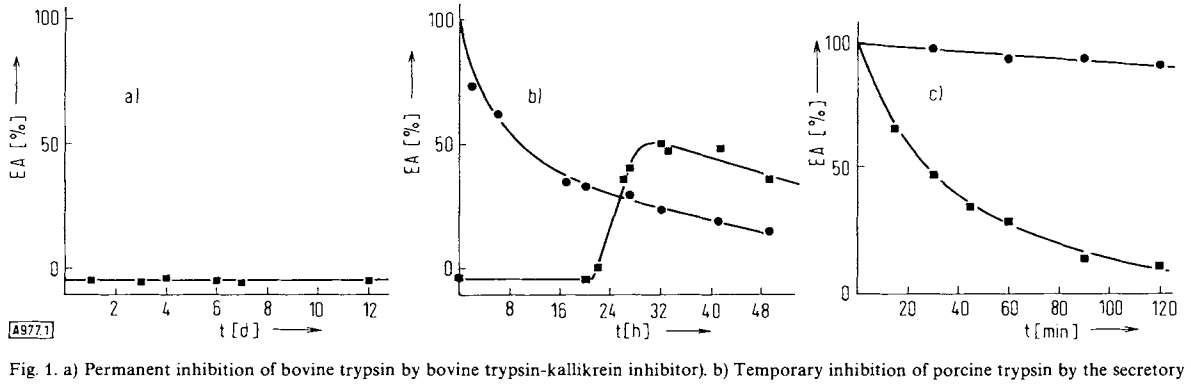

Fig. 1. a) Permanent inhibition of bovine trypsin by bovine trypsin-kallikrein inhibitor). b) Temporary inhibition of porcine trypsin by the secretory trypsin inhibitor I (Kazal type) from pig pancreas with an initial excess of inhibitor. c) Progressive inhibition of human plasmin by human α_1-antitrypsin [46]. (■ · · ■): enzyme activity of the enzyme-inhibitor solution, (● — ●): enzyme activity of the enzyme solution in the course of the autolysis. EA = enzyme activity, t = incubation time.

difficult to measure; they are much greater than those of the best substrates, and generally around 10^7 to 10^{14} l/mol, which corresponds to a free energy of association of 10 to 15 kcal/mol[67, 71]. For reliable values, the thermodynamic equilibrium of the complex formation must be reached[71], and the association constant must be greater than 10^8 l/mol, as is generally the case (for other methods for the determination of the association constants see Refs. [19, 81—85]).

The pH dependence of the association constants can be determined by the same methods. The association constant is found to change by 7 orders of magnitude (!) in the pH range from 2—6, whereas it only changes by a factor of 10 from pH 6 to pH 8 (Fig. 2). The enormously increased dissociation of the complexes at low pH values thus offers ideal conditions for the use of affinity chromatography in isolation processes.

5. Reactive Site

5.1. Reactive Site—Definition

The reactive site of the inhibitors is defined as the part of the molecule that enters into direct molecular contact with the active center of the enzyme on formation of the enzyme-inhibitor complex. The amino acid side chain responsible for the substrate-analogous accommodation in the specificity pocket of the enzyme is that of the "reactive amino acid residue" P_1; if the notation of *Schechter* and *Berger* is used here for the reactive site of proteinase inhibitors[86, 87].

$H_2N\text{-}P_x\text{----}P_4\text{-}P_3\text{-}P_2\text{-}P_1\text{-}P'_1\text{-}P'_2\text{-}P'_3\text{-}P'_4\text{----}P'_x\text{-}COOH$

The inhibitors of the enzyme trypsin and of the enzymes plasmin, kallikrein, acrosin, and silkworm cocoonase, which are similar to trypsin in their cleavage specificity, have arginine[17–19, 48, 62, 63, 89, 90] or lysine[17–19, 64, 88–90] as the "reactive amino acid residue" P_1, whereas alanine, leucine, isoleucine, and serine have been found as the amino acid residue P'_1. The activity and specificity of the inhibitors is retained on replacement of arginine by lysine (or *vice versa*), as is shown by the homology of the sequences in the reactive sites of the secretory pancreatic inhibitors of cattle[91], sheep[33, 92] (arginine inhibitors) and pigs[92] (lysine inhibitors) and by the results of the "enzymatic replacement reaction" on the soybean inhibitor[93] (see Section 6.3) and the occurrence both of arginine and of lysine in the isoinhibitors of snails[94], cuttlefish[38], and garden beans[210]. In all the trypsin inhibitors whose covalent structures have been established (see Section 8.2), the reactive site $P_1\text{-}P'_1$ is situated in a loop closed by a disulfide bridge, as had been postulated by *Ozawa* and *Laskowski, Jr.*[88]. The inhibitors thus become "cyclic substrates".

By analogy with the trypsin inhibitors, the amino acids tryptophan, tyrosine, phenylalanine, and leucine were to be expected as the residue P_1 in chymotrypsin inhibitors, according to the specificity of this enzyme. Leucine was found in the reactive sites of the chymotrypsin inhibitors from soybeans (*Bowman-Birk*)[74, 128, 228–230] and from lima beans[30]. A corresponding change in specificity as a result of a Lys↔Leu exchange was shown to be probable for both inhibitors, since corresponding homologous sequence regions have been found (see Section 8.1). This mutation appears to be a sufficient but by no means always necessary condition for the change in specificity, since association and inhibition of chymotrypsin has also been observed for "reactive sites" of the trypsin type[95, 96, 213].

In an enzymatic replacement reaction (see Section 6.3), *Leary* and *Laskowski, Jr.*[211, 212] replaced Arg^{63} by Trp^{63} in the reactive site of the soybean inhibitor (Kunitz) and hence brought about the conversion from trypsin to chymotrypsin specificity.

5.2. Partial Proteolysis

In a series of elegant experiments on the soybean inhibitor (Kunitz) *Laskowski, Jr. et al.*[18, 19] demonstrated that the peptide linkage $\text{-}P_1\text{-}P'_1\text{-}$ in the reactive site can be partially hydrolyzed in the course of the inhibition in the same way as hydrolysis takes place in a substrate. "Partial" means here that only some of the $\text{-}P_1\text{-}P'_1\text{-}$ linkages are hydrolyzed. Proteolysis at the reactive site of the native inhibitor with a single-stranded polypeptide chain ($I\text{-}P_1\text{-}P'_1$-intact) converts the protein into a modified inhibitor (I*, $\text{-P-COO}^{\ominus}$ $H_3\overset{\oplus}{N}\text{-P'}$-hydrolyzed). The native and the modified inhibitor have similar activities and specificities as inhibitors, and similar association constants[97]. The modifying partial proteolysis is based on the establishment of a stationary thermodynamic equilibrium, which can be brought about by catalytic quantities of enzyme (trypsin[97] or chymotrypsin[96]). The native inhibitor and the modified inhibitor react with the enzyme to form the same stable enzyme-inhibitor complex C[98, 99], which can dissociate again to give either the free enzyme and the native inhibitor or the free enzyme and the modified inhibitor. The reversibility of the equilibrium, *i.e.* the resynthesis of the peptide linkage $\text{-}P_1\text{-}P'_1\text{-}$ in the active site of the modified soybean inhibitor with formation of native inhibitor by catalytic quantities of enzyme (2 mole %), has been demonstrated by *Niekamp, Hixson, Jr.*, and *Laskowski, Jr.*[99] (see Section 6.3).

The equilibrium constant $K_{hyd}=[I^*]/[I]$ for the stationary equilibrium between the native and the modified inhibitor is strongly dependent on the pH (Fig. 3), with a minimum at pH = 6—7 and high values for the cleavage of the peptide

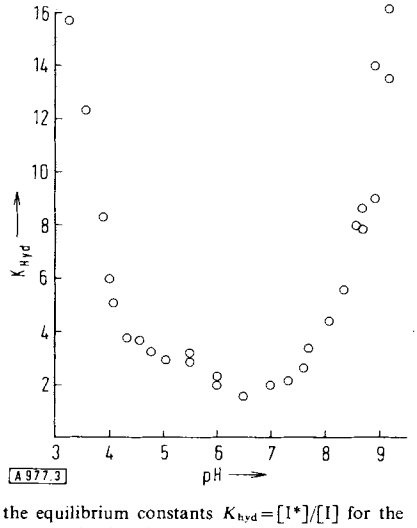

Fig. 3. pH dependence of the equilibrium constants $K_{hyd}=[I^*]/[I]$ for the equilibrium of the partial proteolysis of native (I) to modified (I*) soybean inhibitor (Kunitz) [19]. Somewhat improved data have recently been published from the same laboratory [227].

linkage -P_1-P'_1- in acidic solutions at pH = 3—4[118]. It thus proceeds as a special "substrate" hydrolysis at a very unphysiological pH value at which normal proteins are not hydrolyzed. The partial proteolysis has been demonstrated for a series of proteinase inhibitors[18,19,33,48,64,74,96,98,100,101,232–234] and used identification of the reactive sites. The degree of hydrolysis was estimated by analytical polyacrylamide gel electrophoresis[99] or by removal of the new C-terminal basic residue P_1 with carboxypeptidase B[88,100] or by Edman degradation and quantitative mass-spectral determination of the new N-terminal residue P'_1[101], though the reversibility of the proteolysis has been demonstrated in very few cases. The thermodynamic equilibrium may lie far over on the side of the broken peptide linkage as in the case of the soybean inhibitor (Kunitz), with 86% of modified inhibitor, or it may lie predominantly on the side of the native inhibitor, as in the case of the secretory pancreatic inhibitors, with approximately 25% modification.

The trypsin-kallikrein inhibitor (Kunitz) from bovine organs, in which no direct modification by trypsin has so far been observed, may be regarded as an extreme case. According to *Kress*, *Wilson*, and *Laskowski*, *Sr.*[102], however, this inhibitor is also hydrolyzed at the reactive site and at other peptide linkages after selective reduction of the disulfide bridge Cys^{14}-Cys^{38} (see Section 10). A trypsin-kallikrein inhibitor (Kunitz) modified only at the reactive site, which cannot be obtained directly by partial proteolysis with trypsin, has been synthesized indirectly *via* a series of chemical and enzymatic reactions by *Jering* and *Tschesche*[213]. This synthetic modified inhibitor is active toward trypsin, and is completely converted back into the native ("virgin") inhibitor by catalytic quantities of trypsin[213] and of chymotrypsin[231].

6. Mechanisms

6.1. Mechanism of Association

As a result of the partial proteolysis, a modified protein (I*) still possessing the full biological activity is formed from the native inhibitor (I). In the case of the system β-trypsin/soybean inhibitor (Kunitz), which has been studied in detail by *Luthy*, *Praissmen*, *Finkenstadt*, and *Laskowski*, *Jr.*[97], a very different reaction rate constant for the complex formation (L*→C) is found for the modified inhibitor (I*). The complex formation of I* must therefore also be taken into account for the thermodynamic equilibrium of the association of trypsin (T) and the inhibitor (I or I*) in the steady state. The complete system is therefore represented by eq. (1)[97]:

$$T + I \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} C \overset{k_3}{\underset{k_{-3}}{\rightleftharpoons}} L^* \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} T + I^* \qquad (1)$$

Eq. (1) represents the formal minimal mechanism, in which L and L* are loosely associated, non-"covalent" enzyme-inhibitor complexes (see Section 8.4). The existence of other intermediates is conceivable. The intermediates L and L* have been detected; it has been shown[97] that the equilibrium constants $K_L = k_{-1}/k_1$ and $K_{L^*} = k_4/k_{-4}$ are probably equal, whereas very different values with very similar pH dependence were found for the analogous rate constants k_2 and k_{-3}. Rapid establishment of the preliminary equilibrium with formation of the intermediate L was found, with $k_{-1} \gg k_2$[97]. Eq. (1) corresponds to the usual mechanism for the reversible substrate hydrolysis by serine hydrolases, the only formal difference being that no dissociation of the acylenzyme complex with liberation of the enzyme nucleophile occurs, since the inhibitors form only one reaction product, *i.e.* the complex C.

This two-step process for the complex formation is supported by the concentration-dependent transition from a second order to a first order reaction[97]. The initial loose association $T + I \xrightarrow{k_1} L$, which is probably a diffusion-controlled second order reaction, is followed by the non-diffusion-controlled complex formation $L \xrightarrow{k_2} C$ in a first order reaction. The fact that the second order rate constants for the association of trypsin and soybean inhibitor (Kunitz) are independent of the viscosity of the solvent had already led *Haynes* and *Feeney*[89] to the conclusion that the complex formation is not based on a diffusion-controlled process.

A series of findings indicate that the formal mechanism proposed for the β-trypsin/soybean inhibitor (Kunitz) system is generally valid. A comparative study with α-trypsin[97] gave the same first order rate constant k_2 for the reaction L→C as for β-trypsin. The association constant of the loose Michaelis complex L between α-trypsin and native inhibitor I, however, is an order of magnitude smaller than that of β-trypsin; $K_{L\alpha} = 10 K_{L\beta}$. This result corresponds to the lower stability of the complexes of α-trypsin with soybean inhibitor (Kunitz)[103,104], trypsin-kallikrein inhibitor (Kunitz) from bovine organs[104], and hen ovomucoid[105]. More kinetic data concerning the association of enzyme and inhibitors are given in Refs. [150, 244—248].

6.2. Kinetically Controlled Dissociation

If eq. (1) is generally valid, the same product, *i.e.* the stable enzyme-inhibitor complex C, is obtained regardless of whether it is prepared from the native or the modified inhibitor and the enzyme. Under conditions such that a sudden dissociation of the complex is forced (kinetically controlled dissociation), such as rapid adjustment of the pH to 2[98] or introduction of the complex into 6 M guanidinium chloride[93] in neutral solution, the products will be determined only by the relative values of the dissociation rate constants k_{-2} and k_3, and not by the position of the thermodynamic equilibrium between the native and the modified inhibitor. Since the rate constants for the conversion of the modified inhibitor (I*) into the native inhibitor (I) are generally much higher than for the reverse reaction, the kinetically controlled dissociation of the complex leads one to expect predominantly native inhibitor. Corresponding results were obtained for the kinetically controlled dissociation of the trypsin complexes from native and modified soybean inhibitor (Kunitz) by *Finkenstadt* and *Laskowski*, *Jr.*[98] and *Sealock* and *Laskowski*, *Jr.*[93], as well as for the dissociation of the trypsin complex from trypsin-modified Bowman-Birk soybean inhibitor and for the dissociation of the chymotrypsin complex from chymotrypsin-modified Bowman-Birk soybean inhibitor by *Frattali* and *Steiner*[106]. Predominantly native inhibitor was found in every case, though the equilibrium in both cases lies mainly on the side of the modified inhibitor.

The resynthesis of the broken peptide linkage -P_1-P'_1- in the modified inhibitor by complex formation with subsequent

kinetically controlled complex dissociation shows that the relation $k_{-2} \gg k_3$ is valid for these systems. It further follows that the dissociation rate constants $K_D = k_{-2} + k_3 \approx k_{-2}$ must roughly correspond to the complex dissociation constants k_{-2}.

It is interesting to note that the kinetically controlled resynthesis of the broken peptide linkage -P_1-P'_1- in the modified inhibitor is the best evidence at present for the reactive site of the inhibitor.

6.3. Enzymatic Replacement Reaction

By skillful combination and using the relationships given by the thermodynamic and kinetic constants, *Sealock* and *Laskowski, Jr.*[93] managed to replace the reactive amino acid residue arginine-63 in the soybean inhibitor (Kunitz) by lysine in a series of enzymatic reactions, and were thus able to demonstrate the fundamental equivalence of arginine and lysine as amino acid residues P_1 in the reactive sites of trypsin inhibitors, which had already been shown to be probable for homologous inhibitors.

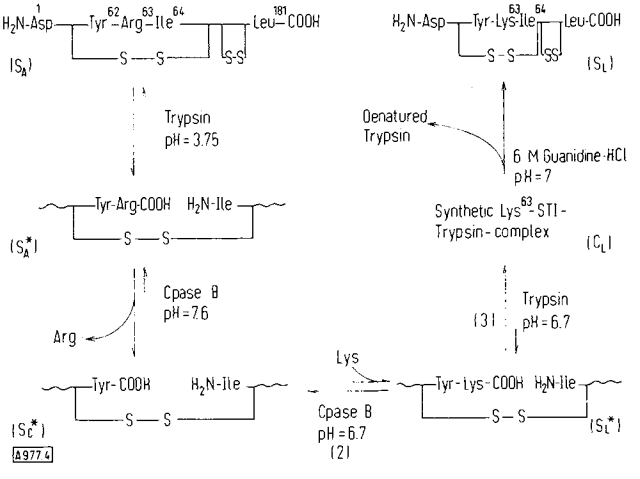

Fig. 4. Reaction steps in the course of the "enzymatic replacement reaction". The position of the equilibrium is qualitatively denoted by the relative size of the arrows [93]. Cpase = carboxypeptidase; STI = soybean trypsin inhibitor; S_A = native soybean inhibitor (Kunitz); S_A^* = modified inhibitor; S_C^* = de-Arg^{63} modified inhibitor; S_L^* = modified synthetic Lys^{63} inhibitor; C_L = trypsin complex with synthetic Lys^{63} inhibitor; S_L = intact synthetic Lys^{63} inhibitor.

Corresponding to the scheme in Figure 4, modified soybean inhibitor (peptide linkage Arg^{63}-Ile^{64} broken) (S_A^*) was converted into de-Arg^{63} modified inhibitor (S_C^*) with carboxypeptidase B, with loss of the inhibitory activity. On subsequent incubation with an excess of lysine and carboxypeptidase B [eq. (2)], the thermodynamically unfavorable enzymatic incorporation of lysine is coupled with the thermodynamically strongly favored complex formation of once again active Lys^{63} modified inhibitor (S_L^*) [eq. (3)]. Since the de-Arg^{63} modified inhibitor (S_C^*) does not form strong complexes with trypsin, the coupling of the two reactions and the displacement of the equilibrium can be forced [eq. (4)]. The synthetic Lys^{63} soybean inhibitor is isolated in the form of the trypsin complex (C_L) and subjected to kinetically controlled dissociation. "Native" Lys^{63} inhibitor (peptide linkage Lys^{63}-Ile^{64} intact) (S_L) is isolated as the reaction product[18,19,93].

Incubation of the synthetic Lys^{63} inhibitor with catalytic quantities of trypsin at pH = 3.75 led in a *slow* reaction to an

$$S_C^* + \text{Lys} \xrightleftharpoons{\text{Cpase B}} S^* \qquad K = 10^{-2}\ \text{l/mol} \qquad (2)$$

$$S^* + T \rightleftharpoons C_L \qquad K = 10^{9}\ \text{l/mol} \qquad (3)$$

$$S_C^* + \text{Lys} + T \rightleftharpoons C \qquad K = 10^{7}\ \text{l/mol} \qquad (4)$$

inhibitor that was electrophoretically indistinguishable from modified authentic Arg^{63} inhibitor[19]. The values of K_{hyd} for the hydrolysis of the peptide linkage -P_1-P'_1- in the reactive site of the Lys^{63} and Arg^{63} inhibitors thus appear to be equal; this demonstrates the thermodynamic equivalence of arginine and lysine. According to observations by *Sealock* and *Laskowski, Jr.*[19,93] on Arg^{63} and Lys^{63} soybean inhibitors and by *Tschesche* and *Obermeier*[101] on homologous lysine and arginine inhibitors of the pancreas (Kazal type), however, the rates of the reactions with trypsin are lower by a factor of about 10 for lysine inhibitors.

The enzymatic arginine↔lysine exchange leads to homologous proteins such as would correspond to the gene products after a mutation of the Arg^{63} DNA codon to the Lys^{63} DNA codon. The biological realization of such arginine↔lysine or lysine↔arginine mutations in reactive sites of the inhibitors has been found in the sequencing of the secretory pancreatic inhibitors (see Section 8.1), and also appears from initial observations to occur within the same species in the secretory isoinhibitors of snails[94] and of garden beans[210]. To emphasize this analogy between biological mutation and enzymatic replacement reactions, *Laskowski, Jr.* (with every reservation) coined the term "enzymatic mutation"[19].

The same reaction scheme was used by *Leary* and *Laskowski, Jr.*[211,212] for the enzymatic replacement of Arg^{63} with Trp^{63} by incubation of the de-Arg^{63} modified inhibitor (S_C^*) with excess tryptophan and carboxypeptidase A in the presence of chymotrypsin. After kinetically controlled dissociation of the chymotrypsin complex, native Trp^{63} soybean inhibitor, which strongly inhibits chymotrypsin (see Section 5.1), was isolated as well as de-Arg^{63} modified inhibitor.

7. Chemical Modification

Chemical modifications at the reactive side chains of bifunctional amino acids of inhibitors have been used in large numbers to study the association and to characterize the reactive sites. The possibilities offered by this method can be illustrated by a number of examples (see also Ref. [19]).

Contrary to previous observations[107], we have found that the removal of the positive charge from the side chain of the basic amino acid residue P_1 in the reactive site of lysine inhibitors by deamination does not inactivate the trypsin-kallikrein inhibitor from bovine organs[108]. Pure loss of the charge, with no additional steric effect, rules out the ionic interaction of the side chain with the negative charge of Asp^{189}[*] in the specificity pocket of trypsin[109]. Steric effects such as the lengthening of the side chain of the basic residue P_1 (by approx. 1.5 Å) appear to reduce the activity even when the positive charge is retained, as seems to be shown, according to *Haynes* and *Feeney*, by the reduced activity of a series of guanidinated lysine inhibitors[89]. However, this is contradicted by the observations of *Kassell* and *Chow*[110] on the guanidination (and amidination) of the trypsin-kallikrein inhibitor (Kunitz) from bovine organs.

Elimination of the charge on the side chain with a simultaneous increase in size is brought about in lysine inhibitors by acylat-

ing reagents such as maleic anhydride or citraconic anhydride and in arginine inhibitors by dicarbonyl reagents such as butanedione, cyclohexanedione, and phenylglyoxal, and leads to inactivation of the inhibitors[89, 111]. This method has been used by *Fritz et al.*[111] for the classification of a large number of inhibitors as lysine or arginine inhibitors, and has proved generally useful for rapid preliminary studies. *Kowalski* and *Laskowski, Jr.*[112] recently also used this method for the determination of the constants $K_{hyd}=[I^*]/[I]$ (see Section 5.2) for modified inhibitors, since the acylation of the newly formed α-amino group on the residue P'_1 generally inactivates the modified soybean inhibitor, and probably modified proteinase inhibitors in general. However, this method can be applied to lysine inhibitors only after their guanidination.

As was first shown by *Chauvet* and *Acher*[90] in the identification of the reactive site (Lys^{15}-Ala^{16}) of the trypsin-kallikrein inhibitor (Kunitz) by polyalanylation with the *N*-carboxy anhydride of DL-alanine, at lysine residues 26, 41, and 46 in the trypsin-inhibitor complex can react with acylating agents without forcing the complex to dissociate, without simultaneous partial or complete acylation of the lysine residue 15 (P_1), and/or without deactivation of the recovered substituted inhibitor. Making use of this high stability of the complex, *Fritz, Schult, Meister*, and *Werle*[113] and *Tschesche, Jering*, and *Schorp*[114] were able to prepare acylated active or reactivable derivatives of the trypsin-kallikrein inhibitor (Kunitz), which have the same biological activity and specificity but completely different physiological behavior in the circulation (kidney function *etc.*) and other physico-chemical constants (isoelectric point *etc.*).

By nitration of tyrosine residues in the immediate neighborhood of the reactive site -P_1-P'_1- in the free inhibitor and in the inhibitor fixed in the complex, it is possible to determine their steric accessibility and hence their possible masking. The size of the contact site can thus be estimated, particularly if these results are supplemented by spectrophotometric titrations and p*K* determinations on the corresponding *o*-nitrotyrosines for the free inhibitor and for the inhibitor bound in the complex[92, 103].

Since the contact area generally involves only a few amino acid residues of the reactive site, it is understandable that the biological activity is not affected by removal of some residues from the amino terminal end, provided that this does not lead to a change in the residual structure and that the reactive site is not directly degraded. According to *Kassell* and *Chow*[110], guanidinated trypsin-kallikrein inhibitor (Kunitz) is fully active after Edman degradation of the N-terminal tripeptide. The same is true of the secretory pancreatic inhibitor I of pigs, which does not lose its activity on removal of the N-terminal tetrapeptide[44, 45, 115] or pentapeptide[66].

8. Structure of the Proteinase Inhibitors

8.1. Amino Acid Sequences and Homologies

The primary structure of the therapeutically interesting trypsin-kallikrein inhibitor (Kunitz) from bovine organs (Fig. 5a) has been established by *Kassell* and *Laskowski, Sr.*[116]; the structure was confirmed by *Chauvet* and *Acher*[117], by *Dlouhá, Pospíšilová, Meloun, and Šorm*[118], and by *Anderer* and *Hörnle*[119] (kallikrein inactivator[39] from bovine lung with Asn^{50} instead of Asp^{50}).

An interesting feature is the homology of more than 40% with bovine colostrum inhibitor, whose sequence was established by *Čechová, Jonáková*, and *Šorm*[50] (Fig. 5b); it contains an additional nine amino acids and a glycoprotein fraction.

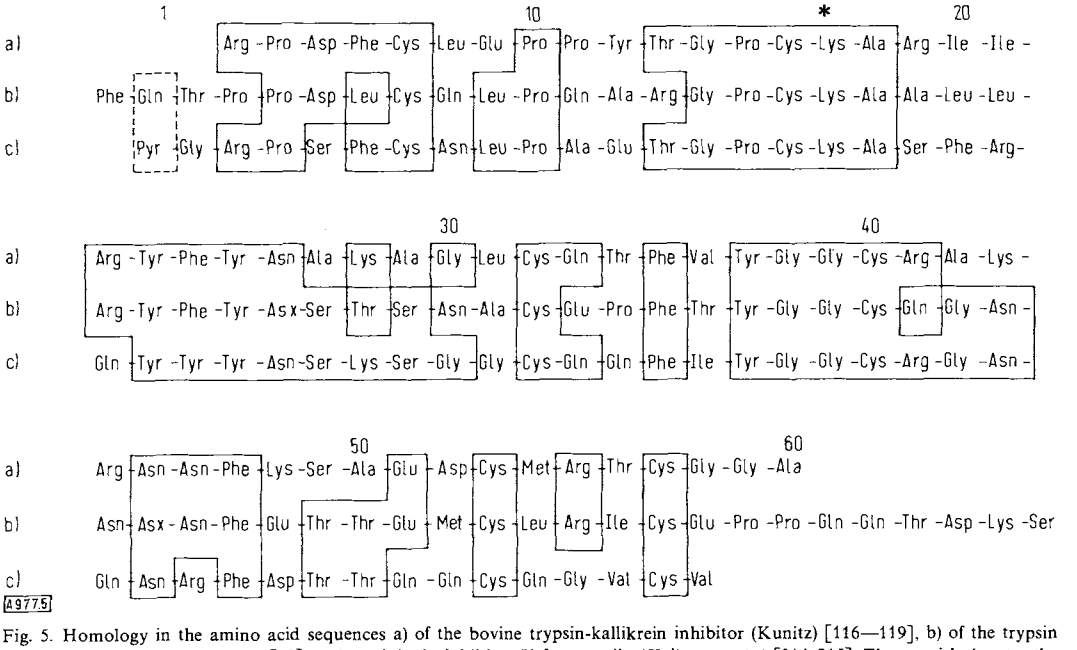

Fig. 5. Homology in the amino acid sequences a) of the bovine trypsin-kallikrein inhibitor (Kunitz) [116—119], b) of the trypsin inhibitor from bovine colostrum [50], and c) of the isoinhibitor K from snails *(Helix pomatia)* [214, 215]. The asterisk denotes the reactive site. Other proteins homologous to these inhibitors have recently been elucidated: d) Snake venom proteinase inhibitor II (from *Vipera russelli)* by *Takahashi, Iwanaga, Hokama, Suzuki*, and *Kitawaga* [236]. f) Proteinase inhibitor from turtle egg white by *Laskowski, Jr. et al.* [237] (partial sequence).

The genes of the two inhibitors evidently have a common phylogenetic origin, though the colostrum inhibitor must be regarded as a secretory protein, whereas the homologous trypsin-kallikrein inhibitor occurs only intracellularly in tissue

[*] The amino acids in trypsin were numbered as in chymotrypsinogen A; see *K. A. Walsh* and *H. Neurath*, Proc. Nat. Acad. Sci. USA *52*, 884 (1964); *O. Mikes, V. Tomašek, V. Holeysovsky*, and *F. Šorm*, Biochim. Biophys. Acta *117*, 281 (1966); *B. S. Hartley* and *D. M. Shotton* in *P. D. Boyer*: The Enzymes, Academic Press, New York 1971, vol. 3, 3rd ed., p. 323.

and has been found in many bovine organs. While colostrum inhibitors probably occur in many mammals and have so far been detected in cattle and pigs[77, 179], the trypsin-kallikrein inhibitor has been found only in a limited number of ruminants (cattle and sheep).

points to a common source gene for this inhibitor with a particularly broad specificity.

Another remarkable feature is that the bovine trypsin-kallikrein inhibitor (Fig. 6a) shows no homology with the secretory bovine pancreatic inhibitor (Kazal) (Fig. 6b), whose sequence

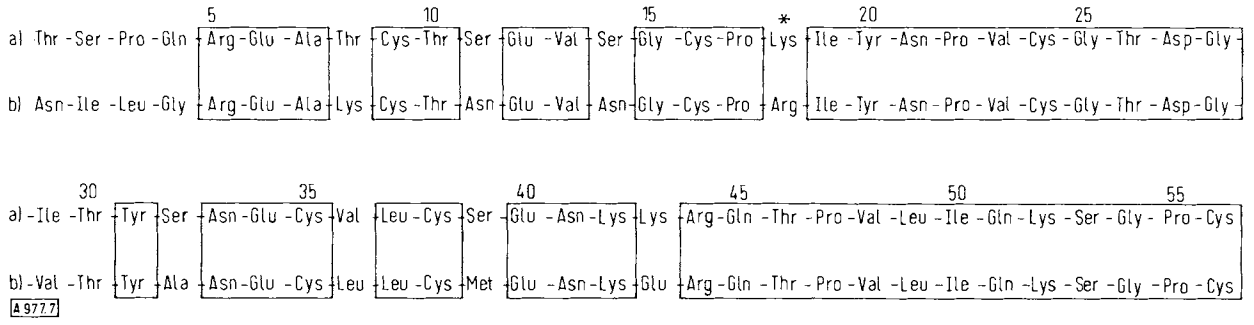

Fig. 7. Homology in the amino acid sequences of the secretory pancreatic inhibitors a) of pigs (inhibitor I) and b) of sheep [92]. The asterisk denotes the reactive site. The ovine inhibitor could be shown to be identical in amino acid sequence to the bovine inhibitor [91] (Fig. 6b) except for Ala^{32} which is Ser in the bovine species. Similar homologies have been found in the human inhibitor by *Greene* and *Bartelt* [238].

The amino acid sequence of the isoinhibitor K from the edible snail (*Helix pomatia*, Fig. 5c) was established by *Tschesche* and *Dietl*[214, 215]. This isoinhibitor surprisingly has the same degree of homology with the bovine trypsin-kallikrein inhibitor (Kunitz) as the bovine colostrum inhibitor. This agreement despite the great phylogenetic separation of cattle and snails

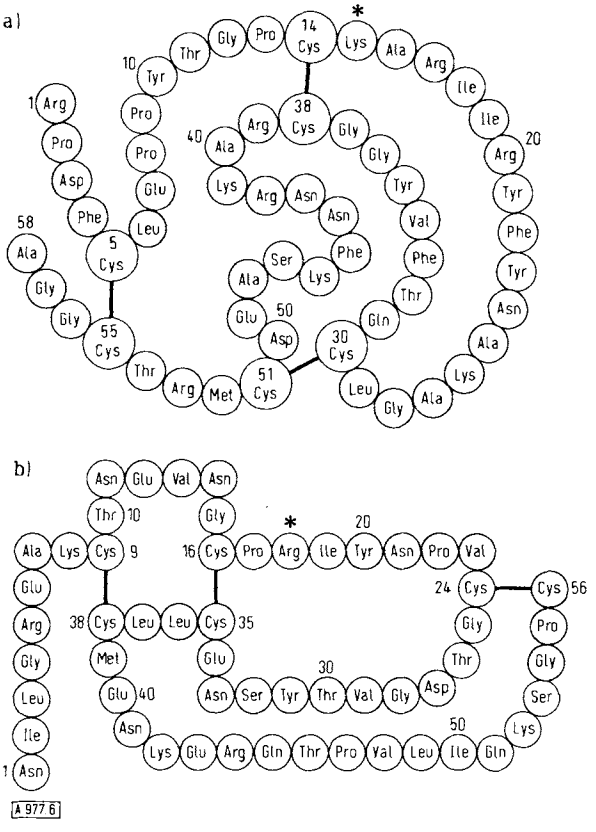

Fig. 6. Comparison of the complete covalent structures of a) the bovine trypsin-kallikrein inhibitor (Kunitz) [116—119] and b) the secretory trypsin inhibitor (Kazal) from bovine pancreas [91, 134, 135]. The asterisk denotes the reactive site. The disulfide bridges of the trypsin-kallikrein-inhibitor were determined by *Kassell* and *Laskowski, Sr.* [116] and confirmed by *Anderer* and *Hörnle* [119] on the inhibitor from bovine lung; those of the secretory trypsin inhibitor were determined by *Guy, Shapanaka*, and *Greene* [134, 135] and confirmed on the porcine inhibitor by *Tschesche* and *Schneider* [92, 136].

was established by *Greene, Giordano*, and *Bartelt*[91]. This is underlined by the general differences in the physiological functions of the two inhibitors, which are also reflected in different specificities, in the inhibitory behavior, and in the sites of their cellular biosynthesis.

The primary structures of the pig pancreatic inhibitors (I, Fig. 7a, and II) have been elucidated by *Tschesche* and *Wachter*[45, 115, 120] and confirmed by *Bartelt* and *Greene*[121]. *Hochstrasser* and *Werle et al.*[33, 122] and *Tschesche* and *Obermeier*[92] determined the sequence of the inhibitor from sheep (Fig. 7b). A comparison of all the structures that have been established so far provides a preliminary picture of the invariant sequences and of the sequences that can be varied by exchange of individual amino acids. The high variability at the amino end agrees with the unimportance of this part of the sequence to the biological activity[44, 45, 66, 92, 123] and to the correct folding and renaturing after reduction and reoxidation[125]. The remarkable $Arg^{18} \leftrightarrow Lys^{18}$ mutation for the residue P_1 at the reactive site has already been mentioned (see Section 5.1); apart from this, no amino acid exchange is observed in this region (residues 15—28) or in the C-terminal part (residues 44—56).

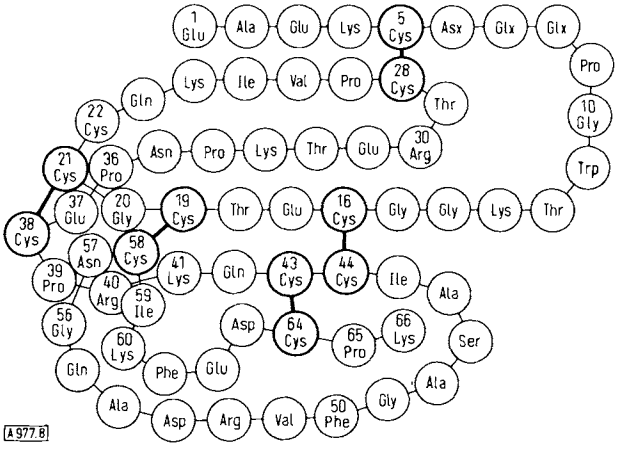

Fig. 8. Complete covalent structure of the inhibitor from *Ascaris lumbricoides* according to *Induni* [137].

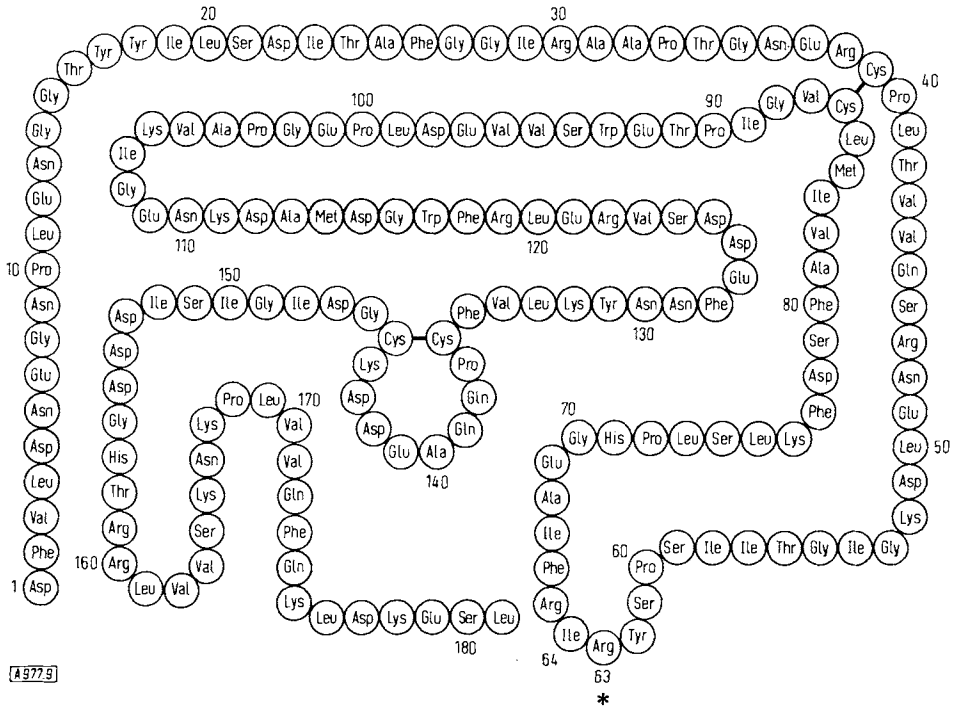

Fig. 9. Complete covalent structure of the trypsin chymotrypsin inhibitor from soybeans (Kunitz) according to *Koide, Tsunazawa*, and *Ihenaka* [126, 240, 241]. The asterisk denotes the reactive site.

The sequence of a trypsin-chymotrypsin inhibitor isolated by *Portmann* and *Fraefel*[124] (cf. [3]) from pig Ascarides has been elucidated by *Fraefel* and *Acher*[125] (Fig. 8). No pronounced homology with the animal inhibitors mentioned so far is found, except in the partial sequences Thr-Tyr-Gly-Gly-Cys-Glu (residues 37—42) in the bovine colostrum inhibitor and the similar sequence Thr-Lys-Gly-Gly-Cys-Glu (residues 12—17) in the Ascaris inhibitor.

A series of primary structures of plant inhibitors have recently also been determined. The complete sequence of the soybean inhibitor (Kunitz) (181 amino acids) was determined by *Koide, Tsunasawa*, and *Ikenaka*[126,240,241] (Fig. 9). It shows no homology with the second inhibitor from soybeans, *i.e.* the Bowman-Birk inhibitor[127] (71 amino acids), whose sequence was established by *Odani, Koide*, and *Ikenaka*[128] (Fig. 10a). On the other hand, extensive homology with this inhibitor

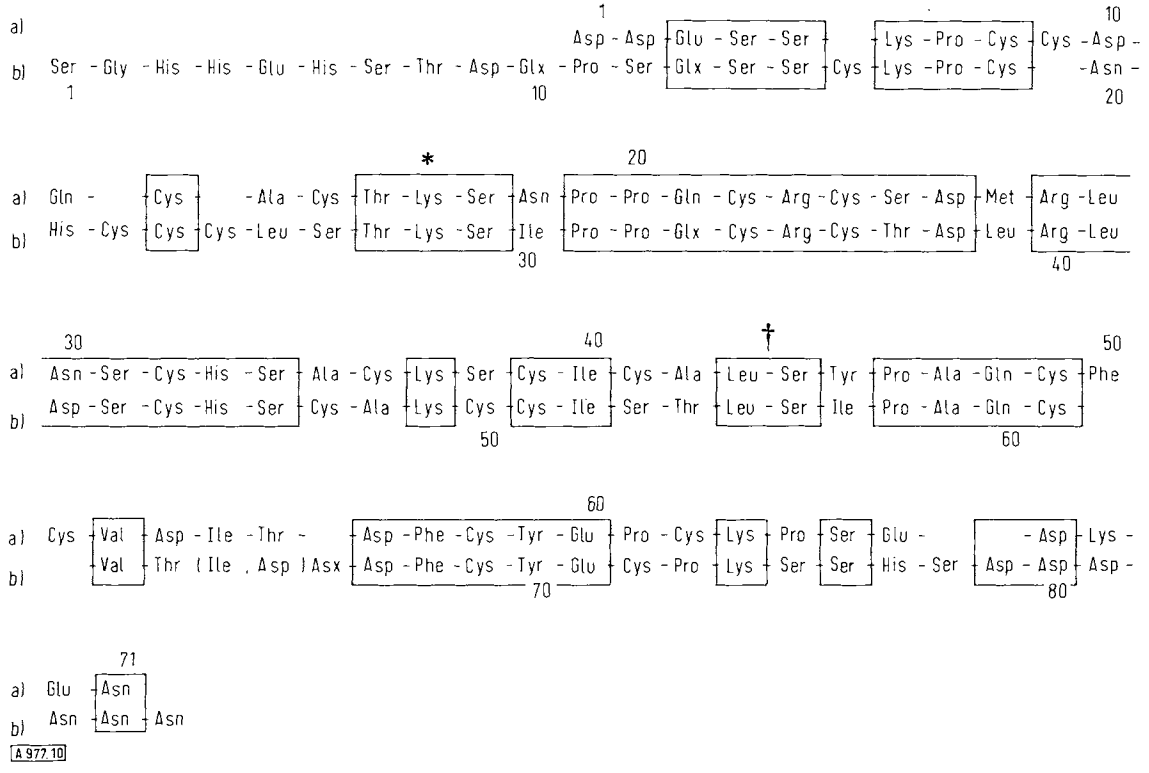

Fig. 10. Homology in the amino acid sequences of a) the soybean inhibitor (Bowman-Birk) [128] and b) the trypsin-chymotrypsin inhibitor IV from lima beans [130]. The asterisk (*) denotes the antitryptic and the cross (†) the antichymotryptic site. In the Bowman-Birk inhibitor the partial sequences Ala^{13} to Cys^{24} are homologous to Ile^{40} to Cys^{51}, in the limabean inhibitor IV the corresponding partial sequences Cys^{23} to Cys^{34} and Cys^{50} to Cys^{61}.

is found in the trypsin-chymotrypsin inhibitor from lima beans[129] (84 amino acids) (Fig. 10b). The sequence of the lima bean inhibitor was determined by *Tan* and *Stevens*[30, 130]; it has the peculiarity that it contains two homologous sequences within the single-stranded polypeptide chain, one of these sequences containing the antitryptic site and the other the antichymotryptic site[30]. On the basis of this observation, it was postulated that this "double-headed" inhibitor with two independent reactive sites sould have developed by gene duplication and divergent evolution. It is worth noting in this connection[128] that sequences similar to Lys-Ser-Asn-Pro-Pro-Gln-Cys-Arg (residues 16—23) in the Bowman-Birk soybean inhibitor (Fig. 10a) and Lys-Ser-Ile-Pro-Pro-Glx-Cys-Arg (residues 28—35) in the lima bean inhibitor (Fig. 10b) also occur in the sequence of the groundnut inhibitor (Arg-Ser-Asx-Pro-Pro-Glx-Cys-Arg) (*Hochstrasser*, *Illchmann*, and *Werle*[33, 131]), though the total sequence is otherwise quite different from that of the other two inhibitors. The assumption that these regions are particularly important to the antitryptic activity has not yet been confirmed. Similar sequences with otherwise pronounced differences are also found in the groundnut inhibitor (Ala-Pro-Pro-Tyr-Phe-Glx-Cys, residues 23—29) and in the inhibitor from corn seeds (Leu-Pro-Pro-Leu-Glx-Lys-Thr-Cys, residues 26—33), which were also investigated by *Hochstrasser*, *Illchmann*, and *Werle*[33, 132].

Due to their very different primary structures, all the trypsin inhibitors mentioned here are excellent examples of convergent protein evolution in nature.

8.2. Covalent Structures

The complete covalent structure is determined by the crosslinking of the polypeptide main chain by disulfide bridges. The three cystine residues in the trypsin-kallikrein inhibitor (Kunitz) connect postions 5 and 55, 14 and 38, and 30 and 51[116, 119] (Fig. 6a); the three cystine residues of the secretory pancreatic inhibitors (Kazal type) connect residues 9 and 38, 16 and 35, and 24 and 56[92, 133–136] (Fig. 6b), whereas the five bridges in the Ascaris inhibitor connect positions 5 and 28, 16 and 44, 19 and 58, 21 and 38, and 43 and 64[137] (Fig. 8). In the soybean inhibitor (Kunitz), residues 39 and 86 and residues 136 and 145[138] are joined by two disulfide bridges (Fig. 9). The recently determined structure of the trypsin-chymotrypsin-inhibitor (Bowman-Birk) from soybeans (double headed inhibitor, see Section 9) is held by 7 disulfide bridges, which connect the half-cystine residues 8 and 62, 9 and 24, 12 and 58, 14 and 22, 32 and 39, 36 and 51, and 41 and 49[230][*].

The biological activity of the proteinase inhibitors is destroyed on complete reduction of the disulfide bridges, but is generally recovered on mild reoxidation[19, 92, 123].

Only provisional conclusions can be drawn from the few available data on the complete covalent structures and on the position of the reactive sites. The hypothesis proposed by *Ozawa* and *Laskowski, Jr.*[88] that the reactive site peptide linkage -P_1-P'_1- is present as a "cyclic substrate" in a ring closed by a disulfide bridge ("disulfide loop") is supported by the structures of the trypsin-kallikrein inhibitor (Kunitz) (P_1-P'_1 = Lys^{15}-Ala^{16}[90]), the secretory pancreatic inhibitors (Kazal type) (P_1-P'_1 = Arg/Lys^{18}-Ile^{19}[18, 64, 92, 100]), and of the soybean inhibitor (Kunitz) (P_1-P'_1 = Arg^{63}-Ile^{64}[88]), and is probably also valid for the Ascaris inhibitor, whose reactive site has not yet been identified. The trypsin-chymotrypsin inhibitor (Bowman-Birk) contains the antitryptic and the antichymotryptic site in a disulfide loop. Both halves of the molecule could each be separated by peptic hydrolysis of the bond Asp^{56}-Phe^{57} and by cyanogen bromide cleavage of the bond Met^{27}-Arg^{28} into a (single headed, see Section 9) trypsin inhibitor and a chymotrypsin inhibitor (*Odani* and *Ikenaka*[239]). The serum inhibitors α_1-antitrypsin and α_1-antichymotrypsin[46], in which at first no cystine was detected at all, and which were regarded as exceptions, have also been shown to contain a disulfide bridge[204].

The antitryptic site in all the trypsin inhibitors whose sequences have been established is situated in the N-terminal part of the polypeptide chain, which is then closed by a disulfide bridge to form a ring. There seems to be some reason to assume that the C-terminal part is arranged parallel or antiparallel to parts of this ring, and that the rigid conformation required for the reactive site, which is also manifested in the low values of the hydrolysis constant K_{hyd}, is fixed by hydrogen bonds as in the β-structure. This type of construction could also be deduced from the covalent structure of the secretory pancreatic inhibitors and both halves of the molecule of the soybean inhibitor (Bowman-Birk), and has been detected for the trypsin-kallikrein inhibitor by X-ray structural investigations[139, 140].

8.3. Three-Dimensional Structure of the Trypsin-Kallikrein Inhibitor (Kunitz)

The three-dimensional structure of the trypsin-kallikrein inhibitor (Kunitz) was elucidated in the first X-ray crystal structural analysis of an inhibitor with a resolution of 2.5 Å by *Huber*, *Kukla*, *Rühlmann*, *Epp*, and *Formanek*[139]. The molecule is pear-shaped, with a length of 29 Å and a maximum diameter of 19 Å (Fig. 11, cf. Figs. 5a and 6a). The shape is determined by a double-stranded, antiparallel pleated sheet structure formed by the residues Ala^{16} to Gly^{36} and twisted through almost 180°. The two antiparallel strands are held together at the tip of the molecule by the disulfide bridge Cys^{14}-Cys^{38}. The segment of the residues Cys^{38} to Ser^{47} crosses the pleated sheet structure at Phe^{45}, which is connected by hydrogen bonds *via* its carbonyl oxygen and its nitrogen atom to Tyr^{21}, so that a short section of a three-stranded β structure is formed. Another hydrogen bond from the carbonyl oxygen of Thr^{11} to the nitrogen of Gly^{36} fixes the N-terminal part of the main chain in the form of a parallel pleated sheet structure. Two segments of a polyproline-II helix are formed by the residues Arg^{39} to Lys^{41} and Glu^{7} to Tyr^{10}. These segments contain the sequence Pro^{8}-Pro^{9}, which evidently favors the formation of this structure[140]. The disulfide bridge Cys^{30}-Cys^{51} binds three turns of an α-helix of the carboxyl terminus to the pleated sheet structure, while the bridge Cys^{5}-Cys^{55} fixes a distorted helical segment of the residues Asp^{3} to Glu^{7}, which does not form hydrogen bonds, close to the amino end.

The interior of the molecule is filled with hydrophobic residues, mainly phenylalanine and cystine. Nearly all the hydrophilic residues are located on the surface and are directed into

[*] A figure of this interesting structure could, unfortunately, not be added in proof.

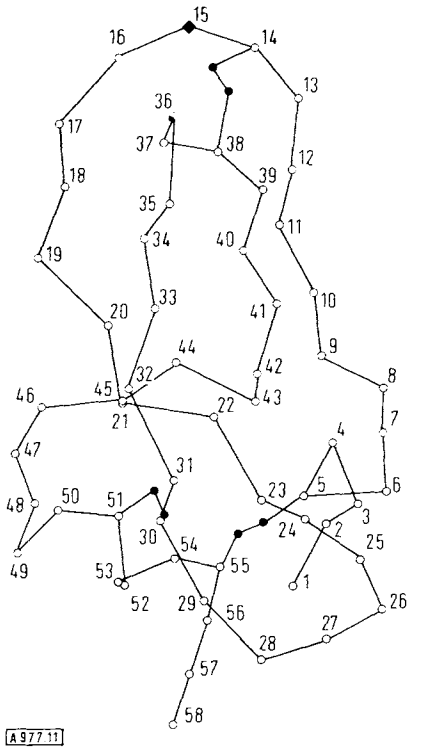

Fig. 11. Projection of the three-dimensional structural model of the trypsin-kallikrein inhibitor (Kunitz) [139]. The positions of the α-carbon atoms of the peptide chain are indicated. ● = sulfur atoms of the disulfide bridges, ● = Lys^{15}.

the surrounding solvent. All negative charges are situated at the base of the molecule, whereas the positive charges seem to be concentrated at the "tip" of the molecule, which contains the reactive site (Lys^{15}-Ala^{16}), *i.e.* the site of contact with the proteinases. The inhibitor thus has a large dipole moment, which possibly facilitates its correct orientation with respect to the proteinase[140, 141].

Very recent results obtained by *Deisenhofer* and *Steigemann*[159] at a resolution of 1.5 Å show that the peptide linkage Lys^{15}-Ala^{16} is strained. This linkage is already distorted in such a way that a tetrahedral arrangement is preformed; it is not planar anymore.

8.4. Structure of the Complex C

Initial model investigations on the three-dimensional structure of the complex C from trypsin-kallikrein inhibitor (Kunitz) and chymotrypsin have been carried out by *Blow*, *Wright*, *Kukla*, *Rühlmann*, *Steigemann*, and *Huber*[141, 142]. *Stroud*, *Kay*, and *Dickerson*[143] have considered the association of the inhibitor, with the model of the trypsin molecule.

The X-ray structure of the crystalline trypsin complex was established by *Rühlmann*, *Kukla*, *Schwager*, *Bartels*, and *Huber*[198] with a resolution of 2.8 Å. The structure found

Table 1. Hydrogen bonds between the trypsin-kallikrein inhibitor (Kunitz) and trypsin (the arrangement according to [142] based on model investigations on the inhibitor and α-chymotrypsin have been corrected according to the results of the X-ray structural analysis of the complex of the inhibitor and trypsin according to [198] and [242].

is extremely similar to that predicted from the structures of the components[141, 142].

The peptide linkage Lys^{15}-Ala^{16} of the inhibitor is situated at the calatytically active site of the enzyme in the complex, so that the inhibitor completely covers the surface of the enzyme and the side chain of Lys^{15} is inserted into the specificity pocket of the enzyme. Eleven[242] hydrogen bonds and more than 200 van der Waals contacts seem possible between trypsin (or chymotrypsin) and the inhibitor (Tables 1 and 2). These are all confined to the near neighborhood of the catalytically active residues Ser^{195}, His^{57}, and Asp^{102} of the enzyme[*]. Water is completely excluded from this contact region. Most of the contacts are made by the flexible side chains of the residues Lys^{15}, Ala^{16}, Arg^{17}, and Arg^{39} of the inhibitor with parts of the enzyme for which it is known that amino acid substitutions between trypsin and chymotrypsin are particularly conservative[**]. The insertion of the lysine side chain into the specificity pocket of the enzyme is favored by the possibility of ion-pair formation between the ε-amino group of Lys^{15} and the β-carboxylate group of Asp^{189}; however, chymotrypsin can also incorporate lysine, though it has Ser^{189} instead of Asp^{189}[142, 198]. It is assumed that the binding pocket of chymotrypsin also contains space for water molecules, which could help in the dispersion of the positive charge of Lys^{15}[142] (cf. Section 9).

After the formation of the loose Michaelis complex L or L* from the enzyme and the inhibitor, the formation of an acylenzyme intermediate with covalent linkage of the enzyme to the inhibitor as in normal substrate hydrolysis seems sterically possible, since the peptide linkage Lys^{15}-Ala^{16} (P_1-P'_1) is brought into contact with the catalytically active residues Ser^{195} and His^{57} in exactly the same way as that of a hydrolyzable substrate[142]. It is therefore likely that this peptide linkage P_1-P'_1 can be attacked. A reaction of this type in the inhibitor-enzyme interaction is supported by the partial proteolysis (see Section 5.2) of this peptide linkage in a series of proteinase inhibitors. The fundamental question of the molecular structure of the complex C has been provisionally answered through the X-ray structural analysis of the complex of trypsin with trypsin-kallikrein inhibitor (Kunitz)[198].

This complex is an adduct with a tetrahedral intermediate state, a situation approaching a covalent bond between the enzyme and the inhibitor and a geometry of the Lys-Ala peptide bond between tetrahedral coordination at the carbonyl carbon and planar configuration. Stabilization purely by secondary valence interactions or an acylenzyme complex structure had formerly been under discussion as alternatives. According to *Birktoft* and *Blow*[199] and *Henderson*[144], native chymotrypsin and acylated chymotrypsin differ in the position of the β-oxygen of Ser^{195}, which is turned through 120° about the C_α—C_β axis into a "bonded" position in the acyl derivative. A "bonded" position of this atom, corresponding to a situation of covalent bond between it and the carbonyl carbon of Lys^{15} (P_1) of the inhibitor, is clearly shown by the X-ray structural analysis of the complex. The covalent peptide linkage between residues P_1-P'_1 (Lys^{15}-Ala^{16}) (I)[***] is still present in the complex[198]. The mean value of the distance between the β oxygen of Ser^{195} to the carbonyl carbon of Lys^{15} is about 2.3 Å and, therefore, is longer than that of a covalent bond. However, it favors a strong interaction of the serine nucleophile with the electrophilic center, the carbonyl carbon of Lys^{15}. The tetrahedral arrangement is stabilized by the hydrogen bond between $N^{\varepsilon 2}$ of His^{57} (E) and the hydroxyl group of Ser^{195}[198]. This structural characteristic is in agreement with the transfer of the hydroxyl proton of Ser^{195} to His^{57} on formation of the tetrahedral adduct[201]. The position of $N^{\varepsilon 2}$ of His^{57} in the complex allows the rotation of the β-oxygen of Ser^{195} from the "native position" into the "bonded acyl position" without a change of more than 0.3 Å in the O—N contact distance. The hydrogen bond is thus retained *via* the covalently bonded oxygen, as a strong proton acceptor, but the energy of the transition state of the reaction leading to the complex C is reduced (Fig. 12)[198].

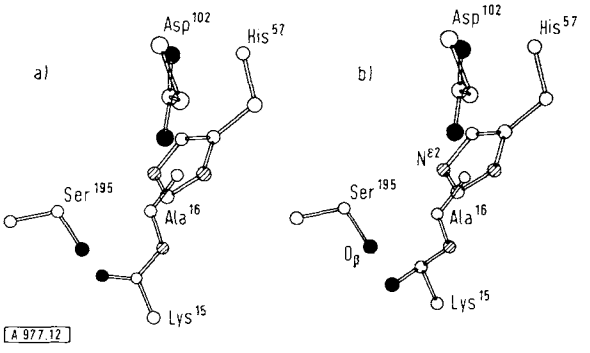

Fig. 12. Comparison of the atomic arrangements of the catalytically active residues Asp^{102}, His^{57}, and Ser^{195} of trypsin (for numbering, see footnote in Section 7) and of the residues of Lys^{15}-Ala^{16} (P_1-P'_1) of the reactive site of the trypsin-kallikrein inhibitor (Kunitz) in the complex. a) Hypothetical arrangement in the model of a complex of trypsin and native, unmodified inhibitor, b) arrangement found from the X-ray crystal structural analysis [198] with tetrahedrally coordinated carbonyl carbon of Lys^{15} in the inhibitor. ○ = C, ● = O, ⊘ = N.

The distance of 4.1 Å between the amide nitrogen of the "substrate leaving group" of Ala^{16} (I) and $N^{\varepsilon 2}$ of His^{57} (E), as well as the unsuitable orientation of the imidazole ring, prevents the direct proton transfer[145] and hence the formation of the acylenzyme intermediate[198, 242]. A structural reorientation of the imidazole ring with rotation about the C_α—C_β and C_β—C_γ axes would be necessary in order to bring the ε2-nitrogen closer to the amide nitrogen of Ala^{16} (I). This necessitates weakening of the hydrogen bonds between the β-oxygen of Ser^{195} (E) and $N^{\varepsilon 2}$ of His^{57} and between $N^{\delta 1}$ of His^{57} and the β-carbonyl oxygen of Asp^{102} (E)[198].

The tetrahedral structure of the complex is stabilized by two further hydrogen bonds between the enzyme and the inhibitor (see Table 1) and the hydrogen bond from the amide nitrogen of Ala^{16} (I) to the carbonyl oxygen of Gly^{36} (I). The latter hydrogen bond belongs to the twisted pleated sheet structure of the inhibitor[139] (see Section 8.3).

The inhibitor chain of Tyr^{35} to Cys^{38} and the space-filling disulfide bridge Cys^{14}-Cys^{38} completely exclude water from the contact site on the surface of the enzyme, and thus stabilize the hydrogen bonds. On formation of the acylenzyme intermediate with cleavage of the peptide linkage between Ala and Lys, the hydrogen bond from the amide nitrogen and a number of hydrophobic contacts of Ala^{16} (I) must obviously be weak-

[*] See footnote in Section 7.

[**] "Conservative" here means that the character of the amino acid (hydrophilic, hydrophobic) is unchanged or that no substitutions due to mutation occur.

[***] E = enzyme, I = inhibitor.

ened. Normal substrates of the enzyme, on the other hand, have a less rigid structure, and the flexibility of the polypeptide chain allows the access of water to the imidazole ring of His^{57}. The amide nitrogen of the leaving group is protonated, with formation of the acylenzyme intermediate.

The final fine-structure analysis of the inhibitor[159] will show the extent to which deformation of the reactive site peptide linkage P_1-P'_1 (Lys^{15}-Ala^{16}) toward the tetrahedral arrangement in the complex sterically favors the formation of the adduct[198].

The molecular structure of this tetrahedral complex already offers an explanation for the differences in the reaction rate constants $k_{-2} > k_3$ observed for the soybean inhibitor (Kunitz) (see Section 6.2). The protonation of the amide nitrogen of the leaving group (P'_1) calls for a change in the conformation of His^{57} of the enzyme before the proton transfer[159, 198].

Many objections have been raised against the general validity of the model with covalent linkage of the enzyme and the inhibitor in the stable complex C (tetrahedral complex or acylenzyme complex). *Feinstein* and *Feeney*[146, 147] have reported observations on the association of inhibitors with catalytically inactive enzymes. *Foster* and *Ryan*[148] observed complex formation between anhydrochymotrypsin and the chymotrypsin inhibitor from potatoes, and *Dlouha* and *Keil*[149] have observed complex formation between bovine trypsinogen and the trypsin-kallikrein inhibitor (Kunitz) (for a discussion see Ref. [19]).

The X-ray structural analysis recently carried out by *Sweet, Janin*, and *Blow*[200] on the crystalline complex of pig trypsin with soybean inhibitor (Kunitz) also showed tetrahedral coordination of the carbonyl carbon for the molecular structure of the complex C at the reactive site. Thus, the same intermediate state was found here as for the complex of trypsin with trypsin-kallikrein inhibitor (Kunitz).

The model discussed and verified by the X-ray structural analysis for the stable complex C, with an interatomic distance corresponding to a covalent linkage between the enzyme and the inhibitor, corresponds to the suggestion of *Finkenstadt* and *Laskowski, Jr.*[18, 150] for the "central" intermediate C. It is in agreement with the kinetic data and the symmetry of the observed enzymatic catalytic processes of the enzyme-inhibitor association of the soybean inhibitor (Kunitz), and explains the phenomenon of the partial proteolysis reaction. In view of the structural similarity of the serine proteinases, it is very probable that many other enzyme-inhibitor complexes are constructed according to the same principle. It still remains to be shown, however, whether a complex having the particular structure of a tetrahedral adduct has a more favorable association energy than a complex that is stabilized by pure secondary-valence interactions.

9. Specificity

The inhibition specificity of inhibitors for proteinases having different proteolytic specificities is important to their physiological function. It can vary considerably over a wide range. A large number of data have been assembled in the literature[12-24], but these data are not always reliable, owing to defective methods or impure materials. Moreover, the constants for the association of different enzymes with the same inhibitor can differ by several orders of magnitude, and consequently cannot always be determined under comparable experimental conditions.

The broad variation in inhibitory specificities is a consequence of the molecular protein interactions between enzyme and inhibitor, a detailed understanding of which is only now beginning through the combination of sequence data and X-ray structural data.

Two enzymes can be inhibited cooperatively, competitively, or independently by one inhibitor molecule[19]. No examples of cooperative inhibition are known as yet. Competitive inhibition can take place *via*: 1. the same reactive site (single-headed inhibitor), 2. several overlapping reactive sites (multi-headed inhibitor), and 3. several non-overlapping reactive sites ("multi-headed" inhibitor).

Only a few examples of the first type have been investigated in detail. The identity of the antitryptic site and of the antichymotryptic site of soybean inhibitor (Kunitz) has been conclusively demonstrated by *Bidlingmeyer, Leary*, and *Laskowski, Jr.*[96]. The same site is also responsible for the inhibition of cocoonase, the trypsin-like enzyme of the silkworm[19].

According to *Fritz, Schiessler, Brey, Tschesche*, and *Fink*[151], the secretory inhibitors of the mammalian pancreas, which have previously been regarded as very trypsin-specific, also inhibit the proteinase acrosin from boar sperm and from human sperm[152] and a pancreatic proteinase that converts proinsulin into insulin[153]. Initial findings point to the presence of the same reactive site in this and other "single-headed" inhibitors. Out of the series of structurally similar serine proteinases with comparable specificities, such as trypsin, plasmin, thrombin, urokinase, cocoonase, acrosin, and pancreatic kallikrein[154], "single-headed" inhibitors inhibit only certain enzymes, depending on their specificity, and the affinities also differ very considerably in some cases. We found that different isoinhibitors from the edible snail inhibit trypsin with the same association constant, but differ very considerably in the inhibition of pancreatic kallikrein[214]. A still more pronounced selectivity was found for the isoinhibitors of the cuttlefish, all of which inhibit trypsin, chymotrypsin, and pancreatic kallikrein, but not plasmin[38].

The selectivity can even become more pronounced within a class of homologous inhibitors, and can change into species specificity. Thus the secretory pancreatic inhibitors (Kazal type) of cattle and of pigs have the same sequence regions in the reactive site apart from the Arg↔Lys mutation of the residue P_1 (see Section 8.1); they both inhibit pig and bovine trypsins, but they do not measurably inhibit human trypsin[155]. On the other hand, the human trypsin inhibitor inhibits not only human trypsin I and II[156] but also bovine trypsin[157]. Despite this difference in species specificity, extensive homology of these pancreatic inhibitors must be expected on the basis of evolutionary relationship. Sequence comparisons within this class are therefore of special interest.

In the second case, where there are several overlapping reactive sites, extensive molecular studies are necessary, since no definite conclusion can be drawn from competitive inhibition experiments. Independent and overlapping reactive sites for trypsin and chymotrypsin have also been discussed on the basis of changed specificities of chemically modified trypsin-kallikrein inhibitor (Kunitz)[113, 158], as has a single site for

both enzymes (first case, see also Section 8.3). *Sevilla* and *Righi*[95, 160] found that the antitryptic activity of the trypsin-kallikrein inhibitor (Kunitz) disappears on acetylation, whereas the antichymotryptic activity is only reduced. The presence of two independent, but overlapping reactive sites (double-headed) is concluded from this evidence. Another possible example is the trypsin-chymotrypsin inhibitor from Japanese radish seeds[161]. The resynthesis of the peptide bond (between Lys^{15} and Ala^{16}) in the "synthetic" modified trypsin-kallikrein inhibitor (Kunitz) by trypsin[213] *and* chymotrypsin[231] (see Section 5.2) has, in our opinion, conclusively demonstrated the identity of both reactive sites (single headed). The third case, *i.e.* the presence of independent non-overlapping sites, has been found for the inhibition of trypsin and chymotrypsin by the inhibitors from soybeans (Bowman-Birk)[74, 162], lima beans[30, 163, 164], and other beans[19, 165, 166] and for the canine submandibular inhibitor[202] and the ovoinhibitor from hens' egg-white[167] and several bird ovomucoids[168].

The "double-headed" trypsin-chymotrypsin inhibitor (Bowman-Birk) has been converted into a "single-headed" chymotrypsin inhibitor by cleavage of the peptide bond in the trypsin-specific site and subsequent removal of the reactive lysine residue by carboxypeptidase B[162]. In the Lima bean inhibitor, whose single-stranded polypeptide chain has two homologous regions (Fig. 10b), the antitryptic site (Lys^{28}-Ser^{29}) was found in the N-terminal region. The antichymotryptic site (Leu^{55}-Ser^{56}) is situated in the corresponding position in the homologous C-terminal region[30]. The different specificities of two homologous regions with only two other conservative point mutations seem to be entirely due to the amino acid substitution lysine↔serine, which calls for a double base change in the genetic code.

The ovoinhibitor from hens' egg-white, a glycoprotein with only one polypeptide chain (MW 49000), binds two moles of trypsin and two moles of chymotrypsin separately and independently of one another[167], and can therefore be described as "multi-headed"[168].

The inhibitors of blood plasma mostly also have broad specificities, and in addition to trypsin or chymotrypsin, some of them also inhibit plasmin, pancreatic kallikrein, thrombin, C1-esterase, or elastase[46]. It has not yet been established whether they have several reactive sites or only one. The independent inhibition of two moles of trypsin has been observed for α_2-macroglobulin[169]. However, this very high molecular weight protein has been shown to be built up from subunits[226], and an abnormal inhibition mechanism is also probable, since trypsin, plasmin, and thrombin can hydrolyze low molecular weight substrates even in the complex with α_2-macroglobulin[170].

10. Temporary Inhibition

In addition to hen ovomucoid[75] and all the mammalian secretory pancreatic inhibitors (Kazal type) investigated so far[42, 43, 65, 76, 171] (see Section 4.2), the temporary inhibitors for trypsin also include the seminal inhibitors from guinea pig seminal vesicles[48] and from boar sperm[172] (cf. below). The trypsin-kallikrein inhibitor (Kunitz) from bovine organs also becomes a temporary inhibitor for trypsin on reduction of the disulfide bridge Cys^{14}-Cys^{38}, though the native inhibitor exhibits permanent inhibition and is completely resistant to more than 20 proteolytic enzymes[173, 174].

Two alternative mechanisms have been discussed for the proteolytic inactivation of the inhibitors during temporary inhibition. *Laskowski, Sr.* and *Wu*[76], on the basis of the change in the rate of inactivation on addition of excess inhibitor (and of excess trypsin) to the complex, postulated an attack by free trypsin on the inhibitor bound in the complex. *Tschesche* and *Klein*[65] found that the proteolytic degradation of the pancreatic secretory inhibitor to form modified and inactive products occurs both in solution (with dissolved trypsin) and on insoluble trypsin resin used for complex formation. On steric grounds, therefore, they favored degradation from the associate L or L* with simple reorientation of the enzyme molecule. This view is supported by the observation of the progressive degradation of the inhibitor even under completely unphysiological conditions in the pH range from 2.5 to 10 and with less than the equimolar quantity of trypsin; in this case, no trypsin activity toward natural or synthetic substrates can first be detected[65]. The maximum modification and inactivation occurs at pH = 3.4[65, 78]. *Laskowski, Sr. et al.*[77] were able to show that the complete reliberation of the trypsin from a mixture of excess inhibitor and trypsin that had been incubated at pH = 3.4 until 20% of the initial activity was present ultimately proceeds more rapidly after neutralization to pH = 8.0 than when the incubation is continued in acidic solution. This observation justified the conclusion that the inactivating cleavage occurs after the modifying proteolysis in the reactive site (pH optimum at pH < 7), and that the pH optimum for the inactivating cleavage is around pH = 8.0, *i.e.* at the normal pH optimum for tryptic activity.

By correlation of the inactivation with the cleavage of individual peptide linkages of the inhibitor, we were able to demonstrate the correctness of this hypothesis for the inhibitor I of pigs[175]. Corresponding results were obtained by *Schneider* and *Laskowski, Sr.*[205] for the inhibitor II of pigs. After the modifying cleavage of the peptide linkage P_1-P'_1 at the reactive site, after which the inhibitor is still active, the molecule is inactivated by proteolysis of the peptide linkage Arg^{44}-Gln^{45} (Fig. 13). Selective chemical blockage of this bond against cleavage with trypsin by modification of the Arg^{44} side chain with butanedione consequently retards the degradation in

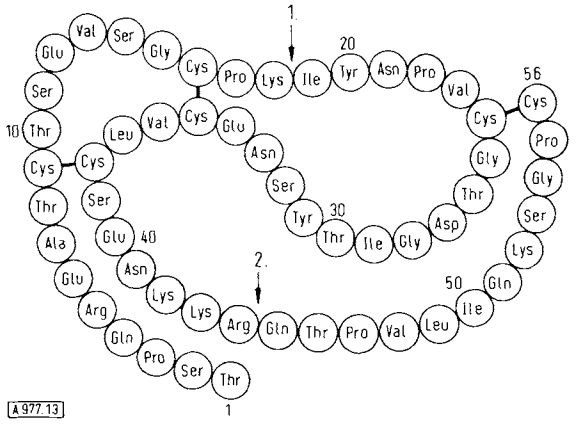

Fig. 13. Complete covalent structure of the secretory trypsin inhibitor I from pig pancreas with reactive site (first cleavage site in the partial proteolysis) and "nominal point of rupture" for inactivation (second cleavage site in the partial proteolysis) during temporary inhibition (see also Fig. 7a).

the temporary inhibition[175]. Finally, the bonds Lys^{52}-Ser^{53} and Lys^{42}-Lys^{43} are hydrolyzed on proteolysis[175, 205].

Thus, the peptide linkage Arg^{44}-Gln^{45} could be regarded as the nominal point of rupture of the molecule. Cleavage at this linkage by reorientation of the enzyme molecule trypsin is energetically not very favorable, owing to the high association constant at the reactive site. However, since it inactivates the molecule, one must expect a steady displacement of the equilibrium until inactivation is complete.

Because of the proteolytic degradation of the inhibitor by the enzyme, this property of temporary inhibition depends on the specificity of the enzyme. We found[203] that the seminal inhibitor from boar sperm, which inhibits the enzymes trypsin, plasmin, and acrosin, acts as a temporary inhibitor toward trypsin, but inhibits the sperm enzyme acrosin permanently[172].

11. Physiological Function

The physiological function of many proteinase inhibitors has not yet been explained. This is true in particular of all inhibitors from plants. It has been suggested that their function is concerned with the interruption of proteolytic processes in the resting stage of the seeds[176], while another view is that they "generally play a part in the maintenance of the latent life form by inhibition of autolysis"[177]. In the case of plants that live symbiotically with bacteria (*e.g.* Leguminosae), the protection of plant tissue against the bacterial proteinases at the point of colonization and a protective function against overgrowth by the bacteria have also been discussed[8].

Green and *Ryan*[216] recorded a very pronounced increase in the proteinase inhibitor concentration in all the leaves of potatoes and tomatoes as a result of damage to single leaves by insects. This effect can also be produced by mechanical injury, and is due to the release of a "wound hormone" (PIIF, proteinase inhibitor inducing factor) at the site of the injury[217].

The physiological function of the secretory pancreatic inhibitors, which occur in all mammals, is very probably the prevention of premature zymogen activation of the digestive enzymes by inhibition of the activating key enzyme trypsin (in cases of premature trypsinogen activation) in the duct system and in the storage sites (acinar cells) of the glands. The trypsinogen is then activated in the duodenal tract by enterokinase. This view is strongly supported by the simultaneous and parallel secretion of the pancreatic inhibitors with the zymogens[42, 43], as well as by the limited specificity of these inhibitors and the fact that they inhibit temporarily. The latter property allows the recovery of the inhibited trypsin after secretion into the duodenal tract for the digestive function.

On the other hand, the function of the trypsin-kallikrein inhibitor (Kunitz) that occurs in tissue can hardly be concerned with the basic biochemical processes, since it does not occur in all mammals and it appears in the tissues only after birth[178]. Its function has been correlated with the special position of ruminants[8], where a special metabolism by the gastrointestinal fauna must be taken into account. The homologous colostrum inhibitor (see Sections 2 and 8.1), which appears to be secreted by all mammals[179], may have the function of protecting the immune bodies of the mother[180] against enzymatic degradation during their passage through the small intestine and allowing their undegraded reabsorption[179].

The snail inhibitors[36, 63], which have a broader inhibition spectrum than the trypsin-kallikrein inhibitor (Kunitz), are secreted into the snail's slime[36], and could therefore function as protection against the proteinases of the snail's natural biotope. In the case of the Ascaris inhibitors, the protective function against the digestive enzymes of the host organisms is obvious[3, 72]. However, objections against a simple "defense mechanism" have been put forward[243] and the inhibitors have been viewed as part of a macromolecular transport system that is necessary for the worm to stay alive[243].

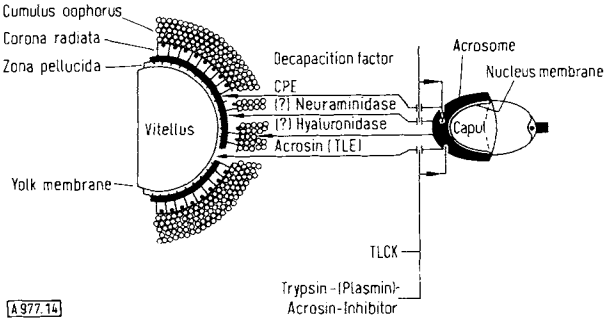

Fig. 14. Schematic representation of ovum and sperm with the penetration enzymes of the acrosome and their inhibitors [184]. Cumulus oophorus = granulosa cells; CPE = corona penetrating enzyme, TLCK = irreversible acrosin inhibitor, 7-amino-1-chloro-3-tosylamino-2-heptanone ($N\alpha$-tosyl-L-lysyl chloromethyl ketone).

Inhibition of acrosin *in vitro* and *in vivo*[47, 48, 181, 182, 184] has been conclusively demonstrated by the inhibitors of mammalian sperm and sperm plasma. Acrosin, the trypsin-like enzyme from the acrosomal cap at the head of the spermatozoon, is responsible for the penetration of the egg-cell membrane (zona pellucida), and together with the "corona penetrating enzyme" and hyaluronidase and neuraminidase[183, 186], it is the key enzyme for the fertilization process (Fig. 14). The acrosin activity is high in epididymal spermatozoons (storage form) and is absent in ejaculated spermatozoons that have come into contact with the secretion of the seminal vesicles. However, it reappears in "capacitated" spermatozoons that have spent some time in the female genital tract. It is only through this process of "capacitation" that the spermatozoons acquire their ability to fertilize the ovum. *Zaneveld, Polakoski, Robertson,* and *Williams*[47, 182, 185] and *Stambaugh* and *Buckley*[183] have shown that capacitated spermatozoons are decapacitated again by *in-vitro* treatment with seminal inhibitors of the seminal vesicles, and the fertilization of the ovum can be prevented in this way *in vivo*. These findings open up possibilities for antienzymatic contraception with proteinase inhibitors.

The spermatozoons, with their lysosomal enzymes, introduce a considerable potential of proteolytic enzymes in the female genital tract, these enzymes being inhibited by the secretion of the seminal vesicles (seminal plasma). It is not yet certain whether this merely provides protection for the female mucosal epithelium or whether there is an unknown physiological function in connection with capacitation. The hormonal regulation of sperm plasma inhibitors in the seminal vesicles, the sites of their biosynthesis, is known[187] (Fig. 15).

The concentrations of the trypsin and chymotrypsin inhibitors of blood plasma are also subject to hormonal control[188].

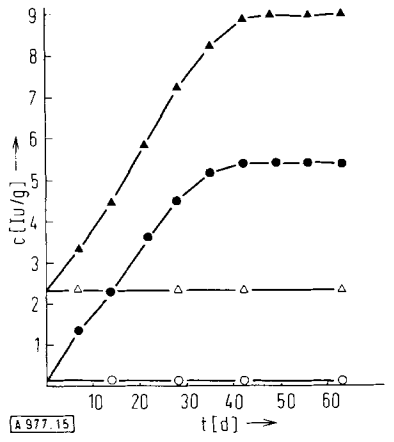

Fig. 15. Inhibitor concentration c in the seminal vesicles of mice [187]. Normal: (○ – ○), 30 days after castration: (○ – ○) and after stimulation of the normal (▲ – ▲) and of the castrated mice (● – ●) with testosterone. 1 IU inhibits approx. 1 mg of trypsin.

The inhibitor concentration in mice and rats increases significantly from birth to maturity[189]. However, the physiological and pathophysiological function of the serum inhibitors is still largely unknown.

Inhibitors may also play a part in the control of the concentrations of some polypeptide hormones in the blood stream. As was first shown by *Tschesche*, *Kolb*, *Standl*, and *Diete*[219] in human beings and by *Tschesche* and *Brush*[220] in rats, an insulin-degrading sulfhydryl enzyme can be inhibited *in vitro* by proteinase inhibitors, and the degradation can be retarded in this way. An inhibitor for the insulin-specific proteinase of rats has been detected in human serum by *Brush*[221].

The observation by *Schumacher*[190] that serum inhibitors, particularly α_1-antitrypsin, occur in the cervical mucus of women and that their concentration depends on the menstrual cycle and is extremely low one to two days before ovulation[190] (Fig. 16) is related to the biochemical processes involved in fertilization. In addition to these inhibitors, it is possible that a low molecular weight trypsin-chymotrypsin inhibitor is also present in the cervical secretion of women[206]. Acrosin is also inhibited by serum inhibitors (α-antitrypsin and antithrombin III as progressive inhibitors[191] and inter-α-trypsin

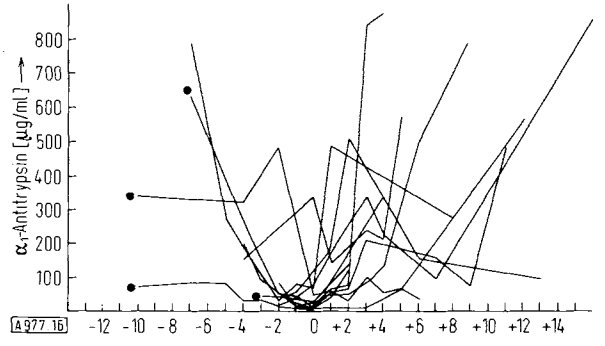

Fig. 16. Content of α_1-antitrypsin in human cervical mucus in the course of 12 menstrual cycles. For ease of comparison, the day of ovulation (the last day of the low basal temperature) was chosen as zero on the abscissa [190]. ● : ovulation induced by gonadotropins.

inhibitor with immediate action[191,207]). Sufficient ovoinhibitors or ovomucoids are available for the inhibition of the sperm proteinases after the penetration of the spermatozoon into the ovum. It has been shown that boar acrosin is inhibited by ovomucoid from hen's egg white[47,192] and by the inhibitor from the nidamental gland of the cuttlefish[193]. *Feeney*[35] has described the inhibition of the acrosin-like pancreatic enzyme trypsin by many ovoinhibitors and ovomucoids from poultry eggs.

The plasma inhibitors from the sera of warm-blooded (and cold-blooded) animals probably have many control and regulatory functions. It is well known that many clinical pictures are accompanied by concentration changes in the α_1-globulin fraction, which consists mainly of α_1-antienzymes (α_1-antitrypsin, α_1-antichymotrypsin, and α_1-antiplasmin) and which constitutes 90% of the trypsin-inhibiting capacity of human serum[8][*]. A greatly increased susceptibility to pulmonary emphysema has been observed in homozygotes with α_1-antitrypsin deficiency of genetic origin[194], and angioneurotic edema is also attributed to a considerable deficiency of complement esterase inhibitor. Proteinase inhibitors also appear to inhibit selectively the growth of transformed cells, whereas normal cells are influenced less strongly if at all. This could offer new approaches for the treatment of malignant cells[218].

12. Outlook

The principle of temporary and local limitations of enzyme activities by inhibitors of a protein nature has been found not only in endo-proteinases of the serine hydrolase type. Inhibitors for exopeptidases, such as carboxypeptidase A and B[195], lipase[196], phospholipase[197], amylase[222], ribonuclease, and deoxyribonuclease[223] have recently also been isolated. It must therefore be expected that further inhibitors for important metabolic enzymes will also be discovered. A third possibility for the control of enzyme activities in the body must therefore be considered alongside the principles of biological regulation already known:

1. repression (or activation) of the genetically controlled protein synthesis at the DNA transcription stage,
2. inhibition (or activation) of allosteric enzymes by effectors of the intermediate metabolism (including interconvertible enzymes), and
3. inhibition (temporary, permanent, progressive) of enzymes that are already present by specific inhibitors.

The investigation of the specific enzyme-inhibitor interaction and its physiological and pathological aspects for medicinal molecular biology and applied therapy is still in its infancy. However, proteinase inhibitors are already on the market as medical supplies and have found wide therapeutre application[249].

I am very grateful to Professor M. Laskowski, Jr. (Purdue University, Lafayette), Dr. R. Huber (Max-Planck-Institut für Biochemie, München), and Dr. H. Fritz (Universität München), for the opportunity to examine work that has not yet been published, and also to Dr. H. Fritz for many stimulating discussions. My own investigations in this field were supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagen-

[*] The designations antitrypsin and antichymotrypsin for these proteinase inhibitors is a misnomer, since these pancreatic enzymes will be inhibited but do not occur in serum.

werk, the Fonds der Chemischen Industrie, and the Sonderforschungsbereich SFB 51.

Activation of Molecular Oxygen[**]

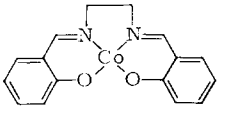
By G. Henrici-Olivé and S. Olivé[*]

Molecular oxygen as a ligand in transition metal complexes is of interest for biochemistry, and for inorganic and organometallic chemistry. Several examples of O_2 complexes, as well as the kinetics and mechanism of their formation are presented. The influence of other ligands on the activation of O_2 is discussed on the basis of a MO description of the electronic structure of the oxygen molecule and of the bonding within the metal-oxygen complexes. Reactions of coordinated oxygen are described.

1. Introduction

The fixation and activation of molecular oxygen on soluble transition metal compounds is a topic of current interest. In fact, the oxygen molecule itself is a relatively reactive entity. It forms compounds with nearly all elements, one of the consequences being that the earth's crust contains about 50% by weight of bound oxygen. What do we really mean then by "activation of molecular oxygen"?

One challenge comes from biochemistry. The respiratory pigments are able to fix oxygen molecules from the atmosphere, to transport them to their sites of reaction, and there to release them. This, in a sense, is a catalytic process, since the natural "oxygen carriers" (*e.g.* hemoglobins, hemocyanines) are not irreversibly oxidized during the process, but retain their activity. Although it appears well established that transition metals (particularly iron) play an important role, our knowledge about the structure of the natural metal complexes involved, the bonding of the oxygen, and the valency state of the metal is still poor. Investigation of the natural products is complicated by their macromolecular protein component. Therefore, low-molecular model substances containing a transition metal center and being able to combine reversibly with oxygen have attracted considerable interest.



Presumably not only the reversibility but also in particular the activation of the oxygen molecule are of importance in natural systems. Obviously, the oxygen has to react with substrate molecules once it has been transported by the hemoglobin to the site of its action. Thus the question arises: is the O_2 molecule also activated in the synthetic oxygen complexes and, if so, can the chemist make use of this activated oxygen for scientifically or technically interesting oxidation reactions? Present commercial processes for the oxidation of olefins are generally based on heterogeneous catalysis. Selectivity appears to be especially critical[1]. Thus, it would certainly be a rewarding goal to use oxygen fixed at soluble transition metal species for catalytic and specific oxidation of substrates such as olefins or amines, which could be introduced into the metal-oxygen complex as ligands. Several approaches of this kind have already been undertaken.

2. Oxygen-Metal Complexes

A great number of transition metal complexes with oxygen as a ligand are known. As early as 1852 *Fremy*[2] reported that "ammonia-cobalt salts", and particularly the nitrate, absorb oxygen from the air, and release it again when dissolved in water. But it was a long way from there to the more sophisticated cobalt(II) chelates, which are considered today as suitable model substances for the natural oxygen carrier systems, and to the catalytically active transition metal-oxygen complexes. Competent reviews[3-8] describe this way, which can only be high-lighted here.

2.1. Oxygen-Cobalt Complexes

By far the greatest number of synthetic oxygen complexes are based on cobalt, and one of the most thoroughly investigated systems is the chelate complex [2,2'-ethylenebis(nitrilomethylidine)diphenolato]cobalt(II) (Co(salen)) *(1)* and its many derivatives.

(1)

Early investigations concentrated on reversible oxygenation in the solid state[9]. The compound *(1)* is perfectly planar, and crystallizes in a layer lattice[*]. The oxygen uptake occurs in the ratio $Co:O_2=2:1$, and it is assumed that the O_2 molecule is bound between two layers by two cobalt atoms, one in each layer. The oxygen can be removed from the complex by mere heating. The reversibility is astonishing: up to 3000 oxygenation-deoxygenation cycles have been carried out with the same sample; after 300 cycles the remaining activity was 70%[10], after 3000 cycles 50%[11]. There have even been efforts to develop the Co(salen) system to a technical process for the production of oxygen from air[4,10], but so far it does not appear that this would be able to compete with the Linde process.

In the meantime it has been found that Co(salen) and its ring-substituted derivatives form reversible oxygen adducts also in solution, in certain aprotic complexing solvents such as dimethylformamide (DMF) or dimethyl sulfoxide (DMSO), or in non-complexing solvents in the presence of strong bases such as pyridine or DMF. Depending on the chelating ligand, on the solvent, or on the added base, and on the temperature, the formation of binuclear complexes ($Co:O_2=2$) or mononuclear complexes ($Co:O_2=1$) has been observed[12-14]. Mostly the ratio $Co:O_2$ has been judged from the

[**] Sections of this progress report have been taken from the following book due for publication in 1974 by Verlag Chemie, Weinheim: *G. Henrici-Olivé* and *S. Olivé*: Homogeneous Catalysis with Transition Metal Complexes.

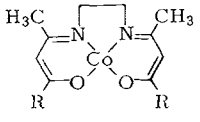
[*] There are other crystalline modifications of the compound which are less, or not at all, active for O_2 uptake.

oxygen uptake. However, some of the adducts have also been isolated in pure form, and it was found that one solvent (or base) molecule is incorporated per Co center. Hence, the related oxygenation equilibria can be formulated as, *e.g.*:

$$\text{Co(3-methoxy-salen)} + L + O_2 \rightleftharpoons \text{Co(3-methoxy-salen)}LO_2$$

(adduct isolated with L = pyridine), and

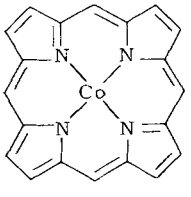
$$2\,\text{Co(salen)} + 2L + O_2 \rightleftharpoons (\text{Co(salen)})_2L_2O_2$$



(adduct isolated with L = DMF or DMSO)[12].

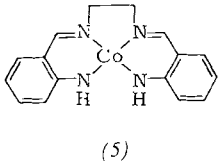
X-ray structural analysis of the binuclear adduct with DMF has shown that the oxygen molecule forms a bridge between the two cobalt centers:

DMF(salen)Co—O—O—Co(salen)DMF

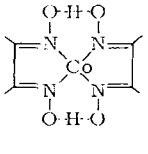


The coordinating ligands about the cobalt atoms form distorted octahedra. The equatorial positions are occupied by the quadridentate salen ligand. The DMF molecule is bonded in an axial position through its oxygen atom, the other axial position being occupied by one of the oxygen atoms of the O_2 bridge[15].

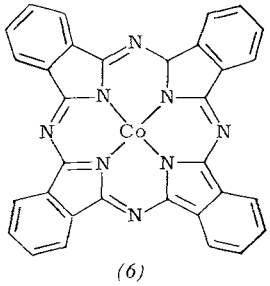
A similar chelate, [4,4'-ethylenedinitrilodi-2-pentanonato]cobalt(II) (Co(acacen)) *(2a)*, also forms reversible 1:1 adducts in non-aqueous solvents and in the presence of a base such as pyridine or dimethylformamide, although only at $T<0$ °C[16].



(2a), R = CH_3
(2b), R = C_6H_5

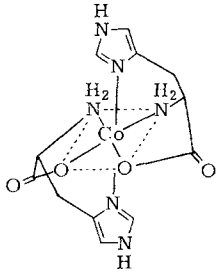


In the natural oxygen carriers the metal is surrounded by four nitrogen ligands, iron in hemoglobin for instance by the characteristic system of four pyrrole rings (porphyrin). Co-porphyrins *(3)* in fact also fix molecular oxygen reversibly[17], and bis(2,3-butanedionedioximato)cobalt(II) *(4)* ("cobaloxime") does the same[18]. However, the chelate complex [2,2'-ethylenebis(nitrilomethylidine)dianilido]cobalt(II) (Co(amben)) *(5)*, although structurally similar to Co(salen), fails to react with oxygen[17], and phthalocyanine-Co *(6)*, although similar to the porphyrins in the immediate vicinity of the metal, does not react either[17,19]. These few examples indicate that the electronic requirements for the fixation of oxygen appear to be rather critical.



(3)

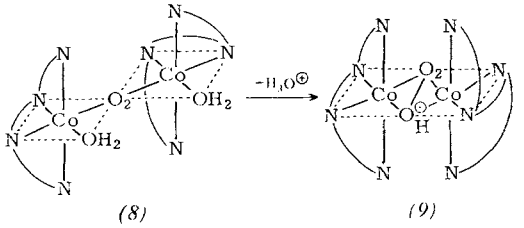
(5)



(4)

(6)

Bis(histidinato)cobalt(II) *(7)* is different from the cobalt species mentioned so far, since no free coordination site is available. Nevertheless a binuclear complex with O_2 is formed in water. Presumably the O_2 molecule displaces the carboxylate group of one of the histidine ligands[20,21]. A variety of cobalt(II) complexes with other amino acids and with dipeptides have also been shown to take up oxygen reversibly[3,4].



(7)

A further important class of cobalt complexes able to fix molecular oxygen is found in the hexaminecobalt(II) ion and related compounds. The ion $[Co(NH_3)_6]^{2+}$, which historically was the first example to be investigated[2,22], is oxygenated in aqueous ammonia, the oxygen displacing one of the NH_3 ligands. A brown binuclear complex, with bridging O_2, is formed; decrease of the oxygen pressure or increase of the ammonia concentration deoxygenates the complex[4]:

$$2[Co(NH_3)_6]^{2+} + O_2 \rightleftharpoons [(NH_3)_5CoO_2Co(NH_3)_5]^{4+} + 2NH_3$$

Chelating aliphatic amines such as ethylenediamine (en), diethylenetriamine (dien), or triethylenetetramine (trien) can replace the ammonia as ligand[23], but the oxygenated complexes then have a certain tendency to undergo subsequent processes which are accompanied by color changes and can be followed spectrophotometrically[24]. In the case of the quadridentate ligand trien, the rapid reversible formation of complex *(8)* is followed by a slow irreversible transformation to what is assumed to be the dibridged species *(9)* with an additional bridging OH group[24,25]. Complex *(9)* is very stable; only on acidification does it decompose to Co^{II}trien, O_2, and H_2O. Evidence for dibridged complexes has also been reported with other nitrogen ligands[26,27].

(8) *(9)*

In other cases, subsequent irreversible oxidation of Co^{II} to Co^{III} with formation of hydrogen peroxide is found, particularly with dien as ligand[26,28]:

$$\text{dien}Co^{II}O_2Co^{II}\text{dien} \xrightarrow{H^+} 2\,\text{dien}Co^{III} + H_2O_2$$

2.2. Oxygen Complexes of Other Transition Metals

The number of oxygen complexes with other transition metals is relatively small as compared with those of cobalt[7, 8].

After *Vaska*'s discovery[29] that the complex $Ir(CO)(Cl)(P(C_6H_5)_3)_2$ in benzene solution reversibly takes up molecular oxygen, forming a 1:1 adduct, several similar complexes have been reported by a number of authors[8]. So far, they are restricted to Group VIII metals, particularly Ru, Os, Rh, and Ir. All have triphenylphosphane or related ligands ($C_6H_5PR_2$, $As(C_6H_3)_3$, $Sb(C_6H_5)_3$, *etc.*). The chlorine ligand may be replaced by Br, I, OH, NO_3, N_3, CN, NCO, or NCS; instead of CO, the complexes may contain NO, or this neutral ligand may be missing. Other related complexes, giving also reversible 1:1 adducts, are $[Rh\{(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2\}_2][PF_6]$[30], and $Ru(Cl_2)(As(C_6H_5)_3)_3$[31].

Several other transition metal complexes have been found to form irreversible, relatively stable oxygen complexes, *e.g.* the iridium analog of the rhodium complex mentioned above[30], and also $M(P(C_6H_5)_3)_2$ with M = Ni(0), Pt(0), or Pd(0) gives irreversible mononuclear oxygen complexes[32]. Another stable rhodium complex was reported to be binuclear, having a bridging O_2 molecule:

$Cl(py)_2Rh{-}O{-}O{-}Rh(py)_2Cl$ (py = pyridine) [33]

One may safely predict that the catalog of oxygen fixing transition metal species (particularly of Group VIII metals) will greatly increase in the future. Today the discovery of such complexes appears to be still more or less accidental, but with increasing knowledge of ligand influences on bonding properties it will probably become possible to estimate which environment could make a certain metal ion susceptible to oxygen uptake.

2.3. Kinetics and Mechanism of Oxygen Uptake

It appears now generally agreed that the binuclear, O_2-bridged complexes are formed in a two step mechanism[12, 13, 21]:

$$Co^{II} + O_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Co^{II}O_2 \quad (1)$$

$$Co^{II}O_2 + Co^{II} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Co^{II}O_2Co^{II} \quad (2)$$

(Ligands are omitted for the sake of simplicity of formulas)

Wilkins et al. accumulated kinetic evidence for the above mechanism from studies on cobalt(II) complexes with various nitrogen-containing ligands in water[21, 25, 26]. Although in these cases the formation of the mononuclear intermediate has not been observed directly, the rate of oxygen uptake is best accommodated by formation of such an intermediate according to eq. (1). The binuclear bridged species have strong absorption peaks in the region 350—420 nm. Their formation was studied by mixing oxygen-free solutions of the cobalt(II) chelates with oxygen-saturated water in a stopped-flow apparatus, and following the increase in optical density in the region mentioned. A large excess of the Co species compared with the oxygen concentration ensured pseudo-first order conditions and complete consumption of the molecular oxygen (*i.e.* reverse reactions are maintained negligible). Formation of the bridged complex obeyed first order kinetics over several half lives (empirical rate constant k_{obs}). Assuming steady state conditions for the intermediate, the following rate law applies for the mechanism given by eqs. (1) and (2):

$$\frac{d[CoO_2Co]}{dt} = \frac{k_1 k_2 [Co]^2 [O_2]}{k_{-1} + k_2 [Co]} = k_{obs}[O_2] \quad (3)$$

This equation indicates that a non-linear dependence of the experimental rate constant k_{obs} on the concentration of the starting cobalt(II) compound is required by the assumed mechanism. Eq. (3) may be rearranged to give:

$$\frac{[Co]}{k_{obs}} = \frac{1}{k_1} + \frac{k_{-1}}{k_1 k_2 [Co]} \quad (4)$$

In fact the plot of $[Co]/k_{obs}$ *versus* $1/[Co]$ was found to be linear, corroborating the two-step mechanism.

In non-aqueous solvents, mononuclear complexes have been observed and even isolated in several cases (see Sections 2.1 and 2.2). The preponderance of the mono- or the binuclear complex appears to be governed by the relative values of the related rate constants, and in certain cases by different solubilities of the two species (*e.g.* poor solubility of the binuclear complex would shift both equilibria, eqs. (1) and (2), to the right).

In the presence of excess oxygen, evidence has been found for a third equilibrium[13]:

$$CoO_2Co + O_2 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} 2CoO_2 \quad (5)$$

It has been postulated that the 1:1 species resulting from eq. (1) and from eq. (5) would be different in their electronic distribution (formulated $Co^{III}O{-}O^*$ and $Co^{II}O_2$ respectively), and that the stable 1:1 complexes would always arise from eq. (5). Further clarifying work appears necessary (cf. also Section 3).

3. The Bonding of Oxygen to Metal

3.1. The Electronic Structure of the Oxygen Molecule

Figure 1 shows the molecular orbital energy level diagram for a homonuclear diatomic molecule, taking into account the symmetry-allowed interaction between σ_s and σ_p orbitals (see, *e.g.* [34]). The electronic configuration of the oxygen atom is s^2p^4; hence 12 electrons have to be placed into this scheme, leading to the configuration $(2\sigma_g)^2(2\sigma_u)^2(1\pi_u)^4(3\sigma_g)^2(1\pi_g)^2$. Since the $1\pi_g$ level is degenerate, each of the two electrons occupies one of the two orbitals, *i.e.* the free oxygen molecule has two unpaired electrons, and therefore is paramagnetic. The two unpaired electrons confer the character of a biradical upon the molecule in its ground state. Consequently, the predilected reaction partners of O_2 are radicals and paramagnetic metal ions.

The molecular orbital diagram given in Figure 1 is valid for a free oxygen molecule. For O_2 under the influence of the electrostatic field of a transition metal ion in a complex the situation may be somewhat different. It was first postulated by *Griffith*[35] that this influence might remove the degeneracy of the $1\pi_g$ level, and that in certain cases the energy difference

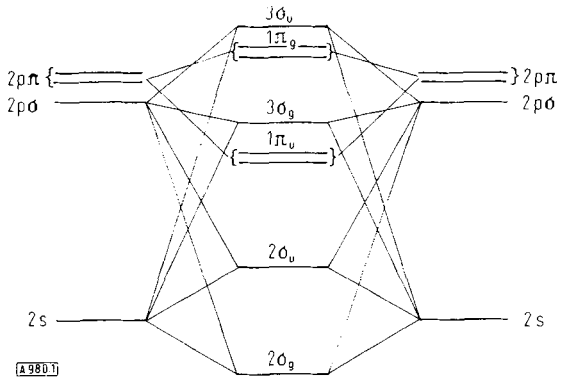


Fig. 1. Molecular orbital energy level diagram for a homonuclear diatomic molecule of the first short period, with σ_s-σ_p interaction.

between the two orbitals may become larger than the energy of pairing, *i.e.* the two electrons will then be located in the more stabilized of the two orbitals with their spins paired (Fig. 2).

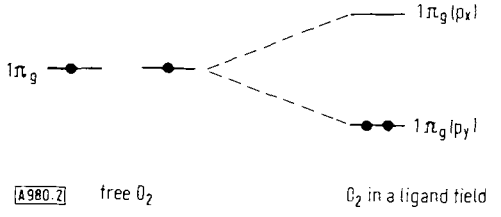

Fig. 2. Influence of a ligand field on the electron distribution in the oxygen molecule.

Griffith has also indicated that in this situation the oxygen molecule has an electronic configuration comparable with that of ethylene in its ground state. We may therefore visualize the electron distribution in terms of a trigonal sp^2 hybridization at the two oxygen atoms. One of the sp^2 hybrid orbitals of each oxygen atom is used for mutual σ bonding and the other two are each doubly occupied; in other words, they form a set of four lone pair orbitals (n_O) oriented in the same way as the four hydrogen atoms in ethylene (see Fig. 3). In molecular orbital language that means that the four lone pair orbitals are linear combinations of $2\sigma_u$, $3\sigma_g$, $1\pi_u(p_y)$ and $1\pi_g(p_y)$, so oriented as to minimize interorbital electronic interaction, whereas $2\sigma_g$ is responsible for the σ bond. There is also one effective π bond in the molecule, $1\pi_u(p_x)$; the lowest energy, empty antibonding orbital is $1\pi_g(p_x)$.

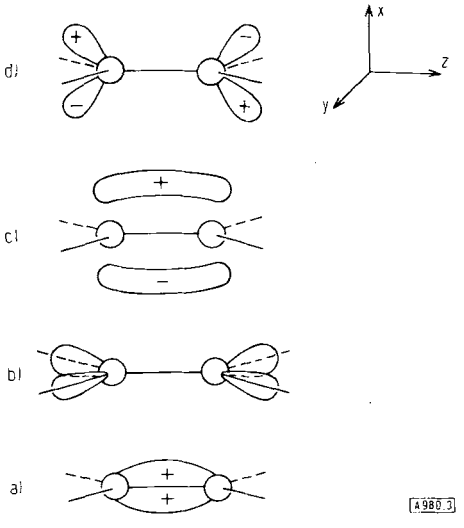

Fig. 3. The "valence state" molecular orbitals of the oxygen molecule: a) σ-bonding MO; b) sp^2 lone pair orbitals (n_O); c) π-bonding MO, $1\pi_u(p_x)$; d) π^*-antibonding MO, $1\pi_g(p_x)$ (according to [35]).

3.2. Structure and Bonding in the Complexes

X-Ray structural analysis, optical spectroscopy, magnetic measurements, and theoretical MO considerations have shed some light onto the bonding in transition metal-oxygen complexes.

We shall first discuss the mononuclear complexes resulting from the interaction of oxygen with Schiff base cobalt(II) compounds, such as Co(salen) *(1)* or Co(acacen) *(2a)*. The non-oxygenated starting materials are paramagnetic, having one unpaired electron per Co center (low spin d^7 configuration)[36]. As mentioned in Section 2.1, a strongly coordinating axial ligand is necessary in order to enable these compounds to become oxygenated in solution. The purpose of the axial ligand may be rationalized considering the d-orbital energy levels of cobalt in different environments (see Fig. 4). In the square planar starting material, d_{xz}, d_{yz}, and d_{z^2} are the most stable orbitals, and the unpaired electron is located in the d_{xy} level, where it is not available for an approaching O_2 molecule. (The x and y axes are in the plane defined by Co and the Schiff base ligand.) A strong axial fifth ligand leads to a square pyramidal arrangement; it raises the d_{z^2} orbital above the d_{xy} level, thus resulting in the electronic configuration $(d_{xz})^2(d_{yz})^2(d_{xy})^2(d_{z^2})^1$[37].

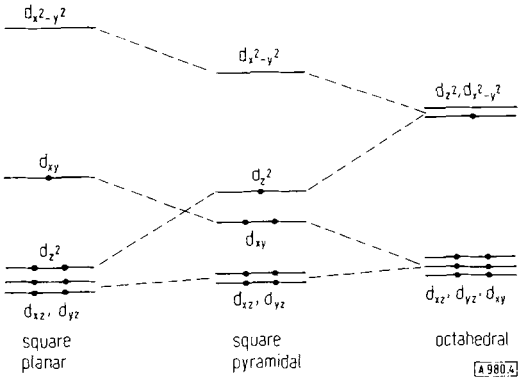

Fig. 4. Energy levels of the d orbitals in various environments.

This latter configuration appears to be a necessary prerequisite of oxygenation[36, 38]. This view is supported by EPR studies. In the presence of a Lewis base, *e.g.* pyridine, Co(acacen) and related compounds have similar EPR signals. Figure 5 shows the spectrum of Co(acacen)py in frozen toluene solution at 77 °K[36]. It indicates the interaction of the unpaired electron with the ^{59}Co nucleus ($I=7/2$) and with the ^{14}N nucleus of the pyridine ligand ($I=1$). The signal is best interpreted assuming that the unpaired electron is associated with the $3d_{z^2}$ orbital[36, 38]. In the absence of such base (no oxygenation!) a different EPR signal is observed which can be fitted to the configuration $(d_{xz})^2(d_{yz})^2(d_{z^2})^2(d_{xy})^1$[38].

After oxygenation the complexes still have one unpaired electron per Co center[16, 36]. Since Co^{II} has one, and gaseous O_2 has two unpaired electrons, spin pairing must have occurred. The best interpretation of this phenomenon would appear to assume that upon coordination the symmetry of the oxygen molecule is sufficiently reduced to split the other-

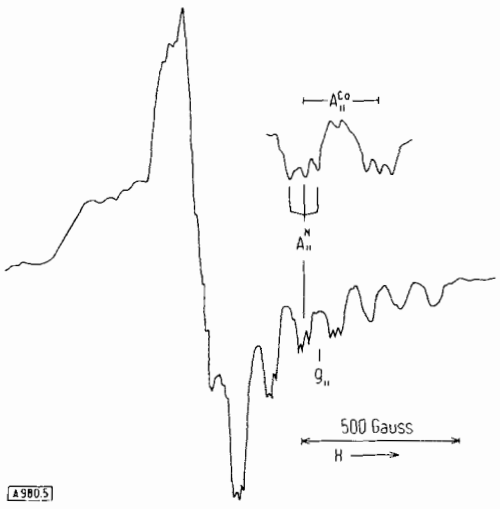

Fig. 5. EPR spectrum of Co(acacen)py in frozen toluene solution at 77 K (after [36]).

wise degenerate antibonding $1\pi_g$ orbitals and to constrain the two antibonding electrons to be paired in the more stable of the two[35, 36] (cf. Fig. 2).

The EPR of the oxygenated complex (Fig. 6) indicates that the unpaired electron has only a small spin density at the Co nucleus ($a_{Co} \approx 10$ gauss as compared with 80—100 gauss for the non-oxygenated parent compounds, Fig. 5). It may be concluded that the unpaired electron is delocalized onto the oxygen ligand, thus making it similar to a superoxide ion. This would mean that the complex approaches the formulation $Co^{III}(O_2^-)$. The very fact, however, that the unpaired electron has a definite spin density at the Co nucleus shows clearly that the assignment of integral oxidation numbers is meaningless in this kind of bonding. The situation appears to be better described by stating that the unpaired electron moves in a molecular orbital made up of a 3d atomic orbital of Co and the empty antibonding π orbital of O_2:

$$\psi = c_1 3d_{Co} + c_2 1\pi_g(p_x) \qquad \text{with } c_2 > c_1 \qquad (6)$$

The X-ray structural analysis of a related mononuclear cobalt-oxygen complex, Co(bzacen)pyO_2 [Co(bzacen)=*(2b)*, py = pyridine] gives concordant as well as additional information. Figure 7 shows a perspective view of the complex[39]. The cobalt is bonded to only one of the oxygen atoms of

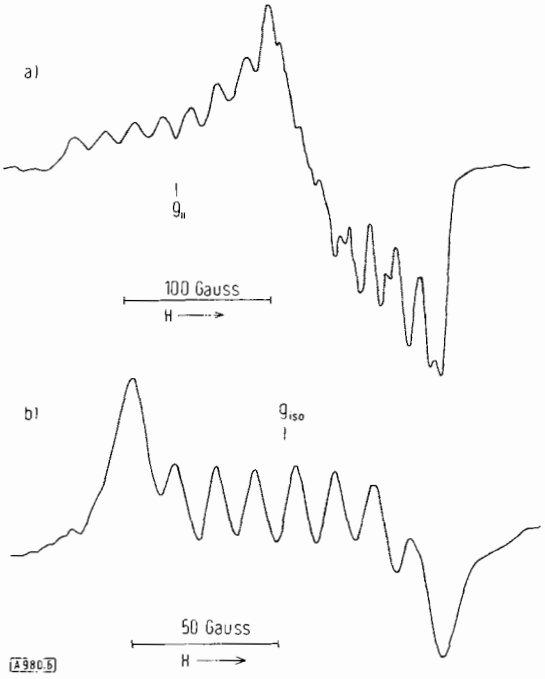

Fig. 6. EPR spectra of Co(acacen)pyO_2; a) frozen toluene solution at 77 K; b) fluid toluene solution at 215 K (after [36]).

the O_2 ligand. Coordination about cobalt is approximately octahedral with the four Schiff base ligand atoms coplanar with the metal atom. The bond angle Co—O—O is 126°, and the O—O distance of 1.26 Å corresponds in fact approximately to that found in a superoxide anion (cf. Table 1).

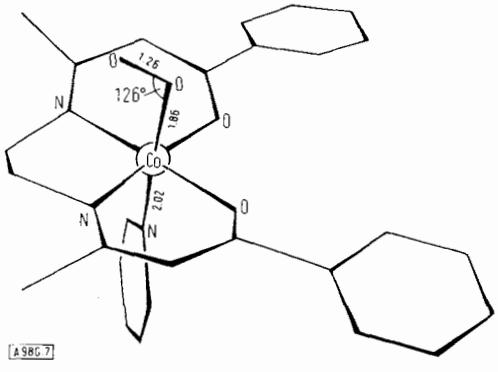

Fig. 7. Perspective view of the mononuclear oxygen complex Co(bzacen)pyO_2 (after [39]).

Table 1. Oxygen-oxygen bond distances.

Compound	Type	Structure	O—O [Å]	Ref.
O_2	free molecule	O=O	1.2074	[41]
KO_2	superoxide	O_2^-	1.28	[41]
H_2O_2	peroxide	O_2^{2-}	1.49	[42]
Co(bzacen)pyO_2 [a]	reversible O_2 complex		1.26	[39]
$[(NH_3)_5Co—O—O—Co(NH_3)_5]^{4+}$	μ-peroxo complex		1.65	[43]
$[(NH_3)_5Co—O—O—Co(NH_3)_5]^{5+}$	oxidized μ-peroxo complex		1.31	[44]
$(O_2)Ir(Cl)(CO)(P(C_6H_5)_3)_2$	reversible O_2 complex		1.30	[45]
$(O_2)Ir(I)(CO)(P(C_6H_5)_3)_2$	irreversible O_2 complex		1.51	[30]

[a] Cf. Fig. 7.

The same arrangement has also been reported for Co(acacen)-pyO_2[40] [Co(acacen) = *(2a)*]. The bent bond C—O—O requires some further comment. The molecular orbitals of O_2 in its "valence state", *i.e.* with the two antibonding π electrons paired under the influence of the field of a transition metal, have been shown in Figure 3. From this picture two natural possibilities for coordination arise, one [*(10)*] in which the metal lies in a lone pair direction, the metal—O—O angle being approximately 120°, and the other [*(11)*] in which the metal lies on the x axis of the O_2 molecule[*], and forms a coordinative double bond comparable with that between transition metals and olefins (M = metal):

(10)   *(11)*

Evidently, the cobalt complexes discussed so far belong to the first type. (Other metals form bonds of the second type, see below.) As soon as the oxygen molecule has approached the transition metal as the sixth ligand, the d-orbital splitting becomes that of an octahedral complex (Fig. 4, right-hand side). A coordinative σ bond is established between one of the oxygen lone pairs and d_{z^2} of cobalt, and there is also a considerable amount of back-donation from one of the doubly occupied d-orbitals of the cobalt to the antibonding empty $1\pi_g(p_x)$ of the oxygen molecule. This latter back-bonding weakens the O—O bond, as evidenced by the bond distance, 1.26 Å (cf. Table 1).

The binuclear cobalt-oxygen complexes $[(NH_3)_5Co—O—O—Co(NH_3)_5]^{4+}$ and L(Co(salen))—O—O—(Co(salen))L (L = dimethylformamide) have also been investigated by X-ray structural analysis. They possess bent Co—O—O—Co bonds, with Co—O—O bonds angles of 112°[43] and 120.4°[15] respectively (see Fig. 8).

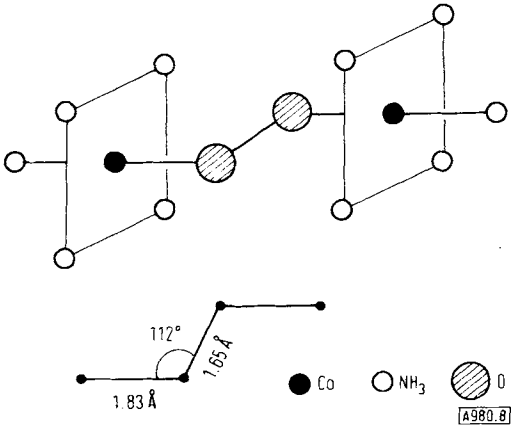

Fig. 8. Structure of $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}(SCN)_4$ (after [43]).

Interestingly, these binuclear cobalt-oxygen complexes are diamagnetic, whereas the parent compounds, *e.g.* $[(NH_3)_6Co]^{2+}$ or Co^{II}(salen), are paramagnetic (low spin d^7, one unpaired electron). If again we assume that the unpaired electrons of the free oxygen molecule are paired in one of the $1\pi_g$ orbitals under the influence of the cobalt neighbors, the diamagnetism of the complex implies that the unpaired electrons of the two cobalt centers are now paired in a four-center molecular orbital embracing Co—O—O—Co. This hypothesis finds experimental corroboration by EPR: The complex $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$ can easily be oxidized to $[(NH_3)_5CoO_2Co(NH_3)_5]^{5+}$. The latter is paramagnetic (one unpaired electron), and has a 15-line EPR signal[46], showing the interaction of the unpaired electron with two identical Co nuclei (^{59}Co: $I = 7/2$). Similar EPR spectra have been found with other oxidized oxygen-bridged Co complexes[18,47,48]. A particularly well resolved signal was observed[48] when the binuclear oxygen complex of bis(histidinato)cobalt(II) *(7)* was oxidized with Ce^{4+} (see Fig. 9).

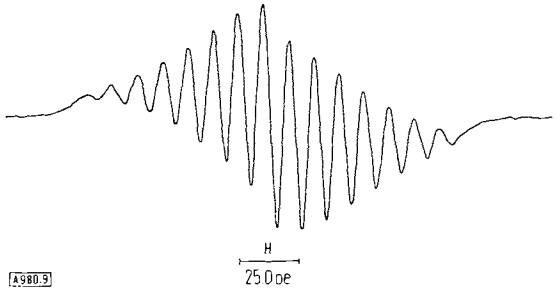

Fig. 9. EPR spectrum of the binuclear oxygen complex of bis(histidinato)-cobalt(II) *(7)* (after [48]).

These spectra show that the unpaired electron moves in fact in a molecular orbital including the two cobalt nuclei in a symmetric way. A proposal for the four center MO is given in Figure 10. The four centers are held together by a π bond between the empty antibonding π orbital of the oxygen, $1\pi_g(p_x)$, and two doubly occupied d-orbitals of the two cobalts. This type of bonding brings spin density into the antibonding π orbital of the oxygen molecule and thus weakens the bond. From the relatively small EPR coupling constant, $a_{Co} \approx 12$ gauss, it can be concluded that the four-center MO is mostly localized on the O—O part of the complex. This is in agreement with the O—O bond distance found for the oxidized complex (see Table 1), which is similar to that of a superoxide, O_2^-.

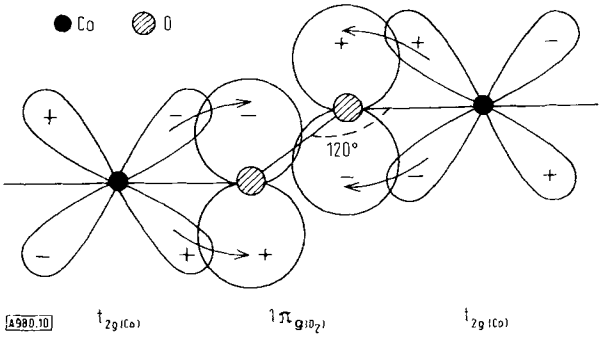

Fig. 10. Four-center molecular orbital in $[(NH_3)_5Co—O—O—Co(NH_3)_5]^{4+}$ and similar complexes (after [4]).

The bent Co—O—O—Co bond indicates that there is also σ interaction between a lone pair on each oxygen atom and vacant $d(e_g)$ orbitals of the metal on either side.

The original diamagnetic complexes, such as $[(NH_3)_5CoO_2Co(NH_3)_5]^{4+}$, on the other hand, may be assumed to have two electrons in this same four-center orbital, making the O—O part then similar to a peroxide ion, O_2^{2-}. In fact the O—O bond distance is large, even somewhat larger than in a peroxide (see Table 1).

[*] The coordinate systems for the oxygen molecule and the transition metal center are independent.

Although it is customary to designate these bridge-bonded, binuclear cobalt-oxygen complexes as μ-superoxo- and μ-peroxo-cobalt(III) complexes, it should be born in mind that the assignment of integral oxidation numbers is not correct (EPR evidence). It was suggested[7] that the term metal-oxygen complex should apply to all relevant species containing a complexed O_2 moiety, as is customary with the analogous metalnitrogen complexes.

Vaska's oxygen complex $Ir(Cl)(CO)(P(C_6H_5)_3)_2O_2$ (see Section 2.2), and some related complexes of iridium and rhodium, have the oxygen molecule bonded symmetrically. X-Ray studies[30, 45, 49, 50] have revealed equal distances between the metal and either of the two oxygen atoms; the arrangement of the ligands is trigonal-bipyramidal, with the phosphanes situated at the apices (see Fig. 11). The symmetric position of the two oxygen atoms suggests a bonding [*(11)*] similar to that of the Dewar-Chatt model for the metal-olefin complexes[51, 52]. A σ bond is formed between the filled bonding π orbital of the oxygen and an empty d orbital of the metal. Back donation occurs, to off-set the resultant dipole, from a filled d orbital to the antibonding $1\pi_g$ orbital of the O_2.

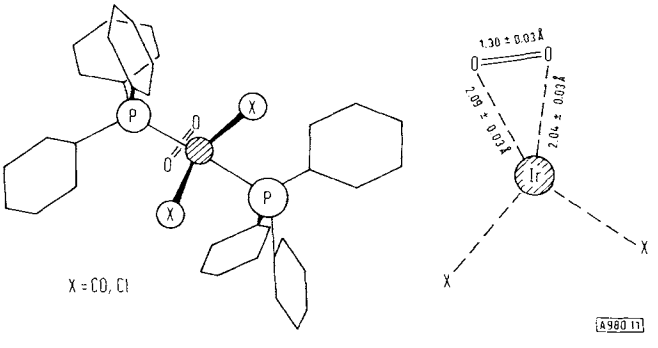

Fig. 11. Structure of $IrO_2(CO)(Cl)(P(C_6H_5)_3)_2$ (after [45] and [4]).

Presumably the π bonding predominates in transition metal-oxygen complexes. This is indicated by the observation that higher electron density at the metal center favors complex formation. Thus, as the electronegativity of the halide in the iridium complex (Fig. 11) decreases (Cl > I), the strength of the bonding of the oxygen molecule to the metal increases (see Table 1; note that in the iodide complex the O_2 is irreversibly bound). At the same time, the O—O bond is destabilized, *i. e.* the bond length is increased, indicating the higher electron density in the antibonding π orbital.

Variation of the donor strength of the phosphane ligand (cf. Fig. 11) has concordant consequences: the better the donor $[(p\text{-}ClC_6H_4)_3P < (C_6H_5)_3P < (p\text{-}CH_3C_6H_4)_3P < (p\text{-}CH_3OC_6H_4)_3P]$ the higher the rate of oxygen uptake, and the greater the stability of the oxygen complex[53].

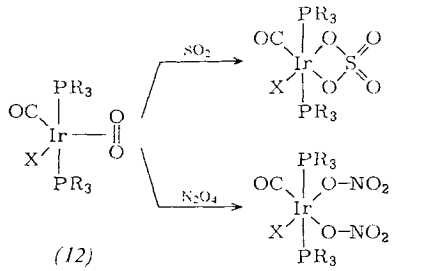
The importance of π bonding in metal-oxygen complexes is also reflected in the observation that d^{10} metals, which do not possess empty d-orbitals, also form complexes with O_2 but not with H_2[54].

After the discussion of the different modes of attachment of the oxygen molecule to the metal center, the question may arise how the oxygen is bonded in the natural oxygen carriers such as hemoglobin or myoglobin. The macromolecular character of these compounds makes a direct X-ray determination of the geometry of the oxygen unlikely. The bent-bonding mode, as well as the symmetric attachment are able to provide reversibility (cf. Section 2), and in this sense both could be models for the natural compounds. Thus one may ask which molecular properties are decisive for the type of bonding. For energetic reasons the symmetric attachment should always be favored since the bonding π-MO of O_2 is estimated[35] to have a smaller ionization potential than the lone pair orbitals. It was suggested by *Mingos*[55] that the complex is forced into the bent-bonding mode whenever the highest occupied metal orbital has a symmetry different from that of the oxygen acceptor orbital $1\pi_g$[*]. The latter is a π orbital; in the cobalt complexes discussed above the donating orbital is d_{z^2}, a σ orbital (cf. Fig. 4, center). In the square planar d^8 complexes of Ir^I and Rh^I, on the other hand, the highest occupied orbital is d_{xy} (2 electrons), which has π symmetry.

From this point of view the bonding of O_2 to the iron(II) center in hemoglobin should be expected to be of the symmetric type. Although the ligand arrangement is similar to that in the cobalt(II) complexes, it has to be taken into account that one electron less has to be placed into the MO energy diagram (Fig. 4, center), the highest occupied orbital then being d_{xy}, which is a π orbital in this symmetry.

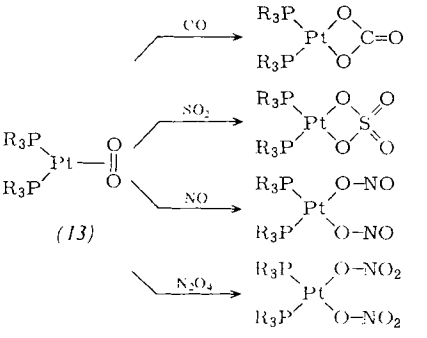
4. Reactions of Coordinated Oxygen

The X-ray crystallographic studies of the synthetic transition metal-oxygen complexes discussed in the preceding section have indicated that a certain activation of the oxygen molecule takes place upon coordination, as shown by an elongation of the O—O bond. This suggests the use of the activated oxygen for specific oxidation reactions, not possible with free gaseous oxygen. In fact, several cases of homogeneous catalysis of hydrocarbon autoxidation and epoxidation with oxygen complexes have been reported[56]. It appears, however, that most or all of these reactions have the characteristics of radical chain processes[57]. The transition metal catalyzes the decomposition of peroxides, as does Co-naphthenate. This kind of oxidation, which is generally very unspecific and gives a large amount of acidic by-products, will not be treated here.



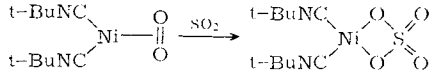
The desired specific oxidation of substrate would require simultaneous coordination of oxygen and substrate molecule to the same metal center prior to reaction. In the case of olefins, only a non-catalytic reaction of this type has been achieved up to now. In several cases, however, the catalytic oxidation of phosphane, carbon monoxide, or isocyanide ligands has been reported.

4.1. Non-Catalytic Reactions



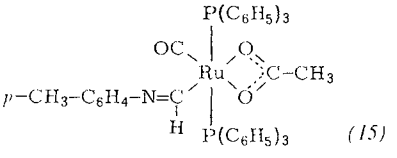
The stoichiometric oxidation of SO_2, CO, CO_2, NO, and N_2O_4 has been repeatedly observed, particularly with $IrX(CO)(O_2)(P(C_6H_5)_3)_2$ *(12)*[58], $PtO_2(P(C_6H_5)_3)_2$ *(13)*[54, 59] (X = Cl, Br, I), and with $NiO_2(t\text{-}BuNC)_2$ *(14)*[60].

These reactions involve an increase of the formal valency state of the metal, together with the formation of a stable anion (or two anions) attached to the metal:



[*] This was concluded from considerations based on an approximate form of the second order Jahn-Teller effect [55].

(12)



(13)

(14)

R = C_6H_5

An unusual reaction of this type was found when $Ru(O_2)(CO)(CN\text{-}p\text{-}CH_3C_6H_4)(P(C_6H_5)_3)_2$ was heated in ethanol: the alcohol is oxidized to coordinated acetate, and a hydride ion of the alcohol is donated to the *p*-tolyl isocyanide ligand, forming the uncommon formimidoyl ligand[61]:

(15)

When the acetate ligand is cleaved from (15) by iodide, hydride moves to the metal, and the original isocyanide ligand is regenerated in $RuHI(CO)(CN\text{-}p\text{-}CH_3C_6H_4)(P(C_6H_5)_3)_2$. This hydride may react with excess of acetate, the hydride returning to the isocyanide.

The oxidation of primary amine ligand to nitrile and of methylamine to cyanide has been achieved with the corresponding hexakis(amine)ruthenium(II) ion under a slight oxygen pressure[62].

The first case of oxidation of a hydrocarbon with molecular oxygen at a transition metal center under mild conditions appears to be the rhodium(I)-promoted oxidation of a terminal olefin (1-hexene) to a ketone (2-hexanone)[63]. A free radical type of reaction has been excluded. Although the yield is small (some 20—30%, referred to the metal), this reaction is remarkable. If $RhCl(P(C_6H_5)_3)_3$ (16) is brought together with O_2 at ambient temperature in benzene solution, two of the three phosphane ligands are oxidized to phosphane oxide (see Fig. 12, reaction sequence on the left-hand side). If olefin is present it appears able to compete with a phosphane ligand P for a coordination site, and becomes oxygenated instead of one of the phosphane ligands. It appears to be significant that the system provides an acceptor (the phosphane) for one of the oxygen atoms.

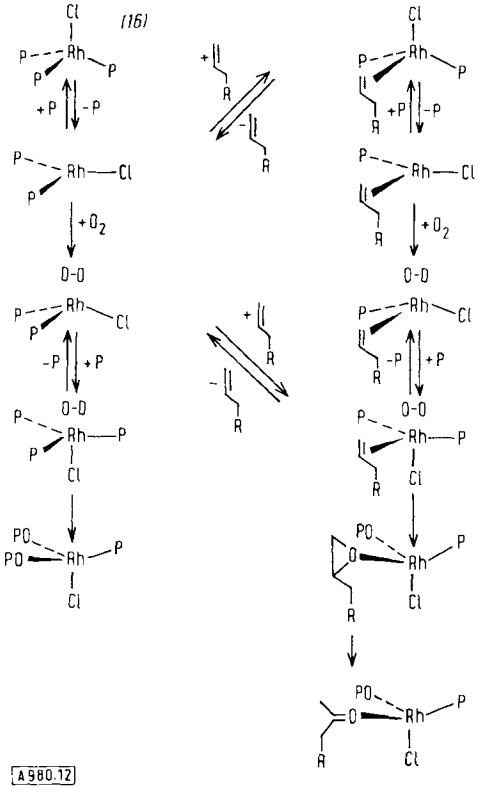


Fig. 12. Rhodium(I)-catalyzed oxidation of 1-hexene to 2-hexanone. The phenyl groups of the phosphane and phosphane oxide ligands have been omitted; R = *n*-C_3H_7 (according to [63]).

4.2. Catalytic Reactions

Triphenylphosphane is oxidized to triphenylphosphane oxide by several transition metal-oxygen complexes. Thus, *Wilke et al.*[32] found that $M(P(C_6H_5)_3)_4$ (M = Ni(0), Pd(0); Pt(0)) react with oxygen, in benzene or toluene solution, to give the complex $M(P(C_6H_5)_3)_2O_2$. At elevated temperature (with M = Pd, Pt at $T > 90$ °C, with M = Ni already at $T > -35$ °C) the oxygenated complex decomposes to metal and two molecules of phosphane oxide. In the presence of an excess of phosphane, the metal may be scavenged, regenerating the starting complex, *i.e.* the process becomes catalytic. With the Ni(0) compound some 50 mol of phosphane have been oxidized per mol of Ni complex; with Pd(0) a turnover of at least 500 was obtained.

The mechanism of this reaction has been studied, for the case of Pt(0), by *Halpern et al.*[64,65] on the basis of optical absorption spectroscopy and kinetic measurements. A solution of $Pt(P(C_6H_5)_3)_4$ in benzene exhibits strong absorptions in the range 400—560 nm. The same absorptions, with identical intensity, are observed when ethylene is displaced from the complex $Pt(P(C_6H_5)_3)_2(C_2H_4)$ (at the same Pt concentration), by adding $P(C_6H_5)_3$ in the ratio 1:1. It is convincingly concluded that the predominant species in both cases is $Pt(P(C_6H_5)_3)_3$. Therefore, the first step in the mechanism of the catalytic oxidation of the phosphane with $Pt(P(C_6H_5)_3)_3$ is assumed to be:

$$PtP_4 \rightarrow PtP_3 + P \qquad (7)$$

(The phenyl groups have been omitted in this and the following equations.)

The subsequent reaction sequence has been established investigating the two component reactions separately:

$$PtP_3 + O_2 \xrightarrow{k_1} PtP_2O_2 + P \quad (8)$$

$$PtP_2O_2 + P \xrightarrow{k_2} PtP_3O_2 \xrightarrow[fast]{2P} PtP_3 + 2PO \quad (9)$$

Each reaction was followed spectrometrically by monitoring the concentration of $Pt(P(C_6H_5)_3)_3$ in the region mentioned above. Reaction (8) was studied under conditions ensuring minimum interference from reaction (9) ($[O_2] \ll [Pt]$). The kinetic experiments on reaction (9) were performed by adding a large excess of $P(C_6H_5)_3$ to a benzene solution of $Pt(P(C_6H_5)_3)_2O_2$, and spectrometrically measuring the formation of $Pt(P(C_6H_5)_3)_3$. The resulting rate laws are[65]:

$$-d[PtP_3]/dt = k_1[PtP_3][O_2] \quad (10)$$

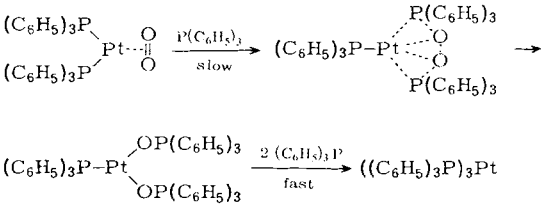
$$+d[PtP_3]/dt = k_2[PtP_2O_2][P] \quad (11)$$

with $k_1 = 2.61\ mol^{-1}\ s^{-1}$ and $k_2 = 0.151\ mol^{-1}\ s^{-1}$, at 25°C. The mechanism was further checked under conditions such that both reactions are occurring simultaneously, *i.e.* with a large excess of $P(C_6H_5)_3$, with constant O_2 pressure, and measuring the rate of consumption of oxygen:

$$-d[O_2]/dt = k_1[PtP_3][O_2] \quad (12)$$

Assuming stationary state conditions:

$$d[PtP_3]/dt = k_1[PtP_3][O_2] - k_2[PtP_2O_2][P] = 0 \quad (13)$$



and making use of the conservation relation

$$[PtP_3] + [PtP_2O_2] = [Pt]_{total} \quad (14)$$

the rate law for the oxygen consumption is:

$$-\frac{d[O_2]}{dt} = \frac{k_1 k_2 [Pt]_{total}[P][O_2]}{k_1[O_2] + k_2[P]} \quad (15)$$

Perfect agreement between the measured rate of O_2 uptake and values calculated from eq. (14) with the rate constants given above, lends strong support to the assumed reaction sequence, eqs. (8) and (9)[65]. However, the detailed mechanism of the individual steps, particularly of the transformation of the phosphane into the phosphane oxide at the metal center, is not elucidated from these kinetic data. Intuitively, *Halpern et al.* interpreted this step in terms of a "dissociative insertion" reaction [eq. (16)].

$$(C_6H_5)_3P-Pt(OP(C_6H_5)_3)_2 \xrightarrow[fast]{2\,(C_6H_5)_3P} ((C_6H_5)_3P)_3Pt + 2\,(C_6H_5)_3PO \quad (16)$$

Other complexes which have been reported to catalytically oxidize triphenylphosphane to the oxide include $Ru(O_2)(NCS)(NO)(P(C_6H_5)_3)_2$[66], for which a similar reaction mechanism with "dissociative oxygen insertion" has been suggested; furthermore $RuCl_2(P(C_6H_5)_3)_3$[67], which is relatively active, converting 10 mol of $P(C_6H_5)_3$ into $OP(C_6H_5)_3$ per mol of Ru complex in 15 min at 20°C, and *Vaska*'s complex, $IrX(CO)(P(C_6H_5)_3)_2$[68][*] which was, however, found to be reactive only at elevated temperature (110°C, turnover 4—5 in 9 h).

An interesting simultaneous catalytic (although slow) oxidation of phosphane to phosphane oxide, and of CO to CO_2, was achieved by exposing $RhCl(CO)(P(C_6H_5)_3)_2$ to a slight pressure of CO and O_2 at 100°C[70].

The catalytic oxidation of *tert*-butyl isocyanide to the corresponding isocyanate has been observed with the complex $((CH_3)_3CNC)_2NiO_2$ *(14)*, at room temperature[71].

Finally, a ligand reaction has also been found for binuclear metal-oxygen complexes, namely $X_2(RNH_2)_3Co—O—O—Co(RNH_2)_3X_2$, with X = organic anion, *e.g.* acetate, and R = organic group, *e.g.* propyl[72]. The complexes are formed if the organic cobalt salt is dissolved in the amine, and oxygen is introduced into the solution. They are diamagnetic, irreversible, and soluble in alcohols or dimethylformamide. Thermolysis of the dry complexes leads to a homopolar cleavage of the O—O bond with subsequent radical reactions involving amine ligand. In the case of R = propyl, the main products are allylamine and dipropylamine. It is suggested that the primary radical formation by cleavage of the O—O bond is followed by the dehydrogenation of the propyl groups. The resulting allylic groups exhibit weak C—N (75.2 kcal/mol) and C—H bonds (82.5 kcal/mol[73]). Radical cleavage of these bonds leads to the observed alkylation of the primary amine. After the thermolysis the cobalt is present as paramagnetic, mononuclear Co^{II}. It dissolves in fresh amine and the resulting solution takes up oxygen at essentially the same rate as during the first oxygenation; thermolysis leads to the same products (catalysis).

5. Outlook

The transition metal-oxygen complexes may be divided into four classes, with different properties, reaction patterns, and prospects for the future.

Reversible oxygen complexes: This group includes all models for the natural oxygen carriers. Although much has already been elucidated concerning the bonding in such complexes, the actual mode of fixation of the oxygen to the metal in the natural complexes still remains a matter of speculation (cf. Section 3.2).

Stable oxygen complexes: Although interesting in themselves as regards bond lengths, bond angles, and symmetry properties, this category does not yet present any prospects for practical use. The situation here is similar to that in the field of transition metal-nitrogen complexes: the isolable stable complexes do not appear to be suitable for catalysis (see, *e.g.* [74]).

[*] The catalytic oxidation of styrene to benzaldehyde at 110°C with *Vaska*'s complex was also reported [68]. However, no effort was made to exclude a radical mechanism. The free radical alternant copolymerization of styrene and O_2 is well established [69]; the copolymer decomposes at elevated temperature to benzaldehyde and formaldehyde.

Complexes with oxidized ligands: This group might, in some cases, be of interest for synthetic purposes. Free oxygen would not react under mild conditions with SO_2, CO, NO, N_2O_4; some of the metal-oxygen complexes, however, transform these substrates easily to oxidized, anionic ligands. Since the latter are generally more strongly bonded to the metal than the starting material, the reaction stops there, and no catalysis is to be expected (Section 4.1).

Complexes that catalytically oxidize ligands: Evidently catalysis is possible only if the oxidized ligand is easily displaced by substrate molecules. Although present knowledge is still far away from a specific catalytic oxidation of certain substrates, particularly olefins, some progress has already been achieved (Section 4.2).

Obviously, the first and fourth classes are the most interesting from the point of view of catalysis, in the sense of oxygen transport as well as for oxidations of practical interest. At the present it is not yet possible to predict which complex will perform which task, but the problem should perhaps not be seen isolated. It may be expected that the investigation of bonding and ligand influences within different types of complexes (with O_2, N_2, CO, olefins, diolefins, *etc.*) will prove mutually stimulating, and will provide a better insight into possibilities and limitations of homogeneous catalysis with transition metal complexes.

Electronic Transitions in Transition Metal Compounds at High Pressure

By H. G. Drickamer[*]

Very high pressure is becoming increasingly important for investigating electronic structure. The relative shift in energy of electronic orbitals which is commonly observed at high pressure can frequently lead to a new ground state for the system. These electronic transitions may result in changes in electrical, optical, or magnetic properties as well as changes in chemical reactivity. Electronic transitions in metals and insulator-metal transitions have been widely studied by physicists. Recently, it has been found that electronic transitions in aromatic hydrocarbons and their electron donor-acceptor complexes can induce chemical reactivity and lead to the formation of new classes of hydrocarbons.

Electronic transitions in transition metal complexes may lead to changes in spin state; both increase and decrease in multiplicity with increasing pressure have been observed. In addition, it has been shown that Fe(III) and Cu(II) reduce at high pressure in a variety of compounds. The behavior of these transition metal ions is described in some detail in relation to the general area of high pressure and electronic structure.

1. Introduction

Over the past two decades it has become apparent that very high pressure is a powerful tool for studying electronic structure. Its application first became common in solid state physics and geophysics, but has more recently been extended to physical, inorganic, and organic chemistry.

The pioneering work of *Bridgman*[1] provided techniques for studies at up to 12 kbars (1 kbar = 987 atmospheres), and in some cases up to 30 kbars, using hydrostatic media. These techniques have been applied to many problems of solid state physics, as well as to investigations on the physical chemistry of solutions[2], relaxation processes in solution[3], electronic and molecular spectroscopy[4], and also to the study of organic reaction mechanisms[5, 6].

In addition, *Bridgman* developed techniques for electrical resistance and pressure-volume measurements utilizing quasihydrostatic media at 70 kbars or above. In the past fifteen years the static pressure range has been extended to several hundred kilobars. More important—measurements such as optical absorption and emission and Mössbauer resonance which are sensitive to electronic structure are now possible.

In this review we discuss studies of transition metal ions in this high pressure range. In order to place these investigations in their proper context a brief review of the general effects of pressure on electronic structure will first be given. The experimental techniques have been covered in detail elsewhere[7–9] and will not be discussed here. There exist reviews[9–13] with extensive references to the literature on high pressure and electronic structure. We list here primarily very recent references, or those not included in the above literature. In general we express energies in electron volts and optical peak locations in cm^{-1} or kilokaysers (one eV per atom $\hat{=}$ 23 kcal per g-atom $\hat{=}$ 8000 cm^{-1} = 8.0 kK).

From our viewpoint the primary effect of compression is to increase overlap of adjacent electronic orbitals. A very general consequence of this increased overlap is the relative shift in energy of one type of orbital with respect to another. Since orbitals of different quantum number differ in radial extent, or in orbital shape (angular momentum) or in compressibility, this *relative shift in energy* is not surprising. Under many circumstances there may be an excited state which lies not too far in energy above the ground state so that the pressure-induced shift may be sufficient to establish a new ground state for the system, or greatly to modify the characteristics of the ground state by change in configurational interaction. This event we call an electronic transition, which may occur discontinuously at a definite pressure or over a range of pressures, and may have a variety of physical and chemical consequences. We discuss first (Section 2) the kinds of shifts in orbital energy which have been observed, and second (Section 3), the variety of electronic transitions. In both cases strong emphasis is on events relevant to transition metal chemistry.

2. Shifts of Energy Levels

The early high-pressure optical measurements concerned themselves in large part with studies of the change in the gap between the top of the valence band and the bottom of the conduction band[9–11], in insulators or semiconductors. For many substances this gap decreases rapidly with increasing pressure leading ultimately to metallic conductivity in such materials as iodine and higher acenes (*e.g.* pentacene). For materials like germanium, gallium arsenide, and zinc sulfide with complex band structure the gap may actually increase at low pressure.

Other studies include the behavior of color centers in alkali halides[9, 11], transitions from the $4f^n$ to the $4f^{n-1}5d$ configuration in rare earth ions[14], excitations among 3d configurations in transition metal ions[9–13], excitations from π to π^* states in aromatic hydrocarbons and related heterocyclic compounds[9, 11] including aromatic ligands in transition metal complexes, and electron donor-acceptor excitations in both molecular complexes and transition metal complexes[9–13]. We discuss in more detail those types of excitations of particular interest to coordination chemistry.

2.1. d-d Excitations

The interesting properties of transition metal ions center around the number and arrangement of electrons in the partially filled d shell. In the free ion the five orbitals are degenerate, and, in accordance with Hund's rule, the electrons are arranged to give maximum multiplicity in the ground state. Excited states with partially or completely paired spins lie higher in energy because of the increased interelectronic repulsion associated with spin pairing. The interelectronic repulsion is most conveniently expressed in terms of the Racah parameters B and C, which we take here to be empirically determined. When the ion is placed in a crystal lattice, or in a complex, the fivefold degeneracy is partially removed, as orbitals of different symmetry are affected differently by the nearest neighbor atoms or ions (the ligands). For instance, in an octahedral complex (six neighbors), the D_{z^2} and $d_{x^2-y^2}$ orbitals of $E_g(\sigma)$ symmetry are increased in energy relative to the d_{xy}, d_{yz}, and d_{xz} orbitals of $T_{2g}(\pi)$ symmetry. This splitting (Δ) is a measure of the field due to the ligands. In molecular orbital language the splitting is between the antibonding E_g orbitals and the essentially nonbonding T_{2g} orbitals.

In most complexes the electrons are still arranged in a high spin configuration because the spin pairing repulsion is larger than the potential energy necessary to occupy the T_{2g} orbitals. If the ligand field Δ is sufficiently large the potential energy effect may more than compensate for the interelectronic repulsion, and a low spin configuration results. In low spin systems the ligands usually have low lying states of π symmetry which are empty and can bond with the metal d_π orbitals. This "back-donation" of metal electrons into ligand orbitals stabilizes the d_π orbitals and so gives the large value of Δ. Thus the 3d electrons tend to be delocalized in low spin complexes. Molecules of lower symmetry such as metalloporphyrins or phthalocyanines may exhibit intermediate spin or mixed spin states.

For high spin complexes the ligand field increases with increasing pressure. A simple point charge model would predict $\Delta \sim R^{-5} \sim \rho^{5/3}$, where R is the metal ion—ligand distance and ρ is the density. Figure 1 compares the measured values of Δ for NiO with the prediction (solid line) from density data.

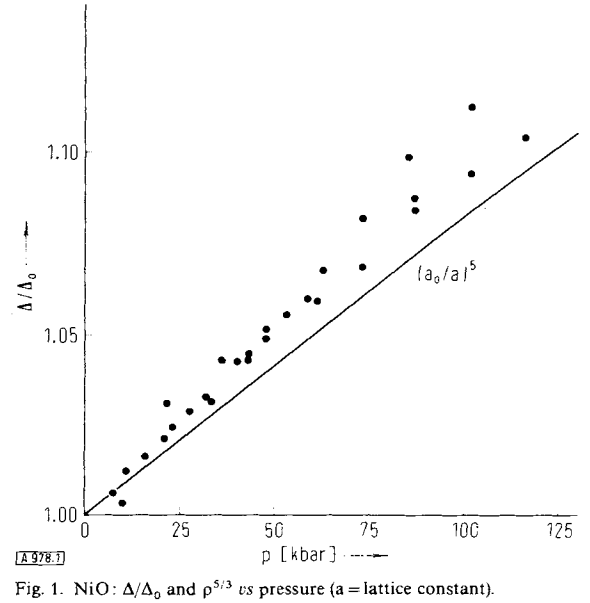

Fig. 1. NiO: Δ/Δ_0 and $\rho^{5/3}$ *vs* pressure (a = lattice constant).

The point charge model is inadequate to calculate Δ even approximately for *any* system, and NiO is far from an ionic crystal so the modest agreement shown may be in large part fortuitous. Measurements on several systems indicate that Δ generally increases somewhat more rapidly with density than the simple model predicts. Figure 2 shows the change in the Racah parameters with pressure for $MnCl_2$ and $MnBr_2$. The decrease shown is typical of most complexes. It is associated with a spreading of the 3d orbitals with pressure and increased shielding of 3d electrons from one another by ligand electrons. The spreading of the 3d orbitals is also reflected in the generally observed decrease of the isomer shift of Fe(II) and Fe(III) ions with pressure (decreased shielding of 3s electrons by 3d electrons) as observed in Mössbauer resonance studies (see Section 3.1).

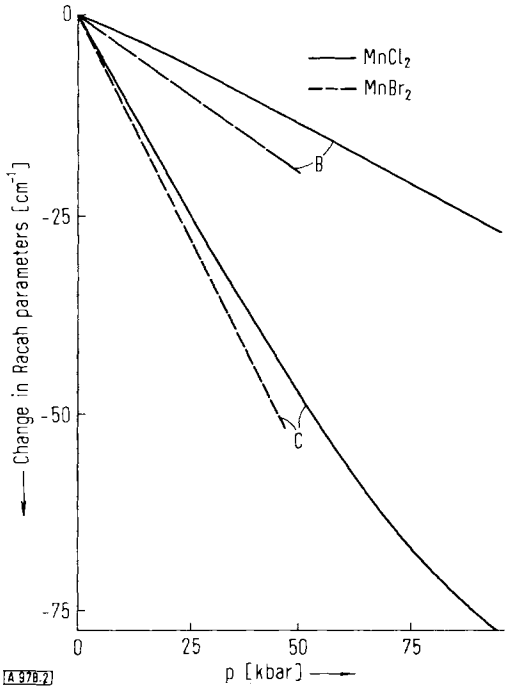

Fig. 2. Change in Racah parameters B and C with pressure for $MnCl_2$ and $MnBr_2$.

2.2. π-π^* Excitations

Aromatic hydrocarbons are characterized by conjugated π orbitals. In the ground state they are nonpolar and not very reactive, especially in solids. There are excited states (π^* states) which have nodes either at or between the carbons. These excited states generally have greater self-complexing ability, are more reactive, and probably involve stronger intermolecular forces than the ground state. The larger the aromatic molecule the smaller the energy of the π-π^* excitation and also the greater the self-complexing ability. These π-π^* excitations decrease in energy by 0.5—1.0 eV per 100 kbars. As discussed later, this implies a higher probability of mixing of π-π^* orbitals and of electron occupation of the π^* orbitals at high pressure.

Heterocyclic aromatic molecules also exhibit π-π^* excitations with very similar characteristics. In Figure 3 we illustrate the shift of a π-π^* excitation in 1,10-phenanthroline. Both the large red shift (to lower energy) and the broadening are typical. These heterocyclic molecules are frequently involved

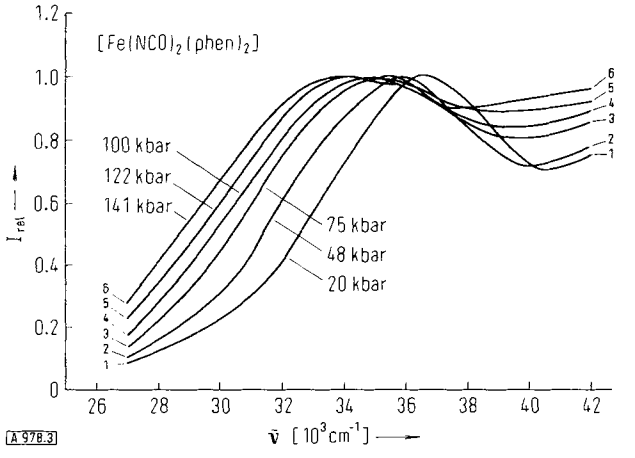

Fig. 3. 1,10-Phenanthroline: π-π^* excitation *vs* pressure.

as ligands in some of the more interesting transition metal complexes.

2.3. Electron Donor-Acceptor Excitations

A wide variety of complexes exhibit relatively intense, broad optical absorption peaks which correspond to electron transfer between two entities of the complex. Molecular electron-donor acceptor complexes have been widely studied[15, 16]. The excitations tend to shift strongly to lower energy with increasing pressure[9, 11]. Similar excitations (ligand to metal or metal to ligand) are frequently observed in transition metal complexes. The halide complexes of the heavy metals (*e.g.* K_2OsBr_6) exhibit a pair of peaks at 16—17 kK and 21—22 kK which *Jørgenson*[17] has assigned to ligand to metal (π-T_{2g}) electron transfer split by spin orbit coupling. As is shown in Figure 4, the center of the peak system shifts to lower energy by some 2.5 kK at 120 kbars, while the spin-orbit splitting increases by $\sim$3.0 kK. A red shift of this magnitude is typical for this type of excitation. Tetrahedral cobalt complexes also exhibit increased spin-orbit splitting at high pressure[10, 11].

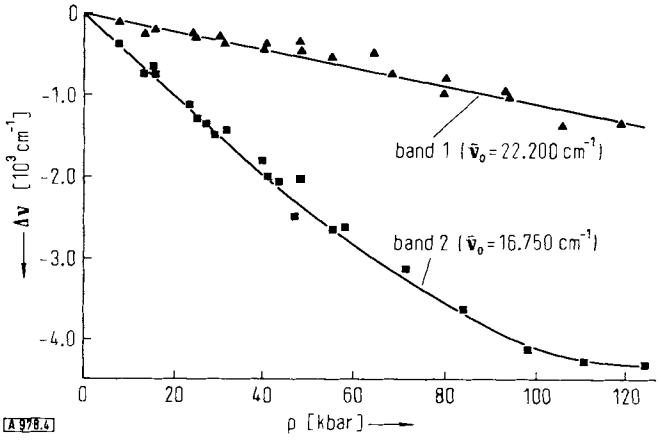

Fig. 4. Location of charge transfer peaks *vs* pressure (K_2OsBr_6).

3. Electronic Transitions

As indicated earlier, the relative shifts in energy levels discussed above can lead to a new ground state for a system, or a ground state whose properties are greatly modified by configuration interaction. Let us first discuss some general characteristics of these electronic transitions, which may occur discontinuously at some definite pressure or over a range of pressures. They may be easily reversible, or may reverse with considerable hysteresis, or may result in a new stable compound. These characteristics are discussed in a detailed study[9, 18] of which we can give only the barest essence here. The various transitions may to a greater or lesser degree be cooperative phenomena. When a site transforms there may be an electrical polarization and/or mechanical strain introduced, which may act either to inhibit or to accelerate the transformation of neighboring sites. The continuous or discontinuous nature of the transformation depends on the sign of the interaction and its magnitude relative to the thermal energy (kT). Hysteresis implies the locking-in of a transformation by interaction among transformed sites.

These transitions involve the thermal transfer of an electron from one type of orbital to another or from one mixture of orbitals to another. Typically, however, we employ optical absorption to measure the shifts in relative energy of the orbitals which ultimately lead to the transition. The energies involved in optical and thermal transfers between the same electronic states differ for a number of reasons. Some of these are illustrated in Figure 5, which is a schematic configuration coordinate diagram. The horizontal axis represents some relative nuclear displacement of the system, while the vertical axis measures energy.

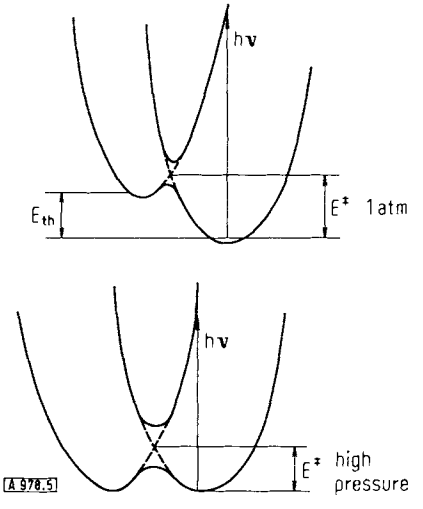

Fig. 5. Schematic configuration coordinate diagram.

Optical processes are represented vertically on such a diagram because they are rapid compared with nuclear displacements (the Franck-Condon principle). Thermal processes are sufficiently slow so that they can occur on a path of minimum energy requirement. This is a major difference, but there are others which can be of comparable magnitude. Configurational interaction, which involves mixing of electronic configurations by partial violation of the Born-Oppenheimer conditions through spin-orbit or other couplings is also illustrated in Figure 5. In solids of the complexity of most of those discussed here there is almost always a vibration suitable enough to mix configurations of any symmetry. A third factor, not illustrated here, is that of selection rules. Optical processes are subject to parity and spin selection rules, while in the time scale typical of thermal processes all selection rules are relaxed.

Finally, Figure 5 is greatly oversimplified in that only one configuration coordinate is illustrated. Actually, the total number of such coordinates equals the number of normal modes of the system. For a thermal process, the pressure selects the volume as its conjugate coordinate, but optical processes may involve other coordinates.

In view of these complications, to what degree can the observed optical shifts be related to the thermal transformations? An analysis has been presented[9, 19] which relates the location of the optical peak (ν_{max}), its half-width ($\delta E_{1/2}$), and the force constants of the ground and excited state potential wells (ω and ω') to the thermal energy (E_{th}). At 25 °C, if the energies are in eV, one obtains:

$$E_{th} = h\nu_{max} - 3.6(\delta E_{1/2})^2 \left(\frac{\omega}{\omega'}\right)^2 \quad (1)$$

This result is based primarily on the Franck-Condon argument. It can be extended to include multiple configuration coordinates, but it is difficult to generalize the magnitude of the effect of configurational interaction. The analysis is approximate and the data to test it are crude; nevertheless, we shall see that useful results are obtained.

It is our purpose here to discuss primarily electronic transitions in transition metal complexes. It is, however, appropriate to outline briefly the other types of electronic transitions which have been observed to place the above in their proper context.

Over 20 years ago *Bridgman*[20] discovered a cusp in electrical resistance and a volume discontinuity in cesium. *Sternheimer*[21] showed that these are associated with a change from s to d character of the conduction band (*i.e.* a 6s→5d transition). About a decade ago a second maximum in the resistance of cesium was observed near 135 kbars. Recent work indicates that hybridization of the empty 4f and atomic 5p orbitals into the conduction band are both involved. Transitions which probably have a similar basis are observed in rubidium at 145 and 300 kbars. A transition in cerium metal near seven kilobars involves promotion of a 4f electron into the 5d shell, or into the conduction band. Resistance anomalies in other rare earth metals at higher pressures may be associated also with 4f→5d transitions. This is consistent with the shift to lower energies of the 4f→5d excitation in divalent rare earth salts which we mentioned earlier. Alkaline earth metals like calcium and strontium exhibit metal to semimetal (or semiconductor) transitions because of changes in the band structure at high pressure.

A variety of insulator-metal transitions have been observed. In molecular crystals like iodine or pentacene the energy gap decreases continuously with pressure, and metallic conductivity appears, with no apparent discontinuity in resistance or structure. Silicon, germanium, and related compounds undergo a first order change in structure which transforms them to metals like tin. Some semiconducting oxides undergo a discontinuous transition without structure change to a metallic state. The work of *McWhan et al.*[22-24] on these compounds has been especially enlightning. In particular these authors have demonstrated the parallelism between change of chemical composition and increase of pressure. *Jayaraman*[25, 26] has shown that samarium chalcogenides transform from semiconductor to metal by promotion of an electron from the 4f orbitals to the conduction band.

Transitions with chemical consequences have been observed in certain aromatic hydrocarbons and their electron donor-acceptor complexes. We have indicated earlier that the π-π^* excitations of these hydrocarbons as well as the D-A excitations of the complexes decrease rapidly in energy with increasing pressure. If the excited state at one atmosphere is not too high in energy, it may be occupied at high pressure with consequent changes in intermolecular interactions including reactivity. It has been observed that pentacene forms a new type of polymer at high pressure[9, 27]. The complexes of perylene ($C_{20}H_{12}$) and pyrene ($C_{16}H_{10}$) with iodine also react[9, 28]. In this case, the iodine does not enter into the product although its presence is necessary to bring the hydrocarbon into a reactive configuration. The product structures have been rather completely elucidated. Perylene forms a new type of layered dimer, while pyrene forms a similar tetramer. These types of reactive electronic transitions may have important implications for solid state organic chemistry.

3.1. Transition Metal Complexes

With this background, we now consider changes of spin state and oxidation state of transition metal complexes. Most of our observations concern complexes of iron. Iron is of interest not only in chemistry and physics but also in biology and geophysics. Further, in addition to optical absorption, we have available Mössbauer resonance spectroscopy to sharpen our identification of the states involved.

We offer only a very brief outline of the principles of Mössbauer resonance here. Under certain circumstances, the energy of a gamma ray emitted by ^{57}Fe in the solid state is a measure of the separation of nuclear energy levels. This separation is perturbed by electronic wave functions. From the measured perturbations information can be inferred about the electronic structure—very much as in the employment of nuclear magnetic resonance. For this study there are two useful types of pertubation. Electronic wave functions which overlap the nucleus (s electrons) affect the energy difference between the ground and excited state (the isomer shift). From our viewpoint, changes in the isomer shift reflect changes in shielding of 3s electrons by 3d electrons. This depends on the number of 3d electrons (oxidation state) and the radial extent and shape of the 3d orbitals (covalency). An electric field gradient at the iron nucleus partially removes the degeneracy of the excited state and gives two peaks in the spectrum instead of one. The electric field gradient may arise from the arrangement of the ligands (a long range, small effect) or from the partially filled 3d shell (a short range, large effect). Because of these perturbations ^{57}Fe in one chemical state is not in resonance with ^{57}Fe in a different state. By moving a radioactive source with respect to an absorber we utilize the Doppler velocity to bring about resonance, and express the perturbation energies in terms of this resonant velocity.

We are concerned here primarily with transformations involving three states; high-spin ferrous, high-spin ferric, and low-spin ferrous. Figure 6 exhibits typical spectra for these states. The high-spin ferrous ion exhibits a large positive isomer shift (IS) (low electron density) because of the six 3d electrons shielding the 3s electrons, and a large quadrupole splitting (QS) because the field of the 3d electrons is not spherically symmetric. The high-spin ferric ions with five 3d electrons

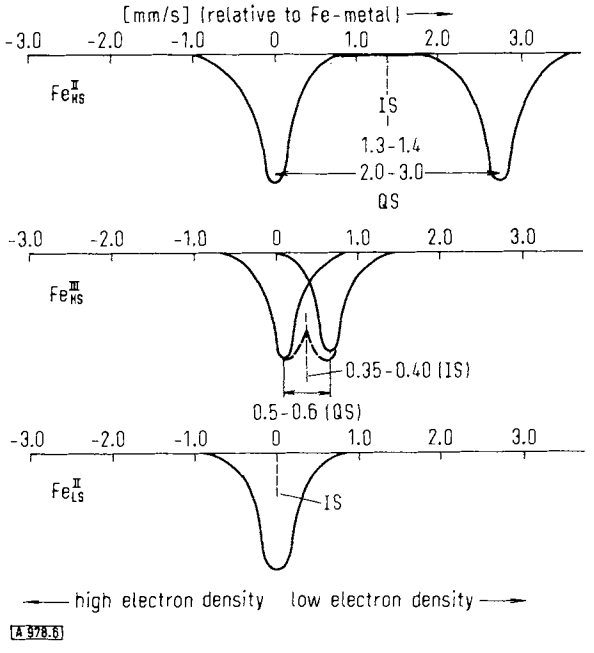

Fig. 6. Characteristic Mössbauer spectra.

has a smaller isomer shift, and, since the field of the 3d shell is spherical, only a small quadrupole splitting. The low-spin ferrous ion has a spherical electric field and thus a small quadrupole splitting. The low value of the isomer shift reflects the delocalization of the 3d electrons by "back donation" as discussed in Section 2.1, and the resultant high electron density at the nucleus. Our discussion will be largely limited to three transitions: 1. Fe^{II}_{HS} (high spin) → Fe^{II}_{LS} (low spin); 2. Fe^{II}_{LS} → Fe^{II}_{HS}; 3. Fe^{III}_{HS} → Fe^{II}_{HS}.

3.1.1. Spin Changes

We consider first the high-spin to low-spin transition. Since, as shown in Section 2.1, the ligand field increases with pressure, one might expect that at some pressure, Δ could become larger than the spin pairing energy. One example is Fe(II) as a dilute substitutional impurity in MnS_2. In the isomorphous FeS_2 (pyrites), iron is low spin at all pressures. Since the lattice parameter of MnS_2 is distinctly larger than that of FeS_2 it is not surprising that iron in MnS_2 is high spin. One can think of the Fe(II) as being under a large negative pressure in MnS_2 relative to its situation in FeS_2. Figure 7 shows the Mössbauer spectra as a function of pressure. At low pressure (up to 40 kbars) one sees only the Fe^{II}_{HS} spectra. At 65 kbars the iron is over 50% converted to low spin. At 138 kbars the conversion is complete. The process is reversible with some hysteresis. This is, then, a transition from a paramagnetic to a diamagnetic ground state.

Let us now consider the transition from Fe^{II}_{LS} to Fe^{II}_{HS} with increasing pressure. We first look at the evidence for this somewhat surprising event. We consider complexes of iron with 1,10-phenanthroline. In tris complexes each of three phenanthrolines complexes through two nitrogens so that the Fe(II) is in an approximately octahedral field of six nitrogens. Because of back donation (see Section 2.1) to the ligands Δ is 2.0—2.5 eV and the iron is low spin. Figure 8 shows Mössbauer spectra as a function of pressure. At low pressure one observes only low spin iron. Above ~40 kbars a measurable amount of Fe^{II}_{HS} appears; and at 140 kbars there is about 30% conversion. Complexes involving substituted phenanthrolines may exhibit up to 60% conversion. The process is reversible, with hysteresis.

Complexes also form with two molecules of phenanthroline and two other ligands. These bis complexes are usually high spin at one atmosphere. At a modest pressure they convert partially or even completely to low spin, but above about 40—50 kbars the amount of high spin again increases[9, 29, 30].

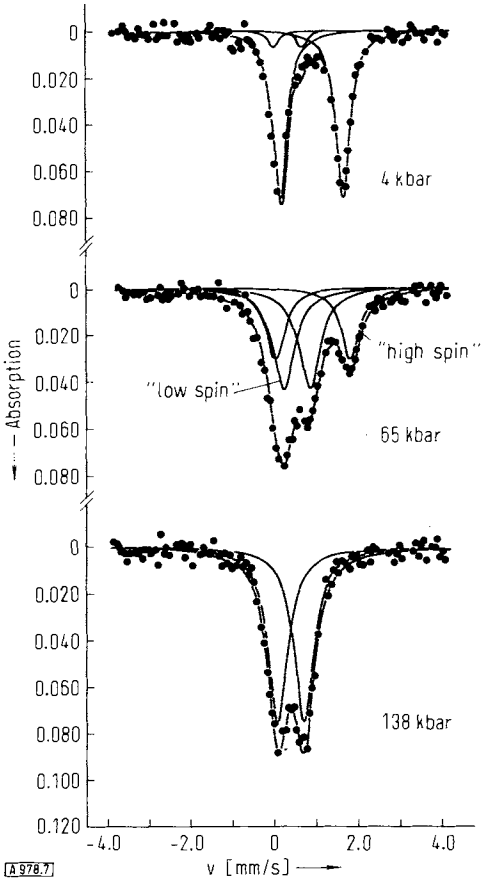

Fig. 7. Mössbauer spectra of Fe^{II} in MnS_2 at 4 kbar, 65 kbar, and 138 kbar.

The LS→HS transition seems paradoxical at first on both thermodynamic and electronic grounds. One must remember that it is the volume of the system *as a whole* which must decrease with increasing conversion at constant *T* and *p*. This volume decrease may involve changes in intermolecular forces as well as bond lengths. It is not, of course, necessary that any particular bond must shorten.

The back donation which provides the large ligand field depends on the availability of the ligand π* orbitals. As already shown (Fig. 3), the π-π* energy difference decreases rapidly with pressure. If there is significant mixing of the π and π* orbitals they will become less available for back donation from the iron. In Table 1 a calculation for phenanthroline is given using Eq. (1). At one atmosphere the π orbital is stable by about 1.35 eV. Above 50 kbars the energy difference is such that there could be considerable thermal π-π* transfer and hybridization inhibiting back donation. The calculation is very crude, but it illustrates that the hypothesis is feasible. This could be called an induced electronic transition, since a transformation on the ligand changes the bonding to the iron and thus its spin state.

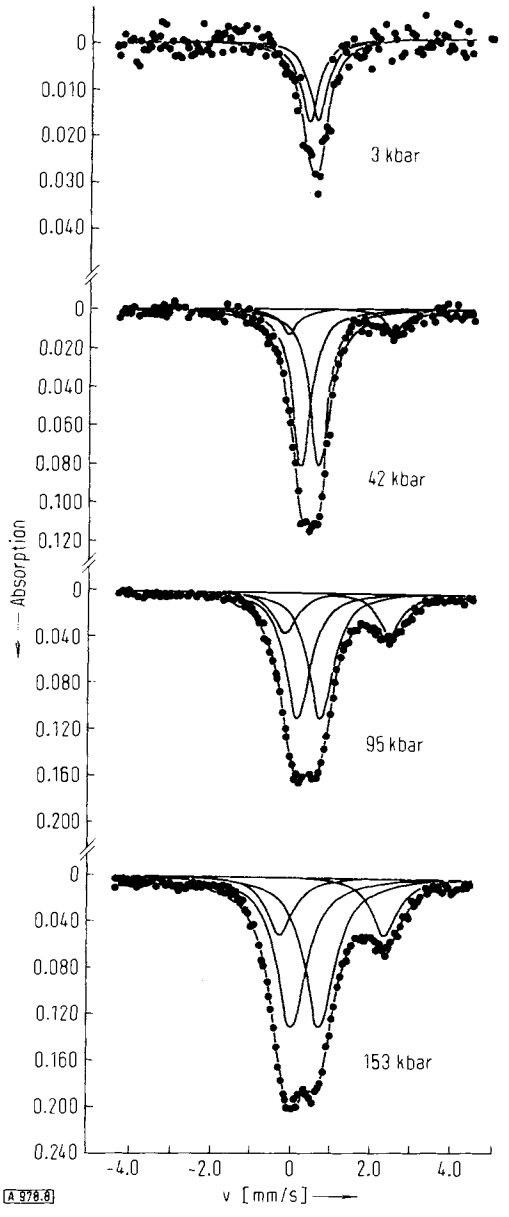

Fig. 8. Mössbauer spectra of Fe^{II} in $Fe(phen)_3Cl_2 \cdot 7H_2O$ at various pressures.

Table 1. Comparison of the energies associated with thermal and optical excitation: π-π^* transition in 1,10-phenanthroline.

p (kbar)	$h\nu_{max}$ [eV]	$\delta E_{1/2}$ [eV]	E_{th} [eV]
0	4.6	0.95	+1.35
50	4.45	1.05	+0.45
100	4.30	1.14	−0.40
150	4.20	1.20	−0.98

One would expect that, at any pressure, the amount of low spin present for a series of related compounds would depend on the size of the ligand field. Δ is difficult to measure directly for these complexes, but it has been shown[31] that there is a good correlation between the Fe^{II}_{LS} isomer shift and Δ; the smaller the isomer shift (*i. e.* the larger the back donation) the larger is Δ. Figure 9 shows the relative amounts of Fe^{II}_{HS} and Fe^{II}_{LS} at 100 kbars for a series of substituted phenanthrolines. It can be seen that the correlation with the isomer shift of Fe^{II}_{LS} is, indeed, very good.

An increase in spin multiplicity with pressure has also been observed in other iron compounds. The ferrocyanides are low spin compounds with relatively large ligand fields. At room temperature they remain low spin to 200 kbars, at least. However, at 100 °C and 150 kbars $Cu_2Fe(CN)_6$ exhibits

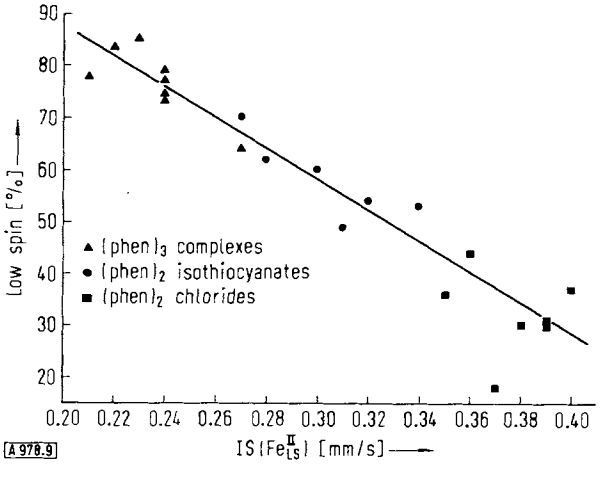

Fig. 9. Percent low spin Fe^{II} *vs* Fe^{II}_{LS} isomer shift in phenanthroline complexes.

65% high spin ferrous ion and $Ni_2Fe(CN)_6 \sim 18$—20%. $Zn_2Fe(CN)_6$, which is isomorphous, shows no conversion. Neither do the sodium nor potassium salts with slightly different structure. At 150 °C and 150 kbars the zinc salt shows ~25% conversion and the sodium and potassium salts only small traces thereof. Apparently cation electrons also interact with the ligand orbitals in these compounds.

One also observes an increase in spin state with pressure in some substituted ferrous phthalocyanines[9, 32]. This planar molecule involves four pyrrole rings bridged by nitrogens with the iron in a site of D_{4h} symmetry. The iron is in an intermediate spin state. When pyridines or picolines are coordinated axially to the iron a low spin Fe(II) (S=O) state results, primarily because of back donation to the nitrogens on the axial ligands. At high pressure a partial conversion of low spin to intermediate spin iron is observed as the back donation is reduced.

3.1.2. Reduction of Fe(III) and Cu(II)

The third electronic transition of interest here is the reduction of Fe^{III}_{HS} to Fe^{II}_{HS} with pressure. Recent studies on Cu(II) are also discussed briefly. Once again Mössbauer spectra are presented as primary evidence. In Figure 10 we show an Fe(III) spectrum at low pressure, the continuing increase in the amount of Fe^{II}_{HS} with pressure, and the reversibility (with hysteresis) upon release of pressure. The reduction takes place by transfer of a ligand electron (probably from a nonbonding orbital) to the metal 3d orbital. The electron and the hole on the ligand probably remain closely associated. There should be a definite relationship between the amount of reduction (*i. e.* the fraction of ferric sites still present) and the area under a ligand-metal charge transfer peak in the optical spectrum. Figure 11 exhibits such a relationship for two hydroxamate-iron complexes (AHA = acetohydroxamic acid, SHA = salicylhydroxamic acid) and a protein (FA = ferrichrome A) which complexes to Fe(III) through three hydroxamate groups. The solid line shows the conversion obtained from Mössbauer measurements while the points represent relative area under the optical absorption peak. The agreement is good.

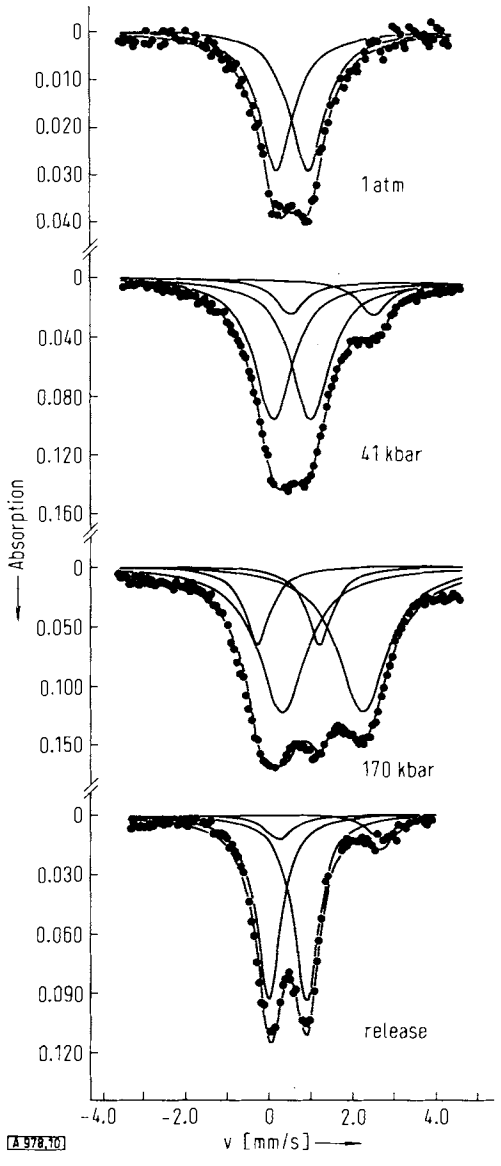

Fig. 10. Mössbauer spectra of tris(2,4-pentanedionato)iron(III) at various pressures.

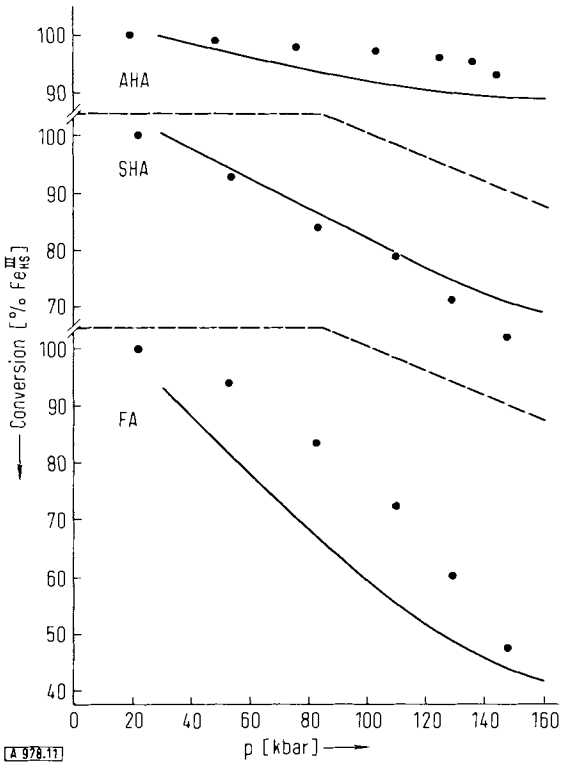
One would expect that, for a series of related compounds, the conversion would correlate with the electron donor abilities of the ligands. One such study involves the chelates of β-diketones shown in Table 2[9, 33]. At one atmosphere one can measure relative donor character of the ligands by such parameters as the acid dissociation constant, the Hammett σ, the appearance potential from mass spectroscopy, or the half wave potential from polarography. These measurements cannot be obtained on the solid under pressure. However, they correlate well with the ferric isomer shift; a lower isomer shift corresponds to better donor ability. With increasing pressure, the ligand nonbonding orbitals approach the metal 3d orbitals in energy, so the reduction, in general, increases with pressure. This tendency will be augmented in those systems where the isomer shift decreases (relative electron donor ability increases) with pressure, and diminished where the isomer shift increases (relative donor ability decreases). Figure 12 shows the change of conversion between 60 and 160 kbars for the series of compounds of Table 2, plotted against the change of isomer shift in this pressure range. The expected relationship applies very well.



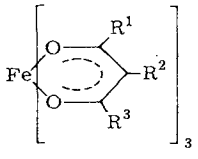


Fig. 11. Comparison of conversion of Fe^{III} to Fe^{II}—from optical (•) and Mössbauer data (—).

Table 2. Tris(β-diketonato)iron(III) complexes.

Ligand	R^1	R^2	R^3
(1)	CH_3	H	CH_3
(2)	C_6H_5	H	C_6H_5
(3)	$C(CH_3)_3$	H	$C(CH_3)_3$
(4)	C_6H_5	H	CH_3
(5)	CF_3	H	CH_3
(6)	CF_3	H	2-Furyl
(7)	CF_3	H	2-Thienyl
(8)	CF_3	H	C_6H_5
(9)	CH_3	CH_3	CH_3
(10)	CH_3	C_6H_5	CH_3
(11)	CH_3	NO_2	CH_3
(12)	CH_3	C_2H_5	CH_3

We can also use Eq. (1) to relate the location and half-width of the charge transfer peak to the reduction of Fe(III). In Table 3 there are shown, for three ferric hydroxamates and the related protein ferrichrome A, the pressure at which 10% reduction occurs, the location and half-width of the charge transfer peak, and the resultant value of E_{th} (assuming $\omega = \omega'$). It can be seen, as one would expect, that within the accuracy of the data and of the analysis $E_{th} \approx 0$.

A recent study[34] on complexes of Cu(II) with organic ligands shows that reduction occurs for these compounds also at high pressure. Cu(II) has nine 3d electrons and Cu(I) has ten. Because of the filled 3d shell, Cu(I) has no d-d excitations. As illustrated in Fig. 13 for $Cu(dtc)_2$ (dtc = diethyldithiocarbamate) the conversion is demonstrated by a decrease in integrated intensity of the Cu(II)-ligand charge transfer peak (b)

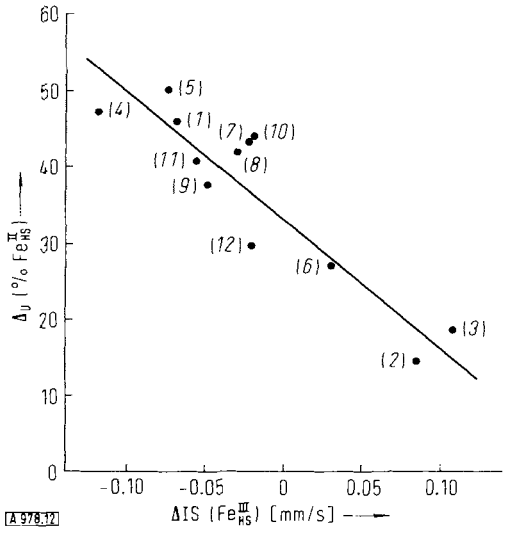

Fig. 12. Change in conversion of Fe^{III} to Fe^{II} *vs* change in isomeric shift between 60—160 kbar.

Table 3. Optical and thermal excitation: Ligand-metal charge transfer in ferric hydroxamates and ferrichrome A (10% reduction of Fe(III).

Ligand	p [kbar]	$h\nu_{max}$ [eV]	$\delta E_{1/2}$ [eV]	E_{th} [eV]
AHA	125	2.80	0.90	0.11
BHA	105	2.70	0.875	−0.06
SHA	70	2.54	0.84	−0.02
FA	37	2.65	0.835	+0.11

and growth of a new peak (c) at lower energy—in a region typical for cuprous charge transfer peaks. Furthermore, the d-d excitation [peak (a)] near 16 kK also decreases in intensity as one would expect.

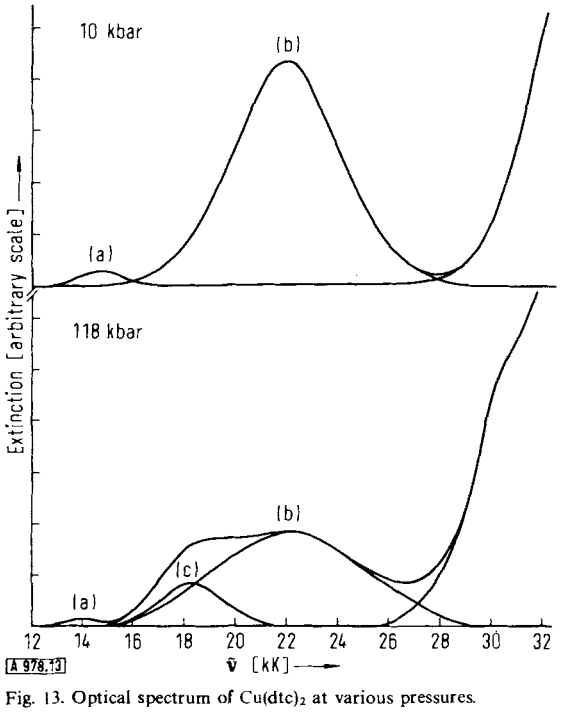

Fig. 13. Optical spectrum of $Cu(dtc)_2$ at various pressures.

The ferric porphyrins have been widely studied as prototypes for hemoglobin, although the applicability is limited by the fact that iron in hemoglobin is apparently in the ferrous state. Porphyrin is a planar molecule with four pyrrole rings connected by methine groups. There are various substituents on the periphery of the pyrroles. In hemin and hematin there is respectively, one Cl^- or one OH^- coordinated axially to the iron which is some 0.5 Å out of the plane of the ring and is high spin. The high spin state would be very improbable with the iron in the plane. In imidazole protoheme two imidazoles are coordinated axially to the iron which is in the plane of the ring and is low spin. Of course, it is something of an oversimplification to speak of definite spin states and oxidation states for iron where the bonding is so complex.

With pressure the ferric ion reduces in all three compounds[9]. At relatively high pressure the ferrous ion produced appears to be in an intermediate spin state in all three cases. For the imidazole protoheme the increase in spin multiplicity is caused by decreased back donation to the imidazoles. For the hemin and hematin the decrease in spin state is apparently associated with the effect of pressure in forcing the iron back into the molecular plane. The large increase in the ferric quadrupole splitting which is observed is consistent with this interpretation.

These reductions illustrate an electronic transition resulting from the shift of energy levels of one member of a complex (the ligand) with respect to those of the other member (the metal).

4. Summary

We have shown that pressure has a very significant effect on the relative energy of electronic orbitals. In a wide variety of circumstances the relative change in energy is sufficient to establish a new, or a greatly modified ground state. These electronic transitions occur in a wide variety of materials; here we have emphasized changes in the coordination chemistry of transition metal ions. It is hoped that this brief outline will amply demonstrate the power of pressure as a tool for investigating electronic structure.

The Variety of Thermal Pericyclic Reactions

By James B. Hendrickson[*]

The six-electron thermal pericyclic reactions are examined systematically as to the number and kind which are possible by varying both the σ shell and the combinations of different atoms in all orientations, on both a six-atom and a five-atom framework. A simple unifying nomenclature is offered for these reactions, which number in the thousands. Further, in order to comprehend this very large number of possible reactions, they are also organized systematically in terms of their value for basic synthesis operations: construction, elimination, refunctionalization, *etc.* The methodology is aimed at providing a basis of selection for the invention of useful new reactions. A discussion of reaction energetics leads also to an analysis of molecular features which can facilitate reaction.

1. Introduction

The common thermal pericyclic reactions[1] are characterized by a cyclic transition state of three pairs of electrons, stabilized by an optimal overlap of all involved orbitals and by the delocalization of six electrons in a cycle. This resonance stabilization of six electrons in a cyclic transition state was early recognized by *Evans*[2], and *Dewar*[3a] has recently discussed pericyclic reactions in terms of the analogy with aromatic systems. Any cycle of $(4n+2)$ delocalized electrons[3b] is the basis for a stabilized aromatic molecule as well as a set of pericyclic reactions, derived formally as shown below by removal of various of the σ bonds in the underlying molecular frame.

The reactions are equilibria and a rough calculation of bond energies usually identifies the more stable molecular species and preferred direction of reaction. As the generalized reaction is nominally unaffected by changes in the involved atoms or by other molecular species present (*e.g.*, reagents, solvents) it is capable of considerable variety as well as synthetic utility. In the latter connection it is often an excellent means of generating carbon-carbon bonds or hindered, sensitive, or otherwise difficultly accessible molecular groups, generally with a high order of stereospecificity. The purpose of this article is to examine the number and form of all the theoretically possible variants of the reaction obtainable by varying the σ-bond shell linking the involved atoms as well as by varying the involved atoms themselves.

2. The Six-Center Model

The problem of molecular permutations may be approached by writing the three shifting electron pairs as alternating bonds around a six-atom cycle and then generating all combinations of 0 to 6 immobile σ bonds (B) linking these atoms. These immobile σ bonds constitute the "shell" or backbone of the reacting species. There are thirteen possible shells, shown in Table 1 with and without the three shifting electron pairs. The shells are defined specifically as σ bonds; in some cases extra π bonds occur, as in Diels-Alder addition to acetylenic dienophiles, but these are involved neither in the skeletal shell nor in the shifting electron set and so are not separated in the definition. The reacting pairs of molecules are all oriented in Table 1 with the more stable form on the right and its energy preference as calculated from bond energies for the all-carbon (C_6) example; with other combinations of atoms, of course, the equilibrium preference may be reversed. In six of the thirteen cases the two forms are identical in the parent example shown.

The variety of shells as well as the variety of atom combinations parallels the variety of polysubstituted benzenes in orientation and the letter notation used here is the same as that recently introduced for polysubstituted benzenes[4]. All the shells except $B=3_L$ possess symmetry: two kinds of two-fold (plane/axis through opposite atoms in $B=2_O$ and 4_U or opposite bonds in $B=1$, 2_M, 3_V, 4_T and 5); four-fold in $B=2_P$ and 4_X; and

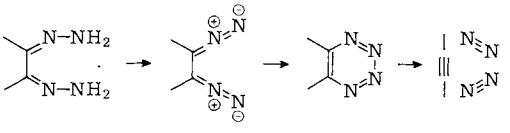
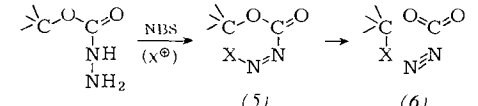
[a] Circled atoms transferred *via* σ-bonds; numbers under structures are calculated equilibrium preferences (kcal/mol) for the C_6 cases.
[b] N, O are generalized for v=3 and v=2 atoms or groups, respectively.
[c] Orientations of hetero-atoms (Z) shown.
[d] In parenthesis for each shell are shown the minimum obligatory valencies for each of the six atoms, listed in clockwise order from a symmetry element (*i.e.*, from an atom # 1).



six-fold in B=0, 3_Δ and 6. The numbers of identifiably different positions on the shells are also entered, clockwise from a symmetry element.

The various shells are also characterized by the mode of reaction in each direction, *i.e.*, by the number of reacting molecules or components and by the number of components formed. Thus *cycloadditions* are characterized by the combined reaction of two (or three) components, *fragmentations* and *rearrangements* by the transformation of one molecule into, respectively, two or more components, or simply a rearranged one; the rearrangements are sigmatropic (B=4_X and 4_U) or electrocyclic (B=5). The full-shell case of B=6 is then the parent aromatic case, the valence-bond description of benzene, or, with other atom combinations, of pyridine, pyrimidine, pyrylium salts, *etc.*

	forward	reverse
Cycloaddition	B=0, 1, 2, 3, 4_T	B=0, 1, 2_O, 2_P
Fragmentation	none	2_M, 3, 4_T
Rearrangement	4_X, 4_U, 5	4_X, 4_U, 5



Each atom position in any shell has an obligatory minimum formal valency (v=1, 2, or 3), indicated by the number of bonds incident to each atom in Table 1. The six required minimum valencies for each shell are listed. The maximum valency of v=3 is found for B=6. For instance, the valency list for B=4_T is 322223. In all cases B≤3 (with the exception of B=3_Δ) and also 4_U there are atoms of minimum valency v=1. These are singly σ-bonded atoms which are transferred from one cyclic atom to another. This *σ-transfer* is of special interest in synthetic chemistry for atoms other than hydrogen. A few cases are known with free carbon groups (not elsewhere cyclically bonded to the skeleton) transferred in this fashion[5, 6], all of them sigmatropic rearrangements, but in most cases of this sort[1] it is hydrogen (v=1) which is transferred.

Heteroatoms or groups of v=2 include O, S, SO, SO_2, and N—R, while those of v=3 are primarily N but may also be P or O^+, and any valency can be represented by an appropriate metal atom or ion. The number of combinations created by placing atoms of v=1, 2, or 3 in the various positions in each shell may now be tabulated. These are shown in Table 1, groups of v=3, 2, and 1 being symbolized respectively as N, O, and H. The orientation of heteroatom placement on the six-atom cycle follows again the same pattern of combinations as do the shells and the polysubstituted benzenes[4]. The notation used is C_5Z=monosubstituted shell; C_4Z_2=two heteroatoms: *ortho* (O), meta (M), *para* (P); C_3Z_3=three heteroatoms: V, L, Δ; *etc.* The maximum number of combinations is found in the B=3_L form since it possesses no symmetry. Table 1 lists only the variations in v=3 and 2 sites (N and O), the v=1 (H) site variations being shown in Table 2. The replacement of more than three carbons by heteroatoms has not been tabulated owing to the increase in possible N_nO_m combinations and the low likelihood of there being viable reactions in many cases with four or five (often vicinal) heteroatoms in the cycle[7]. However, some are known reactions. Thus the oxidation of 1,2-bishydrazones to acetylenes[8] may proceed as *(1)*→*(2)*→*(3)*→*(4)*, the final reaction being B=$3_\Delta(C_2N_4)_O$.

(1) *(2)* *(3)* *(4)*

Similarly, the recently discovered pericyclic refunctionalization of alcohols[9], *(5)*→*(6)*, has the form B=$2_M(C_2N_2OX)$, with only two carbons in the cycle. The example also exhibits σ-transfer of both C and H.

NBS = *N*-bromosuccinimide *(5)* *(6)*

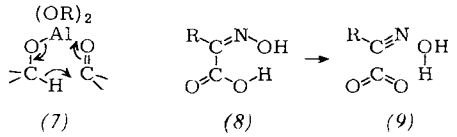
[a] As in Table 1 with hydrogen atoms (v = 1) in all possible locations.
[b] Hetero-atoms (Z) as in Table 1, excluding hydrogens atoms.
[c] Number and orientation of hetero-atoms (other than hydrogen).



The simplest pericyclic reaction, $B=0(H_6)$, appears to be the preferred reaction path for hydrogen scrambling, the high entropy of organizing three hydrogen molecules into a six-electron cyclic transition being offset by the stabilization gained[10].

The combinations with v = 1 sites have been handled separately in Table 2, which shows those shells B > 1 containing v = 1 sites (circled in Table 1) reproduced in their several combinations with H occupying v = 1 sites. The variations possible with v = 2 (O) and v = 3 (N) substitution of the remaining sites are then tabulated under Z_1, Z_2, and Z_3.

The total number of permutations of shells and atoms in the six-atom/six-electron set is not available from a simple formula owing to the varying symmetries of the thirteen shells and the atom combinations, as well as the limitations imposed on valency possibilities by the shells. However, the major collection of C_5Z, C_4Z_2, and C_3Z_3 in Table 1 with the v = 1 possibilities in Table 2 (and the 13 C_6 cases) yields a total of 1683 formally possible reactions: with the nonlisted, presumably much less viable cases (C_2Z_4, CZ_5, *etc.*) the number will easily be over 2000. Furthermore, there are similar galaxies of pericyclic reactions derivable from other sets of $4n+2$ electrons on frames of various numbers of atoms, the five-atom/six-electron set being explored in detail below. Such collections are reminiscent of the varieties of structure available to heterocyclic molecules, and a sensible anthology of known reactions would best be treated in a survey of reactions comparable to the Ring Index[11] for heterocyclic molecular structures.

To facilitate description and comparison of pericyclic reactions, now often buried in obscure and difficultly retrievable literature descriptions, we require a simple categorizing nomenclature based on shell and atom-combination variations. (Simplicity must be emphasized because of the multitude of reactions requiring mutual discrimination.) If the shell is annotated by B, the atom combinations can be simply listed in parentheses as above, the total number of atoms being thereby implicit, *e.g.* $(C_4Z_2)=(C_4N_2)$, (C_4NO), (C_4OH), *etc.* for six-atom cases, $(C_3Z_2)=(C_3O_2)$, (C_3NH), *etc.*, for five-atom cases. The permutations of position for these atoms are most easily handled by subscripting the letter symbol for orientation of any subset of like atoms, either carbons or heteroatoms as a group, as with $(C_4NO)_P$ indicating *para*-orientation of NO or $(C_2N_4)_M \equiv (C_2N_4)_T$ for *meta*-placed carbons, the equivalent of four nitrogens oriented "T". The added subscript for these permutations may be regarded as optional and is anyway unnecessary for C_5Z or CZ_5. This single subscript is simple and offers a valuable subset breakdown for most cases, but it is inadequate to describe fully the complete orientation of atoms either among themselves in complex cases like $(C_3NOH)_L$ or with respect to their orientation on the shell in others. On the other hand a fully sufficient but more complex notation will probably be too unwieldy to learn and use. An initial catalog of known pericyclic reactions culled from the literature is appended to this article, organized on the above format.

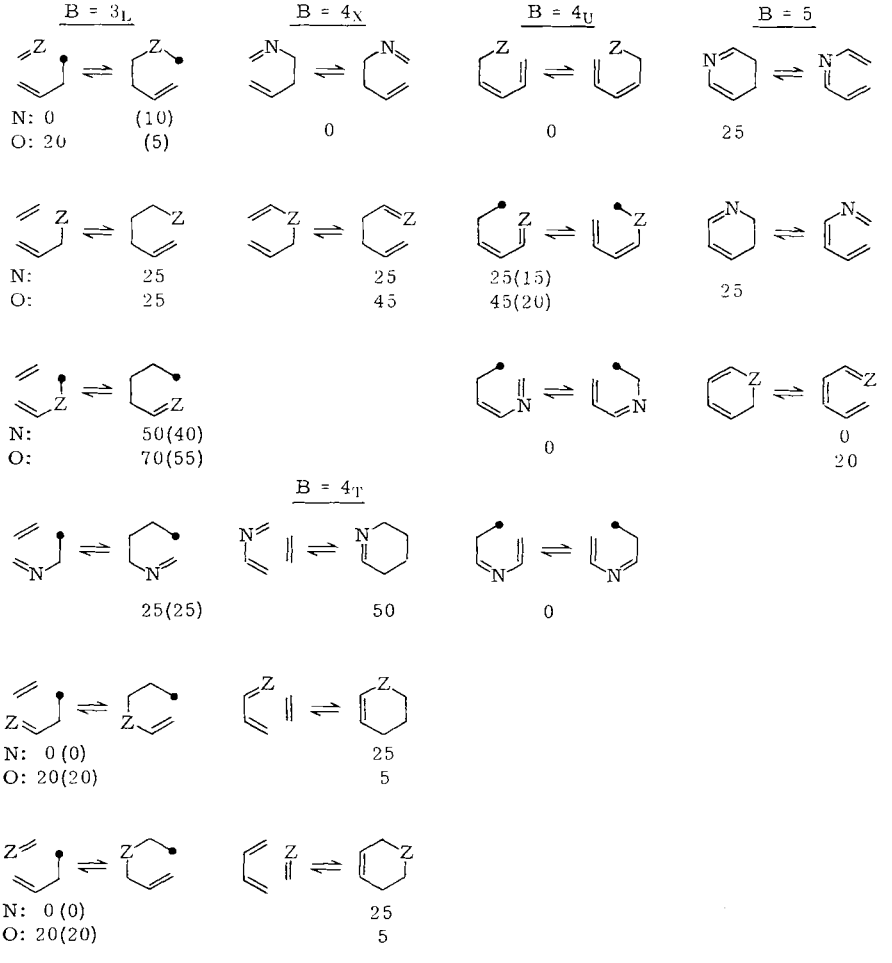
For purposes of focusing only on the unity of the general reaction and its varietal possibilities, we shall ignore considerations of the concerted nature of these reactions required by orbital symmetry conservation[1]; in many cases such mechanistic facts are unknown anyway. If we do this we see that many reactions commonly thought about in other contexts fit into our pattern. Thus, while all-carbon analogs (or C + H) of shells below B = 3 appear to be unknown (unless we accept hydrogen transfer as $B=2_P$ $(C_4H_2)_P$ and catalytic allylic hydrogen exchange as $B=2_O$ $(C_3H_3)_V$, there are a number of cyclic reactions containing heteroatoms that may be included, such as the Meerwein-Ponndorf-Verley reduction and Oppenauer oxidation with $B=2_P$ $(C_2MO_2H)_M$ (cf. *(7)*), or its analogs with other metals, the Cannizzaro and Leuckart reactions, and the thermal fragmentation of α-hydroxyimino acids *(8)*→*(9)*; $B=2_M$ $(C_2NO_2H)_O$) as well as a number of other pyrolytic decarboxylations.

(7) *(8)* *(9)*

The possible variations in the shell of the generalized pericyclic reaction are large but finite. The present tabulation allows

the possible reactions to be encompassed and examined in detail with a view to discovering new reactions of potential utility and observing the scope of others not fully explored. The main reactions with some precedent to date are largely those with fuller shells ($B \geq 3$) and chiefly carbon skeletons (or C + H), in particular $B = 3_L$, 4_X, 4_T, 4_U, and 5.

An approximate calculation of the energy difference between two partners may be made to ascertain the preferred direction of reaction. This is quickly accomplished as the difference between the bond energies of the three bonds made and the three broken. Approximate bond energy values are given in Table 3 in the form most useful for this purpose, with the "π" column indicating the net energy change on going from triple to double or double to single bond, and the "σ" column the energy of single bonds. Except for halogens, bond energies generally vary with chemical environment and so the averages shown are rounded off for easier calculation, but equilibrium preferences under about 20 kcal/mol must be regarded as suspect[12].



The monosubstituted (C_5Z) examples of these five classes are collected in Scheme 1, 29 combinations on 18 skeletons with substituted $v = 2$ sites labeled as Z(= N or O) and $v = 3$ sites labeled as N. The sites marked with heavy dots represent $v = 1$ sites (in 4_U and 3_L) and may be separately regarded as occupied by C or, more likely, by H. The calculated energy preferences are shown below the more stable form, labeled for Z = N or O. In cases with $v = 1$ sites the first number shown is that for the case of the transferred atom as carbon; the number in parenthesis is the energy preference if the transferred atom is hydrogen instead of carbon.

Table 3. Approximate bond energy changes [kcal/mol] [12].

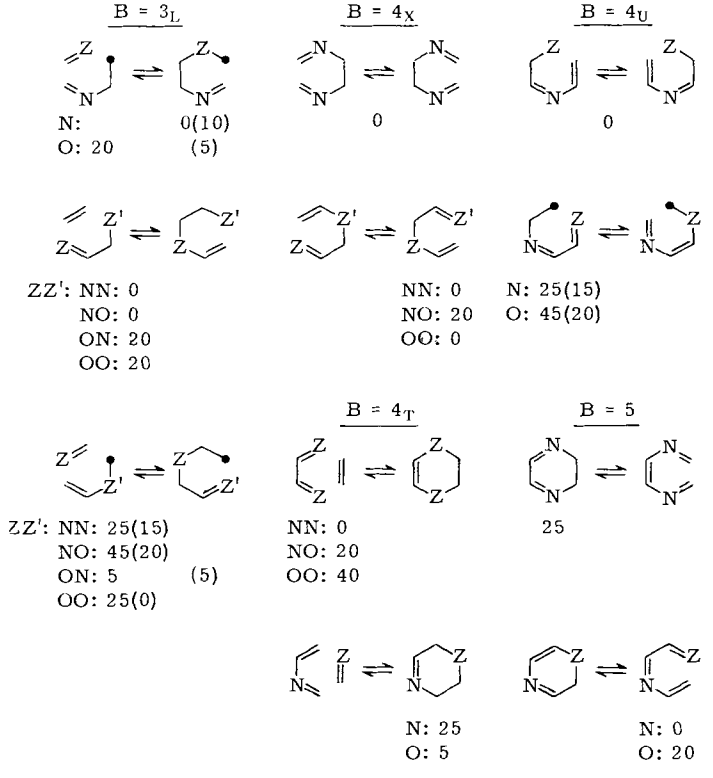
[d] Approximate strain release.

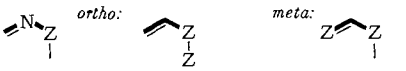
There are few authentic examples of known thermal reactions[13] from these 29 combinations (42 combinations with transfer atom as H as well as C). The most studied is the

Scheme 1. Combinations of C_5Z in higher shells. Calculated energy preferences [12] shown under favored form in kcal/mol (Z = N or O). Heavy dot = σ-transfer atom: first listed energy for C, in parenthesis for H.



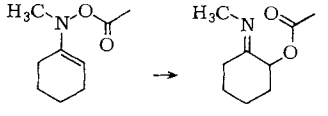
Claisen rearrangement[14], $B=4_X$ (C_5O). In this case as in many others the clear thermodynamic preference apparently derives mainly from the energy released on formation of the carbonyl group. An example of the other $B=4_X$ reaction (C_5N) is known[17] in which the starting imine is incorporated in an isocyanate and the driving force is provided by opening a cyclopropane (*(10)→(11)*). The reaction may be capable of further extension in other instances in which its potential synthetic utility in forming a C—C bond could be exploited.

(10) *(11)*



Cases of "hetero-substituted" [4+2] cycloadditions ($B=4_T$) have been systematically reviewed[15]; only the first of the three cases tabulated (Scheme 1) appears to be without reported examples. The cracking of enol and ynol ethers[18] exemplifies the fifth case of $B=3_L$ and a complex example of the second $B=5$ skeleton has been reported[19] in which the starting imine is again an isocyanate.

The much larger group of C_4Z_2 examples needs more reorganization to appreciate easily. The numbers of atom combinations for shells $B=3_L$, 4_X, 4_T, 4_U, and 5 total 121. The number of *para*-oriented heteroatom cases is the least (26 cases on 11 σ-skeletons) and is fully tabulated in Scheme 2. Again the number of known cases is relatively few.

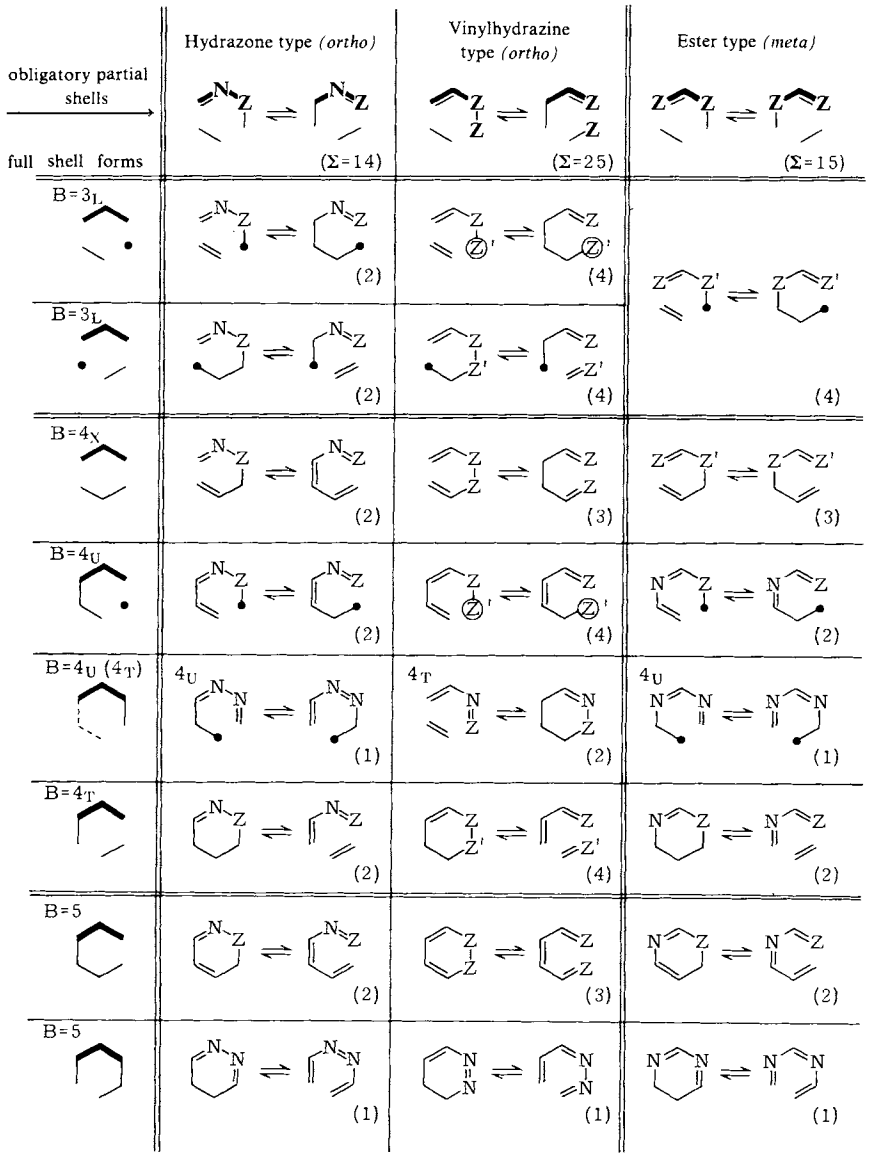


Scheme 2. Combinations of *para*-C_4Z_2 in higher shells (cf. Scheme 1).

The *ortho*- and *meta*-oriented heteroatom examples are greater (49 *ortho* and 46 *meta*) but a perusal of these shows certain cases to be more interesting, in part because the precursors are more easily created. These cases include as *ortho* examples hydrazones, oximes and their enolized tautomers, and as *meta* examples the set of Z=C—Z compounds, *i.e.* the family of carboxylic acid derivatives. The selected cases are all characterized by exhibiting an obligatory partial shell of two adjacent *(ortho)* bonds, as shown below.

hydrazones oximes — vinylhydrazines and -hydroxylamines — esters etc.

This limitation selects 16 of the 19 *ortho* σ-skeletons, leaving out saturated hydrazines (two cases of $B=3_L$) and the three Diels-Alder reactions with Z=Z dienophiles ($B=4_T$). The latter are well documented[15] in the cases of oxygen, azo compounds such as azodicarboxylic acid derivatives, and nitroso compounds acting as dienophiles. Of the 18 *meta* skeletons only 7 are included, *i.e.*, those in which the shell itself links the two *meta* heteroatoms. This omits mainly cases of acetals (and their nitrogen analogs), Z—C—Z, in either reactant species. This selection of 7 *meta* and 16 *ortho* skeletons, while somewhat arbitrary, apparently includes virtually all the known examples (except the cycloadditions noted above for Z=Z). Scheme 3 illustrates the 54 cases thus selected from the 95 *ortho*- and *meta*-heteroatom examples. The calculated energy preferences are tabulated separately in a parallel Scheme 3A. Recognizable as known reactions are the strongly preferred $B=4_X$ vinylhydrazines, variants of the Cope rearrangement, which include the Fischer indole synthesis $(C_4N_2)_O$ and the $(C_4NO)_O$ analogs reviewed by *Hill et al.*[20]; another example is the α-acetoxylation of ketones, *((12)→(13))*[21].



(12) *(13)*

Other examples are the family of ester pyrolysis elimiminations (Scheme 3, ester type; $B=3_L$ $(C_3O_2H)_L$, $(C_3OSH)_L$, $(C_3NOH)_L$, *etc.*). Of these, imino ether pyrolysis would appear to be the most promising of the four eliminations. The ester types also include allylic rearrangements ($B=4_X$).

The "ene reaction" ($B=3_L(C_5H)$) shows an equilibrium preference for the cycloaddition direction, but the reverse fragmentation proceeds with facility at room temperature in the second vinylhydrazine case in Scheme 3 ($B=3_L$ $(C_3NOH)_L$[22]). As calculated, the reaction direction is reversed here, largely because of cleavage of the weak N—O bond.

3. The Five-Center Model

The basic definition of the common thermal pericyclic reaction requires three pairs of electrons in a cyclic transition, but not necessarily six atoms. Hence rings with numbers of atoms other than six may be considered for the cycle, as they are considered for parent aromatics. The most common parent aromatic is the five-atom frame, exemplified in cyclopentadienyl anion, pyrrole, furan, thiazoles, imidazole, tetrazole, *etc.* The seven-atom frame is the six-electron aromatic, tropylium ion, from which a set of seven-atom/six-electron pericyclic reactions can be generated with fewer σ bonds in the shell.

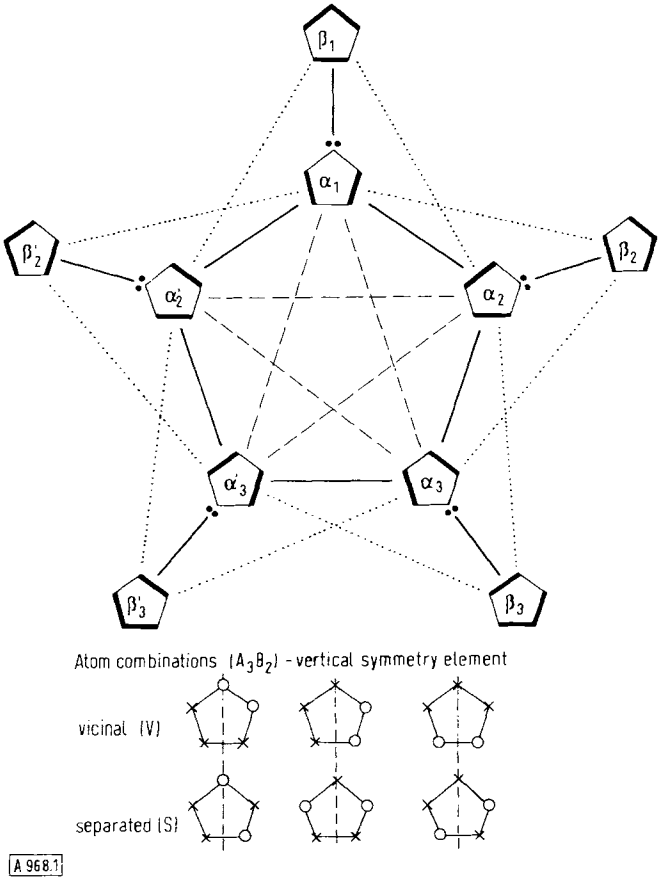
[a] Equilibrium preference is as written (to the right) for positive values, to the left for negative [12]. Energies in parenthesis are for σ-transfer of H.

Similarly, four-atom/six-electron aromatics may be conceived, along with a galaxy of related pericyclic reactions. The seven-atom frame suffers more in entropy considerations for cycloaddition variations and is not treated here, while the four-atom frame suffers from bond-angle constraints and is also not explored.

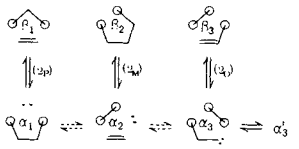


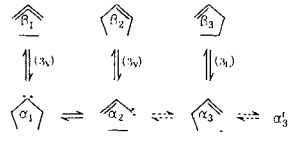
The five-atom, or pentagonal, cases may be constructed from the six-atom (hexagonal) cases above by replacing two atoms linked with a shifting bond with one atom bearing an unshared pair to be involved in the transition. This creates a basic set of a cycle of five atoms containing two bonds and an unshared pair, as in the full-shell (B=5) exemplar of aromatic resonance, cyclopentadienyl anion *(14)* and its hetero-substituted analogs, the 33 possible five-membered neutral heterocyclic aromatics (with N, O, S; O and S count as v=3 in Table 4 since some forms involve $=O^{\oplus}-$ and $=S^{\oplus}-$).

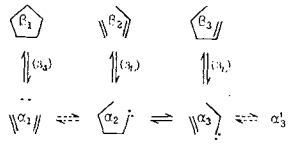
(14)

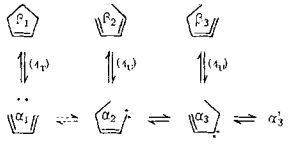
The symmetry of the basic electron set is lower—one symmetry element (plane or axis) rather than three. Accordingly there are five forms (instead of two) through which the six shifting electrons pass to return to a starting orientation, the symmetry element rotating through $2\pi/5$ with each shift. These are shown, as the inner ring of five forms labeled α, in Figure 1. Each one of the α-forms may also shift to a corresponding β-form, with three bonds and the same symmetry element, as shown. The β-forms correspond to the second species in a six-atom shift with two atoms formally replaced by one as noted above. The α⇌β equilibrium is also a six-electron pericyclic shift and involves a valency change at the one atom bearing the unshared pair in the α-form. The α→β reaction is formally an oxidation (Δv = +1), and β→α a reduction[23]. The dotted paths in Figure 1 denote two- or four-electrons shifts, not involving the full cycle of six electrons, and commonly represent formal resonance forms (those inside the α-form circuit are four-electron shifts, *e.g.*, allylic resonance; those outside are two-electron changes).

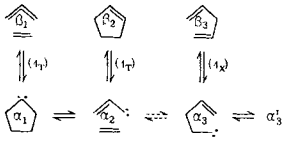
We may now construct the (eight) possible immobile shells of σ bonds among the five cyclic atoms, as before. Again the orientations mirror those of five-ring substituent patterns, there being two orientations each for the B=2 and 3 shells and these orientations are of course complementary. The two orientations are labeled *vicinal* (V)—corresponding to $B=2_O$ or 3_V in the six-rings—and *separated* (S). Hence the eight shell combinations are B=0, 1, 2_V, 2_S, 3_V, 3_S, 4, and 5. All of these shells have one symmetry element and only B=0 and 5, with full fivefold symmetry, have more. In superimposing

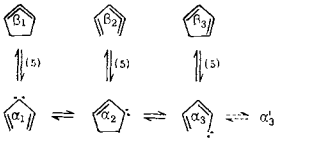


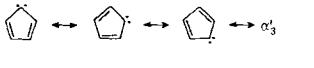












A 968.1

Fig. 1. Transformation pathways among five-ring forms.

the shells on the shifting electron net we obtain for each case (except B=0 and 5) only three identifiably different ring positions and only six of the ten forms of Figure 1 remaining unique. These pentagonal shells (with vertical symmetry elements) are presented with the six equilibrating forms for each in Table 4, following the format of Table 1 for hexagonal shells. The list of valencies for each is a clockwise reading of v_i from the top atom on the symmetry element of the shell and is the list for the α-forms only, as the β-forms each have one atom of higher valency.

On the α⇌β arrows are noted in parentheses the corresponding form in the hexagonal series derived by formal replacement of the atom with the unshared electron pair in the pentagonal α-form with two atoms linked by a double bond in the hexagonal frame; the same atom in the pentagonal β-form is hence replaced by two atoms linked by a single bond in order to become the corresponding hexagonal reaction partner. In this formal correspondence the pentagonal B=5 corresponds to the hexagonal B=6, *i.e.* aromatic resonance. Furthermore, certain inter-α transformations are shown with dashed equilibria, which is to imply that that reaction is

Table 4. Combinations of five-center thermal pericyclic reactions ($\alpha \rightleftharpoons \alpha'$).

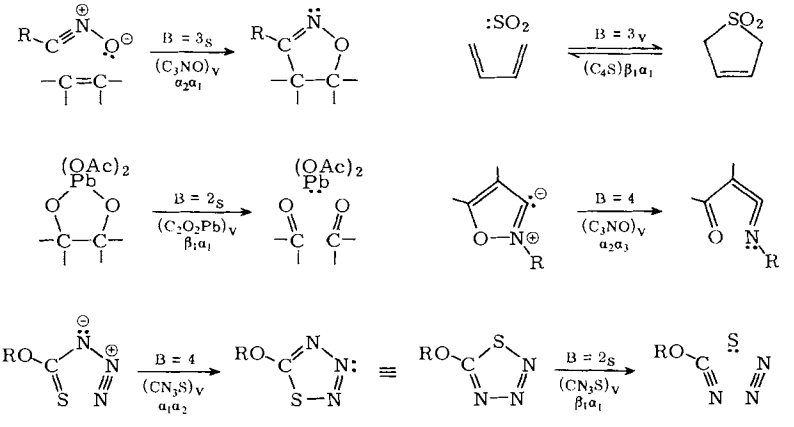
[a] Circled atoms transferred *via* σ-bonds; minimum obligatory valencies in parentheses (cf. Table 1); numbering starts from the top center atom on the vertical symmetry element.

[b] N, O are generalized for v=3 and v=2 atoms, respectively.

[c] Orientation of the hetero-atom Z is shown.



equally viable for the six electrons in a linear fashion, *i.e.*, does not require a cyclic transition state[24]. This occurs in any shift in which the atom bearing the unshared pair in one partner is not linked by a shell bond to that containing the pair in the other partner. By contrast, all $\alpha \rightleftharpoons \beta$ shifts have obligatory cyclic transitions. This may be illustrated by observing a possible six-electron cyclic mechanism for the reaction of zinc with *cis*-dibromides yielding the corresponding olefin as an example of B=1 ($C_2X_2Zn/\alpha_1\beta_1$)[26], *(15)*, and comparing it with the linear *trans*-elimination mechanism of the otherwise analogous iodide-initiated elimination, *(16)*, which is a *trans*, non-cyclic version of B=1 ($C_2X_3/\alpha_1\alpha_2$).

(15) (16)

In substituting different atoms into the pentagonal shells we note first the valency change at one atom ($\Delta v = \pm 1$) in the $\alpha \rightleftharpoons \beta$ interconversions, which lays restrictions on the kinds of groupings acceptable at those atoms. The major such groupings are listed for the three different valency conditions in Table 5. Owing to the greater number (six) of possible interconversions in the pentagonal shells and the valency change limitations at one site for the $\alpha \rightleftharpoons \beta$ interconversions, a tabulation of atom or group combinations on each shell is less clearly constructed. In most cases a given heteroatom-substituted shell will not be capable of most of the six equilibria; indeed in many cases only one will be viable. The table of N/O atom combinations (+C) is presented as before, nevertheless, and derived for the valencies of the α-forms (Table 4). A second table (Table 6) is presented for combinations with one atom present (Q) capable of the $\alpha \rightleftharpoons \beta$ valency change; it may occupy any of three sites on any shell (excluding B=0 and 5), and the site it occupies dictates which of the three $\alpha \rightleftharpoons \beta$ transformations is viable for that species. Hence Table 6 is organized to show C_3QZ (Z=N or O), C_2QZ_2, and C_1QZ_3 for each position of Q (note that there are three C_4Q species also for each shell). The atoms Q are those of Table 5, undistinguished here as to valency since the same atoms tend to appear in all three valency lists in Table 5.

In general it may be observed, in simplification of Table 6, that each box for one shell with Q in one position tabulates the successive restrictions in variety as oxygens are substituted owing to the number of v=3 sites which it may not occupy. The first line, for nitrogens only, shows the substitution at any position by nitrogens and hence the maximum variety of single atom substitution. As the first column of boxes represents a form with symmetry, the numbers are smaller and are always $C_3QN=2$, $C_2QN_2=4$, $CQN_3=2$ or 8 ways to substitute nitrogens while the two asymmetric placements of Q are greater (and alike) as $C_3QN=4$, $C_2QN_2=6$, $CQN_3=4$, or 14 ways in each to substitute nitrogens. The totals are placed in parenthesis for each box. Since oxygen may occupy either v=1 or 2 sites, some shells show the same number of combinations, *e.g.* B=1 and B=2S, but in general, as the shells become larger (thus increasingly excluding oxygen), the number of combinations decreases, as in the hexagonal series above.

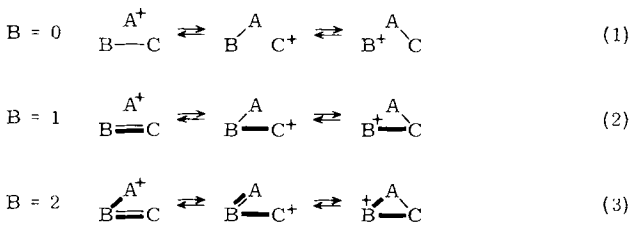
Note: * denotes thermodynamically preferred partner.

Common examples of these various pentagonal frame pericyclics will include those in Scheme 4. Only one of the many examples of 1,3-dipolar cycloaddition[27] is illustrated for $B=3_S$ while the cycloaddition of sulfur dioxide to dienes[28] ($B=3_V$) is also known in reverse as the analogous fragmentation of CO from bridged olefinic ketones[29]. Lead tetraacetate (and periodate) cleavage of glycols, amino alcohols, *etc.*, is shown for $B=2_S$, and B=4 is illustrated by *Woodward*'s isoxazolium reagent[30]. In each case the frame is oriented with the shell symmetrically placed on a vertical axis as in Tables 4 and 6. The two consecutive reactions of thioacyl azides included are especially noteworthy illustrations of the possible variations[31].

4. Other Pericyclic Systems



The simplest formal set of pericyclic reactions is that based on the $(4n+2=2)$-electron aromatic, cyclopropenium ion, *i.e.*, a two-electron/three-atom system for which the full shell is B=3, the aromatic cation itself. The shells are characterized

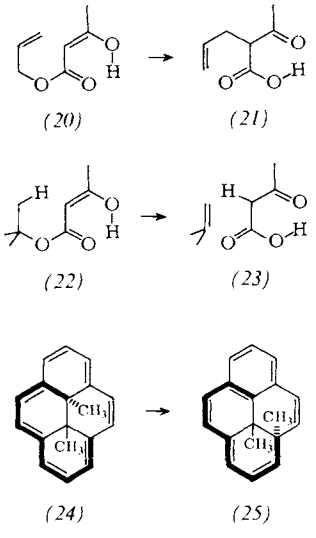
by three forms, with the charge on each atom by analogy with the five-atom cases above, and the lower shells are shown in equations (1) to (3). The B=1 shell includes olefin protonation and the Wagner-Meerwein rearrangements while B=2 characterizes cyclopropyl tosylate solvolysis[32].

Much more complex sets can in principle be generated from the ten-electron aromatics. Here there can be in the potential pericyclic reactions not only the many shell combinations up to B=10 having all shell bonds on the periphery with the shifting electrons, but also combination with shell bonds

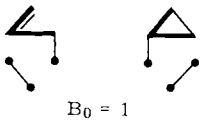


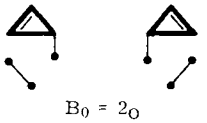
crossing the outer electron periphery as they do in naphthalene *(17)* and azulene *(18)*.

(17) *(18)* *(19)*

Examples appear to be available in the rearrangement of allyl acetoacetates (*(20)*→*(21)*) or pyrolytic elimination of tertiary acetoacetate esters (*(22)*→*(23)*)[33] with shells B=6 and B=5, respectively, including in each case the crossing or bridging shell bond of naphthalene. A sigmatropic rearrangement (σ-transfer of carbon) has been reported[5] (*(24)*→*(25)*, B=8 (C_{10})).

(20) *(21)*





(22) *(23)*

(24) *(25)*

Furthermore, the ten-electron pericyclics do not require a frame of ten atoms as in these cases, since the aromatic indenyl anion *(19)* provides a basis for a nine-atom set in the six-electron series.

The presence of shell σ bonds across the mobile-electron periphery in naphthalene and the related ten-electron pericyclics serves to introduce the question of such bonds in the more familiar six-electron cases. A cross-bond can be laid on a hexagonal frame either to form a triangle (*meta*-connected) or a quadrangle (*para*-connected). Because of severe bond distortion in the latter skeleton its analysis is left out here. The *meta*-connected cross-bonds can be incorporated into three partial shells defining the three-membered ring part of the frame, shown in Scheme 5 labeled with the notation of the partial standard peripheral shell required. The first is a set of cases incorporating a simple 1,2-shift into the pericyclic transition; the second is an interconversion of allyl and cyclopropyl skeletons; and the third can be discarded from practical consideration as an allylic rearrangement within a cyclopropene.

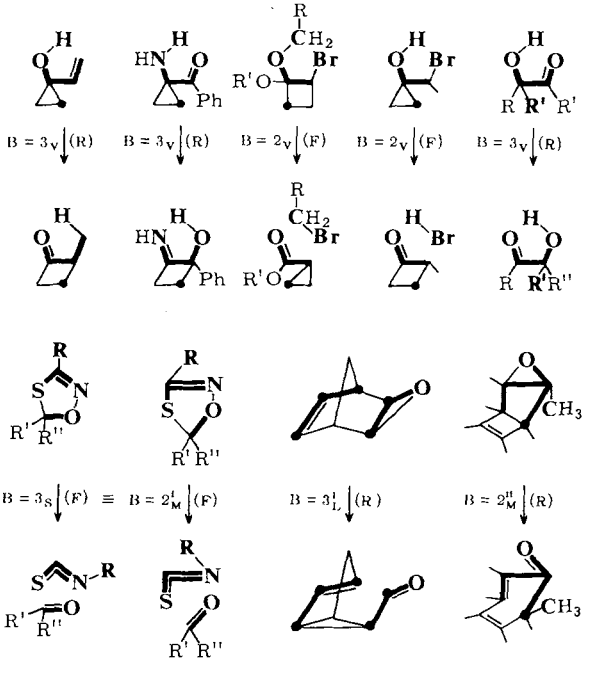
The number of unique ways in which a *meta*-connected cross-bond can be attached to each of the thirteen standard peripheral shells equals the number of unique sites on that shell marked in Table 1. These fall into the three partial shell sets as enumerated in Scheme 5 beside each set. The first set (rearrangement of A) is more clearly seen and easily enumerated as a pentagonal frame with the rearranging group, A, understood as bonded to the unshared electron pair which shifts to the adjacent site (Fig. 1, α⇌α'). The example shown in Scheme 6 is the simplest rearrangement frame and corresponds to the $\alpha'_3 \rightleftharpoons \alpha_3$ reaction for B=1 and is identical with a cross-bond on a B=0 hexagonal frame. The ten rearrangements corresponding to the ten cross-bond shells of Scheme 5 are listed in Scheme 6 with the shells symmetrically placed as in Table 4. This allows the use of Table 4 to enumerate the atom combinations for these ten rearrangement shells, *i. e.*, 486 possibilities for each one[34]. Alternatively, the ten shells can be constructed from $B_O=1$ by leaving the bond across which group A migrates in its symmetrical placement as shown in Scheme 6 and subsequently adding all possible shell combinations to it so that the $\alpha'_3 \rightleftharpoons \alpha_3$ migration is maintained in all; this presentation was used for the examples in Scheme 7.

Scheme 6. Rearrangements in a five-center model.

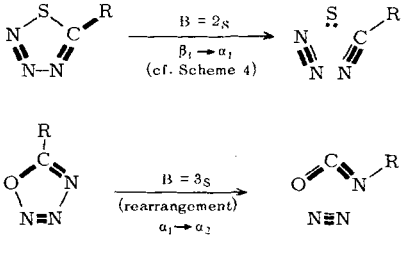
Pentagonal shell [a]	Corresponding hexagonal shell [b]	Reaction model [c]
B=1 ($\alpha_3 \rightleftharpoons \alpha'_3$)	B=0	CF
B=2_V ($\alpha_1 \rightleftharpoons \alpha_2$)	B=1	F/C
B=2_S ($\alpha_2 \rightleftharpoons \alpha_3$)	B=1	F/C
B=3_V ($\alpha_2 \rightleftharpoons \alpha_3 \rightleftharpoons \alpha'_3$)	B=2_P; 2_O	R
B=3_S ($\alpha_1 \rightleftharpoons \alpha_2$)	B=2_M	F/C
($\alpha_3 \rightleftharpoons \alpha'_3$)	B=2_O	R
B=4 ($\alpha_1 \rightleftharpoons \alpha_2 \rightleftharpoons \alpha_3$)	B=3_L; 3_V	R
B=5 ($\alpha_1 \rightleftharpoons \alpha_2$)	B=4_U	R
 B=1 ($\alpha'_3 \rightleftharpoons \alpha_3$)		



[a] Shells symmetrically placed on vertical symmetry element (as in Table 4).

[b] Six-center shell plus cross-bond: ten cases are enumerated in Scheme 5.

[c] C=cycloaddition; F=fragmentation; R=rearrangement; both forward and reverse modes are shown.



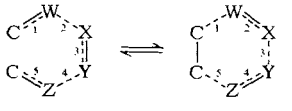
Enumeration of the atom combinations for the allyl-cyclopropyl shift set is not so easy. Translation from the hexagonal frame to the pentagonal frame necessitates a requisite shell bond out from the pentagonal frame to the sixth atom (in the three-membered ring), and this places further limitations on the possible atoms to which the sixth atom is attached, but multiplies the result by the three atoms (C, N, and O) which may be used in that sixth atom position. In any case these shells are more easily apprehended on the hexagonal frame of Scheme 5 and the 16 shells could be enumerated separately as in Tables 1 and 2, yielding lower totals because of the increased minimum obligatory valencies at the two ends of the cross-bond.

Examples of both sets are known, and they exhibit cycloaddition, fragmentation, and rearrangement modes (illustrated in Scheme 7). The first row in Scheme 7 consists of several parallel rearrangements discussed by *Conia et al.*[35]; the acyl-

Scheme 7. Examples of pericyclic reactions with cross-bonded shells.

oin rearrangement[36] is included as a possible parallel. In the second row is a fragmentation[37] written on both pentagonal and hexagonal frames as well as two three-ring openings (cyclopropyl-allyl type) with crossed bonds[38]. The second of these actually has two crossed bonds, one of each type. Equation (4) draws a parallel between the behavior of thioacyl azides[31] and acyl azides. If the latter initially rearrange on heating like the former, there is a basis for a rearrangement with fragmentation which constitutes a different possible view of the mechanism of the Curtius (and analogously, the Wolff) rearrangement as a pericyclic reaction, taking a different course

(4)



from that of the thioacyl case since sulfur can act as a "Q" atom with valency change while oxygen cannot.

5. Pericyclic Reactions in Synthesis

The very large number of formal possibilities for pericyclic reactions creates a need for imposition of a system of organization oriented to their value and potential success as useful chemical reactions. We may impose such a system based on the kinds of transformations important to synthesis. There are three such reaction families which alter skeletal carbons in synthesis, the first changing function (hetero-atom) attachments at a carbon, the other two forming (or cleaving) σ- and π-bonds, respectively, between carbons[39]:

Refunctionalization:	Y C—Z ⇌ Y—C Z
Construction/cleavage:	C C ⇌ C—C
Elimination/addition:	C—C ⇌ C=C

Each of these may be laid on the generalized six-electron shell (of five or six atoms) in the pericyclic reaction and will partially define and limit the possible combinations of shells and atoms in the set. This is illustrated by the synthetically most important construction (and reverse cleavage) reaction in equation (5) for the six-atom set, in which only five shell bonds (1—5) and four atoms (W, X, Y, Z) now remain to be defined. The elimination/addition family may be created from this set by inclusion of a single obligatory shell bond between the two carbons; this may be notated as the *minimal obligatory shell*, $B_O = 1$. Similarly, refunctionalizations are a set derived by replacing the lower carbon with a heteroatom and defining $W \neq C$.

(5)

Taking the construction set as an initial basis for exploration (which may then be adapted to the other two), we may further limit the set of possible combinations in several ways of importance to synthesis. These ways will further define atoms and shell bonds in eq. (5), and thus limit the remaining possible combinations.

As shown in Table 1 the number of molecular components involved on one side or another of the thirteen cases varies from one to three. These represent important synthetic differences and fall into six practical families or reaction modes (see Table 7). When starting material and product are each one component, the reaction is a *rearrangement* (R), electrocyclic or sigmatropic, as in $B = 4_X 4_U$, 5. When the starting material is a single molecule but the product is more than one, the reaction is a *fragmentation* (F), a synthetic opportunity for prior assembly of the two construction parts into one molecule to facilitate pericyclic transformation with a loss of an extraneous, possibly equilibrium-driving fragment. The reverse reactions are *cycloadditions* of two (C_2) or three (C_3) components into one molecule, the former a synthetically useful device for joining two synthons[40]. Common to the lower shells are reactions with two or three components on each side, labeled as *cycloaddition-fragmentations* of two or three starting components (CF_2 and CF_3, respectively). These distinctions (Table 7) characterize each pericyclic reaction and

represent different synthetic opportunities and probabilities of practical success; in the latter connection, R, F, and C_2 are the three most valuable and are necessarily found in the higher shells. The six modes may be grouped into three in terms of the number of starting molecules or components (k) in the reaction: $k=1$, R and F; $k=2$, C_2 and CF_2; $k=3$, C_3 and CF_3.

Table 7. Summary of reaction modes in six-center models.

Shell	σ-transfers [a]	Mode [b]	Code [c]
B=0	6	CF_3	CF_3-6
1	4	$CF_2 \rightleftarrows CF_3$	CF_2-4; CF_3-4

3_Δ	0	$C_3 \rightleftarrows F$	C_3-0; F-0
3_L	1	$C_2 \rightleftarrows F$	C_2-1; F-1
3_V	2	$C_2 \rightleftarrows F$	C_2-2; F-2
4_X	0	R	R-0
4_T	0	$C_2 \rightleftarrows F$	C_2-0; F-0
4_U	1	R	R-1
5	0	R	R-0

Summary [d]	Mode	Shell
$k=3$	CF_3	B=0, 1
	C_3	2_M, 3_Δ
$k=2$	CF_2	1, 2_O, 2_P
	C_2	3_L, 3_V, 4_T
$k=1$	F	2_M, 3_Δ, 3_L, 3_V, 4_T
	R	4_X, 4_U, 5

[a] Number of σ-bonded atoms transferred.
[b] Rearrangement (R); fragmentation (F); cycloaddition of two (C_2) or three (C_3) components; cycloaddition-fragmentation starting with two (CF_2) or three (CF_3) components.
[c] Label combining number of components as in "mode" [b] with numbers of atoms σ-transferred.
[d] k = number of starting material components.

A second distinction bearing on practicality is that of σ-transferred atoms (Table 1, footnote [a]). Because of their more demanding stereoelectronic requirements and the generally greater bond strengths of σ- over π-bonds, σ-transfers are relatively disfavored processes, at least with atoms other than hydrogen, and current precedent bears this out. In construction reactions [eq. (5)] it is then important to sort the possibilities with respect to whether either or both of the carbons to be bonded are σ-transferred. Again, the number of σ-transfers is a function of the shell and is also summarized in Table 7, along with a unified label code for each reaction identifying both its component mode (above) and its σ-transfers.

A third way of sorting the combinations of reactions defines the number of carbons in each of the synthons united in a construction reaction, *i.e.*, the number of carbons involved in the six-atom set of equation (5). Here we are focusing on the number of carbons in each starting synthon which are part of the six-atom pericyclic set in construction, *i.e.* a total of two to six involved carbons in the two synthon carbon skeletons. There are seven possible combinations of synthon skeleton sizes (the number of linear linked carbons in each synthon) and these lead to a linear span of $n \leq 6$ carbons in the product of the construction reaction[41]:

Product span: C_6 (1+5), (2+4), (3+3) [42]
C_5 (1+4), (2+3)
C_4 (1+3), (2+2)
C_3 (1+2)
C_2 (1+1)

This division of the possible combinations allows conceptualization of involved synthon sizes in a pericyclic construction, but does not necessarily limit the mode of reaction: the two synthons may be brought together as two components in a cycloaddition mode or may be joined prior to the pericyclic construction reaction by mutual linking to a heteroatom as would be the case with a rearrangement or fragmentation mode (*e.g.*, the Claisen rearrangement, $B=4_X(C_5O)$). It may be noted that only in those cases $(1+n)$ with one synthon employing only one involved carbon are σ-transfers of a construction carbon possible; this is a logical consequence of equation (5).

		Total	20	322	182	90	36	(630)

[a] Minimal obligatory shell shown for starting material; cf. eqn. (5).

[b] Number of combinations of heteroatoms (v=1 (H), 2 (O), 3 (N)); the asterisk * implies σ-transfer of carbon.

[c] The C_4Z_2 atom combinations have Y=C in the three-carbon cases (1+2) considered synthetically as an extraneous, "reagent" carbon; in the two-carbon (1+1) constructions, X or Y=C as noted in C_3Z_3 and X=Y=C in C_4Z_2, referred to eqn. (5).

[d] Zero sums are listed for cases that require cleavage of the C—C σ-bond between X and Y.

These three categories of synthetic or practical importance constitute the basis for Table 8, a more useful breakdown of the possible construction reactions. Each of the seven combinations of synthon skeleton sizes above further delimit equation (5) with more carbons and minimal obligatory shells (B_0), as illustrated in the third column of Table 8. The increased shells above B_0 are labeled as B_0+1, B_0+2, *etc.*, progressing by addition of one more shell bond each time at the positions indicated by dotted bonds, in Table 8[43]. In some cases the lower symmetry allows more than one shell of the same description, as in the 3-carbon case of $B_0+1=2_M$ in which two 2_M shells are possible when the obligatory bond between the upper carbons is a necessary part of the shell. One should observe that in $C_4(1+3)$ construction the two heteroatoms are necessarily *ortho* and a π-bond is created between them in the construction pericyclic, whereas they are also *ortho* in $C_4(2+2)$ but the bond between them (σ or π) is broken in the reaction. In $C_3(1+2)/C_3Z_3$ there are three vicinal heteroatoms while in $C_2(1+1)/C_2Z_4$ there are four.

A summary of the numbers of combinations of construction reactions by mode and σ-transfer of carbon is presented in Table 9, where it will be seen that all fragmentations (and cycloaddition-fragmentations) require σ-transfers of carbon[44]. Because of the limits on the general reaction imposed

by defining two atoms as carbons unbonded in equation (5), the total numbers, while still considerable, are lower than those in Tables 1 and 2. While not strictly comparable, since Table 1 does not incorporate C_2Z_4 and Table 2 does not include B=1 shells with σ-transfers of H, the total of 911 construction reactions in this summary (Table 9) represents a substantial reduction from the 1670 reactions in Tables 1 and 2 (or over 2000 if the noted omissions were included). If the modes C_2, F, and R are regarded as the only generally realistic ones there are 122 reactions in this summary with no σ-transfer of carbon and 145 with such σ-transfer, for a total of 267 construction reactions on a six-atom frame. It seems likely that a number of these represent viable chemical reactions which are presently unknown.

Table 9. Summary of six-center pericyclic constructions by mode.

[a] Numbers of combinations are separated into those with no σ-transfer of carbon and those which require σ-transfer of carbon; the latter are flagged with asterisks.
[b] Reaction modes subdivided by number of components, k, in the starting material.

The same organization can be applied to the pentagonal frame although some new complexities appear. The greatest of these lies in the lower symmetry whereby a single reaction between two species does not fully characterize a shell; there are instead the ten α and β electron forms (Fig. 1). Hence for construction, the definition analogous to equation (5) can be handled in two equivalent ways. In one of these a single α/β pair is chosen for reference, *e.g.*, $\alpha_1 \rightleftharpoons \beta_1$, and the three non-equivalent positions for the construction pair of adjacent carbons (relative to the symmetry line) are written with an appropriate pair of interconverting structures. In the other approach, which we adopt here, the construction pair of adjacent carbons is kept constant, symmetrically placed across the vertical symmetry line, and the six symmetrically non-equivalent electron forms of Figure 1 are allowed to interconvert with respect to those carbons. Shown in Figure 2 this five-reaction set is the equivalent of equation (5) for the six-atom series above; there are three starting materials for construction (circled) and three products (the set for cleavages is the same with the reaction arrows reversed). It may be noted here that the sixth conversion $\alpha_3 \rightarrow \alpha'_3$, is not a construction on this definition.

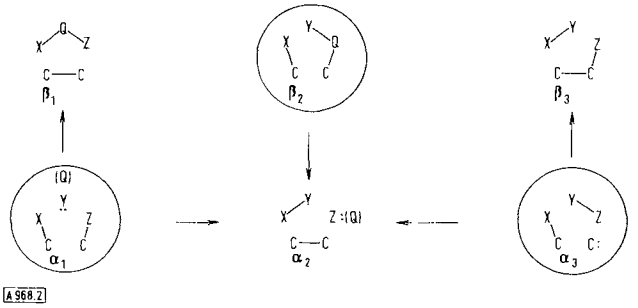

Fig. 2. Five-center electron forms in construction (starting materials are circled).

The valency changes in the five-atom set represent another variable not present in the six-atom series. In the construction

Table 10. Five-center shells and reaction modes for construction.

* Requires σ-transfer of carbon.

from starting material α_1 there are two possible routes but the $\alpha_1 \rightarrow \beta_1$ reaction will only occur if atom Y = Q, capable of valency change $\Delta v = +1$. The comparable choice of two routes starting with α_3 will similarly depend on a valency change ($\Delta v = +1$) but the atom "Q" is now carbon; hence the $\alpha_3 \rightarrow \beta_3$ conversion requires C: to be a carbene[45] whereas for $\alpha_3 \rightarrow \alpha_2$ there is no carbon valency change and C: is a carbanion. In the $\beta_2 \rightarrow \alpha_2$ construction the atom Z = Q undergoes the reverse valency change, $\Delta v = -1$; should Q = C the product must be a carbene.

With respect to the three synthetically important distinctions applied above, the six reaction modes (CF_3, C_3, CF_2, C_2, F, R) are the same but their relation to the possible shells is more complex. The placement of each shell with respect to the two fixed carbons defining construction allows sixteen variations (including B = 0) in general, or only ten if the electron form has the same vertical symmetry element as the two placed construction carbons, *i.e.*, α_1 and β_1; these shells are detailed in Table 10 with their characteristic reaction modes set out below. The number of σ-transferred atoms is included

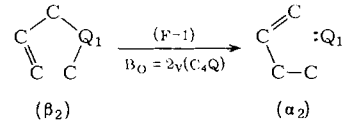
Notes: Atom combinations are shown in parenthesis; Q_1, Q_2, Q_3 represent the numbers of possible valency-change atoms or groups of Table 5, with $V = 1 \rightleftarrows 2$, $2 \rightleftarrows 3$, $3 \rightleftarrows 4$, respectively. The two parentheses in $C_2(1+1)$ represent C_3Z_2 (with Y = C) first and C_2Z_3 second.

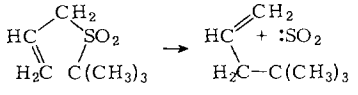
* Carbene products.



[a] Carbene starting materials in $\alpha_1 \rightarrow \beta_1$ with atom Y = C.

[b] No σ-transfer of carbon; all other σ-transfer involve carbon (see Table 10).

in Table 10 following the code format used in the six-atom Table 7. Here another variable also arises in the change from a σ-bond to an unshared pair, —A⇌:A, not found in the six-atom cases. This change is not included as a σ-transfer since the stereoelectronic demands here must be substantially less than in a true σ-transfer and so the practicality of such reactions is of a higher order. In virtually all cases in which the shell requires a σ-transfer, one (or both) of the construction carbons must be σ-transferred and these are flagged in Table 10. The only exceptions are B=1(a), 2_V(a), and 2_S(a) for conversions starting with the α_3 form and B=2_S(a) in the $\beta_2 \rightleftharpoons \alpha_2$ conversion, where it is atom Y that is σ-transferred. The distinctions among combinations of synthon skeleton sizes are fewer here, only the six listed above for C_2—C_5 but the greater asymmetry of the five-ring set requires that both (1+2) and (2+1) be enumerated for C_3 and both (1+3) and (3+1) for C_4, *i.e.*, placing the carbon-skeleton moieties on both the left and right side in the forms of Figure 2. The five-atom cases, however, do allow the variation of using an extraneous, or "reagent" carbon only at site Y and only in the C_2(1+1) examples, which may thus be either C_2Z_3 or C_3Z_2 atom combinations.



A complete tabulation of these separate combinations is assembled as Table 11, comparable with Table 8. As before no C—C σ-bond cleavages are allowed, carbene products and carbene starting materials (other than α_3) are flagged, the latter appearing in $\alpha_1 \rightarrow \beta_1$ when atom Y=C. Blank positions indicate either no possible reaction or one duplicated in another column, usually $\alpha_1 \rightarrow \alpha_2$ equivalent to $\alpha_3 \rightarrow \alpha_2$ by anion resonance. In the enumeration, hydride and halide ($H:^{\ominus}$ and $X:^{\ominus}$) were disallowed in a starting material. Table 11 is further summarized as before in Table 12, sorted by reaction mode and σ-transfers of carbon.

The full tabulations in Tables 8 and 11 are extensive and complicated at first sight. This is not unexpected in view of the many possible combinations of pericyclic reactions. However, their breakdown by several different useful distinctions creates their value, for it is possible to find reactions incorporating several specified features and the groups so defined rarely number over a dozen and so are easily examined. The definitions allow formulation of the specific reactions in the group for examination of new useful reactions. Hence the tables, though complex, serve as a useful source base for the invention of new constructions. As an example, examine the five-atom pericyclic reaction uniting a one- and a three-carbon moiety (*i.e.* C_4(1+3)) by the $\beta_2 \rightarrow \alpha_2$ route such that all atoms are linked prior to reaction, which requires $k=1$ or F and R reaction modes. The smallest shell is then $B_0=2_V$ as a fragmentation with one σ-transfer of carbon (F-1); larger shells ($B_0+1=3_V$ or 3_S; $B_0+2=4$) are rearrangements with a σ-transfer (R-1) for B=3 and none (R-0) for B=4[46]. The basic case may be written as in equation (6) and the number of atom-combinations is only the number of possible groups Q_1.

(6)

We tried the specific example (6a) and found a smooth thermal conversion at 300 °C[47]. The starting material is easily

(6a)

created by bubbling SO_2 into *tert*-butyllithium solution and alkylating the resultant *tert*-butyl sulfinate with allyl bromide. The conjugated isomer, *via* potassium carbonate-catalyzed isomerization, is incapable of pericyclic fragmentation and indeed is stable at 300 °C and decomposes into a number of products at higher temperatures. The reaction thus shows considerable potential for construction, especially as it is capable of creating a quaternary carbon in the product, even though the reaction requires a σ-transfer of one construction carbon.

Table 12. Summary of five-center pericyclic constructions by mode.

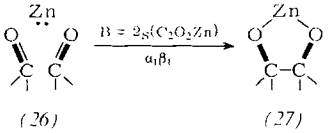
[a] Numbers of combinations shown include Q, a value for the number of valency-change groups possible.
[b] σ-transfer of carbon required.
[c] Reaction modes subdivided by number (k) of starting components.

Assuming from Table 11 and 12 that the only practical reactions are in C_2, F, and R modes with no more than one σ-transfer of carbon in F and R and none in C_2, we may collect the possible examples into the more graphic presentation of Scheme 8[48].

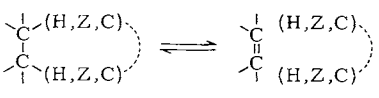
adding a shell bond between the carbons in equation (5), or in the five-atom set in Figure 2. Focusing on the immediate environment of the pair of carbons allows a subdivision into three successive partial shells, B_0, as shown in Scheme 9, illustrated as six-atom reactions but understood to include



Scheme 8. Selected five-center construction reactions.

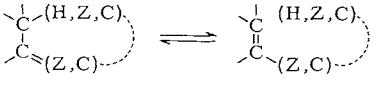
[a] These products also appear in other reactions and are not counted here.

The 25 transformations generalized in the chart represent 200 + 65Q combinations of atoms (including carbon), depending on the number of viable Q groups (Table 5). Two reactions here are not obligatory pericyclics in an α→α′ conversion since the initial and final atoms bearing unshared pairs are not shell-bonded, as noted above. They are included nevertheless, *viz.*, $B=3_S(\alpha_1\rightarrow\alpha'_2)$ and $B=3_V(\alpha_3\rightarrow\alpha_2)$. The familiar 1,3-dipolar addition[27] (C_2—O) as a construction reaction is seen in $B=3_S(\alpha_1\rightarrow\alpha_2$, or its resonance duplicate, $\alpha_3\rightarrow\alpha_2)$. That some constructions may, however, be valid in lower shells is implied in the pinacol reduction (*(26)→(27)*) which may be formulated as $B=2_S(C_2O_2Zn/\alpha_1\beta_1)$, as a C_3—O cycloaddition mode and hence not included in Scheme 8, although it is of course included in the more general Table 11.



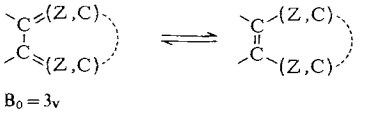
Elimination-addition equilibria can be formulated in a completely analogous manner to construction (cleavage) simply by

five-atom examples by contraction of the undefined, dotted right-hand region of each set. There are a total of 15 variations possible, described roughly to relate them to commonly understood families of reactions. A number of these variations are trivial, such as the ketone-enol equilibria, β-eliminations, and conjugate additions, many of which need not be pericyclic. A number of others involve construction or cleavage and so would more reasonably be considered under the previous discussion of construction reactions. Such a procedure implies more central importance given to making and breaking the C—C σ-bond. However, decarboxylations may more usefully be seen as eliminations and are noted in Scheme 9; since the carboxyl, however, occupies all the remaining atom positions in the six-atom set, there are only a few variations possible, all well known. Finally, the allylic rearrangements and double-bond isomerizations may more clearly be seen as refunctionalizations of allylic (three-carbon) systems and are treated below. Thus the synthetically most important groups may be reduced to these three: $B_0=1/HZ$ and ZZ; and $B_0=2_O/ZZ$.



This important set of eliminations/additions is enumerated for the six-atom frame in Table 13 in a manner analogous to that for constructions in Table 8. The total number of

Scheme 9. General types of pericyclic addition/elimination reactions.



$B_0 = 1$

HH	Dehydrogenation/hydrogenation
HZ	Acetate (and Chugaev) pyrolyses

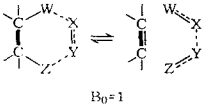
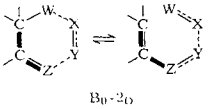
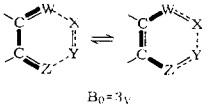
CZ	Cleavage/construction (decarboxylation)
CC	Cleavage/construction (decarboxylation)

$B_0 = 3_V$







ZZ	α-Diketone reduction/enediol oxidation
ZC	Unsaturated ketone reduction (or conjugate addition)
CC	1,4-Addition to dienes/1,4-elimination

[a] Labeled for analogous five-center system.

possible reactions is listed followed by an enumeration of the HZ and ZZ cases from Scheme 9 ($W \neq C \neq Z$); these are broken down into cases with no carbons at X,Y(C_2Z_4), one "reagent" carbon at those sites (C_3Z_3) or two (C_4Z_2). Reactions taken as "viable" and separatedly totaled are the R, F, and C_2 modes.

three categories with one, two, and three carbon bonds to heteroatoms, respectively (these are the functional families, Z = 1, 2, and 3, in Ref. [39]). The three types are illustrated on the six-atom frame, but the five-atom set is easily examined, at least in the first two, by following the analysis for constructions (cf. p. 63) and substituting heteroatom B for one construc-

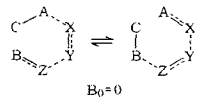
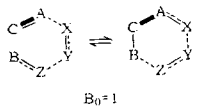
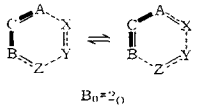
A comparable breakdown of eliminations and additions on the five-atom frame, analogous to the analysis in Table 13, can be made in a similar fashion but is of course considerably more complex, as it is for constructions. The Corey carbene procedure[49] is an example of elimination of the ZZ sort from the first group [($B_0 = 1$) in Scheme 9] on a five-atom frame, annotated as $B_0 + 2 = 3_S(C_3O_2/\alpha_1\beta_1)$.

Refunctionalization reactions can also be analyzed in a comparable way. Again, as shown in Table 14, a focus on the different reaction types with respect to the functionality of the involved carbon undergoing refunctionalization yields

tion carbon. In all the substitution group the central carbon is necessarily σ-transferred (Table 14), and few examples are presently known. In each case the various possible shells represent all combinations on filling the dotted shell bonds, which are missing in the basic parent definition of B_0. However, in the substitutions it was also assumed that a shell bond must always exist between A—X since otherwise a cycloaddition to a C—H or C—Z σ bond is implied; this more stringently limits the possible shells. In Table 14 only "viable" reaction modes (R, F, C_2) were listed. In some cases the shells allow σ-transfer of B = H and so the reactions are poten-



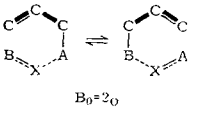




tial reductions. The Meerwein-Ponndorf-Verley reduction (and probably the analogous Cannizzaro and Leuckart reductions) is a likely example of $B_0+2=3_L(C_2O_2AlH)_M$; F-1, in the second group. In general, despite their considerable number, these refunctionalizations appear to be of little potential value and examples presently known are rare.

Examining the refunctionalizations further in terms of synthon carbon-skeleton size, we may follow the same analysis as that used for constructions above and examine re-ordering of functionality on C_2, C_3, and C_4 skeletons, in which the skeletal carbons are part of the pericyclic atom set. Thus we will successively replace A, then A and X, and finally A, X, and Y with carbons and link all carbons with shell bonds. In this way we see that the C_2 and C_4 skeletons become, respectively, olefins and dienes and their refunctionalizations are simply the addition/elimination reactions of Table 13. With the C_3 skeleton we may separately analyze allylic refunctionalizations as shown in Table 15, again for the six-atom cases. The five-atom cases are found in Table 11 for $C_4(1+3)$ by replacing the C_1 synthon carbon by heteroatoms.

6. Energy Considerations



Most of these pericyclic reactions have not been realized experimentally, but a great many could be of practical importance. The previous sections provide protocols for selecting or devising pericyclic reactions to fit specific interconversion requirements. There remains the question of the availability of means for manipulating the reactions to improve the probability of their success. The reactions are equilibria and the thermodynamic energy preference of any given reaction is amenable to calculation from bond energies (Table 3), but the values available are taken from unrelated experimental situations and are often highly dependent on molecular environment[50]. The study of pericyclic equilibria themselves could provide more meaningful bond energy data under nonpolar

Table 14. General types of pericyclic refunctionalization reactions.

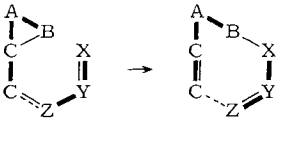
conditions. Unfavorable equilibria may often be reversed in practice by removal of the higher-energy reaction partner, as realized and discussed by *Evans et al.*[51] in their manipulation of a pentagonal $B=3_S(C_3SO/\alpha_3\alpha'_3)_V$.

The reactions are also self-contained and thermal, so that the key experimental feature is the required threshold temperature and this is rarely amenable to alteration by external influences (solvents, catalysis, *etc.*). This temperature directly reflects the activation energy and is very widely different among known cases. Many presently unknown pericyclic reactions may have been overlooked simply because relatively simple and well-known potential substrates have not been deliberately heated above 300 °C. Many others which do not appear to proceed may be pre-empted by competitive reactions of lower activation energy, perhaps involving catalytic acid-base initiation *via* Z—H and Z: groupings activated at elevated temperature. We have at present only very primitive approaches to any semiquantitative assessment of activation energy and resonance stabilization of the transition state, or of the position of the transition state on the reaction coordinate. We lack in most instances even qualitative evaluation of the effects of varying atom combinations or substituents on the pericycle, or of the relative importance of stereoelectronic demands.

There are, however, a few qualitative considerations about the activation energy—and thus the required threshold temperature—which may be useful in the selection and design of reactions. The high degree of molecular organization required to approach a pericyclic transition reflects a generally high entropy of reaction as a factor in the activation energy. At the grossest level this implies that preassembly of the involved atoms is to be preferred, *i.e.*, rearrangements (R) and fragmentations (F) over cycloadditions (C) in reaction mode. This is qualitatively borne out by the generally higher temperatures required for cycloadditions like the Diels-Alder reaction than for known fragmentations and reorganizations. Furthermore, the stereoelectronic requirements of the reaction may be assessed by application of the Woodward-Hoffmann rules to examine in models the required geometry for maximum overlap of the correct orbitals. This further allows an evaluation of the steric hindrance of non-bonded groups in the transition state. The valuable generalization of a preference for chair conformation in the Claisen rearrangement[14] can be used to evaluate the steric difficulties of axial substituents in the transition.

The involvement of π bonds in the pericycle is probably preferred over that of σ bonds, not only because of their lower energy but also because the more accessible π cloud is more mobile or polarizable and so more adapted to stabilizing overlap early on the reaction coordinate. Conversely, σ-transfer of carbon is unfavorable not only because of inaccessibility of the tight σ bond for overlap but also because of the higher entropy implicit in correct rotation of the carbon and its substituents on the two axes (cf. *(28)*).

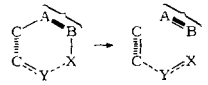
The effects of substituents for resonance stabilization of the pericycle are poorly understood in general. In the Diels-Alder cycloaddition the generalization concerning electron-withdrawing substituents on one component and electron-donating ones on the other[52] may have more to do with the initial association of the two components than with stabilization of the transition state and so not be useful if carried over to considerations of fragmentation or rearrangement modes.

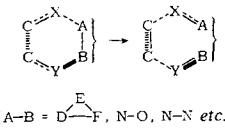


(28)

Transition state theory implies that lowering the energy of the products or raising that of the starting materials will lower the activation energy[53]. An analysis of the options for achieving this can be helpful in reaction design. In the hexagonal frame three bonds are broken and three are made. A more favored reaction will result if the former are relatively low-energy bonds, such as σ bonds between heteroatoms (N—N, N—O, *etc.*) or in strained three-membered rings (see Table 3). Similarly, if the bonds made release large amounts of energy the same effect is achieved, as in liberation of N_2 or CO_2.

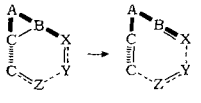
Placement of such vicinal atom pairs at the proper sites in the pericycle should facilitate the reaction and this provides a basis for an analysis of equation (5), shown in Table 16, for construction and elimination reactions. In the first example, the possible combinations are listed as before for formation of a π bond (between atoms A and B) and extrusion (σ-bond breaking), as in N_2 and CO_2. The opportunities for using these favorable products are clearly more limited than the possibilities for designing the reactions enumerated in the last section. The second set of examples similarly explores the breaking of a weak σ bond, between A and B (*e.g.* the cleavage of N—N and N—O bonds; noted in the discussion of Scheme 3). A minimal shell prerequisite is taken to be the B—Y bond since without it a cycloaddition to a σ bond (with σ-transfers) is required. In selecting examples from the last section for synthesis, these further limitations can be placed on the selection if desired. Since decarboxylation implies C—C cleavage, it was omitted from the enumerations of construction reactions previously (Section 5) and such constructions are best formulated *via* Table 16.

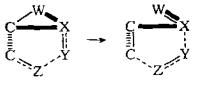


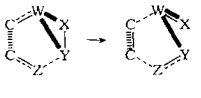


Cleavage of a three-membered ring may be utilized as part of the second set in Table 16, but there are three further options, explored in Table 17 and utilizing in part cross-bond shells. In the first set atoms A—B are not varied in the enumeration, as in Table 16, but the given A—B combinations include six kinds (C—C, C—N, N—C, N—N, O—C, O—N), thus considerably magnifying the totals. Also the obligatory shell bond B—X was chosen to eliminate cycloadditions with σ-transfers in construction; in elimination, however, this condition is not necessary and an additional 30 examples exist with no shell bond at B—X but rather a partial shell at X—Y and Y—Z (and C—C) as in equation (7), *i.e.* $B=3$ (F-1)(18) and $B=4_U$(R-1)(12).

(7)







In general, since the options for utilizing three-membered ring opening to facilitate reaction are far more than those for other favorable bonds, there is a strong implication that design of pericyclic synthetic reagents incorporating such rings

Table 16. Enumeration of possibilities for lowering activation energy.

[a] Constructions and eliminations as in Table 16. The last two sets are labeled with standard shell labels for the peripheral shells and primed to indicate a cross-bond, which changes the reaction mode in some cases.
[b] Atom combinations for H, O, N, C in positions X, Y, Z; in set I, atoms A and B are not varied.

should be especially profitable. The bond energies (Table 3) make particularly favorable the opening of epoxide with attendant carbonyl formation [Table 17, set 2 (X = C, W = O) or set 3 (X = O, W = Y = C)]. Relevant examples are illustrated in the second row of Scheme 7. The opening of epoxide may also be pericyclic in the transformation *(29)*→*(30)*[54], *i.e.*, $B = 3_V(C_2N_2OH)_O$, with a calculated $\Delta E = 5$; here the equilibrium is shifted, however, by the second reaction, losing nitrogen.

(29) *(30)*

Similar analyses for favorable bond making or breaking in pentagonal frames can be set up by defining the bonds made or broken in each of the three starting materials of Figure 2, but the analysis is predictably much more complex. It may be noted that for bonds broken, most of these are bonds to the construction carbon itself, thus excluding N—N, N—O, *etc.* combinations but offering many potential three-membered ring cleavages (with σ-transfer of carbon) for facilitated construction reactions.

Finally, the special feature of the valency change at the "Q" atoms in the pentagonal frame (α⇌β transformations) can confer a special favorability in energy considerations as this change frequently affords a strong driving force. This is especially clear in the unique high-energy carbene implicit in the $\alpha_3 \rightarrow \beta_3$ transformation, but is also illustrated in the pinacol reduction (*(26)*→*(27)*).

7. Summary and Outlook

The number of six-electron thermal pericyclic reactions possible by the expansion of the basic aromatic definition is very large. Depending on the level of discrimination in the definition of involved atoms and groups, the number is in the thousands. Any practical comprehension of the scope of so large a group of reactions requires a systematic ordering in terms of meaningful molecular features so that particular reactions fulfilling specific requirements may be selected for examination. To this end the features of synthetic utility (construction, elimination, refunctionalization, *etc.*), reaction mode (R, F, C_2, *etc.*), σ-transfer, synthon skeleton size, and energy facilitation were introduced as bases for division of the total into manageable subsets of reactions. The difference between the potential and the realized scope of the thermal pericyclic reaction is still enormous. This fact leads to the prediction of several kinds of research:

1. New pericyclic reactions can be invented to fulfill specific synthetic needs by design of appropriate molecular units which, by attachment and pericyclic reorganization, can reshape a given structure in desired ways.

2. Many transformations now understood as ionic and/or multistep processes of other kinds may, on reexamination, also possess a pericyclic path.

3. Many relatively simple compounds, normally thought of as stable, may undergo pericyclic reorganization at higher than normal temperatures. It must be appreciated that high temperature is not necessarily destructive.

Examples of all of these possibilities are considered in the present report. The next step would appear to be the construction of a thorough organized catalog of presently known pericyclic or potentially pericyclic transformations. A search for these examples in the literature has been begun and an abbreviated Appendix of known pericyclic reactions is included here. The author welcomes correspondence both on the methodology of organization for the full catalog and on specific examples, easy to overlook, from the literature.

The author wishes to express his gratitude both to members of his research group, and to Mr. Samuel Silver, at Brandeis University, and to many interested chemists in lecture audiences over the past year for stimulating discussions, relevant conceptual points, and interesting pericyclic reactions.

8. Appendix

Selected Literature Examples

The list of 130 examples selected below is a sampling, mostly from the past five years, containing all the shell types and many atom combinations. The total number of known pericyclic examples is probably several hundred. Some 720 earlier references in the extensive review of *Mathieu* and *Valls*[116] have not been included. Some references contain multiple pericyclic reactions and appear in more than one location. Asterisked examples imply cases for which the listed pericyclic mechanisms were not considered by the authors.

[a] Halogens collectively noted as X, metals as M, H placed last in atom lists; single subscripts following these lists are for carbon orientation of 2 or 3 carbons, other atom orientation (O, M, P) for four carbons; a second subscript for like heteroatoms appears as well in $C_{2-3}Z_{2-3}$ cases in which orientation uncertainty would otherwise exist.

[b] Mode is in parentheses for cases in which the pericyclic frame itself shows cycloaddition of two or three components (C_3, C_2, CF_3, CF_2) or fragmentations (F) into two components but the components are actually linked outside the reactive frame by a bridge [40], *e.g.* in an internal Diels-Alder reaction.

[c] Construction reactions indicated by "m+n", the number of carbons involved in each synthon is quoted (cf. Tables 8—12); cleavages are not listed.

[d] Elimination and addition follow notation of Scheme 9, *i.e.* both added and eliminated atoms are quoted, the number following (1, 2, or 3) reflecting the minimal shell bond levels of Scheme 9 ($B=1, 2_O(2_V)$, or 3_V).

[e] The first letter indicates the atom forming a new bond to carbon, the second that breaking a bond to carbon; letters in parentheses refer to the bond levels given in Tables 14 and 15: S = substitution; K = ketalization; E = ester refunctionalization; A = allylic refunctionalization.

[f] Review article.

[g] Cross-bond frames are labeled with the peripheral shell bonds only but distinguished with a prime; only the allyl-cyclopropyl interconversions of Scheme 5 are listed here, the rearrangements being listed as five-center cases (see note [h]).

[h] Rearrangements attendant on five-center reactions, corresponding to the first group in Scheme 5 but annotated as five-center models; the migrating atom is noted as ~C, ~H, *etc.* All rearrangements of carbon are formal constructions with cleavage; the construction aspect is noted in the list.

Common "Name" Reactions as Pericyclics

[3] a) *M. J. S. Dewar*, Angew. Chem. *83*, 859 (1971); Angew. Chem. internat. Edit. *10*, 761 (1971). b) Although thermal pericyclic reactions of 4n-electrons do occur [1], they are not treated here.

[4] *J. B. Hendrickson*, J. Amer. Chem. Soc. *93*, 6854 (1971). The letters for the B=2 shell correspond to *ortho* (O), *meta* (M), and *para* (P); the letters for the B=3 and 4 shells visually indicate their orientations: lines joining the midpoints of the shell bonds form the letter used in each case. As a notation the letter is used as a subscript to the number of shell bonds, *e.g.* $B=4_T$ for the Diels-Alder reaction, *etc.* The single notation letter thus serves economically to indicate aromatic substituent orientation or pericyclic reaction shell or atom combinations in that shell.

[23] With respect to valency v_i, at atom i, $\Delta v_i=0$ in 5α- and 6-rings, and $\Sigma v_i=r+2B$ where r=ring size ($\max \Sigma v_i=3r$); for β-forms ($r=5$), $\Sigma v_i=r+2B+1=6+2B$.

[24] These linear fragmentations [25] may formally be analogously characterized by the ten possible shell bond combinations on five atoms with the attendant possible atom combinations overlaid. Of the ten unique shell bond combinations the first or full-shell (B=4) set is again a single resonant molecule and only three are true fragmentations, shown below. The other six shell-bond combinations (not shown) are additions of two or three components into a transition complex which subsequently fragments.

The possible atom combinations from the four valencies (*i.e.* H, O, N, and C), are totaled in parentheses for each set.

[25] *C. A. Grob* and *P. W. Schiess*, Angew. Chem. *79*, 1 (1967); Angew. Chem. internat. Edit. *6*, 1 (1967).

[26] Since more than one interconversion exists in the five-atom set for each shell/atom combination, the α or β electron-form is also indicated in the notation as $\alpha_1\beta_1$ for $\alpha_1\rightarrow\beta_1$, *etc.* The notation of shell here implies its symmetric orientation with respect to the vertical symmetry element.

[33] *C. Frisell* and *S.-O. Lawesson*, Ark. Kemi *17*, 401 (1961).

[34] In fact the B=5 is now no longer a resonance example but a rearrangement corresponding to the hexagonal frame with a cross-bond on $B=4_U$ (across positions 2 on $B=4_U$ in Table 1). Hence the number of possibilities for introducing heteroatoms (N only) is increased: C_4N (3), C_3N_2—V (3), C_3N_2—S (2), C_2N_3—V (2), C_2N_3—S (3), CN_4 (2), for a total of 15 rather than 6 and an overall total of 495 instead of 486. An example of C_3N_2—S is illustrated:

[40] The cycloaddition of three components is seldom likely to be of synthetic value, although there are important cases in which two components are linked by bonds uninvolved in the reaction, as in certain [2+2+2] cycloadditions [1], *i.e.* $B=3_{\Delta}$.

[41] As an example, the product span C_4 implies construction of a linear four-carbon partial skeleton from two synthons of one and three carbons respectively or of two carbons each. In the former, this may be attachment of a single-carbon unit to a large molecule bearing three (linear) carbons involvable in a pericyclic transformation, or *vice versa*; the numbers of course refer only to the obligatory pericyclic carbons but either synthon may be larger than one or three carbons. The Fischer indole synthesis ($B=4_X(C_4N_2)$) is an example of the $C_4(2+2)$ combination. The concept of the product span, the minimum obligatory linear skeleton produced in a reaction, will be explored further in a forthcoming publication.

[42] Only seven combinations are noted in the text, although nine are listed. The first and the last—(1+5) and (3+3)—synthon pairs for a product span of C_6 are not included as simple constructions since they do not unite two separate carbon skeletons but only rearrange one, creating one C—C bond by breaking another; the two are the [1,5] and [3,3] sigmatropic rearrangements, respectively, *i.e.* $B=4_U$ and $4_X(C_6)$.

[43] There are some limitations on the higher shells which may be built and still contain a given partial shell. Thus 3_{Δ} cannot be created containing a 2_O partial shell, nor a 4_U from 3_{Δ}. The logical situation is exactly paralleled by the limitations on adding substituents in certain orientations to particular n-substituted benzenes and is fully explicated in the pathways graph (Fig. 2 in Ref. [2]). This graph in effect also delimits those shells which may be formed from given lower shells, since the nomenclature used is the same.

[44] This is also a logical requirement of equation (5). We impose the condition of a shell bond linking each construction carbon to its neighbor so that there are π-bonds at C=W and C≡Z, thus forbidding σ-transfer of carbon. This is a minimal obligatory shell, $B_0=2_M$, for which the product is one-component, and hence not a fragmentation. This result is maintained in any larger shell, B_0+n, containing $B_0=2_M$ as well (see Ref. [43]).

[45] The question of whether a carbene will undergo a six-electron cycloaddition to, say, a diene, rather than a four-electron cycloaddition (to form a three-membered ring) is left unanswered; the tabulations include the six-electron carbene cycloadditions as possibilities.

[46] Some of the B=3 cases have the central carbon of the three-carbon synthon acting as Q and hence the product is a carbene and the reactions are unlikely to be observable (these are asterisked).

[47] *J. B. Hendrickson* and *R. Bergeron*, Tetrahedron Lett. *1973*, 3609; it may be noted that the reaction occurs in the gas phase (in a sealed tube), enhancing the likelihood that it may be concerted.

[48] There is only one fragmentation, F-2, for the α_1 starting material (in shell $B=2_V$; cf. Table 10); this was also included in Scheme 8. The $\alpha_1 \rightarrow \beta_1$ conversion is a construction analogous to the elimination reaction (X=Z=O; Y=C) investigated by *Corey et al.* (see [49]).

[49] *E. J. Corey* and *R. A. E. Winter*, J. Amer. Chem. Soc. *85*, 2677 (1963); *87*, 934 (1965).

[50] As examples, quoted values [12] for simple C—H and O—H energies vary over a 15 kcal/mol range, while C—H and C—C values in allylic positions turn out lower than simple saturated ones by 10—15 kcal/mol; whether the latter difference is really applicable to pericyclic calculations or only reflects the experimental system used in its determination is unclear. Furthermore, values for special bonding situations of interest here (*e.g.* $>C=NR_2^{\oplus}$, $-N=C=O$, *etc.*) are not available while those for other situations ($-CO-O- \rightarrow CO_2$, 30 kcal/mol) seem out of line with qualitative experience.

[53] Alternatively, the larger the calculated equilibrium ΔE the lower the activation energy in the preferred direction. The lowering of activation energy (from a model of $\Delta E \approx 0$) should be a third to a half of the substrate-product ΔE.

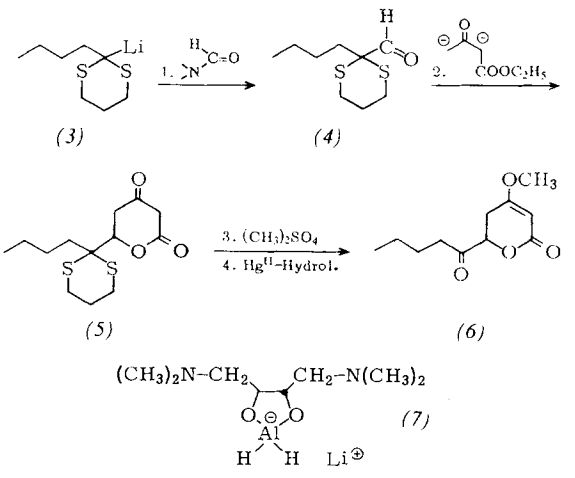
Synthesis of (±)-Pestalotin and (±)-Epipestalotin and of Optically Pure (−)-Pestalotin by Asymmetric Synthesis[**]

By *Dieter Seebach* and *Hartmut Meyer*[*]

Kimura et al.[1] isolated pestalotin *(1)*, which is a synergist of gibberellin, from the phytopathogenic fungus *Pestalotia cryptomeriaecola*. *Ellestad et al.*[2] obtained the same compound (LL-P880α) from the unidentified *Penicillium* species of Lederle culture P880. They established the (6-*S*, 1′-*S*)-configuration *(1a)* as probable for their material ($[\alpha]_D = -86.2°$), and meanwhile isolated two further dihydro-1′-hydroxy-4-methoxypyrones as metabolites from the same source[3]. Dihydromethoxypyrones occur in many other natural sources, *e.g.* kawain *(2)* in kawa root. Such compounds have hitherto been prepared by Reformatsky synthesis from 4-bromo-3-crotonic esters[1,4] or by way of hydroxypropiolic esters[5].

(1a), *threo*
(1b), *erythro*



(2)

We report here a simple method of preparing *(1)* in good yield; it is applicable to analogs and enables (±)- as well as (+)- and (−)-pestalotin *(1a)* and the diastereoisomeric epipestalotin *(1b)* to be obtained.

The synthesis of didehydropestalotin *(6)* and experimental details[6] are shown in Scheme 1. The key step is treatment of the aldehyde *(4)* with the dianion[7] of acetoacetic ester, which affords the oxo lactone *(5)* directly after work-up. Conversion into the enol ether and hydrolysis of the thioacetal group by Hg(II) provides the (±)-ketone *(6)* [total yield *(4)*→*(6)*: 59%].

Hydrogenation of *(6)* by $NaBH_4$ in 2-propanol leads to a 1:1.2 mixture (>95%) of (±)-epipestalotin *(1b)* and (±)-pestalotin *(1a)*, which are eluted in that order in *ca.* 80% yield from a silica gel column by ether. The NMR spectra of (±)-*(1a)* (m.p. 82°C) and (±)-*(1b)* [m.p. 71°C, mixed m.p. with *(1a)* 56—62°C] differ mainly in the shift of the 1′-H signal, which has been given[1,2] for (−)-pestalotin as δ = 3.65, whereas for *(1b)* it appears at 3.90.

For the preparation of optically active pestalotin we reduced *(6)* with the chirally modified lithium hydridoaluminate *(7)*[8] in ether at −78°C, which gave an optical yield of *ca.* 10%. The optically active pestalotin *(1a)* was separated as described above from the epipestalotin *(1b)*, which was also optically active. On recrystallization from ether/pentane, (±)-*(1a)* became enriched in the crystals, and the active material in the mother liquor whence it was isolated in optically pure

Scheme 1. Synthesis of *(6)*. 1. *(3)* is treated in THF at −78°C with 2 equiv. of DMF, yielding *(4)* (95% yield, b.p. 71—75°C/0.06 torr). 2. After reaction of *(4)* with the acetoacetic ester dianion (1:2) for 30 min in THF at −78°C the mixture is poured into the five-fold volume of water, stirred for 12 h, acidified, and *(5)* is extracted with CH_2Cl_2 [80% yield, m.p. 129—131°C (dec)]. 3. Treating a 7% solution of *(5)* in acetone with 1.2 equiv. of $(CH_3)_2SO_4/K_2CO_3$ for 3 h gives the dithiane derivative of *(6)* (81% yield, m.p. 125.5°C). 4. A 4% solution of this derivative in 95% aqueous CH_3OH is boiled for 1.5 h with 1.2 equiv. each of $HgCl_2$ and HgO; the solution is filtered, diluted with 0.05 N HCl (1:1) and stirred for 12 h; part of the *(6)* crystallizes and the remainder is obtained by working up with CH_2Cl_2 (91% yield, m.p. 83°C).

state. On use of (*S*,*S*)-*(7)* prepared from (*R*,*R*)-tartaric acid, (+)-*(1a)* (*e.g.* $[\alpha]_D = +63.5°$) was obtained, and use of (*R*,*R*)-*(7)* led to (−)-*(1a)* {$[\alpha]_D = -85.0°$ (c = 0.76, CH_3OH), m.p. 80.5—81.0°C, mixed m.p. with (±)-*(1a)* 74—78°C}, whose spectroscopic data (UV, IR, NMR, ORD and MS) all agreed with those of the natural product[1,2]

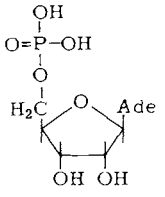
A New Type of Model Nucleotide: 5′-Deoxy-5′-adenosineacetic Acid[**]



By *Hartmut Follmann*[*]

Few suitable model compounds have so far been available for structure-activity investigations of biochemically important

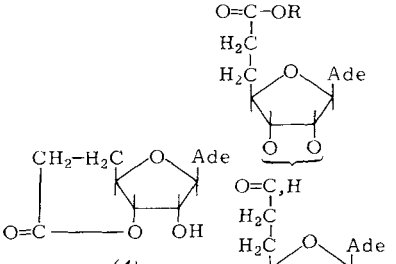
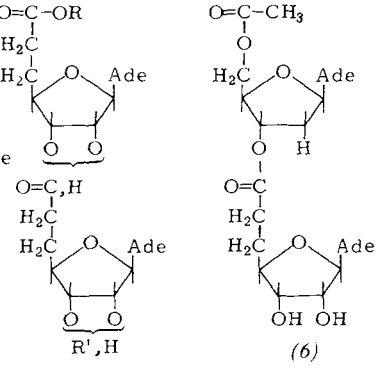
mononucleotides such as adenosine 5'-phosphate [AMP, *(1)*]. From "adenosine-5'-aldehyde", the dialdose derived from adenosine, we have recently synthesized[2], among other 5'-*C*-alkyl derivatives, adenine-9-(5',6'-dideoxy-β-D-riboheptofuranuronic acid) *(2a)*[1] and its *trans*-5',6'-didehydro compound *(3)* which have substituents containing two additional C atoms attached to C-5'. Unlike the short-chain uronic acids ("adenosine-5'-acid")[3] and the longer-chain 5'-*O*-(carboxymethyl)nucleosides[4], these new adenosine derivatives are model nucleotides that correspond exactly to the natural nucleotides but contain a carboxylate group in place of the phosphoric ester group, and resist hydrolysis. We have found that these carboxylic acids can replace AMP as building unit in oligonucleotides and as enzyme substrates.

(1)



(2a), R = H
(2b), R = C_2H_5



(3)

Ade = Adenine

When *(2a)* (0.1 M in pyridine) is condensed with itself or with an equivalent amount of the ethyl ester *(2b)* in the presence of dicyclohexylcarbodiimide under the conditions of a dinucleoside phosphate synthesis[5], there is formed, besides the lactone *(4)*, the dimer *(5a)* (25% yield) or *(5b)* [20% together with 10% of *(5a)*], respectively, as 2'(3')-isomer mixtures; these products are comparable with the dinucleotide pApA or the dinucleoside phosphate ApA. A small amount (<5%) of the trimeric diester *(5c)* can also be isolated. If *(2a)* is esterified with 5'-*O*-acetyl-2'-deoxyadenosine, there results the homogeneously linked nucleoside ester *(6)*[6].

(4)

R', H

(6)

Ade = Adenine *(5a)*, R = R' = H
(5b), R = C_2H_5, R' = H
(5c), R = H, R' = [*(2a)*-H]

Like the conversion of *(1)* into oligoadenylic acids, the condensation of *(2a)* to give *(5a)*—*(5c)* is accompanied by strong hypochromism of the UV absorption band and an intense longwave Cotton effect in the CD spectrum. Both effects are equal or very similar to the corresponding values for ApA and ApApA (Table 1). The compounds must therefore have conformations with comparably strong, intramolecular stacking of the bases which depends only on a suitable distance between the adenine rings and not on the structure or charge of the linking units[7].

The enzyme AMP aminohydrolase (EC 3.5.4.6) from rabbit muscle deaminates the carboxylic acids *(2a)* and *(3)* to the inosine derivatives only slightly more slowly than it converts the natural substrate *(1)* (AMP) (Table 2). The K_m value for *(2a)* is increased to only 2.7 times that for AMP, and

for the more rigidly structured *(3)* only 4.5 times. With 28% of the V_{max} value of AMP, *(2a)* is in fact a better substrate than 5'-deoxy-5'-adenosinemethanephosphonic acid[8] which is also isosteric with AMP. On the other hand, the short-chain uronic acid derived from adenosine has no biochemical activity as substrate or inhibitor of the enzyme. In view of the reaction mechanism, which has been studied several times[9], these results constitute direct proof that a monoanion at a definite distance from the adenine base is the determining structural element of a substrate for binding and catalysis by AMP

Table 2. Reaction velocity (V_{max}) and Michaelis constants (K_m) for substrates of AMP aminohydrolase in Tris: morpholinoethanesulfonic acid buffer pH = 6.0, 0.2 M in KCl, at 30°C.

Substrate	*(1)*	*(2a)*	*(3)*

[1] Nucleosides with additional CH_2 groups between C-4' and the terminal CH_2OH group are also termed "homonucleosides" (cf. Ref. [8]). However, we consider 5'-deoxy-5'-adenosineacetic acid a better name for *(2a)* because it is short and shows unambiguously the relation to adenosine.

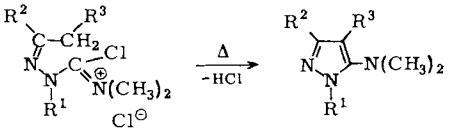
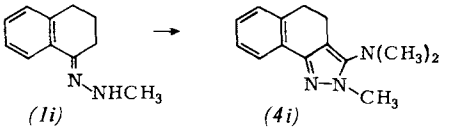
Substituted 5-Dialkylaminopyrazoles from Hydrazones and Phosgeneimonium Salts[1]

By *Thérèse van Vyve* and *Heinz Gunter Viehe*[*]



Phosgeneimonium salts (dichloromethyleneammonium salts) *(2)* react easily with nucleophiles such as amines, alcohols[2], amides[3], and compounds containing activated CH-bonds[4]. *N*-Monosubstituted hydrazones *(1)* have now been found to react with phosgeneimonium salts such as dichloromethyleneammonium chloride *(2a)* to give the substituted 5-dialkylaminopyrazoles *(4)*[5].

Primary condensation of *(2)* with the secondary amino group of *(1)* leads to formation of the new semicarbazone derivatives *(3)*, which subsequently cyclize either spontaneously on reflux or on heating to give *(4)*. Examples are listed in Table 1.



Reaction stops at the semicarbazide chloride stage *(3j)* when cyclohexanone methylhydrazone is condensed with 1-dichloromethylene-4-methylpiperazine-1,4-diylium dichloride *(2b)*; prolonged refluxing with $POCl_3$ leads to formation of the pyrazole derivative *(4j)*. *(3j)* can be converted into the semicarbazone and thiosemicarbazone.

5-Dialkylaminopyrazoles (4)

Hydrazone *(1)* (1 mol) in chloroform solution is added dropwise at room temperature to the stirred suspension of *(2a)* (1 mol) in the same solvent. Stirring is continued under reflux until all *(2a)* is dissolved. The intermediary *(3)* is cyclized on prolonged refluxing (3—10 hours) in chloroform or on heating in the dry state to about 100 °C for 2 h. The solution of *(4)* in chloroform or methylene chloride is then treated with aqueous alkali; after separation the organic layer is dried with potassium carbonate. Most of the pyrazoles *(4)* can be purified by bulb-to-bulb vacuum distillation.—*(4j)*, on the other hand, is prepared *via (3j)* by refluxing *(2b)* (5.08 g, 20 mmoles) and cyclohexanone methylhydrazone (2.52 g, 20 mmoles) in 30 ml dry $CHCl_3$ for 30 minutes. After removal of solvent the residue is refluxed in 50 ml freshly distilled $POCl_3$ for 8 h. Finally, the residue is dissolved in a little water at 0 °C and treated with an excess of solid K_2CO_3. Extraction with CH_2Cl_2 and bulb-to-bulb distillation gives 1.72 g (37%) of *(4j)*.

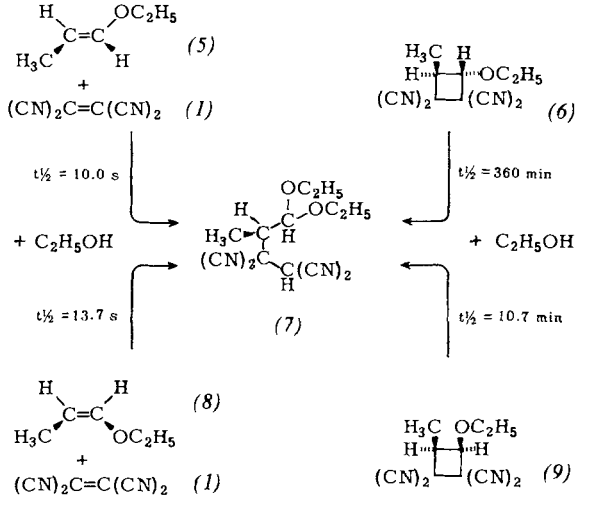
Trapping of the 1,4-Dipole Formed in the 2+2-Cycloaddition of Tetracyanoethylene to Enol Ethers

By *Rolf Huisgen, Reinhard Schug*, and *Gerd Steiner*[*]

The 2+2-cycloadditions of tetracyanoethylene *(1)* to *cis-trans*-isomeric enol ethers, leading to cyclobutanes, are not highly stereospecific[1]; the intermediates capable of rotation are formed reversibly[2]. The additions of *(1)* to various enol ethers in acetonitrile occur 2600—29000 times faster than in cyclohexane[3]; from the dependence of the rate constants on solvent polarity, and from the dipole moments of the reactants, it is possible to calculate the dipole moments of the transition states, which amount to two-thirds of the values estimated for zwitterions of type *(2)*[3]. The influence of structural variation of the enol ether on the rate constants[4], the activation parameters[5] and the solvent dependence of the activation volume[6] also indicate zwitterionic intermediates in these 2+2-cycloadditions of *(1)*.

Scheme 1



Since kinetic evidence never proves a reaction mechanism but only allows exclusion of other conceivable routes, we sought chemical proof by trapping the intermediates with reagents which are not able to combine with the reactants. Alcohols proved suitable; *(1)* is sufficiently stable in pure alcohols in the cold[**].

Whereas *(4)* is formed quantitatively from *(1)* and ethyl vinyl ether in aprotic media[7], the reaction in ice-cold methanol leads to 70% of the 1:1:1 adduct *(3)* together with 30% of *(4)* (Scheme 1) [^{1}H-NMR spectrum ($CDCl_3$) of *(3)*: $\tau = 6.56$ (s, OCH_3), OCH_2CH_3 as an ABX_3 system at 6.26, 6.37 and 8.73; 4.96 (s, 4-H), 5.23 (t, 1-H), 7.42 (d, 2-H_2)]. Owing to the acidity of the 4-H, *(3)* dissolves in aqueous sodium carbonate and is reprecipitated by acid. The acetals of Table 1 are obtained analogously by reaction of enol ethers with *(1)* and alcohols; these 1:1:1 adducts are characterized by elemental analyses and spectra.

Is it true that the zwitterionic intermediate *(2)* is trapped by alcohol or does the acetal *(3)* arise by alcoholysis of the cyclobutane *(4)*? *(4)* is in fact converted into *(3)* by methanol, but in a slower reaction which presumably occurs *via* the same 1,4-dipole *(2)*. We have previously described the slow equilibration of the *cis-trans*-isomeric cyclobutanes *(6)* and *(9)* in the polar aprotic solvent acetonitrile[1]. In Scheme 2 are collected the half-reaction times at 25 °C for the reactions of *(1)* with ethyl *trans-* *(5)* and *cis*-propenyl ether *(8)* (0.25 mol/l) in ethanol [determined by photometry of the orange charge-transfer complex of *(1)* and ethanol] and for the ethanolysis of *(6)* and *(9)*, followed by NMR spectroscopy. The formation of the acetal *(7)* from *(5)* or *(8)* with *(1)* is 2200 and 47 times faster than the one by ethanolysis of the epimeric cyclobutanes *(6)* and *(9)*. Thus, ethanol does indeed trap an intermediate in the course of the 2+2-cycloaddition of *(1)* to enol ethers.

Table 1. Acetalic interception products of type *(3)* from enol ethers, tetracyanoethylene and alcohols.

Enol ethers	Alcohol	1:1:1-Adducts M.p. [°C]	$\tau_{1\text{-H}}$	$\tau_{4\text{-H}}$
Ethyl vinyl ether	Ethanol	Oil	5.17	4.93
Ethyl vinyl ether	Methanol	Oil	5.23	4.96
Ethyl propenyl ether	Ethanol	60—61	5.45	4.71
Methyl propenyl ether	Methanol	92—93	5.63	4.81
Ethyl propenyl ether	Methanol	52—54	5.57	4.77
Methyl propenyl ether	Ethanol	95—96	5.56	4.79
Methyl propenyl ether	2-Propanol	99—100	5.32	4.31
Methyl propenyl ether	*tert*-Butyl alcohol	117—120	5.21	4.22
Ethyl 1-isobutenyl ether	Ethanol	79—80	5.63	4.70
3,4-Dihydro-2*H*-pyran	Ethanol	109—110	5.41	4.55

Scheme 2

A final objection: Perhaps the acetalic 1:1:1 adducts might not be formed from 1,4-dipoles of type *(2)*, *i.e.* not by interception of intermediates in the formation of cyclobutanes, but instead in some unknown (although difficultly conceivable) manner from the three components. If this were the case, then this route *x* must be so fast that it suppresses the 2+2-cycloaddition since ring opening of the cyclobutanes in alcohol is much slower. Kinetic measurements show that enol ethers react with *(1)* in alcohols *more slowly* than is assumed for the 2+2-cycloadditions. The expected values are based on the linear relations between $\log k_2$[3] and the empirical parameter E_T of the solvent polarity[8]. According to the extrapolation, *e.g.* for 3,4-dihydro-2*H*-pyran, the reaction with *(1)* in ethanol and methanol should be 38 and 880 times faster than in acetonitrile. However, Table 2 reveals that four enol ethers in alcohols give smaller rate constants than in acetonitrile. This decrease of the rate constant in alcohols is often observed in cases of specific solvation of a reactant by hydrogen bonding with alcohols[9, 10].

[*] Prof. R. Huisgen, Dipl.-Chem. R. Schug, and Dr. G. Steiner
Institut für Organische Chemie der Universität
8 München 2, Karlstr. 23 (Germany)

[**] *R. H.* thanks Dr. *H. E. Simmons*, E. I. Du Pont de Nemours and Co., Wilmington (USA), for providing this information in July 1971.

Table 2. Rate constants of the reactions of *(1)* with enol ethers in alcohols (to give dialkyl acetals) and in acetonitrile (to give 2+2-cycloadducts) at 25 °C.

Enol ether	Solvent	$10^2 k_2$ [l·mol^{-1} s^{-1}]
3,4-Dihydro-2*H*-pyran	Methanol	0.38
	Ethanol	0.21
	Acetonitrile	0.70
Methyl *cis*-propenyl ether	Ethanol	0.93
	Acetonitrile	50
Methyl *trans*-propenyl ether	Ethanol	0.79
	Acetonitrile	41
Ethyl 1-isobutenyl ether	Methanol	33
	Ethanol	21
	Acetonitrile	63

As a result of kinetic control, tetracyanoethylene *(1)* and enol ethers in alcohol afford the acetal as trapping product and the 2+2-cycloadduct side by side. The relative rate constants of the reactions of the intermediate of type *(2)*, *i.e.* k_A [Alcohol]/$k_{Cycliz.}$, depend on the structure of the enol ether and of the alcohol; for the *cis*-form (*trans*-form) of methyl propenyl ether at 0 °C the following values of the ratio acetal/cyclobutane are found: in methanol 12.3 (2.3), in ethanol 5.3 (2.3), in 2-propanol 4.6 (1.4) and in *tert*-amyl alcohol 1.4 (0.59).

(8), respectively, with tetracyanoethylene (TCNE)[1], leads to the acetals *(4)* and *(7)* which contain two chiral centers (C-1 and C-2). Surprisingly, the addition of ethanol occurs stereospecifically. With ethanol at 0 °C the *cis*-propenyl ether *(1)* gives 84% of the acetals *(4)* and *(7)*[1] in the ratio 18:1 together with 16% of the *cis*-cyclobutane *(2)* (Scheme 1). The reaction is complete in 15 min; NMR analysis identifies the products of the kinetically controlled reaction.

Scheme 1

On the other hand, the *trans*-propenyl ether *(8)* combines with TCNE in ethanol to give preferentially the acetal *(7)* [*(4)*:*(7)* = 1:17]; there is also formed 30% of the 2+2-cycloadducts, these being composed of 29% of the *trans*-cyclobutane *(5)* and ≈1% of the *cis*-isomer *(2)* (Scheme 1). The methyl and ethyl groups of the enol ether and the alcohol can be exchanged: now TCNE in methanol reacts with the ethyl *cis*-propenyl ether *(9)* to give the acetals *(4)* and *(7)* in the proportion 1:29, while the *trans*-enol ether *(10)* gives rise to *(4)* and *(7)* in a 13:1 ratio. Reaction of the *cis*-zwitterions of type *(3)* with alcohols is 5–8 times faster than the cyclization to *(2)*. This preference for formation of acetals rather than of cyclobutanes is less for the *trans*-zwitterions of type *(6)*, the ratios being 2.3 and 1.7, respectively (Table 1). If the zwitterions from the enol ethers *(1)* and *(8)* with TCNE were formed in random conformations, the stereospecificity should be small and the reaction in alcohol would be expected to afford the diastereoisomeric acetals *(4)* and *(7)* in approximately identical ratios. From the high stereospecificity of the acetal formation it must be concluded that most

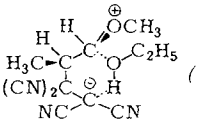
(10)

(12)



of the zwitterions arise in the 'U'-conformations *(3)* and *(6)*, *i.e.*, in the state where the Coulomb potential of the charge centers is lowest; a donor-acceptor interaction between the electrophilic and nucleophilic centers may contribute to the stabilization of the spatial arrangement.

In acetonitrile the zwitterions *(3)* and *(6)* undergo cyclization to *(2)* and *(5)* and *cis-trans*-isomerization by rotation in the proportions 1:5 and 1:4, respectively, which correspond to 16% and 20% of non-stereospecifically formed cyclobutanes[2].

The stereospecificity of acetal formation in alcohol is higher. Clearly a configuration-stabilizing interaction of the zwitterion and alcohol occurs at an early stage. The concurring 2+2-cycloaddition in alcohol is strikingly more stereospecific than the one in acetonitrile. In alcohol the ring closure to the cyclobutane has a chance only if the zwitterions are formed in the conformations *(3)* and *(6)* that are ideal for cyclization. Some "badly oriented" zwitterions, nevertheless, are formed and are trapped by the alcohol as shown by comparison with the 98—99% stereospecificity of acetal formation on ethanolysis of the pure methoxycyclobutane *(2)* and on methanolysis of the ethoxycyclobutanes *(11)* and *(12)* (Table 1). The comparatively slow ring opening of the cyclobutanes[1] produces almost wholly "ideal" zwitterions whose reaction with alcohol is highly stereospecific.

(13)

(14)

The configuration of the acetals *(4)* and *(7)* must be proved by X-ray structure analysis. As shown in Scheme 1 and in *(13)* we favor selective attack of the alcohol on the carbonium-oxonium center "from above" rather than reaction *via* the hydrogen bonded chelate *(14)* which should lead to compounds that are epimeric at C-1.

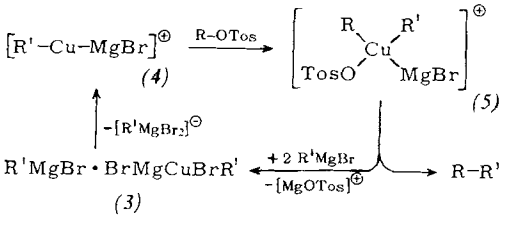
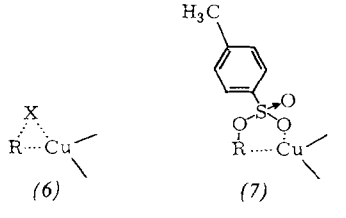
Improved Carbon-Carbon Linking by Controlled Copper Catalysis[**]

By *Gerd Fouquet* and *Manfred Schlosser*[*]

During a search for the simplest and most effective pathway from 1-octanol to decane most of the conventional C—C linking reactions failed. Even a new variant[1] involving condensation of alkyl iodide with Grignard reagent in the presence of dilithium tetrachlorocuprate as catalyst produced yields which were hardly satisfactory (63% of decane) in view of our actual aim of preparing optically active dipropylcyclopropane *(2)*[2] starting from (*R,R*)-bis(hydroxymethyl)cyclopropane *(1)* (X=OH).



(1) *(2)*



Our attempts to improve the method were guided by the following considerations:

1) Copper(I) compounds[3] prefer tetragonal coordination. Cuprates of the type $MCuXR$[4, 5] (M=MgX, Li, *etc.*; X=halide, alkoxide, or organic group) acquire the stable tetracoordination by self-association or by association with another organometallic species that may be present in excess. It is important that the mixed complex[6] expected in our case, *i.e. (3)*, be allowed to form without interference.

2) The role of initiator is assumed by the monomeric cuprate or the cation *(4)* derived therefrom which, as an electron-deficient compound, can undergo carbene-like (*(6)*) insertion into

a CX bond (*e.g.* to give *(5)*). Insertion should be facilitated by leaving groups which, like *p*-toluenesulfonates *(7)*, are capable of 1,4-interactions.

(6) *(7)*

As shown in Table 1, a "catalyst breeding" step (mixing of Grignard reagent and copper catalyst at −78 °C followed by gradual warming to room temperature, below which no condensation occurs) and use of *p*-toluenesulfonates instead of iodides or even bromides leads to a striking improvement. The Grignard component can be varied at will. In contrast, only primary *p*-toluenesulfonates react well, while secondary and tertiary ones give poor yields of product—if any—presumably owing to steric hindrance of insertion. The smooth reaction of *(1)* (X=OTos) to give *(2)* also confirms that no carbocationic, -radical, or -anionic intermediates are involved.

Surprisingly, it also proved possible to replace acetate groups[11] occupying allylic and benzylic positions by the hydrocarbon moiety of Grignard compounds, apparently because acetates can likewise exhibit a chelating action. Thus *trans*-crotyl acetate was converted regio- and stereoselectively into *trans*-2-octene *(8)* (88%).

Table 1. Condensation reactions between *p*-toluenesulfonates (R—OTos) and Grignard compounds (R'—MgX).

R in R—OTos [a]	R' in R'—MgBr [b]	R—R' Yield [%] [c]
[d]	C_2H_5	79
C_2H_5	C_6H_{11}	98
C_2H_5	C_6H_5	90
C_8H_{17}	C_2H_5	98
C_8H_{17}	$(H_3C)_3C$	96
C_6H_5	C_2H_5	0
C_6H_5	C_6H_{11}	51
C_6H_5	$(H_3C)_3C$	0
C_6H_{11}	C_2H_5	3
$-(CH_2)_{12}-$	$(H_3C)_3C$	99

[a] OTs = $OSO_2-C_6H_4-CH_3$.
[b] Grignard reagent always added in excess (1.4 equiv.).
[c] Glc analyses; internal reference substance; calibration factors for peak area correction; standard deviation ±3%.
[d] *(1)*, X = OTos.

(8)

Similarly, *cis*-2-octene (50%) was obtained from *cis*-crotyl acetate.

2,2-Dimethyldecane:

Octyl *p*-toluenesulfonate (40 mmol) in tetrahydrofuran solution (50 ml) was treated at −78 °C with *tert*-butylmagnesium bromide (56 mmol in 32 ml of diethyl ether) and Li_2CuCl_4[1] (0.2 mmol in 2 ml of tetrahydrofuran)[7]. The reaction mixture was allowed to warm to room temperature during 2 h and stirring was continued for other 12 h. An aliquot sample was withdrawn and, after decane had been added as an internal standard, subjected to glc analysis. The main part of the reaction mixture was acidified with 2 N sulfuric acid, washed twice with water (2 × 50 ml), dried ($CaSO_4$), and evaporated. Distillation and rectification (b. p. 77—78 °C/15 torr) yielded 5.1 g (75%) of pure 2,2-dimethyldecane[8].

trans-2-Octene:

In the same manner *trans*-crotylacetate[9] (100 mmol), *n*-butylmagnesium bromide (140 mmol), and Li_2CuCl_4 (0.2 mmol) were mixed in a total volume of 50 ml of tetrahydrofuran and 40 ml of diethyl ether. A 62% yield of *trans*-2-octene[8, 9] (b. p. 120—122 °C) was isolated by spinning band column distillation; in addition 9% of 5-methyl-5-nonanol (b. p. 78 to 80 °C/2 torr) was obtained. According to glc (6 m 15% silicone rubber SE-30, 100 °C; 2 m 5% + 25% $AgNO_3$ + diethylene glycol, 30 °C) the yields amounted to 88% and 11%, respectively[10].

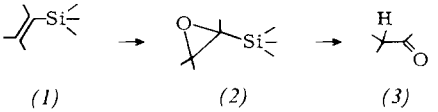
[7] Subsequent addition of the *p*-toluenesulfonate, *e.g.* after 3 h at 0 C, leads to the same result.

[8] Identity and purity were checked by elemental analyses, vpc, as well as mass, ^1H-, and ^{13}C-NMR and infrared spectra.

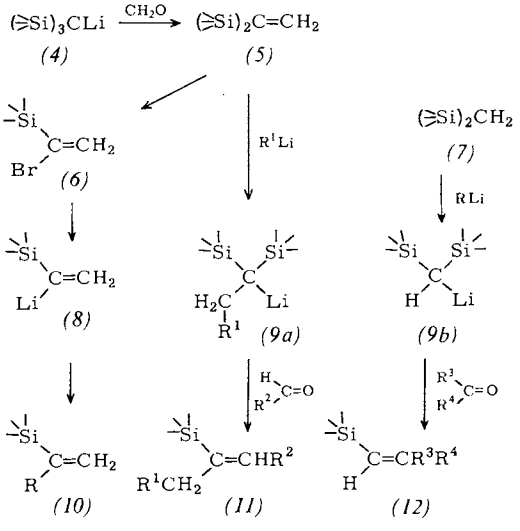
[9] Corrected for an impurity of 5% *cis* isomer present in the starting material.



[10] Formation of this normal acetate reaction product may be even further reduced (< 5%) if larger amounts of CuI (*ca.* 1 equiv.) are used instead of Li_2CuCl_4.

[11] *Note added in proof:* Lithium dialkylcuprates can also undergo condensation reactions with *tertiary* allylacetates; however, they overwhelmingly involve attack at the vinylogous position and allylic shift of the double bond (*P. Rona, L. Tökes, J. Tremble*, and *P. Crabbé*, Chem. Commun. *1969*, 43; *R. J. Anderson, C. A. Henrik*, and *J. B. Siddall*, J. Amer. Chem. Soc. *92*, 735 (1970)).

Convenient Synthesis of Vinylsilanes and Their Use in Ketone Synthesis[**]



By *Bengt-Thomas Gröbel* and *Dieter Seebach*[*]

Vinylsilanes *(1)* can be converted into carbonyl derivatives *(3) via* epoxides *(2)*[1]. Thus all C—C coupling reactions in which vinylsilanes are formed represent potential methods for producing carbonyl compounds.

(1) *(2)* *(3)*

We now describe new α-silyllithium reagents *(8)* and *(9)* from which vinylsilanes *(10)*—*(12)* having different substitution patterns are accessible by simple C—C bond formation or by Peterson olefination.

Compound *(8)*[2] is produced from tris(trimethylsilyl)methyllithium *(4)*[3] which is first converted into the olefin *(5)*[4] in 70% yield by a Peterson reaction[5]. Compound *(5)* can be transformed into *(6)*[6], which is subjected to bromine-lithium exchange with *tert*-butyllithium[7]. The substituted reagents of type *(9a)* are prepared in more than 90% yield by addition[2a, 8] of alkyllithium compounds R^1Li to *(5)*. Solutions of reagent *(9b)*[3a] are also obtained in yields exceeding 90% by metalation of *(7)* in an improved process.

Compound *(8)* was subjected to the action of alkyl halide, aldehyde, or ketones, whereupon the products *(10)* were

Dimethylarsenido-Transition Metal Complexes—Stable Organometallic Lewis Bases

By *Wolfgang Malisch* and *Max Kuhn*[*]

Complexes of the type $L_nM{-}AsR_2$ (M = transition metal, L = ligand; *n* = f(M)) are regarded as being capable of existence provided that electronegative substituents (R = CF_3, C_6F_5, Cl) reduce the donor strength of the As atom sufficiently to suppress association *via* ligand elimination producing doubly bridged dinuclear or polymeric polynuclear complexes $[L_{n-1}M{-}AsR_2]_x$[1, 2]. That only bridged complexes have so far been obtained in the case of compounds with R = CH_3[5], in spite of numerous attempted syntheses[3, 4], lends support to this concept.

We have now found that under certain conditions (25 °C, 12 h, nonpolar medium) mononuclear complexes of this type with M = Cr, Mo, W, and Fe can be prepared in good yields by use of the cyclopentadienylcarbonylmetalates and dimethylchloroarsane or by exchange reactions starting with the analogous trimethylsilyl compounds[6].

[*] Dr. W. Malisch and Dipl.-Chem. M. Kuhn
Institut für Anorganische Chemie der Universität
87 Würzburg, Am Hubland (Germany)

These first representatives of monomeric dialkylarsenido-transition metal complexes prove to be unexpectedly stable. Thus they can be kept without decomposition in common organic solvents for a considerable time; in some cases decomposition can be induced only by heating the pure substances.

Hence in contrast to previous assumptions[1,4], the introduction of electropositive substituents does not necessarily render the system more labile for the increased basicity is compensated by an enhanced stability of the M—CO unit. In fact, both criteria seem to be of comparable importance in discussions of association processes involving CO elimination (compare ν_{CO} for corresponding C_6F_5 or CF_3 derivatives[1]).

A characteristic feature of the complexes *(1)—(4)* is their ready reaction (1) with various halides. This reactivity closely resembles that of trialkylarsanes but contrasts sharply with that of all R_2As-transition metal complexes so far known[1,2].

Stereochemical Control by Secondary Through-Space Interaction: *exo/endo*-Stability of 7-Acceptor-Substituted 2,4-Norcaradienes[1]

By *Wolf-Dieter Stohrer* and *Jörg Daub*[*]

An acceptor (A) attached to C-7 of a norcaradiene can adopt an *exo* or an *endo* orientation. The *endo* arrangement *(1)* should permit a stabilizing through-space charge transfer directly from the antisymmetric highest occupied orbital of the diene to the antisymmetric acceptor orbital, in addition to the direct interaction between the Walsh orbital and the acceptor orbital[2]. A secondary interaction of this kind can be ruled out for the *exo* arrangement *(2)* and should therefore favor the *endo* over the *exo* arrangement.

(1) *(2)*

(a), A = CH_2^+

However, experiments show the *exo* form of 7-acceptor-substituted norcaradienes to be the more stable[3,4].

EH calculations[5] confirm this unexpected difference in stability: the *exo* cation *(2a)* is found in a model calculation to be 0.53 eV more stable than its *endo* isomer *(1a)* (the bisected arrangement is assumed for the cationic substituents), whereas the difference $\Delta E_{endo} - \Delta E_{exo}$ amounts to only 0.31 eV for the corresponding 7-methyl derivatives. Thus the lower stability of the *endo* cation cannot be ascribed solely to steric effects. The same qualitative EH results as for *(1a)* and *(2a)* are also obtained for other acceptor-substituted norcaradienes[6].

According to *Hoffmann*[2], the stabilizing influence of a C(7)-acceptor on norcaradienes arises from interaction between the occupied antisymmetric Walsh orbital of the three-membered ring and the unoccupied antisymmetric acceptor orbital. In norcaradiene, however, this Walsh orbital is not localized but mixes, as discussed in detail for the analogous case of semibullvalene[7], with the antisymmetric orbitals of the diene. In accord with the general rules, the occupied antisymmetric diene orbital and the occupied Walsh orbital undergo mixing to a bonding combination of lower energy and an antibonding one of higher energy.

Owing to the raised energy of the orbital and the high coefficient density at C(7) (cf. Fig. 1, center)[7], the latter combination is an even stronger donor than the Walsh orbital in an isolated cyclopropane[8] and is primarily responsible for the stabilizing interaction with the acceptor. This interaction is *a priori* (with the coefficient at C-7) of equal magnitude for the *endo* and the *exo* form (Fig. 1, left-hand side and right-hand side, respectively). The sign of the acceptor orbital in the *endo* and *exo* form is fixed since the primary interaction with the coefficient at C-7 is bonding in character, *i.e.* the coefficients on C-7 and on the acceptor necessarily have the same sign. Therefore, contrary to initial expectations, the additional secondary through-space interaction between the diene and the acceptor is not bonding, but *antibonding*, in nature (Fig. 1, left-hand side) and thus destabilizing. This destabilization, which is clearly apparent from the calculated orbital energies, is absent in the *exo* form (Fig. 1, right-hand side) thus accounting for its higher stability[9].

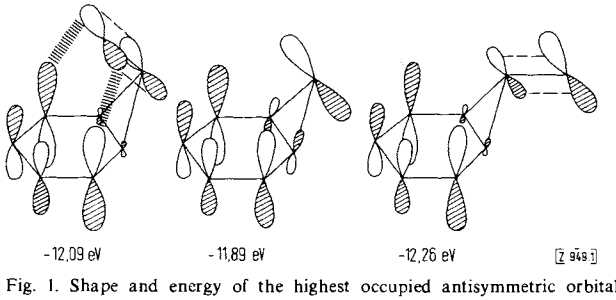

Fig. 1. Shape and energy of the highest occupied antisymmetric orbital in 2,4-norcaradiene (center) and in CH_2^+-substituted norcaradiene in the *endo* (left-hand side) and *exo* form (right-hand side).

Photochromism of 4-Substituted Benzofuroxans[**]

By *Gion Calzaferri, Rolf Gleiter, Karl-Heinz Knauer, Hans-Dieter Martin*, and *Erika Schmidt*[*]

Benzofuroxans are an interesting class of compounds from both a preparative and a theoretical point of view. Whereas

	(1)	*(2)*	*(3)*	*(4)*	*(5)*	*(6)*
R^1	NO_2	NO_2	NO_2	Br	Br	Cl

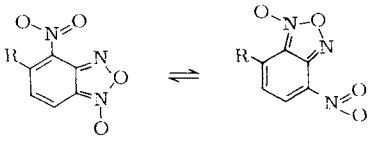
[**] This work represents part of Project No. 2.477.71 of the Schweizerischer Nationalfonds. *K.-H. K.* wishes to acknowledge a grant from Hoffmann La Roche, Basel. We are grateful to Frl. *E. Rommel* for her assistance in recording the spectra.

furoxans undergo both thermal and photochemical isomerization (*e.g. (1)*)[1] the analogous isomerization (2) of benzofuroxans has so far only been detected as a thermally induced process[2].

In the present communication we shall show that (2) can also be photochemically induced.



With this aim in mind we studied 4-substituted benzofuroxans since for these derivatives the thermal equilibrium (2) is shifted largely to the left-hand side for stereochemical reasons (R > H)[2] and the isomers exhibit different electronic spectra. Conventional flash spectroscopy[3] was employed to detect a photoreaction (2') since half-life times of $\tau_{1/2} \leqslant 10^{-1}$ s were to be expected for the thermal reverse reaction (2')[2,4].

On irradiation of ethanolic solutions of the benzofuroxans *(1)* to *(4)* in a flash apparatus a short-lived transient (half life (25 C) $10^{-2} - 5 \times 10^{-4}$ s) was observed in each case which underwent thermal reversion to the starting compound. The reaction was found to be of first order and independent of the oxygen concentration of the solution. At low temperature (−150 C) the photochemical intermediate was sufficiently stable for recording an electronic spectrum.

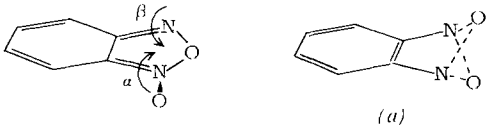
The ^{1}H-NMR spectrum of an irradiated solution of *(1)* in $(CD_3)_2CO$ could also be recorded at −80 °C. Apart from the AB spectrum of protons H-5 and H-6 ($\delta_A = 8.76$, $\delta_B = 7.81$ ppm; $J = 8$ Hz) of the starting material, a new AB spectrum ($\delta_A = 8.38$, $\delta_B = 8.00$ ppm; $J = 8$ Hz) was detected.

The electronic spectra recorded prior to and after irradiation are very similar with respect to the positions and intensities of the bands. Hence we conclude from this observation and from the pronounced reversibility of the thermal reverse reaction that the transient is an isomer of the starting compound and rule out previously discussed[2,4] alternatives to the furoxan structure.

Two isomerization reactions can be considered for *(1)* to *(3)*: 1) a photoreaction according to (2') or 2) a Boulton-Katritzky rearrangement[2] (3).

(3)

The second reaction type can be ruled out as a photoisomerization on the basis of the following findings: According to eq. (3) reaction of *(1)* should yield *(2)* and reaction of *(2)* should afford *(1)*. However, the electronic spectra of the two transients *(1a)* and *(2a)*, respectively, differ from those of *(1)* and *(2)*. Moreover, these rearrangements (*(1)* → *(2)* and *(2)* → *(1)*) should proceed irreversibly in the flash experiment since the solutions of *(1)* and *(2)* are stable under the experimental conditions. No irreversible reaction is observed. Eq. (3) would predict that *(3)* yields an identical product on irradiation, which is certainly not the case.



The following facts indicate isomerization according to eq. (2'): A comparison of the activation parameters listed in Table 1 for the thermal reverse reaction of the transients *(1a)* → *(1)*, *(2a)* → *(2)*, *(3a)* → *(3)*, *(4a)* → *(4)* with those from the thermal isomerization[2,4] of *(5)* and *(6)* shows good agreement. In contrast, an activation energy of > 20 kcal/mol was estimated for isomerization of *(3)* according to eq. (3)[5].

On irradiation of *(1)* the signal of the proton H-5 in the NMR spectrum is shifted upfield by 0.38 ppm, and that of the proton H-6 downfield by 0.19 ppm. Similar shifts in the same directions have been reported for isomerizations according to (2)[4,5].

Our results indicate that benzofuroxans isomerize according to eq. (2') on irradiation. This reaction permits synthesis of benzofuroxans displaying strong steric hindrance in position 7 and the study of their properties.

The isomerization of benzofuroxans according to eq. (2) has been postulated to involve dinitrosobenzene[2,4] but no unequivocal proof has yet been forthcoming.

Brief irradiation of benzofuroxans at −40 °C effects no change in the optical density in the spectrum; the lifetime of any possible intermediate must therefore be $< 10^{-4}$ s at this temperature.

(a)

Model CNDO/2 calculations performed on the isomerization (2)[6] revealed a disrotatory but nonsynchronous motion of the two oxygen atoms for the minimum energy pathway[7]. Transition states are found at $\alpha = 90$, $\beta = 0$ and $\alpha = 180$, $\beta = 90°$[8]. Between these values a local minimum *(a)* occurs at $\alpha = 135$ and $\beta = 22.5°$ (0.5 eV more stable than the transition states). It remains to be established whether this minimum is merely an artifact of the calculation method.

Tri-*tert*-butylstannylamine and Tri-*tert*-butylstannyl-*N*-deuterioamine: The First Primary Stannylamines

By *Hans-Jürgen Götze*[*]

Whereas the primary amines R_3SiNH_2 ($R=CH_3$, C_2H_5)[1] and R_3GeNH_2 ($R=C_6H_5$)[2] have been known for some time, attempts to prepare a homologous stannylamine R_3SnNH_2 *(1)* have hitherto been unsuccessful. Reaction of trialkyltin halides[3] or trialkylphenyltin[4] (alkyl = CH_3, C_2H_5, C_3H_7, i-C_3H_7, i-C_4H_9, neopentyl, and C_6H_{11}) in liquid NH_3 with KNH_2 or $LiNH_2$ invariably leads to the secondary *(2)* or tertiary stannylamines *(3)*, the primary amines *(1)* which probably represent the initial reaction product undergoing condensation with elimination of ammonia.

$$R_3SnX + NH_3 \xrightarrow[-HX]{(+KNH_2)} R_3SnNH_2 \qquad (1)$$

$$2\,(1) \xrightarrow{-NH_3} (R_3Sn)_2NH \qquad (2) \qquad \text{or} \qquad 3\,(1) \xrightarrow{-2\,NH_3} (R_3Sn)_3N \qquad (3)$$

X = Halogen, C_6H_5;
(2), R = C_3H_7, i-C_3H_7, i-C_4H_9, neopentyl, C_6H_{11}
(3), R = CH_3, C_2H_5, C_3H_7

However, the corresponding reaction of tri-*tert*-butylphenyltin with KNH_2 at 0 °C has now been found to constitute the first preparation of tri-*tert*-butylstannylamine *(1a)*.

$$[(CH_3)_3C]_3SnC_6H_5 + NH_3 \xrightarrow[-C_6H_6]{(+KNH_2)} [(CH_3)_3C]_3SnNH_2 \qquad (1a)$$

No by-products such as *(2)* or *(3)* were observed. Evidently the bulky *tert*-butyl group hinders condensation of *(1a)*. Tri-*tert*-butylstannyl-*N*-deuterioamine *(1b)* could also be prepared in a similar manner with KND_2 in ND_3.

The primary stannylamines *(1a)* and *(1b)* are colorless liquids which are rapidly hydrolyzed to tri-*tert*-butyltin hydroxide and small amounts of hexa-*tert*-butyldistannoxane even by traces of moisture; at 100 °C hydrolysis proceeds quantitatively to give the distannoxane. Both compounds react with CO_2 to give bis(tri-*tert*-butylstannyl) carbonate *(4)* if the reaction is accompanied by hydrolysis.

$$2\,(1a) \xrightarrow[-2\,NH_3]{+H_2O,\,+CO_2} [(t\text{-}Bu)_3SnO]_2CO \qquad (4)$$

In contrast to the behavior of other stannylamines[5] the Sn—N bond in *(1a)* and *(1b)* is not cleaved by CCl_4.

[*] Dr. H.-J. Götze
Lehrstuhl für Analytische Chemie der Universität
463 Bochum, Postfach 2148 (Germany)

The composition and structure of compounds *(1a)* and *(1b)* were established by elemental analysis, molecular-weight determination, and by mass and vibrational spectroscopy (Table 1). The mass spectrum of *(1a)* (selection): *m/e* (relative intensity) = 250 (5.8%) $(C_4H_9)_2SnNH_2$, 194 (3.6%) $C_4H_9(H)SnNH_2$, 177 (4.5%) C_4H_9Sn; 136 (8.4%) $SnNH_2$, 120 (1.6%) Sn. Only the fragments corresponding to ^{120}Sn are given. The molecular ion of $(C_4H_9)_3SnNH_2$ (*m/e* 307) was not observed.

Table 1. IR and Raman data for the primary stannylamines *(1a)* and *(1b)* in cm^{-1} [a,b].

[a] IR spectra: Perkin-Elmer grating spectrometer Model 325.
[b] Raman spectra: Cary 82 (Varian).

Experimental:

All operations should be carried out with rigorous exclusion of moisture and CO_2 (argon atmosphere): A solution of $(t\text{-Bu})_3C_6H_5Sn$[6] (4.25 g, 0.012 mol) in diethyl ether (30 ml) is allowed to react in a two-limbed pressure apparatus[4] with KNH_2 (2.0 g, 0.036 mol) in liquid NH_3 (50 ml) at 0 °C. The mixture is frequently shaken throughout the reaction (*ca.* 24 h). After evaporation of NH_3 and ether, vacuum distillation of the crude product affords *(1a)* as a colorless liquid, b. p. 53—54 °C/0.15 torr; yield 2.2 g (62%). Compound *(1b)* can be prepared analogously with KND_2 in ND_3: b. p. 60 to 61 °C/0.2 torr.

Rapid Procedure for Liquid-Phase Peptide Synthesis: The Crystallization Method

By *Manfred Mutter* and *Ernst Bayer*[*]

Polyethylene glycols are particularly suitable as solubilizing C-terminal protecting groups in peptide synthesis in homogeneous solution[1-3]. Hitherto, lower-molecular reagents and coupling components have been separated from the peptide chain growing on the polyethylene glycol by means of diafiltration[1,2], so that a single synthetic cycle including change of solvent required about a day. The synthesis can be accelerated by crystallization of the polymeric peptide at each stage. Polyethylene glycol differs from other solvents such as polyvinyl alcohol used in the liquid-phase method by its marked

[*] Dr. M. Mutter and Prof. Dr. E. Bayer
Lehrstuhl für Organische Chemie der Universität
74 Tübingen, Auf der Morgenstelle (Germany)

[**] Times required for the two syntheses: 7 and 10 days, respectively, including isolation and purification.

tendency to crystallization and formation of a stable helical structure[4–6]. So long as this conformation and the tendency to crystallize is retained as the peptide sequence grows on the polyethylene glycol, purification could be effected by crystallization at each stage and the synthetic cycle would be shortened to 1—2 hours.

X-ray investigation has now shown that the same reflections are given by the free polyethylene glycols (*e.g.* PEG 15000) and the polyethylene glycol peptide esters (*e.g.* the octapeptide BOC-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met) when these are precipitated in crystalline form from diethyl ether by methylene chloride ($d_1 = 3.81$ Å; $d_2 = 4.643$ Å).

The ability to crystallize avoids the possibility of inclusions, such as occur with gelatinous precipitates[7], and the excess of protected amino acid used can be removed quantitatively.

Figure 1 shows the principles of the synthesis together with the times required for individual operations.

acid/1.2 N HCl) and the polymeric peptide is again precipitated by ether, washed, and dried.

By this method we have synthesized, *inter alia*, the difficult partial sequence 14—20 of ACTH H-Gly-Lys-Lys-Arg-Arg-Pro-Val-OH and the biologically active peptide "Substance P"[8–10] in short times, using PEG of molecular weight 6000 and 15000, respectively[**]. This rapid procedure for liquid-phase synthesis retains the previous advantages of the method, and the operations have been simplified to the extent that coupling with an amino acid group is effected in a shorter time than in the solid-phase method and, further, the synthesis can be automated.

Polyethylene glycols having molecular weights in the range 20000 to 2000 are suitable for the crystallization procedure, and capacities of 0.1 mmol/g to 1 mmol/g of polymer can be achieved.

(A) $PEG{-}OH + HOOC{-}CHR{-}NH{-}BOC \xrightarrow[2.\ H^{\oplus}]{1.\ CDI,\ DCCI} PEG{-}OCO{-}CHR{-}NH_3^{\oplus}X^{\ominus}$

(B) Separate activation of the *N*-protected amino acid by DCCI [11] and filtration of the DC-urea or use of active esters

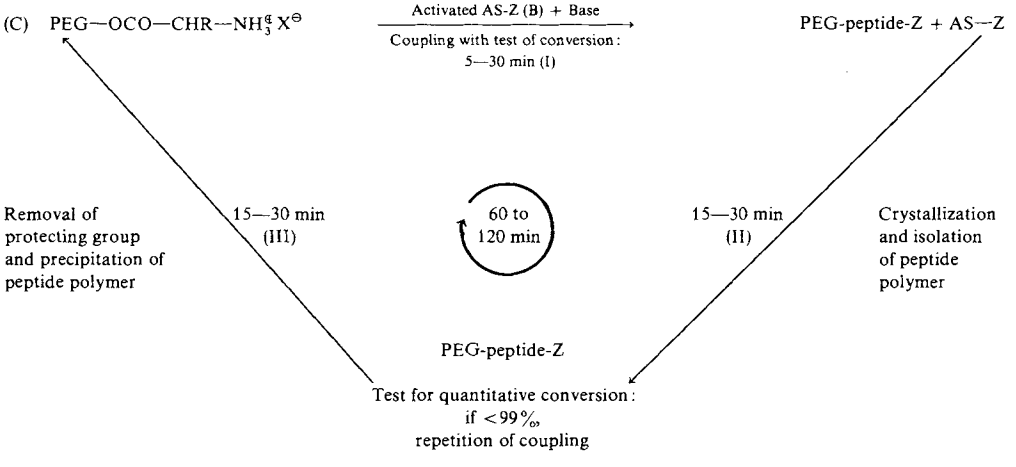

Fig. 1. Synthetic cycle of the crystallization procedure of the liquid-phase method. Abbreviations: PEG = polyethylene glycol; AS = amino acid; CDI = 1,1'-carbonyldiimidazole; others according to [12].

Synthesis cycle: 1,1'-Carbonyldiimidazole or DCCI is used for esterification (A) of the first C-terminal amino acid with polyethylene glycol[1, 2]. A 10% solution of the polymeric peptide in CH_2Cl_2 is treated at 0 °C with the activated derivative of the next amino acid (B) in 1.5—3-fold excess while the tertiary base needed to neutralize the free amino group is simultaneously added dropwise. After 5 min the degree of conversion is tested on aliquot portions of the mixture (C). When coupling is complete (max. time 30 min) the solution is concentrated (20%) and ether is added to it with vigorous stirring until the polymeric peptide is quantitatively precipitated (100—200 ml of ether per 20—30 ml of CH_2Cl_2). The peptide polymer is filtered off (glass frit), washed twice with diethyl ether, and dried. At this stage the quantitative removal of the excess reagents can be tested by the simple procedure of thin-layer chromatography (R_F of the peptide polymer = 0). Then the protecting group is removed (*e.g.* by glacial acetic

Correlation of the ^{13}C-NMR Chemical Shifts of Carbonyl and Thiocarbonyl Groups[**]

By *Hans-Otto Kalinowski* and *Horst Kessler*[*]

Empirical correlations between structural parameters and spectral data are of use both to the practical spectroscopist as well as the theoretician. The linear relationship found by us between the chemical shifts of ^{13}C=O- and ^{13}C=S-groups enables one to predict the value of these shifts to within a few ppm (cf. Table 1).

[a] Calculated according to eq. (1).
[b] Original value recalculated with $\delta^{TMS} = 193.4 + \delta^{CS_2}$.
[c] Original value recalculated with $\delta^{TMS} = 128.7 + \delta^{C_6H_6}$.

The chemical shifts listed in Table 1 can be reproduced by eq. (1) (correlation coefficient $r = 0.997$)[11]:

$$\delta_{C=S} = 1.45\,\delta_{C=O} - 46.5\ \text{ppm} \qquad (1)$$

The utility of this equation can be readily illustrated using phenylisocyanate as example. The following assignments have been made for the signals of the different carbon atoms in this compound[4, 6]:

Thus, the signal of the C=O groups should coincide with the signals of the C-3 and C-5 atoms. However, the chemical shift calculated from the value for phenylisothiocyanate using eq. (1) is 125.0 ppm. The off-resonance spectrum, on the other hand, shows quite clearly that the CO signal is overlapped, not by the signals of C-3 and C-5, but by those of C-2, C-6, and C-4 ($\delta_{C=O} = 125.2$ ppm)[11].

Equation (1) can also be used in the investigation of tautomeric equilibria: In the case of acetic acid—thioacetic acid (178.1 and 194.5 ppm, resp.) the deviation from the calculated value for $CH_3C(S)OH$ (211.9 ppm) can—in agreement with other spectroscopic studies[8]—be considered as indicative of the thioacetic acid being present in the thiol form.

It can be seen from Table 1 that the difference between the chemical shifts found for ^{13}C=O and ^{13}C=S ($\Delta\delta_{O,S}$) decreases with increasing donor action of the substituents. In principle, this also applies for the difference[7] between the n,π* energies of C=O- and C=S-compounds. Unfortunately, however, there are too few unequivocally assigned n,π* transitions available as yet to make such a correlation possible.

The chemical shifts of ^{13}C are essentially determined by the paramagnetic shielding[9] [eq. (2)].

$$\sigma_p = -\frac{\text{const}}{\Delta E}\left(\frac{1}{r^3}\right)_{2p}[Q_{AA} + \Sigma Q_{AB}] = -\frac{A}{\Delta E} \qquad (2)$$

r = average radius of the 2p orbital of carbon
Q_{AA}, Q_{AB} = charge density and bond order terms
A = collection of all terms excepting ΔE
ΔE = mean excitation energy of all occupied orbitals.

Laboratorium Niederrad,
6 Frankfurt (Main) 70, Theodor-Stern-Kai 7 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Alteration of the lowest excitation energy (HOMO→LUMO n,π* for the C=X group) could have the largest influence on σ_p. For substituted benzophenones and thiobenzophenones the following correlation has been derived:

$$\Delta(n,\pi^*)/\Delta(n,\pi^*)^O = 1.54^{[10]}$$

Assuming that the agreement of this correlation with that of eq. (1) is not incidental, then, for eq. 2, we may write:

$$\frac{\Delta\sigma_p^O}{\Delta\sigma_p^S} = \frac{\Delta A^O \Delta\Delta E^S}{\Delta A^S \Delta\Delta E^O} = \frac{\Delta(n,\pi^*)^S}{\Delta(n,\pi^*)^O} \quad (3)$$

Furthermore, if it is assumed that the energy of the n,π* transition approximates to ΔE and the diamagnetic influence on the ^{13}C chemical shift can be ignored, eq. (4) should be valid, *i.e.* all the terms in eq. (2) except ΔE change in the same direction or not at all in the transition from carbonyl to the corresponding thiocarbonyl compounds. We are at present carrying out MO calculations to test this prediction.

$$\Delta A^O/\Delta A^S = 1 \quad (4)$$

Selenium Oxide Tetrafluoride

By *Konrad Seppelt*[*]

The search for the unknown selenium oxide tetrafluoride ($SeOF_4$) has now lasted almost thirty years[1]. Since the discovery of pentafluoroorthoselenic acid $HOSeF_5$[2] the general concensus of opinion was that $SeOF_4$ might be very unstable. Thus $SeOF_4$ was not detectable in the vacuum pyrolysis of the potassium salt $KOSeF_5$[3].

However, it has now proved possible to synthesize $SeOF_4$ using pure sodium pentafluoroorthoselenate[4] as starting material.

[*] Dr. K. Seppelt
Anorganisch-chemisches Institut der Universität
69 Heidelberg 1, Im Neuenheimer Feld 7 (Germany)

Selenium oxide tetrafluoride can be trapped as a white solid at 196°C. It decomposes above −100°C with liquifaction and frothing to give a colorless viscous liquid, which, according

$$NaOSeF_5 \xrightarrow{200°C/10^{-3}\,Torr} NaF + SeOF_4$$

to its NMR spectrum, is a mixture of several substances. The mass spectrum (75eV) of $SeOF_4$ shows the ions $SeOF_4^+$ (*m/e*=172, 14%), $SeOF_3^+$ (153, 100%), SeF_3^+ (137, 53%), $SeOF_2^{2+}$ (134, 89%), SeF_2^{2+} (118, 27%), $SeOF^+$ (115, 97%), SeF^+ (99, 29%), SeO^+ (96, 20%), and Se^+ (80, 35%). The only impurity found is $SeO_2F_2^{2+}$ (150, 57%).

Like its sulfur analog SOF_4, $SeOF_4$ very probably has a trigonal bipyramidal structure.

The fluorine atoms can rapidly interchange position. Accordingly, only one singlet is observed in the ^{19}F-NMR spectrum at δ = −88.7 ppm (solution in CF_3Cl, −110°C, $CFCl_3$ as external standard; 56.4 MHz). Remarkably, $SeOF_4$ has an absorption in common with SOF_4 at very low field strength (δ = −88.4 ppm[5]). The absence of the ^{77}Se isotope signals is a clear indication of the mobility of the fluorine atoms. Thus, isotope signals are observable in the case of the rigid molecules SeF_6, SeO_2F_2, and $SeOF_2$[6] but not in the case of SeF_4[7].

In the solid-state Raman spectrum [(−180°C, cm^{-1}) 1013 m, 755 m, 712 s, 608 m, 427 m, 387 w, 234 m] the band at 1013 cm^{-1} can be assigned to νSeO. This is the highest frequency so far recorded for a selenium-oxygen stretching vibration—for comparison, $SeOF_2$: 1005 cm^{-1}[8]—and would suggest the presence of a real double bond. Unequivocal assignment of the remaining bands is impossible without polarization and IR measurements.

It follows from the existence of the compounds $SeOF_4$ and $HOSeF_5$ that the chemistry of selenium is much more diverse than the chemistry of sulfur or tellurium; in the case of the latter elements only SOF_4 and $HOTeF_5$ have so far been found. This diversity is all the more surprising since selenium(VI) compounds are generally less stable than their sulfur and tellurium homologs. Finally, selenium oxide tetrafluoride is the only known compound of hexavalent selenium with fivefold coordination. The unusual coordination number also explains the instability of $SeOF_4$: the high viscosity of the "decomposition products" is indicative of polymerization. The previously reported decomposition[3] into SeF_6 and SeO_2F_2 could not be confirmed.

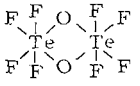
Diselenium Dioxide Octafluoride and Ditellurium Dioxide Octafluoride

By *Konrad Seppelt*[*]



Selenium oxide tetrafluoride was recently detected as an unstable molecule that polymerizes above $-100\,^{\circ}C$[1]. From the polymerizate a homogeneous fraction can be separated which, considering its high volatility, can only be the oligomeric $(SeOF_4)_2$ or $(SeOF_4)_3$. Vapor density measurements (Mol. wt.: obs. 343.8, calc. 341.9) and the mass spectrum [75 eV; *m/e* 325 ($Se_2O_2F_7^+$ 0.6%), 172 ($SeOF_4^+$ 19%), 153 ($SeOF_3^+$ 100%), 137 (SeF_3^+ 26%), 134 ($SeOF_2^+$ 7%), 118 (SeF_2^+ 7%), 115 ($SeOF^+$ 15%)] favor the dimer *(1)*.

$$2SeOF_4 \xrightarrow{-100\,^{\circ}C} (SeOF_4)_2$$

The structure of a molecule with this empirical formula must contain a four-membered ring:

(1)

(2)

This structure is supported by the ^{19}F-NMR spectrum, which contains a highly resolved A_2B_2 pattern ($\delta_A = -55.5$, $\delta_B = -93.3$ ppm; $J_{AB} = 228$, $J_{^{77}Se_A} = 1398$, $J_{^{77}Se_B} = 1306$ Hz; $CFCl_3$ as external standard). Accordingly, each half of the molecule contains two fluorine atoms in the four-membered ring plane as well as one above and one below the plane.

A center of symmetry in the molecule should be observable in the vibrational spectra. In fact only one, presumably accidental, coincidence is observed, despite the large number of IR and Raman bands [IR, gaseous (cm^{-1}): 760 vs, 732 vs, 705 m, 670 w, 627 m, 559 w, 497 m, 431 m, 407 s, 352 m, and 268 w.—Raman, liquid (cm^{-1}): 774 m p, 722 vs p, 651 sh p, 647 s p, 634 w dp, 620 w dp, 472 s p, 430 m dp, 425 sh dp, 314 w dp, 288 s p, 254 sh dp, 249 s p, 194 w dp, 162 m p, 150 sh dp, 102 s p].

No $TeOF_4$ could be detected in the vacuum pyrolysis of lithium pentafluoroorthotellurate[2]; however, the colorless ditellurium dioxide octafluoride *(2)* (b. p. 77.5 °C, m. p. 28 °C) analogous to *(1)* is formed.

$$LiOTeF_5 \xrightarrow{200\,^{\circ}C/10^{-3}\,Torr} LiF + \{TeOF_4\} \downarrow (TeOF_4)_2 \quad (2)$$

Proof of structure once again follows from a molecular weight determination (obs. 429.7, calc. 439.2), the mass spectrum [75 eV; *m/e* 444 ($Te_2O_2F_8^+$ 18%), 425 ($Te_2O_2F_7^+$ 54%), 409 ($Te_2OF_7^+$ 37%), 222 ($TeOF_4^+$ 5%), 203 ($TeOF_3^+$ 34%), 187 (TeF_3^+ 100%), 168 (TeF_2^+ 17%), 165 ($TeOF^+$ 15%), 149 (TeF^+ 10%)], the ^{19}F-NMR spectrum (A_2B_2 type; $\delta_A = 53.5$, $\delta_B = 25.6$ ppm; $J_{AB} = 188.5$, $J_{^{125}Te_A} = 3700$, $J_{^{125}Te_B} = 3600$ Hz), and the vibration spectra [IR (cm^{-1}): 736 s, 719 vs, 698 s, 660 m, 641 s, 635 m, 405 s, 330 s, 308 s, 285 m, and 269 s.—Raman (cm^{-1}): 749 m p, 710 w dp, 680 vs p, 656 s p, 606 w p, 589 s dp, 357 m p, 336 m dp, 236 s p, 192 s p, 145 w p].

The stability of *(1)* towards hydrolysis is a sign of good steric shielding of the selenium by its octahedral surroundings. On the other hand, *(2)* is sensitive to hydrolysis. *(2)* reacts especially rapidly with fluoride donors such as KF with formation of higher polymers $(TeOF_4)_n$.

The ring structure discussed here for oxide fluorides is unusual, and, in our opinion, novel. Similar structures have previously only been observed in ions, *e.g.* $I_2O_{10}H_2^{4-}$[3] and $As_2O_2F_8^{2-}$[4]. The dimerization of $SeOF_4$ and of the hypothetical $TeOF_4$ with coordinative saturation (to the octahedron) shows how unfavorable fivefold coordination is and how even a four-membered ring system, despite the strained valence angles, constitutes a preferred structure for the molecules. The *cis* structure in the $O_2SeF_4(O_2TeF_4)$ system, which is also found in $(F_5SO)_2SF_4$[5], can only be explained electronically, since the *trans* structure leads to a sterically unhindered configuration. The distance between the two Se and Te atoms in *(1)* and *(2)*, respectively, is about 30% smaller than van der Waals distances would allow; on the other hand, it is only about 20% greater than a chalcogen-chalcogen single bond. This estimation was based on the most plausible angle at the oxygen (100°). An interchalcogen interaction (Se ··· Se or Te ··· Te) would appear highly improbable due to a lack of available electrons.

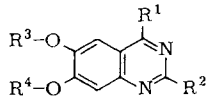
Reviews

Abstracts of selected progress reports and review articles

Use of lasers in the separation of isotopes is described by *C. B. Moore*. A species in a mixture of isotopes can be selectively excited by lasers. Numerous possibilities have been discussed for separation of the excited atoms or molecules, *e.g.* spontaneous predissociation, isomerization, or very fast reactions. Photopredissociation has functioned well in the only experimental separation of cited and nonexcited species to have been performed so far. A 1:1 mixture of CD_2O and CH_2O afforded D_2 and H_2 in a ratio of 1:6 (alongside 5% of HD). [The Application of Lasers to Isotope Separations. Accounts Chem. Res. *6*, 323—328 (1973); 31 references]

[Rd 686 IE—L]



The photochemistry of aliphatic azo compounds in solution is the subject of a review by *P. S. Engel* and *C. Steel*. On UV irradiation one of three unimolecular reactions occurs: nitrogen elimination, *cis-trans* isomerization, or rearrangement to a hydrazone. The authors consider, *inter alia*, spectroscopy and triplet energies, as well as photosensitization. [Photochemistry of Aliphatic Azo Compounds in Solution. Accounts Chem. Res. *6*, 275—281 (1973); 69 references]

[PR 99 IE –E]

An improved method for the production of esters of phosphoric acid involves reaction of phosphorus halides *(1)* with (thio)-phenols *(2)* in the presence of a carbamate catalyst at temperatures of up to 250 °C. The N atom of the carbamate should form a complex with the P atom of *(1)*; examples of suitable carbamates are ethyl carbamate, ethyl *N*-phenylcarbamate, ammonium carbamate, and silver dithiocarbamate. High yields are obtained without contamination of the phosphoric acid esters with by-products. Monosubstitution, disubstitution, or trisubstitution of *(1)* can be achieved by the choice of temperature. The reaction of $POCl_3$ with cresol in the presence of ethyl carbamate, for example, leads at 105—110 °C to cresyl dichlorophosphate. Addition of phenol and heating to 135—150 °C leads to cresyl phenyl chlorophosphate, which is converted into cresyl diphenyl phosphate with further phenol at 200—210 °C. [DOS 2230912; Monsanto Co., St. Louis]

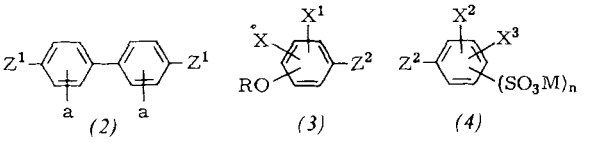
[PR 125 IE—V]

To prepare organic compounds containing labeled atoms, starting compounds, at least one of which contains a labeled atom, are brought into contact with fiber structures containing an enclosed enzyme that catalyzes the synthesis of the desired compound. Fiber-forming polymers of this type include cellulose esters, polyolefins, (co)polymers of acrylonitrile, (meth)acrylates, vinyl chloride, styrene, or polyamides. The enzyme reagents, which are made insoluble by the enclosure, can be easily recovered and reused. For example, [β-^{14}C]-L-tryptophan is obtained from [β-^{14}C]-DL-serine with an enzyme obtained from *E. coli* cells and enclosed in cellulose triacetate. Deuterium-labeled reduced nicotinamide adenine dinucleotide can be synthesized stereospecifically from NAD^+ and [1,1-D_2]-ethanol with alcohol dehydrogenase enclosed in cellulose triacetate. [DOS 2225797; Snam Progetti S.p.A., Milan] [PR 128 IE—V]



Transparent candle material that retains its transparency during storage, does not darken or discolor, and burns uniformly, consists of a thermoplastic polyamide resin and a combustible solvent that can dissolve the polyamide resin below about 100 °C to form a transparent gel. Unsaturated fatty acids and fatty alcohols, among other substances, are used as solvents. For optimum properties, the candle material should contain 5 to 35 wt.% of the polyamide resin. [DOS 2210220; Avon Products, Inc., New York] [PR 129 IE—E]

Magnetic data supports in which the magnetizable particles are incorporated directly in the support material so that the tape forms a homogeneous mass are produced from polypropylenes with molecular weights of 100000 to 5 million and containing 15 to 30 wt.% of material that is soluble in boiling heptane. In addition to polypropylene, copolymers of propylene with ethylene, vinyl acetate, and (meth)acrylic esters and mixtures of polypropylene with ethylene/propylene or ethylene/vinyl acetate copolymers may also be used. The polymers mentioned have good pigment tolerance and outstanding mechanical properties. The polymer is generally loaded with magnetic pigment in a weight ratio of 40:60 to 15:85. [DOS 2116760, Badische Anilin & Soda-Fabrik, Ludwigshafen] [PR 130 IE—E]

Bis-stilbene compounds such as *(1)* are used as optical brighteners for organic materials; detergents may contain 0.01—2 wt.% of at least one of these compounds *(1)*. They are prepared by reaction of equivalent quantities of *(2)*—*(4)* in the presence of a strongly basic alkali metal compound and a preferably hydrophilic, strongly polar solvent [DOS 2209221; Ciba-Geigy AG, Basel]

BOOK REVIEWS

Wörterbuch der Chemie und der chemischen Verfahrenstechnik. Dictionary of Chemistry and Chemical Engineering. Vol. 2, English/German. By *L. De Vries* and *H. Kolb*. Verlag Chemie GmbH, Weinheim/Bergstr. and Academic Press, New York—London 1972. 1st ed viii 644 pp., bound DM 135.—.

The English-German edition of this technical dictionary now takes its place alongside the German-English edition, which appeared in 1970[*]. It consists of the actual dictionary section and an appendix containing a table of the chemical elements, a list of British and American weights and measures, and a temperature conversion table, as well as the abbreviations used. The terms listed (about 67000 entries) cover the vocabulary of pure and applied chemistry, particularly process

[*] Cf. Angew. Chem. internat. Edit. *10*, 947 (1971).

engineering, reactor technology, and the metal, petroleum, rubber, and textile industries, as well as the adjoining fields of physics, biology, medicine, mathematics, mineralogy, and crystallography and the disciplines of biochemistry, biophysics, atomic physics, *etc.*

In addition to the technical terms, the clearly legible and carefully prepared book (the number of printing errors found was negligible) also lists a large number of substances with their trivial names and systematic names. Some of the shortcomings found in the German-English edition have been eliminated in the present English-German edition. On leafing through the book, it was noted that the nomenclature rules were not strictly followed in some cases. For example, the German for manganous sulphate is Mangan(II)-sulfat, not Manganosulfat, while manganese fluosilicate is Manganfluorosilicat and not Mangansilicatfluorid. The translation of esters of hypophosphorous acid is also incorrect. These errors ought to be corrected in the next edition.

Nevertheless, the dictionary is a valuable aid to scientists and engineers, and a mine of information for technical translators.

Christian Weiske [NB 174 IE]

Laboratory Methods in Infrared Spectroscopy. Edited by *R. G. J. Miller* and *B. C. Stace*. Heyden & Son Ltd., London—New York—Rheine. 2nd ed., 1972, xi, 375 pp., numerous figures and tables, bound DM 56.50

IR spectroscopy has become a dependable workhorse for many problems of structural elucidation, identification, and quantitative analysis. The special strengths of IR spectroscopy are that it can be used for the investigation of substances in any aggregation state and that analyses can be carried out on samples in the microgram range and under extreme conditions. The present book may be very helpful in problems of this type that lie close to the limits of the range of application.

The editors have been able to bring together the experience of many practical workers in a manner that is rarely found in publications. The book, which contains numerous figures, diagrams, tables, and spectra, will undoubtedly prove useful in many IR laboratories.

Bernhard Schrader [NB 178 IE]

Physik griffbereit. Definitionen—Gesetze—Theorien (Physics at Your Fingertips. Definitions—Laws—Theories). By *B. M. Jaworski* and *A. A. Detlaf*. Friedr. Vieweg & Sohn, Braunschweig 1972. 1st ed., 892 pp., 259 figs., 26 tables, bound DM 24.80.

According to the foreword by the translator and German editor *F. Cap*, the present book is intended as a concise reference work for preparation for examinations and lectures and to provide "the internationally usual minimum of general and 'theoretical' physics that is to be expected of any physicist".

In agreement with this aim, the selection of material covers a wide range and is not to be found in the hitherto known German-language literature. The opening chapter on the fundamentals of classical mechanics includes basic concepts such as velocity and acceleration and the principal points of analytical mechanics, *i.e.* Lagrangian and Hamiltonian functions, as well as the variation principle. Hydromechanics and aeromechanics have a chapter to themselves. A chapter on thermodynamics contains both the classical theory and the principal concepts of the statistical approach. Two chapters on electricity and mangetism and on waves include the subject matter of normal lectures in electrodynamics and optics. In addition to the central points such as the Maxwell equations, the special theory of relativity, and geometric and wave optics, marginal fields such as acoustics, thermoelectric phenomena, and luminescence are also touched upon. The last chapter is devoted to advanced experimental physics and contains the fundamentals of atomic, nuclear, and elementary particle physics.

With this range of subject matter the book is well able to fulfill its authors' aims over wide areas. The smooth transition between the material of introductory theoretical lecturers and that of special experimental courses should help the student to form links between areas that are often treated as quite isolated from one another in Germany.

The selection of material is perhaps open to criticism with respect to solid-state physics. Many concepts crop up only as items scattered throughout the book, so that one cannot speak of a didactically systematic treatment of the subject. Important concepts such as Brillouin zone and *Umklapp* process are missing.

Some readers will notice a lack of up-to-dateness in the chapter on atomic physics, since recent developments as important as optical pumping and laser physics are omitted.

The most serious omission, however, is undoubtedly the absence of any bibliography at the ends of the various chapters. Reference to at least a few suitable text books for further reading would greatly enhance the value of the book.

On the whole, the book can be recommended to anyone who is less concerned with experimental facts than with having at hand a quick reference to fundamental theories.

R. Tilgner [NB 163 IE]

Annual Reports in Synthesis—1971. Eds. *J. McMurry* and *R. B. Miller*. Academic Press, New York—London 1972. 1st edn., xiv, 347 pp., $ 7.50.

This report, which is in its second year, is one more attempt to save the synthetic organic chemist from drowning in the continuously increasing deluge of information. Its eight chapters (C—C Bonding, Oxidations, Reductions, Heterocyclic Syntheses, Protecting Groups, Useful Preparative Methods, Various Reviews, and 'Completely Different Reactions') present the facts in the briefest form—reference, reaction equation and sometimes yield—and cover 49 primary journals of organic chemistry for the period between March 1st 1971 and March 1st 1972. As in the comparable collection of references in 'Reactiones Organicae' of the journal Synthesis, the series aims primarily at presenting the information in rapidly assimilable visual form.

To provide an idea of the completeness of this "box of cards in book form" its entries were compared with the short communications on synthetic methods that appeared during the above period in Angewandte Chemie and the Journal of the American Chemical Society. Very few gaps were noticeable. The rare mistakes that the Reviewer noted (*e.g.* pp. 120, 138, 168) were misprints. Although, to save time and expense, no index is provided, the information sought can generally be rapidly found through the detailed List of Contents. Longer thumbing through the book is rewarded by discovery of one or more methods new to the reader.

As the series is a considerable help in the study of the literature our first wish is for continuation of the series, but this can be coupled with a request for more cross-references in future volumes. This aid to the literature should, in the well-worn phrase, be to every chemist's hand and it is to be hoped that this will in fact occur in view of the extraordinarily cheap price of about one cent per reference.

Henning Hopf [NB 172 IE]

Synthetic Nucleotides. Vol. 1. By *G. R. Pettit*. Van Nostrand Reinhold Comp., New York—London 1972. 1st ed., viii, 252 pp., bound £ 10.00.

In this book, *G. R. Pettit* presents a long-needed comprehensive tabular survey of synthetic nucleotides.

All the important nucleotides mentioned from 1945 to June 1971, together with their methods of synthesis, are discussed in nine chapters, starting with the mononucleotides having the bases U, C, T, A, and G and their derivatives and proceding *via* the oligonucleotides to the polynucleotides. In each chapter the tables are preceded by brief descriptions and formulas for well-planned and well-proven syntheses.

In addition to the literature references, each table contains a brief outline of the phosphorylation method and information about the solvent and the chromatographic procedure. UV values, melting point, and yield are given. The tables also show whether R_f values, electrophoresis values, and elemental analyses are given in the original literature for the characterization of the nucleotides and what spectroscopic methods and enzymatic tests have been used.

The author has put a great deal of work into separating the wheat from the chaff in the nucleotide chemistry literature of the past 25 years, some of which is rather obscure. It is pleasing to know that the author intends to continue this work in the same way as his "Synthetic Peptides". It should be pointed out, however, that the present book has a number of shortcomings, both with regard to its content and of a technical nature.

In a book that claims complete coverage of the results of the last 25 years, the number of references (barely 350) is far too small. Furthermore, a good 10% of these are connected with the historical discussion in the introductory chapter. The author rightly criticizes the fact that the characterization of the nucleotides is often based on faith. It is therefore difficult to understand why he does not cite articles in which abundant use is made of enzymatic and spectroscopic techniques. Moreover, the table should also give experimental values from other publications. Another desirable feature would have been references to other recent important reviews.

Despite these reservations, the book should certainly be very useful to nucleotide chemists and to chemists who wish an insight into this field. It should find a place in any library.

Kay Schattka [NB 176 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

The Scientific Principles of Crop Protection. By *H. Martin*. Edward Arnold, London 1973 6. Edit., VIII, 423 p., bound £ 12.—.

Contents: Plant Resistance; External Factors; Biological Control; Pesticides; Measurement and Mechanics of Toxicity; Fungicides; Insecticides; Herbicides; Fumigants; Seed Treatment; Soil Treatment; Traps; Centres and Vectors of Infection.

Analytical Chemistry of Neptunium. By *V. A. Mikhailov*. From the series "Analytical Chemistry of the Elements". Edited by *A. P. Vinogradov*. Israel Program For Scientific Translation, Jerusalem–London/Halsted Press, New York 1973. VII, 235 pp., bound £ 9.35.

Contents: Separating Neptunium from Foreign Elements; Quantitative Determination of Neptunium.

Coordination Chemistry – XIV. Edited by the International Union of Pure and Applied Chemistry in collaboration with the National Research Council of Canada and the Chemical Institute of Canada. Symposium Editor: *A.B.P. Lever*. Butterworths, London 1973. 651 pp., bound £4.50. – Plenary lectures at the XIV. International Conference on Coordination Chemistry, 22–28 June 1972 in Toronto/Canada.

Chemistry of Marine Natural Products. By *P. J. Scheuer*. Academic Press, New York–London 1973. XI, 201 pp., bound $ 14.00.

Contents: Isoprenoids; Sterols; Benzenoids; Nitrogenous Compounds; Nonaromatic Compounds with Unbranched Carbon Skeletons.

Advances in Quantum Chemistry, Vol. 7. Edited by *P.-O. Löwdin*. Academic Press, New York—London 1973. XVI, 445 pp., bound $ 29.50.

The Challenge to Macromolecular Science[**]

By Paul J. Flory[*]

The adaptation of polymeric materials for the artifacts of man originated in antiquity. Techniques for processing fibers, hides, wood, rubber, and naturally-occurring resins have precedents that predate recorded history. These are amongst the oldest technologies that have evolved over the centuries and up to the present. By contrast, the *science* of polymers, or macromolecules, made a late appearance—late, that is, relative to other branches of science. The modern science of molecules that we call chemistry had its beginnings around 1860. The foundations of quantum theory and quantum mechanics were established from 1900 to 1925, the theory of relativity from 1905 to about 1920. The basic concepts underlying macromolecular science were not put forward until after these epoch-making advances had determined the course and content of chemistry and physics for decades to come.

The motif of macromolecular architecture—the concatenation of atoms, or groups of atoms, to form covalently linked chains of great length—did not achieve widespread acceptance as the structural principle pervading virtually all polymeric substances until 1930 and doubts concerning its reality lingered for some years thereafter. Polymeric chemical structures had been suggested—even advocated—as much as 70 years earlier. However, for reasons difficult to grasp in retrospect linear macromolecular structures were rejected in every instance. Instead, small cyclic structures were ascribed to substances now recognized as polymeric, in the molecular sense of this term. Thus, rings of three to twelve members were proposed for proteins, rubber, cellulose, starch, and various synthetically prepared polymers. The preoccupation of chemists in general with molecules representable by concise formulas conveniently expressed on the printed page seems to have generated an overpowering conviction that all substances should be so constituted. The much larger chemical structures suggested from time to time for the most commonplace of substances, and the most important ones in the environment of man, were consistently cast aside, probably on this account.

Not until the late 1920's was it clearly established that cellulose and starch are high polymers consisting at the molecular level of long chains. The epic of natural rubber is similar: determination of the chemical structure of the unit at the beginning of this century, appearance of a variety of cyclic formulas, and finally, in the late 1920's, the belated acceptance of the polymeric chain formula.

The polypeptide hypothesis regarding the chemical structure of proteins put forward by *Hofmeister* and by *Fischer* about 1902 did not gain widespread acceptance before 1930. As late as the mid 1920's leading organic chemists of the period vied with one another in matches of ingenuity to invent esoteric cyclic structures for proteins, all seemingly in a vain effort to avert adoption of the polypeptide chain structure as the pattern for life-giving proteins, the abundance of chemical and physical evidence in support of the polypeptide structure notwithstanding. Evidently the vision of a polymeric structure for materials of such supreme importance was repugnant. Whether the polypeptide chain was regarded as inherently objectionable or merely something to be opposed because it departed from the structures that were in the mainstream of chemists' endeavors is a matter for conjecture. Bear in mind that *Fischer* had completed his *tour de force* in synthesizing a polypeptide of 30 units during the first decade of the century. Yet, even he clung to the belief that proteins consisted of chain molecules no longer than those he had synthesized, a number of these being "colloidally" aggregated to form the protein "particle."

[**] Based on an address delivered at the dedication of Midland Macromolecular Institute, Midland, Michigan (USA), on September 28, 1972. The text will also appear in the International Journal of Polymeric Materials and in *H.-G. Elias*: Trends in Macromolecular Science (Midland Macromolecular Monographs, Vol. 1), published by Gordon & Breach, New York—London.

The saga of polynucleotides is even more striking. According to opinions that went essentially unchallenged until the mid 1940's, they were tetrameric. Only in the 1950's was it established that they consist of long chains of nucleotide units numbering as many as hundreds of thousands.

Evolution of ideas regarding synthetic polymers followed a similar course. Synthetic polymer chemistry developed rapidly once their molecular nature was understood and hence the skills of the chemist could be turned systematically to their preparation in ever-increasing variety. The influence of the pioneering work of *Staudinger* and *Carothers* in this period cannot be over-estimated. Their work placed the macromolecular hypothesis on a firm footing and at the same time elaborated methods of measurement and synthesis.

It is important to observe that macromolecules are not clearly demarcated from their analogs of lower molecular weight. In every series of macromolecular homologs, species of intermediate chain length occur. The chemical bonds joining atoms in macromolecules are not discernibly different from those in small molecules; they are described by the same geometrical parameters. Any sharply drawn distinction between the domain of the molecules that are commonplace in the laboratory and the macromolecules that are commonplace everywhere else must necessarily be arbitrary. Hence, the science of macromolecules is fundamentally coextensive with the rest of chemistry, and with some of the ramifications of physics too. Not to be overlooked, however, is the inescapable fact that definite alterations in concept and theory are required for the understanding of macromolecules. Knowledge in the domain of giant molecules is not to be gained by simple deduction from concepts and rules gathered for small molecules. Modifications in viewpoint and method are required, and in some respects a different set of guidelines must be adopted.

The relatively late emergence of macromolecular science has had an important consequence that weighs heavily on present and future. The basic pattern of chemistry as a discipline, with its traditional subdivisions, became established prior to the appreciation of the molecular nature of polymers, and prior to the appearance of theories and generalizations describing their behavior. Macromolecules were therefore left out of the syllabus in its formative years. Only a few desultory remarks on colloids found a place in the textbooks, and these were generally misleading, if not wrong altogether. The subject has not gained entry since. Irrespective of one's views on the proper place for polymer chemistry and physics in the curriculum, its virtual absence therein at present is a fact to be reckoned with.

The relevance of polymer science to industrial technology is self-evident, and, I think, widely recognized. I have already alluded to the close temporal correlation between the emergence of polymer science and the proliferation of synthetic polymeric materials. If the former did not in fact furnish the main impetus for the latter, at least it has played a major role in bringing into being what posterity may refer to as the age of polymers. Incidentally, I also believe it is a valid assertion that pure and applied polymer science continue to enjoy a mutually fruitful relationship.

The relevance of polymer science to biology seems not so well appreciated. Custom, and perhaps prejudice rooted in the never-dying vitalistic view of things living, seem to sustain the impression that biopolymers are unrelated to the technological members of the polymer family. To be sure, biopolymers have acquired certain attributes in the course of their evolution that are not shared by their less refined relatives. But there are basic properties and behavioral patterns shared by all polymers: the thermodynamics of their solutions, rules governing their spatial configurations, manifestation of high elasticity under suitable conditions, crystallization, *etc.* The tendency to relegate biopolymers and technological polymers to different categories works to the detriment of the fuller understanding of both. If molecular biology is to rest on a sound *molecular* basis, then logic dictates that that basis be provided by the science of polymeric molecules. For this purpose a polymer science concerned with the fundamentals of macromolecular behavior in the broadest sense is required.

There is a further role for macromolecular science, and one for which it is especially well suited. I refer to the communication between science and the public. Most subjects at the forefront of science pertain to matters abstruse and quite remote from the interests and awareness of the nonspecialist. Chemistry is illustrative: its compounds, theories, and reactions offer relatively few opportunities for cultivation of interest on the part of the public at large. Polymeric materials, being exemplified in profusion in a multitude of articles of commerce, not to mention biopolymers too intimate to require mention, are ideally suited as subjects for communication of science to a wider audience. It is here that polymer science enjoys a special opportunity by virtue of its subject and purview.

Nevertheless, macromolecular science still has a long way to go if it is to meet the challenges I have indicated. Much basic and creative science needs to be carried forward. Coherence of the subject through systematization of existing knowledge is of ever increasing importance as research spreads into new directions. At the same time, the importance of cultivating connections between macromolecular science and related fields should not be overlooked.

Polymers as Reagents in Organic Synthesis

By C. G. Overberger and K. N. Sannes[*]

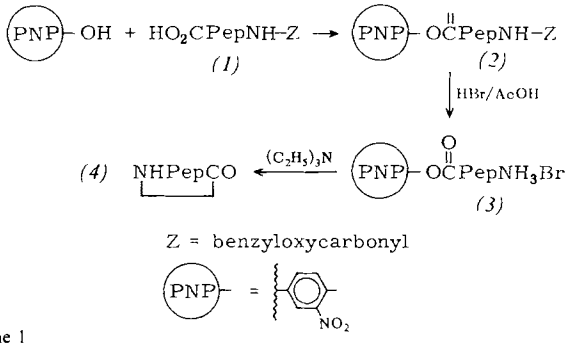
Polymeric reagents offer a range of unique advantages. Intramolecular reactions, such as the cyclization of peptides or Dieckmann cyclizations, can be brought about by attaching the reactive molecules at remote points along a polymer chain. In contrast, if the reactive molecules are anchored in close proximity on a polymeric support then intermolecular reactions occur, as demonstrated for a ketone synthesis. Apart from such proximity effects, cooperative effects can also be exploited, *e.g.* in the formation of a 2:1 complex of a crown ether and an alkali metal ion. The hydrolysis of an ester with polyvinylimidazole provides a detailed illustration of hydrophobic interactions. The simple separation of polymer-bound and low-molecular compounds by filtration is another significant advantage.

1. Introduction

One of the first applications of a macromolecule as a "solid support" in organic synthesis has served to revolutionize the field of peptide fabrication. Condensing specific sequences of amino acids onto a growing peptide, which is attached to an insoluble polymer, has, at least in principle, changed peptide synthesis from one of tedious, multi-faceted separations to a procedure which has been automated. No further account[1] of this field will be given in this report except for certain studies which apply to the topic under discussion. Instead, this report contains what we thought to be novel applications of polymeric reagents in synthetic organic chemistry. No attempt at inclusiveness has been made.

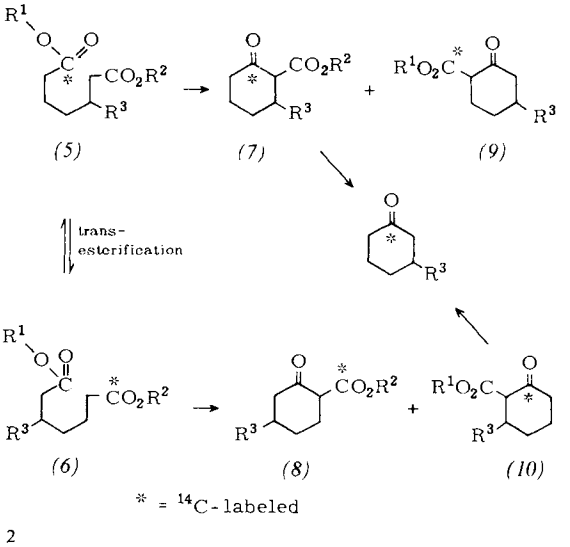
2. Proximity Effects

2.1. Dilution or Separation of Reactants



The ability to control the relative rates of competitive reactions in a given system constitutes a good portion of successful synthetic chemistry. In particular, cyclization reactions are successful only when the rate of the intramolecular ring closure reaction is higher than that of the competing intermolecular coupling reaction. Traditionally, high dilution of the reactant has been used to reduce the rates of the latter reaction and thereby increase the amount of desired cyclic product formed. Obviously this method has its limitations.

Another method of limiting the rate of intramolecular reactions consists, in theory, of anchoring each molecule to be cyclized to a functional group along a polymer chain at intervals that preclude intermolecular (strictly speaking "intrapolymeric") reactions.



The ring closure of amino acids attached to a polymeric support demonstrates the feasibility of this type of reaction[2, 3].

As outlined in Scheme 1, the *N*-blocked amino acid *(1)* is attached to poly-4-hydroxy-3-nitrostyrene to form the polymer ester *(2)*. Removal of the blocking group affords the amine *(3)* which, upon treatment with triethylamine, undergoes cyclization with simultaneous separation of the newly formed cyclic peptide *(4)* from the insoluble macromolecular support.

Another study has demonstrated the feasibility of performing Dieckmann reactions on diesters which are bonded to solid supports[4]. Potassium salts of ^{14}C-labeled pimelate half esters were treated with either chloromethylated polystyrene or benzyl chloride to form compounds *(5a)*, *(5c)*, *(5e)* and *(5b)* and *(5d)* respectively (Scheme 2). Treatment of *(5a)*, *(5c)*, or *(5e)* with base affords 15—46% yields of cyclized products (Table 1).

Scheme 1

Scheme 2

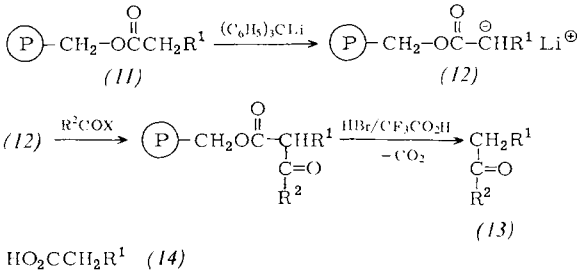
The University of Michigan
Ann Arbor, Mich. 48104 (USA)

[**] Based on a lecture delivered on the occasion of the dedication of the Midland Macromolecular Institute, Midland, Michigan (USA) on September 28, 1972. The text will also appear in the International Journal of Polymeric Materials and in *H.-G. Elias:* Trends in Macromolecular Science (Midland Macromolecular Monographs, Vol. 1) published by Gordon & Breach, New York—London.



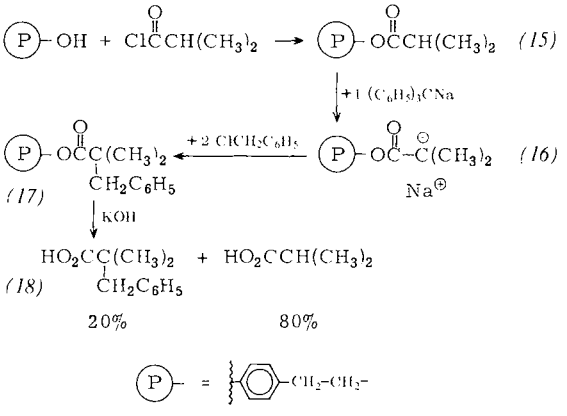
There are additional advantages offered by the solid support system that warrant discussion. For example, *(5b)* affords two cyclic products, the alkyl and benzyl esters *(7b)* and *(9b)* respectively, when treated with base (Table 1). Also, reactions begin to interfere. The successful acylation reactions employed 0.1—0.3 mmol of ester/gram of polymer and competing reactions were evident at concentrations of 1.5—2.0 mmol of ester/gram of polymer.

Table 1. Examples of Dieckmann cyclizations of the diesters *(5)* (see Scheme 2: Ⓟ = polymer).

Cpd.	R^1	R^2	R^3	*(7)* : *(8)*	Yield [mol-%] *(9)* + *(10)*
a	Ⓟ-$C_6H_4CH_2$	$C(C_2H_5)_3$	H	99.69 : 0.31	—
b	$C_6H_5CH_2$	$C(C_2H_5)_3$	H	98.30 : 1.70	10
c	Ⓟ-$C_6H_4CH_2$	$C(C_2H_5)_3$	C_2H_5	97.25 : 2.75	—
d	$C_6H_5CH_2$	$C(C_2H_5)_3$	C_2H_5	96.80 : 3.20	21
e	Ⓟ-$C_6H_4CH_2$	C_2H_5	H	mixture	—

the group R^3 occupies a different relative position on the ring in *(7b)* and *(9b)*. While reaction of *(5a)*, for example, with base might form *(7a)* as well as *(9a)*, the cyclic compound *(9a)* remains attached to the polymer support and can be separated from *(7a)* by filtration. This eliminates the need for the separation of the two similar keto esters as is the case in reactions of *(5b)* and *(5d)*. Evidently a hindered ester [1,1-diethylpropyl in *(5a)* and *(5c)* instead of ethyl as in *(5e)*] must be used to prevent transesterification. Once this has been done, the procedure can serve very nicely in the preparation of specifically labeled ring compounds. As mentioned, this method can probably be extended to systems with various ring sizes.

Successful acylation[5] and alkylation[6] of active methylene esters bound to polymer supports have been reported. Again, in the acylation of active methylene esters the competing self-condensation reaction is reduced to negligible proportions by attaching the active esters at intervals sufficiently large to prevent intrapolymeric reactions. Another undesired reaction, diacylation, is also prevented, presumably for similar reasons. The reactions in Scheme 3 provided a *single* ketone in each case (Table 2). Analogous reactions without the polymer support resulted in several ketonic compounds. Reasonably, it was observed[5] that if the concentration of ester bound to the polymer becomes too high the intrapolymeric



Scheme 3

Table 2. Examples of the preparation of ketones *(13)* with polymer-supported esters *(11)* having active methylene groups (see Scheme 3; Ⓟ = polystyrene).

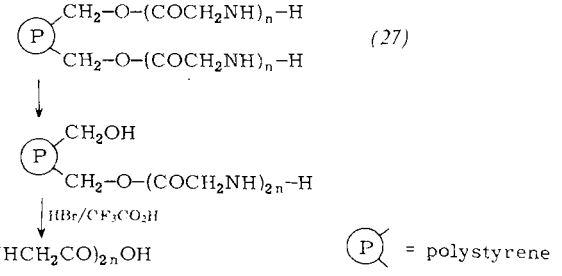
The alkylation of isobutyric acid[6] which was esterified onto a non-benzylic support, as depicted in Scheme 4, afforded only 2,2-dimethyl-3-phenylpropionic acid *(18)* and unreacted isobutyric acid in 20 and 80% yields, respectively.

Scheme 4

2.2. Forced Combination of Moieties Connected to the Same Macromolecule

In contrast to the effect obtained by separating interreactive molecules by bonding them remotely on a macromolecule, a system could, in principle, be constructed with two types of molecules held in close proximity in order to promote this "intrapolymeric" reaction. In practice this type of proximity effect is involved in the reaction outlined in Scheme 5[7].

Scheme 5



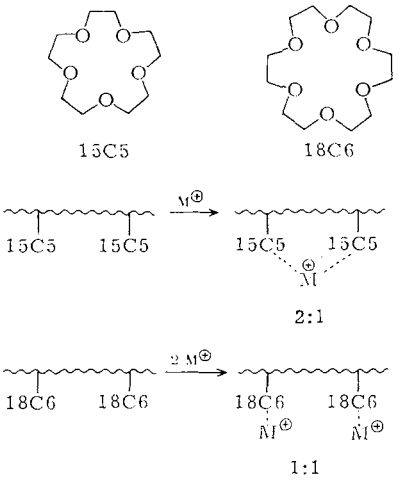
A small percentage (2.3—2.5%) of chloromethylated polystyrene groups were esterified with a limited amount of an enolizable acid *(19)* and the remainder of the groups with a nonenolizable acid *(21)* to give the mixed ester *(22)*. The addition of base results in internal condensation to form *(24)* which after esterolysis and decarboxylation provides *only* ketone *(26)* and starting acids *(19)* and *(21)* (Table 3). Analogous

Table 3. Examples of intrapolymeric synthesis of ketones *(26)* with enolizable acids $R^1CH_2CO_2H$ *(19)* and nonenolizable acids R^2CO_2H *(21)* (see Scheme 5, Ⓟ = polystyrene).

R^1	R^2	*(26)*, yield [%]	Yield [%] in analogous reaction in solution
$CH_3(CH_2)_5$	*p*-ClC_6H_4	35	30
C_6H_5	C_6H_5	45	—
$C_6H_5CH_2$	C_6H_5	85	42
$CH_3(CH_2)_3$	C_6H_5	95	—
$C_6H_5CH_2$	*p*-ClC_6H_4	85	20

reactions under similar conditions but without the polymer support lead to a more complex mixture of products. The intrapolymeric nature of the reaction *(23)*→*(24)* in Scheme 5 is evidenced by the fact that no ketone was observed when two batches of polymeric esters—one with an enolizable and one with a nonenolizable ester—were reacted and worked-up under conditions similar to those used for *(22)*. This finding is in line with the fact that a larger ratio of $R^2:R^1$ in *(22)* results in higher yields of *(26)*.

In the solid-phase synthesis of peptides, side-reactions limit the length of the peptide chain that can be obtained in purified form. Thus a "chain doubling" reaction (Scheme 6) resembling



Scheme 6

the condensation of two esters bound to a polymer chain has been reported in the Merrifield synthesis of peptides[8]. Chain doubling takes place only when the distance between peptide residues on *(27)* permits its occurrence. The study in question used 0.5 to 0.7 mmol of peptide/gram of peptide resin. A lower concentration of peptide residues would tend to reduce chain doubling. Other factors that may prove to be important in these intrapolymeric reactions are the chain length of peptide, the nature of the polymeric leaving group, degree of cross-linking of the support, and the solvent system.

3. Cooperative Effects

The fact that juxtaposition of reactive moieties can be "ensured" if they are pendant groups of a polymer is the basis of another advantage of polymeric reagents which has been termed "cooperative effects". In a polymer the reaction of two pendant groups with a third molecule from the solution mimics a bimolecular reaction which has much less stringent entropy requirements than a termolecular reaction in solution. This phenomenon has been called on to explain kinetic results of enzyme prototype systems.

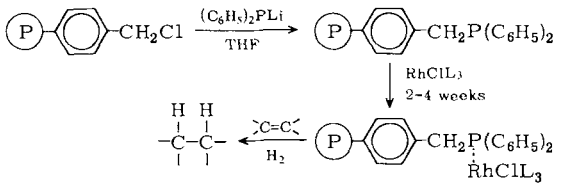
Recently, complexes of alkali metal ions with either polymeric crown ethers or their monomeric crown ether analogs have been studied[9]. The cyclic monomeric ethers 15C5 and 18C6 (Scheme 7) form 2:1 and 1:1 complexes, respectively, with

Scheme 7

fluorenylpotassium in THF, and solid complexes with KCNS. Available evidence points toward the same stoichiometry with polymeric ethers. This difference in the stoichiometry of 15C5 and 18C6 ethers has been reasonably attributed to the difference in ring diameter of the two ethers. The generally larger ratios of polymeric to monomeric complexing strength in the 15C5 ether systems compared to the corresponding ratios in the 18C6 system (Table 4) can be readily explained by assuming that two crown units complex with each alkali metal ion in the former system. Two crown units are held in close proximity in the polymer, and the "polymeric" 2:1 complex would form more readily than would the three-unit complex in the 15C5 monomeric system. The difference between polymeric and monomeric systems would not be expected to be so great for the 1:1 complexes.

Table 4. Ratios of complexing abilities of analogous polymeric *versus* monomeric crown ethers (Ⓟ = polymer, 15C5 and 18C6, see Scheme 7).

M^+	Ⓟ-15C5 : 15C5	Ⓟ-18C6 : 18C6
Li^+	>10 : 1	6.2 : 1
Na^+	2.3 : 1	1.6 : 1
K^+	3.8 : 1	1.1 : 1
Rb^+	6.4 : 1	1.1 : 1
Cs^+	19.7 : 1	



4. Selectivity of Substrate

4.1. Influence of Size

If the active site of a macromolecule is located inside a semiordered insoluble polymer, it is not difficult to visualize a situation in which the rate of reaction of substrates would depend

on their ability to gain access to this active site. For example, the size of a molecule would certainly be one such factor.

A system such as is described above has been reported in a study in which the selective hydrogenation of olefins was demonstrated with a polymer-supported rhodium(I) catalyst *(28)* (Scheme 8)[10]. As Table 5 shows, the relative rate of

Scheme 8 *(28)*

hydrogenation of cyclic olefins depends upon the size of the ring when the catalyst is coupled to a macromolecule as in *(28)*, while this effect is not evident with tris(triphenylphosphane)rhodium(I) chloride as catalyst.

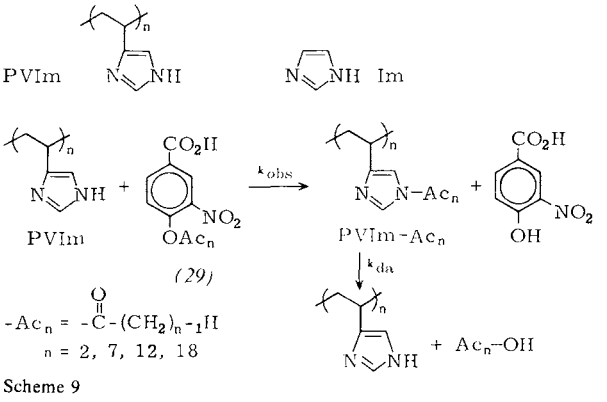


Table 5. Examples of hydrogenation rates of cyclic olefins with polymer-bound catalyst *(28)* and with $RhCl[P(C_6H_5)_3]_3$ (2.5 mmol/l) (see Scheme 8; Ⓟ = polymer).

olefin	Relative rate	
	(28)	$RhClL_3$
cyclohexene	1	1
cyclooctene	0.39	1
cyclododecene	0.22	0.67
2-cholestene	0.03	0.72

4.2. Hydrophobic Effects and Interactions

In aqueous solutions, apolar (hydrophobic) bonding between two hydrophobic molecules has been shown to increase the rate of hydrolysis of esters by polymeric catalysts.

Hydrolysis of the ester bond in 3-nitro-4-dodecanoyloxybenzoic acid *(29)*, n = 12 (Scheme 9) with the synthetic, macromo-

Scheme 9

lecular catalyst polyvinylimidazole (PVIm)[13] was *ca.* 10^3 times as fast as with monomeric imidazole (Im)[14]. These hydrolysis rates were found to be critically dependent on the chain length of the acyloxy group of the substrate and on the solvent composition. The bulk of the rate enhancement was thus attributed to apolar (hydrophobic) association of catalyst and substrate.

During the study of the polyvinylimidazole- and imidazole-catalyzed hydrolyses of the ester *(29)* in ethanol-water mixtures of various compositions a very interesting autocatalytic or *accelerative kinetic pattern* was observed (see Fig. 1). The rate of the reaction continuously increased so that at 75% completion the rate was *ca.* 5 times faster than the initial rate.

On observing the deacylation rates of the polymeric acyl imidazoles PVIm—Ac_n (see Scheme 9), it was noted that for the cases exhibiting the accelerative behavior, deacylation of the intermediate was the rate-determining step. This again demonstrates the influence of apolar bonding on the rates of ester hydrolysis. The acylated polymer is more hydrophobic than the non-acylated polymer.

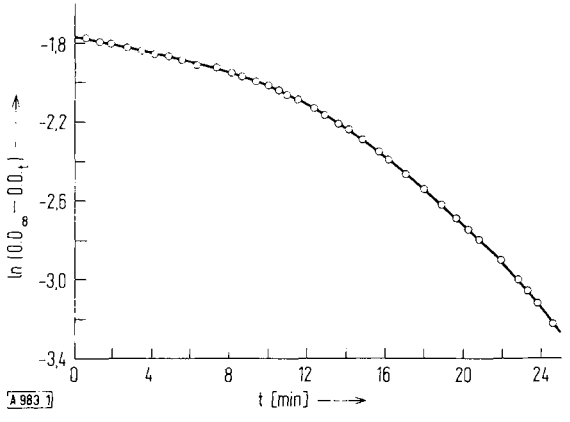

Fig. 1. Kinetics of the accelerative pseudo-first-order hydrolysis of the ester *(29)*, $n = 12$, 40 vol% C_2H_5OH/H_2O, $[PVIm] = 5.0 \times 10^{-4}$ mol/l [*(29)*, $n = 12$] $= 5.0 \times 10^{-5}$ mol/l, $\mu = 0.02$, [Tris buffer] = 0.02 mol/l, pH = 8.0, 26 °C. O.D. = optical density.

Table 6 shows the surprisingly large dependence of the deacylation rate on the chain length of the acyl group. This observation

is rationalized by considering formation of a polysoap-like structure as the polymer is increasingly acylated with long-chain groups[15].

Figure 2 shows the effect of varying the degree of acylation of PVIm with dodecanoic acid on the hydrolyses of *(29)*, $n = 7$, and *(29)*, $n = 2$. Particularly for *(29)*, $n = 7$, the rate increased as the content of long-chain acyl groups increased. These results served to elucidate the cause of the accelerative behavior[15]. Progressive intramolecular micellarization occurring along the polymer chain creates an increasingly nonpolar molecule. This results in an enhancement of the apolar associa-

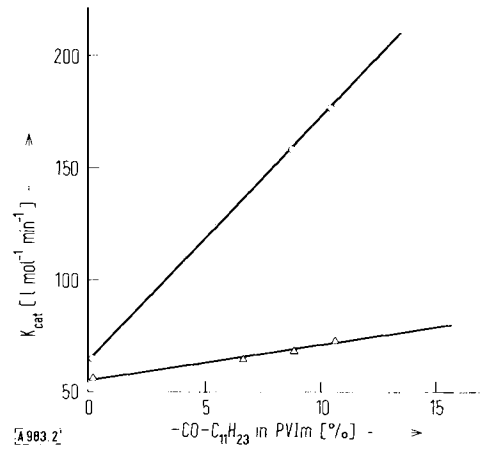

Fig. 2. Catalytic hydrolysis of the esters *(29)*, $n=7$ (O—O) and *(29)*, $n=2$ (Δ···Δ) with PVIm having various degrees of dodecanoylation. 33 vol% C_2H_5OH/H_2O, $\mu=0.02$, [Tris buffer] = 0.02 mol/l, pH = 8.0, 26 °C.

tion of substrate and catalyst. Undoubtedly, a conformational change accompanies this process of polysoap formation which is evidenced through the kinetics of the hydrolysis reaction.

The situation described above may be considered conceptually similar to the *allosteric effect* displayed by certain enzyme systems[16]. The catalytic function of enzymes may be affected and controlled by interaction with small molecules, not only directly, at the active site, but also indirectly, at distant, secondary allosteric sites. Generally, a conformational change accompanies the appearance of allosteric phenomena. The accelerative behavior is evidence of a conceptually similar occurrence in the case of the synthetic, macromolecular catalyst, polyvinylimidazole.

Hydroxylamine is known to be more than 10^5 times as effective as water in acyl transfer from acetylimidazole[17]. Figure 3 demonstrates the effect of added hydroxylamine on the

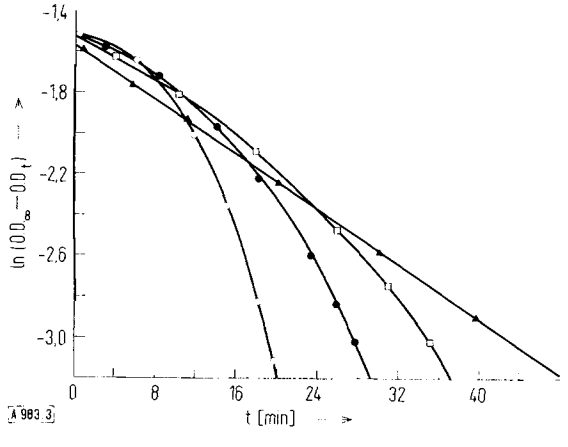

Fig. 3. Effect of increasing concentration of hydroxylamine on accelerative behavior in the hydrolysis of the ester *(29)*, $n=12$. 40 vol% C_2H_5OH/H_2O, [PVIm] = 5.0×10^{-4} mol/l, [*(29)*, $n=12$] = 5.0×10^{-5} mol/l (O—O); with [NH_2OH] = 3.0×10^{-4} mol/l (●—●); 4.5×10^{-4} mol/l (□—□); 11.1×10^{-4} mol/l (▲···▲). O.D. = optical density.

accelerative behavior. The acceleration diminishes with increasing hydroxylamine content in the system; this can be explained by a decrease in the concentration of the intermediate. Eventually, the accelerative behavior is completely eliminated, indicating that the intermediate is being destroyed at a faster rate than the substrate is being hydrolyzed.

The viscosity of PVIm in ethanol/water mixtures of various compositions (Fig. 4) indicates a contraction of the macromole-

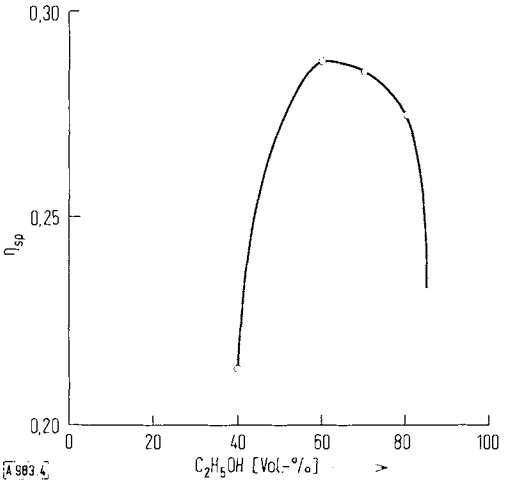

Fig. 4. Solution viscosity of polyvinylimidazole as a function of ethanol concentration (ethanol-water); [PVIm] = 4.229 (g/l), $\mu=0.02$, 26 °C.

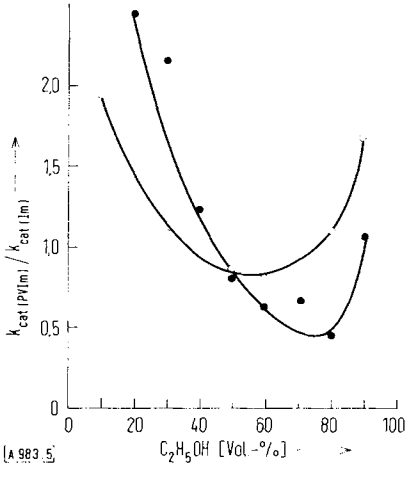
cule in low and high ethanol compositions[18]. Shrinkage of the polymer coils at low ethanol contents might be the result of intra- and inter-molecular nonpolar interactions, whereas



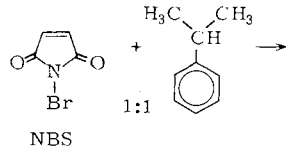


Fig. 5. Ratios of the rate constants for polyvinylimidazole- and imidazole-catalyzed solvolysis of *p*-nitrophenyl acetate (O—O) and of *p*-nitrophenyl heptanoate (●—●) as function of the ethanol concentration (ethanol-water). pH ≈ 8, $\mu=0.02$, 26 °C.

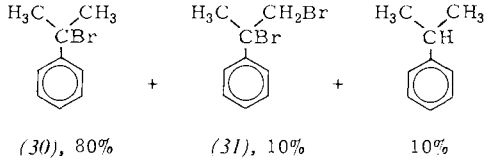
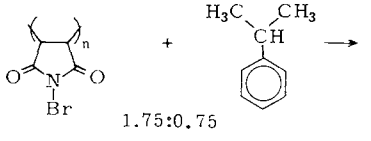
that in solvents of high ethanol content is ascribed primarily to intra- and inter-molecular hydrogen bonding[18]. Figure 5 shows the kinetic manifestation of this conformational process for the hydrolysis of *p*-nitrophenyl acetate and *p*-nitrophenyl heptanoate.

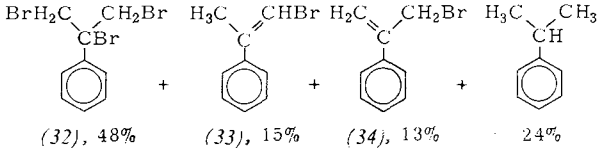


5. Change in Mechanism

The bromination of cumene with *N*-bromosuccinimide (NBS) in carbon tetrachloride results in the expected benzylic bromination product *(30)* and a dibromo product *(31)* (Scheme 10). However, when poly-*N*-bromosuccinimide (poly-NBS), prepared by bromination of polymaleimide, was used as the brominating agent (1.5 h in CCl_4 with benzoyl peroxide), a

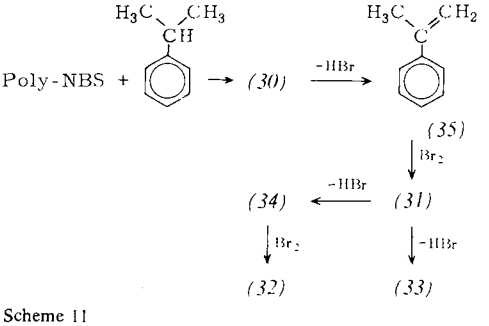


completely different set of products was obtained (Schemes 10 and 11)[11]. (The bromine comes from reaction of poly-NBS



NBS

(30), 80% *(31)*, 10% 10%



Poly-NBS

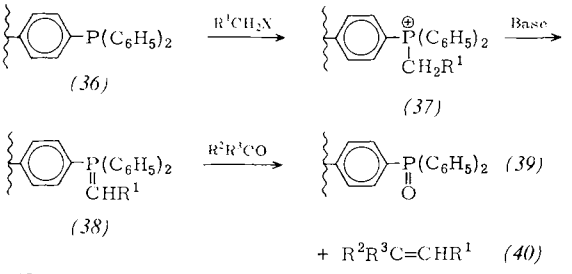
and HBr.) This demonstrates another feature of macromolecular reagents; that of a change in mechanism upon anchoring the functional moiety to a large carrier molecule.



Scheme 11

The polar medium provided by neighboring succinimide units in poly-NBS may be responsible for the changed mechanism (especially the repeated dehydrobromination) and different products obtained. This idea is substantiated by the fact that the bromination of cumene with NBS in a *more polar* solvent, acetonitrile, results in products similar to those obtained with poly-NBS in carbon tetrachloride.

6. Simple Separation of Polymeric Reagent

Polymeric phosphoranes *(38)* have been prepared (Scheme 12) and reacted with carbonyl compounds to form olefins[12].

Scheme 12

These Wittig reactions on polymeric supports afford product yields comparable with monomeric reactions but the removal of the phosphane oxide formed in the reaction is accomplished by simply filtering off the polymer to which the P—O unit *(39)* remains attached. As in solid phase peptide synthesis, the main advantage lies in the ease of separation.

Mechanical Fabrication of Thermoplastic Polymers[**]

By Turner Alfrey[*]

One of the most important features influencing the mechanical behavior of a fabricated thermoplastic item is the spatial arrangement of the polymer molecules. *Inter alia* processes developed for controlling the pattern of orientation of the polymer molecules are discussed.

1. Introduction

The mechanical fabrication of thermoplastic polymers embraces a wide range of operations. Some processes, such as extrusion and injection molding, are carried out at high temperatures where the polymers behave as viscoelastic fluids. Other processes, such as bottle blowing and vacuum forming, entail only moderate deformations, and can be carried out at temperatures where the polymers behave as viscoelastic solids. Some thermoplastic polymers are capable of being fabricated at still lower temperatures (below the glass temperature for amorphous polymers; below the melting point for crystalline polymers), by processes similar to the rolling, forging, and drawing of metals. In some processes, a crystallizable polymer enters the fabrication zone in a metastable, supercooled amorphous state, and crystallization occurs during the mechanical deformation.

The primary purpose of any fabrication operation is, of course, the establishment of a desired geometrical shape. A less apparent, but most important, feature which is simultaneously established is the spatial arrangement of the polymer molecules within the fabricated article. This includes orientation in amorphous polymers, morphology and orientation in crystalline polymers, and phase geometry in multiphase systems such as composites and foams.

The physical properties and performance of fabricated thermoplastic items depend upon the molecular structure (mainly established during polymerization) and the spatial arrangement of the polymer molecules (established during fabrication).

2. Amorphous Thermoplastics

Consider first the influence of molecular orientation in amorphous thermoplastics, using atactic polystyrene as a specific example. At room temperature, unoriented polystyrene is a brittle, glassy, amorphous polymer. Uniaxially oriented polystyrene is highly *anisotropic*. In the direction of orientation it can have a high tensile strength and ductile extensibility, and resistance to environmental stress-crazing and cracking[1]. On the other hand, in the transverse direction it is even weaker and more susceptible to stress-cracking than unoriented polystyrene[2]. The tensile strength in the orientation direction increases monotonically with increasing level of orientation, while the elongation-to-break rises to a maximum and then decreases.

Molecular orientation occurs inevitably in most mechanical fabrication operations, the pattern of orientation in the part being governed by the process *kinematics*—the pattern of flow and deformation followed by the polymer during fabrication. The *effects* of orientation can be either favorable or unfavorable, depending on the directions of orientation relative to the stresses encountered in service. Planned, controlled molecular orientation can be a valuable aid in achieving optimum properties and performance. Uncontrolled orientation will have beneficial effects only by accident; usually it is a source of weakness and failure. Controlled molecular orientation in fabricated polymeric articles can be classified as uniaxial, biaxial, or "crossed".

Fibers and monofilaments are subjected in service mainly to tensile and bending loads; and consequently, uniaxial orientation can provide satisfactory mechanical performance. Natural fibers, such as cotton and silk, exhibit molecular orientation, and most synthetic fibers are subjected to controlled uniaxial orientation during manufacture.

Apart from fibers and monofilaments, most thermoplastic articles are subjected to multiaxial stresses in service. In films, sheets, and thin-walled vessels, biaxial stresses are usual. Consequently, uniaxial orientation is often detrimental in such items, whereas biaxial orientation can often be employed to advantage. Biaxially oriented polystyrene sheets (*e.g.* stretched 3:1 in both directions at 110 °C) are strong and tough in all directions in the plane. Tensile strength, impact strength, and resistance to stress-cracking agents are all strongly enhanced, compared with unoriented polystyrene[3]. Biaxially oriented high impact polystyrene exhibits improved strength, impact strength, and fatigue resistance.

"Crossed" molecular orientation was employed by *Cleereman*, who rotated the core of the mold during injection molding of thin-walled polystyrene tumblers[4]. The direction of molecular orientation varied through the wall, in a fashion similar to cross-laminated plywood. This led to a threefold increase in hoop strength, and a 10000-fold increase in time-to-fail in a stress-cracking test in which tumblers were filled with corn oil or motor oil and pressurized. Such tumblers with crossed molecular orientation can be used as parisons for a subsequent bottle-blowing operation, yielding blown bottles with superior properties.

3. Crystalline Thermoplastics

Molecular orientation is also important in crystalline polymers, although the pattern of behavior does not exactly

[**] Lecture at the occasion of the dedication of Midland Macromolecular Institute, September 28 and 29, 1972. The text will also appear in the International Journal of Polymeric Materials and in *H.-G. Elias*: Trends in Macromolecular Science (Midland Macromolecular Monographs, Vol. 1), Gordon & Breach, New York—London.

parallel that exhibited by glassy amorphous polymers. For example, *Kresser*[5] has reported that the tensile strength of polypropylene systematically increases (approximately four-fold) with increasing uniaxial orientation, while the elongation-to-break systematically decreases. In any particular application, the optimum level of orientation represents a compromise in which both strength and toughness must be given consideration. Furthermore, in crystalline polymers, orientation can be introduced in two fundamentally different fashions:

1. A crystallized specimen can be stretched at a temperature which is higher than the glass transition point but lower than the melting point of the crystal. This requires extensive reorganization of the original crystal morphology.

2. Molten polymer can be oriented, followed by crystallization of the oriented melt. The crystal morphology so obtained, and the resulting physical properties, are different from those obtained by stretching already crystalline polymers.

Clark and *Garber*[6] have emphasized the effects of mechanical processing on the morphology and properties of crystalline polymers, in the cases of blown film, injection-molded specimens, and spun fibers. For example, blown polyoxymethylene film exhibits row-nucleated ("shish-kebab") morphology, and much higher elongation than *spherulitic* polyoxymethylene. Injection molding of polyoxymethylene yields a skin-core structure: a skin layer formed from multiple nuclei under high shear stress during filling; a continued growth inward of twisting lamellae after mold filling; and a spherulitic core nucleated and crystallized under quiescent conditions.

4. Films

The manufacture of Saran film involves a biaxial orientation step carried out in a bubble, at a temperature below the melting point of the crystal. Molten (but crystallizable) polymer is extruded as a tube, and rapidly quenched past the crystallization range. This metastable, supercooled, amorphous tube is passed between nip-rolls into a bubble zone of trapped air. Here the tube undergoes both machine-direction and circumferential stretching, which induces crystallization. The product, a biaxially oriented, crystalline, thin-walled tube, is passed through converging rolls and nip-rolls, and either slit or wound up as a flattened tube. Machine direction orientation can be made greater, equal, or less than the circumferential orientation by controlling mechanical variables in the bubble zone. Mechanical properties in the two directions, and shrinkage characteristics, can be made balanced or unbalanced, as called for in various specific end uses[7].

Such bubble processes belong to a class of operations which are susceptible to complete mechanical analysis—namely those involving membranes of rotational symmetry[16]. This class includes both batch operations such as vacuum forming and continuous operations. In all these operations, whether batch or continuous, certain common features are encountered—namely, the geometry of rotationally symmetric surfaces, and the equations of equilibrium for membranes of rotational symmetry. The meridianal direction and the "hoop" direction, by symmetry, are also principal directions of stress and strain (as well as of curvature). The third principal direction is normal to the surface; and the stress in this direction can be taken as zero. The stress at any point is thus specified by two components: σ_M and σ_H[*]. These principal stresses are everywhere non-negative in the processes under consideration. Since we usually are dealing with large deformations of a nearly incompressible material, it is usually convenient to define the state of deformation in terms of the two principal extension-ratios, λ_M and λ_H. If the material properties are simple, a complete predictive mechanical analysis can be made, by combining the laws of geometry, the equations of equilibrium and the material properties. In the Saran film process, where crystallization accompanies deformation, such a predictive analysis is impossible. Even so, a complete mechanical analysis can be made by setting the process into steady state operation, and then making the following measurements: (a) the air pressure in the bubble; (b) the machine tension; (c) the meridianal curve, $r(z)$; (d) the location of a moving particle along the meridian, as a function of time.

With this information, the equations of equilibrium can be used to calculate $\sigma_M(z)$ and $\sigma_H(z)$. The extension ratios, λ_M and λ_H, can be calculated for every point in the stretching zones. The trajectories on the biaxial stress plane and the biaxial extension-ratio plane can now be plotted, with the aim of correlating them with the directional physical properties of the product.

Some thermoplastic polymers can be fabricated at relatively low temperatures, by methods similar to those used in metal fabrication (crystalline polymers below their melting points; amorphous polymers below their glass temperatures). These low-temperature operations, such as cold rolling[8], drawing[9], and forging[10], invariably introduce large orientations which strongly influence the mechanical performance of fabricated parts. In low temperature forming, the polymer must yield in a ductile manner, rather than fracture. This eliminates many thermoplastic materials; but sometimes mechanical pretreatment can convert an unusable thermoplastic to a usable condition. For example, polystyrene is too brittle to cold-roll, but *oriented* polystyrene can be cold-rolled and further oriented[8].

5. Multiphase Systems

In multi-phase systems, such as composites and foams, another aspect of spatial arrangement is encountered. This is the geometrical disposition of the phases, which is established during fabrication.

The use of fibrous composites to achieve outstanding mechanical performance goes back to ancient times, and in recent years the role of fiber geometry has been the subject of intensive study[12]. In cross-plied laminates, the properties of a ply depend upon the mechanical properties of fiber and matrix material, and the geometrical arrangement within the ply; properties of the laminate depend upon the anisotropic properties of the individual plies and the geometry of their arrangement in the composite. The geometrical disposition of fibers in flexible composites, such as automobile tires, is as decisive a factor as in rigid structural composites.

Phase geometry is also important in laminar composites. Some sword-makers of early times hammered down alternate layers of hard and soft steel, obtaining blades which would take a fine cutting edge and yet were strong and tough[13]. Today,

[*] Subscript M: meridianal direction; subscript H: hoop direction.

many multilayer thermoplastic film laminates are manufactured which exhibit combinations of properties which cannot be matched by any one of the constituent thermoplastic materials. For example, films containing alternating "hard" and "soft" layers can exhibit mutual interlayer mechanical reinforcement. Thin layers of a high modulus, low elongation material, sandwiched between thin adhering layers of a high elongation material, may be prevented from undergoing transverse fracture; and thereby forced to undergo large ductile deformations when the composite is stressed[14]. Such a layered composite has both a high modulus and a high elongation-to-break; it has a much higher work-to-break than any of the individual layers. It is possible to prepare multilayer plastic films containing up to hundreds of parallel layers, by co-extrusion from the melt. The geometrical arrangement of the phases in such a multilayer film is controlled by the flow-pattern developed during the mechanical fabrication operation. One method of developing such flow patterns has been described by *Schrenk et al.*[11]. Different molten polymers are introduced as radial layers into an annular channel and pumped down the channel while the inner shaft, the outer cylindrical surface, or both are rotated. The molten polymer follows helical flowlines of varying pitch, and the initially thick radial layers are twisted into thin spiral laminae. The eventual layer distribution in the tubular film depends in a predictable manner upon the feed-port geometry, the volumetric rates of the various polymers, and the angular velocities of the two rotatable surfaces.

Finally, polymeric *foams* represent a broad class of multiphase systems whose properties depend upon phase geometry as well as upon the material properties of the bulk polymers. Expanded polymers range from elastomeric through semi-rigid (*e.g.*, polyethylene) to rigid[15]. They can be high-density or low-density; open-celled or closed-celled; linear or cross-linked; amorphous or crystalline. They can be directly utilized as end-products, or incorporated into structures such as sandwich panels, which efficiently utilize their unique density-property characteristics.

Over the years, much progress has been made in the understanding of molecular structure of polymers, and in the controlled synthesis of desired molecular structures. Molecular weight distributions, degree of stereoregularity, copolymer sequence distributions, and related molecular features are most important in determining mechanical properties. But in many cases the supramolecular structure, subsequently established by mechanical means, is equally important in determining the performance of a fabricated item.

Polymers in Medicine[**]

By Donald J. Lyman[*]

The problems encountered in the use of artificial materials in the body are discussed, using as example the artificial heart. In the quest for suitable materials, numerous investigations have been carried out, including, *inter alia*, studies on the adsorption of proteins on polymer surfaces and on the passivation of such surfaces by coating with proteins or by the growth of cell cultures. The development of passive artificial substances is also discussed.

1. Introduction

The use of materials in the body to repair or restore damaged, diseased, or ravaged tissue and organs is not new. The first recorded use was that of a gold plate in 1588 to repair a cleft palate. Later in the 1800's, there were numerous reports on the use of metal plates and pins to fix broken bones. However, with the advent of the polymer industry and the ready availability of a variety of materials (polymers) having properties more similar to the body, there was a tremendous increase—particularly since the middle 1950's—in the use of materials in surgery.

These uses have been quite broad, ranging from temporary assist materials, such as sutures, staples, surgical adhesives, plasma extenders, bone pins and braces, to relatively simple artificial parts of a more permanent nature, such as vascular grafts, heart valves, hydrocephalic drain tubes, joints, reinforcing meshes, as well as a variety of soft tissue replacement materials for cosmetic surgery, to the more complex devices such as the artificial kidney, the artificial lung, and the artificial heart, which can duplicate some physiological process.

Indeed the imagination and skill of the surgeon and the support and technical assistance from industrial companies have resulted in a great variety of devices being available (see Table 1). However, even with all these successes there have been many failures, most of which have been due to improper choice of material for the intended use. These materials are not inert in the body, but react on and are in turn acted on by the biological environment[1]. Moreover, the materials often tried were those readily available from many commercial processes and did not have the purity and reproducibility that we would like in a biomedical material.

Table 1. Present and possible uses of biomaterials (polymers) in the body.

Arteries, bladder, bladder stimulator, blood, blood-pressure regulator, bone, bone plate, breast, chin, cornea, diaphragm, disc, ear cartilage, elbow, elbow joint, eyeball, fallopian tube, finger joint, heart, heart valve, Herrington rod, hip joint, hydrocephalus shunt, inner ear, intrauterine device, jawbone, kidney, knee joint, liver, lunate, lung, nerve scaffolding, nose cartilage, radial head, reinforcing mesh, shoulder joint, skin, skull, tendon, testicle, toe, trachea, trapezium, ulnar head, ureter.

Medical advances in this field have been highly dependent on the availability of new polymers, which would not only satisfy a variety of industrial or consumer needs but also these medical needs. During the 1960's, a new research area developed whose objectives were to provide knowledge of how polymers interact as they interface with living systems, so that biomedical polymers can be developed in their own right. This research requires the coupling of many traditional disciplines as well as creating new interdisciplinary studies.

2. The Artificial Heart

The area that I have found most fascinating is the use of polymers in the repair of the vascular system and in the extracorporeal handling of blood. In the present paper this work will be described, using the artificial heart as the background for my remarks.

For some time, the Division of Artificial Organs, under the direction of *W. J. Kolff*, has been developing artificial heart devices. Much of this work has been concerned with a Kwan-Gett hemispherical heart[2] (cf. Figs. 1 and 2) and the development of optimum surgical procedures as well as pre- and post-operative care techniques. Considerable progress has been made, as indicated by the world's record time of two weeks which a calf has remained alive after implantation of an artificial heart.

However, there are still problems such as: occasional mechanical failure, poor fit, inadequate pumping, improper blood pumping pressure, need for improved valves, *etc.* Also, we

still do not have an ideal material to interface with the blood. As a result we find clots on the surface of the artificial heart, and there is evidence that these clots break loose and can lead to emboli and subsequent damage to distant tissues (cf. Fig. 3). The cellular elements such as red blood cells and

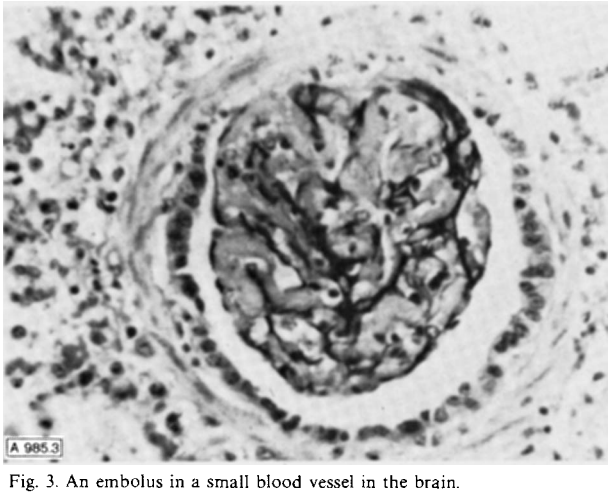

Fig. 3. An embolus in a small blood vessel in the brain.

platelets are damaged and destroyed (cf. Fig. 4). The protein constituents are also damaged. While these studies give an overall picture of the effect of the material on blood, there are two factors that must be kept in mind: 1. The animals

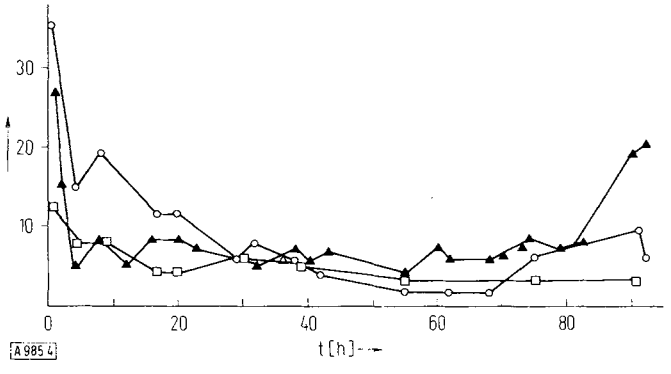

Fig. 4. Changes in the blood of a calf after implantation of an artificial heart. □ : plasmahemoglobin [mg/100 g], ▲ : clotting time [min], ○ : red blood corpuscles [10^4/cm^3].

own defense mechanisms can often clear the damage, thus masking a potential effect; 2. The tests, in themselves, give no clues as to the initiating steps in this damage.

We developed[4] a simple *ex-vivo* test which allows us to look more closely at this problem. If blood is allowed to flow over a polyvinyl chloride surface for several minutes in the absence of an air interface, a clot is formed (cf. Figure 5). On the surface of the plastic a thrombocyte can be seen

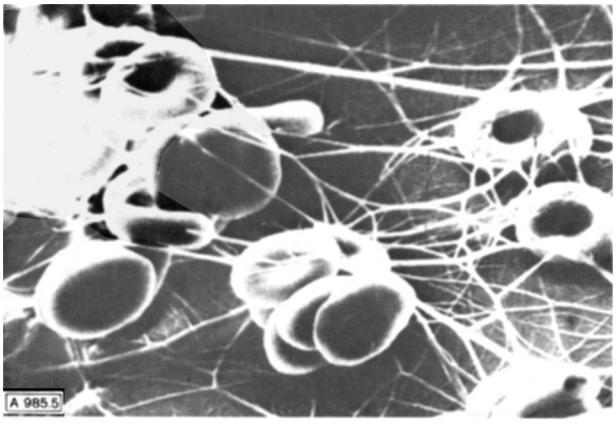

Fig. 5. Scanning electron microscope picture of a clot formed on a polyvinyl chloride surface in a flow-through *ex-vivo* cell showing platelets on the surface of the material and the fibrin mesh entrapping red blood cells. (Picture by *Rodman*, University of Iowa.)

with fibrin strands extending from its pseudopods. This fibrous mesh entraps red blood cells. However, while this has been valuable for guiding research and for screening polymers[4, 5], it still does not explain why the platelets adhere, and to what surface they are actually adhering. Our work has been directed toward answering these questions as well as the related one of how does one synthesize a non-thrombogenic polymer. This requires developing knowledge of the events occurring at the molecular level as the blood comes into contact with the polymer which initiate these adverse reactions. To do this, one must use model experiments (*in-vitro* and *ex-vivo*) to isolate and study the individual events that *might* occur at the molecular level in the *in-vivo* situation.

3. The Adsorption of Proteins on Polymer Surfaces

3.1. General

Blood coagulation has been studied for over 100 years, with many studies being directed toward identification of the activating molecule. These studies reached a high point in 1964 with the proposal of an enzymatic cascade blood clotting mechanism[6] resulting from surface contact of a particular protein molecule.

Our studies began here; on how proteins are adsorbed and activated on polymer surfaces. One tool that we have used extensively in this work has been infrared multiple internal reflectance spectroscopy. This method allowed us to examine directly the adsorbed protein-polymer substrate complex, without having to rely on indirect methods to estimate the interaction. Since both the infrared absorption of the adsorbed protein and the polymer appear in the spectrum (cf. Fig.

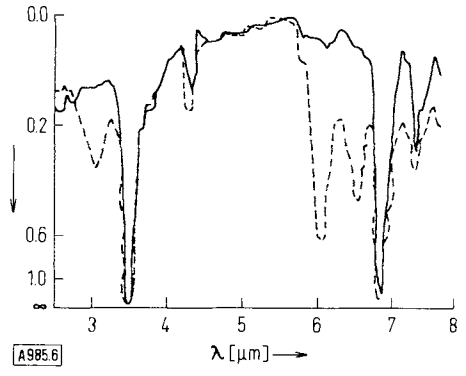

Fig. 6. IR multiple internal reflectance spectra of polyethylene (——) and γ-globulin (– – –) adsorbed on polyethylene.

6) one can use band ratios to determine the quantity of protein adsorbed[7] and the rates of adsorption[8].

We studied the adsorption of the more common blood proteins on a variety of neutral, hydrophobic polymers. Experiments were done in the absence of an air interface under both static and flow adsorption conditions. Figures 7 and 8 show typical

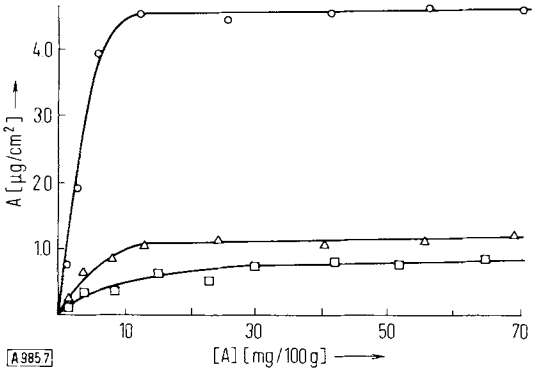

Fig. 7. Adsorption isotherms of albumin on various polymer surfaces: ○: copolyether-urethane-urea (PEUU-1), △: silastic rubber, □: fluorinated ethylene-propylene copolymer. Ordinate: A = amount of albumin adsorbed; Abscissa: albumin concentration in the solution in which the copolymer is dipped.

adsorption curves. It soon became apparent that the proteins were physically and essentially irreversibly adsorbed onto these neutral hydrophobic polymers with formation of a type of monomolecular layer. Electron micrographs and infrared spectra data (no shifts in Amide I—Amide II bands) would indicate that no gross structural alterations occur, *i.e.* the adsorbed proteins retain their globular form. As these studies continued we began to find differences in rates of adsorption, plateau concentration, effect of flow velocity on the amount of adsorbed protein, *etc.*, as we varied the adsorbing protein on the polymer surface.

At this stage, the *in vivo* experiments involving implanted cannulas that we were carrying out concurrently with the help of *William Edmark* (Providence Hospital, Seattle), began to influence our thinking. On all of the surfaces examined by us, a platelet plug appeared to be at the site of clot initiation. In many cases, the total clot appeared to be an aggregated platelet mass. On considering these contrasting sets of experiments, I began to feel that there was an overemphasis on "contact surface activation" by the Hageman factor (Factor XII) and that the mechanism on the implanted polymer surface might more nearly resemble what happens when the natural vessel wall is cut.

We began, therefore, to study the adhesion of platelets to various polymer surfaces. In the beginning, we simply dipped films into blood, then rinsed and stained the surfaces. All the surfaces had large numbers of platelets on them, and all appeared surprisingly similar. However, since it was known that proteins denature at an air interface and it was possible that we were simply coating our polymer with denatured protein by the dipping—essentially a Langmuir transfer of protein to the surface—we redesigned our system to avoid an air interface.

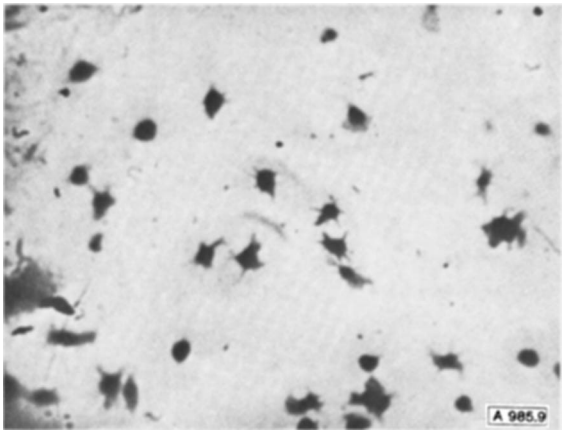

Fig. 9. Stained platelets adhering to a fluorinated ethylene/propylene copolymer surface after exposure in our flow-through *ex-vivo* cell (after Ref. [4]).

The flow-through cell was simply a small glass chamber to which we could clamp the polymer films to be examined and which could be filled with buffered saline. Human venous blood is introduced directly (*via* a vena puncture) to the cell, thus displacing the original salt solution. Care must be taken to avoid air bubbles. The cell is then quickly rinsed and the adsorbed platelets fixed and stained. On some surfaces, pseudopod development could actually be observed (see Fig. 9). If the blood is exposed for longer times, an actual clot resembling that shown earlier in Figure 5 is formed.

As we examined a series of neutral hydrophobic polymers under these conditions and compared the number of platelets adhering at one minute exposure, we were able to establish

that the number of platelets is greater, the more thrombogenic the plastic material is[4]. At longer times of exposure, all surfaces begin to look rather similar. This is not unexpected, since all are considered thrombogenic, the only difference being in how long they take to clot[3, 9, 10].

3.2. The Passivation of Polymer Surfaces

Since our protein adsorption studies indicated that a polymer surface could be coated with a layer of protein without altering the protein structure, we explored the possibility of passifying a polymer by pre-coating it with albumin. Indeed, when we tested such pre-albuminated surfaces in our flow-through platelet test cell, we found essentially no platelet adhesion[11]. If our hypothesis is true, this albuminated surface should be non-thrombogenic. *Lande*, who used albuminated membranes in an artificial lung[12], was also able to detect markedly reduced platelet damage. Later, *Andrade* prepared covalently bonded albumin surfaces on Gott vena-cava rings[13]. These were shown to be as non-thrombogenic as heparinized surfaces[5]. Hence, if we could avoid platelets adhering to a surface we should be able to avoid the formation of a clot.

In view of our interest in materials for artificial heart devices, we began to explore a variety of segmented copolyether-urethanes and urethane-ureas for possible candidates. In this polymer family the mechanical properties can be tailored to meet great variety of requirements. One of these polymers, a copolymer based on polypropylene glycol, 4,4'-methylene(diphenyl isocyanate) and ethylenediamine appears to have a fair balance of mechanical and fabricating properties. Examination of this copolyether-urethane-urea in our platelet cell gave surprising results: it showed very low platelet adhesion[15]. Also, when Gott rings were implanted in the inferior vena cava of dogs, they were proved to be as non-thrombogenic as rings with heparinized surfaces[14].

We carried out some preliminary studies on implanting a polyurethane hemispherical Kwan-Gett heart[3]. Although we did not achieve long survival times with these initial implantations, the heart, on removal, was as clean and shiny as when implanted. There was no evidence of clots, fibrin deposition or platelet deposits anywhere in the heart. Because of the heavy scheduling of other types of hearts, and other surfaces such as fibril coated surfaces[*], we shifted our efforts back to gaining an understanding of how these two types of non-thrombogenic surfaces function. What are the similarities and differences between an albumin coated surface and a segmented copolyether-urethane-urea surface? Since precoating a polymer surface with albumin passifies the surface and prevents platelet adhesion, can this same effect be achieved *in situ;* in other words, can the urethane surface preferentially and rapidly adsorb albumin from the blood?

On examining the nature of protein adsorption onto polymer surfaces in more detail[8], data supporting this hypothesis began to emerge. In the series of polymer surfaces examined, those having higher rates of albumin adsorption and also having higher plateau concentrations of albumin on the surface were less thrombogenic. There also appeared to be an inverse relationship for γ-globulin adsorption, *i. e.* the more γ-globulin on the surface, the more thrombogenic the polymer appeared to be.

It is assumed, of course, that adsorptions occurring in a mixture, *e. g.* whole blood, are similar to those observed in a simple, single solute. This is currently being checked. However, this assumption is supported by our platelet adhesion studies which show that both γ-globulin coated surfaces and fibrinogen coated surfaces are more active toward platelets[8] than are albumin surfaces. It is also supported by the work of other investigators[17, 18] which shows the adverse effects of γ-globulin on platelet adhesion and release reactions. Thus it would appear that the way to achieve a non-thrombogenic surface is to either pre-coat the polymer with a passifying layer of albumin or have a polymer of such a chemical structure that it forms this passifying albumin coating rapidly *in situ.*

Our work is currently proceeding along several lines involving: 1. Investigations on the nature of the protein-polymer interaction; 2. Determination of the actual chemical and inherent water structure of the proteinated surfaces; and 3. Determination of the nature of the platelet-protein surface interaction. These studies will allow us to develop much of the basic knowledge of blood interactions with polymeric surfaces; knowledge which is necessary if we are to advance the repair of the vascular system and the extracorporeal treatment of blood.

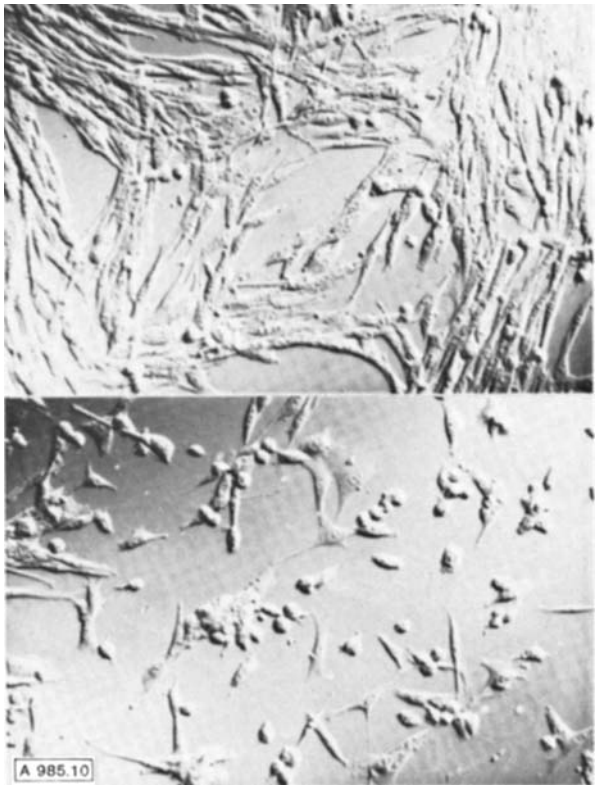

Fig. 10. Cell culturing of baby hamster kidney cells. Top: onto glass, showing adhesion and growth. Below: onto a polyurethane surface, showing no growth.

Recently, there has been increased interest in cell culturing on surfaces as an alternate method of passivation[19]. The neo-intima which develops provides a natural surface to the blood. However, lack of cellular adhesion to the Silastic

[*] It should be noted that, after much implantation and post-operative study, the world's record long-term survival was achieved by the Division of Artificial Organs using a fiber coated surface [16].

Rubber substrate has necessitated the use of Dacron fiber-coated surfaces to prevent the cellular deposits from being stripped off. This, of course, is not without its own problems. Therefore, *Hill* and I investigated the adhesion of baby hamster kidney (BHK-21) cells[20] to polymer surfaces. Normally, if the BHK-21 cell adheres, it will grow to form a monolayer; if it does not adhere, it will ball up and die (cf. Fig. 10). On examining a series of copolyether-urethane-ureas, which were chemically identical except for the length of the polyether segment, we noticed an interesting phenomenon[21]. When the polyether segment had a molecular weight of 400, 700, or 2000, the BHK-21 cells adhered and grew normally; when the polyether segment had a molecular weight of 1000, the cells did not adhere and grow. Parallel experiments on platelet adhesion showed the same result, *i.e.* platelet adhesion on the polymers whose polyether segments had molecular weights of 400, 700, or 2000, but no adsorption on the polymer whose polyether segment had a molecular weight of 1000.

These four types of copolymers showed similar critical surface tensions and protein adsorption. However, it must be kept in mind that these involve gross measurements, and that the cells are apparently capable of recognizing some microarchitectural differences in these copolymers. Indeed, preliminary studies on the tacticity of the polypropylene glycol segments and on the film morphology would indicate that the copolyether-urethane-urea containing the polyether segment with a molecular weight of 1000 is different from the others. We are now working on the determination of the structure of these surfaces and shall couple this information with our other blood studies.

These studies are of double interest to us. Platelets are rather difficult to handle, so if we do have a cell line that mimics their action we could do more quantitative studies on the nature of the polymer surface interaction. Also, if each cell line has its own surface recognition pattern, we might be able to make a surface that will preferentially adhere (and grow) one cell line in the presence of others. This would allow us then to develop scaffolding polymers to assist the body in the controlled repair of its own tissue and organs, whether it be a nerve, the trachea, or a blood vessel.

Structure-Property Relationships in a Polymer[**]

By E. H. Andrews[*]

The way in which polymer molecular structure controls structure on higher levels of organization in a solid polymer is briefly reviewed, as is also the way in which structure, on all levels, controls physical properties. The "line of descent" from molecular structure to physical properties is then illustrated for *cis*-polyisoprene (natural rubber). It is shown how the crystalline-amorphous morphology in the solid is controlled both by the chemical microstructure of the polymer and by the physical conditions (temperature, time, strain) under which solidification occurs. By changing these "processing conditions" great changes can be effected in the morphology.

1. The Role of Molecular Structure

This paper is not primarily concerned with molecular structure, but it is impossible to discuss "structure-property" relationships without beginning at this point. One of the main ideas behind this paper is that the molecular structure of a polymer does not uniquely define its solid-state properties and that the latter often depend much more strongly on the higher levels of structure ("morphology"). It must never be forgotten, however, that the morphology of a solid polymer itself derives

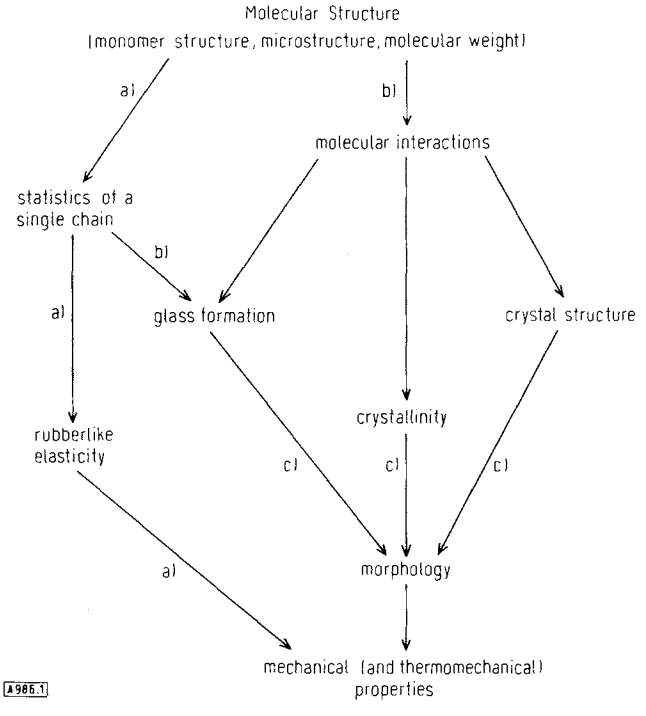

Fig. 1. Property-structure lines of descent (schematic).

from the "interaction" of the molecular characteristics with the conditions under which the morphology is formed. We have only to remember that polymers as materials are what they are because they possess a characteristic molecular structure, namely that of a long chain.

The proper perspective in structure-property relationships can best be given diagrammatically. In Figure 1 is shown a kind of "family tree" or line of descent, tracing the properties of polymers back to their molecular structure. To avoid overcomplicating the diagram, I have restricted it to the thermomechanical category of properties and omitted the electromagnetic and chemical property categories. Clearly, however, these aspects could be included in a similar manner.

Reference to Figure 1 reveals immediately the very complicated nature of the dependence of mechanical properties (including thermomechanical properties) upon molecular structure. This is why many early attempts to relate properties directly to molecular structure met with only limited success.

There is one property, that of rubberlike elasticity, which is largely dependent upon the independent behavior of single molecules (route (a) in Figure 1). This behavior is found at temperatures sufficiently high that the kinetic motion of the molecules swamps the constraint of molecular interactions. The material then behaves, to a first approximation, as an assembly of non-interacting chains.

All other mechanical properties, however, depend strongly on molecular interaction. Indeed the temperature range over which rubberlike behavior is observed is itself limited by the phenomenon of glass formation where molecular interactions predominate.

The role of interaction is indicated by routes (b) in Figure 1. According to the molecular structure, interactions result in the establishment of structures of a higher order, namely glasslike and crystal structures. Which of these two structures will form as a polymer is cooled from the melt or precipitated from solution depends both on the inherent capacity to crystallize and on the relative rates of cooling (or precipitation) and crystallization. Both capacity and kinetics are controlled by the molecular microstructure as well as by the more obvious thermodynamic parameters. Commonly both crystalline and amorphous regions occur in the solid polymer and their relative amounts and arrangements (size, shape, orientation, organization) depend not only upon the factors mentioned above but also on mechanical parameters such as stress or strain obtaining in the system during the formation of the morphology in Fig. 1c).

Finally, the mechanical properties are dependent directly on the morphology, since the response of the solid to stress or strain is the averaged sum of the responses of the individual components in the morphology. If the polymer is a homo-

[*] Prof. Dr. E. H. Andrews

[**] Based on a lecture given on the occasion of the dedication of Midland Macromolecular Institute, Midland, Michigan (USA), on September 29, 1972. The text will also appear in the International Journal of Polymeric Materials and in *H.-G. Elias*: Trends in Macromolecular Science (Midland Macromolecular Monographs, Vol. 1) published by Gordon & Breach, New York—London.

geneous glass, the "morphology" must be construed in terms of appropriate concepts such as free-volume, close-range order, and mean molecular orientation. If the polymer is a "composite" of crystalline and amorphous phases the situation is more complex, involving the totality of structural characteristics in both phases together with specific phase interactions (*e.g.* tie molecules anchored by the crystalline phase but extending through the amorphous phase).

It is clearly impossible to deal here with the whole area defined by Figure 1. In what follows, the kinds of dependence discussed above will be illustrated mainly by examples drawn from our experience over some years of a single polymer—*cis*-polyisoprene or natural rubber.

Apart from the importance of this material in the history of polymer science, there are additional advantages of working with polyisoprene. It can be readily and quantitatively isomerized to change its microstructure; it crystallizes sufficiently slowly to allow control of the morphology; it can be obtained in a wholly amorphous condition for comparison with semicrystalline specimens and, finally, the amorphous phase can be changed from glassy to rubberlike by passage through the glass transition temperature at the reasonably convenient temperature of $-70\,^{\circ}C$, without changing the crystalline phase in any way.

The examples chosen below to illustrate structure-property relationships are as follows. Firstly, the effect of small microstructural changes on the morphology and kinetics of crystallization. Secondly the effect of strain on morphology, strain being regarded as a "processing variable", and thirdly, the effect of morphology upon some high-strain mechanical properties such as modulus, yield stress, and fracture stress. The work is discussed here in review form only and further details will be found in the references.

2. The Effect of Molecular Microstructure on Crystalline Morphology and Kinetics

Final properties, we have asserted, depend on morphology and this, in turn, depends upon those kinetic processes which give rise to it. It follows that crystallization kinetics, interacting with the "processing conditions" (thermal history, for example) are of central importance to the subject. *Andrews*, *Owen*, and *Singh*[1] have investigated the effect of small changes in molecular microstructure upon the crystallization kinetics of *cis*-polyisoprene. The changes were of two kinds, namely small amounts (up to 10%) of isomerization of the initially *cis* polymer and chemical crosslinking by peroxide decomposition involving equally small numbers of monomer units.

The linear growth rates of lamellar crystals (grown in very thin films of the melt) were measured directly using electron microscopy and an osmium tetroxide staining technique which arrests crystal growth after any chosen period of time. The dramatic results are shown in Figure 2. At a given temperature ($-26\,^{\circ}C$) the linear growth rate, G, of the crystals is reduced one-thousand fold by the random introduction of one isomerized unit in ten homopolymer units (10% isomerization). There is a linear dependence of log G upon the fraction β of isomerized material. A similar effect is produced by crosslinking, although this appears to be only half as effective as isomerization in suppressing the crystal growth rate.

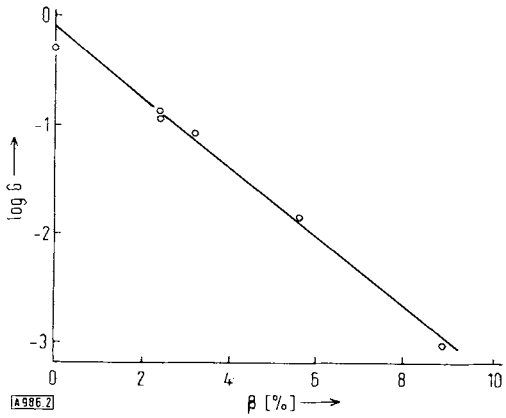

Fig. 2. Single crystal growth rate G (in μm/h) at $-26\,^{\circ}C$ as a function of the fraction β of *trans* isomer in *cis*-polyisoprene (after [1]).

Since the temperature dependence of G was unaffected by isomerization or crosslinking, it was concluded that the reduction in G could not be due to changes in the thermodynamic parameters (heat of fusion, melting temperature, interfacial energies) which appear in the classical equations[2] for growth by secondary nucleation. Instead, the authors explained their result in terms of a novel "exclusion" mechanism, as follows.

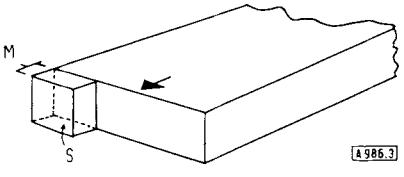

Fig. 3. Crystal growth by secondary nucleation (S) in the direction of the arrow. M = monolayer.

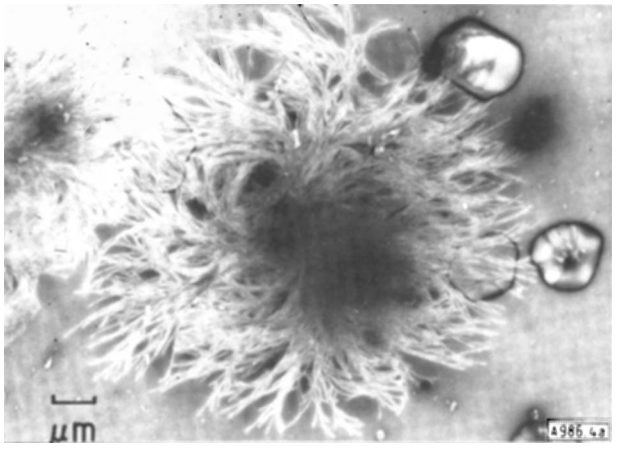


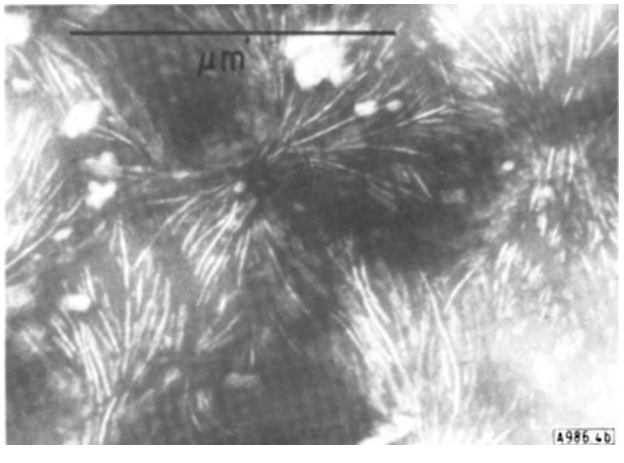
Continuous growth of a polymer crystal occurs by a modification of the classical "secondary nucleation" process. In this process, the slowest (and thus the rate controlling) step is the deposition of a new block of solid material on to a smooth growth surface (Fig. 3). Once this block (the "secondary nucleus") has been deposited, a new monolayer is rapidly completed because atoms or molecules crystallize readily at any step on the surface. In polymer crystallization the process is probably more complex, involving the secondary nucleation of each separate molecule on to the growth surface. In either case, however, it is necessary to establish a secondary nucleus which is large enough to be thermodynamically stable. This "critical size" requirement suggested that an uninterrupted sequence of homopolymer units, sufficient in number to form a critical size nucleus, was a requirement for the attachment of a new molecule to the growth surface. *Andrews et al.* were able to show theoretically that the crystal growth rate G would be affected by the fraction β of randomly distributed "foreign" units according to the equation

$$\ln(G/G_0) = -(N-1)\beta \qquad (1)$$

where G_0 is the growth rate for the homopolymer and N is the number of monomer units required in uninterrupted sequence. Not only does eq. (1) describe exactly the relationship found in Figure 2, but the value deduced for N gave a width for the secondary nucleus of 1.98 nm compared with an independent thermodynamic estimate of 1.94 nm.

It appears, then, that the growth kinetics are extremely sensitive to molecular imperfections of whatever kind, the effects being far more marked than those of molecular weight variation[3], for example. The amount and perfection of crystallinity achieved in a polymer subjected to a given processing history is thus likely to be equally sensitive unless care is taken to anneal the material.

The influence of small amounts of isomerization upon the ultimate (*i.e.* well annealed) morphology is negligible. Thus provided time is given for the crystals to grow to their full extent, the results are wholly similar. In normal polymer conversion processes, however, such as extrusion, fiber spinning, blow molding, *etc.*, morphology may be strongly affected by changes in crystal growth kinetics. For example, regions which crystallize under high shear stress will have a very different morphology from regions which crystallize after the shear stress has relaxed. Rapidly crystallizing species may thus have a "high shear" morphology due to transient shear stresses, whilst slowly crystallizing species may reveal little or no "memory" of the time spent by the melt under shear.



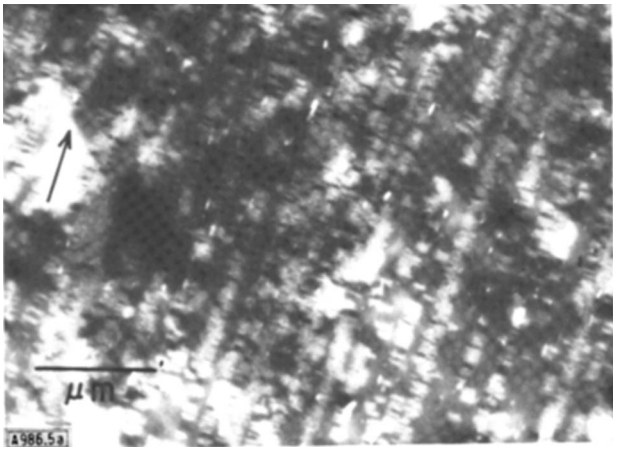


Fig. 4. a) Spherulite grown in a thin film of natural rubber (stained with OsO_4) (after [1]). b) As Fig. 4a, but in a film crosslinked by exposure to disulfur dichloride vapor (after [4]).

Crosslinked specimens of *cis*-polyisoprene, unlike isomerized material, *do* exhibit important morphological differences from the uncrosslinked case[4] (Fig. 4 and 5). Figure 4a shows a spherulite grown in an uncrosslinked thin film and Figure 4b one grown in a crosslinked film. In the latter, the lamellae are relatively short and discontinuous by comparison with

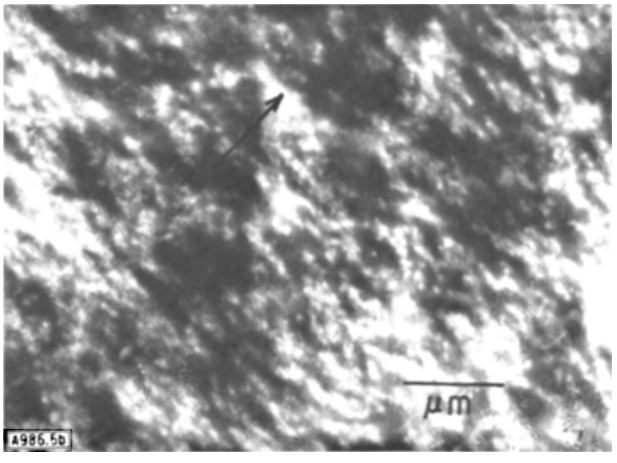

Fig. 5. a) Row nucleation in a thin film of natural rubber crystallized at 200% strain (stained with OsO_4) (after [4]). b) As Fig. 5a, but in a film crosslinked by disulfur dichloride vapor (after [4]).

the former. This may be due either to the physical impedance of growth by localized regions of high crosslinking or to an increased tendency for nucleation of lamellae resulting in a large population of "young" (and thus short) crystals. Figure 5a and b show a similar contrast for crystallization in a strained film (see Section 3.1). The long row-nucleated structures, often up to 10—20 µm, typical of uncrosslinked rubber are strongly suppressed by crosslinking. Row nuclei still occur in crosslinked specimens, but are typically only a fraction of a micron in length, though much more numerous. The explanation of this may at first appear to be a physical blockage of row-nucleus growth, but is more likely to arise from the increased elasticity of the melt (which opposes the shape change involved in the formation of a long cylindrical nucleus).

3. The Effect of Mechanical Constraint on Morphology

3.1. Strain in the Melt

During polymer conversion the melt is normally subject to deformation, either by shear in the die or mold, or by subsequent drawing or blowing processes. The degree to which these processes affect polymer morphology depends on the time, temperature, and the severity of the deformation. If the stresses relax before crystallization is initiated, the latter

occurs isotropically, but if stresses are present during even the early stages of solidification the effect on morphology can be profound.

Natural rubber films have a sufficiently high molecular weight to sustain applied stress in their melt condition even in the absence of crosslinking. They therefore afford a model thermoplastic system in which the effects of melt stress can be studied by the application of *static* strain (not possible in most polymer melts).

The results of this study are already well-documented[5], and Figures 4a and 5a have already been given to show the morphological differences between a film crystallized unstrained and one crystallized from a strained (200%) melt. Kinetic evidence[2] reveals that the stress relaxes rapidly in the strained (uncrosslinked) film, so that most of the crystallinity develops in a relaxed film. The *initial* crystallization, however, consisting of a row nucleus, forms rapidly under stress and governs the subsequent growth morphology even after the stresses have relaxed.

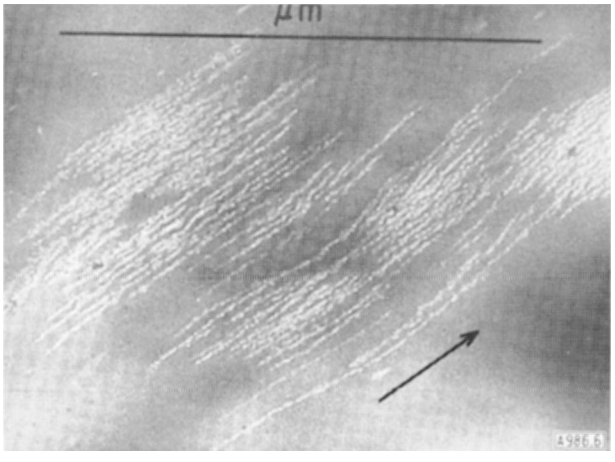

Fig. 6. γ-Filaments in thin film of natural rubber crystallized at 400% strain.

At higher melt strains the density of row-nucleation increases, and the crystal melting temperature is elevated until spontaneous crystallization occurs at room temperature in a form described by *Andrews*[5] as γ-filaments (Fig. 6). Alongside the

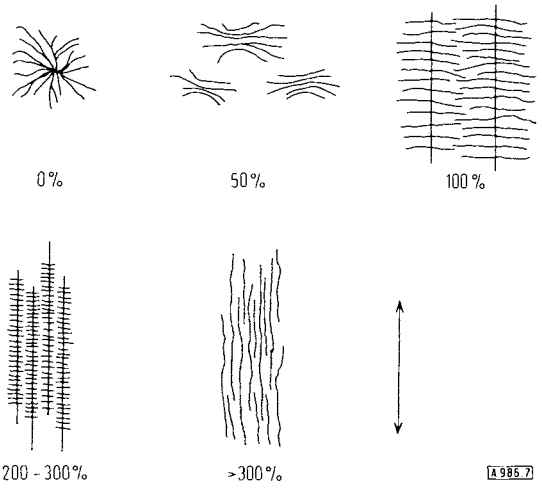

Fig. 7. Morphological effects of melt strain (direction of arrow) in crystallized natural rubber (schematic).

obvious morphological changes associated with crystallization from a strained melt must be included the hidden morphological variable of molecular orientation in the amorphous phase. Figure 7 summarizes schematically the morphological effects of melt strain in natural rubber. In all cases the molecular chain axis is normal to the plane of lamellar crystals but lies parallel to the length of row nuclei and γ-filaments. This encourages the view that the lamellae are essentially similar to the folded-chain single crystals obtained by precipitation from dilute solution, and the variation in their thickness with crystallization temperature[2] reinforces this view.

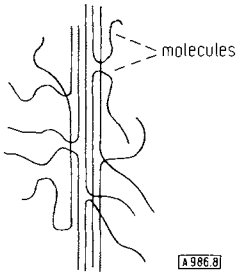

Fig. 8. Possible structure of row nuclei and γ-filaments (schematic).

In the same way, row nuclei and γ-filaments are probably highly imperfect extended chain crystals as sketched in Figure 8. The row nuclei formed at intermediate strains (Fig. 9 shows

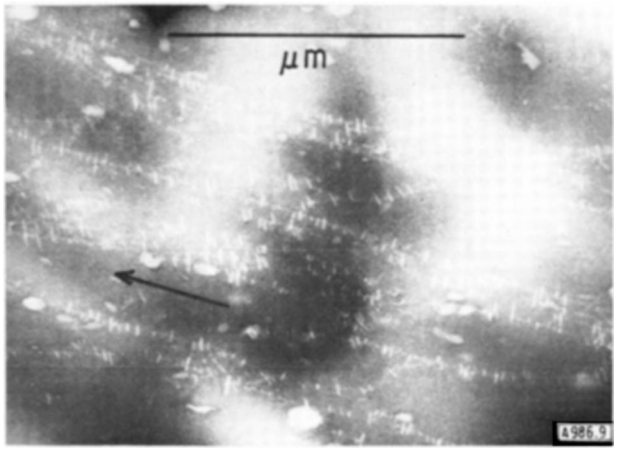

Fig. 9. Early stages of row-nucleated crystallization showing row nucleus.

the early stages) are often very cleanly defined filaments of diameter as little as 3 nm. By contrast, γ-filaments are always particulate along their length[5, 6] (Fig. 6). This difference may well arise because the γ-filaments form very rapidly (almost spontaneously) whereas the rate of growth of row-nuclei at lower strains (although greater than that of lamellar crystals by a factor of 10^2) is still measurable[4] at some 100 µm/h. The degree of perfection is thus much lower in the γ-filaments.

The qualitative features outlined in Figure 7 are not restricted to *cis*-polyisoprene, but appear to be quite general for the melt crystallization of thermoplastics. Thus almost identical patterns of behavior have been found for isotactic polymethyl methacrylate, polycarbonate[7], *trans*-polyisoprene[8], *trans*-polychloroprene, isotactic polystyrene[9, 10], and polyethylene[3].

The quantitative aspects of row-nucleated morphology depend, of course, upon the amount of row-nucleated material formed, since the row-nucleation density increases with time to a certain level and then remains constant. The final row-nucleation density has been measured[4] for *cis*-polyisoprene as a function of strain and temperature and is shown in Figure 10. The effect of strain is self-evident, but the effect of temperature is very interesting. As the melt becomes warmer the row-nucleation density first decreases to a minimum around -12 °C and then rises again. At high strains this rise is dramatic and clearly foreshadows the spontaneous γ-crystallization observed at slightly higher strains and temperatures.

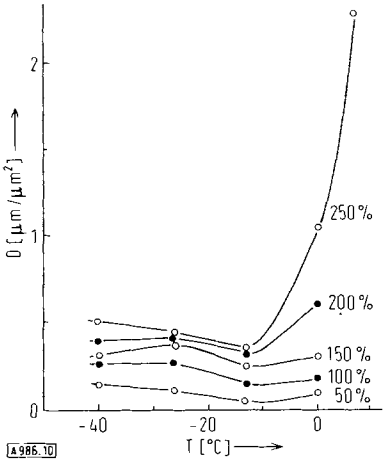

Fig. 10. Final row-nucleation density D for *cis*-polyisoprene as a function of strain (given alongside the curves) and temperature (after [4]).

3.2. Hydrostatic Pressure

Finally in this section we refer to a different mechanical constraint which can be imposed upon the melt during crystallization, namely that of hydrostatic pressure. It has been established that, in linear polyethylene, crystallization under high

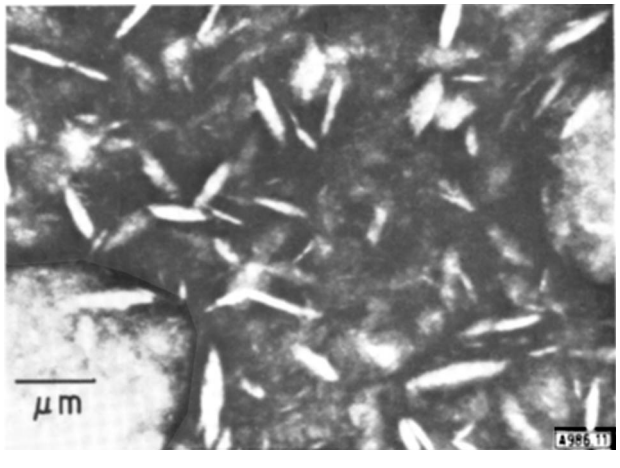

Fig. 11. Thin film of natural rubber crystallized at 20 °C at 4 kbar (after [13]).

pressure gives rise to a thickening of the normal folded-chain lamellae from a few hundred angstroms to several microns[11, 12]. The thickening at sufficiently high pressures and temperatures is such that the molecules unfold completely into an extended chain form. Material in this condition is extremely friable, *i.e.* has no mechanical strength, emphasizing the importance of intercrystalline amorphous material in imparting the toughness usually associated with polyethylene.

Some preliminary experiments[13] have been carried out on the crystallization of thin films of natural rubber under gas pressures of up to 5 kbar. The most obvious effects are that the nucleation density is vastly increased so that unstrained films no longer exhibit a spherulitic habit but, instead, show a high concentration of separate single crystal zones shaped like oblate spheroids (Fig. 11). Since there is good evidence[14, 15] that the "aspect ratio" (length-to-thickness ratio) of lamellae in a bulk polymer strongly affects its elastic modulus, the destruction of the spherulitic habit by pressure could significantly affect mechanical properties. Needless to say, many polymer forming processes involve the application of hydrostatic pressure as well as shear stress.

4. Morphology and Mechanical Properties in Natural Rubber

4.1. The Investigation

The investigations[16] detailed in this section, and carried out by *P. E. Reed*, were based on the thin film studies described in Section 3.2. Bulk specimens of lightly crosslinked natural rubber were crystallized at -26 °C under tensile strains ranging from 0 to 6 to develop the whole range of morphologies revealed by the thin film work. Crystallization was taken to completion in all cases giving a crystalline fraction of 0.3 ± 0.05 for all samples, and tensile tests were carried out at temperatures below -26 °C covering both the rubberlike and glassy regions of the amorphous polymer (above and below -70 °C respectively). From the stress-strain curves, mechanical parameters such as initial modulus, yield stress, fracture stress, and fracture strain could be obtained.

Basic to this work is the assumption that the morphology in bulk is essentially similar to that in thin films for equivalent melt strains, apart from the "three-dimensional" character of the former. Thus at zero melt strain we expect a spherulitic structure, at 50—100% spherulites flattened to bring their lamellar plane normals (molecular axis) towards the strain axis, at 100—400% cylindrical row-nucleated "shish-kebab" structures and at strains greater than 400%, γ-filaments. Because both lamellae and row nuclei are such small structures, thin sectioning of the bulk fails to reveal anything but a loss of spherulitic morphology with increasing strain. However, both light scattering[17] and X-ray[6] studies (of polychloroprene) provide strong indirect evidence that bulk morphologies correspond closely to their thin film counterparts at equivalent melt strain.

Reed's collected data for the mechanical properties of crystalline natural rubber is shown in a series of 3-dimensional graphs, Figures 12 to 16. Each diagram shows one mechanical property (*e.g.* fracture stress) plotted vertically as a function of pre-strain (*i.e.* melt strain, the "morphological variable") and of the temperature of testing. The results will be discussed separately.

4.2. The Initial Modulus

The initial tangent modulus to the stress-strain curve is shown for crystallized specimens in Figure 12. Spherulitic material (corresponding to pre-extension of 0% strain or extension ratio of unity) deforms in an essentially rubberlike manner above −60 °C, although its modulus is an order of magnitude greater than that of noncrystalline material. (On the scale of Figure 12 both these moduli are of negligible magnitude.) There is evidence from other sources[15] that the moduli of spherulitic polymers are strongly affected by detailed spherulite structure such as the lamellar aspect-ratio referred to earlier. The morphological evidence (Fig. 4b) thus suggests that crosslinked rubber, with discontinuous lamellae, should have a significantly lower modulus in the spherulitic form than uncrosslinked material. This accords with the observation that raw rubber increases its stiffness by at least two orders of magnitude when crystallized spherulitically compared with the tenfold change found here.

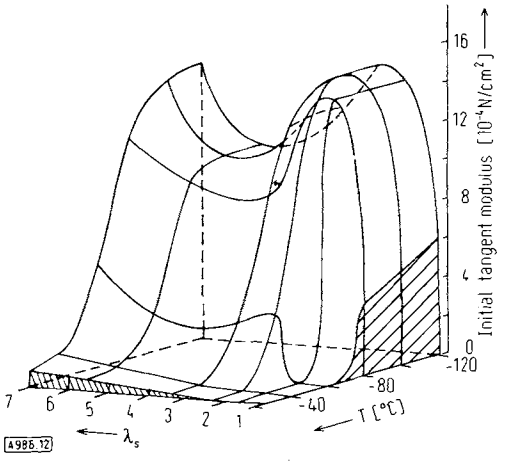

Fig. 12. Initial tangent modulus of crystallized natural rubber as a function of pre-strain and temperature. Yield surface shown plain, brittle fracture surface shaded (after [16]).

As the pre-extension increases, the morphology changes from spherulitic to row-nucleated and finally to γ-filaments, but the progressive rise in initial modulus above −40 °C can be attributed almost wholly to the increased orientation of the amorphous phase.

At an intermediate temperature of, say −60 °C, the effect of changing morphology is more dramatic, the modulus rising very sharply on the establishment of row-nucleated structures in place of spherulites, but thereafter remaining fairly constant. It is suggested[18] that this is due to a "fiber-reinforcement" mechanism in which the "shish-kebabs" act like oriented stiff fibers embedded in soft matrix. The effect fails to manifest itself at higher temperatures because the amorphous matrix is too soft, and fails to transmit significant shear stress from one "fiber" to another (this stress transmission is important because the fibers are discontinuous). At −60 °C the amorphous material is entering its glass transition range and losing its rubbery character.

Once the amorphous phase is fully glasslike (below −80 °C), the dependence of modulus on morphology follows a pattern which is not greatly affected by further reduction in temperature. The glassy state modulus of spherulitic polymer increases only twofold as the morphology is transformed to a row-nucleated form. That this increase can be attributed wholly to amorphous orientation has been convincingly demonstrated by studies on polychloroprene[6]. Clearly the elastic constants of the glassy and crystalline phases are now sufficiently alike for no "fiber reinforcement" to be observed. What is observed, however, is a wholly unexpected *decrease* in modulus with the establishment of the row-nucleated morphology above 100% pre-strain. This could be due to any of three causes. Firstly *Reed*[16] has shown that crystallization, under constant strain, into a row-nucleated morphology results in a relaxation of molecular orientation in the amorphous regions between lamellae. The *amorphous* orientation thus actually decreases with increasing pre-strain during the establishment of row-nucleated morphologies. This would reverse the trend observed for small pre-orientations, but would not really explain the persistence of the downturn in modulus up to high pre-extensions. Secondly, the lamellar orientation having now become uniformly transverse to the direction of testing, it could be argued that fiber reinforcement effects are minimized. *Reed*[16] found, however, that specimens tested at different angles to the direction of pre-extension showed very little difference in modulus at −120 °C, even when the angle was 90°. This shows that no "fiber reinforcement" occurs with lamellae in a glassy matrix as already proposed above.

Thirdly it is possible that the mutually aligned lamellae in row-nucleated structures are able to deform cooperatively by crystallographic mechanisms (*e.g.* [001] slip) to increase the compliance of the bulk. Until mutual alignment is achieved such deformations are relatively ineffective (*e.g.* in the randomness of the spherulite), but a stack of parallel crystals can deform "as one". Since the lamellae are reasonably extensive at intermediate pre-extensions they effectively separate the glassy matrix into "slices" perpendicular to the tensile axis, so that the matrix has relatively little ability to constrain the deforming crystals. As the row nuclei become more closely spaced with increasing pre-extension the horizontal continuity of the lamellar array diminishes and the matrix exerts a more effective constraint. This, together with the continuing rise in amorphous orientation, eventually causes the modulus to rise again at high pre-extensions.

This explanation of the dependence of modulus on morphology, although qualitative, is in reasonable accord with our present understanding of strengthening mechanisms in two-phase systems and opens the way to more quantitative investigations.

4.3. Yield and Brittle Fracture Stresses

In the glassy region, below −80 °C, the stress-strain curves of both crystallized and amorphous natural rubber exhibit either brittle fracture or yield followed by strain hardening, according to the temperature and pre-orientation. *Reed*'s data[16] for crystallized and amorphous rubber respectively are given in Figures 13 and 14. For pre-extensions above 300%, where spontaneous crystallization occurs during pre-extension, the data for the amorphous glass have been extrapolated algebraically. The regions of morphology and test temperature over which brittle fracture occurred are shown shaded. The testing rate was held constant throughout.

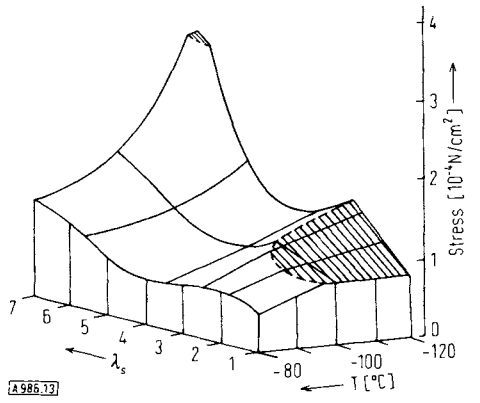

Fig. 13. As Fig. 12, but for yield and brittle fracture stresses of crystallized material (after [16]).

The differences between Figures 13 and 14 are not great, indicating that brittle fracture, yield, and strain hardening are all strongly affected by amorphous orientation in low

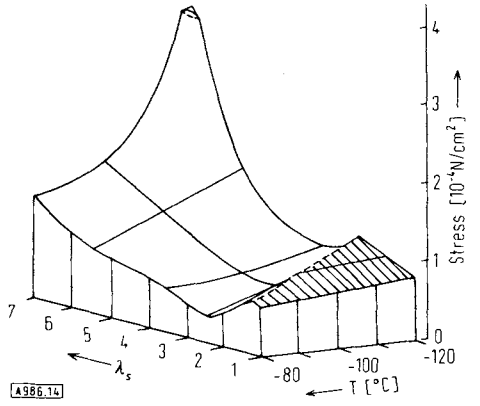

Fig. 14. As Fig. 13, but for amorphous material (after [16]).

crystallinity polymers. This is further borne out by studies[6] on polychloroprene at 18% crystallinity. At higher crystalline content, we have shown elsewhere[18] (for polyethylenes) that inter-lamellar attachments play a much stronger part in determining yield behavior.

Closer inspection of Figures 13 and 14 naturally reveals differences between the crystalline and amorphous cases. At low pre-extensions the brittle-ductile transition temperature is suppressed by the presence of crystallinity from -80 to about -95 °C. This is almost certainly due to the contribution of some low-stress ductility by the crystals. The second difference is that the shallow minimum which occurs in the yield stress as pre-extension increases, falls at a pre-extension ratio of 4 for the crystallized material but at 2.5 to 3.5 for the oriented amorphous specimens. This may again be explicable in terms of amorphous orientation since the local orientation in the amorphous phase of row-nucleated crystalline structures relaxes to a condition appropriate to a lower-than-nominal pre-extension (see Section 4.2).

If λ_s is the pre-extension ratio, *Reed*[16] calculated that the residual amorphous orientation in a row-nucleated specimen after crystallization would be

$$\lambda_{AR} = 4.41\lambda_s/(6.3 - 0.3\lambda_s)$$

which gives $\lambda_{AR}=3.5$ for $\lambda_s=4.0$ in good agreement with the shift of the minimum, at least at the lower temperatures. The occurrence of a minimum in yield stress thus appears to relate solely to amorphous orientation.

The third difference between amorphous and crystallized material is the rise in yield stress in the latter at large pre-extensions and low temperatures. This is perhaps directly attributable to the γ-filaments which we have suggested contain a large proportion of extended chain material. Whilst we have seen that crystals in a glassy matrix provide no reinforcement of modulus (because the elastic constants of the two phases are too similar), the λ-filaments *can* provide considerable strengthening when the glassy matrix begins to flow, providing of course, the γ-filament itself does not yield. This reinforcement-against-yield will be greater with γ-filaments than with lamellar structures because (a) [001] or chain-axis slip will be easier in the latter and (b) because gross tensile deformation causes buckling of lamellae and rapidly brings the [001] direction into the plane of maximum shear stress; in contrast, γ-filaments will not tend to reorient as a consequence of matrix flow.

It is likely that the yield phenomena discussed here are all associated with shear yielding. At lower temperatures *Reed* and *Natarajan*[19] have shown that a new mechanism of yielding (that of crazing) comes into play in natural rubber, and the competitive nature of these two yielding mechanisms has been widely recognized in glassy polymers[20].

4.4. Breaking Stress and Strain

Figures 15 and 16 show the breaking strain and stress respectively as functions of the usual variables for crystallized material. In the experiments, specimens are deformed in two stages, namely pre-extension to produce variable morphology and deformation during test. The variable of real significance is, of course, the total strain accommodated by the specimen before fracture and in Figure 15, therefore, is plotted this

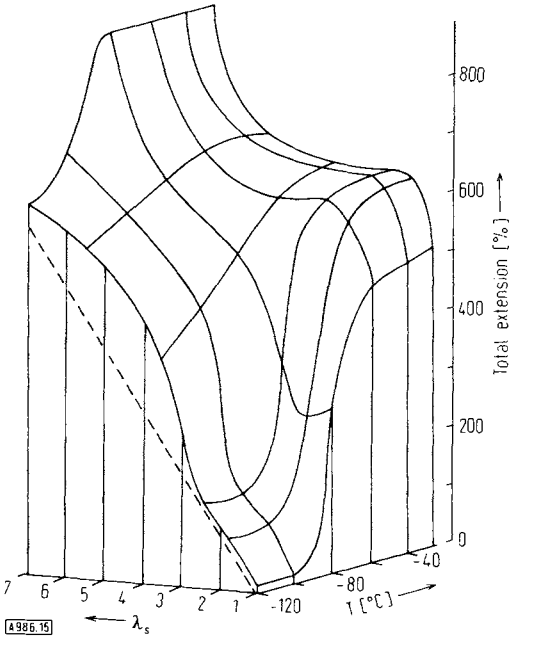

Fig. 15. As Fig. 12, but for total breaking strain. The broken line indicates the pre-strain (after [16]).

total strain given as the pre-extension plus the deformation during testing.

Plotted in this way it can be clearly seen that the fracture strain has a "plateau" value of some 600% over most of the experimental range except for two regions. The first of these is the region of brittle behavior already noted at low temperatures and low pre-extensions. Here very little extension occurs during test, the total strain deriving almost wholly from the room-temperature pre-extension. The second exception occurs at high pre-extension and temperatures above T_g where total extensions up to 900% are consistently recorded. This improvement in extensibility occurs with a morphology of γ-filaments in a rubberlike matrix and almost certainly results from a fiber strengthening mechanism which inhibits crack propagation normal to the fiber (γ-filament) axis. This mechanism is familiar in materials such as wood and arises from the relative weakness of inter-fibrillar bonds which encourages longitudinal fibrillation and blunts transverse cracks[21]. *Reed*[16] obtained striking fibrillation effects in specimens with very high pre-orientations.

Whilst the total extensibility of non-brittle specimens does not vary by a factor of more than 1.5 (and then only at high pre-extensions), the associated fracture stresses display drastic variations with morphological changes. This can be seen from Figure 16, where the load-bearing capacity nearly

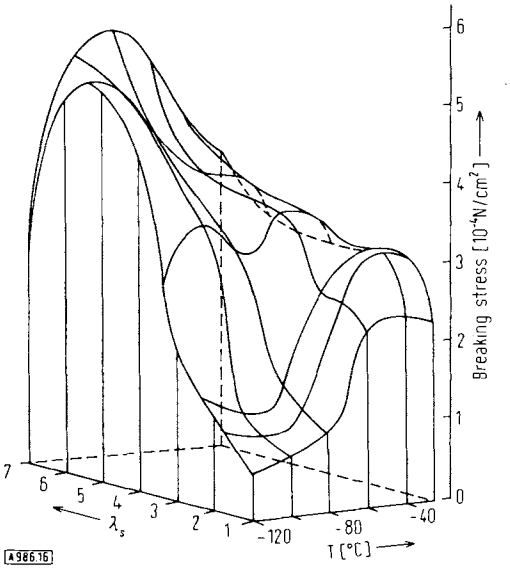

Fig. 16. As Fig. 12, but for true breaking stress. Changes in sample cross section accounted for (after [16]).

doubles at large pre-extensions as the temperature falls from −26 °C to −120 °C, and, at low temperatures, increases tenfold as the morphology changes from spherulitic to γ-filamentous. The breaking stress in Figure 16 is in all cases corrected for changes in specimen cross-section, *i.e.* it is the true load-bearing capacity of the material at the point of fracture.

At temperatures well above T_g, the breaking stress is fairly independent of pre-extension. Here the stress-strain curves are rubberlike and the morphology must undergo severe deformation before fracture. Since the actual fracture stress is independent of starting morphology, it is probably governed entirely by the amorphous matrix.

At low pre-extensions (up to $\lambda_s = 3$), the effect of reducing temperature through T_g is to produce embrittlement. Fracture here occurs in relatively poorly aligned material and the ultimate load-bearing capacity is understandably low. As pre-orientation increases, however, there is a rapid increase in the low temperature strength until (at $\lambda_s > 5$) reductions in temperature actually *increase* the strength of the material to a maximum before embrittlement once again causes a reduction. In the high strength region of Figure 16 the stress-strain curve, typically, exhibits yield and immediate, rapid strain hardening. As strain hardening becomes increasingly severe (with further reduction in temperature or increase in λ_s) the break in the stress-strain curve at yield is eliminated and brittleness again supervenes. This rapid strain hardening is typical of crystallized material and is not found in oriented amorphous polymers. It is thus attributable directly to the crystalline morphology.

The strength rise at −120 °C with initial pre-orientation is apparently associated with a rise in yield stress. Incipient yield appears to lead directly to fracture, and earlier these fractures were classified as brittle because there is no post-yield extension. Such a rise in yield stress can be attributed to amorphous orientation alone, although parallel tests on non-crystalline specimens showed that the latter always yielded at lower stress than the crystallized ones. Once yield is fully established, with significant post-yield deformation, the high breaking stress of the crystallized material is obviously a direct result of strain hardening which occurs far less rapidly in amorphous material. What is the cause of this strain hardening?

It has already been suggested that yield in the crystalline phase is progressively suppressed as lamellar or "shish-kebab" structures give way to extended-chain or γ-filament fibrillar morphologies. Since the yield stresses for amorphous and crystalline specimens are not very different in the intermediate range of pre-extensions, it seems likely that here, at low temperatures, the onset of yield is controlled by the glassy phase. As significant plastic deformation accumulates, however, the glassy phase can only continue to deform if the attached crystalline material also deforms to accommodate the change of shape. Whilst this is relatively easy for lamellar crystals, it becomes progressively more difficult as the crystalline phase assumes a fibrillar character. This mechanism has already been invoked to explain the rise in yield stress at high pre-extensions and extends naturally to the post-yield region. A further factor may be the increased amount of inter-fibrillar connection as the γ-filaments become more closely packed with increasing pre-extension.

Eventually the strain-hardening mechanism is self-defeating; the material becomes so inextensible that it becomes prey to weakening by flaws, lacking any plastic flow to blunt incipient cracks. A new brittle condition is thus established and the strength falls drastically at $\lambda_s > 6$.

5. Conclusion

The detailed discussion of *cis*-polyisoprene has illustrated the validity of the original proposition, namely that the properties of polymeric solids depend upon their structure at all levels and not solely upon their molecular structure. The complexity

of the data given in Figures 12—16 underlines the difficulty of providing simple rules in this area of structure-property relationships. Appeal has to be made to the anisotropic responses of both crystalline and amorphous phases to stress and, additionally, to specific mechanical interactions between the phases. It is in this latter area, for example, that molecular weight probably exercises a profound influence on mechanical behavior.

The work reported here, then, represents just a fraction of the painstaking task of "mapping" properties in the multidimensional reference frame of structure. It is only as we continue this mapping that a rational and consistent picture will emerge.

Biopolymers: Origin, Chemistry, and Biology

By Melvin Calvin[*]

A brief statement concerning the way in which biopolymers may have originated in the nonbiological world is made, including experimental evidence. This also includes a discussion of such matters as the way in which the code might have originated, that is, the relationship between polypeptides and polynucleotides as well as the secondary and tertiary structure resulting from the primary structure determination. The importance of the interaction of biopolymers with lipids for the formation of limiting membranes, leading to the formation of cells and other self-organizing cellular type organelles, is discussed. Thus, the second critical physical-chemical problem for cellular organization, namely, the biopolymer-lipid interaction, is now coming under scrutiny, both in terms of synthetic systems as well as natural ones.

1. Introduction

The collection of ideas presented here was compiled over a period of several months into the form of a review article containing four separate but closely interrelated sections. The first section discusses the origin of biopolymers, particularly of proteins, including the chemistry which may be involved. The next section describes the secondary-, tertiary-, and quaternary-structures of biopolymers and the interaction between proteins and nucleic acids. This is followed by a section on the origin of the genetic code. The last section deals with the interaction between the proteins and lipids.

[**] This article is based on an address presented at the dedication of the Midland Macromolecular Institute, Midland, Michigan, September 29, 1972. All lectures given at the dedication will be collected in *H.-G. Elias:* Trends in Macromolecular Science (Midland Macromolecular Monographs, Volume 1), Gordon & Breach, New York—London.

Why has this particular sequence been chosen? Many of the phenomena (reactions) under discussion are actually extrapolations and modifications of reactions with which polymer chemists are familiar. However, there seems to be a kind of curtain separating the polymer chemist, whose background is oriented to the structure and synthesis of macromolecules of any kind and the determination of the basic principles involved, and the group that has grown up in biology and biochemistry and which has learned about the physical chemistry and the chemistry of the behavior of the kinds of biopolymers they deal with[1]. The biochemists have felt that these things are almost magic, and they believe new rules, or laws, or chemistry, may be required to understand in detail how the naturally-occurring biopolymers (proteins, nucleic acids, *etc.*) perform their function. There appears to be some "mystique" about this, so an attempt is made in the following article to outline some of the reasons for this "mystique", which is generally in the minds of those who grew up from the side of biology. The behavior of biopolymers is interpreted in terms which are thoroughly familiar and which may even

appear somewhat naive to the polymer chemist. It must be remembered, however, that most of the work discussed here is being carried out by people who are not polymer chemists, and that is why some of the material may seem obvious to those of you who happen to be polymer chemists. Some of it, however, may not be obvious to you and could possibly give you fresh ideas for your line of research.

2. Formation of Biopolymers, Particularly Proteins

Let us begin with a consideration of the general scheme by which the two major biopolymers are constructed by living organisms. These are the proteins and the nucleic acids, and a sequence is shown schematically in Figure 1, beginning

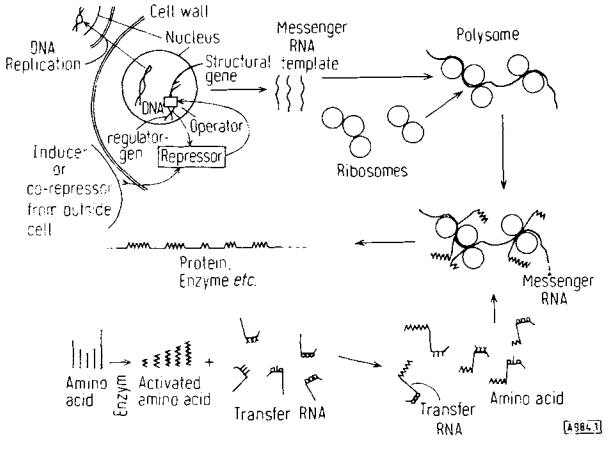

Fig. 1. Protein biosynthesis.

with the DNA double helix of the cell which can in some way (which is still not clarified) reproduce itself. That is, it can copy a particular sequence of nucleotide monomers in some particular order, and make a complementary copy, giving rise to a double set.

In addition, there is another type of reaction which occurs inside the cell. Instead of copying the DNA into another DNA strand, part of the DNA (which is an enormously long polymer, made up of essentially four bases hooked together by ribose phosphate linkages) can be copied into a ribose phosphate polymer, with a series of slightly different bases but related to the initial sequence. That part which is so copied contains in it the "message" for a particular protein. That is why this type of material is called "messenger RNA". The messenger RNA then leaves the cell nucleus and thus becomes the message for constructing a particular protein. The message is contained in the sequence of bases in the polymer. As is known, it takes three of these bases to designate a particular amino acid. The particular "messages" are then hooked onto the catalysts, which are themselves made up partly of protein and partly of nucleic acid and some lipid substances.

The situation is now ripe to put together the amino acids into a peptide. In order to do this, the amino acids must be suitably prepared. Each one of the different length straight lines in Figure 1 represents a different amino acid. The zigzag line represents the amino acid, acylated with a phosphate residue (aminoacyl phosphate or aminoacyl adenylate). This is then handed over to a small piece of polymer (RNA) constructed of about 70—100 monomeric units, containing in it somewhere a certain triplet (three bases in a row) which is characteristic of a particular amino acid; this distinction is designated by the different symbols in Figure 1 (circles, lines, crosses, squares), representing a different sequence of the three bases. Thus, each activated amino acid is loaded onto the terminus of a specific small oligomer (small polymer of the order of 70—100 units). We now have the amino acid loaded onto a particular transfer RNA (tRNA) with a particular triplet of bases characteristic of that amino acid. These are now free to attach themselves to the messenger RNA, the attachment taking place at points in the messenger where the complementary base triplets are to be found. Thus the sequence of the amino acids which go into the polymer to make the polypeptide is established. The polypeptide, is then "zipped up" to construct the protein. Generally, the protein is itself a characteristic polypeptide, having a typical shape and structure, which will be discussed in Section 4.

All of these reactions—the copying reaction (replication), the transcription into RNA, the activation, the loading, and the zipping-up on the ribosomes—are dependent for their specificity in part at least on the proteins which are themselves thus made. This is a "chicken and an egg" problem, and it sets the stage for the next part of the discussion.

How did this reflexive system, which is represented schematically in Figure 1, arise? As chemists, we would like to see if chemistry could have designed such a system and put it together in just this way. This is, of course, what should be understood as the nonbiological origin of the polymers and of the genetic code. How could this relationship between particular triplets and particular amino acids come into being?

I believe this relationship is the result of chemistry and not, as some of the biologists believe, a "frozen accident". However, experimental evidence for this is, as yet, forthcoming. Most polymer chemists will find this a rather amenable point of view, and it is to be hoped that many will turn their attention to devising experiments which will show that there is some reason for a triplet corresponding to a particular amino acid and not to some other one. This remains to be proved in the laboratory and is still a subject of considerable controversy.

Let us now return to the possible ways in which the proteins and nucleic acids might have come into being in a nonliving world: The world with which we are dealing is a world in water; it is not a world in methylene chloride, dioxane, DMF, or other solvents. And all of the reactions which are described in Figure 1 occur in water. Whatever reactions we use, whatever reactions we call upon to do the originating of the protein and the nucleic acid, should be essentially in an aqueous medium to begin with. This can be modified somewhat by the resulting polymer itself in terms of the protein-lipid interaction. The reactions do, however, occur primarily in an aqueous environment.

We set out to try and generate polypeptides and other polymers in an aqueous environment[2]. Chemically and thermodynamically this is rather a difficult operation. The formation of the biopolymer from the monomer is, in the case of the proteins, nucleic acids, carbohydrates, and lipids, the result of a dehydration condensation. To make a dehydration condensation occur in water is a tricky operation. Living organisms have long ago learned how to do this, but the

question now is whether we, as chemists, can accomplish something similar. The reactions which must be accomplished in this aqueous environment are shown in Figure 2. The

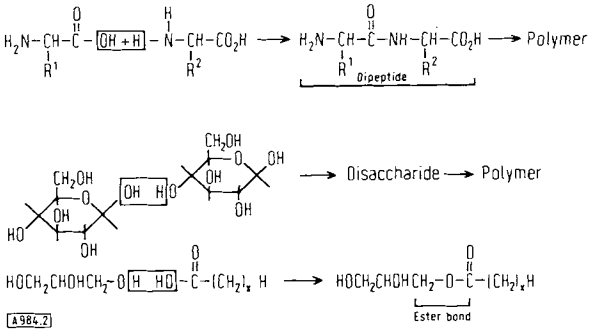

Fig. 2. Dehydration condensation in the formation of polypeptides, carbohydrates, fats.

proteins and peptides are formed from a bifunctional molecule, from which a water molecule can be eliminated, a bifunctional dimer remaining which, in turn, can grow at either end. Formally, the same kind of system occurs in each of the four cases—proteins, polysaccharides, lipids, nucleic acids. In each case, the water molecule is eliminated and a new bifunctional molecule is formed. This type of operation can go on continuously, but, in the case of the lipids, not to the same extent as with the proteins or polysaccharides; elimination of water gives rise to the ester bond which can react further. This is, however, not quite in the same category but it is possible to make fairly large molecules. This case has been mentioned at this point, since the lipids play an important role in the whole evolutionary scheme.

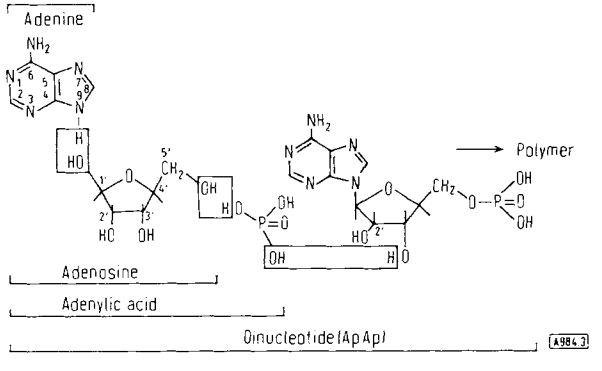

Fig. 3. Dehydration condensation in the formation of polynucleotides.

Figure 3 shows the methods for the formation of the nucleic acids by dehydration condensation reactions. Here, actually, there are three points of dehydration involved. The first cleavage of water effects formation of the amino glycoside on a base, whereby the NH group of the base reacts with the glycosidic semiacetal hydroxy of the sugar. The second takes place between the phosphate ester and the primary hydroxy group with formation of the terminal 5′-phosphate. In this case the ribose sugar is shown which forms RNA. (The DNA, of course, is the material in which the 2′-carbon lacks the hydroxyl, *i. e.*, carries two hydrogen atoms). The third dehydration condensation occurs between the monophosphate ester and the secondary hydroxy group on the 3′-carbon atom of another nucleotide. The result is a bifunctional molecule, with both functions available; at one end the phosphate ester is available and at the other end the 3′-alcohol hydroxy group. The nucleic acids are built on the same principles as the two other major biopolymers shown in Figure 2.

We asked the question: Is there any way to generate the polypeptides? Many reactions are known which might be used for the linking of polypeptide bonds in an aqueous environment. Only a slight modification of the existing knowledge of reactions was required. One of the important reagents that has been used for the dehydration condensation of a variety of functional groups is the carbodiimide R—N=C=N—R[*]. The carbodiimide structure has the ability to remove water, in stages, by more or less specific reactions with acid groups such as carboxyl, phosphate, and certain alcohols. This leads to condensation reactions[3]. Carbodiimide has been used widely for nucleotide and polypeptide synthesis, but usually not in aqueous environments. It was necessary to change the R groups, to make them useful in aqueous environments. This can be achieved by making the R groups hydrophilic so that the carbodiimide can be dissolved in water. This is useful since the carbodiimide does not hydrolyze very rapidly directly but does so by virtue of its reaction with the carboxyl group and then with the phosphate.

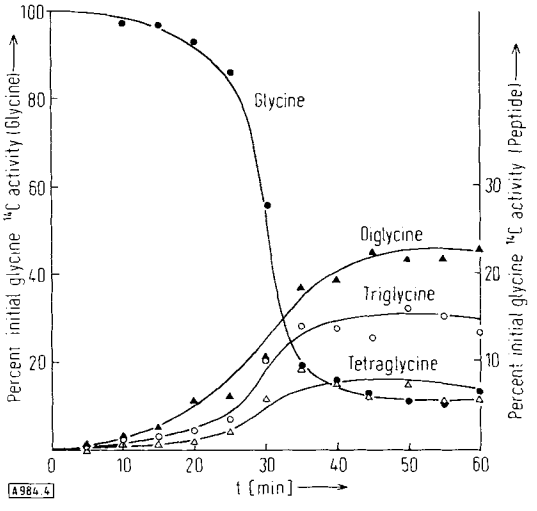

Fig. 4. Polypeptide formation by dicyandiamide in homogeneous solution.

Now arose the next question: How could this type of reaction occur in a natural environment? It turned out that there was a very easy way in which this particular structure could have evolved in a natural environment. As we know, ammonia and HCN were two of the primary molecules on the earth's surface. Reactions between these two materials can lead to cyanamide, probably through cyanic acid or hydroxylamine. Cyanamide is a tautomeric form of carbodiimide which, however, is not stable; it tends to dimerize to the dicyandiamide (DCDA) $H_2N—C(=NH)—NH—CN$, which is the common form of cyanamide. It also contains the same type of π-bonds as carbodiimide. We used DCDA as one of the starting materials to demonstrate this type of dehydration condensation in the formation of biopolymeric materials. We took an amino acid, adjusted the pH to slightly acid conditions, and added the water-soluble carbodiimide material (dicyandiamide) to

[*] R = *e. g.* cyclohexyl.

see if we could produce polypeptides in the homogeneous aqueous environment. The results of some of these experiments are shown in Figure 4[4]. We started with glycine and carried out the reaction at pH 3.5; the glycine disappears and the dimer (diglycine), trimer (triglycine), and tetramer (tetraglycine) are formed. The reaction is very slow and does not proceed very far. One can hardly call the tetraglycine a "polymer", but at least the reaction does occur in aqueous solution.

The next question was: Is the reaction in any way selective? Do the amino acids self-select each other when they condense? This is a natural question to ask in the ordinary course of evolutionary studies. About five or six years ago, *Steinman*, in trying to answer this question, attached an amino acid B on polymer beads *via* the carboxyl group and used an amino protected amino acid A to couple to it. He measured the relative rates of coupling of amino acid A to the polymer-bound amino acid B in an homogeneous environment; this is a model, of sorts, for polypeptide formation. Table 1 shows the relative rates of coupling. It can be seen that the rates differ by a factor of about ten[5]. The is the measured coupling efficiency, and the calculation is based upon the frequency of a particular pair (phenylalanylglycine, glycylphenylalanine, or isoleucylglycine, *etc.*) in today's existing proteins with a statistical analysis of the situation, normalizing the frequencies to glycylglycine as unity. There seems to be slight relationship between the efficiency of coupling in the heterogeneous system and the occurrence in nature of these particular pairs of peptides. This idea has been developed still further, and there are now better ways of studying the possible self-selection of amino acids in peptide formation.

Table 1. Comparison of experimentally determined dipeptide yields and frequencies calculated from known protein sequences relative to Gly-Gly = 1.0.

Dipeptide [a]	Values Obs.	Calc.
Gly-Gly	1.0	1.0
Gly-Ala	0.8	0.7
Ala-Gly	0.8	0.6
Ala-Ala	0.7	0.6
Gly-Val	0.5	0.2
Val-Gly	0.5	0.3
Gly-Leu	0.5	0.3
Leu-Gly	0.5	0.2
Gly-Ile	0.3	0.1
Ile-Gly	0.3	0.1
Gly-Phe	0.1	0.1
Phe-Gly	0.1	0.1

[a] The dipeptides are listed in terms of increasing volume of the side chains of the constituent residues. Gly = glycine, Ala = alanine, Val = valine, Leu = leucine, Ile = isoleucine, Phe = Phenylalanine. Example: Gly-Ala = glycylalanine [5].

There are two other methods by which polypeptides have been made, one of which was carried out in a nonaqueous environment. Table 2 shows the results of experiments in which *Sidney Fox* used molten glutamic acid containing a small amount of pyrophosphoric acid as a solvent (hardly an aqueous environment) and to which an equimolar mixture of all the other amino acids, other than aspartic and glutamic[6], was added. Here, again, it can be seen that the incorporation into the resulting polypeptides is not statistical. The main point about these data is that they show the variable frequency of incorporation, ranging from 0.5% to 5%, and that selectivity is evident.

The final study is, perhaps, the most elegant, and one doesn't know whether it will continue. This is the work of *Aharon Katchalsky*, who used aminoacyl adenylates as starting material and montmorillonite clay as the catalyst, both of which are readily available in nature. The aminoacyl adenylate is available in nature because the adenylic acid can be generated by ordinary chemical reactions and the coupling of the amino acid to the adenylic acid (linking a phosphate and a carboxyl anhydride) can be easily achieved using the carbodiimide dehydration condensation reaction in an aqueous environment. So the system with which *Katchalsky* began is achievable biologically. *Katchalsky*'s discovery ought to be described in detail because it is the starting point of a very interesting idea. The aminoacyl adenylate used is the activated amino acid in the first stage of normal biological amino acid activation; although it is usually a part of an enzyme complex it, nevertheless, is a suitable starting material for this type of study. At first, *Katchalsky* tried to polymerize this material in a homogeneous aqueous solution. The aminoacyl adenylate can be regarded as a mixed anhydride of a carboxylic acid group and phosphoric acid which also contains the free amino group of the amino acid. Thus, the free amino group can act as a nucleophile toward the carboxy group of the anhydride grouping.

Table 2. Amino acid composition of proteinoid prepared in the presence of 200 ppm of pyrophosphoric acid. Asp: Glu: equimolar mixture of basic and neutral amino acid = 2:1:3, *i.e.*, 33%:16%:50%. The mixture was incubated for 150 h at 100 °C.

Amino acid	%	Amino acid	%
Thr	0.55	Lys	2.79
Ser	0.63	His	2.53
Gly	2.93	Arg	1.83
Ala	1.31	Total	7.15
Val	1.33		
Met	0.86	Asp	51.9
Ile	0.71	Glu	13.3
Leu	3.44	Total	65.2
Tyr	3.87		
Phe	5.87		
NH_2	5.02		
Total	27.6		

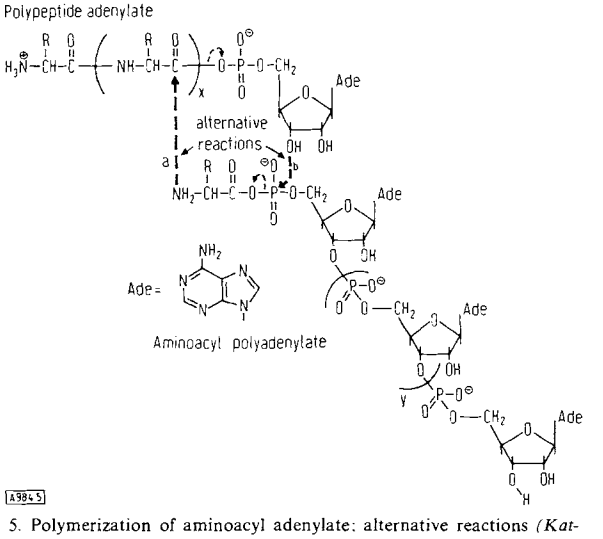

Fig. 5. Polymerization of aminoacyl adenylate: alternative reactions *(Katchalsky)*.

Figure 5 outlines *Katchalsky*'s basic idea; but it shows more as well. If one considers the aminoacyl adenylate skeleton attached to the polynucleotide chain one can see that the amino group can act as a nucleophile toward the acyl group of the anhydride (reaction a), a reaction that leads to the formation of a polypeptide (poly)adenylate and free adenylic acid. The alternative reaction, which *Katchalsky* had considered, but had not published any experimental information on, is that in which the secondary hydroxy of the sugar will attack—once again as a nucleophile—the phosphate in the mixed anhydride (reaction b), resulting in the reverse type of polymerization, the products being a free amino acid and the (poly)aminoacyl polyadenylate. There are, of course, alternative reactions which can occur (rearrangements, *etc.*) to stop or slow down the polymerization reactions.

As *Katchalsky* reported in his publication of 1970[7a] and in more detail in May 1972[7b] in Göttingen, shortly before his death, the reaction is slow in homogeneous solution and the polymers which are formed are not very large (8—10 units). He found, however, that if he performed this reaction in the presence of a properly prepared montmorillonite, the whole system changed. The reaction became extremely rapid and the polypeptides reached fairly high degrees of polymerization—*i.e.* high for this kind of a reaction[8].

We have both attempted this type of reaction and have, indeed, been able to prepare polypeptides and polynucleotides from the same starting material. We can now begin to see the real relationship between the polynucleotides and polypeptides—or the nucleic acids and proteins—and how they can arise as a result of the stereochemistry of the reaction.

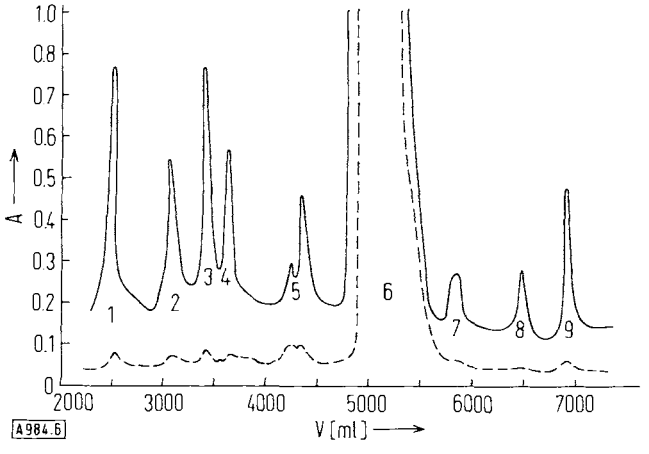

Fig. 6. Polypeptides from alanyl adenylate on montmorillonite *(Katchalsky)*. Chromatography of fraction II on Sephadex G-25 with gel bed 3 × 4 × 150 cm. 1—9, see text and Table 3.

Katchalsky found that a number of discrete polypeptides were formed from alanyladenylate and montmorillonite. Figure 6 shows a chromatogram of the second fraction. Table 3 gives more information about the two principal components contained in the initial extract of this reaction. Fraction I consists mostly of adenylic acid and three types of polypeptides. Fraction II, however, contains mostly polypeptides with some adenylic acid. In the gel permeation chromatogram of fraction II (Figure 6) one can see the presence of some nine components; the largest component is adenylic acid, and the components 1, 2, 3 and 4 are polypeptides. In addition, there are two

Table 3. Composition of the main fraction obtained from 1 g alanyl adenylate on montmorillonite.

Fraction	Component	MW	Degree of polymerization	Wt. [mg]	No. in Fig. 6
I	Peptide	640	9	10.3	
	Peptide	1120	16	35.2	
	Peptide	1900	27	20.0	
	Adenylic acid		1	470.5

	Adenylic acid		1	260.1	6

unidentified inorganic salts and two unidentified organic compounds. When I spoke to *Katchalsky* he said he thought they might be polynucleotides; and I think so too.

Perhaps someone else will pursue this work further in the future: In my opinion it represents an extremely important step towards understanding the nature of polymerization reactions. Why is it that you do not get a random distribution but discrete groups of polymers? I think these discrete groups occur because no simple addition reaction takes place. Amino acids are added and polynucleotides are constructed and subsequently form a polypeptide-polyadenylate, and these materials regulate the size of the polypeptides which are found. It will probably turn out that the polynucleotide is also discrete in some way.

3. The Origin of the Genetic Code

It is known that in today's living organisms the specification of the linear array of amino acids in a polypeptide is contained in a corresponding linear array of bases in a polynucleotide. A series of three bases in the polynucleotide (DNA) specifies a specific amino acid in a polypeptide, or protein. This correspondence of a triplet of bases with a particular amino acid is universal in all living organisms. One form of expressing

Table 4. The genetic code.

	AUG	Met	CUG		GUG		UUG	
	AUC	Ile	CUC		GUC		UUC	Phe
	AUU		CUU		GUU		UUU	

this is shown in Table 4. Here one can see there is a certain amount of redundancy in the code, but the universality of it throughout the living world is now fairly well established.

Thus, in addition to the question of how these biopolymers may actually have been formed abiogenically we must turn to the question of how the linear relationship between the two major biopolymers, that is, the polypeptides (proteins) and the polynucleotides (DNA), evolved. That is: What is the possible origin of the genetic code?

There are those who believe that the particular specificity we now find in living organisms between a particular triplet and a particular amino acid, as assembled in Table 4, is the result of an accident in some early catalytic reaction which, by virtue of a selective advantage in producing autocatalytic systems, has now been frozen into *all* of biology[9]. Selection followed because a single autocatalytic system eventually dominated all the others. Another way of expressing this "frozen accident" notion is to state that a renewed chemical evolution under exactly the same starting conditions could very well lead to a completely different codeal relationship[10, 11]. It is my personal belief, however, that this would *not* be the case. I believe that the codal relationship reflects some characteristic molecular interactions between amino acids (polypeptides) and nucleotides (polynucleotides).

A modicum of evidence for this already exists in the form of some experiments carried out on the rate of coupling of amino acids to nucleotides. Some years ago[12] we attached a nucleotide (adenylic acid) to a synthetic polymer (polystyrene); the polystyrene was in the form of microspheres. The next step was to measure the rate of coupling of two different amino acids to each of these two polystyrene-nucleotide preparations. The coupling was performed using an *N*-protected amino acid adenylate. The reaction is shown in Figure 7

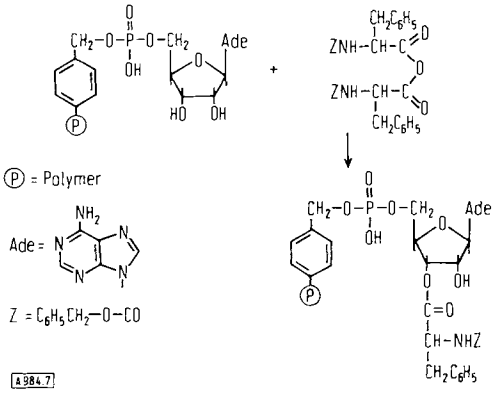

Fig. 7. The coupling of a polymer-AMP complex with the anhydride of an *N*-protected amino acid (24h at room temperature in pyridine) to an *N*-protected phenylalanyl-AMP polymer.

and the results, as well as those of analogous reactions, are given in Table 5[13]. It can be seen that glycine reacts more rapidly with adenine and cytosine than does phenylalanine, and adenine reacts more rapidly with both amino acids than does cytosine. The overall range of reactivity is roughly a factor of three.

Here the beginning of a kind of selectivity in a reaction rate is apparent[14]. However, I believe that this kind of selectivity will be very much enhanced if both the amino acid and the nucleotides are each, respectively, part of a polymer. For example, one would expect the alternative reactions (a) and (b) indicated in Figure 6 to be very dependent upon the nature of the amino acid and the nature of the nucleotide

Table 5. Coupling of a polymer-nucleotide complex with the anhydride of an *N*-protected amino acid. The proportion [%] of bound nucleotides reacted are quoted.

Amino acid \ Base	Adenine	Cytosine
Phenylalanine	6.7	2.9
Glycine	10.0	6.5

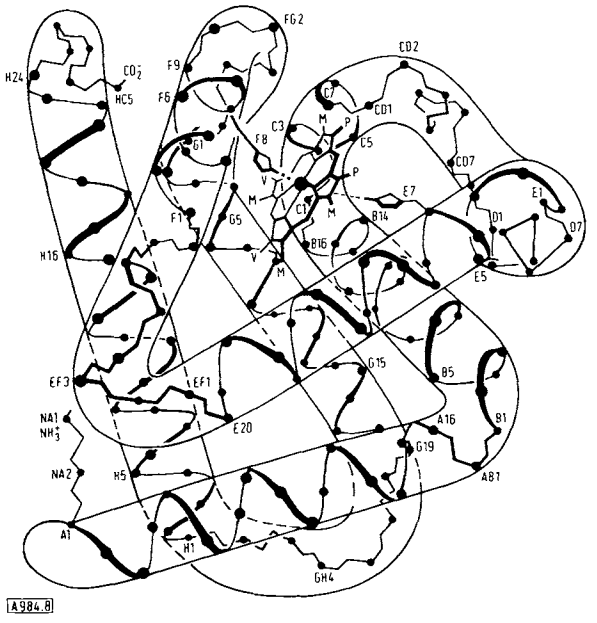
involved. Furthermore, one would expect that selectivity would be increased with the length and character of the polynucleotide, on the one hand, and possibly even with the polypeptide on the other. This last experiment is yet to be done, but is underway.

4. Secondary and Tertiary Structure of Protein and Interaction with Nucleic Acids

This part of our discussion will be concerned with what is known about the secondary, tertiary and quaternary structures, above all, of proteins. There are several principles which should be emphasized here: One is the way in which proteins fold up, in their secondary and tertiary structures, another is the way enzymes interact with substrates, and a third is the way in which the proteins interact with the nucleic acids. (The protein-lipid interaction is discussed in Section 5.)

Myoglobin, with its tertiary structure, is shown in Figure 8. The left-hand side of the figure shows the alpha helical structure and the drawing on the right-hand gives a more three-dimensional view of the same material, to show that the myoglobin is a folded protein, with the heme stuck in the center. This secondary and tertiary structure is built into the molecule as a result of the amino acid sequence in the polypeptide which takes up this structure, given the opportunity, in water[15]. In the structure of cytochrome c, the hydrophobic sidechains of the amino acids are more or less in the middle of the molecule and the hydrophilic parts are on the outside of the molecule. This is the only characteristic which has so far approached a generalization on the structure of soluble proteins. In general, the structure of soluble proteins is such that when they fold up in their secondary and tertiary structures they do so in a way which places the hydrophobic chains on the inside (away from the water environment) and the hydrophilic chains on the outside, towards the water environment.

It is for this reason that I had the reservation, mentioned earlier, about the generation of polypeptide and polynucleotide structures in a purely aqueous environment. Modifications can occur during the course of formation of these biopolymers which will remove their functions from the water environment into a nonaqueous environment, by virtue of their own structure, so to speak.



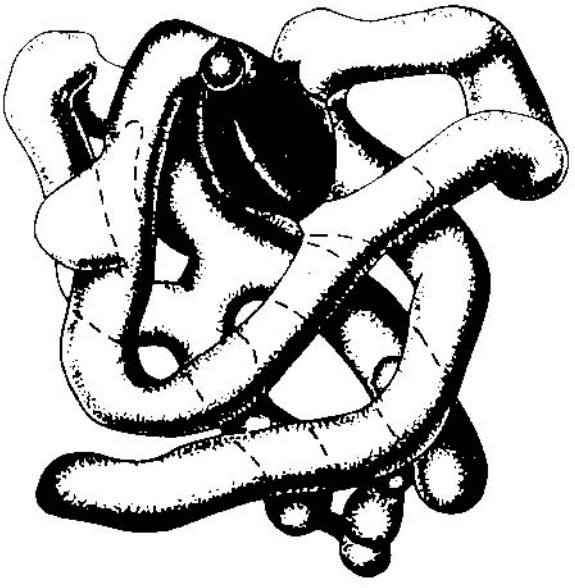


Fig. 8. Tertiary structure of myoglobin.

The lysozyme molecule has a cleft, into which the substrate is incorporated. Figure 9 shows the mechanism of the polysaccharide hydrolysis, and the actual function of the active site.

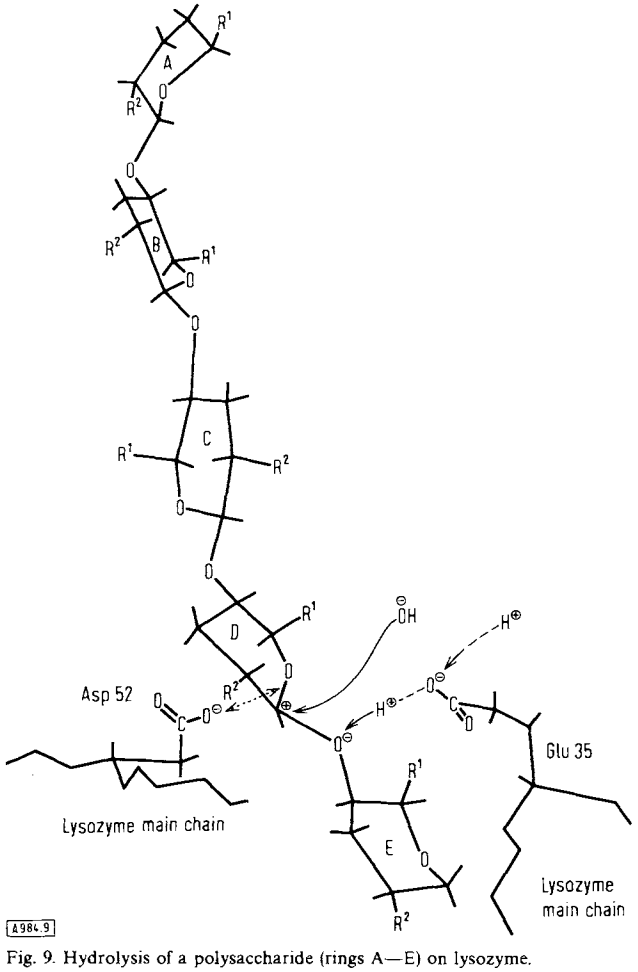

Fig. 9. Hydrolysis of a polysaccharide (rings A—E) on lysozyme.

One can see how the polysaccharide lies in the active site of the lysozyme. The glycosidic linkage is hydrolyzed: one part of the substrate is transferred to the polymer (Asp 52) thus letting the other part go free. The Asp glycosidic ester, in turn, is very rapidly hydrolyzed. This is the way in which the hydrolytic enzymes and many of the transferases function. Thus, the tertiary structure is evolved to give the particular tertiary architecture which will take hold of the proper substrate.

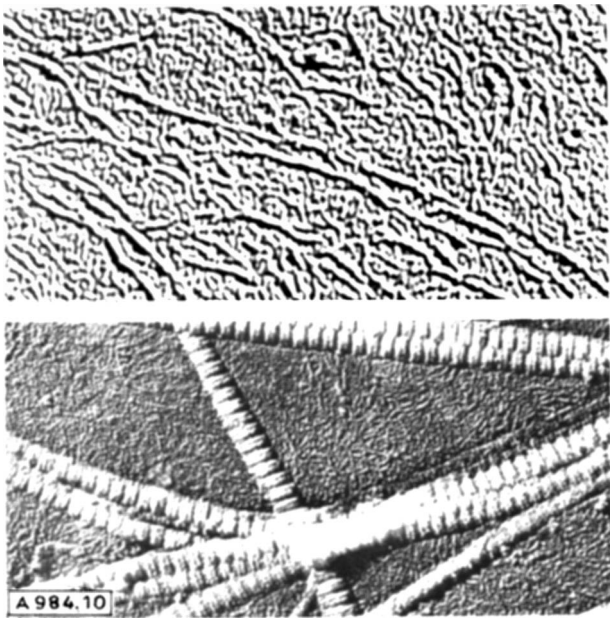

Fig. 10. Structure of collagen. For details see text.

The next figure (which is an old one) reaches into the area visible under the electron microscope. In collagen (Fig. 10), we can see that molecules can be refolded into their tertiary structure and, even further, that these molecules can actually reassemble into more complex quaternary structures which are dependent upon their primary sequence[16]. The upper part of Figure 10 shows the separated collagen fibrils, and the bottom part the reaggregated fibrils, which strongly resemble the natural ones. The fibrils are highly ordered arrays as a result of protein-protein aggregation.

The next few figures show the dissociation and re-aggregation of the tobacco mosaic virus (a relatively simple virus particle) which consists of a set of identical protein molecules and

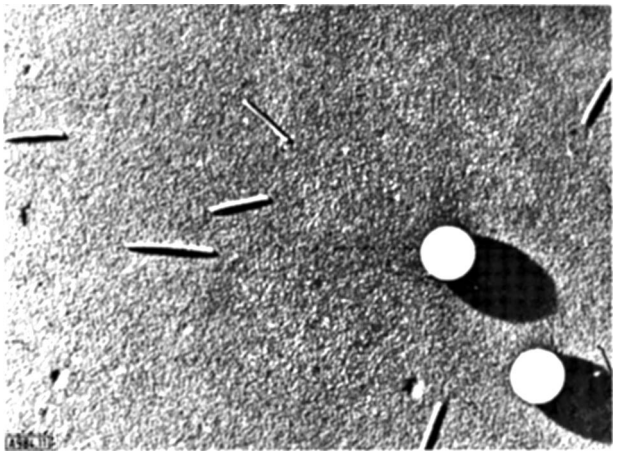

Fig. 11. Tobacco mosaic virus (TMV), native.

one nucleic acid molecule. These two can be separated and then reassembled again into a complete virus particle[17]. More

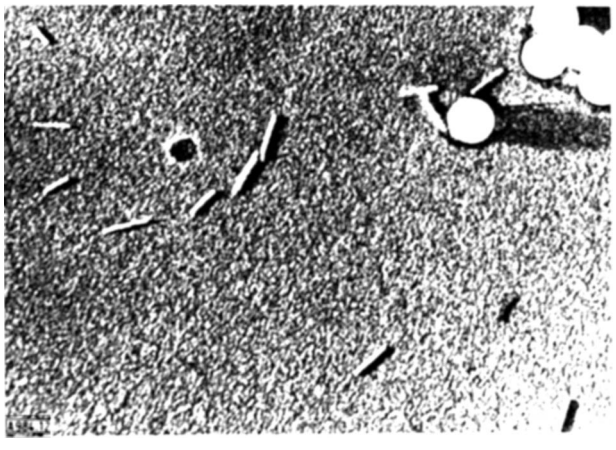

Fig. 12. Reconstituted TMV protein.

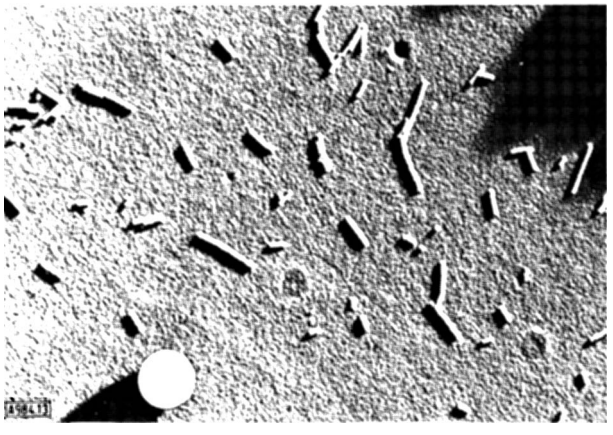

Fig. 13. Reconstituted TMV.

complex virus particles have now been reconstituted as well. Figure 11 shows the native tobacco mosaic virus (TMV), with its uniform particles, and Figure 12 shows the reassembly of the TMV protein without the nucleic acid. The protein is separated from the nucleic acid, redissolved, and, by changing the salt concentration, reaggregated with the result shown here. One can see that the material has reaggregated with the correct dimensions in one way, but not in the other; in contrast to the native TMV, all the particles have different lengths because there is no nucleic acid "information" to give the correct dimensions. In Figure 13 you can see the reconstituted TMV virus particle, which occurs when the nucleic acid component is put back into the protein solution. This same type of experiment has been done with much more complex particles such as T4 bacteriophages, MS2 phages, *etc.* Progress is also being made in the reassembly of very complex structures[18]. The TMV particle itself is shown diagramatically in Figure 14. The tertiary structure of the subunit protein material in TMV has not yet been established, but we know that there is a sequence of 120 amino acids.

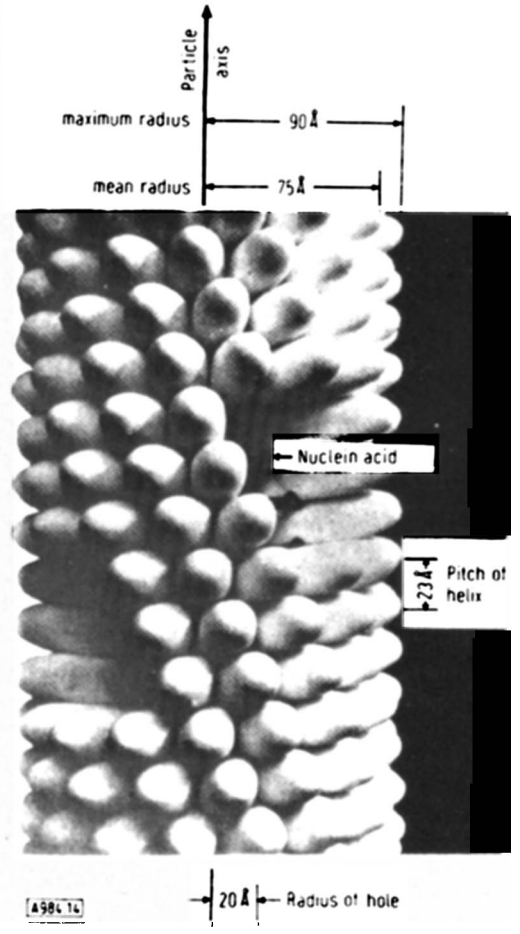

Fig. 14. Diagrammatic structure of TMV.

5. Interaction of Protein and Lipids

Protein-lipid interaction is one of the areas of very high scientific activity, in the technological polymer area and more selectively than hithertofore in the biochemical laboratory. Lipids have been used for handling biochemical proteins for some time. The present concept of membrane structure—protein embedded in the bilipid membrane—is shown in Figure 15. A phospholipid consists of the hydrophilic ends (the phos-

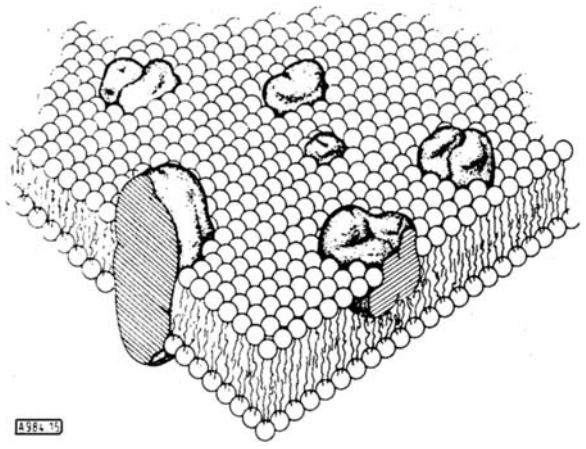

Fig. 15. Present concept of membrane structure showing protein embedded in bilipid membrane.

phoethanolamine end represented by spheres) and the lipid chains. The globules which are membrane proteins in various stages of insertion into the bilipid membrane make the total actual biological membrane itself. These proteins may be either structural elements or transport proteins, which carry material into the cell through the biological membrane. The fact that many of the proteins are directly associated with lipids implies that there must be hydrophobic connections on the outside of the proteins in order to be able to perform this type of insertion. This has not yet been established in the laboratory. Clearly, there are hydrophobic parts on the proteins, but whether they are on the outside or the inside, or both, is a subject of some concern.

Fig. 16. Liposomes of phospholipid and cytochrome *(Horne* and *Watkins)*.

A synthetic "biological cell" is shown in Figure 16. These liposomes (soft spheres) are formed by shaking the solution of a phospholipid (lecithin) with a protein cytochrome. The multiple and single bilipid layers are visible in the electron micrograph; these layers are filled with protein[19]. This work was done about eight years ago in Great Britain. I have called the spheres "Bangasomes" after the man who first constructed them[20]. The spheres are generally called liposomes; their osmotic properties, transport properties, and a variety of other properties resemble those of living cells. How do materials get in and out through that membrane? What is the mode of their transport? Can specific proteins be associated with the membranes to produce these specific results? These are questions still unanswered. Studies are now in progress; this field is really just blossoming out as a new area and marks the advent of a new era. Only now have the polymer physical chemists become active in this field.

As is known, it is quite common to use detergents, anionic, cationic and non-ionic, for the isolation of a particular enzyme from a living cell. The procedures for the soluble proteins (soluble enzymes) are now well established. The insoluble enzymes, however, are a different story. The isolation of membrane-attached enzymes from the membrane of the cell, the membrane of the mitochondrion, or the membrane of other internal cellular structures present more difficulties; it is necessary to use detergents of various types for enzyme extraction. A few years ago, we naively (and this quality has some merits as well as demerits) began to isolate the enzymes in which we were interested (the RNA-instructed DNA polymerase, RIDP). We had to learn that detergents are necessary. We also learned that when the detergents were eliminated, the enzyme itself seemed to be eliminated, or at least the activity of the enzyme was eliminated. This gave rise to the idea that perhaps the activity of the enzyme was dependent upon the presence of detergent molecules, *i. e.*, the lipid component in some way was changing the conformation of the enzyme and inducing its activity, or at least raising it. Therefore, the residual enzyme activities which are observed when synthetic detergents are *not* used for extraction are simply due to the natural phospholipid, which was released when the solution was sonicated.

We found that when we added small amounts of certain types of non-ionic detergents it was possible to recover the enzyme activity. This constitutes a new development. No one really believed that the intrinsic activity of the enzyme was dependent upon its association with a detergent molecule. Previously it has been assumed that the detergent molecules are solubilizing entities to dissolve the enzyme out of the lipid membrane. The detergent does, in fact, take the enzyme out of the lipid membrane, but large amounts of the detergent are not needed to make the enzyme active.

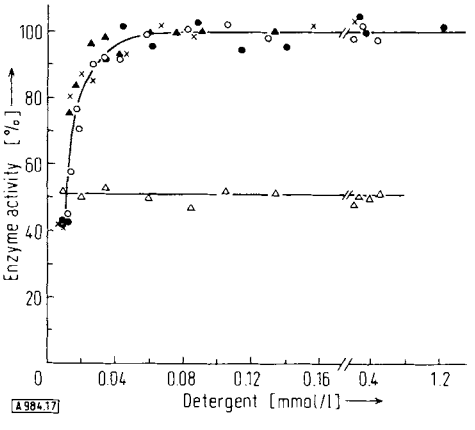

Fig. 17. Activation of RNA-instructed DNA polymerase by detergent. 100% = maximum activity.

The activation of the RNA-instructed DNA-polymerase by detergents is shown in Figure 17. RIDP is the enzyme which copies RNA into DNA, which is popularly known as "reverse transcriptase activity". Research on this enzyme resulted in one of the major breakthroughs of the last two or three years in this field, particularly in connection with tumor viruses. The activity of the enzyme is increased by addition of suitable amounts of various types of non-ionic detergents[21, 22]. On a molecular basis, this is a positive molecular interaction. Observation of interaction happened to be made during the development of techniques for the study of enzymes. Not uncommon to this type of work, this turned out to be the central problem.

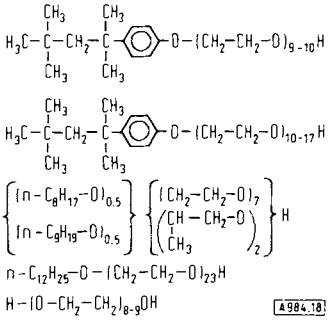

Fig. 18. Structure of detergents used in RNA-instructed DNA polymerase activation. From top to bottom: Triton X-100, Triton X-1017, Triton DN 65, Brij 35, polyethylene glycol-400.

We were actually studying the inhibition of the RIDP enzyme activity by certain drugs with a view toward the possible use of such drugs to inhibit the transformation of normal cells into cancer cells by the viruses which carry this enzyme. The RIDP enzyme copies the virus-RNA in DNA which is then inserted into the DNA of the cell, thus making a transformed cell. The rationale was to find a drug which would inhibit the RIDP enzyme and thus block the transformation into cancer cells. This meant that we had to study inhibition of the enzyme activity under various conditions. It also gave rise to our studies on the effect of detergents on enzyme activity. We found that we had some excellent enzyme inhibitors in the drug itself. Rifampicin and its derivatives are lipophilic substances. Here, it turns out that if there is too much

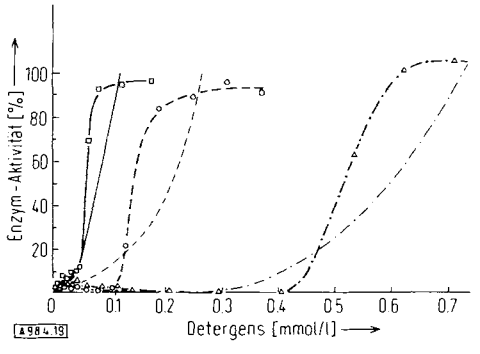

Fig. 19. Suppression of drug effect on RNA-instructed DNA polymerase by detergents (□, ○, △) (see text).

detergent the drug is ineffective in its inhibition of RIDP enzyme activity.

The structure of the non-ionic detergents which were used in this study is shown in Figure 18. Some of the detergents (the Tritons) are aromatic and others are not. This fact is important. The effect of three different detergents on the ability of a certain drug, which has a hydrophobic tail and a hydrophilic end, to inhibit the enzyme is shown in Figure 19. An attempt was made to plot the critical micelle concentration for each of the detergents. The ability to deter the drug from inhibiting the enzyme is dependent upon micelle formation[22]. We interpret this finding as follows: if there is too much detergent present there is micelle formation; the micelles dissolve the drug, and thus remove it from the hydrophobic portion of the enzyme. The drug no longer can act on the enzyme, so the enzyme returns to its full activity.

Figure 20 shows two magnifications of a tissue culture which has been transformed into malignancy. As soon as the cells have been transformed into malignancy they overgrow each other, and they make little "piles" called foci. We have found that by suitable adjustment of the drug concentration it is possible to prevent the virus from transforming cells as determined by this focus formation inhibition[23]. We have even gone a stage further and been able to show that the formation

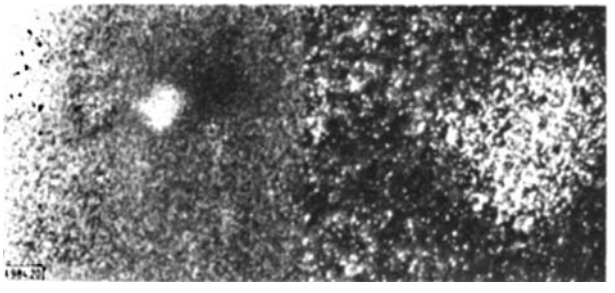

Fig. 20. MSV focus formation on Balb/3T3 cells (dark field illumination).

of tumors in whole animals can be prevented[24]. Again, this required a suitable combination of detergent and drug to prevent the detergent from spoiling the activity of the drug.

I hope that some of the things described above will give the reader some concept of the kind of a china shop one can get into, if one has the will to do it. I have tried to give those of you who are not in the biochemistry-molecular biology business some idea of the way in which a polymer chemist could influence the development of our fundamental concepts of the nature of life, its origin, and the application of our knowledge to the problems of the day.

The work described in this paper, which will also be published in the "International Journal of Polymeric Materials", was sponsored by the U.S. Atomic Energy Commission and by the Elsa U. Pardee Foundation for Cancer Research.

cis-trans-Isomerism of Thyrotropin Releasing Hormone (TRH) in Aqueous Solution[**]

By *Wolfgang Voelter, Oskar Oster*, and *Karl Zech*[*]

A prerequisite for explaining the mode of action of peptide hormones is an accurate knowledge of their structure. Since nuclear magnetic resonance measurements can yield a wealth of information about the structure of dissolved peptide molecules we have investigated synthetic[1] TRH by pulse Fourier transform ^{13}C-NMR spectroscopy[2][***].

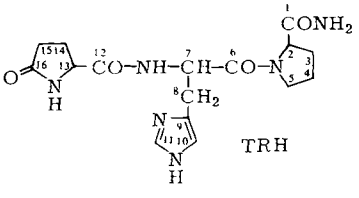

Figure 1 shows the broad-band proton decoupled spectrum of TRH. Almost all the signals can be assigned by comparison with the spectra of simple amino acids, TRH derivatives, and derivatives of TRH components obtained as intermediates in the synthesis of the hormone. An additional aid for assignment of the signals is provided by the proton off-resonance spectrum[1].

Remarkably, as can be seen in Figure 1, the intense signals of the C-atoms 3, 4, 5, and 6 are each accompanied within a distance of 1—2 ppm by a further signal (3', 4', 5', and 6', resp.) whose intensity is only 10—20% of the remaining signals.

To explain this phenomenon we have synthesized the proline derivatives and proline-containing dipeptides and recorded their ^{13}C-NMR spectra.

[***] All the compounds investigated have rotations, melting points, and analytical data as given in the literature; for the preparation of the substances cf. Refs. [1, 5]. The PFT ^{13}C-NMR spectra were recorded on a Bruker HFX-90 multinuclear NMR spectrometer (22.628 MHz for ^{2}H; pulse width 4—5 μs; pulse interval 0.41 s).

The carbon atoms of the proline ring of Boc-Pro-NH_2 give rise to two signals (Fig. 2). The spectrum can be interpreted only in terms of the presence of a *cis-trans* isomeric pair. ^{13}C-NMR spectroscopy thus proves to be an excellent tool for the detection of *cis*- and *trans*-isomers of proline compounds; previously, these were mainly differentiated by proton resonance spectroscopy[3].

Although the intensities of PFT ^{13}C-NMR resonances are not suitable for quantitative determinations they can provide a rough estimation of the equilibria of chemically similar carbon atoms. Thus, a comparison of the intensities of the ^{13}C-NMR signals of proline carbon atoms would indicate that 20—30% of the *cis* and 80—70% of the *trans* isomers of Boc-Pro-NH_2 are present in equilibrium in aqueous solution at room temperature.

The assignment of signals to the *cis* or *trans* isomers by ^{13}C-NMR spectroscopy is also possible in the case of Boc-Gly-Pro. ^{1}H-NMR investigations[3] have already shown that solutions of this compound contain up to 70—80% of the *trans* isomer. The more intense resonances of the proline carbon atoms in the PFT ^{13}C-NMR spectrum of Boc-Gly-Pro can therefore be assigned to the *trans* isomer.

Furthermore, the positions of the proline carbon-atom signals in the spectrum of glycylproline are characteristic for the *cis* isomers of prolines.

On the basis of these findings the resonances of the C^{α}, C^{β}, C^{γ}, and C^{δ} atoms of the proline rings of the compounds listed in Figure 2 can be accurately assigned to the *cis* or *trans* isomers.

Figure 2 shows, moreover, that Boc-Ala-Pro must be present almost exclusively as the *trans* isomer in aqueous solution. From the intensities of the acetylproline resonances it follows that an approximately 1:1 *cis-trans* isomeric equilibrium is set up in aqueous solutions of this compound at room temperature.

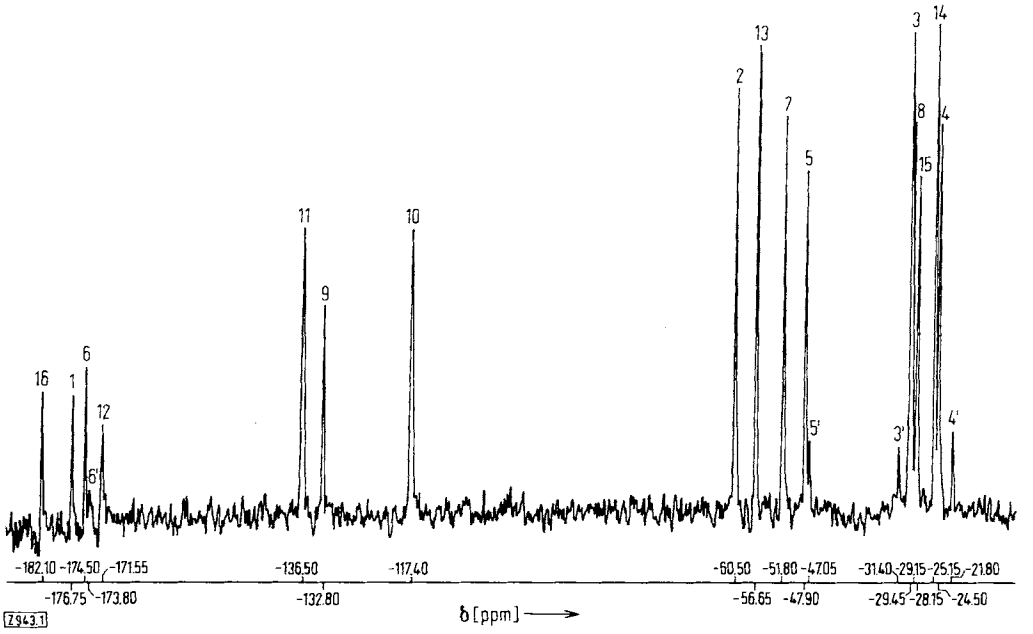

Fig. 1. Pulse Fourier transform (PFT) ^{13}C-NMR spectrum (broad-band proton decoupled, referred to TMS = 0) of TRH, 200 mg in 1.5 ml D_2O, accumulation of 16384 pulse interferograms. 3',4',5',6' see text.

These findings lead to the conclusion that aqueous solutions of TRH contain 10—20% of the *cis* isomer and 90—80% of the *trans* isomer.

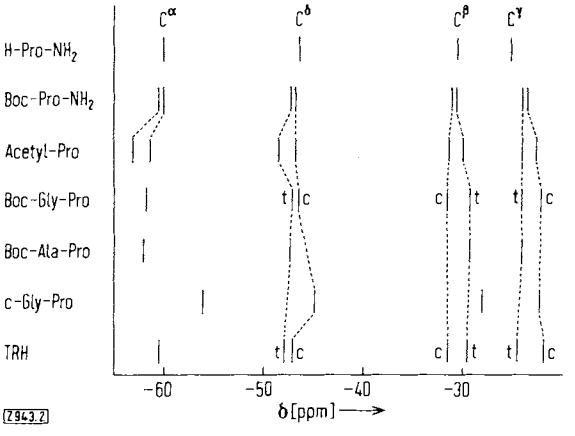

Fig. 2. ^{13}C-NMR line spectra of substituted prolines (referred to TMS = 0). All the values, except those for c-Gly-Pro (DMSO), were determined in water. t = trans, c = cis.

A ^{1}H-NMR investigation of TRH has recently been published[4]. *Cis-trans* isomerism could not be detected, even with a 250-MHz spectrometer.

Stable 1,1-Diiodo- and 1-Chloro-1-iodocyclopropanes

By *Rolf Mathias* and *Peter Weyerstahl*[*]

1,1-Diiodocyclopropanes have long been considered as unstable and nonisolable[1]; only their reduction *in situ* to iodocyclopropanes has so far been described[2]. We have now been able to prepare and unequivocally characterize the diiodocyclopropanes *(1)* (Table 1); they were prepared from the corresponding olefins and iodoform by a modified Makosza reaction[3] using CH_2Cl_2 as solvent[4]. Remarkably, the aromatically substituted representatives *(1d)—(1f)* are very much more stable and are formed in higher yields than the aliphatic compounds *(1a)—(1c)*. This could be due to the possibility of electron delocalization in *(1d)—(1f)*. *(1g)* is an exception; however, it should be remembered that *trans*-stilbene reacts only very poorly with dihalocarbenes.

The same reaction with chlorodiiodomethane[5] instead of iodoform affords the even more stable 1-chloro-1-iodocyclopropanes *(2)* in good yields.

(1), X = I; *(2)*, X = Cl

Experimental:

A 50% aqueous solution of sodium hydroxide (50 ml) is added dropwise to a vigorously stirred mixture of haloform (0.1 mol), olefin (0.3 mol), triethylbenzylammonium chloride (TEBA) (0.5 g), and CH_2Cl_2 (100 ml). The final mixture is heated at 50 °C for 3 h and then acidified with dilute sulfuric acid under ice-cooling. The aqueous phase is separated off, extracted with CH_2Cl_2, and the combined organic phases are dried over $MgSO_4$. The dry organic phase is transferred to a refrigerator, and, after removal of solvent, the residue is worked-up as indicated in Table 1.

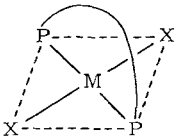
Square Planar Transition Metal Complexes with a Bidentate Ligand Spanning *trans*-Positions[***]



By *N. J. DeStefano, D. K. Johnson*, and *L. M. Venanzi*[*]

Although there are a very large number of square planar complexes containing bidentate ligands[1], there appears to be only one well-established example of a compound in which the organic ligand spans *trans*-positions, *i.e.* $[NiBr_2\{(C_6H_{11})_2P(CH_2)_5P(C_6H_{11})_2\}]$[2].

In the course of a study of square planar complexes, we have prepared[3] the bidentate ligand 2,11-bis(diphenylphosphinomethyl)benzo[*c*]phenanthrene *(1)*. Molecular models indicate that this ligand should promote the formation of square planar complexes in which the two phosphorus atoms span *trans*-positions.

(1)

(2)

(2) = *trans*-$[MX_2(1)]$: M = Ni; X = Cl, Br, I, NCS
M = Pd; X = Cl, Br, I
M = Pt; X = Cl, I

The reaction of a suitable substrate, *e.g.* NiX_2, $[PdX_2(PhCN)_2]$, $Na_2[MX_4]$, *etc.*, with ligand *(1)* gives complexes of type *(2)*, *trans*-$[MX_2(1)]$.

Department of Chemistry
University of Delaware, Newark, Del. 19711 (USA)
[**] Present address: Laboratorium für Anorganische Chemie, Eidgenössische Technische Hochschule, CH-8006 Zürich, Universitätsstrasse 6 (Switzerland)

[***] First presented at the 163rd ACS National Meeting, Boston, Mass., April 10—14, 1972. We thank the National Science Foundation for the support of this work, Matthey-Bishop, Inc., for a loan of platinum metal salts, Dr. *R. M. Lane* for carrying out some preliminary experiments, and Dr. *P. S. Pregosin* for much valuable assistance with the NMR measurements.

Satisfactory analytical data were obtained for all the above compounds. These are monomeric and non-electrolytes in dichloromethane solution. The *trans*-configuration of the phosphorus atoms in complexes *(2)* is established by their NMR spectra:

(i) The ^{31}P-NMR spectrum of $[PtCl_2(1)]$ shows a value of $^1J_{(^{195}Pt-^{31}P}$ of 2579 Hz (as compared with values of 3731 and 2584 Hz for *cis*- and *trans*-$[PtCl_2(Ph_2PCH_2Ph)_2]$[4], respectively, in agreement with previously published data for complexes of this type[5].

(ii) The ^{1}H-NMR spectra of all the complexes of type *(2)* examined to date appear in the form of 1:2:1-triplets and it has been shown[5] that such multiplets are indicative of *trans*-configuration[6].

As complexes $[NiX_2(Ph_2PCH_2Ph)_2]$ (X = Br or I) give mixtures of tetrahedral and square planar species[7] and complexes $[NiX_2(Ph_2P(CH_2)_5PPh_2)]$ (X = Br or I) have tetrahedral structure[8], the fact that ligand *(1)* forms only square planar complexes with nickel(II) provides confirmation for the hypothesis, based on studies of molecular models, that this ligand does indeed promote the formation of square planar species.

It is interesting to note that, while the ligand $(C_6H_{11})_2P(CH_2)_5P(C_6H_{11})_2$ reacts readily with cobalt(II) halides to give tetrahedral complexes of the type $[CoX_2L]$[2], compound *(1)* does not appear to react with cobalt(II) salts. This is not unexpected as molecular models show that there would be severe overlap of the terminal benzene rings if ligand *(1)* were to form tetrahedral complexes. This ligand, however, does react with substrates containing Co^I, Rh^I, Ir^I or Ag^I and the products obtained are under investigation.

[6] This criterion has been criticized on the grounds that $^2J_{P\text{-}P}$ in some *cis*-complexes is sufficiently large to give rise to triplets [*J. G. Verkade*, Coord. Chem. Rev. *9*, 1 (1972) and references therein]. However, as the methylenic protons in the square planar complexes *trans*-$[MX_2(Ph_2PCH_2Ph)_2]$ give rise to triplet patterns while those of the *cis*-isomers give the expected doublets, it is felt that the above geometrical assignments are correct.

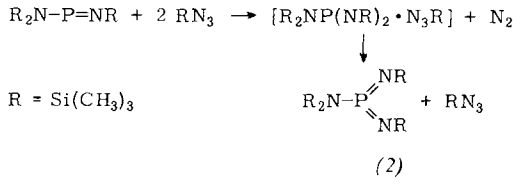
A Phosphorus(v) Derivative Having Coordination Number 3: Bis(trimethylsilyl)aminobis(trimethylsilylimino)phosphorane[**]

By *Edgar Niecke* and *Wilhelm Flick*[*]



The question of the existence of phosphorus(v) stabilized by p_π-p_π bonding (see *(1a, b)*) has been under study for some time. Thus the intermediacy of such species has been postulated in oxidative phosphorylation, oxidation of perfluoroacylphosphanes, and the hydrolysis of *N*-monoalkylphosphoramidates, organomono- and diphosphates[1], and invoked in enzymatic and nonenzymatic transphosphorylations[2] without any such compound actually having been isolated to date[3].

(1a) *(1b)*

Since the synthesis of the first phosphabenzenes[4] established the existence of phosphorus(III) compounds having coordination number 2, it was to be expected that, given suitable substituents, the oxidized form with P^V and coordination number 3 should be stable and detectable by spectroscopy.

Starting from the synthesis of phosphazene from phosphanes and azides, we treated bis(trimethylsilyl)aminotrimethylsilyliminophosphane[5] with trimethylsilyl azide[6]. The reaction proceeds with liberation of N_2 at room temperature, giving initially a phosphorane-silyl azide adduct[7] which decomposes above 100 °C to form the diiminophosphorane *(2)*.

(2)

Bis(trimethylsilyl)aminobis(trimethylsilylimino)phosphorane *(2)* is an extremely hygroscopic crystalline solid which can be distilled without decomposition in a vacuum: m. p. 36 °C, b. p. 95 °C/0.1 torr. Its composition and monomeric structure were established by elemental analysis, cryoscopic molecular-weight determination, and mass, NMR (^{1}H, ^{29}Si, ^{31}P), and IR spectra.

Apart from the molecular ion [*m/e* (rel. int.)] 365 (9%), the mass spectrum contains the following characteristic fragments of higher mass numbers: $M-CH_3$ 350 (100%); $M-2CH_3$ 335 (3%); $M-Si(CH_3)_3$ 292 (3%); $M-NSi(CH_3)_3$ 278 (2%); $M-Si(CH_3)_3$, CH_3 277 (3%).

In the ^{1}H-NMR spectrum (50% solution in C_6H_{12}; TMS internal) two silyl proton signals of equal intensity appear at room temperature, that at higher field belonging to the silylimino groups. This signal shows the expected doublet structure at high resolution[8]. A reversible exchange leading to equilibrium between silylamino and silylimino protons[9] at 90—95 °C could be detected by high-temperature measurements. Silylimino H: $\delta = -0.11$ ppm (d), $^4J_{HP} = 0.65$ Hz; silylamino H: $\delta = -0.32$ ppm; $\Delta G_c^{\neq} = 19.0$—19.3 kcal/mol (neat sample; 60 MHz).

The ^{29}Si-NMR spectrum (70% solution in TMS[10]) indicates two differently bonded silicon atoms in agreement with the proton spectrum. As expected the amount of ^{29}Si—^{31}P interaction is greater for the silylimino groups observed at higher field. Silylimino Si: $\delta = 8.0$ ppm, $^2J_{SiH} = 6.8$, $^2J_{SiP} = 16.7$ Hz; silylamino Si: $\delta = -9.4$ ppm, $^2J_{SiH} = 6.7$, $^2J_{SiP} = 1.2$ Hz.

In the ^{31}P-NMR spectrum (70% solution in C_6H_{12}; H_3PO_4 external) the unusual electronic situation of the phosphorus in *(2)* is reflected in a downfield signal shift compared to iminophosphoranes of coordination number 4[11]: $\delta = -55.0$ ppm.

IR spectrum (range 1500—600 cm^{-1}, tentative assignment): ≈ 1435 sh, ≈ 1415 sh, 1390 m all $\delta_{as}CH_3$; 1332 s, br $\nu_{as}P{=}N$;

[*] Dr. E. Niecke and Dipl.-Chem. W. Flick
Anorganisch-chemisches Institut der Universität
34 Göttingen, Hospitalstrasse 8—9 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

≈1275 sh, 1248 vs both $\delta_s CH_3$; 1018 m $\nu_s P{=}N$; 945 s, br $\nu_{as}NSi_2$; 9.15 νPN; ≈865 sh, 838 vs, ≈830 sh all $\rho_{as}CH_3$; 772 m, 756 m both $\rho_s CH_3$; 685 m, ≈675 sh, 639 m, 610 m-w all νSiC. Comparison of $\nu_{as,s}(P{=}N)$ with the value for a "pure" P=N stretching vibration of 1210—1220 cm^{-1}[12] suggests that contributions from the polar resonance structure

$$[(CH_3)_3Si]_2N-\overset{\oplus}{P}[=\overset{\ominus}{N}Si(CH_3)_3]_2$$

must also be taken into consideration in descriptions of the bonding in *(2)*[13].

The chemistry of the phosphorane *(2)* is largely determined by the considerable electrophilic character of the phosphorus. Thus, *e.g.*, alcohols undergo ready addition to form the corresponding monophosphazenes *(3)*.

$$(2) + HOR \longrightarrow R_2N-\underset{\displaystyle HNSiR_3}{\overset{\displaystyle OR}{P}}=NSiR_3$$

R = CH_3 *(3)*

(3): yield 70%. IR: ν(P=N) = 1335; ν(PO—R) = 1182; ν(P—OR), ν_{as}(PNSi) = 1092, 1062 cm^{-1}. ^{31}P-NMR: δ = −1.8 ppm, $^3J_{HP}$ = 11.8 Hz.

Experimental:

$(CH_3)_3SiN_3$ (15 g, 0.13 mol) is added dropwise with stirring to $[(CH_3)_3Si]_2NPNSi(CH_3)_3$ (14 g, 0.05 mol) at 40 °C in a 100 ml two-neck flask fitted with a dropping funnel and a reflux condenser; the reaction mixture evolves N_2 and warms up to about 50 °C. After evolution of gas has ceased, stirring is continued for 2 to 3 h and unreacted silyl azide then drawn off. The solid residue is fractionated by molecular distillation at 100—120 °C, the phosphorane distilling over at 95 °C/0.1 torr. Renewed distillation affords 12 g (65%) of pure product.

X-Ray Structure Analysis of the Triple-Decker Sandwich Complex Tris(η-cyclopentadienyl)dinickel Tetrafluoroborate

By *Erich Dubler, Marcus Textor, Hans-Rudolf Oswald*, and *Albrecht Salzer*[*]

We have performed an X-ray structure analysis on the complex $[Ni_2(C_5H_5)_3]BF_4$ recently synthesized by *Werner* and *Salzer*[1, 2] in order to confirm the "triple-decker sandwich" structure proposed on the basis of chemical properties and NMR spectra.

The single crystals prepared from a solution in propionic anhydride are orthorhombic: space group $P2_12_12_1$; $a = 17.019(2)$, $b = 11.454(2)$, $c = 8.074(1)$ Å; $d_{exp} = 1.66$, $d_{calc} = 1.69\ g\,cm^{-3}$; $Z = 4$. A total of 1216 independent reflections (180 not observed, $I \leqslant 3\ \sigma_I$; $2\theta \leqslant 45°$; $\theta/2\theta$ scan) were recorded on a Picker FACS 1 diffractometer with $Mo_{K\alpha}$ radiation.

The positions of the Ni atoms could be determined from Patterson syntheses. A series of consecutive least-squares refinements and difference Fourier syntheses revealed the positions of the C, B, and F atoms. It became apparent that assumption of fixed geometry of the rings, particularly with regard to twisting in the plane of the ring, led to an incomplete description of the positions of the C atoms in the three crystallographically distinct cyclopentadienyl ligands ("cp rings").

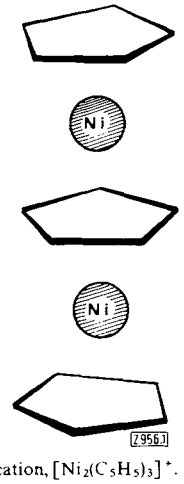

Fig. 1. Structure of the tris(η-cyclopentadienyl)dinickel cation, $[Ni_2(C_5H_5)_3]^+$.

This is probably due less to true thermal vibrations than to characteristic disorder phenomena in the crystals. Refinement converged to a value of $R = 6.3\%$.

The structure of the complex cation $[Ni_2(cp)_3]^+$, as shown in Figure 1, agrees essentially with the proposed triple-decker sandwich structure[1]. Neglecting the observed disorder with regard to twisting in the ring plane, the cp ring atoms are depicted in an idealized manner (most probable positions from difference Fourier syntheses).

The average distances between the Ni atoms and the C atoms of the two terminal cp rings are 2.09 and 2.08 Å, whereas

[*] Prof. Dr. H. R. Oswald, Dr. E. Dubler, Dr. M. Textor, and A. Salzer
Anorganisch-chemisches Institut der Universität
CH-8001 Zürich, Rämistrasse 76 (Switzerland)

values of 2.13 and 2.16 Å were found for the average Ni—C distances to the bridging cp ring; the distances from the Ni atoms to the centers of the rings are found to be: outer cp rings 1.745 and 1.711 Å, inner cp ring 1.771 and 1.805 Å.

The findings that the metal —C distances to the two terminal cp rings are shorter than to the bridging cp ring accords well with the picture obtained from the substitution reactions of the $[Ni_2(cp)_3]^+$ ion with Lewis bases[3].

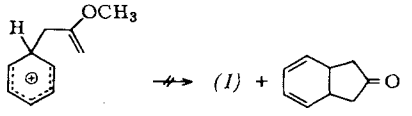
Simple Synthesis of Bicyclo[3.2.2]nona-6,8-dien-3-ones from Arenes[**]



By *H. M. R. Hoffmann* and *A. E. Hill*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 60th birthday

We have found a simple one-stage transformation of benzene into bicyclo[3.2.2]nona-6,8-dien-3-one *(1)*, which uses the silver salt promoted reaction with 2-methoxyallyl bromide[1] and proceeds at room temperature. After work-up with dilute acid one isolates 1-phenyl-2-propanone and *(1)*, m.p. 56 °C, IR (CCl_4) 1698 cm^{-1}, NMR (CCl_4)[2]: $\delta = 6.2$—6.4 (m, $4H^a$), 3.1—3.4 (br m, $2H^b$), 2.35 ppm (d, $4H^c$, $J \approx 4$ Hz)[3].

(1) *(2)* *(3)*

(4) *(5)*

The analogous reaction with *p*-xylene afforded *p*-xylylacetone (0.54 g, 10%) and the 6,8-dimethyl derivative *(2)* (0.19 g, 3.5%)[4], IR (CCl_4): 1695 cm^{-1}, NMR (CCl_4): $\delta = 5.7$—6.0 (complex d, $2H^a$), 2.7—3.0 (br m, $2H^b$), 2.28, 2.32 ($4H^c$), 1.80 (d, $6H^d$, $J = 1.4$ Hz)[3]. As a minor bicyclic isomer [*(2)* : *(3)* = 3.5 : 1] the symmetric 1,5-dimethyl derivative *(3)* was isolated. NMR (CCl_4): $\delta = 5.92$ (s, $4H^a$), 1.32 (s, $6H^b$), 2.20 (s, $4H^c$)[3]. Toluene reacted in similar fashion.

Since dihydroindanones as, *e.g.*, *(5)* in the case of benzene, are not formed under our conditions, we suggest that the bicyclics described arise in a concerted cycloaddition rather than stepwise *via* the conventional cyclohexadienyl cation *(4)*, the exclusive formation of which might have been expected in the reaction of benzene with a carbenium ion or electrophile[5].

[**] We thank the Science Research Council for selective support in the field of organometallic chemistry.

Interestingly, bicyclo[3.2.2]nona-6,8-dien-3-ones are sensitive to acid, which is liberated throughout the silver trifluoroacetate induced reaction. In neat deuteriotrifluoroacetic acid the parent bicyclic *(1)* was cleanly transformed into phenylacetone after 3 h at room temperature. While this cleavage will lower the yields, it is clear that a range of new and interesting bicyclics has now become readily accessible.

Bicyclo[3.2.2]nona-6,8-dien-3-one (1)

Benzene (40 ml) and 2-methoxyallyl bromide[6] (5 g, 33 mmol) are diluted with isopentane (100 ml) and mixed with Na_2CO_3 (2 g). The resulting suspension is stirred with a vibromixer (100 cps), while a mixture of silver trifluoroacetate (10 g, 46 mmol) and Na_2CO_3 (4 g) is added in small portions at room temperature over a period of 9 h. The reaction mixture is stirred for a further 16 h in the dark and then worked up by careful addition of nitric acid (10%, 100 ml), evaporation of the bulk of isopentane, and extraction of the resulting suspension with $CHCl_3$ (3×100 ml). The combined organic layer is washed with water, dried, and the solvent removed. A yellow oil is obtained; preparative glc (carbowax 20M, 206 °C) affords 1-phenyl-2-propanone (0.89 g, 20%) as a colorless oil and bicyclo[3.2.2]-nona-6,8-dien-3-one *(1)* (0.27 g, 6%; work-up by fractional distillation gave a yield of 11%).

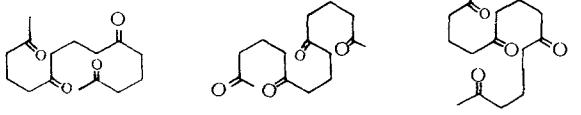
Synthesis of 2,6,10,14-Pentadecanetetrone, a δ-Tetraketone ("Harries' Tetraketone")

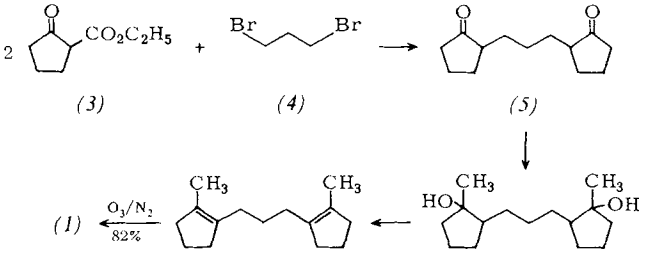
By *Burchard Franck, Volker Scharf*, and *Marieluise Schrameyer*[*]

After hydrolysis of 1706 g of the ozonide of a caoutchouc sample previously subjected to partial isomerization by addition of HCl and subsequent dehydrohalogenation, *Harries*[1] succeeded, in 1914, in isolating a 0.05% yield of a tetraketone $C_{15}H_{24}O_4$ (m. p. 123 °C) which he suspected to have the structure *(1)*[2]. This "Harries' tetraketone", although of unproven structure, permitted the dramatic disproof of the cyclic formula of caoutchouc *(2)* in favor of a higher molecular formula[1]. Moreover, if the compound really is the 2,6,10,14-pentadecanetetrone *(1)*, it represents the highest known member in the series of poly-δ-carbonyl compounds whose importance as synthetic and biosynthetic precursors[3–6] arises from their ability to undergo diverse intramolecular condensations. We have now been able to prepare the highly reactive δ-tetraketone *(1)*, to establish its identity with Harries' tetraketone, and to convert it into condensation products.



[*] Prof. Dr. B. Franck, Dr. V. Scharf, and Dipl.-Chem. M. Schrameyer
Organisch-Chemisches Institut der Universität
44 Münster, Orléans-Ring 23 (Germany)

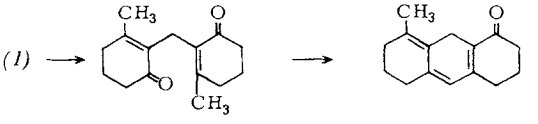
Some of the possible ring closure reactions of the tetraketone *(1)* are suggested by the conformations *(1a)*—*(1c)*. Owing to the reactivity of *(1)* the synthetic pathway chosen involved



(1)

(2)

(1a) *(1b)* *(1c)*



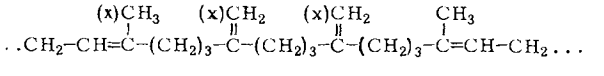
introduction of the four keto groups in the last step by ozonolysis of a diolefin *(6)*. Thus attention was focused on the hitherto unreported compound 1,3-bis-(2-methyl-1-cyclopentenyl)propane *(6)* as key intermediate[7]. Condensation of the potassium salt of ethyl 2-oxocyclopentanecarboxylate *(3)* with 1,3-dibromopropane *(4)* in boiling toluene and subsequent hydrolysis and decarboxylation of the product (2% HI, 100 °C, 120 h)[8] yielded 2,2'-trimethylenedicyclopentanone *(5)* in 34% yield based on *(3)*. Compound *(5)* was converted into the diol *(7)* (89%) which yielded a dominant proportion of the desired compound *(6)*, alongside the five other possible isomers, on dehydration (boiling with benzene/*p*-toluenesulfonic acid).

(3) *(4)* *(5)* *(1)* *(6)* *(7)*

Compound *(6)* was obtained as the analytically pure isomer (GC, NMR) by microdistillation over a spinning band column (Normag 8101): b.p. 78 °C/0.01 torr; yield 60% based on diol. Its ^{1}H-NMR spectrum contains a singlet at $\tau = 8.40$ ($2CH_3$) but no signal due to an olefinic proton. In the mass spectrum the molecular ion (54%) is accompanied by the fragments C_8H_{12} (100%), C_7H_9 (72%), and C_6H_7 (39%) formed by allylic cleavage and loss of methyl as the most intense peaks. Ozonolysis of the diene *(6)* with O_2-free ozone (ozone desorbed from a silica gel cold trap at −80 °C with N_2[10]) in methanol/methylene chloride at −20 °C and subsequent catalytic hydrogenolysis afforded an 82% yield of 2,6,10,14-pentadecanetetrone *(1)* which crystallized as colorless platelets of m.p. 123 °C, as reported by *Harries*[1]; IR (KBr): 1715 cm^{-1} (C=O). The ^{1}H-NMR spectrum ($CDCl_3$) shows three resonances at $\tau = 7.67$ (12H), 7.98 (6H), and 8.24 (6H) for CH_2—CO, CH_3—CO, and central CH_2 between two CO groups respectively. The mass spectrum is characterized by a very small $M^{\oplus}$ peak (*m/e* 268) and numerous other fragments, some of which are formed by McLafferty rearrangement.

Having established the structure *(1)* for Harries' tetraketone, we proceeded to investigate its acid- and base-catalyzed condensation and found the linear annelating conformation *(1a)* to be product-determining. Thus the action of concentrated sulfuric acid (20 °C, 2 h) or BF_3-ether/methylene chloride (40 °C, 40 h) gave 3,3'-dimethyl-2,2'-methylenedicyclohexenone *(8)* in 25 and 12% yield respectively; m.p. 25—27 °C (colorless needles); ^{1}H-NMR ($CDCl_3$): $\tau = 8.04$ (s, $2CH_3$); 6.66 (s, bridging CH_2); MS: *m/e* 232 ($M^{\oplus}$, 100%); 217 ($M^{\oplus} - CH_3$, 45%); 189 ($M^{\oplus} - C_3H_7$; 31%); 176 ($M^{\oplus} - CH_2CH_2CO$, 60%); IR (KBr): 1670 cm^{-1} (C=O). Heating in 2.5 N NaOH (95 °C, 45 min) converts *(1)* in 37% yield, and likewise *(8)*, into a deep yellow product whose mode of formation and spectroscopic data show it to be 8-methyl-1,2,3,4,5,6,7,9-octahydro-1-anthracenone *(9)*; UV ($CHCl_3$): $\lambda_{max} = 355$ nm; ^{1}H-NMR

(1) *(8)* *(9)*



($CDCl_3$): $\tau = 8.21$ (s, CH_3); 4.21 (s, =CH—); IR (KBr): 1660 cm^{-1} (C=O); semicarbazone: m.p. 180 °C (pale yellow needles); MS: *m/e* 271 ($M^{\oplus}$, 71%); 254 ($M^{\oplus} - CH_3$, 79%); 228 ($M^{\oplus}$ − HNCO, 76%).

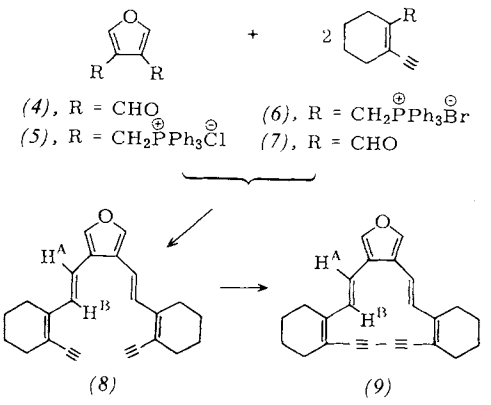
The Synthesis of Tetradehydrocyclotetradeca[*c*]furans ("Didehydro[14]annuleno[*c*]furans"), 18 π-Electron Analogs of Isobenzofuran[1][****]

By *Philip J. Beeby*, *Rex T. Weavers*, and *Franz Sondheimer*[*]



An interesting group of compounds results from the fusion of furan at the 3,4-position to fully unsaturated carbocycles. Examples are the $4n$ π-electron systems cyclobuta[*c*]furan *(1)*[2] and cycloocta[*c*]furan *(3)*[3], and the $(4n+2)$ π-electron system isobenzofuran *(2)*[4]. We now report the synthesis

(1) *(2)* *(3)*

of the two first macrocyclic examples of this series, the $(4n+2)$ π-electron systems 10,11,12,13-tetradehydro-6,7,8,9,14,15,16,17-octahydrodibenzo[6,7:12,13]cyclotetradeca[*c*]furan *(9)* and 7,12-dimethyl-8,9,10,11-tetradehydrocyclotetradeca[*c*]furan *(12)*.

Wittig reaction of 3,4-furandicarboxaldehyde *(4)*[5,6] and two molar equivalents of the phosphonium salt *(6)*[7] in dimethylformamide with ethanolic lithium ethoxide at 80 °C led to *ca.* 30% of the unstable liquid di-*trans* compound *(8)*. This substance could also be obtained, though only in *ca.* 10% yield, by the Wittig reaction of the bis(phosphonium) salt *(5)*[6] and the aldehyde *(7)*[8] at 95 °C. Oxidative coupling of *(8)* with cupric acetate in pyridine at 70 °C under relatively dilute conditions, rigorously excluding oxygen, then yielded 50% of the tetradehydrocyclotetradeca[*c*]furan ("didehydro-[14]annuleno[*c*]furan"[*****]) *(9)* as yellow needles, which decomposed on attempted melting point determination [*m/e* 326.166 (calcd. 326.167); λ_{max} (ether) *ca.* 265 sh (ε 13200), *ca.* 280 sh (21000), 300 (39900), and 382 nm (3500)[9]].

Substances related to *(9)* have been shown to exhibit conformational mobility[10] and the position of the olefinic protons H^A and H^B (external or internal) was unknown. It was therefore decided to prepare the corresponding dimethyl compound *(12)*, in which the olefinic protons H^C must be external. The dimethyl series is also preferable since the methyl ^{1}H-NMR resonances are sharp singlets (see Ref. [1]), whereas the allylic proton resonances in the cyclohexene series [*e.g.*, in *(8)* and *(9)*] are rather broad multiplets.

Reaction of the bis(phosphonium) salt *(5)* with two molar equivalents of *n*-butyllithium in tetrahydrofuran at −70 °C gave the corresponding bis(ylide), which was then treated with two molar equivalents of *cis*-3-methyl-2-penten-4-ynal *(10)*[11] (−15 to 20 °C)[12]. This reaction resulted in *ca.* 15% of the di-*trans* compound *(11)* as plates, m.p. 75—78 °C (decomp.) [*m/e* 248.119 (calcd. 248.120); λ_{max} (ether), 285 (ε 24600) and 310 nm (25800)]. Coupling of *(11)* with cupric acetate in pyridine, as before, then gave the tetradehydrocyclotetradeca[*c*]furan ("didehydro[14]annuleno[*c*]furan") *(12)* in 25—30% yield as yellow needles, which decomposed on attempted melting point determination [*m/e* 246.101 (calcd. 246.105); λ_{max} (ether) *ca.* 265 sh (ε 7200), *ca.* 275 sh (10700), 301 (17500), and 395 nm (1900)[9]].

Table 1. ^{1}H-NMR parameters of *(8)* and *(9)* (at 60 MHz) and *(11)* and *(12)* (at 100 MHz) in $CDCl_3$ (τ-values, internal standard TMS, *J* in Hz).

[***] Present address: Chemistry Department, University of Otago, Dunedin (New Zealand)

[****] We thank the Science Research Council for financial support.

[*****] *Editorial note:* According to IUPAC Rule C-41.2, "dehydro" only denotes the loss of *two* hydrogen atoms when used on its own with a trivial name. If more than two hydrogen atoms are missing, then their exact number should be indicated by the appropriate multiplying prefix in front of "dehydro". The correct name would thus read "tetradehydro ...".

The ^{1}H-NMR parameters of compounds *(8)*, *(9)*, *(11)*, and *(12)* are given in Table 1. The assignments of the H^A and H^B protons in *(8)* and *(9)* follow from the NMR spectra of the corresponding dideuterio derivatives (D instead of H^A), prepared from D_2-3,4-furandicarboxaldehyde [*(4)*, R = CDO instead of CHO][13] and *(6)*. The chemical shift differences for each resonance on passing from the precursors *(8)* and *(11)* to the corresponding macrocycles *(9)* and *(12)* are also given in Table 1. The fact that the "fixed" outer proton

signals in *(9)* and *(12)* have all moved slightly downfield could be due to the weakly diatropic nature of the macrocyclic

rings in these substances. As regards the protons on the *trans* double bonds of *(9)* and *(12)*, it is evident that the H^A resonances have shifted slightly downfield and the H^B resonances upfield. In view of the behavior of related substances[10] we believe *(9)* and *(12)* are probably conformationally mobile[14]. The observed shifts of the H^A and H^B signals would then indicate the predominance of a conformation having H^A external and H^B internal.

The tetradehydrocyclotetradeca[*c*]furans *(9)* and *(12)*, like isobenzofuran *(2)*, are $(4n+2)$ π-electron systems, but appear to be more weakly diatropic[4]. In view of the marked difference in properties between isobenzofuran *(2)* [$(4n+2)$ π-electrons] and cyclobuta[*c*]furan *(1)* [$4n$ π-electrons], it will be of interest to compare the properties of *(9)* and *(12)* with related macrocyclic systems containing $4n$ π-electrons.

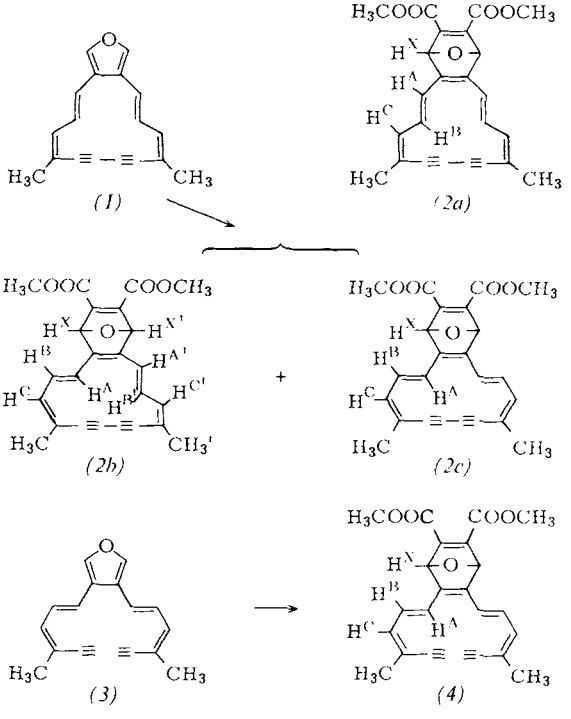
[12] The alternative route, corresponding to the reaction of *(4)* and *(6)*, could not be followed, since the phosphonium salt could not be prepared from *cis*-5-bromo-3-methyl-3-penten-1-yne and triphenylphosphane.

[13] This dideuterio compound was synthesized by reduction of diethyl 3,4-furandicarboxylate with $LiAlD_4$, and subsequent oxidation with MnO_2 and then with $Pb(OAc)_4$ [5].



[14] Attempts to prove this through cooling were unsuccessful, since the NMR spectra of *(9)* and *(12)* at *ca.* −70 °C were essentially unchanged.

The Synthesis of 1,3,5,7,9-Cyclotetradecapentaene-11,13-diynes ("1,3-Didehydro[14]annulenes"). The Interconversion between Nonequivalent Conformers of Diatropic Dehydroannulenes[1][***]

By *Rex T. Weavers* and *Franz Sondheimer*[*]

We describe the synthesis of the alkylated "1,3-didehydro[14]annulenes"[****] *(2)* and *(5)*[2], which were required as models for related benzoannelated compounds, described in the following communication[3]. As expected, the ^{1}H-NMR spectra of these $(4n+2)$ π-electron systems showed them to be strongly diatropic. However, an unexpected interconversion between nonequivalent conformers was observed, these being the first diatropic dehydroannulenes to exhibit this phenomenon[4].

7,12-Dimethyl-8,9,10,11-tetradehydrocyclotetradeca[*c*]furan *(1)*[1] was treated in benzene with dimethyl acetylenedicarboxylate (DMAD) for 16 h at room temperature. This dienophile was chosen so as to obtain a single product possessing a potential plane of symmetry. The resulting adduct dimethyl 8,13-dimethyl-9,10,11,12-tetradehydro-1,4-dihydro-1,4-epoxybenzocyclotetradecene-2,3-dicarboxylate *(2)*, a tetraalkylated 1,3-didehydro[14]annulene, formed red-brown crystals[5] [90% yield; *m/e* 388.130 (calcd. 388.131); λ_{max} (ether) *ca.* 275 sh (ε 10600), *ca.* 315 sh (45400), 332 (54400), 435 (8100), 512 (250), 524 (240) *ca.* 560 sh (250) and 573 (280)]. As a model, the rather unstable "open" adduct *(4)* was prepared, in 30% yield, from the terminal diacetylene *(3)*[11] and DMAD.

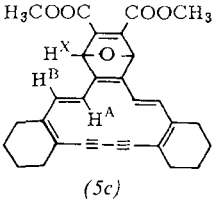
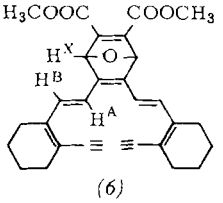
[****] *Editorial note:* According to IUPAC Rule C-41.2, "dehydro" only denotes the loss of *two* hydrogen atoms when used on its own with a trivial name. If more than two hydrogen atoms are missing, then their exact number should be indicated by the appropriate multiplying prefix in front of "dehydro". The correct name would thus read "tetradehydro ...".



Similarly, reaction of the octahydrodibenzo analog of *(1)*[1] with DMAD led to the adduct dimethyl 11,12,13,14-tetradehydro-1,4,7,8,9,10,15,16,17,18-decahydro-1,4-epoxytribenzo-[*a,e,i*]cyclotetradecen-2,3-dicarboxylate *(5)*, a "hexaalkyl-1,3-didehydro[14]annulene", as orange-red needles[5] [75% yield; *m/e* 468.192 (calcd. 468.194); λ_{max} (ether) 318 (ε 38400), 337 (40400), *ca.* 425 sh (5400), 438 (6100), *ca.* 505 sh (250), *ca.* 520 sh (210), 554 (160), and 567 nm (190)]. The corresponding "open" adduct *(6)* was obtained as orange needles[5] in 35% yield from the corresponding analog of *(3)*[1] and DMAD.



(5a)

(5b)

(5c)

(6)

The ^{1}H-NMR spectra of both the "didehydro[14]annulenes" *(2)* and *(5)* were found to be temperature dependent. The spectrum of *(2)* at −60 °C indicated it to be a *ca.* 7:3 mixture of the unsymmetrical conformer *(2b)* and the symmetrical conformer *(2c)*, these being strongly diatropic. The bands assigned to these conformers are given in Table 1. The fact that there were two high-field doublets corresponding to H^A shows both *(2b)* and *(2c)* to be present. That there was only one high-field double doublet corresponding to H^B (with the same intensity as one of the H^A bands) indicates the absence of conformer *(2a)*. The fact that there were three H^X, three CCH_3 and three OCH_3 resonances confirms the presence of one symmetrical and the unsymmetrical conformer. The individual assignments are based on the integration of the spectrum [which also gives the indicated ratio of *(2b)* and *(2c)*] as well as on double resonance experiments.

Heating the "didehydro[14]annulene" *(2)* above −60 °C results in the coalescence successively of the OCH_3, CCH_3, H^X, H^C, and finally the H^A, H^B signals (approximate coalescence temperatures: −25, −10, 0, +10, and +40 °C, respectively). Above 75 °C, "average" bands due to the H^A, H^B protons appear, the spectrum at 100 °C being given in Table 1. If the conformers *(2b)* and *(2c)* are assumed to be present in the ratio of 7:3, the calculated "average" positions of the H^A and H^B resonances are τ 8.06 and 5.57, respectively, in quite good agreement with the observed values.

In order to obtain quantitative data regarding the diamagnetic ring current in *(2b)* and *(2c)*, the ^{1}H-NMR spectral data of the model *(4)* are also given in Table 1, as well as the chemical shift differences for the various resonances on passing from *(4)* (at 30 °C) to *(2b)* and *(2c)* (at −60 °C). This shows the magnitude of the upfield shift of the inner proton signals and the downfield shift of the outer proton signals.

Table 2. ^{1}H-NMR parameters of *(5)* and *(6)* in $CDCl_3$ at 100 MHz (τ values, TMS internal, *J* in Hz).

[a] In addition, *(2b)* and *(2c)* at −60 °C show singlets at τ = 6.16, 6.22, and 6.25 (OCH_3).
[b] The chemical shift of this proton could not be determined.
[c] In addition, *(2)* at 100 °C shows a singlet at τ = 6.25 (OCH_3).
[d] In addition, *(4)* shows singlets at τ = 6.17 (OCH_3) and 6.57 (≡CH).

equal. This shows that *(5)* exists mainly as the unsymmetrical conformer *(5b)* or mainly as an approximately equal mixture of the two symmetrical conformers *(5a)* and *(5c)*. However, the presence of two small additional H^X bands (Table 2, footnote [a]) indicates that all three conformers are present to some extent.

Heating *(5)* above $-60\,^{\circ}C$ again results in the coalescence of the various ^{1}H-NMR signals, the approximate coalescence temperature being $-25\,^{\circ}C$ for H^X and $0\,^{\circ}C$ for H^A, H^B. Above $25\,^{\circ}C$, "average" bands due to the H^A, H^B protons appear, and the spectrum at $60\,^{\circ}C$ is given in Table 2. The spectral data of the model *(6)* are also given in Table 2, as well as the chemical shift differences on passing from *(6)* (at $30\,^{\circ}C$) to *(5)* (at $-60\,^{\circ}C$). The differences indicate the upfield shift of the inner proton resonances in *(5)* and the downfield shift of the outer proton resonances.

It is apparent that "didehydro[14]annulene" *(5)* is appreciably less diatropic than *(2)*, as indicated by comparison of their ^{1}H-NMR spectra with those of the corresponding models *(6)* and *(4)* (Tables 1 and 2). Presumably, this effect is due to steric interaction in *(5)*, reducing its planarity. The fact that *(5)* is more "mobile" than *(2)*, as shown by comparison of the coalescence temperatures, is probably due to the same factor.

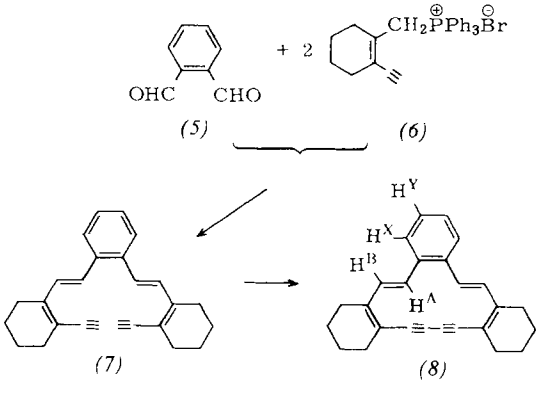
The Synthesis of Tetradehydrobenzocyclotetradecenes ("Benzodidehydro[14]annulenes"). The Effect of Benzoannelation on the Diamagnetic Ring Current of Macrocyclic $(4n+2)$ π-Electron Systems[1][***]



By *Rex T. Weavers* and *Franz Sondheimer*[*]

The fact that "aromatic" macrocyclic and bridged macrocyclic $(4n+2)$ π-electron systems show a diamagnetic ring current, as determined by ^{1}H-NMR spectrometry, is now well established[2]. It was of considerable interest to investigate the effect on the ring current produced by benzoannelation of these systems. There are indications that it suppresses the ring current[3], although little quantitative data is available. We now describe the synthesis of the tetradehydrobenzocyclotetradecenes ("benzodidehydro[14]annulenes")[****] *(4)* and *(8)*, and show that annelation of the benzene ring reduces, but does not completely suppress, the diamagnetic ring current of the 14-membered ring.

Wittig reaction of *o*-xylylenebis(triphenylphosphonium bromide) *(1)*[4] and two molar equivalents of *cis*-3-methyl-2-penten-4-ynal *(2)*[5] in dimethylformamide with ethanolic lithium ethoxide at $80\,^{\circ}C$ led to a stereoisomeric mixture, which on chromatography on alumina (Woelm, neutral) gave the di-*trans* compound *(3)* in 14% yield as light yellow needles, m.p. 128—130 °C (decomp.) [*m/e* 258.142 (calcd. 258.141), λ_{max} (ether) 293 (ε 25800) and 331 nm (29900)]. Oxidative coupling of *(3)* with cupric acetate in pyridine at $60\,^{\circ}C$ under relatively dilute conditions then furnished 5% of 8,13-dimethyl-9,10,11,12-tetradehydrobenzocyclotetradecene *(4)* as pale orange needles, m.p. 174—175 °C [*m/e* 256.125 (calcd. 256.125): λ_{max} (ether) 263 (ε 10500), 276 (13100), 318 (54000), *ca.* 370 sh (6000), 393 sh (4900), and *ca.* 410 sh nm (3000)].

Wittig reaction of phthaldialdehyde *(5)* and two molar equivalents of the phosphonium salt *(6)*[6] essentially under the previously indicated conditions again gave a stereoisomeric mixture. Chromatography on alumina yielded *ca.* 25% of the *cis,trans* isomer corresponding to *(7)*, followed by *ca.* 35% of an inseparable mixture of the di-*trans* isomer *(7)* and the corresponding di-*cis* isomer (assignments based on ^{1}H-NMR spectrometry). Oxidative coupling of this mixture essentially as before, and separation by multiple-run preparative layer chromatography on Kieselgel, then led to 11% of di-*trans* 11,12,13,14-tetradehydro-7,8,9,10,15,16,17,18-octahydrotribenzo[*a,e,i*]cyclotetradecene *(8)* as yellow needles, m.p. 160—161.5 °C [*m/e* 336.188 (calcd. 336.188); λ_{max} (ether) 264 (ε 10600), *ca.* 280 sh (13900), 313 (34900), and 368 sh nm (5600)][7].

The ^{1}H-NMR parameters of *(3)* and *(4)* are given in Table 1. In the assignment of the benzenoid protons, the assumption has been made that H^X is more affected than H^Y by the

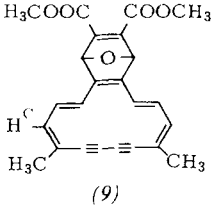
[****] *Editorial note:* According to IUPAC Rule C-41.2, "dehydro" only denotes the loss of *two* hydrogen atoms when used on its own with a trivial name. If more than two hydrogen atoms are missing, then their exact number should be indicated by the appropriate multiplying prefix in front of "dehydro". The correct name would thus read "tetradehydro ...".



unsaturated substituents. Comparison of the spectra of these substances (Table 1) shows that *(4)* is moderately diatropic, as evidenced by the magnitude of the downfield shift of the H^C and CH_3 resonances. The fact that the H^A signal in *(4)* has moved upfield as compared to that in *(3)*, and the H^B signal downfield, points to a conformation having H^A internal and H^B external. However, in view of the fluxional behavior of the related diatropic compound *(9)*[1], we believe that *(4)* is probably also conformationally mobile[8], the indicated conformation predominating. The mobility is substantiated by the fact that the downfield shift of the resonance due to H^C, which is fixed, is considerably greater than that of H^B.

Table 1. ^{1}H-NMR parameters of *(3)* and *(4)* in $CDCl_3$ at 100 MHz (τ values, TMS internal, *J* in Hz).

	(3) [a]	*(4)*	Δ *(4)*—*(3)*
H^A	3.12 d	5.01 d	+1.89
J	15.5	16	
H^B	2.83 dd	2.56 dd	−0.27
J	15.5,10	16,7.5	
H^C	3.51 d	2.92 d	−0.59
J	10	7.5	
CH_3	8.01 s	7.64 s	−0.37
H^X	2.47 m	1.75 m	−0.72
H^Y	2.78 m	2.49 m	−0.29

[a] In addition, *(3)* shows a singlet at τ = 6.68 (≡CH).

Interestingly, the benzenoid proton (H^X, H^Y) resonances in the ^{1}H-NMR spectrum of *(4)* have shifted appreciably downfield as compared with those of *(3)*[9] (Table 1), this effect, as expected, being greater for H^X than H^Y. This is a reversal of the behavior of the benzene protons of benzocyclobutene derivatives, in which the $4n$ π-electron cyclobutadiene ring causes the benzenoid proton resonances to shift to higher field[10].

(9)

(10)

The ^{1}H-NMR spectrum of *(8)* ($CDCl_3$, 100 MHz) consisted of 2H multiplets at τ = 2.01 (H^X) and 2.58 (H^Y), 2H doublets at 3.06 and 4.02 (H^A, H^B), as well as 8H multiplets at 7.4 (allylic H) and 8.2 (nonallylic H). This again is presumably a fluxional molecule. The ^{1}H-NMR spectrum of the acyclic analog *(7)* was not available, but the diatropic nature of *(8)* is indicated by the downfield shift of the allylic proton resonances (*ca.* −0.3 ppm) as compared with the normal value, as well as by the downfield shift of the benzenoid proton resonances H^X (−0.46 ppm) and H^Y (−0.20 ppm) relative to those of the model *(3)*.

Comparison of the ^{1}H-NMR spectral data shows the relative magnitude of the ring currents in the "didehydro[14]annulenes" *(4)*, *(9)*[1] and *(10)*[11]. The macrocyclic ring in the tetraalkyl compound *(9)* is strongly diatropic, in the benzoannelated compound *(4)* it is moderately diatropic, and in the fused furan *(10)* it is at most weakly diatropic. In view of the conformational mobility of these substances [*(9)*, *(4)*, *(10)*], this is most easily seen by the downfield shifts, as compared with the respective models, of the H^C bands (*ca.* −2.0, −0.6, and −0.3 ppm, respectively) and of the CH_3 bands (*ca.* −1.0, −0.4, and −0.1 ppm, respectively). The corresponding cyclohexene-fused compounds [cf. *(5)* in [1], *(8)* in this communication, and *(9)* in [11]] follow the same order, as shown by the downfield shifts of the allylic proton resonances (*ca.* −1.1, −0.3, and −0.1 ppm, respectively).

Synthesis and Reactions of 1-Benzothiepin

By *Ichiro Murata, Toshio Tatsuoka*, and *Yoshikazu Sugihara*[*]

Although several substituted derivatives have been prepared, the parent 1-benzothiepin *(1)* has never been synthesized because of its thermal instability[1-3]. *Traynelis* and *Yoshikawa* have recently reported the synthesis of *(1)* from 2,3-dihydro-2-chloro-1-benzothiepin and $KOC(CH_3)_3$[4]; however, none of its properties have so far been reported.

(1), X = H *(1a)*, X = D *(2)*, X = H *(2a)*, X = D *(3)*

In the course of other investigations[5] we had been able to isolate 6-thiatetracyclo[5.4.0.0^{2,4}.0^{3,5}]undeca-1(7),8,10-triene *(2)*—a valence isomer of *(1)*—in moderate yields[5d, 5e]. We describe here the novel synthesis of 1-benzothiepin *(1)* by Rh^I-catalyzed isomerization of *(2)*[6].

[*] Prof. Dr. I. Murata, Dipl.-Chem. T. Tatsuoka, and Dr. Y. Sugihara
Department of Chemistry, Faculty of Science, Osaka University
Toyonaka, Osaka 560 (Japan)

Treatment of *(2)* with 7.8 mole-% of dicarbonyl-2,4-pentanedionatorhodium(I) (16 h at 0 °C in chloroform) leads to 57% of *(1)* (pale yellow needles, m. p. 23.5—24.5 °C)[7], which was purified by low-temperature column chromatography on alumina (deactivated with 5% water) at −20 °C. All manipulations during work-up have to be carried out below −10 °C in order to avoid contamination with naphthalene. The structure of *(1)* was established by a combination of elemental analysis[7], UV and NMR spectroscopy: The UV spectrum of *(1)* [λ_{max} (cyclohexane) = 217 nm (log ε = 4.07), 256 (4.07), 295 sh (2.96), 345 nm (broad, weak) (2.55)] is closely similar to those reported for the substituted 1-benzothiepins[2a]. The NMR spectrum [100 MHz ($CDCl_3$), TMS int., −20 °C: δ = 5.90 (2-H), 6.34—6.56 (3-H, 4-H), and 7.09 (5-H), 7.15—7.5 (aromat. H)] was assigned on the basis of relative chemical shifts, shielding of 2-H being larger than that of 3-H[2a]. [3,4-D_2]-1-Benzothiepin *(1a)*, obtained from *(2a)*[5e], exhibited in addition to the multiplet of the four aromatic protons (δ = 7.05—7.4), two equally intense broad singlets (1 H) at δ = 5.85 and 7.00.

Chemical proof of the structure of *(1)* was gained by catalytic hydrogenation in ethanol over a large amount of palladium-charcoal. This reduction yielded 2,3,4,5-tetrahydro-1-benzothiepin, which was identical with an authentic sample[8]. Warming of *(1)* in carbon tetrachloride leads to formation of naphthalene and sulfur with a (NMR spectroscopically determined) half-life of transformation of 80 min at 40 °C.

Treatment of *(1)* with *m*-chloroperbenzoic acid in CH_2Cl_2 at −20 °C afforded 1-benzothiepin-1,1-dioxide in 87% yield, m. p. 138—139 °C ([8]: 140—141 °C). NMR, δ = 6.6—7.1 (m, 3 H), 7.4—7.9 (m, 4 H) and 8.1—8.4 (m, 1 H). Irradiation of *(1)* in THF (450-W high-pressure mercury arc lamp, pyrex filter, 4 h at 0 °C) yielded the known valence isomer *(3)*[5e] along with a small amount of naphthalene. *(3)* is also formed from *(2)* by irradiation or by $AgClO_4$ catalysis[5e].

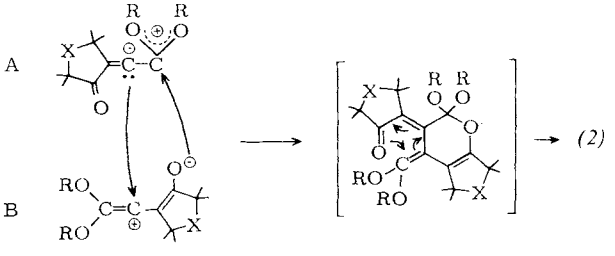
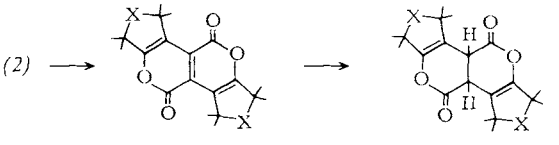
Dimerization of "Push-Pull" Substituted Allenes



By *Rolf W. Saalfrank*[*]

The dimerization of allenes in a [2+2]cycloaddition[1] leading to 1,2-bis(methylene)cyclobutane derivatives is well known. Far less attention has been paid to allene dimerizations proceeding with substituent participation, such as the formation of dehydroacetic acid from allenecarboxylic acid[2] or the dimerization of triphenylchloroallenes to give derivatives of rubrene[3]. The present communication reports the dimerization of the diethoxyvinylidene-tetrahydrofuranones *(1a)* and -cyclopentanones *(1b)* affording the tetracyclic compounds *(2a)* and *(2b)* respectively, which resembles the dimerization of triphenylchloroallenes mentioned above.



(1a), X = O
(1b), X = CH_2
R = C_2H_5
(2a), X = O
(2b), X = CH_2

The allenes *(1)* can be described in terms of the resonance structures A and B. It is assumed that 1,4-dipolar cycloaddition of the α,β-unsaturated keto system of one allene molecule to the ketene acetalic double bond of another leads initially to the cisoid 2,2-diethoxypyran intermediate *(3)*. This intermediate then undergoes an electrocyclic reaction analogous to hexatriene-cyclohexadiene isomerization to give the dimer *(2)* whose structure follows unequivocally from the spectroscopic data listed in Table 1.

(1) *(3)*
X = O, CH_2;
R = C_2H_5

In boiling glacial acetic acid the diethoxypyrans *(2)* are converted almost quantitatively into the fused α-pyrones *(4)*.

(4a), X = O
(4b), X = CH_2
(5a), X = O
(5b), X = CH_2

These strongly fluorescing substances exhibit powerful emission on excitation of their saturated methylene chloride solutions by a nitrogen laser. Owing to their remarkable stability they are particularly suited for use as laser dyes. The following spectroscopic data not listed in Table 1 were obtained for compounds *(4a)* and *(4b)*: UV spectrum (C_2H_5OH): λ_{max} = 410 nm (ε = 10 500) and 420 nm (12100) respectively; dye

laser emission spectrum (CH_2Cl_2): λ_{max} laser ≈ 485 and 510 nm, and 495 and 515 nm respectively[6].

Reduction of the α-pyrones *(4)* with zinc in glacial acetic acid gives the fused lactones *(5)* in good yields[7].

4,4,9,9-Tetraethoxy-1,1,3,3,6,6,8,8-octamethyl-1,3,4,6,8,9-hexahydro-2,5,7,10-tetraoxaindeno[5,4-e]indene (2a) and -1,2,3,4,6,7,8,9-octahydro-5,10-dioxaindeno[5,4-e]indene (2b)

A benzene solution of 2,2,5,5-tetramethyltetrahydrofuran-3,4-dione (5.5 g, 35 mmol) or 3,3,5,5-tetramethyl-1,2-cyclopentanedione (5.4 g, 35 mmol) is rapidly added dropwise to a stirred, cooled benzene solution of 2,2-diethoxyvinylidenetriphenylphosphorane[1a] prepared from 2,2-diethoxyvinyltriphenylphosphonium tetrafluoroborate (18.0 g, 40 mmol). The solvent is drawn off at room temperature, the resinous residue extracted several times with light petroleum, and triphenylphosphane oxide is filtered off. After removal of the light petroleum and subsequent bulb distillation (*ca.* 110°C/0.5 torr), 2-(2,2-diethoxyvinylidene)-3,3,5,5-tetramethylcyclopentanone *(1b)* (5.1 g, 20 mmol) is obtained which undergoes almost complete dimerization to *(2b)* on prolonged heating at about 140—160°C. 4-(2,2-Diethoxyvinylidene)-2,2,5,5-tetramethyltetrahydrofuran-3-one *(1a)* cannot be isolated under the above experimental conditions and *(2a)* is obtained directly on removal of the light petroleum. The dimers *(2)* can be recrystallized from ether.

1,1,3,3,6,6,8,8-Octamethyl-1,3,6,8-tetrahydro-2,5,7,10-tetraoxaindeno[5,4-e]indene-4,9-dione (4a) and -1,2,3,6,7,8-hexahydro-5,10-dioxaindeno[5,4-e]indene-4,9-dione (4b)

(2a) or *(2b)* (5 mmol) is refluxed in glacial acetic acid (20 ml) for 30 min. After cooling and filtration, the greenish yellow, strongly fluorescing crystals of *(4a)* or *(4b)* are washed with methanol.

ESR Spectrum of a Perpendicular Benzyl Radical[1]

By *Kurt Schreiner* and *Armin Berndt*[*]

In the same way as the *planar* benzyl radical constitutes a textbook example for π-π delocalization or conjugation, the perpendicular benzyl radical *(1a)* represents a prototype for π-σ delocalization or hyperconjugation, whose significance in chemistry has recently received increasing recognition[2]. INDO calculations[3,4] on *(1a)* predict ESR coupling constants of considerable magnitude for the *ortho* C atoms (17.05 G), *ortho* H atoms (1.97 G), and *meta* H atoms (2.78 G) which arise almost exclusively from π-σ delocalization since the minimal π spin densities at the ring C atoms would lead only to coupling constants of 0.5, 0.3, and 0.2 G by spin polarization.

(1a), R = H
(1b), R = $C(CH_3)_3$

Experimental checks of the INDO results have hitherto been limited to model radicals[4-6] having relatively small spin densities at the exocyclic π center and angles of twist of only about 60°.

The 1,1-di-*tert*-butylbenzyl radical *(1b)* represents the first benzyl radical twisted through 90°. We prepared it by reaction of the oxalic diester[7] of 1,1-di-*tert*-butylbenzyl alcohol with potassium/sodium alloy in benzene. Since *(1b)* is stable for several days at room temperature under the conditions of its preparation, it can be generated in concentrations high enough to determine coupling constants of ^{13}C in natural isotopic abundance. These coupling constants together with the *g* factor of 2.0024 provide proof of the structure and the stereochemistry of the radical *(1b)*.

The following coupling constants can be deduced from the ESR spectrum shown in Figure 1; $a^H = 0.47$ G for 18 equivalent protons (2 tBu), $a^H = 0.31$ G (1 H, *i. e. para* proton), and $a^H = 0.82$ and $a^H = 0.91$ G for two sets of two equivalent protons (*ortho* and *meta*). An ESR spectrum recorded at higher concentration and amplification reveals ^{13}C coupling constants of 45 (1 C), 18.2 (2 C), and 11.7 G (7 C). We assign the largest constant to C^1 since it shows excellent agreement with $a^C = 45.2$ G[8] of the central C atom of the *tert*-butyl radical. $a^C = 18.2$ G (2 C) lies in the range expected for the *ortho* C atoms of a highly twisted benzyl radical from the known relationship $a^C = 19\ \rho_C \cos^2\theta$[5]. The assignment of $a^C = 11.7$ G to the six C atoms of the methyl groups of the *tert*-butyl substituents follows from a comparison with the ^{13}C coupling constants

[*] Prof. Dr. A. Berndt and Dipl.-Chem. K. Schreiner

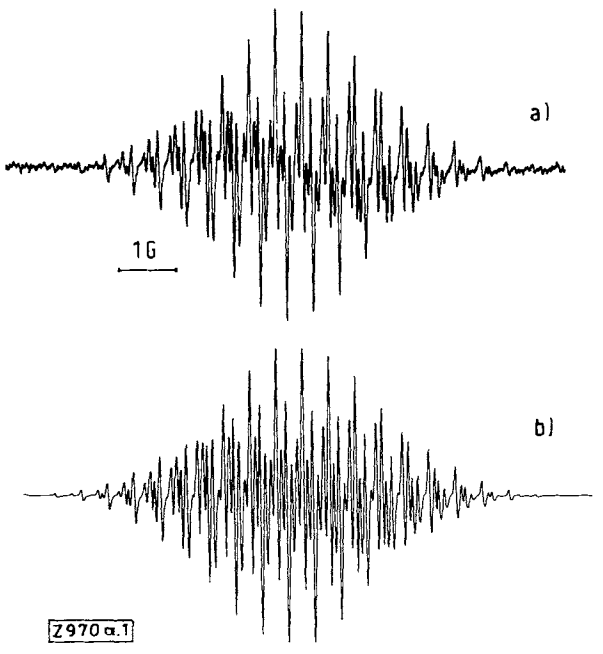

Fig. 1. a) ESR spectrum of the 1,1-di-*tert*-butylbenzyl radical *(1b)* in benzene at 25 °C; b) computer simulation with the coupling constants given in the text, line width 0.03 G.

of the 1,1-di-*tert*-butylmethyl radical (11.7 G for 6 C[9]). The remaining coupling constant of 11.7 G for one C atom is assigned to C^2 since a contribution of *ca.* 12 G is to be expected in this position due to spin polarization (cf. $a^C = 12.35$ G for the methyl C atoms of the *tert*-butyl radical[8]).

Since $a^C_{C^1}$ and $a^C_{C(CH_3)_3}$ for *(1b)* are in complete accord with the corresponding data for the *tert*-butyl and the 1,1-di-*tert*-butylmethyl radical respectively, for which π-π delocalization is precluded, the angle of twist in *(1b)* must be 90° or almost 90°. Supporting evidence comes from the very small coupling constant of the *para* proton (0.31 G as against 6.14 G in the planar benzyl radical[10]) and the very large coupling constant of the *ortho* C atoms (18.2 G) which are both in good agreement with the values calculated for a benzyl radical twisted through 90° (0.23 and 17.05 G).

The contribution from π-σ delocalization in a^H_o and a^H_m found for *(1b)* (0.82 and 0.91 G) is thus considerably smaller than that predicted by INDO calculations (1.97 and 2.78 G) and found experimentally for a^H_m of model radicals[4-6].

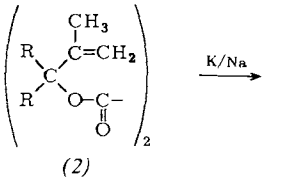
Homohyperconjugation in a Perpendicular Allyl Radical[1]

By *Henning Regenstein* and *Armin Berndt*[*]



The conformations A and B of the *n*-propyl radical, for which quantum mechanical approximation calculations are available[5-7], represent prototypes for the π-σ delocalization termed *homohyperconjugation*[3] established experimentally for numerous radicals derived from rigid bicyclic systems[3,4]. The "W" or "anti-W" arrangement of π- and σ orbitals required for this π-σ interaction also occurs in extensively twisted π radicals[2]. The perpendicular allyl radical *(1a)*, which has the two relevant protons H_a and H_b of A and B in a similar geometrical arrangement, can be regarded as a prototype of such systems.

A B

(1a), R = R' = H
(1b), R = $C(CH_3)_3$, R' = CH_3

We have now prepared the first stable allyl radical devoid of π-π delocalization, the 1,1-di-*tert*-butyl-2-methylallyl radical *(1b)*, by reaction of the oxalic diester *(2)* with potassium/sodium alloy[8]. Compound *(2)* is obtained by reaction of di-*tert*-butyl ketone with 2-lithio-2-methylpropene and subsequent treatment with oxalyl chloride [*(2)*: m.p. 115 °C; NMR (in CCl_4, δ relative to TMS): singlets at 1.26 (18H), 1.92 (3H), 4.84 (1H), and 5.30 ppm (1H)].

(2)

(1b)
R = $C(CH_3)_3$

The ESR spectrum (Fig. 1) of the radical *(1b)*, which is stable for several days at room temperature, can be simulated with the values $a^H = 0.45$ (18H, 2tBu), $a^H = 0.71$ (3H, CH_3), $a^H = 3.40$ (1H), and $a^H = 0.96$ G (1H). Together with the *g* factor of 2.0025 these coupling constants prove the structure of *(1b)*. Its stereochemistry follows from the ^{13}C coupling constants of 46 (1C), 18 (2C), and 12 G (9C), which could be determined when the amplification of the spectrum was increased. Since these constants are in very good agreement with the corresponding constants of the 1,1-di-*tert*-butylbenzyl radical[9] which is known to be twisted through 90°, *(1b)* must likewise be twisted through 90° or almost 90°. In this conformation the bulky *tert*-butyl groups are located at the farthest possible distance from the methyl groups on C^2.

The orthogonality of the p orbitals on C^1 and C^2 ensures that the π-spin density at C^3 is virtually zero. Coupling con-

[*] Prof. Dr. A. Berndt and Dipl.-Chem. H. Regenstein
Fachbereich Chemie der Universität
355 Marburg, Lahnberge (Germany)

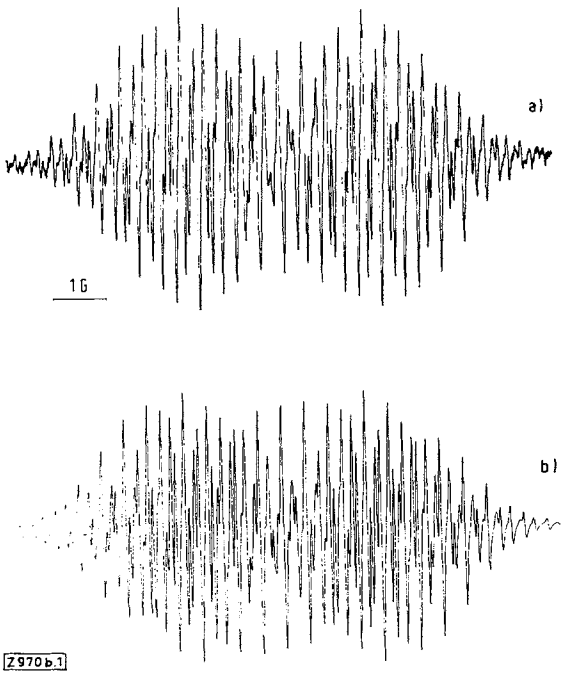


Fig. 1. a) ESR spectrum of the 1,1-di-*tert*-butyl-2-methylallyl radical *(1b)* in benzene at 25 °C; b) computer simulation with the coupling constants given in the text, line width 0.04 G.

stants due to spin polarization are therefore expected to be of the order of 0.0 G for H_a and H_b. The considerably larger experimental values of 0.96 and 3.40 G must consequently arise from another mechanism, as underlined in particular by the exceptionally large ratio of 3.5 for the coupling constants of two protons attached to the same π center C^3. Coupling constant ratios of about 1 are usually found for such protons (allyl radical: 14.8/13.9[10]; radical anion of butadiene: 7.6/7.6[11]).

Interpretation of the exceptionally large coupling constant of 3.40 G requires an experimentally unequivocal assignment to H_a or H_b, which is currently in progress. Since the geometry of the C^3—H_b σ bond relative to the p orbital of the unpaired electron, which is important for π-σ interactions, is almost identical with that of the C—H_{ortho} σ bonds of the benzyl radical that is twisted through 90°[9], the contribution from π-σ delocalization should be of comparable size for H_b and H_{ortho}. As a^H_{ortho} is 0.91 or 0.82 G[9], we assign $a^H = 0.96$ G to H_b. The exceptionally large coupling constant $a^H = 3.40$ G can then be readily explained in terms of homohyperconjugation in twisted π radicals[2]. This interpretation is supported by quantum mechanical approximation calculations for the conformations A and B of the *n*-propyl radical comparable with *(1)* which yield values of 1.0[5], 2.0[6], or 0.2 G[7] for H_b, and 3.0[5], 3.24[6], or 4.37 G[7] for H_a.

Bis(*N*,*N'*-methylsilanetriyl)tris(sulfur Diimide)—A Bicyclic Derivative of S_4N_4[**]

By *Herbert W. Roesky* and *Hartmut Wiezer*[*]

The sulfur atoms of tetrasulfur tetranitride can be replaced in part by metal atoms[1]. We now report the synthesis of a new cage compound in which two Si atoms are linked *via* three SN_2 bridges.

Reaction of methyltrichlorosilane with *N*,*N'*-bis(trimethylstannyl)sulfur diimide[2] *(1)* yields an ether-soluble yellow crystalline compound *(2)*,

$$\underset{(1)}{2CH_3SiCl_3 + 3(CH_3)_3Sn{-}NSN{-}Sn(CH_3)_3} \rightarrow \underset{(2)}{CH_3Si(NSN)_3SiCH_3} + 6(CH_3)_3SnCl$$

whose composition is established by elemental analysis and above all by its mass spectrum[3]. The molecular ion M^+ at *m/e* 266 has a relative intensity of 100%; the following fragments are also observed: 251 M−CH_3 (63%), 223 M−CH_3Si (5%), 220 M−NS (5%), 206 M−N_2S (5%), 192 M−N_3S (76%), 191 $CH_3Si_2N_4S_2$ (20%), 177 $CH_3Si_2N_3S_2$ (2%), 164 $(CH_3)_2SiN_3S_2$ (32%), 160 $(CH_3)_2Si_2N_3S$ (42%), 149 $CH_3SiN_3S_2$ (42%), 146 $(CH_3)_2Si_2N_2S$ (30%), 145 $CH_3Si_2N_3S$ (9%), 118 $(CH_3)_2SiN_2S$ (20%), 105? (12%), 103 CH_3SiN_2S (11%), 102 SiN_3S (18%), 101? (20%), 85 CH_3SiN_3 (41%), 74 SiNS (22%), 70 SiN_3 (60%), 58 $(CH_3)_2Si$ (20%), 46 NS (34%), 43 CH_3Si (40%).

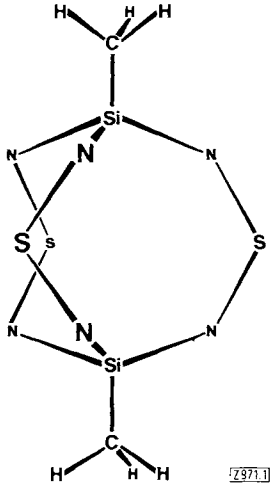

Fig. 1. Proposed structure of bis(*N*,*N'*-methylsilanetriyl)tris(sulfur diimide) *(2)*.

Compound *(2)* can be sublimed (sublimation temp. 65 °C/0.1 torr) and melts at 95—96 °C. The ^{1}H-NMR spectrum contains just one signal at δ = −0.50 ppm (TMS as external standard).

[*] Prof. Dr. H. W. Roesky and Dipl.-Chem. H. Wiezer
Anorganisch-chemisches Institut I der Universität
6 Frankfurt am Main, Niederurseler Hang (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

The IR spectrum exhibits few bands and is suggestive of a symmetrical molecule [tentative assignment: ν_{as}CH 2980 w, ν_sCH 2930 w, δCH 1400 w, ν_{as}NS 1312 vs, ν_sNS 1190 vs cm^{-1}; the absorptions at 1270 m, 812 s, and 780 s cm^{-1} are not open to unequivocal interpretation].

To summarize our findings we suggest a structure having C_{3h} symmetry for compound *(2)* (Fig. 1). Models show the sulfur atoms of the eight-membered ring to have *exo-* and *endo* orientations and thus to be at a maximum distance from each other. Hence strain-free bonding is possible.

Experimental:

A solution of CH_3SiCl_3 (2.98 g, 2 mmol) in ether (50 ml) is added dropwise to a stirred solution of *(1)* (11.61 g, 3 mmol) in ether (250 ml). After refluxing for 3 h the solvent and $(CH_3)_3SnCl$ are removed under vacuum and the residue is sublimed. Yield of *(2)*: 1.1 g (44%) of yellow transparent leaflets.

Triphenylcyclotriphosphane as a New Ligand in Transition Metal Complexes[**]

By *Marianne Baudler* and *Manfred Bock*[*]

Following the synthesis of triphenylcyclotriphosphane *(1)*[1], the first established[2] derivative of P_3H_3[3], we have now succeeded in incorporating this neutral[4] three-membered phosphorus ring as a ligand into transition metal complexes.

(η-Triphenylcyclotriphosphane)tetracarbonyliron(0) *(2)* and -tricarbonylnickel(0) *(3)* are formed on reaction of *(1)* with tetracarbonylirontetrahydrofuran *(4)*[5] and tetracarbonylnickel *(5)*, respectively.

$$(C_6H_5P)_3 + [M(CO)_{n-1}L] \xrightarrow{-L} [M(C_6H_5P)_3(CO)_{n-1}]$$
(1)

(4), M = Fe, L = THF *(2)*, M = Fe, $n = 5$
(5), M = Ni, L = CO *(3)*, M = Ni, $n = 4$

The golden red monomeric complex *(2)* is readily soluble in carbon disulfide, tetrahydrofuran, and benzene. On heating, carbon monoxide is liberated above 60 °C before melting occurs (≈110 °C). Even after a few days at −20 °C transition can already be observed to products of higher relative molecular mass and lower solubility.

Owing to its instability, especially in dilute solution at reduced pressure and towards $Ni(CO)_4$, the lemon yellow complex *(3)* cannot be obtained absolutely pure. It decomposes at room temperature with grey coloration within a few hours; even more rapid conversion with brown and black coloration is promoted by dissolution or warming, CO being liberated above 60 °C.

[**] Contributions to the Chemistry of Phosphorus, Part 58. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 57: *M. Baudler* and *A. Zarkadas*, Chem. Ber. *106*, 3970 (1973).

The ^{31}P-NMR spectra of *(2)* and *(3)* provide unequivocal information about the symmetry and bonding of the three-membered ring phosphorus ligand. They each display a sharp singlet at δ = +4.8 and +15.8 ppm, respectively (benzene, 25 °C, 85% H_3PO_4 ext.)[6] not subject to splitting or broadening at low temperature (tetrahydrofuran, −70 °C). The complexes are thus diamagnetic and the three phosphorus atoms equivalent. *(1)* must therefore be bonded through the plane of the P_3 ring as a trihapto ligand[7] and act as donor for an electron pair. The upfield shift of the ^{31}P-NMR signal of *(2)* and *(3)* compared to that of pure *(1)* (δ = +3.4 ppm[1]) reveals that complex formation is associated with a weak additional shielding of the phosphorus, which should be interpretable in terms of the acceptor properties of this ligand leading to delocalization of electrons of the transition metal[8].

A qualitative explanation of the bonding in *(2)* and *(3)* invokes 1) overlapping of a free metal orbital of suitable symmetry with the doubly occupied lowest energy P_3 ring molecular orbital (C_{3v} symmetry), formed by combination of three P atomic orbitals, which is preferentially localized above the plane of the ring, and 2) back-donation from an occupied metal orbital to the corresponding antibonding unoccupied P_3 ring molecular orbital. The extent to which d hybrid components play a role in the P AOs and thus in the P_3 ring MOs requires further study.

The intact cyclic structure of the phosphane ligand is confirmed by the IR spectra of *(2)* and *(3)*; their shape in the ring vibration region 540—390 cm^{-1} is characteristic for that found for *(1)*. For *(2)* the νCO vibration range contains four well-separated bands of almost equal intensity (2043, 2012, 1975, 1940 cm^{-1}) which, assuming a trigonal-bipyramidal structure, indicate the three-membered ring ligand to have an equatorial position (C_{2v} symmetry). Two intense CO bands (2070, 1999 cm^{-1}) appear for *(3)* (C_{3v} symmetry), which essentially agree with those of the monophosphane complex $[Ni(CO)_3P(C_6H_5)_3]$[9].

Owing to the poor thermal stability of the new complexes, neither the molecular ion nor fragments formed by successive removal of CO are observed in the mass spectrum; with *(2)* the only ion of significant intensity at higher mass numbers is $(C_6H_5P)_3^+$.

(η-Triphenylcyclotriphosphane)tetracarbonyliron(0) (2)

Compound *(1)* (2.0 g, 6.17 mmol) in THF (50 ml) is refluxed with a fivefold stoichiometric amount of *(4)* [from $Fe(CO)_5$ (6.05 g, 30.88 mmol)] in THF (150 ml) with stirring for 12 h (color change from violet-red to red-brown). After concentration to 50 ml, the same amount of a freshly prepared solution of *(4)* in THF is added and the mixture heated for a further 12 h. The crude red product obtained on complete removal of the solvent in a vacuum is dissolved in benzene (50 ml) and chromatographed over silica gel (0.05—0.2 mm); an unknown brown substance (≈10%) which cannot be eluted with benzene appears as residue. Removal of the solvent from the eluate and drying in a high vacuum afford *(2)* as a foamy solid having a golden-red luster; yield 2.3 g (76%). M. W. 490 (osmometric in C_6H_6 (45 °C)).

(η-Triphenylcyclotriphosphane)tricarbonylnickel(0) (3)

Compound *(5)* (0.53 g, 3.10 mmol) is added from a one-way syringe to a suspension of *(1)* (1.0 g, 3.09 mmol) in *n*-pentane (10 ml) at room temperature. Liberation of CO ceases after about 1 h. In order to avoid conversion of *(1)* into pentaphenyl-cyclopentaphosphane, stirring is performed only towards the end of the reaction and for 0.5 h after completion of the reaction. After insoluble products (≈100 mg) have been

filtered off, and the solvent rapidly drawn off in a vacuum, there remains a bright lemon-yellow foamy solid whose ^{31}P-NMR spectrum and elemental analysis show it to consist of 90% of *(3)*; yield 1.3 g (90%). The decomposability in dilute solution rules out reproducible osmometric molecular-weight determinations; however, values obtained provide an indication of a monomeric structure for *(3)*.

Reactions of λ^3-Phosphorins with Diazoalkanes in the Presence of Alcohols and Phenols

By *Peter Kieselack* and *Karl Dimroth*[*]

We report here on a new, versatile method for the synthesis of λ^5-phosphorins *(2)* having one C- *and* one-O-linked substituent on phosphorus in high yields from λ^3-phosphorins *(1)*[1].

(1) *(2)* (1)

The λ^5-phosphorins *(2)* are formed by reaction of *(1)* with diazoalkanes in the presence of alcohols or phenols. The reaction, which is initiated by a nucleophilic attack of the diazoalkane at the phosphorus atom, permits a wide range of possibilities as regards variation of the substituents on the phosphorin, on the hydroxy compound, and on the diazoalkane. Of particular interest is the reaction with diazoacetic ester, which leads to λ^5-phosphorins such as *(2k)* and *(2l)* having a reactive methylene group in the α-position to the phosphorus atom and thus opens up new synthetic possibilities. Equation (1) summarizes the course of the reaction.

Table 1 lists a few of the λ^5-phosphorins *(2)* that have been synthesized by this method.

4-Benzyl-1-methoxy-1-methyl-2,6-diphenyl-λ^5-phosphorin (2e)

An ethereal solution of diazomethane from nitrosomethylurea (300 mg, 3 mmol) is added with stirring at room temperature to a solution of 4-benzyl-2,6-diphenyl-λ^3-phosphorin (677 mg, 2 mmol) in benzene (25 ml) and methanol (10 ml). The reaction, which proceeds with strong evolution of nitrogen, is complete within a few minutes. Chromatography in benzene on silica gel and recrystallization from a little benzene/methanol affords 650 mg of *(2e)* [^{1}H-NMR (C_6D_6/TMS): δ = 1.6 (d, PCH_3), J_{P-H} = 14.5 Hz; 2.9 (d, $POCH_3$), J_{P-H} = 13.4 Hz; 3.75 (s, 2 benzyl-H); 6.9—7.6 (m, 17 aromatic H)].

Ethyl 1-(1-methoxy-2,4,6-triphenyl-λ^5-phosphorin)-acetate (2l)

A solution of 2,4,6-triphenyl-λ^3-phosphorin (1.3 g, 4 mmol) and ethyl diazoacetate (1 ml, *ca.* 10 mmol) in anhydrous benzene (50 ml) and absolute methanol (10 ml) is boiled under reflux. Further diazoester (4.5 ml) is added portionwise over a period of 30 h until λ^3-phosphorin can no longer be detected by thin-layer chromatography. Working up of the product as described above affords 1.4 g of *(2l)* [^{1}H-NMR (CCl_4/TMS): δ = 0.9 (t, $OCCH_3$), J_{H-H} = 7 Hz; 3.26 (d, PCH_2) J_{P-H} = 19 Hz; 3.35 (d, $POCH_3$), J_{P-H} = 14 Hz; 3.68 (q, OCH_2C), J_{H-H} = 7 Hz; 6.9—7.37 (m, 15 aromatic H); 7.63 (d, 3-H, 5-H), J_{P-H} = 31 Hz].

Kinetic Investigation of Peptide Coupling[**]

By *Manfred Mutter* and *Hanspaul Hagenmaier*[*]

Very little has so far been published on the kinetics of individual peptide coupling reactions[1], though a knowledge of such is always essential in the optimization of peptide syntheses. To the best of our knowledge IR spectroscopy has not previously been used for such investigations. The principle can be illustrated with a few examples. In peptide syntheses with symmetric anhydrides[2] the anhydride band at 1810—1820 cm^{-1} becomes weaker, while an amide band appears between 1640 and 1700 cm^{-1}.

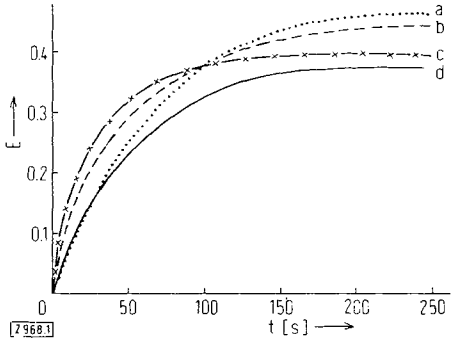

Fig. 1. Trace of coupling reactions by the "stop-flow" method in the region of the amide band (1635—1645 cm^{-1}). Total concentration of reagents: 10^{-2} mol/l in methylene chloride. PEG = polyethylene glycol. In brackets: relative reaction rate $v_{rel.}$. a) Dibutylamine + Boc-Pro-anhydride (1.00); b) H-Gly-OC_2H_5 + Ac_2O (1.64); c) H-Pro-PEG [4] + Ac_2O (2.57); d) Dibutylamine + Ac_2O (1.36). Equal volumes of the reaction solutions were fed together by means of a dual-piston pump into an an arrow-shaped mixing block and pumped through the flow cuvette (layer thickness 0.2 mm, NaCl).

Figures 1 and 2 show the kinetic course of a few coupling (*N*-acylation) reactions. The change in the amide and anhydride band, respectively, for each reaction is plotted against

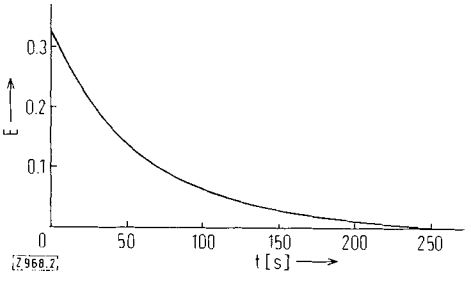

Fig. 2. Kinetic course of the coupling reaction H-Gly-Ala-Pro-PEG (10^{-2} mol/l) + Ac_2O (10^{-2} mol/l). Trace of the anhydride band at 1820 cm^{-1}. $v_{rel.}$ (referred to reaction a in Fig. 1) = 1.11.

time. As expected, both curves yield the same rate constants. For the determination of relative coupling rates $v_{rel.}$, measurements can be performed in a concentration range from 10^{-1} to 10^{-3} mol/l. For absolute rate constants a calibration curve must be recorded and the measurements carried out at higher dilution.

The change in the absorption bands can be measured directly in the reaction solution by a flow technique. This method is thus also suitable for monitoring heterogeneous reactions *e.g.* peptide syntheses on solid supports[3]. The simplicity of the procedure would suggest far reaching possibilities for the application of IR spectroscopy to kinetic investigations.

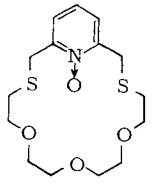
Novel Ligand Systems for Complexing Alkali Metal Ions[**]

By *Fritz Vögtle* and *Edwin Weber*[*]

Two fundamental types of neutral ligand systems for the specific complexing of alkali metal and alkaline earth metal salts have been described in the last few years: crown ethers[1, 2] and cryptating agents[3, 2]. In the continuation of our studies on medio- and macrocyclic polyethers[4] we have discovered a series of novel ligand systems *(1)*—*(4)*, which specifically complex alkali metal ions. The new ligand systems are readily accessible under dilution-principle conditions without use of the "template effect"[2].

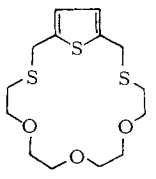
(1) *(2)* *(3)* *(4)*

While *sodium* permanganate is instantaneously solubilized by *(2)* (m.p. 90—91 °C; δ = 3.96) and *(3)* (m.p. 58—59 °C; δ = 3.87)[5, 6], remarkably, $KMnO_4$ remains completely undissolved. In contrast to *(2)*, *(3)* also renders $NaMnO_4$ soluble in benzene. Lithium, rubidium, cesium, ammonium, and silver salts are not solubilized by *(2)* and *(3)* in organic solvents.



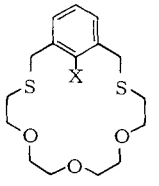
Addition of sodium iodide to solutions of *(3)* in $CDCl_3$ leads to a down-field shift of the characteristic α-CH_2 singlet by about 0.15 ppm; an intense band appears at 1640 cm^{-1} in the IR spectrum, and in the UV region a new band is observed at 243 nm, apart from the ligand absorption at λ = 273 nm.

In view of the observed Na^+-specificity of compounds *(2)* and *(3)* it is interesting to note the structural characteristics that deviate from those of the usual crown ethers and cryptate ligands; a) the *meta*-bridged aromatic ring, b) the sp^2 nitrogen as potential donor atom, and c) the heteroatom *beta* to the aromatic ring. Highly informative is a comparison of the 18-membered cycles *(3)*, *(5)* (colorless viscous oil, δ = 4.25) and *(6)* (colorless viscous oil; δ = 4.01) with [18]crown-6, dibenzo[18]crown-6, and dicyclohexyl[18]crown-6[1, 2], which

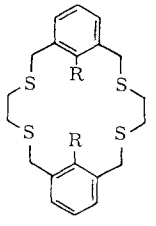


[*] Prof. Dr. F. Vögtle and Dipl.-Chem. E. Weber
Institut für Organische Chemie der Universität
87 Würzburg, Am Hubland (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

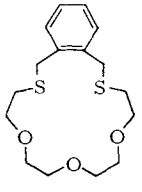


have the same number of ring members and which, in addition to complexing sodium, rubidium, and cesium, also complex potassium. *(5)* solubilizes $NaMnO_4$ in chloroform and benzene even more readily than *(3)*. Remarkably, *(5)* is the only 18-membered ring compound described here which also solubilizes *potassium* permanganate, albeit not to the same extent as $NaMnO_4$. The thiophenophane *(6)*, on the other hand, shows a much lesser tendency to complex sodium ions; even trace amounts of $KMnO_4$ are not solubilized in chloroform.

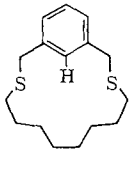


(5)

(6)



(7a), X = H
(7b), X = OCH_3



(8), R = OCH_3

In the transition from *(3)* to cyclophane *(7a)* (m.p. 56—57 °C; $\delta = 3.88$) the ability to solubilize $NaMnO_4$ in benzene—but not in chloroform—is lost. Interestingly, we have now found that the ability to solubilize $NaMnO_4$ in benzene reappears in the presence of a cyclophane such as *(7b)* (colorless viscous oil; $\delta = 3.87$) containing an intraannular methoxy group. It can thus be concluded that the pyridine nitrogen in *(3)*, the OCH_3 group in *(7b)*, and the pyridine *N*-oxide oxygen in *(5)* participate in the specific complexation of sodium ions; potassium ions (*e.g.* in $KMnO_4$) are complexed neither by *(6)* nor by *(7a)* and *(7b)*. In this connection, it is also interesting to note that the two OCH_3 groups in *(8)*[7], in association with the four sulfur atoms of the 18-membered ring, do not effect solubilization of $NaMnO_4$ and $KMnO_4$ in chloroform or benzene.

(9)

(10)

While the 17-membered orthocyclophane *(9)* (m.p. 47—49 °C; $\delta = 4.03$) also promotes solubilization of $NaMnO_4$—but not $KMnO_4$—in organic solvents (chloroform, less so in benzene), absence of the pyridine nitrogen and bridgeoxygen atoms as in *(10)* (m.p. 76—79 °C; $\delta = 3.87$) results, as expected, in a complete loss of complexing abilities[8].

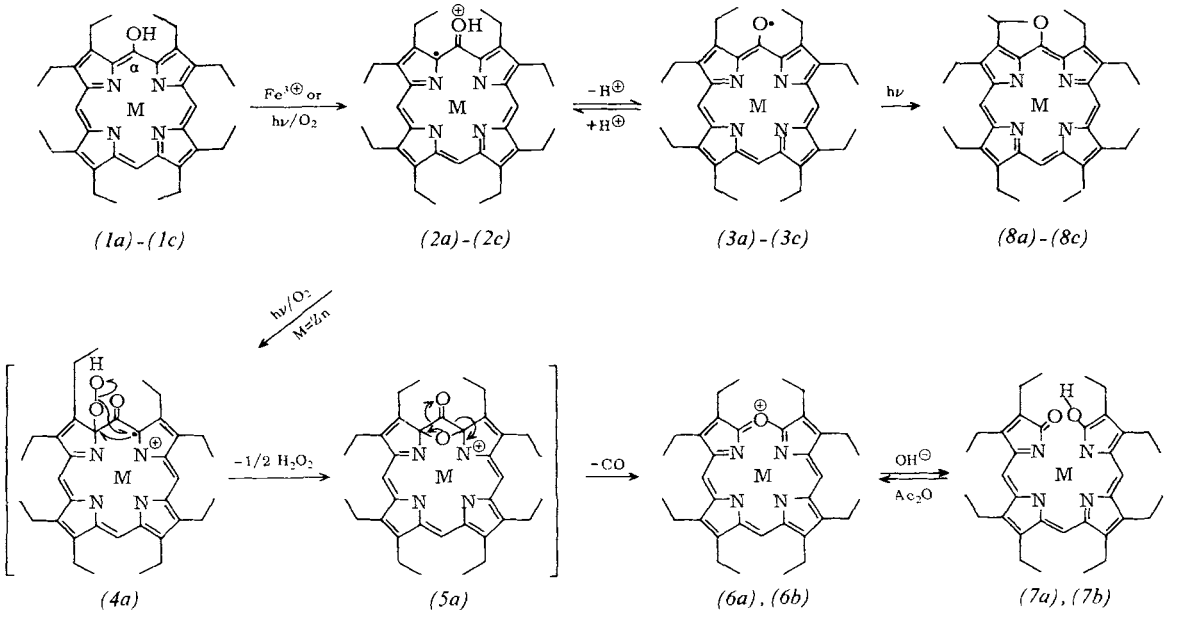
[8] Note added in proof (January 14, 1974): Of the cycles *(1)* (m.p. 133—135 °C; $\delta = 3.97$) and *(4)* (colorless oil; $\delta = 3.93$) which have, in the meanwhile, been obtained in pure form, only *(4)* solubilizes $NaMnO_4$ in chloroform; $KMnO_4$ and $BaMnO_4$ are not solubilized. *(7c)*, X = —C≡N (m.p. 72—74 °C; $\delta = 4.17$) behaves similarly to *(7a)*. The complexing properties of the disulfone (m.p. 251—253 °C; $\delta = 4.48$) obtainable from *(7a)* resemble those of the sulfide.

Oxidative Decarbonylation of Octaethyl-α-hydroxyporphinatozinc(II)[**]

By *Siegmund Besecke* and *Jürgen-Hinrich Fuhrhop*[*]

Metalloporphyrins are oxidized *in vitro* by hydrogen peroxide[1] or molecular oxygen[2] to hydroxy compounds [*e.g. (1b)*], which have also been detected as primary products in the biological degradation of heme to biliverdin[3]. All that is known about the subsequent reaction of α-hydroxyheme with molecular oxygen to give biliverdin is that, in biological systems[4], the α-methine carbon atom of the porphyrin undergoes oxidation and cleavage as carbon monoxide. We report here on a novel photoreaction in which octaethyl-α-hydroxyporphinatozinc(II) *(1b)* is transformed, with loss of one molecule of carbon monoxide, into a compound containing a biliverdin residue.



Irradiation of *(1b)* in benzene/methylene chloride in presence of air with visible light leads to formation of a π-radical *(2b)*, *(3b)*[5], which converts into a species lacking an intense Soret band [electron spectrum: 662 nm (32000), 394 (27000)] and exhibiting a pronounced diamagnetic ring current [NMR: methine H: $\delta = 9.18$ (2H), 9.27 (1H)]. These findings, the molecular ion peak at $m/e = 600$, and the absence of a carbonyl absorption in the IR spectrum, point to a porphyrin *(6b)* in which a methine group has been replaced by an oxygen atom whose unpaired electrons participate in the conjugative system of the macrocycle. Hence the structure of the octaethyl-α-hydroxyporphinatozinc(II) ion *(6b)* (iron analog, see [1, 6]).

Treatment of a methanolic solution of *(6b)* with a slight excess of potassium hydroxide leads, within a few minutes, to quantitative yields of the compound *(7b)* with biliverdin skeletal structure. With acetic anhydride this reaction was reversible. On passage of nitrogen through the solution in which the reaction *(2b)* → *(6b)* had been carried out, an amount of CO (80—90%) approximately equivalent to the amount of porphyrin could be detected in the escaping gas stream, whereas the test for CO_2 was negative *(Dräger tubes)*.

Irradiation of the nickel compound *(1c)* in the presence of oxygen under analogous conditions also led to initial forma-

(a), M = 2 H; (b), M = Zn; (c), M = Ni

tion of a π-radical (2c), (3c); however, in this case no subsequent addition of oxygen took place but rather conversion into the cyclic ether (8c) in high yield. The same cyclization reaction takes place with the zinc complex radical (2b) if irradiation is carried out in the absence of oxygen.

Metalloporphyrin compounds without substituents on the methine bridges react with oxygen and light to give formylbiliverdins, *i.e.* the methine carbon atom remains as component of a formyl group during cleavage of the macrocycle[7]. We ascribe this diverse behavior to the fact that the initial hydroperoxide of type (4), presumably formed in both cases, cannot form a dioxetane ring with the methine carbon atom in the case of the hydroxyporphyrins, and a hydroxyl radical is cleaved off instead.

We believe that the sequence (2b)→(6)→(7b) reproduces the essential degradation reactions of natural hydroxyheme and, because of the easily monitorable reaction conditions, uniform reaction course, and use of molecular oxygen as oxidizing agent, that it is a far more suitable model system than the previously used Warburg system[1, 6], which probably contains hydrogen peroxide.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The metabolism of hormones, drugs, and other substances by the gut is discussed in a paper by *K. Hartiala*. These substances can be modified by non-synthetic reactions such as oxidation, reduction, and hydrolysis or by synthetic reactions for instance by conjugation with other residues, so as to fulfill special requirements in the body. Individual sections are devoted to the activity of intestinal microorganisms, to steroid metabolism, and to the adaptability of the gut. [Metabolism of Hormones, Drugs, and Other Substances by the Gut. Physiol. Rev. *53*, 496—534 (1973); 372 references]

[Rd 673 IE—R]

The metabolism and function of vitamin D is discussed in an article by *J. L. Omdahl* and *H. F. DeLuca*. The metabolism and function of vitamin D, whose vitamin nature arose as a result of civilization, are dynamically interrelated; this complex system plays the major role in controlling the concentration of calcium and phosphate in the body. [Regulation of Vitamin D Metabolism and Function. Physiol. Rev. *53*, 327—372 (1973); 231 references]

[Rd 672 IE—R]

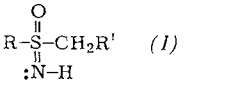
The transformation of mammalian cells by two DNA tumor viruses is accompanied, as *R. O. Brady*, *P. H. Fishman*, and *P. T. Mora* have found, by a reduction in both the content of higher ganglioside homologs and the activity of the enzyme hematoside *N*-acetylgalactoseaminyl transferase. These changes are related reversibly with changes in growth properties. With both viruses the synthesis of the enzyme is possibly suppressed by a common repressor or impaired by the special

nature of the attachment of the virus to the cell genome. Similar changes in distribution and synthesis of gangliosides have been observed in the transformation by RNA viruses. [Membrane Components and Enzymes in Virally Transformed Cells. Fed. Proc. *32*, 102—108 (1973); 34 references]

[Rd 671 IE—R]

The effects of hormones on enzyme levels in the mammalian organism is discussed in an article by *H. C. Pitot* and *M. B. Yatvin*. In their function, the hormones can be compared with the inducers and repressors of microorganisms. Very little is known, however, about the mode of action of the hormones on the enzyme content of the cell. The authors deal, *inter alia*, with the influences of amine, steroid, and polypeptide hormones. [Interrelationships of Mammalian Hormones and Enzyme Levels *in Vivo*. Physiol. Rev. *53*, 228—325 (1973); 932 references]

[Rd 674 IE—R]



The cytological chemistry and physiology of blue-green algae are surveyed in a paper by *C. P. Wolk*. After reviewing the structure and chemical composition of cell walls and outer layers, membranes, and intracellular components, the author turns his attention to metabolism: photosynthesis, respiration, and metabolism of carbon, nitrogen, and sulfur. The final section is concerned, *inter alia*, with the genetics, motility, regulation and development phenomena, and the relationship of these microorganisms with other algae. [Physiology and Cytological Chemistry of Blue-Green Algae. Bacteriol. Rev. *37*, 32—101 (1973); 839 references]

[Rd 675 IE—R]

Chemical transmission in invertebrate central nervous systems has been studied by *H. M. Gerschenfeld*. Because of their size the neurons of many invertebrates offer experimental advantages over those of vertebrate animals; the investigated processes and compounds are, in principle, similar in vertebrate animals. Central nervous systems and neuromuscular junctions, their microanatomy, their physical properties, and the transmittive nature of a few compounds are discussed on the basis of well investigated taxa. [Chemical Transmission in Invertebrate Central Nervous Systems and Neuromuscular Junctions. Physiol. Rev. *53*, 1—119 (1973); 973 references]

[Rd 676 IE—R]

Sulfoximides and their derivatives as reagents for organic syntheses are considered by *C. R. Johnson*. Sulfoximides of type *(1)* are exceptionally versatile in their reactions and are potentially asymmetric. They are suitable for the synthesis of oxiranes, aziridines, cyclopropanes, alcohols, and alkenes. Apart from the alkenes, all these compounds can be obtained in optically active form from chiral sulfoximides. [The Utilization of Sulfoximines and Derivatives as Reagents for Organic Synthesis. Accounts Chem. Res. *6*, 341—347 (1973); 31 references]

(1)

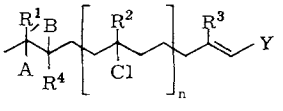
[Rd 689 IE—L]

The surface of mammalian cells has been investigated by *M. M. Burger* with the aid of plant agglutinins (lectins). In transformed cells and tumor cells growth control is interrupted; at the same time these cells are agglutinated more strongly than the corresponding starting cells by several lectins. Protease-treated cells behave similarly. During protease treatment the intracellular level of cyclic AMP decreases transiently; however, this can be counteracted and growth control restored by addition of the nucleotide. A change in cell surface, which manifests itself in increased agglutinizibility, and a phase low in cyclic AMP content can also be observed during normal mitosis. A working hypothesis is discussed, according to which growth control runs its course *via* processes on the cell surface. [Surface Changes in Transformed Cells Detected by Lectins. Fed. Proc. *32*, 91—101 (1973); 69 references]

[Rd 685 IE—R]

The enzymic dehydrogenation of lactate and ethanol has been studied by *J. J. Holbrook* and *H. Gutfreund*. Chemical, spectrophotometric and fluorometric methods jointly provide information about enzymic intermediates and their reactions. Results of the analysis of equilibrium and kinetics of partial reactions, of the participation of protons, and of experiments on chemical modification can be combined in a reaction scheme taking into consideration all viewpoints. [Approaches to the Study of Enzyme Mechanisms. Lactate Dehydrogenase. FEBS Lett. *31*, 157—169 (1973); 76 references]

[Rd 679 IE—R]



The nature of antigen receptors on the surfaces of lymphocytes is analyzed by *E. R. Unanue, H. D. Engers*, and *M. J. Karnovsky*. Most B cells (cells originating from bone marrow) carry on their surface on average 10^5 randomly distributed immunoglobulin molecules which are responsible for binding of the antigen. It is still unclear whether T cells (cells derived from the thymus) contain immunoglobulin molecules. They could not be detected in most of the T cells investigated. The thymus does contain a few cells with immunoglobulin on the surface; however, many of these do not react with antibodies against the alloantigen Θ. [Antigen Receptors on Lymphocytes. Fed. Proc. *32*, 44—47 (1973); 36 references]

[Rd 683 IE—R]

Patents

Abstracts of selected "Deutsche Offenlegungsschriften" (DOS), *i. e.* provisionally published specifications as filed with the German Patent Office

Unsaturated chlorine compounds *(1)* are suitable for the control of pests, particularly of invertebrates; they act by intervention in the hormone system of the animal organism. In insects, for example, the transformation to the imago, the laying of viable eggs, and the development of normal laid eggs are disturbed. They are practically non-toxic to vertebrates. The

(1)

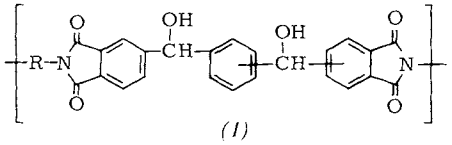
compounds are readily broken down, and there is consequently no danger of cumulation. [DOS 2213177; F. Hoffmann-LaRoche & Co. AG, Basel]

[PR 140 IE—N]

Cobalt(II) complexes *(1)* or *(2)* are used as catalysts for aldol condensations. The complexes *(1)* ($n = 3$) can be prepared from cobalt(II) bipyridine complexes and hydrazines. Tris(hydrazinium chloride) complexes *(2)* are obtained from cobalt

$[Co(RNHNH_2)_n]X_2$ *(1)* $[Co(N_2H_4 \cdot HX)_3]X_2$ *(2)*

R = H, alkyl, aralkyl, aryl or haloaryl; X = halogen; $n = 2, 3$



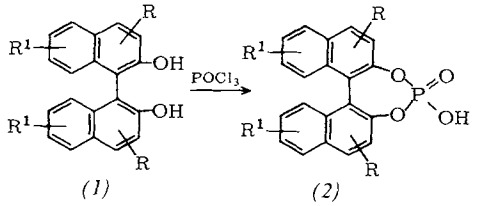
halide, hydroxylammonium halide, and a hydrazone. They are very readily soluble in water, and can be used as homogeneous catalysts in aqueous media. The complexes exhibit compound-specific properties. For example, cyclohexanone condenses quantitatively in the presence of $[Co(N_2H_4)_2]Br_2$ to form 2-(1-cyclohexenyl)cyclohexanone, whereas the polycondensation is promoted with the cobalt(II) chloride analog. [DOS 2166039; Cincinnati Milacron Chemicals, Reading (USA)]

[PR 127 IE—V]

As binders for the electric powder-spraying process, use is made of curable polymer powders of 1) 25—60 wt.% of styrene, α-methylstyrene, α-chlorostyrene, *p*-chlorostyrene, *p*-*tert*-butylstyrene, or mixtures of these; 2) 30—65 wt.% of acrylic esters with alcohol residues (C_{1-12}) or methacrylic esters with alcohol residues (C_{2-12}) or mixtures of these; 3) 0—25 wt.% of methyl methacrylate; 4) 4—20 wt.% of glycidyl (meth)acrylate; 5) 3—15 wt.% of (meth)acrylic, itaconic, maleic, or fumaric acid with an average molecular weight of 3000—20000. The polymer powder is still capable of running at a temperature of at least 50 °C, and has coalescence temperatures of 80 to 120 °C. This ensures smooth coalescence of the powder on the substrate to be coated. [DOS 2122313; Bayer AG, Leverkusen]

[PR 137 IE—Ö]

Heat-resistant polyimide or polyamide imide films are coated, in accordance with the invention, on at least one side with a thin adhesive layer of polyimides having the repeat grouping *(1)*. R is a bifunctional aliphatic, aromatic, carbocyclic or heterocyclic residue. The polyimide layer may contain a polar



(1)

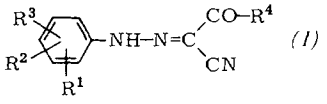
solvent. The adhesive films can be used for the bonding of printed circuits and for the sheathing of electric conductors, as well as for the production of composite materials. The bonding of the films to various supports can be carried out between 150 and 350 °C under a pressure of 0.01 to 1 kg/cm². [DOS 2221136, Rhône-Poulenc S. A., Paris]

[PR 144 IE—E]

Optical isomers of binaphthylylenephosphoric acids *(2)* and hydrogenated derivatives are suitable for the separation of

(1) *(2)*

R, R^1_4 = H, F, Cl, Br, alkyl (C_1—C_8), NO_2



optically active organic bases into the optical antipodes and for the separation of *cis-trans* isomeric bases. They are prepared by reaction of binaphthyl-2,2'-diols *(1)* and phosphorus oxide chloride with subsequent resolution. [DOS 2212660; Richardson-Merrell, S.p.A., Naples]

[PR 157 IE—K]

For continuous perfluorination, perchlorinated compounds with trichloromethyl or pentachloroethyl groups and functional groups are allowed to react in the vapor phase with anhydrous hydrogen fluoride. Perchlorinated compounds containing further functional groups are compounds of this type that contain at least one ether, aldehyde, ketone, acyl chloride, or nitrile group, *etc.*, and that have no hydrogen that can be substituted by a chlorine atom. The reactants are led, under an absolute pressure of 1—4 bars, through a static catalyst bed consisting of three successive zones, in which the temperature increases by at least 10 °C between each pair of zones (first zone: 220—250 °C; second zone: 250—275 °C; third zone: 275—350 °C). All the chlorine atoms have been replaced by fluorine atoms *e.g.* in hexachloroacetone, trichloroacetyl chloride, octachlorobutanone, and trichloroacetaldehyde. [DOS 2221844; Rhône-Progil, Paris]

[PR 152 IE—J]

Hydrazones *(1)* are valuable insecticides, which are suitable *e.g.* for the control of species of Lepidoptera and mosquitoes, particularly in the larval form. They can be prepared by

(1)

R^1 = halogen, alkyl (C_1—C_4), alkoxy (C_1—C_4), CN, NO_2, CF_3, phenylazo, *p*-chlorophenoxy

R^2 = H, halogen, CF_3, alkyl (C_1—C_4)

R^3 = H, halogen

R^4 = halogen, α-naphthyl, 2-furyl, 2-thienyl

diazotization of anilines and reaction of the resulting diazonium salt with an aroylacetonitrile. [DOS 2222147; American Cyanamid Co. Wayne, N. J.]

[PR 141 IE—N]

The vulcanization of synthetic rubbers with high-energy radiation has not in the past led to products comparable with sulfur-vulcanized rubbers, since it was necessary to use excessively high radiation doses, which lead to overcuring and to side reactions, and are also uneconomical. By choice of certain synthetic rubbers and adjustment of the vulcanization conditions, qualitatively satisfactory vulcanized products can now be obtained by irradiation with doses of 0.5 to 7 megarad. The rubbers chosen are diolefin polymers and copolymers with weight average molecular weights of 50000 to 900000 and a molecular weight distribution of 1.01 to 30. Instructions are given for the distribution of the monomer units as a function of their contribution to the crosslinking. [DOS 2226106; The Firestone Tire & Rubber Co., Akron]

[PR 124 IE—S]

Biodegradable emulsifiers for polychloroprene. Octyl sulfate salts *(1)*, preferably with linear octyl chains, can be used as biodegradable emulsifiers for polychloroprene. The aqueous emulsion of the monomer material is prepared in the usual manner. *(1)* may be added either alone or in combination with known emulsifiers during any stage of the polymerization. The only condition is that it must be present at least during the acidification of the latex before coagulation. Approximately 0.05 to 2.0 parts by weight of *(1)* per 100 parts by weight of polymerizable monomer are generally used. Comonomers may also be used in addition to chloroprene if the content of comonomer is not greater than 25 mole %. [DOS 2210957, Petro-Tex Chemical Corp., Houston]

[PR 145 IE—E]

The ammonoxidation of olefins, particularly isobutylene, to form β-olefinic nitriles (methacrylonitrile) is carried out in the presence of a catalyst whose active component consists of 1—15 wt.% of MoO_3, 25—50 wt.% of Fe_2O_3, and 45—70 wt.% of TeO_3, and which is applied to a support such as kaolin, alumina, kieselgur, or silica. The reaction is carried out at 300—600 °C (preferably at 350—500 °C) in the presence of a static-bed catalyst or in a fluidized bed. The contact time with the catalyst is 0.5—15 s; the yields are satisfactory. [DOS 2210395; Société Nationale des Petroles d'Aquitaine, Courbevoie]

[PR 146 IE—J]

The selective isomerization of long-chain 1-olefins *(1)* to 2-olefins is carried out by bringing the 1-olefin into contact with a calcium metal/aluminosilicate/molecular sieve catalyst coated with a monoatomic layer of sodium. The temperature should be between the freezing point of the 1-olefin and 150 °C. About 70% (or more) of the 1-olefins can be isomerized in 10—15 min *e.g.* at room temperature and at atmospheric pressure. Example: conversion of 1-hexadecene (25 °C, 10 min)

$$CH_2=CH-CHRR^1 \qquad (1)$$

R^1 = *n*-alkyl
R^2 = any substituent that does not react with Na
Total number of C atoms: 6—25

into 88% of 2-hexadecene and 8% of 3-hexadecene; 4% of the starting material did not react. [DOS 2209379; Akzona Inc., Asheville]

[PR 147 IE—J]

BOOK REVIEWS

Electrochemistry. Vol. 2. Specialist Periodical Reports. By *G. J. Hills.* The Chemical Society, London 1972. 1st ed., viii, 299 pp., numerous formulae, bound £ 7

This second volume of the series presents a survey of the publications that appeared in 1970 in important areas of electrochemistry. The remarkable intensity of electrochemical reseach can be seen from the size of the book (despite a concise treatment of the individual facts) and from the 700 literature references from 1970 alone. Competent commentators deal with the synthetic aspects of organic electrochemistry (focal points: nucleophilic substitutions on aromatic compounds and olefins, reductive coupling and bond fissure, stereospecific electrode reactions), investigations on salt melts, and reactions at solid metal electrodes, as well as with the further investigation of the double layers at the phase boundaries between electrode and electrolyte. Recent developments in ion-specific membranes are presented in another chapter.

The presentation of the book and the printing, which is surprisingly careful in view of the quick publication are excellent. If the tempo and the quality can be maintained, the later volumes will be welcomed by grateful readers who wish to keep abreast of the general situation in electrochemistry.

Herbert Lehmkuhl [NB 167 IE]

Analytical Chemistry of Phosphorus Compounds. Edited by *M. Halmann.* John Wiley & Sons, Inc., New York—London 1972. 1st ed., x, 850 pp., numerous figures and tables, bound £ 16.80.

Phosphorus occupies a central position in both the animate and the inanimate worlds. The uses of phosphorus compounds in many areas of research and of life are correspondingly numerous. An essential condition for the development of phosphorus chemistry was the availability of efficient analytical methods.

Until now, the original publications and analytical findings have been scattered chaotically in the chemical literature. Workers in the phosphorus field will therefore welcome this compilation of the most important methods of separation, identification, and determination by a team of outstanding experts under the leadership of *M. Halmann.* Both the classical "wet methods" and the possibilities of modern spectroscopic techniques are discussed clearly and with reference to the literature. However, the specialist will be disappointed by the occasional repetitions and by the omission of practical hints and methods that have proved to be essential in the laboratory. It should be possible to eliminate these gaps in the second edition without upsetting the excellent arrangement of the book.

As an unselfish assistant to the advancing chemist, analysis has repeatedly paved the way for new knowledge. The publication of this monograph will therefore please workers in the phosphorus field.

Leopold Horner [NB 175 IE]

Ultracentrifugation of Macromolecules. By *J. W. Williams.* Academic Press, New York—London 1972. 1st ed., xvii, 118 pp., bound $ 9.50.

The present book has resulted from the copying of seminar lectures during the author's visiting professorship at the University of Uppsala.

It deals in great detail with the thermodynamics of ideal and non-ideal solutions and of chemical equilibrium under the influence of high gravitational accelerations. The various ways of taking the average of the molecular weights for polydisperse systems are also discussed. In the Appendix the reader finds an introduction to the theory of ultracentrifugation, and several solutions of the Lamm differential equation are discussed. The influence of polydispersity on the boundary layer in sedimentation velocity experiments is then dealt with.

The book contains evaluations and interpretations of experimental data on the molecular weights and sedimentation coefficients of synthetic macromolecules (polystyrene, dextran) and of natural macromolecules (β-lactoglobulin B, lysozyme, chromatrypsinogen A). The section on self-association in protein solutions can be strongly recommended.

There is unfortunately nothing in the book about the theory and possible applications of isopyknic ultracentrifugation as an equilibrium method, or about the band separation technique for sedimentation velocity experiments with the associated advantages (no Johnson-Ogston effect). Experimental details such as the various optical systems and the evaluation formulas are also omitted.

On the whole the book is of interest only to the analytical investigator, since there is no mention anywhere of modern techniques of preparative ultracentrifugation.

Paul Schmider [NB 177 IE]

Vibrational Spectroscopy of Solids. By *P. M. A. Sherwood.* Cambridge University Press, Cambridge 1972. 1st ed., xi, 254 pp., numerous figures, bound £ 5.90.

IR and Raman spectra of crystals reflect some of the properties of the structural elements, their interactions, as well as the whole lattice. In particular, the spectra recorded using single crystals with polarized radiation enable one to draw conclusions regarding the arrangement of the lattice units and their symmetry. Until now, the information necessary for the interpretation of these spectra has not been very widely known among chemists, and crystal spectra were often interpreted in the same way as the spectra of gases. Several authors have recently written accounts of this field for chemists. The author of the present work first points out the typical and possible differences in the spectra of molecules in the gas phase and in the solid state. He then discusses the dynamic properties of the crystal and their quantization, as well as the application of group theory. Chapters on the interaction of the radiation with the crystal and on second order effects then follow. Finally, the excitations that can be observed in addition to the vibrational transitions are discussed: excitons, magnons, and plasmons.

The author intentionally applies the theory only to very simple lattice units. Since difficulties arise in the application of the theory to more complicated molecules, it would have been useful to include spectra of this nature and to demonstrate their interpretation. A rather disturbing feature is the needless introduction of "Unit Cell Analysis" instead of "Factor Group Analysis". On the whole the text is very readable and comprehensible, and can be strongly recommended as an introduction.

Bernhard Schrader [NB 179 IE]

Quantenbiochemie für Chemiker und Biologen (Quantum Biochemistry for Chemists and Biologists). By *J. Ladik.* Ferdinand Enke Verlag, Stuttgart 1972. 1st ed., 252 pp., 111 figures and 11 tables, bound DM 19.80.

Quantum mechanics reduces not only the problems of chemistry (as stressed by *Dirac* in 1929) but also those of molecular biology to the solution of mathematical equations; the difference lies mainly in the complexity of biological systems. In this book, *Ladik* presents a survey of the biochemical problems that can be tackled with the aid of quantum-mechanical calculations and the nature of the results that can be obtained at the present time. After an introduction to the principles of quantum mechanics, without presupposing any existing knowledge of physics, chemistry, or biology, the author discusses in particular the relationships between the electronic structure and the biological properties of DNA; chapters on proteins, carcinogenic substances, and porphyrins then follow. A final look ahead outlines the possibilities of a molecular genetics and a molecular gerontology, as well as of the quantum-mechanical treatment of pharmaceutical problems.

The book seems excellently suited for arousing an interest in the connections between the current problems of molecular biology and the physical principles of quantum mechanics, and for providing a link between the languages of the biochemist and of the quantum chemist. In this light it does not seem an excessively serious fault that the selection of the literature is occasionally rather one-sided or that there are a few shortcomings in the German translation.

The book was not written for the specialist, but it can be recommended as readable and stimulating to all those who are interested in current questions of molecular biology outside their own field of work.

Martin Klessinger [NB 183 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Ligandenfeldtheorie. By *P. Schuster.* Vol. 19 of the series "Chemische Taschenbücher". Edited by *W. Foerst* and *H. Grünewald.* Verlag Chemie, Weinheim 1973. ix, 192 pp., stitched DM 28.—.

Contents: Elektronenzustände; Elektronenwechselwirkung; Anwendung der Ligandenfeldtheorie auf Grundzustände von Komplexionen; Spin-Bahn-Kopplung; Spektren von Übergangsmetallkomplexionen im Rahmen der Ligandenfeldtheorie; Ligandenfeldtheorie im Rahmen anderer quantenchemischer Methoden.

Principles of Reaction Kinetics. By *P. G. Ashmore.* 2nd Edit., No. 9 of the series "Monographs for Teachers" The Chemical Society, London 1973. 78 pp., stitched 80 p.

Contents: Introductory Survey; Rates and Rate Laws for Elementary Reactions; Rate Laws for Some Complex Reactions; Chain Reactions; Résumé of Aims and Principles.

Chemical Instrumentation. A Systematic Approach to Instrumental Analysis. By *H. A. Strobel.* Addison-Wesley Publishing Company, Reading/USA 1973. 2nd Edit. xxii, 903 pp., bound $ 22.50.

Contents: Measurement and Instrumentation; Electronics; Optics; Spectrometric Methods; Electroanalytical Methods.

Progress in Bioorganic Chemistry, Vol. 2. Edited by *E. T. Kaiser* and *F. J. Kézdy.* John Wiley & Sons, New York—London 1973. xiii, 257 pp., bound £ 8.25

Contents: Reaction Kinetics in the Presence of Micelle-Forming Surfactants; The Apolar Bond; Mechanisms of Action of Folic Acid Cofactors; Catalytic Activity of Pepsin.

Eléments de Chimie Minérale. By *H. Wahl.* Masson et Cie., Editeurs, Paris 1973. xi, 174 pp., stitched 52 F

Contents: L'Air; L'Eau; Oxygène; Hydrogène Famille des Halogènes; Famille de l'Oxygène; Famille de l'Azote; Famille du Carbone; Famille du Bore.

Condensed Pyridazines Including Cinnolines and Phthalazines. Edited by *R. N. Castle.* Vol. 27 of the series "The Chemistry of Heterocyclic Compounds". Edited by *A. Weissberger* and *E. C. Taylor.* John Wiley & Sons, New York—London 1973. xii, 1124 pp., bound *ca.* £ 33.45.

Contents: Cinnolines; Phthalazines; Azolo- and Azinopyridazines; Oxa and Thia Analogs.

Electronen und Chemische Bindung. By *H. B. Gray.* de Gruyter Berlin—New York 1973. xi, 194 pp., stitched DM 24.—.

Contents: Elektronen in Atomen; Zweiatomige Moleküle; Lineare dreiatomige Moleküle; Trigonal-planare Moleküle; Tetraedrische Moleküle; Trigonal-pyramidale Moleküle; Gewinkelte dreiatomige Moleküle; Die Bindung in organischen Molekülen; Bindungen unter Beteiligung von d-Valenzorbitalen.

Gas and Liquid Chromatography Abstracts 1972. Edited by *C. E. H. Knapman* and *R. J. Maggs*. Applied Science Publishers Ltd. Barking, for the Institute of Petroleum, London 1973. xviii, 230, 21 pp., bound £ 8.00.

Physikalische Chemie. By *W. J. Moore*. de Gruyter, Berlin—New York 1973. Revised and expanded 4th Edith. xvi, 1134 pp., bound DM 78.—.

Selected Molecular Rearrangements. By *T. S. Stevens* and *W. E. Watts*. Van Nostrand Reinhold Company, London 1973. x, 212 pp., bound £ 5.50.

Contents: Nucleophilic Rearrangements; 1,2-Electrophilic Rearrangements; Alkali-Induced Rearrangements; Pericyclic Rearrangements; Aromatic Rearrangements.

Protein-Protein Interactions. Edited by *R. Jaenicke* and *E. Helmreich*. 23rd Colloquium of the Gesellschaft für Biologische Chemie, April 13—15, 1972 at Mosbach/Baden. Springer, Berlin—Heidelberg—New York 1972. viii, 646 pp., bound DM 78.—.

Contents: Quaternary Structure of Proteins; Approaches for Determining Protein Complexes; Heterologous Protein Interactions; Muscle; Multienzyme Complexes; Antigen-Antibody Interactions; Self-Assembly; Intercellular Interactions.

Progress in Surface and Membrane Science, Vol. 6. Edited by *J. F. Danielli, M. D. Rosenberg*, and *D. A. Cadenhead*. Academic Press, New York—London 1973. xiii, 280 pp., bound $ 22.50.

Contents: The Silver Halide Surface; The Mercury-Solution Interface; Contact-Angle Hysteresis; Ion Binding and Ion Transport; Cytomembranes; Interactions of Blood Proteins with Polymeric and Artificial Surfaces.

Fast Ion Transport in Solids. Solid State Batteries and Devices. Edited by *W. van Gool*. North-Hollans Publishing Company, Amsterdam 1973. xvi, 728 pp., bound Dfl. 100.00/$ 35.10.—Proceedings of the NATO Sponsored Advanced Study Institute on Fast Ion Transport in Solids, Solid State Batteries and Devices, Belgirate, Italy, September 5—15, 1972.

Hard and Soft Acids and Bases. Edited by *R. G. Pearson*. From the series "Benchmark Papers in Inorganic Chemistry". Edited by *H. H. Sisler*. Dowden, Hutchinson & Ross, Stroudsburg/USA 1973. xiii, 480 pp., bound $ 23.00.

Polymer Transition Temperature Data Sheets. Compiled by *W. A. Lee* and *R. A. Rutherford*. Rubber and Plastics Research Association of Great Britan, Shawbury Shrewsbury 1973. Loose-leaf book £ 10.00.

Addition and Elimination Reactions of Aliphatic Compounds. Vol. 9 of the series "Comprehensive Chemical Kinetics". Edited by *C. H. Bamford* and *C. F. H. Tipper*. Elsevier Amsterdam 1973. xiii, 515 pp., bound Dfl. 160.00/$ 56.10.

Contents: Electrophilic Additions to Unsaturated Systems; Addition of Unsaturated Compounds to Each Other; Elimination Reactions; Carbene and Carbenoid Formation and Reactions; Kinetics of Alkene Isomerizations.

Reviews in Macromolecular Chemistry, Vol. 9. Edited by *G. B. Butler, K. F. O'Driscoll*, and *M. Shen*. Marcel Dekker, New York 1973. v, 369 pp., bound $ 21.50.

Contents: Mathematical Modeling of Polymerization Reactions; Mechanical Properties of Polymers; Anionic Cyclopolymerization; Thermodynamics of Equilibrium Polymerization.

Applied Spectroscopy Reviews, Vol. 6. Edited by *E. G. Brame, Jr.*, Marcel Dekker, New York 1973. xiv, 375 pp., bound $ 21.50.

Contents: Spectra of Biopolymers; Infrared Fourier Transform Spectroscopy; Neutron Scattering and Vibrational Spectra of Molecular Crystals; Diagnostics of High-Temperature, High Density Plasma by Radiation Analysis; Spectroscopy of Liquid Crystals; Metals Analysis by Emission Spectroscopy.

Determination of Organic Structures by Physical Methods, Vol. 5. Edited by *F. C. Nachod* and *J. J. Zacherman*. Academic Press, New York—London 1973. xv, 367 pp., bound $ 26.00.

Contents: Electron Diffraction; Spin Saturation Labeling; Nuclear Polarization; Ion Cyclotron Resonance Spectroscopy; Nuclear Quadrupole Resonance; Mössbauer Spectra of Organometallics; Automated Chemical Structure Analysis Systems; NQR Applications in Organic and Metalloorganic Chemistry.

The Total Synthesis of Natural Products, Vol. 1. Edited by *J. A. Simon*. Wiley-Interscience, New York—London 1973. ix, 603 pp., bound £ 12.50.

Results and Problems of *O*-Glycoside Synthesis

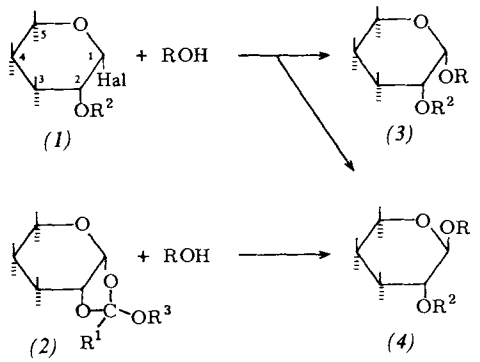
By Günter Wulff and Gerhard Röhle[*]

Considerable problems attend the synthesis of biologically important natural products whose carbohydrate components display a greater or lesser degree of complexity. The present progress report surveys recent developments in the formation of *O*-glycosidic bonds starting from 1-halo sugars and from sugar 1,2-orthoesters. Particular emphasis is placed on attempts to reach a better understanding of the steric course of glycosylation reactions on the basis of mechanistic considerations. Studies on the silver-salt dependence of the Koenigs-Knorr synthesis led to improvements in preparative applications and to new concepts concerning the reaction course. The introduction of sugar 1,2-orthoesters as glycosylation components has greatly enriched our preparative armoury for the synthesis of *trans* glycosides. Remarkable progress has also been made in the synthesis of *cis* glycosides, in part by exploiting novel neighboring group effects.

1. Introduction

In recent years a steadily increasing research effort has been centered on the production of glycosides, and particularly of oligo- and polysaccharides. Crucial impetus has come from the increasing interest shown by biochemists in these substances. The studies were directed above all to the glycoproteins, the immunoactive oligo- and polysaccharide moieties of bacterial cell walls and red blood cells, the glycolipids (*e.g.* cerebrosides and gangliosides), and antibiotics with carbohydrate constituents. Plant glycosides have also received due attention (*e.g.* cardiac glycosides, saponins, flavonoid glycosides). All these studies set a highly promising development in motion.

Whereas the methodological prerequisites are nowadays fulfilled for the synthesis of more complex compounds belonging to the class of oligo- and polypeptides, which were long at the forefront of scientific interest, many problems still await solution for the systematic construction of fairly long sugar sequences. In contrast to the peptides, not only can the sequence of the basic units vary but so can the site of linkage of two chain members and the configuration at the anomeric C atom. The diverse protecting groups required for such syntheses are already known in large numbers; however, the main obstacle lies in formation of the glycosidic linkage. The yields attained are usually rather modest, and steric control is difficult to achieve.



This report will therefore deal essentially with the problems of glycosidic bond formation *per se* from a methodological standpoint. We shall confine our attention exclusively to syntheses starting from 1-halo sugars (1-haloses) [*e.g. (1)*][***] and 1,2-orthoesters [*e.g. (2)*][***] which serve mainly for the preparation of *cis*- *(3)* and *trans* glycosides *(4)* of complex alcohols.

Methods for the preparation of glycosides of simple alcohols, *e.g.* alcoholysis of free sugars (Fischer synthesis)[1] and more specialized techniques starting from unsaturated sugars[1,2], 1-hydroxy sugars[3], 1-*O*-acyl sugars[1,4], sugar anhydrides[1,5], sugar dithioacetals[6,7], sugar thioglycosides[7a], and earlier studies will not be considered. Many of them are cited in the review literature[1,6–9]. Details of oligosaccharide[10–12]

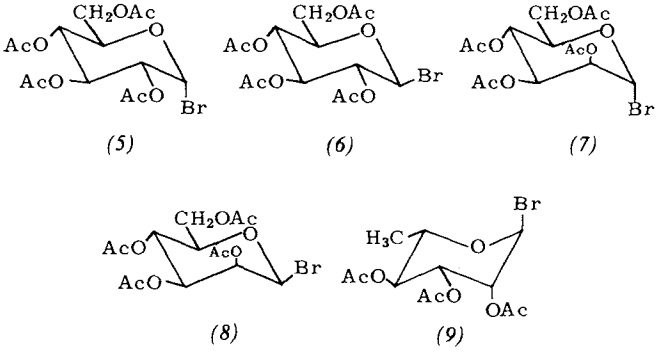
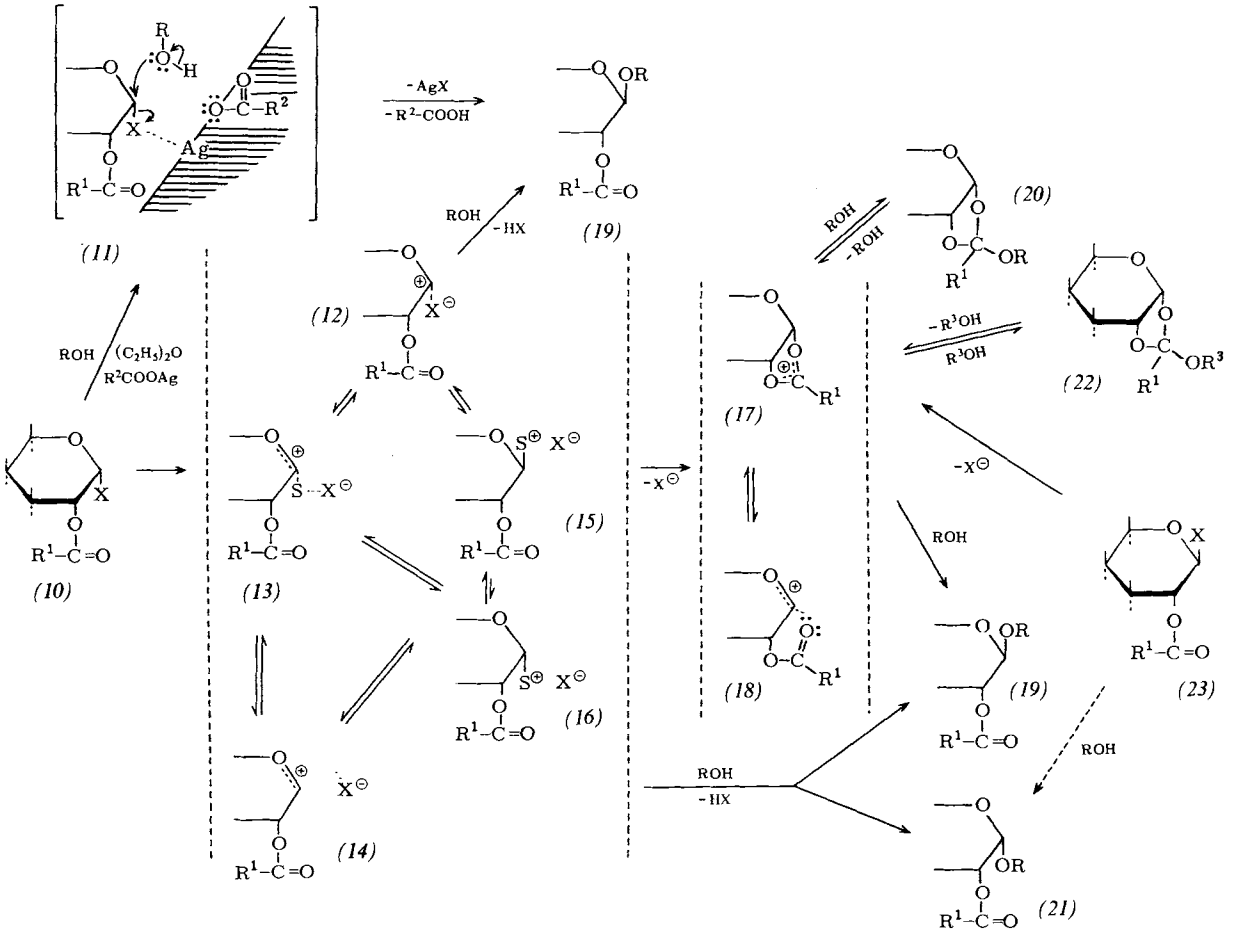
and polysaccharide syntheses[5, 13] will be found in the pertinent references.



2. Possible Reaction Routes

2.1. General



We shall begin with an attempt to classify the numerous glycosylation reactions starting from 1-haloses or orthoesters according to the probable mechanism. Only after having accrued this information can we explain the often surprising steric course of the reaction and the by-products formed, or recognize possibilities of increasing yields. The more preparative aspects will be considered in Sections 3, 4, 5, and 6.

Unfortunately only fragmentary data concerning the reaction mechanism of glycosylation reactions[14-16] have so far become available; only the solvolysis of 1-halo sugars has been studied in detail[16]. The schemes appearing in this report and the classification of reaction types are therefore based merely on a combination of literature data and our own results, and categorize some reactions preferentially according to their steric course. None of these mechanisms can be regarded as proved in a strict sense; the classification should consequently be viewed as a basis for discussion.

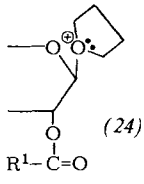
The acylated 1-halo sugars widely used in glycoside syntheses are usually obtained as the thermodynamically more stable form having an axial halogen on C-1. For the D-sugars existing mainly in the C-1 conformation [(5)—(8)] and the L-sugars occurring predominantly in the 1-C conformation [e.g. (9)], these will be the α-halides, e.g. 2,3,4,6-tetra-*O*-acetyl-α-D-glucosyl bromide (5) and -mannosyl bromide (7), as well as 2,3,4-tri-*O*-acetyl-α-L-rhamnosyl bromide (9)[17, 18].

(5) (6) (7) (8) (9)

Scheme 1. Reaction pathways of peracylated 1,2-*cis* (10) and 1,2-*trans* haloses (23) and 1,2-orthoesters (22) (S = solvent).

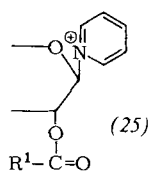
The corresponding β-halides having equatorial halogen [*e.g.* *(6)* and *(8)*] can only be prepared in kinetically controlled reactions; they are rather unstable and much more reactive than the α-halides. This is attributed to the anomeric effect, *i.e.* a destabilization arising from electrostatic interaction between the parallel p orbitals of oxygen and halogen[18,19]. Practically only chlorides and bromides are employed in glycoside syntheses.

The steric course of the glycosylation reaction of peracylated haloses is, however, determined not by the axial or equatorial orientation of the halogen but by its interaction with the neighboring substituent on C-2 of the halose. Glycosylation with the 1,2-*cis* haloses *(5)* and *(8)* generally proceeds with inversion at C-1 to give 1,2-*trans* glycosides of type *(4)*, whereas the 1,2-*trans* haloses *(6)*, *(7)*, and *(9)* afford 1,2-orthoesters under certain conditions but mainly 1,2-*trans* glycosides under others[15,20]. Hence 1,2-*cis* glycosides [type *(3)*] are relatively difficultly accessible from peracylated haloses. They generally have to be prepared by special techniques (see Sections 2.3 and 4).



2.2. The Key Role of Acyloxonium Ions

The possible reaction pathways of peracylated 1,2-*cis* *(10)* and 1,2-*trans* haloses *(23)* and of 1,2-orthoesters *(22)* are depicted in Scheme 1[*].



Preferential formation of *trans* glycosides *(19)* from *cis* haloses *(10)* with Walden inversion would be most readily explained by assuming an S_N2 mechanism[20]. However, available evidence indicates this mode to occur only rarely in glycosylation reactions. Our own studies show glycosylations in the presence of insoluble silver compounds (*e.g.* Ag_2CO_3, Ag_2O, silver 4-hydroxyvalerate) in certain solvents (particularly diethyl ether and probably also chloroform with iodine) at low temperatures to constitute a special case. Here the alcohol definitely participates in the rate-determining step of the reaction[21,22]. The halose adsorbed onto the silver compound undergoes a concerted reaction with the alcohol [cf. *(11)*]. This type of reaction requires solid silver compounds having a particular structure and solvents contributing to transition-state stabilization (see Section 3.1)[**]. The course of glycosylation in the presence of Ag_2CO_3 or Ag_2O in benzene at the boiling temperature is still unclear (modification due to *Meystre* and *Miescher*[26]). A characteristic feature shared by all reactions mentioned so far is that they proceed best in solvents of relatively low polarity.

Owing to the ready formation of the resonance-stabilized glycosyl cation [*(12)*—*(14)*] an S_N1 mechanism[***] has to be assumed for the solvolysis of haloses[16] and for glycosylation in the presence of soluble catalysts or acid acceptors[27–29]. It should be noted that bases or metal compounds added are not only acid acceptors; they can considerably enhance the rate of halogen release by a "push-pull" mechanism[30,31] in certain cases in cooperation with the solvent.

By analogy with the solvolysis schemes drawn up by *Winstein et al.*[32] and *Schleyer et al.*[24], the halose could react *via* an intimate ion pair *(12)*, a solvent-separated ion pair *(13)*, or a free ion *(14)*, depending upon the catalyst and solvent. In strongly nucleophilic solvents (ether, pyridine, *etc.*) the occurrence of oxonium [*e.g.* *(24)*] or ammonium ions [*e.g.* *(25)*] of type *(15)* with solvent participation can be expected.

(24)

(25)

That only the *trans* glycosides *(19)* are obtained in spite of the S_N1 mechanism could be explained in terms of a direct reaction between the alcohol and the intimate ion pair *(12)*[16]. Such ion pairs are known to react with nucleophiles with inversion[23,24,32,33]. However, an explanation of this kind is probably of restricted validity for 1-chloro sugars[34] since bromo haloses bearing nonparticipating substituents on C-2 have been shown to furnish mixtures of *cis*- and *trans* glycosides[35,36]. Accordingly, a neighboring group effect involving the 2-acyloxy group and C-1 must be responsible for the stereospecifity. This effect could consist in an interaction of the p orbitals of the carbonyl oxygen with the cation [as in *(18)*] or in formation of an acyloxonium ion *(17)*. Since no orthoesters *(20)* could be detected during the initial stages of the reaction[37] solvolyses appear to proceed *via* *(18)* owing to the large excess of nucleophile. In contrast, the usual glycosylation reactions with soluble catalysts should generally proceed *via* the acyloxonium ion *(17)*.

Studies on acyloxonium ions in general[38] and on the mode of reaction of transient acyloxonium ions *(17)* formed from sugar 1,2-orthoesters[39] have revealed that the ambidentate cations can, in principle, react in two different ways with an alcohol. Thus two possible reaction paths are open to *(17)*.

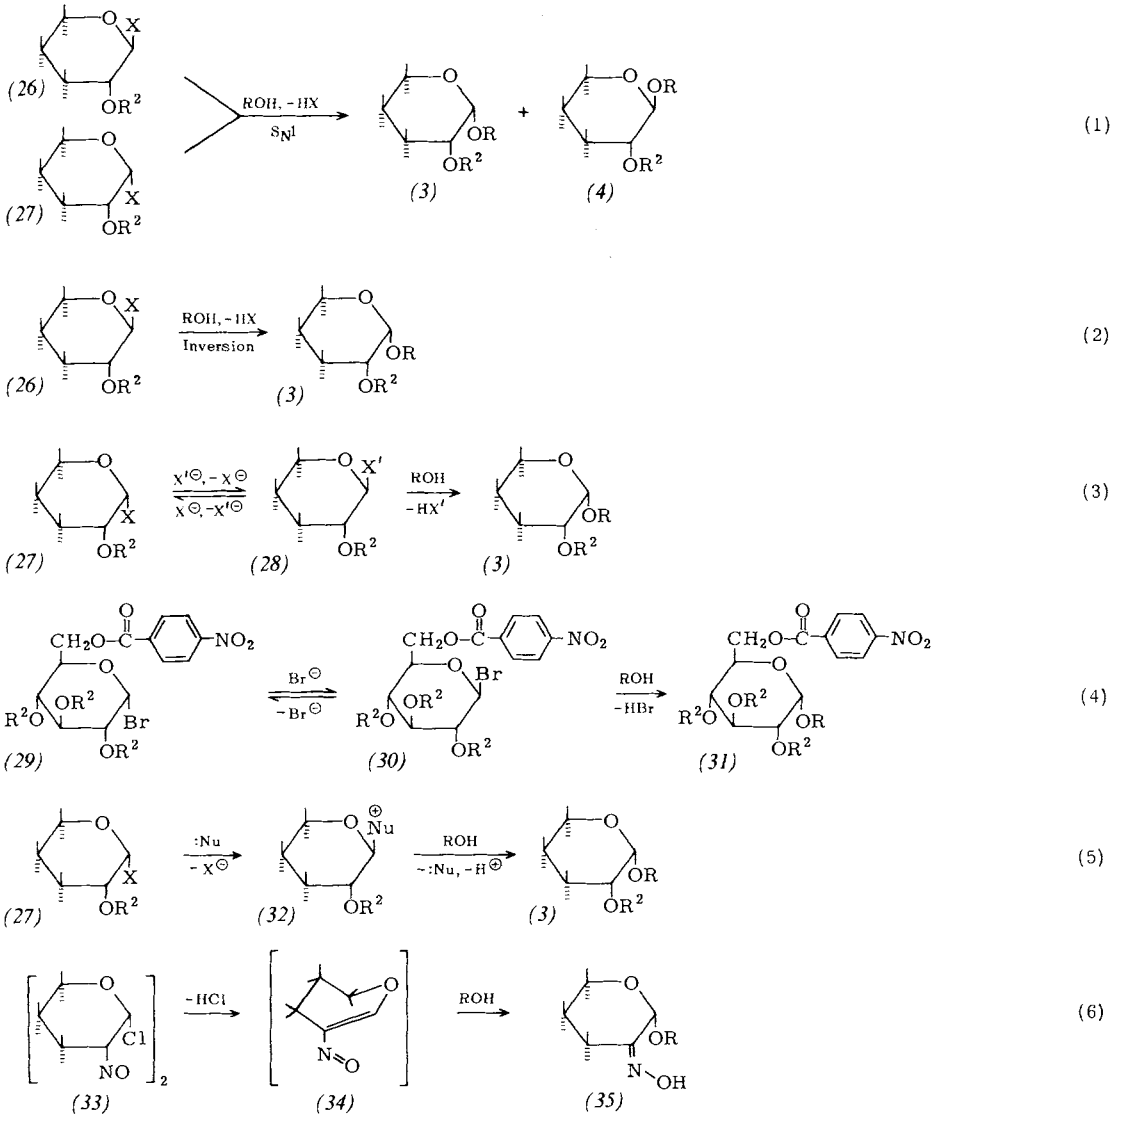
1) In neutral or alkaline solution a kinetically controlled reaction yields predominantly the orthoester *(20)*. With silver salicylate in tetrahydrofuran, for example this reaction is almost quantitative[40,41]. The acyloxonium ion *(17)*, and hence the orthoester *(20)*, are apparently formed particularly readily *via* an intermediate oxonium ion *(24)* of type *(15)*[42,43]. Orthoesters *(20)* can also be obtained from *cis* haloses in collidine[44] or in triethylamine[45], as well as in ethyl acetate on addition of $PbCO_3$[46]. While affording a simple preparation of orthoesters, this type of reaction frequently occurs as an undesired competing process in glycoside syntheses. This also applies to glycosylations in the presence of insoluble silver compounds. Pronounced orthoester formation is observed especially with sterically hindered alcohols whose concerted reaction to give the glycoside is too slow[40].

2) If the positive charge on the acyloxonium ion *(17)* is blocked by the anions of catalysts such as $AgClO_4$, pyridinium perchlorate, or soluble mercury salts in suitable solvents, the alcohol can attack at C-1 in a thermodynamically controlled

[*] A completely analogous scheme could be drawn for the C-2 epimeric sugars (*e.g.* D-mannose). In this case the *cis* haloses happen to be the more reactive compounds insofar as the halogen occupies an equatorial position.

[**] Here and in the following the traditional classification of mechanisms as S_N1 and S_N2 has been adopted [23, 24]. The occurrence of ion pairs in S_N2-type reactions as postulated by *Sneen* [25] has been disregarded. Reactions are formulated as proceeding *via* ion pairs only when their formation determines the rate of reaction.

[***] Solvolysis can also assume S_N2 character in nonpolar solvents with strong nucleophiles [16].



reaction yielding *trans* glycosides *(19)* stereospecifically. Elevated reaction temperatures favor formation of *(19)*[*].

The course of glycosylation described above is crucially based on the occurrence of acyloxonium ions. Although no definite proof for their formation has been obtained, the known reactions[38,39] of such ions provide a good explanation of the reaction course. Further evidence for the intermediacy of acyloxonium ions came from the occurrence of orthoesters, of orthoester-type by-products[48–50], and of by-products arising from orthoesters (or acyloxonium ions)[49,50], as well as the isolation of acyloxonium salts on reaction of *cis* haloses with $AgBF_4$[47]. Acyloxonium ions could be formed especially readily from *(14)* and *(15)* by nucleophilic attack of the carbonyl group on C-1, particularly since the acyloxonium ion is more stable than the glycosyl cation[47].

With highly polar solvents (acetonitrile, nitromethane) and catalysts having strongly complexing anions [$Hg(CN)_2$ or $HgBr_2$][51], however, no acyloxonium ion is apparently formed; instead the reaction proceeds *via* the glycosyl cation *(14)*. Reaction with the alcohol leads to a mixture of *cis* and *trans* glycoside [*(21)* and *(19)*] in a ratio depending on the structure of the sugar and the reaction conditions. This represents a possible method of obtaining *cis* glycosides after separation of anomers[51]. The reaction also occurs as an undesired side reaction in the preparation of *trans* glycosides, expecially in polar solvents.

trans Haloses *(23)*, *e.g.* *(6)*, *(7)*, and *(9)*, generally react with an alcohol in the presence of insoluble silver salts or bases by way of the intermediate acyloxonium ion *(17)* to give orthoesters *(20)*[20]. Small amounts of *cis* glycosides *(21)* are also formed by direct reaction. *trans*-1-Bromo-2-acylcyclohexanes behave similarly[52]. In accord with the reaction mechanisms postulated so far, attack by the alcohol on the acyloxonium ion can, however, also be directed towards C-1 by Lewis acids so that *trans* glycosides *(19)* are formed with retention.

Finally, the acyloxonium ion *(17)* has also been postulated as an intermediate in glycoside syntheses from sugar 1,2-orthoesters[39,46]. In this case *(17)* is formed by heating orthoesters *(22)* derived from simple alcohols (*e.g.* ethanol)

Scheme 2. Possibilities of systematic synthesis of *cis* glycosides.

[*] In the absence of other nucleophiles these acyloxonium ions can undergo intramolecular reaction with additional neighboring *trans* acyl groups, thus leading to rearrangement products [47].

with catalysts and can react with an added alcohol to give the *trans* glycoside [*(22)*→*(17)*→*(19)*]. Transesterification

[(22)→(17)→(20)] yielding the new orthoester (20) can occur as competing reaction. A further possible preparation of *trans* glycosides (19) consists in rearrangement of an orthoester formed by another route into the isomeric glycoside [(20)→(17)→(19)][39, 53] (see Section 5).

2.3. Preparation of *cis* Glycosides

For the reasons mentioned in the foregoing Section, peracylated haloses and orthoesters are of little value for the directed synthesis of *cis* glycosides. Syntheses of *cis* glycosides generally start from 1-halo sugars bearing a nonparticipating substituent on C-2. The resulting possibilities of systematically building up *cis* glycosides are summarized in Scheme 2.

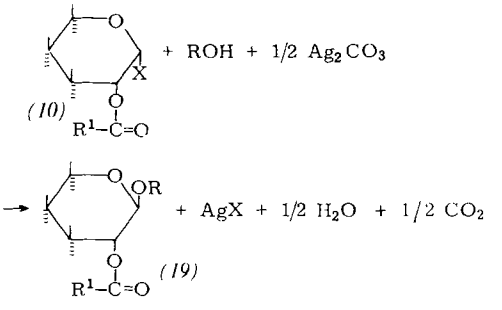
In most cases, reactions of such haloses [(26) or (27)] under typical S_N1 conditions (*e.g.* solvolysis) [eq. (1)] lead to a mixture of *cis* and *trans* glycosides [(3) and (4)], irrespective of the anomeric configuration at C-1. The proportion of *cis* glycoside can be varied to a certain degree by changing the reaction conditions and the kind of alcohol; however, it is determined mainly by the structure of the halose.

The corresponding *trans* haloses (26) are more favorable for the preparation of *cis* glycosides, in combination with reaction conditions promoting an S_N2-type transition state or formation of intimate ion pairs [eq. (2)]. Nonpolar solvents and insoluble silver salts, or the use of 1-chloro compounds, are thus most conducive to *cis* glycoside formation. Owing to partial isomerization to the *cis* halide during reaction and a side reaction *via* glycosyl cations, this method can produce considerable quantities of *trans* glycosides.

A rather promising principle [eq. (3)] has been applied by *Lemieux*[54, 55]. In an equilibrium reaction with tetraethylammonium halide, a *cis* halose (27) is converted into the more reactive *trans* halose (28) which then rapidly reacts to give the *cis* glycoside (3). A similar principle could apply to the *cis* glycoside synthesis described by *Igarashi*[56] in which a *cis* halose bearing a benzyl substituent at C-2 is reacted with an alcohol in the presence of silver perchlorate and collidine. *Igarashi*[57] showed, however, that the relatively unstable *cis*-1-perchlorate results on reaction of a halose with $AgClO_4$ in the absence of alcohol. The exceptionally high yields of *cis* glycoside could however be better rationalized by initial formation of a *trans*-1-perchloric ester (28), $X' = ClO_4$, which rapidly isomerizes to the *cis* ester in the absence of alcohol, but is transformed much more rapidly into the *cis* glycoside when alcohol is present.

Surprisingly, certain substituents on C-6, C-4, and C-3 of the halose appear to exert a powerful influence on the stability of the *trans* haloses[30, 58, 49]. Thus a *p*-nitrobenzoyl group on C-6 apparently shifts the equilibrium between *cis* and *trans* haloses in the direction of the latter, thereby facilitating further fast reaction to give the *cis* glycoside[30, 34, 58] [see eq. (4)], whereas a *p*-methoxybenzoyl group as substituent on C-6 leads almost exclusively to the *trans* glycoside[34].

The fact that positively charged substituents on C-1 are most stable in the equatorial position—the so-called reverse anomeric effect[60]—opens up a further possibility for the formation of reactive *trans* compounds. *West* and *Schuerch*[61] treated *cis* haloses with a nucleophile (:Nu), *e.g.* with triethylamine, to give a *trans* onium compound (32) [cf. (25)] that reacts further with alcohols to form the *cis* glycosides [see eq. (5)].



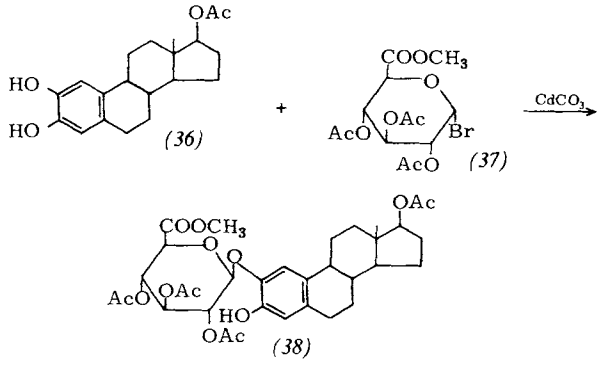
A completely different directing effect was exploited by *Lemieux*[62] for glycosylation with 2-nitroso *cis* haloses (33) [eq. (6)]. In dimethylformamide these haloses react *via* an intermediate nitrosoglycal (34) with stereospecific 1,4 addition of the alcohol to the diene system to give the *cis* glycoside (35) in high yield[63]. The *cis* glycosaminide or the *cis* glycoside can be obtained from this product (see Section 4.6).

3. Glycosides form 1-Haloses Having Participating Substituents on C-2

Since the successful studies by *Koenigs* and *Knorr*[64] dating from 1901, 1-halo sugars have been converted in large numbers into glycosides by treatment with alcohols under a variety of conditions. We shall now report a selection of recent results[*].

3.1. In the Presence of Insoluble Salts

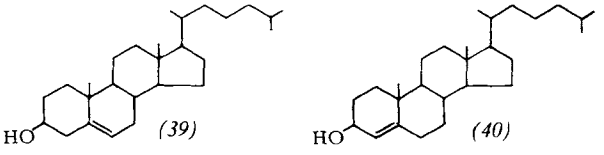
In the original form of the Koenigs-Knorr synthesis, the halose was allowed to react with an alcohol in the presence of an insoluble silver compound, usually Ag_2O or Ag_2CO_3 (for a survey see ref.[65–67]). The water formed also reacts with



the halose and reduces the yield. This water is nowadays removed by the following principal methods:

1) An inorganic dessicant (*e.g.* drierite) is added to the reaction mixture and the process is performed at room temperature. This technique is frequently employed in the synthesis of oligosaccharides in which the halose (in chloroform or methylene chloride) is reacted with the alcohol in the presence of Ag_2CO_3, $CaSO_4$, and I_2 (examples[68–70]). Good results are obtained with primary alcohols. It is assumed that iodine suppresses the formation of orthoester-type by-products[48], probably by stabilization of a bimolecular transition state on Ag_2CO_3 leading to the glycoside[22].

2) The variant due to *Meystre* and *Mieschер*[26] has been extensively used, above all in the synthesis of steroidal glycosides: the resulting water is distilled off as an azeotrope with solvent benzene. Yields are moderate to good[26, 71, 72]; however, sensitive alcohols can lose water and undergo other changes[65]. *Conrow* and *Bernstein*[73] have demonstrated that the otherwise difficultly accessible glycosides of phenolic steroids can be readily obtained by use of $CdCO_3$ (in place of silver compounds) in boiling toluene. Even estrogens having a pyrochatechol structure [*e.g.* (36)], which are oxidized by silver compounds, can be converted into the glucuronide



[*] No attempt at complete coverage of the literature has been made. Apart from methodological advances, a number of characteristic examples have been chosen from recent publications wherever possible.

(38) with glucuronyl halide *(37)* in toluene in the presence of this new catalyst[73a]. *trans*-Alkyl glycosides can also be conveniently prepared in the presence of HgO[74].

The yields of the above glycosylation reactions are often rather poor, particularly with secondary alcohols, and cannot be raised significantly by a large excess of halose. This is due to side reactions whose products can in turn also sometimes undergo glycosylation. Apart from the reaction with water, the main contenders are those leading to the orthoester *(20)*[40] and to products arising from the intermediate acyloxonium ion *(17)* (*e.g.* alkyl acetate, alkyl 3,4,6-tri-*O*-acetyl-α- and -β-glucopyranoside)[43, 49, 50]. In the absence of an alcohol, too, the halose reacts with Ag_2O or Ag_2CO_3 to give orthoester-type products[40, 43, 48, 50]; after reaching a given conversion, however, the reaction becomes very slow[40, 43]. The major reaction product, whose structure has yet to be elucidated, undergoes extremely ready conversion into a 2,3,4,6-tetra-*O*-acyl sugar on work-up of the reaction mixture[43, 50].

In our new glycosylation variant[21, 40] we react the halose with the alcohol in the presence of the silver salt of a hydroxy carboxylic acid (preferably 4-hydroxyvaleric acid) in diethyl ether as solvent. Considerable importance attaches to the nature of the solvent used. This method is particularly effective for glycosylation of steroidal alcohols [*e.g.* cholesterol *(39)* and tigogenin *(41)*][40] (see Table 3). Since no water has to be removed (the silver salt yields the free hydroxy carboxylic acid and AgHal) and the reaction proceeds at a considerable rate even at −10 °C, the method is also suitable for highly sensitive alcohols. Allyl alcohols of the steroid series [*e.g.* 4-cholesten-3-ol *(40)*], which usually lose water to form the corresponding diene (*e.g.* 3,5-cholestadiene), can be glycosylated by the above method[40]. Reaction in diethyl ether at low temperature is also favorable for Ag_2O; however, orthoesters are more readily formed with that catalyst[40].

A comparison of the yields obtained in the presence of various silver salts is informative with regard to the function of the silver compound in these reactions (see Table 1).

Surprisingly, the "classical" silver compounds Ag_2O and Ag_2CO_3 were found not to be the best reagents. Instead, apart from silver 4-hydroxyvalerate mentioned above, silver salts of other hydroxy carboxylic acids (especially salicylic

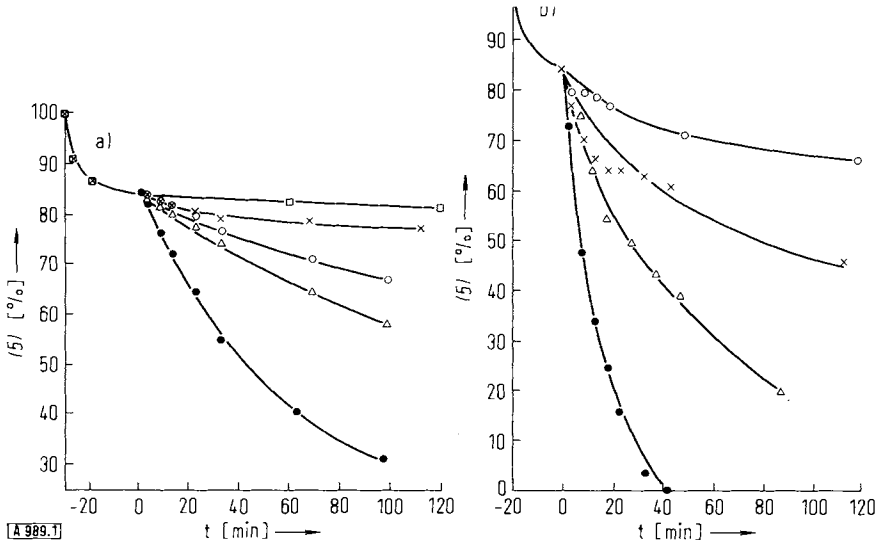
acid)[75] and dicarboxylic acids (especially maleic acid) proved particularly favorable. A striking connection is observed between product formation and the distance between the two functional groups in the silver salt. In principle, both the carboxy group (with formation of 1-acyl glycoses) and the hydroxy group of the silver salt are capable of reaction with the sugar in place of the alcohol to be glycosylated[49, 76], and the salts of simple acids (propionic acid, trichloroacetic acid) as well as 6- and 5-hydroxy carboxylic acids do indeed preferentially form the 1-acyl glycoses. Possibly, the 4-, 3-, and 2-hydroxy carboxylic and 1,4-, 1,3-, and 1,2-dicarboxylic acids in solution and sometimes the corresponding silver salts in the crystalline state are capable of neighboring group participation between OH or OAg and the carbonyl group [*e.g.* in *(44)* and *(45)*] which lowers the extent of a nucleophilic attack by the acid anion on the sugar. The relationship between the yield and possible number of ring members is obvious[*].

A better understanding of this reaction has been sought in detailed studies of its stereochemistry[49] and kinetics[22]. The

[*] It is still unclear why silver salts whose anions can form a six-membered ring should be more prone to orthoester formation.



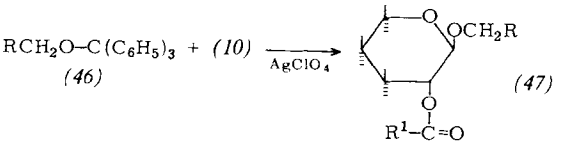


Fig. 1. a) Kinetics of the reaction of 2,3,4,6-tetra-*O*-acetyl-α-D-glucosyl bromide *(5)* in diethyl ether at 0°C in the presence of Ag_2CO_3 with methanol (•, 1.07; ▵, 0.53; ○, 0.32; ×, 0.11; □, 0 equivalents of CH_3OH). b) As for Fig. 1a; however, reaction is carried out with equivalent amounts •, water; ▵, methanol; ×, isopropyl alcohol; ○, cholesterol *(39)*. Alcohols and water were added 30 and 20 min, respectively, after the initial reaction of Ag_2CO_3 and *(5)*. The amount of unreacted *(5)* is plotted [22].

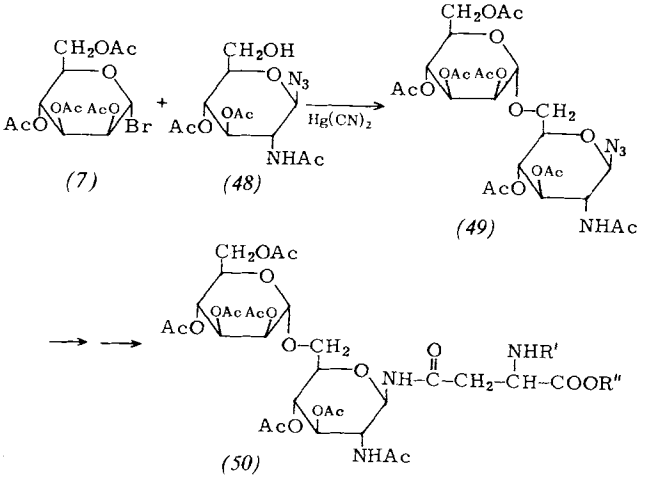
reaction rate depends upon the amount and nature of the alcohol (see Fig. 1). Addition experiments with competing nucleophiles of different strengths, in which the rates and product patterns were compared, also clearly indicated that the rate-determining and product-determining steps of the reaction are identical. In contrast to solvolysis reactions of haloses and glycosylations in the presence of soluble catalysts, the alcohol here participates in the rate-determining step. The reaction itself can probably be best depicted as shown in *(11)*[22]. Significantly it can apparently only take place on the surface of an insoluble silver salt, the halose halogen first interacting with the silver. The actual reaction takes place owing to a "push-pull" effect only on addition of the alcohol. A certain resemblance can be detected between the postulated reaction course and the mechanism assumed by *Kornblum et al.*[77] for the reaction between alkyl halides and silver nitrate or nitrite.



3.2. In the Presence of Soluble Catalysts

Increasing use is being made of soluble catalysts in the production of *trans* glycosides by the Koenigs-Knorr synthesis since they usually react faster, and some offer the advantage of working in homogeneous phase. $Hg(CN)_2$, $HgBr_2$, or $AgClO_4$ are preferentially used in oligosaccharide syntheses. Silver perchlorate has been used primarily in combination with Ag_2CO_3[78, 79] in order to raise the rate of reaction.

Reaction of haloses with trityl ethers *(46)* derived from the alcohols in the presence of $AgClO_4$ according to *Bredereck*[29] has also proved of value. The method affords good yields of *trans* glycosides *(47)* from primary alcohols[29, 80]. In both cases mentioned they probably first form the 1-perchlorate sugars[57, 81] which can rapidly react further to the acyloxonium ion *(17)*[29].

Of the mercury salts, which have now been employed for some time, most frequent use is nowadays made of $Hg(CN)_2$[83] introduced by *Helferich*[82]. Reaction is usually carried out in benzene/nitromethane as solvent since *trans* glycosides are then formed almost exclusively, while the *cis* glycoside can predominate in pure nitromethane[84, 85]. The method was extensively used, for example, by *Jeanloz et al.* (*e.g.*[86, 87]) for synthesizing oligosaccharides of biological interest. As an example we can consider the synthesis of a glycoprotein precursor in which the α-linked *trans* disaccharide *(49)* is formed from a glucosamine derivative *(48)* and 2,3,4,6-tetra-*O*-acetyl-α-D-mannosyl bromide *(7)* in 74% yield[86]. After reduction of the azide to the amino group in *(49)*, it is reacted with an aspartic acid derivative to give a structure of type *(50)* occurring in glycoproteins. Other schools have also conducted syntheses in the presence of $Hg(CN)_2$, mainly with the aim of producing oligosaccharides (see, *e.g.*, refs.[88–90]).

Problems arise in the preparation of oligosaccharides and glycosides in which 2-amino-2-deoxy sugars form the glycosidically bound component. Although neighboring group participation of the C-2 substituents in the respective haloses is possible during glycosylation (*e.g.* in 2-*N*-acetyl, 2-*N*-benzoyl, 2-*N*-benzyloxycarbonyl sugars), and the reaction therefore leads to *trans* glycosides[91], the yields are nevertheless low, since these haloses are relatively unstable and frequently also give rise to derivatives of oxazoline *(68)*[91a,92] or of oxazolidone[92].

As already mentioned, large amounts of *cis* glycosides are formed with $Hg(CN)_2$ in polar solvents[84,85]. A mixture of $Hg(CN)_2$ and $HgBr_2$, likewise introduced by *Helferich*[51,93], ensures even better yields of *cis* glycosides from glycosylations performed in polar solvents. The $HgBr_2$ formed anyway during the reaction accelerates dissociation of the haloses by complex formation (probably as $[HgBr_3]^-$)[93]. Isolation of the pure glycosides involves separation of the *cis/trans* glycoside mixture. Although the mixture rarely contains more than 50% of the *cis* glycoside this was until recently the best available synthesis of *cis* glycosides and was used primarily for preparing α-linked disaccharides[51,93,94]. Primary alcohols, however, usually afford *trans* glycosides[88,95], and use of the method with *trans* haloses, *e.g.* 2,3,4-tri-*O*-acetyl-α-L-rhamnosyl bromide *(9)*, leads to excellent yields of *trans* glycosides[96].

4. *cis* Glycosides from Haloses Having Nonparticipating Substituents on C-2

4.1. From *cis* or *trans* Haloses under Typical S_N1 Conditions

On reaction of haloses having nonparticipating substituents (the benzyl ether group is generally used in this case) with alcohols under typical S_N1 conditions, both the *cis* and the *trans* halose give the same ratio of *cis* and *trans* glycoside [see eq. (1)]. A number of syntheses starting from *trans* haloses included in Section 4.2 should conceivably be listed under the present heading since the corresponding *cis* halose might possibly give the same ratio of *cis* and *trans* glycoside. Thus *Austin et al.*[36] prepared mixtures of *cis*(α) and *trans*(β) glucosides and galactosides, from which both anomers could be obtained pure by reaction of the α and β chloride of 2,3,4,6-tetra-*O*-benzyl-D-glucose and -D-galactose. The method was later extended to other sugars[97]; however, the yields of *cis* glycoside are generally only moderate.

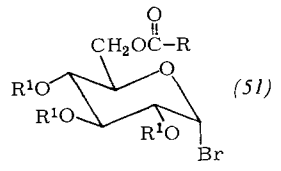
The 2,4-dinitroanilino[98], *p*-methoxybenzylideneamino[99], bis(phenoxy)phosphinylamino[92], dichloroacetylamino[100], and trifluoroacetylamino groups[101] have been used as functional groups on C-2 for haloses of 2-amino-2-deoxy sugars not displaying neighboring group effects. Here, too, glycosylation yields mixtures of *cis* and *trans* glycosides which have to be separated. The method is used with amino sugars to produce both *cis* and *trans* glycosaminides.

4.2. From *trans* Haloses with Inversion

It has long been established practice in the systematic construction of *cis* glycosides to start from *trans* haloses [see eq. (2)] whose substituents on C-2 are incapable of neighboring group participating (for earlier work, see refs.[1,6,9,10]).

Wolfrom et al.[102,103] used the nitric ester group on C-2, which however strongly deactivates the halogen on C-1. While fair yields are obtained with primary alcohols[102], they are much lower with secondary alcohols, particularly in disaccharide synthesis[103]. The chlorosulfate protecting group, readily introduced by acylation with SO_2Cl_2, has been used successfully in the preparation of α-D-xylosides[104], as has the 2,3-carbonyldioxy group in the preparation of β-D-mannosides[105]. The 2-trichloroacetoxy and 2-hydroxy group on C-2 are also very suitable as nonparticipating functional groups[106-108]. Detailed studies of glycosylation with 3,4,6-tri-*O*-acetyl-β-D-glucopyranosyl chloride and -β-D-galactopyranosyl chloride in benzene in the presence of mercury succinate[108,109] and in methylene chloride in the presence of silver carbonate/silver perchlorate[110] have been conducted by *Helferich* and *Müller*[108-110]. They obtained surprisingly good yields, especially of α-linked oligosaccharides of glucose and galactose (see Table 3).

4.3. By Previous Anomerization of the Halose



Lemieux, Hendriks, et al.[54,55] introduced the halogen-ion catalyzed reaction of *cis* haloses for the synthesis of *cis* glycosides (see eq. (3)). They treated perbenzylated *cis* haloses of D-glucose[54], D-galactose[110a], or L-fucose[110b] with alcohols in the presence of tetraethylammonium bromide and ethyldiisopropylamine (Hünig base). In methylene chloride as solvent (in some cases with addition of dimethylformamide) they obtained remarkably good yields of *cis* glycosides (see Table 3). With substituents prone to acyl migration in the alcohol component the Hünig base could be replaced by a molecular sieve[111b]. Apart from disaccharides this method has already yielded two trisaccharides which function as components of blood-group active oligosaccharides[110a,b].

Igarashi et al.[56] studied the reaction of *cis* haloses with alcohols in the presence of silver perchlorate and *sym*-collidine in several solvents: By varying the reaction conditions they found an exceptionally specific synthesis of *cis* glycosides in diethyl ether as solvent, and obtained a variety of α-linked disaccharides consisting of two molecules of D-glucose in very good yields (see Table 3).

This procedure represents a logical development of the reaction described by *Hasegawa et al.*[111] which is conducted in the presence of Ag_2CO_3 and $AgClO_4$ in chloroform (benzene) with 10—20% dioxane, and also affords *cis* glycosides, admittedly in not such good yields.

4.4. Steric Control of Glycosylation by Substituents on the Halose

It has recently been found that certain substituents on C-6, C-4, and C-3 of the halose have a pronounced effect on the steric course of the reaction, thus providing a means of stereochemical control [see eq. (4)]. Following initial observations by *Ishikawa* and *Fletcher*[58] on 6-*p*-nitrobenzoyl haloses, which yield mainly *cis* glycosides on solvolysis, *Fréchet* and *Schuerch*[34] undertook systematic studies on the effect of the substituent on C-6 of haloses *(51)* upon the *cis/trans* ratio of the glycosides produced on solvolysis (see Table 2). They found a striking dependence of the *cis/trans* ratio of the resulting methyl glycosides upon the substituent on C-6[34];

(51)

$R^1 = CH_2-C_6H_5$

Table 2. Methanolysis of *(51)* to *trans*(β) and *cis*(α) methyl glycoside [34].

R	*trans*:*cis*
p-CH_3O—C_6H_4	93:7
C_6H_5	84:16
3,5-$(NO_2)_2$—C_6H_5	75:25
CH_3	65:35
p-NO_2—C_6H_4	8:92

however, this ratio is strongly dependent upon the concentration of the alcohol and the reaction conditions[30]. *Flowers et al.*[59, 112] were then able to show for fucose derivatives that a substituent on C-3 and C-4 also influences the steric course of glycosylation.

The corresponding 1-chloro compounds usually react with extensive inversion (presumably owing to intimate ion pair formation)[34]. In contrast to the foregoing descriptions we also observed consistent inversion on reaction of the bromides in the presence of insoluble silver salts under S_N2 conditions, regardless of the substituent on C-6[49].

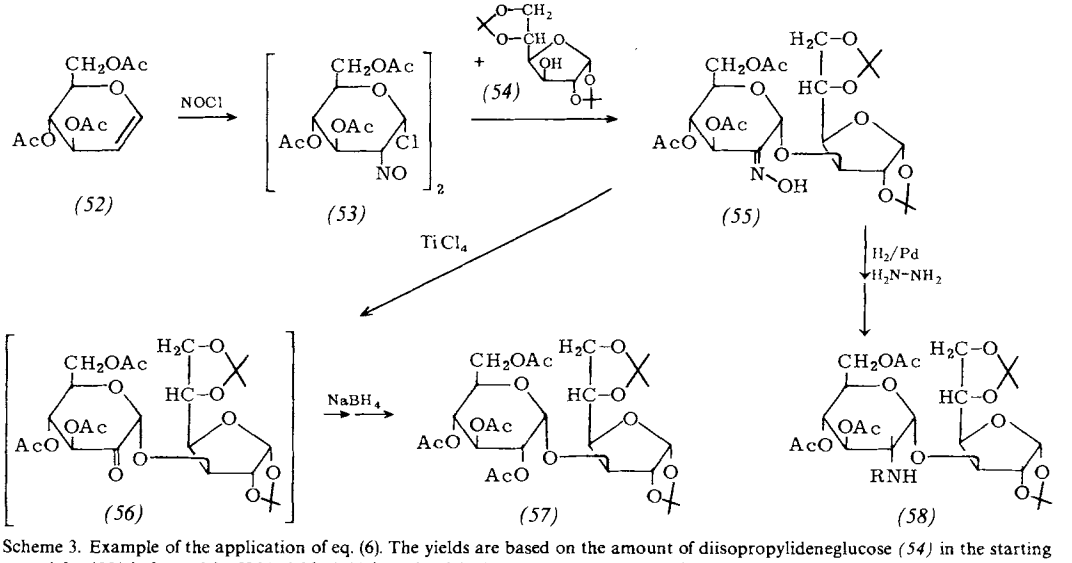
Meanwhile the utility of the new method has been established for the synthesis of α-linked steroidal glycosides[113] and oligosaccharides[59, 114, 115] (see Table 3).

4.5. Exploitation of the Reverse Anomeric Effect

West and *Schuerch*[61] treated *cis* haloses with a powerful nucleophile (triethylamine, dimethyl sulfide, or triphenylphosphane) which can only react with the halose to form an onium compound [see eq. (5)]. These reactive intermediates then react with alcohol to give the *cis* glycoside almost exclusively. The scope of this promising method has not yet been published.

4.6. From 2-Nitroso Haloses

Unlike the substituents on C-2 considered so far, the nitroso group exerts a *cis*-directing action on glycosylation. This fact constitutes the basis of an effective *cis* glycoside synthesis developed by *Lemieux, Nagabhushan, et al.*[116]



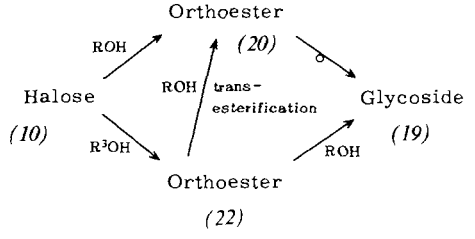
Nitroso sugars of type *(33)* [cf. eq. (6)] are easily obtained from the readily accessible acetylated glycals [*e.g.* glucal *(52)*] by *cis* addition of nitrosyl chloride to give *(53)*[117]. These compounds crystallize as dimers. Glycosylation of alcohols is best carried out in dimethylformamide at room temperature without addition of an acid acceptor. The complicated equilibria established on dissolution of *(53)* in DMF have been thoroughly studied, both in the absence[118] and in the presence of alcohol[63].

Condensation with an alcohol gives good yields, even in the case of complex sugar derivatives such as 1,2:5,6-diisopropylidene-α-D-glucofuranose *(54)* which is usually difficult to glycosylate.

The content of *trans* glycoside is generally low; in one case, however, 8.7% of *trans* product was obtained[63], and in another, under different conditions, the *trans* glycoside even predominated[119].

Deoximation is best performed with acetaldehyde/HCl or $TiCl_4$[120]. The keto sugars *(56)* can be isolated in high yields, but are usually reduced directly. In syntheses starting from glucal, the reaction with $NaBH_4$ or B_2H_6 is rather stereoselective. Only 4% of α-D-mannosido derivative accompany 96% of the α-D-glucosido derivative *(57)*[55]. In contrast, syntheses starting from galactal give comparable yields of the α-D-galactosido and α-D-talosido compounds. The same applies to the direct reduction of the oximino glycosides, which is stereoselective, giving more than 90% of the α-D-glucosamido compound [*e.g. (58)*], only in the case of glucal[121] (Scheme 3).

The above method is well suited to the preparation of *cis* glycosides[55, 116] and *cis* glycosaminides[116, 121]. It is, however, rather involved and separation of by-products can present problems. A favorable application lies in the introduction of α-linked D-glucosaminide[116, 121] and D-glucoside groups[55, 116] which are abundant in Nature (see Table 3).

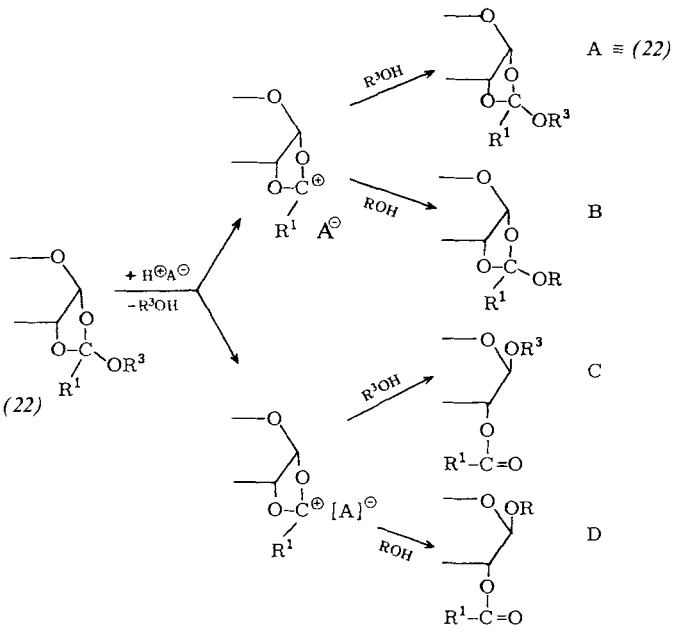


Scheme 3. Example of the application of eq. (6). The yields are based on the amount of diisopropylideneglucose *(54)* in the starting materials. *(55)* is formed in 59% yield, *(58)* in 52% yield (+ <5% α-D-mannosamine derivative), *(57)* in 43% yield (+*ca.* 1.5% α-D-mannose derivative).

5. Glycosides from Orthoesters

Of the methods available for preparation of *trans* glycosides *(19)*, the route proceeding *via* the orthoesters *(22)* has become increasingly significant during the past decade. In addition to other schools, *Kochetkov et al.*[39, 46, 53, 122] have played a leading role in the systematic study and application of the orthoester method (for a detailed review, see ref.[39]).

Starting from a halose *(10)*, the initial step consists in preparing the orthoester *(22)* of a simple alcohol R^3OH, which is then reacted with the more complex alcohol ROH to form the glycoside *(19)*. Alternatively the orthoester *(20)* of the



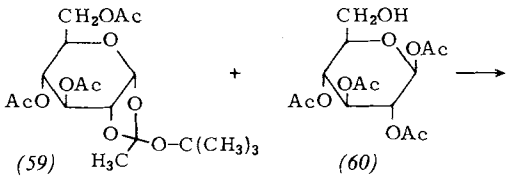
ROH = alcohol to be glycosylated
R^3OH = methanol, ethanol, or *tert*-butyl alcohol

complex alcohol may be prepared[41, 53, 123] and then rearranged to the glycoside[53, 124].

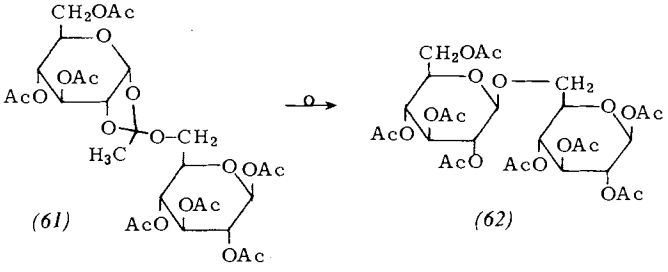
Preparation of the orthoesters closely resembles the Koenigs-Knorr synthesis: the starting materials are an acylated halose, an alcohol and a halogen-binding additive. *trans* Haloses *(23)* yield the orthoester directly in neutral or basic solution[125]. Unter certain conditions the more readily accessible *cis* haloses *(10)* can also be used. Orthoesters [*(20)*, *(22)*] are best obtained from *cis* halose in the presence of a strongly nucleophilic solvent which cannot form strong bonds but merely an oxonium *(24)* or ammonium ion *(25)*. The orthoester *(20)* is then readily formed *via* the acyloxonium ion *(17)*. For instance, orthoesters are formed from *cis* haloses and an alcohol with collidine[44], with $PbCO_3$ in acetic ester[46], and with silver salicylate in tetrahydrofuran[41]. The last-named method[41] provides almost quantitative yields of the orthoesters of highly complex alcohols. Kinetic studies and examination of by-products have shown the reaction to proceed with participation of solvent tetrahydrofuran [*(10)*→*(24)*→*(17)*→*(20)*][42]. Reaction of *cis* haloses with an alcohol in the presence of tetrabutylammonium bromide is especially suited to the preparation of orthoesters, too, intermediate anomerization yielding the *trans* halose[45]. A primary anomerization to the β-nitrate is also involved in the reaction of *cis* haloses with alcohols in the presence of silver nitrate. The β-nitrate reacts further *via* the acyloxonium ion intermediate, furnishing the orthoester[126].

A characteristic feature of sugar orthoesters is their sensitivity towards acids, which leads to their hydrolysis in aqueous solution. On rigorous exclusion of water the orthoester can be made to yield the glycoside with an alcohol ROH in the presence of catalytic amounts of acid or Lewis acid. In principle, the products A—D may be expected.

The orthoesters A and B are formed by transesterification, where A ≡ *(22)* (starting material). D is the desired glycoside, C the glycoside of the more simple alcohol. Choice of the reaction conditions provides a large measure of control of products. Formation of A and C is usually suppressed by starting from orthoesters of lower alcohols which can readily



be distilled off during the reaction, or by chosing a group such as *tert*-butyl[53] whose recombination is largely precluded for steric reasons so that the added alcohol is more likely to become bonded to the sugar. Although it gives very good yields, glycosylation with *tert*-butyl orthoesters suffers from the instability of these compounds and the consequent impairment of reproducibility.

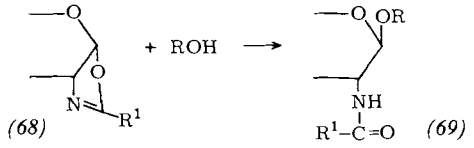


Whether orthoester or glycoside is formed depends upon the ratio of catalyst to orthoester, *i.e.* the critical ratio[39]. Glycosylation (C, D) predominates above the critical ratio, and transesterification (A, B) below. Consideration of the reaction scheme reveals that at high catalyst concentrations ($H^{\oplus}A^{\ominus}$) its anion can mask the positive charge of the acyloxonium, thus hindering nucleophilic attack of ROH which then takes place at the glycoside C-1. At low $A^{\ominus}$ concentrations direct attack and fresh orthoester formation becomes more likely[39]. However, at higher catalyst concentrations the formation of other by-products, such as the acetate ROAc[127, 128] and the dialkyl ether ROR[128, 129], becomes very pronounced. *cis* and *trans* 3,4,6-Tri-*O*-acylglycosides can also result[130, 131].

Each solvent-catalyst combination has a characteristic critical value. In polar solvents, like nitromethane, $HgCl_2$ and $HgBr_2$ are examples of suitable catalysts, whereas in nonpolar solvents, like chlorobenzene and dichloroethane, the perchlorates of pyridine and lutidine represent a better choice. The last-named combinations actually give the best yields.

The orthoester method has been successfully applied to numerous glycoside syntheses. Apart from glycosides of simple alcohols, those of *e. g.* hydroxy amino acids[53, 123], of steroidal and triterpenoidal alcohols[46, 127, 128], of glycerol derivatives[132], and, above all, of saccharides[39, 46, 53, 122] have also been prepared. The main strength of the method lies in the synthesis of di- and oligo-saccharides. A two-step synthesis of peracetyl gentiobiose *(62)* warrants mention as an example[53] (see also Table 3).

(59) (60)



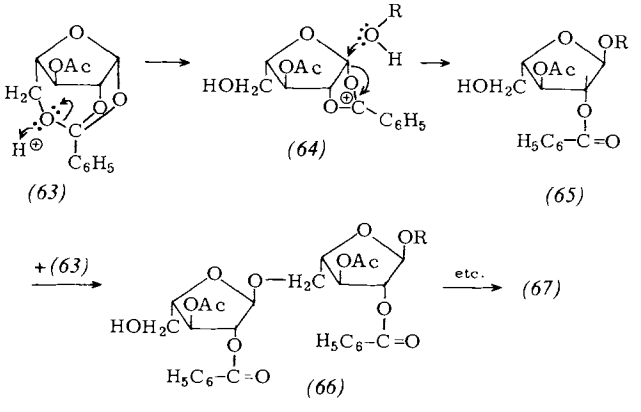
(61) (62)

Polysaccharides can also be built up relatively easily by the orthoester method[5, 13, 39, 133]. One possible route is to start from 1,2-orthoester derivatives bearing a free hydroxy group: polycondensation analogous to the disaccharide synthesis furnishes polysaccharides. A particularly elegant strategy, however, utilizes polymerization of tricyclic orthoesters [*e.g. (63)*] since no alcohol has to be eliminated. The sole requirement is an initiator alcohol which attacks the glycosidic C-1 atom of the sugar after acid-catalyzed ring cleavage to give *(65)* which can then be glycosylated to *(66)*. Frequent repetition of the process results in polymerization to form a linear polysaccharide *(67)* as shown for the synthesis of arabinan[133].

One disadvantage of the method is that electrophilic attack by $H^{\oplus}$ can also take place at the oxygen of C-2, resulting in 1→2 linked arabinose moieties in addition to 1→5 linked units. The arabinan obtained in 20% overall yield in the above example contains 92% of 1→5 linkages and 8% of 1→2 linkages[133]. With tricyclic xylose orthoesters, anhydride formation may occur instead of condensation[134].

As shown by *Micheel et al.*[135], and subsequently also by other authors[136, 137], oxazoline derivatives *(68)* of 2-amino-2-deoxy sugars frequently provide a very good entry into the *trans* glycosaminides *(69)* by a reaction resembling that of the orthoesters.

(68) (69)



6. Outlook

The yields obtained on glucosylation of four alcohols by various methods are listed in Table 3[*]. The tabulated data clearly show the striking advances inherent in precisely those methods which have been developed in the last few years. Astonishingly enough, the preparation of *cis* glycosides now appears to be just as practicable as that of their *trans* counterparts, although it should be borne in mind that the starting materials for their synthesis are usually far less readily accessible. However, just a few years ago direct preparation of *e.g. cis*-linked disaccharides gave very poor yields; they were in fact usually obtained by isomerizing *trans* glycoside [138].

Table 3. Comparison of the yields obtained in the glucosylation of the four alcohols cholesterol *(39)*, 1,2,3,4-tetra-*O*-acetyl-β-D-glucopyranose *(60)*, 1,2:3,4-diisopropylidene-α-D-galactopyranose *(70)*, and 1,2:5,6-diisopropylidene-α-D-glucofuranose *(54)* by various procedures. The yields are based on the alcohol used.

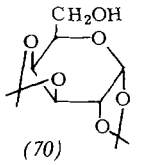
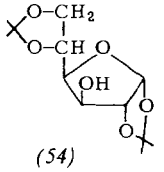
(63) (64) (65) (66) (67)

[*] Owing to the varying time requirements (*inter alia* for the preparation of the glycosylation components), the varying purity of the final products, and the difficult reproducibility of some syntheses, the reporting of product yields can be problematic. Nevertheless, we consider that the numerical data do give a general idea of the performance of the methods.



Only time will show whether, and to what extent, some of the very young methods[54-56,61,109,114] prove of value in other cases too.



(39)

(60)

(70)

(54)

In spite of this progress, the syntheses of extended oligosaccharides still remain problematic. Perhaps syntheses on insoluble polymers, akin to *Merrifield*'s proven method for oligopeptides[147], could result in substantial improvements. The construction of relatively long oligosaccharide sequences by this method requires a series of protecting groups of various reactivities. The first member of the chain must be bound so firmly to the polymer *via* an anchoring group that subsequent removal of protecting groups and glycosylation steps are unable to sever the linkage. On completion of the syntheses, however, this group should be removable under conditions which do not modify the oligosaccharide chain. So far the allyl alcohol group (cleaved by ozone)[148], the nitrobenzyl- and nitroveratryl alcohol groups (cleaved photochemically)[149,150], and the carboxylic and sulfonic ester groups (cleaved by alkalis)[151,152] have been used for this purpose.

Apart from "persistent" protection of sugar hydroxy groups the hydroxy group required for subsequent glycosylation must only be temporarily protected and easily deblocked. The choice of blocking agent is largely determined by the other groups present. β-Benzoylpropionyl (removed with cyclization by hydrazine)[153], chloroacetyl (removed by thiourea)[154], *p*-nitrobenzoyl (removed by alkali)[155], and 1-thioglycoside (removed by Hg-salts)[156] show promise as protecting groups.

The main difficulty encountered in glycoside synthesis on polymers comes from the failure of any known glycosylation reaction to give even approximately quantitative yields. The number of error sequences will thus rise rapidly with increasing chain length. In spite of initial successes in the synthesis of di- and trisaccharides[148,150-152,155,157], application of this technique, and also of the systematic synthesis of higher oligosaccharides by other methods, will have to wait until the yields in the actual coupling step have been substantially increased. The numerous side reactions and resulting by-products thwart attempts to increase yields by use of a large excess of glycosylation reagent.

Future work in the field will therefore probably proceed on two fronts. One will be concerned with further optimization of known synthetic principles; precise mechanistic knowledge of the various glycosylation reactions and the attendant side reactions could greatly facilitate this work. The other will require a constant lookout for novel linking reactions, since the scope for improvement of existing methods appears to be limited.

We are indebted to Professors B. Helferich, Bonn (Germany), K. Igarashi, Osaka (Japan), N. K. Kochetkov, Moscow (USSR), R. U. Lemieux, Alberta (Canada), C. Schuerch, Syracuse (USA), and U. Zehavi, Rehovot (Israel) for the communication of unpublished results. Our own work reported in this article profited from the excellent cooperation of Dr. W. Krüger, Dr. U. Schmidt, and Dr. W. Schmidt, and was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Thanks are also due to Professor R. Tschesche, Bonn, for his interest, and to Professor H. Paulsen, Hamburg, for reading through the manuscript.

Phase-Transfer Catalyzed Two-Phase Reactions in Preparative Organic Chemistry

By Eckehard V. Dehmlow[*]

Quaternary ammonium and phosphonium salts catalyze reactions between substances located partly in an aqueous and partly in an organic phase. Use of such phase-transfer catalysts simplifies and accelerates numerous reactions traditionally conducted in nonaqueous media. These reactions include carbene reactions, nucleophilic substitutions, alkylations of ketones and nitriles, Wittig and Darzens reactions, formation of ethers and esters. Other reactions such as hydrolysis and oxidation can be accelerated.

1. Introduction

1.1. Principles and Terminology

Reactions between substances located partly in an organic phase and partly in an aqueous phase are frequently slow and ineffective. Attempts are therefore generally made to obtain all the components, for example in nucleophilic substitutions, in a homogeneous medium. If a hydroxylic solvent is selected many reactions still proceed relatively slowly owing to extensive solvation of the anions; solvolytic side reactions may also interfere. While polar aprotic solvents are often more suitable for such reactions, they are usually more expensive and more difficult to recover; traces of water may sometimes also interfere. Moreover, increased formation of undesirable *O*-alkyl products usually occurs in alkylations of mesoionic anions.

The past few years have witnessed the ascendance of a new technique in which reactions are conducted in aqueous-organic two-phase systems in the presence of an ammonium or phosphonium salt. Typical examples are:

1) Generation of dichlorocarbene from chloroform, concentrated sodium hydroxide, and a few mol-% of triethyl(benzyl)-ammonium chloride.

2) Alkylation of benzyl cyanide in the presence of aqueous sodium hydroxide and a small amount of the above ammonium salt.

3) Reaction of 1-chlorooctane with aqueous sodium cyanide. This can be accomplished in 1.8 hours in 99% yield if 1.3 mol-% of tributyl(hexadecyl)phosphonium bromide is present. Without the catalyst no 1-cyanooctane is formed, even after two weeks' boiling.

[*] Prof. Dr. E. V. Dehmlow
Institut für Organische Chemie der Technischen Universität
1 Berlin 12, Strasse des 17. Juni 135 (Germany)

Other variants of such reactions are carried out with molar quantities of the ammonium or phosphonium salt.

The new method has no need of the anhydrous solvents otherwise required and will therefore attract increasing industrial interest. As will be demonstrated in this report, most experience has so far been gained in the fields of carbene generation and alkylation. Nevertheless other reactions (hydrolyses, condensations, oxidations, *etc.*) have also been executed in two-phase systems with catalysts.

No uniform terminology has yet been adopted for the new method. *Brändström*[1] has proposed the term "extractive alkylation" for the specific case of alkylation in the presence of molar amounts of catalyst, and otherwise speaks of applications of ion-pair extraction in preparative organic chemistry. *Makosza* employs expressions such as "catalytic alkylation"[2, 3] and "catalytic development of dihalocarbenes"[4]. The most illustrative term seems to be that of "phase-transfer catalysis"[5, 6] introduced by *C. M. Starks* which will therefore be adopted here.

1.2. Ion-Pair Extraction

This topic leads up to phase-transfer catalysis proper, from both a preparative and a mechanistic viewpoint, and will therefore be considered first.

In analytical and inorganic chemistry, typical ionic compounds are frequently extracted from aqueous solution into organic solvents in the form of ion pairs (for reviews, see refs.[7, 8]). The idea that salts might have a significant solubility in organic phases is relatively strange to the preparative organic chemist. However, *Brändström* and *Gustavii*[9] showed that with suitable solvents it is possible to extract the salts of most amines in almost quantitative yield. Tertiary amines are more readily extracted than their secondary or primary counterparts. A high molecular weight and absence of hydrophilic groups favor extraction. The salts of hydrohalic acids, nitric acid, perchloric acid, tetrafluoroboric acid, and also hydrogen sulfates, azides, cyanides, and nitrites can be transferred to the organic phase without difficulty. Of crucial importance are the following factors:

1) Working concentrations should be as high as possible. Since the ion pairs associate in organic media, unfavorable extraction constants (in dilute solution) can thus be overcome.

2) Choice of solvent is important. *Brändström* and *Gustavii*[9] used an amine bearing hydrophilic side groups as model compound, *viz.* 1-(2-allylphenoxy)-3-isopropylamino-2-propanol, and after a single run under defined conditions were able to extract the following quantities: with chloroform 100%, with 1,2-dichloroethane 93%, with methylene chloride 88%, with ether or carbon tetrachloride 0.6%, with ethyl acetate 16%. Chloroform and methylene chloride will therefore be the extractants of choice.

3) The presence of an excess of anion (as acid or inorganic salt) strongly enhances the extractability of the organic salt.

Given a rough knowledge of their extraction behavior the application of these principles even permits the separation of amines having different structures and properties (*e.g.* primary/secondary; strongly lipophilic/strongly hydrophilic) by simple extraction into chloroform (for details and procedures see ref.[10]).

In the same way as alkylammonium salts of inorganic acids, the salts of weak organic acids can also be extracted and obtained in crystalline form. *Brändström*[11, 12] uses commercially available tetrabutylammonium hydrogen sulfate as standard starting material. It is converted into the ammonium hydroxide by aqueous caustic soda and immediately extracted into a chloroform or methylene chloride solution of the organic compound. Concentration of the organic phase furnishes the pure ammonium salt which is soluble in most organic solvents and can subsequently undergo reaction in anhydrous solvent. The following types of compounds could be extracted as tetrabutylammonium salts[11, 12]: carboxylic acids, phenols, β-diketones, β-cyanoacetic esters, β-keto esters and sulfones, acylmalonic esters, and benzamide. On the other hand, quantitative ion-pair extraction is unsuccessful with still weaker acids such as alcohols, benzyl cyanide, benzyl ketones, aliphatic carbonyl compounds, and malonic esters. However, these compounds can be alkylated by the phase-transfer technique (see Section 2.3).

The isolated tetrabutylammonium salts possess preparative interest on two counts: firstly, they can be alkylated within seconds or minutes; secondly, choice of a suitable solvent can promote *C*-alkylation as against *O*-alkylation compared to the conventional procedure[13–17] (cf. Tables 1 and 2).

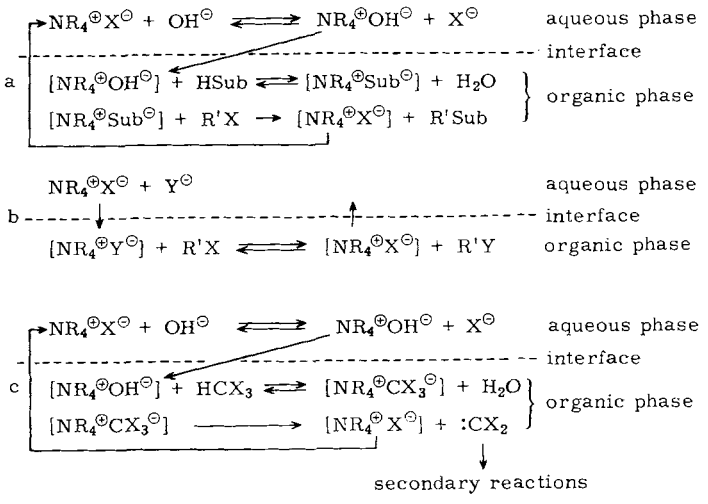
Table 1. Isopropylation of tetrabutylammonium pentanedionate [13].

Solvent	*C*-/*O*-Alkylation
DMSO	0.72:1
Acetone	0.72:1
Acetonitrile	0.92:1
Chloroform	1.04:1
Dioxane	1.91:1
Toluene	13.8:1

Table 2. Alkylation of tetrabutylammonium pentanedionate in chloroform [14].

Alkylating agent	Rel. yield [%] mono- + bis-*C*-alkyl	*O*-alkyl	Reaction time [min]
CH_3I	98.5	1.5	10
C_2H_5I	88	12	15
$(CH_3)_2CHI$	50.5	49.5	30
n-C_4H_9I	87	13	15

The pronounced reactivity of the ion pairs in alkylation is explained by the fact that they are only slightly solvated in chloroform and methylene chloride.



1.3. Course of Phase-Transfer Catalysis

The alkylations discussed above can now be transformed conceptually step by step into phase-transfer catalyzed reactions:

1) Reaction is carried out without isolation of the ammonium salt. Tetrabutylammonium hydrogen sulfate is dissolved in two molar equivalents of sodium hydroxide solution and added dropwise to a molar equivalent of alkyl halide and of the compound to be alkylated. The reaction is often exothermic; the mixture becomes neutral within a few minutes.—This constitutes "extractive alkylation" according to *Brändström*[16]

2) In the next step the procedure is extended to compounds whose low acidity precludes their quantitative extraction as ion pairs (*e.g.* benzyl cyanide, see Section 1.2). The organic phase will then contain both ion pairs and unchanged substrate. Although the local concentration of ion pairs is low, the reactivity of the anion is so high that it is always rapidly removed from the partition equilibrium. Consequently, alkylation takes *ca.* 30 minutes and is sometimes exothermic and sometimes requires heating[1].

3) Reduction of the amount of ammonium ion present to a few mol-% will not cause any fundamental change. A certain concentration of the ion pair will still be present in the organic phase and rapidly be consumed. The ammonium salt migrates back and forth between the phases. It transfers the hydroxide ions as an ammonium hydroxide ion pair from the aqueous phase to the organic medium, where it is converted into an ion pair with the substrate as anion. This is then alkylated. The ammonium salt returns again to the aqueous medium where the hydroxide is regenerated (Scheme 1a).

Scheme 1. Course of phase-transfer catalysis. For details see text. Ion pairs are enclosed in square brackets.

The simpler Scheme 1b applies to other nucleophilic displacements, such as the reaction between cyanide and chlorooctane mentioned in the introduction.

Generation of dihalocarbenes from aqueous sodium hydroxide, ammonium salt, and haloform can likewise be interpreted as in Scheme 1c.

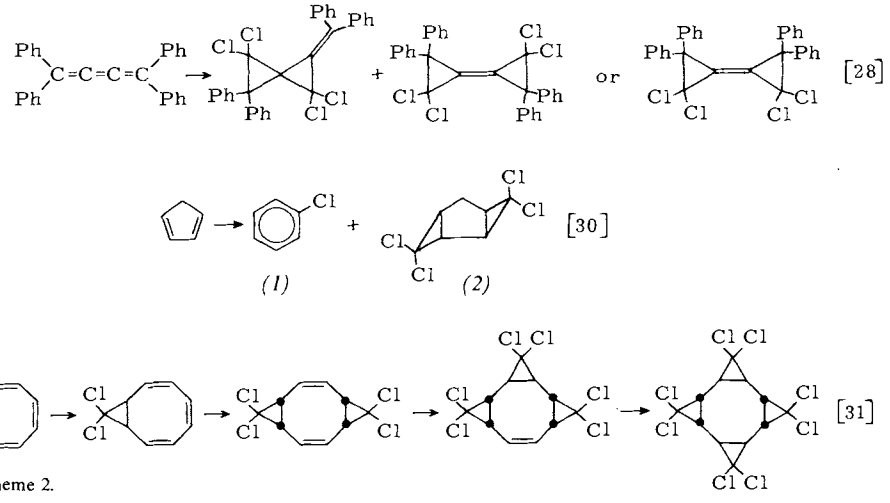
All these reactions can, of course, only proceed quantitatively if the aqueous/organic partition equilibrium permits preferential transfer of $X^{\ominus}$ into the aqueous phase. This is not necessarily always the case. For instance, reaction between cyanide and iodooctane comes to a halt after 5—30% conversion. Replacement of the aqueous phase by fresh cyanide starts the reaction off again until the concentration of iodide once more reaches the equilibrium value. Before attempting an unknown reaction it may be necessary to first examine the partitioning behavior of the anions involved.

That the course of phase-transfer catalysis described above appears reasonable does not constitute proof of its validity. Several authors have considered other possibilities. The catalysts employed are all more or less typical detergents, and hence it was suspected that reaction occurs at the interface[4, 18, 100a] or in a micellar phase[19–23]. Much interest is in fact currently being focused upon the micellar catalysis of a wide range of organic reactions[24]

More detailed mechanistic studies afforded the following evidence which is all in favor of the concepts described: small ions (*e.g.* tetramethylammonium) are not suitable as catalysts. In contrast, large ions (*e.g.* tetrabutylammonium and tetradodecylammonium which are not surfactants) are very effective, regardless of their molecular shape[6, 25, 100b]. In anhydrous nonpolar solvents the salts used undergo only slight association[6]. The mixing speed has no influence on the reaction kinetics once a limiting value for thorough mixing has been reached[6, 28, 100b]. The rate constant of the alkyl halide/-cyanide reaction is proportional to the amount of catalyst and of first order in alkyl halide[5, 6]. The same applies to the reaction of thiophene oxide with 1-bromooctane in benzene/water in the presence of various catalysts[100b]. On solvolysis of 2-bromooctane with aqueous sodium hydroxide/ammonium salt catalyst, an elimination-substitution ratio was found that is typical of reaction in anhydrous media[25, 26]. Finally, the anion transfer equilibrium aqueous phase/organic phase can be determined. It depends upon the relative concentrations, the amount of water present, and the polarity of the organic medium[6].

Selectivity data for dichlorocarbene generation are available[5] which show that the same kind of free dichlorocarbene species is formed as in other methods[27]. However, the actual phase-transfer process has not yet been subjected to kinetic analysis. Nevertheless, the only question open to conjecture is whether the reaction with solvent chloroform already occurs at the interface[100a] or, at least in part, after penetration into the organic phase. Formerly dihalocarbenes were generally assumed to be exceptionally sensitive to moisture, since chloroform is known to undergo hydrolysis to formate. It was found, however, that the carbene formed by the phase-transfer technique undergoes further reaction so rapidly that it is hardly hydrolyzed. This would contraindicate formation of the major portion of the carbene at the interface.

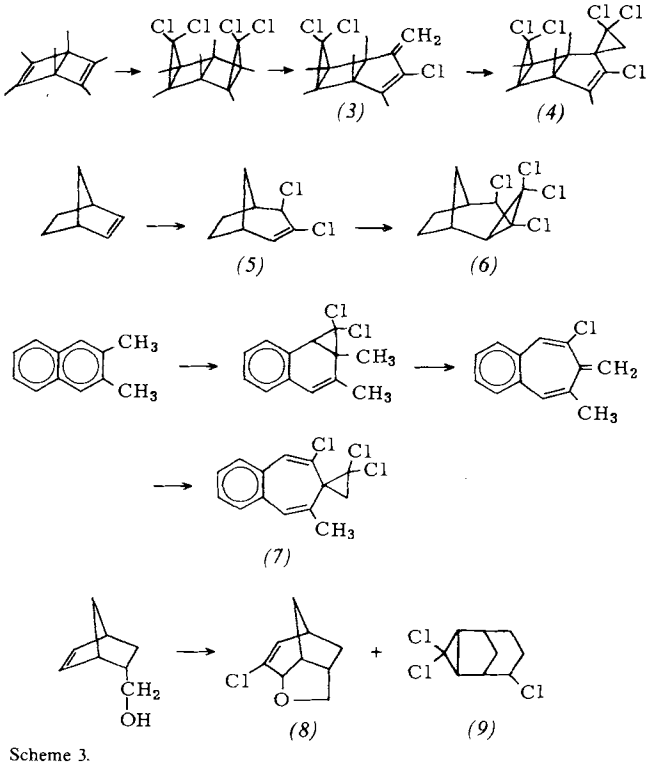
2. Preparative Applications



2.1. α-Elimination

2.1.1. Dichlorocarbene Additions (Mąkosza Reaction)

The preferred catalyst for generation of dihalocarbenes from haloform with 50% sodium hydroxide is triethyl(benzyl)ammonium chloride[4]. However, trihexyl(methyl)-[5] and cetyltrimethylammonium chloride[19] are also recommended. The inexpensive reagents chloroform and caustic soda are best employed in large excess[28].



Selectivity comparisons of addition of CCl_2 to normal olefins were mentioned in Section 1.3. If relatively unreactive substances are presented to the carbene a complicated situation will arise: the highly reactive CCl_2 can react with the substrate, the solvent, itself, or its precursor. Dihalocarbene will therefore display various "net reactivities" towards "poor" substrates. It is found that the CCl_2 generated by phase-transfer reaction is exceptionally reactive towards substrates which hardly react, if at all, with conventionally generated dichlorocarbene (*e.g.* from potassium *tert*-butoxide and chloroform). This is because the carbene is formed close to its site of further reaction and a large excess is easily generated.

Apart from normal alkenes and enol ethers[4, 5, 19], the Makosza reaction can also be used to dichlorocyclopropanate sterically hindered olefins (*e.g.* triphenylethylene) and electron-deficient olefins (*e.g.* methacrylonitrile), as well as acetylenes[*][28, 29]. However, addition is no longer observed with tetraphenylethylene and the di-, tri-, and tetrachloroethylenes.—Conventional dihalocarbene reagents usually add only once to conjugated olefins; electron withdrawal by the chlorine atoms deactivates the molecule towards a second attack. Single and multiple additions can easily be accomplished with "phase-transfer dichlorocarbene" depending upon the reaction conditions[28, 30, 31]. Schemes 2 and 3 show typical examples.

Scheme 2.

The isolation of tricycloheptane *(2)* deserves particular attention. The corresponding monoadduct is transformed into *(1)* extremely readily by base. In other cases multiple adducts are

Scheme 3.

[*] Hydrolysis to secondary products occurs here: cyclopropenones and conjugated acetylenic ketones are formed [28, 57].

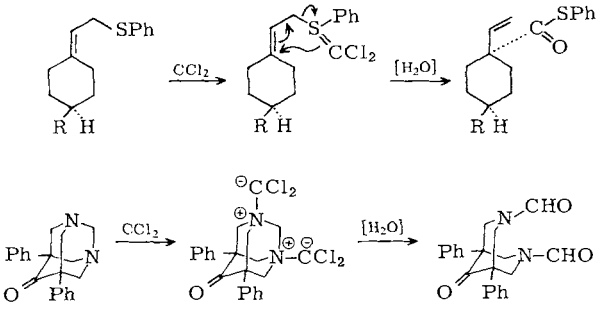
final products of a series of reactions [*(4)*, *(6)*, *(7)*]. The intermediate *(3)* can be obtained with dichlorocarbene from potassium *tert*-butoxide/chloroform[30a]. Depending on the conditions the major product from norbornene can be chosen as *(5)* or *(6)*[32]. *Weyerstahl et al.* observed conversion of alkylaromatic compounds into spirononatrienes by CCl_2. Formation of *(7)* is typical; alkylbenzenes usually afford several isomers[33]. In other cases side groups participate in the reaction, *e.g.* with *(8)* and *(9)*[34]. Ring enlargements occur with 1,4,5,8-tetramethoxynaphthalene and tetramethylpurpurogallin to yield substituted benzocyclooctatrienones and 2,3-benzohomotropones[101].

Further experience is available concerning the reactions of dichlorocarbene generated by phase-transfer catalysis with the following types of substrates: sterically hindered arylated olefins[28, 35, 36], ferrocene-substituted alkenes[37], steroidal olefins[38], methylfurans and -thiophenes[33b], phenanthrene[39], indenes[52], bicyclo[2.2.1]heptenes[32, 40] and -heptadienes[30], enolacetates of bicyclo[3.2.1]octanones[41], Schiff bases[53], and enamines[54] (for general procedure see footnote[*]).

2.1.2. Insertions of Dichlorocarbene

C—H insertion reactions of dichlorocarbene generated conventionally from potassium *tert*-butoxide and chloroform or with sodium methoxide/trichloroacetic ester are rare and give poor yields. Somewhat better results are obtained on generation from sodium trichloroacetate[42], and even better ones on preparation from bromodichloromethyl(phenyl)mercury[43].

Dichlorocarbene generated by phase-transfer catalysis also displays an enhanced net reactivity since it is formed in the immediate vicinity of the substrate and is less likely to undergo undesirable side reactions with the solvent or with itself. Nevertheless, yields of preparative utility only occur on inser-

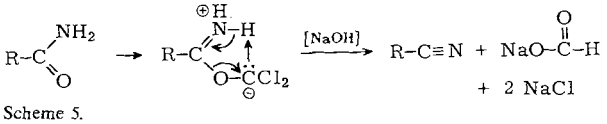


[*] Substrate (0.5 mol) and triethyl(benzyl)ammonium chloride (1 g) are dissolved in chloroform (500 g) and vigorously stirred with 50% NaOH (500 g), first at 0 °C and then at room temperature. After *ca.* 12 h the reaction mixture is poured into a large volume of water, separated, and reextracted with chloroform. Brownish, insoluble deposits (polymeric CCl_2?) are disregarded. Any stubborn emulsions which may occur are destroyed by repeated slow pouring into fresh water. After drying the organic phase is drawn off and purified by distillation, crystallization, or chromatography [28].—Other variants employ molar amounts of substrate/chloroform/caustic soda at 45 °C (dropwise addition of the chloroform) with stirring of the reaction mixture for only 1 h [4, 5].

tion into bridgehead positions or α to activating groups. A striking difference is observed with the isomeric decalins: only the *cis* compound with an exposed tertiary hydrogen reacts well. In a number of cases[20, 22] the chloroform is added dropwise at 65 °C to the two-phase system substrate-in-benzene/NaOH. Generally, however, the same procedure (see Section 2.1.1) is adopted as for addition (cf. Table 3).

Table 3. C—H insertions of dichlorocarbene.

Compound	Position of insertion	Yield [%]	Ref.
Cumene	1-	22, 18	[44, 45]
Ethylbenzene	1-	2	[45]
Tetralin	1-	21	[45]
Methylcyclohexane	1-	4	[44]
Trishomobarrelene	1-	60	[46]
cis-Decalin	9-	29	[44]
trans-Decalin	9-	< 3	[44]
Adamantane	1-	54	[20]
Diamantane	1-	63	[22]
	4-	37	
Methoxycyclohexane	1-	5	[44]
THF	2-	18	[45]
Diisopropyl ether	1-	13	[44]
1-Methyl-1,2-dihydroquinoline	2- and 4-	30	[47]



Formal insertions into C—S bonds[48] and C—N bond rupture[49] have also been observed (Scheme 4). They appear to begin with attack at the heteroatom.

Scheme 4.

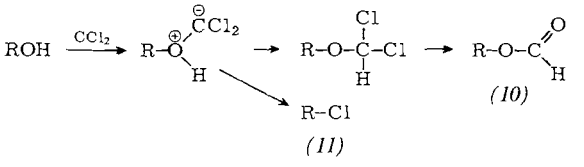
2.1.3. Nitriles from Amides with Dichlorocarbene

Independently of each other, *Saraie et al.*[50] and *Höfle*[51] found that aromatic and aliphatic amides, thioamides, aldoximes, and ureas are converted into nitriles by dichlorocarbene from a phase-transfer reaction (for general procedure see footnote[*]). The yield lies between 10 and 20% for lower aliphatic amides and up to 95% for lipophilic (long-chain or branched) compounds. Hydrolysis predominated with the lower compounds and some bisamides. The reaction mechanism of Scheme 5 appears plausible.

Scheme 5.

[*] A carboxamide (50 mmol) and triethyl(benzyl)ammonium chloride (2.2 mmol) are dissolved or suspended in chloroform (30 ml), warm 40% NaOH (50 ml, 0.7 mol) is added and the reaction mixture refluxed for 30 min. Reaction is stopped by cooling and addition of chloroform (*ca.* 50 ml) and the mixture is separated. After washing with 2 N HCl (2 ml) and drying over $MgSO_4$, the solvent is drawn off and the nitrile purified by distillation or sublimation [51].

2.1.4. Preparation of Isocyanide



The well-known carbylamination reaction

$$R{-}NH_2 \rightarrow R{-}N{\equiv}C:$$

usually gives modest and poorly reproducible yields, shortcomings which can be rectified in the phase-transfer version of the reaction[55, 56]. Yields of between 20 and 60% are obtained on use of molar amounts of amine and chloroform or bromoform. Presumably much higher yields can be obtained, as in the addition and insertion reactions, if the inexpensive reagents are used in excess.

2.1.5. Conversion of Alcohols into Chlorides by Dichlorocarbene

Tabushi et al.[21] discovered that phase-transfer generation of dichlorocarbenes in the presence of alcohols usually gives only small amounts of the expected formates *(10)*; alkyl chlorides *(11)* are formed instead. This reaction appears to be very general[21, 29, 57] and gives high yields. Rearrangements sometimes occur, thus suggesting carbonium ion intermediates.

(10)

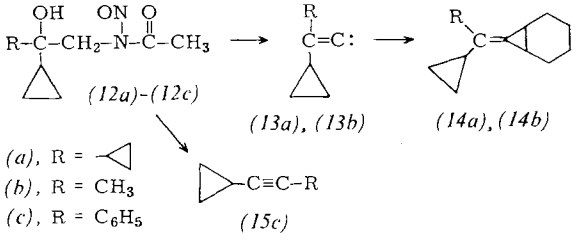
(11)

2.1.6. Bisdehydroxylation of Glycols

Preliminary experiments with α-glycols showed varying modes of product formation with dichlorocarbene under phase-transfer conditions: *cis*-1,2-cyclooctanediol yields a mixture of cyclooctanone and cyclooctene and its dichlorocarbene adduct, whereas *meso*-dihydrobenzoin was transformed into *cis*-stilbene and *trans*-stilbene oxide[102].

2.1.7. Other Halocarbenes

In principle, the generation and reaction of dibromocarbene can be performed in exactly the same way as for dichlorocarbene[28, 58-61]. However, yields are somewhat lower if the procedure is adopted without modification. The depleted reactivity of bromoform compared to chloroform is also apparent from the exclusive formation of CCl_2 in a competition experiment[59]. *Skattebol* demonstrated that a two- to four-fold molar excess of bromoform and a prolonged reaction time (48—92 h) can give very good yields[60] in many cases. *Makosza et al.* propose working with a twofold molar excess of bromoform in presence of a small amount of ethanol (0.8 ml with 0.4 mol of $HCBr_3$)[61]. They assume a specific solvation and stabilization of the tribromomethylide-triethyl(benzyl)ammonium ion pair by ethanol.

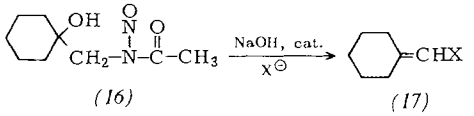


1,1-Diiodocyclopropanes were hitherto assumed to be not isolable. They have recently become available from iodoform by phase-transfer catalytic generation of diiodocarbene in methylene chloride/aqueous sodium hydroxide/olefin mixtures[103]. Some of these compounds are stable at −30 °C over long periods of time. Similarly, olefin adducts of chloroiodocarbene can be obtained from chlorodiiodomethane[103]. Bromofluorocarbene[62], chlorofluorocarbene[62, 63], and

fluoroiodocarbene[64] can likewise be generated from dibromofluoromethane, dichlorofluoromethane, and fluoroiodomethane, respectively, with caustic soda and triethyl(benzyl)ammonium chloride. Stirring of the reaction mixture for 1—4 h appears to suffice for yield maximization. Addition of ClCF to a substrate having a free hydroxy group proceeds without complications (cf. Section 2.1.5)[63]. The facile production of iodine-containing carbenes from polyiodomethanes is remarkable since phase-transfer reactions are frequently inhibited by iodide ion. The iodide ion transfers preferentially to the organic phase[2,5]. Methylene chloride serves as cosolvent in all these preparations.

The basicity of the two-phase system is insufficient to convert methylene chloride and bromide into the carbenes, even if the reaction is conducted at elevated temperatures in an autoclave[57]. Attempts to generate chlorophenylcarbene from benzylidene chloride were likewise unsuccessful. However, it proves possible to scavenge adducts of chloro(phenyl)thiocarbene (2 hours' reaction at 40—50 °C)[18]. Small quantities of 1,2-dichloro-1,2-bis(phenylthio)ethylene occur as by-product. Chloro(methyl)thiocarbene behaves similarly[82].

2.1.8. Alkylidenecarbenes



Treatment of *N*-hydroxyalkyl-*N*-nitrosoacetamides having structure *(12a)* and *(12b)* in pentane/cyclohexene with caustic soda in the presence of catalytic amounts of trihexyl(methyl)ammonium chloride leads to the alkylidenecarbenes *(13a)* and *(13b)* respectively. These carbenes are scavenged, *e.g.* by cyclohexene, as *(14a)* and *(14b)*. With *(12c)*, however, rearrangement to acetylenes *(15c)* occurs instead[65]. Cyclohexylidenecarbene can be generated and scavenged similarly[66]. If *(16)* is decomposed in the presence of nucleophiles (X = azide, iodide, thiocyanate, *etc.*), the compounds *(17)* can be isolated. With isobutyraldehyde and cyclohexanone, *(16)* furnishes the compounds *(18)* and *(19)* respectively. Intermediacy of the carbene has yet to be established[67].

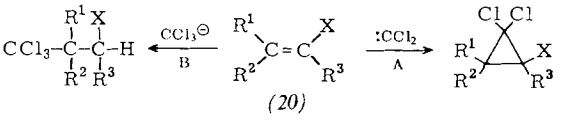
2.2. Reactions of Trihalomethyl Anions



2.2.1. Addition of Chloroform to Double Bonds

As shown in Section 1.3, the primary product of the phase-transfer reaction between sodium hydroxide and chloroform is the trichloromethyl anion (in the form of its ion pair). It is in equilibrium with dichlorocarbene and chloride ion (Scheme 6).

Scheme 6.

Depending upon whether electron-rich or electron-poor olefins are present, either the electrophilic CCl_2 or the nucleophilic $CCl_3^{\ominus}$ is scavenged from the equilibrium, or in some cases both[29,68,69]. The direction of the reaction is affected by small changes in electron distribution, as is apparent from Table 4. Analogous reactions occur with bromoform.

(20)

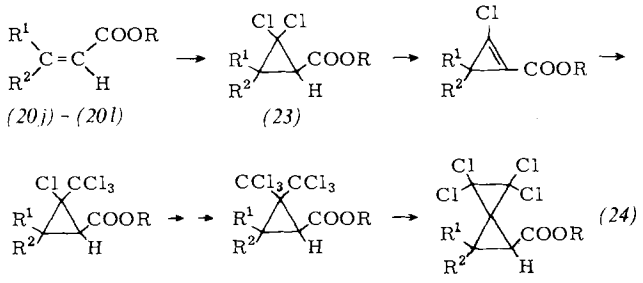
Table 4. Reactions of compounds *(20)* with chloroform, sodium hydroxide, and triethyl(benzyl)ammonium hydroxide as catalyst [29,69].

(20)	R^1	R^2	R^3	X	Direction
(a)	H	H	H	OAc	B
(b)	H	H	H	CN	B
(c)	H	H	CH_3	CN	A + B
(d)	CH_3	H	H	CN	B
(e)	Ph	H	H	CN	B
(f)	H	H	H	SO_2R	B
(g)	H	H	H	COOR	B
(h)	H	H	CH_3	COOR	A
(i)	H	CH_3	CH_3	COOR	A
(j)	CH_3	H	H	COOR	A [a] + B
(k)	CH_3	CH_3	H	COOR	A [a]
(l)	H	Ph	H	COOR	A [a]

[a] Followed by a secondary reaction, see Section 2.2.3.

Hydrolysis of the nitrile and ester plays a very minor role. α,β-Unsaturated carbonyl compounds mainly polymerize under the reaction conditions.

2.2.2. Nucleophilic Substitution by $CX_3^{\ominus}$



Trihalomethyl(phenyl)mercurials *(22)* are important halocarbene precursors. On moderate heating they generate the carbene without intervention of the $CX_3^{\ominus}$ ion[71]. The hitherto difficult preparation of these compounds is improved by the phase-transfer catalyzed reaction. A solution of 20 g sodium hydroxide and 37 g potassium fluoride per 100 g of water is treated with a suspension of 0.05 mol *(21)* and 0.4 g triethyl(benzyl)ammonium chloride in CHX_3 at 20 °C[70].

(21) *(22)*

2.2.3. Formation of Tetrachlorospiropentanes

Tetrachlorospiropentanes *(24)* are formed on reaction of *(20j)—(20l)* with the caustic soda/haloform/catalyst system[29]. *(23)* occurs as intermediate[57]. Two successive cycles of dehydrochlorination and addition of $CX_3^{\ominus}$ take place. The last step is initiated by $Cl^{\oplus}$ abstraction from the molecule by trichloromethylide. This type of reaction can also be performed with α,β-unsaturated steroidal ketones[57].

(20j) - (20l) (23) (24)

2.3. Alkylation of Carbanions

A great deal of information has accumulated about alkylations with simple and more complicated monohalo and bishalo compounds and about the promotion of *C- vs. O*-alkylation (see Section 1.2[104]).

Table 5 provides a survey of the classes of compounds so far alkylated by the phase-transfer method. The quaternary ammonium salts of relatively strong C—H acids can be isolated and then subjected to further reaction (cf. refs.[13–15, 17]). More weakly acidic compounds can only be alkylated catalytically. Depending upon the structure of the carbanion and alkylating agent, mono-*C*-alkylation predominates on suitable choice of the molar ratios. Simple aldehydes are prone to self-condensation under the reaction conditions. Hence the method can be applied only to the reaction of aldehydes bearing an α-hydrogen with reactive alkyl or benzyl halides if high yields of preparative interest are desired (for procedure see footnote[*]). Detailed investigations of the dependence of yields of such alkylations upon the type of catalyst used were performed in isolated cases[100b, 106].

Table 5. Compounds alkylated by phase-transfer catalysis [a].

Class of cpd.	Ref.
Substituted phenylacetonitriles	[1, 2, 5, 73, 87, 104]
Phenylthioacetonitrile	[74]

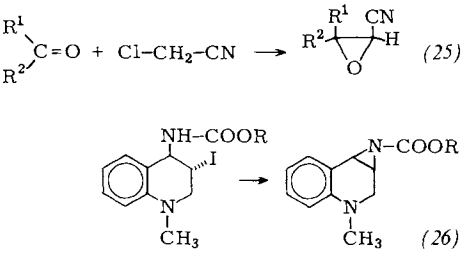
Hydrazobenzenes	[85]
1,4-Benzodiazepin-3-one	[86]

[a] For a structural tabular survey of individual substrates and alkylating agents including yields, see ref. [106].

[*] *2,2-Dimethyl-3-phenylpropanol:* A mixture of NaOH (140 g, 3.5 mol), water (140 g), benzene (200 ml), and tetrabutylammonium iodide (14.7 g, 0.04 mol) is heated to 70 °C. A mixture of isobutyraldehyde (288 g, 4 mol) and benzyl chloride (380 g, 3 mol) is added dropwise over a period of 5 h with stirring. Stirring is then continued for 2 h. Distillation of the organic phase affords 364 g (75 %) of product having b. p. 95 °C/7.2 torr [72].

Alkylation of malonic ester, benzyl cyanide, or benzyl methyl ketone: A mixture of the substrate (0.1 mol) and alkyl iodide (0.2 mol) in CH_2Cl_2 (100 ml) is added dropwise to a stirred mixture of tetrabutylammonium hydrogen sulfate (0.1 mol) and sodium hydroxide (0.2 mol) in water (100 ml). With methyl iodide the reaction is exothermic and complete within 10 min; with *n*-butyl iodide the mixture is boiled for 30 min. After phase separation the methylene chloride is evaporated off under reduced pressure. Tetrabutylammonium iodide is precipitated by addition of ether to the residue. Filtration is followed by distillation.—Variants of the method employ only 2—5 mol-% of catalyst and triethyl(benzyl)ammonium chloride or other salts [1].



2.4. Alkylation of Other Anions

2.4.1. Esterification

Esterifications can be accomplished in neutral solution by neutralizing one equivalent of acid and one equivalent of tetrabutylammonium hydrogen sulfate with two mol of aqueous sodium hydroxide and boiling the resulting mixture with the alkylating agent for 15—30 min[88, 89]. Almost quantitative yields are obtained even with sterically hindered acids (*e.g.* 2,4,6-trimethylbenzoic acid)[89]. The method can also be applied to dicarboxylic acids but finds its match with very hydrophilic compounds: tartaric acid is esterified in only 40 % yield.—When dimethyl sulfate is used as alkylating agent only 10 mol-% of catalyst are required[89].

2.4.2. Darzens Reaction to Give Oxiranes and Formation of Aziridines

The oxirane *(25)*[90] and the aziridine *(26)*[91] have recently been prepared by phase-transfer catalysis.

(25)

(26)

2.4.3. Ether Formation

The catalytic version of the Williamson ether synthesis[25] gives high yields in the case of symmetrical ethers (from alkyl halide, caustic soda, and catalyst). However, reaction of alcohol and alkyl halide bearing different groups yields a mixture of symmetrical and unsymmetrical ethers.

Very recently it was reported that high yields of methyl ethers can be obtained from saturated primary alcohols as well as from primary, secondary, and tertiary alcohols activated by electron-withdrawing or unsaturated groups with dimethylsulfate/aqueous sodium hydroxide/tetrabutylammonium hydroxide catalyst at 45 °C. Even neopentyl alcohol can be reacted[108].

2.4.4. Nucleophilic Displacements

The reaction

$$RX + Y^{\ominus} \rightarrow RY + X^{\ominus}$$

can be drastically accelerated by phase-transfer catalysis. The systems investigated contained chloride, bromide, iodide, methanesulfonate, and *p*-toluenesulfonate as leaving groups

and cyanide, bromide, acetate, iodide, thiocyanate, and cyanate as nucleophiles[5, 92, 100b]. If $X^{\ominus}$ is iodide or *p*-toluenesulfonate the reaction stops on reaching the phase partioning equilibrium of the anions. Thus the aqueous phase must be renewed several times to ensure complete reaction. In other cases (*e.g.* X = Br, Y = Cl) the progress of the reaction is halted by the chemical equilibrium. Here, too, the aqueous phase must be replaced to achieve complete reaction (for procedure see footnote[*]).

Primary C_4 to C_{16} alcohols have been converted into chlorides by boiling with conc. hydrochloric acid in presence of hexadecyl(tributyl)phosphonium bromide[109]. Average yields were around 60% after 8 h, and rose to 95% after 45 h.

In many cases the hydrolysis of esters and alkanesulfonyl chlorides is likewise accelerated by addition of a quaternary ammonium salt. Reaction is frequently exothermic and requires no external heating. On application of the technique to esters of long-chain acids the acid anions preferentially associate with the ammonium ion and hydrolysis remains incomplete or proceeds as slowly as if no catalyst were present[5].

2.5. Other Reactions Accelerated by Phase-Transfer Catalysis

2.5.1. Oxidation by $KMnO_4$

In the presence of trihexyl(methyl)ammonium chloride, neutral aqueous permanganate oxidizes terminal olefins to the carboxylic acids having one less carbon atom[5]. The reaction is exothermic; the temperature is maintained at 35—45 °C by the rate of olefin addition (cf. also ref.[100b]). Strongly basic aqueous permanganate with triethyl(benzyl)ammonium chloride as catalyst converts nonterminal olefins into *cis*-glycols in CH_2Cl_2 at 0 °C[93].

2.5.2. Replacement of Active Hydrogen Atoms by Deuterium

In the case of ketones replacement can be conducted with $NaOD/D_2O$/catalyst within 30 min at 30 °C[5].

2.5.3. Reductions with Boron Hydrides

Tetraalkylammonium tetrahydridoborate can be extracted quantitatively into CH_2Cl_2 from the caustic soda/tetraalkylammonium salt/$NaBH_4$ system when the alkyl groups contain 12 or more carbon atoms. After drying, this solution is added to the substrate to be reduced with methyl iodide which liberates diborane[94] according to

$$2BH_4^{\ominus} + 2CH_3I \rightarrow B_2H_6 + 2CH_4 + 2I^{\ominus}$$

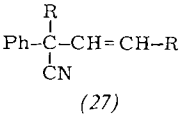
Quite analogously, one can prepare solid tetrabutylammonium cyanotetrahydridoborate[110]. This reagent is useful for the reduction of iodides and bromides at room temperature in hexamethylphosphoramide solvent. Under these conditions carbonyl groups, amides, cyanides, and aromatic nitro groups are not affected. In the presence of 0.1 N acid, however, aldehydes are reduced while ketones are not attacked at room temperature.

2.5.4. Benzoin Condensation

Tetrabutylammonium cyanide permits the benzoin condensation to be carried out in water at room temperature within 1.25 h[95].

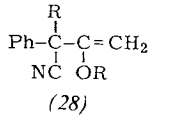
2.5.5. Wittig Reaction

Märkl and *Merz* recently showed that non-stabilized phosphonium salts can also be deprotonated with caustic soda in methylene chloride[96]. Since phosphonium salts are themselves phase-transfer catalysts, no ammonium salt is necessary. In the presence of aldehydes, Wittig reaction is faster than the undesired degradation to phosphane oxide. In the examples described R^1 is aryl or styryl; R^2/R^3 is H, CH_3, or phenyl. Yields between 20 and 88% are reported (for procedure see footnote[*]).



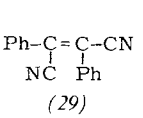
$$R^1CHO + Ph_3\overset{\oplus}{P}-CHR^2R^3 \xrightarrow{CH_2Cl_2,\,NaOH} R^1CH{=}CR^2R^3 + Ph_3PO$$

2.5.6. Other Reactions



A sulfur ylide can be generated from trimethylsulfonium iodide in the system methylene chloride/aqueous sodium hydroxide/tetrabutylammonium salt. Reaction with benzaldehyde gives *e.g.* 90% 2-phenyloxirane within 48 h at 50 °C[111]. Ketones give rise to lower yields. In a similar fashion, trimethyloxosulfonium iodide is transformed into the related ylide which is useful for the formation of cyclopropyl ketones from aromatic α,β-unsaturated ketones[111].

If conjugated olefins are formed HX eliminations can be accelerated by phase-transfer catalysis[106]. An investigation of the effectiveness of *n*-alkyl(triethyl)ammonium salts relative to the chain lengths showed maximum activity with the *n*-hexyl compound. The catalytic effect decreased strongly towards shorter chains but only slightly towards longer alkyl groups[106].



Catalyzed addition of phenylacetonitrile to acetylenes affords *(27)* (R = H, Ph, SR) or, in the case of ethoxyacetylene, *(28)*[97, 98]. DMSO/solid NaOH/catalyst is used here.

(27)

(28)

(29)

The catalytic reaction of phenylacetonitrile with CCl_4 to yield *(29)* also deserves mention[99].

[*] *1-Decyl acetate:* 1-Bromodecane (55 g, 0.25 mol), Na-acetate·$3H_2O$ (270 g, 1.98 mol), and trihexyl(methyl)ammonium chloride (10 g) are stirred for 1 h at 105 °C. Gas chromatography indicates practically quantitative reaction [92].

1-Thiocyanatodecane: A mixture of 1-bromodecane (100 g, 0.45 mol), NaSCN (160 g, 7.98 mol), water (50 ml), and trihexyl(methyl)ammonium chloride is stirred for 2 h at 88—105 °C. Gas chromatography indicates quantitative reaction of the bromodecane [92].

[*] *cis- and trans-Stilbene:* 50% caustic soda (10 ml) is run into a vigorously stirred mixture of benzaldehyde (2.06 g, 20 mmol), benzyl(triphenyl)phosphonium iodide (7.86 g, 20 mmol), and CH_2Cl_2 (10 ml). A weakly exothermic reaction ensues which is complete after *ca.* 10 min. The organic phase is separated off, washed with water, dried, and the solvent removed under reduced pressure. Addition of ethanol (15 ml) and cooling in an ice bath induces crystallization of *trans*-stilbene [m. p. 123—124 °C, yield 1.2 g (33%)]. Vacuum distillation of the filtrate affords *cis*-stilbene [b. p. 60- -62 °C/0.01 torr, $n_D^{20} = 1.6215$, yield 1.7 g (47%)] [96].

3. Outlook

The first publications on phase-transfer catalysis, which appeared in Polish in 1965, attracted little attention. Since about 1969, the method has been adopted by several research groups and publicized. Steadily increasing interest has been the result. Owing to its simplicity and the low cost of the reagents, the method should soon find universal application, not least in many technical processes. We can predict that it will be extended to more and more types of reaction. It is the author's wish to have stimulated the readers' imagination in this respect.

The author's own work cited in this report was supported by the Deutsche Forschungsgemeinschaft. Thanks are due to Doc. Dr. Makosza and Prof. Dr. Brändström for kindly providing access to papers currently in the press.

Photochemistry with Circularly Polarized Light

By Ole Buchardt[*]

The reactions induced by circularly polarized light are reviewed and a general discussion of the induction of optical activity by circularly polarized light is presented. It is concluded that three different mechanisms, or their combinations, can cause asymmetric induction. In each case the optical yield is dependent on the optical anisotropy factor g, the ratio between the circular dichroism ($\Delta\varepsilon$) and the extinction coefficient (ε). The results are discussed in terms of the presumed mechanisms, and particular attention is paid to the asymmetric synthesis of helicenes. It is concluded that this kind of photochemistry may have analytical importance.

1. Introduction

Introduction of optical activity into a chemical system without the use of any asymmetric chemical agent has attracted the attention of chemists for a long time, particularly in connection with the question of the origin of optical activity in living organisms[1-5].

Already in the pioneering paper of *Le Bel* in 1874[6] it was inferred that asymmetric induction could be caused by circularly polarized light, and the possibility was definitely stated by *van't Hoff* in 1894[7]. The detection of circular dichroism by *Cotton*[8] further corroborated that circularly polarized light could induce optical activity in chemical systems, and in the following years a number of papers appeared which described attempts to test the possibility. However, it was not until 1929 that such an attempt met with unequivocal success[9].

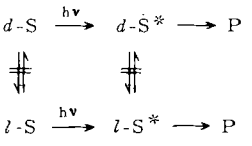
Universitetsparken 5, DK-2100 Copenhagen Ø (Denmark)

2. How Can Asymmetric Induction with Circularly Polarized Light Occur?

The first condition to be met is that the light must be absorbed, since only light absorbed by a molecule can induce a photochemical reaction (Grotthus-Draper law)[*]. Secondly it is necessary to irradiate with light of such a wavelength that the circular dichroism is different from zero, or if broad band light is used, the integral of the circular dichroism over all wavelengths used must be different from zero.



It is furthermore convenient to distinguish between three different mechanistic principles for asymmetric induction with circularly polarized light, namely:

1. Asymmetric destruction:
2. Partial photoresolution; and
3. Asymmetric synthesis[10].

[*] This does not in principle exclude a sensitized photochemical reaction where a chiral or prochiral molecule transfers energy to another prochiral molecule. However, so far no such mechanism has been proposed to explain asymmetric induction by circularly polarized light.

2.1. Asymmetric Destruction

In order to observe only asymmetric destruction we must have a substrate which consists of a racemic mixture whose enantiomers do not interconvert thermally or photochemically at the temperature at which the irradiation with circularly polarized light takes place. Furthermore, the substrate must undergo a photochemical reaction, *i.e.*

Irradiation with circularly polarized light of a wavelength where the circular dichroism is different from zero will excite more of one enantiomer than of the other (Cotton effect)[8, 12], thus

$$\frac{-\mathrm{d}[d\text{-S}]}{\mathrm{d}t} \neq \frac{-\mathrm{d}[l\text{-S}]}{\mathrm{d}t}$$

and after any time of irradiation and until there is no more substrate left, we will have different concentrations of *d*-S and *l*-S, and thereby an asymmetric destruction has been effected.

Obviously the optical yield[*] will be wavelength-dependent, and *Kuhn*[13] has shown that the observed rotation of the substrate after partial destruction is

$$\frac{g}{2} \times \mathrm{T} \times (1-\alpha) \ln \frac{1}{1-\alpha}$$

where α is the degree of destruction and T is the rotation which the total amount of substrate would have shown if it had been optically pure, and g is the optical anisotropy factor[14].

$$g = \frac{\varepsilon_L(d\text{-S}) - \varepsilon_R(d\text{-S})}{\varepsilon}$$

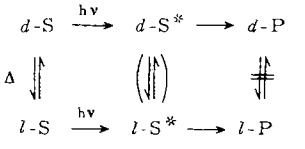
$\varepsilon_L(d\text{-S})$ and $\varepsilon_R(d\text{-S})$ are the extinction coefficients for the *d*-substrate with left and right circularly polarized light, respectively. Naturally

$$\varepsilon_L(d\text{-S}) = -\varepsilon_R(l\text{-S});\ \varepsilon_L(l\text{-S}) = -\varepsilon_R(d\text{-S})$$

Kuhn furthermore concluded that the maximal rotation would be equal to $g \times \mathrm{T} \times 0.184$, and that at a sufficiently high degree of photodestruction rather high optical purity of the remaining substance could be expected, *i.e.*, with $g = 0.04$, when 60% is left, the optical yield would be 1%; at 98.2% destruction 8%; at 99.995% destruction 20%; and if destruction is continued until only few molecules are left, quite high optical yields could be expected[13].

2.2. Partial Photoresolution

Partial photoresolution can take place in systems which undergo light-induced inversion, *i.e.*,



Again the wavelength must be such that the circular dichroism is not zero, and it can be shown that the maximum optical yield is:

$$\frac{|g|}{2} \times 100\%$$

2.3. Asymmetric Synthesis

Evidently there is a possibility that the products from asymmetric destruction themselves can be asymmetric and thus their formation would constitute what should be called an asymmetric synthesis, although, if such a reaction were completed, no asymmetric induction would be observed.

Otherwise an asymmetric synthesis can be expected in systems of the following kind, *i.e.*[*]

where there is a thermal equilibrium between the two enantiomeric conformations[**].

By irradiating with circularly polarized light of a wavelength for which the circular dichroism is not zero, differential excitation of the two enantiomers (*d*-S and *l*-S) will take place. If the relaxation to products is faster than a possible racemization in the excited state, and the products as indicated are chiral, an asymmetric synthesis has been performed.

The maximum optical yield can be calculated as

$$\left|\frac{\varepsilon_L(d\text{-S}) - \varepsilon_L(l\text{-S})}{\varepsilon_L(d\text{-S}) + \varepsilon_L(l\text{-S})}\right| = \left|\frac{\varepsilon_L(d\text{-S}) - \varepsilon_R(d\text{-S})}{\varepsilon_L(d\text{-S}) + \varepsilon_R(d\text{-S})}\right| = \frac{|\Delta\varepsilon|}{2\varepsilon}$$

or, expressed as a percentage,

$$\frac{|g|}{2} \times 100$$

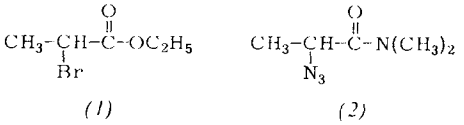
From the above discussion it is apparent that the magnitude of the optical yield is dependent on g. Unfortunately g values are as a rule rather small; for strong absorption bands $g < 10^{-3}$, and even for weak absorption bands with a strong rotatory power, the g values are only expected to be of the order of magnitude of 10^{-2}[14].

3. Experimental Results

In most of the early work the source of optical rotation and the circularity of the light are not well defined and it is often difficult to understand why optical activity was observed. Furthermore, as the optical activity in several cases was marginally small, this makes it difficult to understand the mechanism, and the major emphasis has been placed on the most recent results in the following discussion.

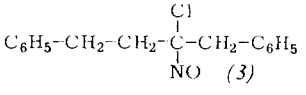
[*] *d*-P and *l*-P only mean that the two products are enantiomers.

[**] It is interesting to note that virtually all but the very simplest molecules will exist in either enantiomeric conformations or enantiomeric states; *i.e.*, even a molecule like methane has conformations which are enantiomers and thus any notion that symmetric precursors should somehow be able to transfer "chirality of light" to give products in quantitative optical yield is unrealistic for this reason alone.



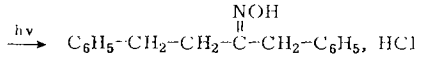
3.1. Asymmetric Destruction

As early as 1896 *Cotton*[8, 15] reported some unsuccessful attempts to destroy racemic salts of tartaric acid asymmetrically; similarly, an attempt to asymmetrically destroy, *inter alia*, racemic diazocamphor also met with failure[11].



The first positive results were obtained by *Kuhn* and *Braun*[9] who successfully destroyed ethyl α-bromopropionate *(1)* with right and left circularly polarized light and obtained a low level of optical activity; the products from the photodestruction were not identified, and the source of the optical activity was not certain. However, *Kuhn* and *Knopf*[13, 16] shortly thereafter reported their elegant experiments with *N,N*-dimethyl-α-azidopropionamide *(2)*, which on irradiation with right or left circularly polarized light to 40% conversion gave mixtures with rotations at the sodium D-line of $+0.78°$ and $-1.04°$, respectively. The observed rotation is in good agreement with the *g*-factor of the substrate, which was calculated to be 0.02—0.03[14]. The signs of rotation are also in good agreement with theory[13, 16]. The products consisted of *N,N*-dimethylurea and an oily optically inactive, unidentified substance[13].

At the same time *Mitchell*[17] irradiated racemic "humulene nitrosite"[*] with right and left circularly polarized light, and obtained rotations ($\lambda = 546$ nm) of $+0.11°$ and $-0.09°$, respectively; however, the source of the rotation was not established[18]. In related experiments *Mitchell et al.* observed that 2-chloro-2-nitroso-1,4-diphenylbutane *(3)* became optically active upon irradiation to *ca.* 50% conversion[19]. Interestingly, these results have recently been repeated and found to be reproducible[20]. Marginal optical activity results on irradiation of the 4-(2-nitrophenyl)-1,4-dihydropyridine derivative *(4)* with circularly polarized light to give *(5)*[21].



More recently, in connection with an attempt to undertake an absolute asymmetric synthesis, it was reported that asymmetric destruction of the 2-cyclopentenone dimer *(6)* could be effected with circularly polarized light[22]. It has also been shown that racemic hexahelicene undergoes asymmetric destruction, with formation of unknown products[23] (see Section 3.3).

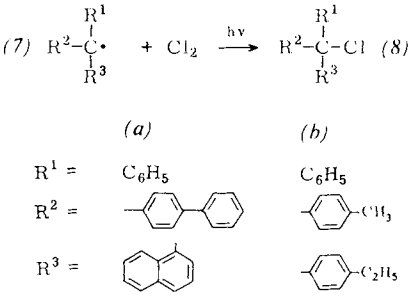
(4) *(5)*

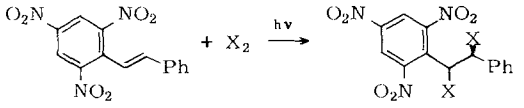
(6)



[*] Product of uncertain structure formed on addition of N_2O_3 to the sesquiterpene humulene.

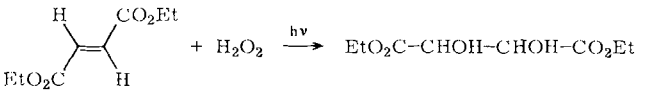
3.2. Partial Photoresolution

So far only a rather limited amount of work has been done, but the results appear to be encouraging enough to merit further exploration. *Stevenson et al.*[24, 25] found that aqueous solutions of racemic trioxalatochromate(III), di-μ-hydroxo-bis[dioxalatochromate(III)], and *cis*-dioxalatodiaquochromate(III) upon irradiation with circularly polarized light were partially resolved into their enantiomers. It was also shown that *trans*-dioxalatodiaquochromate(III) became optically active under the same conditions; this is presumably due to its light-induced isomerization to the *cis*-form, which is then partially resolved by circularly polarized light. This was independently corroborated by other workers who irradiated potassium trioxalatochromate(III) ($g = 0.04$) with circularly polarized light and also obtained photoresolution[26]. In a closely related experiment *Stevenson*[27] demonstrated the applicability of this method in a partial photoresolution of tris(2,4-pentanedionato)chromium(III).



3.3. Asymmetric Synthesis

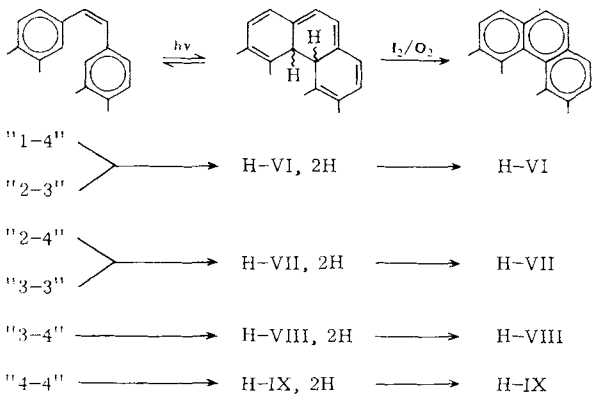
The chemical literature contains several reports of absolute asymmetric synthesis with circularly polarized light. However, in all the early work the rotations were marginal and the source of optical activity not well established. The first reports to claim a successful asymmetric synthesis were those of *Karagunis* and *Drikos*[28, 29]. They stated that irradiation of mixtures of chlorine and triarylmethyl radicals *(7)* with circularly polarized light resulted in the generation of optical activity, which they ascribed to an asymmetric synthesis of the triarylmethyl chloride *(8)*. The source of optical activity was not identified and, in view of the very complex character of the reaction mixture, it is difficult to understand the details of these results.



The results of *Davis et al.*[30, 31] also appear rather puzzling. They found that irradiation of mixtures of bromine and 2,4,6-trinitrostilbene *(9)* led to a light-induced addition of bromine to the double bond. After irradiation with circularly polarized light, marginal optical activity of the reaction mixture could be observed[30]. Similar results were described for chlorine and trinitrostilbene[31]. In this case also, the source of the optical activity was not identified, and it is noteworthy that a later attempt to reproduce the results failed[20].

Ten years later *Davis et al.*[32] reported that irradiation of a mixture of diethyl fumarate *(10)* and hydrogen peroxide with circularly polarized light resulted in the formation of

(9) X = Cl, Br



(10) *(11)*

optically active diethyl tartrate. However, the source of optical activity was not definitely determined. These results have also proved to be non-reproducible[22]; not only were later workers unable to measure any optical activity, but they even failed to detect any diethyl tartrate by gas chromatography.

Recently two independent attempts to synthesize helicenes asymmetrically with circularly polarized light have been undertaken. It was found that if the previously described[34] light-induced formation of helicene[*] from either 1-phenyl-2-(2-benzo[c]phenanthryl)ethylene ("1—4")[*] or 1-(2-naphthyl)-2-(3-phenanthryl)ethylene ("2—3") was carried out with circularly polarized light, optically active hexahelicene was formed[23, 35, 36]. Similarly, it was shown that optically active

Scheme 1. Principle of light-induced helicene synthesis, after [34].

A related attempt to generate optically active 1,2-dichloropropane by the light-induced reaction of propene with chlorine using circularly polarized light was also reported to be successful[33]. A later attempt to reproduce this failed to reveal any optical activity[22].

[*] For simplicity, the helicenes for which there are no definitive IUPAC nomenclature rules will here be designated as follows: hexahelicene = H-VI; octahelicene = H-VIII; 2-fluorohexahelicene = 2-F-H-VI, *etc.* The precursors are symbolized by the number of benzene rings already present: 1-phenyl-2-(2-benzo[*c*]phenanthryl)ethylene = "1-4"; 1-(4-fluorophenyl)-2-(benzo[*c*]-phenanthryl)ethylene = *p*-F-"1-4", *etc.*

hepta- (H-VII), octa- (H-VIII), and nonahelicene (H-IX) could be generated by irradiation of the corresponding diarylethylenes with circularly polarized light[36-38] (Scheme 1).

In each case both right and left circularly polarized light was used, and it was found that in the wavelength regions employed, *i.e.*, 290—370 nm[23,27], 340—400 nm[36], and 370 ± 6 nm[38], right circularly polarized light led to a product with a negative rotation, whereas left circularly polarized light gave a positive rotation (measured at 589 and 436 nm, Table 1).

A priori, the observed asymmetric induction could be caused by any one of the three previously discussed mechanisms (Section 2), or combinations thereof. Thus asymmetric destruction of the helicenes appeared to be a possibility, and since the primary light-induced reaction which leads to dihydrohelicenes is photoreversible, the optical activity could also be due to a partial photoresolution at this stage[23,37]. The oxidation to helicenes is believed to be thermal[39-42].

However, the fact that this reaction also has the potential for an asymmetric synthesis was one of the main reasons for studying it[43]. From Scheme 2 it is seen that the diarylethylenes, *e.g.*, the "1-4" precursor, form mixtures of equal amounts of enantiomeric conformers which can thermally racemize by either of the two pathways shown.

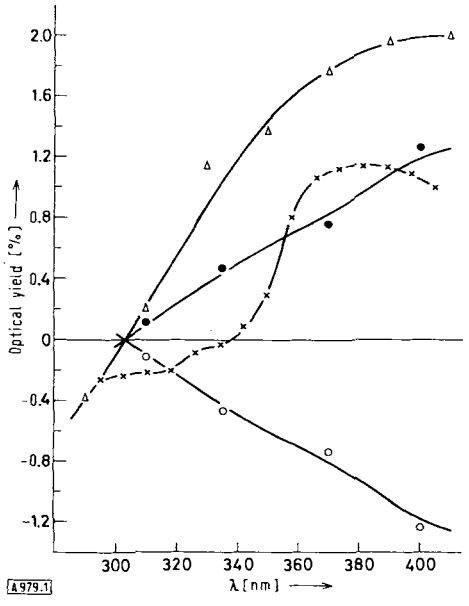
In order to shed more light on the mechanism, two types of experiments were performed:

a) It was attempted to destroy hexahelicenes asymmetrically under circumstances where asymmetric induction was observed with the diarylethylenes; however, no optical activity was observed. Furthermore, in the case of asymmetrical destruction rotations opposite to those found would be expected[23,36]. However, on prolonged irradiation of racemic helicenes with circularly polarized light, asymmetric destruction did in fact take place, and rotations opposite to those of the original experiments were found[23].

b) The wavelength dependency of the optical yield was examined for some of the helicene precursors (Fig. 1)[36,38].

Finally, a valid mechanism should be able to explain why the "1-4" substrate only gives a fraction of the optical yield which is found in the case of the "2-3" precursor (Table 1).

The first mechanism (asymmetric destruction) can be discarded: (a) Since no optical activity could be observed with the pure helicenes under otherwise similar conditions; (b) because of the sign of rotation; (c) since the optical yield as a function of wavelength is not proportional to the *g*-factor (as shown for octahelicene in Fig. 1); (d) because this



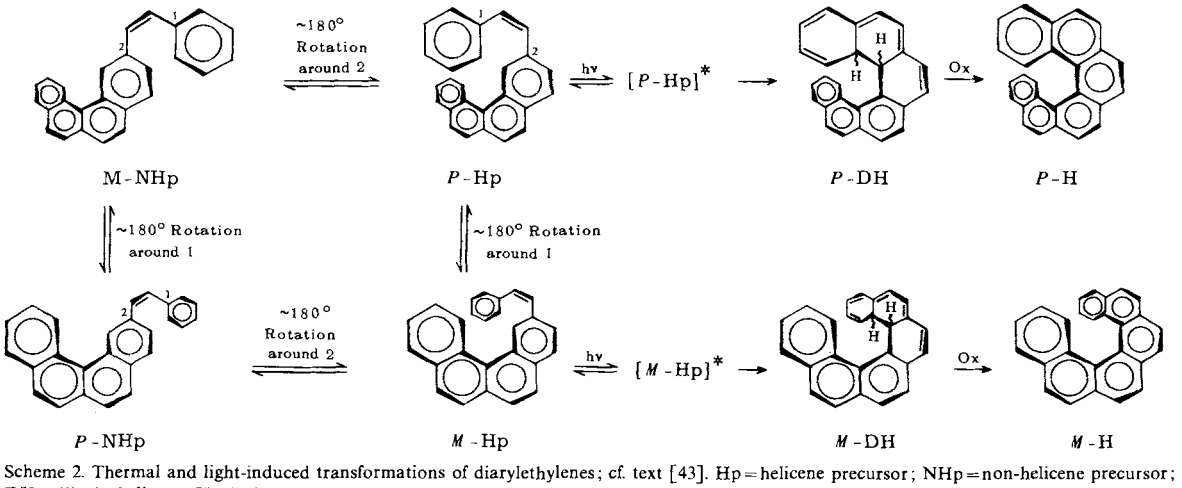


Fig. 1. Wavelength dependence of the optical yield for: ●, "2-4" irradiated with left circularly polarized light; ○, "2-4" irradiated with right circularly polarized light; △, "3-4" irradiated with left circularly polarized light; ×, "*g*" of octahelicene.

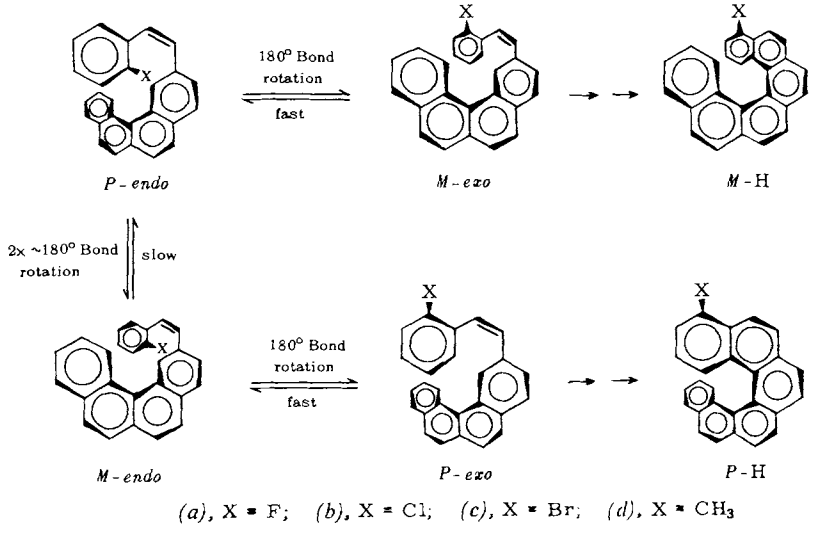
mechanism cannot explain the difference in optical yield of hexahelicene from the "1-4" *versus* the "2-3" precursor (Table 1).

The second mechanism (partial photoresolution) can be discarded because: (a) The literature indicates that the oxidation of dihydrohelicenes is too fast[39,40]; (b) because the optical yield curves (Fig. 1) which reflect the *g*-values of the substrates, *i.e.*, the dihydrohelicenes, would be expected to be different[36,38]; (c) this mechanism could not easily explain the difference in optical yield from the "1-4" *versus* the "2-3" precursor.



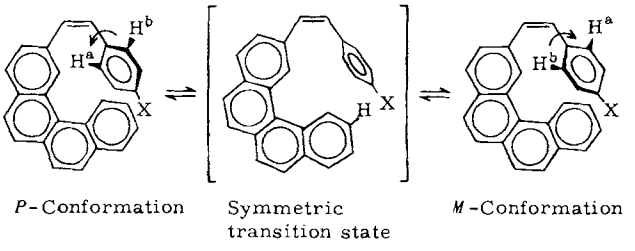
We can thus conclude that the mechanism responsible for the asymmetric induction is the asymmetric synthesis, which fits the experimental results in a satisfactory manner: (a) The

Scheme 2. Thermal and light-induced transformations of diarylethylenes; cf. text [43]. Hp = helicene precursor; NHp = non-helicene precursor; DH = dihydrohelicene; H = helicene.

sign of the rotation is correct; (b) the optical yield curves follow the expected g-curves for the substrates, cf. ref.[36]; (c) the difference in optical yield for the "1-4" *versus* the "2-3" precursor can be explained as follows: From Scheme 2 it can be seen that in the "1-4" precursor it only takes a rotation of $\approx 180°$ about the phenyl-ethylene bond to interchange the enantiomers, whereas racemization in the "2-3" precursor is believed to be a process requiring more energy. It was therefore proposed that some racemization could take place in the excited singlet state of "1-4", which is presumably responsible for the ring closure[40], whereas this is not the case for the "2-3" precursor. The more trivial explanation that the difference was due to different g-values of the two precursors was not excluded[36].

A solution of this problem was attempted by irradiating a series of *ortho*-substituted "1-4" precursors (Table 1; Scheme 3).

Scheme 3. Transformations of *ortho*-substituted "1-4" hexahelicene precursors.



It seems reasonable to assume that the substituent does not contribute significantly to the electronic structure of the molecule. Therefore it is expected that both the *endo* and *exo* forms will have nearly the same circular dichroism and absorption spectra as the unsubstituted compound.

From Scheme 3 it is seen that closure to the helicenes can only take place from the *exo*-conformations and that rotation of $\approx 180°$ about the phenyl-ethylene bond will interchange the *M-endo* form with the *P-exo* form, *etc.*

This means that racemization by a simple $\approx 180°$ rotation is no longer possible, and if, as expected, the majority of the substrate molecules exist as the *exo*-enantiomers, the optical yield from these compounds will be of the same order of magnitude as that from the "2-3" precursor[44,45]. The results, listed in Table 1, are in excellent agreement with the bond-rotation hypothesis, *i.e.*, that the difference in optical yield from "1-4" *vs.* "2-3" is due to racemization in the excited state of the "1-4" precursor[38,46].

The corresponding *para*-substituted "1-4" precursors were also irradiated with circularly polarized light, and, *a priori*, it was expected that they would behave like the unsubstituted "1-4" precursor. As can be seen from Table 1, this is not the case; the optical yield increases with increasing size of the substituent[38]

An explanation for this was found by inspection of molecular models, where it is seen that the *para*-substituent in the phenyl group interacts sterically with the hydrogen in the 11-position of the benzo[*c*]phenanthryl group in the transition state for racemization (Scheme 4). Thus, as the *para*-substituent increases in size, the activation energy for racemization could

Scheme 4. Racemization of *para*-substituted "1-4" hexahelicene precursors.

be expected to increase (Fig. 2), thereby prohibiting the racemization in the excited state.

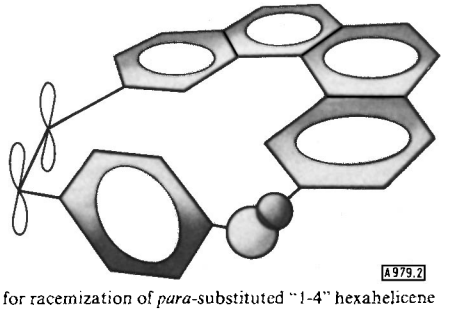


Fig. 2. Transition state for racemization of *para*-substituted "1-4" hexahelicene precursors.

Finally it should be mentioned that when 1-phenyl-2-(2-hexahelicenyl)ethylene is irradiated with circularly polarized light to complete disappearance, the octahelicene formed is optically inactive, but if the reaction is stopped before that, the octahelicene has a small but significant rotation[37].

4. Miscellaneous Results

Besides the literature quoted and discussed so far, there are several reports of fruitless attempts to induce optical activity with circularly polarized light. Some examples of these are:

Light-induced decarboxylation of α-methyl-α-cyanobutyric acid and α-methyl-α,β-dichlorosuccinic acid[47]; utilization of the Ciamician reaction of nitroaromatics in an asymmetric transformation of 2-nitrobenzaldehyde dipentyl acetal with circularly polarized light to pentyl 2-nitrosobenzoate[48]: addition of bromine to angelic acid[49]; preparation of the hydrogen sulfite adduct of acetaldehyde during irradiation with circularly polarized light[50].

Some positive results which apparently never have been explained are that the rate of mutarotation of a sugar was dependent on whether irradiation took place with right or left circularly polarized light[51]. The irradiation of photographic material with circularly polarized light led to the formation of optically active substances[52].

Furthermore, there have been attempts to utilize the combination of a magnetic field with photochemistry to induce optical activity, cf. ref.[53][*]; and attempts to show that circular polarization of *Bremsstrahlung* (γ-rays) can cause asymmetric induction have been reported[5, 55, 56].

5. Conclusion

Although photochemistry with circularly polarized light has been a subject of study for many years, it appears to be a promising area for further investigation. It seems reasonable to expect that new systems that will give asymmetric induction by irradiation with circularly polarized light can be found, in spite of the fact that few positive results have so far been reported.

Photochemistry with circularly polarized light using selected substrates permits a partial optical resolution or destruction which may be of interest in some cases. Of more importance may be the possibility of obtaining CD spectra of otherwise unresolvable (conformeric) enantiomers as well as new information about the chemistry of excited states.

Received: February 7, 1973 [A 979 IE]
German version: Angew. Chem. 86, 222 (1974)

[*] As a result of the Faraday effect, the passage of plane polarized light through a medium placed in a magnetic field whose direction is parallel to the direction of the light will cause either magnetic optical rotatory dispersion (MORD) or, if the light corresponds to an absorption band of the substrate, magnetic circular dichroism (MCD) [12]. Thus, in principle, optical activity can be induced by circularly polarizing the light in the medium, cf. refs. [53—54].

Recent Discoveries in the Evolution of Proteins

By Roger Acher[*]

Is it possible to reconcile the great diversity of present-day proteins with a unitary theory of the evolution of these molecules? The mechanisms of diversification of proteins are undoubtedly not yet all known, but it is clear that the linear construction of polypeptide chains lends itself to operations such as addition, insertion, deletion, and fusion. Combinations of these modifications would explain the development of an infinite number of entirely different proteins from one ancestral molecule.

1. Introduction

If it is accepted that proteins are the second reflection of genes by the double mechanism of the transcription of deoxyribonucleic acids into messenger ribonucleic acids and the translation of the latter into polypeptide chains[1], the variation of their amino-acid sequence can give us a fairly faithful picture of the events that affect or have affected the genes. The neo-Darwinian theory of evolution assumes that genes have been modified in the course of time by mutations similar to those that can be observed today, *i. e.* by random minor mutations, and that natural selection has led to evolutionary lines. This theory accounts for the fact that the variation of organisms, as revealed by paleontology, is diffuse in its endeavors and yet progressive in its results, the most recent species being the most highly adapted. The observations on which this view is based are thus essentially morphological. It must be pointed out that while natural selection does not act equally on all the organs, but acts, for example, at one time on the organs of locomotion and at another on the respiratory organs, *etc.*, and so leads to inequalities in the evolutionary rhythms of these organs, coordination must have existed between the individual evolutions of the various parts to lead to animals as highly organized as mammals and birds.

The evolution of molecules, *i. e.* of genes and consequently of proteins, presents no new theoretical problems with regard to the evolution of organisms if one accepts the Darwinian view. The combination of mutation and selection can also be invoked here, and the provision of a chain of enzymes to ensure regulated biosynthesis of histidine presents no more difficulty than *e. g.* the integration of specialized elements leading to an eye having the property of accommodation. On the other hand, the theory also has its weaknesses, such as the arbitrary choice of the organ or of the molecule designated to play a predominant role in the future, the fact that the advantage of the initial mutation is too small for selection to seize upon, the difficulty of explaining the coordination of the various individual evolutions, *etc.*

The question has been raised whether proteins really evolve, *i. e.* pass through structures increasingly efficient on the biological level, or whether the action of selection stops on the morphological plane (the deoxyribonucleic acids constituting the genes evolve them by definition). In this case the substitutions observed in the proteins from one species to another would have no evolutionary significance. It seems difficult to accept that evolution has been quantitative only at the level of the proteins and qualitative at the anatomical level. On the other hand, the number of different proteins present in a mammal is considerably greater than that found in a bacterium[2], and cellular differentiation must have led to multiplication and specialization of the proteins.

A special difficulty in the study of the evolution of proteins is that whereas an organ more or less expresses its function in its form and thus permits comparative evaluation from one species to another, this is not so for a molecule, even in the fairly rare cases in which its three-dimensional structure is known. The conformation of a protein is not functionally intelligible by itself. The "biological" function of a protein is determined by its ability to associate with other molecules, *i. e.* to participate in specific interactions. In these interactions, the morphology of the protein on the one hand and the nature of the exposed chemical groups on the other are fundamental, since the first of these factors determines the possibility of contact and the second the possibility of bonding. Since the soluble proteins are more or less globular macromolecules, it is clear that some of the residues will be buried and will not intervene directly in external interactions; on the other hand, these residues take part in interactions within the globule, so ensuring its stability. The constraints that evolution can exert on the protein will differ according to whether the residues concerned are on the surface or buried, and the three-dimensional structure of the protein must therefore be known for an interpretation of the substitutions. The conformation of the molecules that react with the protein (substrates, receptors, antigens, *etc.*) must also be known, since natural selection acts on the function that results from the interaction. Insofar as biological properties cannot yet be translated on the atomic level, the meaning of amino-acid substitutions is still difficult to perceive. One is usually reduced to taking stock of the structural variations of the proteins in the hope of learning closer details of the action mechanisms.

It is clear that one can only study the proteins of species that are now living, *i. e.* species at the ends of their evolutionary lines. One can postulate that the physiological functions, and consequently the proteins involved in them, have evolved with rhythms very roughly parallel to that of the evolution of the general morphology. In this case the proteins of existing lower species could be regarded as relatively close to the ancestral proteins. It is possible to verify this assumption by examining species that are morphologically similar, but for which paleontology indicates that they belong to lines that diverged a long time ago.

[*] Prof. Dr. R. Acher

For example, the primitive bony fish *Polypterus bichir* belongs to the line of Polypteriforms, which separated about 300 million years ago from the line of the Actinopterygians (modern bony fish)[4]. Nevertheless, it possesses the same neurohypophyseal hormones as the latter, whereas mammals and birds, which branched off at roughly the same period, have different neurohypophyseal hormones. Further examples are necessary, however, before the parallelism of the morphological and molecular evolutions can be broadly accepted.

Great progress has been made in recent years in the purification and sequence analysis of proteins, and the number and size of the known proteins have considerably increased since 1966[5]. Automated determinations of amino-acid sequences will considerably increase the volume of the "Atlas of Protein Sequence and Structure"[6], whose contents are already doubling annually. The number of living species is probably of the order 5—10 million[7], and if each species is assumed to possess its own specific proteins, with a purely arbitrary average of 100000 proteins per species, there must be 500 to 1000 billion proteins to try the endurance of biochemists and their instruments. However, progress in the determination of sequences will tell us little about the relations that exist between structure and biological activity until similar progress has been achieved in the study of conformations.

Insofar as all hereditary variations known at present are mutations, and evolution by definition implies changes in the genetic material, the current "mutations" of proteins are particularly valuable for the elucidation of the mechanisms that might have been involved in their evolution. This progress report will therefore examine the different types of structural variations shown both by molecular genetics and by comparative biochemistry with the aid of selected examples.

While classification of biological species is relatively easy, the same cannot be said of the classification of molecular species. The sequence of each protein is assumed to be determined by a structural gene, which itself consists of a sequence of deoxyribonucleotides. The fate of this structural gene is to some extent independent of the fate of the biological species. The formation of a new biological species from an old one (speciation) can take place without modification of the structural gene. Conversely, the structural gene may be duplicated and give two lines of proteins without the formation of two new biological species. A protein is recognized primarily by its biological function; isolation of the proteins of different species on the basis of this criterion gives a family of "homologous" proteins that have structural similarities among themselves. When several proteins apparently having the same function but differing from one another in their amino-acid sequences ("isologous" proteins) are found in a single species ("polymorphism"), each of these proteins is assumed to correspond to a separate structural gene; in this case, particularly if polymorphism is not general to all the species compared, it may become difficult to pick out the lines of homologous proteins among the isologous proteins. In a given biological species, moreover, proteins having different functions may show structural similarities that lead one to assume that the structural genes must have been derived from a common ancestral gene by duplication and mutation. The structural analogies are less pronounced in this case than in the case of isologous proteins. These chemically similar but functionally different proteins could be referred to as "analogous" proteins.

2. Families of Homologous Proteins

A number of cases are known in which the protein is recognizable on the ladder of vertebrates both by its function and by certain structural elements. Paleontology has shown that the vertebrates developed during the last 500 million years, so that the variations of their proteins extend over a sufficiently long time to reveal general trends. The families that now offer a range extending from the lower vertebrates to the mammals are still limited in number: cytochrome c, the α and β chains of hemoglobin, fibrinopeptides, and neurohypophyseal hormones. The observations gathered so far indicate that there is little variation in the length of the polypeptide chain, and that the most common type of modification is the substitution of amino-acid residues. The substitution of an amino acid can be brought about by the substitution of a single base in the triplet of nucleotides that codes each residue at the gene level (point mutation), and this explains why the phenomenon is so frequent.

2.1. Substitutions of Amino Acids

Comparison of the sequences of the proteins of a single family shows that certain positions are immutable, while others are substituted with various frequencies. The substitutions must not affect the general conformation of the molecule, which determines its function. It is therefore interesting to examine first the reasons for the invariability of certain positions of the polypeptide chain.

2.1.1. The Functional Invariability of Hydrophobic Residues

Through the crystallographic study of three-dimensional structures it has been possible in certain cases to localize, in space, the immutable positions in a family of proteins and to interpret the constraint in terms of the requirements of conformational stability.

2.1.1.1. Cytochrome c

Cytochrome c is an electron-transporting protein found in the mitochondria of aerobic organisms. Regardless of its source, the molecule always consists of a single polypeptide chain of 104 to 112 residues covalently bonded to the same prosthetic group. The iron atom is bivalent or trivalent, according to whether the cytochrome c reacts with cytochrome reductase or with cytochrome oxidase. This dual interaction should necessitate a fairly rigorously defined conformation. Since the cytochromes c of all the species studied react in a similar manner with beef cytochrome oxidase, we may therefore expect to find a close conformational relationship between them. This is fully confirmed by X-ray analysis of horse and bonito ferricytochromes c[8]. In vertebrates the chain always contains 104 residues, with an acetylated N-terminal group, while it is extended to 108 residues in insects, 108 to 110 in mushrooms, and 112 in plants, always by N-terminal elongation[8] (Fig. 1). The number of invariable positions in 29 species ranging from man to wheat is 35, *i.e.* approximately one third of the residues. Statistical calculations indicate that the number of invariant residues will not fall below 32[8]. An invariable sequence of 11 residues is found (positions 70 to 80 in the numbering of mammalian cytochromes c). The invariant residues contribute on the one hand to the

formation of a central hydrophobic pocket and to the bonding with the heme, which is enclosed in this pocket, and on the other to bonding with enzymes such as cytochrome oxidase.

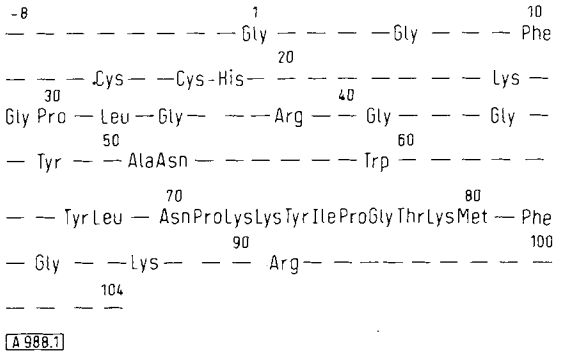

Fig. 1. Structural pattern of the cytochromes c. Residues indicated are constant in the cytochromes c presently known (after [9]).

Buried invariant residues: The heme is bonded to the peptide chain by two sulfide linkages connecting cystine residues 14 and 17. The heme iron, on the other hand, is hexacoordinated with the four nitrogens of the porphyrin, one nitrogen of the imidazole ring of histidine 18, and the sulfur of methionine 80. The heme is also tightly enclosed in a hydrophobic pocket (Fig. 2). The long invariable sequence 70—80 is folded in such a way as to form one wall of the apolar pocket, and the hydrophobic residues in the immediate vicinity of the heme on either side have the greatest tendency to remain invariable or to undergo conservative hydrophobic substitutions. Of the 26 hydrophobic residues (Val, Leu, Ile, Met, Phe, Pro) found in horse cytochrome c, nine are invariant, ten undergo conservative substitutions, and six are replaced by nonhydrophobic residues (Table 1). The pocket never contains charged residues.

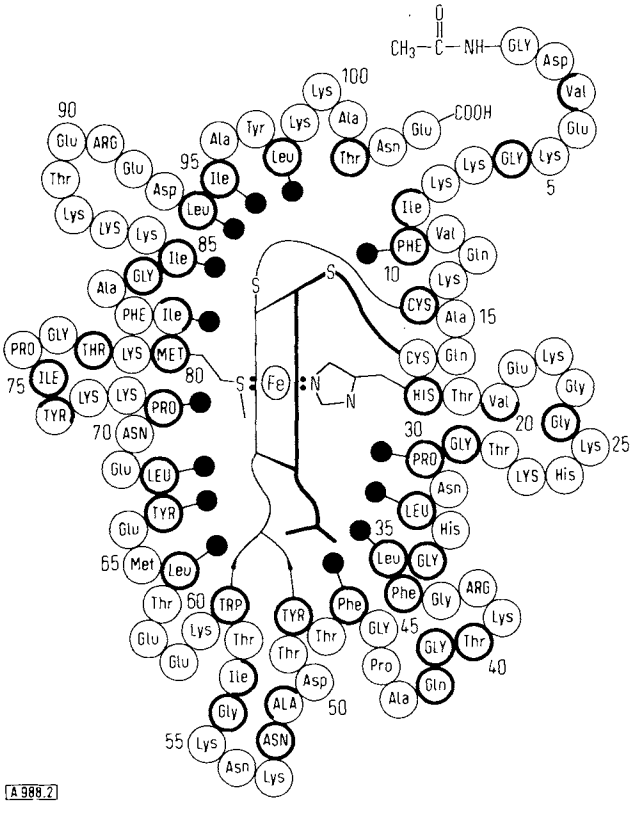

Fig. 2. Heme packing diagram of the cytochrome c molecule (schematic). *Heavy circles* indicate residues that are buried in the interior of the molecule, and attached *black dots* mark side chains which pack against the heme. *Light circles* indicate residues on the outside of the molecule, and *dark half-circles* show groups that are half-buried at the surface. *Arrows* from tryptophan 59 and tyrosine 48 to the buried propionic acid group represent hydrogen bonds. Residues designated by *capital letters* are totally invariant among the proteins of 29 species (after [8]).

Table 1. Variability of amino acid residues in cytochromes c (comparison of horse cytochrome c with those of 28 other species).

Residue type	Total number of residues	Invariant	With a conservative substitution [a]	With a radical substitution
Acidic (Asp, Glu)	12	0	1	11 (92%)
Basic (Lys, Arg)	21	7	1	13 (62%)
Ambivalent (Asn, Gln, Ser, Thr, His, Tyr, Trp, Cys, Ala)	34	11	13	10 (30%)
Hydrophobic (Val, Leu, Ile, Met, Phe, Pro)	25	9	10	6 (24%)
Glycine	12	8	3	1 (8%)
Total	104	35	28	41

[a] Conservative substitutions involve changes within the classes shown at left; in addition, exchange of Ala with residues of the hydrophobic class and of Gly with those of the ambivalent class are also regarded as conservative (after [8]).

Surface invariant residues: The polar residues on the surface of the globular proteins either play a part in the interactions (active sites), or ensure the correct folding of the chain by remaining in the aqueous medium, or, in the case of charged residues, ensure a suitable equilibrium of the basic and acidic groups to maintain an optimum pH for the molecule. Table 1 shows that the basic residues (lysine and arginine) are fairly often invariant, unlike the acidic residues. It is known that the cytochrome c-cytochrome oxidase interaction requires the participation of one or more lysine residues of the cytochrome c, particularly lysine 13 in horse cytochrome, since blockage by acetylation or succinylation inhibits the association.

X-ray studies show that the acidic and basic residues are separated on the surface of the molecule, with two basic zones surrounding an acidic zone, and that the substitutions lead to little change in this general arrangement. This distribution, which is unusual in globular proteins, undoubtedly allows recognition of, and association with, other macromolecules (reductase, oxidase, mitochondrial membrane). The lysine 13 that is involved in the association with cytochrome oxidase is situated just above the pocket in which the heme is accommodated. This position is occupied either by a lysine residue or by an arginine residue (conservative substitution) in the various cytochromes c.

Invariability of glycines and prolines: Out of 12 glycine residues found in horse cytochrome c, eight are invariable and three undergo conservative substitutions (Table 1). These residues, which present no steric hindrance, are situated in positions where only these residues can be inserted to ensure the preservation of the general conformation, particularly at the corners and close contacts of the chains. Of the four prolines, three are invariable and are situated at angles.

2.1.1.2. The Globins

It is possible to distinguish three families, *i.e.* the myoglobins, the α-hemoglobins, and the β-hemoglobins, which are three variations on a common theme.

Myoglobin: Myoglobin is an oxygen-storing protein found in the muscles of vertebrates. The group of fully sequenced myoglobins is limited at present to about a dozen mammalian species; the N-terminal sequences of the myoglobins of chicken and of coelacanth are also known. However, it is interesting to consider the myoglobins after the cytochromes c, since on the one hand the three-dimensional structure of sperm-whale myoglobin is known[10, 12a], and on the other this is again found to be a single peptide chain combined with heme. Of 153 residues contained in the chain, 99 are invariant[11, 12]. It is difficult to establish how many of these are truly invariant, since practically no myoglobins of lower vertebrates are known. The heme, which is attached to the chain only by secondary bonds, is connected *via* the hexacoordinated iron to a nitrogen of the imidazole ring of histidine 93 and to molecular oxygen. Moreover, the heme is embedded in a pocket edged with hydrophobic residues.

The chain has eight helicoidal segments and forms roughly a compact globule with the hydrophobic groups inside and nearly all the polar and charged groups on the outside. Human myoglobin and sperm-whale myoglobin differ in 26 residues. If the three-dimensional structure of sperm-whale myoglobin is taken as the model, it is found that 20 substitutions have taken place in surface positions of the molecule, two on the surface of pockets, and four in the interior of the protein. Three differences in the interior result from hydrophobic substitutions (no. 28: Ile-Val; no. 99: Val-Ile; no. 142; Met-Ile). The fourth (no. 110: Ala-Cys), which had already been observed in the interior of α-hemoglobin, could concern an unreactive residue[11]. The invariability of the hydrophobic interior is thus remarkable.

Myoglobin apparently has no precise surface constraints (interactions with other proteins *etc.*), and the surface residues should theoretically be easily varied. However, this does not seem to be the case.

Human myoglobin has three times as many residues in common with the myoglobins of other mammals as with the α and β chains of human hemoglobin, and it is clear that the myoglobins form a distinct family. It is nevertheless remarkable that the general conformation of myoglobin is found not only in the chains of vertebrate hemoglobins but also in the monomeric hemoglobins of certain invertebrates.

α and β Hemoglobins[17]: The normal hemoglobin of all vertebrates, with the exception of the cyclostomes, consists of four polypeptide subunits, two of an α type and two of a β type, forming a roughly spherical globule with a diameter of 50 to 60 Å. Two or three hemoglobins differing from one another in the sequence either of the α chain or of the β chain are sometimes found in a single species, and it is difficult to tell *e.g.* which of the two or three α chains belongs to the normal line. Nevertheless, it may be considered that there are at least two quite distinct families, that of the α hemoglobin and that of the β hemoglobin, which must have separated after the appearance of the cyclostomes and before the appearance of fishes. The invariability of the residues is determined here not only by the need for a hydrophobic internal part and the polypeptide-heme contacts, as in the case of myoglobin, but also by the contacts between the α and the β chains that are necessary to the preservation of the tetrameric structure of hemoglobin.

The two families of proteins include a relatively large number of known molecules from mammals[6, 13], as well as the α chains of a species of birds[14] and of a species of fish[15] and the β chain of an amphibian species[16]. The three-dimensional structure of horse hemoglobin was determined by *Perutz et al.*[18], who have established the details of the tetrameric architecture of the molecule. It was confirmed that the α and β chains have a secondary structure resembling that of myoglobin, though the amino-acid compositions are rather different. Each is found to have the seven or eight helicoidal segments and the heme insertion pocket. *Perutz* succeeded in localizing the residues that are bonded to the heme on the one hand and those that are in contact in the α_1-β_1 and α_1-β_2 interactions on the other. In the α chain (141 residues), eighteen residues are in contact with the porphyrin nucleus of the heme and the histidine residue 87 is coordinated to the iron. Sixteen residues are involved in the α_1-β_1 contacts and ten in the α_1-β_2 contacts (Fig. 3). In the β chains (146 residues), 20 residues are in contact with the porphyrin nucleus of the heme and the histidine residue 92 is coordinated to the iron. Eighteen residues are involved in the β_1-α_1 contacts and nine in the β_1-α_2 contacts. The contacts between peptide chains and heme or between peptide chains of different types are mainly apolar, whereas the contacts between identical chains are few in number and polar.

The mutations of human hemoglobin have been investigated by *Perutz* and *Lehmann*[19], who found that those affecting the residues in contact with the heme or involved in the α-β contacts are nearly always pathological, while those affecting superficial residues, which are generally polar, usually have no clinical significance. This observation should be correlated with the fact that the residues in contact with the heme or involved in α-β interactions are generally invariant (at least in mammals). In the family of β chains, for example, there are 70 invariant residues out of 146 in mammals, but

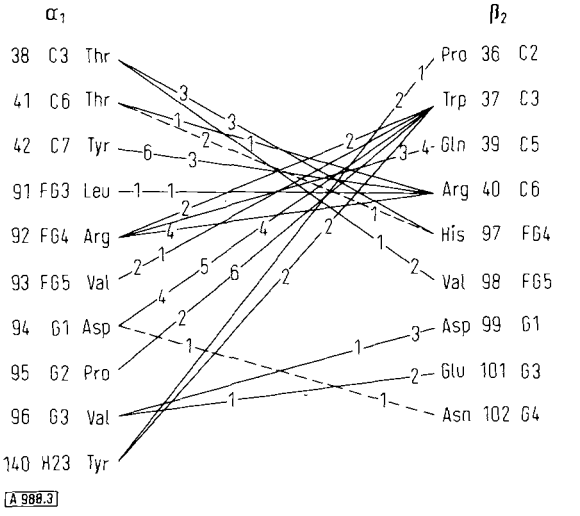

Fig. 3. "Vital" contacts between residues of unlike chains (α_1-β_2) in hemoglobin. The contacts comprise 10 residues in α_1 and 9 residues in β_2, all being invariant except residues no. 38 and 96 in α_1 and no. 39 and 101 in β_2. Plain connecting lines indicate van der Waals contacts; broken ones indicate that the contact includes a hydrogen bond. The numbers on the lines give the number of atoms contributed to the contact by the two residues on each side (after [18]).

this number falls to 54 when the β chain of the frog *Rana esculenta* is included in the family[16]. Out of the 21 residues in contact with the heme, 16 are invariant (76%). Of the nine residues involved in the "vital" α_1-β_2 contacts (Fig. 3), seven are invariant (87%), whereas of the 17 residues involved in the α_1-β_1 interactions, only eight are invariant (45%) in all the β chains known at present. Of the 100 residues without contact, 25 are invariant. Two long sequences (residues 30—40 and 96—108) are almost entirely invariant, and this rather exceptional character can be explained by the succession of residues that take part in the essential contacts.

2.1.1.3. Pancreatic Serine Proteases

Both the sequences[20-23] and the three-dimensional structures[24-26] are known for four proteolytic enzymes of the pancreas, *i.e.* chymotrypsins A and B, trypsin, and elastase. Though they belong to phylogenetically different families, the homology of their sequences and the characters of their active centers suggest that the respective structural genes are derived from a common ancestral gene[27]. It is interesting to note that the positions occupied by identical residues are usually those situated in the hydrophobic interior[26].

All the chemical and crystallographic data thus clearly indicate that in globular proteins the residues involved in the construction of the central nucleus, in the constitution of pockets containing a prosthetic group of hematinic nature, or in the interactions between subunits are usually hydrophobic and invariant in the course of evolution, whereas the residues situated on the surface are hydrophilic and lend themselves fairly readily to substitutions. It can be deduced that changes that affected the central part had a profound effect on the general conformation and resulted either in the disappearance of the function and elimination of the protein or in the appearance of a very different function as a result of a new conformation and the creation of a new family of proteins. The filiation will then be difficult to detect both chemically and biologically.

2.1.2. The Sequential Variability of Proteins

The crystallography and the comparative chemistry of proteins show that the interior of the protein globule is resistant to evolutionary variation, whereas the surface part lends itself to amino-acid substitutions with a rhythm that varies with the protein. The biological importance of the surface of the molecule varies from region to region; the active sites of enzymes (site of catalysis, of specificity, of coenzyme attachment, *etc.*), the zones of interaction between subunits in polymeric enzymes, the sites for the attachment of protein hormones to their receptors, *etc.* are undoubtedly less variable than other parts whose function is limited to the presence of hydrophilic groups that indirectly ensure correct folding of the chain.

The few enzymes whose three-dimensional structures are known and for which the role of the surface can be studied have unfortunately not been examined comparatively in several species. The zones of contact of cytochrome c with cytochrome reductase or cytochrome oxidase are unknown; myoglobin and hemoglobin do not appear *a priori* to have a biologically functional surface. On the other hand, the comparison of proteolytic enzymes is interesting from this point of view.

2.1.2.1. The Biological Significance of Substitutions

If molecular evolution is assumed to be progressive, as morphological evolution is assumed to be, the substitutions in the functional sites are fundamental. One is led, in fact, to distinguish "neutral" substitutions, which do not affect function and which are probably the more numerous and may in some measure reflect the antiquity of the separation of two species, from "active" substitutions that modify the biological properties.

On the chemical level it is necessary to differentiate between conservative substitutions (replacement of one basic residue by another or of one hydrophobic residue by another) and alterative substitutions, though it is sometimes difficult to place the substitution in one category or in the other. Substitutions of chemically equivalent amino acids, such as Arg/Lys, Val/Ile, and Ser/Thr, seem more frequent if one examines a large number of sequences[6]. The problem is whether these should really be regarded as substitutions on the functional level. Nevertheless, on the genetic level they correspond to different triplets[2], and conservative replacement requires mutation as well as alterative replacement. The nature of the substitutions will thus depend on the genetic code (neighboring triplets) and on the physicochemical properties of the residues (neighboring functional groups and configurations). The second factor becomes increasingly important with increasing specificity of the function of the residue, and in the limiting case the residue is irreplaceable.

If we consider the "mutability" of an amino acid over a large number of proteins, regardless of the position occupied, we find for example that some, such as serine, are very readily substituted, whereas others, such as cysteine and tryptophan, show little tendency to undergo substitution[6]. The ease of substitution may depend on whether analogs exist among the 20 amino acids that occur in proteins. It would undoubtedly be necessary to inquire into the evolutionary factors that have limited the number of amino acids that occur in proteins to 20, which include a number of pairs that are practically identical.

2.1.2.2. Inequality of Substitution Rhythms in Protein Families

It is known that morphological evolution has no uniform rhythm, and that a given line can show periods of intense variations and other periods of very slight mutability or even almost total arrest, as in the case of living fossils. Since each organism contains an extremely varied protein population, one might ask whether all the families of proteins vary with a more or less similar rhythm or whether each family has its own particular fate. In fact, the various organs evolved with different rhythms, undoubtedly depending on function, and the same must be true of the proteins.

If it is assumed *a priori* that the structural genes have the same variability, the difference in the substitution rates should depend on the percentage of residues that perform a function. This hypothesis cannot yet be verified, but the number of point mutations undergone in each family can be estimated by considering the substitutions, the genetic code, and the superposition of substitutions, referring this number to 100 residues, and expressing it per 100 million years (Table 2)[6]

Though the values are very approximate, and are particularly open to criticism on the ground that they presuppose a uniform

Table 2. Number n of accepted point mutations per 100 residues and per 100 million years [a].

Proteins	n
Fibrinopeptides	90
Growth hormone	37
Pancreatic ribonuclease	33
Immunoglobulins	32
κ chain, C region	39
κ chain, V regions	33
γ chain, C regions	31
λ chain, C region	27
Lactalbumin	25
Hemoglobin chains	14
Myoglobin	13
Pancreatic secretory trypsin inhibitor	11
Animal lysozyme	10
Gastrin	8
Melanotropin β	7
Myelin membrane encephalitogenic protein	7
Trypsinogen	5
Insulin	4
Cytochrome c	3
Glyceraldehyde 3-phosphate dehydrogenase	2
Histone IV	0.06

[a] For most of the proteins the time was extrapolated from probable time of divergence of the mammalian orders at 75 million years ago. For lysozyme, trypsinogen, insulin, glyceraldehyde 3-phosphate dehydrogenase, and histone IV the following times for the divergence of other lines from the mammalian line were used: birds, 300; fish, 400; insects, 900; and plants, 1500 million years (after [6]).

rate of variation within a given line of proteins, it is clear that some families vary much more than others.

It is difficult to understand why the family of myoglobins is more stable than that of the α and β chains of hemoglobin, whereas the functional constraints are apparently smaller in the former case, and also why the β family is more variable than the α family though the two chains appear to have exactly the same role. Cytochrome c is particularly stable, but the bewildering immutability of the histones (those of peas and beef differ in only two residues though the divergence of the lines occurred 1500 million years ago) remains a mystery.

2.1.2.3. Phylogeny and Drift of the Proteins

Paleontology shows us approximately when the lines of vertebrates diverged, and it is possible to compare the divergence times on the one hand and the numbers of substitutions observed on the other for several families of proteins. It appears that the number of substitutions increases with increasing time since divergence. With the aid of certain assumptions it is possible, by calculation, to construct phylogenetic trees based only on the number of substitutions[6, 28], and these trees correspond fairly closely to those derived from paleontological data.

The fact that in a given family of proteins, *e.g.* the β-hemoglobins (Table 3), the number of substitutions between two species is a function of the divergence time and is independent of the species chosen strongly suggests that the substitutions observed are mostly neutral from the standpoint of natural selection. The sequences of proteins would thus be biological "clocks". Since the zoological groups are defined by the morphologies, which become increasingly different with increasing time since the separation of the lines, the percentage of substitutions with respect to a reference species should in principle allow the identification of the class or subclass of the species from which the protein was obtained. However, it is necessary to choose a recent reference species; the lamprey, for example, belongs to a line that branched off from that leading to the other vertebrates about 500 million years ago, and the percentage of substitutions with respect to the proteins of this species should theoretically be of the same order for nearly all vertebrates.

Table 3. Percentage n of substitutions in the amino-acid sequence of β-hemoglobins of various species and paleontological time of divergence since the common ancestor.

Zoological classification	t [10^6 a]	n [%]
Class Mammalia		
Subclass: Eutheria		
Order Primates		
Hominoidea		
(man)	0	0
(gorilla)	20	1
Cercopithecoidea		
(rhesus monkey)	60	5
Order Artiodactyla		
Ruminantia		
(sheep)	75	18
Suiformes		
(pig)	75	16
Tylopodes		
(llama)	75	14
Order Perissodactyla		
(horse)	75	17
Order Rodentia		
(mouse)	75	18
Subclass Metatheria		
Order Marsupialia		
(kangaroo)	130	26
Class Amphibia		
Order Anura		
(frog)	320	46

It should be noted that, while roughly equal percentages of substitutions are found for similar divergence times, this does not mean that the modified positions in the polypeptide chains are the same. On the other hand, there are exceptions, since the birds have the same neurohypophyseal hormones as the amphibians, from which they diverged about 350 million years ago, whereas they are different from the mammals, from which their divergence was more recent. Thus, while the drift of proteins, a passive phenomenon, is numerically large, it must not be allowed to mask the true evolution, which must by definition be accompanied by a change in function.

2.2. The Length of the Polypeptide Chain

On examining a line of homologous proteins, one cannot help noticing that the number of residues remains practically constant. All the cytochromes c of vertebrates contain 104 amino-acid residues, all the α-hemoglobins have 141—142 residues, all the neurohypophyseal hormones have 9 residues, *etc.* To explain this stability it is necessary to consider the mechanism of protein biosynthesis; this involves transcription of the structural gene, which is a deoxyribonucleic acid (DNA), into a messenger ribonucleic acid (mRNA), followed by translation of the mRNA into an amino-acid sequence. One mRNA codes several proteins, and the translation of each involves the reading of a sequence of triplets from an initiating triplet (AUG or GUG) to a terminating triplet (UAA, UAG, or UGA). In addition to the RNA polymerase of the particular transfer RNAs, which recognize the initiation and termination signals, protein factors that have not yet been satisfactorily

identified also take part in this process[29]. It is strange to find that a phenomenon that involves such a large number of molecules, and which is therefore very susceptible to the action of mutations, can lead to a practically constant result. The few variations observed are therefore particularly instructive.

2.1.1. Shortening and Elongation of the Chain

The known families of homologous proteins include few representatives from lower species. In some cases observed (cytochromes c), a slight shortening appears to have occurred in higher vertebrates.

2.1.1.1. N-Terminal Modification of the Chain

The cytochromes c of plants, mushrooms, and insects respectively contain 8, 6—4, and 4 residues more than those of vertebrates, these extra residues forming an N-terminal elongation of the chain[9]. It appears that the initiation signal has been displaced and that a later initiation gives a shorter chain in the higher species.

However, this is not a general phenomenon, since the hemoglobins of invertebrates and the corresponding proteins of plants have roughly the same number of residues as the α or β chains of vertebrate hemoglobins. An N-terminal deletion of six residues is observed in frog β-hemoglobin[16], but the shortening does not seem to have any evolutionary value; nevertheless, it appears that the N-terminal ends of the chains are more susceptible to variation than the central part.

2.2.1.2. C-Terminal Modification of the Chain

Shortening or elongation seems to be less frequent at the C-terminal than at the N-terminal end, as if the termination signal were less susceptible to displacement or as if displacement were incompatible with the preservation of a functional molecule.

The presence in pigs and other mammals of a peptide known as α-melanocyte stimulating hormone (α-MSH) because of its special biological properties and having the sequence of the first 13 residues of corticotropin, which itself has 39 residues, could point to a premature termination of corticotropin biosynthesis. In a recently isolated abnormal human hemoglobin known as Constant Spring (CS) hemoglobin, the α chain contains 172 residues instead of the usual 141. It is interesting to note that this is due to an elongation of 31 residues at the C-terminal end, as if the termination signal had been displaced in the direction of an elongation[30]. A C-terminal elongation of 10 residues has also been observed in a β chain of a human hemoglobin[31]. Though CS hemoglobin represents only 1—2% of the total hemoglobin in the case studied, and the molecules in question are abnormal, it is conceivable that the mechanism shown here could occur in the course of evolution.

2.2.2. Insertion and Deletion in the Interior of the Chain

On comparison of homologous proteins, one sometimes finds that a given species has one or two additional residues or the absence of one or two residues in relation to the general molecular pattern. For example, carp α-hemoglobin has 142 residues instead of 141 (insertion), and the β-hemoglobins of cattle and of sheep have 145 residues instead of 146 (deletion). The homology of the sequences allows the localization of the variation in the interior of the chain. Insertions and deletions of this nature have been observed in abnormal human hemoglobins, and it is possible to explain these observations by an intragenic crossing-over that affects the peptide sequences. The central insertions and deletions appear to affect at most five consecutive residues, and often fewer. Their influence on the general conformation and function generally seems to be slight.

3. Polymorphism : Isoproteins

The extreme purification of proteins has shown that the same tissue of the same species quite often contains two or more molecules that apparently perform the same function and have very similar amino-acid sequences. This polymorphism is not due to incomplete dominance, since each protein corresponds to a different structural gene. These molecules have been named isoproteins (isoenzymes, isohormones), and have been assumed to result from duplication of an initial structural gene. It should be noted that while some proteins are more likely to exhibit polymorphism than others and the degree of polymorphism depends on the species, it is very unusual for a protein not to exhibit this phenomenon. Thus, cytochrome c, which does not appear to show the phenomenon in vertebrates, occurs in yeast in the two forms iso-1-cytochrome c and iso-2-cytochrome c[32].

The biological significance of this multiplication is not clear. It is possible that the existence of two or more genes that produce proteins having similar functions protects the species against an inactivating mutation, which would be lethal in the case of a single gene. It is also conceivable that successive mutations ultimately bring one of the proteins to the point where it can perform a different function, and that this is the first step in the formation of a new protein. It may nevertheless be noted that the proportions of the isoproteins vary considerably, and that the disappearance of the most abundant isoprotein by mutation does not seem to be accompanied by a corresponding rise in the quantities of the less abundant ones.

The definition of the isoproteins is not very specific, but since proteins are usually named according to their function they are generally proteins having almost identical biological activities but relatively different amino-acid sequences.

3.1. Strict Isoproteins: The Chymotrypsinogens

The chymotripsinogens A and B have been found in beef pancreas. They are similar in size, both consisting of a polypeptide chain of 245 residues, and very probably also in conformation[21]. The activations of these chymotrypsinogens by trypsin, which involve the scission of an Arg 15-Ile 16 linkage, are similar, though chymotrypsinogen B is activated 15 times as quickly under comparable conditions. Since the only substitution in the first 35 residues of the chain is an alanine in the B protein in place of a serine in the A protein, it appears that the activation region in the former could be more flexible because of the absence of a hydrogen bond. Two of the three autocatalytic cleavages that follow activation in chymotrypsinogen A are also found in the activation of the B protein, and the specificities of the enzymes are practically identical.

It is remarkable that the two chymotrypsinogens, which are functionally so nearly identical, differ in 52 residues, *i.e.* in 21% of the sequence, and are produced in roughly equal quantities by the pancreas. At first sight there seems to be no reason for the duplication. In fact, it must have happened twice, since a less well-characterized chymotrypsinogen C has also been isolated. The three enzymes also occur in pigs, but the study of other species has not progressed sufficiently to show whether this is a general phenomenon among the vertebrates.

3.2. Derived Isoproteins: The Globins

The hemoglobins of vertebrates, with the exception of the cyclostomes, are tetrameric molecules containing two types of chains α and β such that they can be characterized by the formula $\alpha_2\beta_2$. The α and β chains are isoproteins in the sense that their functions are apparently similar, whereas their sequences, though related, are different. The complete sequences of these chains are known for some 20 species of vertebrates, mostly mammals, and the duplication may be assumed to be a general phenomenon. Moreover, polymorphism occurs even in species having monomeric hemoglobins, such as the lamprey and the invertebrates, and the corresponding proteins of plants.

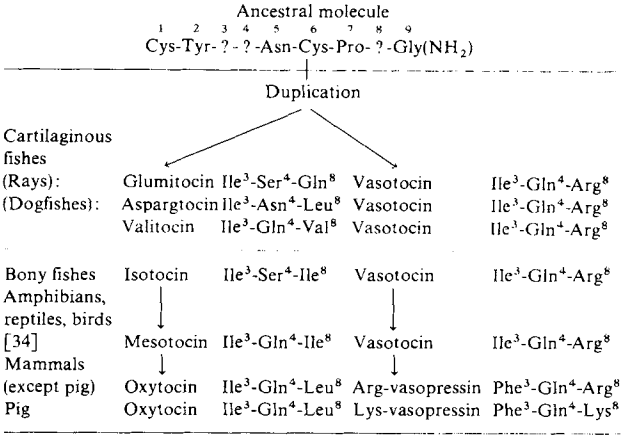
The α and β chains are roughly equal in length (141 residues for the α chain and 146 for the β chain) and their conformations, which are very similar[18], closely resemble that of myoglobin. In man there is 57% substitution between the α and the β chains. A minor hemoglobin having the formula $\alpha_2\delta_2$ is also found, the δ chain, like the β chain, containing 146 residues and differing from the latter in only 7% substitution[6]. The fetus also contains a special hemoglobin having the formula $\alpha_2\gamma_2$, in which the γ chain has 146 residues like the β chain, and differs from the latter in 27% substitution. Other chains, ε and ζ, exist in the embryo, but these have not yet been characterized. In other species of mammals it is not unusual to find two or more hemoglobins in the adult that differ from one another either in the α or in the β chain, so that while there is always at least one representative of the α type and one of the β type in a given species, several proteins of each type, each corresponding to a different structural gene, may exist in variable proportions.

It is therefore possible to distinguish here two degrees of polymorphism and two categories of isoproteins, *i.e.* the strict isoproteins having the same number of residues (*e.g.* the group β, δ, and γ) and the derived isoproteins, which do not have the same number of residues and which also exhibit a higher degree of substitution between them. If it is accepted that the percentage of substitution reflects the time that has elapsed since the duplication, *i.e.* the evolutionary distance, one can assume, taking man as an example, that the α-β duplication with 57% substitution was the earliest, the β-γ duplication with 27% substitution was later, and the β-δ duplication with 7% substitution was the most recent.

Moreover, since the myoglobin in the muscle performs a function very similar to that of hemoglobin, and the chain length (153 residues) and particularly the conformation are similar to those of the α and β chains[18], it may be regarded as a derived isoprotein. Human myoglobin differs from the human α chain in 74% substitution[33], and the duplication would thus have been earlier than the α-β duplication. It is interesting to note that the difference in length arises only when the substitution is greater than 50%, *i.e.*, in the interpretation adopted, when the duplication is already very old. If the first duplication of the globins is assumed to have been the myoglobin-α chain duplication[3], it must be observed that the protein that became myoglobin does not appear to have duplicated further and has undergone fewer substitutions than the proteins that became the chains of hemoglobin. The factors that lead one structural gene to undergo duplication more readily than another are as obscure as those that favor substitutions in one line rather than in another.

4. The Biological Differentiation of Proteins

4.1. Differentiation by Substitutions: Analogous Proteins



Certain proteins that have different biological properties are found to be so similar in the numbers of residues and in the amino-acid sequences that it is plausible to regard them as being derived from a common molecular stock. These functionally different but chemically related proteins may be referred to as analogous proteins. The degree of resemblance obviously varies within each group, and the relationship may be disputable in the limiting case.

4.1.1. The Neurohypophyseal Hormones

Although these are peptides and not proteins, the example may serve to illustrate the transformation of isologous proteins into analogous ones. Nine neurohypophyseal hormones, all of them nonapeptides, have now been identified in some 40 species belonging to all classes of vertebrates except the cyclostomes (Table 4, Fig. 4).

The biological activities of the peptides of lower vertebrates have been measured mainly in mammals, so that their true function is not well known. Nevertheless, it is interesting to note that in the classes that preceded the mammals, such as the amphibians and the reptiles, mesotocin (Ile^8-oxytocin) and arginine vasotocin (Arg^8-oxytocin) both possess a pronounced oxytocic activity and that they could be considered as isopeptides. However, the vasotocin also takes part in the regulation of water and electrolytes, and is thus capable

Table 4. Hypothetical scheme of the evolution of neurohypophyseal hormones. One gene duplication and a series of subsequent single substitutions in positions 3, 4, or 8 produce two molecular lines.

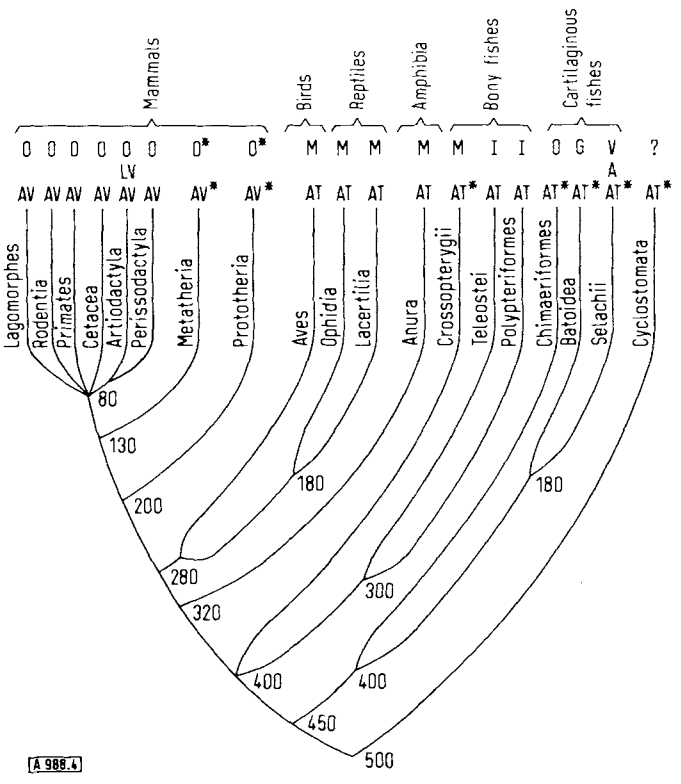


Fig. 4. Neurohypophyseal hormones and species evolution according to paleontological data. Letters indicate hormones identified in modern representatives of the groups (an asterisk means that identification is not chemical but pharmacological). O, oxytocin; AV, arginine vasopressin; LV, lysine vasopressin; M, mesotocin; I, isotocin; A, aspargtocin; V, valitocin; G, glumitocin; AT, arginine vasotocin. The numbers give the time in millions of years since the divergence. (The formulas of the hormones are given in Table 4.)

of acting on receptors on which mesotocin has no action. Two new molecules, oxytocin and usually arginine vasopressin (Phe^3-Arg^8-oxytocin), act on different receptors in mammals, the former acting on the uterus and the mammary gland and the latter on the kidney. The reciprocal activities are negligible, and the similarity was established only after the determination of the chemical structures.

It may be assumed that the functional differentiation of proteins, though more complicated than that of peptides, could have occurred progressively after the duplication by substitutions and by modification of the chain length, but that at a certain degree of differentiation the functions become quite separate though the structures are still related.

4.1.2. The Pancreatic Serine Proteases

Three proteolytic enzymes of the pancreas, *i.e.* chymotrypsin, trypsin, and elastase, while having different specificities, have been found to be analogous, first by determination of the amino-acid sequences[20-23] and then by comparison of the conformations[24-26]. The chain lengths are slightly different: 241 residues for beef chymotrypsin A, 223 residues for beef trypsin, and 240 for pig elastase. The general conformations are remarkably similar, but the differences in specificity can be explained by specific variations in the conformation of the substrate binding site[34a].

Trypsin, chymotrypsin, and elastase all have a pocket, which engages the side chain of the amino-acid that determines the specificity (Fig. 5). If the numbering of beef chymotrypsinogen A is used for these three enzymes, the position 216 bordering the mouth of the pocket is occupied by a glycine residue in trypsin and in chymotrypsin, which allows the introduction of a long, bulky side chain, and by a valine residue in elastase, which restricts access to small aliphatic residues. At the base of the pocket, on the other hand, position 189 is occupied by aspartic acid in trypsin, which allows ionic bonding with basic residues, while this position in chymotrypsin is occupied by serine, which cleaves peptide linkages at neutral hydrophobic residues[26]. The differentiation of the specificities here appears to be based on alterative substitutions. The data on the "trypsin-like" and "chymotrypsin-like" enzymes of lower vertebrates may allow the evolutionary history of the substrate pocket to be traced. A common feature that has been retained by the pancreatic serine proteases is the hydrolytic action mechanism, and the functional differentiation is apparently limited to the specificity of substrate binding.

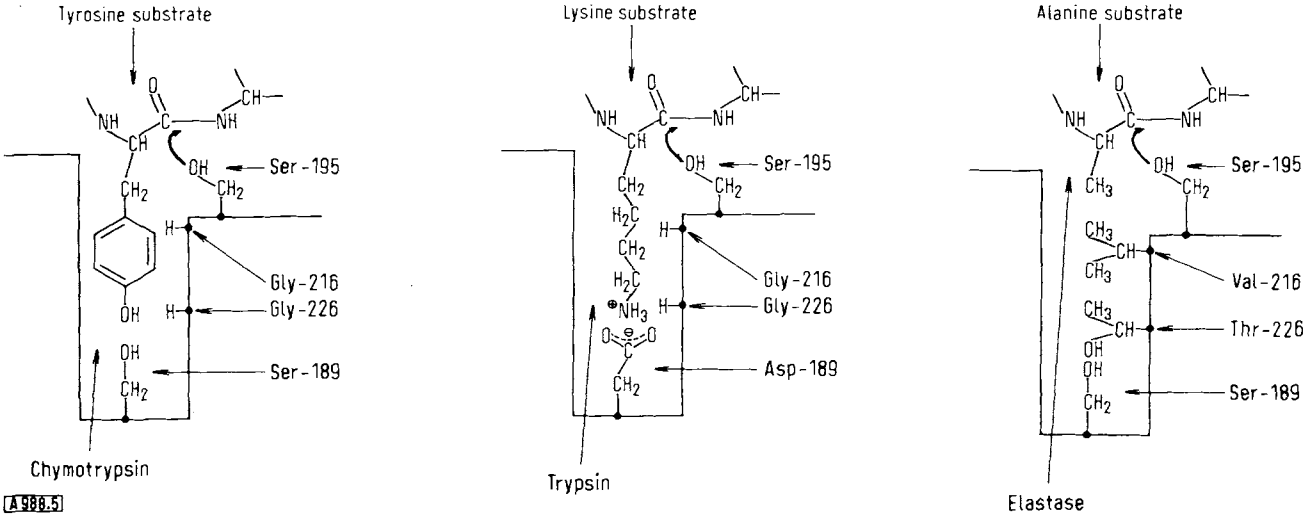

Fig. 5. Differences between the substrate binding sites of chymotrypsin, trypsin, and elastase (schematic). The nucleophilic attack of the active center serine γ-oxygen upon the substrate is indicated by the curly arrow (after [34a]).

4.2. Differentiation by Hybridization

When two similar structural genes (*e.g.* coding two isoproteins) are situated on the same chromosome, faulty alignment of

the chromatids during the synapsis is possible, with crossing-over of the non-allelic genes. After separation, the two chromosomes each possess a hybrid gene, but one of the hybrids has the initial part of the first parent gene joined to the terminal part of the second, while in the second hybrid the situation is reversed. Consequently, one of the hybrid genes

The ferredoxin found in bacteria consists of a chain of 55 residues having an internal symmetry, with 44% homology between the two halves of the chain in the ferredoxin of *Clostridium pasteurianum* (Fig. 6). This symmetry has also been found in other bacteria, and points to an intragenic duplication.

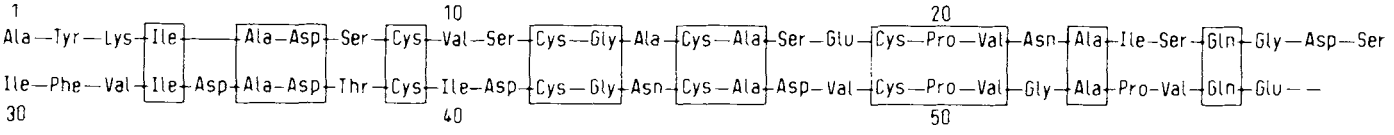

Fig. 6. Homologies between the two halves of the ferredoxin molecule of *Clostridium pasteurianum* suggesting an intragenic duplication (after [6]).

will code a polypeptide chain having the N-terminal sequence of one protein and the C-terminal sequence of another.

Hybridization between the β and δ chains of hemoglobins is a typical example. Lepore human hemoglobin, which is a hemoglobin resulting from a mutation, consists of a normal α chain and a hybrid δ-β chain. Anti-Lepore hemoglobin consists of a normal α chain and a hybrid β-δ chain. The β and δ chains both contain 146 residues, as do the two hybrids β-δ and δ-β. In Boston Lepore hemoglobin residues 1—87 correspond to the δ chain and residues 116—146 to the β chain. Since the δ and β chains have the same sequence for residues 88—115, the crossing-over site cannot be exactly localized.

In Miyada anti-Lepore hemoglobin, the β-δ chain has residues 1—12 of the β chain and residues 22—146 of the δ chain; since the sequence 13—21 is common to both chains, it has not been possible to localize precisely the crossing-over site.

Hybridization has also been postulated in the case of the clupeines from herring sperm[6]. Clupeine Z is identical with clupeine YI in the sequence 1—6 and with clupeine YII in the sequence 6—30.

Hybridization between genes may be limited to genes of identical length, *i.e.* formed by an earlier duplication, but it represents an accelerated differentiation mechanism in relation to differentiation by point mutations involving the substitution of amino acids one at a time.

4.3. Differentiation by Intragenic Duplication

Certain proteins appear to have repetitive regions along their polypeptide chain that suggest that after duplication of the ancestral structural gene the two daughter genes combined and continued to function as a single gene. The length of the chain was thus doubled. Though the mechanism of such intragenic duplication is not very well understood, this interpretation could account for the discontinuous elongation of the polypeptide chains and for a certain periodicity in the amino-acid sequences.

4.3.1. Ferredoxins

Ferredoxin is a non-heme protein containing iron, and is found in photosynthetic anaerobic bacteria, blue-green algae, green algae, and higher plants. It takes part in a wide variety of biochemical processes such as photosynthesis, the fixation of nitrogen, the reduction of sulfate, dehydrogenations, and redox reactions.

On the other hand, the ferredoxin found in higher plants such as spinach has a chain about twice as long (97 residues) as those of the bacterial ferredoxins, while that of *Chromatium sp.* is of intermediate length (81 residues). All these ferredoxins have a homologous region, the elongation with respect to the bacterial ferredoxins appearing to be at the N-terminal end in plants and at the C-terminal end in *Chromatium sp.* All the evidence suggests growth by intragenic duplication with a base unit corresponding to about 25—28 residues.

4.3.2. Immunoglobulins

Intragenic duplication also appears to have occurred in the immunoglobulins. It is known that the immunoglobulin molecule is built up symmetrically from two identical light chains (215—220 residues) and two identical heavy chains (446 residues), the four chains being joined by disulfide bridges. The fact that the length of the heavy chain is almost exactly double that of the light chain naturally suggests a duplication. On the other hand, there appears to be a symmetry in the light chain itself between the N-terminal half and the C-terminal half. The N-terminal half seems to be subject to substitutions and is described as variable (V), whereas the more stable C-terminal half is described as constant (C). The heavy chain appears to consist of one V unit and three C units, the elongation taking place discontinuously in blocks of 110 residues at a time.

5. Fusion of Proteins

The above examples illustrate how the evolution of proteins starting with an ancestral structural gene could have led, by duplications followed by point mutations and hybridization, to molecules having different sizes, sequences, and functions. However, new proteins could also be built up from proteins that are already well differentiated by fusion of polypeptide chains. This fusion may result from the fusion of adjacent structural genes, but also seems to occur without fusion of the genes, in which case each part of the sequence is still governed by an autonomous structural gene.

5.1. Bifunctional Enzymes by Fusion of Adjacent Genes

The biosynthesis of histidine in *Salmonella typhimurium* is controlled by an operon in which nine adjacent structural genes code the enzymes that take part in the synthesis of the amino acid. The second structural gene of the operon

codes the histidinol dehydrogenase and the third codes the imidazolylacetol phosphate:L-glutamate aminotransferase. The termination signal of the first enzyme and the initiation signal of the second are separated by a sequence of intercistronic nucleotides, which is not normally expressed. Following a double mutation, the punctuation signals have no longer been recognized, and a single gene formed by the sequence of the two original genes and the intercistronic region has been transcribed into a protein having a molecular weight of 140000, whereas the molecular weights of the dehydrogenase and of the aminotransferase are 59000 and 84000 respectively[35,36]. This fused protein has two catalytic activities and a dimeric structure like the original enzymes, which suggests that the conformations of the separate proteins have been preserved despite the covalent fusion. It may be assumed that the junction polypeptide region corresponding to the sequence of intercistronic nucleotides is particularly flexible.

It is possible that certain large enzymes such as β-galactosidase and DNA polymerase have resulted from fusions of this nature. Proteolytic cleavage of DNA polymerase could yield two fragments, each having one of the activities of the initial enzyme. The fusion of adjacent genes appears to be a plausible mechanism for the formation of complex proteins in the course of evolution.

5.2. Fusion of Proteins without Fusion of Genes

The immunoglobulins (see Section 4.3.2), which play an essential part in immunological reactions, are symmetrical molecules consisting of a pair of heavy chains and a pair of light chains. In man, immunoglobulins G (IgG), A (IgA), M (IgM), D (IgD), and E (IgE) have a heavy chain of the γ, α, μ, δ, and ε types respectively. These heavy chains are associated with light chains of two types, κ and λ. In mice 97% of the light chains are of the κ type, whereas in man one finds 66% of the κ type and 34% of the λ type[6,37]. The light chains (220 residues) consist of a variable (V) N-terminal half and a constant (C) C-terminal half. In the chains of the κ type examined so far, whereas the constant region (C_κ) behaves as if it were coded by a single gene, the V_κ region could correspond to three genes, in view of the three subclasses that can be distinguished. The amino-acid sequence of a given light chain would thus be controlled by two separate genes, one for each half. Similarly, in the heavy chains, the N-terminal quarter is described as the variable and the remainder as the constant region, and these two regions should be under the control of separate genes.

6. Polymeric Proteins and Immobilized Proteins

All the examples discussed above are concerned with the possible evolution of a single polypeptide chain, which is assumed to act independently in the performance of a function. However, it is clear from the number of units involved and the structure of the associations that cell physiology calls for more complicated protein systems.

The enzymes required for the essential regulation of metabolic chains[38] consist of subunits joined to one another by noncovalent bonds ("polymeric proteins"). These regulatory enzymes, which are often described as "allosteric", are generally sensitive to the action of the end product of a chain of enzymes which is *not* a steric analog of their substrate. A growing number of functions appear to depend on polymeric systems, examples being oxygen transport (hemoglobin) muscle contraction (myosin, actin), and hormone action (thyrotropin).

A general type of molecular assembly appears to be involved, the number of subunits that take part being variable but possibly very large. Except in the case of hemoglobin[118], little is yet known about the manner in which the subunits are associated. In any case, the adaptation of the conformations of the subunits to form a polymeric architecture presents an evolutionary problem if the associations are assumed to have been formed from free monomeric proteins (*e.g.* the α and β chains of hemoglobin). It is necessary here to envisage new constraints from the standpoint of natural selection, these constraints affecting the nature of the contact sites. The transition from a "monomeric" function to a "polymeric" function introduces a new element, that of structural coordination.

At a higher level of integration, the cell may be regarded as a microheterogeneous system in which the surface effects predominate over the statistical mass-action relations, and in the limiting case become responsible for the channeling of activities[39]. The proteins, and particularly the enzymes that are immobilized in the membrane structures, for example, then become dependent on the matrix in which they are incorporated as well as on their own biological function. Because of the multiplicity of the molecules involved (lipids, saccharides, *etc.*), the "microenvironment" should have a powerful effect on the conformation of the immobilized proteins. At this level of complexity it is difficult to perceive the point of impact of natural selection.

7. Conclusion

In order to establish a relationship between protein molecules it seems reasonable to compare cell differentiation and molecular differentiation. For example, the cells of both the anterior and intermediate lobes of the pituitary are derived from the buccal ectoderm; it is therefore very interesting that the α-MSH (13 residues) synthesized by the cells of the intermediate lobe represents the N-terminal part of the corticotropin synthesized by those of the anterior lobe. On the other hand, glucagon, a hyperglycemic hormone secreted by the α cells of the islets of Langerhans in the pancreas, and secretin, a hormone produced by the duodenal mucosa, which stimulates the secretion of pancreatic juice (29 and 27 residues respectively) have 15 amino acids in common, and also 7 conservative substitutions. The pancreas is differentiated from the duodenum, and this may explain the similarity. There is also a certain similarity between the extracellular proteins secreted by the glands derived from the endoderm[140]. Proteins as different as the proteolytic enzymes of the pancreas, the coagulation factors produced in the liver, and the pancreatic and gastric hormones have been grouped together under the heading of "enterosecretory proteins".

Though the evolution of proteins has occurred by specific chemical mechanisms, it is nevertheless only one aspect of the undissociable phenomenon of the evolution of organisms.

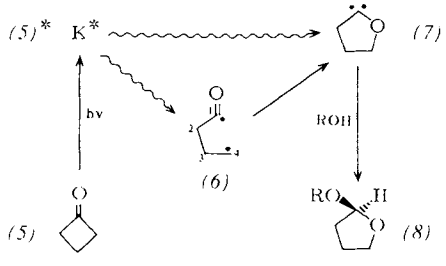
Stereospecificity as an Argument against the Intermediacy of 1,4-Alkyl/Acyl Diradicals in the Light-Induced Cyclobutanone-Tetrahydrofurylidene Isomerization in Condensed Phase[1]

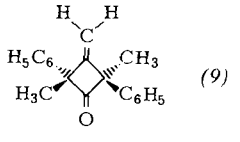


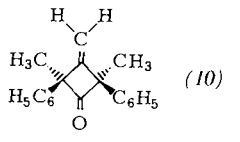
By *Gerhard Quinkert, Peter Jacobs*, and *Wolf-Dieter Stohrer*[*]

Four-membered cyclic ketones play a hitherto poorly understood role within the family of electronically excited cycloalkanones[2]. π*,n-Excited common-sized cycloalkanones ($m = 5$, 6, 7) *(1)** yield mainly isomeric enals *(3)*, ketenes *(4)*, and cycloalkanones *(1) via* 1,*m*-alkyl/acyl diradicals (α-oxo-α,ω-alkylenes) *(2)*[3] as primary photoproducts.

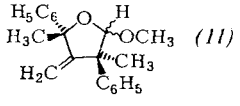
[*] Prof. Dr. G. Quinkert, Dr. P. Jacobs, and Doz. Dr. W.-D. Stohrer Institut für Organische Chemie der Universität, Laboratorium Niederrad 6 Frankfurt am Main, Theodor-Stern-Kai 7 (Germany)

π*,n-Excited cyclobutanones *(5)**, on the other hand, undergo stereospecific ring expansion[5] (with retention at C-4, which migrates from the C atom to the O atom of the carbonyl group) furnishing tetrahydro-2-furylidenes *(7)* which can be trapped by alcohols with the formation of acetals *(8)*[6].

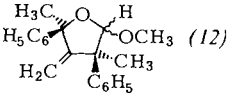




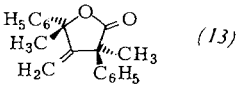
The stereochemical result corresponds with a reaction course which either excludes 1,4-alkyl/acyl diradicals *(6)* or permits these bifunctional intermediates only if they are configurationally stable at C-4. Since *Hoffmann*'s concept of through-bond coupling[7] attributes an enhanced rotational barrier to the 3,4-bond of 1,4 diradicals, the examples known until now[5] are unsuitable as a basis for unambiguously deciding between the above alternative modes of ring expansion by means of the criterion stereochemistry.



Configurationally isomeric 3-methylenecyclobutanone derivatives represent suitable test compounds: in the corresponding



diradicals the configuration-preserving effect of through-bond interaction is overcompensated[8] by the configuration-changing effect caused by formation of the allyl system.



The stereoisomers *(9)* and *(10)* were prepared by conventional methods and their configuration established non-empirically by NMR spectroscopy of suitable derivatives[9]. UV irradiation of their methanolic solutions at room temperature yields a binary mixture of acetals in both cases. Chromic acid oxidation of the heterocyclic photoproduct *(11)*, obtained from *(9)*, affords exclusively *(13)* and that of the acetalic photoproduct *(12)*, derived from *(10)*, yields exclusively *(14)*. The configuration of the two γ-lactones follows from the formation of *(13)* [together with *(15)*] from *(9)* and of *(14)* [in addition to *(16)*] from *(10)* on Baeyer-Villiger oxidation.

(14)

(15)

(16)

Since the four-membered rings of both *(9)* and *(10)* are subject to stereospecific expansion and undergo neither configurational nor constitutional isomerization we conclude that the resulting "*oxacarbenes*"[10] *are formed directly from the electronically excited four-membered cyclic ketones and not via intermediate 1,4-alkyl/acyl diradicals.*

Low Temperature Electronic Spectroscopic Observations on Light-Induced Cyclobutanone-Tetrahydrofurylidene Rearrangement[1]

By *Gerhard Quinkert, Klaus H. Kaiser*, and *Wolf-Dieter Stohrer*[*]

Electronically excited cyclobutanones undergo cycloelimination to ethylene and ketene (or their derivatives), decarbonylation to cyclopropyl compounds, and/or isomerization to ring-expanded oxacarbenes (tetrahydro-2-furylidenes)[2]. The kinetically unstable oxacarbenes can be trapped by alcohols, olefins, or oxygen to give the usual secondary products[3] and thus constitute experimentally well substantiated transients. As C_2 retains the spatial orientation of its ligands on migrating from the C atom to the O atom of the original carbonyl chromophore[4], 1,4-alkyl/acyl diradicals (α-oxo-α,ω-alkylenes) can be ruled out as intermediates during light-induced cyclobutanone-tetrahydrofurylidene isomerization; they do, however, play a plausible role in the genetic interpretation of the structure of cycloelimination and decarbonylation products provided their formation goes with or follows oxacarbene formation. Elucidation of the complex reaction mode of electronically excited four-membered cyclic ketones requires the availability of an experimental method permitting proof of the existence and of subsequent reactions of the oxacarbenes. Since these transients should absorb in the same region as the isoelectronic azo compounds, we have carried out a UV spectroscopic transient analysis using a low temperature technique that has proved of value in other cases[5].

It should be noted that 2,2-bis(trifluoromethyl)-3-phenylcyclobutanone *(1)* gives neither the corresponding acetal at room temperature[6] nor a photoproduct exhibiting maximum electronic absorption around 360 nm[7] at −186 °C in 2-methyltetrahydrofuran (MTHF). On the other hand, many cyclobutanone derivatives which are at least partially converted into acetals on irradiation of their alcoholic solutions lead to a photoproduct, on exposure to light of wavelength >300 nm in MTHF (and sometimes in other solvent glasses) at −186 °C, whose electronic absorption spectrum corresponds to that of (*Z*)-azo compounds[7].

(1)

(2)

The species concerned ought to be oxacarbenes whose kinetic stability depends on the substituents present and on the viscosity of the glass matrix. In some cases[7, 8] the primary tetrahydrofurylidene undergoes thermal conversion into a likewise kinetically unstable secondary intermediate. For example, 2,2,4,4-tetramethylcyclobutanone is rapidly converted into a colorless primary phototransient [λ_{max} = 357 nm in ethanol/isopentane/ether (EPA) = 5:2:5; λ_{max} = 363 nm in methylcyclohexane/3-methylpentane] by 302 nm light at

[*] Prof. Dr. G. Quinkert, Dipl.-Chem. K. H. Kaiser, and Doz. Dr. W.-D. Stohrer
Institut für Organische Chemie der Universität, Laboratorium Niederrad 6 Frankfurt am Main, Theodor-Stern-Kai 7 (Germany)

−186 °C, which slowly transforms into a red secondary thermo transient (λ_{max} = 437 nm in EPA). The colorless Fluorolube glass permits observation of a broad ESR signal and the red solution shows a well structured signal. Further studies should reveal whether the thermo transient is the 1,4-alkyl/acyl diradical formed from the oxacarbene.

The Peculiar Behavior of Electronically Excited Cyclobutanones: A Photochemical Example of the Consequence of Through-Bond Interaction[1, 2]

By *Wolf-Dieter Stohrer, Gerhard Wiech*, and *Gerhard Quinkert*[*]

π*,n-Excited common-sized cycloalkanones ($m = 5, 6, 7$) *undergo ring cleavage to 1,m-alkyl/acyl diradicals (α-cleavage)*, while π*,n-excited cyclobutanones ($m = 4$) generally *undergo ring expansion to isomeric oxacarbenes (tetrahydro-2-furylidenes)*[3]. In both cases the photoreaction is initiated by stretching of the C^1—C^m bond. Why do four-membered cyclic ketones behave differently from their higher homologs?

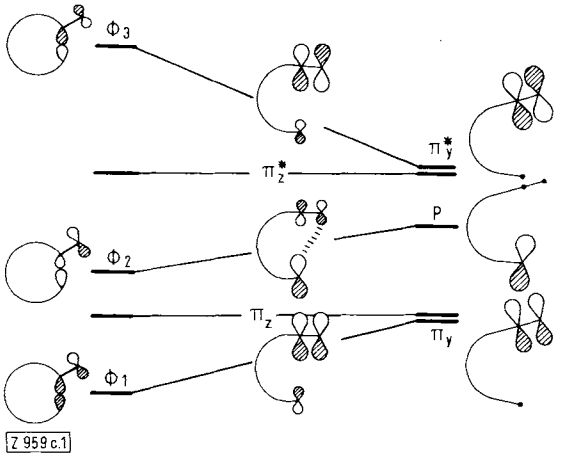

Fig. 1. Correlation diagram for the α-cleavage of a cycloalkanone; the σ orbitals ϕ_1, ϕ_2, ϕ_3 of the ketone which participate in the α-cleavage (or oxacarbene formation) are contructed in a conventional manner from the σ and σ* orbitals of the CC bond to be broken and the n orbital of the oxygen "lone" pair.

The correlation diagram for the α-cleavage of "normal" ketones is depicted in Figure 1. The σ orbitals ϕ_1 and ϕ_3 of the ketone correlate with the acyl orbitals π_y and π_y^* lying in the molecular plane whereas orbital ϕ_2 is transformed into orbital p at C^m. On α-cleavage in the π*,n state the ketone having the configuration $\phi_1^2\pi_z^2\phi_2\pi_z^*$ transforms into the acyl radical of configuration $\pi_y^2\pi_z^2\pi_z^*$ and into the alkyl radical of configuration p. The antibonding character in the C^m—O region of orbital ϕ_2, which is occupied by one electron along the entire reaction coordinate, withstands concerted oxacarbene formation as a competing reaction to α-cleavage.

In the four-membered cyclic ketone special conditions prevail in that the two C atoms are not decoupled on stretching of the C^1—C^4 bond: above a certain C^1—C^4 distance the initially predominating *through-space interaction* is replaced by *through-bond coupling*[4]. Dominance of through-bond coupling is characterized by reversal of the original energy sequence of orbitals ϕ_2 and ϕ_3[4]. This means that the two orbitals tend to cross on cleavage of the C^1—C^4 bond, a true crossing being forbidden by the pseudosymmetry of the system (see Fig. 2).

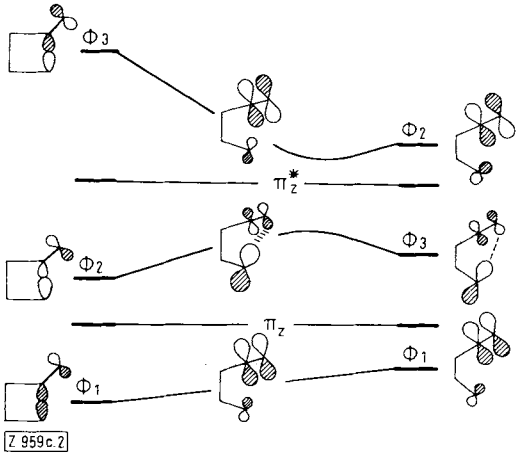

Fig. 2. Correlation diagram for the cleavage of the C^1—C^4 bond in cyclobutanone.

For a small stretching distance C^1—C^4, the highest occupied σ orbital, as in the "normal" ketones (Fig. 1), has ϕ_2 character: the region C^1—C^4 is bonding while C^4—O is antibonding.

For a large stretching distance C^1—C^4 the highest occupied σ orbital has ϕ_3 character: the area important for oxacarbene formation, C^4—O, is bonding and C^1—C^4 is antibonding. These perturbational considerations are confirmed by EH calculations[5] for the correlation diagram of Figure 2[6]. Thus extension of the C^1—C^4 bond in an electronically excited cyclobutanone creates a situation in which the highest (in the π*,n state singly) occupied σ orbital, in contrast to "normal ketones", has bonding character in the region C^4—O and therefore favors oxacarbene formation.

This qualitative MO analysis neither requires a 1,4-alkyl/acyl diradical as an intermediate nor rules such a species out, in contrast to stereochemical studies[3]; everything will depend on the structural scenery in which the transition from a higher to the lowest energy surface takes place (see ref.[7]).

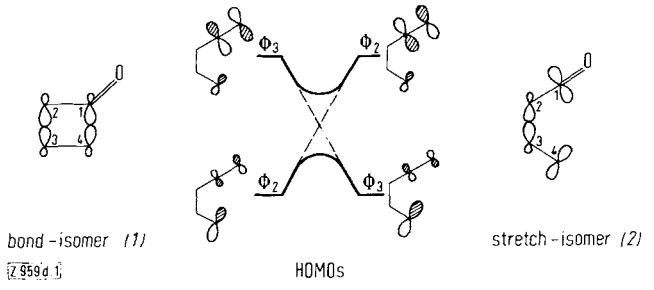
A Simple EH Model for the Photochemical Cyclobutanone-Tetrahydrofurylidene Isomerization[1]

By *Wolf-Dieter Stohrer, Gerhard Wiech*, and *Gerhard Quinkert*[*]

The light-induced cyclobutanone-tetrahydrofurylidene isomerization[2] commences with an extension of the C^1—C^4 bond. Beyond a certain stretching distance the ordering of the σ orbitals ϕ_2 and ϕ_3 is reversed[3]. The structural areas before or after this change in orbital sequence belong to the bond or stretch isomers, respectively (see Fig. 1), and the stretching of the C^1—C^4 bond in cyclobutanone is thus a typical example of bond-stretch isomerism[4]. The bonding properties in the stretch isomer *(2) a priori* favor (photochemical) ring closure between centers C^4 and O to afford the corresponding oxacarbene[3].



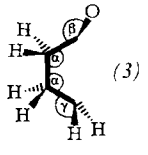


Fig. 1. Behavior of the σ orbitals ϕ_2 and ϕ_3 in "bond-stretch" isomerization.

In order to develop an appreciation of the dynamics of the ligands at C^1 and C^4, which is associated with the bond-stretch isomerism, we have calculated a complete energy surface for the ground state and for the lowest excited state of *(3)* as a function of the degrees of freedom α, β, and γ by the EH method[5].

Curve A—E (Fig. 2) represents the ground state. The transition from *(1)* to *(2)*, formally symmetry-forbidden, by definition causes maximum B. All conformations before this maximum relax to the original reactant A (cf. the nodal properties of ϕ_2); all conformations beyond it (cf. the nodal properties of ϕ_3) relax either to minimum C (1,4-alkyl/acyl diradical) favoring C^1—C^4 interaction by through-bond coupling[6], or to minimum E (oxacarbene) emphasizing through-space interaction between centers C^4 and O. The highest, doubly occupied

[*] Doz. Dr. W.-D. Stohrer, Dipl.-Chem. G. Wiech, and Prof. Dr. G. Quinkert
Institut für Organische Chemie der Universität, Laboratorium Niederrad
6 Frankfurt am Main, Theodor-Stern-Kai 7 (Germany)

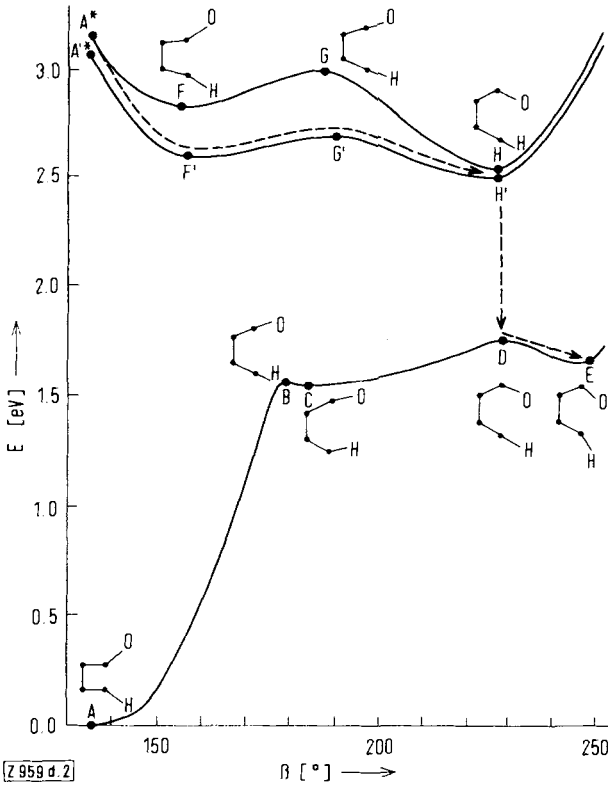

Fig. 2. Vertical sections through calculated energy surfaces: A—E: of the EH ground state; A*—H and A'*—H': of the lowest EH excited state with the O atom in the molecular plane and displaced by 30° from the molecular plane respectively.

orbital ϕ_3 of the 1,4-alkyl/acyl diradical is essentially concentrated on C^4 and the species can be regarded as a carbanion exhibiting pronounced through-bond stabilization[7]. If, in a formal analogy, C^4 in the oxacarbene is defined as a "carbanion" subject to extreme through-space stabilization by interaction with the O atom, then the transition between C and E could be interpreted as inversion of a carbanion. The height of the inversion barrier D would determine the kinetic stability of the oxacarbene.

The points A*—H (Fig. 2) characterize the lowest EH excited state of *(3)* with the O atom in the molecular plane. At minimum F the π^*,n-excited bond isomer has a somewhat longer C^1—C^4 distance than in the ground state, and further extension of this bond causes a considerably shallower rise in energy because the C^1—C^4 bonding orbital is populated by one electron only. The transition from the π^*,n-excited bond isomer to the π^*,n-excited stretch isomer is accompanied—as in the ground state—by an inward displacement of the oxygen towards C^4 ($\beta > 180°$) in order to optimize the stabilizing interaction in the singly occupied orbital ϕ_3; unlike the situation in the ground state the system retains the planar arrangement at C^4. The inward displacement of the oxygen induced by ϕ_3 lowers the energy of the unoccupied orbital ϕ_2 which is concentrated in the carbonyl region where it has antibonding character. The calculations show that at $\beta \approx 190°$ ϕ_2 crosses the hitherto singly occupied π^* orbital, which remains practically unchanged, at G and takes over its electron (Fig. 3).

In this way the deviation, whose inward direction was predetermined, is favored not only by ϕ_3, but initially also by ϕ_2 until the antibonding interaction between C^4 and O, which is weak at first, becomes so strong during the course of displacement that it "stops" the stabilizing displacement at minimum H on the σ^*,n-excited energy surface. Further stabilizing displacement of the O atom towards C^4 is then only possible

if the electron in the C^4—O antibonding orbital ϕ_2 changes to the C^4—O bonding orbital ϕ_3. If this internal conversion ("σ-coupled"[8] transition from H to D) occurs sufficiently

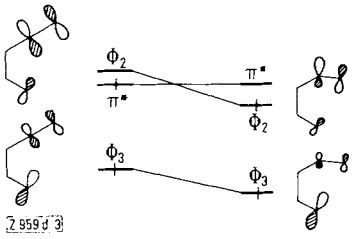

Fig. 3. Energy sequences of the orbitals ϕ_3, π^*, and ϕ_2 of the "stretch" isomer of cyclobutanone for $\beta < ca.\ 190°$ and $\beta > ca.\ 190°$.

rapidly to preclude thermal equilibration at H then the mobile molecule continues its initial motion after reaching D and thus arrives at E[9].

Just as an electron in ϕ_2 favors bending of the three-center system O—C^1—C^2, an electron in the π^* orbital of the CO group of the π*,n-excited cyclobutanone will cause the oxygen to become twisted out of the molecular plane[11]. In order to discover the effect of this tendency on our unrealistic, but transparent model, we have calculated a second energy surface for the lowest EH excited state with the O atom twisted out of the molecular plane by 30°. The new energy curve A'*—H' corresponds qualitatively to that one characterized by A*—H. The lower energy of the former curve is a consequence of σ*π* admixture in the nonplanar system. In this way crossing of the energy surfaces of the "π*,n"- and "σ*,n"-excited stretch isomers is avoided: the crossing point G of the energy surfaces of the π*,n- and σ*,n-excited stretch isomers becomes a true maximum G'.

According to our simple model, the light-induced cyclobutanone-tetrahydrofurylidene isomerization is a diabatic rearrangement in which the oxacarbene is formed in the photochemical primary process[12].

Hexakis(trifluorophosphane)vanadium Hydride[1]

By *Thomas Kruck* and *Hans-Ulrich Hempel*[*]

Although trifluorophosphanemetal hydrides are characterized by a considerably greater thermal stability than the carbonylmetal hydrides, which have comparable compositions and structures, corresponding derivatives have so far only been obtained for metals of Groups 7A and 8 (type $HM(PF_3)_5$: M = Mn, Re; type $H_nM(PF_3)_4$: M = Fe, Ru, Os with $n=2$; M = Co, Rh, Ir with $n=1$)[2]. However, the stabilization of transition metal-H bonds by PF_3 ligands provided an early indication that the first hydrido complex *(3)* to be isolated would be a stable vanadium compound HVL_6 in which the central atom could assume the true coordination number 7. Our successful synthesis is based on complete CO/PF_3 exchange on a carbonylmetalate(−I). This preparative finding itself appears remarkable since complete substitution of CO by PF_3 ligands has hitherto only been accomplished with carbonylmetal(0) complexes.

UV irradiation of a solution of bis(diglyme)sodium hexacarbonylvanadate(I) *(1)*[3] in di(2-methoxyethyl) ether (diglyme) saturated with trifluorophosphane afforded an almost quantitative yield of hexakis(trifluorophosphane)vanadate(−I), which is isoelectronic with $Cr(PF_3)_6$ and likewise has an octahedral configuration, in the form of its colorless bis(diglyme)-sodium salt *(2)*.

$$\underset{(1)}{[Na(C_6H_{14}O_3)_2][V(CO)_6]} \xrightarrow[-6CO]{PF_3,\ C_6H_{14}O_3,\ h\nu} \underset{(2)}{[Na(C_6H_{14}O_3)_2][V(PF_3)_6]}$$

$$(2) \xrightarrow{H_3PO_4} \underset{(3)}{HV(PF_3)_6}$$

The composition of *(2)* was established by elemental analysis[4] and by its IR spectrum [ν_{P-F} (cm^{-1}) in KBr: 867 s, 833 vs, 778 s].

The hydrido complex *(3)* can be obtained in almost 70% yield from *(2)* by the action of 90% phosphoric acid and subsequent sublimation at 60 °C/10^{-2} torr. Further sublimation of the product over P_4O_{10} furnishes *(3)* as pale yellow crystals which do not decompose below 135 °C when heated in a sealed tube. The compound is sparingly soluble in saturated hydrocarbons and owing to its strongly acidic character it reacts with oxygen- and nitrogen-containing donor solvents with spontaneous formation of onium salts.

The IR spectrum of gaseous *(3)* contains two bands in the ν_{P-F} region at 911 vs and 846 s cm^{-1} and is thus almost identical with that of hexakis(trifluorophosphane)chromium(0) [ν_{P-F} (gas): 916 vs, 851 s cm^{-1}]. This indicates that hexakis(trifluorophosphane)vanadium hydride has a structure deviating only insignificantly from a regular octahedron.

Further evidence for the presence of a true complex metal hydride comes from the following findings:

1) The substance is diamagnetic[4] having $\chi_m = -236 \times 10^{-6}$ $cm^3\ mol^{-1}$.

2) The mass spectrum[4] (20 eV) displays the molecular ion at *m/e* 580 and fragments derived by successive loss of PF_3 from the ions $HV(PF_3)_5^+$ (*m/e* 492) and $V(PF_3)_5^+$ (*m/e* 491). The absence of $V(PF_3)_6^+$ (*m/e* 579) is remarkable.

3) The ^1H Fourier NMR spectrum[4] of a solution of *(3)* in $Ni(PF_3)_4$ contains a five-line multiplet centered at 18.4 τ; the remaining two of the theoretically predicted seven lines

[*] Prof. Dr. Th. Kruck and Dipl.-Chem. H.-U. Hempel
Institut für Anorganische Chemie der Universität
5 Köln 41, Haedenkampstrasse 2 (Germany)

are apparently not registered owing to the low solubility of *(3)*.

In addition to $HV(CO)_3(\pi\text{-}C_6H_3(CH_3)_3)$[5] we now have another defined hydrido complex of vanadium in $HV(PF_3)_6$. Whether the above synthetic route is suitable for the preparation of hexakis(trifluorophosphane)metal hydrides of higher homologs of vanadium which may also be capable of existence is currently under study.

Experimental:

All operations are performed under nitrogen; the solvents are purified in the usual way and saturated with nitrogen.

Bis(diglyme)sodium hexakis(trifluorophosphane)vanadate(1) (2)

A solution of *(1)* (7.00 g, 13.7 mmol) in diglyme (150 ml) is cooled to −45 °C and saturated with PF_3 in an irradiation apparatus (Duran 50) with internal cooling and an external vacuum jacket. The vigorously stirred reaction mixture is irradiated for 24 h with an external high-pressure mercury arc lamp (Q 600 Hanau) until evolution of CO is no longer observed. The solution must be resaturated several times with PF_3 during the reaction. The solvent is then removed in a high vacuum and the residue washed twice with light petroleum. The product thus obtained is sufficiently pure for the synthesis of *(3)*. Analytically pure samples are obtained by recrystallizing from diglyme with light petroleum. Yield: 11.64 g (98 %).

Hexakis(trifluorophosphane)vanadium hydride (3)

Compound *(2)* (5.00 g, 5.7 mmol) and crystalline orthophosphoric acid (50 g, 510 mmol) are heated to 60 °C in a flask fitted with a cold trap. The resulting hydrido complex is immediately drawn off into the cold trap (−196 °C) by a high vacuum and then sublimed at 50 °C/10^{-2} torr over P_4O_{10} in order to remove residual traces of water. Yield 2.26 g (68 %) of *(3)*.

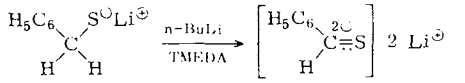
Doubly Metalated Thiobenzyl Alcohol—Thiobenzaldehyde Dianion[**]

By *Dieter Seebach* and *Karl-Heinz Geiss*[*]

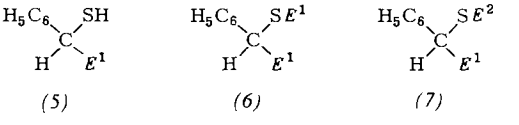
Carbonyl compounds and their analogs always react with nucleophiles (*N*) *(1)* at the C atom. The polarity of this reaction can be reversed in favor of electrophiles (*E*) in the case of dianions *(2)*.



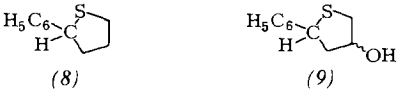
[*] Prof. Dr. D. Seebach and Dipl.-Chem. K.-H. Geiss
Institut für Organische Chemie, Fachbereich 14 der Universität
63 Giessen, Ludwigstrasse 21 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft. We thank *G. Protschuk* for his assistance in a number of experiments.

Dianions of this kind have hitherto been generated exclusively by reaction of carbonyl derivatives with alkali metals[1]. We

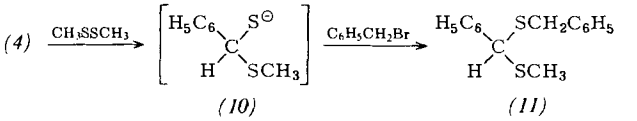


(1) *(2)*



(3) *(4)*

now report the first preparation of such a reagent with X=S by double metalation of the corresponding hydrogenated precursor.



Reaction of a solution of lithium benzyl sulfide *(3)* with *n*-butyllithium, in the presence (2.5 h) or absence (4.0 h) of tetramethylethylenediamine (TMEDA), at −5 °C in THF/pentane (1:1) leads to an orange-colored suspension of the dilithium salt *(4)*. The presence of the dianion is deduced from its reactions with various electrophiles, which we generally add at −78 °C. The products listed in Table 1 can be divided into three different types *(5)*, *(6)*, and *(7)*.

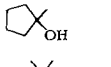
(5) *(6)* *(7)*

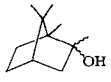
(8) *(9)*

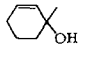
(10) *(11)*

1) Thiols of type *(5)* are formed with an aldehyde, a ketone, or trimethylchlorosilane (molar ratio 1:1).

2) Derivatives of type *(6)* are produced with halides, epoxides, or trimethylchlorosilane (molar ratio 1:2).







3) Compounds of type *(7)* formed by addition of two different electrophiles to C and S are obtained by consecutive treatment with (i) aldehyde, ketone, or trimethylchlorosilane and (ii) methyl iodide (molar ratio 1:1 in each case).

Special mention should also be made of the tetrahydrothiophenes *(8)* and *(9)* obtainable with 1,3-dibromopropane and epichlorohydrin, respectively, and the mixed dithioacetal *(11)* resulting on benzylation of the primary adduct *(10)* generated with dimethyl disulfide, which is apparently stable under the reaction conditions. Yields (not optimized) and physical data of the derivatives *(5)*—*(9)* and *(11)* are given in Table 1. All the IR and NMR spectra and the results of elemental analysis are in accordance with the structures given. Products having more than one center of asymmetry were isolated as mixtures of diastereoisomers.

Doubly metalated thiobenzyl alcohol is remarkably stable[2]. After storage for two weeks at +5 °C about 30 % of the dianion remains undecomposed. The decomposition products have not yet been studied in detail.

(4) is a readily available, strongly nucleophilic, heterosubstituted carbanion whose reaction products with electrophiles

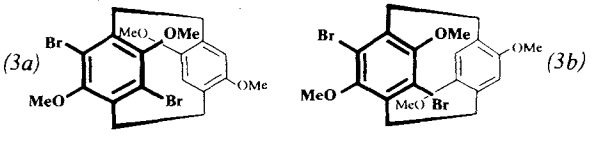
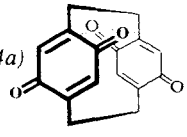
The Pseudogeminal "Quinhydrone" of the [2.2]Paracyclophane Series[1]

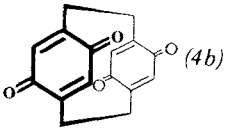
By *Walter Rebafka* and *Heinz A. Staab*[*]



For the investigation of intramolecular donor-acceptor interactions a comparison of the two stereoisomeric "quinhydrones" *(1a)* and *(1b)* of the [2.2]paracyclophane series[2] was thought to be promising: although the total electron affinity of the acceptor and the total ionization energy of the donor are the same in *(1a)* and *(1b)* the sterical conditions for π-electron overlap and the differences of charge densities on opposite carbon atoms are characteristically different in the two systems. Therefore some information about the importance of sterical factors and of local conditions to donor-acceptor interactions was to be expected.

Synthesis and properties of the pseudoortho compound *(1a)* have been reported recently[1]. The pseudogeminal stereoisomer *(1b)* was not obtainable in an analogous reaction sequence since ring contraction of *both* diastereomeric 5,8,14,17-tetramethoxy-2,11-dithia[3.3]paracyclophanes using three different methods yielded only the chiral 4,7,12,15-tetramethoxy[2.2]paracyclophane *(2a)*[1] but not the achiral pseudogeminal *(2b)*. The exclusive formation of *(2a)* with the sterically more favored arrangement of the four methoxy groups is explained on the assumption that a two-step radical mechanism of the three ring-contraction methods allows formation of the thermodynamically more stable stereoisomer by the rotation of an aryl unit through 180°[3]. On the basis of this assumption the following synthesis of *(2b)* was developed.





Treatment of 1,4-dibromo-2,5-dimethoxy-3,6-dimethylbenzene[4] (prepared from 1,4-dimethoxy-2,5-dimethylbenzene[5] by electrophilic bromination, 80%, m.p. 125–126°C) with *N*-bromosuccinimide/carbon tetrachloride yielded 1,4-dibromo-2,5-dimethoxy-3,6-bis(bromomethyl)benzene[4] (85%, m.p. 194–195°C) which was cyclized with 1,4-bis(mercaptomethyl)-2,5-dimethoxybenzene to give 5,8-dibromo-6,9,14,17-tetramethoxy-2,11-dithia[3.3]paracyclophane[4] (conditions cf.[1], 7–15%, m.p. 235–237°C)[6]. By irradiation in triethyl phosphite (450-W Hg high-pressure lamp, 16 h) a mixture of both stereoisomeric 4,7-dibromo-5,8,12,15-tetra-

[*] Dipl.-Chem. W. Rebafka and Prof. Dr. H. A. Staab
Institut für Organische Chemie der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

methoxy[2.2]paracyclophanes *(3a)* and *(3b)* was obtained (total yield 35–40%), the now sterically favored *(3b)* with pseudogeminal arrangement of the four methoxy groups prevailing in the ratio of about 2:1. *(3a)*[4] (m. p. 137–138 °C) and *(3b)*[4] (m. p. 157–159 °C) were separated by chromatography (silica gel; benzene/CCl_4, 2:1). Halogen-metal exchange of *(3b)* with *n*-butyllithium (ether/*n*-hexane) and hydrolysis yielded *(2b)*[4] [56%, m. p. 229–230 °C; ^{1}H-NMR ($CDCl_3$): τ=4.15 (s, 4 arom. H), 7.6—6.35 (AA'BB', 8 methylene-H)] whereas the corresponding reaction with *(3a)* led to *(2a)*[1]. Demethylation of *(2b)* and oxidation of the intermediate tetrahydroxy[2.2]paracyclophane to the bis-quinone *(4b)* were carried out according to the corresponding steps of the synthesis of *(4a)*[1] with slight modifications because of the low solubility of the pseudogeminal compounds (60% yield). The pseudogeminal structure of *(4b)*[4] (yellow needles, dec. >200 °C) was confirmed by X-ray analysis[7] [^{1}H-NMR (CF_3COOH): τ=3.44 (s, 4 ring-H), 7.55—6.08 (m, 8 methylene-H); MS: M^+ 268, fragmentation similar to *(4a)*[1]].

(4a)   *(4b)*

Catalytic hydrogenation of *(4b)* (Pd/C, 1 equiv. H_2, dioxane) and subsequent recrystallization from dioxane gave *(1b)* as black crystals [(dec. >350 °C, 75% yield)[4]; MS: M^+ found 270.0898, calc. 270.0891; ^{1}H-NMR ([D_6]-dimethyl sulfoxide): τ=6.5—8.0 (m, 8 methylene-H), 4.14 and 3.98 (singlets for 2 ring-H each), 1.30 (s, 2 hydroxyl-H)]. In contrast to that of *(1a)*[1] the IR spectrum (KBr) of *(1b)* shows a very broad ν(OH) absorption around 3200 cm^{-1} and a ν(CO) absorption shifted to 1620 cm^{-1}, indicating strong hydrogen bonds.

Apart from UV absorptions at 246 (ε 9.350), 277 (5.150), and 320 nm (3.200), *(1b)* exhibits a typical broad charge-transfer absorption between 400 and 600 nm similar to *(1a)* (λ_{max} 500 nm). However, its extinction ($\varepsilon \approx 1.700$, in methanol) is ten times higher than for the corresponding band of *(1a)*. In contrast to *(1a)*, the ^{1}H-NMR of which shows no change up to 200 °C (in [D_6]-dimethyl sulfoxide), a reversible coalescence of the singulets at τ=4.14 and 3.98 is observed for *(1b)* at 160 °C in the same solvent. Obviously this coalescence is the result of an exchange of oxidation states between the two rings with simultaneous proton transfer ($\Delta G^{\neq}_{160\,°C} \approx 22.2$ kcal/mol).

The "intramolecular quinhydrones" *(1a)* and *(1b)* as well as the bis-quinones *(4a)* and *(4b)* form paramagnetic anions in which according to ESR measurements a fast electron exchange between both rings takes place[8].

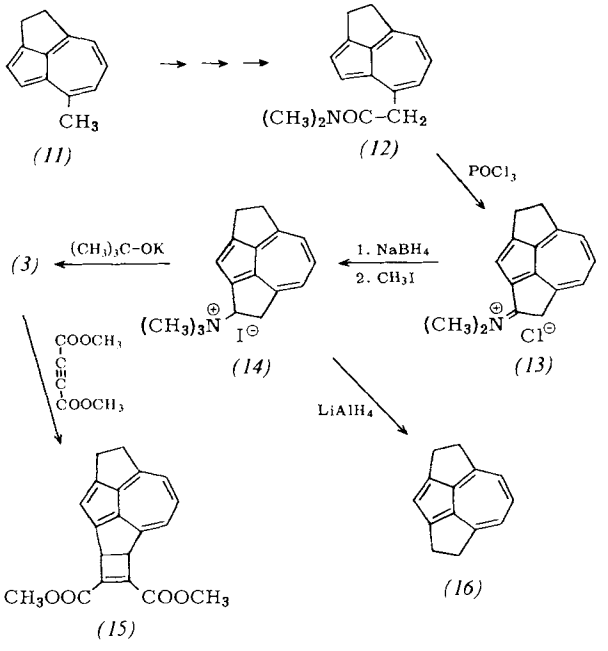
Cyclopent[*cd*]azulene and 1,2-Dihydrodicyclopent-[*cd,ij*]azulene

By *Klaus Hafner*, *Klaus-Peter Meinhardt*, and *Winfried Richarz*[*]

Alkyl and aryl derivatives[1] of cyclopent[*cd*]azulene *(1)* exhibit a notable reactivity in cycloaddition reactions with alkenes, alkynes, and carbenes[2]. An examination of the hitherto unknown parent hydrocarbon *(1)* therefore appeared desirable. The 2a,8b-dihydro derivative *(2)* has recently been prepared by *Paquette et al.*[3] and by *Vogel et al.*[4]. We wish to report a simple synthesis of *(1)* and of 1,2-dihydrodicyclopent[*cd,ij*]azulene *(3)* which is likewise characterized by a pronounced reactivity of the double bonds in its five-membered rings.

(1) *(2)* *(3)*



[*] Prof. Dr. K. Hafner, Dipl.-Chem. K.-P. Meinhardt, and Dipl.-Ing. W. Richarz
Institut für Organische Chemie der Technischen Hochschule
61 Darmstadt, Schlossgartenstrasse 2 (Germany)

4-Azulenylacetic acid *(4)* (m.p. 122 °C, decomp.)[5], prepared in 75% yield by reaction of 4-methylazulene[6] with sodium *N*-methylanilide and subsequent carboxylation of the resulting sodium 4-methyleneazulenide[7], proved to be useful as starting material for the synthesis of *(1)*. By treatment with sulfinylbis-(dimethylamine)[8] in benzene for 2h at 60 °C *(4)* can be converted almost quantitatively into the carboxamide *(5)*. Cyclization in $POCl_3$ (60 °C, 2 h) yields 95% of the ketimonium chloride *(6)* (perchlorate: red-brown crystals, m.p. 243 to 244 °C, decomp.). Reduction of *(6)* by $NaBH_4$ in methanol at 20 °C followed by quaternization with methyl iodide affords the iodide *(7)* (yield 90%; blue-violet crystals, decomp. >110 °C), and Hofmann degradation with 2 N NaOH at 20 °C finally gives rise to a 90% yield of the hydrocarbon *(1)* (brown leaflets having metallic luster, m.p. 69—70 °C, decomp.). Compound *(1)* is yellowish brown in solution and prone to autoxidation but thermally stable.

The 60 MHz ^{1}H-NMR spectrum of *(1)* (in CCl_4), which provides structural proof for the compound, contains a multiplet centered at $\tau = 1.93$ for the four protons of the seven-membered ring in addition to the signals of the two AB systems for the protons of the five-membered rings at $\tau = 3.18$ and 2.54 ($J_{AB} = 4.5$ Hz). The electronic spectrum of *(1)* (in *n*-hexane) shows a pronounced vibrational structure in the UV and visible regions.

Reduction of the quaternary salt *(7)* by $NaBH_4$ in methanol at 0 °C yields 1,2-dihydrocyclopent[*cd*]azulene *(8)* (yield 37%; dark blue needles, m.p. 71 °C) which is isomeric to *(2)* and whose 2-oxo derivative *(9)* is accessible by direct cyclization of *(4)* in acetic anhydride/pyridine (yield 83%; red-brown crystals, m.p. 131—132 °C). Oxidation of *(9)* with selenium dioxide in dioxane (60 °C, 3h) affords cyclopent[*cd*]azulene-1,2-dione *(10)* (10% yield, dark green needles, decomp. >240 C), an isomer of acenaphthenequinone.

Compound *(3)* was prepared similarly to *(1)* starting from 4,8-dimethylazulene[6]. 5-Methyl-1,2-dihydrocyclopent[*cd*]-azulene *(11)* (blue needles, m.p. 132 °C) obtained analogously to *(8)* is converted into the carboxamide *(12)* (yield 95%; blue rhomboids, m.p. 115 °C) which is cyclized to the tetracyclic ketimonium salt *(13)* (yield 45%; perchlorate: red-brown needles, decomp. >270 °C). Reduction ($NaBH_4$) and quaternization with methyl iodide finally yield the iodide *(14)* (air-sensitive blue powder). Treatment of *(14)* with potassium *tert*-butoxide in tetrahydrofuran at −20 °C furnishes the highly strained, thermally unstable tetracyclic hydrocarbon *(3)* which is yellowish green in solution and could hitherto only been trapped as the cycloadduct *(15)* (dark green crystals, m.p. 108 °C) by reaction with dimethyl acetylenedicarboxylate at 0 °C. Reduction of *(14)* by lithium tetrahydridoaluminate in ether at 20 °C affords 1,2,4,5-tetrahydrodicyclopent[*cd,ij*]-azulene *(16)* as pale blue needles (m.p. 180 °C, decomp.; yield 85%).

An Aza[13]- and an Aza[17]annulenyl Anion[1][**]

By *Gerhard Schröder*, *Günter Frank*, *Herbert Röttele*, and *Jean F. M. Oth*[*]

The pyrrolyl or aza[5]annulenyl anion has long been known and possesses considerable interest from both a theoretical and a preparative standpoint[2]. The synthesis and properties of the azoninyl or all-*cis*-aza[9]annulenyl anion have recently been described[3]. We now wish to report an aza[13]- *(2)* and an aza[17]annulenyl anion *(5)*.

Photolysis of the adduct of ethoxycarbonylnitrene to the double bond of the four-membered ring in tricyclo[6.4.0.0^{9,12}]dodeca-2,4,6,10-tetraene at −70 °C affords two isomeric *N*-

[**] We are grateful to Badische Anilin- & Soda-Fabrik AG, Ludwigshafen, for a gift of cyclooctatetraene.

ethoxycarbonylaza[13]annulenes *(1)*[4]. Photolysis of the addition product of ethoxycarbonylnitrene to tricyclo-[8.6.0.0^{2,9}]hexadeca-3,5,7,11,13,15-hexaene leads to three isomeric *N*-ethoxycarbonylaza[17]annulenes *(4)*[5].

Treatment of the azaannulenes *(1)* and *(4)* respectively with potassium *tert*-butoxide in THF at 0 °C alway furnishes the same aza[13]- and aza[17]annulenyl anions, according to NMR spectroscopic evidence. On the basis of the NMR spectra (see Table 1) and double resonance experiments considering in particular the number of inner and outer protons, the characteristic absorptions of the protons in α and β position to the nitrogen, and the coupling constants, these anions must be assigned the configurations *(2)* and *(5)*[6] respectively.

The following three points warrant attention:

1) The configurationally isomeric azaannulene *(1)* or *(4)* gives rise to only one azaannulenyl anion, *(2)* or *(5)*. We thus conclude that the aza[13]- and the aza[17]annulenyl anions must be configurationally labile.

2) The nonbonding electron pair on the nitrogen of *(2)* and *(5)* is directed towards the center of the ring. Taking account of the statements made under 1, we deduce that the spatial requirement of a hydrogen on the sp^2 C atom is greater than that of the lone pair of the sp^2 N atom.

3) The difference between the resonance signals for the inner and outer protons is *ca.* 10 ppm for *(2)* and *ca.* 14 ppm for *(5)*. These values indicate that the magnetic field induces a considerable diamagnetic ring current in these species.

Protonation of *(2)* and *(5)* with water-saturated ether containing a small amount of acetic acid yields crystals of aza[13]-*(3)* and aza[17]annulene *(6)*, respectively, which decompose on attempted melting-point determination. The compounds were purified by column chromatography [*(3)*: Al_2O_3 (basic); *(6)*: SiO_2 (pentane/ether 95:5)]; they are highly sensitive to oxygen. The configurations *(3)* and *(6)* are unequivocally confirmed by NMR data (see Table 1) and by the following experiment: If a solution of *(3)* or *(6)* in CS_2 is shaken with D_2O in a NMR sample tube, the intensities of the upfield signals at τ = 7.20 and 8.5 respectively are each reduced by about 1 H.

We assign the upfield signals in the ^{1}H-NMR spectrum of *(3)* and *(6)* to the inner protons, and the downfield signals to the outer protons. The difference in the center of gravity of these signals amounts to *ca.* 4.7 ppm for *(3)* and *ca.* 5 ppm for *(6)*. The induced diamagnetic ring current is now considerably smaller than in *(2)* and *(5)*, but, unlike that in *(1)*[4] and *(4)*[5], it is however still readily detectable. This finding accords with previous results for aza[9]annulenes[3].

Table 1. Data of *(2)*, *(3)*, *(5)*, and *(6)*.

A Simple Synthesis of 3(5)-Aminopyrazole[**]

By *Günter Ege* and *Philipp Arnold*[*]

Dedicated to Professor Hans Plieninger on the occasion of his 60th birthday

3(5)-Aminopyrazole has formerly been accessible only by way of multistage syntheses[1-3]. We now report a one-stage preparation of 3(5)-aminopyrazole *(2)* utilizing commercially available starting materials and giving 70% yields of the pure product. The reaction involves addition of aqueous hydrazine solution to 2-chloroacrylonitrile in alkaline solution (potassium carbonate).

[*] Prof. Dr. G. Ege and P. Arnold
Organisch-Chemisches Institut der Universität
69 Heidelberg, Im Neuenheimer Feld 7 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Extraction with ethyl acetate or ether and distillation of the crude oil[4] furnishes pure *(2)*. As shown in the reaction scheme, the overall reaction proceeds *via* several unisolated intermediates and it has not yet been established whether the cyclization occurs with *(1a)* or *(1b)*. Remarkably, in the present synthesis, ring closure takes place in alkaline solution whereas comparable cyclizations invariably have to be performed in acidic media[2, 5]. Like other aminoazoles having a 2-aminopyrrole structure, compound *(2)* reacts with 1,3-dicarbonyl compounds to give pyrazolo[2,3-*a*]pyrimidines *(3)*[6].

3(5)-Aminopyrazole (2)

Hydrazine hydrate (55 g, 1.1 mol) is added to a solution of K_2CO_3 (140 g, 1 mol) in water (400 ml). To this vigorously stirred mixture is then added dropwise 2-chloroacrylonitrile[7] (87.5 g, 1 mol) at 5—10 °C (ice-salt cooling) under nitrogen over a period of 1 h. Stirring is continued for 1 h at room temperature and 1.5 h at 40—50 °C, and the mixture left to stand overnight. Extraction for 24 h with ethyl acetate[8] and vacuum distillation of the residual crude oil (75 g, 90 %) under nitrogen affords 58 g (70 %) of *(2)*, b. p. 120—122 °C/0.3 torr. Compound *(2)* solidifies on cooling, preferably with seeding (m. p. 36 °C). The IR spectrum accords with that of authentic 3(5)-aminopyrazole[2]. Picrate: m. p. 222 °C from methanol.

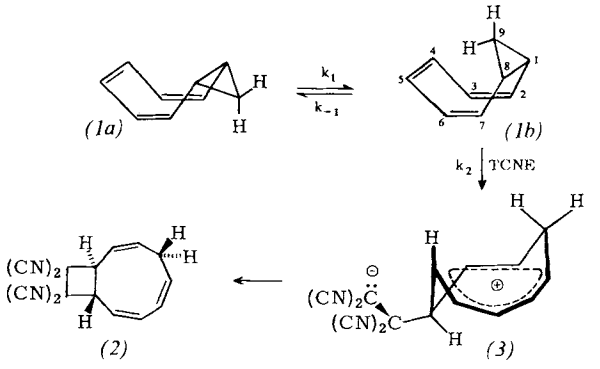
Reaction of *cis*-Bicyclo[6.1.0]nona-2,4,6-triene with Tetracyanoethylene[**]



By *Gernot Boche, Heinrich Weber,* and *Jürgen Benz*[*]

cis-Bicyclo[6.1.0]nona-2,4,6-triene *(1)* reacts with tetracyanoethylene (TCNE) to form the *trans*-linked 1:1 adduct *(2)*[1, 2]. In a detailed study of electrophilic addition reactions to *cis*-bicyclo[6.1.0]nonatriene the formation of *(2)* was formulated as involving attack by TCNE on C^3 of the coiled conformation *(1b)*. The *exo*-3-*trans*-1,3-bishomotropylium zwitterion *(3)* was postulated as intermediate[2, 3].

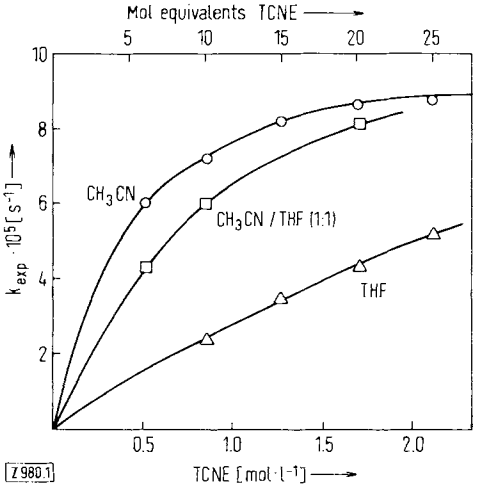
[*] Dr. G. Boche, Dipl.-Chem. H. Weber, and J. Benz
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We are indebted to BASF, Ludwigshafen, for a gift of cyclooctatetraene, and to Miss *G. Schneider* for assisting with the kinetic measurements.

Since conformational equilibration *(1a)*⇌*(1b)* is certainly rapid the bimolecular reaction *(1b)* + TCNE $\xrightarrow{k_2}$ *(3)* would represent the rate-determining step of such a mechanism. Hence the pseudo-first order rate constant k_{exp} determined

experimentally with an excess of TCNE should be a linear function of the TCNE concentration.

We have performed a kinetic study of the reaction of *(1)* (0.085 mol/l) with TCNE (6—25 mol. equiv.) in acetonitrile (CH_3CN), tetrahydrofuran (THF), and CH_3CN/THF (1:1) at 31.3 °C. Figure 1 shows a plot of k_{exp} *versus* increasing TCNE concentration.



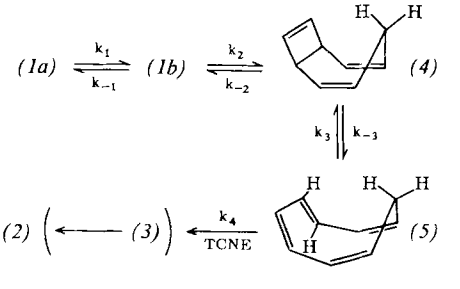


Fig. 1. Rate constant k_{exp} for the reaction of *(1)* with TCNE in various solvents at 31.3 C *vs.* TCNE concentration.

Since the k_{exp} values do not vary in a linear fashion with the TCNE concentration but instead tend to a plateau value, a direct reaction of *(1)* with TCNE can be ruled out.

The kinetic data do however indicate a reaction course in which cycloaddition to TCNE is preceded by a rate-determining valence isomerization of *(1)*[4]. In the reaction sequence formulated below, in which *cis*-bicyclo[6.1.0]nonatriene *(1)*

is in equilibrium with bicyclo[5.2.0]nona-2,5,8-triene *(4)* and the latter in turn with *cis,trans,cis,cis*-cyclononа-1,3,5,7-tetraene *(5)*[5], the Cope rearrangement *(1b)*⇌*(4)* should be fast and the valence isomerization *(4)*⇌*(5)* slow[6]. Compound *(5)*, which could also be trapped in a Diels-Alder reaction[7], then reacts with TCNE.

The rate constant k_{exp} of this scheme can be expressed by

$$k_{exp} = K \times k_3 - \frac{k_{-3}}{k_4} \times \frac{k_{exp}}{[TCNE]} \quad (1)$$

where K is the rate constant between *(1a)* and *(4)*. In accord with eq. (1), a plot of k_{exp} *versus* $k_{exp}/[TCNE]$ now gives a straight line of slope k_{-3}/k_4 which intersects the ordinate at $K \times k_3$[4].

Further confirmatory evidence comes from the ratio $k_{exp}(CH_3CN) : k_{exp}(THF)$ with, *e.g.*, 25 equiv. of TCNE, which amounts to only 1.7 (see Fig. 1). This almost negligible solvent dependence is hardly reconcilable with the formation of the zwitterion *(3)* in the rate-determining step.

Our kinetic findings are therefore plausible when *cis,trans,-cis,cis*-cyclononatetraene *(5)* is assumed as reactive intermediate.

Can we summon any additional evidence that *(5)* isomerizes to *(1)* and reacts with TCNE to give *(2)*, and that the cycloaddition *(5)*+TCNE competes successfully with the isomerization *(5)*→*(1)*?

We were able to produce *(5)* by protonation of the *cis,cis,cis,-trans*-[9]annulene anion[8]. At −28 °C it is transformed with a half-life of 34 min into *(1)*. However, if *(5)* is allowed to react with TCNE in dimethyl ether at −50 °C then the cycloadduct *(2)* is formed. In contrast, *(1)* does not react under these conditions.

The agreement between these experiments and the kinetic findings in various solvents reveals that the highly strained *cis,trans,cis,cis*-cyclononatetraene *(5)* assumes the role of reactive intermediate in the reaction of *cis*-bicyclo[6.1.0]nonatriene *(1)* with TCNE[10]. In the (2+2) cycloaddition of *(5)*, the zwitterion *(3)* represents a possible but not a necessary intermediate.

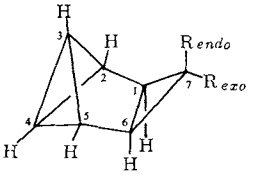
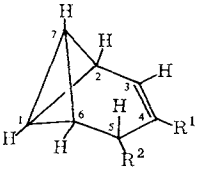
[8] In addition to *(5)*, protonation of the *cis,cis,cis,trans*-[9]annulene anion also yields all-*cis*-cyclononatetraene and the *trans,cis,cis,cis* isomer. The latter isomerizes at −30 °C to *trans*-dihydroindene and reacts with TCNE at −60 °C to give a bicyclic adduct, m.p. 153—154 °C. The stereochemistry of the ring linkage is unknown [9].

[9] *H. Weber*, Diplomarbeit, Universität München 1972.



[10] *Note added in proof* (March 4, 1974): The kinetics of the reaction of *anti*-9-methyl-*cis*-bicyclo[6.1.0]nona-2,4,6-triene with excess TCNE in CH_3CN at 31.3 °C leads to the same result as for *(1)*.

Novel Isomers of Cycloheptatriene: Tricyclo[4.1.0.0^{2,7}]hept-3-ene and Tetracyclo-[4.1.0.0^{2,4}.0^{3,5}]heptane

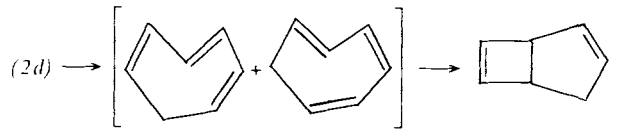


By *Manfred Christl* and *Gisela Brüntrup*[*]

We recently reported the conversion of benzvalene into *(1a)* by reaction with dibromocarbene[1]. In the present communication it is shown how previously unknown, highly-strained hydrocarbons are accessible *via* their halogen derivatives by the use of this reaction. The isomerizations of the compounds prepared throw new light on the reactivity of the bicyclobutane system.

Reaction of benzvalene with methyl trichloroacetate and sodium methoxide leads to formation of the dichloro derivative *(1b)* (colorless liquid, b.p. 77—79 °C/13 torr) in 84% yield[2]. On heating *(1a)* and *(1b)* rearrange into the allyl compounds *(2a)* (m.p. 38.5—39.5 °C)[2b] and *(2b)* (b.p. 91—93 °C/13 torr)[2b] respectively. When carried out in carbon tetrachloride solution at 80 °C, rearrangement of *(1a)* proceeds quantitatively within 15 h, whereas in the case of *(1b)* the solution must be heated for five days at 100 °C. When *(2a)* is heated for 75 h at 115 °C in tetrachloroethylene, drastic bond rearrangement takes place with formation of 3-bromobenzyl bromide.

(1a), R = Br
(1b), R = Cl
(1c), R = H



(2a), $R^1 = R^2$ = Br
(2b), $R^1 = R^2$ = Cl
(2c), R^1 = Br, R^2 = H
(2d), $R^1 = R^2$ = H

Reduction of *(2a)* with $LiAlH_4$ affords the monobromo derivative *(2c)* (colorless liquid, b.p. 60 °C/11 torr, yield 81%)[2b], which on reaction with sodium in liquid ammonia is converted into the unsubstituted tricyclo[4.1.0.0^{2,7}]hept-3-ene *(2d)* (colorless liquid, b.p. 111—112 °C, yield 70%)[2b]. Diagnostic for the bicyclobutane systems in *(2c)* and *(2a)* are the characteristic values of the ^{13}C—H coupling constants of the bridgehead protons 1-H and 7-H. Their values of 212 and 209 Hz, respectively, are somewhat larger than in tricyclo[4.1.0.0^{2,7}]-heptane (200 Hz)[3]. Reduction of *(1b)* with sodium in liquid ammonia affords tetracyclo[4.1.0.0^{2,4}.0^{3,5}]heptane *(1c)* (colorless liquid, b.p. 104 °C) in 70% yield. Its NMR spectrum shows an interesting long-range coupling of 2.4 Hz between the distant 4-H and 7-H_{exo}, as revealed by decoupling of 4-H.

On heating in C_2Cl_4 solution at 150 °C, *(2d)* is converted (reaction halflife *ca.* 1.5 h) into bicyclo[3.2.0]hepta-2,6-diene *(4)*, the photoisomer of cycloheptatriene, which could be identified by its NMR spectrum[4]. We assume, by analogy with the thermolysis of tricyclo[4.1.0.0^{2,7}]heptane[5], that a synchronous $[_\sigma 2_s + _\sigma 2_a]$ reaction takes place initially with formation of *cis-trans-cis*- and/or *trans-cis-cis*-cycloheptatriene [*(3a)* and *(3b)* resp.], which then lose their high strain by conrotatory "tying-off" of the cyclobutene ring with formation of *(4)*.

[*] Dr. M. Christl and G. Brüntrup
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

(2d) (3a) (3b) (4)

On completion of reaction the product contains, in addition to *(4)*, about 10% of cycloheptatriene, which is formed in a side reaction, since ring expansion of *(4)* proceeds only very slowly at 150°C. A hydrogen shift onto the carbon atom projecting into the ring of the intermediate *(3)* might take place as a branch reaction; this would constitute a direct route to the cycloheptatriene. Treatment of *(2a)* with silver tetrafluoroborate at room temperature yields pure cycloheptatriene.

Despite its strain energy of approximately 100 kcal/mol *(1c)* is thermally pretty stable. On heating in tetrachloroethylene at 150°C it rearranges with a reaction halflife of *ca.* 5 h into cycloheptatriene.

If a synchronous reaction were to take place here, as in the case of *(2d)*, one could expect formation of *(4)* in a process involving electrocyclic ring expansion of the *cis-trans*-norcaradiene intermediate to the *cis-trans-cis*-cycloheptatriene *(3a)*. Either *(3a)* is converted into cycloheptatriene *via* a rapid 1,5 H-shift or diradical processes are involved[5].

The $AgBF_4$-catalyzed rearrangement of *(1c)* in cycloheptatriene proceeds explosively at room temperature. At −70°C, however, the reaction rate is already so slow that there is no hope of being able to observe the possible intermediate norcaradiene directly at considerably lower temperatures before its valence isomerization.

Trialkoxycyclopropenylium Ions[**]

By *Eckehard V. Dehmlow*[*]

Although alkoxy groups are among the best stabilizers of carbenium ions, trialkoxycyclopropenylium ions have so far not been accessible. We were recently able to show that diethyl triangulate [diethoxycyclopropenone *(2)*] is formed during the pyrolysis of diethyl squarate *(1)* in anhydrous ether[1]. Reaction of *(2)* with trimethyloxonium or triethyloxonium fluoroborate in methylene chloride and subsequent treatment of the concentrated reaction product after a few hours with anhydrous ether affords the crystalline salts *(3a)* (m.p. 87°C[***]) and *(3b)* (m.p. 113°C[***]).

The structure of *(3a)* and *(3b)* follows from elemental analysis and spectral data: while the NMR spectrum of *(3b)* in $CDCl_3$ shows only a singlet and a triplet (2:3) at $\tau = 5.28$ and 8.48 respectively, that of *(3a)* contains a quartet at $\tau = 5.24$, a singlet at 5.55, and a triplet at 8.43 (4:3:6). Thus the symmetrical structure of the ions is verified. The shifts of the signals compared to those of *(2)* [$\tau = 5.71$ (q), 8.57 (t)] and the

increased difference of about 0.34 ppm of the chemical shifts of the methylene and methyl signals indicate that the positive charge is considerably delocalized to the environs of the oxygen atoms.

The mass spectrum of *(3a)* reveals three primary fragmentations from the molecular ion 157: loss of CH_2O, loss of CH_3CHO (base peak), and loss of C_2 to the stable trialkoxycarbenium ion.

Compounds *(3a)* and *(3b)*, like *(2)*, are hygroscopic. However, while *(2)* is opened relatively slowly to *(4a)* and *(4b)* on reaction with water or ethanol, treatment of *(3b)* with water leads to immediate conversion into *(4b)*. This finding is somewhat surprising, since triaminocyclopropenylium salts can be recrystallized from water[2]. Their hydrolysis with alkali affords diaminocyclopropenones as well as ring-opening products[3].

The recently described tris(alkylthio)cyclopropenylium salts[4, 5] react similarly with water yielding dialkylthiocyclopropenones[5].

All attempts to transform *(1)* into the tetraalkoxycyclobutenediylium ion by reaction with an excess of Meerwein reagent have so far failed. *(1)* was still IR spectroscopically detectable even after prolonged reaction time.

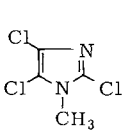
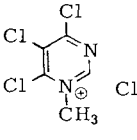
Highly Chlorinated Systems by Ring Closure Reactions

By *Gunther Beck* (lecturer), *Helmut Heitzer*, and *Hans Holtschmidt*[*]

Cyanomethylated and cyanoethylated secondary aliphatic amines *(1)* are converted by chlorination at 20—50 °C *via* isolable dichloro derivatives *(2)* into highly reactive non-isolable α-chloroalkylamines *(3)*, which spontaneously cyclize into five- and six-membered ring compounds *(4)* that are very sensitive to hydrolysis.

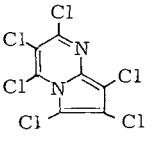


(1), X = H, X' = H
(2), X = Cl, X' = H
(3), X = Cl, X' = Cl



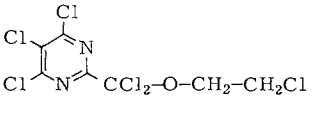
(4) (n = 0,1)

Further chlorination of compounds *(4)* at 50—130 °C affords stable imidazoles [*e.g. (5)* from dimethylaminoacetonitrile], 1-alkylpyrimidinium chlorides [*e.g. (6)* from 3-dimethylaminopropionitrile], or conjugated bicycles [*e.g. (7)* from 3-pyrrolidinopropionitrile].

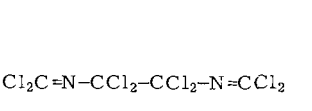


Still further chlorination between 100 and 200 °C leads to cleavage of *one* of the three N—C bonds marked A, B, and C in *(4)* (special case of "dealkylating high-temperature chlorination" of amines). Obviously the N—C bonds that are cleaved are those which lead to formation of the thermodynamically most stable end products.

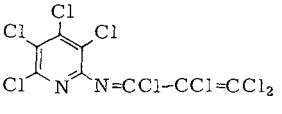
(5)



(6)



(7)



Cleavage at "A" usually occurs when $n = 1$, and affords pyrimidines, *e.g.* 4,5,6-trichloropyrimidine [from *(6)*] or *(8)* (from 3-morpholinopropionitrile). When $n = 0$, cleavage occurs at "B" and leads to perchlorodiazaalkadienes, *e.g. (9)* [from *(5)*]. The one case of cleavage at "C" observed so far occurred with bicyclic intermediate *(4)* from 3-piperidinopropionitrile: the 2-aminopyridine derivative *(10)* is the major product obtained.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

The chalones are the subject of a review by *J. C. Houck* and *H. Hennings*. These compounds are cell specific, but not species specific mitotic inhibitors, which have been detected in mammals. Chalones from epidermis, melanocytes, fibroblasts, and lymphocytes are discussed. These involve proteins or glycoproteins, whose molecular weights differ very widely from one another. The article concludes with a discussion of the experimental difficulties and sources of error in the measurement of mitosis. [Chalones. Specific Endogenous Mitotic Inhibitors. FEBS Lett. *32*, 1—8 (1973); 50 references]
[Rd 680 IE—R]

The role of soluble protein factors in the translational control of protein synthesis in eukaryotic cells is the subject of a review by *V. M. Pain* and *M. J. Clemens*. As the slowest step, chain initiation is assumed to be the most important starting point of the regulating initiation factors. Under certain conditions the elongation or the loading of the t-RNA can be the site of regulation. Also included among the soluble factors are ribonucleases and their inhibitors which may likewise have a controlling function. [The Role of Soluble Protein Factors in the Translational Control of Protein Synthesis in Eukaryotic Cells. FEBS Lett. *32*, 205—212; 160 references]
[Rd 681 IE—R]

The reactivity and stability of arenediazonium ions constitute the subject matter of a report by *H. Zollinger*. After classifying the reactions of these ions the author goes on to consider nucleophilic reactions at N_β and at C-1 and the homolytic cleavage of the C-1—N_2 bond. It remains to be established

whether there is a common intermediate in homolytic and heterolytic decomposition of the diazonium ions. [Reactivity and Stability of Arenediazonium Ions. Accounts Chem. Res. *6*, 335—341 (1973); 65 references]

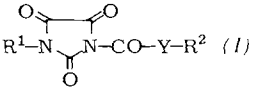
[Rd 688 IE—L]

Immunoglobulin receptors have been studied by *C. W. Pierce, R. Asofsky*, and *S. M. Solliday*. These authors have investigated the relation between the immunoglobulin class of the antigen receptors, which are located on the cell membrane of the precursors of antibody producers and that of the antibodies that are finally secreted by successors of these cells after stimulation by an antigen. The original precursor cells obviously contain receptors of the IgM class, independent of the type of antibody secreted later. A solitary immunization by an antigen leads to a temporary shift, longer immunization, on the other hand, to a permanent shift into the IgG class. [Immunoglobulin Receptors on B Lymphocytes: Shifts in Immunoglobulin Class During Immune Responses. Fed. Proc. *32*, 41—43 (1973); 21 references]

[Rd 682 IE—R]

The biological action of vitamin E and selenium is discussed by *A. T. Diplock* and *J. A. Lucy* on the basis of experiments on rat liver. Vitamin E evidently hinders the oxidation of selenide-containing non-heme iron proteins of the mitochondria and endoplasmic reticulum, which are responsible for detoxification processes. With the aid of molecular models it can be shown that vitamin E may form specific complexes within the cell membrane with highly unsaturated lipids that stem from the nutrient. Membranes free of vitamin E are very sensitive to phospholipases *in vivo* and towards dialuric acid and hydrogen peroxide *in vitro*; this could be due to their high permeability. [The Biochemical Modes of Action of Vitamin E and Selenium: a Hypothesis. FEBS Lett. *29*, 205—210 (1973); 37 references]

[Rd 677 IE—R]



The carbohydrate components of surface glycoproteins of virus transformed cells are compared with those of normal cells by *L. Warren, J. P. Fuhrer*, and *C. A. Buck*. During growth transformed cells contain, in contrast to control cells, a sialic acid rich material of low elution volume in gel filtration whose formation depends on the presence of a sialyl transferase. In the case of temperature sensitive virus mutants the sialic acid rich material and the transferase were detected in large amounts only at lower temperatures at which the transformation also takes place. [Surface Glycoproteins of Cells before and after Transformation by Oncogenic Viruses. Fed. Proc. *32*, 80—85 (1973); 32 references]

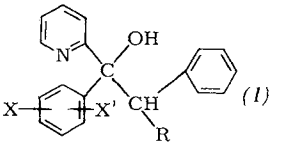
Polyimides of 1,4-benzoquinonetetracarboxylic acid with structural units *(1)* (R = aliphatic or aromatic residue) are obtained by reaction of 1,4-benzoquinonetetracarboxylic anhydride with diamines in solution at temperatures around 200 °C. These polyimides are stable up to 480 °C. They are partly soluble in organic solvents and readily soluble in a dithionite vat. They can be readily processed from the vat to form foils, films, fibers, and coatings, which are then converted back into the insoluble form by reoxidation with air and

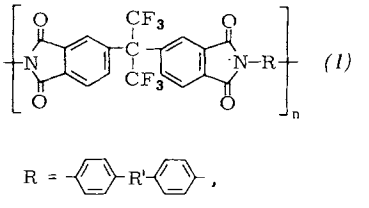


(1)

other oxidizing agents. From hydroquinonetetracarboxylic anhydride one obtains soluble polyimides, which also become insoluble on reoxidation. [DOS 2055211; Battelle-Institut e. V., Frankfurt a. M.]

[PR 132 IE—A]

The aggregation of blood platelets is inhibited by substituted quinazolines *(1)* or their salts. They differ in their biological action from anticoagulants such as heparin, and are suitable



(1)

R^1 = H, alkyl (C_1—C_5), NH_2, alkylamino (C_1—C_4), alkoxy (C_1—C_4), CN, (halogen-substituted) phenyl, benzyl, phenethyl; R^2 = H, alkyl (C_1—C_5); R^3, R^4 = alkyl (C_1—C_5); $R^3 + R^4 = -CH_2-$

for the treatment of thromboembolic diseases. [DOS 2152521; Bristol-Myers Co., New York]

[PR 118 IE—N]

A laminar composite structure consisting of a reinforcing material and a polyimide *(1)* that can be blended in the melt is claimed. Synthetic organic fibers and materials such as asbestos, mica, graphite, and polytetrafluoroethylene are suit-

(1)

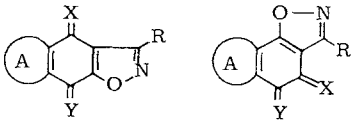
R' = —O—, —S—, —O—R''—O—; R'' = divalent aromatic residue

able for use as reinforcing materials. The type of structure described is suitable for high-temperature applications, *e. g.* for building panels. [DOS 2223819; E. I. du Pont de Nemours and Co., Wilmington]

[PR 119 IE—A]

Elastomeric olefin copolymers of ethylene and/or α-olefins and possibly dienes are obtained in high yields in liquid media at high monomer concentrations (at least 50 wt.%) and in the presence of a highly active catalyst system. The catalyst system is obtained by mixing a hydride or an organometallic compound of metals of groups I, II, and III of the periodic system [$Al(C_2H_5)_3$, $Al(iC_4H_9)_3$, $Al(C_2H_5)_2H$, $Al(iC_4H_9)_2H$ and $Al(C_2H_5)_2Cl$ are particularly suitable] with the product of the reaction of titanium or vanadium compounds with anhydrous Mg, Mn, In, or Ca halides. With the catalyst system described, it is possible to adjust the molecular weight of the copolymers or terpolymers to low and very low values with the aid of hydrogen or other chain-transfer agents without



appreciable deterioration of the activity of the catalyst. [DOS 2150437; Montecatini Edison S.p.A., Milan]

[PR 134 IE—A]

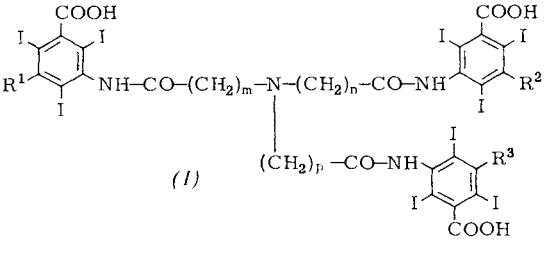
Diethyl ketone can be prepared by decarboxylative dehydration of propionic acid in the presence of 0.25—1 mole of steam per mole of propionic acid on a catalyst containing thorium oxide at 350—400 °C in yields of 98—99.4%. The life of the catalyst is almost unlimited; practically no soot is deposited on the catalyst even when reactors made from high-grade steel containing nickel are used. [DOS 2111722; Badische Anilin- & Soda-Fabrik AG, Ludwigshafen]

[PR 149 IE—J]

Quinone derivatives *(1)* **and** *(2)* regulate the growth of plants and stimulate parthenocarpy. They also have a herbicidal and algicidal action. When used in concentrations of about 10 to 80 g/are they are found to be inactive against gramineae,

(1) *(2)*

R = halogen, lower alkyl, phenyl, pyridyl
A = (substituted) condensed benzene or pyridine ring
X, Y = —O—
X + Y = —O—CR=N—O—



so that they can be used as selective herbicides or algicides. Their most important application, however, is probably in the production of seedless fruits, *e.g.* tomatoes, cucumbers, melons, *etc.* [DOS 2215722; Shionogi & Co. Ltd., Osaka]

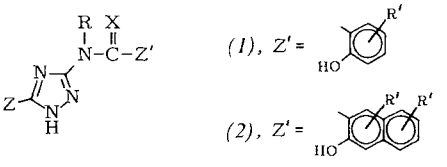
[PR 143 IE—N]

The catalytic fluorination of vinyl chloride with hydrogen fluoride in the gas phase is carried out in the presence of a catalyst consisting of an (oxide) halide of trivalent, tetravalent, or pentavalent vanadium on active charcoal between 100 and 400 °C. The active charcoal should contain 1—40 wt.% of vanadium, and the catalyst should be treated with hydrogen fluoride before the reaction. The following fluorinated compounds are obtained: CHF_2—CH_3 (85—91%), $CHClF$—CH_3 (3—11%), and CHF=CH_2 (1—11%). [DOS 2215019; Solvay & Cie, Brussels]

[PR 153 IE—J]

Iodinated *N*-acyl derivatives of aromatic amino acids *(1)*, because of their low toxicity, high water-solubility, and low tonus (osmotic activity), are suitable for use as X-ray contrast media, particularly for vasographic work. They can be pre-

(1)

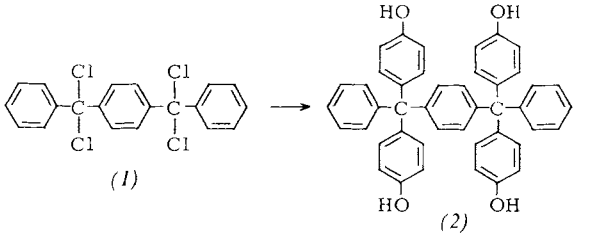


pared by reaction of 2 moles of a 3-(ω-haloacylamino)-2,4,6-triiodobenzoic acid with 1 mole of a 3-(ω-aminoacylamino)-2,4,6-triiodobenzoic acid. [DOS 2132614; Mallinckrodt Chemical Works, St. Louis]

[PR 154 IE—K]

Self-extinguishing fiber-reinforced polyolefin compositions consist of crystalline polypropylene or copolymers of propylene with up to 25% of other olefins, 10 to 50% of glass fibers, 4 to 45% of at least one commonly used flame-inhibiting organic halogen compound, 2 to 23% of antimony oxide, and 0.5 to 3% of a polypropylene or copolymer thereof modified with maleic anhydride. Examples of organic halogen compounds are chlorinated paraffins and chlorinated cyclic compounds, and preferably the 2:1 addition product of hexachlorocyclopentadiene with cyclooctadiene. In addition to their self-extinguishing properties, the polymers modified in this way exhibit an improved tensile strength. [DOS 2059022; Farbwerke Hoechst AG, Frankfurt/Main-Höchst]

[PR 164 IE—A]



1,4-Bis(4,4'-dihydroxytriphenylmethyl)benzene *(2)* is prepared by reaction of 1,4-bis(α,α-dichlorobenzyl)benzene *(1)* with phenol; *(1)* can be obtained by chlorination of 1,4-dibenzylbenzene or of 1,4-dibenzoylbenzene by known methods. *(2)* can be used for the production of branched polycarbonates whose melts exhibit increased creep strength and which possess

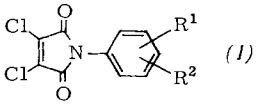
improved non-Newtonian flow behavior and increased thermal stability. The new tetraphenol can also be used for the production of other plastics, *e.g.* of epoxy resins or phenol-formaldehyde resins. [DOS 2113347; Bayer AG, Leverkusen]

[PR 170 IE—U]

***N*-Triazolylsalicylamides** *(1)* **and *N*-triazolylbenzosalicylamides** *(2)* [R = H or alkyl (C_{1-4}); Z = H, alkyl (C_{1-18}), aryl, or alkylaryl (C_{0-18}), alkylenealkoxy or alkylenearyloxy (C_{2-18}), heterocycles (C_{4-5}) with one or two N atoms; X = O or S; R' = H, OH, SH, S-alkyl, S-alkenyl] are added to olefin

(1) *(2)*

polymerization products, *e.g.* polypropylene, to improve their resistance to oxidation. In the presence of the triazolylamides *(1)* and *(2)*, the usual catalytic effect of heavy metals on the degree of decomposition of the polyolefin is not observed. [DOS 2164234; S. A. Argus Chemical N. V., Brussels]



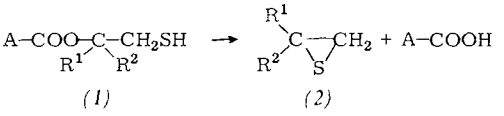
[PR 171 IE—E]

Polyoxazolidones with terminal NCO groups are obtained by reaction of organic polyisocyanates with polyepoxides at 100—150 °C in the presence of a Friedel-Crafts catalyst, *e.g.*

methylenedi(phenyl isocyanate), bisphenol A-epichlorohydrin adduct, $AlCl_3$, $FeCl_3$, or $ZnCl_2$. The epoxy/isocyanate equivalent ratio is 0.7—0.02. The reaction product is then trimerized to the isocyanurate preferably at 20 °C within 10 minutes with a catalyst such as tertiary amine, tertiary phosphane, or Friedel-Crafts catalysts. The products are suitable for the production of particularly flame-resistant foams, coatings, and molded articles. [DOS 2205731; Mitsubishi Chemical Ind. Ltd., Tokyo]

[PR 161 IE—A]

Dichloromaleimides *(1)* can be used for the control of plant and animal pests. They have good activity against bacteria



(1)

and fungi, and cause no side effects in warm-blooded animals. [DOS 2215787; Ciba Geigy AG, Basel]

[PR 142 IE—N]

Organic episulfides *(2)* can be prepared by decomposition of mercaptoalkyl esters *(1)* in the gas phase at 180—300 °C in the presence of Al_2O_3, which may contain 0.01—3 wt.% of Na_2O or up to 0.5 wt.% of Fe_2O_3 or up to 0.5 wt.%

(1) *(2)*

A = preferably CH_3
R^1, R^2 = H, alkyl, aryl, cycloalkyl

of SiO_2. The specific area of the catalyst is preferably between 10 and 250 m^2/g. [DOS 2222239; Société Nationale des Petroles d'Aquitaine, Courbevoie]

[PR 150 IE—J]

Polyamide imides are prepared by reaction of a) the reaction product of an acid containing three carboxyl groups with a) polyamine, b) an aliphatic unsaturated anhydride, and c) a polyisocyanate. Trimellitic anhydride is mentioned as a particularly suitable tricarboxylic acid. Suitable anhydrides include maleic, itaconic, and tetrahydrophthalic anhydrides as well as *endo-cis*-5-norbornene-2,3-dicarboxylic anhydride. Phenylenediamine, 4,4'-diaminodiphenylmethane, and 4,4'-diaminodiphenyl ether are used as polyamines. Examples of suitable polyisocyanates are 2,4-toluylene and diphenylmethane diisocyanates. The polymers are made into flexible films, which can withstand high temperatures *e.g.* in the field or electrical insulation. [DOS 2155678; General Electric Co., Schenectady]

[PR 133 IE—A]

BOOK REVIEWS

Methodicum Chimicum (Chemical Methods). Edited by *F. Korte*. Vol. 1: Analysis. Part 1: Purification, Wet Methods, Determination of Structures; Part 2: Trace Analysis, Biological Methods, Classes of Substance, Automation. Georg Thieme Verlag, Stuttgart, and Academic Press, New York—London 1973. 1st ed., x, 1263 pp., 413 figs., 14 schemes, 265 tables, bound DM 421.60 (individual volume price DM 496.—).

The aim of the Methodicum Chimicum, according to the Foreword, is to present "a short critical account of chemical methodology for science and practice". Accordingly, the main basis of classification in the present first volume, which deals with analytical methods in organic chemistry, is the *method*. The term "analysis" is given an extremely wide interpretation here. Thus in addition to separation methods (Chapter 2), methods for the chemical determination of classes of compound and functional groups (Chapter 3), spectroscopic and photometric methods (Chapter 5), fragmentation methods (Chapter 6), diffraction methods (Chapter 7), equilibrium and kinetic methods (Chapter 8), and special physical methods (Chapter 9), the book includes biochemical and biological methods (Chapter 13). The trace analysis of elements in organic materials (Chapter 10) is treated separately as a special problem, and the importance of chemical reactions for analytical purposes is also surveyed (derivative formation before the analysis, Chapter 4).

However, the division of the subject matter according to method is not rigorously followed. In two chapters (11 and 12), as a second aspect, the *application* of analytical methods to individual classes of substances is described for two important groups: for compounds of industrial interest (pesticides, drugs, food additives and impurities, organic compounds in water and effluents, petroleum products, fats, oils, and waxes, industrial gases) and for carbohydrates, proteins, and nucleic acids. Moreover, individual sections in the chapters on methods are predominantly problem-oriented: determination of configurations (3.8), determination of tautomer equilibria (8.3), detection and identification of electron donor-acceptor and δ complexes (9.6).

The scope of the volume is also very wide with regard to the information provided by the methods. In addition to the methods for the solution of the "normal" analytical problems (molecular weight determination, elementary analysis, detection, identification, quantitative determination, determination of the constitution and stereochemistry of molecules), it also deals with methods that lead predominantly to data on properties and charge distribution in molecules. A selection of methods for the investigation of macromolecules are also discussed. This diversity of the aspects considered and the wide scope make the list of contents seem rather motley. These factors also explain the large number of experts (103 are named) responsible for the 83 sections. In principle this presents a number of dangers. Repetitions have been avoided as far as possible, and are irritating only in the case of photoelectron spectroscopy (clear description of principle, measuring methods, theory, and applications in Section 5.10, described again as a recent development in 14.2.3). Disadvantages due to the separation of related groups of problems as a result of the chapter divisions chosen are also avoided in most cases by the use of cross references.

Cross references would have been useful between Section 5.1.9 (Electronic Spectroscopy), which deals with analytical applica-

tions, and Section 9.5, which deals, under the title "Nature, Multiplicity, and Properties of Excited States in Photochemical Reactions of Organic Molecules", mainly with the theory of the excitation and deactivation of electrons; it would also have been preferable to bring together the parts on elementary analysis (Sections 3.1, 3.2, and 14.4).

In general, attention should be drawn to the clarity of the description, the often very pointed indication of the possibilities and limitations of the methods, and the extensive list of references to monographs and relevant publications. These make the book very valuable as a source of information. However, it is also natural, simply because of the diversity of the methods discussed and of the aspects involved, that the extent and nature of the descriptions will vary from section to section, so that the user cannot expect to obtain the same kind of information from each contribution. A number of articles, particularly those on separation methods, methods of chemical analysis, trace analyses, and the analysis of special classes of substances, provide instructions for practical work, either directly or indirectly *via* literature references; in this respect, a comprehensiveness such as one might expect of a lexicon is found *e.g.* for the analysis of pesticides (11.1). Extensive tables are also given in many of the descriptions of physical methods to demonstrate their usefulness as aids, and special mention should be made of the description of IR spectroscopy (5.2), which is quite adequate for routine analyses. As far as other methods are concerned, the information for the user consists of a more or less comprehensive description of their principles, the principles of the equipment and/or measuring technique, and (usually with the aid of examples) the possible applications.

Though such a compilation of methods will undoubtedly be used mainly as a reference work for special problems, it is nevertheless gratifying that an attempt is made in the first volume of the "Methodicum Chimicum" to include even subsidiary aspects of analysis. This is outstandingly achieved in the chapters "Principles for the Assessment of Analytical Methods" (1) and "Aspects of the Choice of Suitable Separation Methods" (2.12); it is a pity that the similarly intended sections on "Use of Combined Instrumental Methods" (14.1) and "Trends in the Development of Instrumental Analysis" (14.2) are too short in comparison with these.

The richness of content of the volume and the variety of aspects discussed will guarantee it the wide range of users that it is intended to serve; though it is expensive, it will certainly be valuable in the handling of various problems.

Günter Kresze [NB 186 IE]

Mechanism—An Introduction to the Study of Organic Reactions. Oxford Chemistry Series. By *R. A. Jackson*. Clarendon Press, Oxford 1972, 1st ed., xiii, 136 pp., numerous figures, bound £ 1.10.

How can one determine, and in the ideal case prove, the mechanism of a reaction? The present book attempts to deal, at the second-year undergraduate level, with the criteria that are necessary for a study of reaction mechanisms: analysis of the reaction products, kinetic studies, reactive intermediates, stereochemical studies, "other arguments" (Hammett equation, solvent effects, Hammond postulate). Each chapter ends with a series of questions, and hints on the solution of the problems are given, together with the answers, at the end of the book. A short bibliography and the brief subject index complete the book. The problems are presented very clearly and skillfully with the aid of interesting examples. Anyone who has mastered the subject will enjoy reading the book. The student who is new to the material will sometimes have to consult a textbook as he works through the book, since some prior knowledge is presumed even with regard to the subject matter. The "Conclusions" at the end of each chapter provide the student with an additional opportunity to check that he has understood the essentials.

On the negative side, whereas there are only a few printing errors, the examples of cycloadditions in the chapter on stereochemistry are not very good, and the Woodward-Hoffmann rules should not be excluded at this level. In a new edition of the book, the literature references should always appear with the examples themselves in the individual chapters. Some of the reviews cited are too advanced for the readers at whom the book is aimed; lighter alternatives are available in these cases.

On the whole this book can be recommended to interested students preparing for final examinations. The price is also within the reach of students—a good example to some German publishers producing literature for students.

Jürgen Sauer [NB 190 IE]

Laser-Grundlagen und Anwendungen (Laser Principles and Applications). By *H. Weber* and *G. Herziger*. Physik-Verlag, Weinheim 1972. 1st ed., xi, 252 pp., 185 figures, 26 tables, bound DM 78.—.

The growing importance of laser applications in research and industrial production justifies a general account of the properties of laser light sources for readers with no prior knowledge of quantum mechanics. The book surprises the reader by its unconventional presentation and illustration, which enable one to take in even complicated laser effects at a glance. This presentation is no doubt excellently suited to the rapid instruction of the type of reader for whom the book is primarily intended, *i.e.* technologists and engineers. However, the specialist is more likely to be irritated by the many inconsistencies (which can surely be weeded out from the next edition) than to find pleasure in the unusual approach to quantum phenomena with the aid of analogy models.

Starting with a relatively broadly conceived introductory chapter on the spectral properties of classical radiation sources and optical resonators, the book deals with the following topics: laser oscillators, short light pulses, nonlinear optics, laser applications, and special optical elements of laser physics. Numerous comparisons from mechanics, hydromechanics, and electrotechnology are given as introductions. A useful addition to the relationships derived in this way would have been a simple mathematical description to enable the practical worker to estimate the feasibility of a laser project. Thus the section on dye lasers, deals at some length with triplet effects, but ignores the obvious derivation of the required pump rise times or a calculation of the inversion at the laser threshold, taking into account the connection mentioned in the text between fluorescence and reabsorption.

The book is very suitable for use as an easily understandable introduction to the physics of the laser. It can be recommended in particular to readers who wish to gain a quick general picture before tackling the specialist literature on their proposed application.

Gerd Marowsky [NB 181 IE]

Surface and Defect Properties of Solids, Vol. 1. Specialist Periodical Reports. The Chemical Society, London 1972. 1st ed., viii, 264 pp., numerous figures, bound £ 6.00.

In the nine chapters of this volume of "Specialist Periodical Reports", eleven authors present a survey of important results from the chemistry of solids published between January 1970

and April 1971. The earlier work connected with these results is naturally also discussed.

The first four chapters deal with the influence of one-dimensional and two-dimensional lattice defects on the structure and behaviour of solids. Ordered nonstoichiometric phases are described in "Shear Structures and Nonstoicheiometry". The shear structures can be observed directly by a high-resolution electron microscope phase contrast method, which is described in the next chapter. This method is particularly suitable for layer structures; in this way one can obtain a picture of the individual carbon layers in graphite and paracrystalline carbons, but investigations on polymers and macromolecules, *e.g.* DNA, are also reported. It is shown in two further chapters that dislocations are decisive for the occurrence of solid-state reactions even in organic chemistry, *e.g.* in polymerizations in molecular crystals. Five chapters deal with investigations on the surfaces of solids and their reactivity. As a result of recent progress on the equipment side, the methods of electronic spectroscopy are particularly suitable for the detection of foreign atoms in surfaces and their bonding. Photoemission, Auger spectroscopy, ESCA, and a few other methods are described in two chapters. Progress has also been made in the IR spectroscopy of molecules adsorbed on metals. Two further chapters deal with isotope exchange between gas molecules adsorbed on metals and some aspects of the selective action of metal catalysts.

This is the start of an attempt to forge a path through the jungle of wildly proliferating literature by means of handy reviews published at regular intervals, which is to be welcomed if it is kept up. The book will be of use to all workers and institutes concerned with surface and solid-state chemistry, though some of the authors almost exclusively cite English-language literature.

Hanns-Peter Boehm [NB 189 IE]

Air Pollution. Part A: Analysis. By *J. O. Ledbetter*. Marcel Dekker Inc., New York 1972. 1st ed., xii, 424 pp., numerous figures and tables, bound $ 11.75.

The concept of air pollution has not only been a focus of public interest for some time, but is now also attracting the interest of scientists, particularly of engineers, chemists, and analysts. The present work is capable of providing a conceptually and technically sound basis for the scientific treatment of air analysis problems. It should be emphasized that the author has not yielded to the temptation simply to give a collection of procedures under the sub-title "Analysis". On the contrary, he has managed to present all the facts relevant to the assessment of the analytical problem and to the evaluation of the analytical results in a succinct, precise, and impressive manner. In the first chapter, which deals with the background of the problem, the reader is acquainted with the essential basic facts, definitions, and units of measurement. The author then considers the sources of air pollution, and takes this opportunity to survey the principal components of air pollution.

Another chapter is devoted to the physical and chemical processes that take place in the atmosphere and that control the distribution, the dilution, the deposition, and the reaction of polluting substances in the atmosphere. This is followed by a very detailed description of the mathematical and statistical methods used in the design of measuring plans and in the interpretation of the sets of results obtained.

After a brief excursion into the physical chemistry of gases and the physics and chemistry of aerosols, four chapters are devoted to the actual analytical technique. The first deals with the design of measuring plans, presents a survey of the technical equipment necessary for sampling, and finally raises a number of practical points that must be noted in connection with air sampling. The chapter on the actual measuring technique begins with a description of the main characteristics of analytical methods, *e.g.* detection limits, reproducibility, and cross-sensitivity, then touches briefly on the procedures for the presentation of experimental results, and finally gives a very succinct review of the physical and chemical principles of the measuring procedures, including spectrochemical methods, chromatographic procedures, classical wet methods of analysis, and the methods of electroanalysis. The principles of the evaluation of smells, noises, and radioactive radiation are also discussed.

In two further chapters the author first goes into details of the measurement of aerosols, particularly with regard to the determination of particle sizes and their distribution, and then deals with a series of specific procedures.

The work ends with a chapter on the effects resulting from air pollution. The book is very readable and is provided with instructive diagrams; each chapter ends with a number of examples for practice and with references, which are unfortunately almost entirely confined to the Anglo-Saxon literature. German readers may be slightly irritated by the fact that the selection of examples, procedures, and equipment described in detail is essentially determined by the conditions prevailing in the United States. Nevertheless, it is to be hoped that this handy book will find a wide circulation among specialists and students.

Heinz Hartkamp [NB 187 IE]

Glycoproteins. Their Composition, Structure and Function. BBA Library, Vol. 5, Part A and B. Edited by *A. Gottschalk*. Elsevier Publishing Company, Amsterdam—London—New York 1972. 2nd ed., xxxviii, 1377 pp., 153 figs., 200 tables, bound, together $ 125.—.

Glycoproteins are found in bacterial cell walls and in plant hemagglutinins, and play a very specific role as components of animal tissue, *e.g.* in the proteins of serum and of eggs, in a number of enzymes, in collagen and fibrinogen, in thyroglobulin and the gonadotropic hormones, in the mucins of the mucous membranes, the joints, the blood-group substances, *etc.* The agglutination and virus-binding reactions are due to the glycoproteins of the cell membranes. The relatively short carbohydrate chains of these conjugated proteins contain eight to ten saccharide residues, and a special characteristic is that these include *N*-acetylamino sugars and sialic acid. In all these cases the characteristic properties can be destroyed by neuraminidase. The protein component is joined to the carbohydrate component *via* the amide group of asparagine or *via* the hydroxyl group of the hydroxy amino acids.

The then known physical, chemical, and analytical properties of the glycoproteins had been described in the first edition of this work[1]. The new edition, appearing six years later, indicates already by its size how much has been discovered in the meantime. A comparison of the contents shows that the emphasis is also beginning to shift from "static" descriptions to the function and biogenesis of the glycoproteins.

The first part presents a detailed and critical discussion of the methods for the determination of purity, molecular parameters, and composition of the glycoproteins, *i.e.* amino acid and sequence analyses, determination of amide nitrogen, characterization and identification of the sugars by gas chromatography, structural analysis of the carbohydrate component by chemical and enzymatic methods, and the methods for the detection of the sugar-protein linkage. A particularly difficult problem is presented by the increasingly recognized

heterogeneity of the carbohydrate chains in these substances, which may be regarded as stages or parallel products of their biosynthesis. The analytical part is followed by a description of the occurrence of glycoproteins in the plant and animal kingdoms and of individual groups of glycoproteins as well as their isolation, structure, and biological properties. The astonishing diversity of structure and function that was referred to earlier becomes evident here; there are metal binders and anti-freezes, enzyme inhibitors and cell-differentiating agents, immunoglobulins and nerve membrane components.

The second part initially continues this description with the mucins, blood-group substances, collagen, and sulfated glycoproteins. This is followed by the carbohydrate-containing hormones, enzymes, and other functional proteins and the virus/cell interactions. An important part is devoted to the biosynthesis, metabolism, and turnover of amino sugars and glycoproteins. This part includes not only the individual synthesis and breakdown steps but also the description of the specific enzymes, *e.g.* neuraminidase, and the reactions catalyzed by them.

The individual articles are written by a number of well-known experts in their field, sometimes with the co-authorship of *A. Gottschalk*, who in any case has carefully edited and coordinated all the contributions to give a homogeneous appearance to the entire monumental work. By means of detailed references extending up to very recent literature, and by the inclusion of many details, numerous illustrative tables, and clear formula schemes and diagrams, all the material has been worked out and prepared in such a way that this second edition, even more than the first, has become a "handbook", not merely on grounds of size, but, in the best sense of the word, because of its content. From this work one can learn the research in this field has advanced and one can also find out about its historical development, in which the editor played such a great part. The production of the volumes corresponds to their price, which will unfortunately be within the reach only of libraries and very well-endowed institutes, though the work should be accessible to as many as possible of those who are interested. They will find it to offer comprehensive information, sound instruction, and a wealth of noteworthy critical suggestions.

L. Jaenicke [NB 188 IE]

Analysis of Herbicides[**]

By Hans-Peter Thier[*]

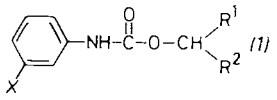
Herbicides, like other pesticides, leave undesirable residues on the treated plants. To analyze them, the plant material is extracted and the herbicidal residues are separated from the bulk of the co-extractives of natural origin, about which too little is known. Quantitative determinations at the ppm level are best performed by gas chromatography with highly sensitive, specific detectors. In food control, where the history of the sample is unknown, the herbicide residues are identified and determined quantitatively together with the residues of other pesticides.

1. Introduction

In modern plant protection, numerous insecticides, acaricides, and fungicides are used to guard the growing plants and harvests against damage by insects, mites, or fungus diseases and thus to prevent threatened economic losses. A logical addition to this group of substances is the herbicides[1–4]. These are used to allow the use of more rational cultivation methods, in which harvest losses can be avoided and labor saved.

Herbicides in the broadest sense are any compounds that can influence the growth of higher plants. They intervene in various steps of the respiration, photosynthesis, or nucleic acid metabolism, and so inhibit the normal development of the plants[5–8].

The most drastic are the total herbicides, which are used to eliminate vegetation from paths, railway embankments, and ditches. They are also used in agriculture, *e.g.* to kill the tops of potato plants before harvesting by machine.



[*] Priv.-Doz. Dr. H. P. Thier
Institut für Angewandte Chemie der Universität Erlangen-Nürnberg

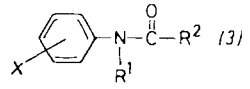
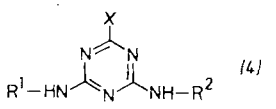
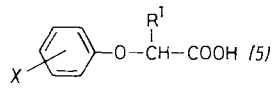
[**] Based on a plenary Lecture to the "Trace Analysis" Conference of the "Analytical Chemistry" Group of the German Chemical Society in Erlangen, April 2 to 5, 1973.



Most of the active substances are selective herbicides, which are used to combat weeds. Depending on the manner in which they act, they are used before sowing, before or after the cultivated plants emerge, or only during the later stages of their development. In addition to their use in agriculture, *e.g.* for cereal crops or sugar beet, they are being increasingly used in vegetable and fruit growing and in vine cultivation. In these areas they are displacing the traditional mechanical weeding, which is no longer sufficiently economical, and in many cases it is only through the use of such agents that machine harvesting is possible in large monocultures, *e.g.* for spinach.



Finally, growth regulators are used to influence the cultivated plants themselves. Examples are the shortening and thickening of the stalks of cereals, the prevention of undesirable lateral branches in tobacco plants, and the thinning of fruit in fruit growing.



In recent years the herbicides have far surpassed the other pesticides in their economic importance. At the same time, new compounds are continuously being developed and officially adopted. Thus in 1969 the list of compounds permitted for use in pest control[9] in the German Federal Republic contained only 44 herbicides, whereas the number had increased to 65 in 1972. Table 1 shows a selection of these compounds, which are generally marketed in several formulations and under many trade names.

(1)

(2)

(5)

and the influence of its microflora[15] must also be taken into account. Since the active compound is known in analyses of this nature, the analyst's job amounts only to a quantitative determination; the detection sensitivity in plant material or soil samples should be as high as possible[16] ("Individual Methods", see Section 3).

In the crops that are consumed as food, the herbicide residues are generally far below the maximum permissible tolerance levels calculated on the basis of chronic toxicity tests on animals[1]. However, higher concentrations can occur in some cases, since excessive application, application at the wrong time, or unfavorable weather influences cannot be ruled out in agricultural practice.

2. Objectives of Residue Analysis

If plant protection agents are not broken down quickly enough after use, the cultivated plants contain measurable residues after harvesting, and these may be absorbed into the human body on consumption of fruit, vegetables, or cereal products. The herbicides do not have such worrying properties as some insecticides, *e.g.* the high acute toxicity of numerous organophosphates or the pronounced persistence of some chlorinated hydrocarbons; nevertheless, any exposure of man to additional hazards is undesirable.

There are thus two main objectives in the analysis of herbicides, which differ in the questions raised and the analytical methods used.

The first objective is to learn about the behavior and the fate of a herbicide in nature. This will involve investigations on how quickly and by what route the compound is absorbed by the plant[10], in which parts of the plant it accumulates, at what rate and by what chemical reactions it is decomposed or metabolized[11, 12], and what external factors, such as climate or other ingredients of the formulation, influence this breakdown. The reactions that take place in the soil[13, 14]

The second objective of herbicide analysis is therefore the continuous control of agricultural commodities placed on the market. The history of the product in these cases is usually unknown, and the analyst consequently requires analytical methods that allow both the identification and the quantitative determination of any residues present. The scope of such a "screening analysis" and the detection sensitivity required will be decided by the tolerances established for food products under the country's regulations. In the German Federal Republic, for example, the residues of 50 herbicides in plant foodstuffs must not exceed levels between 0.01 and 1.0 ppm[17] (see Section 4).

3. Individual Methods

Every residue analysis comprises three steps: the extraction of the sample material, the clean-up of the crude extract to concentrate the herbicide and separate it from co-extracted matter and the final determination of the residue in the purified extract.

The main difference from other trace analyses of the same type is that in the case of plant material or soil samples, too little is known about the numerous natural constituents of the substrates. Consequently, these substances can only be separated by empirically developed methods, and difficulties may be expected as soon as a different sample material is to be analyzed. Special difficulties are usually encountered in the isolation of herbicides in the presence of low molecular weight, lipophilic, and volatile plant constituents such as essential oils and flavor substances that occur *e.g.* in onions, cabbage, or carrots.

3.1. Extraction and Clean-Up

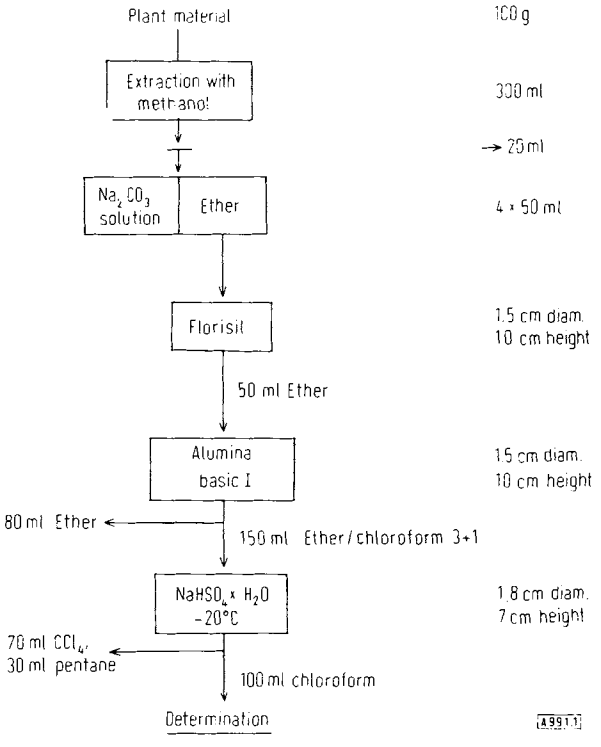
The analysis is generally carried out on 50 to 100 g of plant material or soil sample. Most of the lipophilic herbicides are extracted from this material by homogenization with a low-boiling water-miscible solvent such as acetone, methanol, or acetonitrile. The crude extract, which also contains most of the water from the sample, is concentrated under vacuum and is subsequently partitioned between the remaining aqueous solution and petroleum ether, ether, methylene chloride, or chloroform.

In addition to the herbicide to be analyzed, other lipophilic material such as fats and waxes, flavor substances, and coloring agents also pass into the organic phase. Herbicides with free carboxy, phenolic hydroxy, or amino groups [*e.g. (5)*] can be very easily separated from this mixture by extraction with alkaline or acidic solutions, since they pass into the aqueous phase as salts. Carbanilic esters *(1)* or *N*-phenylureas *(2)* are often hydrolyzed to the anilines, which can be isolated by steam distillation.

In most cases, however, the extract must be further purified by adsorption chromatography. The preferred technique is separation on columns packed with alumina or the magnesium silicate Florisil®, from which the herbicide in question can be eluted with a solvent mixture of suitable polarity. Columns packed with silica gel, activated carbon, or magnesium oxide are less commonly used. This is also true of thin layer and thick layer chromatography, which are used only when a satisfactory separation cannot be achieved in any other way. The extract may occasionally be further purified by other methods, as in the analysis[18] of the three chlorotriazine derivatives *(4a)*, *(4b)*, and *(4c)* by chromatography on a column packed with $NaHSO_4 \cdot H_2O$ at -20 °C. A clean-up of this type is illustrated schematically in Figure 1.

A simpler clean-up can be used in the determination of the very water-soluble herbicides *(7a)*, *(7b)*, and *(8)*. Because of their strong absorption on organic material, these compounds can sometimes be extracted only in the presence of strong acids. They are separated from the aqueous extract on a strongly acidic ion exchanger[19], from which they are subsequently eluted with salt solutions.

In every clean-up step, part of the pesticide is inevitably lost, either through losses on evaporation of solvents or through irreversible adsorption on the surface of glassware or of adsorbents. Moreover, interfering substances may be introduced into the analysis by packaging material[20], solvents[21–23], reagents[24], filter paper[25], *etc.* In any clean-up procedure, therefore, it is necessary to determine first, in one's own laboratory, the percentage of recovery by fortifying untreated sample material with the pesticide at the level expected in the analysis. A recovery of 70% on addition of 0.1 ppm of a herbicide may be regarded as satisfactory, as long as the results are reproducible.



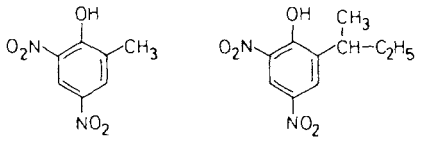


Fig. 1. Clean-up scheme for the analysis of the chlorotriazines *(4a)*, *(4b)*, and *(4c)* simplified after [18].

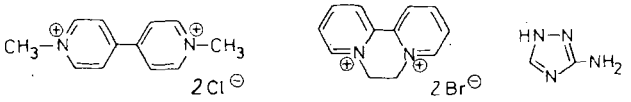
3.2. Determination

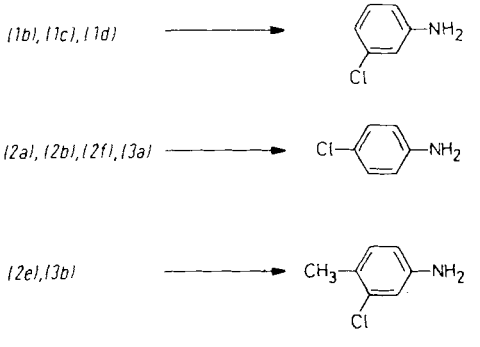


Even when the extracts have been thoroughly purified, they usually still contain a few milligrams of unwanted substances of unknown composition as well as microgram quantities of the herbicide to be determined. Methods such as IR spectrometry, mass spectrometry[26, 27], or polarography[28] can therefore only rarely be used, possibly in monitoring water, which has a very low content of organic matter. Measurements of biological activity[29], which would be very suitable because of their specificity, are generally too time-consuming for routine analyses.

On the other hand, there are many photometric methods, and colorimetric methods in particular[16, 30] not requiring large-scale apparatus. Thus dinitrophenols such as DNOC *(6a)* and dinoseb *(6b)* can be sensitively determined by means of the yellow color of the phenolate, while the dications of the bipyridine compounds[31] paraquat *(7a)* and diquat *(7b)* are reduced to colored radical-ions by sodium dithionite.

Herbicides with free aromatic amino groups, such as amitrole *(8)*[32], are diazotized and coupled with chromotropic acid or similar compounds to form an azo dye. Carbanilic esters *(1)*, *N*-phenylureas *(2)*, and other herbicides can also be determined in the same manner[16, 30] if they are hydrolyzed to the anilines during the clean-up or before the determinative step; *N*-(1-naphthyl)ethylenediamine is used as the coupling component in most cases. However, interference can be caused here by *o*-aminoacetophenone, which is thought to be formed from tryptophan on alkaline hydrolysis[33]. When high blanks

(6a) (6b)



(7a) (7b) (8)

are obtained, therefore, the dye solution must be further purified by chromatography on a cellulose column.

If the herbicide does not offer any point of attack for a colorimetric determination, the problem can be overcome by direct UV measurement (*e.g.* in the case of α-naphthylacetic acid[34]) or by the preparation of suitable derivatives, *e.g.* by acid hydrolysis of the 2-chlorotriazines *(4a)*, *(4b)*, and *(4c)* to the 2-hydroxy compounds[1,8], whose cation has an absorption maximum at 240 nm. Fluorimetric determination is also possible in a few cases, *e.g.* for α-naphthylacetic acid[35] or β-naphthoxyacetic acid[36].

All optical measurements are sensitive (detection limit in most cases between 1 and 10 μg), but they are also very non-specific. In addition to accompanying natural substances from the sample material, the determination frequently also responds to the metabolites of the herbicide under investigation. Interference may also be caused by other pesticides that have the same functional groups or form a similar derivative (Scheme 1).

Scheme 1.

In a quantitative determination by chromatographic methods, on the other hand, one simultaneously obtains information about whether the value obtained does in fact refer to the compound to be analyzed. In thin layer chromatography, however, co-extractives can seriously alter the R_f values and hinder the quantitative estimation, which is usually based simply on a visual comparison of the spot size with a standard series. Methods of this type have been described *e.g.* for the determination of the triazine derivatives *(4a)*, *(4b)*, and *(4c)* in UV light[16,18] and for the carbanilic esters propham *(1a)* and chlorpropham *(1b)*, which are hydrolyzed by heating of the plate and treated with *p*-dimethylaminobenzaldehyde to form colored compounds[37].

During the past few years, gas chromatography has become one of the most important determinative methods for residue analysis[38,39,92]. This is due to the development of new, highly sensitive detectors[39-42], with which herbicides containing characteristic elements or functional groups can be selectively determined in the nanogram range. Because of this low detection limit, only a small aliquot of the extract is required for the analysis, with the result that the interference by co-extracted material is greatly reduced.

The separation is always performed on packed glass columns containing 0.5—15% of a liquid phase on a substantially inert support material. The columns have to be very carefully conditioned to avoid losses due to irreversible adsorption or decomposition.

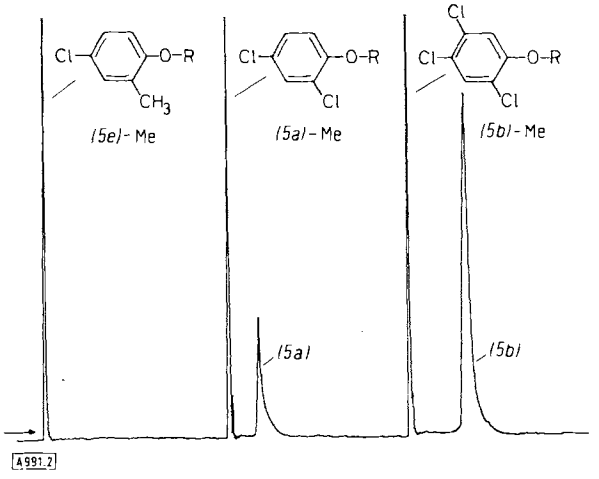
In the microcoulometric detector[42-44], nitrogen compounds eluted from the separating column are reductively pyrolyzed with H_2 on a nickel catalyst; the resulting NH_3 is then neutralized in a titrating cell with coulometrically generated $H^{\oplus}$ ions. In the Coulson electrolytic conductivity detector[44-49,90], the compound is degraded in the same manner, but the NH_3 is then dissolved in a film of water and the conductance of the solution is monitored. After suitable modification, both detectors can also be used for the determination of herbicides containing Cl, Br, I, P, or S[39,50,51]. Alternatively, these elements can be detected with emission-spectrometric detectors, in which excitation is achieved in a flame or in a microwave plasma (flame photometric detector[52,53] and microwave emission detector[54-56]) and a strong spectral line of the element in question is quantitated.

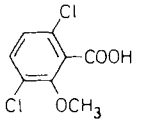
The equipment required for the thermionic nitrogen detector (N-TID) is more simple[57-60]. In this case a crystal of Rb_2SO_4 or RbBr is positioned on or a few millimeters above the flame jet of the conventional flame ionization detector; the gas flow rates are adjusted to give a relatively cool reducing flame. The carbon signals are lowered by the hindered combustion, whereas compounds containing nitrogen (and phosphorus) increase the ionization current to a much greater degree than in the normal flame ionization detector. A selectivity of C : N = 1 : 3000 can be achieved with an optimum arrangement[61]. The detection limit is reported to be 1 pg of N/s; the linear range is about 10^4.

The signal area/g is proportional to the nitrogen equivalent in the compound to be determined. The N-TID is therefore particularly suitable for the analysis of the triazine herbicides *(4)*[28,62,63], which all contain five N atoms in the molecule. For the analysis of carbanilic esters *(1)* or *N*-phenylureas *(2)*, however, it can only be used in some special cases[64], since these compounds mostly decompose during the gas-chromatographic separation[65].

The electron capture detector (ECD)[42] has been the most widely used so far in residue analysis. In this device the carrier gas is first ionized by β rays from a ^3H or ^{63}Ni source to form positive ions and slow electrons; on application of a D.C. voltage (often pulsed), these are collected to produce a basic current. If other molecules pass through the detector, they capture some of these electrons and form negative ions, which later recombine with the positive ions of the carrier gas molecules. The loss of electrons is recorded as a decrease in the basic current. The relatively narrow linear response of the detector can be extended to a range of about 10^4 by a mode of operation in which the basic current is kept constant by continuously modulating the pulse frequency[66,67].

The specificity of the ECD is due to the difference in the electron affinities of organic molecules. The detector is particularly sensitive to compounds containing nitro groups or halogen atoms (I > Br > Cl > F). The size of the signal depends mainly upon the number of capturing species (Fig. 2), but is also affected by their position in the molecule and the type of bonding[68].





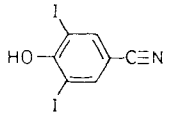


Fig. 2. Gas chromatogram of the methyl esters of the three chlorophenoxy carboxylic acids *(5e)*, *(5a)*, and *(5b)* (R = CH_2—$COOCH_3$) (1 ng in each case) with the electron capture detector (ECD). Operating conditions: 1 m 10% SE-30, 170 °C, 120 ml/min of Ar (5% CH_4), ECD (^{63}Ni).

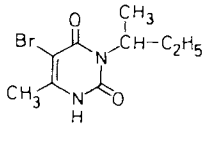
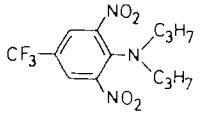
In the analysis of herbicides, the ECD is employed primarily for the determination of the widely used chlorophenoxy carboxylic acids[69] such as 2,4-D *(5a)* and 2,4,5-T *(5b)*, the chlorobenzoic acids[70] such as dicamba *(9)*, and the halogenated[71] and nitrated[72] phenols such as ioxynil *(10)* and dinoseb *(6b)*. Before the gas chromatography, these compounds are all methylated with diazomethane[71,73], BF_3/methanol[74], or dimethyl sulfate[75], and they can be detected in quantities of 0.1–1 ng. A number of other herbicides, such as bromacil *(11)*[76] and trifluralin *(12)*, or diuron *(2c)*[91], can be determined directly.



(9)



(10)

(11)

(12)

It can be seen from Figure 2 that herbicides containing only one chlorine atom are not detected by the ECD at the nanogram level. The detection sensitivity here can be improved in a range of about 10–100 by preparation of derivatives that contain additional electron-capturing groups.

For the *N*-phenylurea monuron *(2a)*, for example (Fig. 3), the 4-chloroaniline formed on hydrolysis may be allowed to react with 4-chloro-3,5-dinitro-α,α,α-trifluorotoluene[77], or it may be diazotized and converted by Sandmeyer reaction into 1-chloro-4-iodobenzene[78]; another possibility is bromination of *(2a)* with simultaneous hydrolysis to form 2,6-dibromo-4-chloroaniline[79].

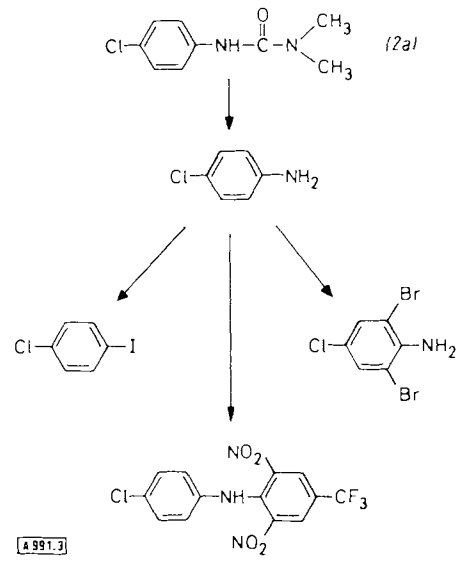


Fig. 3. Derivatives of monuron *(2a)* that are suitable for gas-chromatographic detection with the electron capture detector (ECD).

Misinterpretations are possible, however, since the same derivatives are also obtained from metabolites of monuron and from all other herbicides that yield 4-chloroaniline on hydrolysis [*e.g. (2b)*, *(2f)*, *(3a)*]. Another disadvantage is that foreign material from the sample that is still present in the extract also forms corresponding derivatives, and this can lead to complicated gas chromatograms that are difficult to interpret[79,80].

When the ECD or the N-TID is used, the liquid phase of the gas chromatographic column must be particularly stable to high temperatures, since even traces of volatile components or decomposition products (bleeding of the column) would soon coat the radioactive source of the ECD or the crystal of the N-TID and reduce the detection sensitivity. It is necessary to use highly purified silicone derivatives, which are stable at least up to 300 °C, and whose polarity can be varied by variation of their content of methyl, phenyl, trifluoroisopropyl, or cyanoethyl groups.

4. General Methods

Though the methods for the quantitative residue determination of individual, known herbicides are not always entirely satisfactory, the analyst often has several methods to choose from, and with enough experience, good results can be obtained through critical interpretation.

The difficulties are much greater in screening analyses for market control. This calls for both the identification and the quantitative determination of residues of herbicides covering a wide range of different chemical structures; as far as possible, moreover, the same procedure should be applicable to the control of fruit, vegetables, cereal products, and the derived processed food products.

The analytical possibilities here are limited by the large number of compounds to be detected, so that there are practically no alternatives to column chromatography for the clean-up and gas chromatography for the final determination. Though

the highly sensitive, specific detectors allow the analysis of extracts that have not been very highly purified, the gas chromatogram in this case, unlike in the individual determinations, must not contain additional peaks due to co-extractives from the plant material, since these could be misinterpreted as being due to residues of another pesticide. In addition to these methodological restrictions, the amount of time and work required for an analysis in the course of routine work must be as small as possible.

Moreover, the material to be analyzed is often in the form of large pieces (fruit, vegetables), and any residues may be on the surface or they may be very unevenly distributed in the interior. A precondition for a reliable analysis is therefore careful sampling in accordance with statistical principles so that the sample taken for analysis really is representative of the material under investigation.

The same analytical problem was encountered about ten years ago in the residue analysis of insecticidal chlorinated hydrocarbons and organophosphates as well as of a number of fungicides in foods from plants. Suitable multi-residue methods have now been devised for this purpose, and some have already been officially adopted[81-83]; these methods make use of a thermionic phosphorus detector (P-TID) and particularly the electron capture detector (ECD) for the final determination. The determination of insecticide and fungicide residues is now one of the routine analyses in food control.

Instead of carrying out separate analyses for herbicide residues, therefore, it is more logical to extend the procedures already used in order to detect as many pesticides as possible at the same time. However, in an analysis with such a wide scope, a general method cannot be expected to allow the detection and quantitative determination of every compound

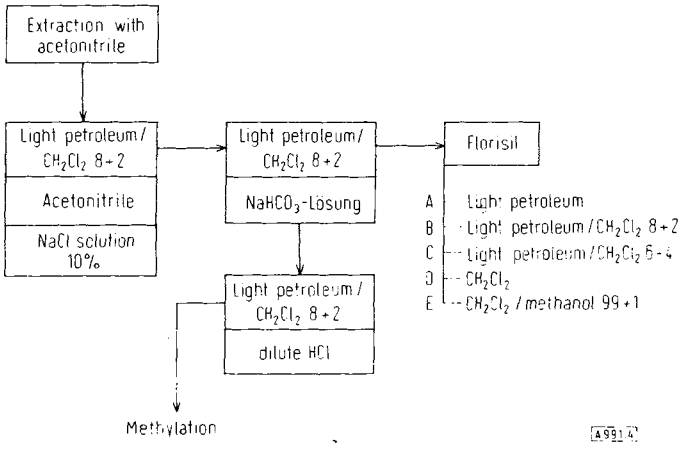

Fig. 4. Scheme for the clean-up [84] of plant material in a general method for residues of herbicides and other pesticides (see also Table 2).

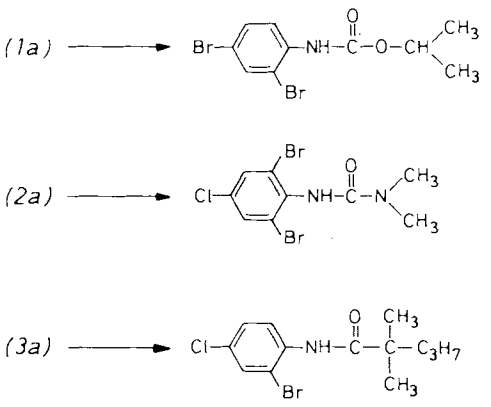
can be achieved by suitable choice of this solvent, which should be just sufficiently polar to take up all pesticides, but as little as possible of the substances derived from the plant itself.

The herbicidal acids and phenols [*(5), (6), (9), (10)*] are separated from the organic phase by extraction of their salts into an aqueous solution. Without further clean-up these can generally be methylated with diazomethane and analyzed by gas chromatography with the ECD[85]. The neutral pesticides are purified by column chromatography on Florisil of suitably adjusted activity, which retains coloring matter and residual lipids particularly well. By elution with solvent mixtures of increasing polarity, it is possible to separate the pesticides so that chemically similar compounds are found in the same or neighboring fractions (Table 2).

Table 2. Fractionation of pesticides on a Florisil column, with the detectors used (A–E see Fig. 4. ECD = electron capture detector, P-TID and N-TID = thermionic detectors for phosphorus and for nitrogen respectively).



Pesticide group	Detector	Fraction				
		A	B	C	D	E
Insecticides and acaricides						
Chlorinated hydrocarbons	ECD	++	++			
Organophosphates	ECD, P-TID		++	++		++
Various fungicides	ECD	+	++	+		
Herbicides						
Triazines *(4)*	N-TID				++	
Carbanilic esters *(1)*	→ECD		+	+		
N-Phenylureas *(2)*	→ECD			++	+	
Anilides *(3)*	→ECD			++		

under optimum conditions. A compromise must therefore be adopted between the number of pesticides covered by the analysis, the detection sensitivity that can be attained, the recovery in the clean-up procedure, the possible separation of interfering substances, and the amount of work involved.

In an analytical procedure of this type (Fig. 4)[84], it is best to extract the plant material by homogenization with acetonitrile, since only a fraction of the plant lipids is then co-extracted. In the usual analyses for insecticides[81-83] this crude extract is diluted with a surplus of water and extracted with petroleum ether or methylene chloride. Since this must be expected to lead to losses of polar pesticides, it is better to dilute the crude extract with an organic solvent and then to remove acetonitrile and extracted water together with water-soluble substances of natural origin. An additional purification effect

In the gas-chromatographic examination of the various fractions, most of the insecticides and fungicides are detected with the ECD, the remaining organophosphates with the P-TID, and the triazines *(4)* and a few other herbicides with the N-TID. Bromo derivatives[86] of numerous herbicidal carbanilic esters *(1)*, *N*-phenylureas *(2)*, and anilides *(3)* are then prepared in the same fractions; these can also be analyzed with the ECD (Scheme 2).

The bromination conditions are so chosen that each herbicide forms only one monobromo or dibromo derivative, which is thermally stable and allows both identification and quantitative determination. This is achieved by reaction with bromine containing 5% of iodine (as a catalyst for aromatic substitution) for 10 min at room temperature in acetic acid or in the absence of solvent. Because of the high detection sensitivity

Scheme 2.

of the resulting bromo derivatives, it is possible to use such a high dilution that there is practically no interference due to residual organic matter from the sample (Fig. 5).

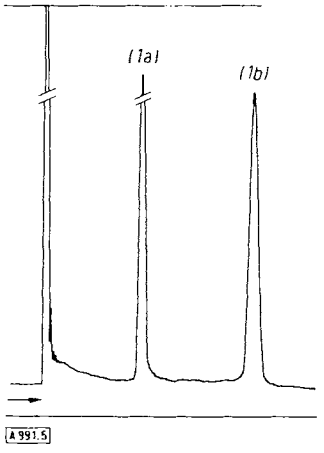


Fig. 5. Gas chromatogram of an extract from potatoes with 0.1 ppm each of propham (*1a*) and chlorpropham (*1b*) after bromination [86]. Operating conditions: 1 m 10% SE-30, 200 C, 120 ml/min of Ar (5% CH_4), ECD (^{63}Ni), 0.25 ng-equivalent of (*1a*) and (*1b*) injected.

Even with a great deal of experience, interference[187] and misinterpretations[24] cannot be ruled out in general methods of this type, where one is dealing with nanogram quantities and at the ppm to ppb level. The result should not therefore be regarded as certain unless it can be confirmed by a second analytical method (photometry, combination of gas chromatography with mass spectrometry[27], *etc.*).

5. Automation

Though investigations for herbicide residues involve a large number of individual analyses, few attempts have been made to automate the procedures. The photometric or gas-chromatographic final determinations would present no problems in this respect, since flow-type cells or automatic injection devices are available nowadays for continuous measurements, and there are integrators and computers of a suitable size for control and evaluation. However, the automatic clean-up of the samples still raises great difficulties.

A suitable apparatus has been designed for the residue analysis of some triazine derivatives (*4*)[49, 88, 89], and this could serve as a model for other similar determinations. It involves the extraction of 40 g of a soil sample with warm acetonitrile, precipitation of colloids with calcium chloride solution, evaporation of the solvent under mild conditions, and extraction of the residual aqueous solution with hexane/ether (2 : 1). The final determination is carried out by gas chromatography with the Coulson electrolytic conductivity detector; it is possible to deal with six samples per hour.

The extracts obtained in this way are sufficiently pure for analysis with a highly selective detector, but not for the electron capture detector (ECD), which is still indispensable for a general method. It would therefore be necessary, above all, to automate the column chromatography for the purification of the extracts, but no satisfactory solution to this problem has yet been found. The analyst has a wide scope here for the optimization of the known methods and for new ideas.

Trace Analysis of Organic Compounds

By Klaus Beyermann[*]

The trace analysis of organic compounds presents a number of additional difficulties in comparison with the trace analysis of inorganic compounds. Thus special problems arise in sampling and in the storage of samples (*e.g.* because of the instability of many organic compounds). It is also difficult to choose suitable mild separation methods and to find highly sensitive, molecule-specific determination methods.

1. Introduction

Very little attention has been given in the past to the trace analysis of organic components. For example, there are hardly any textbooks in this field, and the majority of lecturers at conferences on the subject deal with the (admittedly great) problems of the trace analysis of inorganic compounds. The relatively modest place allotted to this topic does not agree with the great importance of organic compounds, and is quite incomprehensible when one compares the number of these compounds with that of inorganic substances.

There are several conceivable reasons for this low level of representation. Thus possible explanations are that the trace analysis of organic compounds is not important, or that the trace analysis of organic compounds, though important, is very difficult.

[*] Prof. Dr. K. Beyermann
Institut für anorganische und analytische Chemie der Universität
65 Mainz, Johann-Joachim-Becher-Weg 24 (Germany)

If one adopts the second view, there are two assertions that have to be proved:

1. the trace analysis of organic compounds is of great interest; and

2. the trace analysis of organic compounds raises problems that are even greater than the well-known difficulties of the trace analysis of inorganic compounds.

2. Interest in the Trace Analysis of Organic Compounds

The interest in the trace analysis of organic compounds can be demonstrated by the number of publications for 1972 reported in "Analytical Abstracts" (see Table 1).

Table 1. Classification of the analytical publications from the year 1972 reported in "Analytical Abstracts".

Area	Overall proportion [%]	Trace analysis [%]
Biochemistry	30	6
Organic chemistry	12	1
Food chemistry	9	2
Pharmaceutical chemistry	4	0
Air and water chemistry	3	1
Agricultural chemistry	3	1
Inorganic chemistry	25	8
Miscellaneous (instrumentation)	14	1
	100	

61% of all publications are concerned with the analysis of organic components. The greatest number (about 30%) are publications from the field of biochemical analysis. Only a relatively small number of articles are devoted to the analysis of components in drugs, in air, in water and effluents, and in agriculture. About 11% of the publications dealing with organic analysis are concerned with trace analysis. This corresponds to about 0.1% of all publications in the field of chemistry as a whole.

Further classification of the articles on the trace analysis of organic compounds reveals investigations on hormones, steroids, amino acids, physiological blood constituents, enzymes and amboceptors, and anesthetics (each of these groups accounting for about 1% of the publications) in the field of biochemistry. Important topics in connection with food analysis are determinations of residues from insecticides and hormones as well as other contaminating substances of animal or human origin.

Trace analyses of organic compounds play a relatively important part in the fields that are currently in the focus of public interest and that fall under the headings "protection of the environment" and "purity of food". It is clear, therefore, that there is great interest in the analysis of traces of organic components.

3. The Difficulties of the Trace Analysis of Organic Compounds

The comparatively small number of lectures and publications is therefore probably due to the difficulties of the trace analysis of organic compounds. Some examples will be given below in support of this assertion. A comparison with the problems of the trace analysis of inorganic compounds seems advisable, since there are more publications in this field and its difficulties are probably better known.

3.1. Difficulties in Sampling and in the Storage of Samples

The difficulties of sampling can be illustrated by the determination of the insecticide content of air. It is well known that after insecticides have been sprayed, they disappear in time either through chemical transformation or through physical processes, in most cases evaporation. Insecticides that can evaporate in this way have a correspondingly high vapor pressure. A certain insecticide content can therefore be anticipated in the air. It is likely that some of the insecticide will be held on dust particles, but because of its high vapor pressure it will also be present to an appreciable extent as a free component in the gas phase. Difficulties arise in the determination of this fraction in the ng/m^3 range, since condensation to reduce the vapor pressure results in the formation of aerosols, which cannot be quantitatively determined. The lower the temperature to which the gas sample is cooled for "quantitative" condensation, the smaller are the aerosol particles, with the result that the yields deteriorate.

One method that gives high yields even for nanogram quantities[11] involves the passage of the air containing insecticide through gauzes coated with polyethylene glycol. The nonpolar active substances dissolve in the polyethylene glycol with high yields, as can be shown by the use of ^{14}C-labeled insecticides. They can then be determined by gas chromatography. Examples of chromatograms of the total insecticide content in air samples are shown in Figures 1 and 2.

The fraction that is not in the form of aerosols amounts to many times the quantity that is associated with dust. If inhaled air and exhaled air are analyzed under identical conditions, distinctly lower insecticide concentrations are found in the latter (see Fig. 3).

The substances are partly deposited in the respiratory tract and absorbed into the body. The same results were found in (as yet unpublished) experiments with guinea pigs, which

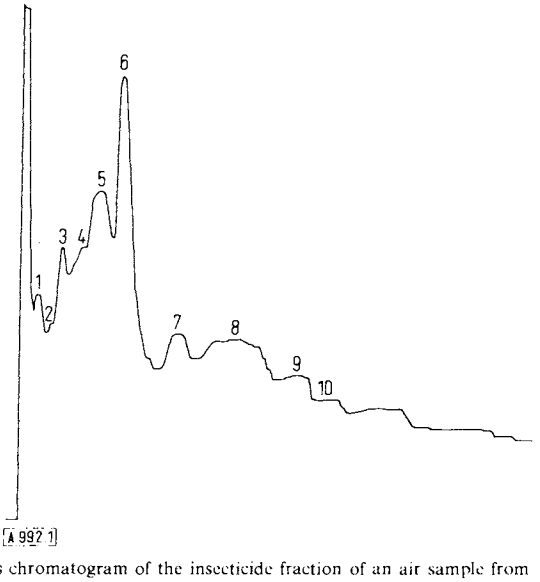

Fig. 1. Gas chromatogram of the insecticide fraction of an air sample from an agricultural area (Heidesheim near Mainz). Quantity of air investigated: 3 m^3. The contents found are about 170 ng/m^3 for aldrin and about 300 ng/m^3 for DDT. 1 = Phosdrin, 3 = CDEC, 5 = aldrin, 6 = daconil, 7 = ethylparathion, 8 = dieldrin, 9 = *o,p*-DDT; 2 and 4 have yet to be identified (after [1]).

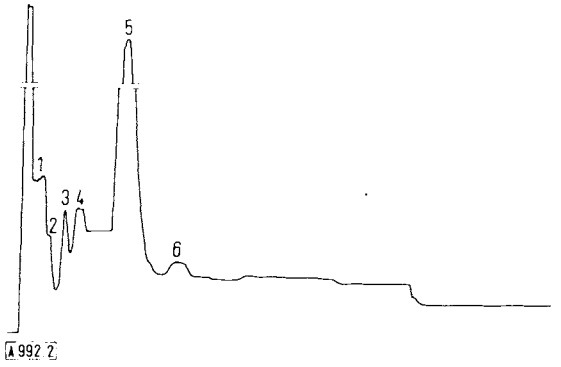

Fig. 2. Gas chromatogram of an air sample taken at the confluence of the Rhine and the Main. Conditions as for Fig. 1. 1 = Phosdrin, 3 = CDEC, 5 = daconil, 6 = ethylparathion; 2 and 4 have yet to be identified (after [1]).

clearly demonstrated the absorption of inhaled ^{14}C-labeled insecticides.

In the analysis of blood samples in clinical work, differences are often found according to the point from which the sample

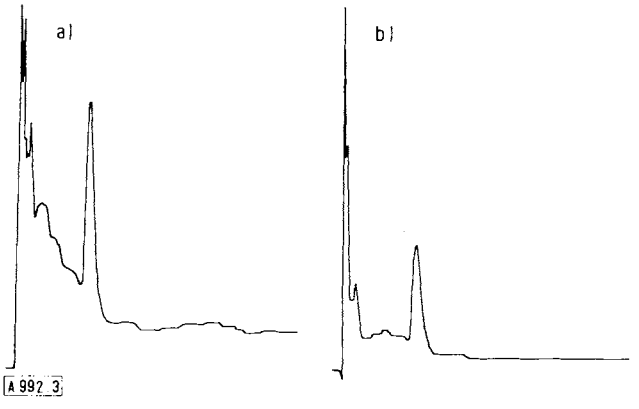

Fig. 3. Comparison of the insecticide content of a) inhaled and b) exhaled air under otherwise identical analytical conditions (after [1]).

was taken, since the concentrations of many substances in venous blood are different from those in arterial blood[2]. The sampling conditions, including the point from which the sample was taken, must therefore be indicated very precisely in analyses of this type.

The same problems arise in the storage of samples containing organic trace components as in the trace analysis of inorganic compounds, *i.e.* adsorption on the walls of the storage vessels.

Insecticides in water samples, for example, are adsorbed on the walls of polyethylene vessels after a very short time[3]. Quinine, which has to be analyzed in ng/ml concentrations by fluorescence spectroscopy in cells, is practically all situated on the wall of the glass vessel within seconds, even when the alkaloid solution is 0.1 N in sulfuric acid[4]. To avoid losses of this nature, it is recommended that the walls of the apparatus should be saturated with a solution of the trace component to be determined in a suitable concentration. It is better to keep the wall area of the vessel as small as possible in every case in order to minimize the adsorption effect. A change of solvent or of the composition of the test solution is also helpful in many cases.

Problems that are not found in the trace analysis of inorganic compounds arise because of the ease of decomposition, oxidation, or enzymatic-bacterial transformation of the samples to be stored. This is a serious problem in the storage of blood samples.

Though the literature data[5-8] are unfortunately rather contradictory, they show, for example, that the concentrations of bilirubin and of cholesterol change within two days even when the serum samples are stored at 3 C. The phosphate and ammonia contents of the blood samples increase rapidly, since organic compounds are decomposed with formation of these inorganic products.

The enzyme activities in blood or serum samples are also influenced by the manner in which the samples are stored. The activities of lactate dehydrogenases and phosphatases decrease within two days when the sample is kept at 0 °C. An entirely new problem to the trace analyst who has been concerned with inorganic compounds is presented by the behavior of some enzymes, whose suspensions in aqueous ammonium sulfate solution lose their activity on freezing and thawing[9].

This instability leads to problems of organization in clinical laboratories where a very large number of samples must be examined. Efforts are made to avoid bacterial decomposition by storage at −23 °C or by freeze drying, as well as by the addition of chemical stabilizers. However, this procedure is not entirely free from problems, since these additives can interfere with the analyses. The safest method is to work up the samples as soon as possible.

The problem of the instability of the samples is particularly serious where constant concentrations or activities of calibration standards must be maintained for long periods.

3.2. Digestion Methods

Digestion methods play a much greater role in the trace analysis of inorganic compounds than in the analysis of organic trace components. In particular, destructive digestion methods are rarely of any interest in the latter field.

On the other hand, sample preparation is very important in the disintegration of cellular tissues to liberate special components or to obtain selected cell fractions or particle fractions. The methods used here range from centrifugation in solutions of specified density, ultracentrifugation, and electrophoresis of whole cells to immunological methods.

The removal of the main component, protein, to obtain traces of low molecular weight substances is also a problematic step. It can lead to low values *e.g.* by occlusion of the trace components or as a result of their adsorption on the precipitated protein, but it can also lead to high values through removal of amino acids from the proteins (in amino acid analyses).

3.3. Separation Methods

The most critical step in the trace analysis of organic compounds lies in the choice of a suitable separation method. All the test materials in which great interest is shown (blood, tissue, food, urine, and apparently even systems as "simple" as air or water) are complicated and consist of a large number of principal and minor components. Separations are unavoidable in the great majority of cases.

A "preliminary" publication (more than 250 pages long) on the influence of 9000 drugs on the results of clinical analyses[10] shows that the "blood system" cannot by any means be regarded as a constant matrix. From the precision standpoint, therefore, the trace component in which one is interested should preferably be separated from this variable system for trace analysis.

Whether this conscientiousness is a waste of time in view of the fact that trace separations in organic analysis are generally associated with particularly poor yields is a decision that must be left to the investigator in each individual case. However, losses can often be very effectively recognized and taken into account by the isotope dilution method.

A serious problem in the separation of traces from biochemical sources is that many of these substances are hydrophilic. The only separation methods that can really be considered for them are consequently methods in which water is used as an essential component of the system.

The commonly used separation methods include the chromatographic methods, ion exchange, electrophoresis, immunoelectrophoresis, and a number of liquid-liquid partition methods. A recent survey is given by *Kienitz* and *Runge*[11].

Methods that are familiar from the trace analysis of inorganic compounds, such as coprecipitation, can occasionally also be useful in organic chemistry. Thus biogenic amines in ng/ml concentrations can be coprecipitated in very high yields as tetraphenylborates on creatininium tetraphenylborate[12] and separated from other components.

Nanogram quantities of amines can be isolated almost quantitatively and selectively from a crystalline KCl/NH_4Cl/creatinine mixture by extraction with methanol.

To improve the efficiency of separations, it is sometimes suggested that derivatives of the trace components should be prepared, *e. g.* in the field of ultramicropreparative gas chromatography. However, problems are often also encountered here, since the organic substances in microgram quantities react differently with the reagent present in a very large excess than in the usual, roughly stoichiometric ratios as in preparative organic chemistry. The disturbing influence of water is particularly drastic in some derivative formation reactions if the quantity of the trace component is small in comparison with the water films that are adsorbed even on small micro vessels (in microgram quantities). The result is a severe limitation of the separation methods.

In the trace analysis of organic compounds, especially in the biochemical field, there is one problem that is practically unknown to the trace analyst in inorganic chemistry. In organic materials, the components in which we are interested are often substances the chemical nature of which is largely unknown. Examples of such substances are the metabolites of drugs or the many substances that are excreted in the urine. Thus *Scott*'s research group[13], for example, is constantly finding new components by UV spectrophotometry that they cannot fully identify.

The detection of specific isomers is another problem that is fairly unusual in the trace analysis of inorganic compounds. In protein analysis, we are often interested in only one conformer of a protein.

Another interesting problem that is troublesome in analysis is the detection of a trace component in a specific "bound form". Thus in the blood, very many drugs are more or less strongly bound to certain blood proteins. In many cases, only the fraction that is not bound to protein is pharmacologically active. In analysis, one tries to use mild methods for separation, and as far as possible methods that do not disturb the equilibrium, such as ultrafiltration, gel filtration, or some types of dialysis.

3.4. Determination Methods

In the methods for the determination of organic trace components, serious problems are again encountered in addition to those found in the trace analysis of inorganic compounds. In the analysis of organic substances, meaningful results are nearly always obtainable only by molecule-specific determination methods. Elementary analysis in the trace and micro ranges gives only hints at best. For this reason, an extremely effective tool for the trace analysis of inorganic compounds, *i. e.* radiochemical activation analysis, is almost useless for the trace analysis of organic compounds.

With the aid of highly refined special procedures, however, the molecule-specific determination methods of instrumental organic analysis (UV, IR, NMR, and MS) can also be used for the investigation of submicrogram quantities.

A sensitivity increase of one to two powers of ten can often be achieved here by electronic averaging. The instruments often allow the accumulation of results with equal validity over a range of as much as four powers of ten. However, the times required then become unacceptably long (several weeks) in many cases.

Figure 4 shows the example of the investigation of 25 ng of tyrosine, with part of the IR spectrum of this compound. No spectrum can be recorded in the usual manner. If the region is scanned 2448 times and the data collected in an

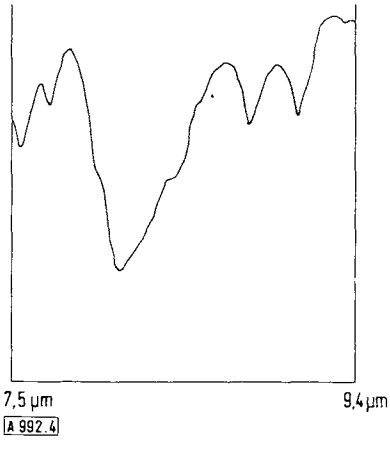

Fig. 4. IR spectrum of a sample of 25 ng of tyrosine after scanning of the range 2448 times and collection and processing of the data in an electronic averager (after [14]).

electronic averager, one finally obtains the spectrum shown, which is identical with the spectrum of larger quantities of tyrosine[14].

Mention should be made of the fundamental difficulty of most molecule-specific instrumental methods of analysis, *i. e.* that they require more or less pure substances. Preliminary separations thus acquire corresponding significance within

the analytical plan as a whole. After the trace component has been isolated (with the least possible loss), it must be quantitatively transferred into the instrument with the aid of micro techniques.

In addition to the spectroscopic methods mentioned, there are a large number of more or less molecule-specific methods. Thus gas chromatography is becoming increasingly reliable through the introduction of highly sensitive, element-specific detectors, and its results are easier to interpret.

Extremely high sensitivity, coupled in most cases with excellent specificity, is offered by enzymatic methods and immunological techniques. Among the latter, radioimmunoassay is at present often the only practicable possibility for the fast, specific determination of organic trace components in a large number of samples.

The method is based on the principle that the substance to be determined, which must act as an antigen, is allowed to react with a specific antibody. This antibody is added as the "reagent" in a substoichiometric quantity for the analysis. A small quantity of the substance to be analyzed, but in a radioactively labeled form, is also added to the sample. The antigen originally present in the sample itself and the added antigen compete to react with the substoichiometric quantity of antibody. If there is a large quantity of antigen that originally came from the sample, correspondingly less of the radioactively labeled antigen will be bonded to the antibody, and the activity found after isolation of the antigen-antibody complex is then a measure of the antigen concentration in the sample.

The analytical method depends on the availability of the radioactively labeled antigen and of the antibody, and it is necessary to verify that the latter reacts specifically and stoichiometrically with the antigen. Interference due to other plasma components, whose concentrations may vary, must be ruled out.

The effectiveness of the method was recently demonstrated once again in an example in which other methods of trace analysis were also compared[15]. This was the determination of digoxin and digitoxin in blood. About 10 to 20 % of people over 60 years of age require cardiotonic agents of this type. Because of their very narrow therapeutic range, it is desirable to know their concentration in the patient's blood. Thus good therapeutic results are obtained *e.g.* with digoxin in a concentration of 1 ng/ml of serum, but toxic effects appear at a concentration of 2 to 3 ng/ml. The objective determination of such low concentrations has until now been possible only by very complicated analytical methods; however, an elegant alternative is now offered by radioimmunoassay.

4. Closing Remarks

The trace analysis of organic compounds is a fascinating field, and is of great general importance. In addition to the difficulties of the trace analysis of inorganic compounds, the investigator in this field is very often faced with numerous other problems. Their solution calls for so much knowledge from neighboring fields that it seems justifiable here to consider analytical chemistry as an independent scientific field with interdisciplinary connections.

Chemically Produced Excited States

By Emil H. White, Jeffrey D. Miano, Carol J. Watkins, and Eves J. Breaux[*]

Electronically excited states of organic molecules are formed in many chemical reactions. Such chemically produced excited states are (with one exception) identical to light produced excited states, and they undergo the molecular transformations expected of such states ("photochemistry without light"). The excited states can also be used in energy transfer experiments. This review covers the generation of chemically produced excited states, the chemical reactions they undergo, and the possible role of chemically produced excited states in biology.

1. Introduction

Life on earth is dependent on a number of complex processes that utilize sunlight as the source of energy, the most important of which are probably photosynthesis, vision, photoperiodism, and phototaxis. In plants and animals, the sunlight that is absorbed forms electronically excited states of molecules; these excited states start chains of physical and chemical steps that lead to the synthesis of sugars, detection of the surroundings, setting of the biological clock, movement towards the sun, *etc.*[1]. In recent years it has been shown that the same excited states that are formed by the absorption of light can be produced by certain chemical reactions in total darkness. The present review will outline the generation, possible function, and uses of these chemically produced excited states.

2. Excited States

Electronically excited states (referred to hereafter as excited states) can be viewed as electron isomers of the stable forms of molecules and atoms; the stable forms are usually called ground states. Excited states have different distributions in space of their electrons as compared to the ground states (Fig. 1), and consequently they have different shapes, reactivities, and properties[2].

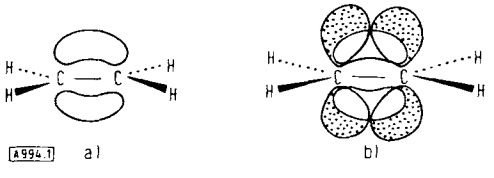

Fig. 1. Electron distribution in ethylene: (a) ground state, ○ = bonding orbital (contains two electrons); (b) first excited singlet state, ○ = bonding orbital, ⊖ = anti-bonding orbital (each contains one electron). Although not indicated, the geometries of the two states are different [2].

Energy is required to convert ground states into excited states. Thermal energy is often used to excite atoms, but most molecules would decompose before temperatures high enough to form excited states could be reached. Excited states of molecules are normally formed by the action of light in the visible and ultraviolet regions of the spectrum (Fig. 2, path 4), or by energy transfer from other excited molecules (equation 1, where the asterisk signifies the excited state).

Donor D* + Acceptor A → A* + D (1)

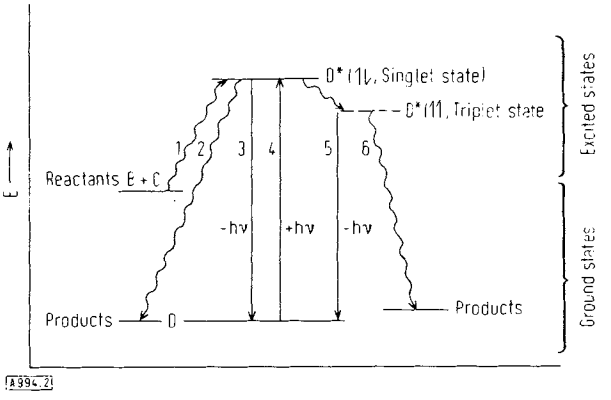

Fig. 2. Excited state processes [5]. Path 4: photoexcitation; 3 (or 4, 3): fluorescence; 4, 2: photochemical reactions; 5: phosphorescence; 1: chemical excitation; 1,3: chemiluminescence; 1,2 (1,6): "photochemistry without light".

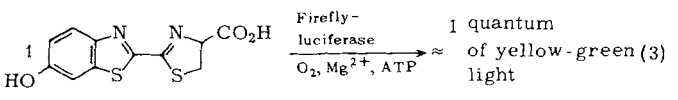
Most ground states have fully paired electrons, as do excited states formed directly on absorption of light (such as that depicted in Fig. 1b). Molecules with all electrons paired are called singlet states.

A third general pathway for the formation of excited states exists, the direct formation in chemical reactions (Fig. 2, path 1)[3]. Such chemically produced excited states have been thought of largely as curiosities in the past; recent discoveries in this area, however, indicate a bright future for them[3,4].

Singlet excited states in liquid solutions have, with rare exceptions, very short lifetimes ($\approx 10^{-5}$—10^{-9} s)[5]. During this period of time they decay by one of several competing processes: 1) light emission and return to the ground state (Fig. 2, path 3); 2) chemical reaction (isomerization, dimerization, reaction with the solvent, *etc.*, Fig. 2, path 2); 3) energy transfer [eq. (1)]; 4) quenching, in which process the ground state is reached with release of the excess energy to the medium as heat; and 5) electron spin reversal, in which case a new excited state is produced bearing two electrons with parallel spins (called the triplet state) (Fig. 2). Triplet excited states are also highly reactive, decaying by the processes listed above. A summary of the above statements and an indication of the usual nomenclature is given in Figure 2.

3. The Chemical Generation of Excited States

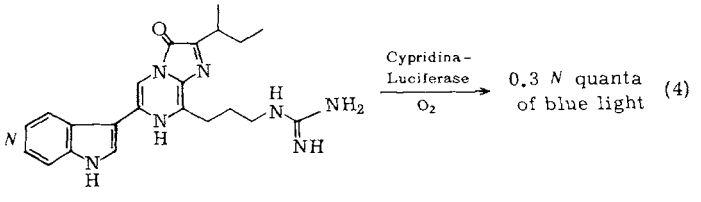
It is possible that every chemical reaction yields some excited states. The excited states can be detected by the processes



[*] Prof. Dr. E. H. White, J. D. Miano, C. J. Watkins, and E. J. Breaux
Department of Chemistry
The Johns Hopkins University
Baltimore, Maryland 21218 (USA)

outlined in the previous section. Measurement of the light emission (chemiluminescence) is the simplest and most sensitive method, however. By the criterion of chemiluminescence, even simple reactions such as the neutralization of acids and bases[6] and amide formation[7] (equation 2) have been shown to yield excited states.

$$2C_6H_5NH_2 + C_6H_5COCl \rightarrow C_6H_5CONHC_6H_5 + C_6H_5\overset{\oplus}{N}H_3Cl^{\ominus} \qquad (2)$$

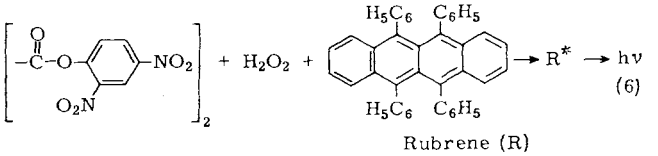


The above reactions are very inefficient in the production of excited states, however, and very sensitive counters are required to detect them. Quantum yields (Φ_{cl} = photons emitted/molecules reacted) of about 10^{-15} have been reported for simple chemical reactions of this type[6].

In contrast, several chemical reactions are efficiently chemiluminescent and bright light emissions are possible[8]. Many of these reactions produce light more efficiently than any commercial unit utilizing electrical energy[9]. Topping the list is the enzyme catalyzed air oxidation of firefly luciferin, which has been reported to be effectively 100% efficient in the overall process of light production [eq. (3)][10]. The efficiencies of

(3)

two other bioluminescent systems have also been measured *in vitro*. The reaction employed by the ostracod *Cypridinia* is ≈30% efficient in light production [eq. (4)][11], and the

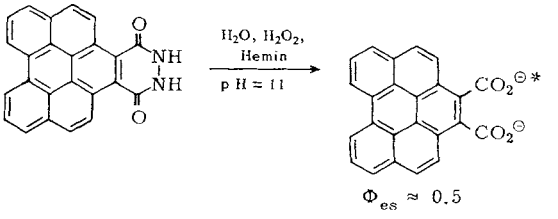


(4)

reaction employed by the luminous bacterium *Photobacterium fischeri* [eq. (5)] is reported to be about 5—10% efficient[12].

$$N\,RCHO \xrightarrow[O_2,\,FMNH]{\text{Enzyme}} < 0.1\,N \text{ quanta of bluish light} \qquad (5)$$

The most efficient *chemiluminescent* system reported to date (not involving enzymes) is the hydrogen peroxide-oxalate ester reaction in the presence of rubrene as the energy acceptor and ultimate light emitter [eq. (6)][13]. Under optimum condi-



(6)

tions, 0.23 N photons are emitted per N molecules of ester that react. This and related systems are now the basis of a commercial chemiluminescent light generator.

Although the efficiency of light emission is important in chemiluminescence, the quantity of interest in the present review is the efficiency of the chemical production of excited states, Φ_{es}. The overall efficiency of chemiluminescence, Φ_{cl}, is a product of three efficiencies [eq. (7)],

$$\Phi_{cl} = \Phi_r \Phi_{es} \Phi_{fl} \qquad (7)$$

Φ_r, the fraction of reacting molecules that pursue the correct chemical pathway, Φ_{es}, defined above, and Φ_{fl}, the efficiency of fluorescence of the ultimate light emitter in the reaction. Since Φ_{cl} and Φ_{fl} are directly measurable, $\Phi_r\Phi_{es}$ can be readily determined. For reactions that produce high chemical yields of the light emitters, Φ_r has been assumed to be ≈ 1, permitting an estimate of Φ_{es}[14]. The highest value of Φ_{es} found to date for a non-enzymatic chemiluminescent reaction is ≈0.5 (50% efficient), a value reported for the light emission of a cyclic hydrazide based on perylene [eq. (8)][15a]. Recently, other quite different systems have been shown to yield chemically produced excited states with high efficiencies (20 to 100%)[15b].

(8)

It is thus apparent that some chemical reactions produce excited states quite efficiently. It would be valuable to be able to predict which reactions or reaction types in solution are in this category. In the gas phase, the known chemiluminescent reactions are sufficiently varied that no general relationships have been established other than the requirement that sufficient energy be available to form the excited states. For chemical reactions in solution, other variables are involved. Most organic reactions proceed in several steps with the formation of several intermediates. Normally, the individual steps are not energetic enough to form excited states of the immediate product formed (in contrast to many gas phase reactions). However, two general exceptions to this somewhat pessimistic statement have appeared in the past decade; two reaction types that lead efficiently to excited states have been discovered. The first is the thermal decomposition of 1,2-dioxetanes and the second is the one electron transfer reaction of radical anions and cations. Most of the known efficient chemiluminescent reactions proceed by one of these two processes; both will be outlined in later sections of this paper. Further research on chemical energy generation will undoubtedly reveal still other fundamental reaction mechanisms leading to excited states[16].

1,2-dioxetane

We will be concerned in this review principally with the reactions that generate excited states efficiently, particularly those carried out in liquid solutions since these systems permit energy transfer to large molecules of chemical and biochemical interest. A brief section on gas phase chemiluminescence is included, however, to exemplify the added physical information that can be obtained from simpler systems.

3.1. Gas Phase Reactions

Chemiluminescent reactions in the gas phase generally involve light emission by atoms or small molecules[17]. These reactions are of interest because of their occurrence in flames and in the upper atmosphere. The emission spectra frequently show considerable detail, which permits identifying the vibrational level as well as the electronic state of the emitting molecule. For example, the reaction of atomic oxygen with acetylene or carbon suboxide leads to three different excited states of carbon monoxide. The following reaction was proposed for the chemiluminescence[17b]:

$$O(^3P) + C_2O(^3\Sigma) \rightarrow CO(A^1\Pi, d^3\Delta, c^3\Sigma) \rightarrow h\nu \qquad (9)$$

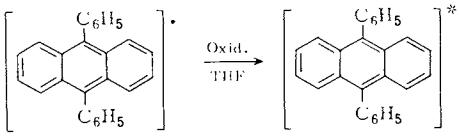
Vibrational levels of up to $v'=9$ were observed for the excited states formed by this pathway[17b], whereas other pathways for the formation of CO in the acetylene oxidation have led to values of v' up to 33[18]. Laser emission by vibrationally excited CO has been observed recently in the atomic oxygen-acetylene reaction[19].

The reaction of basic solutions of hydrogen peroxide with chlorine leads to the formation of excited states of oxygen, which emit in the infrared region of the spectrum[20]. Visible

$$H_2O_2 + Cl_2 + NaOH \rightarrow \begin{array}{l} O_2(^1\Delta_g) \rightarrow h\nu(1.27\,\mu m) \\ + \\ O_2(^1\Sigma_g^+) \rightarrow h\nu(0.762\,\mu m) \end{array} \qquad (10)$$

light is also emitted; the pooling of energy by two excited states in contact dimers has been proposed to account for this fact[20, 21]. Emission from vibrationally excited levels was also seen. The singlet oxygen ($^1\Delta_g$ and $^1\Sigma_g^+$) and the encounter

$$\begin{array}{l} (O_2\,^1\Delta_g)_2 \rightarrow h\nu\,(634\,nm) \\ (O_2\,^1\Delta_g + O_2\,^1\Sigma_g^+) \rightarrow h\nu\,(478\,nm) \end{array} \qquad (11)$$

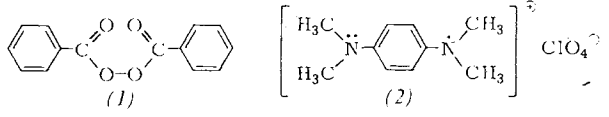


complexes apparently exist in and emit light from bubbles of oxygen gas which arise from the reaction mixture. If a fluorescent acceptor such as violanthrone[22] is added to the system, the overall light emission becomes much brighter. In this case, energy transfer from the singlet oxygen occurs, and since violanthrone is far more efficient in fluorescence than the various emitting forms of oxygen, more light is produced.

A number of gas phase chemiluminescent reactions occur in the upper atmosphere. Perhaps the most studied is the "air afterglow", which was first noted as a long lived yellow-green emission from electrical discharges in air. The afterglow involves an emission from excited nitrogen dioxide[23]. This reaction is used as a secondary standard for measuring quantum yields in chemiluminescence[24, 25] and as a means of measuring the concentrations of oxygen atoms[26].

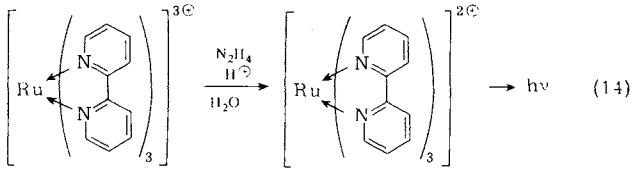
$$NO + O \rightarrow NO_2^* \rightarrow h\nu \qquad (12)$$

3.2. Chemically Produced Excited States by Electron Transfer



The formation of excited states by electron transfer has proven to be an excitation method of wide applicability. In this

(13)



method, excited states are formed by the removal of an electron from a radical anion [eq. (13)], by the addition of an electron to a radical cation, or by cation-anion annihilation[27, 28]. In most of the cases studied, the excited state is capable of light emission and the overall process represents a simple example of chemiluminescence.

The precursor radical anions are usually prepared by the reaction of alkali metals with aromatic and heterocyclic compounds. Oxidation of the anions thus generated (to yield excited states) is often carried out with benzoyl peroxide *(1)* or Wurster's blue perchlorate *(2)*, although many other oxidizing agents have been used.

(1) *(2)*

Radical cations can be prepared from aromatic and heterocyclic compounds by oxidation with sulfuric acid, silver ion, *etc.* Reduction of the radical cations then leads to excited states, a wide variety of reducing agents having been used. In a reaction related to the reduction of radical cations, metal chelates such as tris(2,2'-bipyridyl)ruthenium(III) have been reduced with hydrazine [eq. (14)] or aqueous base to give chemiluminescence[28].

(14)

Radical anions and cations can also be formed electrolytically. The excitation step (anions $-1e$; cations $+1e$) can also be carried out at electrodes, and where controlled potential techniques are applicable, the energy input can be set at any value over a continuous range. The electrolytic method may simplify the chemiexcitation process by reducing the number of reagents in solution. However, the introduction of an electrode means that the reaction is no longer homogeneous; adsorption and local concentration effects must therefore be taken into consideration. Alternating current electrolysis can be used for the alternating production of anions and cations at the same electrode[29]; this method increases the probability of cation-anion annihilation. In a double potential step experiment, potentials of the alternating current can be set independently of each other for maximum efficiency of production of the cations and anions[27]. Cation-anion annihilation has been studied using a.c. electrolysis on such compounds as anthracene, 9,10-diphenylanthracene, perylene, rubrene, quaterphenyl, and 1,1,4,4-tetraphenylbutadiene[29].

Two possible processes for electron transfer excitation involving a cation and an anion of the same compound are shown schematically in Figure 3[27]

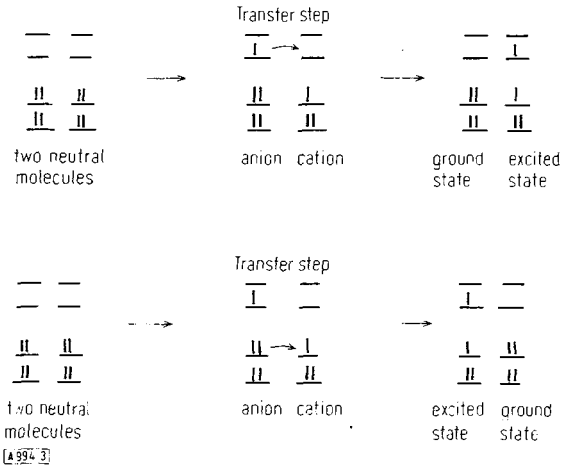


Fig. 3. Chemiexcitation *via* cation-anion annihilation.

Chemiexcitation *via* electron transfer may take more than one step, however. The multiplicity of the initial excited state is not known for any case, but the emitting species can be either a singlet or a triplet. Chemiluminescence has been observed from the following species during radical ion recombination reactions (where $A^{\ominus}$ is an anion and $C^{\oplus}$ is a cation)[30]: $^1A^*$, $^1C^*$, $^3A^*$, $^3C^*$, and $^1(A^{\ominus}C^{\oplus})^*$. In most cases, the spectrum of the light emitted matches the fluorescence spectrum of the emitting molecule, indicating that the emitter is an excited singlet. Triplet emission has been reported for the oxidation of the radical anions of phenanthrene *(3)*[31] and *N*-phenylcarbazole *(4)*[32a]. In the former case, it was

(3) *(4)*

proposed that efficient oxygen scavenging permitted detection of the phosphorescence. In the latter case, the emission may have been misidentified, since the observed emission is similar to the fluorescence of carbazole anion, which could have been formed by cleavage of the N—phenyl bond by the alkali metal used to make the radical anion[32b].

Electron transfer reactions represent a unique type of chemiexcitation in that the formation and destruction of chemical bonds are not involved in the excitation step[3]. Thus, this method would be expected to be a favorable case for the study of chemical excitation mechanisms. This process has been extensively studied, and several mechanisms have been proposed for the excitation process[27, 28, 33–35]. Cation-anion

$$A^{\ominus} + C^{\oplus} \rightarrow {}^1A^* + C \quad \text{(a)} \qquad (15)$$
$$A^{\ominus} + C^{\oplus} \rightarrow {}^1C^* + A \quad \text{(b)}$$

$$A^{\ominus} + C^{\ominus} \rightarrow {}^3A^* + C \quad \text{(a)}$$
$$A^{\ominus} + C^{\ominus} \rightarrow {}^3C^* + A \quad \text{(b)}$$
$$^3A^* + {}^3C^* \rightarrow {}^1A^* + C \quad \text{(c)} \qquad (16)$$
$$^3A^* + {}^3C^* \rightarrow {}^1C^* + A \quad \text{(d)}$$
$$^3A^* + {}^3A^* \rightarrow {}^1A^* + A \quad \text{(e)}$$
$$^3A^* + {}^3A^* \rightarrow {}^1C^* + C \quad \text{(f)}$$

annihilation, *e.g.*, could lead to an excited singlet directly [eq. (15)] or through annihilation of initially formed triplets [eq. (16)]. Cation-anion annihilation involving two different species may proceed *via* a charge-transfer complex [eq. (17)].

$$A^{\ominus} + C^{\oplus} \rightarrow (A \cdot C)^* \qquad (17)$$

One example of this type of charge-transfer complex is seen in the fluorescence emission observed from solutions of salts of the *N*-(2,6-dichlorobenzyl)quinolinium ion *(5)*, such as the iodide, bromide, thiocyanate, azide, or nitrite[36].

(5) *(6)*

In some cases[37], the energy produced by a single electron transfer reaction would appear to be insufficient to account for the energy emitted. A radical-ion aggregate mechanism involving multiple electron transfers with the transferred energy localized on one molecule (or ion) of the aggregate has been suggested to account for these observations[27, 34, 38]. *Freed* and *Faulkner*[35, 15b] have provided evidence for the intermediacy of the triplet state in the "energy-deficient" electron transfer reactions of fluoranthene *(6)*. Triplet-triplet annihilation could result in the formation of an excimer [eq. (18)] which could subsequently emit light. *Weller* and *Zachariasse*[39] have shown for a number of aromatic systems that sufficient energy should be available directly from electron transfer to populate the triplet but not the singlet excited state, thus favoring eq. (16) over eq. (15) for those cases. Furthermore, they observed dimethylanthracene excimer emission not due to excimers formed from excited singlet and ground state molecules [eq. (19)]. This observation suggests that the excimers were formed by triplet-triplet annihilation [eq. (18)], which in turn indicates the possibility of other triplet-triplet annihilation reactions forming excited singlets [eq. (16c), (16d) (16e) (16f)].

$$^3A^* + {}^3A^* \rightarrow {}^1A_2^* \qquad (18)$$

$$^1A^* + A \rightarrow {}^1A_2^* \qquad (19)$$

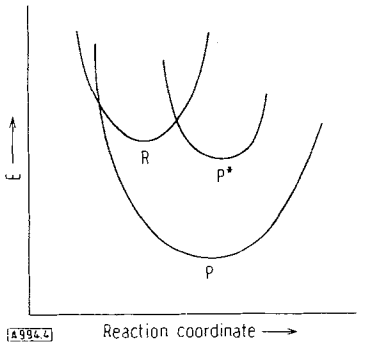
$$A^{\oplus} + A^{\ominus} \rightarrow {}^1A_2^* \qquad (20)$$

A third possible way of forming an excimer would be directly from the electron transfer reaction [eq. (20)]. Such an excimer mechanism has been suggested[40] for the oxidation of 9,10-diphenylanthracene radical anions. However, this process is probably not of major importance in producing chemiluminescence[41].

Chemiluminescence has been seen in double potential step experiments after one type of ion has been produced but before sufficient voltage has been applied to produce the ion of opposite charge. This "preannihilative emission" has been attributed to radical-ion aggregates, heterogeneous electron transfer at an electrode, or impurities in the solution[27, 41, 42].

Electron transfer reactions can lead to either ground state or excited state products depending on the configuration of the reactants, since the potential energy surface of the reactants may cross various product states at different configurational arrangements (Fig. 4)[28]. The probability of a particular reaction is related to the differences in free energy and configuration between product and reactant curves. The theoretical estimation of rates of formation of various products has been developed by *Marcus*[33] and reviewed by *Hercules*[41]. The expression for the rate constant is:

$$k = Z\kappa\rho\exp(-\Delta F^*/kT) \qquad (21)$$



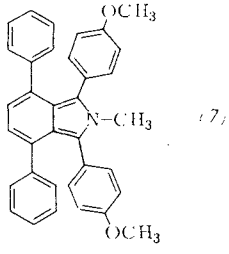


Fig. 4. Crossing between energy surfaces (R = reactants, P = products).

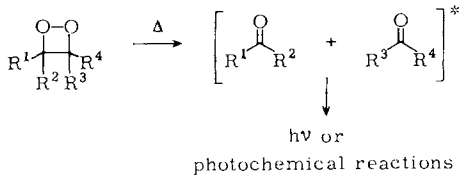
where Z is a diffusion-controlled rate constant, about 10^{11} l mol^{-1} s^{-1}, κ and ρ are usually about 1, and ΔF^* is an indication of the accessibility of the intersection [eq. (22)]:

$$\Delta F^* = w^r + \lambda/4\,[1+(\Delta F_R^{0'}/\lambda)]^2 \quad (a)$$
$$\Delta F_R^{0'} = \Delta F^{0'} + w^p - w^r \quad (b) \qquad (22)$$

In the above equations, w^r is the work required to bring the reactants together to the most probable separation distance in the activated complex, w^p is the work required to bring the products to the same separation distance, $\Delta F^{0'}$ is the standard free energy of the reaction under the given conditions, and λ is a reorganization term dependent on the differences in bond lengths and orientation polarization in the states just preceding and following electron transfer.

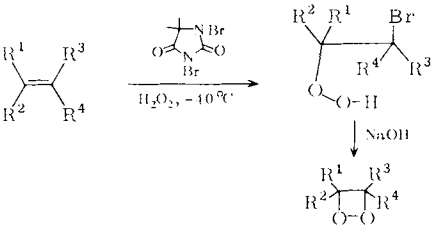
Early studies indicated that the quantum yields for such transfers were low. For example, a maximum efficiency of 0.3% was reported for the conversion of electrical energy to light using 1,3-bis(4-methoxyphenyl)-*N*-methyl-4,7-diphenylisoindole *(7)*[27]. Since the fluorescence quantum



(7)

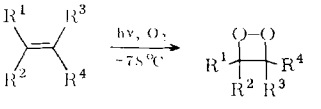
yield for this compound is 0.50, this figure corresponds to 0.6% efficiency for conversion of electrical energy to excited singlets. Recently, however, considerably higher quantum yields have been reported[43].

3.3. Chemically Produced Excited States from Dioxetanes



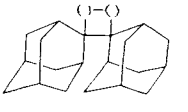
The important role of 1,2-dioxetanes in chemiluminescence has been established only recently. The dioxetane ring was first proposed as a critical intermediate in the oxygen-dependent chemiluminescent reactions of the lophines (arylimidazoles)[44], indoles[45], acridine compounds[46], peroxalates[47], and aminoethylenes[48], largely on the basis of the products formed and the likely pathways for their formation. Dioxetanes have also been proposed as intermediates in the bioluminescence of the firefly[49] and the crustacean *Cypridina hilgendorfii*[50].

In 1968, the first dioxetane was synthesized and characterized by *Kopecky* and *Mumford*[51]. They showed, also, that dioxetanes decompose to give excited states of the carbonyl products formed [eq. (23)], thus confirming the earlier hypothesis.



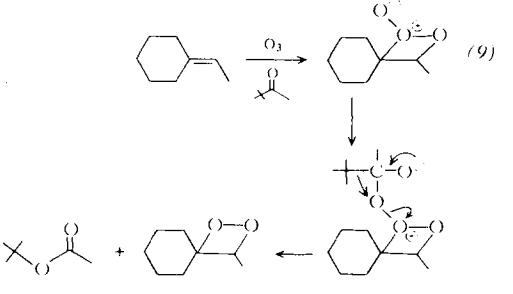
(23)

Several synthetic routes have been employed in the synthesis of 1,2-dioxetanes. The route of *Kopecky et al.*[52] involves the intramolecular displacement of a halogen by the hydroperoxide group [eq. (24)].



(24)

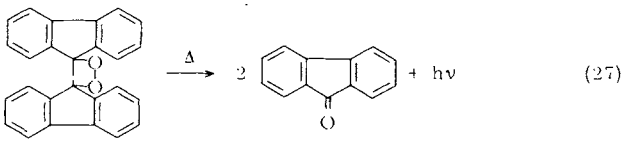
A second route utilizing singlet molecular oxygen was developed by *Bartlett, Schaap et al.*[53] and independently by *Foote* and *Mazur*[54]. They found that electron rich olefins lacking available allylic hydrogens react with singlet oxygen to give 1,2-dioxetanes [eq. (25)]. *Schaap* and *Bartlett* have also used triphenyl phosphite ozonide to imitate the singlet oxygen



(25)

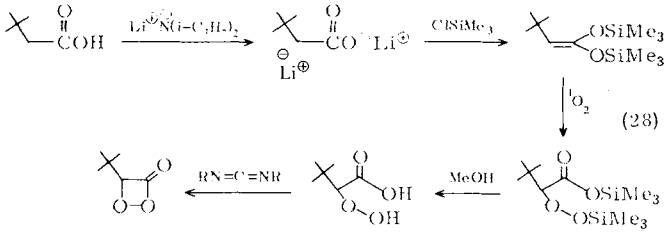
reaction with olefins[55]. Singlet oxygen generated by the methylene blue sensitization of molecular oxygen was used in the synthesis of peroxides of 2,2'-biadamantylidene *(8)*, a very

(8)



stable dioxetane[56]. Finally *Story et al.*[57] have reported that ozonolysis of olefins in solvents which readily undergo Baeyer-

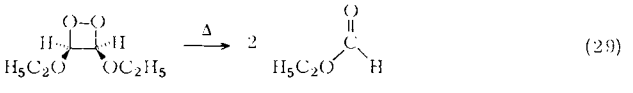
(9)



(26)

Villiger oxidation is a synthetic route to 1,2-dioxetanes. Their proposed mechanism postulates the molozonide *(9)*[58] described by *Staudinger* as the key intermediate [eq. (26)]. *Yang* and *Carr*[59] have reported using this method to synthesize the 1,2-dioxetane of 9,9'-bifluorenylidene, which according to the authors decomposes upon heating to give fluorenone and light [eq. (27)]. It should be noted, however, that *K. R. Kopecky et al.* have recently questioned the claim that dioxetanes are formed in ozonolyses[60].

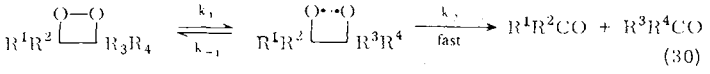
(27)



A derivative of a 1,2-dioxetane, a 1,2-dioxetanone, has recently been prepared by *Adam* and *Liu*[61] [eq. (28)]; however, efforts to isolate the compound in pure form were unsuccessful. Lastly,

(28)

Bollyky[67] has postulated the formation of 1,2-dioxetanones in chemiluminescence from the reactions of singlet oxygen with ketene and diphenylketene.



Kopecky and *Mumford*'s discovery that the thermal decomposition of 1,2-dioxetane leads to excited state carbonyl products prompted investigation into the nature of these products. *White*, *Wiecko* and *Wei*[4b] reported that the decomposition of trimethyl-1,2-dioxetane gave a 5% yield of a triplet carbonyl product based on the products formed. *Wilson* and *Schaap*[53d] studied the decomposition of *cis* diethoxy-1,2-dioxetane, which gives excited ethyl formate [eq. (29)]. They reported that

(29)

thermal decomposition was first order and gave the excited product in the triplet state (presumably *via* ethyl formate singlet precursors, cf. ref.[62]) with 20—100% yield based on observations of the sensitized fluorescence of dibromoanthracene and diphenylanthracene. Finally, *Turro* and *Lechtken*[62] have shown that the thermal decomposition of tetramethyl-1,2-dioxetane efficiently and selectively yields acetone triplets and that the triplets are not formed from excited singlet precursors *via* intersystem crossing. Their yield of singlet acetone was less than 1%, while the yield of triplet acetone was about 50% (error range ±50%).

Several explanations have been published in an attempt to rationalize why 1,2-dioxetanes should decompose thermally to give electronically excited products. *Rauhut*[47] has suggested that from energy considerations alone, it would appear that reactions involving a highly exothermic discrete step which directly yields small product molecules having few bonds capable of accepting vibrational energy could have potential for electronic excitation. Energy considerations alone do not explain all of the facts, however, for there are large complicated molecules (such as the luciferins) with many bonds and vibrational modes that form excited states *via* dioxetane intermediates[49, 50]. Thus, additional factors must be involved. Two mechanisms have been considered for the thermal decomposition of 1,2-dioxetanes: a biradical and a concerted mechanism. *Richardson et al.*[63] have proposed a biradical mechanism [eq. (30)] on the basis of rates of decomposition of dioxetanes

(30)

coupled with thermodynamic calculations. They proposed that in a two step mechanism—with the first step rate determining—resonance interactions by substituents would be unimportant, while these effects could influence the rate of the concerted mechanism where π-carbonyl character may be developed in the activated complex. This expectation was based on an analogy of the dissociation kinetics of alkyl-substituted cyclobutanes compared to acyl- and carboxyl-substituted cyclobutanes. *Richardson et al.* found that compounds *(10)* and *(11)* have the same rate: this result is consistent with the two step biradical process (Table 1).

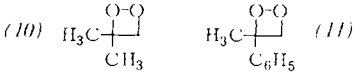


Table 1 [63]. Measured activation constants for the decomposition of *(10)* and *(11)*.

Cpd.	E_a [kcal/mol]	$\Delta H^{\neq}$ [kcal/mol]	$\Delta S^{\neq}$ [eu]
(10)	23.0±0.1	22.4±0.1	−5.0±0.2
(11)	22.9±0.2	22.3±0.2	−5.3±0.9

Values of the activation constants were also calculated and these were found to be in good agreement with the observed activation parameters (Table 2)[63].

Table 2 [63]. Calculated activation constants for the decomposition of *(10)* and *(11)*.

Cpd.	E_a [a]	$\Delta S^{\neq}, k_{-1}$ [eu]	$\Delta S^{\neq}$ [eu]	$10^4\ k$ [s^{-1}] 60°C
(10)	22.9	−5.4	−2.3	72
(11)	22.9	−5.9	−2.8	44

[a] kcal/mol with $E_{-1} = 8.5$ kcal/mol.

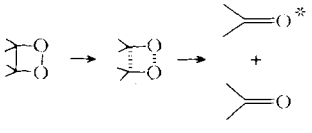
Richardson and *O'Neal* have calculated thermochemical and activation parameters for several methylated derivatives of 1,2-dioxetanes[64a, 66] and 1,2-dioxetanones[64b] based on the biradical two step mechanism. The calculations indicated that increased methyl substitution increases the stability of 1,2-dioxetanes. These authors have also calculated the available energies from the decomposition of 1,2-dioxetanes (Table 3). To reach an excited state, the sum of the heat of reaction for a 1,2-dioxetane giving carbonyl products ($-\Delta H_r^0$) and E_1 (the activation energy) must be equal to or greater than the energy difference between the 0 vibrational level in the

Table 3. Calculated available energies from the decomposition of 1,2-dioxetanes [64a, 66].

1,2-Dioxetane	ΔH_f^0 [kcal/mol] [a]	$(E_1 - \Delta H_f^0)$ [kcal/mol]
Unsubstituted	−55.4	76.9
1-Methyl	−58.8	80.5
1,1-Dimethyl	−61.1	84.0
1,2-*cis*-Dimethyl	−63.2	84.9
Trimethyl	−65.6	89.3
Tetramethyl	−68.8	93.5

[a] $\Delta H_r = H_f^0$ (1,2-dioxetane) $- \Delta H_f^0$ (carbonyl products).

first excited state of the carbonyl product and the ground state.



Richardson cites 81—87 kcal/mol[65] as this apparent threshold and shows that all but the unsubstituted dioxetane in Table 3 have sufficient energy[64a, 64b]. *Bollyky*[67] has independently calculated the decomposition energies of four dioxetane derivatives by the EHMO method (Table 4).

Table 4. Decomposition energy of dioxetanes as calculated by the EHMO method [67].

Dioxetane	Products	Calc. energy [kcal/mol]
Unsubstituted	Formaldehyde	−197
Tetramethoxy	Dimethyl carbonate	−206
-one	CO_2, formaldehyde	−184
-dione	CO_2	−132

He concludes that dioxetanes which contain at least one sp^2 carbon appear to have lower decomposition energies and thus have increased stabilities and lifetimes. However, *Adam et al.*[61a, 61b] have presented experimental evidence contrary to this conclusion.

The other major mechanism possible for the first order decomposition of 1,2-dioxetanes is the concerted mechanism. *McCapra*[3c, 68] suggested that the concerted decomposition of a 1,2-dioxetane should produce a carbonyl group in an excited state (antibonding) [eq. (31)], on the basis of ideas provided

(31)

by *Woodward* and *Hoffmann*[69] on orbital symmetry. *McCapra* suggested, further, that charge transfer might be playing a significant part in the excitation, perhaps allowing a mixing of states and providing a lower pathway for the excitation[3c]. Both *Kearns*[70] and *McCapra*[3c] have attempted to rationalize the decomposition of 1,2-dioxetanes by means of orbital correlation diagrams. *Kearns*' orbital correlation and state correlation diagrams for the decomposition of a 1,2-dioxetane are shown in Figures 5 and 6[70c]. According to the orbital correlation diagram, *Kearns* explains that the ground state electronic configuration of the dioxetane ($\ldots\sigma_{CC}{}^2\pi_{OO}{}^{*2}$) correlates with a highly excited electronic state of the carbonyl products[68, 70b]. "The lowest excited singlet and triplet states with electronic configuration $\ldots\pi_{OO}{}^{*1}\sigma_{OO}{}^{*1}$ are, however, stabilized by cleavage of the O—O bond"[70c]. As shown in the state correlation diagram (Figure 6), there is a crossing of curves which would allow the dioxetane to go over into an excited state of the product. While small distortions from C_2 symmetry would prevent crossing of the ground state curve with an excited singlet state, crossing of an excited triplet state curve could occur. *Kearns* suggests that one of the carbonyl ketones may be left in an excited triplet state as a result of the curve crossing, and that dioxetanes should be photochemically unstable with respect to cleavages.

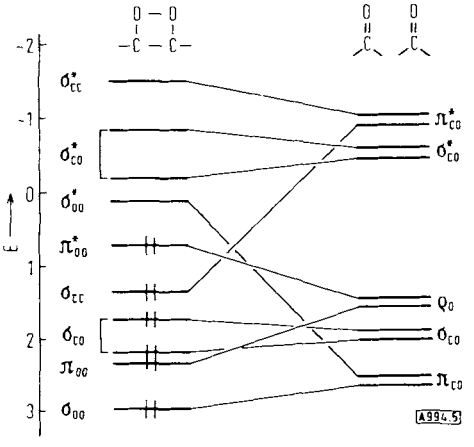


Fig. 5. Orbital correlation diagram depicting the cleavage of a 1,2-dioxetane into two carbonyl fragments (reprinted from [70c]).

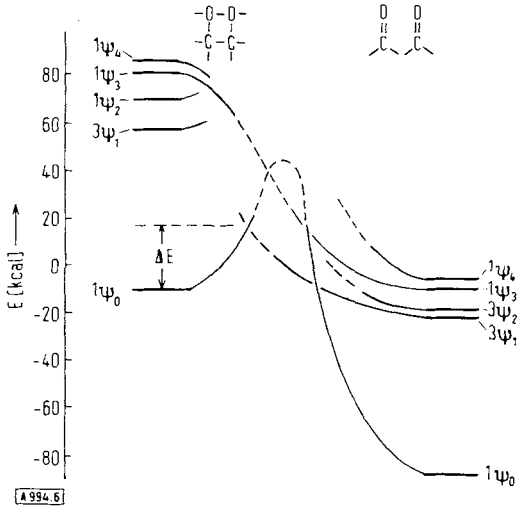

Fig. 6. State correlation diagram depicting the cleavage of a 1,2-dioxetane into two carbonyl fragments (reprinted from [70c]).

Turro and *Lechtken*[71a] have presented further evidence in support of the concerted mechanism. They argue that the biradical mechanism should exhibit four characteristics: an entropy effect, a negative substituent effect, a solvent effect, and a statistical effect. They report that only one criterion is actually observed (the negative substituent effect). Furthermore, they state that the biradical mechanism does not explain the basis for the high yield of triplet states. They propose a pericyclic mechanism in which the transition state becomes asymmetric at some point and thus lowers the prohibition to spin interconversion. In their analysis they apply the formalism of a spin-orbital coupling operator to help rationalize the formation of chemically produced excited states.

Doubt has been cast on their solvent effects recently, however, by *Wilson et al.*[71b]. These authors showed that tetramethyl-1,2-dioxetane decomposes by two competitive paths in meth-

anol and ethanol and that the faster reaction produces no excited states. The rapid "dark" reaction apparently involves an unknown catalyst present in trace amounts. The field of 1,2-dioxetane chemistry continues to be an active one[60, 71c-71f].

3.4. Miscellaneous Methods of Chemiexcitation

In addition to the better known methods of chemiexcitation listed above, a wide variety of methods are available for experimentation. Any reaction that is chemiluminescent can be pressed into service as a source of excited states. A large number of these reactions are covered in various reviews and books on chemiluminescence[3]. Specific mention should be made of the more efficient classes of chemiluminescent compounds such as the hydrazides, the acridine compounds, and the imidazoles. A large number of weakly chemiluminescent compounds were listed in an early article by *Trautz*[72]. No effort has been made in most of the cases to optimize the yields of excited states. This area of research is bound to be a fertile one in the near future.

4. The Transfer of Excitation Energy

4.1. Intermolecular Transfer

Excitation energy can be transferred intermolecularly from an excited donor (D*) to an acceptor (A) to form an excited state of the acceptor molecule (leaving the donor molecule in the ground state) [eq. (1)]. Several mechanisms for intermolecular energy transfer have been proposed. If light is emitted and is then reabsorbed by another molecule, the process is known as radiative energy transfer. Secondly, rigid samples (solids and glasses) may undergo (non-radiative) multiple transfers of excitons[73]. At least two other forms of non-radiative energy transfer can occur in solution[74, 75, 76].

One of these non-radiative processes is operative over only short distances (less than a few angstroms) when the molecules involved are "in contact". In this collisional or exchange mechanism, partial overlap of the electron clouds from two adjacent molecules allows an exchange of electrons, subject to spin selection rules. Collisional exchange has been given a theoretical treatment by *Dexter* and others[77]. An example of this process is the quenching of biacetyl phosphorescence by aromatic hydrocarbons such an anthracene[78]. An alternate explanation for collisional energy transfer reactions in solution involving the formation of a discrete intermediate from the donor and the acceptor has been proposed by *Schenck*[79]. One such intermediate would be a biradical formed during sensitized oxygen transfer[79b]. Further evidence for Schenck intermediates in certain cases has been obtained by *Saltiel*[79d] and by *Turro*[79e].

Resonance or coulombic energy transfer is a second general non-radiative process. Coupling of the oscillating electronic systems of two molecules (corresponding to the coupling of two mechanical oscillators) can result in long-range transfer of energy in solution. The theoretical aspects of resonance energy transfer[80a] have been developed by *Förster*[80b] and discussed by *Bennett* and *Kellogg*[80c]. The efficiency of resonance energy transfer is dependent upon the lifetime of the donor excited state, the distance between the donor and the acceptor, the spins and relative energies of the donor and acceptor states involved in the exchange, and, in some cases, orbital symmetry requirements.

Since energy transfer processes are in competition with other excited state decay mechanisms (emission, quenching), a favorable rate constant is necessary for the observation of energy transfer. The rate may be diffusion controlled for some exchange and resonance transfers[74].

According to current theory[74], resonance energy transfer could occur at separation distances of up to 100 Å. Energy transfer has been observed for distances up to 67 Å[81]. At such distances, multipole interactions greater than dipole-dipole are probably insignificant. For dipole-dipole interactions, the probability of exchange falls off as the inverse sixth power of the separation distance[80b]. Experiments carried out by *Kuhn et al.*[82] using paraffin to maintain a specific distance between monolayers of dyes have resulted in the observation of intermolecular energy transfer.

Energy transfer can occur from either a triplet or a singlet excited state and can produce an excited acceptor of either multiplicity, depending on the system. *Lamola*[76] has pointed out that the efficiency of resonance energy transfer should not be greatly affected by whether the donor transition is allowed or forbidden. Energy transfer has been observed for each of the following cases, where the multiplicities of the excited states are given: singlet-singlet (for example, energy transfer from anthracene to perylene[83a]), triplet-triplet (biacetyl to naphthalene[83b]), triplet-singlet (triphenylamine to chlorophyll a[83c]), and singlet-triplet (perylene to D_{10}-phenanthrene[83d]).

Energy transfer is most efficient when the excited state energy of the donor is nearly the same as the excited state energy of the acceptor. For vertical (Franck-Condon) transitions, overlap between the emission spectrum of the donor and an absorption band of the acceptor favors energy transfer[76]. Non-vertical triplet energy transfer[84] has been suggested to account for transitions that would be endothermic if only spectroscopic states were involved. A non-vertical transition indicates a distortion of molecular geometry to reach an excited state at a minimum energy point (Fig. 7). Proposals describing this distortion include twisting[84a], dissociation[84b], and some degree of bond formation with the donor, possibly in a manner related to the mechanism proposed by *Schenck*[79]. These proposals have been discussed by *Turro*[75] and *Lamola*[76].

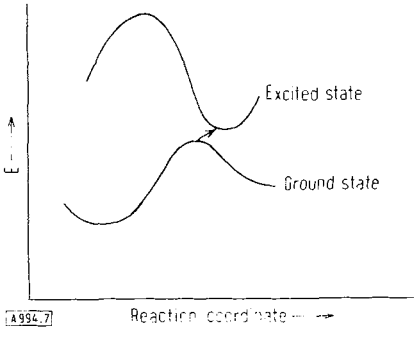

Fig. 7. A non-vertical transition.

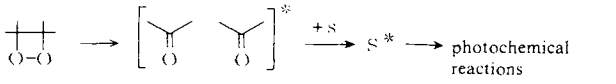
Orbital symmetry considerations are thought to be unimportant with respect to most exothermic energy transfers. How-

ever, it has been proposed[85] that when two or more energy transfer processes are in competition, orbital symmetry selection rules may favor population of one excited state over another. This hypothesis was put forward to explain results obtained for the photosensitization of lactones; population of the π,π^* triplet appeared to be favored over the n,π^* triplet, in agreement with orbital correlation diagrams for face-to-face interaction between the sensitizer and acceptor molecules.

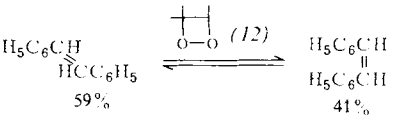
4.2. Intramolecular Transfer



Energy transfer between donor and acceptor moieties in the same molecule has been observed in chromophores including metal chelates[86] such as europium hexafluoroacetylacetonate and in organic molecules, with transfer occurring between such moieties as naphthalene and anthracene[87a]. Intramolecular energy transfer between independent moieties differs from intermolecular transfer only in proximity and orientation effects. The efficiencies of triplet and singlet energy transfer have been measured in some cases[87b] and the rates of energy exchange calculated. Intramolecular energy transfer has recently been observed using the cycloaddition of a norbornylene moiety (acceptor) to a benzene moiety (donor)[87c]. Other workers have studied chromophores in rigid systems[88] in order to determine the effects of distance and orientation on intramolecular energy transfer. Rate data suggest that the exchange mechanism may be operative in some cases[89] while more rigid systems[88c] may involve coulombic or other interactions.

Energy transfer provides a means of producing excited states that are difficult or inconvenient to reach by direct photochemical methods. For example, it can be used to advantage where the absorption band of the molecule of interest overlaps the absorption band of some other component of the system[90a,90b]. Energy transfer introduces the possibility of using chemically produced excited states (rather than photo-produced excited states) in biological[90c] as well as chemical systems (see Section 5).

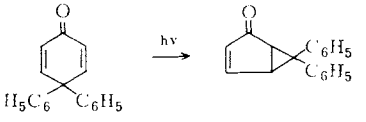
5. Uses of Chemically Produced Excited States



5.1. Chemical Applications

Chemically produced excited states can, of course, undergo "photochemical" changes directly. Precursors could be designed to yield the desired excited state, although with some difficulty. A more useful, and general approach utilizes energy transfer. For example, the decomposition of dioxetanes yields excited states of carbonyl compounds, which under appropriate conditions can transfer the excitation energy to substrates (S), the excited states of which are desired [eq. (32)].

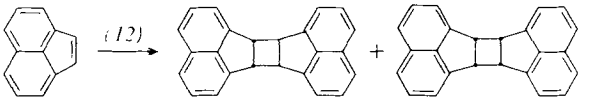
(32)



White et al.[4] have used the decomposition of trimethyl-1,2-dioxetane *(12)* to sensitize various reactions, each of which had been extensively studied through the use of photon excitation. In all the cases studied, it appeared that reactions of the triplet state were involved. When either *cis* or *trans* stilbene was heated in benzene with the dioxetane, isomerization was observed and a "photostationary" state was obtained consisting of ≈41% of the *cis* isomer and ≈59% of the *trans* [eq. (33)]. An overall quantum efficiency of about 4% was found for the

(33)

reaction. Quenching with cyclooctatetraene resulted in a drastic reduction of the apparent quantum yield, (0.04%) and in general, low dioxetane concentrations and high stilbene concentrations increased the apparent quantum yield.



The principle of "photochemistry without light" was also applied to the photoisomerism of 4,4-diphenylcyclohexadienone [eq. (34)][4a,4b].

(34)

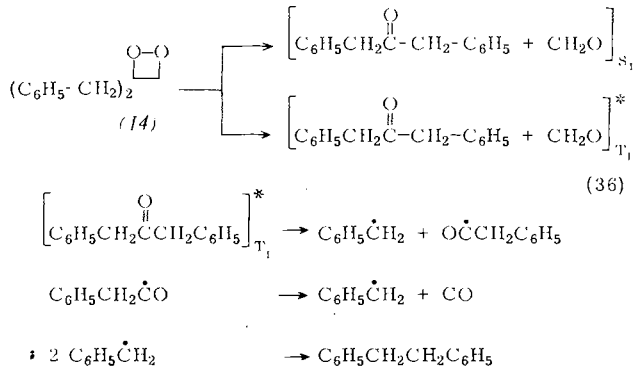
The apparent quantum yield of this reaction was 0.4%. The triplet state of the dienone (involved in the rearrangement) was reported to be 69 kcal/mol[91]; thus quanta of approximately this energy are available from the decomposition of trimethyl-1,2-dioxetane.

The dimerization of acenaphthylene *(13)* using trimethyl-1,2-dioxetane *(12)* as a chemical sensitizer was also reported [eq. (35)][4b]. Both *cis* and *trans* isomers were formed, the

(13)

(35)

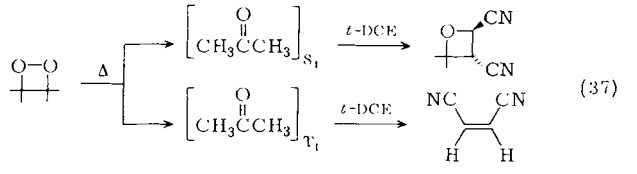
ratio suggesting that triplet excited states were involved. The reaction was strongly quenched by cyclooctatetraene, as expected.



The usefulness of the concept of photochemistry through chemically produced excited states is exemplified by the following simple procedure. A solution of the dioxetane and acenaphthylene is heated in steam for about ten minutes; on cooling, crystals of the *trans* dimer separate. The apparent quantum yield is a simple function of the chemical yield.

In addition to the above transformation, trimethyl-1,2-dioxetane has also been used to sensitize the conversion of santonin to lumisantonin (see Section 5.2).

Richardson et al.[92] have shown that the thermal decomposition of 3,3-dibenzyl-1,2-dioxetane *(14)* produces bibenzyl and dibenzyl ketone in 2.2% and 88% yield, respectively.

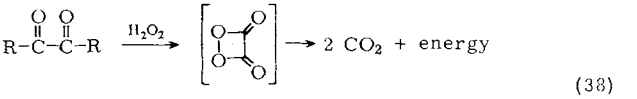


Bibenzyl is presumably formed from triplet dibenzyl ketone in a Norrish Type I process [eq. (36)].

In another interesting example of the use of chemically produced excited states, *Turro* and *Lechtken*[62] have "titrated" the excited states from the decomposition of tetramethyl-1,2-dioxetane with dicyanoethylene. The reaction of excited singlet

(36)

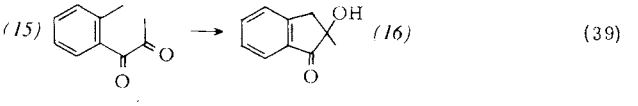
and triplet acetone with *trans*-1,2-dicyanoethylene (*t*-DCE) produced two different products [eq. (37)]. These authors



(37)

have also reported that tetramethyldioxetane sensitized the conversion of 1,2-diethoxyethylene from the *cis* to the *trans* form and that thermolysis of the dioxetane in the presence of norbornene produced norbornene dimers.

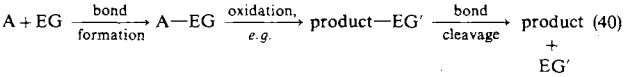
White and *Wildes*[4d] have used chemically produced excited states and energy transfer to produce chemiluminescence. They used trimethyl-1,2-dioxetane to sensitize the fluorescence of lanthanide chelates in solution. When 1,10-phenanthroline-tris[1-(2-thienyl)-4,4,4-trifluoro-1,3-butanedionato]europium-(III) was used as the fluorescent acceptor, at least 80% of the light emitted appeared in a band having a total width of 5 nm. This very narrow band emission allows the system to be used as a chemical source of "monochromatic" light devised to generate a specific number of photons.



Güsten and *Ullman*[93] have performed "photochemistry without light" using oxalic acid derivatives and hydrogen peroxide to sensitize the reactions. It has been proposed that the oxalate-hydrogen peroxide reactions yield 1,2-dioxetanedione, which subsequently decomposes to give excited products [eq.

(38)

R = 2,4-$(NO_2)_2C_6H_3O$ or 2,4,6-$Cl_3C_6H_2O$



(38)][47]. They have used this method to transform 1-(*o*-tolyl)-1,2-propanedione *(15)* to the known photoproduct, 2-hydroxy-2-methylindanone *(16)* [eq. (39)].

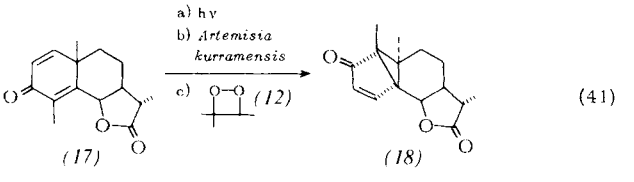
(39)

A chemical sensitization efficiency of 0.006 was reported for the reaction. They have also used this method to convert phenanthraquinone and ethyl vinyl ether to the known photoadduct and have converted *trans*-4-methoxy-4'-nitrostilbene to the *cis* form with a chemical sensitization efficiency of 0.045.

All of the above examples of the uses of chemically produced excited states utilize intermolecular energy transfer. In situations where only low concentrations of reactants are desirable, intramolecular energy transfer may be an answer. One can generalize this approach: intramolecular energy transfer from one of the energy generators (EG) used in chemiluminescence to an acceptor molecule (A) attached by a labile bond to the energy generator [eq. (40)][4a].

(40)

5.2. Possible Biological Uses



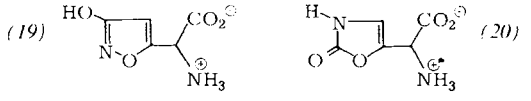
A large number of living organisms are known to produce electronically excited states[94a]; light emission from these chemically produced excited states occurs in the bioluminescence of organisms such as the firefly (Fig. 2, paths 1 and 3). Since chemically produced excited states have been shown to undergo "photochemical" changes in addition to light emission (Section 5.1), it appears reasonable to assume that both pathways will also be available to biochemically produced excited states. That is, chemically produced excited states may be playing a chemical role in biological systems[4c, 94b].

Biochemically produced excited states will presumably be found operating in dark (non-photochemical) reactions that appear, superficially, to be photochemical reactions. Several criteria must be satisfied for a convincing demonstration of the occurrence of "photobiology without light": (1) the organism should contain two or more compounds (A, B,...) that are related by the action of light *in vitro* (A + hν → B); (2) the compounds A and B must not be interconvertible in ground state reactions; (3) the organism (or enzyme system) must be able to convert A into B in the absence of light.

Since the rigor of criterion 2 is dependent on the state of the art and since enzymes might be able to catalyze ground and excited state reactions unknown to the synthetic chemist, additional criteria would be desirable: *e.g.*, the pathways for the biosynthesis of A and B should be known, and the conversion of A into B should be demonstrable with isolated enzyme systems. We will now summarize our preliminary work in this area and list cases where it seems *possible* that biochemically produced excited states are involved in biochemical transformations.

5.2.1. Simple Chemical Conversions

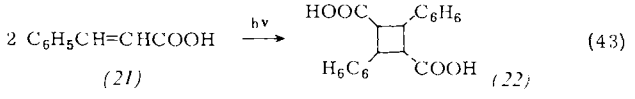
The first example concerns a pair of compounds found in various species of *Artemisia*[95,96]: the sesquiterpene lactone, santonin *(17)* and its photoisomer, lumisantonin *(18)* [eq. (41)] (which is readily made from *(17)* by the action of light).



(41)

White and *Wei*[4c] have recently employed chemically produced excited states in a biogenetic type transformation of santonin to lumisantonin. The excited states resulting from thermolysis of trimethyldioxetanes were used to sensitize the reaction [eq. (41c)]. Investigation of the *in vivo* conversion in *Artemisia kurramensis* indicates, however, that at least part of the reaction is photochemical[97]. Surprisingly, examples of simple photobiological transformations such as the santonin-lumisantonin conversion are not very numerous. One other example has been well documented by *Haskins, Gorz*, and *Williams*; these authors found that the conversion of *trans* to *cis*-β-D-glucosyl-*o*-hydroxycinnamic acid in *Melilotus alba* was sunlight mediated [eq. (42)][98].

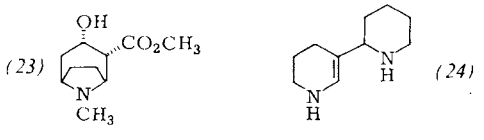
(42)



In their communication, *White* and *Wei* enumerated several other cases where a natural product and its photochemical conversion products have been isolated from the same species[4c]. It was noted that *Eugster et al.*[99] isolated both ibotenic acid *(19)* and muscazone *(20)* from various species of the

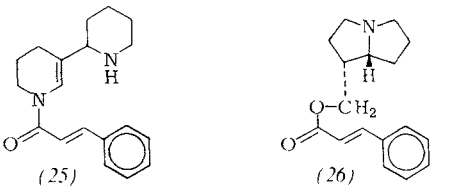
(19) *(20)*

mushroom *Amanita*. Ibotenic acid can be photochemically converted to muscazone *in vitro*; *Eugster* estimated that the amount of light available to the mushroom was insufficient for the *in vivo* conversion, however. One possible alternative would involve a photoisomerization sensitized by an enzymatically generated excited state.



The biosynthesis of cyclobutanes is another biological process which may involve the use of chemically generated excited states. Cyclobutanes can be readily made by the photochemical dimerization of alkenes [*e.g.* eq. (43)]. Both cinnamic acid *(21)* and truxillic acid *(22)* derivatives have been isolated

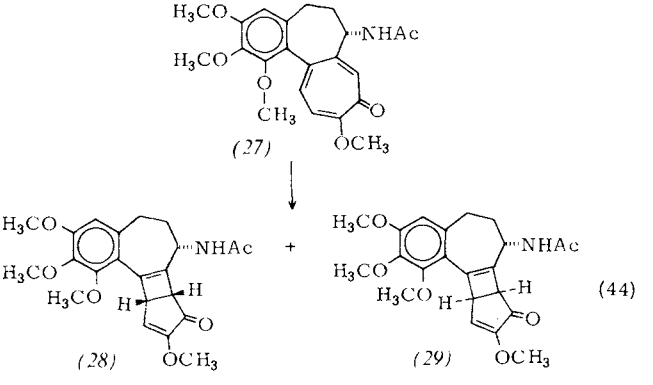
(43)



(21) *(22)*

from various organisms. *Liebermann*[100] and *Hesse*[101] independently isolated truxillic and truxinic acids following acid hydrolysis of the leaves of *Erythroxylon coca*. The dimers occur in the plant as the truxillates and truxinates of (−)-ecgonine methyl ester *(23)*. The cinnamoyl monomer was also isolated from the same plant.

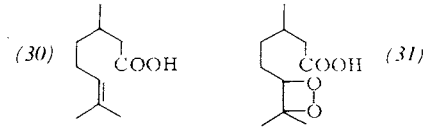
(23) *(24)*



Another naturally occurring alkaloid derivative of α-truxillic acid *(22)* is santiaguine, isolated from *Adenocarpus* species[102]. Santiaguine is the diamide of α-truxillic acid and 1,4,5,6-tetrahydroanabasine *(24)*. It has recently been shown

(25) *(26)*

by ^{14}C labeling studies that the cinnamoyl monomer orensine *(25)*[*], is a precursor of santiaguine in *Adenocarpus foliosus*[103]. Similarly, thesinine *(26)* and its cyclobutane dimer, thesine, have been isolated from *Thesium minkwitzianum*[104]. The most recently reported truxillic acid derivative is gratissimin, which is the dimethyl ester of α-truxillic acid[105]. The biosynthesis of other cyclobutanes such as α- and β-pinene and caryophyllene may also occur *via* the intermediacy of biochemically generated excited states.

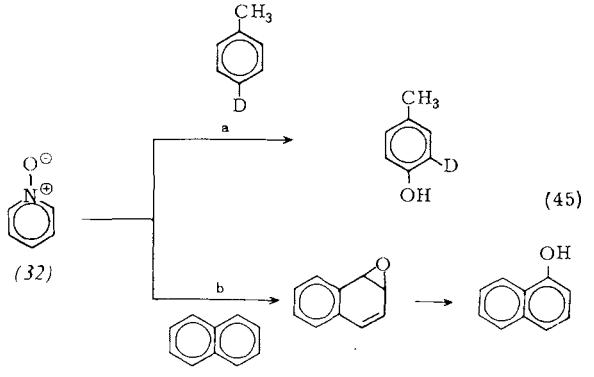


The conversion of colchicine *(27)* into the lumicolchicines *(28)* and *(29)* [eq. (44)] is another reaction in which biochemically generated excited states may be involved. Colchicine and both β- and γ-lumicolchicine [*(28)* and *(29)* respectively] have been isolated from *Colchicum autumnale* and furthermore, colchicine can be converted into the lumicolchicines *in vitro* with light[106].

(27)

(28) *(29)* (44)

Lamola has used the electronically excited states derived from the decomposition of trimethyldioxetane *(12)* to dimerize pyrimidine residues in *E. coli* DNA[107]. The analogous photochemical dimerization of pyrimidine bases is responsible for the lethal effects of short wavelength UV light on organisms[108]. It is interesting in this connection, but disappointing, that trimethyldioxetane, 4-*n*-butyl-3,3-dimethyldioxetane and the 1,2-dioxetane analog *(31)* of the naturally occurring monoterpene, citronellic acid *(30)*, showed no activity in tests for mutagenicity with the bacteria *Salmonella typhimurium*[109].

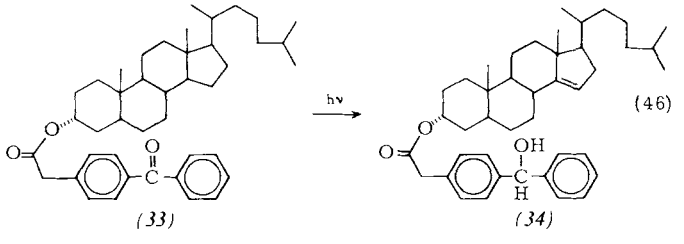


(30) *(31)*

It has been shown that organisms can repair photochemically damaged DNA by an enzyme-catalyzed light-dependent monomerization of the cyclobutane pyrimidine dimers. *Cook*[110] has examined the phylogenetic distribution of the photoreactivating enzyme and has found the photorepair activity occur-

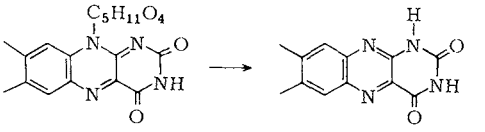
[*] Called "adenocarpine" for the optically active form; Ref. [103].

ring in nocturnal animals (*e.g.*, adult land crab) and in tissue shielded from external radiation (*e.g.*, opossum liver)[111]. The occurrence of photoreactivating enzyme activity in tissue where no light is available (under normal circumstances) is an indication that the excited states needed for the monomerization may be generated chemically. In this connection, however, *Cook* and *Setlow* have both been unsuccessful in their attempts to demonstrate under conditions of darkness the repair of photodamaged DNA using cell extracts known to contain photoreactivating activity[111].



Recently *Jerina*, *Boyd*, and *Daly*[112] have devised a photochemical model for enzymic oxygenations. These workers proposed that a photochemical oxygen atom transfer from pyridine-*N*-oxide *(32)* was a model for enzymatic oxygenations in that it fulfilled the requirements of hydroxylation (eq. (45), paths a and b), NIH shift[*] (path a) and epoxidation (path

(32) (45)



b). Theoretical support of the photochemical model was provided by *Kumaki et al.*[113], who found that the position of enzymic hydroxylation of aromatic compounds is in agreement with calculated parameters for a nucleophilic attack on the first electronic excited state. It is possible that biochemically produced excited states may be involved in the *in vivo* process.

Another photochemical model for a biological process has recently been reported by *Breslow*[114]. It was found that a properly oriented benzophenone triplet could mimic the ability of certain enzymes to oxidize unactivated methylene groups. For example, the photolysis of the benzophenone-4-acetyl ester of 3α-cholestanol *(33)* led to the 14-alkene [*(34)*, eq. (46)].

(33) *(34)* (46)

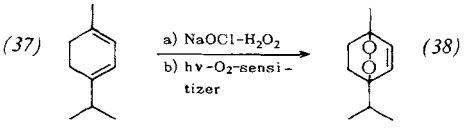
Other biosyntheses which may involve chemically generated electronically excited states are[4d]: 1) the bioformation of lumichrome [eq. (47)], a compound synthesized *in vitro* by the irradiation of riboflavin[115]; and 2) the biogenesis of vitamin D in fish. In the latter case, *Bills* found that neither sunlight nor the food ingested could account for the quantities of vitamin D in cod or catfish[116]. Further, it has been pointed

(47)

out that the amount of vitamin D in the black-backed flounder exceeds the amount that could be formed in a purely photochemical pathway by the total light absorbed by the flounder[117]. In this connection, *Blondin*, *Kulkarni*, and *Nes* have shown that vitamin D can be synthesized from dehydrocholesterol by fish liver homogenates incubated in the dark[118].

Chemically generated excited states may also be involved in the dark regeneration of the biological clock pigment, phytochrome, from the far-red absorbing form[119] and in the dark regeneration of 11-*trans*-retinal from the *cis* form in the visual process[120]. Lastly, the photoactivation of enzymes such as urocanase should be examined in the context of biochemically produced excited states[121].

Chemically produced excited states have been specifically invoked in two instances recently. *Pettus* and *Moore* suggested that biochemically generated excited states may be involved in the biosynthesis of dictyopterene B *(36)* in the algae *Dictyopteris*[122]. The authors noted that the cyclopropane ring of dictyopterene B "may be formed by an enzymatically controlled and photochemically induced (with or without light) di-π-methane rearrangement" of a fatty acid homolog of *(35)*.

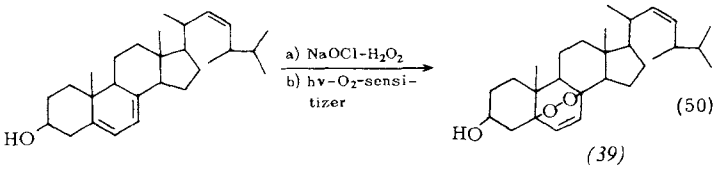


(35) *(36)* (48)

Buu-Hoï and *Sung* have proposed that biochemically generated electronic excited states may be involved in the carcinogenic activity of polynuclear aromatic hydrocarbons[123]. It has been shown that aromatic hydrocarbons combine with DNA under photochemical conditions[124]; further, *Santamaria et al.* have demonstrated that light enhanced the carcinogenicity of the polynuclear aromatic hydrocarbon benzopyrene in mice[125]. The suggestion of *Buu-Hoï* and *Sung* then is that the carcinogenic aromatic hydrocarbons are converted to their electronically excited states and that these react with cellular substrates such as proteins and DNA.

5.2.2. Singlet Oxygen

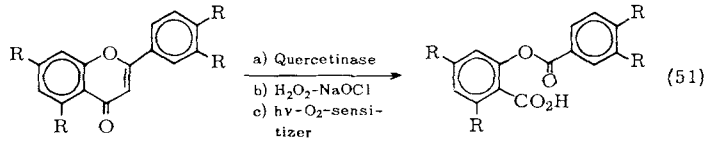
Oxygen in its electronically excited singlet state has been generated chemically from superoxide ion[126a] and from hydrogen peroxide[126b] (see also Ref. [16c]).



The oxidation of hydrogen peroxide by hypochlorite resulted in the formation of excited singlet oxygen which gave the same products as photochemically generated singlet oxygen.

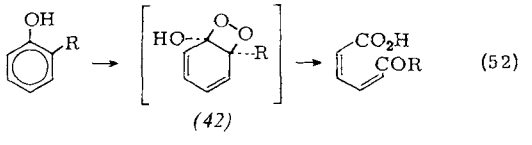
(37) *(38)* (49)

[*] The effect whereby substituents on benzene rings are displaced to a neighboring position by the incoming hydroxy group in enzymic oxygen transfers has been named by its discoverers as "NIH shift", after their place of work (National Institutes of Health).



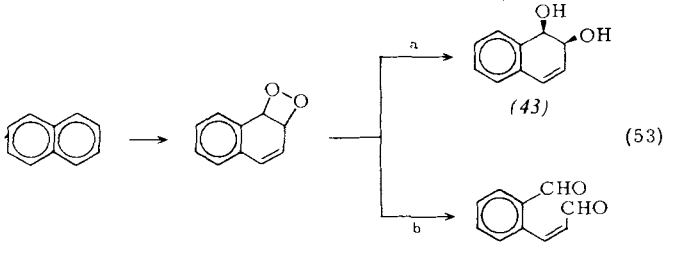
For example α-terpinine *(37)* yielded the endoperoxide ascaridole [*(38)*, eq. (49)], which is the chief constituent of the oil of *Chenopodium*[127]. Similarly, the endoperoxide of ergosterol was formed both by photooxygenation and by reaction with chemically generated singlet oxygen [eq. (50)][126b]. The

(39)



endoperoxide of ergosterol *(39)* is especially interesting because it has been isolated from a mold grown in the dark[128]; analogous dehydrocholesterol endoperoxides have been isolated from mammalian liver[129].

Matsuura et al.[130] have used the hypochlorite-peroxide reaction as a model for the dioxygenase, quercetinase, which converts the flavone quercetin *(40)* to acid *(41)* [eq. (51)].



(40) *(41)*

Singlet oxygen has also been implicated in the cleavage of aromatic nuclei by dioxygenases[131]. The reaction is thought to proceed *via* a dioxetane intermediate [*(42)*, eq. (52)][131].

(42)

Analogous dioxetane intermediates have been postulated in the chemiluminescence of polyacene endoperoxides[132]. Evidence for the *in vivo* intermediacy of the dioxetane originates from the isolation and identification of *cis*-1,2-dihydro-1,2-naphthalenediol *(43)* from several strains of bacteria[133]. It should be pointed out that the decomposition of the dioxetane [eq. (53), path b] could lead to the generation of useful excited states. *Cis*-diols similar to *(43)* have been isolated in the microbial metabolism of benzene[134] and benzoic acid[135], and analogous dioxetane precursors have been proposed.

(43)

Recently, *Allen et al.* observed chemiluminescence from human polymorphonuclear leucocytes during phagocytosis[136]. They proposed that the bactericidal activity of polymorphonuclear leucocytes was due to chemically generated singlet oxygen. In addition, *Chan* has detected singlet-like oxygenation activity in enzyme systems[137, 138]. Horseradish peroxidase was found to convert 1,3-diphenylisobenzofuran to *o*-dibenzoylbenzene, the product observed from photosensitized oxygenation of the parent furan[137]. Similarly, the oxygenation of 1,3-dienes by soybean lipoxidase was reported[138]. Other examples of the involvement of singlet oxygen in biological systems have recently been reviewed[139].

5.2.3. Complex Cases

It would be interesting to see whether chemically produced excited states can be used to replace some or all of the light required for complex photobiological processes such as photosynthesis, phototaxis, photoperiodism (*e. g.*, action on the pineal gland), and visual processes. In preliminary work, we have been unable to initiate "light" dependent chlorophyll synthesis in dark grown *Euglena* with trimethyl-1,2-dioxetane and with 4-*n*-butyl-3,3-dimethyl-1,2-dioxetane[140]. In addition, trimethyl-1,2-dioxetane applied to one side of an etiolated oat seedling did not give a "phototropic" response in darkness[141].

Lastly, generators of electronically excited states such as the dioxetanes may provide a unique mode of drug action since they can deliver excited states to internal organs that are normally inaccessible to light.

6. Conclusion

Chemically generated excited states can be produced efficiently, and utilized to drive "photochemical" reactions. The technique can be useful in that the procedures are simple, simple apparatus is sufficient, and apparent quantum yields can be determined from yield data. In bifunctional molecules used for energy transfer studies, only the chemical method of excitation insures that all the excitation energy resides initially in the donor portion of the molecule; this factor can be important when there is considerable overlap between the absorption spectra of the donor and acceptor. Finally, studies of chemically produced excited states will yield background information which may lead to the discovery of like phenomena in biological systems[*].

We thank the U. S. Public Health Service for its financial support (Grant 5R01 7868), and Dr. G. Cilento for a preprint of his review article[*].

The Crystalline State of Macromolecular Substances

By H. G. Zachmann[*]

Unlike low molecular weight substances, high polymers do not crystallize completely. However long the crystallization process is continued, they still consist of a mixture of crystalline and noncrystalline regions. In the undrawn material, these regions form larger units which are known as spherulites. Questions that are of special interest concern the arrangement of the chains in the noncrystalline regions, the causes of chain folding, and the imperfections in the crystals. The incomplete crystallization is a consequence of kinetic inhibitions. This can be deduced from the fact that the crystalline fraction increases with rising crystallization temperature. If polymerization is carried out in the solid crystalline state, one obtains a completely crystalline polymeric material.

1. Introduction

Macromolecular substances are becoming increasingly important to science and technology as plastics, as fibers, and as bearers of the processes of life. Consequently they have been and still are the subjects of many investigations. We shall be concerned here with only one aspect of their properties, *i.e.* their crystallization behavior.

The study of the crystallization of macromolecular substances is of the utmost scientific interest, since it shows how the order in the crystal is affected if the molecules, instead of being small spheres as they are in low molecular weight substances, are long chains. However, crystallization processes are also of considerable importance to technology, since the mechanical properties of macromolecular plastics and fibers are strongly dependent on the crystallization conditions. Finally, crystal-like ordered states of macromolecules and their transitions are also important in biological processes.

2. The Crystalline State in Unoriented Material

2.1. General Survey

We shall first consider the crystalline state obtained under normal conditions, *e.g.* when a molten macromolecular substance is cooled to a temperature below its melting point. X-ray investigation of the crystalline structure formed in these circumstances yields a diffraction pattern (Fig. 1) with isolated, relatively broad reflections and a diffuse scattering that is often referred to as an "amorphous halo".

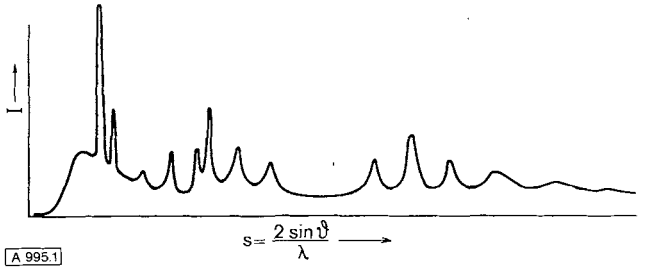

Fig. 1. X-ray large-angle scattering from crystalline polyethylene [1]. The scattering intensity I is plotted as a function of the quantity $s = \frac{2 \sin \vartheta}{\lambda}$, which is a measure of the scattering angle ϑ.

[*] Prof. Dr. H. G. Zachmann
Institut für Physikalische Chemie der Universität
65 Mainz, Jakob-Welder-Weg 15 (Germany)

How is this diagram to be interpreted? An ideally crystalline low molecular weight substance gives a large number of very sharp reflections and no diffuse background. The fact that crystal reflections are obtained for our material shows that some crystallization has occurred. At the same time, however, the small number of reflections and their relatively large half-width indicate that the crystallites are small and highly distorted. Finally, from the presence of the diffuse background, which agrees with the diffraction of the melt, it follows that noncrystalline regions are present as well as the crystallites. *When crystallized as far as possible, therefore, the macromolecular substance is a two-phase system of crystalline and noncrystalline regions.* This result is also confirmed by investigations with other methods, *e.g.* IR spectroscopy, density determination, calorimetry, and nuclear magnetic resonance[2].

An important parameter for the characterization of the two-phase system is the weight fraction of crystalline regions, known as the *crystalline fraction* or the *degree of crystallinity* α. The degree of crystallinity that can be reached is dependent on the crystallization temperature. The degrees of crystallization that can be attained at low temperatures are much lower than those obtained at higher temperatures. This suggests that crystallization remains incomplete for kinetic reasons. After part of the material has crystallized, the mobility of the parts of the chains that have not yet been incorporated into crystallites is so low that they can no longer become ordered. This is in agreement with the fact that an isothermal crystallization has no precisely defined end; the crystallization rate simply becomes steadily smaller, until finally no further crystallization takes place within a finite time.

Table 1. Maximum attainable degree of crystallization α_{max} of some polymers.

Substance	α_{max}
High-density polyethylene	95 %
Low-density polyethylene	70 %
Polyethylene terephthalate	70 %
Nylon 6	60 %
Atactic polystyrene	0 %

The degree of crystallization reached depends not only on the crystallization conditions but also on the chemical structure of the macromolecular substance. Molecules with a high degree of regularity coupled with very high chain mobility can crystallize to a much greater extent than molecules that

do not satisfy these conditions. To illustrate this, Table 1 shows the maximum degrees of crystallization attainable in a number of macromolecular substances. For example, polyethylene, which has very regular, highly mobile molecules, can reach a significantly higher degree of crystallization than polyethylene terephthalate, whose molecules contain rather immobile benzene molecules. Atactic polystyrene, whose molecules have an extremely irregular structure, cannot crystallize at all.

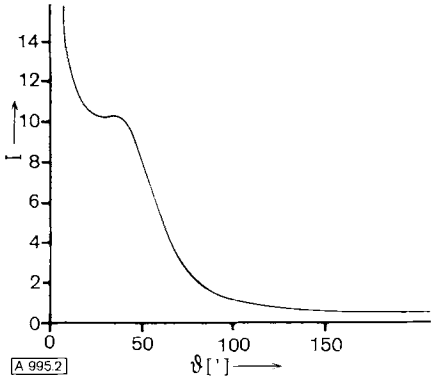

Fig. 2. X-ray small-angle scattering (arbitrary units) from crystalline polyethylene terephthalate. The scattering intensity I is plotted as a function of the scattering angle ϑ [3].

Further details regarding the semicrystalline structure are obtained from the X-ray small-angle scattering. An example of a scattering curve is shown in Figure 2. It shows diffuse scattering that decreases as the scattering angle increases, with a reflection (or in some cases two reflections) superimposed on it. The presence of the reflection is explained by periodic density variations in the material, which are attributed to an alternation of the crystallites and the noncrystalline regions (see Fig. 3). The distance between the centers of gravity of the crystallites, *i.e.* the *long period* L, can be found from the position of the reflection. These investigations lead on the whole to the following conclusions: The centers of gravity of the crystallites are separated by a fairly uniform distance L in the semicrystalline structure. The higher the crystallization temperature, the greater is this distance; it is generally between 50 and 500 Å.

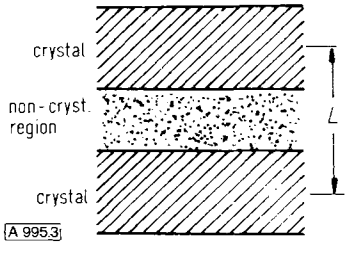

Fig. 3. Schematic representation of the arrangement of the crystallites and the noncrystalline regions. L = long period.

It is especially interesting to compare the above with the results of a microscopic investigation of the crystalline material. If a film about 100 µm thick is examined in polarized light between crossed Nicols, the specimen is found to be completely packed with spherulites. In the simplest case, these are radially symmetrical structures with a black cross. An example is shown in Figure 4. During the crystallization, these spherulites have grown from individual nuclei. They were initially spherical, and the irregular shapes developed only through mutual interference. The diameter of a spherulite is generally 5 to 100 µm. Since the distance between the centers of gravity of the crystallites is of the order of 100 Å, a spherulite consists of a large number of crystalline and noncrystalline regions. To explain the black cross mentioned above, it must be assumed that the crystallites are arranged in such a way that the chains are preferentially normal to the radius of the spherulite.

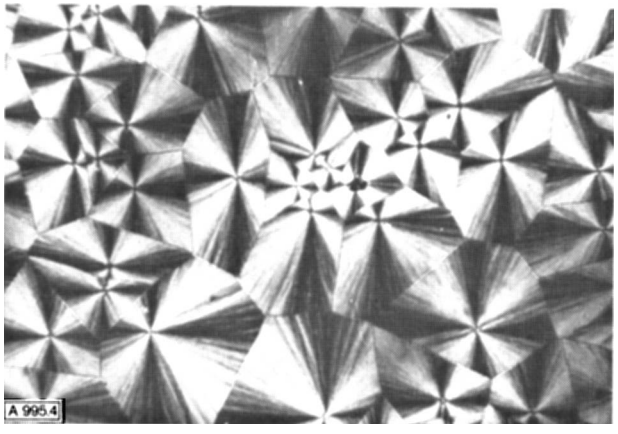

Fig. 4. Polarization micrograph of spherulites in a polyamide [4].

Further information about the fine structure of the spherulites is obtained by electron microscope studies. It is possible to distinguish two types of spherulite:

1. Spherulites built up from fibrils, *i. e.* long filament-like structures. A bundle of fibrils is clearly visible in Figure 5.

2. Spherulites built up from lamellas. The steps between the individual lamellas are clearly visible in Figure 6.

The height of the steps generally agrees with the distance between the centers of gravity of the crystallites as found from the X-ray small-angle scattering. The fibrils in Figure 5 are degenerate lamellas, *i. e.* lamellas that have grown much more strongly in one direction than in the other.

In addition to the simple spherulites shown in Figure 4, there are also spherulites that exhibit complicated birefringence phenomena, as illustrated in Figure 7. If the density of crystal nuclei is high, the spherulites may be so small that they cannot be resolved under the optical microscope. Instead

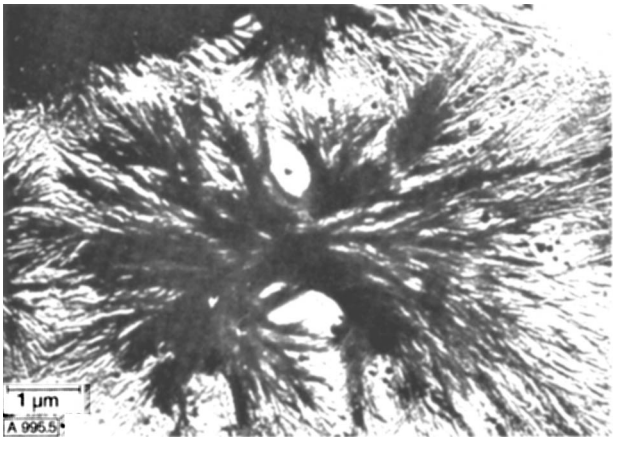

Fig. 5. Electron micrograph of a spherulite in a polyamide [5].

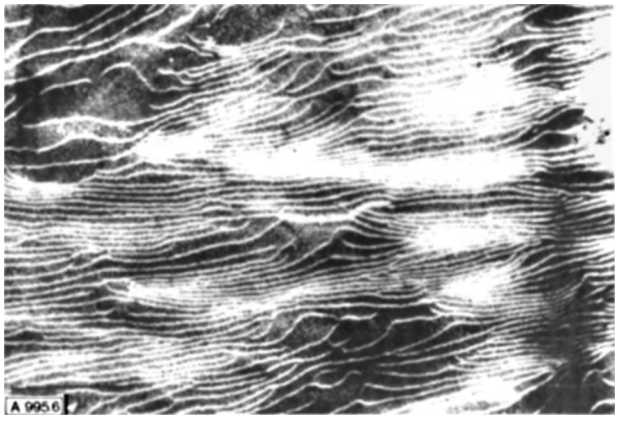

Fig. 6. Electron micrograph of part of a spherulite in high-density polyethylene [6].

of true radially symmetrical spherulites, other units, which may be regarded as precursors of spherulites, are often formed in this case.

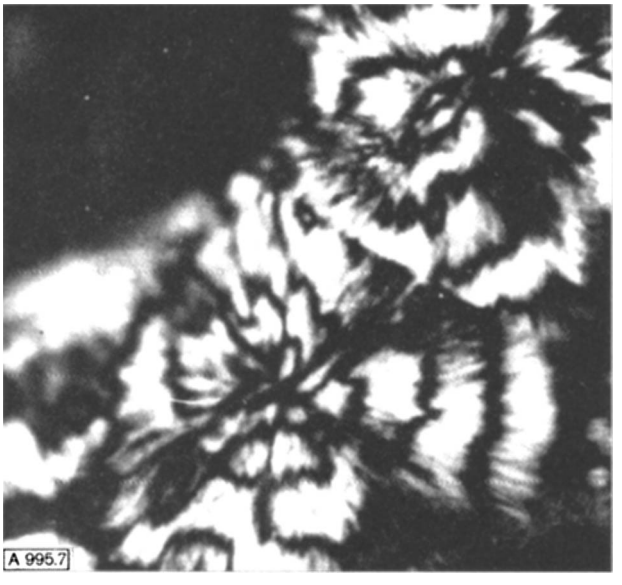

Fig. 7. Polarization micrograph of a spherulite in polyethylene terephthalate [7].

What model can now be given for the structure of a crystalline macromolecular substance? The construction from spherulites, which themselves consist of crystalline and noncrystalline regions, is shown schematically once again in Figure 8. The large polygons bounded by the longer straight lines are the spherulites, the shaded blocks are the crystallites, and the dotted areas are the noncrystalline regions. Figure 8 is not intended to provide any information about the size and position of the crystallites or the nature of the noncrystalline regions. The models that have been proposed are shown in Figure 9 for a small section of a spherulite in each case.

The earliest model is shown in Figure 9a. It shows crystallites that consist of chain segments stretched out parallel to one another, and noncrystalline regions that consist of chain segments passing from one crystallite to another. A lamella or fibril as observed in the electron microscope consists of a crystallite with the associated non-crystalline covering layer. In the second model (Fig. 9b), it is assumed that the chains are folded on the top surfaces and base surfaces of the crystallites; the noncrystalline regions are formed here by a few chain segments that do not fold. According to the last model (Fig. 9c), loops protruding from the surfaces of the crystallites form the noncrystalline regions. (For the sake of clarity, only two loops of this type are shown.) Folding of the chains as indicated in Figures 9b and 9c does not seem very likely at first sight. There is conclusive proof, however, that folding

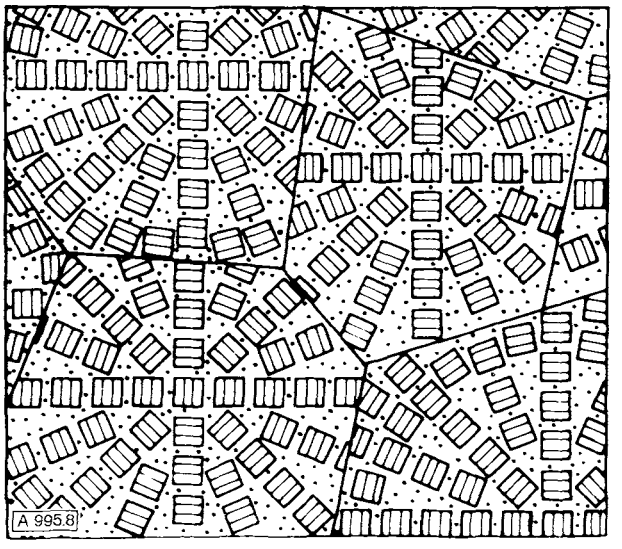

Fig. 8. Schematic representation of the manner in which a spherulite is built up from crystalline and noncrystalline regions [8].

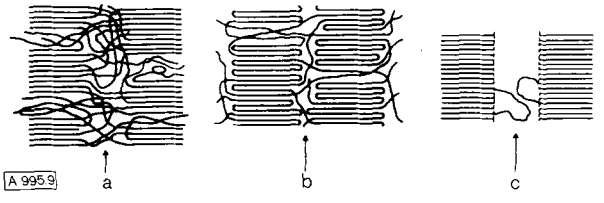

Fig. 9. Models for the noncrystalline regions [9]; for details see text. The arrow shows the direction of the radius of the spherulite.

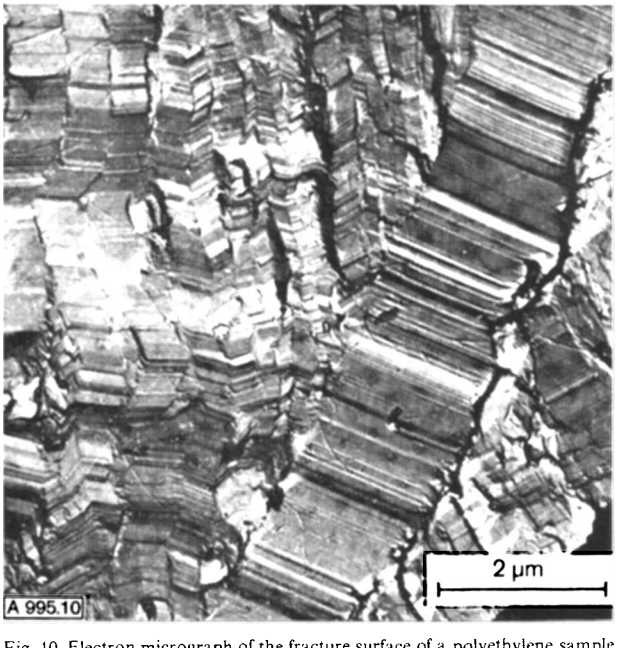

Fig. 10. Electron micrograph of the fracture surface of a polyethylene sample that has been crystallized under a pressure of a few thousand atm [12].

of this type occurs during crystallization from solution[9-11], and there are many indications that it is also possible during crystallization from the melt[6].

The results reported so far were concerned with crystallization under normal pressure. Particularly interesting effects are obtained upon crystallization under a pressure of several thousand atmospheres[12]. Crystallization then proceeds almost to completion; the crystals consist of extended chains. Figure 10 shows an electron micrograph of such a material. The step height corresponds to the thickness of the crystallites, which in turn is equal to the length of the molecules.

Now that we have given a general picture of the experimental results obtained so far and the models proposed, what are the problems that are attracting most attention at present? It seems to me that interest is centered on the following questions:

What kinds of crystal defects are present in the crystallites?

What is the structure of the noncrystalline regions?

How can one explain the folding of the chains and the formation of the spherulites?

We shall now consider these questions in more detail.

2.2. Current Problems

2.2.1. Crystal Defects

The crystalline reflections are broader and less numerous for macromolecular substances than for low molecular weight substances. This must be attributed to the small size of the crystallites and to a particularly high content of defects. In the study of the influence of lattice distortions on the crystalline reflections, according to *Hosemann*[13], the following distortions must be distinguished:

1. Lattice distortions of the first order. These are distortions in which the long-range order is preserved, *e.g.* displacements due to thermal motion.

2. Lattice distortions of the second order, which are also known as paracrystalline distortions. The long-range order is disturbed by these distortions. If they become very pronounced, the crystal changes into a liquid.

Low molecular weight substances exhibit mainly lattice distortions of the first order, whereas high polymers also contain distortions of the second order. By analysis of the half-widths and intensities of the crystalline reflections, it is possible in principle[14] to determine the contributions of the distortions separately.

How are the distortions to be explained at a molecular level? In low molecular weight substances, for example, one finds lattice vacancies, atoms in interstitial sites, dislocations, *etc.* In macromolecular substances there are distortions that are characteristic of chain molecules, and that are known as kinks. These have been intensively studied by *Pechhold*, *Blasenbrey*, and *Woerner*[15]. In an extended chain of CH_2 groups, a kink is formed if a CH_2 group is rotated about an adjacent C—C bond. The sequence of *trans* conformations is then interrupted by a *gauche* conformation. Figure 11 shows schematically an extended chain of C atoms, a chain with a kink, and a chain with a double kink. Figure 12 shows Stuart models of such kinks in polyethylene crystals. Other lattice distortions that are characteristic of substances consisting of chain molecules result from the incorporation of end groups or branching points into the lattice. The defects change the lattice not only at the points where they occur, but also over fairly wide areas in the vicinity of these points. In particular, they cause the above-mentioned paracrystalline distortions. Efforts are being made at present to find a quantitative explanation for the X-ray findings in which the defects are taken into account.

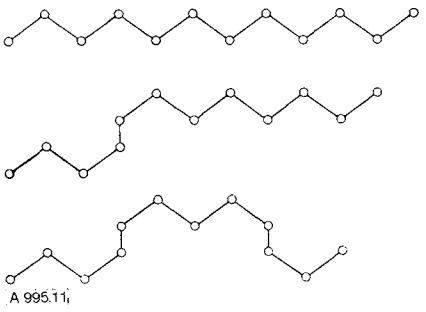

Fig. 11. Chain of carbon atoms a) in the extended state, b) with a kink, and c) with a double kink [15].

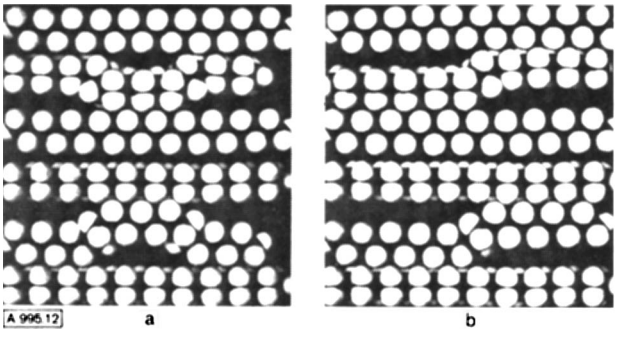

Fig. 12. Stuart models of a) double kinks and b) kinks in a polyethylene crystal [15].

Finally, it should be pointed out that kinks and lattice vacancies are not only formed as a result of disturbances during crystallization, but also arise in thermodynamic equilibrium as a result of thermal motion in an initially ideal crystal. The higher the temperature, the greater is their concentration. *Pechhold* and *Blasenbrey*[16] have established by statistical-thermodynamic calculations that in polyethylene at thermodynamic equilibrium close to the melting point, kinks account for about 1% of the CH_2 groups. The content can of course be considerably higher if the system is not in equilibrium. The number of lattice vacancies at thermodynamic equilibrium has been estimated by *Eby*[17].

2.2.2. Structure of the Noncrystalline Regions

One can only speculate concerning the structure of the noncrystalline regions. The main questions under discussion are as follows: What is the fraction of the tie molecules, that are molecules which connect two crystallites and what is the fraction of loops (see Fig. 9b and 9c)? How long are the loops and what is the distance between their ends? Are there ideal folds present? Efforts have been made to answer these questions directly by IR spectroscopic studies[18,19] and by specific chemical attack on the top surface of the crystallites[20,21]. However, the results were sometimes contradictory.

Some indirect investigations on this problem will now be described.

One of the most effective methods for the study of the nature of the noncrystalline regions is the measurement of the absolute intensity of the X-ray small-angle scattering. The scattering intensity I is measured as a function of the scattering angle ϑ or the derived quantity

$$s = \frac{4\pi}{\lambda} \sin \frac{\vartheta}{2}$$

The following equation is then valid[22]:

$$\int I(s) s^2 \, ds = C \times (\rho_k - \rho_a)^2 \alpha (1 - \alpha) \qquad (1)$$

where ρ_k is the density of the crystallites, and ρ_a is the density of the non-crystalline regions, α is the crystalline fraction, and C is a constant that depends on the experimental arrangement and the intensity of the primary beam. Thus experimental determination of the integral on the left-hand side of the equation yields additional information about the densities of the crystallites and of the noncrystalline regions.

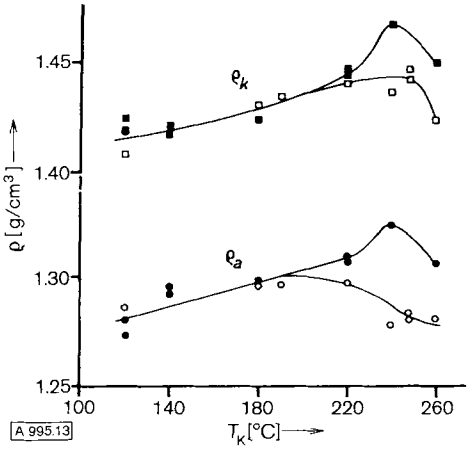

Fig. 13. Densities of the crystallites ρ_k and of the noncrystalline regions ρ_a in polyethylene terephthalate as a function of the crystallization temperature T_K. ■ and ● : Samples cooled slowly after crystallization. □ and ○ : Samples quenched after crystallization [3].

Fischer, *Goddar*, and *Schmidt*[23] were the first to apply this method to problems of the crystalline state. These authors were able to show that the usual assumptions for ρ_a and ρ_k are valid for undrawn polyethylene, but not for the drawn material. Our investigations on polyethylene terephthalate showed that ρ_a and ρ_k do not have the normally assumed values for this material even in the undrawn state. The values found for ρ_k and ρ_a under certain additional assumptions are shown in Figure 13 as functions of the crystallization temperature. Both quantities are strongly dependent on the crystallization temperature. The density of the noncrystalline regions is generally lower than that of the completely amorphous material, which is 1.331 g/cm³. This indicates in particular that the structure of the noncrystalline regions is strongly dependent on the crystallization temperature.

A particularly interesting result was obtained by *Fischer*, *Kloos*, and *Lieser*[24] for polyethylene single crystals. A question that has often been considered is whether the loops protruding from such crystals have the same properties as compact amorphous material. These authors determined the difference between the densities of crystalline and of noncrystalline regions in the single crystals as a function of temperature. The intensity of the X-ray small-angle scattering, which, according to eq. (1), is a measure of this density difference $\rho_k - \rho_a$, is shown as a function of temperature in Figure 14. $\rho_k - \rho_a$ is almost constant up to a certain temperature, beyond which it increases with rising temperature. The temperature at which the curve changes direction agrees well with the glass transition temperature of the amorphous substance. This result may be regarded as evidence that loops projecting from the crystallites behave as completely amorphous material with regard to the glass transition phenomena.

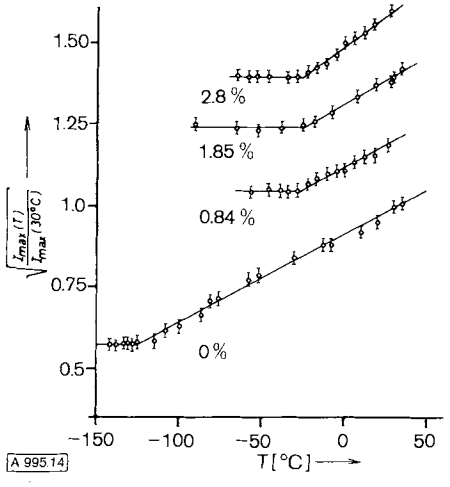

Fig. 14. Temperature dependence of the intensity of the X-ray small-angle scattering from polyethylene single crystals [24] with various contents of methyl groups (values in mole %). $\sqrt{I_{max}(T)/I_{max}(30\,°C)}$ is a measure of the density difference $\rho_k - \rho_a$.

Valuable information about the nature of the noncrystalline regions can be obtained with the aid of nuclear magnetic resonance. Parts of the chain that can undergo segmental motion lead to a narrow component in the NMR signal, while parts that cannot change their conformations lead to a broad component. In a semicrystalline substance above the glass transition temperature, the ^{1}H-NMR signal consists of two components:

1. a narrow component due to chains possessing sufficiently high segment mobility in the noncrystalline regions,

2. a broad component due to the chains in the crystals and to strongly restrained and hence immobile chains in the noncrystalline regions.

The fraction of the area under the narrow component therefore represents the "mobile fraction" y. If all the chains in the noncrystalline regions also possess segment mobility, y is equal to the noncrystalline fraction $1-\alpha$. If there are strongly restrained chains in the noncrystalline regions, on the other hand, y is smaller than $1-\alpha$.

Attempts have been made to compare y and $1-\alpha$. The difficulty in every case lay in the accurate separation of the narrow component from the broad component in the NMR signal. We have now developed a method for polyethylene terephthalate[25] that avoids an arbitrary separation. We have used this method to determine the mobile fraction y from the nuclear magnetic resonance. $1-\alpha$ was then determined from

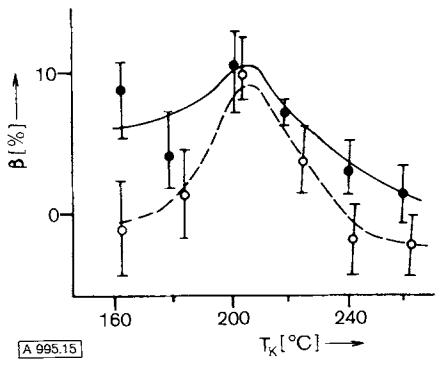

Fig. 15. Rigid noncrystalline fraction $\beta = 1 - \alpha - y_x$ as a function of the crystallization temperature of polyethylene terephthalate [25]. •: Quenched, o: cooled slowly.

the density of the noncrystalline fraction. The difference between the two quantities, which corresponds to the rigid noncrystalline fraction β, is shown in Figure 15 as a function of the crystallization temperature T_k. In the slowly cooled samples, this fraction is practically zero both for low and for high crystalline temperatures. For medium crystallization temperatures, where the crystallization rate is highest, about 5 to 10% of the chains contribute to the rigid noncrystalline fraction. These must be assumed to be chains that join two crystallites and that are relatively highly strained. According to theoretical considerations, the distance between the ends of these chains must be greater than half of the chain length[26]. The rigid noncrystalline fraction β is greater for the quenched samples than for the slowly cooled samples.

Finally, we should mention that the NMR signal has also been separated by various authors into more than two components and interpreted accordingly[27].

2.2.3. Theoretical Interpretation of Chain Folding

A question that is particularly difficult is why the chains fold during crystallization. If the material crystallizes from a dilute solution, in which the crystal nucleus practically consists of a single molecule, folding of this molecule is essential[28]. In crystallization from the melt, however, one would expect a crystal nucleus to be formed from several adjacent molecules. This would lead to the formation of bundle nuclei instead of to chain folding. What factors prevent the formation of bundle nuclei (see Fig. 18b)?

We believe that this is due to entropy effects that are characteristic of substances consisting of chain molecules[29]. When a low molecular weight substance crystallizes, an entire molecule passes from one phase into the other (Fig. 16a). The changes in energy and in entropy accompanying the transition are the same for every molecule. On crystallization of a high polymer, on the other hand, only small segments corresponding in size to the monomer unit pass in succession from one phase into the other (Fig. 16b). The entropy change for such a transition can generally differ from one monomer unit to another, since the entropy of the remaining part of the chain that is not incorporated into the crystal also changes.

Some examples are shown in Figure 17. The transition of a monomer unit from the crystal into the melt is considered in each case. The unit in question is indicated by a circle with an arrow. In Figure 17a, the monomer unit belongs, even after melting, to a chain segment with two fixed ends. The entropy gain on melting in this case is smaller than the average value. In Figure 17b, on the other hand, as a result of the transition, a chain segment N with two fixed ends becomes a chain segment with only one fixed end, to which the unit that has melted belongs. The entropy gain on melting is thus greater than average. Yet other situations are found in the melting processes of Figures 17c and 17d.

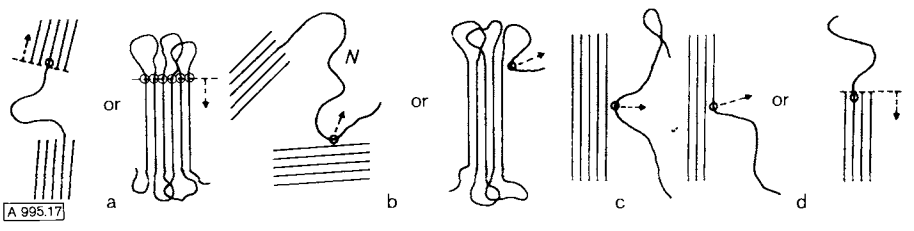

Fig. 17. Examples of the transfer of a monomer unit from the crystal to the melt. For details see text.

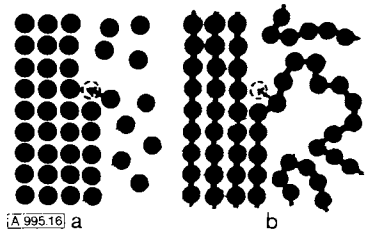

Fig. 16. Schematic representation of the elementary step in the crystallization a) of a low molecular weight substance and b) of a macromolecular substance.

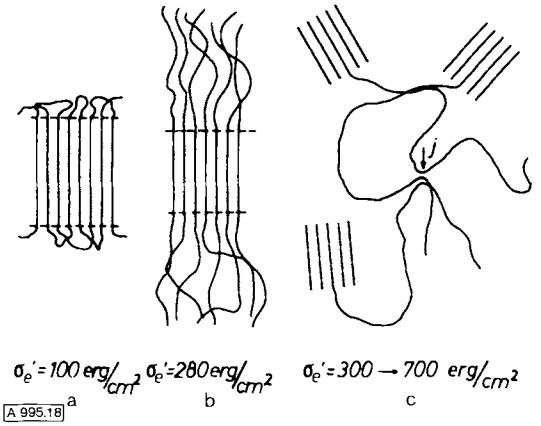

Fig. 18. Additional surface tension σ_e' for various types of nuclei [29]. a) Folded-chain nucleus, b) bundle nucleus, c) nucleus consisting of chains projecting from different crystallites (j = point at which the new nucleus is formed).

These entropy effects have a pronounced influence on the crystal nucleation[29]. For example, if a bundle nucleus is formed (see Fig. 18b) and a new molecule is deposited on

the nucleus, in addition to the changes in the entropy of the monomer units that are just crystallizing, there are also changes in the entropies of the parts of the molecules protruding from the crystals, since the freedom of movement of these tails is restricted by the fact that they are now situated close to the surface of a crystal, and consequently cannot assume so many conformations as before. We have calculated this effect and shown that this acts as an additional surface tension σ'_e ($\approx 280\,erg/cm^2$) during nucleation. An additional surface tension is also present in the case of a folded-chain nucleus (Fig. 18a) because of the folds; however, this amounts to only about $100\,erg/cm^2$. This value already includes an enthalpy contribution of about $60\,erg/cm^2$, which is due to the increased number of *gauche* conformations in a loop. The additional surface tension is particularly high in the case of a crystal nucleus consisting of chains that project from different crystallites (Fig. 18c, $\sigma'_e = 300$ to $700\ erg/cm^2$). A very close relationship exists between the surface tension and the nucleation rate. With increasing surface tension the free energy of nucleation increases, and the nucleation rate consequently decreases. It follows that nuclei with regular short folds are kinetically favored over bundle nuclei.

If the crystallization rate becomes very high, the type of crystal nucleus is no longer determined by the free energy of nucleation. The chains then come together just as they exist in the melt. In this case there is a tendency toward the formation of longer loops with unequal distances between the ends, and of chains that connect different crystallites. The more the molecules penetrate one another in the melt, the greater this tendency becomes[30].

The entropy effects discussed here also play an important role in the explanation of the broad melting range and the superheating phenomena of polymers[28, 31].

3. Drawn Material

So far we have been discussing crystallization under normal conditions. In the manufacture of fibers, it is usual to subject the material to a tensile stress, as a result of which it is drawn to several times its original length. In the course of this drawing process, the molecules become preferentially oriented parallel to the drawing direction. The drawing may be carried out before, simultaneously with, or after crystallization. It is only through this drawing that the fibers acquire the desired technological properties[32].

The changes in structure that occur during the drawing process have been investigated particularly thoroughly by *Balta-Calleja* and *Peterlin*[33]. In the following discussion we shall be concerned only with the structure after the drawing has been completed.

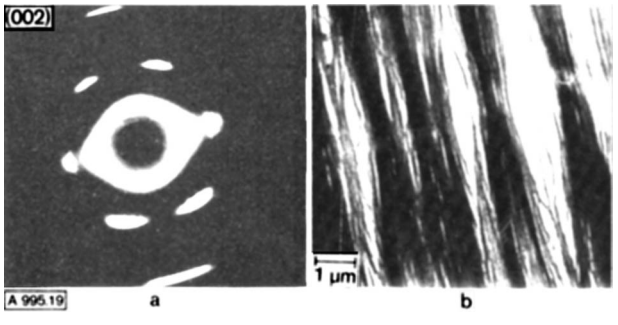

Fig. 19. a) Electron diffraction pattern and b) electron micrograph of a drawn polyethylene film in transmission [34].

The crystalline structure in the drawn material differs considerably from that in the undrawn material. There are no spherulites, but only fibrils. Figure 19b shows an electron micrograph of polyethylene that was drawn after crystallization. One can see individual fibrils, all lying parallel to the drawing direction. The molecules run parallel to the fibrils, as is shown by electron diffraction patterns (Fig. 19a). These fibrils give the fibers their well-known high mechanical strength[35].

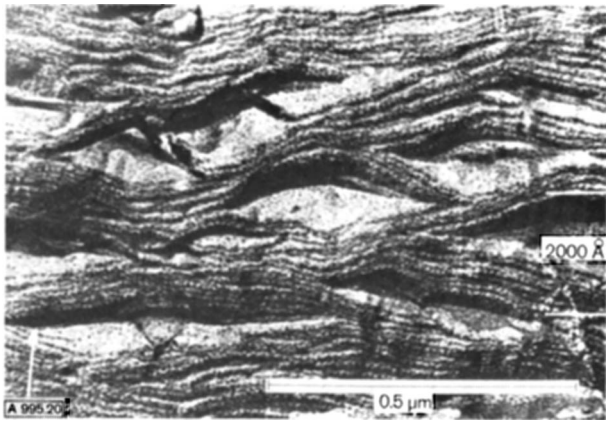

Fig. 20. Electron micrograph of a polyethylene film drawn in the direction of the arrow and annealed for 1 hour at 125 °C after drawing [36].

If the material is annealed after drawing, a distinct structure develops in the lengthwise direction[36]. Figure 20 shows the state at the end of this process. One now finds lamellar structures extending predominantly normal to the drawing direction. A possible interpretation of this process is shown in Figure 21. Immediately after drawing, the noncrystalline

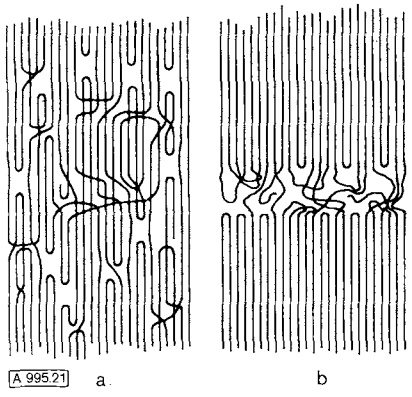

Fig. 21. Schematic representation of the structure of a) unannealed and b) annealed drawn polyethylene [36].

regions are widely distributed, and have the character of small defects (Fig. 21a). During annealing, these defects come together in layers, with the result that a lamellar structure is formed (Fig. 21b).

4. Crystallization During Polymerization in the Solid State

The discussions so far have been concerned with the crystallization of a material from the amorphous state. In this type

of crystallization, the initially coiled and entangled chains must become ordered. One can understand that considerable kinetic inhibitions occur here, and that the crystallization, as described, consequently does not proceed to completion.

Quite recently, the direct transformation of a low molecular weight crystal into one with a high molecular weight by polymerization in the solid state has been achieved. For example, when crystals of the bis(*N*-phenylurethane) of 2,4-hexadiyne-1,6-diol are exposed to ultraviolet light or X-rays, the molecules polymerize and the triple bonds simultaneously turn as indicated in Figure 22. The macromolecules are produced directly

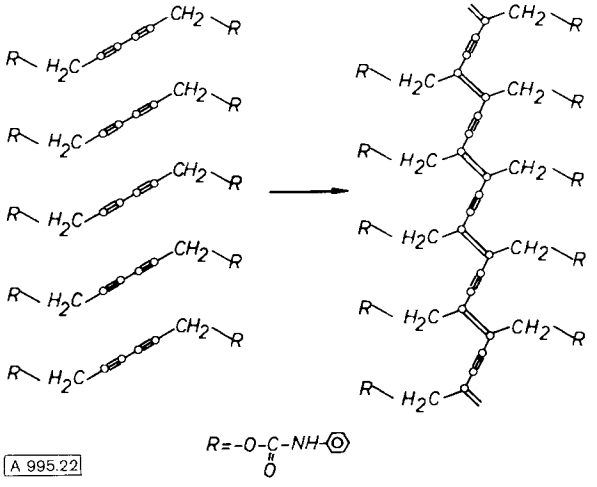

Fig. 22. Change in the position of the CC triple bonds (C≡C) on polymerization of the bis(*N*-phenylurethane) of 2,4-hexadiyne-1,6-diol [2,4-hexadiynylene bis(*N*-phenylcarbamate)].

in the form in which they are present in the crystal[37, 38]. It is not surprising, therefore, that a completely crystalline material is obtained in this case in the form of large single crystals, which do not differ in any way from low molecular weight substances as far as crystalline order is concerned. Figure 23 shows the single crystals obtained, which are many

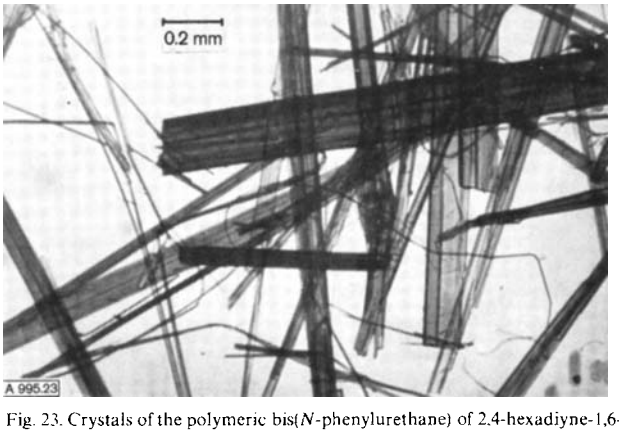

Fig. 23. Crystals of the polymeric bis(*N*-phenylurethane) of 2,4-hexadiyne-1,6-diol obtained by polymerization in the solid state.

times as large as the single crystals prepared from solution. Figure 24 shows the X-ray diffraction pattern, which exhibits a large number of sharp reflections and no amorphous halo. The direct transformation of a low molecular weight crystal into a high-polymer crystal as in the above example is possible

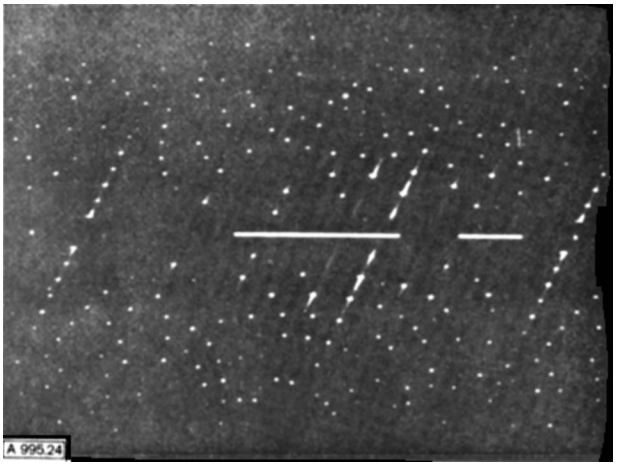

Fig. 24. Weissenberg photograph of the (*hk*0) plane of a polymeric single crystal [38] from Fig. 23.

for only a very small number of substances. It can occur only if the unit cell of the low molecular substance is identical with that of the high molecular weight substance. Substances for which this condition is not satisfied, such as acrylic and vinyl compounds, can apparently also be polymerized in the solid state. However, a liquid phase is presumably formed as an intermediate state during the polymerization[39]. The polymer obtained in such cases, as in a crystallization from the melt, is only partly crystalline.

5. Outlook

The fact that it has been possible to produce ideal crystals of macromolecular substances is very important. It shows that macromolecular substances, in principle, can crystallize completely, and that incompleteness in the crystallization from the melt is due to kinetic inhibition. At the same time, however, it must be emphasized that incomplete crystallization is not merely a fascinating subject for scientific investigation, but is also responsible for some outstanding properties of the macromolecular substances. Incomplete crystallization is the reason for the high strength of fibers coupled with flexibility, the ductility of films, and the low tendency of injection molded material to fracture. An ideal crystal is brittle, is practically inextensible, and shatters easily. It can achieve technical importance only in fields different from those in which the semicrystalline material is important, *e.g.* in the semiconductor field.

Mass Spectral Interaction between the Functional Groups of Multiply Substituted Alkanes

By Herbert Bosshardt and Manfred Hesse[*]

The mass spectral decomposition of di- and polyfunctional alkanes is characterized essentially by two, fundamentally different reactions: On the one hand the structures of the fragment ions are determined by separated degradation of each functional group; on the other hand, however, a relatively large number of fragment ions result from the combined action of two or even more functional groups. This special type of fragmentation has become an important topic in today's mass spectral research. In the present progress report an attempt has been made to summarize the results obtained so far.

1. Introduction

Molecules of the aliphatic series of compounds number among the first organic molecules to have been investigated by mass spectroscopy[1]. Although the initial studies on this class of compounds to derive mechanisms for explaining mass spectral decomposition had already begun in the fifties, and though these mechanisms are now generally accepted, renewed interest has been shown in the spectra of aliphatic compounds by organic chemists working on mass spectrometry. Formerly the prime interest was attached to elucidating the influence of one functional group on the decomposition of monofunctional alkanes, today the interest focuses upon the influence which two or more functional groups within a molecule have on the decay of aliphatic compounds. It soon became clear that although a more or less greater portion of the fragment ions, occurring in the spectra of difunctional compounds, can be explained by the fragmentation of each group on its own, *i.e.* independently of each other, the origin of many fragment ions could still not be satisfactorily explained. However, the existence of such ions can be accounted for by assuming the occurrence of direct or indirect interaction between the functional groups.

The interplay of functional groups, separated by several methylene groups, has already been known in preparative chemistry for a long time. Cyclization reactions of many different types can be used as examples to illustrate this.

In order to prevent side reactions taking place during the formation of medium-sized and large-membered rings, very dilute solutions have been used (cf. *e.g.*[2]). Such conditions enhance the possibility that the reaction center under consideration accepts other functional groups of the same molecule as closest neighbor, *i.e.* the conditions are very much akin to those prevalent in mass spectroscopy (high vacuum).

To which type do the mass spectrometric interactions mentioned above belong, and what would their participation indicate? Is it possible to draw important conclusions about the structure of unknown difunctional alkanes on the basis of their special fragmentation? These and similar questions have initiated a number of interesting research papers in recent years. It would not be out of place to mention at the outset that decomposition reactions caused by interaction of two

[*] Dipl.-Chem. H. Bosshardt and Prof. Dr. M. Hesse
Organisch-Chemisches Institut der Universität Zürich
Rämistrasse 76, CH-8001 Zürich (Switzerland)

or more functional groups would seem to be the rule rather than the exception in the mass spectral decomposition of di- and polyfunctional alkanes.

The fragmentation patterns of compounds with oxygen- and nitrogen-containing functional groups have been studied in detail and constitute the main subject under discussion in the present progress report. These investigations were purposely confined to aliphatic compounds in which the functional groups are connected neither conjugatively nor by rings. This does not infer, however, that alicyclic or aromatic compounds should react differently (such compounds have also been investigated: cf. *e.g. ortho-* and *peri*-effects in aromatic systems[3], in maleic and fumaric acid derivatives[4], in 1,2-dicarboxylic acids from cycloalkanes[5] and cycloalkenes[6], and in cyclohexylsilyl compounds[7]).

2. Interaction between Nitrogen-containing Functional Groups

On comparing the mass spectra of acetylated *n*-alkylamines[8,9] *e.g.* *N*-hexyl-*N*-methylacetamide *(1)* (Fig. 1[8]) with those of *N,N'*-diacetylated α,ω-alkanediamines[8], *eg. N,N'*-tetramethylenediacetamide (*N,N'*-diacetylputrescine) *(2)* (Fig. 2[8]), it is striking that in both cases 43 atomic mass units (amu) are split off from the molecular ion. Thus it would appear—at least at first sight—that there is no principle difference in the fragmentation pattern of mono- and difunctional alkanes. Yet a closer investigation of the two spectra shows

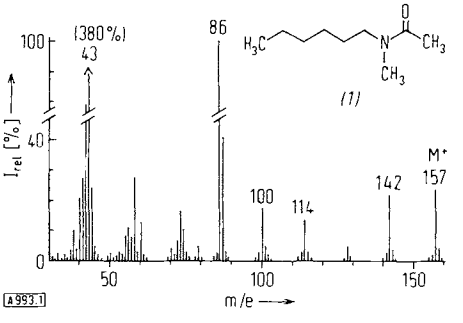

Fig. 1. Mass spectrum of *N*-hexyl-*N*-methylacetamide *(1)* (see Ref. [8]).

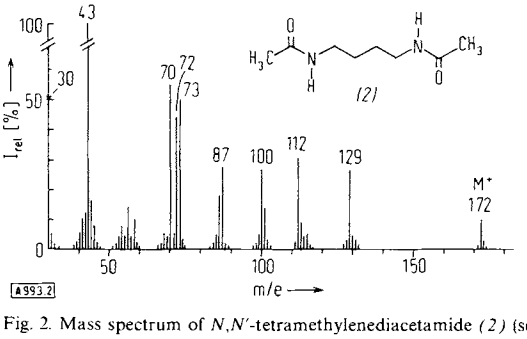
that different fragmentation reactions take place[8,9]: In the case of $(1)^{\ddagger}$, loss of $\cdot C_3H_7$ and $\cdot H$ is followed by CH_2CO-fission, while in $(2)^{\ddagger}$ only a loss of $CH_3CO\cdot$ from the molecular ion is observed. Although both compounds contain the same



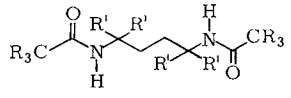


Fig. 2. Mass spectrum of *N,N'*-tetramethylenediacetamide *(2)* (see Ref. [8]).

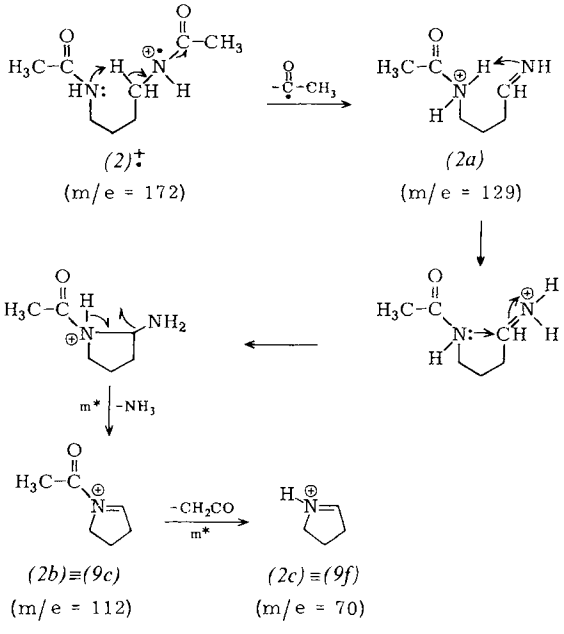
structural unit ($-CH_2NR-COCH_3$), the ion $[M-43]^+$ is formed *via* basically different routes. It may be concluded that the second amide group of compound *(2)* prevents typical decomposition of the *N*-acetylalkyl residue by interaction, and causes a new mode of decomposition.



2.1. Loss of *N*-Substituents (R) from the Molecular Ion[8,10,11]

That $\cdot COCH_3$ splits off from the molecular ion in the case of the *N,N'*-diacetyl compound *(2)* has been proved by the determination of the exact mass and by investigation of the deuterated derivatives D_6-*(2)* and D_{10}-*(2)*; the reaction course is illustrated in Scheme 1.

(2), R = R' = H
D_6-*(2)*, R = D, R' = H
D_{10}-*(2)*, R = R' = D

The actual fragmentation is caused by an attack by one end of the chain (N or O) on the α-hydrogen atom to the amide group of the other, the charge-carrying end. If all four α-positions are blocked by methyl groups, *e.g.* in tetramethyl-*N,N'*-tetramethylenediacetamide, loss of $\cdot COCH_3$ from the molecular ion is not observed[12].

Scheme 1

This loss of the acetyl group is not only observed in the putrescine derivative *(2)*, but also in the decomposition of all acetylated diamines in which the nitrogen atoms are separated by a chain of at least three CH_2-members. This chain should allow at least a cyclic transition state—before the actual fragmentation takes place—to make an approach of the two functional groups possible. Thus the $[M-COCH_3]^+$ signal has been detected in all *N,N'*-diacetylated α,ω-alkyldiamines which contain three to sixteen CH_2-groups[*]. The loss of the *N*-substituent is also not confined

[*] Longer chains have not yet been investigated.

to the acetyl residue; many other *N*-substituents behave analogously, *e.g.* alkyl groups (CH_3[8], C_2H_5[8], $C_nH_{2n}R$[13], $CH_2C_6H_5$[8] *etc.*) and other acyl residues (COC_6H_5[8], $COCH_2$—CH_2—C_6H_5[14] *etc.*).

Interesting in this connection are the mass spectra of α,ω-alkyldiamines, whose nitrogen atoms carry more than one substituent. Such compounds can be classified into two groups:

1. Compounds in which both the nitrogen atoms are identical, but are each substituted with two different groups, *e.g.* *N,N'*-diethyl-*N,N'*-tetramethylenediacetamide *(3)* (Fig. 3).

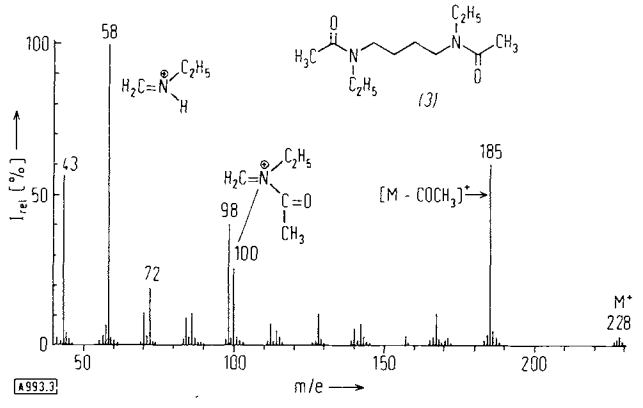


Fig. 3. Mass spectrum of *N,N'*-diethyl-*N,N'*-tetramethylenediacetamide *(3)* (see Ref. [10]).

2. Compounds in which the nitrogen atoms are substituted dissimilarly, *e.g.* *N*-(3-diethylaminopropyl)acetamide *(4)* (Fig. 4).

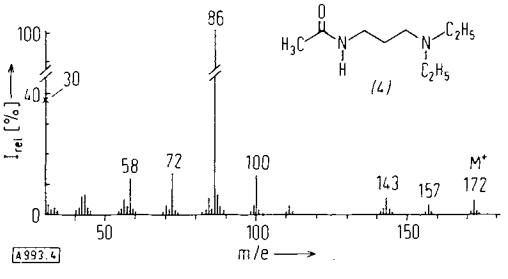

Fig. 4. Mass spectrum of *N*-(3-diethylaminopropyl)acetamide *(4)* (see Ref. [8]).

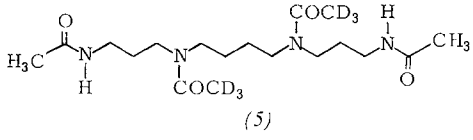

Supposing that the fragmentation reactions involving cleavage of $\cdot C_2H_5$ and $\cdot COCH_3$ are alike, the tendency to lose a *N*-substituent can be estimated from the mass spectra of compounds of the first group[8, 10].

The mass spectrum of *(3)* (Fig. 3[10]) shows only the $[M-COCH_3]^+$ signal and not one at $[M-C_2H_5]^+$. By comparing the abundances of $[M-R]^+$ ions in the mass spectra of other model substances, a sequence was found[8, 13] which illustrates the fission tendency of *N*-substituents (for preparative reasons a direct comparison of acetyl and benzoyl has not yet been possible):

$$H < CH_3 < C_2H_5 < C_nH_{2n}R < CH_2C_6H_5 < COCH_3, COC_6H_5$$

H and CH_3 show the least tendency to split off. Reasons for the different behavior of the radicals are not yet definitely known.

The second case—the two nitrogen atoms of an α,ω-alkanediamine are substituted differently—provides information about charge localization at the moment of cleavage of the substituent R. The spectrum of *(4)* (Fig. 4)[8] indicates only a fission of the ethyl-, but not the acetyl-radical—a result which seems to be contrary to that found in the decomposition of compound *(3)* (Fig. 3). N^1,N^{14}-diacetyl-N^5,N^{10}-bis(trideuterioacetyl)spermine *(5)* eliminates only the central (deuterio)-acetyl group, but not the terminal acetyl groups. Both of the central nitrogen atoms belong to tertiary, the terminal ones to secondary amide groups. If these two findings are correlated with the values given in the literature for the ionization potentials of secondary and tertiary amines and acetamides[*], it can be concluded that substituent is eliminated which is

(5)

attached to the nitrogen atom having the lowest ionization potential, and therefore becomes charge carrier at the moment of fission.—Exceptions concerning this behavior have not been observed in this class of compounds, though a large number of model substances have been investigated.

Within an homologous series of such compounds, the mass spectra are similar, but not alike. Figures 5 and 6 illustrate the dependence of the abundance of $[M-acyl]^+$ ions in *N,N'*-acetylated and *N,N'*-benzoylated homologous α,ω-alkanediamines on the number of chain members.

The curves in the two figures for the cleavage of $\cdot COCH_3$ and $\cdot COC_6H_5$ from the molecular ion run parallel to some extent: the abundance of these ions is lowest in compounds containing five or six CH_2 groups. The abundance increases with the increase in number of CH_2 groups, reaches a maximum value (ten CH_2 groups), and then decreases again. This decrease is presumably determined by the mode of comparison: The relative proportion of $[M-acyl]^+$ ions will decrease with increasing number of chain members.

In the case of the lighter compounds the minimum of the curve for acetamides having five or six CH_2 groups is followed by an increase, which is indicative of a consecutive reaction

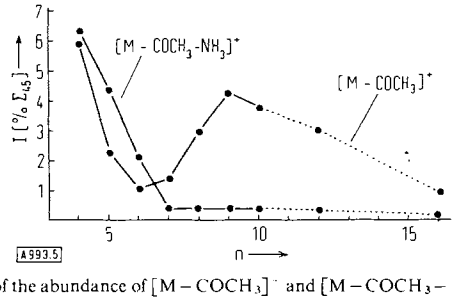

Fig. 5. Dependence of the abundance of $[M-COCH_3]^+$ and $[M-COCH_3-NH_3]^+$ ions on the number *n* of CH_2 groups between the two nitrogen atoms in *N,N'*-diacetylated α,ω-alkanediamines (from 70 eV mass spectra; see Ref. [8]). The abundance refers to the total ion current Σ. It has been calculated only from $m/e = 45$.

[*] Ionization potentials of model compounds: $CH_3CONHCH_3$: 8.90 ± 0.02 eV; $CH_3CON(CH_3)_2$: 8.81 ± 0.03 eV; $(CH_3)_2NH$: 8.24 ± 0.02 eV; $(CH_3)_3N$: 7.82 ± 0.02 eV [15]. (Ionization potentials of the compounds discussed here have not yet been measured.)

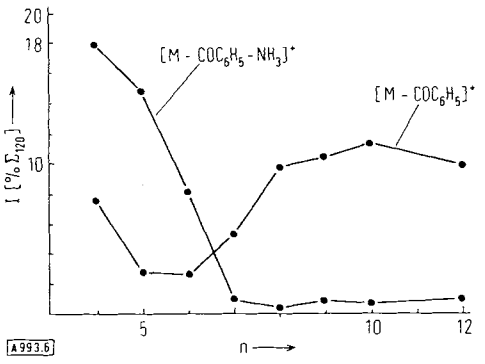

Fig. 6. Dependence of the abundance of $[M-COC_6H_5]^+$ and $[M-COC_6H_5-NH_3]^+$ ions on the number of CH_2 groups between the two nitrogen atoms in *N,N'*-dibenzoylated α,ω-alkanediamines (from 70 eV mass spectra; see Ref. [8]). The abundance refers to the total ion current Σ, which has been counted only from $m/e = 120$, so as to eliminate the intense signal at $m/e = 105$ ($[C_6H_5CO]^+$) in all spectra.

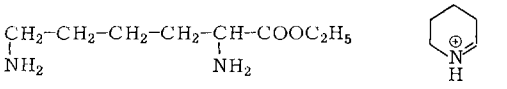
of the $[M-acyl]^+$ ions; this is especially strong in compounds with five or six CH_2 groups. The secondary reaction concerned is the elimination of ammonia.

2.2. Loss of Ammonia or Amine from $[M-acyl]^+$ Ions

In the spectrum of *N,N'*-tetramethylenediacetamide *(2)* (Fig. 2) a signal is registered at $m/e = 112$ *[(2b)*, $C_6H_{10}NO$]. Metastable signals indicate that the corresponding ion results from the $[M-COCH_3]^+$ ion [$m/e = 129$, *(2a)*, $C_6H_{13}N_2O$], *i.e. (2a)* loses NH_3. The loss of NH_3 is followed by elimination of ketene and subsequent formation of the ion *(2c)* ($m/e = 70$) (see Scheme 1)[8]. Deuteration experiments have confirmed that the three hydrogen atoms of ammonia derive from the two NH groups and from the α-position of the amide.

Analogous reactions have also been observed in the homologs of *(2)*. The abundances of the corresponding signals are given in Figures 5 and 6, which afford confirmatory evidence of the elimination of ammonia in diacetylated α,ω-alkanediamines with four to seven CH_2 groups. The spectra of compounds containing a larger number of chain members, are void of signals that would be indicative of this type of fragmentation.



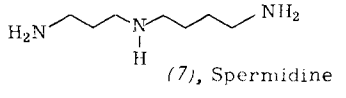
These results would indicate that ion *(2b)* should be cyclic, because its abundance depends on the number of ring members. Acyl cleavage, on the other hand, only proceeds *via* a cyclic transition state (transference of the α-hydrogen to the opposite nitrogen) and is therefore not strongly dependent on the number of ring members. Since *(2b)* is formed from *(2a)*, it is understandable that the abundance (that is, so to say, the concentration) of *(2a)* and its homologous ions is lower (four to seven chain members) if a consecutive reaction leading to *(2b)* or its homologous ions is possible[*].

In the case of trisubstituted tetramethylenediamines the cleavage of a primary amine from the $[M-acyl]^+$ ion is observed instead of the loss of NH_3[8]. Tetrasubstituted tetramethylenediamine derivatives behave differently. Although a large proportion of $[M-acyl]^+$ ions exist, the resulting $[M-acyl-amine]^+$ signals are very weak.

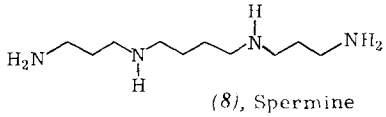
[*] An additional effect can be expected from ions with an eight or nine membered transition state (medium-sized rings) in which, by expulsion of the central hydrogen atoms, the $[M-acyl]^+$ reaction is less favored.

In tetrasubstituted tetramethylenediamine derivatives, instead of NH_3 (as in the *N,N'*-disubstituted amines), a secondary amine should be ejected. This would involve a migration of a radical from one nitrogen atom to the other. It has been demonstrated by deuteration experiments that this reaction does not take place but alternative ones of a completely different nature[16].

The elimination of ammonia from a diamine cation by means of mass spectral fragmentation was first discovered in the case of lysine. The base peak in the spectrum of the ethyl ester of lysine *(6)* is $m/e = 84$; the structure *(6a)* has been proposed



(6) *(6a) ≡ (15c)* (m/e = 84)



for the corresponding ion[17]. Tagging experiments have proved that both nitrogen atoms can be ejected in the expulsion of NH_3 from the $[M-COOC_2H_5]^+$ ion. A similar decomposition reaction has been postulated[18] for the fragmentation of the ethyl ester of putreanine ($H_2N-(CH_2)_4-NH-(CH_2)_2COOC_2H_5$).

2.3. Trimethylenediamine Derivatives

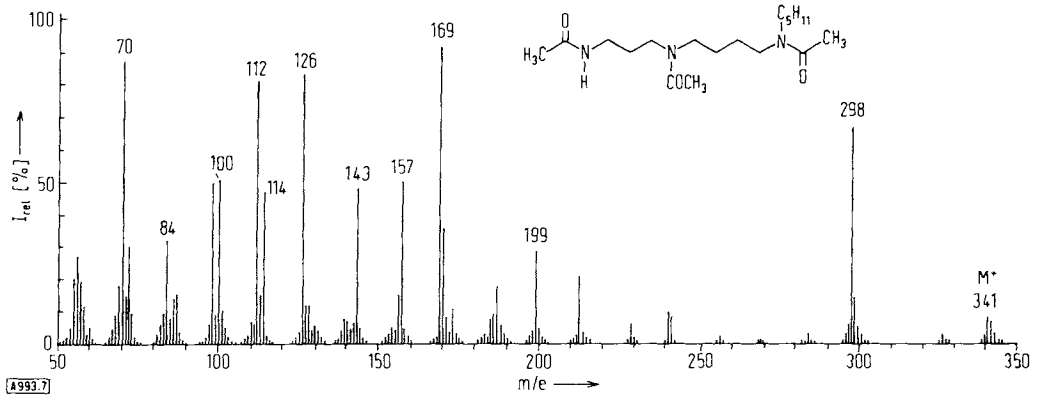
Regarding nitrogen-nitrogen interaction, substances which derive from trimethylenediamine, *e.g.* spermidine *(7)* or spermine *(8)*, are of special interest. The mass spectra of *N*-acetylated trimethylenediamine derivatives are easy to interpret; moreover, the strong polar compounds *(7)* and *(8)* are better to vaporize in an acetylated state in the mass spectrometer than free amines.

(7), Spermidine

(8), Spermine

N,N',N''-triacetyl-*N*-pentylspermidine *(9)* (Fig. 7) is given as an example to demonstrate the fragmentation behavior of this class of compounds[19]. Remarkable in the mass spectrum of this compound is the severe loss of 43 amu ($COCH_3$) from the molecular ion and the two triads $m/e = 100$, 114, 126 and 143, 157, 169. Regarding the mode of formation of the latter, the triad with lower mass numbers corresponds entirely to the other, so only the one with higher mass numbers will be discussed in the following section.

The three ions with $m/e = 143$, 157 and 169 owe their existence exclusively to the fragmentation of the trimethylenediamine unit and not to that of the tetramethylenediamine part. The following decomposition paths have been derived by means of high resolution spectra, spectra of deuterated and other derivatives, as well as by metastable transitions[19].



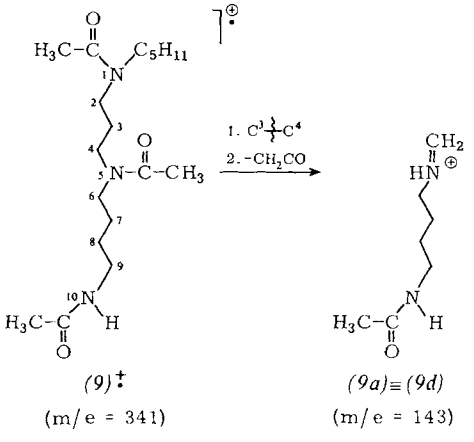


Fig. 7. Mass spectrum of *N,N',N''*-triacetyl-*N*-pentylspermidine *(9)* (see Ref. [19]).

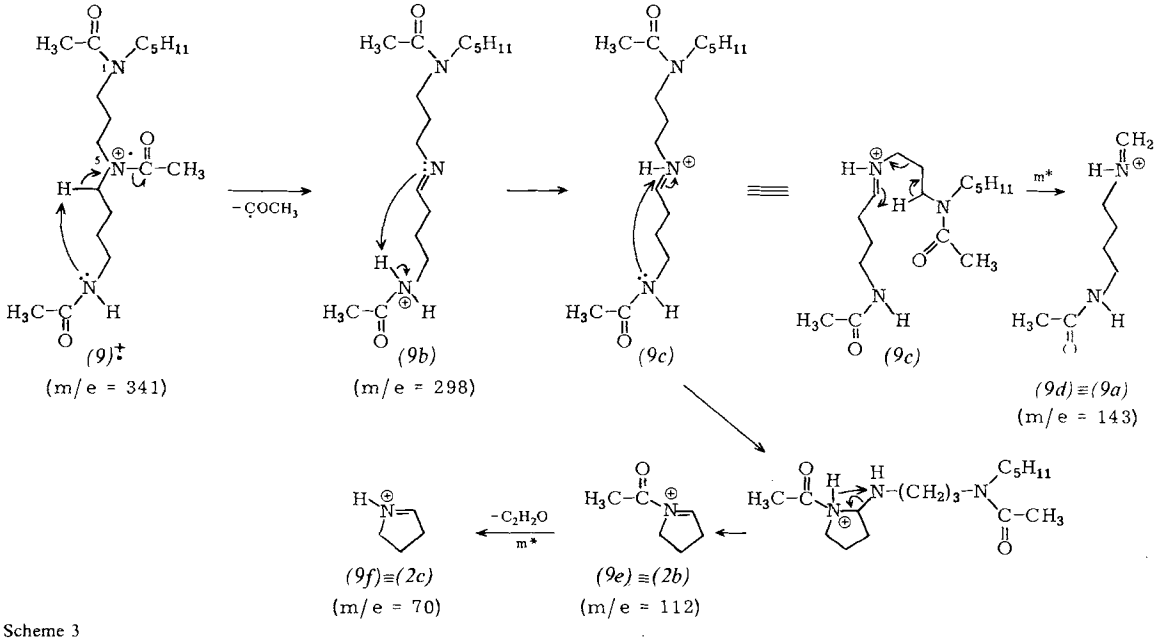
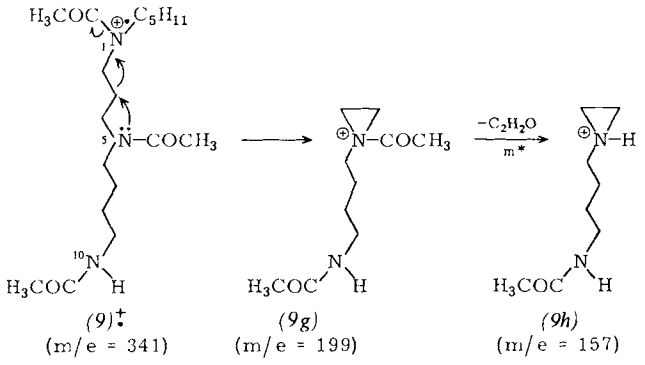
Two mechanisms have been deduced for the formation of the ion $m/e = 143$: α-cleavage to N^5 between C^3 and C^4, followed by the loss of ketene, leads to *(9a)* ($m/e = 143$) (Scheme 2). In addition to this conventional fragmentation there exists a second possible process of formation, initiated by a nitrogen-nitrogen interaction (Scheme 3).



Scheme 2

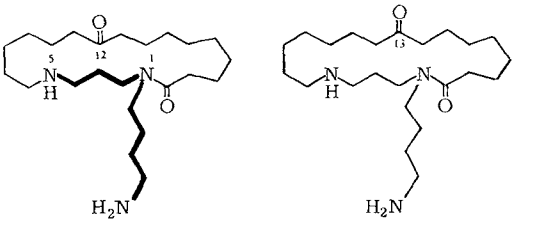
In the first reaction step the acetyl group splits off from the central nitrogen atom with participation of N^{10} and with shifting of one H from C^6 to N^{10} [*(9b)*, $m/e = 298$]. In the following step this hydrogen atom is transferred to N^5 *(9c)*. Finally, *(9d)* ($m/e = 143$) is formed by a McLafferty-like reaction involving the atoms 2 to 6. In addition, starting from *(9c)*, the ions *(9e)* ($m/e = 112$) and *(9f)* ($m/e = 70$) can be formed in accordance with the reaction sequence demonstrated in Scheme 3 and analogously to the decomposition of *N,N'*-tetramethylenediacetamide *(2)* (Scheme 1).



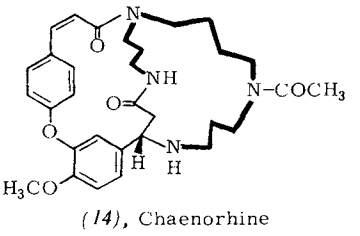
The shifts in the spectrum of the deuterated derivatives favor the structure *(9h)* ($m/e = 157$). It may be assumed that the reaction in this case also is initiated by loss of an *N*-acetyl group (cf. Scheme 4).

The ion of mass $m/e = 169$ can also be formed in two different ways: multiple interference of the nitrogen atoms 5 and 1 leads to formation of *(9l)* ($m/e = 169$), hydrogen atoms being shifted from positions 3 and 4 (Scheme 5). A similar reaction path likewise leads from *(9i)* to *(9l)* (Scheme 6).

The fragmentation of *N,N',N'',N'''*-tetraacetylspermine *(10)* is in agreement with the formulation of the ions 143, 157 and 169 and the proposed routes of formation[13]. Owing to the larger substituent [replacement of the hydrogen atom

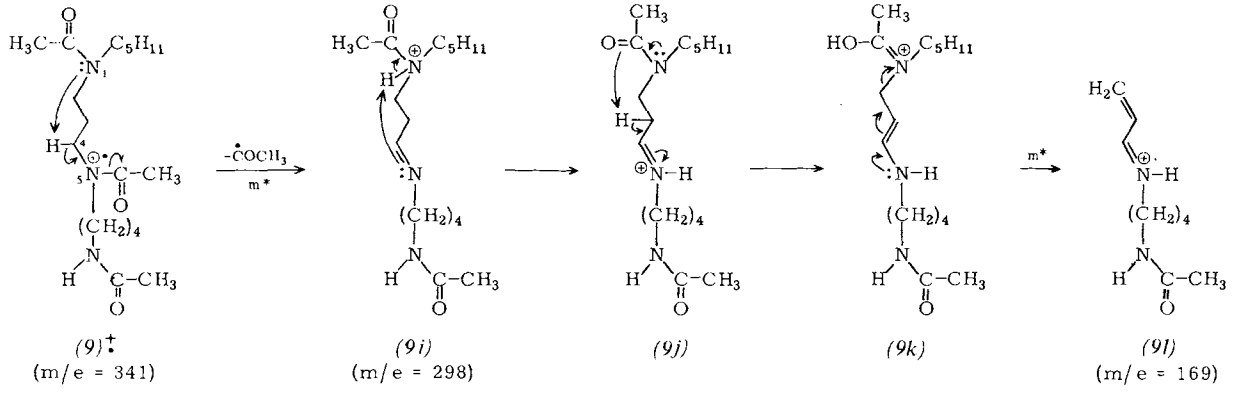


Scheme 3



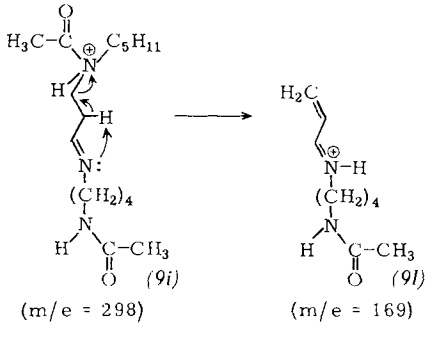
(9)⁺· (m/e = 341) (9g) (m/e = 199) (9h) (m/e = 157)

Scheme 4



at N^1 by $-(CH_2)_3-NH-COCH_3$], the ions of the corresponding triad are registered at $m/e = 242$, 256 and 268 (+99 amu).

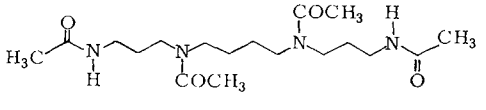
(12), Inandenin-12-one (13), Inandenin-13-one



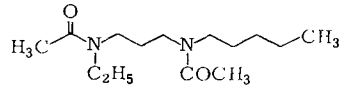
(14), Chaenorhine

(9)⁺· (m/e = 341) (9i) (m/e = 298) (9j) (9k) (9l) (m/e = 169)

Scheme 5



The decomposition of (9)⁺· into (9d) ($m/e = 143$, Scheme 3) requires interaction of all three nitrogen atoms of the molecule. If the nitrogen atom at the end of the tetramethylenedi-



(9i) (m/e = 298) (9l) (m/e = 169)

Scheme 6

amine part is missing, as, *e.g.*, in the compound *N*-ethyl-*N*-pentyl-*N*,*N'*-trimethylenediacetamide (11), the above mentioned triad will still be found (but now shifted to $m/e = 100$, 114, 126), because the "reactive" trimethylenediamine unit is still present; however, as expected, a signal corresponding to (9d) will no longer occur [an ion corresponding to (9a)—caused by conventional fragmentation—is also formed][20].

(10)

(11)

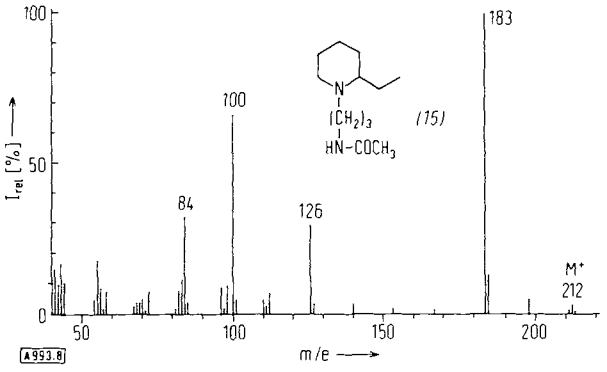
If an *N*-acetylated spermidine or spermine unit is incorporated in a larger molecular structure, the characteristic fragmentation pattern, discussed above, remains unchanged [cf. *e.g.* the discussion of the mass spectra of the alkaloids inandenine and chaenorhine (14)[14], and especially their derivatives (12) and (13)[21]]. This provides a valuable tool for the analysis of unknown alkaloids containing spermidine (7) or spermine (8) as structural elements[12] (cf. also Ref.[22]).

2.4. Mass Spectral S_Ni Reactions[23]

These fragmentation processes, earlier called mass spectral S_N2-like reactions, were first observed[23] in a derivative of the spermidine alkaloid oncinotine (17)[24].

If in an aliphatic, difunctional molecule the charge is localized at a heteroatom, *e.g.* by means of a favored α-fission, a second functional group can attack the carbon atom in the α-position to the charge-carrying heteroatom. During this reaction the charge is taken over by the second functional group and the former charge-carrying group is ejected as a neutral particle.

The spectrum of the 2-ethylpiperidine derivative (15) (Fig. 8, Scheme 7) may be discussed as an example. As expected,



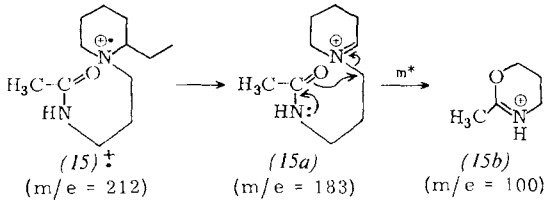


Fig. 8. Mass spectrum of *N*-(γ-acetylaminopropyl)-2-ethylpiperidine *(15)* (see Ref. [23]).

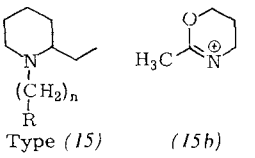
(15c)≡*(6a)*
(m/e = 84)

Scheme 7

the molecular ion first splits off $\cdot C_2H_5$ (in the α-position to the ring nitrogen atom) and yields *(15a)* (*m/e*=183), which gives rise to the most intense signal in the spectrum. In the following reaction step piperideine is eliminated as a neutral fraction (m*) and the ion *(15b)* (*m/e*=100) is formed. On the basis of the following arguments, *(15b)* is assumed to have a cyclic structure. If the aliphatic residue attached to the nitrogen of the piperidine ring carries no further functional group, the S_Ni-reaction will not be observed; instead the product of an onium reaction *(15c)* (*m/e*=84) is favored. The abundance of the ion *(15b)* or the analogous ions depends very strongly on the nature of the functional group at the chain end (Table 1).

The cyclic structure of ion *(15b)* has been derived mainly from the mass spectra of the homologous compounds. It can be presumed that the size of the ring in *(15b)* and analogous ions is directly connected with the abundance of the corresponding signals. Hence for a six-membered ring, *i.e.* for *(15b)*, an abundance maximum can be expected, while with a larger number of ring members the abundance should decrease. This behavior has also been proved experimentally (see Table 1). It follows, at least for this type of compound, that *(15b)* and its homologs are very likely to possess cyclic structures.



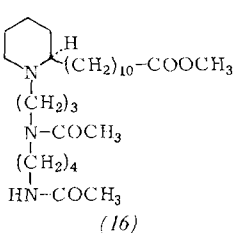


Table 1. Dependence of the abundance (*I*) of the ions analogous and homologous to ion *(15b)* on the nature of the functional group and the number *n* of methylene groups in compounds of type *(15)*.

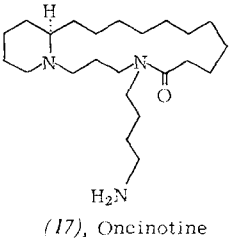


R	*n*	Ring members	Cyclic ion, Type *(15b)* *m/e*	*I* [% Σ_{30}]
$NHCOCH_3$	3	6	100	14.6 [a]
$CONH_2$	3	6	86	10.7
$COOC_2H_5$	3	6	115	1.7
NH_2	3	6	58	1.4
OH	3	6	59	0
$NHCOCH_3$	2	5	86	5.5
$NHCOCH_3$	3	6	100	14.6 [a]
$NHCOCH_3$	4	7	114	2.0
$NHCOCH_3$	5	8	128	0.4

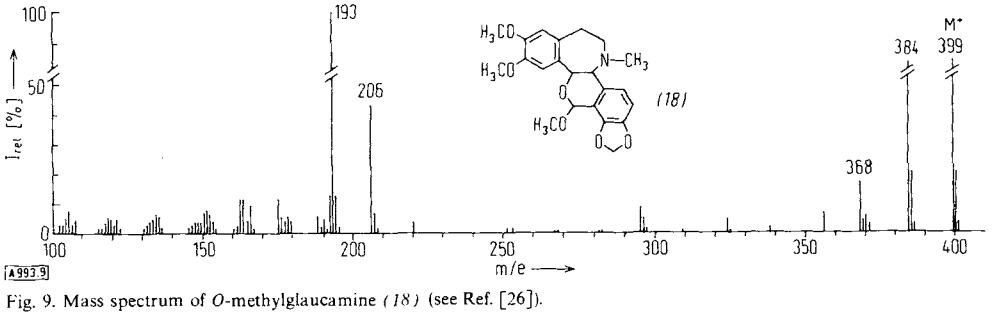
[a] Decomposition of compound *(15)* to ion *(15b)*.

Particularly noteworthy is the fact that a consecutive reaction, in which the ion corresponding to *(15b)* once again enters into such an S_Ni-reaction, has been found to take place[25] in the case of methyl *N*,*N'*-diacetyloncinotinate *(16)*, a degradation product of the natural spermidine alkaloid oncinotine *(17)*[24].

(16)

(17), Oncinotine

It should be emphasized that, in all the cases mentioned above, this decomposition reaction is signified by metastable signals.



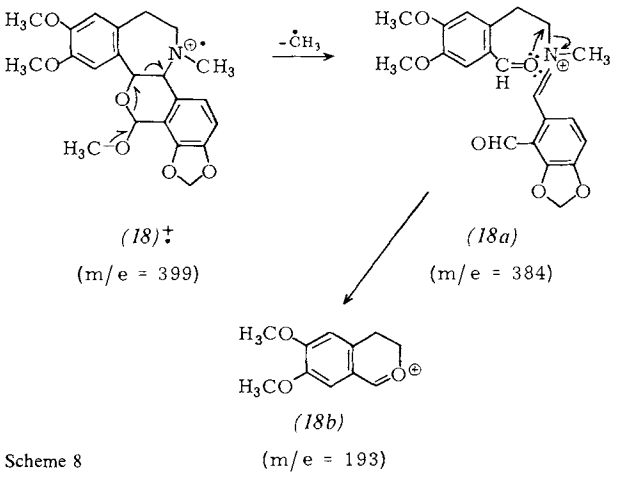


Fig. 9. Mass spectrum of *O*-methylglaucamine *(18)* (see Ref. [26]).

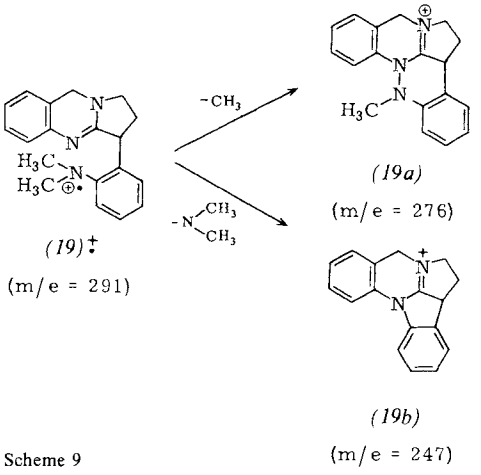
A similar formulation has been used to explain the main fragmentation pattern of the Papaver alkaloid *O*-methylglaucamine *(18)* (Fig. 9)[26]. The base peak is *m/e*=193. The corresponding ion *(18b)* (Scheme 8) derives from the [M−

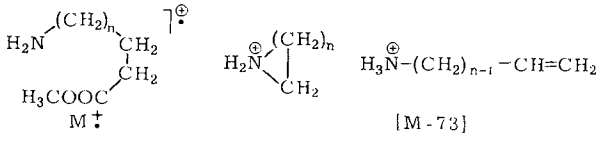


$CH_3]^+$ ion by way of an S_Ni-like fragmentation reaction. This course of decomposition is supported by the spectra of a series of derivatives.

(18)⁺ (m/e = 399) *(18a)* (m/e = 384) *(18b)* (m/e = 193)

Scheme 8

A further fragmentation, which can be explained by the interaction of neighboring nitrogen-containing functional groups, is the cleavage of CH_3 and $N(CH_3)_2$ in the Adhatoda alkaloid vasicoline *(19)* (see Scheme 9) and other, similarly constructed derivatives[27].



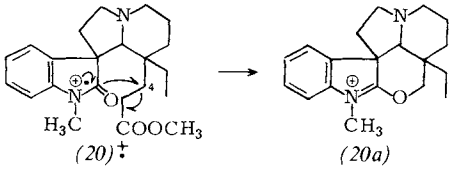
(19)⁺ (m/e = 291) *(19a)* (m/e = 276) *(19b)* (m/e = 247)

Scheme 9

3. Interaction between Nitrogen-containing and Oxygen-containing Functional Groups

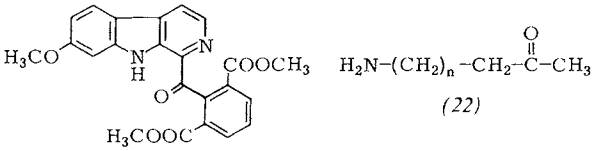
As already mentioned in Section 2.4, oxygen-containing functional groups can also interact with amines. The spectra of methyl ω-aminocarboxylates with longer chains show $[M-CH_2COOCH_3]$ ($[M-73]$)[28] as the most abundant peaks in the upper mass range. Signals of these ions also occur, always weaker, in the spectra of aliphatic carboxylic esters (cf. Ref.[29]).

To explain the strong $[M-CH_2COOCH_3]^+$ signal, an interaction between the NH_2 group and the methoxycarbonyl



M⁺ [M-73]

group can be presumed and the quoted cyclic structure may be proposed for the corresponding ion[28]. The alternative structure—a primary, unstabilized carbocation—is, for energetic reasons, less likely. It could be possible that, similarly as in the elimination of the *N*-acyl radicals (see Section 2.1), the ejection of $\cdot CH_2COOCH_3$ only occurs with hydrogen migration—this would lead to an alternative structure of an ammonium ion. Unfortunately, in the case of these investigations no references to the influence on the abundance of the $[M-73]^+$ ion as a function of the number of chain members are given. General conclusions cannot therefore be made as yet.

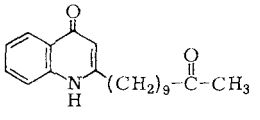


If instead of a methyl ω-amino carboxylate its *N*-acetyl derivatives are examined mass spectrally, the cleavage of the acetyl radical from nitrogen (see Section 2.1) as well as the loss of $\cdot CH_2COOCH_3$ $[M-73]$ from the molecular ion will be observed. Both reactions lose importance as the CH_2 chain becomes longer[8]. The corresponding *N*-benzoyl derivatives behave analogously in the mass spectrometer[8][*].

In this connection reference may be made to the partly unusual fragmentation behavior of the oxindole alkaloid vincatine *(20)*[31]. A characteristic signal is observed in the mass spectrum of this alkaloid at $[M-73]$. High resolution measurements showed that the ion lacks the CH_2COOCH_3 radical. Aliphatic carboxylic acid esters lose, as mentioned above, 73 amu from the molecular ion only to a small extent (cf. Ref.[29]). The unexpected formation of the $[M-73]^+$ ion can be explained by a cyclization to *(20a)*, whereby the oxindole

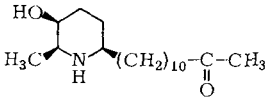
(20)⁺ (m/e = 370, 100%) *(20a)* (m/e = 297, 20%)

oxygen attacks C^4 with formation of a pyran ring. By way of analogy, the mass spectrum of alstonilidine *(21)*, in which $[M-59]$ is the base peak, would indicate participation of a neighboring group (see[32]) during the decomposition, for the preferred loss of an aromatic methoxycarbonyl group is unusual.



(21), Alstonilidine *(22)*

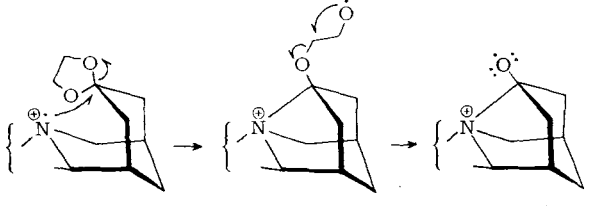
In the mass spectrometer ω-aminoalkyl methyl ketones of the general formula *(22)* show an intense $[M-57]^+$ signal, which corresponds to the elimination of $\cdot CH_2COCH_3$[33]. Since such a fragmentation behavior is indistinctly or not at all observable in the mass spectral decomposition of mono-



[*] For the mass spectrometric behavior of other ω-amino acid derivatives see Ref. [30].

functional aliphatic ketones, the second functional group must be involved in the formation of this ion.

Similar observations have been made in the decomposition of 2-(10-oxoundecyl)-4-quinolone *(23)*[34] and of cassine *(24)*[35].—Of special interest is the interaction of a tertiary amine and an ethylene acetal group, which are sterically so



(23)

(24), Cassine

arranged as to favor interaction. Unexpectedly, the mass spectrum of the ethylene acetal of an alkaloid rearrangement product having the partial formula *(25)* does not show the signal of the molecular ion, but that of the amino semiacetal *(25a)* (or the amino ketone), although the acetal is present (spectroscopic and chemical evidence) (cf. Scheme 10)[36].

(25)$^+$ *(25a)*$^+$

Scheme 10

4. Interaction between Oxygen-containing Functional Groups

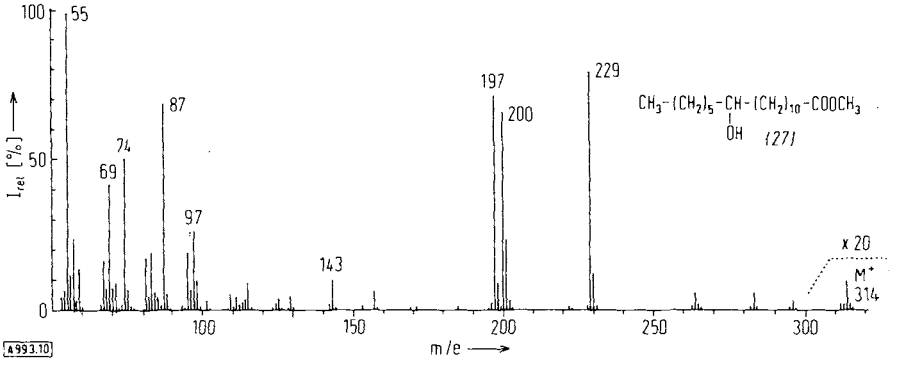
As demonstrated in Section 2, the mass spectral fragmentation pattern of disubstituted α,ω-alkanediamines of general formula *(26)* (X=NH_2, NHCOR; X′=NH_2, NHCOR, COOR *etc.*) is essentially determined by interaction of the two groups X and X′. Nitrogen-containing groups can be replaced by those containing oxygen, which show a more or less distinct interaction, depending on the type of functional group.

$X-(CH_2)_n-X'$ *(26)*

4.1. Methyl Hydroxy- and Methoxycarboxylates[37]

Figure 10 shows the mass spectrum of methyl 12-hydroxystearate *(27)*[37]. The two characteristic abundant signals at *m/e*=200 and 197 do not occur with comparable intensity in the mass spectrum of methyl stearate[29] and in the spectra of *n*-alkanes containing a central hydroxy group[29]. Nor can their appearance be explained from the spectra of corresponding monofunctional compounds. Consequently, other interpretations have been suggested[37].

The mechanism given in Scheme 11 is supported by metastable signals, spectra of homologous compounds and the spectrum of deuterated derivatives, *e.g.* O—D-*(27)*: The H attached to O is transferred to the carbonyl oxygen before α-fission to the hydroxyl group takes place [*(27a)*]. In the subsequent radical termination process, *(27c)* (*m/e*=229) as well as *(27b)* (*m/e*=200) are formed. The ion *(27c)* loses CH_3OH and is thereby transformed into *(27d)* (*m/e*=197). By deuterium labeling [O—D-*(27)*], it could be demonstrated that the hydrogen atom that splits off with the CH_3OH originates from the OH group. The size of the cyclic transition state ion necessary for this H-transfer has no significant influence on the abundance of these fragment ions. Analogous observations



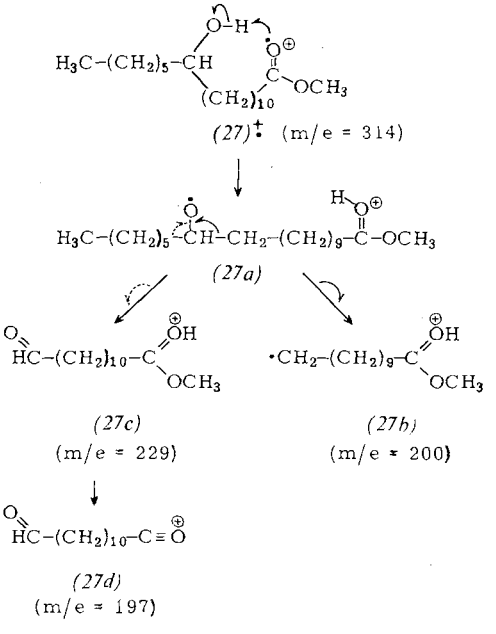


Fig. 10. Mass spectrum of methyl 12-hydroxystearate *(27)* (see Ref. [37]).

(27)$^+$ (m/e = 314)

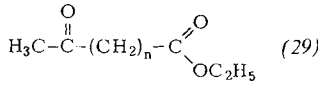
Scheme 11

have been made in the elimination of acetyl from acetylated α,ω-alkanediamines (see Section 2.1).

Such interactions also occur in the mass spectral decomposition of *O*-methylated ethyl carboxylates, *e.g.* *(28)*[38]. In the case of *(28)* the exceptional decomposition shown in Scheme 12, which is evidenced by metastable signals, has been confirm-



Scheme 12

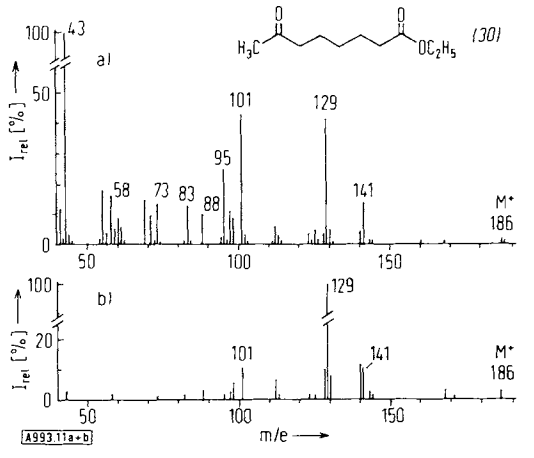
ed: The ion of mass number 173 [*(28a)*], formed by an α-cleavage to the methoxy group, is first converted by loss of CH_3OH into *(28c)* (*m/e* = 141) and then by loss of C_2H_5OH into *m/e* = 95. The reciprocal process [*(28a)* $-C_2H_5OH \rightarrow$ *(28b)* $-CH_3OH \rightarrow$ (*m/e* = 95)] is shown by metastable signals. As has been demonstrated by deuteration experiments, the additional hydrogen atom required in the removal of CH_3OH or C_2H_5OH, originates from position 5 of the compound. The mechanism, mentioned in Scheme 12, can be discussed analogously to the elimination of NH_3 from the $[M-R]^+$ ions in acetylated α,ω-diamines (see Section 2.2). The subsequent reactions of ions *(28b)* and *(28c)* to give *m/e* = 95, have not been completely explained by the deuteration experiments carried out so far[38].

4.2. Ketocarboxylic Acid Esters

The ketocarboxylic acid esters of general formula *(29)*[39] demonstrate most clearly the interaction effects in mass spectral decomposition processes. The spectrum of ethyl 7-oxooc-

(29)

tanoate *(30)* measured at 70 and 12 eV is shown in Fig. 11. All the intense signals, excepting the signal at *m/e* = 129, can be explained on the basis of the spectra of the corresponding monofunctional alkanes[29,40,41]. The ion of mass



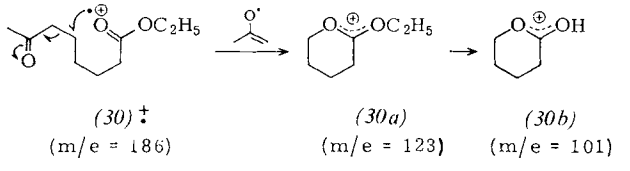


Fig. 11. Mass spectrum of ethyl 7-oxooctanoate *(30)*: a) at 70 eV, b) at 12 eV (see Ref. [39]).

number 129 corresponds to the loss of 57 amu (C_3H_5O) from the molecular ion. An analogous reaction can be observed with amino ketones (see Section 3).

A decomposition mechanism leading to a cyclic ion (Scheme 13) is assumed in the case of the ketocarboxylates of type *(29)*. In the case of compound *(30)* the structure *(30a)*

Scheme 13

with a six-membered ring[*] is suggested for the ion $[M-57]^+$. To confirm the cyclic nature of this ion, the mass spectra of homologous ethyl ketocarboxylates have been investigated (see Fig. 12).

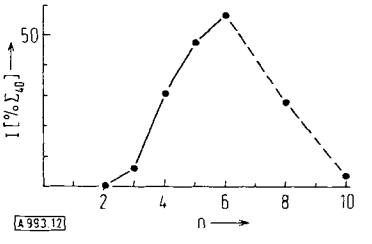

Fig. 12. Dependence of the abundances of $[M-57]^+$ ions on the number *n* of the CH_2 groups between the keto- and ethoxycarbonyl group in ketocarboxylates of type *(29)* at 12 eV (see Ref. [39]). The number of ring members in the $[M-57]^+$ ion is *n* + 1.

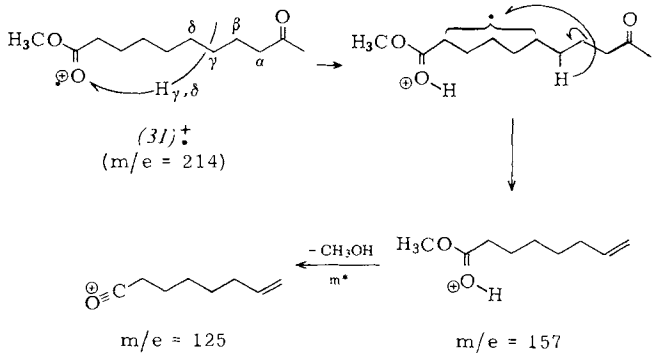
The $[M-57]^+$ signal is most intense in compounds that are able to form a five-, six- or seven-membered ring. The tendency to form smaller or larger rings is much less or even negligible.



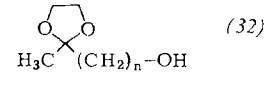
These results agree with those obtained in the fragmentation of *N*,*N*′-dibenzoylated[8] and *N*,*N*′-diacetylated α,ω-alkanediamines[8] and of *N*-(ω-acetylaminoalkyl)-2-ethylpiperidines[23] to cyclic ions (see Section 2).

[*] It seems that the signal at *m/e* = 101 derives from *(30a)*. A proposed structure is *(30b)*. In the spectrum of the corresponding methyl ketocarboxylate this signal is missing [39].

On comparing the spectra of *(30)* at 70 and 12 eV (Fig. 11), it is striking how the intensity of the $[M-57]^+$ signal markedly increases, while at the same time the ionization voltage decreases. This proves that a lesser amount of energy is needed for such molecular rearrangements than for the competition reactions.

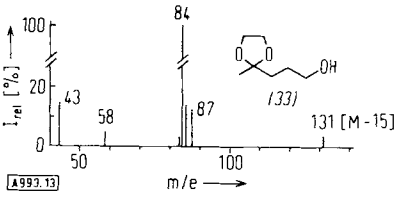
The *O*-acetyl derivatives of ω-hydroxy methyl ketones[39] behave similarly to the ketocarboxylates of type *(29)*. An abundance maximum corresponding to that of the $[M-57]^+$ ions in Figure 12 can also be observed in these compounds, in which the ion, formed by interaction, contains a five- or six-membered ring.

The mass spectrometric decomposition of methyl 10-oxoundecanoate *(31)* has recently been thoroughly studied regarding the loss of 57 amu [$m/e=157$] and resultant cleavage of CH_3OH ($m/e=125$) and CO ($m/e=97$) (m*, deuteration, high resolution data)[42]. On the basis of the D-distribution in the daughter ion $m/e=125$, the following reaction course is suggested:



Scheme 14

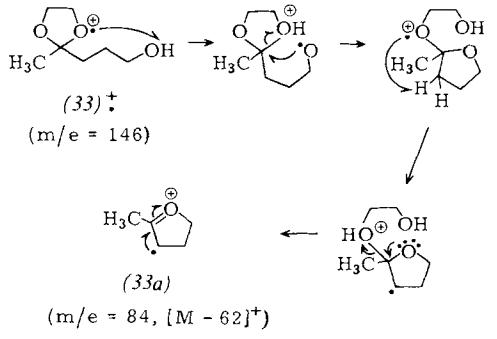
Compound *(31)* decomposes (Scheme 14) in a completely different fashion to that of *(30)* (Scheme 13), although these compounds represent methyl and ethyl esters, respectively, of homologous acids. The homologous series of the methyl esters have not yet been investigated in detail.



It can hardly be presumed that the decomposition reactions are strongly influenced by the nature of the alcohol groups, although in the case of the ethyl ester the onium reaction [loss of C_2H_4 from *(30a)* to *(30b)*] is dominant. Probably it is the difference in chain length of the compounds investigated which is responsible for the different fragmentation paths. The possibility that both mechanisms are correct and that their predominance varies according to the distance between the two functional groups, cannot be ruled out.

4.3. Hydroxyethylene Acetals

Another very illustrative example concerning the interaction of oxygen-containing functional groups in mass spectral fragmentations has been discovered in ethylene acetals of type *(32)*[39]. Mass spectra of ethylene acetals are generally distinguished by intense fragment ion signals resulting from α-cleavages to the acetal oxygen atoms[41,43]. The signals at $[M-(CH_2)_n-OH]^+$ and $[M-15]^+$ in the spectra of the compounds of type *(32)* derive from such processes. The $[M-62]^+$ signals, however, are caused by interaction between the acetal and hydroxy groups (see Fig. 13).



(32)

(33)

Fig. 13. Mass spectrum of the ethylene acetal of 3-(2-methyl-1,3-dioxolan-2-yl)propan-1-ol *(33)* at 12 eV (see Ref. [39]).

The mechanism for the fragmentation of *(33)*, according to the result so far obtained, is outlined in Scheme 15. It is supported by deuteration experiments and by spectra of model

Scheme 15

substances (*e.g.* propylene acetals)[39]. The abundance of the $[M-62]^+$ ion in this type of fragmentation also depends on the size of the ring. Once again the abundance maximum occurs in the case of five- and six-membered rings.—Ions formed by difunctional interaction have also been recorded in the mass spectra of ethylene acetals of ketocarboxylates[39].

4.4. Dicarboxylic Acid Diesters

As expected dimethyl dicarboxylates of straight-chain hydrocarbons also belong to those compounds whose fragmentation is at least partly determined by interaction of the functional groups.

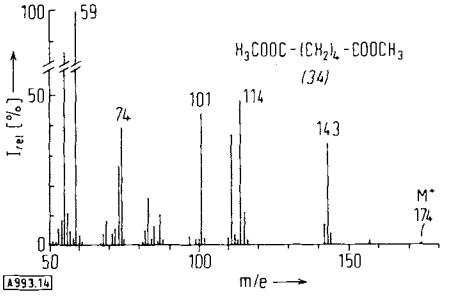


Fig. 14. Mass spectrum of dimethyl adipate at 70 eV (see Ref. [29]).

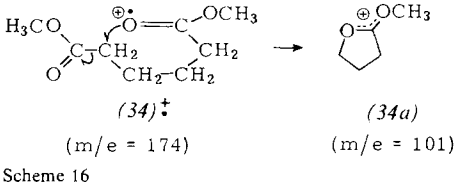
Regarding difunctional interaction, one signal is of special importance: $m/e=101$ $[M-73]^+$.

Cleavage of 73 atomic mass units corresponds to the loss of $\cdot CH_2COOCH_3$ from the molecular ion. Such a fragmenta-



tion is registered only to a very small degree in methyl monocarboxylates (see Section 3)[29]; yet in dimethyl dicarboxylates it can give rise to one of the highest peaks in the spectrum. The values found in the homologous series of these compounds are listed in Table 2. It will be noticed that the most abundant signal occurs in dicarboxylic acids with four or five CH_2 groups. This would indicate, in analogy with the cyclization

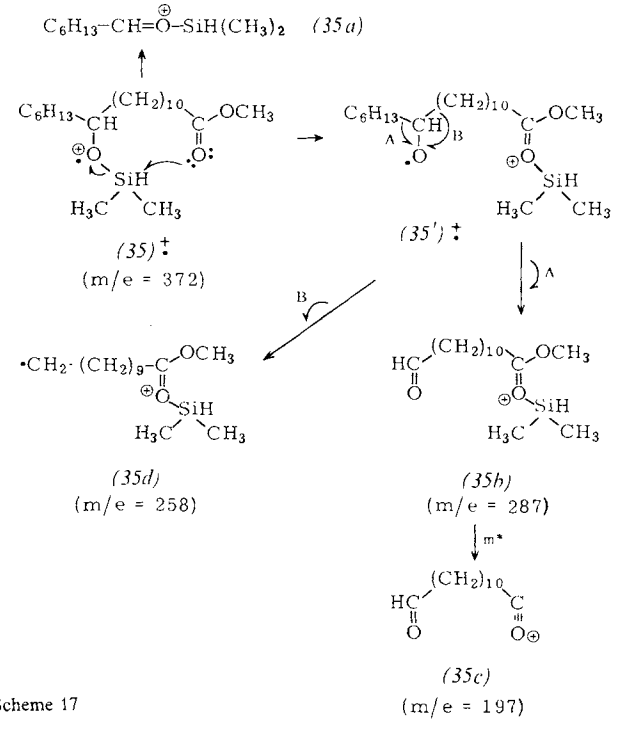
Table 2. Dependence of the abundance (I) of the $[M-73]^+$ signal in the spectra of homologous dicarboxylic acid dimethyl esters on the number n of the methylene groups (data from [29]).

$H_3COOC-(CH_2)_n-COOCH_3$

	n	$[M]^+$ m/e	$[M-73]^+$ m/e	$I_{rel.}$ [%]	I[% Σ_{50}]
	2	146	73	1	0.03
	3	160	87	16	4.37
(34)	4	174	101	44	7.68
	5	188	115	79	9.11
	6	202	129	58	1.45
	7	216	143	28	3.30

reactions discussed above, that cyclic ions are probably also formed here. To explain the fragmentation pattern, the reaction course outlined in Scheme 16 has been suggested[39]. Accordingly, the $[M-73]^+$ signals are most abundant with ions of five- or six-membered rings [type *(34a)*]. Other esters of dicarboxylic acids behave similarly to the dimethyl esters.

(34)$^+$ (m/e = 174) *(34a)* (m/e = 101)



Scheme 16

Interactions of the type discussed in this section can also occur in other compounds having oxygen-containing functional groups: α,α'-disubstituted tetrahydrofuran derivatives[44], diketones[45], hydroxycyclohexanones[46], hydroxybenzyl ethers[47], hydroxylalkyl ethers[47], α,δ-diols[48] (cf. also the discussion on the fragmentation mechanisms of aporphine alkaloids[49]).

5. Interaction between Silicon- and Oxygen-containing Functional Groups

The mass spectral decomposition of the dimethylsilyl ether of methyl 12-hydroxyoctadecanoate *(35)* (Fig. 15), just like that of the trimethylsilyl ether, involves interfunctional interactions[50]. Hence compound *(35)* behaves analogously to the hydroxycarboxylic acid esters[37] (Section 4.1).

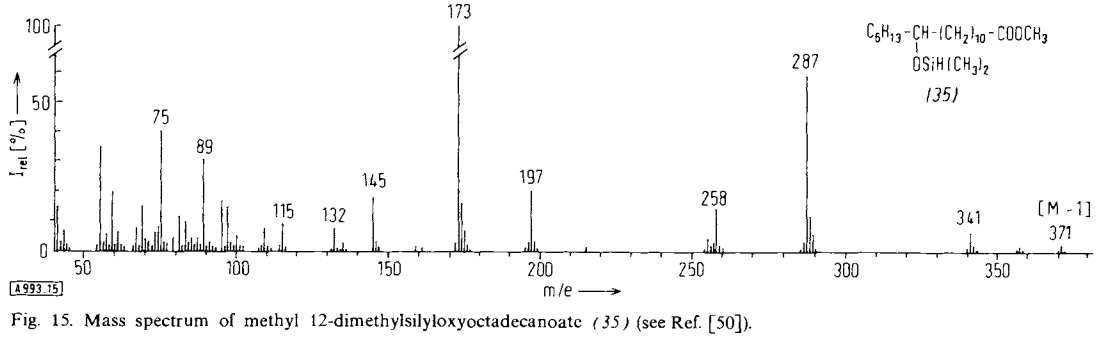
The main fragment ions in the spectra of *(35)*, *(35a)* ($m/e=173$) and *(35b)* ($m/e=287$) correspond to the α-cleavages to the dimethylsiloxy group. The subsequent reactions of these ions include interaction of neighboring groups; some of these are shown in Scheme 17.—During the fragmentation, the dimethylsilyl radical migrates from the alcoholic to the ester function. This can be deduced from the fact that ion *(35b)* is transformed into *(35c)* *via* elimination of $C_3H_{10}OSi$. This is also proved by the occurrence of a metastable signal, by high resolution data, and by spectra of deuterated compounds (trideuteriomethyl 12-dimethylsiloxyoctadecanoate, 12-D- and 2,2-D_2-derivatives). If the 11,12 bond in the isomeric molecular ion *(35')*$^+$ is broken, ion *(35d)* results, which transforms by means of further rearrangement reactions into a more stable radical ion. (For similar decomposition reactions see also Ref. [7, 51] and the literature cited in

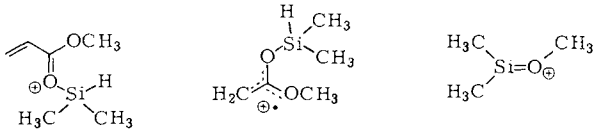
(35)$^+$ (m/e = 372) *(35')*$^+$ *(35d)* (m/e = 258) *(35b)* (m/e = 287) *(35c)* (m/e = 197)

Scheme 17

Ref. [52].) In the lower part of the mass spectrum of *(35)* further signals occur which are due to ions whose origin can also be traced back to difunctional interaction: $m/e=145$ *(35e)*, 132 *(35f)*, 89 *(35g)*.

In the spectra of α-halo-ω-trimethylsiloxyalkanes *(36)* and trimethylsilyl esters of ω-halo fatty acids *(37)* very intense





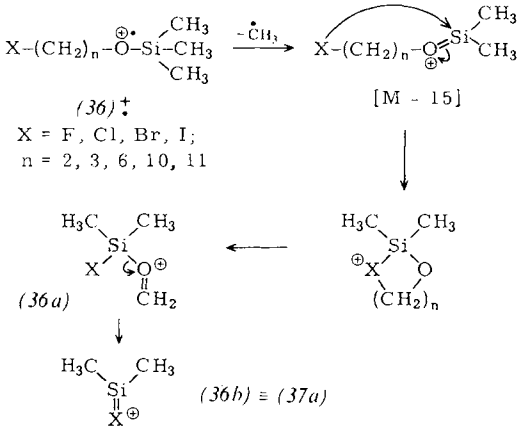


Fig. 15. Mass spectrum of methyl 12-dimethylsilyloxyoctadecanoate *(35)* (see Ref. [50]).

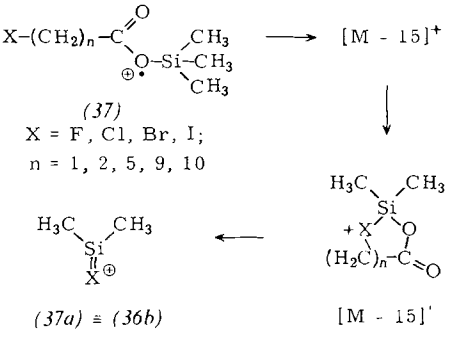
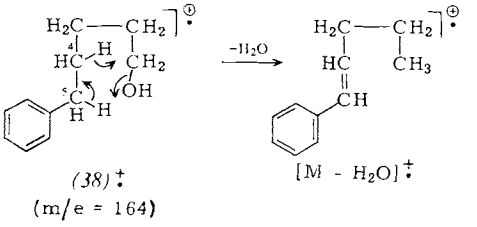


(35e) (m/e = 145) *(35f)* (m/e = 132) *(35g)* (m/e = 89)

ions can partly be observed which are indicative of the involvement of neighboring group participation[52] (see Schemes 18 and 19, respectively).

Scheme 18

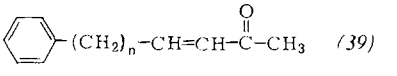
It is interesting to note that in compounds of type *(36)* and *(37)* this effect depends on the chain length of the alkane[*].



Scheme 19

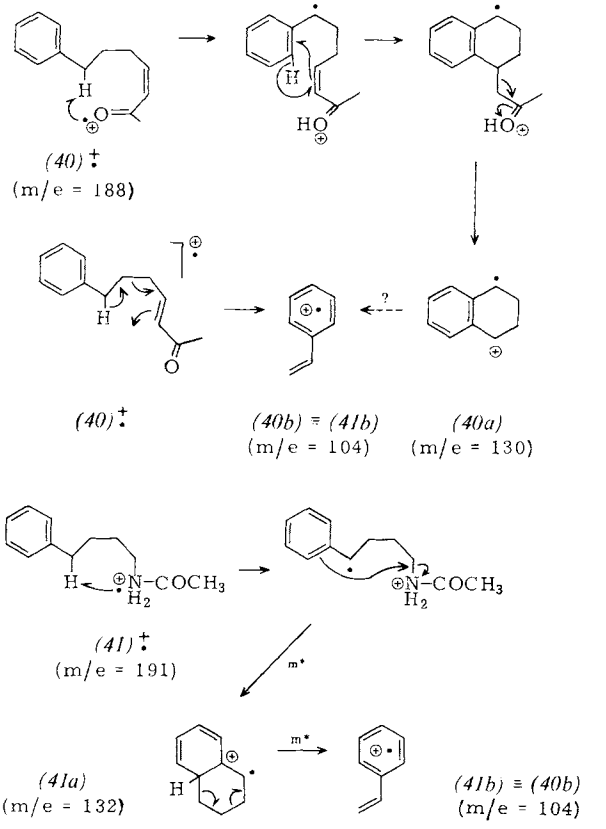
6. Interaction between Other Functional Groups[53]

In the mass spectrometer 5-phenyl-1-hexanol and, even more distinctly, 5-phenyl-1-pentanol *(38)* lose water from the molecular ion. The main site from which one of the protons is removed is from the benzylic position. In the case of *(38)* 14% of the protons lost originate from position 4 and 75% from position 5. The following has been proposed as being the principal mechanism involved[54] (see Scheme 19a).



This finding would suggest classification under the group of fragmentations based on an interaction of the functional groups; it is of special importance because a hydrogen atom, activated by the phenyl nucleus, is split off together with another functional group (OH). Unfortunately further investigations, which would allow a generalization of this reaction, are still lacking.

(38)$^{+\cdot}$ (m/e = 164)



Scheme 19a

A mutual influence of phenyl group and carbonyl function has been proved in the decomposition of phenyl ketones of general formula *(39)*[55].

(39)

The spectrum of 7-phenyl-3-hepten-2-one *(40)* is shown in Fig. 16. Apart from the base peak at $m/e=91$ (tropylium ion)[*] and the signal at $m/e=43$ ($H_3C-C\equiv\overset{\oplus}{O}$), which are also observed in the spectra of the corresponding monofunctional compounds, the other intense signals, *i.e.* those at $m/e=130$, 105, 104, 97[**] and 84, are due to difunctional interactions (cf. Scheme 20). It is noteworthy that the corre-

(40)$^{+\cdot}$ (m/e = 188) *(40b)* ≡ *(41b)* (m/e = 104) *(40a)* (m/e = 130)

(41)$^{+\cdot}$ (m/e = 191) *(41a)* (m/e = 132) *(41b)* ≡ *(40b)* (m/e = 104)

Scheme 20

[*] Difunctional interactions also occur in the mass spectral fragmentation of cycloalkane derivatives [7].

[*] As D-labeling experiments have shown, the formation of $m/e=91$ is of a complex nature and will therefore not be discussed any further in this report (cf. Ref. [55]).

[**] The $[M-91]^+$ ion $m/e=97$ [in the spectrum of *(40)*] could be cyclic.

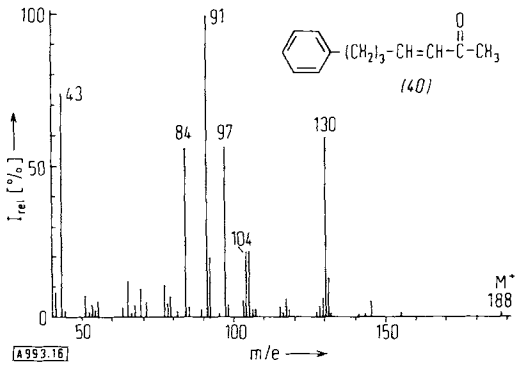


Fig. 16. Mass spectrum of 7-phenyl-3-hepten-2-one *(40)* (see Ref. [55]).

sponding nitrogen compound, *N*-(4-phenylbutyl)acetamide *(41)*, shows a quite similar spectrum (Fig. 17) and consequently

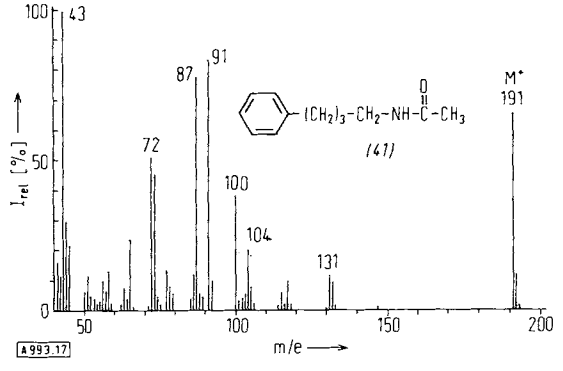

Fig. 17. Mass spectrum of *N*-(4-phenylbutyl)acetamide *(41)* (see Ref. [56]).

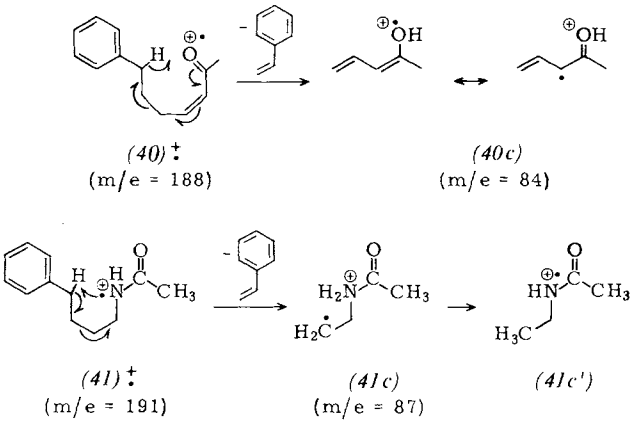
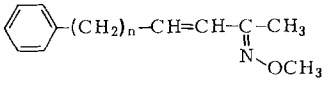


undergoes an analogous decomposition[56]. A comparison with the corresponding monofunctional compounds shows that the occurrence of ions with mass numbers 132, 100, 87 and, to some extent, 104 in the decomposition of *(41)* cannot be explained without considering the effect of a second functional group.

Scheme 20 outlines the formation paths of the ions *(40a)* (*m/e* = 130) and *(40b)* (*m/e* = 104) from *(40)*, and of *(41a)* (*m/e* = 132) and *(41b)* (*m/e* = 104) from *(41)*. In both cases the mode of decomposition has been confirmed by measurements on deuterated compounds. In both examples a benzylic hydrogen atom is transferred to the heteroatom, and the group carrying this heteroatom is then eliminated by cyclization of the molecular residue; *(41a)* loses C_2H_4 (m*) and forms *(41b)*. Whether formation of this ion from *(40)* follows a comparable route, or originates directly from $(40)^{\ddagger}$ by a McLafferty rearrangement, has not yet been investigated. (Experiments with deuterated compounds have shown that the fragmentation to *(41a)*, mentioned in Scheme 20, is the main decomposition reaction.)

The signal at *m/e* = 84 in the spectrum of *(40)* corresponds to that at *m/e* = 87 in the spectrum of *(41)* (see Scheme 21). Both are formed in an analogous manner. Once again, a benzylic hydrogen atom is transferred to the heteroatom and leads to expulsion of styrene as a neutral fragment and formation of *(40c)* and *(41c)* [or *(41c')*] as charged particles.



The investigations on the fragmentation reactions of compounds *(40)* and *(41)* are supported by experiments with homologous, analogous and deuterated derivatives[55,56].

A similar mass spectrometric behavior to that mentioned, above for the phenyl ketones of general formula *(39)* is also displayed by their *O*-methyl-substituted oximes[57].

Scheme 21

A larger number of 3-methoxydecanes, each carrying another substituent (I, Br, Cl, OH, SH, SCH_3, NH_2, $N(CH_3)_2$, =O, ethylenedioxy) at C^8, have already been investigated mass spectrometrically[58]. The spectra would suggest that some

difunctional interactions take place during the decomposition processes. However, a detailed knowledge of the modes of decomposition is still lacking, since a closer study of these reactions using deuterated derivatives has so far only been carried out in one case.

7. Conclusion

Our discussion of the above mentioned fragmentations, which are caused by interaction of functional groups during mass spectral decomposition, has purposely been confined to the investigation of substituted alkanes, although this mode of fragmentation also occurs in other classes of substances.

In summarizing these investigations it can be stated that in nearly all the cases discussed above, the decomposition reactions are determined by additional activated positions (α-positions to heteroatoms, benzyl positions or activated hydrogen atoms on heteroatoms) in the molecule. As would be expected, the di- and polyfunctional compounds differ from the corresponding monofunctional compounds regarding such activation; this is clearly expressed in the mass spectra.

As can be seen from the examples mentioned above, our study of mass spectral fragmentations, which are influenced by neighboring groups, or participation of two functional groups, is still in its infancy and it can be assumed that more detailed research will be carried out in this field during the next few years. A detailed knowledge of the mechanisms

of mass spectral fragmentation should not only interest the mass spectroscopist, but also all organic chemists who resort to the use mass spectroscopy as an analytical method. Only by such combined interest can we expect to gain more structural information from the spectra.

A Convenient Procedure for the Synthesis of Cyclobutanones[**]

By *Abdul Sidani, Jacqueline Marchand-Brynaert,* and *Léon Ghosez*[*]

We have previously reported[1] that *N,N*-dimethyl-*N*-(2-methyl-1-propylidene)ammonium tetrafluoroborate ("tetramethylketeneimmonium tetrafluoroborate") cycloadds readily to olefins and acyclic dienes to give cyclobutylideneammonium salts in high yield. This new method of building four-membered rings is extremely attractive since: (a) "keteneimmonium ions" do not dimerize or polymerize like ketenes or keteneimines and can thus be stored in solution, and (b) α-chloro enamines, the precursors of "keteneimmonium ions", are easily prepared from inexpensive and readily available starting materials[2]. A severe limitation of the method, however, was the use of the expensive reagent $AgBF_4$ for the generation of the cation from the α-chloro enamine.

We have now developed a simple procedure which does not require $AgBF_4$: addition of *N,N*-dimethyl-1-chloro-2-methylpropenylamine *(1)* to a slurry of freshly dried $ZnCl_2$ in refluxing CH_2Cl_2 gives a salt *(2)* which reacts with olefins to form the cyclobutylideneammonium salts *(3)*. Hydrolysis of the crude salts in 1 N NaOH furnishes the corresponding cyclobutanones *(4)* in high yield (Table 1).

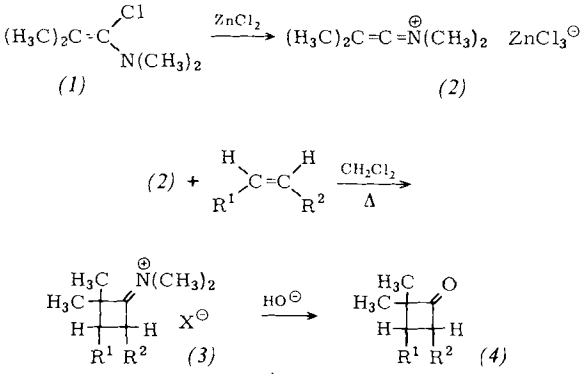

Table 1. Preparation of the salts *(3)* and cyclobutanones *(4)*.

	R^1	R^2	*(3)* [a, b] yield [%]	*(4)* [b] yield [%]
a	H	H	68	89
b		$-(CH_2)_4-$	88	91
c		$-(CH_2)_6-$ [c]	86	97

[a] Isolated as perchlorates.
[b] Identical with authentic samples.
[c] *cis*-Cyclooctene.

It is quite remarkable that *ethylene*, which is normally unreactive in uncatalyzed cycloadditions[3] (for instance, with acrylonitrile it reacts only at 300 °C and 1000 atm.[4]) reacts with *(2)* at room temperature and atmospheric pressure.

2,2-Dimethylcyclobutanone (4a)

Ethylene (dried by passage through a column filled with $CaSO_4$) is slowly bubbled into a slurry of freshly dried $ZnCl_2$ (2.7 g, 0.02 mol) in CH_2Cl_2 (20 ml). The α-chloro enamine *(1)* (2.25 g, 0.0169 mol) is added from a syringe and the mixture is refluxed for 3 h under a continuous stream of ethylene and then hydrolyzed with 1 N NaOH (40 ml). Extraction with CH_2Cl_2 followed by removal of the solvent yields 1.57 g of *(4a)* still containing 6% of *N,N*-dimethylisobutyramide as shown by vpc.

A General Method for the Synthesis of 2-Azetidinones and 2-Azetidinylideneammonium Salts[**]

By *Michel De Poortere, Jacqueline Marchand-Brynaert,* and *Léon Ghosez*[*]

The exceptional reactivity of α-chloro enamines *(1)* toward nucleophilic reagents[1] probably results from a fast pre-equilibrium[2] of *(1)* with an alkenylideneammonium chloride *(2)*, which reacts with the nucleophilic reagent.

We have found that the addition of *N,N*-dimethyl-1-chloro-2-methyl-1-propenylamine *(1)*, $R^1 = R^2 = CH_3$, to solutions of

CH_3	CH_3	C_6H_5	H	C_6H_5	A	*b*	47	68
CH_3	CH_3	$C_6H_5CH_2S$	H	$(CH_3)_3C$	A	*c*	60	42
CH_3	CH_3	C_6H_5	C_6H_5	C_6H_5	B	*d*	65	70
H	$(CH_3)_3C$	C_6H_5	H	C_6H_5	B	*e*	80 [c]	0 [d]

[a] As readily crystallizable perchlorates obtained by treatment of the crude chlorides with a saturated solution of $KClO_4$.
[b] Obtained by direct hydrolysis of the crude salts *(5)*. Yields were not optimized.
[c] *trans*-Configuration assigned on the basis of $J_{3,4}=2$ Hz.
[d] Hydrolysis (reflux, 2h) gave the ring-opened product $(CH_3)_3C{-}CH(CON(CH_3)_2){-}CH(C_6H_5){-}NHC_6H_5$ in 76% yield.

the Schiff bases *(3)* in dry CH_2Cl_2 at room temperature (method A) gives the 2-azetidinylideneammonium chlorides *(5)*. Hydrolysis of the crude salts in 0.5 N NaOH affords the corresponding 2-azetidinones *(6)* which show identical properties with authentic samples prepared by known methods (Table 1).

It seems quite probable that the first step in the cycloaddition is aminoalkenylation[1] of the Schiff base *(3)* to give intermediate *(4)* which cyclizes to *(5)*. Since such an intermediate *(4)* is, in principle, also available from the reaction of α-chloro alkylideneammonium chlorides[3] *(8)* with Schiff bases *(3)* followed by elimination of HCl, it appeared feasible to bypass *(1)* and use its direct precursor. Thus crude *(8d)* and *(8e)* obtained from the reaction of tertiary amides *(7d)* and *(7e)* with phosgene[1] were reacted with *(3)* and then treated with triethylamine to give *(5d)* and *(5e)* in good yields (method B). *(5d)* was hydrolyzed readily to the β-lactam *(6d)*. The hydrolysis of *(5e)* on the other hand was much more difficult and resulted in opening of the four-membered ring (see Table 1).

3,3-Dimethyl-1,4,4-triphenyl-2-azetidinone (6d)

Phosgene (7 ml) is added at 0°C to a solution of *N,N*-dimethylisobutyramide *(7a)* (1.15 g, 10 mmol) in dry CH_2Cl_2 (10 ml). After 2 days at room temperature, the solvent is removed *in vacuo* and the residue reacted with a solution of *N*-(diphenylmethylene)aniline (2.56 g, 10 mmol) in CH_2Cl_2 (10 ml). After 3 h, the mixture is treated with triethylamine (1.01 g) and kept at room temperature for 2 h. Filtration to remove the precipitate and evaporation of the solvent *in vacuo* leaves a residue which is hydrolyzed in 0.5 N NaOH (20 ml). The azetidinone is extracted with CH_2Cl_2 (3 × 20 ml), the combined extracts dried ($MgSO_4$), and the solvent evaporated under reduced pressure. Recrystallization from ethanol yields pure *(6d)* (m.p. 122°C).

Stereochemistry of the Degenerate Norcaradiene Rearrangement: A Stereospecific Symmetry-Forbidden Process[1]

By *Frank-Gerrit Klärner*[*]

The degenerate rearrangement of *cis*-bicyclo[6.1.0]nona-2,4,6-triene follows the course postulated by *Woodward* and *Hoffmann*[2] with a high degree of stereoselectivity. However, it cannot be stated *a priori* whether the stereochemistry is a result of orbital-symmetry control in this system since the least-motion process[3] and orbital symmetry control would both lead to the same result. In contrast, the analogous norcaradiene rearrangement discovered by *Berson* and *Willcott*[4] would proceed with retention at the migrating carbon in an orbital-symmetry controlled reaction[5] but with inversion in the case of a least-motion process. We have studied the stereochemistry of the reaction for optically active methyl 2,7-dimethylnorcaradiene-7-carboxylate *(1)*[6].

Thermolysis of *(1)* (180°C, benzene solution) leads to an equilibrium mixture of the isomers *(1)* to *(5)* [GC: 48.7:39.8:3.1:6.2:2.2] in which *(1)*, *(2)*, and *(3)* are themselves in valence-tautomeric equilibrium with the corresponding cycloheptatriene derivatives[6]. The structures of the new

[*] Dr. F.-G. Klärner
Abteilung für Chemie der Universität
463 Bochum, Postfach 2148 (Germany)

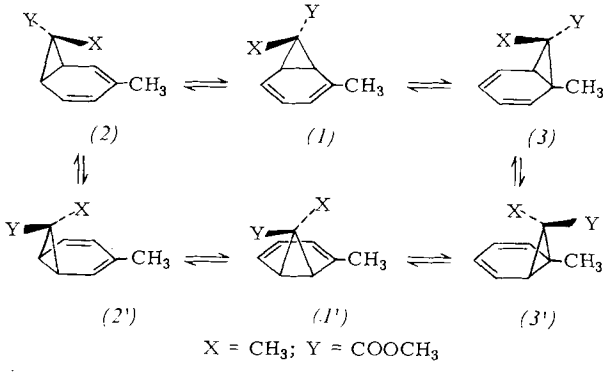
compounds are confirmed by their spectroscopic properties; *(3)* was also synthesized by an independent route[6].

The rearrangement of *(1)*, *(2)*, and *(3)* may either be the result of a sigmatropic carbon shift or proceed *via* products *(4)* and *(5)* which are formed by 1,5-homodienyl hydrogen shift. Starting from *(1)*, *(3)*, and *(4)*, the time dependence of the equilibration taken together with the above equilibrium concentrations yielded the rate constants listed in Table 1[7].

Table 1. Rate constants at 180 °C (in benzene).

	(1)→*(2)*	*(1)*→*(3)*	*(1)*→*(4)*	*(2)*→*(4)*	*(2)*→*(1)*	*(3)*→*(1)*	*(4)*→*(1)*	*(4)*→*(2)*
$k \times 10^5$ [s^{-1}]	1.47	2.00	0.61	0.52	1.78	32.09	4.75	3.27

Analysis of these rate constants shows that rearrangement *via (4)* and *(5)* involving a hydrogen shift is only of minor significance ($\leq 10\%$).



In the case of a sigmatropic carbon shift *(2)*⇌*(1)*⇌*(3)* with *retention*, loss of optical purity of the reactants on equilibration must correspond to the degree of participation of the homodienyl hydrogen shift in the isomerization[8]. If the rearrangement steps proceed with *inversion*, however, then racemization can only occur in the reactions *(2)*⇌*(2')* and *(3)*⇌*(3')*.

Table 2. Racemization of optically active *(1)*.

t [s]	c [a] (exp.)	c [a] (calc.) [b]
0.6288×10^5	80.7	81.1
1.3454×10^5	47.5	46.7
2.3406×10^5	22.8	21.1

[a] c [%] = 100 × [α]/[α]$_0$; [α]$_0$ = rotation of the starting compound, [α] = rotation of *(1)* isolated by gas chromatography.
[b] Calculated values for inversion at C^7 with $k_{22'} = 1.5$ and $k_{33'} = 0.9 \times 10^{-5}$ [s^{-1}].

As seen from Table 2, the rate of racemization of *(1)* could be simulated by an analog computer[9] utilizing the rate constants given in Table 1.

X = CH_3; Y = $COOCH_3$

The reaction scheme could be tested by thermolysis of both optically active *(1)* and optically active *(2)*. Rearrangement products *(2)* and *(3)* obtained on thermolysis of *(1)*, as well as recovered *(1)*, were found to be optically active, as expected. Their optical purity (O.P.), determined with chiral NMR shift reagents[10], agreed with the calculated values within the limits of accuracy of the method (Table 3) when the rate constants from Table 1 were again used in the calculations. The optical purity of *(3)* demonstrates that the stereoselectivity of the migration of C^7 is certainly in excess of 97.5% and according to calculation should be almost 100%.

Table 3. Thermolysis of *(1)* ($[\alpha]_{436}^{25} = +333.8$; O.P.$_0$ = 52.8%).

Product spread [%]	$[\alpha]_{436}^{25}$ [°]	O.P. [%]	c [a] (exp.)	c [a] (calc.)
(1): 65.6	+325.7	51.8	98	93
(2): 27.7	+ 12.5	27.2	52	59
(3): 6.7	+ 59.8	50.2	95	89

[a] c [%] = 100 × O.P./O.P.$_0$.

In contrast, thermolysis of optically active *(2)* (O.P. 27.2%) leads to extensive racemization of the reactant (O.P. 8%) after formation of only 25% of *(1)* and to a high optical purity of the rearrangement product *(1)* (O.P. 18%). This finding rules out a carbon shift with retention. Under the experimental conditions such a process would result in almost complete retention of the optical purity of *(2)* (98%), which cannot be reconciled with the considerable loss (29%) actually observed.

The degenerate rearrangement of norcaradiene[11] and likewise that of *cis*-bicyclo[6.1.0]nona-2,4,6-triene thus proceed with inversion at the migrating carbon, regardless of the fact that in norcaradiene an antiaromatic transition state is formally involved[12]. In the transition state the distance between the interacting orbitals on C^1, C^7, and C^5 is apparently so great that significant overlap is no longer possible and no perceptible electronic stabilization or destabilization occurs.

An explanation[13] for the observed stereochemistry is provided by a least-motion process. Unlike the geometrical isomerization of cyclopropane, the degenerate rearrangement of norcaradiene or *cis*-bicyclo[6.1.0]nona-2,4,6-triene merely requires excitation of a C—C stretching vibration. Once the parting C atoms (C^1—C^7) have left the region of bonding interaction, C^7 will continue its motion until it is "captured" by interaction with C^5, which necessarily leads to inversion. In cyclopropane itself[14] such a process is impossible since the forces retaining the configuration at C^3 will very soon come into play following rupture of the C—C bond to prevent further widening of the angle C^{1}C^{2}C^3 and thus effect restoration of the original bond.

The Sulfonamide-Aminosulfone Rearrangement: A Rearrangement Induced Anionically, Cationically, and Thermally[**]

By *Dieter Hellwinkel* and *Martin Supp*[*]

During attempts to synthesize triarylamines utilizing organolithium compounds, we treated *N,N*-diphenylbenzenesulfonamide *(1)* and the corresponding *p*-toluenesulfonamide *(2)* with phenyl-, butyl- and methyl-lithium. However, we did not obtain the desired products of a nucleophilic substitution of the benzenesulfinate groups, but instead the isomers *(7)* and *(8)* of the starting compounds (showing intense NH stretching vibrations at 3348 cm^{-1}). We also isolated varying amounts of diphenylamine as a by-product. The constitution of *(7)* as a 2-anilinodiphenyl sulfone was proved by comparison with the reaction product of 1,2-bis(phenylsulfonyl)benzene with potassium anilide[1]. Hence *(8)* is the 2-anilino-4'-methyldiphenyl sulfone. We interpret the reaction as proceeding *via* the following sequence:

(1), R' = H
(2), R' = CH_3

(3), *(4)*

(7), m.p. 77 °C
(8), m.p. 94 °C

(5), *(6)*

Remarkably, the phenyl ring bound to the nitrogen is clearly the one which is metalated. This suggests an important resonance contribution of the type

to the ground state of these sulfonamides whose positively charged nitrogen will now favor metalation[2]. The driving force for the rearrangement, which takes place under surprisingly mild conditions, can be seen in the transformation of the phenyl anions *(3)* and *(4)* into the resonance-stabilized nitrogen anions *(5)* and *(6)* respectively. The considerable reaction rate follows from the immediate yellow (in ether) or orange coloration (in THF) due to the anions *(5)* and *(6)* upon addition of RLi to the sulfonamides.

It has long been known that the same products *(7)* and *(8)* are formed in the reaction of *(1)* and *(2)* with concentrated sulfuric acid[3]: we have now also confirmed this reaction (yield > 50%). The MO models which can be formulated for a cationic rearrangement transition state, making the plausible assumption of an intramolecular[4] synchronous reaction, are equally valid for a purely thermal process. Indeed, thermolysis of the sulfonamide *(1)* at 230°C (12 h) gave up to 26% of sulfone *(7)*.

We consider that a similar trichotomy of rearrangement possibilities likewise may well hold for (di)phenylamine derivatives substituted by other acid moieties.

[2] Preferred metalation of the phenyl ring directly bound to the sulfonyl group could have been expected since diphenyl sulfone is known to be metalated very easily in the *ortho* position by butyl lithium [cf. *J. M. Mallan* and *R. L. Bebb,* Chem. Rev. *69,* 693 (1969)]. Therefore, a kinetically controlled primary metalation of the corresponding positions in *(1)* and *(2)* and subsequent transmetalation cannot be excluded. It has meanwhile (*note added in proof.* March 8, 1974) been proved.

^{13}C-NMR Spectra of Diazoalkanes[1]

By *Joachim Firl, Wolfgang Runge,* and *Werner Hartmann*[*]

From the extreme shielding of the terminal C atom and the resonance position of the central C atom in the ^{13}C-NMR spectrum of ketene *(1)*[2] we have concluded, in agreement with other experimental results, that the resonance structure *(1b)* contributes essentially to the ground state. The corresponding resonance structure *(2b)* is generally accepted to be the most important form in the VB description of the isoelectronic diazomethane *(2)*[3,4].

[a] From broad-band decoupled PFT spectra in $CDCl_3$ at 0°C with TMS as internal standard; Bruker HX 90 NMR spectrometer; 22.63 MHz.

Since C atoms in similar bonding situations show analogous NMR shifts, a shielding comparable to that in ketene can be expected for the (terminal) C atom in diazomethane. To substantiate this, we have recorded the ^{13}C-NMR spectra of a series of diazoalkanes (see Table 1).

The characteristic feature of these spectra is the extreme shielding of the formally sp^2-hybridized diazomethylene carbon [typical signal range from 23.1 (diazomethane) to 62.5 ppm (diphenyldiazomethane)]. Its resonance position differs considerably from that hitherto regarded as normal for sp^2-hybridized carbon doubly bonded to nitrogen. In comparison with analogously substituted imines, the resonance of this C atom is shifted 100—120 ppm upfield. The shielding of the sp^2 C in diazoalkanes is exceeded only by that of the terminal C atom in the isoelectronic ketenes[1,5].

The theory of chemical shifts predicts increasing shielding for increasing electron density. The anomalous shielding of the sp^2 C atom found for both ketenes and diazoalkanes qualitatively confirms the close similarity of the π bonding in the two classes of compounds (high π-electron density on sp^2 C). The paramagnetic shift of the methylene C atom in diazoalkanes relative to the ketenes is presumably attributable solely to the greater electronegativity of the N_2 group compared to that of the CO group and the resulting reduction in the σ-electron density.

The π-electronic structure of ketene and diazomethane can be described by two orthogonal π systems[4], of which one (occupied by two electrons) is delocalized over two centers (CO, NN) and the other over three centers, from the terminal hetero atom to the terminal C atom. The second system contains four electrons and is thus isoelectronic to the allyl anion. The anomalous shielding of the terminal C atoms seems to be connected with this special electronic and nuclear configuration. Such a conclusion is supported by similarly exceptional ^{13}C-NMR data for classes of compounds having similar bonding, for instance the nitrile oxides recently described by *Roberts et al.*[6].

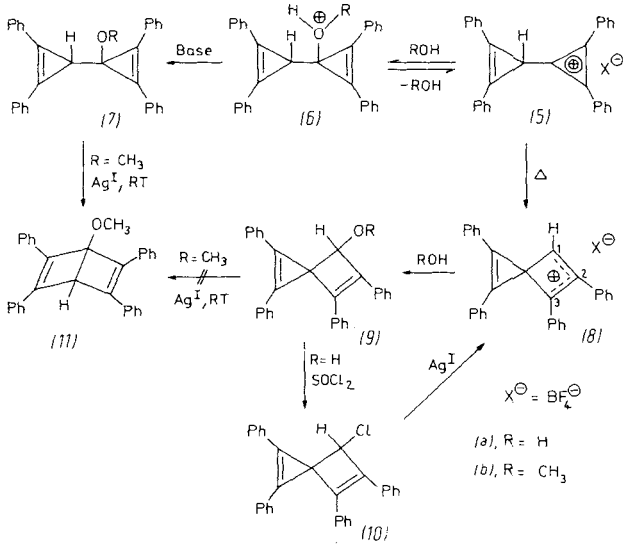
Synthesis and Trapping Reactions of the Spiro[2.3]-hexadienylium System: Ring strain *versus* Aromaticity[1]

By *Robert Weiss* and *Steffen Andrae*[*]

Calculation of the enthalpy gradient between bicyclopropenyl and benzene using standard bond increments and the experimentally determined cyclopropene ring strain[2] yields a value of about 124 kcal. We are attempting a systematic exploitation of the synthetic potential implied by this value in conversions in the $(CH)_6$ series[3,4].



We have now studied the question whether the "ring-strain controlled" rearrangement of bicyclopropenyl to benzene derivatives has a counterpart in the $C_6H_5^{\oplus}$ series. An estimate of the relative enthalpies of the cyclopropenylcyclopropenylium cation *(1)* and the phenyl cation *(4)* reveals that the energy content of *(1)* is some 113 kcal greater than that of (singlet) *(4)*. The *thermodynamic conditions* for a conversion *(1)*→*(4)* are therefore favorable. An intervention of the intermediates *(2)* and *(3)* would also satisfy the *topological conditions* for such a transition.

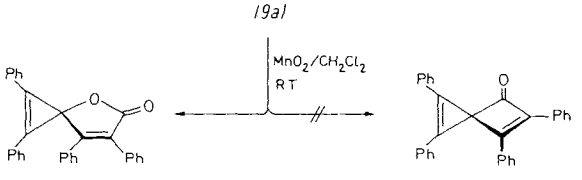
(1) *(2)* *(3)* *(4)*

In the present communication we report the first step of this sequence: the rearrangement of a cyclopropenylcyclopropenylium ion to the hitherto unknown spiro[2.3]hexa-1,4-dienylium system and its trapping reactions (see reaction scheme).

As starting compound we chose the readily accessible cyclopropenylium ion *(5)*[5] which can also be regarded as an ideally

[*] Dr. R. Weiss and Dipl.-Chem. St. Andrae
Institut für Organische Chemie der Universität
8 München 2, Karlstrasse 23 (Germany)

stabilized cyclopropenylmethyl cation. This particular structural feature finds expression in a dualistic behavior. Thus *(5)*, for example, reacts with ROH (R = H, CH_3) at room temperature on addition of base to give bicyclopropenyl systems *(7)*[6] (when R = H the characteristic cyclopropenol ring opening ensues[7]).

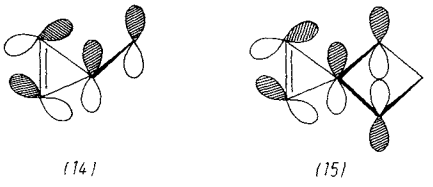


In the absence of an auxiliary base, however, a mobile equilibrium *(5)* $\rightleftharpoons$ *(6)* can be set up. At only slightly elevated temperatures (boiling CH_2Cl_2) the ring expansion *(5)*→*(8)* takes place within a few hours. Compared with *(5)*, *(8)* is the hotter carbonium ion and can be trapped irreversibly by water or methanol to give spiro[2.3]hexadienes *(9)*; predictably, the nucleophile attacks *(8)* exclusively at position 1. The first example of the theoretically interesting[8] class of compounds *(9)* was recently prepared by total synthesis[9]. Our preparation is simpler, gives higher yields, and is in principle more versatile (by using different trapping reagents[10]). The structures of the spirobicyclics *(9)* are confirmed by their analytical and spectroscopic data (Table 1) and by chemical evidence.

Table 1. Yields and physical properties of spiro[2.3]hexadienes *(9)*.

Cpd.	Yield [%]	M.p. [°C]	IR (KBr) [cm⁻¹]	NMR ($CDCl_3$) τ	MS *m/e*
(9a)	51	138	1802 [a]	8.03 (1H, s, br), OH [b] 4.65 (1H, s)	398 ($M^{\oplus}$) base peak
(9b)	68	124	1800 [a]	6.65 [3H, s) 4.88 (1H, s)	412 ($M^{\oplus}$) base peak

[a] C C (cyclopropene).
[b] Signal disappears on shaking with D_2O.



On treatment with $SOCl_2/K_2CO_3$ in anhydrous CH_2Cl_2 at room temperature *(9a)* is converted into *(10)* [colorless oil; characteristic methine proton at τ = 4.40 (1H)]. *(10)* is suitable as neutral source of the spiro[2.3]hexadienylium system *(8)* on action of $Ag^{\oplus}$ ions: in CH_3OH *(9b)* is formed in this way. Oxidation of *(9a)* with MnO_2 provides a structural bridge to a known substance: the product is not the highly strained spiroketone *(12)*, but instead the dimer of diphenylcyclopropenone *(13)*.

Together with the data listed in Table 1 this reaction amounts to structural proof for *(9a)*.

Neither the reverse reaction *(8)*→*(5)* nor reactions ensuing therefrom could be observed. Although *(8)* would appear to be geometrically predestinated for rearrangement to the corresponding Dewar benzene cation, on account of the bisected arrangement of the cyclopropene σ bond and the allyl cation moiety[11], no such reaction occurs [corresponding to *(2)*→*(3)*] under the reaction conditions employed. The possibility that $Ag^{\oplus}$ catalyzed rearrangement[4] of *(7b)* to *(11)* might proceed *via* *(9b)* could be discounted: *(9b)* is inert towards $Ag^{\oplus}$ under conditions of rearrangement[4]. Viewed together, our experimental findings strongly suggest that the spiro[2.3]hexadienylium system represents a pronounced local minimum on the $C_6H_5^{\oplus}$ potential energy surface.

What provides the driving force for the unusual ring expansion *(5)*→*(8)*? An estimate[12] of the enthalpy changes involved in the rearrangement *(1)*→*(2)* shows that about 80—90% of the resonance energy of *(1)* is already provided by the drop in total strain energy; together with the resonance energy of the resulting cyclobutenyl cation it is even overcompensated by at least 7 kcal/mol. The energetics of *(5)*→*(8)* should be essentially similar. However, whereas the anionic counterpart of *(2)* can be stabilized by spiroconjugation[8] and the bisected cyclopropenylmethyl cation *(14)*[11] by σ-π interaction, these two possibilities are ruled out for *(2)* for symmetry reasons[8] (cf. *(15)*[15]).

(14) *(15)*

Any perturbation producing asymmetry in the allyl LUMO, however, causes admixture of the highest occupied cyclopropene Walsh orbital to this orbital and thereby effects a stabilization of the spirocation. Owing to the reduced symmetry of the system, this should also apply to *(8)*. No statement is yet possible about the magnitude of this effect.

[11] Cf. *R. Breslow, J. Lockhart*, and *A. Small*, J. Amer. Chem. Soc. *84*, 2793 (1962).

[12] This estimate is based on the following values:
1) strain energies: a) cyclopropene 54 [2], b) cyclopropenylium ion 74 (= 20 + 54 [13]), c) spiro[2.3]hexadiene 85 kcal/mol [9]; the *upper limit* for the corresponding *cation (2)* was assumed to be 10 kcal/mol higher, on account of the additional angular strain.—2) Resonance energies: a) cyclopropenylium ion *ca.* 39 kcal/mol [13]; an additional drop in energy of the cyclopropenylium ion owing to the donor effect of a cyclopropene substituent as in *(1)* was accounted for by a value of 7 kcal/mol (upper limit) in the calculation [14]. b) cyclobutenyl cation: the resonance energy of the allyl cation (≥ 20 kcal/mol [13]) was adopted as a *lower limit*.

[13] *R. Breslow* in *M. Oki*: Nonbenzoid Aromatic Compounds. Sendai 1970, pp. 111—130.

[14] This value is deduced from pK_{R^+} measurements on *(5)*; *R. Weiss* and *C. Schlierf*, unpublished.

[15] The orbitals schematically depicted in *(15)* are the highest occupied σ orbital ("Walsh orbital") of cyclopropene and the lowest unoccupied π orbital of the cyclobutenyl portion of *(2)*.

A Method for the Evaluation of Inductive and Conjugative Effects—Application to Tropone[1]

By *Claus Müller, Armin Schweig,* and *Hans Vermeer*[*]

In this contribution we wish to point out a powerful method[2-4] *for evaluating inductive and conjugative effects and for distinguishing one from the other.* The quantitative rationalization of such effects is of fundamental importance in organic chemistry.

The method will be illustrated for the case of tropone *(2)*. For this purpose, we start from the measured[5-7] orbital energies of the two highest occupied π MOs of 1,3,5-cycloheptatriene *(1)*. In model calculations we then account, step by step, for all conformational, conjugative, and inductive energy changes suffered by both MOs when going from nonplanar[8] *(1)* to planar[9] *(2)*. Finally we compare the predicted orbital energies of the two highest occupied π MOs of *(2)* with those measured by photoelectron (PE) spectroscopy[6,7]. Good agreement between predicted and measured values then confirms the reliability of the derived conjugative and inductive effects.

The transformation of the two highest occupied π MOs of *(1)* to the corresponding $\pi(b_1)$ (no node at the carbonyl group) and $\pi(a_2)$ (node at the carbonyl group) MOs in *(2)* involves four steps (cf. Fig. 1): 1) Evaluation of the conformational effect. These effects are the MO energy changes occurring on transformation of *(1)* to planar cycloheptatriene *(1a)*. The conformational effect reflects the change of all π-π and σ-π (hyperconjugative) interactions in the transition of *(1)*

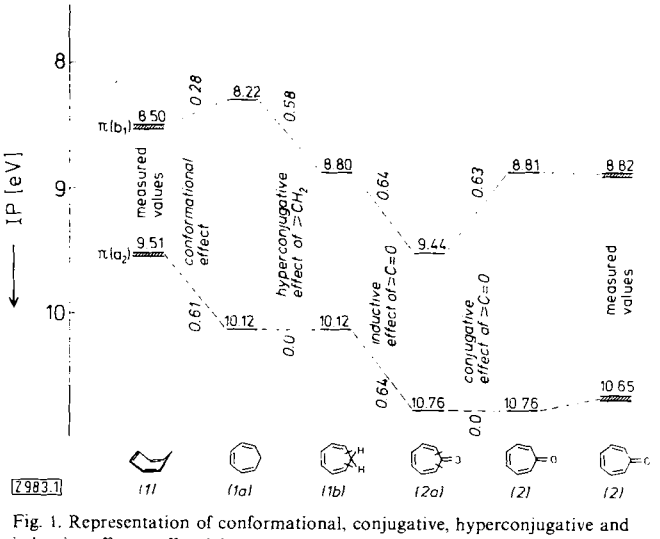

Fig. 1. Representation of conformational, conjugative, hyperconjugative and inductive effects suffered by the two highest occupied π MOs when going from 1,3,5-cycloheptatriene *(1)* to tropone *(2)*. The dashes across the C—C bonds in *(1b)* and *(2a)* symbolize the conjugative decoupling applied to these systems.

to *(1a)*.—2) Calculation of the hyperconjugative effect of the CH_2 group in *(1a)*. Accounting for this effect we arrive at π MO energies of fictitious cycloheptatriene *(1b)* that are not influenced by hyperconjugation.—3) Evaluation of the inductive effect of the carbonyl group. Taking account of this effect we obtain π MO energies of fictitious cycloheptatrienone *(2a)* which are influenced by the inductive effect of the carbonyl group but are free from conjugative effects.—4) Calculation of the remaining conjugative effect of the carbonyl group. Thus we finally arrive at the theoretically predictable $\pi(b_1)$ and $\pi(a_2)$ MO energies of *(2)*.

[*] Prof. Dr. A. Schweig, Dipl.-Chem. C. Müller, and Dr. H. Vermeer
Fachbereich Physikalische Chemie der Universität
355 Marburg, Biegenstrasse 12 (Germany)

The calculation of all the effects listed in 1) to 4) is based on the MINDO/2 method. The conformational effect is evaluated from the difference between corresponding MO energies of *(1a)* and *(1)*. The hyperconjugative effect exerted by the CH_2 group in *(1a)* results from the difference between the corresponding MO energies of *(1a)* and *(1b)*. The calculation of *(1b)* is carried out with conjugative decoupling of the CH_2 group[2-4]. The conjugative effect of the carbonyl group is computed in an analogous manner[2-4] by comparing *(2)* and *(2a)*. Finally the inductive effect of the carbonyl group follows from the energy difference between corresponding MOs in *(2a)* and *(1b)*.

Most impressively, the MO energies of *(2)* predicted in the above manner are in excellent agreement with the measured values. Thus the observed stabilization of the $\pi(b_1)$ and $\pi(a_2)$ MOs (0.32 and 1.14 eV, respectively) are reproduced very satisfactorily by the theoretical values (0.31 and 1.24 eV). On the basis of these results there is good reason to assume that the individual computational steps are reliable too. In particular, the following results warrant attention: 1) Due to the conformational effect the $\pi(a_2)$ MO is stabilized to twice the extent that the $\pi(b_1)$ MO is destabilized; 2) *the hyperconjugative effect of the CH_2 group and the conjugative effect of carbonyl group on the $\pi(b_1)$ MO are nearly the same*; 3) *the inductive effect of a carbonyl group on both π MOs has the same value*; 4) the inductive and conjugative effects of the carbonyl group on the $\pi(b_1)$ MO are expectedly opposite in sign, but of the same magnitude; and last but not least 5) *the conjugative effect between the carbonyl group and the $\pi(b_1)$ MO in (1b) is appreciable (0.63 eV).*

A New Synthesis of Keteniminylidenetriphenylphosphoranes and Thioketenylidenetriphenylphosphorane

By *Hans Jürgen Bestmann* and *Günter Schmid*[*]

On reaction of methylenetriphenylphosphorane *(1)* with isocyanide dichlorides *((2)*, X=N—R) in a molar ratio of 3:1 double transylidation[1] occurs to give keteniminylidenetriphenylphosphoranes *((3)*, X=N—R) alongside methyltri-

[*] Prof. Dr. H. J. Bestmann and Dipl.-Chem. G. Schmid
Institut für Organische Chemie der Universität Erlangen-Nürnberg
852 Erlangen, Henkestrasse 42 (Germany)

phenylphosphonium chloride which precipitates from the reaction solution.

The analogous reaction of compound *(1)* with thiophosgene (*(2)*, X = S) furnishes thioketenylidenetriphenylphosphorane (*(3)*, X = S)[2].

Table 1. Products of type *(3)*.

Compound	X	M.p. [°C]	Yield [%]
(3a)	N—C_6H_5	151—152	80
(3b)	N—*p*-C_6H_4Cl	183	75
(3c)	N—*o,p*-$C_6H_3Cl_2$	161	73
(3d)	N—CH_3	157—158	70
(3e)	N—C_6H_{11}	137—139	68
(3f)	S	218—220	60

The IR spectra of compounds *(3)* all contain a strong cumulene band at 2000 cm^{-1}; an additional absorption at 2150 cm^{-1} is observed in the case of *(3f)*.

Experimental:

An isocyanide dichloride (150 mmol) is added dropwise to a stirred salt-free solution[1b] of methylenetriphenylphosphorane (124 g, 450 mmol) in benzene/tetrahydrofuran (1:1, 1 l). After 1 h the precipitate (methyltriphenylphosphonium chloride), is filtered off under suction, the solvent distilled off from the filtrate, and the residue recrystallized from ethyl acetate. The yields and melting points of the resulting keteniminylidenetriphenylphosphoranes are listed in Table 1.

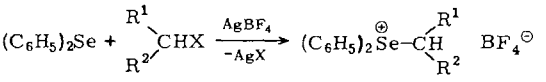
Synthesis and Reactions of Unstabilized α-Selenonio Alkylides



By *Willy Dumont*, *Pierre Bayet*, and *Alain Krief*[*]

Highly stabilized and unreactive α-selenonio alkylides have been described in the literature[1-4]; however, little[5] is known about the reactivity of the unstabilized derivatives towards electrophilic compounds. We therefore investigated whether unstabilized selenonium salts *(1)* can undergo nucleophilic reaction as carbene precursors or potential carbenoids or ylides in presence of a base.

For our study we required selenonium salts having three identical substituents on the selenium, *e.g.* trimethylselenonium iodide *(1a)*[6]

$(CH_3)_3Se^{\oplus}I^{\ominus}$ *(1a)*

or having two substituents bearing no α-hydrogen, *e.g.* alkyldiphenylselenonium salts *(1b)*—*(1d)*. We have now prepared these last salts, which were hitherto unknown, by treating diphenyl selenide[7,8] with an excess of alkyl iodide (or bromide) in the presence of a stoichiometric amount of silver tetrafluoroborate (see *Experimental* and Table 1).

[a] IR and NMR spectra were in accord with the structures given for compound *(3)*.

In addition, dimethylselenonio methylide *(2a)* reacted with cinnamaldehyde and chalcone[10] to give the corresponding oxiranes in 71% and 50% yield, respectively, free from any cyclopropane derivative.

When subjected to the same procedure, enolizable carbonyl compounds such as heptanal, cyclohexanone, methyl ethyl ketone, and acetophenone, did not form significant amounts of the corresponding oxiranes. In the reaction of acetophenone with selenonium salt *(1a)* or *(1b)*, we observed an alkylation leading to propiophenone (13%) and isobutyrophenone (28%); 40% of unreacted acetophenone were also isolated. To account for these results, we assume formation of an

[**] On leave from CNRS (France).

acetophenone anion which is subsequently methylated by the selenonium salt.

This methylation can be avoided by generating the α-selenonio alkylide prior to addition of acetophenone. For instance, we were able to obtain 1-methyl-1-phenyloxirane in 30% yield (not optimized) by reaction with $LiCHCl_2$ in dimethyl ether at −78 °C[11]. Surprisingly, however, other reaction conditions (different temperatures, solvents, and bases) for selenonium salts *(1a)* and *(1b)* led to differing products, which we are currently investigating.

Experimental:

Alkyldiphenylselenonium tetrafluoroborates (1b)—(1d)

$AgBF_4$ (5 g, 0.026 mol) is added slowly (under N_2, at 20 °C) to a solution of diphenyl selenide (6 g, 0.026 mol) in alkyl iodide (or bromide) (0.13 mol). After 2 h, the mixture is shaken with CH_2Cl_2 (200 ml) and the silver iodide is filtered off. The CH_2Cl_2 is evaporated *in vacuo* and the residue [*(1b)—(1d)*] washed with ether (3 × 50 ml) and recrystallized.

Oxiranes (3)

A solution of potassium *tert*-butoxide (0.0075 mol) in DMSO (10 ml) is added slowly at 20 °C to a solution of a selenonium salt *(1)* (0.009 mol) and a carbonyl compound (0.006—0.007 mol) in DMSO (10 ml). After 2 h, the mixture is hydrolyzed and extracted with ether (3 × 100 ml). The ethereal fractions were dried and evaporated and the residue [*(3)*] was purified by vacuum distillation or TLC (silica gel, ether/pentane 1:9).

Lactones and Lactams by Light-Induced Reaction of 2-Vinyloxiranes and 2-Vinylaziridines with Pentacarbonyliron—Insertion of Carbon Monoxide into an Iron-Nitrogen σ Bond[1]

By *Rudolf Aumann, Klaus Fröhlich*, and *Horst Ring*[*]

On light-induced reaction with pentacarbonyliron vinylcyclopropane systems give both carbonyliron complexes possessing an intact cyclopropane ring and 1,2,3,6-η-hexenediyl-6-one-$Fe(CO)_3$ derivatives resulting from cleavage of the cyclopropane ring and insertion of carbon monoxide[2, 3]. 2-Vinyloxiranes *(1)* or 2-vinylaziridines *(5)*, on the other hand, afford high yields of pale yellow lactones *(2)* or lactams *(6)* on photolysis (2—5% solution; 125-W Hg high pressure lamp, Duran filter; 20 °C; 2 h duration) with $Fe(CO)_5$ in benzene.

(1) *(2)*

(a): X = H; 2H instead of $(CH_2)_n$
(b): X = CH_3; 2H instead of $(CH_2)_n$
(c): X = H; n = 1
(d): X = H; n = 2

The products were isolated by fractional crystallization from benzene/hexane and their structures determined by ^{1}H-NMR (double resonance, computer simulation; cf. Fig. 1), IR, mass spectra, and elemental analysis.

Table 1. Lactones *(2)* obtained by light-induced reaction of vinyloxiranes *(1)* with $Fe(CO)_5$.

Product	Yield [%]	M. p. [°C]	*m/e*	$\nu_{(M)-C\equiv O}$ O [a] [cm^{-1}]	$\nu_{C=O}$ [b] [cm^{-1}]

^{12}C Labeling for the Elucidation of Reaction Mechanisms—Benzocyclopropene Formation[**]

By *Jörn Prestien* and *Harald Günther*[*]

Two mechanisms have been proposed for the formation of benzocyclopropene (1,3,5-norcaratriene) *(1)* on basic dehydrochlorination of 7,7-dichlorobicyclo[4.1.0]hept-3-ene *(2)*[1,2]:

Since only path B involves skeletal rearrangement, carbon labeling in combination with ^{13}C-NMR spectroscopy should provide a method of distinguishing between the two routes. With this in mind we have prepared [7-^{12}C]-*(2)* from [^{12}C,D]-chloroform[3] and subjected it to dehydrohalogenation by the known procedure[1]. Figure 1 compares the ^{13}C-NMR spectra (a) and (b) of the product having natural isotope abundance[4] and labeled *(1)*, respectively. Within the error limits (*ca.* 10%), we find the same integral for the signals

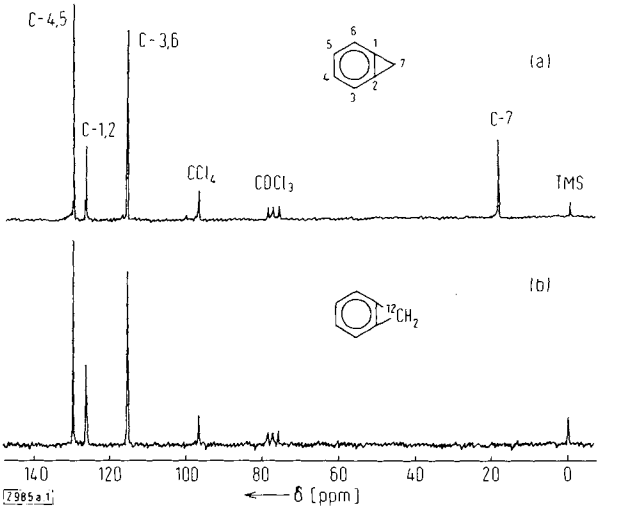

Fig. 1. PFT ^{13}C-NMR spectrum of benzocyclopropene (a) and of [7-^{12}C]-benzocyclopropene (b); 4096 accumulations in each case. Concentration *ca.* 1.1 M in $CCl_4/CDCl_3$ (3:2); tetramethylsilane as internal reference.

[**] Applications of ^{13}C-NMR Spectroscopy, Part 14. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 13: *G. Jikeli, W. Herrig*, and *H. Günther*, J. Amer. Chem. Soc. *96*, 323 (1974).

of the aromatic C atoms: (a) 1.00 : 0.25 : 0.87; (b) 1.00 : 0.28 : 0.81. More detailed evidence comes from the fact that no signal is observed for C-7 in spectrum (b). Hence the reaction gives $\geq 95\%$ of [7-^{12}C]-*(1)* so that path B can be ruled out.

The technique of ^{12}C labeling, to our knowledge used here for the first time in the elucidation of reaction mechanisms, has a number of advantages compared to ^{13}C labeling: 1) No complications due to ^{13}C—^{13}C coupling occur; 2) in the absence of scrambling, as in the present case, the evaluation of the experiment is independent of the relatively inaccurate integration of the ^{13}C signals; 3) [^{12}C]-chloroform (isotopic purity >99.95%) currently costs 80 times less than [^{13}C]-chloroform (isotopic purity 90%).

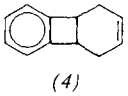
2,3-Epoxybiphenylene—A New Arene Oxide[**]

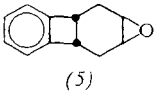
By *Günther Jikeli* and *Harald Günther*[*]

NMR spectroscopic studies in the biphenylene series[1] and other experimental findings[2, 3] suggest that of the valence isomers *(1)* and *(2)* the latter is stable since exocyclic double

(1)

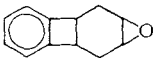


(2)
(2a), X = O



(3)

bonds on the four-membered ring should permit a better bond delocalization in the benzene ring. The *o*-phenylene structure should therefore prove suitable for the stabilization of short-lived dienes of type *(3)* having X = CH_2, C=O, NR, O, or S.



We have successfully applied this principle for the first time to the synthesis of 2,3-epoxybiphenylene *(2a)*. Starting from 1,4,4a,8b-tetrahydrobiphenylene *(4)*[4], prepared[5] from 1,3-butadiene and benzocyclobutadiene *in statu nascendi*[6], reaction with *m*-chloroperbenzoic acid in $CHCl_3$ gave 79% of a 9 : 1 mixture of the isomeric epoxides *(5)* and *(6)* for which we assume the *syn* and *anti* configuration respectively on the basis of NMR experiments with shift reagents.

Compound *(5)* (m.p. 61.0—61.5 °C) was brominated with *N*-bromosuccinimide to give 45% of the dibromide *(7)* (m.p. 139—140°C) after chromatography on silica gel, whose dehydrobromination with potassium *tert*-butoxide in THF/DMSO at −3 °C under argon was complete within 15 min. Rapid work-up in an alkaline medium and crystallization (−78 °C) from pentane afforded *(2a)*, which was further purified by recrystallization from acetone at 10 °C; yield 47%, colorless crystals, m.p. ≥75 °C (decomp.).

The structure of *(2a)* follows unequivocally from the spectra. Accurate mass determination yields $C_{12}H_8O$ (*m/e* 168.05746523). The ^{1}H-NMR spectrum contains a singlet (δ 7.24 ppm, 4H) and an AA'BB' system whose data ($\delta_{AA'}$ 6.118, $\delta_{BB'}$ 3.662 ppm, $J_{AA'} = 1.39$, $J_{AB} = 3.62$, $J_{AB'} = 0.09$, $J_{BB'} = 3.67$ Hz) are typical for the benzene oxide partial structure[7]. Expectedly, the ^{13}C-NMR spectrum displays δ(2,3) at 53.2 ppm[8], in addition to methine resonances at 109.5, 120.6, and 130.1 ppm (C-1,4, C-5,8, C-6,7) and quaternary C atoms at 145.5 and 147.4 ppm. The UV spectrum [λ_{max} (dioxane) 241 (49000), 320 (3400), 332 (6200), 349 nm (7300)[9]] resembles that of 1,2-dimethylenebenzocyclobutene[2]. The IR bands typical of the epoxide ring[10] are observed at 1250 and 850 cm^{-1}.

Pure *(2a)* can be kept for several days at −20°C under argon without decomposition, but is very sensitive to hydrolysis. The hydrolysis product is 2-hydroxybiphenylene which was identified by comparison with a sample prepared by an independent route[11].

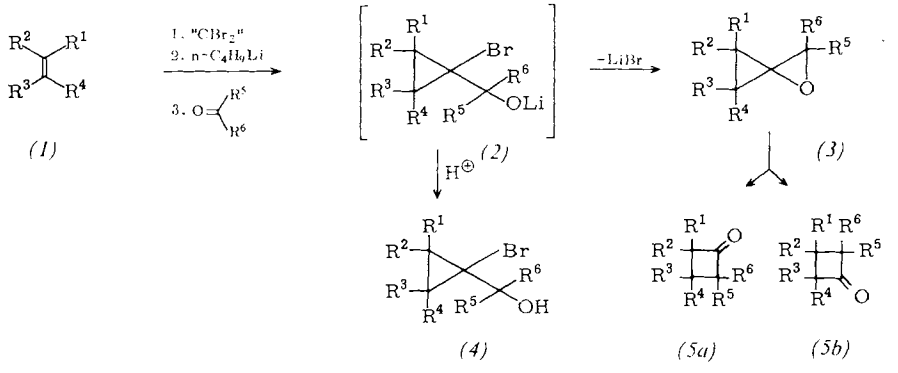
Cyclobutanones from 1-Bromo-1-lithiocyclopropanes and Ketones[**]



By *Manfred Braun* and *Dieter Seebach*[*]

Cyclobutanones are useful intermediates in organic synthesis[1]. Their preparation by cycloaddition of ketenes to double bonds is possible only under certain conditions[2]. We now wish to describe a new method of converting olefins *(1)* into cyclobutanones *(5)* which proceeds *via* oxaspiropentanes *(3)*. *Trost et al.* have demonstrated the synthetic utility of such epoxides prepared from other components for further interesting chemical conversions[1d].

[*] Dipl.-Chem. M. Braun and Prof. Dr. D. Seebach
Institut für Organische Chemie, Fachbereich Chemie der Universität
63 Giessen, Ludwigstrasse 21 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

As starting materials we employ the readily accessible dibromocarbene adducts to olefins[3] which afford the alkoxides *(2)* by bromine-lithium exchange[4] and reaction with aldehydes and ketones below −90°C in tetrahydrofuran. On warming to room temperature the ketone adducts *(2)* eliminate lithium bromide to form the epoxides *(3)* which in some cases can be isolated when working up under basic

(1) *(2)* *(3)* *(4)* *(5a)* *(5b)*

conditions but which rearrange to the cyclobutanones *(5)* (Table 1) under acidic conditions of work-up[1d, 5]. With the aldehyde adducts *(2)* elimination is not spontaneous; the bromohydrins *(4)* are isolated (Table 1). All the new compounds exhibit the expected spectroscopic data; the physical properties of the cyclobutanones already known are in accord with literature reports[7]. It may clearly be seen from Table 1 that the olefinic component *(1)* can be varied between wide limits (mono-, 1,1- and 1,2-di-, as well as tri- and tetra-substituted).

We are currently studying the reactions of the epoxides *(3)* and cyclobutanones *(5)* for the preparation of substituted lactones[1] and vinylcyclopropanol derivatives[1d] (→cyclopentanones[1d] and dienes[8]): All these types of conversions are recorded in the literature and in essence represent functionalizations of the double bond of *(1)* with C—C linking.

A New Reagent for Stereospecific Synthesis of Aziridines from Olefins

By *D. Van Ende* and *Alain Krief*[*]

The increasing biological and chemical interest in polyenes bearing terminal aziridines[1] incited us to look for a general method of aziridine synthesis particularly allowing the regiospecific[2] insertion of a nitrogen moiety in the terminal olefinic part of a polyolefin.

(1) *(2)* *(3)*

Scheme 1.

In this paper we report an aziridine synthesis from monoolefins *(1)* which proceeds according to Scheme 1. We first obtained azido β-bromo compounds *(2)* (Table 1) by addition of a new reagent[4], prepared *in situ* from *N*-bromosuccinimide (NBS) and NaN_3, to a suspension of an olefin in dimethoxyethane (DME)/H_2O (see experimental procedure). We found that our reagent, unlike *Hassner*'s bromine azide[5], can be prepared *in situ* in the presence of an olefin, and can be used in aqueous medium without significant hydrolysis[6]. This reagent adds Br/N_3 units directiospecifically[2,7] to the carbon-carbon double bond (according to the Markownikoff rule). Suitable olefins include citronellyl acetate *(1a)*, citronellyl benzoate *(1b)*, (*E*)-3-methyl-2-pentene *(1c)*, (*Z*)-3-methyl-2-pentene *(1d)*.

Table 1. α-Azido β-bromo derivatives *(2)* prepared.

Cpd.	R^1	R^2	R^3	R^4	Yield [%]
(2a)	CH_3	CH_3	H	$-(CH_2)_2-CH(CH_3)-(CH_2)_2-OCOCH_3$	65
(2b)	CH_3	CH_3	H	$-(CH_2)_2-CH(CH_3)-(CH_2)_2-OCOC_6H_5$	65
(2c)	CH_3	H	C_2H_5	CH_3	55
(2d)	CH_3	H	CH_3	C_2H_5	55
(2e)	CH_3	H	H	n-C_5H_{11}	65
(2f)	CH_3	H	n-C_5H_{11}	H	65
(2g)	H	H	H	n-C_6H_{13}	13

In the last two cases addition proceeds *trans* stereospecifically[8]; *trans* addition is also observed on reaction of *cis*-2-octene *(1e)* and *trans*-2-octene *(1f)*. As in other electrophilic additions, trisubstituted olefins react faster with Br/N_3 than do di- or monosubstituted ones. The low yield of 2-azido-1-bromooctane *(2g)* seems to be the consequence of this low reactivity.

The desired aziridines *(3)* are obtained in fair yield (60—70%) by $LiAlH_4$-mediated cyclization[9] of the azido β-bromo compounds *(2)*. This reaction proceeds stereospecifically.

7-Azido-6-bromo-3,7-dimethyloctyl acetate (2a)[10]

N-Bromosuccinimide (NBS) (623 mg, 3.5 mmol) was added in small portions to a precooled (−5°C) suspension prepared by mixing a DME (16 ml) solution of citronellyl acetate *(1a)* (500 mg, 2.5 mmol) with an NaN_3 (812 mg, 12.5 mmol) aqueous solution (4 ml). The initial yellow color observed faded away after each addition. When all the NBS was consumed, the reaction mixture was allowed to stand (0.5 h, 0°C), then extracted with pentane and purified by preparative layer chromatography[10,11] to give *(2a)* in 65% yield.

[7] The 7-azido-6-bromocitronellyl acetate obtained by our method (contaminated by less than 5% of its directioisomer) is identical (^{1}H-NMR) with a sample prepared according to ref. [5] which contained 13% of the directioisomer.

[8] Compounds *(2c)* and *(2d)* were free from stereoisomer. The stereochemical purity was checked by comparison of the ^{1}H-NMR spectra of *(2c)* and *(2d)* with that of the known 30/70 *(2c)/(2d)* mixture.

[9] Reaction conditions: 50-fold excess of $AlLiH_4$ in ether, the crude product was purified by preparative layer chromatography (SiO_2 Merck, 2 mm, methanol/ether), and *(3)* was extracted with *methanol.*

[10] NBS reerystallized from water; DME peroxide free; preparative layer chromatography (SiO_2 Merck, 2 mm, ether/pentane 3:7).

[11] Unidentified compounds (10%, R_f 0.35) and 6-bromo-7-hydroxycitronellyl acetate (10%, R_f 0.26) were also separated. Lower NaN_3 concentrations in the aqueous solution (1—2 mol/l) or lower NBS/NaN_3 ratios (1:1 or 1:2) favor formation of the corresponding bromohydrin.

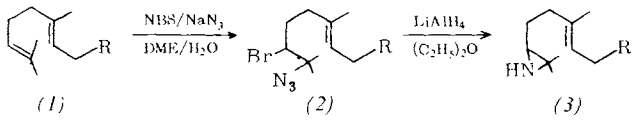
A Highly Potent Reagent for Regioselective and Stereospecific Synthesis of Polyenes Bearing Terminal Aziridine Groups



By *D. Van Ende* and *A. Krief*[*]

The only recorded regioselective syntheses of molecules such as 2,3-epiminosqualene[1] and the 2,3-epimino analog of the *Cecropia* juvenile hormone[2] are due to *Corey*; however, these syntheses suffer from low overall yields due to multistep reactions.

In this paper we report a new method of introducing a nitrogen moiety into the terminal carbon-carbon double bond of polyolefins, particularly those in which all the double bonds are trisubstituted and more or less equally sterically encumbered (Scheme 1). We studied the behavior of different nitrogen-introducing reagents, in various solvent systems, towards three polyolefins, namely geranyl acetate *(1')*, farnesyl acetate *(1'')*, and squalene *(1''')*.

[*] Dipl.-Chem. D. Van Ende and Prof. Dr. A. Krief [**]
Département de Chimie, Facultés Universitaires de Namur
61, rue de Bruxelles, B-5000 Namur (Belgium)

[**] On leave from CNRS (France).

Scheme 1.

In the most successful cases, regioselective conversion of these polyolefins to their terminal azido β-bromo derivatives (Table 1) was achieved by treatment of a suspension of the polyolefin in dimethoxyethane (DME)/water with *N*-bromosuccinimide (NBS) in the presence of sodium azide. These reaction conditions were optimized for monoolefins[3].

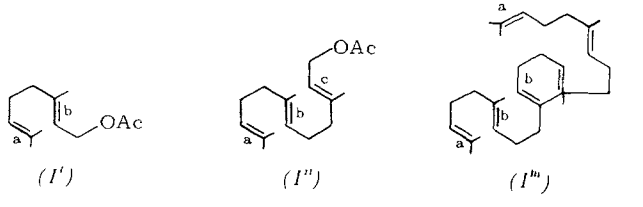


Table 1. α-Azido β-bromo compounds *(2)* and aziridines *(3)*.

Starting polyolefin *(1)*	recovered [%]	*(2)* Yield [%] [a]		*(3)* Yield [%] [b]	
(1')	10	*(2'a)*	70	*(3'a)*	60
		(2'b)	0		
(1'')	20	*(2''a)*	60	*(3''a)*	75
		(2''b)	3		
		(2''c)	0		
(1''')	30	*(2'''a)*	24	*(3'''a)*	75
		(2'''b)	4.5	*(3'''b)*	75
		[4]			

[a] Based on reacted *(1)*.
[b] Based on starting amount of *(2)*.

The structural assignment and regioisomeric purity of each compound were established by ^{1}H-NMR and mass spectral data. All the described α-azido β-bromo derivatives were cyclized to the desired corresponding aziridines *(3)*[5] in fair yields (Table 1) by use of $LiAlH_4$. The structures proposed for aziridines derived from *(2'a)* and *(2''a)* were corroborated by the identity of their IR, ^{1}H-NMR, and mass spectra with those of authentic samples[1, 2].

It is interesting to note that when polyolefins *(1'')* and *(1''')*[6] were treated by a conventional reagent (*i.e.* BrN_3 in CH_3NO_2/CH_2Cl_2) in the absence of water (reaction conditions proposed by *Hassner* in the case of monoolefins)[7] low yields of azido β-bromo derivatives and very little terminal preference were observed[8].

To account for the high terminal selectivity of our new reagent, as opposed to the low regioselectivity of BrN_3, we assume that in our "heterogeneous, highly polar medium (DME/H_2O) the coiled polyolefins would selectively present their terminal olefinic part to the attack of the extensively solvated bromonium ion"[9].

In conclusion, to illustrate the potential of our new reagent, we would point out that our two-step synthesis affords a 48% overall yield of epiminofarnesol *(3''a)* compared to the 15% yield obtained in the previously published five-step synthesis[2].

Synthesis of 3'-Amido-3'-deoxyadenosine 3',5'-Cyclophosphate[***]

By *Michael Morr, Maria-Regina Kula, Georg Roesler,* and *Bernd Jastorff*[*]

Comparative studies on synthetic derivatives of adenosine 3',5'-cyclophosphate (cAMP)[1] have shown the biological properties of cAMP to be very strongly influenced by modification of the phosphate ring[2].

Position 3' is most sensitive: thus replacement of the oxygen by a methylene group leads to complete loss of biological activity[3]. We synthesized the 3'-amido-3'-deoxy analog *(3)* of cAMP in order to determine whether replacement of the oxygen by an NH group has a similar pronounced effect on properties.

Starting from 3'-amino-3'-deoxyadenosine *(1)* isolated from the culture filtrate of *Helminthosporium* sp 215[4, 5] we obtained the 5'-phosphate *(2)* either by chemical phosphorylation with $POCl_3$/triethyl phosphate[6] or by preparative enzymatic phosphorylation with adenosine kinase (E.C. 2.7.1.2.0)[7]. Cycliza-

tion of the triethylammonium salt of *(2)* to give the cAMP analog *(3)* was performed with dicyclohexylcarbodiimide in dimethylformamide/*tert*-butanol/water.

Compound *(3)* was unequivocally characterized by chromatographic comparison with cAMP and isomeric 5'-amido-5'-

deoxy-cAMP[2] and by chemical and enzymatic degradation. Both acid-treatment and incubation with cAMP-specific phosphodiesterase from bovine heart (E.C. 3.1.4.1) led to the 5'-phosphate *(2)* which was then dephosphorylated to the starting compound *(1)* by treatment with 5'-nucleotidase.

The 3'-N—P bond in *(3)* possesses a considerably greater chemical stability (no hydrolysis after 5 h at pH 7 and 37 °C) than the 5'-N—P bond in 5'-amido-5'-deoxy-cAMP[2].

Preliminary biological investigations have shown that *(3)* is a substrate for bovine heart cyclophosphodiesterase and also competes with cAMP for binding sites on protein kinases from bovine brain and rabbit muscle, thus activating these enzymes[8].

3'-Amido-3'-deoxyadenosine 3',5'-cyclophosphate (3)

Compound *(2)* (130 mg, 0.3 mmol) is mixed with triethylamine (0.8 ml), dimethylformamide (15 ml), *tert*-butanol (15 ml), water (7 ml), and dicyclohexylcarbodiimide (618 mg, 3 mmol) and heated to 100 °C for 8 h. After cooling, dicyclohexylurea is filtered off and the solution is evaporated down in an oil-pump vacuum. The residue is extracted with ether (4 × 30 ml) and subsequently treated with water. After filtration the filtrate is concentrated and adjusted to pH 7.5 prior to being poured onto a QAE A25 Sephadex column (HCO_3 form). After washing of the column with water elution was performed with a linear gradient of water and 0.1 M triethylammonium hydrogen carbonate (pH 7.5). The eluate was continuously monitored at 253 nm and collected in fractions. The main fraction was concentrated, stripped three times with ethanol, and subsequently lyophilized from water. The procedure yielded 50 mg of *(3)* (40% yield).

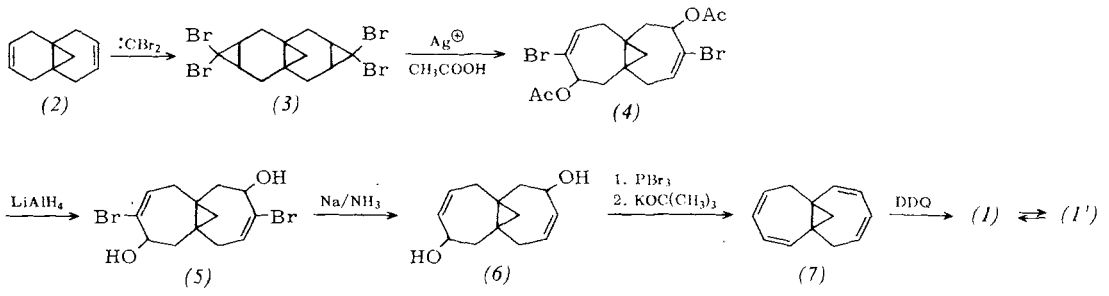
1,7-Methano[12]annulene—the 12π Analog of 1,6-Methano[10]annulene

By *Emanuel Vogel, Heinrich Königshofen, Klaus Müllen*, and *Jean F. M. Oth*[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 60th birthday

That 1,6-methano[10]annulene[1] possesses aromatic character, while the simple [10]annulenes[2]—on account of steric factors—represent reactive polyolefins, categorically underlines the significance of the concept of "bridging"[1,3] for verification of the Hückel rule in the case of the neutral 10π electron system. Moreover, it would appear that this concept could be used as a basis for studies aimed at providing experimental evidence in support of our present ideas on the nature of 4nπ electron systems[4].



(1) *(1')*

Our particular interest centered on 1,7-methano[12]annulene *(1)*, since the geometry of the ring skeleton of this hydrocarbon corresponds to that of the 1,6-methano[10]annulene and may therefore be regarded as its 12π analog[5]. According to molecular models the peripheral annulene ring of *(1)* is only slightly puckered, whereas the unbridged [12]annulene[6], which has a configuration with alternating *cis*- and *trans*-double bonds, exhibits strong angular deformation due to steric interactions of the inner hydrogen atoms. In agreement with geometrical considerations, we have found that the 1,7-methano[12]annulene—as distinct from the [12]annulene parent compound[7]—exhibits all the properties to be expected of a 4nπ system. *(1)* can be prepared from the readily accessible tricyclo[4.4.1.$0^{1,6}$]undeca-3,8-diene *(2)*[1]. Reaction of the diene with bromoform, triethylbenzylammonium chloride, and 50% sodium hydroxide according to the method of *Makosza et al.*[8] afforded the 2:1 dibromocarbene adduct *(3)* (m.p. 169—170 °C; yield 59%), whose outer cyclopropane rings are *anti* to the central cyclopropane ring. Treatment of *(3)* with silver acetate in boiling glacial acetic acid (100 h) results in formation of a mixture of 4,10-dibromo-5,11-diacetoxytricyclo-[5.5.1.$0^{1,7}$]tridecadienes (yield *ca.* 50%)[9], from which a homogeneous isomer of probable structure *(4)* (m.p. 200—202 °C; yield 15%) can be isolated by fractional crystallization from ethyl acetate. *(4)* was then converted into the diol *(6)* (m.p. 189—191 °C; yield 50%); this was achieved by first removing the acetate groups by reduction with $LiAlH_4$ in tetrahydrofuran and then treating the crude *(5)* so obtained in tetrahydrofuran solution with sodium in liquid ammonia (−78 °C).

Attempts to dehydrate *(6)* proved unsatisfactory. *(6)* was therefore converted by treatment with phosphorus tribromide into the dibromide (m.p. 152—153 °C; yield 36%), which, on treatment with potassium *tert*-butoxide in tetrahydrofuran (0 °C), could be readily dehydrobrominated to the tetraene *(7)* and its isomers [b.p. 56—59 °C/0.4 torr (mixture); yield 27%] having mirror-image arrangement of the conjugated double bonds. That *(7)* and the aforesaid isomers are present, follows from the NMR spectra (a singlet for each of the cyclopropane protons). Separation of the readily autoxidizable hydrocarbon mixture was unnecessary. The same dehydrogenating agent, 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), as was used in the synthesis of bridged [10]- and [14]annulenes could also be employed here; however, it was necessary to heat the tetraene mixture with the quinone in boiling anisole (165 °C) for 1/2 h. Chromatography on silica gel afforded *(1)* as a reddish brown liquid (b.p. 72—74 °C/0.2 torr; yield 39%) which crystallizes below −50 °C and is sensitive to air. Recrystallization from methanol at low temperature affords *(1)* as splendid blackish-brown needles having m.p. −6 to −4 °C.

According to CNDO—CI calculations, the UV spectrum of *(1)* [λ_{max} (cyclohexane) = 254 (ε = 54000), 263 (51000), 300 (1000, sh), 425 nm (240)] may be interpreted as that of a polyene; it resembles the UV spectra of dehydro[12]annulenes[10].

Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule
CH-8006 Zürich, Universitätsstrasse 6/8 (Switzerland)

The ^{1}H-NMR spectrum of *(1)* at room temperature, which is displayed in Figure 1 along with the spectrum of 1,6-methano[10]annulene, shows a singlet for the bridge protons at $\tau = 3.94$ and two multiplets for the annulene protons at $\tau = 4.5$ (2-H, 6-H, 8-H, 12-H) and 4.8 (3-H to 5-H, 9-H to 11-H). Remarkably, the signals of aliphatic and olefinic protons—in complete reversal of the resonance behavior in 1,6-methano[10]annulene—occur at unusually low and unusually high field respectively. *(1)* may therefore sustain a relatively strong paramagnetic ring current.

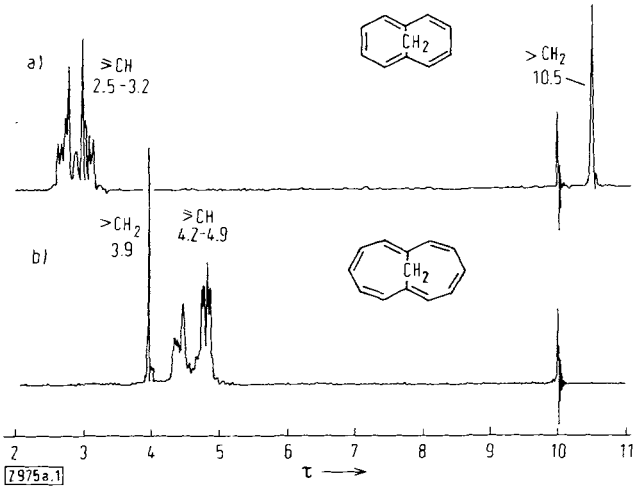

Fig. 1. 60-MHz ^{1}H-NMR spectra of a) 1,6-methano[10]annulene and b) 1,7-methano[12]annulene *(1)* (both recorded in CCl_4 at room temperature with TMS as internal standard).

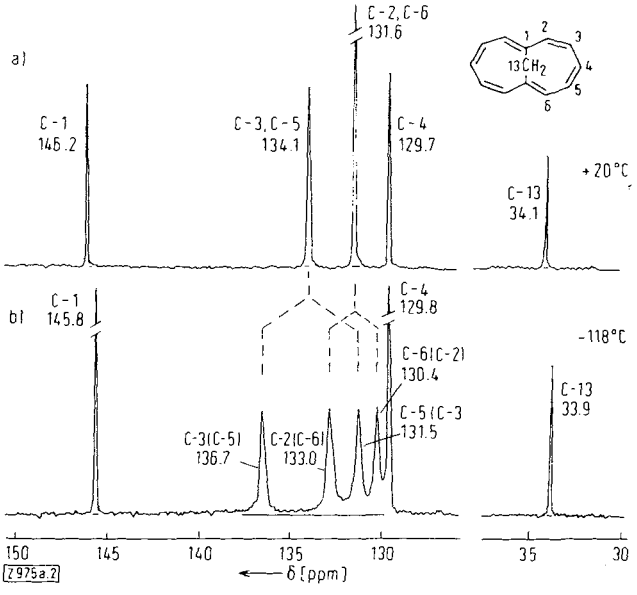
The ^{1}H-NMR spectrum of *(1)* is temperature-dependent, thus indicating the presence of a rapid dynamic process. On lowering the temperature the multiplets of the annulene protons gradually broaden below *ca.* −60 °C, while the singlet of the bridge protons remains unchanged. Change of shape in the multiplet ceases at −135 °C. Analysis of the spectrum at room temperature (region of rapid exchange) and at −135 °C (no exchange)[11] clearly indicates that the dynamic process involves a π-bond shift—*i.e.* the valence tautomerism *(1)*⇄*(1')*, which confers C_{2v} symmetry on the molecule on the NMR time-scale above −60 °C. An attempt to derive the kinetic parameters of the π-bond shift from the temperature dependence of the ^{1}H-NMR spectrum met with difficulties, since the annulene protons form a strongly coupled spin system. This suggested that ^{13}C-NMR spectroscopy would have to be used to determine these parameters.

The room-temperature ^{13}C-NMR spectrum of *(1)*[12] immediately reveals the effective C_{2v} molecular symmetry induced by rapid double bond migration since it shows only four signals for the annulene C atoms, whose assignment (by partial decoupling) is to be inferred as in Figure 2a.

As can easily be seen, freezing of the π-bond shift leads to loss of magnetic equivalence of C-2 and C-6 and of C-3 and C-5. In agreement with this the 4-line ^{13}C-NMR spectrum observed at room temperature transforms between −40 and 120 °C, with broadening and subsequent splitting of the C-2/C-6 and C-3/C-5 signals into a 6-line spectrum (Fig. 2b)



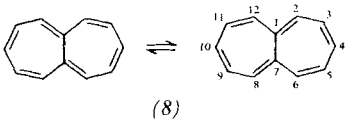


Fig. 2. ^{1}H broad band decoupled ^{13}C-NMR spectra of 1,7-methano[12]annulenes *(1)* at, a) room temperature, and b) −118 °C (in D_8-THF/CS_2 with TMS as internal standard, $\delta_{TMS} = 0$).

corresponding to that of the 1,7-methano[12]annulene with C_2 symmetry. It is possible, by means of a line-shape analysis of the signals of C-2, C-3, C-5, C-6, to derive an activation energy of 5 kcal/mol for the π bond shift. If one considers that further flattening of the peripheral annulene is enforced in the transition state of the bond shift, this value represents an upper limit for the energy difference between the 1,7-methano[12]annulene structure with delocalized and with localized π bonds[13].

(8)

Investigations on *(1)* call one's attention to the 12π system heptalene *(8)*[14,15] and the still unsatisfactorily explained bonding in this molecule. The rapid π-bond shift[15] postulated for *(8)* which so far has eluded experimental detection could also be detected ^{13}C-NMR spectroscopically[16].

[16] The room-temperature ^{13}C-NMR spectrum (CF_2Br_2/CD_2Cl_2) of *(8)* [numbering of C atoms analogous to *(1')*] shows four sharp signals at δ = 140.9 (C-1/C-7), 135.3 (C-2/C-6), 131.2 (C-4), and 130.7 ppm (C-3/C-5). Analogous to the behavior in *(1)*, the C-2/C-6 and C-3/C-5 signals split below −160 C (coalescence temperature); *E. Vogel, H. Königshofen, J. Wassen, K. Müllen*, and *J. F. M. Oth*, unpublished.

1,6-Methano[12]annulene

By *Emanuel Vogel, Max Mann, Yoshiteru Sakata, Klaus Müllen*, and *Jean F. M. Oth*[*]

1,6-Methano[12]annulene may exist as one of the valence tautomers *(1)* and *(2)*, or there could be equilibrium between *(1)* and *(2)*. It can easily be seen that the case of equilibrium corresponds to a π-bond shift, which as distinguished from that observed in 1,7-methano[12]annulene[1], is a non-isodynamic process[2]. According to molecular models, however, *(1)* is much more energetically favored than *(2)*, and it would seem that 1,6-methano[12]annulene ought to be present as *(1)* and not exhibit any π-bond shift.

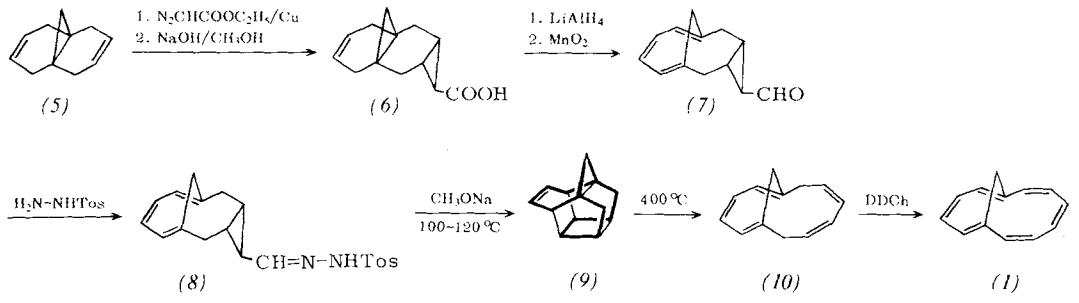
(1) possesses the relatively rigid preferred conformations *(3)* and *(4)*. A feature common to both of these conformations is that the peripheral annulene ring deviates considerably more from planarity than in 1,7-methano[12]annulene. In order to establish the extent to which the properties of [12]annulenes, or [4*n*]annulenes in general, are dependent on the ring geometry[3], it was considered essential to include the examination of 1,6-methano[12]annulene in our studies.

(3)



(4)

1,6-Methano[12]annulene could be synthesized in the same way as the isomeric 1,7-methano[12]annulene from tricyclo[4.4.1.$0^{1,6}$]undeca-3,8-diene *(5)*[4]. To convert *(5)* into the new [12]annulene a C_2 unit had to be added to one of the double bonds; this was achieved by Cu-catalyzed reaction with ethyl diazoacetate. An adduct mixture was formed, which on hydrolysis with methanolic sodium hydroxide afforded tetracyclo[5.4.1.$0^{1,7}$.$0^{3,5}$]dodeca-9-ene-4-*exo*-carboxylic acid *(6)* (m. p. 200—201 °C; yield 15%[5], after fractional crystallization from ethyl acetate). The configuration of *(6)* followed from a comparison of the NMR spectra of the secondary product *(7)* and its stereoisomer having an *endo* aldehyde group: only in the case of the *endo* isomer did the aldehyde group serve as a basis for the diamagnetic anisotropic effect of the cycloheptatriene moiety and therefore absorb at relatively high field strength [τ = 2.42 as against 0.84 in *(1)*]. Treatment of the acid *(6)* with $LiAlH_4$ in tetrahydrofuran afforded the alcohol [b. p. 90—93 C/0.01 torr), which was oxidized and dehydrated by manganese dioxide in carbon tetrachloride to give *(7)* [b. p. 71—72 °C; NMR (CCl_4): AA'BB' system at τ = 3.3 and 4.1 and an AB system at τ = 7.60 and 9.10 with $J = -9.8$ Hz (cycloheptatriene protons)]. Reaction of *(7)* with *p*-toluenesulfonohydrazide in ethanol affords the tosylhydrazone *(8)* (m. p. 200—202 C, decomp.), which is subsequently heated in the presence of sodium methoxide in diethylene glycol diether to 100—120 C (1 h)[6].

Alkaline thermolysis of *(8)* yielded, instead of the expected cyclobutene hydrocarbon, the isomeric cage compound *(9)* [m. p. 168 C; NMR (CCl_4): multiplet at τ = 4.1 (2 olefinic H), AB system at τ = 9.19 and 9.50 with $J = 7.1$ Hz (2 cyclopropane H), and a multiplet at τ = 7.2—7.9 and 8.7—9.1 (10 aliphatic H)]. *(9)* is, however, none other than the product of a sterically favored intramolecular Diels-Alder reaction of the initial cyclobutene hydrocarbon—reacting in the norcaradiene form. Gas-phase pyrolysis of *(9)* at 400 C (in vacuum) results in both a retro-Diels-Alder reaction as well as a cyclobutene-butadiene isomerization of the regenerated cyclobutene hydrocarbon taking place with immediate formation of 7,12-dihydro-1,6-methano[12]annulene *(10)*, a light-sensitive liquid (b. p. 62—63 °C/0.02 torr), in 66% yield. On reaction with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), *(10)* was dehydrogenated to the desired 1,6-methano[12]annulene, which could be isolated by chromatography on silica gel as a relatively stable orange-red compound (yield 36%; needles having m. p. 30—31 C after recrystallization from methanol).

The ^1H-NMR spectrum (CCl_4, 60 MHz) of 1,6-methano[12]annulene, which is not significantly temperature-dependent, shows an AA'BB' system with $\tau_A = 3.83$ (3-H, 4-H) and $\tau_B = 4.27$ (2-H, 5-H)[7] and a narrow multiplet at τ = 4.5 (7-H to 12-H) for the annulene protons, and an AB system at τ = 7.71 (13-H_a) and 3.00 (13-H_b) with $J = -11.51$ Hz for

the two bridge protons. Analysis of the AA'BB' system yielded values for the coupling constants of 2-H to 5-H ($J_{2,3}=5.5$ Hz, $J_{3,4}=10.8$ Hz, $J_{2,4}=0.33$ Hz, $J_{2,5}=1.2$ Hz), which clearly indicate the presence of a cycloheptatriene partial structure[8]. Hence the hydrocarbon must be present almost exclusively as the valence tautomer *(1)*.

The existence in *(1)* of a paramagnetic ring current, which is less obvious than in the isomeric 1,7-methano[12]annulene, is evident if the resonance conditions in *(1)* are compared with those in 9,10-dihydro-1,6-methano[12]annulene *(11)*[9]. According to Table 1 the transition from *(11)* to *(1)* affects the resonances of the protons of the cycloheptatriene moiety such that the AA'BB' system of 2-H to 5-H is shifted about 0.5 ppm upfield, while the doublets of 13-H_a and 13-H_b shift about 0.72 and 3.87 ppm, respectively, downfield.

The observed shifts of the signals can hardly be interpreted in any other way than by *(1)* displaying a paramagnetic ring current, in spite of the relatively strong deviation of the annulene ring from planarity. The remarkable finding that the resonances of the two bridge protons 13-H_a and 13-H_b appear at such different field strengths, would imply that *(3)* is the preferred conformation of the molecule. Model considerations show that the average distance from 13-H_b to the peripheral annulene ring in *(3)*—unlike in *(4)*—is noticeably smaller than that from 13-H_a, and it would be expected, therefore, that the paramagnetic ring current in *(3)* has more influence on 13-H_b than on 13-H_a. An X-ray structural analysis is to be carried out on the hydrocarbon in an attempt to confirm this tentative statement.

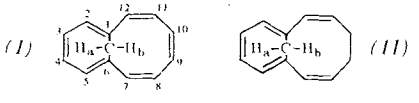


Table 1. Chemical shifts (τ values in CCl_4) of the protons of the cycloheptatriene moieties in *(1)* and *(11)*.

	τ 3-H, 4-H	τ 2-H, 5-H	τ 13-H_a	τ 13-H_b
(1)	3.83	4.27	7.71	3.00
(11)	3.30	3.70	8.43	6.87

The UV spectrum of *(1)* [λ_{max} (cyclohexane) = 254 (ε = 45900), 262 (46100), 337 (1400), 420 (440 sh), 296 nm (820)] resembles the UV spectra of the dehydro[12]annulenes[10] less than does that of 1,7-methano[12]annulene. This could be due to the considerable steric hindrance of the conjugation in *(1)*.

The Dianions of 1,7- and 1,6-Methano[12]annulenes—Novel Aromatic 14π Electron Systems

By *Jean F. M. Oth, Klaus Müllen, Heinrich Königshofen, Max Mann, Yoshiteru Sakata*, and *Emanuel Vogel*[*]

NMR analysis has shown the presence of localized π bonds in the 4nπ electron systems 1,7-methano[12]annulene *(1)*[1] and 1,6-methano[12]annulene *(2)*[2]. In contrast to *(1)* and *(2)*, their dianions *(3)* and *(4)* represent (4n+2)π electron systems and should therefore exhibit aromatic character analogous to the dianions of [8]-, [12]-, and [16]-annulenes[3]. As is shown in the following, the properties of *(3)* and *(4)* are exactly as would be expected.

The polarographic reduction of the bridged [12]annulenes *(1)* and *(2)* (dropping-mercury electrode, 10^{-3} M solutions

[**] *J. F. M. Oth* and *K. Müllen* thank the Schweizerischer Nationalfonds and Ciba-Geigy, Hoffmann-La Roche, Lonza, and Sandoz for their generous support.

in dimethylformamide, conducting salt tetra-*n*-butylammonium perchlorate) shows that both hydrocarbons undergo reversible transformation into their radical anions and dianions at relatively low potentials (see Table 1). Although

Table 1. Halfwave potentials for the reduction of *(1)* and *(2)* (relative to the standard calomel electrode). The reversibility of all reduction processes was demonstrated by cyclic voltammetry.

	$R + e^{\ominus} \rightleftarrows R^{\cdot\ominus}$	$R^{\cdot\ominus} + e^{\ominus} \rightleftarrows R^{2\ominus}$
(1)	−1.47 V	−1.79 V
(2)	−1.51 V	−1.72 V

the first and second reduction steps in *(1)* and *(2)* differ by only about 0.3 and 0.2 V respectively, it proved possible to electrochemically generate either the radical anions or dianions cleanly in a flow cell. In the case of the radical anion of *(1)*, an analysis of its ESR spectrum[4] showed the species to have C_{2v} symmetry. Hence, this radical anion, like those of other [4*n*]annulenes[5, 6], exhibits delocalized π bonding.

On the basis of the observed reduction potentials of *(1)* and *(2)* it was to be expected that both [12]annulenes can also be reduced with alkali metals to give the dianions *(3)* and *(4)* respectively. This in fact was found to be the case. *(3)* and *(4)* can easily be obtained—free from radical anions—by treating the corresponding hydrocarbon with lithium or potassium in 0.02 M D_8-tetrahydrofuran solution at −80 °C. Both the lithium salts and the potassium salts of *(3)* and *(4)* are completely stable at room temperature (in tetrahydrofuran).

The aromatic nature of the dianions *(3)* and *(4)* follows compellingly from a comparison of their ^{1}H-NMR spectra with those of *(1)* and *(2)*. As can be seen in Table 2, the transition from *(1)* and *(2)* to *(3)* and *(4)* is accompanied by a downfield shift of about 1—2 ppm of the annulene proton resonances, while the bridge protons are shifted 10—12 ppm or more upfield. These shifts may be regarded as proof of the existence of a diamagnetic ring current in *(3)* and *(4)*, as shifts of the same order of magnitude and direction have also been established in the formation of dianions of unbridged [4*n*]annulenes[7]. The fact that the resonances of the annulene protons 3-H, 4-H appear—unlike those in [12]annulene—at higher field strength than the resonances of the protons 2-H, 5-H[8], may likewise be regarded as a manifestation of the ring current effect. Interestingly, the noticeable difference in the chemical shifts of the bridge protons (4.7 ppm) in the [12]annulene *(2)*, which was recently attributed to bending of the peripheral annulene ring and the resulting difference in the mean distance of these protons from the ring, is almost absent in the dianion. Accordingly, in *(4)* the contribution of each of the bridge protons to the ring current effect are comparable; this would appear to be compatible only with the assumption that the ring is now strongly flattened[9]. This concept is further supported by the remarkable similarity in the resonance of *(3)* and *(4)*. The conversion of *(1)* and *(2)* into the dianions results, not only in changes in the chemical shifts, but also in extensive equalization of the originally strongly alternating vicinal coupling constants. That the occurrence of a rapid π-bond shift in the dianions can be ruled out on the basis of the temperature independence of their NMR spectra indicates that the C—C bonds of the annulene ring have experienced an adjustment in bond orders[10].

Supporting evidence for the aromatic structure of the dianions *(3)* and *(4)* deduced from comparative ^{1}H-NMR spectroscopy has also been provided by ^{13}C-NMR investigations.

Table 2. ^{1}H chemical shifts (τ values) and H,H coupling constants *J* (in Hz) of *(1)* and *(2)* and their dianions *(3)* and *(4)*. The spectra of *(3)* and *(4)* were recorded in D_8-tetrahydrofuran, the high-field signal of tetrahydrofuran (τ = 8.29) serving as standard.

	τ 2-H	τ 6-H	τ 3-H	τ 5-H	τ 4-H	τ 13-H	$J_{2,3}$	$J_{5,6}$	$J_{3,4}$	$J_{4,5}$
(1) at −135 °C	4.53	4.39	4.80	4.82	4.88	4.02	5.3	12.5	12.2	6.0
(1) at + 25 °C	4.46		4.81		4.88	3.96	9.0		9.2	
(3) at − 80 °C	2.84		3.72		3.59	16.44	8.4		10.7	

	τ2-H = τ5-H	τ3-H = τ4-H	τ7-H = τ12-H	τ 13-H_a	τ 13-H_b	$J_{2,3} = J_{4,5}$	$J_{3,4}$	$J_{2,13b}$
(2) at +25 °C	4.27	3.83	≈4.5	7.71	3.00	5.5	10.8	1.26
(4) at −80 °C	2.44	3.49		15.52	16.08	8.3	8.5	

In the case of *(3)* the ^{13}C-NMR spectrum shows only four signals[11] for the annulene protons; hence, it may be concluded—once again in combination with the temperature independence of the spectrum—that the molecule has C_{2v} symmetry.

[7] Here, the inner annulene protons, insofar as they are available, are to be regarded as pendant to the bridge protons.

[8] This corresponds to the resonance in 1,6-methano[10]annulene: *H. Günther*, Z. Naturforsch. *20b*, 948 (1965).

[9] The flattening of the peripheral ring, which involves considerable strain, is indicative of a high resonance stabilization in *(4)*.

[10] *H. Günther* and *H. H. Hinrichs*, Tetrahedron Lett. *1966*, 787.

[11] In the transition from *(1)* to *(3)* the resonance of the bridge carbon atom shifts to high field by about the same amount as that of the bridge protons (10.5 ppm for C-13; 12.5 ppm for 13-H). Compounds *(1)* and *(3)* are therefore of interest in connection with the question of whether ring current effects are of importance in ^{13}C nuclear magnetic resonance.

Reviews

Abstracts of selected progress reports and review articles

Inositolphosphatide metabolism in externally stimulated cells is reviewed by *E. G. Lapetina* and *R. H. Mitchell*. The conversion of inositolphosphatides in many tissues is accelerated after addition of various types of compounds. The starting point of this stimulation is probably the cleavage of inositolphosphatides to diacylglycerols and cyclic inositol-1,2-phosphate or inositol-1-phosphate taking place on the cell surface. Resynthesis of the inositolphosphatide subsequently takes place within the cell. No biological function of this phenomenon has so far been reported; however, it is a regulation phenomenon independent of cyclic AMP. Rearrangement reactions in organoboron chemistry have been classified in an article by *P. I. Paetzold* and *H. Grundke*. "Rearrangement" is defined here as the migration of a part of the molecule involving cleavage of a boron σ bond. The suggested classification differentiates rearrangements at tri-, tetra-, and higher-coordinated boron. The simplest example for the (3,1) shift at tricoordinated boron is the rearrangement of triallylborane:

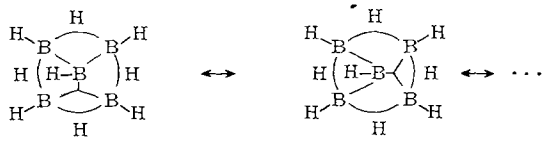
$$(H_2C{=}CH{-}CH_2)_2BCH_2{-}CH{=}\overset{*}{C}H_2 \rightleftharpoons (H_2C{=}CH{-}CH_2)_2B{-}\overset{*}{C}H_2{-}CH{=}C$$

[Umlagerungen in der Organobor-Chemie. Synthesis 1973, 635—660; 169 references]

[Rd 690 IE—L]

Advances in the chemistry of Mannich bases is the subject of an article by *M. Tramontini*. Mannich aminomethylation reactions generally involve combined reaction of a substrate R—H (H = active hydrogen), formaldehyde, and a primary, or secondary amine. Not only can alkylketones, phenols, and

$$R{-}H + \underset{\underset{O}{\|}}{CH_2} + \underset{HN<}{} \xrightarrow[-H_2O]{} R{-}CH_2{-}N<$$



carboxylic acid derivatives be used as the substrate R—H, but also alkynes, heterocycles, and compounds that lead to N-, Se-, or P-Mannich bases of type

$>N{-}CH_2{-}N<$, $Alk{-}S{-}CH_2{-}N<$, $C_6H_5{-}Se{-}CH_2{-}N<$ and $>P(O){-}CH_2{-}N<$

The article provides a comprehensive overview of the advances made from 1960 through 1970. [Advances in the Chemistry of Mannich Bases. Synthesis 1973, 703—755; 461 references]

[Rd 691 IE—L]

The Chemistry of pentaborane(9) (B_5H_9) *(1)* is reviewed in an article by *D. F. Gaines*. The structure of the boron framework of *(1)* has almost the form of a square-based pyramid. Alkylations and halogenations and olefin addition occur exclusively at the apex position (B-1) in the presence of strong Lewis acids; nucleophilic conditions generally favor substitution at the equatorial (B-2) position, but side reactions often reduce yields. Strong Lewis acids react with B_5H_9 to form adducts having the general formula $B_5H_9 \cdot 2L$. Deprotonation

(1)

of B_5H_9, *e.g.* with alkylmetal hydrides gives rise to the anion $B_5H_8^-$; the proton is most likely removed from a bridging hydrogen position. The anion reacts with various group III, IV, and V compounds. [The chemistry of Pentaborane(9). Accounts Chem. Res. *6*, 416—421 (1973); 61 references]

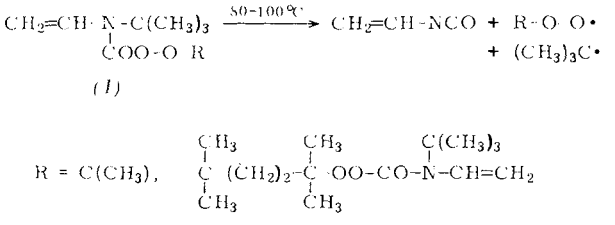
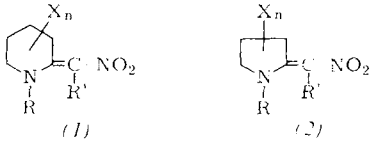
A new synthesis for cephalosporin intermediates *(6)* involves the condensation of the thiazinecarboxylic ester *(4)* with azidoacetyl chloride *(5)*; an interesting feature is the preparation



R^1 = protective group; R^2 = H, halogen, —O—CO—NH_2, alkoxy, aryloxy, —S—Het (Het = heterocyclic group), acyloxy, *etc.*; R^3 = H, CH_3, CH_3O

of *(4)* by an intramolecular Wittig-Horner reaction of *(3)*. [DOS 2318829; Merck & Co., Inc.; Rahway, N. J. (USA)]

[PR 174 IE—K]

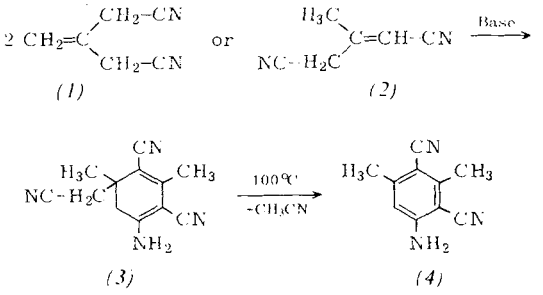


A new route to copolymers containing isocyanate groups starts with peroxycarbamic esters *(1)*, which are used as polymerization initiators. *(1)* decomposes in the course of the reaction

into vinyl isocyanate and free radicals. Polymers with high contents of built-in NCO groups have been obtained with ethylene as well as with styrene, butadiene, and ethyl acrylate. [DOS 2218365; Badische Anilin- & Soda-Fabrik, Ludwigshafen]

[PR 175 IE—A]

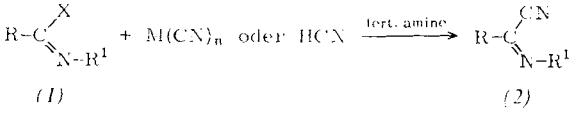
New groups of insecticidal substances having a novel mode of action are 2-nitromethylenepiperidines having the formula *(1)*, preferably obtained by reaction of 6-alkoxy-2,3,4,5-tetrahydropyridines or 2,2-dialkoxy-1-alkylpiperidines with nitroalkanes, and possibly substituted further, *e.g.* by halogenation, as well as corresponding pyrrolidine derivatives *(2)*.



X = alkyl, aryl, OAlk, SAlk, Hal, *etc.*; R = H, alkyl, aryl, NO_2, acyl, *etc.*; R' = H, alkyl, aryl, NO_2, Hal, *etc.*

The compounds have a lethal action on some groups and stages of insects (caterpillars, beetles), while they reduce the mobility or coordination of others (*e.g.* flies). [DOS 2321552, 2321523; Shell International Research Mj., Den Haag (Netherlands)]

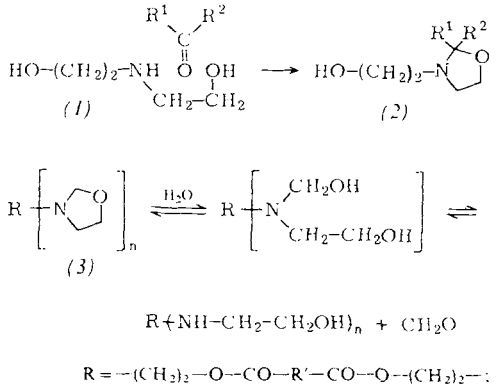
[PR 176 IE—S]



2,4-Dicyano-3,5-dimethylaniline *(4)* is obtained in good yields from β-methyleneglutaronitrile *(1)* or β-methylglutacononitrile *(2)* if the base-catalyzed dimerization of *(1)* or *(2)* is carried out above 100 °C. Under these conditions, the isolable cycliza-

tion product *(3)* undergoes aromatization with elimination of acetonitrile to form *(4)*. The compound *(4)* is a starting material for the preparation of azo dyes. [DOS 2222381; Bayer AG, Leverkusen]

[PR 177 IE—A]



A new process for the preparation of α-imino nitriles *(2)* is based on the reaction of imidoyl halides *(1)* with metal cyanides or with hydrocyanic acid in the presence of a tertiary

amine (R, R^1 = alkyl, aryl, *etc.*; R^1 also: secondary amino, RO). [DOS 2221771; Bayer AG, Leverkusen]

[PR 184 IE—K]

Polyfunctional esters of *N*-hydroxyalkyloxazolidines of the type *(3)* give stable mixtures with polyisocyanates, which cure only on contact with atmospheric moisture. The compounds *(3)* are obtained by transesterification of hydroxyalkyloxazolidines *(2)* with esters of polybasic carboxylic acids such as dimethyl terephthalate or adipate. The compounds *(2)* are formed by the action of aldehydes or ketones on imino dialcohols *(1)*. The ring in *(3)* is cleaved by water. The polyiso-

R = —$(CH_2)_2$—O—CO—R'—CO—O—$(CH_2)_2$—; R' = —$(CH_2)_4$—, *p*-phenylene

cyanates react both with the hydroxy groups and with the amino group to form high polymers. Acrylic varnishes that cure in the presence of atmospheric moisture can be prepared from the methacrylic esters of *(2)* with isocyanates. [DOS 1952092, 1952001, 2018233; Rohm and Haas Company, Philadelphia (USA)].

[PR 185 IE—W]

Gesundheitsschädliche Arbeitsstoffe. Toxikologisch-arbeitsmedizinische Begründung von MAK-Werten (Noxious Industrial Substances. Toxicological and Industrial Medical Grounds for MAC Values). Edited by *D. Henschler*. Verlag Chemie, Weinheim 1972. 1st ed., xiii, 220 pp., 1 figure and 50 tables. Loose-leaf DM 58.—.

This work presents clearly and impressively the brief information assembled by the Commission for the Testing of Noxious Industrial Substances of the Deutsche Forschungsgemeinschaft as a basis for the maximum allowable concentrations (MAC values) of individual noxious substances.

At the start of the discussion of the individual substances, the currently valid MAC values and the last date on which they were fixed are given; these are followed by the principal synonyms, chemical name, molecular and structural formulas, the main physical and chemical properties, and finally information on conversion from ppm to mg/m^3 and *vice versa*. Under the heading "General Action Character" the reader is informed about absorption, metabolism, excretion, and the main effects and modes of action. This is followed by the sections "Experience with Human Subjects", which includes the results of industrial toxicological, occupational medical, and feld investigations as well as descriptions of cases, "Results of Animal Experiments", which includes data on the acute and chronic effects on experimental animals, and finally a brief "Justification of the MAC Value". The arrangement facilitates a clear presentation of the facts and allows fast orientation and the correct toxicological appraisal of the substance.

Unfortunately, the work does not yet include important substances that are of very frequent occurrence and are therefore of great interest (*e.g.* xylene, toluene, and styrene). Moreover despite the understandably advocated view that no MAC values can be given for substances that are believed to cause cancer, one might wonder whether it would have been better to give guide values in the interests of controllability, since no control of these very dangerous emissions, such as benzene, is possible if no limiting value exists.

Finally, the ring-book form chosen allows the easy addition of further material and the replacement of pages as a result of revision.

Georg G. Fodor [NB 182 IE]

MTP International Review of Science. Theoretical Chemistry. Physical Chemistry, Series One. Vol. 1. Edited by *W. Byers Brown*. Butterworths, London University Park Press, Baltimore 1972. 1st ed., 295 pp., numerous figures and tables, bound £ 10.—.

The MTP review is an ambitious project aimed at presenting an encyclopedic survey, initially in 33 volumes, of research in chemistry for the years 1967—1971, with the addition of a new series every two years. The present volume on theoretical chemistry contains $4\frac{1}{2}$ contributions on quantum-chemical topics, $2\frac{1}{2}$ on areas of statistical thermodynamics, and a review on molecular scattering theory. This distribution fully corresponds to the current distribution of interest within theoretical chemistry. Each article contains exhaustive literature references (about 100 to about 450 per contribution), which are critically discussed in the text. This makes the volume a real mine of information.

The quantum-mechanical contributions deal with *ab-initio* calculations for atoms (*J. I. Musher*), for diatomic molecules (*A. C. Wahl*), and for organic molecules (*L. Radom* and *J. A. Pople*), for these last in the Hartree-Fock (or SCF) approximation and for atoms and diatomic molecules with inclusion of electron correlation. The article by *Musher* is rather individual. *Wahl* rightly points out the significance of the reliability that has now been achieved in quantum-chemical calculations to a close contact between experiment and theory. In the article on properties of molecules, *W. N. Lipscomb* discusses second-order properties such as electric polarizability, diamagnetic susceptibility, and chemical shift for diatomic molecules, calculated by the coupled Hartree-Fock method. Other properties of molecules are discussed by *Wahl* and by *Radom* and *Pople*. The articles on statistical thermodynamics deal mainly with liquids, and specifically with their equilibrium theory (*D. D. Fitts*) and the theory of transport processes (*A. R. Allnatt* and *L. A. Rowley*). The importance of computer simulation (molecular dynamics and Monte Carlo method) in present-day research is made particularly clear in the article by *Fitts*.

The theory of intermolecular forces, which is dealt with by *P. R. Certain* and *L. W. Bruch*, comes from quantum chemistry, but affects mainly the statistical theory. Equal consideration is given to both aspects.

The article by *R. D. Levine* on the theory of molecular collisions critically examines in particular the conditions under which the methods suggested (classical and quantum-mechanical) are good and practicable approximations.

On the whole, the author and his team of experts must be congratulated on this survey of recent developments in theoretical chemistry.

Werner Kutzelnigg [NB 185 IE]

Die Woodward-Hoffmann-Regeln und ihre Anwendung [The Woodward-Hoffmann Rules and their Use]. By *N. T. Anh*. Translated and edited by *H.-J. Hansen* and *H. Heimgartner*. Verlag Chemie GmbH, Weinheim/Bergstr. 1972. 1st ed., xiv, 254 pp., 87 figs., 2 tables, bound DM 28.—.

Following the monograph "Die Erhaltung der Orbitalsymmetrie" [The Conservation of Orbital Symmetry] by *Woodward* and *Hoffmann* (1970), another work on this subject is now available; it is a German translation of "Les règles de Woodward-Hoffmann" [The Woodward-Hoffmann Rules] by *N. T. Anh*, which was published in 1970.

The book begins with an introduction (16 pp.) to the elementary concepts of the MO theory, insofar as these are necessary for an understanding of the Woodward-Hoffmann rules. In the main part (165 pp.), the theory of concerted reactions according to the definition given by *Woodward* and *Hoffmann* (electrocyclic, sigmatropic, *etc.*) is first derived and then discussed in detail in separate chapters with the aid of reactions that have actually been observed. The concepts of *Dewar*, *Fukui*, and *Zimmermann* are then briefly presented and the possible application of the rules to several reactions (metal-ion catalysis, photochemistry, *etc.*) is discussed in two sections (49 pp.). An author and subject index completes the book.

The author's aim of appealing both to advanced students and to organic chemists engaged in research is achieved on the one hand by the inclusion of many problems for practice in the text and on the other by the provision of a comprehensive survey of the literature (up to March 1971) for each chapter. In the reviewer's opinion, this includes all the most important contributions on this topic.

Clear drawings, clear language, and the division into "theoretical" and "practical" sections enable even the newcomer to

[1] Cf. Angew. Chem. 6, 1009 (1967).

gain a grounding in this field without any special prior knowledge. For the advanced reader, however, it would have been better if the author of this otherwise very commendable book had taken a more critical attitude with regard to the theory and particularly to the experimental results.

Eckhart Schmidt [NB 191 IE]

Aufschlussmethoden der anorganischen und organischen Chemie [Digestion Methods in Inorganic and Organic Chemistry]. By *R. Bock*. Verlag Chemie GmbH, Weinheim/Bergstr. 1972. 1st ed., 232 pp., 46 figs., 75 tables; bound DM 64.—.

The conversion of samples into a form that is amenable to chemical or physical methods of analysis is achieved by the use of suitable procedures for sample preparation. For example, solid samples that are insoluble in acids or alkalis can be digested by melting; the phosphorus or boron contents of organic substances can be determined after digestion by oxidative methods, and the sulfur content can be determined by combustion of these substances or of gaseous samples, followed by absorption of the combustion gases in alkaline liquids. The author has managed to present a self-contained treatment of the diverse methods of sample preparation and to indicate their sources of error, which affect the correctness of the overall result of an analysis as much as the subsequent quantitative determination, but which, like sampling, frequently do not receive the required care and attention.

The monograph has been systematically and carefully built up, with reference to about 1600 widely scattered publications, which are often difficult to find. The first section deals with general aspects of digestion methods, the digestion procedures, suitable apparatus materials, sources of error and loss of substance, and finally the use of blanks. The purely physical dissolution of inorganic and organic substances is discussed in the second section, and digestion by the use of heat, electrical energy, and UV and γ radiation, *i.e.* degradation methods using pyrolysis, spark discharge, electron bombardment, or photoionization, is described in the third section. The fourth section deals with general methods for digestion by means of chemical reactions, *e.g.* with complexing agents or acids, and fusion with neutral, acidic, or basic salts. Finally, the fifth and sixth chapters are concerned with digestion methods involving oxidation or reduction processes.

This commendable book should find a place in any analytical laboratory. It will provide many inorganic and organic chemists with suggestions for chemical and physical investigations on their samples. It will also be useful in purity checks and trace analyses on technical products.

Hermann Kienitz [NB 192 IE]

Magnetic Resonance. Oxford Chemistry Series. By *K. A. McLauchlan*. Clarendon Press, Oxford 1972. 1st ed., xii, 105 pp., numerous figures, bound £ 1.20.

The independence of chemical research in the field of free radicals on the one hand and of diamagnetic substances on the other has its counterpart, among physical methods, in the division that is made in research, and in theory in general, between electron spin spectroscopy and nuclear spin spectroscopy. It is therefore gratifying that a renewed effort is made here to bring ESR and NMR spectroscopy together under the broader heading of "Magnetic Resonance". In this way it is possible to show the many points in common in the physical principles and in the experimental techniques, and also the characteristic differences between the two methods.

In the space of about 100 pages the author presents the important aspects of magnetic resonance [chapter headings (number of pages): The Principles (20); Spectra from Liquids (12); The g-Factor (10); The Chemical Shift (16); Interactions between Magnetic Particles (12); Analysis of Spectra (12); The Solid State (14)]. However, he is forced to forgo detailed derivations in the formulation of quantitative relationships. The book therefore calls for a good grounding in physics in general, and quantum mechanics in particular. It is mainly suitable for physicists and physical chemists. Advanced students of inorganic and organic chemistry may use it as a guide if they are prepared to work through the material with the aid of more detailed textbooks.

Harald Günther [NB 194 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Comparative Physical Biology. By *N. R. Joseph*. S. Karger Basel 1973. VII, 234 pp., bound DM 83.—.

Contents: Internal Environment; Protoplasm; Electromotive Force; Colligative Properties; Skeletal Muscle; The Heart; Growth and Development; Energy and Entropy; Heterogeneous Equilibrium; Metabolic Energy; Sets and Monograms.

Annual Reports in Organic Synthesis—1972. Edited by *J. McMurry* and *R. B. Miller*. Academic Press, New York 1973. xii, 273 pp., stitched $ 7.40.

Contents: Carbon-Carbon Bonds; Oxidations; Reductions; Heterocycles; Protecting Groups.

Magnetic Resonance and Related Phenomena. Edited by *V. Hovi*. North-Holland Publishing Company, Amsterdam 1973. xxxiv, 555 pp., bound Dfl. 120.00.— Proceedings of the XVIIth Congress, Ampere Turku, August 1972.

Biochemie antimikrobieller Wirkstoffe. By *T. J. Franklin* and *G. A. Snow*. Translated and edited by *W. Goebel*. Vol. 116 of the Series "Heidelberger Taschenbücher". Springer Verlag, Berlin 1973. xii, 183 Vol. 116 of the Series DM 16.80.

Chemistry. Imagination and Implication. By *A. T. Schwartz*. Academic Press, New York—London 1973. xv, 571 pp., bound $ 10.95.

Electron Spin Resonance, Vol. 1. Edited by *R. O. C. Norman*. The Chemical Society London 1973. x, 273 pp., bound £ 7.00.—A volume in the series "Specialist Periodical Reports".

Electron Deficient Compounds. By *K. Wade*. From the series "Studies in Modern Chemistry". Nelson, London 1973. vi, 203 pp., stitched £ 1.95.

Contents: Diborane; Higher Boranes and Boron Polyhedra; Boron Hydrides; Metal Hydrides, Alkyls, and Aryls; Carboranes.

Methoden zur Optimierung chemischer Reaktoren. By *G. M. Ostrowski* and *J. M. Wolin*. Akademie-Verlag, Berlin 1973. xvii, 244 pp., bound DM 68.—.

Modern Aspects of Inorganic Chemistry. By *J. J. Emeleus* und *A. G. Sharpe*. Routledge and Kegan Paul, London 1973. xi, 677 pp., bound £ 5.25.

Liquid Crystals. Edited by *F. C. Tompkins*. Symposia of The Faraday Society No. 5, 1971. The Faraday Division, Chemical Society, London 1973. 188 pp., stitched £ 4.00.

Molecular Motions in Amorphous Solids and Liquids. Edited by *F. C. Tompkins*. Symposia of The Faraday Society No. 6, 1972. The Faraday Division, Chemical Society, London 1973. 197 pp., stitched £ 4.00.

Gmelins Handbuch der anorganischen Chemie. Supplement to 8th Edit. Vol. 5: Kobalt-organische Verbindungen, Part I: Einkernige Verbindungen. Verlag Chemie- Weinheim 1973. viii, xii, 527 pp., bound DM 696.—.

Gmelins Handbuch der anorganischen Chemie. Supplement to 8th Edit. Vol. 6: Kobalt-organische Verbindungen, Part II: Mehrkernige Verbindungen. Verlag Chemie, Weinheim 1972. vi, vi, 243 pp., bound DM 329.—.

Das Leben und Wirken von Hans Fischer. By *A. Treibs*. Hans-Fischer-Gesellschaft, München 1973. 681 pp., bound.

Oxidative Coupling *via* Organocopper Compounds[1]

By Thomas Kauffmann[*]

Dedicated to Professor Heinrich Hellmann on the occasion of his 60th birthday

The type of reaction described here, which achieved preparative importance before the turn of the century in the form of the Glaser reaction, has found new applications in recent years: syntheses of 1,3-dienes, 2,3,6,7-tetraaza-1,3,5,7-tetraenes, 2,3-diaza-1,3-dienes, hydrazine derivatives, bis(heteroallyl) compounds, hetarenes, polyhetarenes, cyclopolyarenes, protophanes, phanes, and heteraprotophanes. The reaction, which consists in the metalation of the starting substance followed by oxidative coupling of the metal derivative, merits special preparative interest when several successive coupling processes are possible (*e. g.* polyyne, polyarene, cyclopolyarene, and protophane syntheses). The main factors limiting its applicability are the high thermal stability of some organic copper compounds and the disproportionation of the ligands that frequently occurs as a competing reaction. Selective asymmetric linkages are not generally possible by this method.

1. Introduction

Table 1 presents a list of reactions discovered before 1920 in which organocopper compounds or copper cyanide play an important role.

The reactions listed in Table 2 are of the same type, but these were discovered within the last decade, and reflect a reawakening of interest in organocopper chemistry. The most significant advance seems to lie in the use of cuprate complexes. The thermal stability of organocopper compounds is enhanced in these complexes, and this favors reactions with organic halides (substitution), and unsaturated compounds (addition). Moreover, the organic residues are spatially proximate in cuprate complexes, so that oxidative couplings may be promoted.

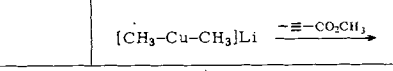

Table 1. Reactions from early organocopper chemistry.

Substitution	sym. (oxidative coupling)	$2R{-}C{\equiv}C{-}Cu \xrightarrow{oxid.} R{-}C{\equiv}C{-}C{\equiv}C{-}R$	Glaser reaction [2]	1869

This work was supported by the Deutsche Forschungsgemeinschaft, the Landesamt für Forschung des Landes Nordrhein-Westfalen, and the Fonds der Chemischen Industrie.

Table 2. Reactions from more recent organocopper chemistry.

Substitution	sym. (oxid. coupling)		[5, 6]	1966
			[7]	1967
	asym.		[8]	1966
			[9]	1967
Addition			[10]	1966
			[11]	1969

We have systematically investigated oxidative coupling *via* organocopper compounds, concentrating on the *exploration of the unusually wide range of applications rather than on the study of the mechanism.* It was possible to exclude the linkage of sp-hybridized C atoms, which has already been extensively studied; the linkage of N atoms was included.

2. Fundamental Aspects

The oxidative coupling of organic compounds *via* metal derivatives as shown in eq. (1), is a symmetrical *substitution with metalation/ligand coupling mechanism*[20]. A characteristic feature is that the two residues to be linked are both bonded to metal at some stage. Though this type of reaction has been known for some time, and is not without importance in preparative work, it has not yet found a secure place in the classification of organic reactions. The occasional reference in textbooks under the heading of free radicals[12] seems unsatisfactory, since free radicals mostly cannot be detected in these reactions[12].

$$\underset{X=H,\,Hal}{R{-}X} \xrightarrow{\text{metalation [20]}} [R-M] \xrightarrow[\text{coupling}]{\text{ligand}} \tfrac{1}{2}R{-}R + M \qquad (1)$$

Numerous metals, particularly transition metals, are suitable for couplings in accordance with eq. (1); however, the reactions generally proceed especially smoothly on copper, and with surprising tolerance as far as the nature of the ligands is concerned. Hetero atoms such as N, P, and S can be linked as well as sp-, sp^2-, and sp^3-hybridized C atoms[13].

The *introduction of copper* into an organic compound can be achieved either directly (terminal alkynes, aryl halides, compounds with NH groups)[14] or *via* an intermediate containing some other metal (metalation-transmetalation route[20]; cf. *e.g.* Sections 3.1.2 and 3.2). The subsequent coupling of the ligands is *oxidative*; an added oxidizing agent may be reduced instead of the metal. An oxidizing agent is necessary if a Cu^I compound with an excessively high thermal stability is formed as an intermediate (cf. *e. g.* Section 3.1.4). The coupling of the ligands, which is represented only by the overall formulation in eq. (1), can proceed *monocentrically* [eq. (2)] or *dicentrically* (two one-electron transfers) [eq. (3)]. The dicentric reaction must take place in an organometallic aggregate, if one ignores the rare cases in which free radicals are involved (possibly at high temperatures).

$$\text{monocentric: } R{-}Cu^x{-}R \rightarrow R{-}R + Cu^{x-2} \qquad (2)$$

$$\text{dicentric: } Cu^x{-}R + Cu^x{-}R \rightarrow R{-}R + 2Cu^{x-1} \qquad (3)$$

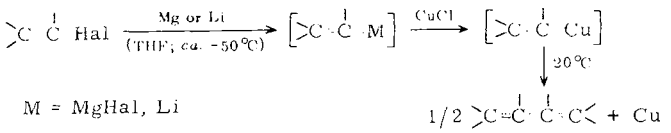
A reaction whose mechanism has been particularly thoroughly studied is the coupling of *m*-trifluoromethylphenyl ligands bonded to Cu^I, which proceeds in the case of the octamer *(1)* in benzene at 74 °C. Since a stable Cu^0—Cu^I cluster *(2)* is formed *via* a labile Cu^0—Cu^I cluster[15], the coupling very probably proceeds dicentrically, as is also assumed in the Glaser reaction[16]. Free radicals cannot be detected in either reaction[15, 16].

$$\underset{(1)}{R_8Cu_8} \xrightarrow{k_1} R_2 + \underset{R = m\text{-}F_3C{-}C_6H_4}{R_6Cu_8} \xrightarrow{k_2} R_2 + \underset{(2)}{R_4Cu_8}$$

Oxidative couplings *via* organocopper compounds have been mainly used where suitable copper compounds are formed directly (Ullmann reaction[17]) and even in aqueous solution (Glaser reaction and variants, dicyanogen synthesis), and where the coupled residues can be readily modified by synthesis and degradation reactions, as in the case of dicyanogen, diacetylenes, and biaryls. A particularly interesting synthetic possibility is offered when the coupling product allows further couplings of the same type. This is generally so in the case of compounds of type *(3)* in which X can be replaced directly or indirectly with copper:

$$\underset{(3)}{X{-}R{-}X} \rightarrow X{-}R{-}R{-}X \rightarrow X{-}R{-}R{-}R{-}R{-}X \rightarrow \cdots\cdots \qquad X = H, Hal$$

Well-known examples of such multiple oxidative couplings are the syntheses of open-chain and cyclic polyynes[18]. (For further examples see Sections 3.2, 3.3, 3.4, 4.5.2, and 4.5.3.)



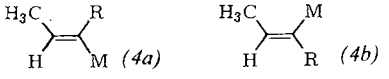
3. Linkages of C or N Atoms with sp^2 Hybridization

3.1. Synthesis of Open-Chain Conjugated Systems

3.1.1. 1,3-Dienes

After the discovery of the oxidative coupling of alkynes *via* organocopper compounds (Glaser reaction), almost a century passed before two research groups working independently applied the reaction to alkenes. Because of the low acidity of these compounds it was necessary to start with halides and to introduce the copper by the metalation/transmetalation route[5, 6, 19, 20] (Table 3).

On thermal decomposition of the stereoisomeric 1-propenylcopper and 2-butenylcopper compounds *(4a)* and *(4b)*, the coupling takes place with full retention. This stereospecificity makes the new 1,3-diene synthesis valuable for preparative



M = MgHal, Li

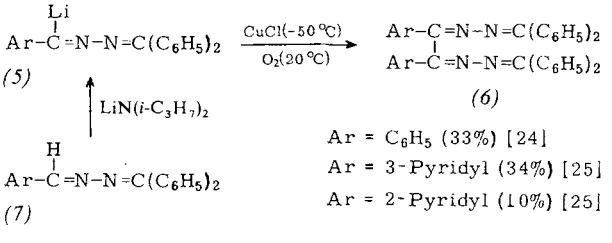
[c] *trans,trans* compound.
[d] Transmetalation with $CuBr_2$.

use and practically rules out the occurrence of alkenyl radicals, since the 1-propenyl and 2-butenyl radicals may be expected to undergo very fast inversion of configuration[5].



(4a) *(4b)*

R = H, CH_3; M = Cu^I, Cu^I←$P(C_4H_9)_3$

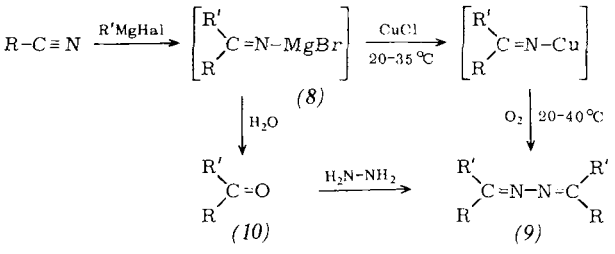
The alkenylcopper compounds required for the coupling have also been prepared by addition of alkylcopper compounds to alkynes[21].

3.1.2. 2,3,6,7-Tetraaza-1,3,5,7-tetraenes

Unlike in the alkenes, the H atom on the sp^2-C atom of the azines *(7)* is so acidic that it can readily be replaced by lithium. These azines have been coupled to form the tetraazatetraenes *(6)* by the successive action of lithium diisopropylamide and $CuCl/O_2$ in THF[24–26]. The lithium compound *(5)*, Ar = C_6H_5, (deep green solution) was detected by NMR spectroscopy of the deuterolysis product. However, only 6% of the compound *(7)* had been metalated at 0 °C.

(5) *(6)* *(7)*

Ar = C_6H_5 (33%) [24]
Ar = 3-Pyridyl (34%) [25]
Ar = 2-Pyridyl (10%) [25]



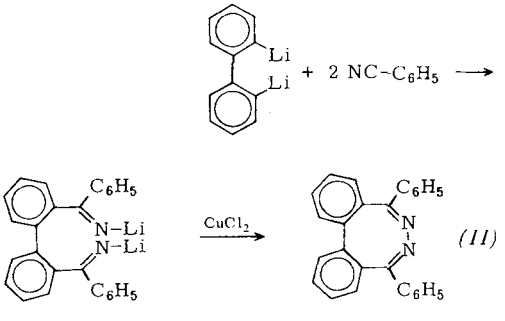
In the case of *(6)*, Ar = C_6H_5, hydrolysis with 30% H_2SO_4 led to the 1,2-diketone in a yield of 63%[25]. Since the azines *(7)* are prepared from aldehydes, the reaction allows 1,2-diketone syntheses

2 Ar—CH=O → Ar—CO—CO—Ar

in which =N—N=C(C_6H_5)$_2$ acts as a masking group.

3.1.3. 2,3-Diaza-1,3-dienes (Ketazines)

Substituted methyleneamidomagnesium halides *(8)*, which are readily obtainable by the action of Grignard compounds on nitriles, are converted by CuCl in THF/ether mixtures into thermally fairly stable copper(I) amides, which react rapidly with oxygen to form ketazines *(9)*. This ketazine synthesis is more elegant than the synthesis nitrile→ketone *(10)*→ketazine *(9)* in which the N atom is first eliminated from *(8)* as NH_3 and then reintroduced with hydrazine. Since the yields (Table 4) are practically the same as in ketone syntheses *via (8)*, it may be assumed that the transmetalation and coupling step proceeds almost quantitatively. The best yields are obtained with catalytic quantities of CuCl[27, 28].

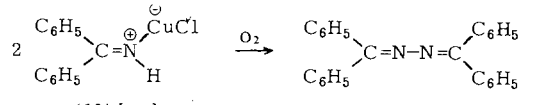


(8) *(10)* *(9)*

Table 4. Synthesis of ketazines *(9)* *via* substituted copper(I) *N*-methyleneamides in THF/ether (for descriptions of experiments and other analogous reactions see [28]).

R	R′	mol Cu / mol nitrile	Yield [%]
C_6H_5	C_6H_5	1	72
		0.3	86
		0.05	94
C_6H_5	*n*-C_4H_9	0.2	79
o-Br—C_6H_4	C_6H_5	0.1	89
p-Br—C_6H_4	C_6H_5	0.1	93
α-naphthyl	C_6H_5	0.1	70
α-naphthyl	α-naphthyl	0.1	64
α-naphthyl	C_2H_5	0.1	64
$(CH_3)_2$CH	C_6H_5	0.2	69
C_2H_5	C_6H_5	0.2	72
C_2H_5	*p*-CH_3—C_6H_4	0.2	76
C_2H_5	C_2H_5	0.2	40

Attempts to make use of the linkage of imino groups for cyclization have been successful in only one case. Despite the application of the dilution principle, the yield of 5,8-diphenyldibenzo[*d,f*][1,2]diazocine *(11)* was only 14%[29].



(11)

The yellow copper(I) amides RR′C=N—Cu with R = R′ = *p*-tolyl or phenyl have been isolated in an almost pure state from dioxane. The dry crystals are stable to air for a few hours at 20 °C; decomposition begins at 140 °C under nitrogen, and the compounds are quantitatively hydrolyzed to the

ketones by hot dilute hydrochloric acid. When oxygen is led into the THF solution, the ketazines *(9)* are formed (100 and 63 % respectively). A yield of 100 % makes the intermediate occurrence of free radicals extremely unlikely[29].

The CuCl-catalyzed oxidation of *free* diphenylmethanimine to the ketazine (92%) at 120 °C/6 atm of O_2 is described in a patent[30]. In our experience the reaction also proceeds in benzene at 20 °C/1 atm of O_2 (40 %)[29]. The intermediate *(12)* containing copper[31] was isolated in the form of colorless crystals (m. p. 132 °C; 82 %) when the reaction was carried out with an excess of CuCl *under nitrogen*. Solid *(12)* is stable in air, but when dissolved in benzene it is rapidly oxidized to the ketazine[29].

(12) [20] 72%

Since substituted methyleneamidomagnesium halides of the type *(8)* are generally more easily obtainable than the free ketimines, which are often unstable, the coupling of the magnesium compounds is likely to be of greater practical importance than that of the free compounds.

3.1.4. Dialkylamino-Substituted 2,3-Diaza-1,3-dienes

N'N'-Dialkyl-substituted amidines *(14)* have also been coupled in preparatively useful yields (Table 5)[32]; the metalated amidines *(13)* (M = Li, MgBr) were prepared by the route indicated (yield 80—100%)[33].

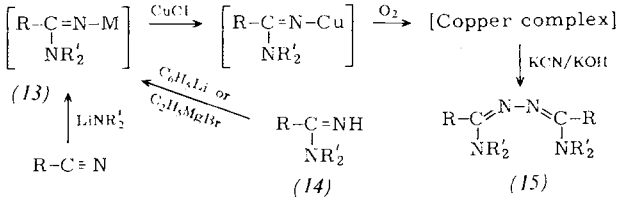


Table 5. Synthesis of 2,3-diaza-1,3-dienes of the type *(15)* from N^1,N^1-dialkylated metalated amidines *(13)* in 1,2-dimethoxyethane/ether mixtures at 85 °C, coupling with $CuCl/O_2$ (yields in brackets: with $CuBr_2$) [32, 33].

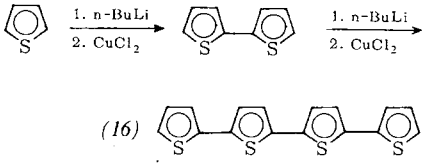
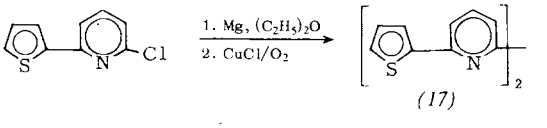
R	2 R'	M	Yield [%]
C_6H_5	$-(CH_2)_5-$	Li	74 (71)
C_6H_5	$-(CH_2)_5-$	Li	18 [a]
C_6H_5	$-(CH_2)_4-$	Li	69
C_6H_5	$-(CH_2)_2-O-(CH_2)_2-$	Li	83
C_6H_5	$-CH_3$ CH_3-	Li	67 (69)
C_6H_5	$-C_2H_5$ H_5C_2-	Li	70
CH_3	$-(CH_2)_5-$	MgBr	53
C_2H_5	$-(CH_2)_5-$	MgBr	59



[a] In this experiment the molar ratio *(13)*/CuCl = 1 : 0.2, otherwise *(13)*/Cu halide = 1 : 1.

In the couplings with $CuCl/O_2$, the first phase yields a crystalline copper(I) compound that is sparingly soluble in 1,2-dimethoxyethane/ether (1 : 1) and that was isolated in a yield of 95% in one case [*(13)*, R = C_6H_5, 2R' = $-(CH_2)_5-$, M = Li][34]. Oxygen reacts exothermally with this compound at 20 °C to form yellow copper complexes, from which the organic ligands *(15)* can be liberated only by treatment with KCN/KOH, glycine, or concentrated NH_3. The copper complexes are so stable that no copper ions are liberated during the reaction. Unlike in the coupling of ketimines (cf. Section 3.1.3) and of unsubstituted amidines (cf. Section 4.4.2), therefore, this coupling cannot be carried out with *catalytic* quantities of CuCl (Table 5, 2nd experiment).

It has been shown for *(14)*, R = C_6H_5, 2R' = $-(CH_2)_5-$, that *free* N^1,N^1-dialkylated amidines can also be coupled with one equivalent of CuCl and oxygen in 1,2-dimethoxyethane at 85 °C to form compounds *(15)*. However, the yield was only 10 %[32].



3.2. Dihetarene and Polyhetarenes Syntheses

Hetarenes of the nucleophilic type ("excess of π electrons") are readily accessible to oxidative coupling, since copper can be conveniently introduced by hydrogen-lithium exchange followed by transmetalation. On reaction of thiophene with *n*-butyllithium[35] and then with one mole of $CuCl_2$, 2,2'-bithienyl was formed in 54% yield[36]; when 2 mol of $CuCl_2$ were used the yield was increased to 85 %[37]. Repetition of the coupling led in a yield of 64 % to quaterthiophene *(16)*[38]; further coupling of this product has not yet been achieved[38, 39]. The other compounds in Table 6 were obtained in a similar manner.

(16)

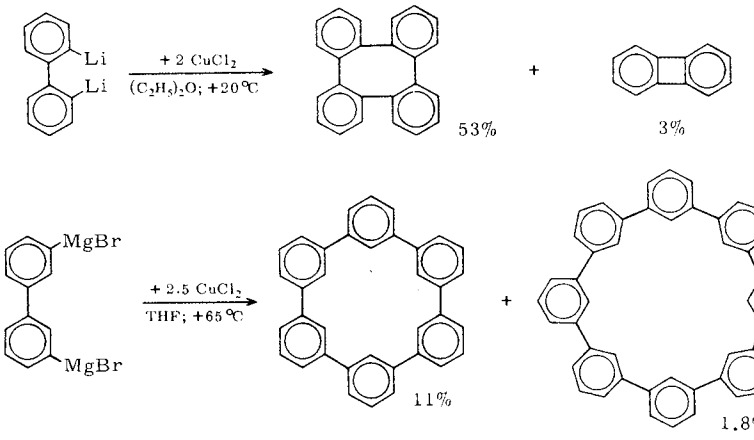
Hydrogen-metal exchange is not generally possible in hetarenes of the electrophilic type ("deficiency of π electrons"). The halides were therefore used as the starting materials for the introduction of copper, which was carried out by halogen-lithium exchange or by formation of a Grignard compound, followed by transmetalation. In addition to 2,2'-bipyridyl and its derivatives (Table 7), the compound *(17)* containing four hetarene rings was also synthesized, but only in a 5 % yield[41].

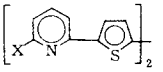
(17)

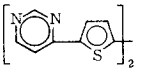
When CuCl is used the reaction yielded deep-colored pyridylcopper(I) compounds, which were stable in THF/ether at +60 °C, and oxidation with oxygen was necessary to initiate the coupling (20 °C). On the other hand the red pyridylcopper(II) compounds obtained with $CuCl_2$ or $CuBr_2$ in solution decomposed even at 0 °C, with almost quantitative formation of the coupling products (Table 7).

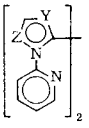
3.3. Cyclopolyarene Syntheses

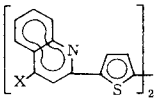
The cyclopolyarenes known at present were mostly prepared by oxidative coupling *via* organometallic compounds of transition metals; here again copper was found to be particularly favorable. Two syntheses in which organocopper compounds were postulated as intermediates[48, 49] are the following:

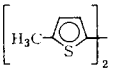


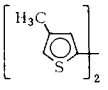












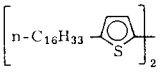


Table 6. Oxidative coupling of nucleophilic hetarenes. The linkage point in every case is in the center of the molecule. T_{max} = maximum reaction temperature. The introduction of lithium was carried out at −60 to 0 °C.

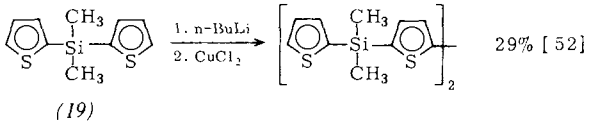
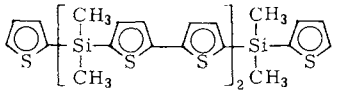
[a] In brackets: yields based on the intermediate lithiopyridines, the quantities of the latter being determined by interception with CO_2 or benzaldehyde.

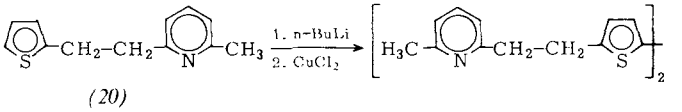


Recently we have been able to prepare the heterocyclic cyclotetraarene *(17a)* by twofold oxidative coupling *via* two different routes[49a].

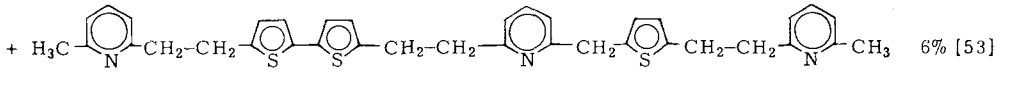
3.4. Protophane and Heteraprotophane Syntheses

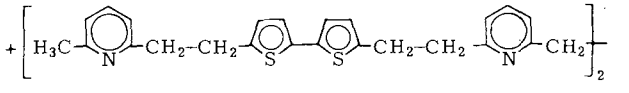


The oxidative coupling of dihetarylalkanes (alkylene-dihetarenes) and dihetarylsilanes provides a very suitable method for the preparation of protophanes and heteraprotophanes (cf. also Section 4.5.2; for nomenclature cf.[50]). On introduction of copper by the metalation/transmetalation route, *(18)*, *(19)*, and *(20)* each give a mixture of tetranuclear and hexanuclear coupling products, since a monolithium compound and a dilithium compound are both formed in the reaction with one mole of *n*-butyllithium. An octanuclear coupling product is also formed from *(20)*.

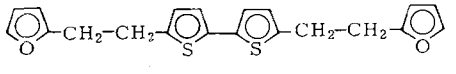


(18)

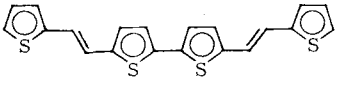




(19)



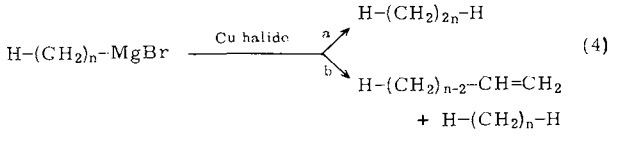
(20)



On the other hand, 1-(2-furyl)-2-(2-thienyl)ethane[54] and *trans*-1,2-di(2-thienyl)ethylene[51] each give only a tetranuclear protophane [*(21)* and *(22)* respectively], since the metalation leads almost exclusively to the monolithium compound in these cases, owing to differences in acidity of the hetaryl

(21) 43%

(22) 28%



residues or delocalization of the negative charge over the entire molecule.

4. Linkage of C or N Atoms with sp^3 Hybridization

4.1. Alkane Syntheses

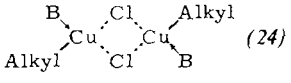
According to literature data, isopentylmagnesium bromide reacts with $CuCl_2$ in ether at about -10 °C to give the coupling product 2,7-dimethyloctane in a yield of more than 60%[55], whereas the reaction of ethylmagnesium bromide with CuCl in the same solvent at 0 °C leads exclusively to ethylene and ethane[56]. How can such different reactions occur?

In our experience, when copper halides are allowed to act on alkylmagnesium halides, as shown in eq. (4), the coupling a) and the disproportation b) generally proceed simultaneously. It is probable that the disproportionation is generally initiated by β-elimination of a copper hydride species from the intermediate organocopper compound, and must

(4)

always be expected if there is an H atom vicinal to the Cu atom as in *(25)* (see below).

Whitesides et al.[57] conclusively demonstrated the copper hydride elimination in the thermolysis of *n*-butyl(trioctylphosphane)copper(I), and postulated the reaction in accordance with eq. (5). The (autocatalytic) disproportionation of ligands of alkylcopper(I) compounds that are not complexed with a phosphane appears to proceed in a similar manner[58].



$$\begin{aligned}&CH_3{-}CH_2{-}CH_2{-}CH_2{-}Cu{\leftarrow}P(C_8H_{17})_3 \rightarrow\\ &CH_3{-}CH_2{-}CH{=}CH_2 + HCu{\leftarrow}P(C_8H_{17})_3\\ &CH_3{-}CH_2{-}CH_2{-}CH_2{-}Cu{\leftarrow}P(C_8H_{17})_3 + HCu{-}P(C_8H_{17})_3 \rightarrow\\ &CH_3{-}CH_2{-}CH_2{-}CH_3 + 2\,Cu + 2\,P(C_8H_{17})_3\end{aligned} \qquad (5)$$

The disproportionation, which leads to a lower yield of the coupling product, can be suppressed in several ways:

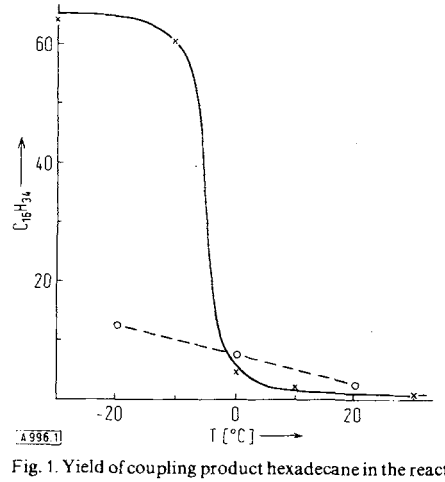
a) The coupling proceeds to a relatively large extent (14 to 88%) if alkylcopper(I) compounds are converted into cuprate complexes *(23)*. Because of the relatively high thermal stability of these compounds, in which the alkyl residues are obviously favorably arranged for the linkage, oxidation with oxygen is necessary for the coupling. Cyclizations have also been achieved (25—30% yield)[7].

$$\begin{matrix}\text{Alkyl–Cu}\\ +\\ \text{Alkyl–Li}\end{matrix} \rightarrow [\text{Alkyl–}\overset{\ominus}{\text{Cu}}\text{–Alkyl}]\ \overset{\oplus}{\text{Li}}$$

(23)

(24)

b) According to our investigations, low temperatures and $CuCl_2$ favor the coupling, whereas higher temperatures and CuCl favor the disproportionation (Fig. 1). The sudden change in the yield at about −5 °C in the reaction of octylmagnesium bromide with $CuCl_2$ (Fig. 1) suggests that the coupling takes place in alkylcopper halide aggregates that progressively decompose with rising temperature, *e.g.* to form *(24)*[59] or monomers, which are less favorable for the coupling[60] (B = diethyl ether).



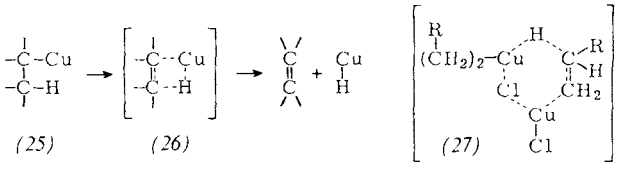


Fig. 1. Yield of coupling product hexadecane in the reaction of octylmagnesium bromide in ether with one mole of $CuCl_2$ (——) or CuCl (----) as a function of the reaction temperature [60].

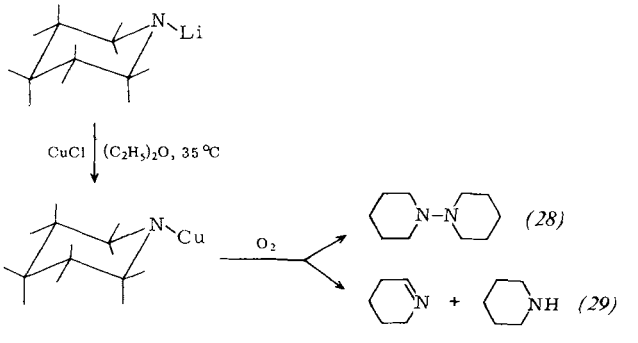
c) The alkyl residue also has a strong influence on the coupling/disproportion ratio; according to Table 8, the coupling component is much higher for the cyclohexyl residue than for cyclopentyl or octyl. The conditions are thus similar to those in the oxidative coupling of secondary amines (cf. Section 4.2). Since *syn* eliminations with coplanar transition states are much less favorable energetically for the cyclohexyl residue, because of its more stable chair conformation, than for the cyclopentyl residue or for open-chain alkanes[61], the exceptional position of the cyclohexyl residue is best explained by the assumption that the disproportionation is introduced by a *syn*-coplanar β-elimination of copper hydride, and is therefore inhibited in the cyclohexylcopper compounds. The most likely transition state for the *syn* elimination of copper hydride is *(26)*, though six-center transition states such as *(27)* are also conceivable.

(25) *(26)* *(27)*

Cu = Cu^I or Cu^{II}

Table 8. Reaction of alkylmagnesium bromides RMgBr with one mole of $CuCl_2$ (yields in brackets: with CuCl) in ether at 0 °C [60] to form the coupling product (R—R) and the disproportionation products alkane (RH) and alkene.



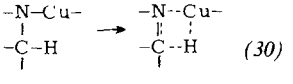
R	Yield [%] R—R	alkane	alkene
octyl	9 (3)	47 (47)	43 (49)
cyclohexyl	58 (26)	21 (39)	21 (34)
cyclopentyl	1	46 [40b]	42 [40b]

4.2. Synthesis of Hydrazine Derivatives

Reactions of *N*-chlorodialkylamines with finely divided copper led to azomethines instead of to the expected tetraalkylhydrazines[62]. Since copper dialkylamides, as shown below, tend to form azomethines, it is probable that the reaction initially gives compounds of this type.

If copper dialkylamides are formed from the lithium amides by transmetalation in boiling ether, hydrazine derivatives are formed as well as azomethines[27,63], but only from six-membered cyclic amines in the cases investigated by us (Table 9)[64,65]. Because of the relatively high thermal stability of the copper(I) amides, the lithium amides must be treated with $CuCl_2$ or $CuCl/O_2$ here.

In the most thoroughly investigated reaction of $CuCl_2$ with lithium piperidide, in addition to the hydrazine derivative *(28)* and the azomethine *(29)*, piperidine is formed in an equimolar quantity with respect to *(29)*. As in the case of



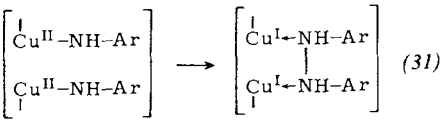
alkylcopper compounds, therefore, disproportionation of the ligands occurs as well as the coupling.

Table 9. Reaction of amines and lithium amides with $CuCl/O_2$ to form hydrazine derivatives and azomethines in ether at 35 C [63].

Li amide	Cu halide: Li amide: free amine	Yield [%] [a] coupling product	azomethine
Li piperidide	1:1:20	110 [c]	60
	(1:2:20) [b]	(59)	(53)
	1:1:2	29	34
	(1:1:0) [d]	(8)	(14) [e]
Li morpholide	1:1:9.5	80	—
Li pyrrolidide	1:1:9.5	—	278 [c]
Li diethylamide	1:1:7.2	—	31
Li (*N*-methylanilide)	1:1:6.6	—	(polymerization)

[a] Yield based on lithium amide.
[b] Because of the stoichiometric proportions, a cuprate complex is probably formed in this case.
[c] The yield of more than 100% shows that piperidine and pyrrolidine respectively are included in the coupling process.
[d] With $CuCl_2$.
[e] 15% of piperidine is also formed.

This disproportionation, which normally predominates over the coupling, appears to be energetically unfavorable in the case of copper compounds of six-membered cyclic amines (piperidine, morpholine). This corresponds exactly to the situation in the alkylcopper compounds (cf. Section 4.1), and can be explained in a similar manner, *i.e.* by hindrance of a concerted *syn*-β-elimination of a copper hydride species [transition state *(30)*?] because of the relatively stable chair conformation of the ring system. In the case of morpholine ("4-oxapiperidine"), for some reason that has not yet been found, this elimination evidently does not occur at all.



(30)

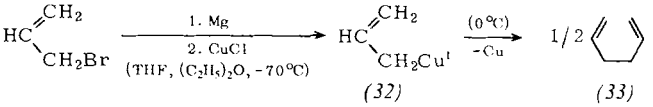
The air oxidation of *free* piperidine in the presence of CuCl (in ether at 35 °C) leads only to a small extent to the coupling product *(28)* (1%) and the azomethine *(29)* (5%).

4.3. Synthesis of Azo Compounds

Primary arylamines are oxidized to azo compounds by oxygen in the presence of CuCl[13]. It is assumed that an aggregated arylaminecopper(II) compound is converted into a hydrazobenzenecopper(I) complex *(31)* (dicentric ligand coupling),

(31)

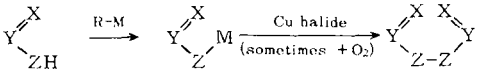
Table 10. Oxidation of hetarylamines with $CuCl/O_2$ to form azo compounds (in pyridine at 20 °C) [67].



Amine	Yield [%]
2- and 4-aminopyridine	0
3-aminopyridine	27
3-aminoquinoline	29
2-aminothiazole	27

whose organic component is then dehydrogenated to the azo compound[66]. We have coupled some hetarylamines in a similar manner (Table 10)[67].

4.4. Coupling of Compounds Containing Allyl and Heteroallyl Groups

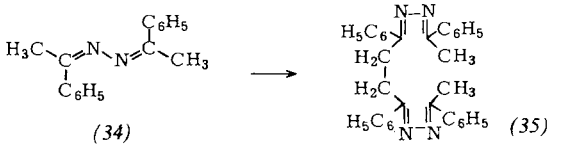


4.4.1. Couplings without Secondary Reactions

Wilke[68] described the coupling of allyl groups bonded to nickel. The resulting 1,5-hexadiene ("bisallyl") *(33)* was also obtainable (99%) *via* allylcopper(I) *(32)*, which occurs as a yellowish precipitate[69].

(32) *(33)*

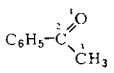
In view of the practically quantitative yield in this coupling, attempts were made to see whether similar smooth coupling is possible with heteroallyl ligands (Tables 11, 12, and 13). The couplings proceeded in accordance with eq. (6), and were followed by secondary reactions in some cases (Table 13).

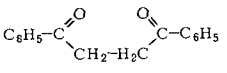


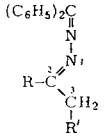
(6)

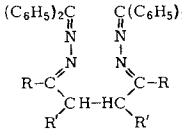
M = alkali metal or MgBr

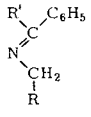
Almost quantitative coupling was achieved only for the 1-azaallyl group (Table 11). The coupling was particularly poor for the groups containing oxygen. Since heteroallylcopper(I) compounds are more stable than allylcopper(I), copper(I) halide/O_2 or copper(II) halide was necessary in most cases as the coupling reagent. In the case of the amides (1-oxa-3-azaallyl group), the result was satisfactory only when copper(II) halide/O_2 was used; it is possible that copper(III) compounds occur here as intermediates.

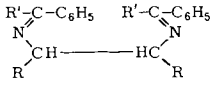


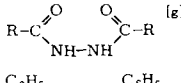


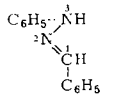


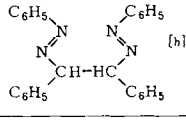






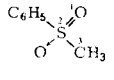


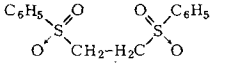


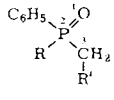


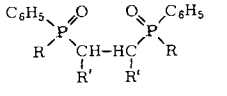
A number of findings call for further explanation. According to Table 11 the 1,4-diketone dibenzoylethane was formed in a yield of only 11% from *acetophenone*[70] (even lower yields with $CuCl/O_2$ or $CuCl_2$). However, the yield increased to about 75% when acetophenone was converted into a *ketazine* by reaction with benzophenone hydrazone, the coupling product of the ketazine (Table 11) being hydrolyzed with hydrochloric acid[71]. It is therefore helpful to mask acetophenone, and presumably aryl methyl ketones in general, with the grouping $=N-N=C(C_6H_5)_2$ for the oxidative coupling.

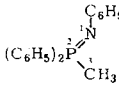
Acetophenone azine *(34)*, which is not listed in Table 11, and which has two points of attack available for the coupling, reacted with one mole of lithium diisopropylamide and one mole of $CuCl/O_2$ to form the dehydrodimer *(35)* (54%) as well as polymeric compounds. Intramolecular coupling of

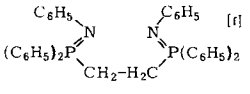












(34) *(35)*

[b] In THF/benzene/ether.
[c] In THF/ether.
[d] With CuCl instead of $CuBr_2$, the reaction led to an orange copper(I) compound that was stable in THF at 60°C and reacted rapidly with oxygen at 20°C with ligand coupling (42%).
[e] A 1-aza-2-phosphaallyllithium compound (orange in THF) was obtained here for the first time (yield 50%, determined by reaction with benzaldehyde and with D_2O) [25].
[f] This coupling product was very sensitive to hydrolysis and could not be obtained in the pure state. It was hydrolyzed by hydrochloric acid to the known bis-(phosphane oxide) [25].

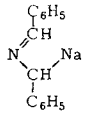
(35) on the methyl group was not possible even on application of the dilution principle[25].

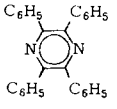
A similar cyclization attempt with *(36)* also failed to give the expected ten-membered ring. Fragmentation occurred, with formation of the known[76] dihydropyridazine *(37)* (17%)[25].

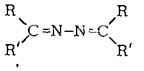
(36)   *(37)*

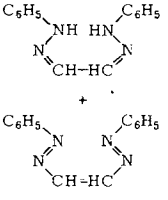
The *azomethines* (2-azaallyl compounds) listed in Table 11 can be readily obtained from amines by known methods, and their coupling products can be smoothly degraded to 1,4-diamines by acid hydrolysis. The coupling of these azomethines thus allows diamine syntheses in accordance with the scheme

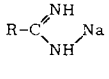
$$2R{-}CH_2{-}NH_2 \rightarrow R{-}CH(NH_2){-}CH(NH_2){-}R.$$











The group =CR'R'' acts here as a masking group.

pounds were stable at room temperature. These stable organocopper(I) compounds are very promising reagents for additions to unsaturated compounds and substitutions on reactive halides[78] similar to corresponding reactions in Tables 1 and 2[79].

4.4.2. Couplings with Secondary Reactions

Some couplings (Table 13) are followed by secondary reactions (elimination, isomerization, dehydrogenation, cyclization with aromatization):

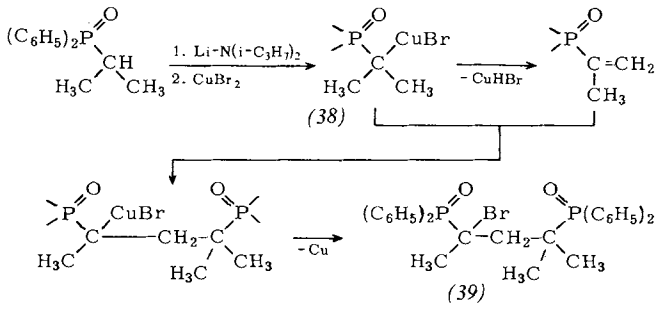


Table 13. Oxidative couplings of heteroallyl compounds associated with secondary reactions. T_{max} = maximum reaction temperature.

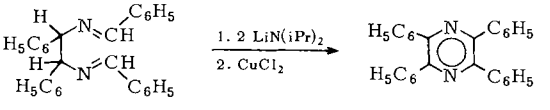
Reactant	1st intermediate	Transmetalation and coupling with	T_{max} [°C]	Product		Yield [%]	Ref.
N-Benzylidenebenzylamine + $NaNH_2$		$CuBr_2$ [a]	35	 *(41)*		20	[70, 73]
Hydrazone + $NaNH_2$		$CuCl/O_2$ [a]	20–30		$R=R'=CH_3$	46	[71, 75]
					$R=H, R'=C_6H_5$	30	[71, 75]
Methylphenyldiimine + *n*-BuLi		$CuCl/O_2$ [b]	−20			30	[29]
						30	[29]
Nitriles + $NaNH_2$		$CuCl$ [b]	85		$R=C_6H_5$	0	[80]
		$CuCl_2$ [b]			$R=C_6H_5$	32	[80]
		$CuCl/O_2$ [b]			$R=C_6H_5$	45	[80]
		$CuCl_2/O_2$ [b]			$R=C_6H_5$	74	[80]
		$CuCl_2/O_2$ [b]			$R=p$-Tolyl	47	[80]
		$CuCl_2/O_2$ [b]			R = 2-Naphthyl	30	[80]

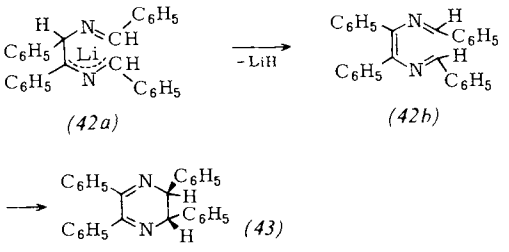
[a] In ether.
[b] In 1,2-dimethoxyethane.



In experiments on the coupling of phosphane oxides (Table 12) the coupling products were formed in a yield of less than 10% when the intermediate organocopper compound satisfied the constitutional condition for the β-elimination of copper hydride. This is especially so (six H atoms vicinal to Cu) in the hypothetical intermediate *(38)*. Significantly only the anomalous product *(39)* (11%), which could have been formed by the indicated route, was obtained in this case[25].

Where the couplings in Tables 11 and 12 were not carried out exclusively with copper(I) halides, the heteroallylcopper(I) com-

(38) *(39)*



(40) may be regarded as an intermediate in the formation of *2,3,5,6-tetraphenylpyrazine (41)* (Table 13), since the *meso* form of *(40)* has been cyclized to *(41)* in 11% yield by the action of lithium diisopropylamide and $CuCl_2$ (in ether at 20 °C)[74].

(40) *(41)*

Copper is presumably only indirectly involved in the actual cyclization step, since the cyclization *(40)*→*(41)* also proceeded, though in a somewhat lower yield (4%), with lithium diisopropylamide alone. *trans*-2,3-Dihydro-2,3,5,6-tetraphenylpyrazine *(43)* was formed as a by-product (7%). It seems reasonable to conclude that the 2,5-diazatriene *(42b)* is formed *via (42a)* and reacts electrocyclically to form *(43)*[74].

In the couplings leading to *s-triazoles*, it was unnecessary to add strong complexing agents to the reaction mixture to

(42a) (42b) (43)

with eq. (7) to 1,2-dihetarylethanes (ethylenedihetarenes). The yields are good even when the organocopper intermediate has a structure that would allow the β-elimination of a copper hydride species (Table 14, experiments 2—4, and 7).

Anomalous linkage was never observed in these couplings. In the reaction of 2-lithiomethylpyridine with $CoCl_2$ (*via* free radicals?), on the other hand, the anomalous coupling products *(44a)* (10%) and *(44b)* (2%) were formed as well as 2,2'-ethyl-

Table 14. Coupling of alkylhetarenes in accordance with eq. *(7)*. [Introduction of lithium with *n*-BuLi or C_6H_5Li, transmetalation with CuCl (yields in brackets: with $CuBr_2$); addition of 1 to 1.1 mol of CuCl at −10 to 0°C to the solution of the organolithium compound. The mixture was generally then warmed to 50—60°C.]

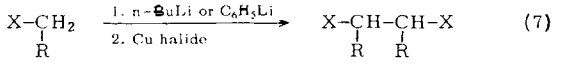
[c] Transmetalation with $CuCl_2$.
[d] In 1,2-dimethoxyethane/diethyl ether (approx. 1:1).



liberate the organic reaction product. The copper complexes formed by coupling are therefore labile. Accordingly, unlike in the coupling of *N,N*-dialkylated amidines (cf. Section 3.1.4), it was possible to convert sodium benzamidide into 3,5-diphenyl-*s*-triazole with no serious decrease in yield (28%) by the use of oxygen and a *catalytic* quantity (0.1 mol) of CuCl[80].

1,3-Diazaallylcopper compounds are formed as intermediates in these couplings. One of these, copper(I) benzamidide[81], has been isolated (80%) after the reaction of sodium benzamidide with CuCl in 1,2-dimethoxyethane at 20—35°C. This yellow compound, which is insensitive to air in the dry state, and which is more easily obtainable by reaction of benzamidine with CuCl in aqueous ammonia solution, reacts with oxygen at 85°C in 1,2-dimethoxyethane to form 3,5-diphenyl-*s*-triazole (45%)[80].

4.5. Synthesis of Dihetarylethanes, Protophanes, and Phanes

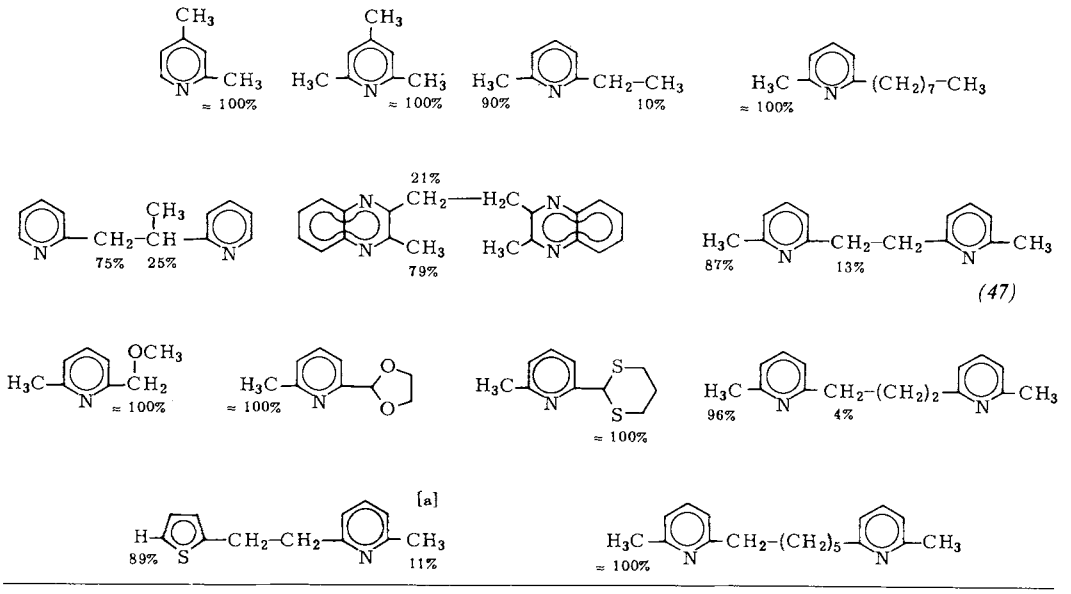
4.5.1. Dihetarylethanes

The oxidative coupling *via* organocopper compounds is a suitable method for the linkage of alkyl groups attached to electrophilic hetarenes[82, 83]. The reaction leads in accordance

(7)

X = Hetaryl

enedipyridine (1,2-di(2-pyridyl)ethane) (11%)[47]. 2-Lithiomethylpyridine reacts in ether with $FeCl_2$, $FeCl_3$, and $NiCl_2$, in the same way as with copper halides to give exclusively 2,2'-ethylenedipyridine (51, 44, and 44% respectively)[47].



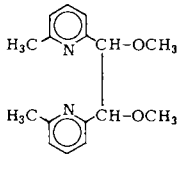
(44a) *(44b)*

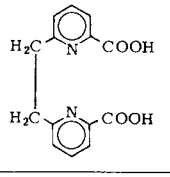
Where *meso* and *racem* forms can occur, both are formed. The (lower-melting) *racem* form is favored when R = alkyl (Table 14, experiments 2—4) and is increasingly favored with increasing size of the alkyl residue. The preferential formation of the *racem* form is evidence against the occurrence of free radicals, since the (higher-melting) *meso* form is preferentially obtained in the peroxide-initiated free-radical dehydrodimerization of 2- and 4-alkylpyridines[85].

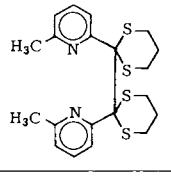
Since lithium can be introduced regioselectively even into more complicated alkylpyridines at low temperatures (Table 15), and experience so far has shown that the metalation position does not change on transmetalation with copper halides, preparatively useful couplings are also possible in cases of this nature (cf. Table 14, experiments 7 and 9, and Section 4.5.2).

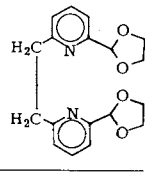
The alkylpyridines with ether, cyclic acetal, or cyclic dithioacetal groups in Table 15 were coupled to only a small extent, if at all, on reaction of the lithium derivatives with copper

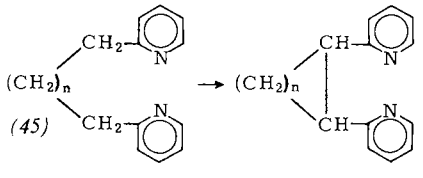
Table 15. Introduction of lithium in the indicated positions, based on the total metalation (=100%), with *n*-BuLi at −70°C in THF [35, 47, 53, 84c, 87].











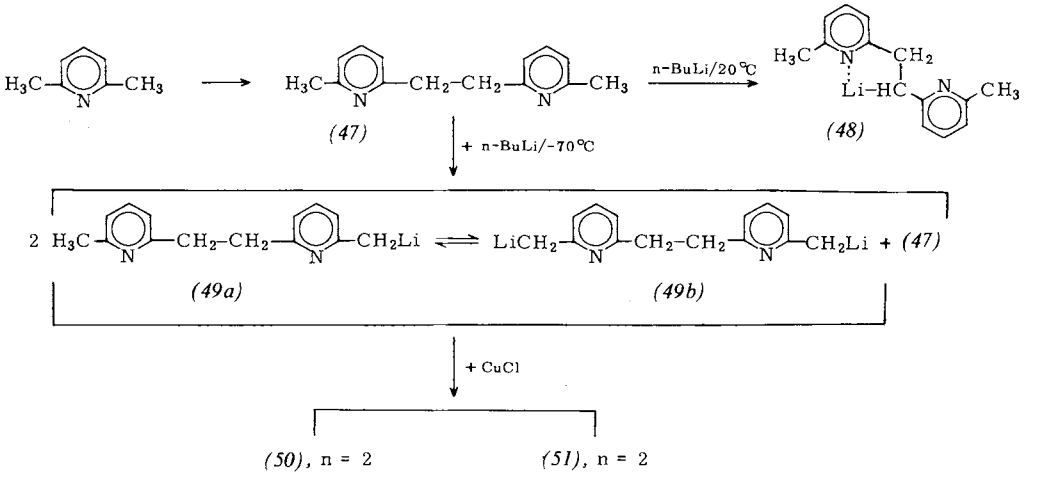
[a] In this case, fast metalation begins only after the addition of tetramethylethylenediamine.

halides or copper halide/O_2. This is probably due to the excessive thermal stability of the organocopper compounds formed. 1,2-Dibromoethane[86] was found to be a better coupling reagent in this case (Table 16)[87].

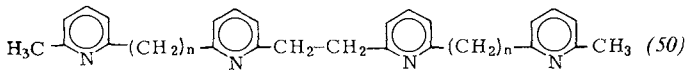
Intramolecular coupling of α,ω-dipyridylalkanes *(45)* with 2 mol of phenyllithium (approx. 20°C) and 2 mol of CuCl (−50 to +20°C), in THF led to α,β-dipyridylcycloalkanes *(46)*. *(45)*, $n=0$, was dehydrogenated under the same conditions to 2,2'-vinylenedipyridine (1,2-di(2-pyridyl)ethylene)[47, 88].

Table 16. Yield [%] of the indicated product on coupling of corresponding organolithium compounds (in THF [35] at −70 to +70°C in cases 1—3 and at −70 to +20°C in case 4) [87].

No.	Coupling with				
1	CuCl	2	6	0	4
2	$CuBr_2$	6	6	0	11
3	$CuCl/O_2$	12	6	0	18
4	$Br-(CH_2)_2-Br$	32	33	41	34



(46), n = 3, 43%; *cis: trans* = 1 : 1



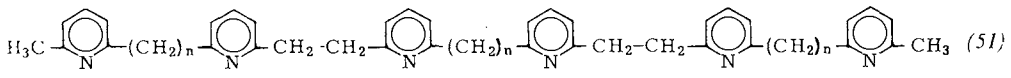
(46), n = 4, 24%; *cis: trans* = 1 : 7

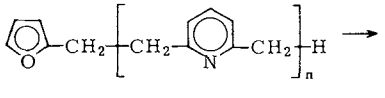
4.5.2. Protophanes

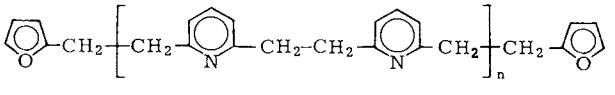
In the case of 2,6-dimethylpyridine, the oxidative coupling *via* organocopper compounds can occur repeatedly, since the

first coupling product 1,2-bis(6-methyl-2-pyridyl)ethane *(47)*, as shown in Table 15, is selectively metalated on the methyl-groups by *n*-butyllithium in THF at −70°C[89,90]. When 1 mol of *n*-butyllithium is used, a mixture of the monolithium and dilithium compounds *(49a)* and *(49b)* is formed. Subsequent reaction of the mixture with CuCl (at −70°C, followed by heating to 60°C) therefore leads to the protophanes *(50)* and *(51)* with $n=2$.

(50)



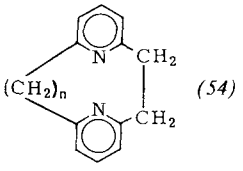




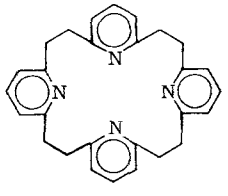
(51)

Table 17. Yields and melting point of pyridinoprotophanes (yields in brackets: coupling with 1,2-dibromoethane instead of with CuCl) [47, 87, 89, 91].

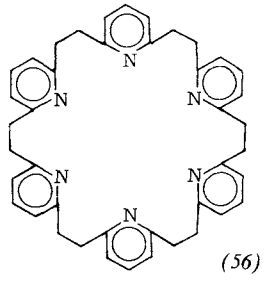
	(50)		*(51)*	
n	Yield [%]	M.p. [°C]	Yield [%]	M.p. [°C]
2	43 (25)	147—148	8 (14)	180—181
3	44 (24)	111—112	8 (13)	142—143
5	46 (22)	79	9 (17)	110—111
6	44 (25)	86	3 (16)	113
8	46 (26)	84	5 (14)	129—130



Tetranuclear and hexanuclear protophanes *(50)* and *(51)*, in which shorter ($n=2$) and longer ($n=3$, 5, 6, 8) alkylene segments alternate, were similarly obtained from higher homologs of *(47)*, which are "externally metalated" even more selectively than *(48)*, according to Table 15[91]. Table 17 shows the yields and the melting points, which are sharp. Unlike electrophilic hetaryl residues, nucleophilic hetaryl residues do not favor the lithium-hydrogen exchange in attached alkyl substituents by *n*-butyllithium. The furyl residue also undergoes practically no metalation at low temperatures. It was therefore possible to couple the compounds *(52)* by the action of *n*-butyllithium (in THF at −40°C) followed by CuCl (at −40°C) to form the protophanes *(53)*, which contain different hetarene nuclei[92].



(52), n = 1
n = 2



(53), n = 1 (28%)
n = 2 (11%)

4.5.3. Phanes

1,2-Bis(6-methyl-2-pyridyl)ethane *(47)* reacts with 2 mol of *n*-butyllithium to form the dilithium compound *(49b)*. Reaction of the latter with 2 mol of CuCl at −70 to +70°C in THF gave the known[47,93] phanes *(54)*, $n=2$, and *(55)* in yields of only 0.7 and 4% respectively; the octanuclear phane *(56)* was also detectable by mass spectroscopy[47]. Under comparable conditions ($CuCl_2$ instead of CuCl), dilithium compounds homologous with *(49b)* gave the dinuclear phanes *(54)*, $n=3$—6 (yields 2, 15, 3, and 4% respectively)[87,94]. With the exception of *(54)*, $n=4$, the compounds are again formed in low yields despite the application of the dilution principle. With 1,2-dibromoethane as the coupling reagent, however, no phane formation was detected[87].

(54)

(55)

(56)

I am very grateful to the colleagues who took part in the investigations described. May the present review be a lasting reminder of years of shared work.

The Pigments of Reddish Hair and Feathers

By R. H. Thomson[*]

Despite sporadic investigations over many years the structures of the pigments responsible for most of the yellow, orange, and brown colors of mammalian hair, and of feathers, have remained unknown. However, recent work has shown that the major reddish-brown pigments, gallophaeomelanins, are polymers containing benzothiazole and tetrahydroisoquinoline units. The yellow-orange and violet trichochromes are minor pigments based on a new chromophore, $\Delta^{2,2'}$-bi(1,4-benzothiazine). Both groups arise *in vivo* from tyrosine and cysteine by a deviation from the biogenetic pathway which normally leads to the formation of eumelanins, the black pigments.

1. Introduction

Plant pigments have been studied intensively over a long period and perhaps 2000 have been accurately documented. Animal pigments are relatively few and not so well defined, and this is particularly true for those which are polymeric, and consequently intractable and difficult to investigate. The hair color of mammals ranges through numerous shades of yellow, orange, and brown, as well as black and white. While the nature of the black pigmentation is now fairly clear[1], until recently little was known about the lighter pigments and the subject was clouded by misleading information and confusing nomenclature.

The omnibus term melanin ($\mu\acute{\varepsilon}\lambda\alpha\varsigma$ = black) is commonly used to describe dark pigments found in animals and plants. In the animal kingdom black pigmentation, widespread in skin, hair, feathers, insect cuticules, melanomas, *etc.*, is attributed to eumelanins ($\varepsilon\tilde{\upsilon}$ = good) while phaeomelanins ($\varphi\alpha\iota\acute{o}\varsigma$ = dusky) cover a broad spectrum from violet to yellow. This is obviously not a satisfactory classification and it is more meaningful to define eumelanins as those pigments found in melanocytes[**] which derive from the tyrosinase oxidation of tyrosine, and phaeomelanins as pigments found in melanocytes which arise by tyrosinase oxidation of tyrosine and subsequent reaction with cysteine. Thus the phaeomelanins, so far found only in feathers and mammalian hair (including so-called red human hair which is really orange), are related biogenetically although they are quite different in structure. They may occur together giving rise to the spots, stripes, and mottled appearance of many animals, and indeed eumelanins and phaeomelanins are jointly responsible for most mammalian coloring. In conjunction with carotenoids, they probably account for most of the colors observed in feathers (blues and greens often arise by diffraction or light scattering in which eumelanins play an important background role). Eumelanins[1] are irregular, crosslinked, polymers, based mainly on 5,6-dihydroxyindole units, and conjugated with protein. These pigments are present in black hair, and various shades of brown, and even blond, hair can be explained by differences in concentration, shape, structure, and oxidation level of the pigment granules.

The distinctive color of "red" hair was at one time ascribed to melanin oxidation products[2]. In 1878 *Sorby*[3] extracted a red pigment from "red" human hair, although the hair still retained its color. This pigment was eventually isolated in 1943 by *Flensch* and *Rothman*[4] who suggested the tentative formula $(C_{15}H_{20}N_2O_9)_2Fe$, and proposed the name "trichosiderin" ($\tau\varrho\iota\chi\acute{o}\varsigma$, $\sigma\acute{\iota}\delta\eta\varrho o\nu$ = hair, iron) "for temporary use until the chemical structure of this compound is established"[*]. In 1956 *Barnicot*[7] showed that "trichosiderin" was an artefact, since extraction of "red" hair with cold dilute alkali yielded an orange-yellow pigment which was converted into the red "trichosiderin" by heating with acid, and later *Boldt* found that the crude pigment obtained by acid extraction could be separated chromatographically into nine[8] components,

[*] Prof. R. H. Thomson

[**] Melanocytes are highly specialized pigment-producing cells.

[*] Although some of the trichosiderin structures have since been established the name was still "temporarily retained" in 1972 [5]. This is abandoned herein in favor of trichochrome [6].

yellow, orange, brown, and violet, some of which were interconvertible. Analysis of these pigments revealed the presence of sulfur but as iron was only detectable in traces the name "trichosiderin" was clearly inappropriate, and these artefacts were named pyrrotricholes ($\pi\upsilon\rho\rho\acute{o}\varsigma$ = fiery).

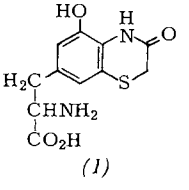
Parallel with these studies on hair, the red feathers of domestic fowls were also examined[9], and these gave similar mixtures of pigments on acid extraction, but after more than 80 years of sporadic investigation nothing was known of the chemical nature of the pigments in reddish hair and feathers beyond that revealed by indicator properties, electronic spectra, and dubious elemental analyses. However, recent work in Naples has established the structures of the trichochromes, and the general nature of the polymeric gallophaeomelanin pigments is now clear.

2. Recent Work

Chemical investigations on the structure of phaeomelanins commenced at the University of Naples in 1964. In preliminary experiments[10] red feathers from New Hampshire hens were extracted with hot hydrochloric acid which gave a mixture of several red and violet pigments. The presence of nitrogen and sulfur was confirmed but iron was found to be absent although it was detectable in the early stages of purification, and is definitely present in hair. Similar treatment of "red" human hair gave a mixture of four red compounds, in much smaller amount, two of which were identical with two of those obtained from feathers.

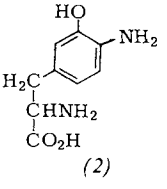
Substantially this work confirmed the results of *Boldt*[8] but as some of these pigments are artefacts, and only a small proportion of the total coloring matter is extracted by acid, a mild alkaline extraction procedure was used for subsequent work[11]. Extraction of hen feathers (New Hampshire) with cold 0.1 M NaOH gave a very complex mixture of pigments. They were conveniently divided into two structurally distinct groups by acidification which precipitated the red-brown gallophaeomelanins leaving the minor pigments (trichochromes), which show intense visible absorption, in solution.

3. Trichochromes



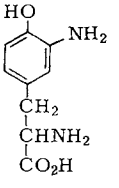
The acid-soluble pigment fraction, after purification on a column of ion-exchange resin and chromatography on Sephadex, was separated into three yellow [B1 (trace), B2 and C1] and two violet pigments [E and F].

Almost from the outset of this investigation *Prota* and *Nicolaus*[10,11] recognized intuitively that the phaeomelanins might be formed *in vivo* by some deviation from the normal course of melanogenesis involving cysteine. A close biogenetical link was apparent from the circumstance that both eumelanins and phaeomelanins are formed in melanocytes, from the operation of a switch mechanism in agoutis[*], and from the consistent 2:1 nitrogen/sulfur ratio in all the feather pigments. In fact, in a very early experiment it was shown that enzymic oxidation[11] of dopa (3,4-dihydroxyphenylalanine, cf. Scheme 3) in the presence of cysteine gave red-brown material closely resembling the gallophaeomelanins. Moreover, when the oxidation was stopped after a short time by acidification, the pale yellow solution changed to violet in a few minutes and it was possible to isolate small amounts of two violet compounds which proved to be identical with the pigments E and F obtained from feathers. Thus from the beginning biogenetic ideas played a predominant role in the structural elucidation studies.

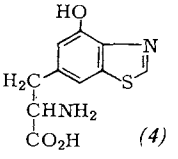


[*] Agoutis are South American rodents which have color-banded hairs, *e.g.*, yellow and black; the pigment distribution between eumelanin and phaeomelanin can change in a very short time.

3.1. Trichochromes B and C

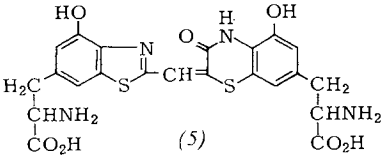


On gentle heating in acidic solution the principal yellow-orange component C (formerly C1) loses carbon dioxide forming a red compound identical with one of the pigments previously obtained by extracting red feathers and hair with hot acid, *i. e.*, decarboxy C is one of the trichosiderins observed by previous workers. Unlike trichochrome C this compound behaves as an indicator, being red in acid (λ_{max} 525 nm) and yellow-orange (λ_{max} 462 nm) in alkaline solution. It possesses two alanyl residues, two phenolic groups and a δ-lactam ring;

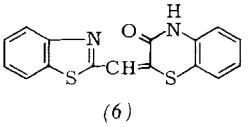


(1)

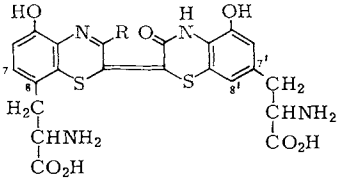
(2)



(3)

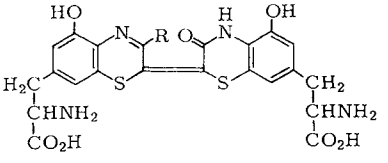


(4)



on degradation[12] with hydriodic acid and red phosphorus it gives the amino acids *(1)* and *(2)* [and also a little *(4)*].

(5)



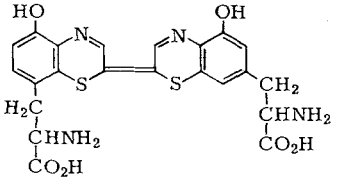
(6)

(7a), R = H

(7b), Trichochrome B, R = CO_2H

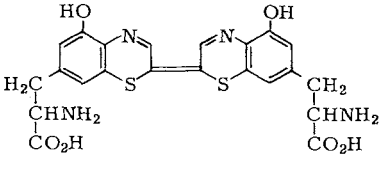
(8a), R = H

(8b), Trichochrome C, R = CO_2H



The red compound could therefore be either *(5)* or *(8a)*, and the former was excluded by spectroscopic comparison with the model compound *(6)*. It follows that trichochrome C has structure *(8b)* since its NMR spectrum differs from that of *(8a)* only in the absence of the methine proton signal at $\delta = 9.13$[12]

Trichochrome B (formerly pigment B2) is isomeric with C and has very similar properties. Degradation of the red decarboxy derivative with hydriodic acid gave the amino acids *(1)*, *(2)*, and *(3)*. As *(2)* is formed from *(1)* under these conditions, presumably *(3)* (obtained in very small amount) is derived from an isomer of *(1)*, and accordingly *Prota et al.*[13] formulate this red compound as *(7a)* and trichochrome B as *(7b)*. Thus trichochromes B and C differ solely in the orientation of the alanyl side chains which is fully consistent with biosynthetic studies (see Section 5).

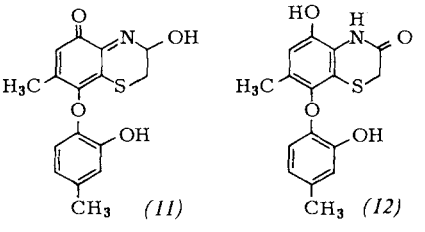


Trichochromes B and C occur in "red" human hair and there is evidence[6] that two other isomers are also present [structures as *(7b)* and *(8b)* but with the alanyl side chains at positions 7,8′ and 8,8′]. The red decarboxylated pigments, obtained by acid extraction, have been identified[6].

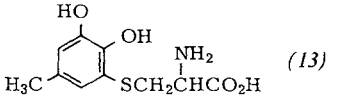
3.2. Trichochromes E and F

The two violet pigments in the acid-soluble fraction from feathers have λ_{max} 482nm in alkaline solution, which shifts to 587nm on acidification. Trichochrome F has two alanyl side chains and two phenolic groups but lacks the amide moiety of C, and on heating with hydriodic acid and red phosphorus it gave the amino acids *(2)* and *(4)* (minor component) obtained previously from *(8a)*. On this basis structure *(10)* was proposed[14] for trichochrome F which is in complete accord with its NMR spectrum (the two azomethine protons resonate at $\delta = 8.21$). The isomeric pigment E, available only in very small amount, has the same chromophore as F, and is regarded[14] as *(9)* since degradation in the usual way afforded the isomeric amino acids *(2)* and *(3)*, identified chromatographically.

(9), Trichochrome E



(10), Trichochrome F

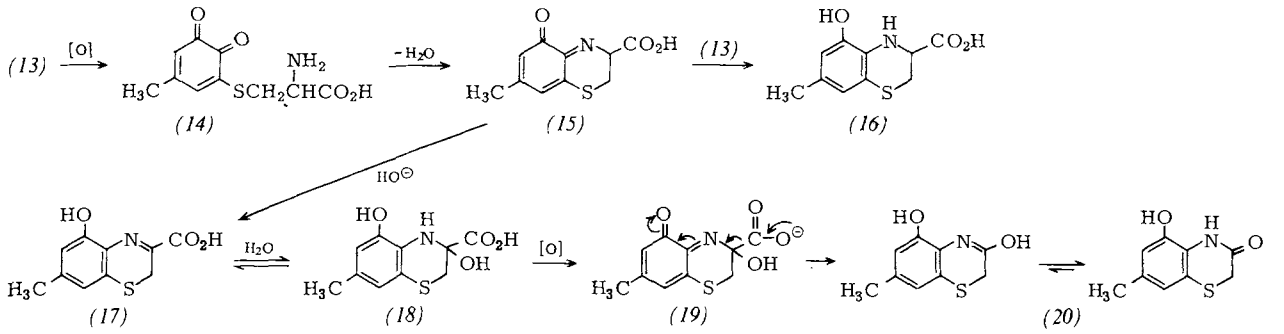


Structures *(9)* and *(10)* were verified by a biogenetic-type synthesis[14]. It will be recalled that small amounts of trichochromes E and F were obtained earlier by oxidizing a mixture of dopa and cysteine. Subsequently it was found that 5- and 2-*S*-cysteinyldopa *(43)* were intermediate products in this reaction, and when a mixture of these was oxidized with alkaline ferricyanide three violet compounds were formed. Two of these were identified, chromatographically, as trichochromes E and F, the third being the symmetrical isomer derived solely from 2-*S*-cysteinyldopa. (The details of these reactions are discussed in Section 5.) This third pigment has been found[6] recently in hen feathers (New Hampshire).

3.3. Model Reactions

The elucidation of the structures of these novel pigments, and the recognition of a new chromophore, was greatly assisted by studies[12, 15] on model compounds. Oxidation of a mixture of 4-methylcatechol (in place of dopa) and cysteine with alkaline ($NaHCO_3$) ferricyanide gave the unstable, yellow, quinone imine *(11)* which rapidly rearranged in stronger base (NaOH) to the isomeric lactam *(12)*. On treating *(11)* with acid the solution immediately became intensely violet and the product had the same chromophore as trichochromes E and F. Although this was gratifying the aryloxy group in these compounds is an undesirable complication, *(11)* being formed from one molecule of cysteine and *two* of 4-methylcatechol.

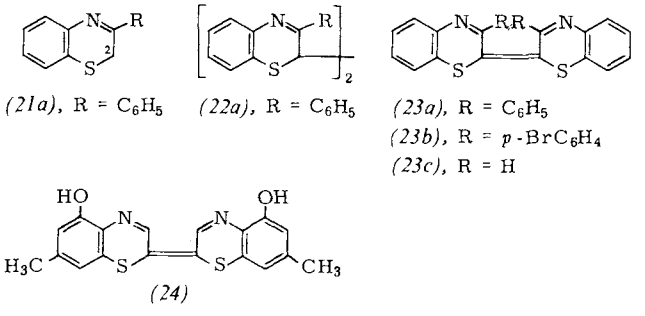
(11) *(12)*



(13)

To avoid this kind of reaction the formation of the dihydrothiazine ring was then examined using 4-methyl-1,2-benzoquinone as the starting point. Reaction with cysteine hydrochloride gave the amino acid *(13)*, whose oxygenation in cold 0.1 M NaOH led to the lactam *(20)* ($\lambda_{max}^{HO^-}$ 322nm). By following this transformation spectrophotometrically a yellow precursor ($\lambda_{max}^{HO^-}$ 370nm) was detected in the early stages, and by stopping the reaction after 20 minutes the labile acid *(17)* could be isolated (after methylation).

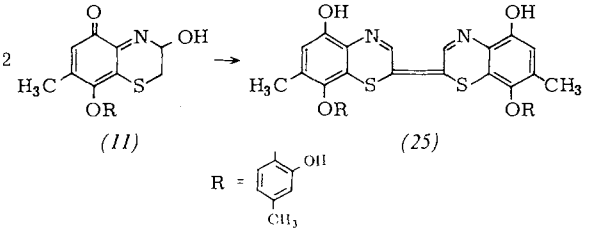
Later[16], cyclization of *(13)* was effected under different conditions. When oxidized at pH 6.8 with mushroom polyphenol oxidase, or nonenzymically with a catalytic amount of oxygen, the amino acid *(16)* was rapidly formed in high yield. As only a small amount of oxygen is required for this reaction it appears that some *o*-quinone *(14)* is formed initially which then cyclizes with elimination of water to give the quinone imine *(15)*; this is then reduced to the product *(16)* by the starting compound *(13)*, more *o*-quinone being formed simultaneously, and so the cycle continues.



Scheme 1 outlines the sequence of reactions by which 1,4-benzothiazine derivatives are formed from the amino acid *(13)* (cf. refs.[15, 16]). It is of interest that the *o*-quinone *(14)* undergoes exclusive 1,2-addition and dehydration to form the quinone imine *(15)*, and the analogous compound from 4-

Scheme 1

methyl-1,2-benzoquinone and 2-aminoethanethiol behaves in the same way[17]; in neither case does the amino group cyclize by 1,4-addition to give an aminoquinone. The reaction in alkaline solution (Scheme 1) proceeds by base-catalyzed aromatization, hydration of the azomethine group in *(17)*, and oxidation of the resulting *o*-aminophenol *(18)* to *(19)* whence decarboxylation again results in aromatization and formation of the lactam *(20)*.



Regarding the conversion of these dihydrobenzothiazine derivatives into compounds of the trichochrome type, it is known that 2*H*-1,4-benzothiazines undergo oxidative dimerization very easily. This was first observed[18] with the 3-phenyl derivative *(21a)* which gave the dehydro dimer *(22a)* on heating with picric acid; the Italian group[19] has shown that this can be effected merely by oxygenation in acidified ethanol at room temperature. Chloranil effects further dehydrogenation and both *(21a)* and *(22a)* give *(23a)* in good yield in cold dioxane[12]. Similarly *(16)* affords *(24)* in a reaction involving oxidative decarboxylation[20].

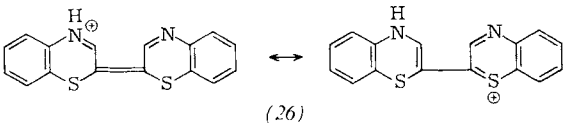
(21a), R = C_6H_5 *(22a)*, R = C_6H_5 *(23a)*, R = C_6H_5
(23b), R = *p*-BrC_6H_4
(23c), R = H

(24)

The formation of synthetic $\Delta^{2,2'}$-bi(1,4-benzothiazines) in this way, presumably a radical coupling process, is relevant to the biogenesis of pigments of this type but the conversion

(11) *(25)*

of the quinone imine *(11)* into *(25)* in acid solution is a non-oxidative process which proceeds in the absence of oxygen.



3.4. The Trichochrome Chromophore

The discovery of a new natural chromophore is a rare event. The trichochromes contain the conjugated system —S—C=C—C=N— and thus belong to the class of polymethine dyes, as do the betacyanin plant pigments. In acid solution protonation generates the mesomeric cation *(26)* resulting, in the case of *(9)*, *(10)*, and *(25)*, in a marked bathochromic shift of about 100 nm (see Table 1). This is reduced to *ca.* 70nm in the lactams *(7a)* and *(8a)*, while in trichochromes B *(7b)* and C *(8b)* the additional carboxyl group at C-3 so diminishes the basicity that protonation on the adjacent nitrogen does not normally occur. However, in acetic acid the thiazine nitrogen becomes more basic and protonation does occur with hydrogen chloride, the absorption maximum shifting to 550nm[12].

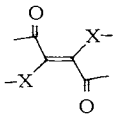


Table 1. Visible absorption of $\Delta^{2,2'}$-bi(1,4-benzothiazines).

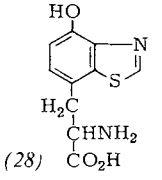
(26)

(27)

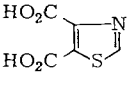
When 3-aryl-2*H*-1,4-benzothiazines of type *(21)* are oxidized with chloranil both *cis* (red) and *trans* (yellow) forms are produced and for *(23b)* these have been isolated and subjected to X-ray analysis[21]. Both forms are stable in the solid state but in solution are interconvertible, even at room temperature, and consequently have very similar UV and visible absorption. Surprisingly, the *cis*-isomer is the more stable despite the crowding in the central part of the molecule.

The parent compound *(23c)* is not known[*]; it would be of interest to observe the *cis-trans* relationship in that case (large groups at C-3 and C-3' being absent) and moreover the *trans* form will be an indigoid dye as defined by *Lüttke*. It has been demonstrated by theory[22] and experiment[23] that the basic chromophore of these dyes can be represented by *(27)*, and the *trans* form of *(23c)* (and the trichochromes generally) contains the essential features, namely two donor and two acceptor groups arranged as in *(27)* to form a doubly cross-conjugated system.



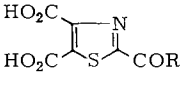
4. Gallophaeomelanins

These are the major pigments found in the feathers of New Hampshire hens *(Gallus gallus)*. They were separated[24] into four main fractions, gallophaeomelanins 1—4, by dialysis and chromatography on Sephadex, and so obtained as red-brown, amorphous, infusible, solids containing C, H, N, O, and S and soluble only in aqueous sodium hydroxide, formic acid, and acidic ethylene chlorohydrin. These fractions are mixtures of very similar macromolecules and are not chemical entities.

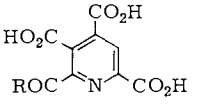


Gallophaeomelanin-1, the most abundant pigment, is protein-free and has an average molecular weight of *ca.* 2000. Gallophaeomelanins-2, -3, and -4 are chromoproteins, containing about 60% of a protein which is shown to differ from feather keratin by the absence of cystine from the sixteen amino acids obtained on hydrolysis. The phaeomelanins are generally intractable and cannot be usefully studied by the usual spectroscopic methods; the UV-visible spectra show no definite maxima while the IR and NMR spectra show only broad bands of little diagnostic value. The structural problem is thus similar to that presented by the eumelanins, and it was tackled in the same way by classical chemical degradation.

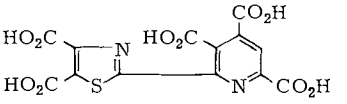
4.1. Gallophaeomelanin-1



This pigment possesses carboxyl, primary amino, and phenolic groups. On alkali fusion[24] it gave a mixture of simple catechols and *o*-aminophenols, 4-amino-3-hydroxybenzoic acid being the most abundant, while oxidation[24] with hydrogen peroxide gave cysteic acid, and small amounts of glycine and aspartic acid. Significantly, pyrrole and indole derivatives, the characteristic degradation products of eumelanins, were absent, showing that phaeomelanins are not structural variants of eumelanins. Larger fragments, chiefly the amino acids *(2)* and *(4)* with smaller amounts of *(1)* and *(3)*, and the benzothiazole derivatives *(28)* and *(37)*, were obtained by heating the pigment in boiling hydriodic acid[24,25], while permanganate oxidation[26,27] yielded small amounts of the thiazole and pyridine acids *(29)*, *(30a)*, *(31a)*, and *(32)*. It was demonstrated that the acid *(29)* is derived from *(30a)* and that *(30a)* and *(31a)* arise from the amides *(30b)* and *(31b)* under the reaction conditions.



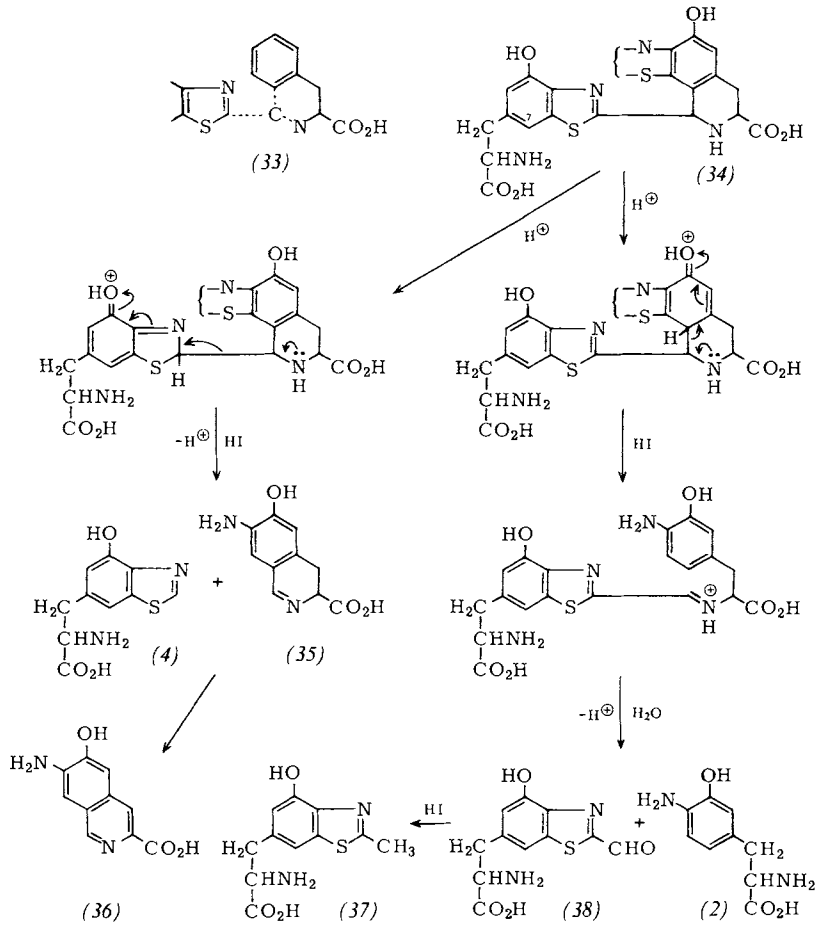
(28)



(29)

(30a), R = OH
(30b), R = NH_2

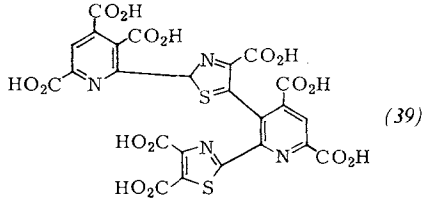
(31a), R = OH
(31b), R = NH_2



(32)

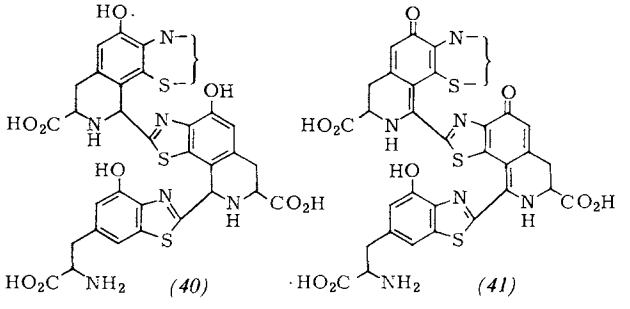
The key compound is *(32)*. While the thiazole part is clearly derived from a benzothiazole unit in the pigment, the origin of the pyridine moiety is less obvious. However, the likely origin of the gallophaeomelanins from dopa and cysteine suggested to *Minale et al.*[27] that a reduced pyridine ring might be formed in the course of biogenesis by cyclization of an alanyl side chain as indicated by *(33)*. If this is now extended to *(34)* (or the isomer with the side chain at C-7 in the benzothiazole unit) most of the degradation products can be explained (Scheme 2). The benzothiazoles *(4)*, *(28)*, and *(37)* could arise by reversed Mannich reactions, the methyl analog *(37)* being formed by reduction of *(38)* (not detected) since a model reaction showed that benzothiazole-2-carbaldehyde is rapidly reduced to 2-methylbenzothiazole in boiling hydriodic acid.

According to Scheme 2 one of the degradation products should be a 3,4-dihydroisoquinoline *(35)*. This was supported by further model experiments[28] and re-examination of the acid degradation products of gallophaeomelanin-1, by extensive chromatography, then led to the isolation[29] of three isoquinoline derivatives, including *(36)* (as its dimethyl derivative). Thus the existence of tetrahydroisoquinoline units of type *(34)* in gallophaeomelanin-1 seems very probable.



The largest degradation product derived from gallophaeomelanin-1 has not yet been mentioned. This was the polyacid *(39)*, obtained in 0.1% yield as its permethyl ester from a permanganate oxidation[27]. This compound must derive from a segment of the macromolecule containing three units such as those depicted in *(40)*, two of which are benzothiazole moieties. However, it is not certain whether all the benzothiazolylalanine *(4)* obtained on degradation comes from terminal residues as in *(40)*; the isomeric amino acid *(28)* must derive from isomeric benzothiazole units. The partial structure *(40)* represents the current view of the general structure of gallo-

[*] *Note added in proof:* This compound has now been synthesized (*G. Prota, E. Ponsiglione,* and *R. Ruggiero*, Tetrahedron, in press).

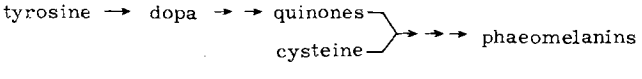


Scheme 2.

phaeomelanin-1 which of course is not a regular polymer. The degradation products include the benzothiazinone *(1)* and sulfoacetic acid[26] showing that some of the sulfur is

(39)

present in 1,4-thiazine rings; the substantial amount of cysteic acid (10%) obtained by hydrogen peroxide oxidation suggests the presence of uncyclized cysteinyl side chains. It is also evident that segments of the gallophaeomelanin-1 macromolecules must exist in a higher oxidation state in order to account for the visible absorption, and probably some of the phenolic rings in *(40)* actually exist in quinonoid form, possibly in conjugation [*(41)*].



4.2. Other Gallophaeomelanins

Gallophaeomelanins-2, -3, and -4 gave the same degradation products as those obtained from gallophaeomelanin-1 and must have the same general structure, probably differing only in molecular weight and attachment to protein[24].

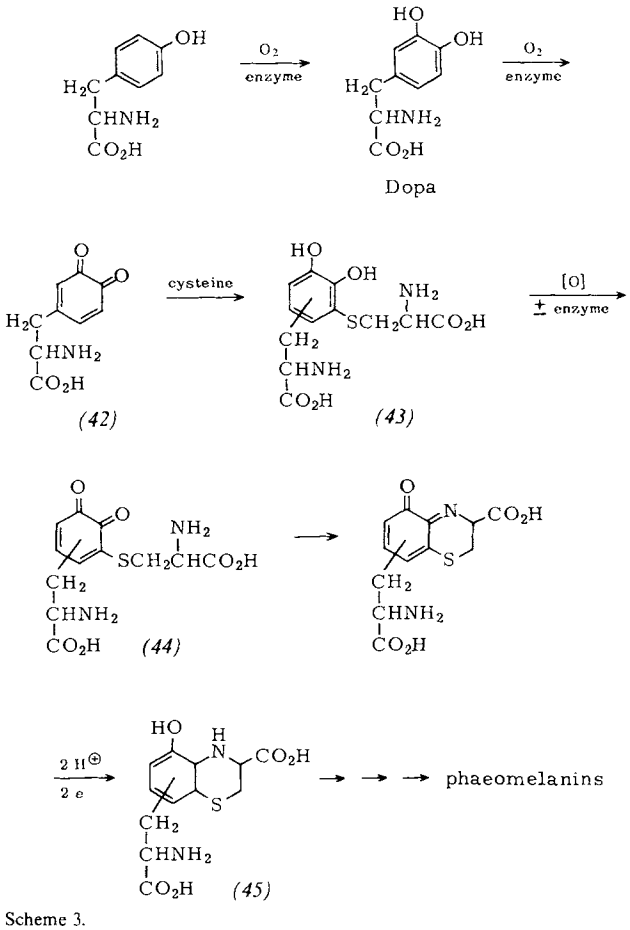
Fattorusso et al.[30] have also examined the red-brown pigments in the feathers of pheasants, partridges, pigeons and Rhode Island hens, in the hair of rabbits and goats, and in human "red" hair by the usual degradative procedures. They were all found to be gallophaeomelanins. The hair of certain brown goats and sheep contains only eumelanins, and the hair of roe deer eumelanins and gallophaeomelanins.

5. Biogenesis

The whole of the Neapolitan research has been guided by the hypothesis[10] that phaeomelanins are formed *in vivo* from tyrosine and cysteine by a deviation from the normal eumelanin pathway. Direct support for this idea was obtained

recently by a cytochemical study[31] of the formation of phaeomelanins in the feather papillae of New Hampshire chick embryos. This established that [3-^{14}C]-cysteine and [2-^{14}C]-tyrosine were specifically incorporated into pigment cells

whereas in the presence of a tyrosinase inhibitor the incorporation was negligible. This is consistent with earlier observations[32] of tyrosinase and dopa oxidase activity in eumelanic and phaeomelanic hair follicles and feather papillae.

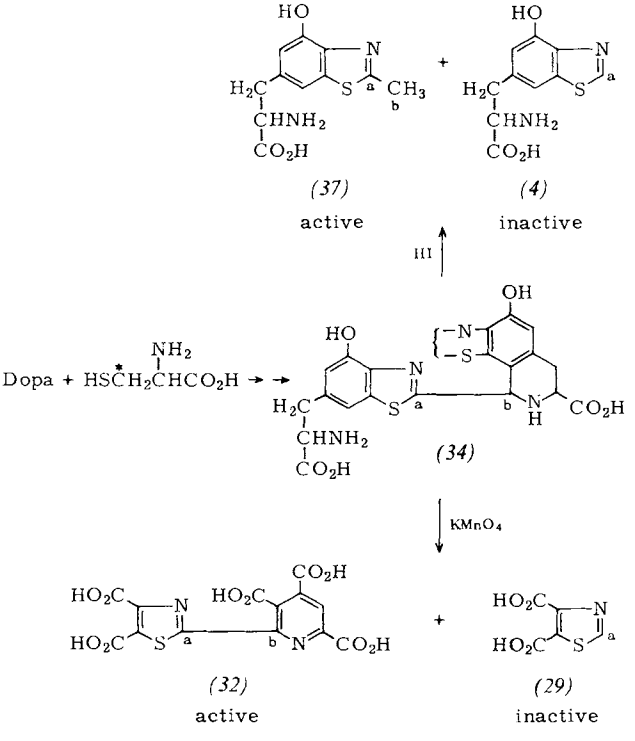


Subsequent study[33a] of the original enzymic oxidation of dopa and cysteine showed that the red-brown, amorphous end products were indistinguishable from gallophaeomelanin-1 and gave the same degradation products, predominately those derived from structural units originating in 5-*S*-cysteinyldopa. Trichochromes are not formed under these conditions; however if the oxidation mixture is acidified after a short time the violet pigments E and F are produced. These must derive from precursors formed at an early stage of phaeomelanogenesis. Examination of the oxidation products during the first 30 minutes of reaction, by automatic amino-acid analysis, revealed that 5- and 2-*S*-cysteinyldopa *(43)* were formed rapidly (the former in larger amount), and then disappeared. Hence the initial reaction is the oxidation of dopa to dopaquinone *(42)*, followed by 1,6-addition of cysteine[33b] which must be a fast reaction superseding the intramolecular addition which dopaquinone undergoes during eumelanin biogenesis. [In synthetic experiments[33] using cysteine ethyl ester and *N*-acetyldopaquinone ethyl ester both products of 1,6-addition can be isolated (after acetylation), the ratio 5-*S*-cysteinyl/2-*S*-cysteinyl derivative being 19:1.] Separate enzymic oxidations of 5- and 2-*S*-cysteinyldopa *(43)* then gave the expected phaeomelanins which afforded the same acid degradation products as before except that, as expected, the acids *(3)* and *(28)* were only obtained from "2-*S*-cysteinyldopa-phaeomelanin".

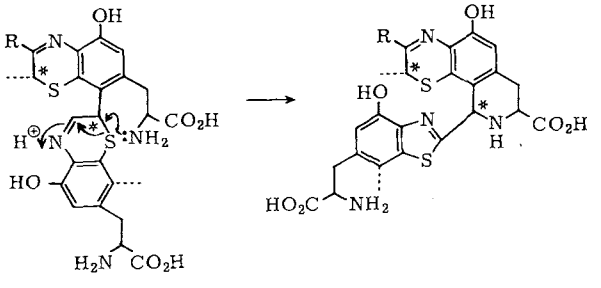
In further *in vitro* experiments *Prota et al.*[16] oxidized 5- and 2-*S*-cysteinyldopa, separately, with mushroom polyphenoloxidase at pH 6.8, following the reaction spectrophotometrically. It was found that within a few minutes the starting compounds were quantitatively converted into new products which were isolated and identified as the labile amino acids *(45)* by comparison with the model compound *(16)*. [The amino acids *(45)* were also formed non-enzymically from the cysteinyldopas *(43)* by oxygenation at pH 8.3.] Only a catalytic amount of oxygen is required in the enzymic oxidation to initiate formation of the *o*-quinone *(44)* after which the reaction proceeds spontaneously as in the model oxidation (Scheme 1).

Scheme 3[20] outlines the first phase of phaeomelanin biogenesis. Enzymic assistance is probably obligatory only for dopaquinone *(42)* formation, as in eumelanin biogenesis. It will be noted that the divergence from the eumelanin pathway follows immediately after dopaquinone formation, and it is the presence or absence of cysteine which determines whether melanocytes produce eumelanins and/or phaeomelanins.

A change in cysteine concentration may account for the color changes in the hair of agoutis, and indeed *Cleffmann*[34] has shown that an increase in the thiol content of agouti pigment cells precedes a change from the production of eumelanin to phaeomelanin. Interestingly, cysteinyldopa has been found recently in a malignant melanoma from a patient with "red" hair[35].



Very little is definitely known about the biogenesis of phaeomelanins beyond the dihydrobenzothiazine stage *(45)*. The red and violet pigments must surely be formed by oxidative dimerization, and while the details are uncertain it is clear from



Scheme 3.

the model experiments that oxidative dimerization of the isomers *(45)* could lead to the formation of all the trichochromes, additional decarboxylation giving E and F, and oxidative decarboxylation producing B and C [cf. *(17)*→*(20)*].

Further information[36] concerning the biogenesis of the macromolecular pigments was obtained from an enzymic oxidation

of dopa and [3-^{14}C]-cysteine. Degradation of the resulting radioactive dopaphaeomelanin with hydriodic acid, and with alkaline permanganate, gave several products of which only *(32)* and *(37)* were active, the specific activity being almost the same as that of the labeled cysteine. Adopting partial structure *(34)* it can be seen that C_b arises from C-3 of cysteine, and C_a from C-2. As the precursor units of *(34)* are benzothiazines a ring contraction must occur in such a way that the sulfur atom of a thiazine ring becomes bonded to C-3 of that ring, C-2 becoming exocyclic. As benzothiazoles cannot be detected prior to pigment formation, it seems likely that polymerization occurs at the benzothiazine stage, followed by ring contraction. To account for this *Minale et al.*[36] suggest that benzothiazine units couple together at C-2 and C-8, and then undergo a transformation, shown in *(46)*, R = H or CO_2H, by which benzothiazole and tetrahydroisoquinoline systems are formed simultaneously. This is an ingenious idea. It assumes preliminary dehydrogenation of the dihydrothiazine ring (cf. Scheme 3) prior to ring contraction, which is reasonable. However, it would be interesting to know if 2*H*-benzothiazines can undergo oxidative coupling with phenols *in vitro*.

(46)

As noted earlier a minor product obtained by degradation of trichochrome C with hydriodic acid is the benzothiazole *(4)*, and this can also be obtained from the dihydrobenzothiazine *(1)* by boiling in hydrochloric acid[25]. This ring contraction is new.

I am grateful to the Laboratorio per la Chimica e Fisica delle Molecole di Interesse Biologico, C. N. R. Arco Felice, Naples, where this review was written, for generous hospitality, and to my Italian colleagues Professors E. Fattorusso, L. Minale, and G. Prota for information and criticism.

Beech Lignin—Proposal of a Constitutional Scheme

By Horst Nimz[*]

The high molecular weight material lignin consists of phenylpropane units linked together by a variety of bond types. During the past eight years, two newly developed degradation procedures have permitted the first direct determinations of the nature of these bonds. The first procedure affords a very mild partial hydrolysis of benzyl ether bonds. Eleven dimeric, trimeric, and tetrameric degradation products were obtained in this way from spruce and beech lignin: they exhibited three different kinds of bonds between the C_9 structural units, and their structures have all been elucidated. In the second procedure, the most important kind of bond in lignin, *i.e.* the arylglycerol-β-aryl ether bond, can be subjected to directed cleavage under mild conditions after introduction of a suitable neighboring group. On application to beech lignin, 91% of the material was degraded giving monomeric to tetrameric phenols. Complete structural elucidation of the twenty dimeric phenols isolated and a knowledge of their relative yields and the yields of the other fractions obtained by gel filtration permitted a structural scheme to be set up for beech lignin in which the C_9 structural units are linked together by no less then ten different kinds of bonds. The structural scheme, which can be readily explained biogenetically, has the same elemental composition as natural beech lignin. Further support for the structural scheme comes from a comparison of the ^{13}C-NMR spectrum of natural beech lignin and a ^{13}C-NMR spectrum calculated for the proposed structure on the basis of about fifty lignin model substances.

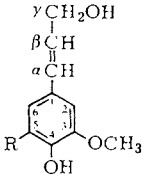
1. Introduction

After cellulose, lignin is the second most abundant polymeric organic natural product. Being a major constituent of wood, large amounts of lignin are obtained as a by-product of cellulose manufacture. According to a recent estimate[1], the annual world production of pulp currently amounts to about 100 million tonnes, some 85% of this amount being produced by chemical processing of wood. Hence about 40 to 50 million tonnes of lignin are also produced in a single year. This is about twice the total global production of plastics. Since lignin has not yet found any large-scale industrial application, part of it is burnt to regain the chemicals used in wood processing or to satisfy the energy requirements of the pulp mills. A not inconsiderable amount is released as effluent and contributes to environmental pollution.

One of the main factors counteracting the utilization of lignin is to be found in its chemical structure, which in turn determines the properties of this high-molecular natural product. In spite of extensive lignin research[2-4] going back almost 140 years, considerable uncertainty surrounded the aromatic character of lignin long after the structure of other polymeric natural products such as cellulose had been established. The situation is characterized by an essay written in 1948 in which lignin is ascribed a purely aliphatic structure[5]. Although, in contrast to such a view, most lignin chemists had never doubted the aromatic nature of the structural units of lignin[6], unequivocal proof was not available until *Lange*[7] obtained microscopic evidence of absorption of monochromatic UV light by microtome sections in the 1940's and *Kratzl*[8] recorded IR difference spectra of lignin *in situ* in the early 1950's.

As early as 1910 *Klason*[9] expressed the opinion that lignin is a condensation product of coniferyl alcohol, hydroxyconiferyl alcohol, or coniferaldehyde, without being able to offer any proof. The chemical behavior of lignin on treatment with bromine[10], nitric acid[11], or mercury acetate[12], and in numerous other reactions, is also best rationalized by assuming the presence of phenylpropane structural units. This assumption could only be proved by hydrogenolytic lignin degradation with copper chromite catalysts to give propylcyclohexanes[13] and by "ethanolysis" leading to guaiacylpropane and syringylpropane derivatives[14]. However, the yields of these monomeric phenols were low.

Two and a half decades were to pass before the degradation of lignin to dimeric and oligomeric cleavage products bearing intact side chains was accomplished; this degradation will be considered in detail below. The principal difficulties encountered in partial lignin degradation came from condensation reactions forming new C—C bonds, and thus opposing degradation, which are promoted by the strong mineral acids or strong alkalies necessary for rupturing ether bonds. Avoidance of these secondary reactions by the use of very mild directed degradation conditions led to success. Meanwhile, the linkages of the C_9 units[*] in lignin had already been established in an indirect manner by *Freudenberg* and his school.



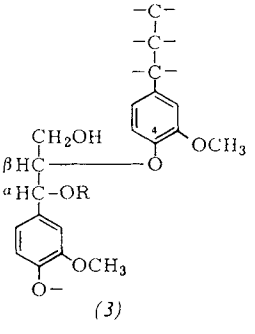
2. Biogenesis of Lignin

Most of our knowledge concerning the linkage of the C_9 units in lignin was deduced by *Freudenberg* and his co-workers from detailed biosynthetic studies performed in the 1950's and 1960's. The experimentally determined chemical and physical properties of lignin available in about 1950, its elemental composition, and results of oxidative dimerization of isoeugenol[15] suggested coniferyl alcohol *(1)* as a probable lignin precursor; its glucoside coniferin had already been detected in cambium by *Tiemann* and *Mendelsohn*[16] as long ago as

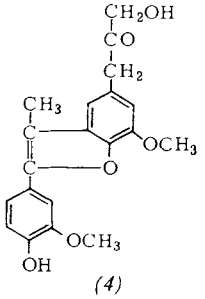
[*] Doz. Dr. H. Nimz
Polymer-Institut der Universität
75 Karlsruhe 21, Hertzstrasse 16 (Germany)

[*] C_9 unit = phenylpropane skeleton; carbon atoms in substituents are not included.

1875. This initially hypothetical assumption was confirmed unequivocally in *Freudenberg*'s school by extensive experiments with labeled lignin precursors and by comparison of natural spruce lignin with the dehydrogenation polymer prepared *in vitro* from coniferyl alcohol[2]. The dimeric and oligomeric intermediates occurring on enzymatic dehydrogenation of coniferyl alcohol *in vitro* served as a basis for a structural scheme of spruce lignin[17]. A corresponding biogenetic path-



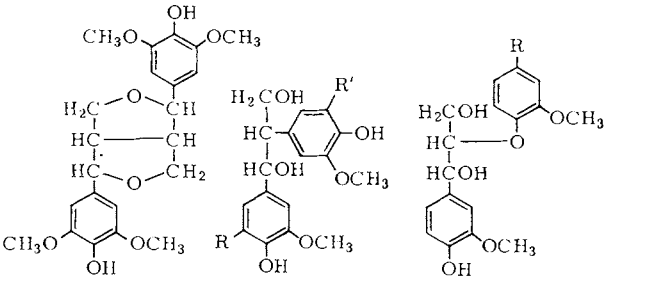
(1), R = H
(2), R = OCH_3



way was assumed for beech lignin, with the difference that synapyl alcohol *(2)* also acts as a precursor in addition to coniferyl alcohol[18].

3. Lignin Degradation by Mild Hydrolysis

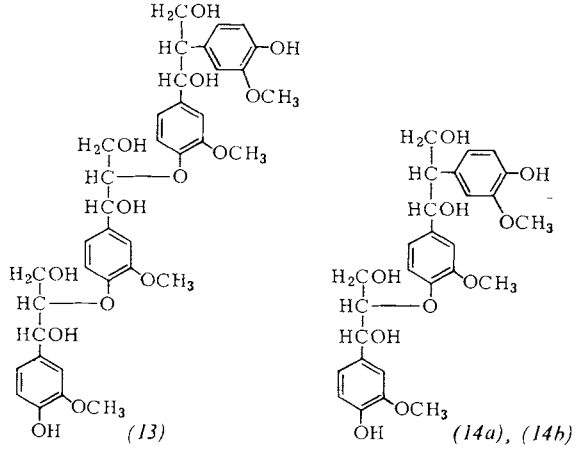
The supplemented *Freudenberg* structural scheme[2] assumes nine different kinds of bonds between the C_9 units of spruce lignin, the commonest being the β-aryl ether bond shown in *(3)* which is designated the β-O-4 bond in lignin chemistry[3]. This bond explains the formation of monomeric arylpropanones (Hibbert ketones) on acidolysis[19] of lignin. In 1964 *Lundquist*[20] was able to isolate phenylcoumarone (phenyl-1-benzofuran) *(4)* as the first dimeric degradation product of lignin from the acidolytic products of milled wood lignin (MWL); its formation can also be explained by cleavage of a β-O-4 bond. However, model studies have shown[21,22] that under the acidolytic conditions required for rupture of the β-O-4 bond lignin is prone to undergo condensation reactions leading to new C—C bonds.



(3)

(4)

Very mild hydrolysis conditions under which no condensation takes place should suffice to cleave acyclic α-O-4 bonds, also shown in formula *(3)* (R = aryl), which account for 8 to 10% of all bonds in spruce lignin[23,24]. Hydrolytic rupture of these benzyl ether bonds would hence lead to partial degradation of lignin and to small quantities of low-molecular cleavage products.



These concepts were successfully implemented by percolation of finely ground, pre-extracted wood with water at 100 °C. After several weeks' percolation, beech wood *(Fagus silvatica)* loses about 40% of its lignin component, while only 20% of the lignin present in spruce wood *(Picea excelsa)* goes into solution under the same conditions[25-27]. Apart from hemicelluloses and high-molecular phenolic components arising from lignin, the aqueous extract contains low-molecular cleavage products of lignin which can be isolated by countercurrent distribution, column chromatography, and recycling chromatography. In all, the structures of eight dimers [*(5)* to *(12)*], two diastereoisomeric trimers [*(14a)*, *(14b)*], and one tetrameric phenol [*(13)*] (Fig. 1) could be established[25-29].

(14a), *(14b)*

Fig. 1. Dimeric, trimeric, and tetrameric phenols obtained by mild hydrolysis of beech or spruce lignin.

Since the degradation products in Figure 1 all arise under conditions leading to no secondary reactions they furnish information about the linkage of the C_9 units in lignin. Isolation of the dilignols[*] *(9)* to *(12)* having β-O-4 bonds constitutes the first direct proof of the occurrence of this type of bond in lignin; the β-O-4 bond had already been assumed to represent the most important bond type in spruce lignin on the basis of biosynthetic studies[2]. The same applies to syringaresinol *(5)*.

In contrast, the three dilignols *(6)* to *(8)* evidence a type of bond (β-1 bond) not included by *Freudenberg* in his original structural postulate[17] since the corresponding dilignol was not detected among the dehydrogenation products of coniferyl alcohol. It was subsequently detected in very low concentrations[30]. The results of lignin degradation with thioacetic acid (see Section 4) nevertheless indicate that the β-1 linkage is one of the principal bond types in lignin. This apparent discrepancy is explained by the slight tendency of coniferyl

[*] Use of the term lignol for the low molecular degradation products of lignin was established by *Freudenberg* [17].

alcohol to undergo coupling at C-1 with loss of the propenyl group. Such linkage only becomes significant when a saturated side chain bearing an α hydroxy group is present[27,31]. A high concentration of preformed oligomers and low coniferyl alcohol concentration are therefore essential conditions for β-1 coupling: these conditions are satisfied in plants.

4. Lignin Degradation with Thioacetic Acid

Since only partial degradation of lignin is accomplished under mild hydrolysis conditions (see Section 3), the yields of degradation products (see Fig. 1) provide no information about the relative proportions of the three types of bonds found in lignin. Moreover, it can hardly be expected that all types of bonds present will be detected. A structural scheme will therefore require complete degradation of lignin to low molecular weight products amenable to structural elucidation. The structure proposed by *Freudenberg* would indicate that extensive degradation of lignin can be accomplished only if the β-O-4 bonds can be cleaved without attendant condensation reactions. This end has been achieved in the following manner[32] (Fig. 2).

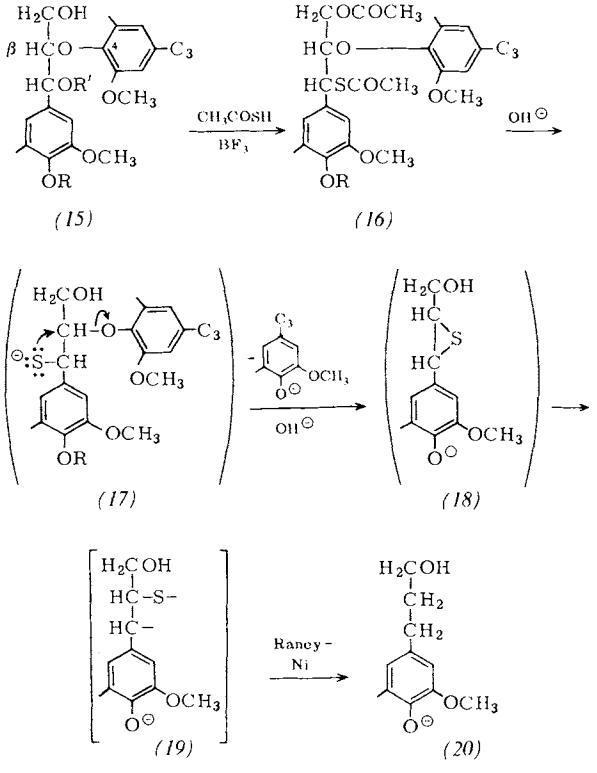

Fig. 2. Cleavage of the β-O-4 bond on degradation of lignin with thioacetic acid.

Dimeric lignin model substances *(15)* containing a β-O-4 bond give high yields of *S*-benzyl thioacetates *(16)*[33] on treatment with thioacetic acid and catalytic amounts of boron trifluoride at 20 °C. Nonbenzylic hydroxy groups are converted into *O*-acetates. Presumably, benzyl cations are formed initially by the action of boron trifluoride and then react immediately with the nucleophilic thioacetic acid or its anion. Hydrolysis of the thioacetates with 2 N NaOH at 60 °C yields intermediate benzyl thiolate ions *(17)* in which the nucleophilic sulfur attacks the neighboring β-carbon atom with displacement of the phenolate ion[34]. The resulting thiirane *(18)* polymerizes to thioethers *(19)*, some loss of γ-carbon atom as formaldehyde sometimes also occurring. Dimeric model substances give varying yields of dithianes[33]. The sulfur in the thioethers *(19)* can be replaced by hydrogen with the aid of Raney nickel[35].

The result of this degradation is a specific cleavage of β-O-4 bonds in lignin under mild conditions precluding secondary reactions. Oxygen functions attached to C-α and C-β are simultaneously replaced by hydrogen. Moreover, since the chirality centers at these carbon atoms are eliminated, the final degradation products are sterically homogeneous compounds, most of which crystallize or can be readily purified by chromatography. This point is of some importance in view of the complicated degradation mixtures obtained from lignin.

The starting material used for lignin degradation was finely ground wood that had been pre-extracted with acetone/water (9:1) and dried over P_2O_5. Successive action of thioacetic acid-boron trifluoride and 2 N NaOH on this material resulted in complete dissolution of the lignin and hemicelluloses of both beech wood *(Fagus silvatica)*[36] and spruce wood *(Picea excelsa)*[32]. Treatment of the alkaline solution with Raney nickel converted the lignin product fraction into a mixture of phenolic degradation products completely soluble in ethyl acetate; the hemicelluloses could be removed by extraction with water. The lignin degradation products were then separated into five fractions (A—E) of varying molecular size by gel permeation on Sephadex LH-20. The components of these fractions are shown in Table 1.

As seen from Table 1, 91% of beech lignin is degraded to mono- to tetralignols. The molecular weight distribution of the oligomeric component (fraction A)[36] shows it to consist of molecules having a molecular weight below 2000 to the extent of 99%. Spruce lignin, on the other hand, gives only 77% of monomeric to tetrameric phenols (B—E)[32].

Chromatography of the monomeric fraction (E) from beech lignin gave 49% of 2,6-dimethoxy-4-propylphenol, 14% of 2-methoxy-4-propylphenol, and 12% of three further identified monolignols. Since the hydroxy groups on the side chains of the C_9 units are largely removed during degradation, the proportion of isolated homogeneous monolignols corresponds to about 40% of the lignin.

In addition, each one of the twenty dilignols present in detectable amounts in fraction D could be isolated and its structure

determined[37]. They are collected as structural types in order of decreasing yield in Figure 3. Although losses predictably occur on chromatographic isolation of the dilignols, their relative yields should not change significantly.

are partly removed as formaldehyde or reduced to methyl groups. The dilignols shown in Figure 3, which contain no such ether linkages, can therefore be unequivocally ascribed to dimeric structural units in lignin. Moreover, the proportion

5. Structural Scheme of Beech Lignin

Model experiments[33] show that thioacetic acid cleaves only ether linkages at C-α and C-β, while γ-hydroxymethyl groups

of those bonds which are cleaved during thioacetic acid degradation of lignin can be calculated from the yields of monomeric to oligomeric phenols listed in Table 1. If lignin were to have a chain-like unbranched structure then the proportion

of cleaved bonds would amount to 67%[*]. Since lignin contains both crosslinked, threefold bonded C_9 units and terminal C_9 units, the latter being presumed to predominate in beech lignin, about 65% of the bonds in beech lignin should be cleaved on thioacetic acid degradation. Hence it follows that this number can be equated to the proportion of α- and β-ether linkages in beech lignin. If it is now assumed that the uncleaved bonds (in all 35%) in lignin occur in the same ratio as that deduced from the yields of dilignols (Fig. 3) then we can estimate the proportions for ten types of bonds between the phenylpropane units of beech lignin (Table 2).

On the basis of the proportions of the various bonds listed in Table 2, a structural scheme was set up for beech lignin (Fig. 4).

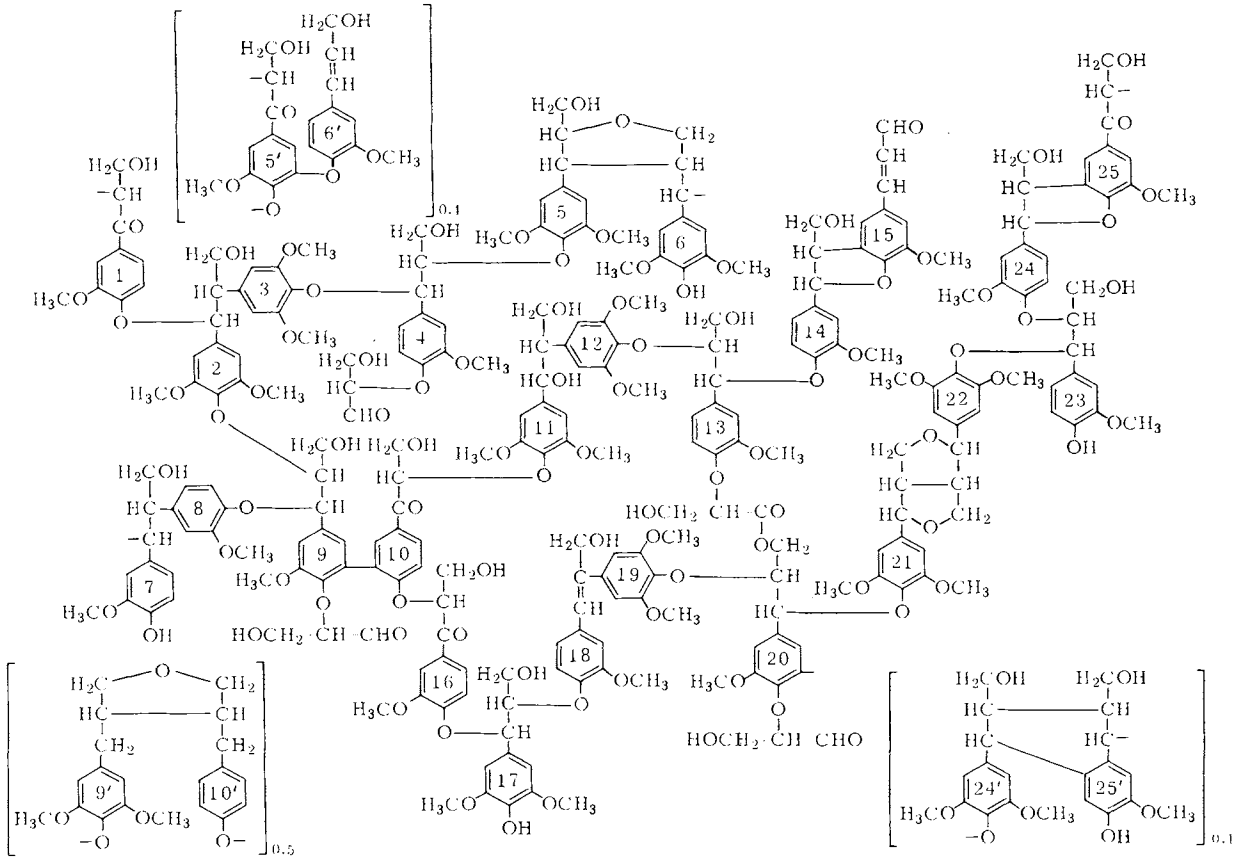

Fig. 4. Proposed structure of beech lignin. The C_9 units are ascribed consecutive numbers. For details see text.

The proposed scheme consists of 25 C_9 units of which six (5/6, 9/10, 24/25) can to some extent be replaced by the dilignol units enclosed in brackets. The scheme shows a representative section from a beech lignin molecule some ten or twenty times larger in which the ten different bond types are randomly distributed. The glyceraldehyde or glyceric acid groups linked by a β-ether bond to the C_9 units 4, 9, 13, and 20 which are not detected on degradation are clearly evidenced by the occurrence of the β-1 dilignol units 2/3, 7/8, 11/12, and 18/19, during whose formation they arise by release of a C_3 side chain[27, 31]. These glyceraldehyde β-ethers could be detected in spruce lignin[38].

The composition depicted in Figure 4 (molecular formula $C_{259}H_{281}O_{95}$) can be rationalized in terms of oxidative coupling of a mixture of fourteen molecules of coniferyl alcohol *(1)*, ten molecules of synapyl alcohol *(2)*, and one molecule of *p*-coumaryl alcohol [*(1)* with H in place of OCH_3], 59 hydrogens being removed (= 2.36 per C_9 unit) and 11 molecules of water added.

Division of the molecular formula by 25 and elimination of the methoxy groups yields

$$C_{10.36}H_{11.24}O_{3.80} = C_9H_{7.16}O_{2.44}(OCH_3)_{1.36}$$

as the mean composition of the C_9 unit in the structural scheme. The deviation from the mean composition of the C_9 unit in natural beech lignin[18]

$$C_9H_{7.10}O_{2.41}(OCH_3)_{1.36}$$

calculated from elemental analysis amounts to only 3% of water and thus lies within the limits of accuracy.

6. Physical Methods of Structural Elucidation

6.1. UV Spectra and Ionization Δε Curves

The UV spectrum[39] of beech MWL differs only slightly from those of other deciduous lignins. A slight shift of the

[*] Since only α- and β-ether linkages involving the C_3 side chains of C_9 units in lignin are cleaved during degradation, a *ca.* 50% relative proportion of monomeric phenols (fraction E, Table 1) means that half of all C_9 units in beech lignin are linked together exclusively *via* ether bonds of this type. A further 25% of the C_9 units obtained as dimers (D) must each be half involved in such bonds. Addition of 1/3 × 11% and 1/4 × 5% for the proportions of trimers (C) and tetramers (B) yields about 67% of ether bonds [36].

maximum at 280nm to 277nm compared with coniferous lignins can be ascribed to the effect of syringyl groups (3,5-dimethoxy-4-hydroxyphenyl) which are absent from coniferous lignins.

The ionization $\Delta\varepsilon$ curve[39] (difference between the extinctions in alkaline and neutral solution) of beech lignin exhibits three maxima: one flat maximum ranging over 320 to 400nm can be assigned to phenolic C_9 units having conjugated carbonyl and vinyl groups in their side chains or to biphenyl units[40] whose absorption regions overlap. Two further maxima at 253 and 300 are ascribed to phenolic units in non-conjugated systems. Additional difference spectra can be obtained after reduction with $NaBH_4$ (reduction $\Delta\varepsilon$ curves) or after catalytic hydrogenation (hydrogenation $\Delta\varepsilon$ curves)[41].

Šutý and *Golis*[42] have recently calculated the values for phenolic and non-phenolic cinnamaldehyde, cinnamyl alcohol, α-keto, biphenyl, and non-conjugated units in beech lignin from the difference spectra of hydrogenated and sulfonated beech MWL. The most serious difference from the structural scheme shown in Figure 4 lies in the number of biphenyl (5-5) bonds, reported as 20 per 100 C_9 units (cf. Table 2: 2.5%). Since no details are given concerning the preparation of the ligninsulfonic acid used, we cannot engage in a discussion of the origin of this discrepancy. In contrast, the value calculated by *Šutý* and *Golis* from the difference spectrum obtained on acidolysis for phenylcoumaran (phenyl-2,3-dihydro-1-benzofuran) units (7%) agrees well with our value (6%, Table 2). It should be pointed out that the method of calculating structural units in beech lignin from UV difference spectra embodies a number of uncertainties, owing to the multitude of chromophoric systems in deciduous lignins, and can easily lead to false conclusions.

6.2. IR Spectra

The rather structureless IR spectrum[18] of beech lignin possesses two bands of medium intensity in the carbonyl range at 1667 and 1750 cm^{-1} which are not sharply distinguished from each other. The former can be assigned to α-carbonyl and cinnamaldehyde groups of which there are 4.8 (1.9% of all C atoms) in the structural scheme. The band at 1750 cm^{-1} showing a spread to low wave numbers can be ascribed to the three aliphatic aldehyde groups and the one aliphatic ester group of the Scheme (Fig. 4). The ^{13}C spectrum (see Section 6.4) of beech MWL indicates the presence of acetyl groups, which are probably bound to hemicelluloses[43] from which complete separation of beech lignin is extremely difficult. For this reason we boiled beech MWL with 0.2% sulfuric acid for 30min prior to elemental analysis.

6.3. ^{1}H-NMR Spectra

High resolution ^{1}H-NMR spectroscopy has afforded valuable services in structural elucidation of low-molecular weight degradation products[29, 37, 44]. It must be borne in mind, however, on evaluation of lignin spectra[44–46] that the high viscosity of the sample solutions and the very limited mobility of the high-molecular crosslinked lignin molecules can lead to line broadening and possibly to a drop in signal intensity. Line broadening and signal overlapping also arise from spin-spin coupling, chirality centers, steric interactions, and owing to the exceptional structural complexity of lignin.

Even in regions where no overlapping would be expected between the signals of different kinds of protons, the unfavorable intensity ratio of the signals effectively precludes quantitative determination of particular kinds of protons. This applies to the α protons in phenylcoumaran units (H-α in the C_9 units 14 and 24 in Fig. 4) which absorb in a region ($\delta = 5.18$ to 5.74 ppm) which should be devoid of any other absorptions due to lignin protons. The proportion of these protons was calculated as 3.18 per 100 C_9 units from the relative intensity of this region of the beech lignin NMR spectrum[42]. However, in view of the fact that 100 C_9 units contain about 1100 protons and the "molecular weight" of these 100 C_9 units is 19656.4, the performance of the method is clearly overtaxed.

In contrast, the intensity ratios of the strongest signals in the spectrum should permit semiquantitative determination of the ratio of aromatic to methoxy protons[45, 46]. Aliphatically and aromatically bonded acetoxy groups can be included in this comparison if observations are performed on acetylated lignin. The relative intensities of the specific absorption regions of these kinds of protons are shown in Table 3.

Table 3. Intensity ratio of the most important signals in the ^{1}H-NMR spectrum of acetylated beech lignin (chemical shifts in ppm relative to TMS).

Type of proton	δ	I_{rel}	No. of groups
Aromatic and α-vinylic	6.3–7.6	2.5	1.1
Methoxy	3.5–4.0	4.1	1.36
Aromatically bound acetoxy	2.2–2.4	0.9	0.3
Aliphatically bound acetoxy	1.8–2.2	4.6	1.53

From Table 3, we calculate 2.5 aromatic and α-vinylic protons, and 0.3 phenolic and 1.53 alcoholic hydroxy groups for each C_9 unit in beech lignin (or per 1.36 methoxy group). In contrast, the structural scheme (Fig. 4) contains 2.55 aromatic and α-vinylic protons, 0.15 phenolic and 0.94 alcoholic hydroxy groups per C_9 unit. The deviations of the hydroxy groups result on the one hand from the carbohydrate components of beech MWL, which can be detected by thermofractography[47], and on the other hand from the fact that only about a third of the lignin is obtained from the wood as soluble MWL by *Björkman*'s method[48]. The insoluble portion remaining in the wood is more extensively crosslinked[49] and should contain fewer free phenolic groups[*]. Moreover, the benzyl aryl ether bonds (0.28 per C_9 unit) assumed in the structural scheme will undergo preferred cleavage as the weakest points of linkage between C_9 units during mechanical lignin degradation by vibrational grinding to prepare MWL, thus also releasing free phenolic groups.

6.4. ^{13}C-NMR Spectra

Compared with ^{1}H-NMR spectroscopy, PFT ^{13}C-NMR spectroscopy[50] has the advantage of greatly superior resolution

[*] *Note added in proof* (April 17, 1974): *W. Schweers* and *O. Faix* [55] recently found that a synthetic "hardwood lignin" (mixed DHP) obtained on dehydrogenating a mixture of coniferyl and sinapyl alcohols contains fewer free phenolic groups than a synthetic "softwood lignin" obtained from coniferyl alcohol alone. The low content of free phenolic groups in beech lignin is evidenced by the intensities of the signals for the C-3 and C-5 atoms in phenolic (148.5 ppm) and etherified (154.5 ppm) syringyl units in the ^{13}C-NMR spectrum (cf. Fig. 5a and Table 4).

owing to a twenty-fold field expansion and spin-spin decoupling. Figure 5a depicts the proton noise decoupled ^{13}C-NMR spectrum of beech MWL.

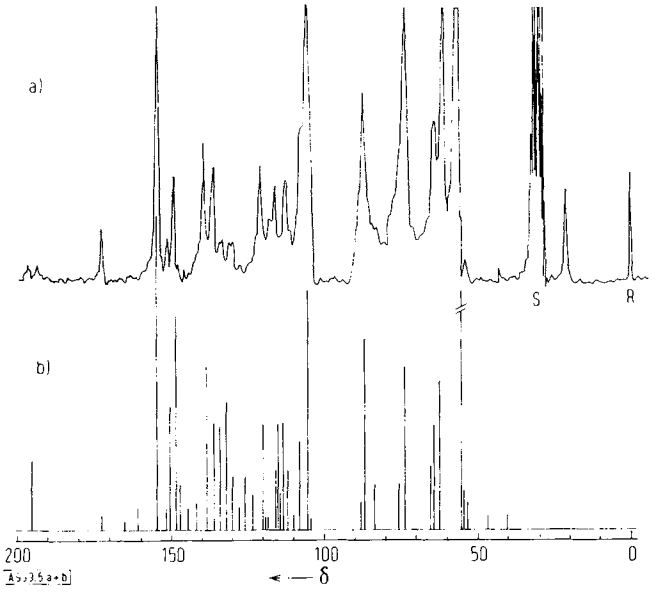

Fig. 5. a) 25.2 MHz PFT ^{13}C-NMR spectrum of a 20% solution of beech lignin (MWL) in hexadeuterioacetone/D_2O (9:1), recorded with a Varian XL 100-15 spectrometer. δ values in ppm downfield from TMS. b) Calculated ^{13}C-NMR spectrum of the structural scheme (Fig. 4). For details see text. S = acetone, R = TMS.

The chemical shifts of nearly all the carbon atoms occurring in the proposed structure (Fig. 4) could be determined from the ^{13}C-NMR spectra of over fifty lignin model substances[51]. They are compared with the δ values from the lignin spectrum (Fig. 5a) in Table 4.

The only carbon atoms not included in Table 4 are the carbonyl carbons of the three etherified glyceraldehyde (C_3) units on C_9 units nos. 4, 9, and 20, and the α, β, and γ carbons of C_9 unit no. 5 of the structural scheme (Fig. 4), for which no suitable comparison samples have yet become available. Furthermore, no distinction is made in Table 4 between the α carbon atoms in benzyl ethers and in non-etherified benzyl alcohols.

On the basis of the δ values (Table 4) determined from the ^{13}C-NMR spectra of model substances, a "calculated spectrum" (Fig. 5b) can be drawn for the structural scheme (Fig. 4). The signals are drawn as lines whose heights represent the number of corresponding carbon atoms. Since the nuclear Overhauser effect and the spin lattice relaxation times (T_1) are neglected, the heights of the lines in the "calculated spectrum" (Fig. 5b) can only be qualitatively compared with the intensities of the signals in the lignin spectrum (Fig. 5a). However, the chemical shifts in the two spectra should not differ significantly. That this requirement is satisfied, apart from a few explicable exceptions, is apparent from a comparison of the two spectra and of the δ values given in Table 4.

The weak signal at 192.7 ppm observed only in the lignin spectrum (Fig. 5a) can be assigned to an α-aldehyde group (*e.g.* in vanillin) such as is found in the dilignol *(12)* (Fig. 1) obtained on mild hydrolysis. It was not included in the structural scheme (Fig. 4), however, since it can only be explained biogenetically by assuming the occurrence of an additional monomeric lignin precursor. No decision could be reached whether glyceraldehyde groups of the proposed structure might possibly be responsible for this signal. The

Table 4. Comparison of the ^{13}C chemical shifts (δ) of beech lignin with those predicted for the proposed structure (Fig. 4). The numbers accompanying the assignment refer to the C_9 units of the structural scheme.

Lignin [ppm] *I* [a]	Values calculated for the proposed structure [ppm]	C_n [b]	Assignment

two signals of medium intensity at 171.8 and 20.8 ppm can be assigned to acetyl groups probably bonded to residual hemicelluloses[43]. When deuterated dioxane is used as solvent, the band at 171.8 ppm possesses a shoulder which can be

attributed to the ester carbonyl carbon atom assumed between the C_9 units nos. 13 and 20 in the proposed structure. All the other signals of the lignin ^{13}C-NMR spectrum differ at most by 1 ppm from those of the "calculated spectrum".

7. Outlook

Lignin is a high-molecular natural product: the ultimate step in its formation is a free-radical coupling of monomeric units which is not subjeet to enzymatic control. Hence lignin differs from other natural products, such as proteins, nucleic acids, and polysaccharides, in which the bonding of the monomeric units and their sequence is determined, by having a random distribution of at least ten different kinds of bonds. Thus any structural scheme proposed for lignin can only represent the average distribution of these bonds, which also reflects to some extent on its elemental analysis. Nevertheless, the proposed structural scheme (Fig. 4) based solely on the results of lignin degradation, must be open to biogenetic interpretation. The fulfilment of this requirement constitutes further proof of *Freudenberg*'s proposal that lignin is formed by oxidative coupling of *p*-hydroxycinnamyl alcohols.

Future structural studies on lignin from other sources, taxonomic studies, and investigation of chemical changes in lignin during industrial wood processing will find an exceptionally powerful tool in ^{13}C-NMR spectroscopy. With the aid of the spectra recorded for more than fifty lignin model substances, all the important signals in the ^{13}C-NMR spectra of coniferous and deciduous lignin can now be assigned. Moreover, comparison of the intensities of corresponding signals in the ^{13}C-NMR spectra of different lignins permits interesting structural comparisons. The technique of comparing calculated and recorded spectra adopted here can also be applied to other lignins.

We are well aware that any lignin formula is open to improvement. In our case this applies particularly with regard to the number of free phenolic groups resulting on drawing the proposed structure and the number of benzyl alcohol and benzyl ether groups for which no reliable analytical determinations have yet been completed. In our opinion, the main value of the proposed structural scheme lies in the clarity it brings to the century-old problem of the structure of lignin, which attracts the interest of chemists, botanists, forestry scientists, and wood technologists. For instance, our scheme recently provided a ready explanation of the discoloration of celluloses containing lignin[52].

The immense problem of finding industrial applications for lignin, which is highly topical in view of environmental pollution, remains a great challenge to the cellulose and lignin chemist. The inherent difficulty of economic degradation of lignin to give low-molecular weight products of industrial value is apparent from the formula given above. It might, however, stimulate the search for new techniques. Only very limited quantities of vanillin and several sulfur compounds, such as methanethiol, dimethyl sulfide and its oxidation products, have so far been produced from the waste liquors from pulp mills. Hydrogenolytic "lignin liquefaction"[53] at high temperatures and hydrogen pressures has not yet found industrial application, presumably owing to competition from natural gas and oil. However, the day is approaching when we shall have to take recourse to lignin as an organic raw material constantly being replenished by nature.

In high-molecular form lignin is currently used as an additive for concrete, drilling muds, storage battery plates, synthetic resins and rubber, and also as dispersing agents, as binders for road surfacing materials and for biquetting or pelletizing of ores, coal, and animal feeds, as adhesive for floor coverings, and for numerous other purposes. However, the amount of lignin utilized is but a fraction of the total amount produced.

We recently found[54] that, owing to their content of phenol groups with free *ortho* positions, water-soluble ligninsulfonic acids occurring in industrial waste sulfite liquors can be effectively crosslinked under mild conditions by oxidative coupling and hence rendered insoluble. The products can be used as ion-exchangers. In addition, wood chips can be pressed with sulfite waste liquor in the presence of an oxidizing agent and a catalyst to give a particle board having excellent strength and satisfactory properties under moist conditions. Since the current consumption of wood for particle boards in the Federal Republic of Germany is of the same order as that for cellulose production this could represent an adequate application for the lignin obtained in pulp mills.

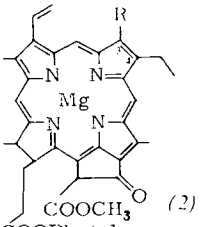
The Reactivity of the Porphyrin Ligand[**]

By Jürgen-Hinrich Fuhrhop[*]

The physical properties and the chemical reactivity of the porphyrin macrocycle, whose formation can be rationalized by a simple statistical argument, are related in many respects to those of aromatic hydrocarbons. The reactivity of the porphyrin ligand in its metal complexes varies within wide limits because of the difference in the inductive effects of different central metal ions on the conjugated π-electron system. One-electron reactions, phlorin formation by addition of hydrogen or oxygen to the methine bridges, and the formation of π complexes predominate. The biochemical reactivity of the porphyrin ligand largely corresponds to its *in-vitro* chemistry.



1. Introduction

Metal-porphyrin complexes[***] *(1)* occur extremely widely in biological redox systems, *e. g.* redox chains of photosynthesis and of respiration. The rigid, planar porphyrin ligand fulfills two main functions here. On the one hand it fixes the redox-active iron ions in a reactive center and at the same time modifies their oxidation potential by the formation of covalent nitrogen-metal bonds in the plane of the porphyrin. A metallic reaction center of this type is involved in the electron transfer in redox chains in the cytochromes[1], is capable of reversibly adding on oxygen in hemoglobin[2], and also plays a part in the activation of molecular oxygen in oxidizing enzymes[3]. These "inorganic" reactions of metal-porphyrin complexes will not be discussed further here.

(1)

Porphin: R^1-R^8 = H, M = 2 H

(2)

Chlorophyll a: R = CH_3
Bacteriochlorophyll: R = CHO, hydrogenated at 3, 4

On the other hand, the macrocyclic porphyrin ligand can also assume the role of the redox active center. The most important example of this is that of the chlorophylls *(2)*,

[**] Parts of this progress report are taken from the author's Habilitation Dissertation, Technische Universität Braunschweig 1972.

[***] Note on nomenclature: As far as we know, there are as yet no definitive IUPAC rules for this class of compounds. The macrocycle consisting of four pyrrole rings and four methine bridges is known as porphyrin. Systems with partly hydrogenated pyrrole rings may be referred to as chlorins: those with one, two, three, and four hydrogenated methine bridges are called phlorins, porphodimethenes, porphomethenes, and porphyrinogens, respectively. The porphyrin having only hydrogen atoms as subsituents is termed porphin (see also *K. Bonnett*, Ann. N.Y. Acad. Sci. *206*, 745 (1973)).

with whose aid the sunlight absorbed by photosynthetically active organisms is converted into chemical redox energy (Fig. 1).

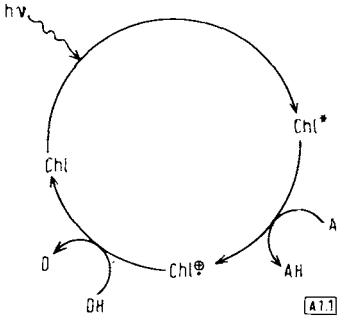

Fig. 1. Scheme of the primary steps of the photosynthesis [4]: an excited chlorophyll molecule (Chl*) transfers its high-energy electron to an acceptor molecule (A) and the resulting chlorophyll radical-cation oxidizes a donor molecule (D). The result of this cycle is the conversion of the absorbed light energy into chemical energy.

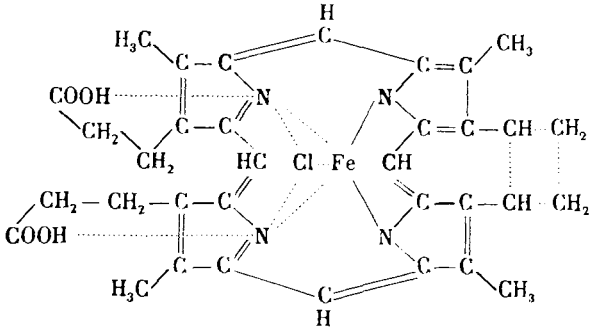
This active role of a porphyrin ligand in redox reactions first became evident in 1953 when *Commoner*[5], by EPR spectroscopy, detected the occurrence of organic free radicals on irradiation of photosynthetically active organisms, these radicals rapidly disappearing again in the dark. The formation of chlorophyll radical-cations in the photosynthetically active center has now been conclusively demonstrated, and the scheme of Figure 1 has been confirmed in broad outline many times[6], with the result that interest has been centered on the reversible formation of free radicals of the metal-porphyrin complexes. Other biologically important activities in which porphyrin ligands are directly involved concern the irreversible addition of oxygen to ironporphyrin complexes, which ultimately leads to cleavage of the macrocycle and formation of bile pigments[7-10], and the weak interaction of the porphyrin π-electron system with other biological redox catalysts, which may play a part in the electron transfer from chlorophyll to the oxidizing agent A (Fig. 1)[11].

The specific reactivity of the porphyrin ligand, in nearly every case, was first detected in biological systems and only later demonstrated *in vitro*. The surprising fact that the fundamental reactions of the porphyrin ligand were systematically studied and largely elucidated only in the last decade, and were able to escape the notice *e.g.* of *Hans Fischer* for such a long time, can be explained by the superiority of modern spectroscopic and electrochemical methods, which only now allow a reliable distinction between nonspecific destruction and a chemically definite, uniform reaction of the porphyrin ligand. We can be sure, for example, that *Hans Fischer* observed the formation of many of the brown and brown-green radicals and oxygenation products of metal-porphyrin complexes, but discarded them after a glance through the hand spectroscope.

However, interest in the reactivity of porphyrin ligands is not confined to biological aspects. A simple model of the porphyrin ring that was proposed in 1949[12] and has been continuously refined since then[13,14] stylizes the basic skeleton of this tetrapyrrole pigment to a cyclic planar hydrocarbon with 18 π electrons, which, according to the Hückel rule, should be particularly stable and should exhibit aromatic character. The fact that many different metal ions can be introduced into the center of this conjugated π-electron system suggests the possibility of varying the chemical reactivity of an aromatic system within wide limits by metal substitution and of systematically investigating the underlying interactions for the first time. This brings the chemistry of the porphyrin ligand within the ambit of general organic and inorganic chemistry beyond the aspects of natural product chemistry.

2. The Formation of the Porphyrin Macrocycle from Monomeric Pyrrole Units

The structure (Fig. 2) suggested for hemin by *Küster* in 1913[15] was not accepted at first either by *Willstätter* or by *H. Fischer*. Their reluctance is easy to understand: no natural product with a comparable ring size was known, and the directed synthesis of a sixteen-membered macrocycle seemed beyond the reach of the methods known at that time. However, a



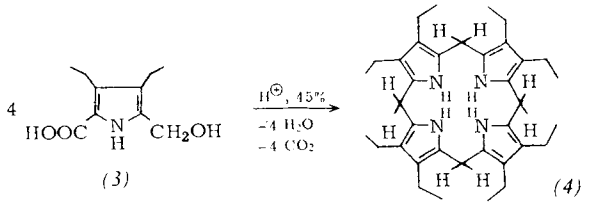


Fig. 2. *Küster*'s original structure for hemin from 1913 [15]. The position of a vinyl group is wrong, but all other structural data correspond to the present-day views. A particularly interesting feature is the suggested interactions of axial ligands and propionic acid side chains with the porphyrin ring, the importance of which is still a matter for speculation.

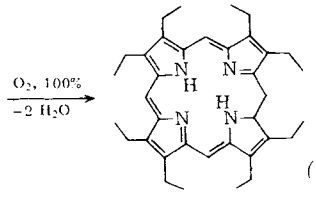
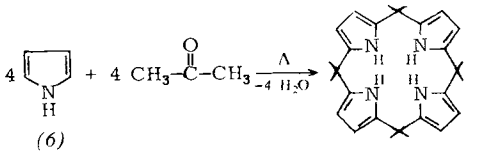
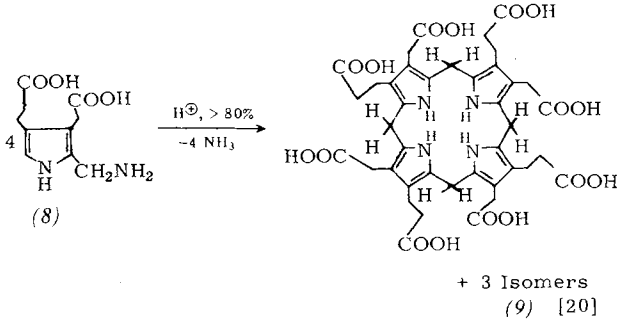


"directed" synthesis in the sense of a special ring-closure reaction is not really necessary. The simple condensation of partly or completely α-unsubstituted pyrroles such as *(6)*, *(8)*, and *(10)*, leads to high yields of porphyrin analogs under a wide range of conditions, regardless of whether the bridges in the primary product are saturated (porphyrinogens, phlorins) or unsaturated (porphyrins).

The porphyrinogens such as *e.g. (9)*, which are usually formed first, are quantitatively oxidized to porphyrins by oxidizing agents, *e.g.* oxygen. It is only in this oxidized state that the macrocycle is stable to acids. Methylene bridges, on the other hand, are readily broken by protons, and in the case of porphyrinogens this leads to decompositions and isomerizations[22].



This surprisingly simple solution to the problem of the synthesis of the porphyrin ring (the enzyme-controlled biosynthesis follows a course similar to that of the reaction *(8)*→*(9)*[23,24]) now also reveals the simple principle that causes the ring closure to occur in high yields after a linear tetramerization of the pyrrole units has taken place: the formation of a strain-free macrocycle by intramolecular condensation is possible only from the tetramer on, and this reaction is several orders of magnitude more probable than the addition of a fifth pyrrole ring. The maximum distance between the two reaction centers in the intermediate *(12)* is 18 Å, and the mean distance $\bar{r}$ is 8 Å (from $\bar{r}^2 = 2l^2 \times Z$[25], where $l = 1.4$ Å



(3) (4)

(10) (11) [21]

and $Z = 16$ are the mean bond length and the number of atoms in the chain); these values correspond to concentrations of 0.5 and 4 mole/l respectively[20]. This concentration range is many orders of magnitude greater than that of the tetrapyrromethane intermediate in the *in-vitro* and *in-vivo* syntheses, and the simple statistical argument is therefore sufficient to explain the formation of the macrocycle. No special matrix is necessary.

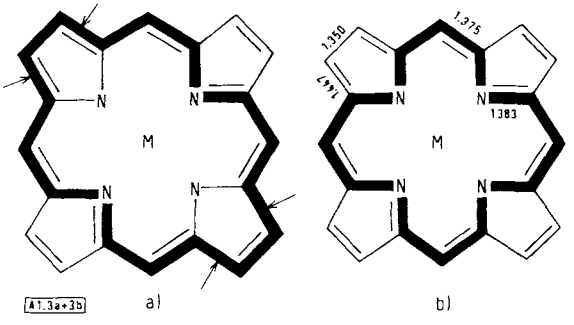
18 Å

(12)

The main condition for such a cyclization is that the activation energy of the intramolecular reaction should be comparable with that of the competing bimolecular reaction. This condition is satisfied in the formation of porphyrinogens: the unsubstituted α-pyrrole position of a pyrromethane is practically as reactive as that of an analogous unsubstituted pyrrole[26]. Under these circumstances the fact that other important products of polycondensations in biological systems, *e.g.* amino acids, nucleic acids, and sugar phosphates, have only one reactive end explains why the spontaneous, almost quantitative formation of macrocycles is confined to the porphyrinogen system. Finally, it should also be pointed out that β-unsubstituted pyrrole carbon atoms are also very reactive in the condensation in acidic solution; this leads to nonspecific condensations. The unsubstituted porphin [cf. *(1)*] cannot therefore be prepared by *Siedel*'s method [*(3)*→*(5)*], which is so successful for octaalkylporphins; it is best synthesized by free-radical oligomerization and ring closure[27].

3. Metal-Porphyrin Complexes and the [16]Annulene-diyl Dianion

The porphin macrocycle contains eleven conjugated double bonds, but only nine of these are required to form a fully conjugated cyclic polyene (Fig. 3a).



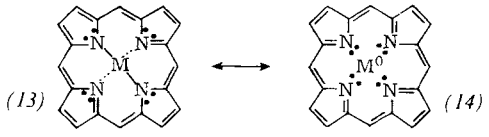


Fig. 3. a) The "outer" conjugation path [51] of the metal-porphin complexes, which is formally the shortest conjugation path [cf. with *(13)*]. It passes through a total of four α,β-pyrrole bonds (arrows), which are distinctly longer than in a corresponding aromatic system. b) The "inner" conjugation path [51] of metal-porphin complexes, in which only bond lengths corresponding to those of comparable aromatic compounds occur [cf. with *(14)*]. The bond lengths indicated (in Å) were measured for tetraphenylporphinatonickel [28].

If the two nitrogen atoms involved are regarded, to a first approximation, as equivalent to methine groups, in accordance with the Grimm hydride shift theory, [18]annulene could be taken as a model to describe porphin. However, the well-resolved X-ray structural analysis of a porphinatonickel derivative[28] showed that all the bond lengths of the inner ring (thick lines in Fig. 3b) are equal, and are close to those of aromatic compounds (*e.g.* $C—C_{benzene} = 1.395$ Å, $C—N_{pyridine} = 1.352$ Å)[29].

The length of the α,β-pyrrole C—C bond, on the other hand, corresponds to that of a C—C single bond in a conjugated polyene (*e.g.* $CH_2=CH—C\equiv N = 1.44$ Å)[29].

From the purely formal standpoint, this last result can be better represented by an electron distribution as shown in *(14)* for metal-porphin complexes than by the usual notation *(13)*, which still reflects the D_{2h} symmetry of the free porphin. If the outer conjugation system is taken into account, as in the [18]annulene model of Figure 3a, different bond lengths would have to be introduced, following the

results of the X-ray structural analysis. A more elegant model is obtained if one considers only the inner conjugation system, which is in contact with the central metal ion, and which is best characterized as the [16]annulenediyl dianion (Fig. 3b). The nitrogen atoms are again replaced by methine groups, and two electrons of the metal ion are also included.

The electronic spectrum of this polyene can be best explained by a model in which all 18 electrons are given a molecular orbital angular momentum that can be figuratively attributed to rotation about the porphin ring[12]. Since orbiting to the left and to the right (positive and negative angular momentum quantum numbers) are equal in energy in the absence of magnetic and electric fields, this postulate leads to singly degenerate energy levels when the angular momentum is different from zero, and hence to the qualitative energy diagram shown in Figure 4 for our simple porphin model.

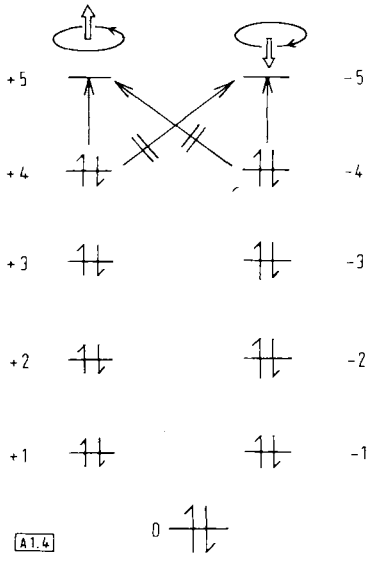

Fig. 4. Qualitative energy level diagram of the porphin ligand with the corresponding angular momentum quantum numbers as given by the simplest free-electron model [12, 30]. The arrows correspond to "allowed" (→) and "forbidden" (↛) electron transitions of lowest energy between the degenerate frontier orbitals. This simple model is sufficient for the interpretation of the most important physical properties of the porphin ring.

The ground state has a closed shell with no resultant angular momentum. The excited singlet states, on the other hand, which are indicated by the arrows, give a resultant angular momentum of ± 1 if the electronic transition takes place between energy levels having the corresponding quantum numbers with the same sign, or ± 9 if the sign changes. The former transition is "allowed" according to *Hund*'s rules, and was assigned to the intense short-wave Soret band of the porphyrins, whereas the latter is "forbidden" and so corresponds to the visible bands that are weaker by a factor of ten (see *e.g.* spectrum a in Fig. 5).

If the electronic excitation takes place while the molecule is in an external magnetic field H_0, the degeneracy of the energy levels is partly eliminated, since the magnetic fields

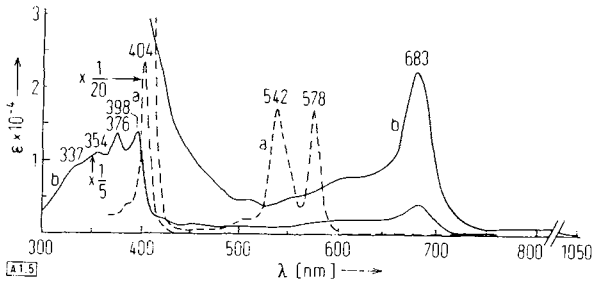

Fig. 5. Electronic spectra of octaethylporphinatomagnesium (spectrum a) and its one-electron oxidation product, the π-radical-cation (spectrum b) [32].

resulting from the "orbiting of the electrons to the left and to the right" interact differently with the external magnetic field (Zeeman effect), the splitting ΔE being proportional to the orbital angular momentum L. Measurement of the Zeeman effect on a porphinato-zinc derivative in DMSO with circularly polarized light gave an angular momentum of $L = 9.5 \pm 0.6$ units for the visible α band and about 1.3 units for the Soret band[30]. This has provided surprising confirmation of the extremely simple free-electron model; the single degeneracy of the highest occupied and of the lowest unoccupied energy levels seems to have been verified experimentally. The interpretation of the Zeeman effect for metal-porphyrin complexes has now been further refined[31], but this has had no effect on the essential consequences.

It has recently also become possible to support the analogy between the porphyrin ligand and the [16]annulenediyl dianion by comparison of the electronic spectra of the two compounds (Fig. 6).

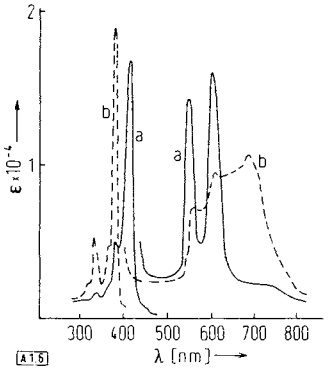

Fig. 6. Electronic spectra of the [16]annulenediyl dianion (spectrum a) and its one-electron oxidation product, the π-radical-anion (spectrum b) (after [33]). Compare Figure 5.

The spectra of octaethylporphinatomagnesium[32] and of the [16]annulenediyl dianion[33] are practically identical, as are those of the π-electron systems with one electron less. The diamagnetic ring currents as found from NMR measurements are also very similar for the two macrocycles[33, 34]. Beyond these simple arguments by analogy based on physical measurements, however, a comparison of the two macrocycles is probably not very fruitful, mainly because of their very different stabilities.

The physical measurements show clearly the benzene-like character of the porphyrin ligands, in the sense that the bond lengths of the inner conjugation system do not alternate and the outside orbitals are singly degenerate. Extended Hückel model calculations led to the same result[13, 14].

4. Central Metal Ions

The chemistry of the central metal ions in metal-porphyrin complexes will be discussed here only insofar as this is necessary to clarify the most important interactions between the porphyrin ligand and the metal ion. Nearly all metals, with the exception of the lanthanoids and actinoids, are now known to be able to form complexes with the porphyrin ligand[35, 36]. The porphyrin ligand is planar in all the metal complexes investigated so far; the decisive bonding factor is the donation of σ electrons from the four nitrogen atoms to the central metal ion, which always leads to stabilization of formally relatively high oxidation states: the σ electrons of the porphyrin ligand neutralize the positive charge on the metal ion and occupy the orbitals of the metal that can enter into σ and π bonds in the plane of the porphyrin with the four nitrogen atoms (mainly s and p orbitals in the metals of the main groups and the $d_{x^2-y^2}$ and d_{xy} orbitals in the transition metals).

The effect of a strong covalent σ bond in a planar ligand field on the metal ion can be briefly demonstrated by an example. Porphinatosilver(II) complexes (a d^9 system with an unpaired electron in the $d_{x^2-y^2}$ orbital) can be oxidized by iron(III) salts to stable, diamagnetic porphinatosilver(III) complexes ($E^{ox}_{1/2} = 440$ mV, SCE)[37]. The only other route by which this oxidation stage has so far been reached is by persulfate oxidation of a guanidine derivative, which is probably also planar[38], whereas *e.g.* the Ag^{II}/Ag^{I} pair in perchloric acid has an equivalence potential of $+1.76$ V[39], a potential at which all organic compounds would be destroyed. The extreme stabilization of the unusual Ag^{III} oxidation stage (a d^8 system) is a good indication of the extreme electron donor capacity of the planar porphyrin ligand. The direct interactions between the metal ion and the porphyrin ligand by π bonds normal to the plane of the porphyrin are negligible by comparison.

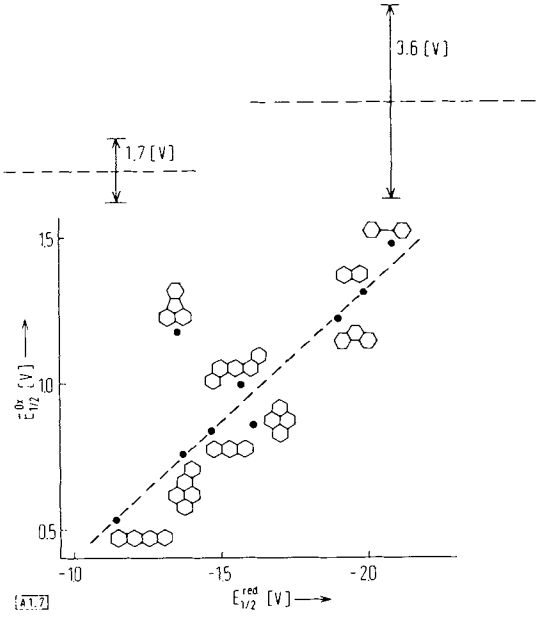
5. π-Radical-Cations and π-Radical-Anions of Metal-Porphyrin Complexes

The simplest reaction of an aromatic compound such as *(16)* is its reversible one-electron oxidation or reduction to form the radical-cation *(15)* or the radical-anion *(17)*.

$$C_{10}H_8^{\oplus\bullet} \underset{+e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} C_{10}H_8 \underset{+e^{\ominus}}{\overset{-e^{\ominus}}{\rightleftharpoons}} C_{10}H_8^{\ominus\bullet}$$

(15) *(16)* *(17)*

The electron is removed here from the highest occupied π orbital (≡highest occupied molecular orbital, "HOMO") or introduced into the lowest unoccupied molecular orbital ("LUMO"). These two orbitals are also known as the frontier orbitals. In alternating aromatic molecules the potentials of the one-electron oxidation (reduction) are proportional to the energies of the highest bonding (lowest antibonding) orbital: the higher the energies of the frontier orbitals, the more difficult do oxidation and reduction become. If the reduction potentials of a series of aromatic hydrocarbons are plotted against their oxidation potentials, the result is a straight line with a slope of about -1; this means that an increase in the oxidation potential corresponds to an approximately equal increase in the reduction potential[40], (Fig. 7). This behavior is as expected[40] since the energy eigenvalues of the bonding and antibonding frontier orbitals in alternant hydrocarbons differ only in sign.



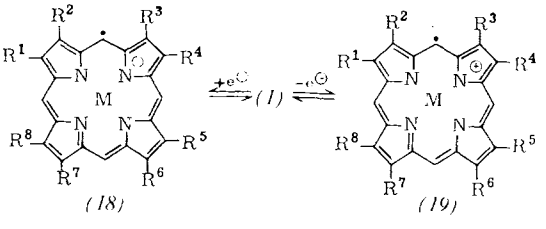


Fig. 7. Half-wave potentials of the one-electron oxidation and reduction of several alternant aromatic hydrocarbons [40]. The linear relation between the two potentials follows from the observation that the redox potentials are linear functions of the eigenvalue coefficients of the outermost orbitals, which are symmetrical with respect to the non-bonding energy level ( ) [40]. The difference $E^{ox}_{1/2} - E^{red}_{1/2}$ is about 1.7 V for tetracene, the most reactive member of the series, and increases to about 3.6 V for biphenyl. (Only the skeletons of the molecules are shown.)

Metal-porphyrin complexes *(1)* also form π-radical-cations *(19)*[32, 41, 44], or π-radical-anions *(18)*[42, 43] on chemical, photochemical or electrochemical oxidation or reduction. Titration of octaethylporphinatomagnesium *(1)*, M = Mg, R^1 $R^8 = C_2H_5$, with $FeCl_3$ in methanolic solution leads to the changes in absorption shown in Figure 8. It has been shown by paramagnetic resonance measurements on the same solutions that the product of the oxidation is quantitatively present

as the free radical[32]. Similar titrations in which the potential of the solution was also followed showed that the equivalence potential in the oxidation of porphyrins is strongly dependent on the central metal ion: the more electronegative this ion is, the more electrons it withdraws from the porphyrin ligand, and the more difficult it becomes to oxidize the latter[37, 41]. A linear relation has even been demonstrated between the one-electron oxidation potential of the porphyrin ligand and the electronegativity of the metal ion in the case of stable bivalent ions (Fig. 9)[41, 45].

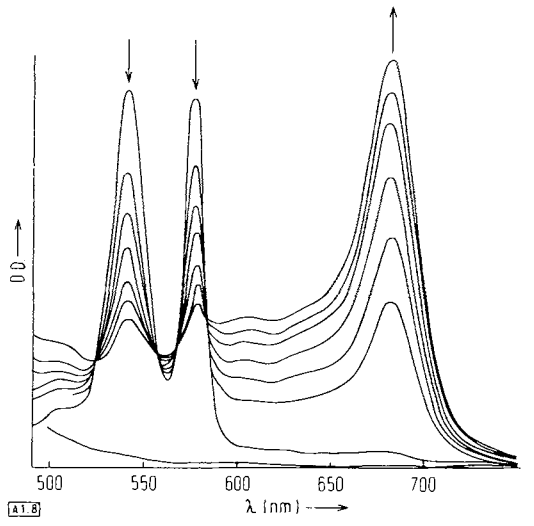

Fig. 8. Chemical oxidation of octaethylporphinatomagnesium in methanol with $FeCl_3$ followed spectrophotometrically.

Such simple relations are no longer observed with ions having higher valencies (*e.g.* Al^{III}, Fe^{III}, *etc.*). In most cases the redox potentials can only be measured polarographically or voltam-

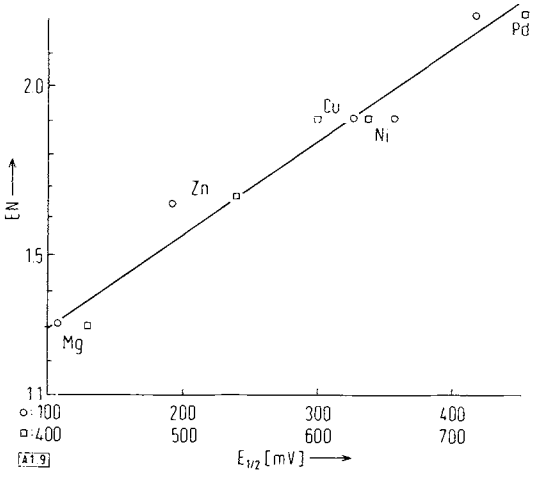

Fig. 9. Midpoint potentials of five metal complexes of octaethylporphin (□) and octaethylchlorin (○) as a function of the electronegativity (EN) of the bivalent central metal ions [45]. (Chlorin is 1,2-dihydroporphin.)

metrically, but a linear relation is still found between the one-electron oxidation and reduction potentials of the porphyrin ligand for nearly all the metal-porphyrin complexes investigated (Fig. 10)[37,41].

A comparison of the straight lines in Figures 7 and 10 immediately shows the characteristic difference in the underlying phenomena. In the conjugation system of Fig. 7 a low oxidation potential is coupled with a low reduction potential, whereas the introduction of metal ions into the porphyrin ligands leads to the opposite situation: a metal ion that has a low tendency to withdraw electrons from the porphyrin ligand (*e.g.* Mg^{II}) activates the ligand for oxidation and deactivates it for reduction[32,37,41]. The corresponding behavior with strongly electron-attracting metals (*e.g.* Sn^{IV}) leads to greater ease of reduction of the porphyrin ligand and to extraordinary stability toward oxidizing agents[65]. The regularity of the redox reactions of metal-porphyrin complexes demonstrated in Figure 10 is a good indication of the dominant role played by the strong inductive action of the central metal ion on the π-electron system of the porphyrin ligand, and shows in turn that d(*xz*,*yz*) interactions hardly occur, since there would otherwise be no explanation for the similarity of the effects of main-group metal and transition metal ions. The

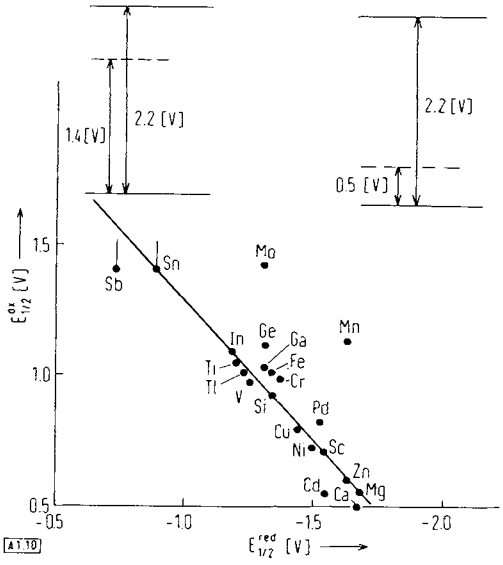

Fig. 10. Half-wave potentials of the one-electron oxidation and reduction of the octaethylporphin ligand in its metal complexes. The greater the difficulty of oxidation of the porphyrin ligand in a complex, the easier is its reduction, and *vice versa*. This behavior points to an inductive effect of the central metal ions, which causes a displacement of the two frontier orbitals of the porphyrin in the same direction in relation to the non-bonding energy-level (---) (cf. Fig. 7).

values of the oxidation and reduction potentials fluctuate by about 1 volt, but the difference between the two potentials for a given metal-porphyrin complex is practically constant ($E^{ox}_{1/2} - E^{red}_{1/2} = 2.25 \pm 0.15$ V). It should also be mentioned here that this energy difference is reproduced extremely well (2.18 eV) by calculations based on the extended Hückel model, whereas the inductive effects of the central metal ions play practically no part in this model[46].

However, Figure 10 also contains two complexes that show very strong deviations, *i.e.* the octaethylporphinato complexes of manganese and of molybdenum. In both cases the difference between the potentials increases to about 2.8 V, and unusual splitting of the Soret band is observed in the electronic spectrum in both cases[47,48]; this has been attributed in the case of Mn^{III} to interactions of the π electrons of the metal and of the porphyrin ligand. It is tempting to conclude that these interactions normal to the plane of the porphyrin cause extra stabilization of one oxidation state in this case, but further experimental support is needed for this conclusion.

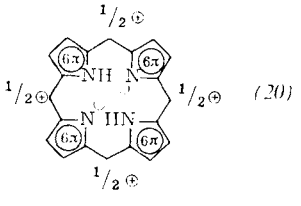

Figure 9 also contains a point of general interest: the conjugation system of chlorophyll *(2)* with a reduced peripheral double bond in a pyrrole ring (chlorins) has an oxidation potential in its metal complexes that is about 300 mV lower than that of the analogous metal-porphyrin complexes[45]. A decrease in potential by about 300 mV has also been observed between chlorophyll and bacteriochlorophyll, which has two reduced pyrrole rings[32]. This fact is probably related to the *in-vivo* observations that magnesium-porphyrin complexes have toxic effects in plants under the action of light and that much lower oxidation potentials are reached in bac-

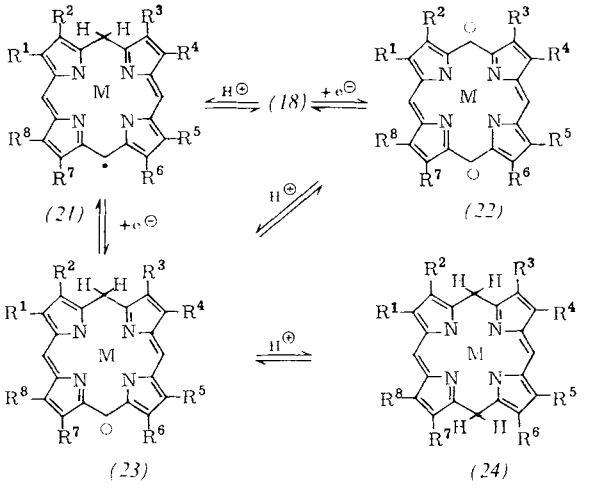
terial photosynthesis than in plant photosynthesis. The greater ease of oxidation of metal-porphyrin complexes with partly hydrogenated pyrrole rings also finds qualitative confirmation in theoretical model calculations: a somewhat higher energy eigenvalue is found for the highest bonding orbital in the chlorins and bacteriochlorins[49].

Many of the radical-anions and radical-cations have been obtained in the crystalline state and their electronic and EPR spectra analyzed in detail[44, 50, 99]; recently, even the X-ray structure of a π radical has been reported[100]. Diamagnetic π-dications[44] and π-dianions[42] have also been obtained. By far the most interesting secondary products of the redox reactions of porphyrins, however, are the phlorins, which were discovered independently by *Mauzerall*[22, 52] and *Woodward*[53, 54] about 15 years ago.



6. The Hydrogenation of the Porphyrin Ligand

The π-electron system of the porphyrin ligand and the nitrogen-metal interaction in the plane have so far been considered in their entirety. The relative reactivities of the carbon centers (methine bridges, α and β positions of the pyrrole rings) will now be discussed. A suitable starting point for this discussion is an electron distribution *(20)*, which was first formulated by *Woodward*[54]. If one assumes that the pyrrole rings still lead an independent existence in the macrocyclic conjugation system of the metal-porphyrin complexes, in the sense that each strives to attain a stable sextet of electrons, then in the neutral porphyrin ligand, *i.e.* formally when no electrons are transferred from the metal to the porphyrin and no redox reaction has taken place on the porphyrin, the methine bridges are positively charged, and nucleophilic additions should take place more easily. On the other hand, if electrons are introduced from the central metal ion or by reduction of the ligand, this has practically no effect on the aromatic system of the pyrrole rings, but there should be a pronounced change in the electron density on the methine bridges. If the electron distribution *(20)* is regarded as qualitatively correct, the reactivities of the pyrrole carbon atoms should be similar to those in pyrrole, *i.e.* they should above all be accessible to electrophilic substitutions, whereas the reactivity of the methine bridges in porphyrin complexes with different metals should reflect the diversity that can be expected from these complexes according to their variable redox behavior (Fig. 10).

(20)

Theory and experiment are in qualitative agreement in showing that nucleophilic, electrophilic, and free-radical addition reactions in the porphyrin ligand all begin on the methine bridges. In the theoretical model proposed by *Fukui*, the coefficients of the frontier orbitals are used as a measure of the relative reactivities of the individual centers of a molecule; the approximation procedure of *Pariser*, *Parr*, and *Pople* was taken as the basis for their calculation in porphyrin. Maximum occupancies for the two frontier orbitals were found on the methine bridges in every case[55]. The chemical evidence for the special reactivity of the methine bridges consists mainly of the general observation that the primary attack of oxidizing and reducing agents and of nucleophilic agents usually occurs here and that electrophilic substitutions can also be carried out here if the partial positive charge on the bridge atoms in *(20)* is reduced by the introduction of a central metal ion. The principal hydrogenation reactions of porphyrin ligands will now be discussed.

On electrochemical reduction[43] or reaction with aromatic π-anions *e.g.* sodium diphenylketyl and sodium anthracenide[42], in aprotic solvents, metal-porphyrin complexes are reversibly converted into their π-monoanions *(18)* or π-dianions *(22)*, depending on the redox potential, with characteristic absorption spectra (Fig. 11). Protonation, *e.g.* with methanol, leads immediately to the formation of a new strong absorption band close to 800 nm (Fig. 11), which indicates

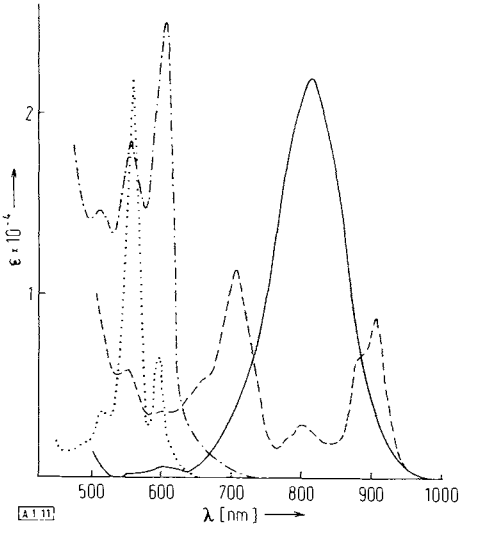


Fig. 11. Long-wave part of the spectra of tetraphenylporphinatozinc *(1)* (····), its π-radical-anion [type *(18)*] (– –), π-dianion [type *(22)*] (– · –), and phlorin radical-anion [type *(23)*] (— —). The spectra of the starting complex and of the dianion are surprisingly similar; the radical-anion *(18)* shows the typical broad free-radical band with long-wave maxima, and the intense phlorin band close to 800 nm is typical of tetrapyrrole pigment-metal complexes in which four pyrrole units are linked *via* three methine bridges and one methylene bridge.

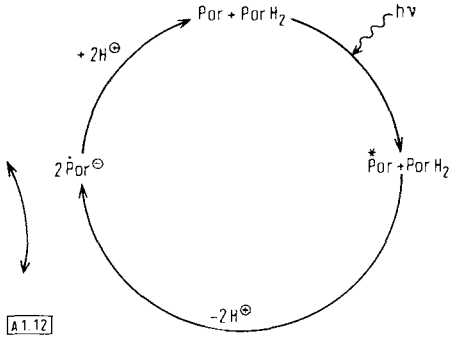
the protonation of a methine bridge [(21), (23)]. On reoxidation of the ligand, the protons of the "phlorins" (21) and (23) are immediately liberated again, and the original porphyrin is formed once more.

Phlorins of the same type are also formed on photochemical reduction of porphyrins and their metal complexes[22, 54] but cannot always be detected, since metal-phlorin complexes are readily reduced further to porphodimethenes (24) with principal absorptions close to 500 nm[56].

The reversibility of the addition of hydrogen to the methine bridges has also been demonstrated in a cyclic process[57], which is similar in outline to the photosynthesis scheme of Figure 1. A mixture of a phlorin and a porphyrin in glycol undergoes conproportionation on irradiation to form two porphyrin radical-anions, which are converted back into the starting materials by a relatively slow dark reaction (Fig. 12).



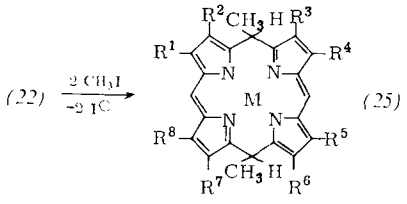


Fig. 12. Irradiation of equimolar quantities of a phlorin ($PorH_2$) and a porphyrin (Por) in glycerol leads to conproportionation into two porphyrin radical-anions, which disproportionate in a dark reaction into the starting materials (cf. Fig. 1). The double arrow on the left indicates that the radical-anions can oxidize or reduce other redox systems.

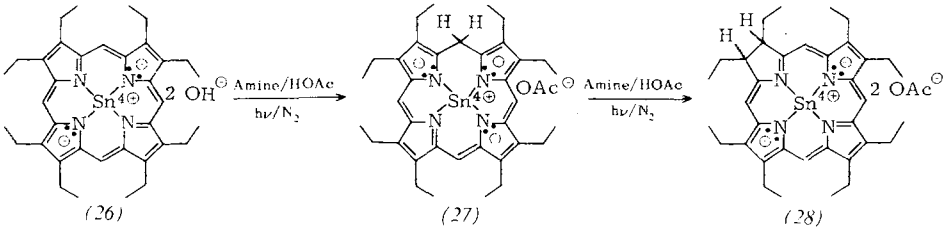
This cycle can be repeated several times. Instead of the formulated disproportionation of the radical-anions formed, an analogous reaction with other molecules is quite conceivable, a weak oxidizing agent taking over the oxidation to the original porphyrin and a weak reducing agent leading to the formation of the phlorin. The two substances reacting with the porphyrin radical would thus be converted into different oxidation states with no change in the composition of the porphyrin redox cycle, and light energy would thus have been converted into chemical energy. This reaction has not yet been demonstrated.

Reduction of porphyrins beyond the phlorin stage in the presence of protons leads first to porphodimethenes (24), which, like the phlorins, are very sensitive to air and are readily converted back into porphyrins. If methyl iodide is added to the solution instead of protonated solvents, however, the relatively stable α,γ-dimethylporphodimethenes (25) are obtained by "reductive methylation".

Buchler showed that the yield of (25) is strongly dependent on the nature of the central metal ion[58]. The yields are generally higher for metal ions with low electronegativities, where the porphyrin ligand itself is relatively rich in electrons, than for strongly electron-attracting metal ions. The nucleo-

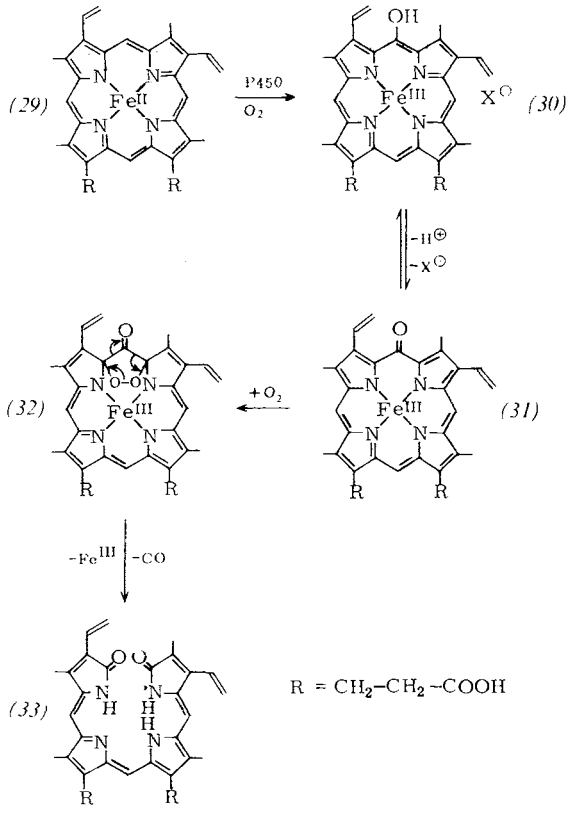


philicity of the methine groups can thus be strongly varied in the oxidation state of the porphyrindiyl π-dianion (22) by the use of different metal ions without affecting the point of attack of this addition reaction. This is in agreement with the model discussed at the beginning of this section. The fact that only the methine bridge situated opposite is attacked at first in the reduction of phlorins can be correlated with the results of model calculations[55], according to which the charge density in this position (1.09) is very much greater than on the neighboring bridges (0.92).

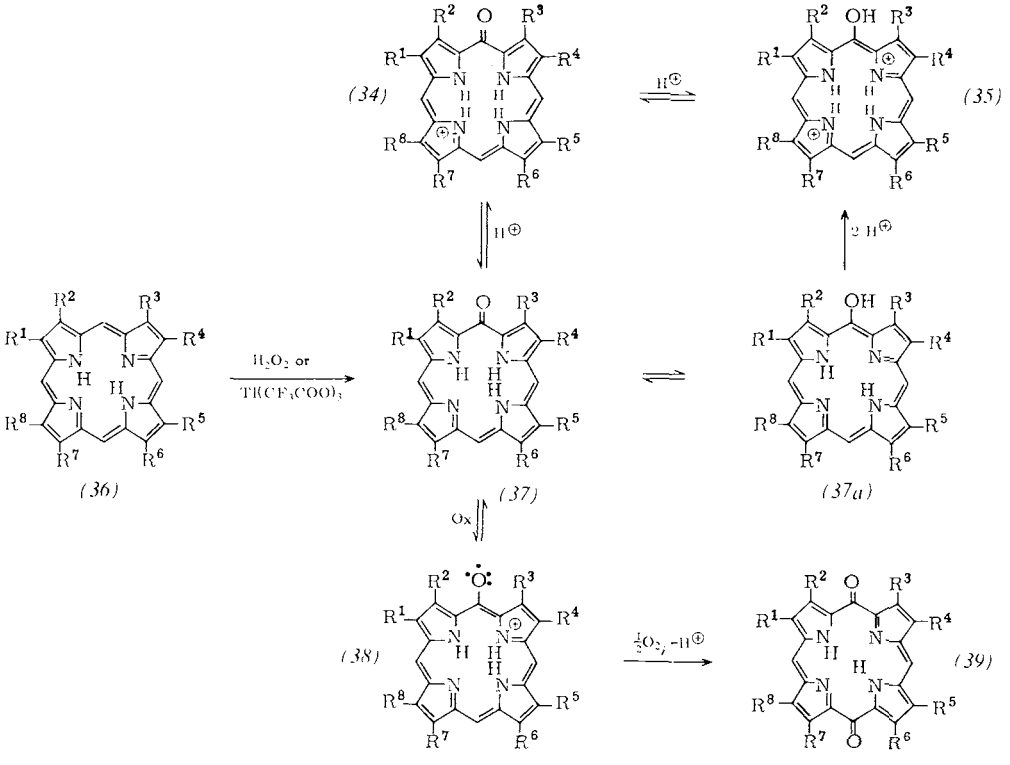
Finally, porphyrins can be reduced to colorless porphyrinogens[59], *e.g.* (4) and (9), in which all four methine bridges are hydrogenated, and which no longer form stable metal complexes. This reduction is still fully reversible by oxidizing agents, *e.g.* oxygen. Further catalytic hydrogenation leads to addition to the α-pyrrole carbon atoms, followed immediately by irreversible cleavage of the porphyrin macrocycle[60].

All hydrogenation experiments on porphyrins and their metal complexes thus confirm the model postulated at the beginning: the methine bridges readily enter into addition reactions, whereas the pyrrole rings do not react. The hydrogenation of β,β'-pyrrole double bonds in porphyrins is of special interest in connection with the synthesis of derivatives of chlorophyll (2). It can be achieved by the use of sterically hindered hydrogen carriers in strongly alkaline solution (*e.g.* diimine with KOH[63] or K_2CO_3[61], isoamyl alcohol with sodium[62]) or with the aid of special intramolecular rearrangements[53], which will not be discussed here. These and other preparative aspects of porphyrin chemistry and the related reactions of chlorins and corrin derivatives have recently been reviewed by *Inhoffen*[63] and *Smith*[64].

However, the direct rearrangement of a metal-phlorin derivative into a metal-chlorin derivative has also been observed in neutral solution in one case. This irradiation of porphinatotin(IV) derivatives (26) leads first to phlorins (27), which rearrange relatively rapidly and almost quantitatively into chlorins (28)[65] without the formation of porphodimethenes (24).



Out of 20 metal-porphyrin complexes used, the closely related porphinatogermanium(IV) was the only other that exhibited this reaction[65]. The strongly electron-attracting Sn^{IV} evidently polarizes the porphyrin ligand so strongly that even the β-pyrrole carbon atoms acquire a partial electropositive character and thus become easier to reduce. This agrees with the lengthening of the β,β'-pyrrole bond observed in X-ray investigations (porphinatonickel: 1.350 Å, porphinatotin(IV) 1.379 Å)[28]. It has recently been shown that chlorins can be converted into phlorins under strongly basic conditions[101]. A detailed review article of inorganic, organic, and biological studies on the reversible redox chemistry of the metalloporphyrin complex has recently been published[103].



7. Reactions of the Porphyrin Ligands with Oxygen

The iron-porphyrin chromophore of hemoglobin and other heme proteins, is not excreted as such on biological degradation of the protein component, but is oxidatively degraded to biliverdin *(33)*, which is then reduced to the familiar bile pigments of the feces and urine[8, 23]. The primary formation of biliverdin presumably occurs in two stages. A cytochrome enzyme (P 450) first hydroxylates the α-methine bridge of the heme *(29)* to form the hydroxyheme *(30)*, which loses acid to establish an equilibrium with the analogous oxophlorin *(31)*. The latter then adds an oxygen molecule to the two neighboring α-pyrrole positions, possibly in a non-enzymatic step, to form *(32)*; like the hydrogenation of these positions, this immediately leads to opening of the porphyrin macrocycle and also to loss of a molecule of carbon monoxide[66, 67, 102] and the central iron atom[110].

The primary occurrence of the enzymatic reaction *(29)*→*(30)* is probable on the basis of different experiments carried out independently by two research groups. By planned inhibition experiments in the oxidation of heme by liver homogenates

and oxygen, *Schmid et al.*[9] demonstrated that a P 450 cytochrome is involved; this cytochrome is known to catalyze (probably exclusively) hydroxylations with molecular oxygen. *Kenner et al.*[110] synthesized α- and β-hydroxymesoheme, and showed that only the "natural" α-isomer was degraded to biliverdin by liver homogenates. The second reaction, *(31)*→*(32)* has so far remained hypothetical, but agrees with existing knowledge about the specific reactivity of the porphyrin ligand, and also readily explains the physiological remo-

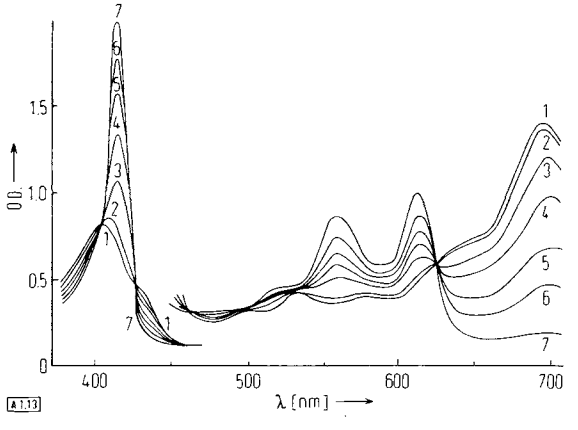
val of carbon monoxide, which has been conclusively demonstrated[67,68]; this reaction can therefore also be regarded as very probable.

Hydroxyporphyrins can be prepared in reasonable yields by oxidation of porphyrins such as *(36)* or of metal-porphyrin complexes[63,68] with hydrogen peroxide. However, the best method is the oxidation of porphyrins with thallium(III) salts, which gives almost quantitative yields[69].

Hydroxyporphyrins *(37a)* probably exist in neutral solution in the tautomeric form of the oxophlorins *(37)*; this was deduced mainly from an anomalous absorption spectrum (Fig. 13) and a strong IR absorption close to 1600 cm^{-1}[79,74].

Protonation, deprotonation, and metal complex formation lead to porphyrin-like spectra; this is the basis for the formulation *e.g.* of the equilibria *(37)*⇌*(34)*, *(34)*⇌*(35)*, and *(30)*⇌*(31)*. Easy interconversion of porphyrin and phlorin structures is therefore observed here just as for the "true" phlorins, which are formed by hydrogenation, and is a good indication that there are only slight energy differences between the macrocyclic "aromatic" conjugation system of the porphyrins and the polyene-like conjugation of the phlorins.

Neutral oxophlorins *(37)* can be very readily oxidized to stable π-radicals *(38)*[71]; the equivalence potential of *(37)*, R^1—R^8 = C_2H_5, with a value of −50 mV (SCE), is about 700 mV lower than that of octaethylporphin itself. The findings can probably be generalized as follows: Phlorins and oxophlorins are more easily oxidized and reduced than the analogous porphins. The resonance stabilization energies of the two systems are approximately equal.



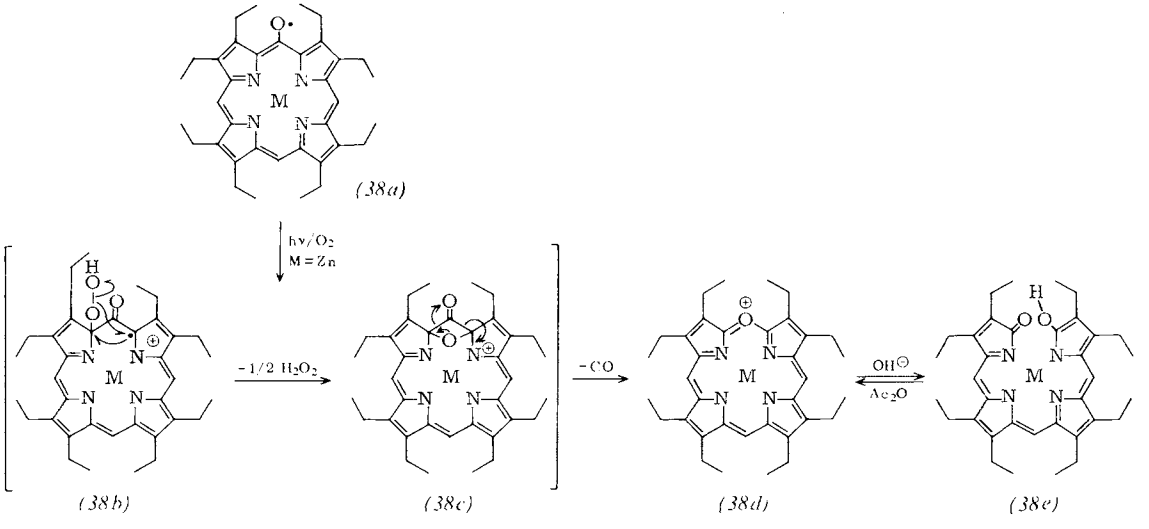


Fig. 13. Spectrophotometric titration of the octaethyloxophlorin cation *(34)*, R^1-R^8 = C_2H_5, in chloroform to form the porphyrin dication *(35)* [70]. This titration is one indication of the easy and reversible conversion of the conjugation system of porphyrins into that of phlorins (cf. Figs. 5 and 11). The left-hand part of the figure was recorded in a 1 mm cell, and the right-part in a 10 mm cell.

It must also be mentioned that phlorin radicals [*e.g. (21), (38)*] are very much less stable toward irreversible additions than the metal-porphin radicals [*e.g. (18), (19)*]. For example, the oxophlorin radical *(38)* reacts rapidly and almost quantitatively with molecular oxygen to form the quinone-like α,γ-dioxoporphodimethene *(39)*; this reaction is again exactly analogous to the results of the hydrogenation of *(21)* to *(24)*, though the influence of the central metal ions on the addition of oxygen has not yet been investigated. A series of photochemical reactions of the oxophlorin radical *(38a)* have recently been studied. They lead, *inter alia*, to an oxaporphyrin *(38d)*, which is formed in good yields and can be quantitatively and reversibly converted into the biliverdin *(38e)*[102]. The reaction sequence *(38a)*→*(38e)* is a plausible alternative to *(31)*→*(33)*. The singlet oxygen of the photo-oxygenation of the zinc complex *(38a)* would then correspond to the peroxide anion of the oxyhemoglobin in the natural process.

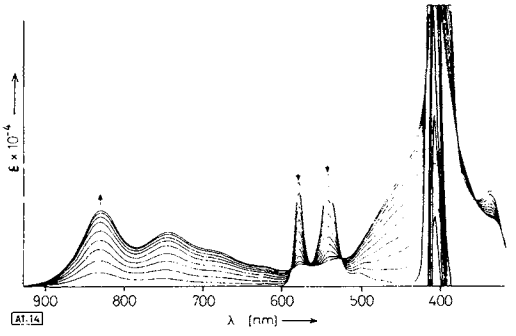
Oxidation of a porphyrin under drastic conditions leads initially, before the macrocycle is degraded, to reaction of all four methine bridges without attack on the pyrrole rings. The reaction of porphyrins with lead dioxide gives almost quantitative yields of the stable xanthoporphyrinogens *(40)* (*xanthos* = yellow), which crystallize well[72,73]; this reaction is analogous to the porphyrinogen formation on hydrogenation of porphyrins, and again demonstrates the particular stability of the pyrrole units.

However, the reaction proceeds quite differently if the starting porphyrin contains vinyl groups as substituents, as in the case of protoporphyrin. The reaction of these unsaturated side chains with lead dioxide results in irreversible, undefined destruction of the macrocycle. Xanthoporphyrinogens react with reducing agents, *e.g.* sodium amalgam, to give the starting porphyrins again in good yields, *i.e.* the oxidative porphyrinogen formation is also reversible.

In addition to the formation of oxophlorins *(37)* from porphyrins *(36)*, a second way in which the porphyrin ligand can react with oxygen has also been observed. If metal-por-

(38a) *(38b)* *(38c)* *(38d)* *(38e)*

phyrin complexes with low porphyrin ligand oxidation potentials (*e.g.* octaethylporphinatomagnesium) are exposed to visible light in the presence of air in benzene solution, spectroscopic examination shows that the porphyrin ligand is quantitatively converted into a chromophore with an intense absorption band above 800 nm (Fig. 14)[74-77]. This reaction



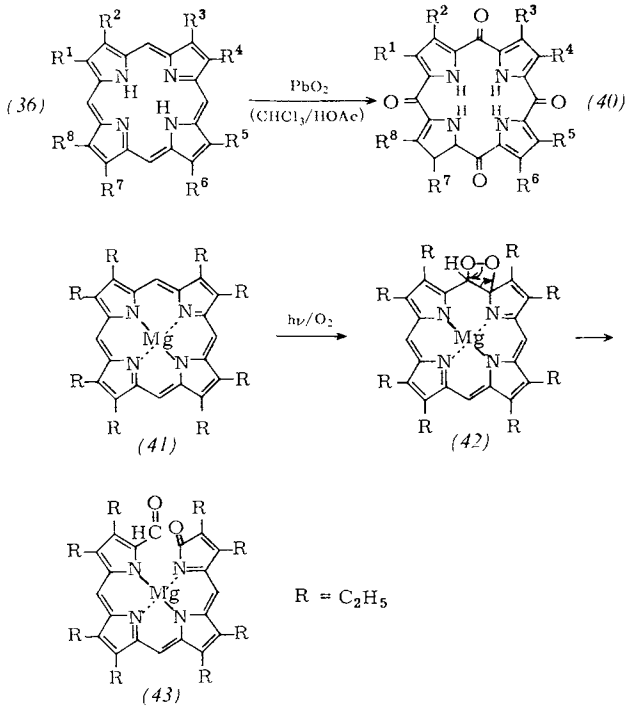


Fig. 14. The reaction *(41)*→*(43)*, such as occurs on irradiation of octaethylporphinatomagnesium in benzene in the presence of air, followed spectrophotometrically [75–77].

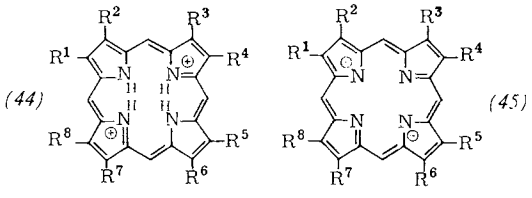


proceeds perfectly uniformly and no intermediates with lifetimes of more than 10 s occur. The quantum yield is of the order of 10^{-3}; in the underlying reaction an open-chain magnesiumformylbiliverdin complex *(43)*, which is extremely readily hydrolyzed, is formed *via* the postulated stage of a short-lived peroxide, possibly *(42)*[77,78].

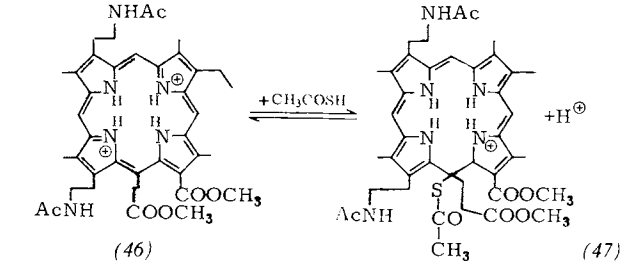
As was indicated above, this reaction can be carried out only if the porphyrin ligand has a low oxidation potential, *i.e.* if it carries the highest possible partial negative charge. This observation is an excellent example of a general pattern of the reactivity of the porphyrin ligand in its metal complexes: Chelates with low potentials in the one-electron oxidation described above react readily with molecular oxygen, but are very difficult to hydrogenate (extreme example: magnesium-porphyrin complexes). Conversely, metal-porphyrin complexes with high porphyrin ligand oxidation potentials

do not react with oxygen, or even *e.g.* with elementary bromine in extreme cases, but are very easy to hydrogenate (most pronounced in tin(IV)-porphyrin complexes)[65]. Between the two extremes there is a close succession of metal-porphyrin complexes with graded reactivities corresponding to Figure 10.

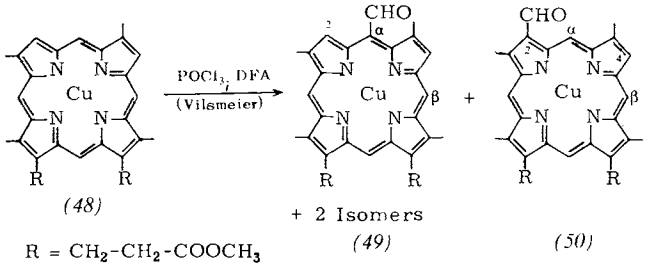
Qualitatively similar relationships between reactivity and redox potentials have also been found for the protonated porphyrins *(44)* and the deprotonated porphyrins *(45)*: for example, the cations *(44)* can be readily hydrogenated photochemically to phlorins[22] and porphodimethenes[22,79], while anions of the type *(45)* can be quantitatively oxygenated in a reaction analogous to *(41)*⇌*(43)*[80,81], but in this case subsequent solvolytic reactions occur immediately in the strongly alkaline solution that is necessary for the formation of *(45)*. Substituents on the methine bridges or on the β-pyrrole carbon atoms also influence reactivity and redox potentials. Substitution of a methine proton by a nitrile group increases *e.g.* the oxidation potential of the porphyrin ligand by about 250 mV[82].

8. The Polyene Character of Phlorins

The physical and chemical properties of the phlorins can be rationalized in the same way as for the porphyrins in Section 3. While singly degenerate frontier orbitals were regarded as related to the aromatic behavior of the porphyrins (electronic spectrum, magnetic ring current, formation of stable radicals, *etc.*), the known properties of the phlorins (no bands differing in intensity by orders of magnitude in the electronic spectrum; no ring current effect; few stable radicals, which tend to undergo irreversible addition reactions) point to their polyene character. The metal complexes of biliverdin behave similarly[77,81].



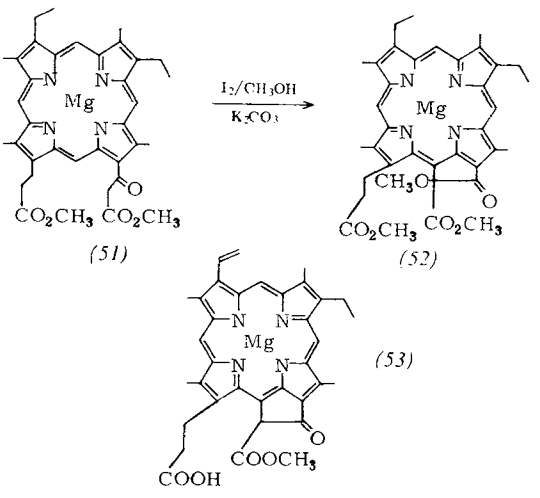
Similar transitions are found for benzene and its derivatives (Wheland and Meisenheimer complexes), but the polyene-like addition compounds here can often be studied only under extreme conditions (interception at low temperature, superacids, *etc.*), whereas phlorins are readily obtainable.



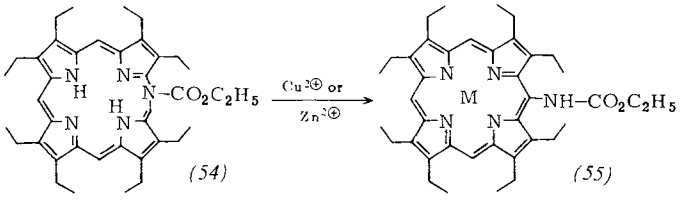
After the introduction of the central metal ions into the oxophlorins *(37)*, it should also be possible to study the influence of inductive effects on the stability of the macrocyclic benzene-like conjugation system. Investigations of this type on the porphyrin-phlorin equilibria are still in their early stages, mainly because of our fragmentary knowledge of the properties of the phlorins and their metal derivatives, and are numbered among the fascinating aspects of metal-porphin chemistry.

9. Other Electrophilic and Nucleophilic Reactions on the Porphyrin Ligand

The reaction patterns proposed for reversible and irreversible redox reactions of the porphyrin ligand are also valid for



other chemical reactions: positively charged porphyrin ligands, *e.g.* the dication *(46)*, readily undergo nucleophilic reactions, *e.g.* *(46)*⇌*(47)*[54], whereas metal-porphyrin complexes in which the porphyrin ligand carries a partial negative charge, *e.g.* *(48)* react more readily with electrophilic agents. Copper and nickel porphyrins have proved to be the best metal complexes for electrophilic substitutions, *e.g.* the Vilsmeier formylation, since the porphyrin ligand has a sufficiently negative partial charge to compensate for the inherent partial positive charge on the methine bridges [see *(20)*], but the metal complexes are also sufficiently stable toward acids to withstand the conditions of electrophilic substitutions (usually strongly acidic solutions); this would not be so *e.g.* for magnesium- or zinc-porphyrin complexes, which are themselves more reactive. As expected, the dimethyl ester of deuterioporphinatocopper(II) *(48)* is formylated with roughly equal probabilities on the methine bridges [*e.g.* *(49)*] and on the β-pyrrole carbon atom [*e.g.* *(50)*][83]. Many other electrophilic substitutions on the porphyrin ring proceed with very good yields, *e.g.* nitration[84] and chlorination[85], but no new points of view would result from the discussion of these reactions.



As was shown in Section 5, the presence of magnesium as the central metal ion makes it easy to oxidize the porphyrin ligand to the radical-cation, and this specific reactivity is probably also utilized in the biosynthesis of chlorophyll. *Kenner et al.*[89] were able to show that the magnesium complex of the 6-β-ketopropionic ester *(51)* can be cyclized to form a protochlorophyll analog *(52)* if *(51)* is oxidized to the π-radical-cation with iodine in methanol in the presence of potassium carbonate. Other reaction conditions did not lead to substitutions of this type; it seems reasonable to conclude that the *in-vivo* synthesis of the carbocycle in protochlorophyllide *(53)* proceeds in a similar manner.

Another aspect of metal-porphyrin chemistry is the tendency of the metal ion to eliminate disturbances of the square-planar ligand field. This effect undoubtedly plays a part in the reactions of metal-phlorin complexes *(21)*, which readily react further to form porphodimethenes *(24)*, whose ligand field is similar to that of the porphyrins, and was recently claimed

by *Grigg*[94] to be responsible for the extreme catalytic activity of copper or zinc ions in the ring contraction *(54)*→*(55)*.

Other reactions of the porphyrin ligand are discussed in detail in the reviews by *Inhoffen*[63] and *Smith*[64].

10. π-Complexes with Metal-Porphyrin Complexes

Metal-porphyrin complexes form definite π complexes with other aromatic molecules or self-associates, some of which have surprising properties. This association type of reaction is important to the biological activity of the metal-porphyrin complexes, since the electron and energy transport in redox chains and light-accumulating aggregates is probably connected with interactions of this type. For example, the photosynthesis reaction of the cycle in Figure 1 can also be symbolized by a light-induced charge transfer of the form

$$\text{Chl A} \overset{h\nu}{\rightleftharpoons} \text{Chl}^{\oplus}\ \text{A}^{\ominus}$$

the reverse reaction then occurring by oxidation of the electron acceptor radical $A^{\ominus}$ by a weak oxidizing agent and reduction of the chlorophyll radical-cation $Chl^{\oplus}$ by a weak reducing agent.

Molecular compounds of the porphyrins have been systematically investigated by *H. Fischer*[85] and *Mauzerall*[86]; the 1:1 or 1:2 complexes normally formed by aromatic compounds with nitrophenols, nicotinic acid, *etc.* were generally detected both in solution and in the crystalline phase. The spectroscopic effects of the complex formation usually consist of relatively slight shifts of the absorption maxima together with band broadening[86], which also occur in the self-association *e.g.* of chlorophyll[87].

Shifts of the methine proton NMR signals have also been used for the detailed elucidation of the structure of chlorophyll associates in solution[87], and have been attributed to the

addition of the magnesium ion to the carbonyl group of the carbocycle of a neighboring molecule.

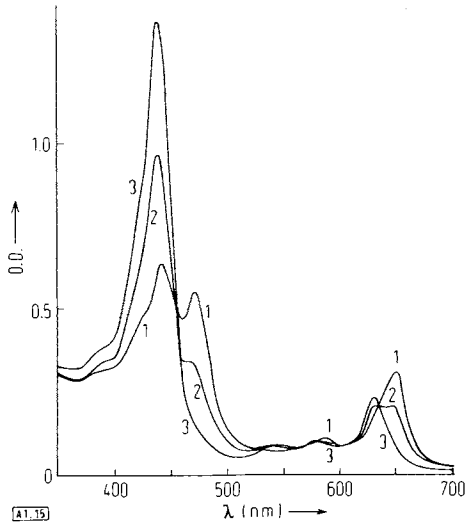


Fig. 15. The spectrum 1 of protochlorophyllide *(53)* in apolar solvents has a maximum at 650 nm and a split Soret band in the near UV. Addition of methanol leads to cleavage of the associate responsible, and spectrum 3 with an intense, sharp UV absorption appears; this corresponds to monomeric *(53)*. Similar changes in the spectrum of protochlorophyllide *(53)* are also observed *in vivo* in etiolated plants. Spectrum 2 corresponds to a mixture of aggregated and monomeric molecules.

Three unusual molecular aggregates of metal-porphyrin complexes will now be discussed briefly. *B. Ke*[88] found that protochlorophyllide *(53)* in apolar solvents forms an associate whose long-wave absorption band is displaced by almost 20 nm in relation to that of the monomer, and whose Soret band is split and strongly broadened (Fig. 15). This spectrum corresponds exactly to that of the "active" protochlorophyllide in etiolated plants, which is immediately hydrogenated to chlorophyll on exposure to light. The spectrum of the monomeric protochlorophyllide, on the other hand, agrees with that of the inactive, unreducible protochlorophyllide of the plants. This *in-vitro* experiment thus indicates that the protochlorophyllide in the plant is initially bonded to a hydrophobic matrix, probably a protein[95], where it forms a self-associate, and can only then be hydrogenated.

Wang[90,91] recently showed that chlorophyll reacts with flavins in solution to form a molecular complex with an absorption maximum at 700 nm, which is reversibly bleached on exposure to visible light. An EPR signal appears at the same time. This reaction is fully reversible in the dark, and may be regarded as a further model for the light-induced electron transfer of the photosynthesis, in which the reversible bleaching of a "P 700" is also observed in the photochemical system I[92].

The molecular complexes described so far are based on the usual weak interactions of π-electronic systems and side chains (ionic bonds, van der Waals forces, *etc.*)[86]. The bonding enthalpy of these complexes is probably less than ≈ 3 kcal/mol in every case[86]. Much stronger bonds have been observed on dimerization of radical-cations. The best defined complex of this type is the diamagnetic dimer of the octaethylporphinatozinc radical-cation, whose high enthalpy of formation of 17.5 kcal/mol and extremely intense charge-transfer band (oscillator strength 0.75) (Fig. 16) at 930 nm led to the formulation of a novel π-π' bond type, in which a new singlet ground state with a low energy is formed by multicenter overlapping and pairing of the electrons in the half-filled outermost orbitals[93]. π-π' bonds of this type between two similar radicals have also been observed for other aromatic free radicals (*e.g. Wurster*'s blue), but the formation enthalpies are once more in the region of weak interactions, and are about one order of magnitude lower than in the case under discussion at present[96].

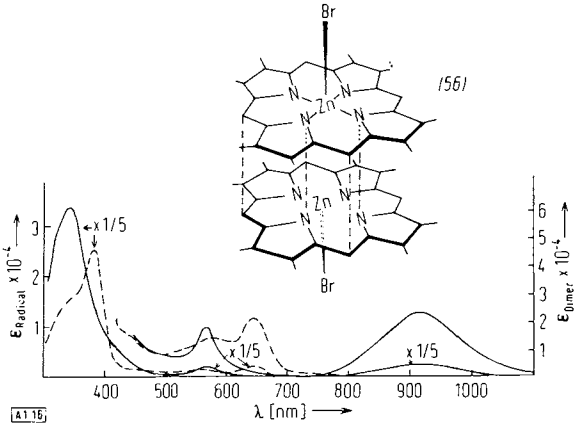

Fig. 16. Electronic spectrum of the octaethylporphinatozinc radical-cation (– – –) and its diamagnetic π-π' dimer *(56)* (——) (as counterion in each case) with an intense charge-transfer band at 930 nm. (Only the skeleton of the dimer is shown.)

11. Outlook

Most of what is known about the reactivity of the porphyrin ligand has been discovered in the course of the last twelve years. The discovery of the phlorins and the elucidation of their structure, the detailed investigation of the metal-nitrogen bond and its retroaction on the π-electron system, the experimental and theoretical proof of the degeneracy of the outermost orbitals, the discovery of the metal-porphyrin radicals and the conclusive detection of chlorophyll radicals in a light reaction of the photosynthesis, the contributions to our knowledge of the photochemical and biological degradation of porphyrins and of the formation of protochlorophyll can be mentioned as special milestones in this recent development, which began with *Woodward*'s synthesis of chlorophyll. Many of these topics contain other interesting problems for future experimental and theoretical studies. Thus 15 years after the discovery of phlorins and oxophlorins *in vitro*, their occurrence in biological systems has not yet been directly detected, though they very probably occur in some reactions of the biosynthesis of metal-porphyrin complexes, and should be easy to detect on the basis of their intense absorption in the near infrared; there is no theoretical model that is even approximately satisfactory for the strong influence of the central metal ions on the reactivity of the porphyrin ligand, and as a final concrete example of an unsolved problem in porphyrin chemistry, we can mention the preparation of the as yet hypothetical oxophlorin peroxides such as *(32)* or *(38c)* and the detailed elucidation of the decarbonylation to biliverdin *(33)* in which two carbon-carbon bonds and a peroxide bridge are broken. If the scheme *(29)*→*(33)* or *(38a)*→*(38e)* should also be confirmed biochemically, new

pathways would also be opened up for clinical research on heme degradation.

On the whole, interest is currently shifting more and more toward problems of the weak or catalytic interactions in which the porphyrins participate. Important examples are the formation and reactivity of charge transfer complexes, the electron distribution in oxyhemoglobin, the activation of molecular oxygen with metal-porphyrin systems for catalytic hydroxylations and oxygenations of hydrocarbons, and the transport of electrons through membranes containing metal-porphyrin complexes (see *e.g.*[97,98]). All these problems are concerned with the ability of the porphyrin ligand to give up or even "nearly" to give up electrons, a property that also determines the "normal" chemistry of the fascinating macrocycle that has been the subject of this progress report.

This work was supported by a grant and material aid from the Deutsche Forschungsgemeinschaft, for which I am grateful. Much of my work would have been practically impossible without the octaethylporphyrin supplied by Prof. Dr. H. Pommer, Badische Anilin- & Soda-Fabrik, Ludwigshafen. Finally, I am very grateful to my tutors and sponsors Prof. Dr. H. H. Inhoffen, Prof. Dr. S. Granick, Prof. Dr. D. Mauzerall, and Prof. Dr. F. Wagner, who provided me with the facilities for independent experiment, and to my untiring coworkers Dr. J. Subramanian, Dr. P. Wasser, A. Salek, S. Besecke, and T. Lumbantobing.

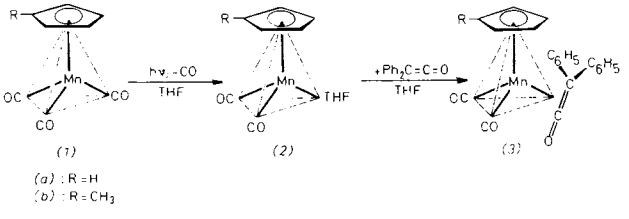
The First π-Diphenylketene-Carbonyl-Transition Metal Complexes



By *Wolfgang Anton Herrmann*[*]

The known reactions of ketenes with carbonyl-transition metal complexes result in deoxygenation and/or decarbonylation of the ketene and usually yield polynuclear metal derivatives[1]. On the other hand, catalytically active compounds of heavy metals are becoming increasingly important in ketene chemistry[2]. The first carbonyl-transition metal complexes containing the structurally intact diphenylketene moiety as ligand have now been synthesized.

Reaction of the THF complexes *(2a)* and *(2b)*, generated photochemically from *(1a)* and *(1b)* respectively, with diphenylketene in a molar ratio of 1:1 affords high yields of dicarbonyl(cyclopentadienyl)(diphenylketene)manganese *(3a)* and dicarbonyl(methylcyclopentadienyl)(diphenylketene)manganese *(3b)*.

[*] Dr. W. A. Herrmann
Fachbereich Chemie der Universität
84 Regensburg 1, Universitätsstrasse 31 (Germany)

The composition of the monomeric, diamagnetic products *(3a)* and *(3b)* was established by elemental analysis and

spectroscopy; the yellow crystalline complexes are air-stable and decompose in a sealed tube on heating to 90 and 93 C respectively.

Table 1. Spectroscopic data of complexes *(1a)*, *(3a)*, and *(3b)*.

	IR [a] ν(M)—C≡O [cm⁻¹]		ν(C)=C=O [cm⁻¹]	^{1}H-NMR [b] τ(C_5H_4R)	τ(C_6H_5)	τ(CH_3)

(3b)	1996 vs (A_1)	1943 vs (B_1)	1750 m, br	^{1}5.68 (4)	≈ ^{m}2.7 (5)	^{1}8.07 (3)

[a] ν(M)—C≡O frequencies in *n*-hexane, ν(C)=C=O frequencies in KBr.
[b] Intensities in parentheses; multiplicities given as superscripts preceding the τ values.

The IR spectra display two bands of almost equal intensity in the stretching region of metal-bonded carbonyl groups (Table 1). The loss of cumulative conjugation in the ketene system as a result of π conjugation with the central metal atom gives rise to a long-wave shift of the ν_{as}(C=)C=O band which appears at 2093 cm^{-1} (*n*-hexane) in the free

diphenylketene.—The mass spectra of *(3a)* and *(3b)* (70 eV; direct inlet: 75 and 85 °C respectively) indicate the occurrence of two synchronous fragmentation processes: apart from the loss of the diphenylketene ligand from the molecular ion, successive elimination of a total of three CO groups is also observed; one of these groups originates from the complexed diphenylketene, presumably with formation of a diphenylcarbene-metal fragment.—In addition to a sharp singlet for the η-cyclopentadienyl ligand, the 60-MHz ^{1}H-NMR spectrum of *(3a)* contains a somewhat broader signal for the phenyl protons. The significant upfield shift of the C_5H_5 signal in *(3a)* as compared to *(1a)* would suggest a transfer of charge density according to ketene→metal[3] and make a bonding of the ketene to the Mn atom *via* the carbonyl function appear rather unlikely owing to the high electronegativity of the O atom.

Formulation of the new compounds as π-olefin complexes also receives support from their chemical properties: whereas the cycloaddition of cyclopentadiene to free diphenylketene in boiling hexane is complete within 2 h[4], *(3a)* and *(3b)* react only very slowly under these conditions. However, the ketene ligand can be removed by reaction with triphenylphosphane in hexane at 60 °C (10 h) yielding $(C_5H_4R)Mn(CO)_2[P(C_6H_5)_3]$[5]. Reaction of *(3a)* with ethylene under pressure (55 atm, 80 °C, 12 h) in benzene leads to displacement of diphenylketene by ethylene, affording a 21% yield of dicarbonyl(cyclopentadienyl)(ethylene)manganese[6].

Procedure:

Diphenylketene[8] (10 mmol, 1.8 ml) is added at room temperature to a stirred solution of $C_5H_5Mn(CO)_2THF$ *(2a)* or $CH_3—C_5H_4Mn(CO)_2THF$ *(2b)*[7] (10 mmol), prepared by UV irradiation, in THF (50 ml) in an N_2 atmosphere. After 2 h the solvent is removed in a water-pump vacuum, and the deep red oily residue is taken up in benzene (5 ml) and chromatographed over alumina (Woelm, Activity I; water-cooled column). Compounds *(1a)* and *(1b)* and unreacted ketene are eluted with benzene, and *(3a)* and *(3b)* as pale-yellow zones with diethyl ether. After removal of solvent, recrystallization of the residue from *n*-hexane/diethyl ether (5:2) at −35 °C affords *(3a)* (2.1 g, 58%) or *(3b)* (2.0 g, 53%) as yellow crystals.

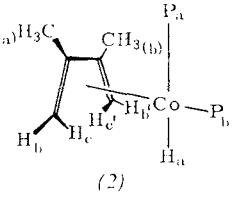
2,3-Dimethyl-1,3-butadienehydridobis(triphenylphosphane)cobalt(I)

By *Peter Veit Rinze*[*]

Hydridocobalt(I) complexes $[CoHL_4]$ react with 1,3-dienes to form compounds of type $[Co(1—3\text{-}\eta\text{-allyl})L_3]$[1–3]. As in the isomerizations of coordinated allyl ligands[4], complexes $[CoH(1—4\text{-}\eta\text{-diene})L_n]$ may be expected to play an intermediate role in these reactions. They have long been postulated as active species in the oligomerizations of dienes catalyzed by cobalt complexes[5], but have hitherto been neither isolated nor detected by spectroscopy. This proves possible, however, on reaction of the dinitrogenhydridocobalt(I) complex *(1)* with 2,3-dimethyl-1,3-butadiene according to eq. (1).



(1)

(1)

(2)

The yellow crystalline product *(2)* is extremely sensitive to air, turns deep red in N_2 above 40 °C, and decomposes above 70 °C. The IR spectrum of *(2)* in Nujol displays a Co—H stretching band at 1862 cm^{-1}. From the ^{1}H-NMR spectrum it may be deduced that at −50 °C in [D$_8$]toluene compound *(2)* exists almost exclusively as (1—4-η-2,3-dimethyl-1,3-butadiene)hydridobis(triphenylphosphane)cobalt(I), for which a trigonal-bipyramidal structure is proposed.

(2)

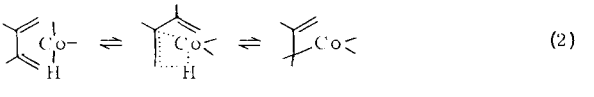


Table 1. ^{1}H-NMR data of the complex *(2)* at −50 °C in [D$_8$]toluene [a].

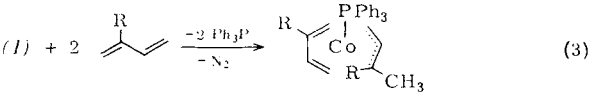
τ	Rel. int.	Coupling constants [Hz] [b]	Assignment
7.48	2		H_b
7.59			$H_{b'}$
8.08	3	$J(P_bCH_{3(a)})=3$	$CH_{3(a)}$
8.20	3		$CH_{3(b)}$
11.22	2	$J(P_bH_c)=12$	H_c
11.39		$J(P_bH_{c'})=15$	$H_{c'}$
27.7	1	$J(P_aH_a)=88$, $J(P_bH_a)=28$	H_a



[a] 100 MHz; without phenyl proton signals. The solvent signal at τ = 7.90 was used as internal standard.
[b] All signals are relatively broad due in part to weak unresolved coupling effects.

The ^{1}H-NMR spectrum proves to be temperature dependent: the intensities of the resonance signals of H_a, $H_{b'}$, and $H_{c'}$ decrease with rising temperature; at −10 °C they have disappeared completely. The τ values of the other signals change by +0.13 ppm at most (for H_b). At 40 °C a new very broad signal appears at τ = 15.6 having a relative intensity of 3. Partial irreversible decomposition of *(2)* sets in at this temperature.

This dynamic behavior of *(2)* in solution can be described by eq. (2). However, no rearrangement occurs to give the

(2)

(3)

R = H[2], CH_3[6]

(1—3-η-allyl) complex which is isolated as a stable product of the reaction according to eq. (3).

That this difference in reaction course is to be attributed not only to electronic effects of the additional methyl substituent but also to steric hindrance of the pentacoordination of the possible (1—3-η-allyl) compound is apparent from the existence of the corresponding (1—3-η-allyl) complexes $[Co(C_6H_{11})(CO)_3]$[1] and $[Co(C_6H_{11})(PF_3)_3]$[3].

Procedure:

All operations are carried out with solvents containing no H_2O or O_2 and under an inert gas. $[CoH_3(Ph_3P)_3]\cdot O(C_2H_5)_2$[7] (15.2 g, 16.5 mmol) in benzene (200 ml) is converted into *(1)* by treatment with N_2. After addition of C_6H_{10} (5.5 ml, 48.7 mmol) stirring is continued at about 20°C until evolution of gas has ceased. The brown solution is then concentrated in a vacuum and hexane is added (50 ml). Yellow crystals precipitate with simultaneous crystallization of benzene at 0°C. After drying at 10^{-1} torr *(2)* still contains benzene of crystallization (exp.: 77.35% C, 6.22% H; calc. for $C_{48}H_{47}CoP_2$: 77.40% C, 6.36% H). Yield 5.2 g (42%).

The Synthesis of Bridged "Didehydrooxa-" and "-thia[17]annulenes", Diatropic Homologs of Furan and Thiophene[1][***]

By *Julian M. Brown* and *Franz Sondheimer*[*]

The synthesis of the methylene-bridged "didehydroaza[17]-annulenes"[***] *(1)* to *(5)* has been described previously[1,2]. These are diatropic 18π-electron systems in which the magnitude of the ring current [*(1)* > *(2)* > *(3)* > *(4)* > *(5)*] was found to decrease with increasing electronegativity of the *N*-substituent. The derivatives *(6)* to *(8)* bearing alkyl groups within the cavity of the π-electron cloud have also been prepared[1,3]. The route used to obtain these aza[17]annulene derivatives has now been applied to the synthesis of the diatropic oxygen *(17)* and sulfur analogs *(18)* and *(19)* which were required so that we could study the effect on the ring current of varying the heteroatom within the same framework of a hetero-annulene. (For the preparation of paratropic and atropic *S*-oxides of *(18)* and *(19)* see ref.[4].)

Wittig reaction of 4-ethyl-4*H*-pyran-3,5-dicarbaldehyde *(9)*[5] and 2 molar equivalents of the phosphonium salt *(10)*[6] in dimethylformamide with ethanolic lithium ethoxide at 90 C led to *ca.* 10% of the *trans,trans* isomer *(14)* as a pale yellow oil[7]. Oxidative coupling of *(14)* with cupric acetate in pyridine at 55—60°C under fairly dilute conditions gave *(17)*, a bridged "didehydrooxa[17]annulene", in 4% over-all yield [based on *(9)*]. Compound *(17)* forms yellow crystals, m.p. 167—168°C (decomp.); λ_{max} (cyclohexane) 260 sh (ε 8700), 305 sh (45000), 312 (47000), 365 (6100), 386 (6900), and 405 nm (6100).

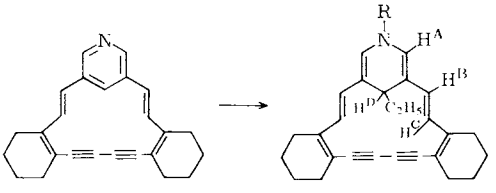
The thiopyran *(11)*, m.p. 98—99 C, was prepared in 20% yield by hydrolysis of *(9)* with sodium carbonate and sodium hydroxide[8] in aqueous ethanol, followed by treatment with phosphorus pentasulfide in boiling toluene. Wittig reaction of *(11)* with *(10)*, and subsequent coupling of the resulting *(15)* (20% yield, yellow oil), as previously, then gave *(18)* in 13% over-all yield [based on *(11)*]. The bridged "didehydrothia[17]annulene" *(18)* forms orange-yellow crystals, m.p. 212—214°C (decomp.); λ_{max} ($CHCl_3$) 268 (ε 14500), 331 (54000), 361 (20800), 398 sh (9400), and 420 sh nm (6700).



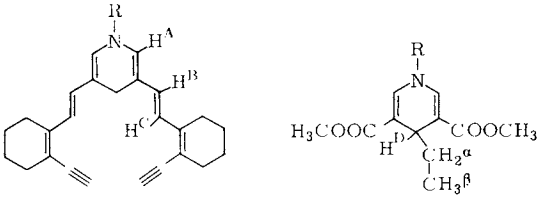
[*] J. M. Brown [**] and Prof. Dr. F. Sondheimer
Chemistry Department, University College
Gordon Street, London WC1H OAJ (England)

[**] The award (to J. M. B.) of a Traveling Scholarship by the Australian National University is gratefully acknowledged.

[***] For the trivial "dehydroannulene" nomenclature used, see *F. Sondheimer* and *R. Wolovsky*, J. Amer. Chem. Soc. *84*, 260 (1962). We would like to continue to name diacetylenic annulenes "didehydroannulenes" or "bisdehydroannulenes" rather than "tetradehydroannulenes", in order to avoid confusion in the literature.

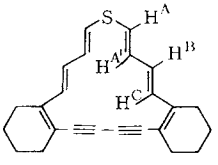
The starting material for the synthesis of the bridge-unsubstituted thia[17]annulene *(19)* was the thiopyran *(13)*, m. p. 169 °C, which was prepared in poor yield (1–6%) by ozonolysis of norbornadiene in acetone at −45 °C (dimethyl sulfide work-up), followed by treatment with phosphorus pentasulfide in boiling toluene[9]. Wittig reaction of *(13)* with *(10)*, as before, led to 45% of *(16)* as pale yellow crystals[10], oxidative coupling of which gave *(19)* (85% yield) as yellow crystals[10]; λ_{max} ($CHCl_3$) 265 sh (ε 13500), 333 (57000), 365 (26000), and 403 nm (9900).

For comparison with *(17)* and *(18)*, the bridge-ethyl aza[17]annulenes *(21)* to *(24)* were required. *(21)*[3] and *(22)*[11] have already been reported; *(23)*[10] and *(24)*[10] have now been prepared from the pyridine derivative *(20)*[2] in *ca.* 50% yield by reaction in tetrahydrofuran with ethyllithium (1 M in benzene) at −20 °C, followed by direct treatment with ethyl chloroformate and acetyl chloride, respectively[11].



(20)

(21), R = CH_3
(22), R = H
(23), R = $COOC_2H_5$
(24), R = $COCH_3$



The ^{1}H-NMR chemical shift data of the bridge-ethyl hetero[17]annulenes *(17)*, *(18)*, and *(21)* to *(24)* are given in Table 1. The numbers in parentheses are the changes on passing from an appropriate atropic model to the heteroannulene. The models for *(17)* and *(18)* are the "open" precursors *(14)* and *(15)*, respectively. It was found impossible to prepare the "open" analogs corresponding to the aza[17]annulenes *(21)* to *(24)*; models chosen for these are the compounds *(25)* to *(28)*[2] containing no ethyl substituent (for H^A, H^B, H^C, and the allylic protons) and the diesters *(29)* to *(32)*[12] (for H^D, H^α, and H^β). It is evident from Table 1 that all the hetero[17]annulenes are diatropic, the outer proton resonances having moved to lower field as compared to the models, and the inner ones to higher field. The relative magnitude of these changes in both directions clearly shows the diamagnetic ring current to decrease in the order $NCH_3 > NH > S > O > NCOOC_2H_5 > NCOCH_3$.

The ^{1}H-NMR chemical shift data of the bridge-unsubstituted thia[17]annulene *(19)* are also given in Table 1, as well as the differences from the model *(16)* (parentheses). Comparison with the corresponding differences of the aza[17]annulenes *(2)* to *(5)*[2] shows that in this series the diamagnetic ring current also decreases in the order $NH > S > NCOOC_2H_5$. The ring current in *(19)* appears to be slightly greater than in the bridge-ethyl thia[17]annulene *(18)*. This effect of the ethyl group has already been found in the corresponding *N*-methylaza[17]annulenes[3], and is probably due to the greater deviation from planarity caused by this group.

(25), R = CH_3
(26), R = H
(27), R = $COOC_2H_5$
(28), R = $COCH_3$

(29), R = CH_3
(30), R = H
(31), R = $COOC_2H_5$
(32), R = $COCH_3$

(33)

The oxa[17]annulene *(17)* appears to be the first diatropic homolog of furan to be prepared[13]. The only previously described diatropic homolog of thiophene is the unbridged thia[17]annulene *(33)*[14]. In the ^{1}H-NMR spectrum of *(33)*, the chemical shifts of H^B (τ = 3.19), H^C (τ = 4.99), and the allylic protons (τ = 7.3—7.6)[15] are similar to those of *(18)* and *(19)* (Table 1). The bridge in *(18)* and *(19)* therefore does not appear to be particularly important for sustaining a diamagnetic ring current in these compounds.

(19) (S)	3.10 (−0.76)	2.85 (−0.75)	7.2 7.6 (−0.3)	5.22 (+2.25)	8.98 (+2.26)		

[a] In addition, all compounds showed a band at τ ≈ 8.0—8.5 (aliphatic H).
[b] The assignments of H^B and H^C are based on nuclear Overhauser experiments and long-range coupling.
[c] Determined at −30 °C, due to line broadening at room temperature.
[d] The signal was obscured by the allylic H band.
[e] The signal in the model *(14)* was obscured by the aliphatic H band.
[f] The signal in the model *(28)* could not be located due to extreme broadening.

[5] This substance was prepared from malonaldehyde and propionaldehyde essentially according to *E. Winterfeldt*, Chem. Ber. 97, 1959 (1964).

[6] *P. J. Beeby* and *F. Sondheimer*, Angew. Chem. *85*, 406 (1973); Angew. Chem. internat. Edit. *12*, 411 (1973).

[7] All compounds, except *(12)* and *(29)* to *(32)*, were isolated by chromatography on alumina (Woelm, activity III). ^{1}H-NMR, UV, IR, and mass spectra compatible with the assigned structures were obtained for all new substances.

[8] See *F. Wille* and *L. Saffer*, Liebigs Ann. Chem. *568*, 34 (1950).

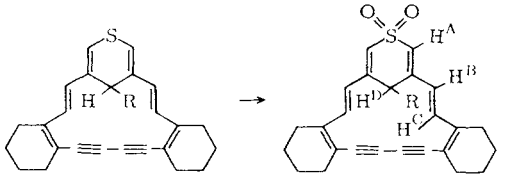
[9] The pyran *(12)*, m. p. 184—185 C, was similarly prepared by ozonolysis of norbornadiene, followed by treatment of the ozonide solution with zinc in acetic acid. However, the yield of *(12)* was very poor and irreproducible, and its further transformation to the oxygen analog of *(19)* could not be carried out.

[10] The substance decomposed on attempted melting point determination.

[11] The conversion of *(20)* into *(23)* was carried out by Dr. *P. J. Beeby*.

[12] The diester *(30)* (m. p. 108—109 C) was prepared from dimethyl pyridine-3,5-dicarboxylate [2] by reaction with ethylmagnesium bromide [3]. Treatment of *(30)* with sodium hydride, followed by addition of methyl iodide, ethyl chloroformate, or acetyl chloride gave *(29)* [3], *(31)* (m. p. 101—102 C), or *(32)* (m. p. 117 C), respectively.

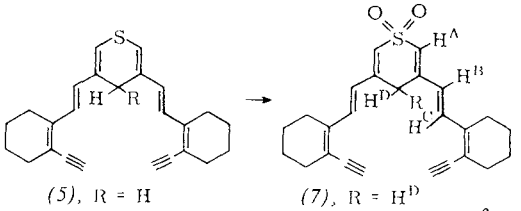
[13] The previously prepared oxa[9]annulene (oxonin) [see *S. Masamune* and *N. Darby*, Accounts Chem. Res. 5, 272 (1972); *A. G. Anastassiou*, *ibid.* 5, 281 (1972)] and oxa[17]annulene [*G. Schröder*, *G. Plinke*, and *J. F. M. Oth*, Angew. Chem. *84*, 472 (1972); Angew. Chem. internat. Edit. *11*, 424 (1972)] appear to be atropic. For the synthesis of a paratropic oxa[15]annulene derivative, see *H. Ogawa*, *M. Kubo*, and *H. Saikachi*, Tetrahedron Lett. *1971*, 4859.



[14] *R. H. McGirk* and *F. Sondheimer*, Angew. Chem. *84*, 897 (1972); Angew. Chem. internat. Edit. *11*, 834 (1972).

[15] The chemical shift of H^A in the ^{1}H-NMR spectrum of *(33)* cannot be compared with those of *(18)* and *(19)*, since the double bonds adjacent to the sulfur atom in *(33)* appear to rotate (*P. J. Beeby*, *R. L. Wife*, and *F. Sondheimer*, unpublished experiments).

The Synthesis of Bridged "Didehydrothia[17]annulene" *S*-Oxides. The Dependence of Ring Current on Geometry in Stereoisomeric Sulfoxides[1]

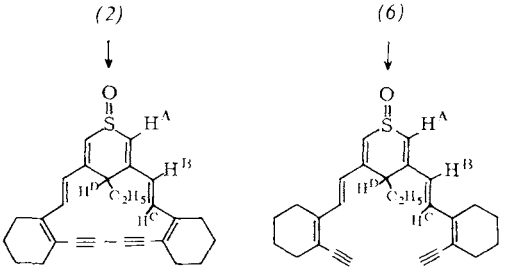


By *Julian M. Brown* and *Franz Sondheimer*[*]

The bridged "didehydrothia[17]annulenes" *(1)* and *(2)*[1] are shown by their ^{1}H-NMR to be diatropic, the sulfur atom presumably contributing two π-electrons to form

(1), R = H
(2), R = C_2H_5

(3), R = H^D
(4), R = CH_2^{α}–CH_3^{β}

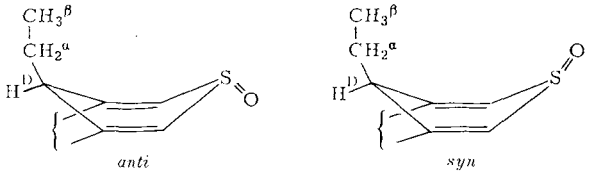


(5), R = H
(6), R = C_2H_5

(7), R = H^D
(8), R = CH_2^{α}–CH_3^{β}

an 18π-electron system. It was of interest to synthesize the corresponding *S*-oxides, in order to study their spectral properties. We now describe an investigation of the sulfones *(3)* and *(4)*, as well as of the stereoisomeric sulfoxides *(9)* and *(10)*.

Oxidation of the thia[17]annulene *(1)* with 2 molar equivalents of *m*-chloroperbenzoic acid in methylene chloride (−20 °C, 1 h) gave 65% of the sulfone *(3)*[2] as orange crystals[3] [λ_{max} ($CHCl_3$) 276 sh (ε 32000), 298 (53000), 310 (64000), 417 (4100), 437 sh (3100), and 467 sh nm (2800)]. Similar oxidation of the thia[17]annulene *(2)* (20 C, 2 h) led to 70% of the sulfone *(4)*[4] as yellow crystals [λ_{max}($CHCl_3$) 277 sh (ε 31000), 300 (67000), 313 (85000), 430 (2700), 444 sh (2600), and 479 sh nm (1500)]. Oxidation of the sulfides *(5)*[1] (−20 C, 2 min) and *(6)*[1] (20 C, 5 min) with 2 molar equivalents of the peracid gave the model" sulfones *(7)* and *(8)*[5] as pale yellow crystals in *ca.* 10% and 25% yield, respectively.



(2) *(6)*

(9), *anti*
(10), *syn*

(11), *anti*
(12), *syn*

Oxidation of the thia[17]annulene *(2)* with only 1 molar equivalent of *m*-chloroperbenzoic acid in methylene chloride (−20 C, 2 h) led to two stereoisomeric sulfoxides. The *anti*-isomer *(9)*, eluted first[2], was obtained in 25% yield as yellow crystals [λ_{max} ($CHCl_3$) 274 sh (ε 23000), 286 (35000), 311 sh (39000), 321 (43000), 412 (2800), 428 (2800), and 456 sh nm (1700)]. The *syn*-isomer *(10)*, eluted subsequently, was isolated also in 25% yield as orange crystals [λ_{max} ($CHCl_3$) 302 (ε 66000), 314 (75000), and 437 nm (1700)]. In order to obtain suitable models, the sulfide *(6)* was oxidized with 1 molar equivalent of the peracid (−20 C, 16 h); this reaction gave 15% each of the *anti*-sulfoxide *(11)* (eluted first) and the *syn*-sulfoxide *(12)* as cream-colored crystals. Attempts to oxidize the sulfides *(1)* and *(5)* containing no ethyl group to the corresponding sulfoxides were unsuccessful.

anti *syn*

The *anti* and *syn* structures (see diagrams) were assigned to the sulfoxides *(9)* and *(11)*, and *(10)* and *(12)*, respectively, on the basis of ^{1}H-NMR experiments using Eu(fod)$_3$ [tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium(III)]. Addition of this reagent caused the H^D signals to move downfield more quickly than either H^A or H^B in the *anti*-sulfoxides *(9)* and *(11)*, whereas the reverse was true in the *syn*-sulfoxides *(10)* and *(12)*.

The ^{1}H-NMR chemical shift data of the sulfones *(3)* and *(4)* and of the sulfoxides *(9)* and *(10)* are given in Table 1. The numbers in parentheses are the changes on passing from the "open" sulfones *(7)* and *(8)* and sulfoxides *(11)*

[**] The award (to J. M. B.) of a Traveling Scholarship by the Australian National University is gratefully acknowledged.

and *(12)* to the corresponding macrocyclic compounds. The sulfones *(3)* and *(4)* are clearly paratropic, the outer proton signals having moved to higher field as compared to the models, and the inner ones to lower field. This is a reversal of the behavior of the sulfides *(1)* and *(2)*[1].

The stereoisomeric sulfoxides *(9)* and *(10)* show remarkably different ^{1}H-NMR spectra. The spectrum of the *syn*-isomer *(10)*, and the changes in chemical shift as compared to its model, are very similar to those of the sulfone *(4)*. The paramagnetic ring current in the *syn*-sulfoxide *(10)* is evidently similar in magnitude to that of the sulfone *(4)*. On the other hand, the *anti*-sulfoxide *(9)* exhibits a spectrum quite different from those of *(4)* and *(10)*, and the changes in chemical shift as compared to its model *(11)* show *(9)* to be atropic[6]. Similarly, the electronic spectrum of the *syn*-sulfoxide *(10)* resembles that of the sulfone *(4)*, but is different from that of the *anti*-sulfoxide *(9)*.

Table 1. ^{1}H-NMR chemical shift data (τ values, 100 MHz, $CDCl_3$) of *(3)*, *(4)*, *(9)*, and *(10)* [a, b]. For details see text.

Compound	Outer H			Inner H			
	H^A	H^B	Allylic H	H^C	H^D	H^γ	H^β
(3)	3.70 (+0.22)	3.97 (+0.24)	7.6–8.0 (+0.1)	1.33 (−1.21)	5.63 (−0.90)	–	–
(4)	3.67 (+0.21)	4.05 (+0.23)	7.6–8.0 (+0.1)	1.07 (−1.46)	4.64 (−1.58)	7.64 (−0.41)	8.88 (−0.28)
(9)	3.17 (−0.20)	3.72 (+0.03)	7.5–7.9 (0.0)	2.18 (−0.43)	5.41 (−0.58)	8.44 [c]	9.27 (−0.05)
(10)	3.59 (+0.28)	4.00 (+0.27)	7.6–8.0 (+0.1)	1.01 (−1.56)	4.63 (−1.60)	7.60 (−0.44)	8.80 (−0.29)

[a] In addition, all compounds showed a band at *ca.* τ = 8.0—8.5 (aliphatic H).
[b] The assignments of H^B and H^C are based on nuclear Overhauser experiments and long-range coupling.
[c] The signal in the model *(11)* was obscured by the aliphatic H band.

The conformations of the thiapyran ring in the sulfoxides *(9)* and *(10)* are presumably those shown in the diagrams, other conformations being disfavored for steric reasons. It is possible that the sulfur orbitals play a part in the observed difference in properties between *(9)* and *(10)*. However, it is tempting to speculate that this difference is due to the fact that the axial sulfoxide oxygen in the *syn*-isomer *(10)* has a 2p orbital which is ideally disposed for overlap with the π-perimeter, giving a paratropic "Möbius" 18π-electron system[7]. The corresponding 2p orbital of the sulfoxide oxygen in the *anti*-isomers *(9)* is not so disposed, and the molecule is consequently atropic. The reason for the paratropic nature of the sulfones *(3)* and *(4)* would then be the same as that proposed for the *syn*-sulfoxide *(10)*.

[1] Unsaturated macrocyclic compounds. Part 108.—Part 107: *J. M. Brown* and *F. Sondheimer*, Angew. Chem. *86*, 346 (1974); Angew. Chem. internat. Edit. *13*, 337 (1974).

[2] All compounds were isolated by chromatography on silica gel (Woelm, activity II), unless indicated otherwise. ^{1}H-NMR, UV, IR, and mass spectra compatible with the assigned structures were obtained for all new substances.

[3] All new compounds decomposed on attempted melting point determination.

[4] Substance *(4)* was isolated by chromatography on alumina (Woelm, activity III).

[5] Substance *(8)* was isolated by direct crystallization since chromatography on silica gel effected little purification, and alumina caused isomerization to the corresponding 2*H*-thiapyran derivative.

[6] The downfield shifts of the inner H^C and H^D resonances in *(9)* are presumably due to local anisotropic effects [see *H. A. Staab* and *R. Bader*, Chem. Ber. *103*, 1157 (1970); *P. J. Beeby* and *F. Sondheimer*, J. Amer. Chem. Soc. *94*, 2128 (1972)] and are not accompanied by upfield shifts of the outer proton signals.

[7] We thank Dr. *H. M. R. Hoffmann* for this suggestion.

Synthesis of Homophthalic Acids by Copper-Catalyzed Direct Arylation of β-Dicarbonyl Compounds with 2-Bromobenzoic Acids.

By *Alle Bruggink* and *Alexander McKillop*[*]

We wish to report a simple, high yield procedure for the synthesis of homophthalic acids *(2)*. The method involves only two steps, namely (i) copper-catalyzed direct arylation of a β-keto ester with a 2-bromobenzoic acid and (ii) hydrolysis of the resulting α-acylhomophthalic acid half-ester *(1)*, $R^2 = OC_2H_5$, with dilute aqueous sodium hydroxide solution.

Other β-dicarbonyl compounds can be converted into substituted benzoic acids *(1)* in the same manner.

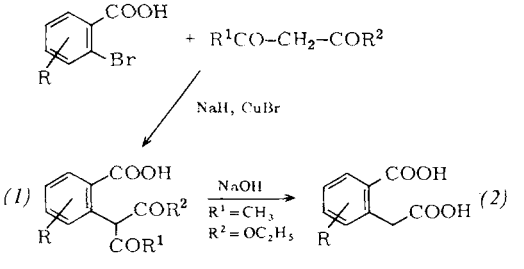

Table 1. Direct arylation of β-dicarbonyl compounds with 2-bromobenzoic acids to give compounds *(1)*, and hydrolysis of *(1)*, $R^2 = OC_2H_5$, to give homophthalic acids *(2)*.

R	R^1	R^2	Yield [%] *(1)*	Yield [%] *(2)* [a]
H	CH_3	CH_3	91	
H	CH_3	OC_2H_5	96	92
H	OC_2H_5	OC_2H_5	92	
H	C_6H_5	OC_2H_5	98	
4-CH_3	CH_3	CH_3	82	
4-CH_3	CH_3	OC_2H_5	99	88
4-CH_3	OC_2H_5	OC_2H_5	90	
4-NO_2	CH_3	CH_3	91	
4-NO_2	CH_3	OC_2H_5	98	90
4-NO_2	OC_2H_5	OC_2H_5	88	
5-CH_3O	CH_3	OC_2H_5	98	91
4,5-$(CH_3O)_2$	OC_2H_5	OC_2H_5	92	
3,4,5-$(CH_3O)_3$	CH_3	CH_3	84	
	OC_2H_5	OC_2H_5	84	

[a] Overall yield.

Treatment of 2-bromobenzoic acid with β-keto esters in the presence of sodium ethoxide and either copper powder or copper(II) salts gave erratic results which were difficult to reproduce[1–3]. The reaction mixtures obtained always con-

[*] Dr. A. Bruggink and Dr. A. McKillop
School of Chemical Sciences, University of East Anglia,
Norwich NOR 88C (England)

sisted of at least three products: the desired compound *(1)*, unchanged 2-bromobenzoic acid, and 2-ethoxybenzoic acid, the latter compound in amounts up to 25%; separation of these mixtures was tedious and yields of pure *(1)* were low (15–45%).

We have found that direct arylation of β-keto esters and β-diketones can, however, be effected in excellent yield when a mixture of the reagents (using a 5—10 fold excess of the β-dicarbonyl compound) and sodium hydride is heated at 60—80 °C for 0.5—2 h in the presence of 6 mol-% of copper(I) bromide. Under these conditions competitive side reactions are eliminated and, consequently, isolation of the pure products *(1)* is straightforward (the reaction mixture is diluted with water, extracted with ether to remove the excess β-dicarbonyl compound, and the aqueous layer acidified with hydrochloric acid). Representative conversions are listed in Table 1.

Retro-Claisen condensation of the α-acylhomophthalic acid half-esters *(1)*, $R^2 = OC_2H_5$, is an extremely facile process owing to intramolecular catalysis by the carboxylate anion. Thus, when *(1)*, $R^1 = CH_3$, $R^2 = OC_2H_5$, is dissolved in aqueous 2 N sodium hydroxide solution at room temperature, both retro-Claisen cleavage of the acetyl group and hydrolysis of the ester function are complete within 20—30 minutes. The homophthalic acids *(2)* are obtained in virtually quantitative yield upon acidification (Table 1).

Octaethylporphinatodioxoosmium(VI): An Extreme Metal Oxidation State within a Porphin System[**]

By *Johann Walter Buchler* and *Paul David Smith*[*]

Porphin derivatives of the homologs of iron, ruthenium[1] and osmium[2], have become known only recently. We now report the oxidation of carbonyl(octaethylporphinato)pyridineosmium(II) *(1)*[2] to octaethylporphinatodioxoosmium(VI) *(2)* with hydrogen peroxide[3].

The electronic spectrum [λ_{max} (log ε; CH_2Cl_2) = 578 (3.95), 470 (4.18), 428 (4.26), and 378 (5.09) nm] and the ^{1}H-NMR spectrum [δ($CDCl_3$) = 2.13 (t; CH_3), 4.25 (q; CH_2), and 10.75 (s; CH) ppm] show that the porphin ligand has remained intact. In the IR spectrum $\nu_{as}(OsO_2)$ appears at 825 cm^{-1} as the most prominent peak (*trans*-$[OsO_2Cl_4]^{2\ominus}$: 837 cm^{-1}[4]). Above 150 °C, *(2)* decomposes. Thus, no mass spectrum is available. Hitherto, hexavalent metals have not been found in metalloporphyrins[5, 6].

Cpd.	Os^n	X	X'
(1)	Os^{II}	CO	py
(2)	Os^{VI}	O	O
(3)	Os^{IV}	OCH_3	OCH_3
(4)	Os^{II}	py	py

Compound *(2)* is reduced by $SnCl_2$ in methanol to the orange Os^{IV} derivative *(3)*[3]. Finally, reduction of *(3)* with sodium dithionite in pyridine as well as photolytic decarbonylation of *(1)* in pyridine afford the Os^{II} derivative *(4)*[3].

The $Os^{II/IV/VI}$ system is the first porphin system in which the metal can take up or release a total of four electrons. This property is explained by the ability of the osmium atom to fit into the porphin ligand in all three oxidation states[6, 7].

Octaethylporphinatodioxoosmium(VI) (2)

Compound *(1)* (200 mg, 0.24 mmol) is dissolved in CH_2Cl_2 (15 ml) in a 50 ml wide-necked Erlenmeyer flask. Addition of CH_3OH (15 ml) is followed by dropwise addition of 30% H_2O_2 (2.5 ml). The mixture is allowed to stand for 1 h at 20 °C, and then heated to 60 °C for 3 h. After evaporation of the CH_2Cl_2, black needles of *(2)* (109 mg, ≈60%) are recovered by suction filtration and are washed with CH_3OH. Chromatography on neutral alumina (grade III) with CH_2Cl_2 yields a single olive-green zone of *(2)*. The compound is crystallized from CH_2Cl_2/CH_3OH and dried at 50 °C/10^{-3} torr.

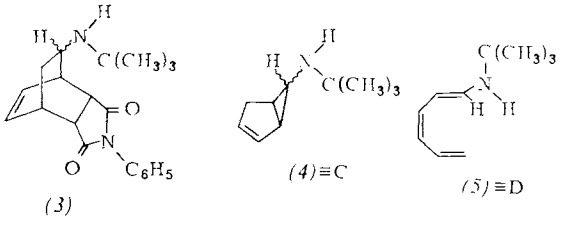
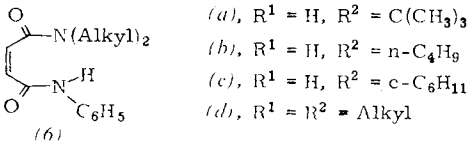
1,2-Photoaddition of Primary and Secondary Amines to Benzene

By *Derek Bryce-Smith*, *Andrew Gilbert*, and *Carl Manning*[*]



We have previously reported the 1,4-photoaddition of primary[1], secondary[1], and tertiary[2] amines to benzene, but we have now found that 1,2- and 1,3-adducts are also produced from primary, and 1,2-adducts from secondary, amines. Thus irradiation of an equimolecular mixture of *tert*-butylamine

[*] Prof. Dr. D. Bryce-Smith, Dr. A. Gilbert, and C. Manning
Department of Chemistry
The University of Reading
Whiteknights Park, Reading RG6 2AD (England)



and benzene under nitrogen at 20 °C (low pressure Hg lamp) gave a basic pale yellow oil, b. p. 32 °C 0.02 torr[**] composed of four 1:1 adducts A, B, C, and D [GLC (Carbowax 20M), elution order C, D, A, B]. The proportions were time dependent.

(1) (1a) ≡ A (2) (2a) ≡ B

(3) (4) ≡ C (5) ≡ D

(6) (a), R^1 = H, R^2 = $C(CH_3)_3$; (b), R^1 = H, R^2 = n-C_4H_9; (c), R^1 = H, R^2 = c-C_6H_{11}; (d), R^1 = R^2 = Alkyl

Components A and B were primary products (*ca.* 1:1 ratio), and were shown (IR, NMR, MS) to be the 1,2-adduct *(1a)* and the 1,4-adduct *(2a)* respectively. Adduct *(1a)* gave the Diels-Alder adduct *(3)*, m. p. 195—198 °C, with *N*-phenylmaleimide, and was readily dehydrogenated (10% Pd on C) to give *N-tert*-butylaniline. Although B *(2a)* was stable under the irradiation conditions, the isolated component A *(1a)* readily photoisomerized to compounds C and D, giving a photostationary state where A:C:D ≈ 2:1:1, the first two components of which were separated by preparative GLC. Comparison of the spectral data for isomer C with those reported for bicyclo[3.1.0]hex-2-ene derivatives indicates the structure *(4)* (1,3-adduct)[***]. The adduct D was thermally and photochemically labile, yielding isomers *(1a)* and *(4)*, and could not be isolated in a pure state. The spectroscopic properties of the mixture enriched in D clearly indicated the 1,3,5-hexatriene structure *(5)*: rearrangements of compounds of this type to 1,3-cyclohexadienes and bicyclo[3.1.0]hexenes are well known.

Analogous reactions have been observed between *n*-butyl- and cyclohexyl-amine and benzene: the products were of the type described above, with minor variations in proportions. Benzene and secondary amines gave slightly different results. The proportion of 1,2-adduct *(1d)* was dependent upon the amine used, but in all cases examined (dimethyl-, diethyl-, di-*n*-butyl-amine, and piperidine) this was between 10 and 15%, the remainder being the 1,4-adduct *(2d)*. The spectroscopic properties of the 1,2-adducts *(1a)* to *(1c)* and *(1d)* were closely similar, but surprisingly the adducts *(1d)* showed no tendency to isomerize either thermally or photochemically, and *N*-phenylmaleimide gave benzene and the diamide *(6)*, with no trace of the expected Diels-Alder adducts. Although secondary amines (diethylamine, piperidine) rapidly react thermally (20 °C) with *N*-phenylmaleimide to yield compounds of type *(6)*, the corresponding reaction with primary amines is anomalous in being much slower; tertiary amines do not react. Hence reaction of the adducts *(1d)* with this dienophile may in principle involve an induced initial decomposition to give the free secondary amine, but it is not clear why the adducts of types *(2a)* to *(2c)* do not give diamides analogous to *(6)*.

Bicyclo[3.1.0]hexenes analogous to compound *(4)* are known to be formed by irradiation of benzene in the presence of certain alcohols and acids, but these appear to arise by a different mechanism involving thermal acid-catalyzed addition to benzvalene[3].

The present reactions provide a simple one-step route to amines of types not readily available by other procedures.

2-Lithiated 1-*tert*-Butyl-3-methyleneaziridine and Its Reaction Products[**]

By *Helmut Quast* and *Carlos A. Weise Vélez*[*]

For a study of the stereochemistry of the thermal reorganization of methyleneaziridines[1] one requires suitably substituted derivatives. Although the preparation of 1-alkyl-2-alkylideneaziridines *(2)* (with or without substituents on C-3) by means of $NaNH_2$ in liquid NH_3 can be generalized, we attempted to modify *C*-unsubstituted methyleneaziridines *(5)*.

(1) (2)

(2a) [1], R^1 = Alkyl, R^2 = H, R^3 = CH_3
(2b) [2], R^1 = $C(CH_3)_3$, R^2 = CH_3, R^3 = H

Alkylation of 1-alkyl-2-methyleneaziridines *(5)* on the exocyclic methylene group in the presence of non-nucleophilic bases met with failure[1b], presumably because of the instability of the expected azirinium intermediates[3]. However, substitution of *(5b)* on the ring atom C-3 was accomplished, giving rise to the compounds *(7)*–*(9)*.

By experiments using ^3H-labeled NH_3 as solvent, *Bottini* and *Olsen*[4] had shown that *(5a)* is formed from *N*-propyl-2-bromoallylamine *via* the anions *(3a)* and *(4a)*[5]. Though no $^1H/^3H$ exchange occurs with $NaNH_2$ in liquid NH_3[4], we were able to generate 2-lithiated 1-*tert*-butyl-3-methyleneaziridine *(4b)*, M = Li, from *(5b)* by means of 1.5–2.0 mol of butyllithium/tetramethylethylenediamine (TMEDA) in ether at −78 °C. This product is colorless and stable up to *ca.* −50 °C.

Institut für Organische Chemie der Universität
87 Würzburg, Am Hubland (Germany)

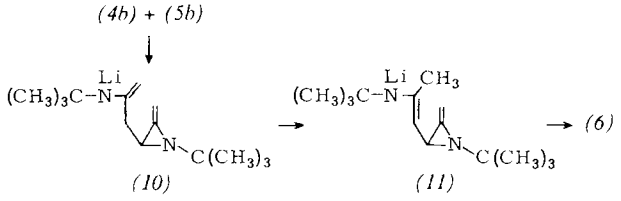
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. The results are taken from the Diplomarbeit of *C. A. Weise Vélez*, Universität Würzburg 1974. We thank Mr. *V. Formáček*, Bruker-Physik AG, Karlsruhe, for the ^{13}C-NMR spectra. C. A. W. V. thanks the Deutsche Akademische Austauschdienst for a grant.

[**] Neutral components [2] were removed prior to distillation.

[***] The only slight inconsistency with published data [3] was that in the present case a *J* value of about 10 Hz was found for the olefinic protons whereas values of 5–6 Hz are reported for related examples.

When the solution of *(4b)*, M = Li, is treated with an electrophilic reagent (X—E) at −78 C to 0 C for 12 h, aqueous work-up and preparative GLC permitted isolation of the ring-substituted methyleneaziridines *(7)*—*(9)* as colorless liquids,

(7), E = D, (X-E = CH_3OD)
(8), E = CH_3, (X-E = CH_3J)
(9), E = $(CH_3)_3Si$, (X-E = $(CH_3)_3SiCl$)



whose structures are proved by IR and ^{1}H-NMR spectra (all in CCl_4). *(7)* [+*ca.* 30% of *(5b)*], IR: 3100 (=CH_2), 2220 (—CHD—), 1770 cm^{-1} (C=C); ^{1}H-NMR (neat; 90 MHz); δ = 1.02 (s, 9H), 1.80 (mc, 1.3H), 4.37 (mc, 1H), 4.44 (mc, 1H). *(8)*, IR: 3090 (=CH_2), 1825 m, 1754 s, 1717 cm^{-1} m (C=C); ^{1}H-NMR (90 MHz): δ = 0.98 (s, 9H), 1.21 (dd, ^3J = 5.3 Hz, ^5J = 0.4 Hz), 4.30 (mc, 1H), 4.41 (mc, 1H). *(9)*, IR: 3095 (=CH_2), 1782, 1740 cm^{-1} (C=C); ^{1}H-NMR (60 MHz[6]): δ = 0.00 (s, 9H), 1.00 (s, 9H), 1.20 (mc, 1H), 4.33 (mc, 2H).

As expected, metalation of *(5b)* with *n*-butyllithium/TMEDA as described above proceeds more slowly than with *sec*-butyllithium/TMEDA. After 8 h at −70 to −60 C and addition of CH_3OD the product contained only 69% of *(7)* and 31% of *(5b)*[7]. Accordingly, use of methyl iodide furnished only 60—70% of *(8)* along with 30—40% of unchanged *(5b)*. However, with *sec*-butyllithium/TMEDA the anion *(4b)* is formed completely in 7.5 h at −78 C, as shown by its quantitative conversion into *(8)* or *(9)* by methyl iodide or trimethylchlorosilane, respectively.

Since methyleneaziridines *(5)* can be readily converted into α-chloroacetone[8], interesting possibilities result from using *(4)* and anions of other substituted methyleneaziridines as synthetic equivalents of enolates of α-hetero-substituted ketones.

A solution of *(4b)*, M = Li, becomes reddish-violet above −50 C and after 5.5 h at −78 to −15 C and addition of 1.5—2 mol of H_2O one obtains sublimable, pale yellow crystals, sensitive to air and moisture (m. p. 73—74 C, from pet. ether, yield 36%), which elemental analyses and mass spectrum show to be a dimer of *(5b)*. According to the ^{1}H-NMR spectrum in C_6D_6, two isomers are present in the ratio A : B = 3—4 : 1. The spectra prove the structure *(E,Z)-(6)*:

IR (Nujol): 3280 (NH), 3065, 3045 (=CH—), 1658 m, 1651 m, 1628 s, 1590 cm^{-1} w (C=N, C=C); ^{1}H-NMR (C_6D_6, 90 MHz) A: δ = 0.991 (s, NH—tBu), 1.08 (s, CH_3), 1.28 (s, =N—tBu), 2.36, 2.66 (AB, ^2J = 17.4 Hz, —CH_2—), 6.10, 6.31 ppm (AB, ^3J = 5.4 Hz, —HC=CH—). B[9]: δ = 0.986 (s, NH—tBu), 1.32 (s, =N—tBu), 2.56, 2.81 (AB, ^2J = 17.0 Hz, —CH_2—), 6.14, 6.49 (AB, ^3J = 5.8 Hz, —HC=CH—). In CD_3OD the AB quartet of the CH_2 group disappears owing to H/D exchange. ^{13}C-NMR of A (C_6D_6, 22.63 MHz): δ_c = 30.3 (q)[10], 31.8 (q), 32.5 (q), 46.4 (t), 51.6 (s), 55.6 (s), 65.4 (s), 135.6 (d), 154.1 (d), 170.7 ppm (s).

The formation of the dimer can be interpreted in terms of *(4b)* + *(5b)* → *(10)* → *(11)* → *(6)*. The step *(11)* → *(6)* is paralleled by the isomerization of vinylmethylenecyclopropanes[11] and their O-analogs[12].

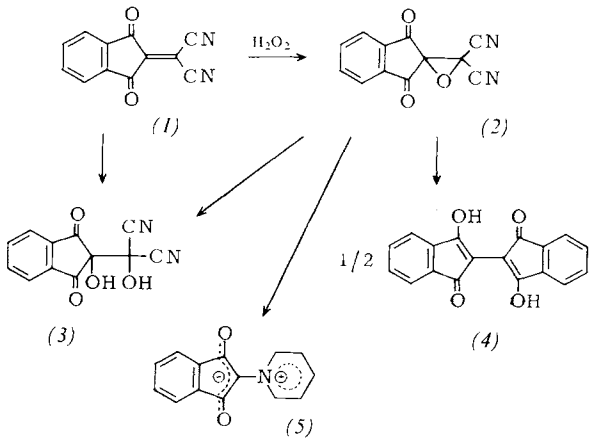
A Pyridinium Ylide of 1,3-Indandione[**]

By *Hans Junek*, *Albin Hermetter*, and *Herwig Fischer-Colbrie*[*]



The exocyclic double bond in (1,3-dioxo-2-indanylidene)malononitrile *(1)* can be readily functionalized to give the epoxide *(2)* by heating with H_2O_2 (35%) in acetone. This reaction corresponds to the behavior of electron-deficient olefins on nucleophilic attack by hydrogen peroxide anions[1]. 1,3-Dioxospiro[indan-2,2'-oxirane]-3',3'-dicarbonitrile *(2)* is obtained in 50% yield [colorless needles, m. p. 205 C (from chlorobenzene)][2].

Compound *(2)* is relatively stable towards protic solvents: only after prolonged heating in glacial acetic acid is it converted into the dihydroxy compound *(3)* (40% yield). (2-Hydroxy-1,3-dioxo-2-indanyl)hydroxymalononitrile *(3)* is also obtained on treatment of *(1)* with H_2O_2 in glacial acetic acid [colorless needles, m. p. 280 C (dec.)][2].

[**] Syntheses with Nitriles, Part 37. Part 36: *H. Junek*, *A. Hermetter*, and *H. Fischer-Colbrie*, Tetrahedron Lett. 1973, 2993.

Nucleophilic reactions proceed with great ease with the oxirane *(2)*; a mechanism involving formal elimination of mesoxalonitrile can be assumed. Thus on reaction of *(2)* with aniline, two indanyl groups combine to form 3,3'-dihydroxy-2,2'-bi-1-indenone *(4)*[3]. The reaction of *(2)* with pyridine in THF leads to a yellowish precipitate *(5)* within a few minutes. 3-Oxo-2-(1-pyridinio)-1-indenolate *(5)*, which can be formulated as an ylide, is a relatively stable compound and can be recrystallized from H_2O or acetonitrile [yellow needles, m.p. 255 °C, 60% yield, IR (KBr): 1580, 1610 cm^{-1}; MS: *m/e* (rel. int. %) = 167 (17), 223 (100); UV (C_2H_5OH): $\lambda = 390$ ($\varepsilon = 17700$), 310 (5350), 235 (30000), 220 nm (18500).

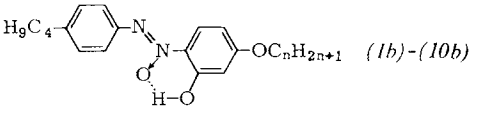
Low Melting Liquid Crystalline *o*-Hydroxy Azo- and Azoxybenzenes

By *Jan van der Veen* and *Theodorus C. J. M. Hegge*[*]

Recently a number of liquid crystalline salicylideneanilines were prepared[1]. As Schiff bases are unstable compared with azo- and azoxybenzenes it was thought worthwhile to investigate whether *o*-hydroxy substituted azo- and azoxybenzenes show liquid crystalline behavior too. The azo compounds were prepared by coupling of the appropriate diazonium tetrafluoroborate with resorcinol in acetone/water at a temperature between 0 and 5 °C. The *p*-hydroxyl group is alkylated by reaction of the potassium salt with an alkyl iodide in dimethylformamide to give the azobenzenes *(1a)*—*(19a)*[2] (Table 1).

(1a)-(19a)



NMR and IR spectra[4] as well as elemental analyses were in accordance with the structures given above.

Compounds *(6a)* and *(7a)* are nematic at room temperature. *(6a)* showing a broad nematic range of 74 °C. Compounds *(1a)*—*(10a)* generally have clearing temperatures (T_c) similar to or somewhat higher than the corresponding compounds without an *o*-hydroxyl group[5]. This could be due to intramolecular hydrogen bonding leading to π-electron delocalization[6]. One can expect that the polarizability along the long axis of the molecules will be larger in *(1a)*—*(10a)* than in the unsubstituted analogs. Consequently the anisotropy in the polarizability and thus T_c[7] will be somewhat higher. No simple explanation can be offered for the minimum in the melting points within the homologous series *(1a)*—*(10a)*. Compounds *(1a)*—*(10a)* do not show the well-known *trans-cis* photoisomerization of azobenzenes since the *trans*-isomer is strongly stabilized by the intramolecular hydrogen bond. Compounds *(1a)*—*(10a)* were oxidized to *one* of the azoxy isomers *(1b)*—*(10b)*, as was indicated by NMR measurements (see experimental procedure and Table 2). The compounds gave correct elemental analyses.

Table 1. Melting points and clearing points (T_c) of the azobenzenes *(1a)*—*(19a)*.

Compound	*n*	M.p. [°C]	T_c [°C]
R = *n*-C_4H_9			
(1a)	1	68	60

(19a)	9	85	128 S → N 116 [b]

[a] A second crystal modification has a m.p. of 17 °C.
[b] S = smectic, N = nematic.

(1b)-(10b)

Table 2. Melting points and clearing points (T_c) of the azoxybenzenes *(1b)*—*(10b)*.

Compound	*n*	M.p. [°C]	T_c [°C]
(1b)	1	82—84	80
(2b)	2	79	101.5
(3b)	3	68	82
(4b)	4	66	92.5
(5b)	5	59—61	88
(6b)	6	57	93
(7b)	7	53	91
(8b)	8	54	93
(9b)	9	63—65	91
(10b)	10	63	92

The clearing temperatures of *(1b)*—*(10b)* are very similar to those of the unsubstituted analogs[8].

[*] Dr. J. van der Veen and Th. C. J. M. Hegge
Philips Research Laboratories
Eindhoven (The Netherlands)

The static dielectric constants were measured at 1592 Hz for some typical compounds[9]. At 50 C compound *(6a)* has a dielectric anisotropy of 0.14 ($\varepsilon_{\parallel}=3.50$, $\varepsilon_{\perp}=3.36$). For the corresponding azoxybenzene [compound *(6b)*] at 60°C ($\varepsilon_{\parallel}=3.52$, $\varepsilon_{\perp}=3.69$) a dielectric anisotropy of −0.17 is found. Substitution of the butyl group in *(6a)* by a cyano group leads to a strong increase of the dielectric anisotropy as expected. For compound *(16a)* a dielectric anisotropy of 10.8 at 105 C is found ($\varepsilon_{\parallel}=16.9$, $\varepsilon_{\perp}=6.1$).

5-Ethoxy-2-(4-butylphenyl-NNO-azoxy)phenol (2b) from (2a)

Compound *(2a)* (2.0 g, 0.007 mol) is dissolved in acetonitrile (90 ml) and ethanol (20 ml). $NaHCO_3$ *(5g)* is added, followed by 30% hydrogen peroxide (20 ml). The reaction mixture is heated to its boiling point on a waterbath and allowed to cool down for 30 min at room temperature. After filtration to remove $NaHCO_3$ the filtrate is cooled to −20 C and then filtered once more. The precipitate [*(2b)*] is recrystallized from acetonitrile. Yield 1.2 g (57%) of *(2b)*.

Rb_4P_6, a Phosphide with Planar Six-Membered Phosphorus Rings[1]

By *Walter Schmettow, Annegret Lipka,* and *Hans Georg von Schnering*[*]

On treating rubidium with red phosphorus (Solidex ampoule; Rb:P = 1:2.5; 450 C; 48 h; addition of a few milligrams of sulfur[2]) we obtained Rb_4P_6 as a compact black substance together with about the same amount of another, red, phosphide that has not yet been studied. Tetrarubidium hexaphosphide is instantaneously hydrolyzed in the air, yielding, along with monophosphane, first a pale yellow higher phosphane which within a few hours assumes a dark brown-to-black color.

In connection with the structure it is important that the compound is established as free from sulfur. Rb_4P_6 crystallizes orthorhombically in Fmmm with $a=9.641(1)$, $b=14.629(3)$ and $c=9.009(1)$ Å (Guinier-Simon photographs[3]); $Z=4$. The atoms occupy the following positions [x; y; z]: Rb(1) in 8g [0.2818; 0; 0], Rb(2) in 8f [1/4; 1/4; 1/4], P(1) in 8h [0; 0.1483; 0] and P(2) in 16m [0; 0.0734; 0.2053]. For 497 reflections $R=0.065$ and $R'=0.097$ (two-circle diffractometer data; Ag-Kα; solution by direct methods[4]).

The structure can be derived from the AlB_2 type by ordered removal of each fourth atom from the boron network. A

Anorganisch-chemisches Institut der Universität
44 Münster, Gievenbecker Weg 9 (Germany)

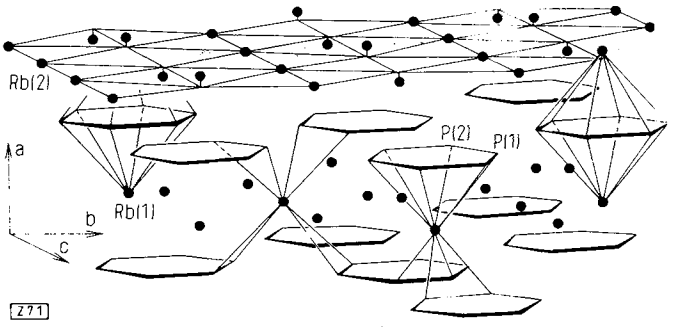

Fig. 1. Rb_4P_6 structure (Rb = black dots; P at the corners of the hexagons). The displacement of Rb(1) from the rubidium plane (above), and its relation to the hexagonal-bipyramidal Rb_2P_6 units, are indicated.

superstructure results in which structural units of AlB_2 type and NiAs type alternate along [011] and [01$\bar{1}$]. Isolated phosphorus six-membered rings thus appear in the Rb_4P_6 structure. These rings are exactly planar and regular to within experimental error (cf. Fig. 1). Each P atom is bivalent towards phosphorus and additionally surrounded trigonal-prismatically by six Rb atoms. The P—P separations in the six-membered ring amount to 2.149 (4×) and 2.150 Å (2×) with a standard deviation of ±0.008 Å, while the distances between the rings exceed 3.7 Å. Unlike the case of the AlB_2 structure, the Rb atoms do not lie strictly in one plane; Rb(1) is removed distinctly from the plane. Hexagonal-bipyramidal Rb_2P_6 units can be recognized, which are formed each from one P_6 ring and two Rb(1) and are connected by Rb atoms. Rb(1) is bonded to ten P atoms (3.46—3.55 Å), and Rb(2) to eight P atoms (3.56—3.62 Å).

It could be shown that the isotypic potassium compound K_4P_6 also exists [$a=9.361(1)$, $b=14.268(2)$, $c=8.644(1)$ Å][5]. A formal P_6^{4-} unit should contain four bivalent and two trivalent, but not six bivalent, P atoms. Rb_4P_6 and K_4P_6 are thus the first alkali-metal phosphides for which this simple, hitherto satisfactory, bonding concept[6] fails. Since the bonding rule needs to be obeyed only by semiconductors, these compounds could display metallic conductivity; otherwise double-bond contributions must be assumed in the P_6 ring; a bond order $n=1.16$ is in at least mathematical agreement with the short P—P separation of 2.15 Å.

No 1,4-dithiocin *(3)* was obtained on reaction of *(5)* with various bases in various solvent systems. The major product was *(8)* [m.p. 45 °C; yield 5—25%; NMR ($CDCl_3$): δ = 6.25 (s, 2-H, 3-H), δ = 6.13 (m, 7-H, 8-H), δ = 5.05 (m, 6-H), AB part of an ABX system at δ = 3.88 and δ = 2.89 (5-H^a, 5-H^b), $J_{5a,5b}$ = 14 Hz, $J_{5a,6}$ = 5 Hz, and $J_{5b,6}$ = 7 Hz, δ = 2.56 ppm (br. s, OH)]. The yield of *(8)* was most reproducible and highest with KOH in DMF/water (3:1). *(8)* is optically active; the rotation of its acetate (m.p. 84 °C) in $CHCl_3$ amounts to $[\alpha]_D^{21} = 134°$.

Attempts to convert the alcohol *(8)* into *(3)* have so far been unsuccessful. In contrast, the preparation of *(10)* and *(11)* could be performed in the following manner: Oxidation of *(8)* with CrO_3 in HMPT for 16 h gave, in addition to 70% of unreacted *(8)*, the ketone *(9)* [yellow oil; yield 10%; NMR ($CDCl_3$): AB systems at δ = 7.10 and 6.21 (7-H, 8-H; J = 9 Hz), at δ = 6.77 and 6.68 (2-H, 3-H; J = 3 Hz), δ = 4.33 ppm (s, 2 5-H); IR ($CHCl_3$): 1665 cm^{-1}]. Treatment of *(9)* with lithium diisopropylamide in THF at −78 C followed immediately by reaction of the highly sensitive enolate with trimethylchlorosilane or acetyl chloride afforded *(10)* and *(11)*, respectively, in 30% yield.

Whereas *(10)* reverts to *(9)* on distillation or preparative thin-layer chromatography, 1,4-dithiocin-6-yl acetate *(11)* could be purified in this way and recrystallized from *n*-hexane/ether [m.p. 45 C; NMR (100 MHz, $CDCl_3$): AB systems at δ = 6.92 and 6.00 (7-H, 8-H; $J_{7,8}$ = 9 Hz with additional allyl coupling for 7-H: $J_{7,5}$ = 1 Hz), and 6.19 and 6.05 (2-H, 3-H; J = 9 Hz), δ = 5.76 (d, 5-H; $J_{7,5}$ = 1 Hz), δ = 2.17 (s, CH_3): UV (cyclohexane): λ_{max} = 225 (ε = 5380), 249 sh (3050), 255 sh (2550), 285 nm (3100); IR ($CHCl_3$): 1760 cm^{-1}; mass spectrum: *m/e* 43 (100%), 45, 94, 113, 158, 200 (M^+, 2%)[4].

(9)

(10), R = $Si(CH_3)_3$
(11), R = $COCH_3$

In accord with theoretical predictions[5], the spectroscopic properties do not appear to indicate an aromatic character of *(11)*, although the NMR spectrum (in particular) is not so clearly olefinic in character as that of *(1)*[2] so that the preparation of *(3)* is certainly still a matter of interest. Compound *(11)* does not form a Diels-Alder adduct with maleic anhydride, tetracyanoethylene, or hexafluoro-2-butyne. On heating above 50 C, *(11)* slowly decomposes with deposition of sulfur to give phenyl acetate, presumably *via* the *syn*-bisepisulfide[2].

Preparation and Properties of Tetraoxotechnetate(VI) and Tetraoxorhenate(VI)

By *Klaus Schwochau, Ludwig Astheimer, Jürgen Hauck*, and *Hans-Joachim Schenk*[*]

The existence of the oxoanions of hexavalent technetium and rhenium analogous to MnO_4^{2-} has not yet been established[1], although their formation has been postulated from spectrophotometric[2] and electrochemical[3] investigations.

We have now succeeded in preparing violet $[(CH_3)_4N]_2TcO_4$ and olive green $[(CH_3)_4N]_2ReO_4$ by controlled potential cathodic reduction of the tetramethylammonium salts of pertechnetate and perrhenate in acetonitrile with $(CH_3)_4NClO_4$ as supporting electrolyte. The pure crystalline compounds were deposited on a platinum electrode in a yield of more than 90%. The potential adjustment was based on the half-wave potentials measured polarographically for a one-electron transition ($E_{1/2}$ = −1.74 V for pertechnetate and $E_{1/2}$ = −2.30 V for perrhenate; saturated calomel electrode). Under similar conditions dark green $[(CH_3)_4N]_2MnO_4$ could also be precipitated; the half-wave potential of permanganate in acetonitrile was found to be $E_{1/2}$ = −0.60 V. Violet-blue K_2TcO_4 can be obtained by reduction of a solution of $KTcO_4$ in dimethyl sulfoxide at a mercury cathode. Tetraoxotechnetate(VI) and tetraoxorhenate(VI) are extremely sensitive to oxygen and atmospheric moisture which cause rapid oxidation and disproportionation; preparations must therefore be carried out in an inert atmosphere (argon) glovebox.

Susceptibility measurements on $[(CH_3)_4N]_2MO_4$ yielded magnetic moments of μ_{eff} = 1.61 (M = Mn), 1.56 (M = Tc), and 1.36 μ_B (M = Re), respectively. These values are in good agreement with theoretical predictions for tetrahedrally coordinated d^1-systems, where orbital contributions from excited states are not negligible. The compounds crystallize in isotypic cubic face-centered lattices with a = 11.09 (Mn), 11.20 (Tc), and 11.35 Å (Re); Z = 4. Reflection extinctions point to the space groups F23 or F$\bar{4}$3m; an unambiguous distinction presumes the localization of the hydrogen atoms. The metal atoms of the tetrahedral anions occupy the corners and the face centers of the unit cell, whereas the nitrogen atoms of the $(CH_3)_4N$ terahedra are placed at $\frac{1}{4}\frac{1}{4}\frac{1}{4}$. The structure resembles the antifluorite lattice.

Infrared measurements show the stretching modes of TcO_4^{2-} and ReO_4^{2-} to be shifted towards lower frequencies by almost 130 cm^{-1} compared to pertechnetate and perrhenate; the wave numbers are $\nu_3(F_2)$ = 780 and $\nu_4(F_2)$ = 340 cm^{-1} for TcO_4^{2-} and $\nu_3(F_2)$ = 785 and $\nu_4(F_2)$ = 325 cm^{-1} for ReO_4^{2-}.

Cubic splitting parameters of $\Delta_{tetr.}(TcO_4^{2-}) = -16.7$ kK and $\Delta_{tetr.}(ReO_4^{2-}) = -20.7$ kK were derived from diffuse reflectance spectra in the visible and ultraviolet. Both results compare

517 Jülich 1, Postfach 365 (Germany)

favorably with the known value[4] $\Delta_{tetr.}(MnO_4^{2-}) = -12.0$ kK. The splitting of the $^2E(\Gamma_8) \rightarrow {}^2T_2(\Gamma_8)$ band indicates strong Jahn-Teller distortion of the oxoanions in the excited state.

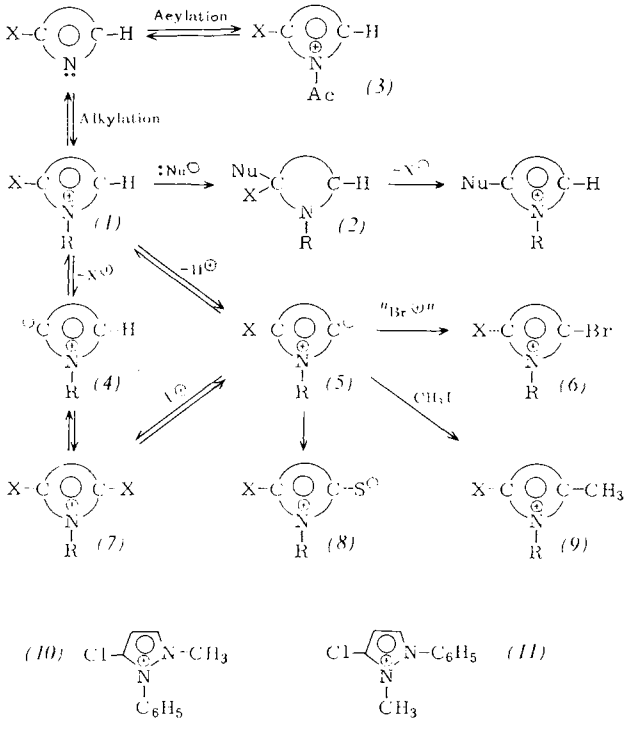
CONFERENCE REPORTS

2nd German-Danish Symposium on Organic Chemistry



The Universities of Aarhus, Hamburg, Kiel, Copenhagen, and Odense organized a German-Danish Symposium on Organic Chemistry at Kiel from August 31 to September 2, 1973.

From the lectures:

Reactions of Azolium Salts with Nucleophilic Reagents

By *Mikael Begtrup*[*]

Azolium ions *(1)*[1] can react with nucleophilic reagents with substitution, proton abstraction, removal of a cation, dealkylation, or ring cleavage.

The substitution reactions of pyrazolium, imidazolium, and 1,2,3-triazolium salts are addition-elimination processes in which the addition step is rate-determining. The rate of substitution of azolium salts with different ring structures consequently increases with increasing stability of the intermediate *(2)*, which can be estimated from the resonance structures. This basis of assessment is inadequate for the prediction of the relative substitution rates of substitution isomers, *e.g. (10)* and *(11)*, since steric factors obviously become more important here. In this case one can determine the ratio of the substitution rates of a suitable pair of isomers. This empirical value normally depends only on the ring system and on the *N*-substituents.

The above-mentioned azolium salts react with electrophilic reagents in the presence of bases *via* the azolium ylides *(5)*. The formation of the ylide is rate-determining. The stability of the ylide can be estimated by measurement of the rate of the base-catalyzed replacement of the ring protons in the starting compound by deuterium.

The faster the deuterium exchange, the faster is the conversion into *(6)* *e.g.* with *N*-bromoacetamide and sodium methoxide. Stronger bases increase the rate of ylide formation. In the presence *e.g.* of sodium hydride in dimethylformamide, even substrates with weakly acidic ring protons react with sulfur and with methyl iodide to form *(8)* and *(9)*, respectively.

The rate of removal of cations, *e.g.* "$Br^{\oplus}$", from the azolium ions *(1)* increases with the stability of the resulting ylide *(4)* (which can again be determined from the rate of deuterium exchange).

In the case of azolium salts from which cations can be removed as well as protons, it is possible for the cation liberated to attack the ylide *(5)* formed by deprotonation, with formation of *(7)*.

This process is reversible, since *(7)* exists in equilibrium with the cations and the ylide *(4)*. The decisive steps for product formation are the nucleophilic substitution of *(1)* and *(7)*. This cation exchange explains the formation of anomalous substitution products of a series of azolium salts.

Acylazolium ions *(3)* can also lose cations. In these cases the free azole acts as the cation acceptor.

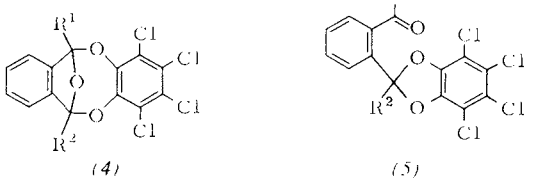
[1] In "azolium salts" the cation consists of a five-membered ring with 6π electrons and at least two nitrogen atoms.

Cycloaddition Reactions of *o*-Quinonoid Compounds[**]

By *Willy Friedrichsen*[*]



o-Benzoquinone diimides [*(1)*, R^1 = benzoyl, benzenesulfonyl; $R^2 = R^3 = H$; $R^2 = R^3 = CH_3$; $R^2 = H$, $R^3 = Cl$] react with diphenylketene and with olefins, like certain *o*-quinones[1], to form 2-oxo-1,2,3,4-tetrahydroquinoxalines *(2)* or 1,2,3,4-tetrahydroquinoxalines *(3)*[2]. Unsymmetrical *o*-benzoquinone diimides [*(1)*, R^1 = benzoyl, benzenesulfonyl; $R^2 = H$, $R^3 = Cl$] form both regioisomers *(2)* in the former case; the structures of the isomers were determined by partial synthesis.

(1) *(2)* *(3)*

Kinetic studies (activation parameters, solvent dependence of the rate constants, competition experiments) agree with the assumption that the reactions leading to *(2)* and *(3)* are Diels-Alder reactions with inverse electronic requirements.

1,3-Diarylisobenzofurans react with *o*-quinones thermally to form 6,11-epoxydibenzo[*b*,*f*][1,4]dioxocins *(4)* and/or dioxoles *(5)*[3] (formulated for the reaction with tetrachloro-*o*-benzoquinone). Investigations on the mechanism [reaction of 1-(tetramethylphenyl)-3-phenylisobenzofuran to form *(5a)* (R^1 = tetramethylphenyl, R^2 = phenyl)[4] and *(5b)*

(4) *(5)*

(R^1 = phenyl, R^2 = tetramethylphenyl), (activation parameters, by measurement of the temperature dependence of the rate constants and of the product distribution)] show that the reaction is entropy-controlled and proceeds *via* an isopolar transition state.

Steric Effects in the Mass Spectra of Monocyclic and Bicyclic Diols and Their Derivatives

By *Hans-Friedrich Grützmacher*[*]

The differences in the mass spectra of stereoisomeric compounds are partly due to elimination reactions of the molecular ions, which must proceed *via* a transition state with a specific steric arrangement. Since the steric conditions for the transition state can be easily checked with the aid of molecular models, a mass-spectrometric identification of stereoisomers is possible in this way without the use of reference spectra.

It is known that a stereospecific 1,4-elimination of H_2O occurs in the molecular ions of cyclohexanol. Investigation of the mass spectra of stereoisomers of the cyclopentanediols, cyclohexanediols, and cycloheptanediols, and their dimethyl ethers also show stereochemical control for the elimination of HOR (R = H, CH_3) and CH_2O from the molecular ions if the substituents occupy the 1,3 or 1,4 positions. In the *trans* compounds the elimination of HOR dominates the fragmentation, whereas the elimination of CH_2O is characteristic of the *cis* compounds. The stereochemical control of the fragmentations also persists in *C*-methylated derivatives of 1,3-cyclohexanediol, with the exception of the 2-methyl and 2,2-dimethyl derivatives, in which fast ring cleavage of the molecular ions occurs.

Surprisingly, however, the expected steric effects cannot be detected in the mass spectra of the positional isomers and stereoisomers of the bicyclo[2.2.1]heptanediols and their dimethyl ethers. On the other hand, the expected effects are again observed in the mass spectra of decalindiols and of corresponding dimethyl ethers, so that mass-spectrometric identification of the stereoisomers is possible in this series of compounds. It is interesting to note that stereochemical control of the elimination reactions is also found for the 1,5-dimethoxydecalins if the methoxy groups can come close together in any conformation of the molecular ions.

Constitution of the Polymers and the Coordination Compounds of Formaldehyde Oxime[**]

By *Kai Arne Jensen*[*]

Evidence obtained from chemical properties and infrared spectra shows that "triformoxime" or "trimeric formaldehyde oxime" is actually a chain polymer. The known acetyl and benzoyl derivatives of formaldehyde oxime are, however, derivatives of a cyclic trimer, 1,3,5-trihydroxyhexahydro-1,3,5-triazine. Similarly, the known hydrochloride, $(H_2CNOH)_3HCl$, and also other salts, contain the cyclic trimer, but on neutralization they depolymerize to formaldehyde oxime. The cyclic trimer could, however, be prepared by a special method. It is readily soluble in water but is rapidly transformed into the water-insoluble polymer. In aqueous solution it is partially depolymerized to formaldehyde oxime.

Analysis of the ^1H-NMR spectra of solutions of $(H_2CNOH)_3HCl$ in deuterium oxide has shown that, in aqueous solution, an equilibrium exists between monomeric and trimeric formaldehyde oxime and, at higher pH values, is shifted completely towards the monomeric form.

The hydrochloride, $(H_2CNOH)_3HCl$, forms very intensely colored coordination compounds with nickel, iron, and manganese salts. There has been some doubt whether these complexes are derived from monomeric or trimeric formaldehyde oxime. According to above mentioned studies the ligand must be the anion of monomeric formaldehyde oxime. This is substantiated by a detailed infrared spectroscopic investigation of the complexes, as well as by other physical methods. In

the course of our studies the compounds were prepared in a pure state for the first time. The transition metal in the three complexes has the oxidation state 4+, also in the iron compound which has hitherto been formulated with iron(III).

Reaction between Electrophiles and Electrolytically Generated Anions

By *Henning Lund*[*]

Transfer of an electron to a neutral molecule produces a radical anion which may react as a radical, a nucleophile, or a base.

In the two latter cases a neutral radical is produced which may accept an electron, thus forming an anion capable of reacting with a proton or an electrophile. If the reaction of the electrophile with anion radicals or anions is to compete with their reaction with protons, the medium must be aprotic.

Electrophiles are generally reducible. In the present investigation we used substrates which are more easily reduced than the electrophiles; direct electron transfer to the latter is avoided by control of the electrode potential.

In dimethylformamide acetic anhydride may be used as electrophile in a reductive acetylation of nitro compounds to *N,O*-diacetylated hydroxylamines. Nitrogen- and other heterocyclic compounds may be reductively acetylated in a similar manner.

Alkyl halides or other alkylating agents may be used as electrophiles too. Fluorenone may be reductively methylated to 9-methoxy-9-methylfluorene with methyl chloride. Other types of compounds have been reductively alkylated, such as mono- and diketones, imines, and disulfides.

The mechanism of the reaction between the radical anion and an electrophile such as methyl chloride seems best descibed as an S_N2-like reaction rather than an electron transfer in solution to the alkyl halide followed by a reaction between an alkyl radical and a substrate radical anion.

The reactivity of a given radical anion depends on its counter ion. Large cations, such as tetrabutylammonium ions, form loose ion pairs, and the anion is thus relatively reactive; Li^+ may be regarded as an electrophile which reacts reversibly with the anion.

1,2,3-Triazolines

By *Carl Erik Olsen*[*]

5-Hydroxy-Δ^2-1,2,3-triazolines *(4)* were early postulated as intermediates in the Dimroth reaction[1], but were not isolated. They also play an important part in the "diazo group transfer reaction"[2].

In the present work, a series of compounds *(4)* were prepared by reaction of monoketones *(1)* with organic azides *(2)* in the presence of potassium *tert*-butoxide. The investigation of their chemical properties led to the scheme shown[3] for the possible base-catalyzed reactions of carbonyl-activated methylene compounds with azides. Which of the possible end products are formed [*(3)* or *(5)*, *(8)*, or *(7)* or *(6)*] depends on the position of the equilibria shown inside the box, the leaving ability of the groups R^1NH and R^5, and the kinetic acidity of the 4-H atom.

On treatment with acid, the triazolines *(4)* yield 1,2,3-triazoles *(8)* or, after removal of nitrogen and 1,2-rearrangement, α-amino ketones or amides.

The stereochemistry at C-4 and C-5 was determined by NMR spectroscopy. The triazoline ring appears to assume an envelope conformation, with the hydroxyl group axial and R^1 equatorial.

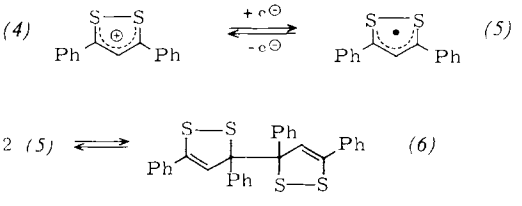
New Aspects of 1,2-Dithiole Chemistry

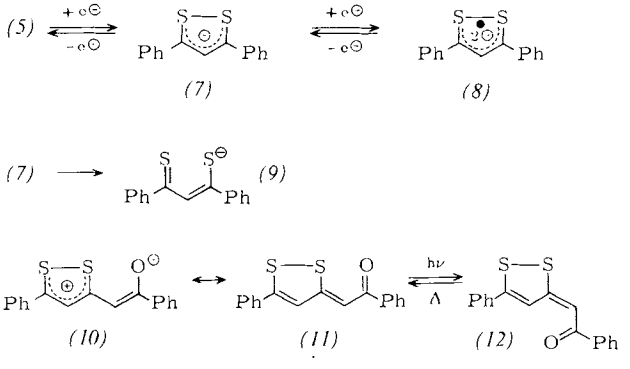
By *Carl Th. Pedersen*[*]

Cathodic reduction of 3,4-diphenyl-1,2-dithiolylium salts such as *(1)* in acetonitrile on a platinum electrode is accompanied by the formation of a dimer *(2)*[1]. The structure of the dimer was confirmed by the formation of 1,2,5,6-tetraphenylhexane upon Raney nickel desulfurization. Attempts to convert the



[*] Lektor Dr. Carl Th. Pedersen
Odense Universitet
DK-5000 Odense (Denmark)

dimer *(2)* into the tetrathiofulvalene *(3)* by electrochemical or chemical methods have been without success.



(1) *(2)* *(3)*

In contrast to the "irreversible electrochemistry" of *(1)* the electrochemistry of its 3,5-diphenyl analog *(4)* was completely reversible[2, 3]. Preparative reduction of the salt resulted in the formation of a grass-green solution which displayed a well resolved ESR spectrum. This was taken as evidence for the formation of the stable radical *(5)*. At lower temperature

(4) *(5)* *(6)*

the color faded and the ESR signal disappeared, at higher temperature the color and the ESR signal reappeared, possibly indicating an equilibrium between *(5)* and *(6)*. Further reduction resulted in the formation of the anion *(7)* and the dianion radical *(8)*. The anion *(7)* was not stable and was rapidly converted into the propanedithionate *(9)*.

(7) *(8)* *(9)* *(10)* *(11)* *(12)*

Photolysis of *(4)* in ethanol resulted in the formation of *(5)* and *(9)*[4]. Although dithiolylidene ketones *(11)* can be considered a kind of inner dithiolylium salts *(10)*, the photochemistry of *(11)* was quite different from that of dithiolylium salts. Irradiation of *(11)* in cyclohexane or ethanol resulted in the formation of the *trans* form *(12)* which reverted to the starting material by a dark process[5]. The rate constant for the thermal back reaction was found to be strongly dependent upon the steric requirements of the substituent in position 4 of the dithiole ring.

NMR Spectroscopic Studies on Hindered Rotation in Primary Amides and Thioamides

By *Ernst Schaumann*[*]

The (thio)amide system is planar as a result of resonance. The anisochronism of the substituents on the nitrogen that is to be expected on the basis of canonical formula *(2)* cannot generally be detected for primary (thio)amides (R′=R″=H), since the NH_2 signal is strongly broadened because of the quadrupole moment of the ^{14}N nucleus. The quadrupole broadening can be eliminated by irradiation at the ^{14}N resonance frequency, and a sharp AB quadruplet is recorded for the NH_2 protons[1]. According to the result of the benzene dilution method and the long-range coupling constants, which are resolved in the case of thioformamide (R=R′=R″=H, X=S), the *cis* proton (R″=H) in thioamides (X=S) is more strongly shielded than the *trans* proton (R′=H), whereas the opposite shielding pattern is found for amides (X=O) at room temperature. In ^{15}N-labeled compounds the $^1J_{^{15}N-^1H}$ coupling having the greater magnitude occurs with the *trans* proton in amides and with the *cis* proton in thioamides.

(1) *(2)* X = O, S

The free energies of activation $\Delta G^{\neq}$ determined from the coalescence of the NH_2 signals are about 3 kcal/mol higher for the primary thioamides, corresponding to a stronger contribution of the canonical formula *(2)*, than for the amides. Moreover, the $\Delta G^{\neq}$ values are distinctly dependent on the hydrogen bond acceptor capacity of the solvent, and for R=alkyl they decrease with increasing size of R and simultaneously increasing positive inductive effect. For R=aryl, a resonance interaction of the (thio)carbonyl group with the aromatic ring competes with the (thio)amide resonance; this interaction is strongest for R=*p*-anisyl (*p*-$CH_3OC_6H_5$) and leads to a rotation barrier that is 0.7 kcal/mol lower than for R=C_6H_5, X=S. A comparison of the $\Delta G^{\neq}$ values found for the primary (thio)amides with the known rotation barriers for *N,N*-dimethyl-(thio)amides (R′=R″=CH_3)[2] shows that for R=H and R=CH_3 the *N*-methyl substitution leads to intensified hindrance of rotation as a result of the positive inductive effect of the methyl group, whereas for R=$C(CH_3)_3$, the steric effect of the substituents on the nitrogen is decisive, and particularly low barriers are found for the tertiary compounds.

On addition of trifluoromethanesulfonic acid, a new signal appears in the spectrum of thiobenzamide at $\delta = 6.37$ ppm (in $CDCl_3$); this signal is not affected by ^{14}N decoupling, but is split with $^3J_{^{15}N-^1H} = 2$ Hz in the case of the ^{15}N compound, and must therefore be regarded as the signal of an SH proton[3]. The increased hindrance of rotation that is to be expected on *S*-protonation is also observed (in $CH_3NO_2/C_6D_5NO_2$, $\Delta G^{\neq} = 17.9$ kcal/mol; on addition of acid, $\Delta G^{\neq} > 19.4$ kcal/mol).

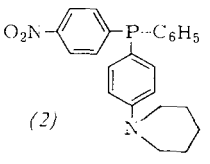
The Electronic Effect of Phosphorus and Its Preparative Consequences



By *G. P. Schiemenz*[*]

The question of the electronic effect of phosphorus as a substituent on the benzene ring led to a need for aromatic phosphanes with (if possible several) second order substituents, and the answer opened up new synthetic pathways.

The sum of the electronic effects of the phosphane phosphorus results in electron acceptor qualities, so that an electrophilic aromatic substitution is possible only in exceptional cases, *e.g.* in the *m*-nitration of triphenylphosphane, in which the phosphorus is not oxidized under controlled conditions; under more severe conditions, the reaction yields (m-O_2N—$C_6H_4)_3PO$, from which tris(m-nitrophenyl)phosphane is obtainable on the 100 g scale by reduction with $HSiCl_3$. The phosphanes (o-, m-, p-CH_3CO—$C_6H_4)_n(C_6H_5)_{3-n}P$, $n=1,2,3$ (only $n=1$ for the *ortho* compound) and p-$(C_6H_5)_2P$—C_6H_4CHO can be prepared by side-chain oxidation and reduction with $HSiCl_3$; the triarylphosphanes containing an o-, m-, or p-acetyl or formyl group in one, two, or three aromatic rings are more readily obtainable from $(C_6H_5)_{3-n}PCl_n$, $n=1$, 2, 3, and the o-, m-, and p-dioxolanyl derivatives *(1)*, R = CH_3, H, with subsequent hydrolysis of the dioxolane ring[1].

(1)

(2)

The acceptor effect of the phosphorus is partly mesomeric, so that particularly in phosphane chalcogenides, o- and (more easily) p-halogen, above all fluorine, can undergo nucleophilic substitution, *e.g.* with R_2N, RHN, HO, NC, and O_2N groups. In $C_6H_5P(X)(C_6H_4$—F-$p)_2$, X = O, S, both fluorine atoms can be replaced by two identical or different groups; the products include (after reduction with $HSiCl_3$) $C_6H_5P(C_6H_4NO_2$-$p)_2$ and chiral phosphanes such as *(2)*, an ideal compound for the discussion of the possibilities of conjugation through phosphorus[2].

Hammett correlations of the phosphanes with acceptor substituents in the *para* position show for reaction on the phosphorus that the σ scale and not the σ^- scale is valid for the acceptors. This confirms the earlier result that even in these particularly favorable systems, the phosphane phosphorus is unable to exert any appreciable $+M$ effect. The evaluation method makes it possible for the first time to obtain information about the electronic effect of phosphorus from reactions on the phosphorus itself rather than on the second substituents[1].

A Convenient Method for the Conversion of Aldehydes into Nitriles[**]

By *Erich Vowinkel*[*]

Aldehydes can be converted into nitriles under very mild conditions and in quantitative yields by treating their oximes with dicyclohexylcarbodiimide (DCC) in the presence of copper(II) halides to form the corresponding isoureas, which decompose spontaneously with loss of *N,N'*-dicyclohexylurea. The entire process is carried out without isolation of the intermediates, and is complete in 1—3 hours at room temperature.

$$R{-}CHO + NH_2OH \xrightarrow[2)\ Cu^{2+},\ N(C_2H_5)_3]{1)\ \text{pyridine},\ H_2O,\ HCl} R{-}CN$$
$$\text{DCC},\ CH_2Cl_2$$

In pyridine/water the first step proceeds quantitatively. The second step, addition of the aldoxime to the carbodiimide, occurs selectively if the DCC is stabilized against the direct attack of water in the two-phase system by addition of triethylamine.

This method fails when oxime formation is disturbed. In the case of the aromatic o-hydroxy aldehydes, for example, the OH group must first be blocked. For this purpose we used benzyl ether protective groups, which can later be removed by hydrogenolysis without affecting the nitrile group (yields 95—99%).

The rate-determining step of the nitrile formation is the addition of the aldoxime to the carbodiimide. With a 20% excess of DCC this step follows first-order kinetics, since the intermediate complex that is assumed to be formed from Cu^{2+}, halide ions, and carbodiimide ligands has only a limited solubility. Electronic and steric factors have little or no influence on the rate of the nitrile formation. Some examples of preparative yields, based on the aldehydes, are: 99.5% for 3-nitrobenzonitrile; 99.4% for 4-diethylaminobenzonitrile; 97.1% for 3-methoxy-2,6-dinitrobenzonitrile; and 97% for ferrocenecarbonitrile.

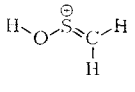
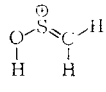
Perturbed Electrocyclic Reactions: A Three-Membered Ring Example

By *James P. Snyder*[*]



Simple thiocarbonyl *S*-oxides are known to decompose under a variety of conditions to give the corresponding ketone or aldehyde and sulfur. Cyclization to a three-membered ring can be considered to be a reasonable, but at present experimentally unverified, first step in the reaction. In order to gain an insight into the possible mechanism of the process, the electrocyclic closure of the sulfur series *(1)*—*(4)* has been investigated by an MO-CNDO-SCF procedure.



(1)

(2)

(3)

(4)

The thiocarbonyl derivative *(1)* behaves exactly as expected for a π-analog of the allyl anion. Conrotatory closure is allowed ($\Delta E = 15$ kcal/mol); disrotatory forbidden ($\Delta E > 37$ kcal/mol). Surprisingly both conrotatory *and* disrotatory closures of the protonated *S*-oxides *(3)* and *(4)* are predicted to be allowed from an orbital symmetry point of view and of similar energy ($\Delta E = 28$ and 29 kcal/mol respectively). This result arises from

[*] Dr. James P. Snyder
Chemical Laboratory II
H. C. Ørsted Institute
University of Copenhagen
Universitetsparken 5
DK-2100 Copenhagen Ø (Denmark)

an energy reordering of both the π-HOMO of the open systems *(2)*—*(4)* and the in-plane lone pair sulfur orbitals for the corresponding three-membered rings relative to the symmetrical ylide *(1)*. The overall consequence of substitution of an electronegative group (*i.e.* $O^{\ominus}$, OH) for CH_2 is an orbital correlation which differs entirely in character from that of the allyl anion case. The energy equivalence of conrotatory and disrotatory closure for *(3)* and *(4)* suggests a variety of stereochemical consequences for similar systems perturbed strongly by substitution.

ABSTRACTS

Reviews

Abstracts of selected progress reports and review articles

Antiaromaticity is discussed in a review by *R. Breslow*. A cyclic conjugated system is considered to be antiaromatic if its π-electron energy is higher than that of the reference compound which is not cyclically delocalized. Suitable reference compounds are, *e.g.*: for cyclobutadiene *(1)* the open-chain analog 1,3-butadiene *(2)* (alternatively: two isolated

(1) *(2)* *(3)* *(4)*

ethylene molecules); for the cyclopropenyl anion *(3)* the allyl anion *(4)* (alternatively: a carbanion and a double bond in isolated molecules). Major antiaromatic effects have been detected in both these systems and in the cyclopentadienyl cation. In the case of higher membered systems it is difficult to decide whether or not they are antiaromatic in the sense of the energy definition. [Antiaromaticity. Accounts Chem. Res. *6*, 393—398 (1973); 38 references]

Membrane-active polypeptides from snake venom—cardiotoxins and hemocytotoxins—are reviewed by *E. Condrea*. In addition to the snake-venom basic polypeptides exhibiting neurotoxic activity, a new group of basic polypeptides showing hemolytic, cytolytic, depolarizing, and cardiotoxic effects have recently been studied. These polypeptides exhibit pronounced structural similarities and a relatively low toxicity for animals. They can be grouped together as membrane-active polypeptides which modify cell membrane structures and impair membrane function, and thus prepare the way for the action of snake venom on normally inaccessible membrane substrates. For instance, they favor the action of phospholipase from snake venom while themselves exhibiting only slight lytic activity. Polypeptides and enzymes from snake venom act synergically. Different cell types react differently toward membrane-active polypeptides, *e.g.* neoplastic cells more readily than normal ones. The article also discusses changes in the membrane due to interaction of S—S groups of the polypeptides with SH groups of the membrane, linkage with membrane by way of electropositive charges, and penetration of the membrane structure with the aid of lipophilic side chains. [Membrane-active Polypeptides from Snake Venom: Cardiotoxins and Haemocytotoxins. Experientia *30*, 121—129 (1974); 58 references]

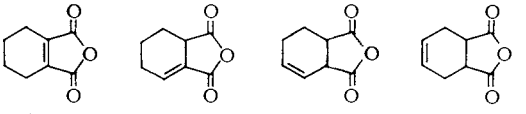
4-(2-Hydroxybutoxy)-2-butanol *(1)* can be used as a cholagogue because of its low toxicity and its high activity. The reaction of 1,2-butylene oxide with 1,3-butanediol in the presence of basic catalysts has proved particularly suitable for its preparation. [DOS 2164847; Nippon Zoki Pharmaceutical Co. Ltd., Osaka]

$$CH_3{-}CHOH{-}(CH_2)_2{-}O{-}CH_2{-}CHOH{-}C_2H_5 \quad (1)$$

[PR 156 IE—K]



Carbon fibers having cation exchange properties are obtained by treatment of carbon fibers with a mixture of 2—96 wt.-% of nitric acid, 2—45 wt.-% of potassium dichromate, and 2—80 wt.-% of water at temperatures up to the boiling point of the solution. The treatment time is 5 min to 10 h. The procedure described leads to only a slight decrease in the mechanical strength of the fibers, which can be used at pH 3—12. The wettability of the fibers and their ability to be bonded when used for the production of fiber-reinforced plastics are improved. [DOS 2205122; Kureha Kagaku Kogyo K. K., Tokyo]

[PR 163 IE—A]

Heat-resistant thermoplastic polyesters are obtained by the use of 4,4'-bis(2-hydroxyethoxy)tetraphenylmethane as the diol component in the production of polyesters by conventional methods from aromatic and possibly aliphatic dicarboxylic acids and possibly other aliphatic or cycloaliphatic diols, particularly ethylene glycol, together with small quantities of cross-linking compounds. Polyesters obtained in this way have glass transition temperatures of up to 120 °C. Because of the higher glass transition temperatures, the range of application of the polyesters is significantly extended. In particular, they are suitable for the production of heat-resistant moldings for the electrical industry. [DOS 2218518; Sandoz AG, Basel]

[PR 165 IE—T]

By isomerization of 1,2,3,6-tetrahydrophthalic anhydride *(4)* on a rhodium catalyst, one can obtain *(1)*, *(2)*, and *(3)*, which are more suitable than *(4)* *e.g.* for the production of tetraazaporphin pigments. The products are essentially isomer mixtures that consist of various quantities of the individual isomers [*e.g.* more than 80 wt.-% of *(1)*] according to the reaction conditions (80—250 °C) or that are liquid at room temperature. The rhodium catalyst may also be used for the isomerization of derivatives of *(4)*, *e.g.* esters or low alkyl derivatives. *(4)* is readily obtainable from maleic anhydride and 1,3-butadiene. [DOS 2211408; Koppers Co., Pittsburgh, Pa.]

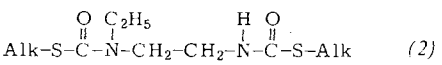
(1) *(2)* *(3)* *(4)*

[PR 168 IE—U]

Pyridine *(1)* **and 3-picoline** *(2)* are obtained in higher yields by the continuous gas-phase reaction of ammonia, acetaldehyde, formaldehyde, and methanol on an SiO_2/Al_2O_3 catalyst if the catalyst has a carbon content of 6—12%. The reaction

$$CH_3OH + CH_2O \rightleftharpoons CH_3OCH_2OH$$

$$NH_3 + CH_3CHO + CH_3OCH_2OH \longrightarrow \underset{(1)}{\text{pyridine}} + \underset{(2)}{\text{3-picoline}}$$



is carried out at 400—550 °C in a fluidized bed with continuous regeneration of the catalyst with air (burning off of C). The C content of the catalyst is adjusted by suitable choice of the regeneration conditions. [DOS 2203384; Rütgerswerke AG, Frankfurt]

[PR 181 IE G]

Esters of *N,N'*-ethylenedicarbamic and ethylenedithiocarbamic acids having the formula *(1)* (R, R^3 = alkyl; R^1, R^2 = H, lower alkyl; X, X^1 = O, S), in particular the compound *(2)* with

(1)

Alk = C_3, C_4-alkyl, are insect metamorphosis inhibitors similar to the natural juvenile hormone. [DOS 2324020; Stauffer Chemical Co., New York (USA)]

[PR 183 IE S]

To prepare heat-curable acrylic polymers, polyacrylic esters containing hydroxy groups are mixed with a polyfunctional 1,3,4-dioxazol-2-one (nitrile carbonate) having the formula *(1)* and cured at 120 to 150 °C. The polymers containing hydroxy groups are obtained by copolymerization of acrylic or methacrylic esters with hydroxyethyl or hydroxypropyl

(1)

(meth)acrylates. The hydroxyl values are between 20 and 150, and the acid values between 0 and 25 mg of KOH/g of substance. The preferred nitrile carbonate is adiponitrile carbonate *(1)*, R = $-(CH_2)_4-$, $n = 2$. On curing, free isocyanate groups are formed, and these crosslink with the hydroxy groups. Adiponitrile carbonate is used mainly as a crosslinking agent for acrylic varnishes. [DOS 2220806; Atlantic Richfield Co., New York (USA)]

[PR 186 IE W]

BOOK REVIEWS

Bakterien-, Phagen- und Molekulargenetik (Bacterial, Phage, and Molecular Genetics). By *U. Winkler*, *R. Rüger*, and *W. Wackernagel*. Springer Verlag, Berlin—Heidelberg—New York 1972. 1st ed., xi, 285 pp., 15 figures, stitched DM 14.80.

The present book is an attempt to fill a gap among the German-language practical textbooks for universities. It appears to me that the attempt has been successful. The book contains a large number of carefully written experimental procedures for practical courses in molecular genetics. Each experiment is preceded by an introduction giving the theoretical background. This is followed by aim, materials, procedure, evaluation, literature data, and sometimes exercises for practice (with answers). The description of the experiments is so detailed that the student can profitably work through an experiment even if he has not carried it out. Each experiment is followed by a suggestion regarding the recording of the results, a safe didactic form that can save the course supervisor a great deal of irritation, but in some cases also slightly relieves the student of the need to think over the experiment.

Besides many experiments with *Escherichia coli* and corresponding phages, the book contains a surprisingly large number of experiments with *Serratia marcescens* and Serratia phages. The main reason why so much space is devoted to this second bacterium is probably that it is one of the author's working organisms. In my opinion it would have been better from the student's point of view to extend the experiments with *E. coli*, the "pet" of molecular biologists. For example, the book fails to describe an experiment as important as the penicillin selection of auxotrophic mutants in *E. coli*. The authors are not consistent in their use of abbreviations; alongside the German DNS, RNS, *etc.*, they use English abbreviations such as EDTA and cpm. A detailed subject index should be regarded as an absolute necessity for the next edition.

The usefulness of the present book to the advanced student would undoubtedly have been increased by more frequent indications of the relationships with current research work, and not just with reviews. The book should be very useful as a German-language introduction and as a handbook for practical courses in molecular genetics. It is to be hoped that it will give many students an understanding of molecular genetics[*].

Klaus Willecke [NB 180 IE]

Koordinationsverbindungen (Coordination Compounds). By *S. F. A. Kettle*. Taschentext Vol. 3. Verlag Chemie, Weinheim 1972. 1st ed., xii, 245 pp., 106 figures and 25 tables, bound DM 16.80.

The "representative coverage" of a field of chemistry as large as modern coordination chemistry in a handy volume of the Taschentext ("pocket text") series is nowadays practically impossible without drastic limitations. The book by *Kettle*, which was first published in English in 1969 and is now available in a German translation, is thus confined mainly to the coordination chemistry of the transition metal ions, omitting all organometallic, compounds and systems containing metal ions in lower oxidation states. The book is arranged not according to groups of substances but according to general aspects such as "Nomenclature and Geometrical Structure" (Chapter 2), "Preparation" (Chapter 3), "Stability" (Chapter 4), "Crystal Field Theory" (Chapter 5), "Ligand Field Theory" (Chapter 6), "Electronic Spectra" (Chapter 7) "Magnetic Properties" (Chapter 8), "Other Methods for the Investigation of Coordination Compounds" (Chapter 9), "Thermodynamic and Related Aspects of Crystal Fields" (Chapter 10), and "Reaction Kinetics" (Chapter 11).

The author's marked interest in problems of electronic structure and static bonding in transition metal complexes can be seen *e.g.* from the fact that Chapters 5 to 8 together with the "theoretically" oriented Appendix occupy more than 125 of the 242 pages in the book, whereas the treatment of *e.g.* equally important topics of reaction kinetics and mechanisms is clearly too short, covering only 17 pages.

[*] For more advanced requirements and as a source of technical hints relating to *E. coli* genetics, see the recent work by *J. H. Miller*: "Experiments in Molecular Genetics", Cold Spring Harbor Laboratory, 1972.

While the section "Quantum-Mechanical Calculation of the Orbital Angular Momentum" has been added to the Appendix in the translation, the references to more advanced and additional literature which are given in the English version have unfortunately been omitted. The retention or the updating of these references would have helped to make the otherwise very readable book even more suitable for use as a basis of, and as supplementary reading for, lectures on coordination compounds.

R. D. Fischer [NB 184 IE]

Die Analyse der organischen Verunreinigungen in Trink-, Brauch- und Abwässern [The Analysis of Organic Impurities in Drinking Water, Water for Industrial Use, and Effluents]. By *W. Leithe*. Wissenschaftliche Verlagsgesellschaft mbH, Stuttgart 1972. 1st ed., xii, 172 pp., 21 figs., 22 tables, bound DM 48.—

The investigation of impurities in water samples from trade, industry, agriculture, and the home is becoming increasingly important. Owing to the extreme diversity of the substances and agents with which water bodies are being increasingly contaminated, it is often necessary to limit the investigation to the determination of total contents of certain groups or to use specific methods for individual substances that are of special interest. In the present book the author tries to provide the first survey of the very topical analysis of organic impurities in water.

An introduction to the problems of the contamination of water, biological self-purification in running water, and the purification processes in clarification plants is followed by a very detailed description of methods for the quantitative estimation of classes of organic material. These include methods for the determination of organic carbon, the potassium permanganate and bichromate consumptions, and the biochemical oxygen demand. This is followed by a description of analytical methods for groups of substances and individual substances, such as fatty acids, cyanides, phenols, detergents, nitrilotriacetic acid, hydrocarbons (benzines and mineral oils), chlorinated hydrocarbons, pesticides, urea, uric acid, coprosterols, urochromes, humic acids, lignin and ligninsulfonic acids, and 3,4-benzpyrene.

With this large collection of special analytical methods for organic contaminants in drinking water, water for industrial use, and effluents, the book is a valuable addition to the standard literature on water analysis, and can be strongly recommended to all chemists concerned with the investigation and assessment of water bodies.

Dieter Eichelsdörfer [NB 193 IE]

Struktur und Reaktivität polarer Organometalle (Structure and Reactivity of Polar Organometallic Compounds). By *M. Schlosser*. Springer-Verlag, Berlin—Heidelberg—New York 1973. 1st Edit., x, 187 pp., 29 figures, bound DM 78.—.

This clearly and fluently written book deals with the structure and reactivity of organometallic compounds of alkali and alkaline earth metals. It is supplemented by a section on C—H acidities, to which a very large amount of space (64 out of 187 pages) has been devoted.

Structures in the crystal lattice, the possible aggregations of polar organometallic compounds in solution (from the dimers resulting from association *via* electron-deficient bonds to the compounds that are dissociated into metal cations and carbanions by solvation), and the connection between aggregation and reactivity are described in detail. The sections on parameters that influence reactions and on the control of reactions are particularly interesting.

Carefully chosen tables, *e.g.* the scale of "organometallically projected" C—H acidities of hydrocarbons, as well as very clear diagrams and a considerable number (447) of references even to very recent literature further increase the value of the book to the organometallic chemist who is more familiar with the other groups of the periodic system.

The book unfortunately contains a number of traps for the non-specialist and for the student; these traps are partly due to the quantitative indefiniteness of the adjective "polar", but are partly also laid by the author himself when he writes *e.g.* "the ideal case of an organometallic reaction is the carbanion process". While reading this book it would be easy to forget that it describes only one (extreme) aspect of organometallic chemistry, and the non-specialist could take the part for the whole.

With and in spite of this reservation, this is a readable, very stimulating book.

Herbert Lehmkuhl [NB 196 IE]

Techniques of Electrochemistry. Vol. 1. By *E. Yeager* and *A. J. Salkind*. Wiley-Interscience, New York—London 1972. 1st Edit., ix, 581 pp., various figures and tables, bound £ 11.70.

To forestall any misunderstandings, it should be stated that this book is concerned exclusively with electrochemical experimental and measuring techniques in the laboratory. As stated in the foreword, preparative methods and techniques for electrochemical reactions and processes will be dealt with in later volumes. Another peculiarity of this book, which is understandable in view of its American orientation, is the strong emphasis that is placed on the theoretical principles and the detailed quantitative discussion of the measuring methods described.

This is particularly noticeable in the first article, by *R. G. Bates*, on equilibrium potentials. It is not until the last few pages that the reader learns anything about the preparation of reference electrodes. However, the instructions for the platinization of platinum electrodes are not precise and therefore cannot be used, while the instructions for silver/silver chloride and calomel electrodes are unnecessarily complicated. The article by *R. Payne* on the electrochemical double layer is much more balanced. The rigid double layer is also referred to on p. 65 as the Perrin layer and on p. 72 as the Helmholtz layer. The measuring methods based on the capacity of the double layer, the surface potential, and voltammetry are described in detail, but almost exclusively for mercury electrodes. *A. Salkind* describes the measurement of the true surface area and the porosity of electrodes from a practical standpoint. The predominantly non-electrochemical methods, which are mostly described for the example of lead dioxide, can also be found in books on catalysis.

The topical field of electrochemical kinetics is finally discussed in two long chapters. *J. Kuta* and *E. Yeager* describe the stationary and non-stationary electrical methods. The relationships from the mercury drop electrode are discussed in particular detail. However, cyclic voltammetry is also touched upon. The non-electrochemical methods are summarily dealt with in the chapter by *B. E. Conway*. The emphasis here is on optical methods. The article, which was completed in 1969, naturally contains little information on fields such as ATR spectroscopy that have developed rapidly only during the past few years. Some parts of the article overlap with the chapter by *Payne*.

The book is addressed to the electrochemist, who will certainly welcome a review of measuring and experimental methods in this field. The book contains no operating procedures. Little importance is attached to experimental skill. For

example, one finds nothing about the pretreatment of solid electrodes, which is always critical. The presentation of the book is good. The typescript will probably not please everyone; it certainly does not make mathematical equations easy to read.

F. Beck [NB 197 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal.

Quantitative Thin Layer Chromatography. Edited by *J. C. Touchstone*. John Wiley and Sons, New York 1973. XIV, 330 pp., bound £ 7.50.

The Stable Isotopes of Oxygen in Research and Technical Applications

By Dieter Staschewski[*]

The stable isotopes of oxygen have proved to be efficient research tools; however, only a small fraction of the possible applications of these isotopes have been examined so far. The present progress report deals with five basic types of isotopic effects whose investigation and evaluation offer information of a new kind about physical, chemical, and biological systems and processes.

1. Introduction

The spectroscopic detection of deuterium in a residue from the evaporation of liquid hydrogen by *Urey* in 1931[1,2] was the start of a new development in research and industry that resulted in the investigation and use of the stable isotopes of the natural elements. Natural oxygen consists of three stable isotopes ^{16}O, ^{17}O, and ^{18}O, whose concentrations in atmospheric oxygen are reported to be as follows[3]:

^{16}O 99.7587 atom %
^{17}O 0.0374 atom %
^{18}O 0.2039 atom %

The isotopes of oxygen also include unstable species having the mass numbers 13, 14, 15, 19, 20, 21, 22, 23, and 24[4,5]. Among the artificially produced radioactive isotopes, ^{15}O has the longest half-life (2.1 min). The short lifetimes of the active isotopes places severe limits on their use, and investigations with the stable isotopes of oxygen are therefore much more common. In the present report the isotopes of oxygen are taken as a basis for a review of the methods and achievements of isotope research and technology. Classification of the data[6–9] leads to five fundamental types of investigations, which differ in objectives and methods. These five types are concerned with the investigation and evaluation of the following effects: 1, isotope effects; 2, fractionation effects; 3, isotopic labels; 4, nuclear and electron spin resonance; and 5, nuclear reactions.

These effects can be used as a principle for the classification of investigations with stable isotopes. Necessarily, many experiments exhibit the characteristics of several categories. For a complete survey, moreover, it would also be opportune to discuss isotope analysis and isotope preparations. These represent the basis of any isotope experiment, and consequently do not fit into the application-oriented scheme of the fundamental effects.

2. Isotope Effects

The isotopy of an element depends on differences in the numbers of neutrons and in the masses of the atomic nuclei. The differences in the atomic nuclei lead to changes in the physicochemical properties of isotopic atoms and molecules; in isotopically substituted substances and systems these changes are defined as the isotope effect. Investigations on isotope effects are mostly concerned with the relative deviations of the non-nuclear properties of the isotopically pure components. The isotope effect of isotope mixtures requires a special treatment, since it cannot always be easily deduced from the properties of the pure components.

The properties of natural oxygen and its derivatives are determined almost entirely by the isotope ^{16}O. The existence of two other stable isotopes makes oxygen a special case in

the series of light elements up to fluorine. Pronounced deviations from the standard set by ^{16}O are to be expected in particular for ^{18}O, which is heavier by two mass units. In principle, the isotope effect in molecular systems leads to variations in the same basic information. Thus the combination of the three oxygen isotopes with the hydrogen isotopes H and D gives a maximum of nine isotopic water molecules (a total of 18 water molecules when tritium is included), and the combination with the carbon isotopes ^{12}C and ^{13}C gives a maximum of twelve stable variants of CO_2. Like the multiplicity of spectral line systems, isotopic multiplicity gives a new dimension to experimental and theoretical investigations.

2.1. Physical Properties of Isotopic Compounds

The changes in properties due to isotopy generally decrease with increasing atomic weight of the elements. Very accurate measurement is therefore usually necessary for the detection of the isotope effect in isotopic oxygen compounds. An absolute determination of the isotopic composition is essential, since the results of the measurements must be extrapolated to an isotope content of 100%.

Distinct isotope effects can be seen in Table 1 for the physical constants of water species with the isotopes H, D, ^{16}O, and ^{18}O. These differences are particularly important in connection

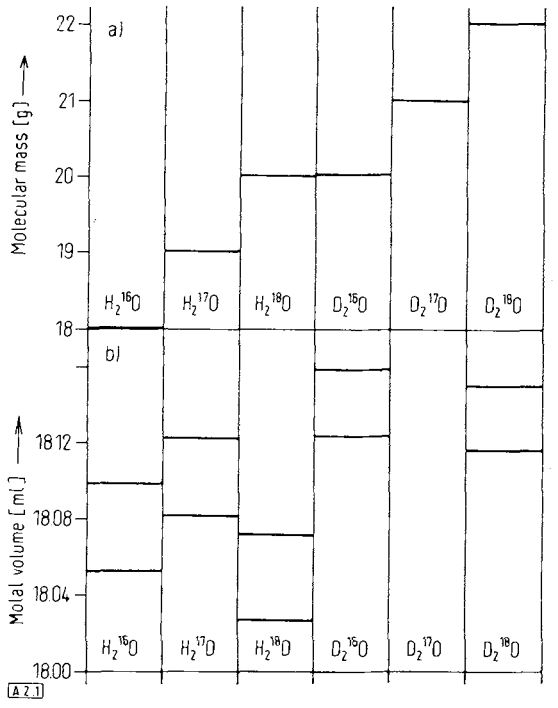

Fig. 1. a) Molecular weights and b) molal volumes of isotopic water species. Temperature dependence of the molal volume in the liquid phase: upper level 30 °C, lower level 20 °C.

Table 1. Physical properties of isotopic water species.

Property	$H_2^{16}O$	$H_2^{18}O$	$D_2^{16}O$	$D_2^{18}O$
Density at 20 °C [g/ml] [10]	0.99797	1.11064	1.10513	1.21622
Temperature of maximum density [°C] [10]	3.98	4.30	11.24	11.46
Melting point [°C] [10]	0.00	0.28	3.81	4.02
Boiling point [a] at 760 torr [°C]	100.00	100.14	101.42	101.54
Heat of evaporation [a] at 25 °C [cal/mol]	10518	10530	10868	10878
Viscosity at 20 °C [cP] [13, 14]	1.0020	1.0564	1.2471	1.3050

[a] Calculated from the vapor pressures according to [11, 12].

with the standardization of fundamental physical constants if water is used for calibration. Since natural water shows considerable variations in its D and ^{18}O contents, it is necessary to redefine the calibration basis for the liter, the g/ml density, the temperatures of 0 and 100 °C, *etc.* As a standard water, "Standard Mean Ocean Water" (SMOW), a mixture of waters taken from depth regions of all the oceans[15], has been in general use for several years. The molal volumes calculated from the densities of the isotopic water species (Fig. 1) show very great irregularity in the trend of the isotope effect; it has not yet been established which water species behaves normally and which behaves anomalously.

The substitution of a light isotope by a heavy one in a molecule leads to a shift of the lines in the Raman and IR spectra. This shift, normally taking a course toward lower frequencies, can be calculated to a first approximation by means of the Teller-Redlich product rule. Thus on replacement of the oxygen in acetone by ^{18}O, the frequency of the CO stretching vibration changes by $-23\,cm^{-1}$ ($1707 \rightarrow 1684\,cm^{-1}$) and that of the CO deformation vibration by $-14\,cm^{-1}$ ($531 \rightarrow 517\,cm^{-1}$)[16]. More pronounced isotope effects of oxygen are found in the molecular spectra of the hydrolysis products of UF_6[17,18]; thus a $\Delta\nu_s(UO)$ of $-52\,cm^{-1}$ ($893 \rightarrow 841\,cm^{-1}$) is found for UOF_4 (Fig. 2), and a $\Delta\nu_{as}(UO_2)$ of $-53\,cm^{-1}$ ($1020 \rightarrow 967\,cm^{-1}$) for UO_2F_2. The former value agrees well with the simplified product rule.

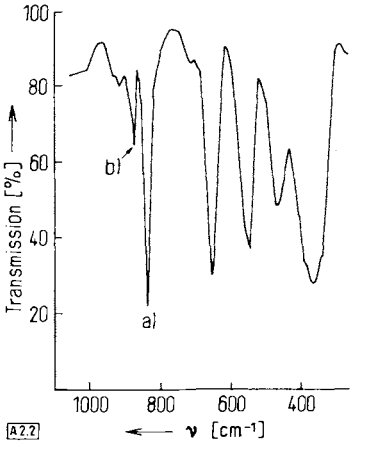

Fig. 2. Isotope effect in the IR spectrum of UOF_4 containing 90 atom % of ^{18}O (from *Jacob et al.* [17]); a) $\nu_s(U^{18}O)$, b) $\nu_s(U^{16}O)$.

In principle, the isotopic frequency shift allows a reliable assignment of the measured frequencies to certain group vibrations or normal vibrations, and is therefore of vital importance to the proof of the molecular structure. ^{18}O introduced into

a compound in the highest available concentration thus serves as an indicator for the identification of the molecular vibrations.

Table 2. Frequency anomalies in the stretching vibrations [cm^{-1}] of XO_4 anions.

Anion	State		$\nu(X^{16}O_4)$	$\nu(X^{18}O_4)$	$\Delta\nu_{exp.}$	$\Delta\nu_{calc.}$ [a]	Ref.

		ν_3	958	982	+24		

[a] Calculated with the aid of the Teller-Redlich product rule.

A previously unknown inverse isotope effect was found by *Pinchas et al.*[19-24] in the vibrational spectra of some anions of oxo acids in aqueous solution (Table 2). On complete replacement of ^{16}O by ^{18}O, the ions $B(OH)_4^-$, PO_4^{3-}, and VO_4^{3-} exhibit a theoretically unexpected increase in the frequencies of the stretching vibrations of the tetrahedral point group or atomic grouping. Even in the cases in which the totally symmetric stretching vibration shows a negative isotope effect or no measurable effect, comparison with the calculated Teller-Redlich shift indicates that the frequency of the ^{18}O form is abnormally high. *Pinchas'* explanation for the inversion of the isotope effect is that the hydrogen bonds $X^{18}O\cdots HOH$ are weaker than the bonds $X^{16}O\cdots HOH$. The resulting anharmonicity loss produces a frequency increase counteracting the normal isotope effect. Marked anomalies have been found in several properties of the ^{18}O derivatives in a series of investigations by *Pinchas*. For example, the dimerization constant of $H_2{}^{18}O$ in dioxane is lower by a factor of 2 to 3 than that of $H_2{}^{16}O$[25].

2.2. Equilibrium Isotope Effects

In thermodynamic equilibrium, the different behavior of isotopic molecules or components causes a splitting of the equilibrium constant into a set of values lying close together. The equilibrium concentrations of the isotopic components can be replaced by corresponding partition functions according to the methods of statistical mechanics. To determine these partition functions, one must know the atomic and molecular weights, the molecular moment of inertia, and all the frequencies of the molecular vibrations. Since the spectra of gaseous compounds and their isotopic variants can be measured very precisely, statistics allows a reliable calculation of the isotope effect for gas equilibria.
